par c.p.g. préparative. Ce mélange 60–40 ne s'isomérise pas en présence d'hydroxyde de potassium. Il est donc évident que la première des octalines doit recevoir la structure Δ^1 (**7**), seule capable de donner naissance à une décalone *trans*.

Le fait d'obtenir un mélange des décalines *cis* et *trans*, en plus d'établir la position Δ^1 de la double liaison dans l'octaline de départ, permet de confirmer la conformation *cis a* de la décalone **1**. Si la décalone avait été *cis e* le groupe carbonyle en 1 serait sur un embranchement équatorial et aucune isomérisation ne se produirait, comme on l'a observé en série polycyclique (18). Le fait d'obtenir deux alcools pour chaque double liaison semble être une caractéristique de la série décalinique *cis* (16). En série stéroïde 5β, on rapporte la formation d'un seul époxyde à partir de double liaison Δ^2 et Δ^3 (19,20) et la réduction de ces époxydes en un seul alcool (19–21) selon la règle d'ouverture diaxiale de Fürst et Plattner (22). Nous étudions la question de savoir: *a*) si deux époxydes se forment à partir de chaque double liaison au lieu des époxydes **9** et **10**; pour des raisons d'encombrement stérique sur la face α, les époxydes isomères ne doivent pas se former; ou *b*) si les époxydes **9** et **10** peuvent, pour des raisons stériques (23), engendrer deux alcools contrairement à la règle de Fürst et Plattner: cette règle souffre en effet quelques exceptions (23–25).

Les acétates énoliques des décalones 1 et 2

Selon notre travail antérieur (1) nous avons soumis les deux décalones **1** et **2** à l'action de l'acétate d'isopropényle et de l'acide sulfurique concentré (réaction à commande cinétique) et la décalone **1**, à l'action de l'anhydride acétique et de l'acide perchlorique aqueux (formation d'acétates énoliques à l'équilibre); le mélange cinétique obtenu de la décalone **2** a été mis en équilibre par l'anhydride acétique et l'acide perchlorique aqueux (1). Les résultats apparaissent au Tableau I. Les mélanges d'acétates énoliques ont été dosés par c.p.g.

Le schéma 2 montre comment les acétates énoliques des décalones **1** et **2**, comme dans notre travail antérieur (2), sont transformés en diéthers méthyliques que l'on compare en c.p.g. à ceux que l'on obtient à partir de composés connus, en l'occurrence **7** et **8**. C'est ainsi que le mélange 59/41 issu de la décalone **1** conduit à un mélange de **19** et de **20** dans les proportions de 65/35 ce qui fait de l'acétate énolique prépondérant l'acétate **15**. Le seul acétate énolique obtenu à partir de la décalone **2**, par la méthode à l'anhydride acétique acide perchlorique, engendre un éther qui ne correspond ni à **19** ni à **20**; nous lui attribuons la formule **21** correspondant à l'acétate énolique **18**. Antérieurement (1), nous avions converti les diols en diéthers méthyliques par la méthode de Williamson; dans ce travail nous avons mis en œuvre la méthode au diazométhane et à l'acide fluoborique (26).

Discussion

Nous ramènerons les acétates énoliques **15**, **16**, **17** et **18** aux trois octalines A, B, C, respectivement Δ^1, Δ^2 et Δ^3. Les récents calculs et estimations de Bucourt et Hainaut (6) indiquent une différence de 0.15 kcal/mole en faveur d'une Δ^2-octaline *cis* par rapport à ses isomères Δ^1 et Δ^3 (A,B,C:R,R′=H), lorsqu'on ne considère que le point de vue conformationnel, c'est à dire que l'on ne fait entrer en ligne de compte que les énergies de déformation des deux anneaux de la molécule. Il faut cependant combiner à cette énergie conformationnelle les résultats des effets stériques des interactions non liées, H3-H5 dans A et H1-H5, H1-H7 dans B et C. Bucourt et

For personal use only.

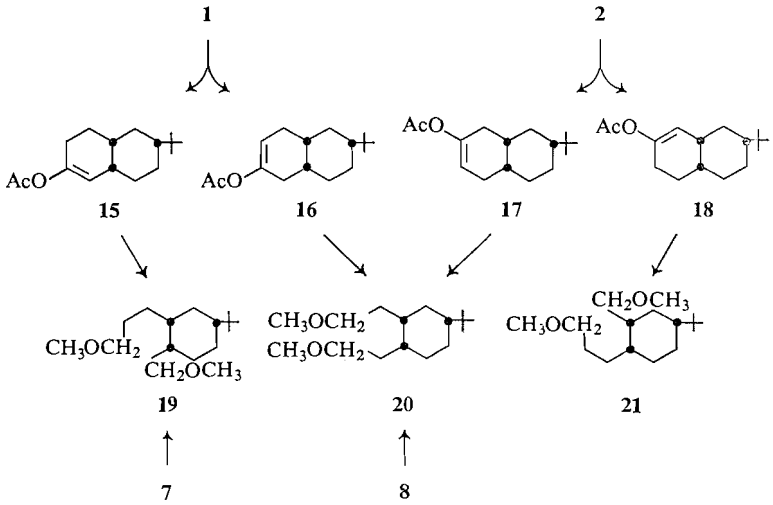

SCHÉMA 2. Preuves de structures des acétates énoliques.

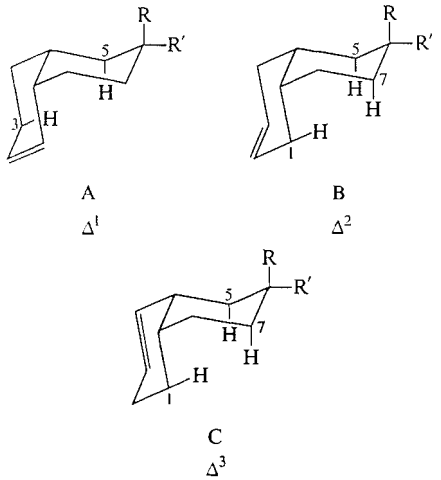
Hainaut estiment alors que les effets stériques deviendront plus importants que les effets conformationnels et que les enthalpies des isomères Δ^1 et Δ^3 seront finalement plus petites que celle de l'isomère Δ^2. D'un autre côté Allinger et ses collaborateurs (7) ont calculé que la différence d'enthalpie entre les Δ^1 et Δ^2-octalines est de 0.8 kcal/mole en faveur de l'isomère Δ^1.



Le Tableau I montre que si l'accord est bon entre les pourcentages des acétates énoliques à l'équilibre et les calculs et les estimations dans la série diméthylée, il n'en va plus de même dans la série *tert*-butylée. D'une part, la présence du seul acétate énolique Δ^1 (**18**) dans le mélange à l'équilibre **17**⇌**18** en série *cis e* indique une forte différence d'énergie entre ces isomères. D'autre part, le fait que l'isomère Δ^2 (**16**) soit plus stable que l'isomère Δ^1 en série *cis a* est d'autant plus significatif qu'il est imprévu et contraire au calculs et aux estimations. Il est vrai que la différence d'énergie libre n'est pas grande entre les deux isomères **15** et **16** et qu'une comparaison des acétates énoliques (ΔF) et des octalines (ΔH) n'est pas possible, en raison du facteur entropique (6) et de la présence dans ces molécules d'éléments dissemblables, un hydrogène et un groupe —OAc, volumineux et polaire. La comparaison des acétates énoliques entre eux peut être plus profitable. L'effet du groupe *gem*-diméthyles se fait sentir par rapport au groupe *tert*-butyle, de façon opposée dans la série *cis a* et dans la série *cis e*. Le pourcentage d'isomère Δ^1 augmente dans la série *cis a* et diminue dans la série *cis e*. Le groupe *gem*-diméthyles cause des interactions non liées entre le méthyle axial et les hydrogènes axiaux. Nous postulons que la décompression stérique qui résulte des interactions CH_3-H8 et CH_3-H10 se fera surtout sentir en position 8 et peu en position 10, car dans cette dernière position toute déformation entraine des perturbations directes dans les angles dièdres de jonction. En série *cis e* l'interaction CH_3-H8 se traduit par un effet réflexe (27) qui fera que H1 se rapprochera de H5 et s'éloignera de H7. Comme l'interaction la plus forte est H1-H5 dans C et H1-H7 dans B, l'effet réflexe diminuera les interactions non liées

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

dans B et les augmentera dans C: le résultat est une augmentation de l'isomère Δ^2, lorsqu'on passe de *tert*-butyle à diméthyle. En série *cis a* l'effet réflexe diminuera les énergies d'interaction des deux isomères A et B: le résultat net doit toutefois être une plus grande diminution dans A que dans B, car dans A une seule interaction est en jeu, elle diminue, tandis que dans B deux interactions interviennent, l'une diminue, l'autre augmente.

En définitive, ce travail justifie les conclusions de Bucourt et Hainaut, à savoir que les interactions métadiaxiales régissent finalement la direction de l'énolisation en série *cis*. Il n'en reste pas moins qu'il faudra expliquer la nature précise des interactions non liées dans les octalines A, B et C et la forme exacte du squelette de ces molécules. Il devrait alors être possible de remplacer les règles simples de l'énolisation préférentielle vers la position 1 (6) ou vers 1 en série *cis a* et vers 2 en série *cis e* (28), qui ne se justifient plus, par une règle fondée sur la variation des interactions non liées en prenant comme base les trois octalines A, B et C, stabilisées par un groupe *tert*-butyle.

Partie expérimentale

Les points de fusion ont été déterminés en tubes capillaires, au moyen d'un thermomètre étalonné avec des substances de points de fusion connu. Les analyses sont de C. Daesslé, Organic Microanalyses, Montréal. Les chromatographies en phase gazeuse (c.p.g.) ont été réalisées à l'aide d'un appareil Kromo-Tog K-2 de Burrell Corporation. Les spectres infrarouges (i.r.) ont été mesurés sur un appareil Perkin–Elmer modèle 21, optique de NaCl. Les spectres de résonance magnétique nucléaire (r.m.n.) ont été mesurés au moyen d'un appareil Varian A-60 avec référence au tétraméthylsilane.

1 Synthèse de la tert-butyl-6α décalone-2 cis (1)

1.1 tert-Butyl-6α $\Delta^{1(9)}$-octalone-2 (3)

L'ènepyrrolidine correspondant à la *tert*-butyl-4 cyclohexanone a été préparée avec un rendement de 93% selon (11). On en condense 566 g selon la méthode II, 2 de Stork *et al.* (11) avec 228 ml de méthyl-vinyl-cétone: après distillation en atmosphère d'azote on recueille 120 g de *tert*-butyl-4 cyclohexanone et 494 g de produit brut contenant les octalones **3** et **4** avec des cétols p.éb. 125 à 140° sous 0.3 mm. Une distillation fractionnée donne 240 g (42.5%) d'un mélange de 60% de l'isomère $\Delta^{1(9)}$ (**3**) (pic à δ 5.62 équivalent à 0.6 H dans le spectre r.m.n.). On chauffe 10 g du mélange à reflux pendant 20 h dans 100 ml de benzène en présence de 100 mg d'acide *p*-toluènesulfonique. On isole à la manière habituelle 5.0 g du mélange des deux octalones contenant par dosage r.m.n. 83% de l'isomère $\Delta^{1(9)}$ (**3**). Le mélange 83/17 est distillé à l'aide d'une colonne à bande tournante (longueur 400 mm, diamètre 8 mm). On fait distiller une fraction de tête équivalent à 45% en poids du mélange brut. Le résidu de distillation, 2.8 g consiste en l'octalone **3** pure qui après distillation dans un ballon de Claisen présente les constantes suivantes: p.éb. 108° sous 0.07 mm, $n_D^{24.5} = 1.5140$: spectre i.r. (CCl_4) 1675 cm^{-1}, C=O; 1625 cm^{-1}, C=C.

Anal. calc. pour $C_{14}H_{22}O$: C, 81.50; H, 10.75. Trouvé: C, 81.77; H, 10.67.

Dinitro-2,4 phénylhydrazone, aiguilles rouges (chloroforme–méthanol) p.def. 179°.

Anal. calc. pour $C_{20}H_{26}N_4O_4$: C, 62.16; H, 6.78; N, 14.50. Trouvé: C, 62.33; H, 6.68; N, 14.50.

Semicarbazone de p.def. 217° (méthanol).

Anal. calc. pour $C_{15}H_{25}N_3O$: C, 68.40; H, 9.57; N, 15.95. Trouvé: C, 68.50; H, 9.53; N, 15.71.

1.2 tert-Butyl-6α décalone-2 cis (1)

On agite en atmosphère d'hydrogène 2.4 g de *tert*-butyl-6α $\Delta^{1(9)}$-octalone-2 pure, 10 ml d'éthanol 95%, 1.0 ml d'acide chlorhydrique 3 *N* et 0.1 g de catalyseur (palladium 10% sur charbon actif), à 25° et pression atmosphérique, jusqu'à absorption de la quantité calculée d'hydrogène, soit pendant 17 h. On essore le catalyseur, évapore l'éthanol. Le résidu est repris par de l'éther; on lave avec une solution de bicarbonate de sodium puis avec une solution aqueuse saturée de chlorure de sodium. On sèche sur sulfate de sodium anhydre, évapore l'éther et distille le résidu. La décalone **1** présente les constantes suivantes: p.éb. 93° sous 0.1 mm; $n_D^{24.5} = 1.4874$; bande i.r. (CCl_4) à 1715 cm^{-1}, C=O. Temps de rétention de 57 min en c.p.g. sur colonne de 2.5 m, 20% de polyester succinique de Craig sur Chromat FB, température de la colonne 195°, hélium 60 ml par min.

Anal. calc. pour $C_{14}H_{24}O$: C, 80.71; H, 11.61. Trouvé: C, 80.38; H, 11.34.

Anal. calc. pour $C_{20}H_{27}N_4O_4$ (dinitro-2,4 phénylhydrazone, p.def. 167°): C, 61.84; H, 7.27; N, 14.42. Trouvé: C, 61.76; H, 7.08; N, 14.46.

Anal. calc. pour $C_{15}H_{27}N_3O$ (semicarbazone p.def. 205.5°): C, 67.88; H, 10.25; N, 15.83. Trouvé: C, 68.01; H, 10.37; N, 15.92.

Par réduction de 240 g du mélange 60–40 des octalones **3** et **4** décrit en 1.1 plus haut, on obtient la décalone **1** pure, homogène en c.p.g. dans les conditions décrites en 1.2.

1.3 tert-Butyl-6α décalone-2 trans (5)

On suit fidèlement les indications opératoires données dans un mémoire précédent (31), soit deux réductions successives et une oxydation de l'alcool saturé formé. Ainsi, 10.0 g d'octalone **3** donnent 3.0 g de décalone *trans* **5**, p.éb. 105° sous 0.6 mm; le distillat cristallise lentement pour donner des aiguilles p.def. 55.5°; bande i.r. (CCl_4) 1720 cm^{-1} (C=O); homogène en c.p.g. dans les conditions décrites en 1.2 plus haut avec temps d'ébullition de 38 min.

Anal. calc. pour $C_{14}H_{24}O$: C, 80.71; H, 11.61. Trouvé: C, 80.43; H, 11.33.

Anal. calc. pour $C_{20}H_{28}N_4O_4$ (dinitro-2,4 phénylhydrazone (chloroforme-méthanol) p.def. 175.5°): C, 61.84; H, 7.27; N, 14.42. Trouvé: C, 61.31; H, 7.27; N, 14.72.

Anal. calc. pour $C_{15}H_{27}N_3O$ (semicarbazone (méthanol) p.def. 214.5°): C, 67.88; H, 10.25; N, 15.83. Trouvé: C, 67.63; H, 10.34; N, 15.58.

2 tert-Butyl-7α décalone-2 cis (2)

2.1 tert-Butyl-6α Δ^1-octaline cis (7) et tert-butyl-6α Δ^2-octaline cis (8)

On dissout 175.0 g de *tert*-butyl-6α décalone-2 *cis* (**1**) dans 500 ml d'éthanol 95%; on y ajoute 25 ml d'une suspension de nickel de Raney préparé selon (32); on agite à 25° et à pression atmosphérique jusqu'à cessation de l'absorption d'hydrogène. On essore le catalyseur, évapore l'éthanol et distille le résidu; on obtient 170 g (97%) d'une huile, p.éb. 116° sous 0.8 mm qui cristallise lentement. En c.p.g. on distingue deux pics, dans le rapport 3 à 2 (2.5 m, 20% Tergitol sur brique 225°) qui sont les alcools **6**. On place 20.0 g des alcools bruts **6** dans un ballon de Claisen en mélange avec 8.0 g de bisulfate de potassium fraîchement fondu et pulvérisé. On chauffe sur un bain de sable à 290° en faisant passer un léger courant d'azote dans le ballon. Les octalines brutes distillent à 195°. Elles contiennent environ 15% de décalols non entrés en réaction. On répète l'opération plusieurs fois, de telle sorte que 170 g de décalols donnent naissance à 155 g d'octalines brutes. Les décalols qu'elles contiennent se mettent à précipiter; au bout de quelques jours, on les essore. Le mélange brut des octalines est dosé en c.p.g.: 61%–39%, **7** et **8**, temps de rétention respectivement de 9.5 et 8.5 min, en utilisant une colonne de 2.5 m, 20% de polyester succinique de Craig sur brique, 195°, hélium 60 ml/min. On fractionne ce mélange au moyen d'un appareil Fisher Prep Partitioner de c.p.g. préparative. On injecte dans une première colonne de 45 × 5 cm, suivie de 5 colonnes de 45 × 3 cm, 20% polyester de Craig sur brique; température de l'injecteur 250° et des colonnes 180°, azote comme éluant, 0.91 kg/cm^2. Le temps de rétention sont les suivants: octaline Δ^1, 45 min et Δ^2, 35 min, si l'on injecte des prises de 2 ml; des prises de 3 ml, ou supérieures provoquent un recouvrement des bandes préjudiciables à une bonne séparation. Dans ces conditions 138 g de mélange des octalines Δ^1 et Δ^2 conduit à 33 g de l'isomère Δ^1 (**7**) et à 15 g de l'isomère Δ^2 (**8**) purs.

La *tert*-butyl-6α Δ^1-octaline *cis* (**7**) présente les constantes suivantes: p.éb. 70.5° sous 0.45 mm; $n_D^{24} = 1.4878$; bandes i.r. à 658 et 1658 cm^{-1}.

Anal. calc. pour $C_{14}H_{24}$: C, 87.42; H, 12.58. Trouvé: C, 87.90; H, 12.23.

La *tert*-butyl-6α Δ^2-octaline *cis* (**8**) présente les constantes suivantes: p.éb. 70.5° sous 0.5 mm; $n_D^{24} = 1.4878$; bandes i.r. à 664 et 1648 cm^{-1}.

Anal. calc. pour $C_{14}H_{24}$: C, 87.42; H, 12.58. Trouvé: C, 87.70; H, 12.31.

Préparation des alcènes 7 et 8 par la méthode de Chugaev

On dissout 1.5 g du mélange des décalols **6** dans 40 ml de toluène anhydre et chauffe à l'ébullition à reflux pendant 18 h en présence de 0.21 g de sodium métallique, sous atmosphère d'azote. On refroidit, enlève l'excès de sodium et ajoute 50 ml d'éther anhydre contenant 0.93 g de bisulfure de carbone. On agite pendant quelques minutes et ajoute 6.0 g d'iodure de méthyle; on chauffe à l'ébullition à reflux pendant 4 h. On distille le solvant, ajoute 10 ml d'éther, filtre. Le xanthogénate cristallisant, on ajoute de l'éther jusqu'à obtention d'une solution limpide. On pyrolyse, en atmosphère d'azote, en laissant tomber goutte à goutte, la solution éthérée dans un ballon qui contient du verre concassé, maintenu à 295°. Le distillat de la pyrolyse est traité par du noir animal et distillé: p.éb. 115–118° sous 20 mm, rendement de 68%. La c.p.g. et le spectre i.r. indiquent un mélange 1–1 des deux octalines **7** et **8**.

2.2 tert-Butyl-7α décalone-2 cis (2)

En refroidissant par un bain de glace, on ajoute à 10.5 g de *tert*-butyl-6α Δ^2-octaline *cis* (**8**) dans un ballon à fond rond, 158 ml d'une solution chloroformique d'acide perbenzoïque contenant 10.5 g d'acide ou 50% d'excès. Il faut ajouter la solution chloroformique lentement car la réaction est fortement exothermique. On ajoute ensuite 10 g de sulfate de sodium anhydre et abandonne le tout à 3° pendant 48 h, en munissant le ballon d'un tube contenant du chlorure de calcium comme protection contre l'humidité. On filtre la solution, on la lave avec une solution aqueuse à 10% d'hydroxyde de sodium pour éliminer les acides organiques, puis avec une solution aqueuse saturée de sulfate de sodium jusqu'à neutralité. On sèche sur sulfate de sodium anhydre, évapore le solvant et recueille le résidu (10.2 g) qui est sans autre soumis à l'action de l'hydrure de lithium et d'aluminium.

L'époxyde brut (10.2 g) est dissous dans 100 ml d'éther anhydre: la solution est ajoutée goutte à goutte, avec agitation, à une suspension de 5.0 g d'hydrure de lithium et d'aluminium dans 250 ml d'éther. On chauffe à l'ébullition à reflux pendant 2 h, détruit l'excès d'hydrure en ajoutant de l'eau goutte à goutte ajoute ensuite 100 ml d'eau et 50 ml d'acide chlorhydrique aqueux 3 *N*. On extrait la couche aqueuse par trois portions de 100 ml d'éther. Les solutions éthérées sont réunies, lavées avec une solution aqueuse à 5% de bicarbonate de sodium, puis avec une solution saturée de chlorure de sodium jusqu'à neutralité. On sèche sur sulfate de sodium anhydre, évapore l'éther et recueille le résidu (10.0 g) qui est immédiatement oxydé.

On dissout 10.0 g des alcools bruts dans 100 ml de pyridine anhydre on y ajoute à température de 25° une suspension de 15.0 g de trioxyde de chrome dans 150 ml de pyridine anhydre. On agite pendant 20 h en protégeant bien de l'humidité. On ajoute alors 500 ml d'eau et 500 ml d'éther; on extrait, sépare la couche aqueuse qu'on extrait encore par trois portions d'éther (3 × 500 ml). On réunit les solutions éthérées, on lave à l'acide chlorhydrique 3 *N*, à l'eau, au bicarbonate de sodium puis avec une solution saturée de chlorure de sodium jusqu'à neutralité. On sèche sur sulfate de sodium anhydre, évapore l'éther et distille le résidu: 9.2 g, p.éb. 104–112° sous 0.4 mm, bande i.r. (CCl_4) à 1715 cm^{-1}; c.p.g.: décalone **1**, 57.3%, décalone **2**, 42.7%, à 35 et 47.5 min respectivement, colonne de 2.5 m polyester succinique de Craig, 20% sur brique, température de la colonne 95°, hélium 60 ml/min. La décalone **1** connue (voir plus haut en 2) a servi à l'identification par la méthode du rehaussement de pic.

Le mélange brut des décalones **1** et **2** est chromatographié en phase gazeuse au moyen d'un appareil préparatif Fisher Prep Partitioner. On injecte le mélange dans une première colonne de 45 × 5 cm, suivie de 7 colonnes de 45 × 3 cm, 20% de polyester succinique de Craig sur brique. Les temps de rétention sont alors de 80 min pour **1**, 100 min pour **2**. La séparation est aisée; il convient toutefois de repasser la *tert-butyl-7 décalone-2 cis* (**2**) sur la colonne pour l'obtenir pure; p.def. 69.5°

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

après cristallisation dans l'éther de pétrole (p.éb. 38°), bande i.r. (CCl_4) à 1715 cm^{-1}, C=O; on obtient 1.1 g.

Anal. calc. pour $C_{14}H_{24}O$: C, 80.71; H, 11.61. Trouvé: C, 80.89; H, 11.38.

Anal. calc. pour $C_{20}H_{28}N_4O_4$ (dinitro-2,4 phénylhydrazone (chloroforme/éthanol) p.def. 202.5°): C, 61.84; H, 7.27; N, 14.42. Trouvé: C, 61.96; H, 7.24; N, 14.39.

Le mélange brut des décalones **1** et **2** reste inchangé par traitement par une solution alcoolique d'hydroxyde de potassium à 2%.

*3 Décalones **1**, **11**, et **12** à partir de l'octaline **7**.*

En suivant les modes opératoires décrits dans la section 2.2 plus haut, 5.0 g de *tert*-butyl-6α Δ^1-octaline *cis* (**7**) sont transformés en époxyde (4.79 g), qui est réduit en alcools (4.5 g) par l'hydrure de lithium et d'aluminium, qui sont à leur tour oxydés en décalones (4.3 g) p.éb. 104–107° sous 0.7 mm. Ce mélange donne un chromatogramme en c.p.g. (2.5 m, 15% de polyester succinique de Craig, 225°, hélium 60 ml/min) montrant un pic principal à 18 min, flanqué de deux épaulements, l'un à 16 min, l'autre à 19 min. Le pic principal, qui représente 90% environ du total, est rehaussé par adjonction de *tert*-butyl-6α décalone-2 *cis* (**1**) au mélange.

Le mélange des trois décalones est isomérisé dans les conditions suivantes: 446 mg du mélange sont dissous dans 10 ml de méthanol contenant 200 mg d'hydroxyde de sodium; on abandonne le tout à 25° pendant 24 h, puis chauffe à 55° pendant 1 h. On ajoute après refroidissement, 250 ml d'éther, on lave avec de l'acide chlorhydrique 3 *N*, puis avec une solution aqueuse saturée de chlorure de sodium jusqu'à neutralité.

On sèche sur sulfate de sodium anhydre, évapore l'éther et distille le résidu; on recueille 322 mg distillant à 105° sous 0.7 mm. On chromatographie en phase gazeuse, dans les conditions décrites pour le mélange avant isomérisation; le chromatogramme montre un pic principal à 18 min, l'épaulement à 16 min a augmenté tandis que celui à 19 min a disparu.

4 Réduction de Clemmensen.

*4.1 tert-Butyl-2α décaline trans (**14**)*

On dissout 200 mg de *tert*-butyl-6 décalone-2 *trans*, pure (**5**) dans 1 ml d'acide acétique glacial; on y ajoute un mélange de 0.2 ml d'eau et 0.1 ml d'éthanol, 0.5 ml d'acide chlorhydrique concentré et 700 mg de zinc traité par 36 mg de chlorure mercurique; (le traitement de ce zinc s'effectue en agitant pendant 5 min, dans 1.0 ml d'eau et 0.3 ml d'acide chlorhydrique concentré les quantités indiquées de zinc et de chlorure mercurique puis en pipettant le liquide surnageant). On chauffe à reflux pendant 17 h, en ajoutant après 5 h 0.5 ml d'acide chlorhydrique concentré. Le reflux terminé, on dilue la solution avec un égal volume d'eau; on extrait par 25 ml d'éther; on répète cette opération 5 fois. Les solutions éthérées réunies, lavées avec une solution à 5% de bicarbonate de sodium jusqu'à neutralité. On évapore l'éther. Le résidu est distillé: on recueille 120 mg de *tert-butyl-2α décaline trans* (**14**), p.éb. 134° sous 0.35 mm, $n_D^{25} = 1.4722$. Le spectre i.r. (CCl_4) montre l'absence de bande carbonyle. Le chromatogramme en c.p.g. montre un seul pic à 60 min (2.5 m, 25% d'huile de silicone 550 sur brique 143°, hélium 70 ml/min).

Anal. calc. pour $C_{14}H_{26}$: C, 86.52; H, 13.48. Trouvé: C, 85.93; H, 13.57.

*4.2 tert-Butyl-2α décaline cis (**13**)*

On réduit selon les indications opératoires données en 4.1, 1.0 g de *tert*-butyl-6α décalone-2 *cis* (**1**) en 600 mg de *tert-butyl-2α décaline cis* (**13**), p.éb. 120° sous 28 mm, $n_D^{23} = 1.4887$. Le spectre i.r. (CCl_4) ne montre pas de bande carbonyle. Le chromatogramme montre un seul pic à 67 min, dans les conditions décrites en 4.1.

Anal. calc. pour $C_{14}H_{26}$: C, 86.52; H, 13.48. Trouvé: C, 86.51; H, 13.36.

*4.3 Réduction du mélange des décalones **1** et **12***

On réduit 300 mg du mélange des décalones **1** et **12** obtenu à la section 3 plus haut, selon les données opératoires décrites en 4.1. Le chromatogramme c.p.g. montre 86% de *tert*-butyl-2 décaline *cis* (**13**) et 14% de *tert*-butyl-2 décaline *trans* (**14**), dont la présence est corroborée par rehaussement des pics avec les échantillons des décalines authentiques préparées dans les sections 4.1 et 4.2.

5 Préparation des acétates énoliques

5.1 Première méthode (acétate d'isopropényle, acide sulfurique concentré)

5.11 Mode opératoire général

On suit les indications données dans un mémoire précédent (2).

*5.12 Acétates énoliques de la tert-butyl-6α décalone-2 cis (**1**)*

On obtient, à partir de 2.0 g de décalone, 1.9 g du mélange des acétates énoliques Δ^1 et Δ^2, (**15**) et (**16**), p.éb. 98° sous 0.45 mm $n_D^{27} = 1.4940$. Bandes i.r. (CCl_4) à 1758 et 1695 cm^{-1}, aucune bande carbonyle cétonique à 1715 cm^{-1}.

Anal. calc. pour $C_{16}H_{26}O_2$: C, 76.75; H, 10.47. Trouvé: C, 77.01; H, 10.35.

Le chromatogramme c.p.g. (2.5 m, 20% de polyester succinique de Craig sur Chromat FB 195°, hélium 60 ml/min), montre deux pics: acétate énolique Δ^2, 41% à 35 min et acétate énolique Δ^1, 59% à 46 min.

Anal. calc. pour $C_{16}H_{26}O_2$: C, 76.75; H, 10.47. Trouvé: C, 77.01; H, 10.35.

*5.13 Acétates énoliques de la tert-butyl-7α décalone-2 cis (**2**)*

On obtient, à partir de 249 mg de décalone, 266 mg du mélange des acétates énoliques Δ^1 et Δ^2, p.éb. 106° sous 0.3 mm, $n_D^{26} = 1.4872$, bandes i.r. (CCl_4) à 1715 et 1680 cm^{-1}; analyse c.p.g. comme en 5.12, indique un mélange 50–50% pour des temps de rétention de 26.7 min (isomère Δ^2) et 33.0 min (isomère Δ^1).

Anal calc. pour $C_{16}H_{26}O_2$: C, 76.75; H, 10.47. Trouvé: C, 76.92; H, 10.33.

5.2 Deuxième méthode (anhydride acétique–acide perchlorique)

*5.21 Acétates de la tert-butyl-6α décalone-2 cis (**1**)*

En suivant les indications données dans un mémoire précédent (2), on obtient, à partir de 478 mg de décalone, 100 mg du mélange des acétates énoliques Δ^1 et Δ^2, qui contient par dosage i.r. de 5 à 8% de décalones de départ et de 92 à 95% d'acétates énoliques dans le rapport de 35.5–64.5, Δ^1 et Δ^2 respectivement, avec des élutions à 46 et 35 min, déterminé par c.p.g. comme plus haut en 5.12.

5.22 Mise à l'équilibre des acétates ***17*** *et* ***18***

On suit le mode opératoire décrit dans un article précédent (1) section 1.4. Le mélange obtenu plus haut à la section 5.13 (200 mg) est mis à l'équilibre et donne 130 mg d'acétate énolique Δ^1 contenant 1–2% de décalone de départ, comme le montrent la c.p.g. et l'i.r.

6 Preuves de structure des acétates énoliques ***15***, ***16***, ***17*** *et* ***18***

*6.1 tert-Butyl-4 bis-(méthoxy-2 éthyl)-1,2 cyclohexane cis, cis (**20**)*

On dissout 2.5 g de *tert*-butyl-6α Δ^2-octaline *cis* (**8**) dans 150 ml d'éther de pétrole (p.éb. 38–40°); on fait passer un courant d'oxygène chargé de 1.8% d'ozone dans la solution refroidie par un bain de CO_2–acétone, jusqu'à coloration bleue persistante. On évapore le solvant en faisant passer un courant d'azote dans le ballon, en laissant revenir le tout à la température de 25°. On reprend l'ozonide par 20 ml d'acétate d'éthyle, 18 ml d'acide acétique glacial, 10 ml d'eau et 15 ml de peroxyde d'hydrogène (30% en volume). On agite 12 h à 25°. On détruit l'excès de peroxyde d'hydrogène en ajoutant du bioxyde de manganèse jusqu'à que cesse l'effervescence. On évapore les solvants sur le bain-marie, reprend le résidu par une solution de NaOH à 10% aqueuse; on filtre; le filtrat est acidifié par adjonction de HCl 10% aqueux jusqu'à pH 2, l'acide brut est extrait par de l'éther; les solutions éthérées sont lavées avec une solution saturée de chlorure de sodium; on sèche sur du sulfate de sodium anhydre, évapore l'éther, on reprend par de l'éther anhydre et ajoute une solution de diazométhane jusqu'à coloration jaune persistante. On évapore l'éther et l'excès de diazométhane et recueille 2.0 g de diester brut.

Le diester brut, 2.0 g, est dissout dans 200 ml d'éther anhydre; cette solution est ajoutée goutte à goutte à une suspension de 2.0 g d'hydrure de lithium et d'aluminium dans 200 ml d'éther. On chauffe à reflux pendant 45 min, détruit l'excès d'hydrure par de l'eau, ajoute de l'acide chlorhydrique concentré jusqu'à disparition de tout précipité et extrait d'une manière continue à l'éther. En évaporant la solution éthérée on recueille le diol brut, que l'on sèche sur P_2O_5 jusqu'à poids constant.

Pour l'éthérification du diol brut on suit la méthode (26). On prépare une solution de catalyseur en mélangeant 1.3 ml d'acide fluoborique 16 *N* dans 20 ml d'éther. On ajoute 3 ml de la solution de catalyseur à 1.6 g de diol brut dans 20 ml d'éther et 50 ml de solution de diazométhane dans l'éther. On garde à 0°; la coloration jaune disparaît en 2–3 min; on rajoute alors 3 ml de la solution de catalyseur et 50 ml de la solution de diazométhane. Au bout de 5 min, on filtre. Le filtrat est lavé avec une solution saturée de chlorure de sodium, on sèche sur sulfate de sodium anhydre et évapore l'éther. On recueille 0.7 g de diéther **20** que l'on distille: p.éb. 98° sous 0.5 mm; $n_D^{23} = 1.4592$.

Anal. calc. pour $C_{16}H_{32}O_2$: C, 74.94; H, 12.58. Trouvé: C, 75.14; H, 12.32.

Un pic en c.p.g., 2.5 m, 20% de Tergitol NPX sur Chromat FB 215°, hélium 60 ml/min: temps de rétention 26.2 min.

*6.2 tert-Butyl-4 méthoxyméthyl-1 (méthoxy-3 propyl)-2 cyclohexane cis,cis (**19**)*

A partir de 1.0 g de *tert*-butyl-6α Δ^1-octaline *cis* (**7**) on obtient comme plus haut en 6.1, 0.23 g de diéther **19**, p.éb. 95° sous 0.3 mm, $n_D^{21} = 1.4605$, pic unique en c.p.g. à 29 min.

Anal. calc. pour $C_{16}H_{32}O_2$: C, 74.94; H, 12.58. Trouvé: C, 74.72; H, 12.31.

*6.3 tert-Butyl-5 méthoxyméthyl-1 (méthoxy-3 propyl)-2 cyclohexane cis,cis (**21**).*

On ozonise l'acétate énolique obtenu plus haut en 5.2 en dissolvant 126 mg dans 20 ml d'éther de pétrole (p.éb. 38–40°), en faisant barboter un courant d'oxygène chargé de 1.8% d'ozone dans la solution plongée dans un bain de CO_2–acétone jusqu'à coloration bleue persistante. On évapore ensuite l'éther de pétrole en faisant passer un courant d'azote dans le ballon, à 0°. Le résidu huileux est séché sous vide (1/20 mg).

On réduit l'ozonide par l'hydrure de lithium et d'aluminium comme décrit précédemment (2) et on éthérifie le diol brut comme en 6.1. On obtient 78 mg de diéther **21**, p.éb. 95° sous 0.3 mm, $n_D^{22} = 1.4562$, pic unique en c.p.g. à 38 min dans les conditions décrites plus haut en 6.1. Ce diéther n'est pas superposable en c.p.g. au diéther **19** et au diéther **20** décrits en 6.2 et 6.1.

Anal. calc. pour $C_{16}H_{32}O_2$: C, 74.94; H, 12.58. Trouvé: C, 75.08; H, 12.42.

6.4 Ozonolyse des acétates énoliques obtenus en 5.12

Comme en 6.1 on ozonise 1.0 g du mélange des acétates énoliques obtenu plus haut en 5.12, on réduit le mélange des ozonides par $LiAlH_4$ (voir (2)), et on éthérifie comme en 6.1 pour obtenir 0.59 g d'un mélange consistant en 35% de diéther **20** pic à 26 min en c.p.g. et 65% de diéther **19**, pic à 29 min en c.p.g. Il y a recouvrement de pics en mélange avec les diéthers purs décrits en 6.1 et 6.2.

Remerciements

Nous remercions le Conseil National de Recherches du Canada de son aide financière (subvention T-14) et les Etablissements Dow Chemical of Canada Ltd., Montréal, pour la quantité généreuse de *tert*-butyl-4 cyclohexanols-1 mise à notre disposition.

Barriers to rotation in *ortho*-alkylphenyl substituted 1,3-benzoxazines[1]

S. BROWNSTEIN, E. C. HORSWILL, AND K. U. INGOLD
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

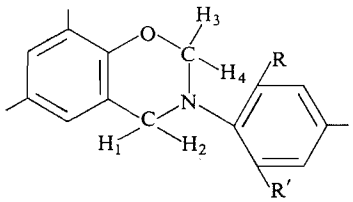
Received April 25, 1969

Four 3,4-dihydro-3-*ortho*-alkylphenyl-2*H*-1,3-benzoxazines have been synthesized. Enthalpies and entropies of activation for rotation about the phenyl–nitrogen bond have been calculated from the temperature dependence of the proton resonance spectra for the *o*-isopropyl ($\Delta S‡ = -4$ e.u., $\Delta H‡ = 10.8$ kcal/mole) and *o*-*t*-butyl ($\Delta S‡ = 0.4$ e.u., $\Delta H‡ = 16.9$ kcal/mole) derivatives. The barrier to rotation for the *o*-methyl and 2,6-dimethyl derivatives was too low to be measured by this procedure.

Canadian Journal of Chemistry, **47**, 3243 (1969)

Introduction

There have been many high resolution magnetic resonance studies of hindered rotation about nominally single bonds (1–5). In most cases reported for hindered rotation about a carbon–nitrogen single bond the magnitude of the barrier to rotation has been attributed to partial double bond character. Thus far no studies have been reported in which changes in the barrier to rotation along a homologous series have been attributed solely to steric effects. In the present investigation proton resonance spectra were obtained for a series of substituted benzoxazines of the following general formula.



It was found that when R′ is a bulky substituent H-1 and H-2, and H-3 and H-4 were not equivalent on the nuclear magnetic resonance time scale.

In principle the non-equivalence of H-1 through H-4 could arise either by hindered rotation about the aryl carbon–nitrogen bond or by a barrier to inversion of the non-planar benzoxazine ring. Provided that R and R′ are not identical, H-1 through H-4 should remain non-equivalent even when ring inversion is rapid, provided that rotation about the carbon–nitrogen bond is slow. The non-equivalence arises from the closer proximity to R′ of, say, H-2 and H-4, compared with H-1 and H-3. If R = R′ this non-equivalence is removed.

When both hindered inversion and hindered rotation occur two different sets of non-equivalent proton signals can be expected. One set would arise from the isomer in which R′ is closest to H-1 and H-3 and the other set when R′ is closest to H-2 and H-4. However, if one of the R groups is more bulky than the other, one of the conformers may be present at a much lower concentration because steric repulsion between R and the benzoxazine ring will raise its potential energy. Therefore, although in principle two sets of non-equivalent proton signals can be expected, in fact only one set may be observable. If R = R′ the existence of two unique isomers would be removed and only one set of non-equivalent proton resonance signals would be observed. The possible situations are summarized in Table I.

In the preceding discussion it is implicitly assumed that there can be rapid inversion about the nitrogen atom. Because of the asymmetry of the benzoxazine ring, H-1 through H-4 will remain non-equivalent when inversion about nitrogen is fast, provided that ring inversion is slow. If ring inversion is rapid but rotation about the phenyl–nitrogen bond is slow, then ring inversion will probably be accompanied by nitrogen inversion to place the *o*-alkylphenyl ring in the conformation with minimum steric strain.

Experimental

Proton resonance spectra were obtained at 100 MHz on a "Varian Associates" HR 100 spectrometer. Probe temperatures were calibrated with a copper–constantan thermocouple in a dummy sample tube and should be accurate within 1 °C. Low temperature spectra were obtained using carbon disulfide as solvent while for the high temperature studies the solvent was *s*-tetrachloroethane. Tetramethylsilane was used as internal reference, and

[1]Issued as NRCC No. 10811.

TABLE I

Relationship between motional freedoms and equivalency of benzoxazine ring protons

Inversion	Rotation	R = R′	R ≠ R′
Hindered	Hindered	Protons different	Two sets of different protons
Hindered	Free	Protons different	Protons different
Free	Hindered	Protons equivalent	Protons different
Free	Free	Protons equivalent	Protons equivalent

chemical shifts are reported as p.p.m. to low field. All melting points were determined on a Kofler hot stage using factory-calibrated thermometers. Infrared (i.r.) spectra were measured in carbon tetrachloride solution on a Perkin–Elmer model 621 spectrophotometer. The i.r. spectra of all the compounds showed no absorption in the 3700–3100 cm^{-1} region. The mass spectra were recorded on an Atlas CH 4 spectrometer. Microanalyses were carried out by Mr. J. R. H. Seguin of these laboratories.

*6-tert-Butyl-3,4-dihydro-3-o-tolyl-2H-1,3-benzoxazine (**1**)*

A solution of 1.5 g of barium hydroxide octahydrate in 25 ml (0.33 mole) of formalin was added to a mixture of 10.9 g (0.073 mole) of 4-*tert*-butylphenol and 7.8 g (0.073 mole) of *o*-toluidine and the mixture shaken at room temperature for 6 h. After the aqueous phase was decanted, the solid was dissolved in benzene and the solution washed with water. Benzene was removed after drying to give 18.8 g of crystalline product which recrystallized from 95% ethanol to produce 12.6 g of colorless crystals, m.p. 88–90°. An analytical sample was recrystallized from pentane, m.p. 90.9–92.0°. The i.r. spectrum showed no absorption in the 3700–3100 cm^{-1} region.

Anal. Calcd. for $C_{19}H_{23}ON$ (mol. wt., 281): C, 81.10; H, 8.24; N, 4.98. Found (mol. wt., mass spectroscopy, 281): C, 81.02; H, 8.21; N, 4.89.

*6-tert-Butyl-3,4-dihydro-3-(2,6-xylyl)-2H-1,3-benzoxazine (**2**)*

Treatment of 3.0 g of 4-*tert*-butylphenol and 2.4 g of 2,6-xylidine with alkaline formalin gave a product containing some starting materials (by thin-layer chromatography). The benzene solution was extracted with 2 *N* hydrochloric acid, with 10% sodium hydroxide solution, and then water. Drying and concentration left 3.8 g of yellow syrup, n_D^{25} 1.5592, pure by thin-layer chromatography.

Anal. Calcd. for $C_{20}H_{25}NO$: C, 81.31; H, 8.53; N, 4.74. Found: C, 81.08; H, 8.51; N, 4.89.

*6-tert-Butyl-3-o-cumyl-3,4-dihydro-8-methyl-2H-1,3-benzoxazine (**3**)*

The use of 4-*tert*-butylphenol with 2-*iso*-propylaniline in the reaction above produced a strongly acidic phenolic compound rather than a benzoxazine.

When 3.3 g of 4-*tert*-butyl-*o*-cresol and 2.7 g of purified 2-*iso*-propylaniline (n_D^{25} 1.5458) were condensed with alkaline formaldehyde the only product was the benzoxazine. After solution in hexane, extraction and concentration, the colorless crystals (2.8 g) melted 91–97°. Recrystallization from ethanol gave 2.4 g of a compound of melting point 93–96°. An analytical sample was obtained from pentane, m.p. 97.5–99.0°.

Anal. Calcd. for $C_{22}H_{29}NO$ (mol. wt., 323): C, 81.69; H, 9.04; N, 4.33. Found (mol. wt., mass spectroscopy, 323): C, 81.39; H, 9.11; N, 4.05.

*6,8-Di-tert-butyl-3-(2,4-di-tert-butylphenyl)-3,4-dihydro-2H-1,3-benzoxazine (**4**)*

A mixture of 0.56 g of 2,4-di-*tert*-butylaniline, 0.56 g of 2,4-di-*tert*-butylphenol and 10 ml of 37% formalin solution (no catalyst) was stirred and heated in a bath at 95° for 2 h. The cooled suspension was filtered, washed with water, and vacuum dried. The colorless crystalline product (1.08 g) after recrystallization from absolute ethanol gave 0.72 g of colorless felted needles, m.p. 173–175.6°. Further recrystallization gave an analytical sample, m.p. 174.7–176.0°.

Anal. Calcd. for $C_{30}H_{45}NO$ (mol. wt., 435): C, 82.70; H, 10.41; N, 3.21. Found (mol. wt., mass spectroscopy, 435): C, 82.24; H, 10.23; N, 3.46.

Results and Discussion

The structural formulae of the compounds studied and chemical shifts for the various types of protons are given in Fig. 1. Theoretical spectra were calculated by computer using a previously reported program (6). To utilize this program for an AB system it is necessary to specify the position, intensity and transition probability for each line. In all the compounds H-1 and H-2 gave significantly broadened lines both at the limits of rapid rotation and slow rotation. This is attributed to long range spin coupling to a proton or protons on the adjacent aromatic ring. To correct for this line broadening a convolution integral was introduced into the computer program to broaden the theoretical spectra by a Gaussian function whose width could be adjusted to that of the experimental line widths in the absence of exchange broadening. In Fig. 2 experimental spectra for H-1 and H-2 of compound **3** are presented along with approximately equivalent theoretical spectra. The rate constant for rotation at a given temperature was obtained by interpol-

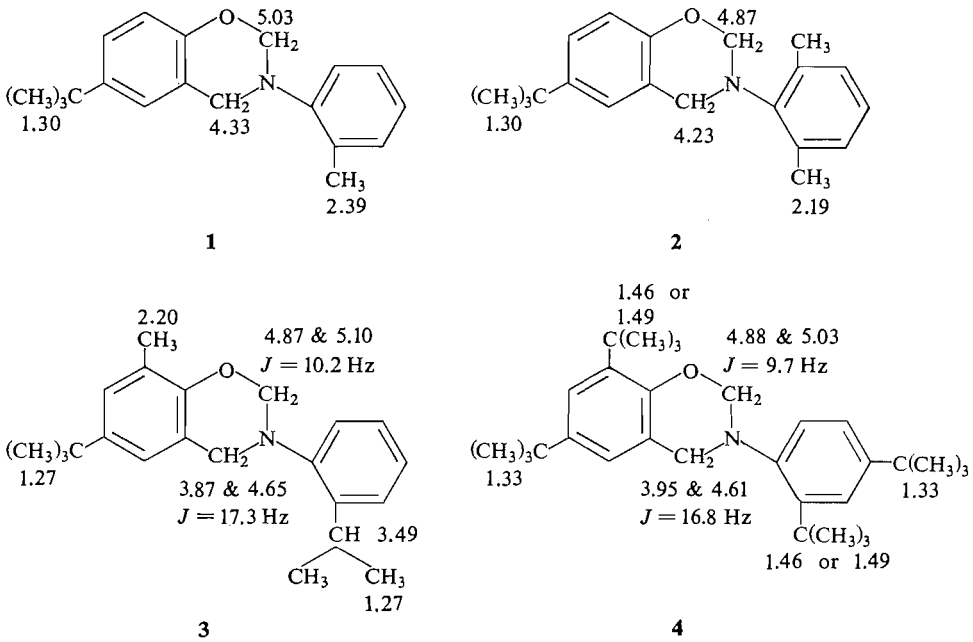

FIG. 1. Structural formulae and chemical shifts of some benzoxazines.

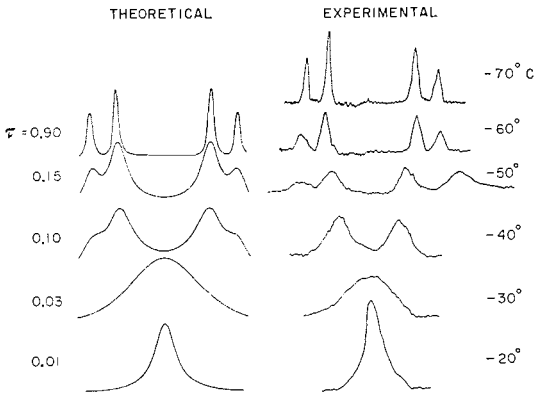

FIG. 2. Theoretical and experimental spectra for H-1 and H-2 of compound **3**.

ation of line widths and peak to trough ratios between theoretical spectra closely matching the experimental spectrum.

At room temperature the benzoxazine ring protons are equivalent, in pairs, for compounds **1**, **2**, and **3** but are non-equivalent in **4**. Lowering the temperature below 0 °C causes an observable non-equivalence in the proton resonance spectra for **3** but the protons in **1** and **2** remain equivalent down to the lowest temperatures studied (−60 °C). From the behavior of the proton resonance spectra of **3** and **4** it can be concluded that there is rapid inversion but that rotation about the carbon–nitrogen bond is slow on the n.m.r. time scale. Further evidence for this conclusion is obtained from the methyl resonances of R in compounds **3** and **4**. If ring inversion is slow there should be two different environments for R, i.e. with the *o*-alkyl substituted phenyl axial or equatorial, regardless of the rate of rotation about the carbon–nitrogen bond. Examination of a space filling molecular model suggests that there is considerable steric hindrance about the nitrogen of the benzoxazine ring. For a given conformation of the ring only one configuration of the benzene ring, relative to nitrogen, can be constructed. Therefore, the averaging effect of inversion about nitrogen alone need not be considered. Since only a single sharp signal is observed for R under conditions that yield non-equivalent benzoxazine ring protons, it is quite likely that ring inversion is a rapid process.

In Fig. 3 the logarithm of the rate constant for rotation about the carbon–nitrogen bond of compound **4**, averaged for results from *both* sets of ring protons, is plotted against the reciprocal temperature. From a least squares analysis of this

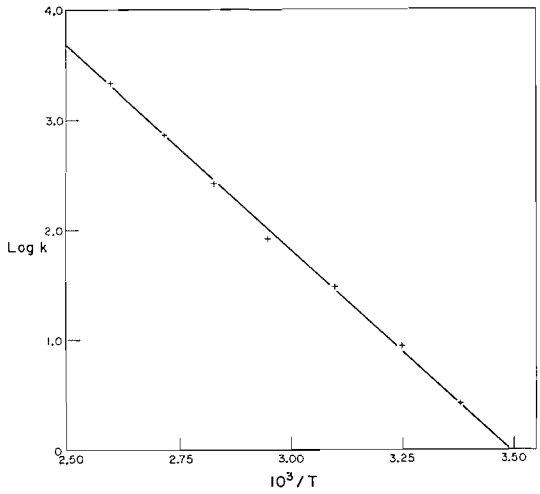

FIG. 3. The variation of rate of rotation with temperature for compound **4**.

data and similar data for compound **3** the following activation parameters were obtained.

$$\text{Compound } \mathbf{3}\ \Delta H^{\ddagger} = 10.8 \pm 0.6 \text{ kcal/mole}$$
$$\Delta S^{\ddagger} = -4 \pm 2 \text{ e.u.}$$
$$\text{Compound } \mathbf{4}\ \Delta H^{\ddagger} = 16.9 \pm 0.3 \text{ kcal/mole}$$
$$\Delta S^{\ddagger} = 0.4 \pm 0.2 \text{ e.u.}$$

The activation entropies are normal suggesting no unusual conformational requirement in the transition state for rotation. The failure to observe any line broadening arising from non-equivalent protons in compound **1** even at -60 °C implies that the rate constant for rotation in this compound is greater than 3.3×10^3 s^{-1} if we assume that all compounds have similar chemical shift differences. If we make the further assumption that $\Delta S^{\ddagger} = 0$ for compound **1** it can be calculated that $\Delta H^{\ddagger}$ for an *o*-methyl substituent is less than 8.9 kcal/mole. The barrier to rotation about the phenyl–nitrogen bond therefore increases by more than 1.9 kcal/mole on changing the *ortho* substituent from methyl to isopropyl and by 6.1 kcal/mole on changing from isopropyl to *t*-butyl.

Etudes stereochimiques. VIII.[1] Sur la serie *exo*-maleopimarique

C. MACIEJEWSKI, M. GILLARD, N. LANGLOIS[2], ET B. GASTAMBIDE
Laboratoire de Chimie Organique, Faculté des Sciences, 51, Reims, France

Reçu le 25 mars 1969

L'action de l'anhydride maléique sur les esters résiniques conduit non seulement à l'adduit classique **3***a* mais aussi à l'*exo*-anhydro-maléopimarate de méthyle (**3***b*) dont la structure est prouvée par des mesures physiques et des transformations chimiques.

Canadian Journal of Chemistry, 47, 3247 (1969)

Le lévopimarate de méthyle (**1**), cela est classique, réagit avec l'anhydride maléique, à la température ordinaire, pour donner un composé d'addition de Diels–Alder dénommé anhydro-maléopimarate de méthyle (**3***a*). Parmi les quatre isomères susceptibles de se former dans la réaction, seul l'adduit **3***a*, de configuration *endo* bien établie (1–3) a été décrit dans la littérature. Cette synthèse diénique était donc considérée jusqu'à présent comme tout à fait stéréospécifique et utilisable par exemple pour la détermination quantitative de l'acide lévopimarique dans les résines (1). On doit signaler, cependant, que Sandermann (4), en titrant par acidimétrie l'adduit formé, a envisagé la formation possible dans la réaction d'un deuxième isomère; cette hypothèse n'a pas été prise jusqu'à présent en considération.

Nous avons donc décidé d'examiner la stéréospécificité de cette réaction et avons isolé un deuxième adduit **3***b* de structure *exo*; ceci est en accord avec les travaux effectués par deux d'entre nous (5) en série citraconopimarique où trois adduits ont été obtenus, l'un de ceux-ci possédant l'inhabituelle configuration *exo*.

Lorsqu'on opère sur de grosses quantités de produits initiaux, la réaction de Diels–Alder est effectuée, non pas avec le lévopimarate de méthyle, mais en traitant à 160° un mélange de résinates de méthyle préparé à partir de la gemme de pin d'Alep selon une méthode mise au point par Mme Carnero (6, 7). La chromatographie sur couche mince montre la présence du composé **3***b* dans les eaux-mères de cristallisation de l'adduit **3***a*: par ordre de vitesses de migration décroissantes, on trouve les résinates de méthyle, l'adduit **3***b*, puis l'isomère **3***a*, et enfin un mélange de composés acides. Nous avons tout d'abord cherché à éliminer les quantités assez considérables de résinates de méthyle n'ayant pas réagi. Après divers essais, seule la chromatographie sur colonne de florisil du produit issu de l'évaporation des eaux-mères semble satisfaisante; on peut ainsi obtenir un mélange des composés **3***a* et **3***b* qui sont ensuite isolés par chromatographie d'élution sur gel de silice. L'*exo*-anhydro-maléopimarate de méthyle (**3***b*) est ainsi obtenu avec un rendement de 8%.

La réaction de Diels–Alder, effectuée d'une manière similiaire à 160° avec de l'abiétate de méthyle commercial ou du palustrate de méthyle, montre la constance du rapport des quantités d'isomères **3***a* et **3***b* formés. Ce rapport varie cependant avec la température utilisée. Des synthèses diéniques effectuées avec le lévopimarate de méthyle et l'anhydride maléique dans l'acétone à 25° et sans solvant à 160° conduisent à des rapports **3***a*/**3***b* respectivement égaux à 77 et 8 d'après la chromatographie gazeuse ou les quantités obtenues.

Ces résultats pourraient s'expliquer par une épimérisation **3***a* → **3***b*, épimérisation du type *endo* → *exo* qui se produirait pour une température élevée de réaction de Diels–Alder. D'après la littérature (8, 9) une isomérisation *endo* → *exo* peut s'effectuer selon deux voies différentes: un mécanisme dit "externe" où l'adduit *endo* par rétroréaction se transforme peu à peu en l'autre isomère avec passage par les composés de départ et une voie dite "interne" où l'épimérisation s'effectue directement sans qu'il y ait

scission. Cependant nous avons observé que l'adduit **3***a* chauffé à 160° ou 220° en présence ou non d'anhydride maléique ne s'épimérise pas comme d'ailleurs à 195° l'adduit **3***b*. De l'ensemble des résultats obtenus, on peut en déduire que, pour la synthèse diénique étudiée, une température de réaction élevée semble améliorer le rendement en isomère **3***b* sans que celui-ci provienne toutefois d'une isomérisation *endo* → *exo*.

La structure de l'adduit **3***b* a été déterminée tout d'abord par voie chimique: ce composé, traité à la température ordinaire par de la soude alcoolique durant six heures, se transforme en fumaropimarate de monométhyle **4**. Les caractéristiques physiques du produit ainsi obtenu sont identiques à celles du composé provenant de l'épimérisation de l'adduit **3***a* (7). Ce résultat ne peut être concevable que si **3***b* a une configuration *exo* et provient de l'attaque du diène par le face α.

On peut d'autre part considérer comme arguments en faveur de la structure **3***b* les observations suivantes: si l'on fait agir sur ce composé l'acide *p*-nitroperbenzoïque, on obtient un époxyde dont la stéréochimie **5** est attribuée par analogie (7) et qui se transforme en époxydetriester **6** sous l'action du diazométhane méthanolique. En traitant **5** par de l'acide sulfurique et du méthanol, on aboutit notamment au composé **6** sans apparition d'aucune substance lactonique comme en série *endo*-maléopimarique. De même le triester **7**, provenant du traitement de **3***b* par du diazométhane en solution méthanolique, est transformé par action de l'acide *p*-nitroperbenzoïque en époxyde (**6**) sans formation, comme en série *endo*, d'un quelconque composé lactonique. Une configuration *exo* est compatible avec les résultats ainsi obtenus.

Des études de résonance magnétique nucléaire permettent de confirmer la structure du composé **3***b*. Celui-ci, en solution dans le deutériochloroforme, donne un pic à δ 0.61 p.p.m. qui correspond au méthyle porté par le carbone-10. Cette valeur de résonance située vers les champs forts s'explique (2) par l'anisotropie magnétique de la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

double liaison *ou* des carbonyles du groupement anhydride. Or la réduction de **3***b* par le borohydrure de sodium (5, 10, 11) conduit au diol **8** qui malgré la disparition de la fonction anhydride donne cependant un pic à 0.59 p.p.m. attribué au méthyle angulaire. Cet effet d'écran confirme la position de la double liaison et se retrouve chez les composés **4** et **7**. Par contre, chez les époxydes **5** et **6**, le méthyle en C-10 donne une résonance à 0.84, valeur tout à fait normale.

En conclusion, on peut affirmer que la série *exo*-maléopimarique est accessible à l'aide d'une réaction de Diels–Alder effectuée à haute température.

Partie expérimentale

Sauf mentionné, les chromatoplaques analytiques (0.25 mm) et préparatives (0.5–0.75 mm) sont confectionnées avec du gel de silice HF 254 + 366; les points de fusion corrigés ont été déterminés à l'aide d'un microscope Leitz; les pouvoirs rotatoires sont mesurés avec un polarimètre Jouan–Roussel en solution chloroformique et à des concentrations exprimées en g/100 ml. Les spectres infrarouge (i.r.) et de résonance magnétique nucléaire (r.m.n.) ont été enregistrés sur des appareils Perkin–Elmer 521 et Varian A60 (δ; t.m.s. interne; *J* en c.p.s.).

Isolement de 3b

La réaction de Diels–Alder est effectuée comme décrite (7) sur 50 g de résinates de méthyle. Le filtrat provenant de la précipitation de l'adduit **3***a* (23 g) est évaporé, puis traité plusieurs fois par de l'eau chauffée préalablement à la température de 50°. Après extraction à l'éther et séchage sur sulfate de sodium, on obtient une huile jaune orangée (45 g) contenant des résinates de méthyle, les deux adduits et des produits acides.

Ce produit brut (8 g) est chromatographié sur 500 g de florisil (diamètre 125 mm, hauteur 200 mm): les résinates de méthyle sont élués par du tétrachlorure de carbone et les deux adduits (2.8 g) par du chloroforme. La séparation des deux adduits (500 mg) est effectuée par chromatographie sur un mélange de gel silice Mallinckrodt célite (2/1) (75 g; 30 × 300 mm) avec contrôle du fractionnement sur chromatoplaques (benzène–méthyl éthyl cétone 9/1). L'adduit **3***b* (170 mg; Rdt total 8%) est élué par du benzène contenant 1% de chloroforme. L'anhydride du (dicarboxy-1′α,2′α éthano)-8α,12α abiétène-13 oate-18 de méthyle (*exo*-anhydro-maléopimarate de méthyle) est recristallisé dans cinq volumes d'éthanol absolu: $F = 193°$; $[\alpha]_D = -42°$ (2.4); i.r. ($CHCl_3$): 1855, 1783 (anhydride) 1725; r.m.n. ($CDCl_3$): 0.61 (CH_3-10), 1.03 (isopropyle, $J = 7$), 1.12 (CH_3-4), 3.60 (CO_2CH_3), 5.42 (H—C═); malgré l'utilisation de plusieurs solvants non n'avons pu mettre en évidence que la moitié de l'octet dû à l'hydrogène 2′β: (quadruplet, $J_{2'\beta\,11\beta} \sim 2$, $J_{2'\beta 12} \sim 4$).

Anal. calc. pour $C_{25}H_{34}O_5$: C, 72.43; H, 8.27. Trouvé: C, 72.31; H, 8.14.

Préparation du composé 4

Une solution de 50 mg d'adduit **3***b* dans 2 ml de soude 2 *N* alcoolique à 80% est agitée pendant 6 h à la température ordinaire. Le mélange réactionnel est jeté dans 15 ml d'eau et extrait par 3 × 3 ml d'éther. Les phases alcalines sont ensuite acidifiées par de l'acide chlorhydrique 6 *N*, puis extraites par du benzène–éther (1/1). Les couches organiques, réunies, sont traitées deux fois par 5 ml d'une solution de carbonate de sodium à 5%, les phases alcalines étant acidifiées puis extraites par du benzène–éther. Le produit brut (49 mg) après plusieurs recristallisations dans cinq volumes, alternativement, de benzène–dioxanne (2/1) et d'éthanol, conduit à 56% de (dicarboxy-1′β,2′α éthano)-8α,12α abiétène-13 oate-18 de méthyle (fumaropimarate de méthyle) **3***b*: $F = 297°$; $[\alpha]_D = +35°$ ($c = 0.6$; éthanol); i.r. (KBr): 3220, 1730, 1710, 1690 (épaulement); r.m.n. (CF_3COOH): 0.76 (CH_3-10), 1.17 (isopropyle, $J = 7$), 1.26 (CH_3-4), 5.48 (H—C═).

Anal. calc. pour $C_{27}H_{40}O_6$: C, 69.42; H, 8.39. Trouvé: C, 69.13; H, 8.44.

Ces constantes sont identiques à celles du produit résultant de l'action de la soude alcoolique sur l'adduit **3***a*.

Epoxyde 5

En opérant comme décrit (7) et à partir de 20 mg de **3***b*, on obtient 92% de produit brut. Après trois recristallisations dans du chloroforme–oxyde d'isopropyle (1/1) l'anhydride de l'époxy-13α,14α (dicarboxy-1′α,2′α éthano)-8α,12α abiétanoate-18 de méthyle (11 mg) présente les caractéristiques suivantes: $F = 298°$; $[\alpha]_D = -11°$ (2); i.r. ($CHCl_3$): 1850, 1783, 855 (époxyde); r.m.n. ($CDCl_3$): 0.84 (CH_3-10), 0.71 et 1.05 (2d isopropyle $J = 7$), 1.19 (CH_3-4).

Anal. calc. pour $C_{25}H_{34}O_6$: C, 69.74; H, 7.96. Trouvé: C, 69.58; H, 7.80.

Action du diazométhane ou de l'acide sulfurique–méthanol sur l'époxyde 5

Une solution de 100 mg de **5** dans du benzène–méthanol (1/7) est traitée une nuit à −20° par un excès de diazométhane éthéré. Par chromatographie préparative sur couche mince, on isole 80 mg d'époxy-13α,14α (diméthoxycarbonyl-1′α,2′α éthano)-8α,12α abiétanoate-18 de méthyle (**6**) huileux: $[\alpha]_D = +11°$ (1.4); i.r. ($CHCl_3$): 3035, 1740, 890, 870.

Anal. calc. pour $C_{27}H_{40}O_7$ (sur 2.3 mg distillé): C, 68.04; H, 8.46. Trouvé: C, 68.41 H, 8.39.

L'action de l'acide sulfurique–méthanol sur 50 mg de **5** selon (7) conduit à 48 mg d'huile (pas de bande i.r. caractéristique d'une γ-lactone) donnant sur chromatoplaque au moins quatre taches. Le composé **6** est isolé (49%) par chromatographie préparative sur couche mince.

$[\alpha]_D = +8°$ (1.5); r.m.n. ($CDCl_3$): 0.74 et 1.06 (2d isopropyle $J = 7$), 0.83 (CH_3-10), 1.11 (CH_3-4), 3.07 (H-14), 3.59 (9H).

Action du diazométhane sur l'adduit 3b

Le composé **3***b* (50 mg) dissous dans 5ml de méthanol est traité à −10° par une solution éthérée de diazométhane. On distille à $85°/10^{-2}$ mm le (diméthoxycarbonyl-1′α, 2′α éthano)-8α,12α abiétène-13 oate-18 de méthyle **7**, composé huileux: $[\alpha]_D = -6°$ (2.4); i.r. ($CHCl_3$): trois bandes vers 1730; r.m.n. ($CDCl_3$): 0.62 (CH_3-10), 1.09 (isopropyle $J = 7$), 1.15 (CH_3-4), 3.52 (6H), 3.65 (3H), 5.43 (H—C═).

Anal. calc. pour $C_{27}H_{40}O_6$: C, 70.41; H, 8.75. Trouvé: C, 70.62; H, 8.71.

L'action du méthanol sulfurique sur **3***b* conduit au même triester huileux.

Action de l'acide p-nitroperbenzoïque sur **7**

En opérant comme pour l'époxydation de **3***b*, le produit brut obtenu (pas de bande i.r. caractéristique d'une γ-lactone) donne cinq taches sur chromatoplaque, dont la plus intense correspond au composé **6**, isolé par chromatographie sur couche épaisse. Les spectres i.r. et de r.m.n. montrent que ce produit est identique aux échantillons obtenus par action du diazométhane ou du méthanol sulfurique sur le composé **5**.

Réduction par le borohydrure de sodium du composé **3***b*

Selon le mode opératoire décrit (5) et à partir de 50 mg de **3***b*, on obtient 45 mg d'un mélange de deux composés séparés sur chromatoplaques préparatives.

La γ-lactone du [carboxy-1′α (ou 2′α) hydroxyméthyl-2′α (ou 1′α) éthano]-8α,12α abiétène-13 oate-18 de méthyle (33%) est recristallisée dans cinq volumes de méthanol: $F = 159°$; i.r. ($CHCl_3$): 1755 (lactone), 1718; r.m.n. ($CDCl_3$): 0.60 (CH_3-10), 1.03 (isopropyle $J = 7$), 1.13 (CH_3-4).

Anal. calc. pour $C_{25}H_{36}O_4$: C, 74.96; H, 9.06. Trouvé: C, 75.13; H, 8.96.

Le (dihydroxyméthyl-1′ξ,2′ξ éthano)-8α,12α abiétène-13 oate-18 de méthyle (47%) est recristallisé dans cinq volumes d'acétate d'éthyle: $F = 155°$; $[\alpha]_D = +5°$ (2.6); i.r. ($CHCl_3$): 3610, 3410, 1720; i.r. (CCl_4 1‰): 3632 (OH libre), 3490 (OH lié); r.m.n. ($CDCl_3$): 0.59 (CH_3-10), 1.01 (isopropyle $J = 7$), 1.15 (CH_3-4), 5.46 (H—C=).

Anal. calc. pour $C_{25}H_{40}O_4$: C, 74.21; H, 9.97. Trouvé: C, 74.19; H, 9.94.

Photolysis and mass spectra of *trans*-cinnamimide[1]

Robert T. LaLonde and Curry B. Davis

Department of Chemistry, State University College of Forestry, Syracuse University, Syracuse, New York 13210

Received March 25, 1969

Using Pyrex filtered light, irradiation of *trans*-cinnamimide in 1,2-dimethoxyethane solution gave β-truxinimide (48% yield), *cis*-cinnamamide and *trans*-cinnamamide. Both *trans*-cinnamimide and β-truxinimide undergo fragmentation in the mass spectrometer to give $C_{16}H_{14}+$, $C_{16}H_{13}+$, $C_{16}H_{12}+$, and $C_{14}H_{12}+$.

Canadian Journal of Chemistry, 47, 3250 (1969)

The solution photolysis of cinnamic acids, esters, and amides is capable of producing under widely varying conditions cyclobutanes, hydrogen abstraction reactions, *cis–trans* isomerizations and internal cyclizations. The following may be given as examples. Coumarin undergoes dimerization affording cyclobutane isomers, the geometry of which is solvent and sensitizer dependent (1, 2). Ethyl *trans*-cinnamate, ethyl *trans*-α-methylcinnamate and analogous lactones undergo isomerization and hydrogen abstraction reactions (3). A different mode of reactivity has been observed for α-phenylcinnamic acid and α-phenylcinnamamide (4). The acid and amide in each case give a β-lactone and a β-lactam and their formation have been viewed as cyclization reactions belonging to the general class of electrocyclic processes.

In connection with a study of the chemistry of α,β-unsaturated *N*-acylimides and imides we have explored the solution photochemistry of *trans*-cinnamimide (**1**).

A carefully degassed 1,2-dimethoxyethane solution of **1** was irradiated in a Pyrex tube

Photolysis and mass spectra of *trans*-cinnamimide[1]

Robert T. LaLonde and Curry B. Davis

Department of Chemistry, State University College of Forestry, Syracuse University, Syracuse, New York 13210

Received March 25, 1969

Using Pyrex filtered light, irradiation of *trans*-cinnamimide in 1,2-dimethoxyethane solution gave β-truxinimide (48% yield), *cis*-cinnamamide and *trans*-cinnamamide. Both *trans*-cinnamimide and β-truxinimide undergo fragmentation in the mass spectrometer to give $C_{16}H_{14}+$, $C_{16}H_{13}+$, $C_{16}H_{12}+$, and $C_{14}H_{12}+$.

Canadian Journal of Chemistry, 47, 3250 (1969)

The solution photolysis of cinnamic acids, esters, and amides is capable of producing under widely varying conditions cyclobutanes, hydrogen abstraction reactions, *cis–trans* isomerizations and internal cyclizations. The following may be given as examples. Coumarin undergoes dimerization affording cyclobutane isomers, the geometry of which is solvent and sensitizer dependent (1, 2). Ethyl *trans*-cinnamate, ethyl *trans*-α-methylcinnamate and analogous lactones undergo isomerization and hydrogen abstraction reactions (3). A different mode of reactivity has been observed for α-phenylcinnamic acid and α-phenylcinnamamide (4). The acid and amide in each case give a β-lactone and a β-lactam and their formation have been viewed as cyclization reactions belonging to the general class of electrocyclic processes.

In connection with a study of the chemistry of α,β-unsaturated *N*-acylimides and imides we have explored the solution photochemistry of *trans*-cinnamimide (**1**).

A carefully degassed 1,2-dimethoxyethane solution of **1** was irradiated in a Pyrex tube

1 2

immersion apparatus. The disappearance of **1** was monitored by observing the decreasing intensity of the 300 mμ absorption maximum. After 113 h, at least 96% of **1** had been transformed. A thin-layer chromatogram (t.l.c.) of the crude product mixture indicated the presence of three new materials, one present in excess of the other two. The chromatogram also revealed the presence of a very small amount of unconverted **1**.

The predominating product was isolated in 48% yield. Its mass spectrum[2] revealed a molecular ion peak at *m/e* 277. Other features of the mass spectra of this product are discussed in another section of this note. That the predominating product possessed a five-membered imide was suggested by the strong infrared (i.r.) carbonyl bands at 1710 and 1770 cm^{-1}. The basis for this suggestion was the appearance of bands at 1710 and 1760 cm^{-1} in the five-membered imide, cyclobutane-*cis*-1,2-dicarboximide[3]. On the other hand, the six-membered imide 1,3-dimethylcyclobutane-1,3-dicarboximide revealed bands at 1710 and 1730 cm^{-1} (5). The absence of a band in the region of 1650 cm^{-1} indicated the loss of carbon–carbon double bonds in the formation of the predominating photo-product. The nuclear magnetic resonance (n.m.r.) spectrum displayed a ten proton aromatic absorption at 2.93 τ and a four proton A_2B_2 pattern centered at 6.11 τ. No signals in the vinyl proton region were observed.

Strong base hydrolysis of the predominating photo-product gave a dicarboxylic acid which on admixture with authentic β-truxinic acid gave no depression in melting point[4]. The dicarboxylic acid was converted to a dimethyl ester. This likewise showed no depression in melting point on admixture with authentic dimethyl β-truxinate.

The two minor products of photolysis were isolated and identified as *cis*- and *trans*-cinnamamide by comparison i.r. spectra.

The evidence presented above attests to the formation of the cyclobutane photoisomer (**2**), by intramolecular cyclization and *cis*- and *trans*-cinnamamide, presumably by nitrogen–carbonyl fission and hydrogen abstraction from solvent. Interestingly, only a single isomer of the truxinimide–truxillimide series was produced. Its formation is consistent with a photochemically allowed *cis,cis* mode of cyclization (6). Possibly this result could mean that the isomerization of a *trans*- to *cis*-cinnamoyl moiety occurs at the amide rather than the imide (**1**) stage. Isomerization of *trans*- to *cis*-cinnamamide under photolysis conditions does occur. Should *trans* to *cis* isomerization occur at the amide stage during the photolysis of **1**, it follows that cyclobutane formation and carbonyl–nitrogen bond fission are faster than is *trans* to *cis* isomerization in **1**. Alternatively, should *trans* to *cis* isomerization occur in **1**, then the absence of other truxinimide isomers could mean that the formation of these isomers from either a *trans* or *cis* excited state is much slower than the bond fission process or the formation of β-truxinimide from a *trans* excited state.

The course of the photolysis of **1** is also of interest in relation to the mass spectrum of **1**. This spectrum displayed two prominent sets of triads among several other peaks. The first of these triads was located at *m/e* 206, 205 (base peak), and 204 and the second at 180, 179, and 178. High resolution mass spectrometry (h.r.m.s.) showed the peaks of the first triad corresponded to $C_{16}H_{14}$ +, $C_{16}H_{13}$ +, and $C_{16}H_{12}$ +. This manner of fragmentation at first was interpreted in terms of either the five-membered imide **2***a* or the six-membered imide **3**, but later identification of *m/e* 180 as $C_{14}H_{12}$ + ($C_6H_5CH{=}CHC_6H_5$ +, by h.r.m.s.), the i.r. spectral characteristics, and conversion to β-truxinic acid eliminated **3** from consideration. However, the

3

mass spectra of the imide **1** (*m/e* 43, base peak) was similar to the spectrum of **2**. The spectra in the region *m/e* 100-M^+ are reproduced in Fig. 1. The h.r.m.s. of **1** revealed the fragments $C_{16}H_{14}$ +, $C_{16}H_{13}$ +, $C_{16}H_{12}$ +, and $C_{14}H_{12}$ + as did the spectrum of **2**. Thus the use of mass spectra for structure information was of questionable value since it was reasoned that if both **1** and **2** could produce $C_{14}H_{12}$ + then it might be possible also for **3** to undergo bond rupture in the mass spectrometer to give a charged species structurally similar to **1** which subsequently would give $C_{14}H_{12}$ +. Though the mass spectral results were not of great utility in determining the structure of **2**, they were of interest nonetheless since they indicated the occurrence of an isomerization in the mass spectrometer which was similar to that observed in the photolysis of **1**.

Experimental

Spectra were obtained as follows: nuclear magnetic resonance (n.m.r.) in solution as indicated, 2% TMS, Varian A60A; i.r. Baird-Atomic Spectrometer; mass spectra, Atlas CH-4 direct inlet, and determined by Dr. John MacLeod and Mr. Robert Ross; ultraviolet (u.v.) Cary model 14, in 1,2-dimethoxyethane and ethanol; melting points were determined on a Köfler micro hot stage and are uncorrected.

trans-Cinnamimide (1)

The procedure of Thompson (7) was used to prepare **1**: m.p. 198–200° (lit. 198.5–199°); mass spectra M^+ *m/e* 277, base peak *m/e* 43; h.r.m.s., *m/e* 206, 206.10916 (calcd. for $C_{16}H_{14}$, 206.10955), *m/e* 205, 205.10148 (calcd. for $C_{16}H_{13}$, 205.10172), *m/e* 204, 204.09372 (calcd. for $C_{16}H_{12}$, 204.09390), *m/e* 180, 180.09409 (calcd. for $C_{14}H_{12}$, 180.09390); u.v. λ_{max}(DME) = 300 mμ, ε = 39 000.

Photolysis of trans-Cinnamimide (1)

The photolysis vessel consisted of a 500 ml round bottom flask fitted with a 19 mm (I.D.) Pyrex, concentric well which accommodated the lamp. The vessel also was equipped with a 12 mm side arm which was fitted with a 2 mm quartz cell containing a 1.90 mm spacer.

The light source was a General Electric AH-4 medium pressure mercury vapor lamp modified for water cooling by sealing the quartz bulb in a 16 mm (O.D.) Pyrex tube. This modified lamp was placed in the concentric Pyrex well. Tap water was circulated between inner Pyrex tube and outer well and was effective in maintaining the reaction temperature between 10–15°. The lamp was operated at a primary input of 275 W.

A 1.01 g sample of *trans*-cinnamimide (3.6 mmoles) was dissolved in 400 ml of anhydrous 1,2-dimethoxyethane in the photolysis flask. The solution was degassed and the flask sealed at reduced pressure. Periodically the light source was turned off, the flask was inverted and the optical densities at 300 and 262 mμ were determined. Optical densities after various time intervals of irradiation are given as follows:

Photolysis time (h)	O.D. λ_{max} 300 mμ	O.D. λ_{max} 265 mμ
0.0	3.5	—
21.0	3.2	—
69.0	1.6	0.1
113.0	0.15	0.55

After irradiation for 113.0 h, the solvent was distilled off on the vacuum line and thereby 1.18 g of crude product

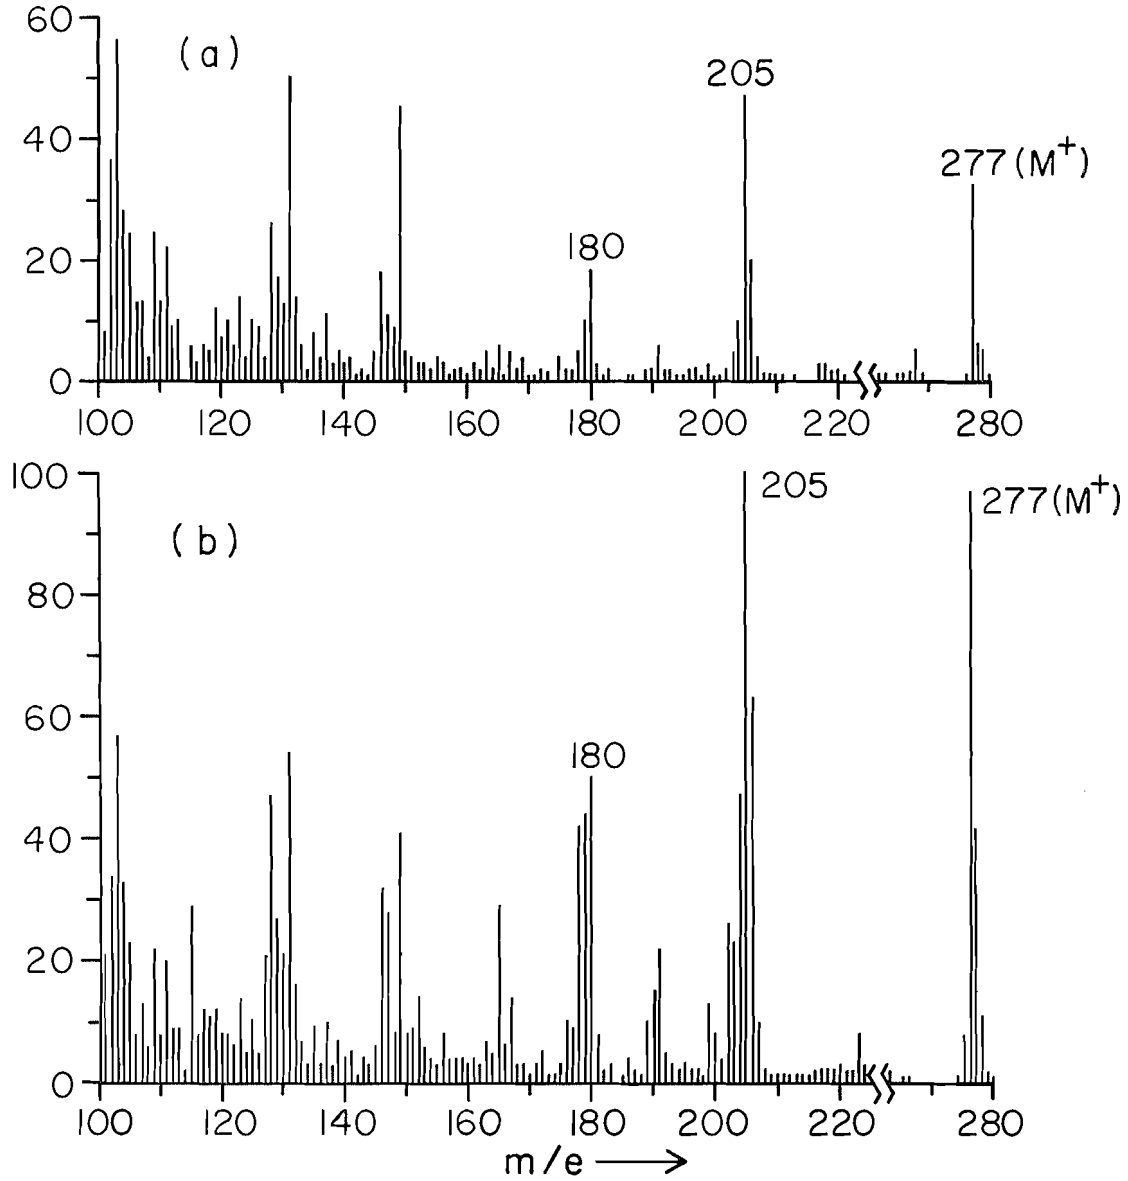

FIG. 1. The mass spectrum in the region *m/e* 100-M^+ of: (*a*) *trans*-cinnamimide; (*b*) β-truxinimide.

was recovered as an oil. This showed four spots on t.l.c. (unactivated 0.25 mm Silica Gel, GF-254, 5% methanol in chloroform). Several recrystallizations from cyclohexane–acetone afforded 202 mg of pure β-truxinimide: m.p. 225–227°; i.r. (KBr) 1770 (sh) and 1710 cm^{-1} (s); n.m.r. (hexachloroacetone) 2.93 τ (singlet, 10H), 6.11 (symmetrical A_2B_2 multiplet, 4H); u.v. λ_{max}(DME) 262 mμ, ε = 700; mass spectrum, M^+ *m/e* 277, base peak *m/e* 205; h.r.m.s., *m/e* 277, 277.11001 (calcd. for $C_{18}H_{15}NO_2$, 277.11028), *m/e* 206, 206.10974 (calcd. for $C_{16}H_{14}$, 206.10955), *m/e* 205, 205.10187 (calcd. for $C_{16}H_{13}$, 205.10172), *m/e* 204, 204.09410 (calcd. for $C_{16}H_{12}$, 204.09390), *m/e* 180, 180.09375 (calcd. for $C_{14}H_{12}$, 180.09390).

The filtrates from recrystallization were combined and the mixture separated on a column of 20 g of activated Silica Gel eluted with a linear gradient of 2-butanol in chloroform. The first material eluted was 32 mg of *trans*-cinnamimide: m.p. 199–200°. The second material eluted (1% methanol in chloroform) was 266 mg of β-truxinimide. Continued elution with about 10% 2-butanol in chloroform produced a total of 450 mg in several fractions. The last four fractions contained 47 mg whose t.l.c. and i.r. spectral properties were identical with those

of *trans*-cinnamamide. The several fractions preceding *trans*-cinnamamide were rich in an unidentified product as shown by t.l.c. Preparative t.l.c. (0.50 mm Silica Gel GF-254, 5% methanol in chloroform) of a portion of the combined fractions afforded an 8 mg sample of t.l.c. homogeneous (R_f 0.25, 5% methanol in chloroform) *cis*-cinnamamide: i.r. ($CHCl_3$) 3570 (m), 3460 (m), 1680 (s), 1630 (m), and 1590 cm^{-1} (m).

Hydrolysis of β-Truxinimide

An 89 mg sample of pure β-truxinimide (0.3 mmole) was dissolved in 30 ml of Claisen's alkali and the reaction mixture was refluxed, under nitrogen, for 24 h. Concentrated hydrochloric acid was added to bring the mixture to pH 2, and the aqueous phase was extracted continuously with ether. The ether extract was dried over anhydrous magnesium sulfate and the solvent evaporated under vacuum to afford 129 mg of a residue. Two recrystallizations from benzene–acetic acid afforded 40 mg (45% yield) of pure β-truxinic acid: m.p. 190–202°. No melting point depression was observed when mixed with an authentic sample of β-truxinic acid[4]: i.r. (KBr) 3000 (very broad), 2300 (broad) and 1700 cm^{-1}; n.m.r. (acetone-d_6) 6.09 τ (cyclobutane methine multiplet, 2H, B_2 of A_2B_2), 5.58 τ (cyclobutane methine multiplet, 2H, A_2 of A_2B_2) and 2.95 τ (aromatic hydrogen singlet, 10H).

A 40 mg sample of β-truxinic acid (0.13 mmoles) was treated with diazomethane. The white crystalline solid was recrystallized to a constant melting point from hexane. An authentic sample of dimethyl β-truxinate was prepared from a sample of the authentic β-truxinic acid. The i.r. spectra of both esters were identical. Dimethyl β-truxinate: m.p. 69–70°; i.r. 1730 cm^{-1} (strong); n.m.r. 6.28 τ (methoxyl singlet, 6H), 6.05 τ (cyclobutane methine multiplet, 2H, B_2 of A_2B_2), 5.63 τ (cyleobutane methine multiplet, 2H, A_2 of A_2B_2) and 2.92 τ (aromatic hydrogen singlet, 10H).

Synthesis of cis-Cinnamamide

Phenylpropiolic acid (m.p. 132–136°) was prepared by the method of Reimer (8) and converted to phenylpropiolyl chloride (b.p. 63–66° at 0.6 mm) through a 2 h treatment with a threefold excess of thionyl chloride at room temperature. A 6.5 g sample of phenylpropiolyl chloride was dissolved in 50 ml of anhydrous ether and excess ammonia gas was bubbled into the solution. The solvent was evaporated from the heterogeneous reaction mixture and the solid washed with 25 ml of water and extracted with chloroform (3 × 30 ml). The chloroform extracts were combined and dried over anhydrous magnesium sulfate. When the solvent was removed on the rotary evaporator, phenylpropiolamide (m.p. 108–109°) was afforded in nearly quantitative yield.

A 1.53 g sample of phenylpropiolamide (0.01 moles), dissolved in 50 ml of methanol, was shaken in an atmosphere of hydrogen at standard pressure along with 2% palladium on barium sulfate catalyst, poisoned with 170 mg of reagent grade quinoline. A total of 259 ml of hydrogen was absorbed over 2.7 h (258 ml calculated for 0.01 mole). No further hydrogen uptake was observed after an additional 30 min of hydrogenation. Removal of the catalyst by filtration, and the solvent on a rotary evaporator produced a residue which was then redissolved in chloroform. The resulting solution was washed consecutively with 30 ml of 1 *N* hydrochloric acid, water and dried over anhydrous magnesium sulfate. Removal of the solvent at the rotary evaporator gave the crude product. One recrystallization from cyclohexane afforded 1.0 g (70% yield) of analytically pure *cis*-cinnamamide: m.p. 83–87°; u.v. λ_{max}(EtOH) 255 mμ, ε = 10 600; i.r. ($CHCl_3$) 3570, 3460, 1680, 1630, and 1590 cm^{-1}; n.m.r. 4.07 τ (vinyl hydrogen doublet, J = 12 Hz, 1H), 3.23 τ (vinyl hydrogen doublet, J = 12 Hz, 1H) and 2.6 τ (aromatic hydrogen multiplet, 5H).

Anal. Calcd. for C_9H_9NO: C, 73.46; H, 6.12; N, 9.53. Found: C, 73.38; H, 6.36; N, 9.24.

1,2,3,4,5-Pentaphenylimidazolium benzoate

James G. Smith and Hazem M. H. Ghonima
University of Waterloo, Department of Chemistry, Waterloo, Ontario

Received February 24, 1969

The compound reported to be *N,N'*-dibenzoyl-*N,N'*-diphenylstilbene-α,α'-diamine is shown to be 1,2,3,4,5-pentaphenylimidazolium benzoate.

Canadian Journal of Chemistry, 47, 3254 (1969)

In connection with other work (1) the synthesis of *N*-benzoyl-*N,N'*-diphenylstilbene-α,α'-diamine (**1**), reported by Everest and McCombie (2), was repeated. The synthesis proceeds by the initial preparation and subsequent alkaline hydrolysis of a compound whose structure was considered

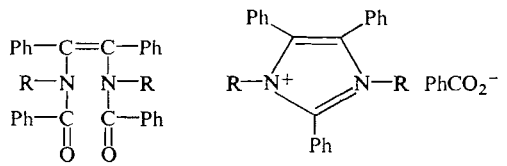
1 2 3

to be *N,N'*-dibenzoyl-*N,N'*-diphenylstilbene-α,α'-diamine (**2**). This structure (**2**) was indicated by the conversion of the compound with aqueous alkali to **1** plus benzoic acid.

It has been found that the infrared (i.r.) spectrum (Fig. 2) of the compound is incompatible with structure **2** since no amide carbonyl band appears in the 1630–1650 cm^{-1} region. Furthermore, the remarkably easy hydrolysis of one *N*-benzoyl group appears unlikely for a compound of structure **2**. Structure **3** was felt to be compatible with the i.r. spectrum, with the ready formation of **1** by alkaline hydrolysis (6), and with the fact that both **1** and **3** gave the same picrate; however, at the time, no convenient way of firmly establishing this structure was available.

Recently, the synthesis of a related compound, 1,2,3,4,5-pentaphenylimidazolium chloride (**4**), has been described (3). With this as a starting point, the proposed structure **3** has been confirmed. The imidazolium chloride (**4**) underwent facile hydrolysis to **1** in alcoholic alkali. Treatment of the chloride (**4**) with silver benzoate produced the benzoate (**3**) and treatment of the benzoate with excess lithium chloride in *N,N*-dimethylacetamide produced the chloride (**4**). Thionyl chloride also effected this last conversion, although the conversion of **1** to **4** by this means was not successful.

In view of the above results, the structure **5** assigned by McCombie to products from similar reactions are suspect. While a detailed structure proof has not been performed, the fact that both these compounds lack carbonyl bands in their i.r. spectra and both are obtained under reaction conditions similar to those producing **3**, strongly indicates that their true structure is **6**. McCombie's reaction conditions thus provide a convenient, although inefficient, means of preparing these pentaarylimidazolium salts.



5 6

R = *m*-tolyl or *m*-chlorophenyl

Experimental

Infrared spectra were recorded on a Beckmann IR-10 spectrophotometer using Nujol mulls. The spectra reported in Fig. 1 and 2 were recorded on a Beckmann IR-9 spectrophotometer using either a Nujol mull (Fig. 1) or a split Fluorolube–Nujol mull (Fig. 2).

1,2,3,4,5-Pentaphenylimidazolium Benzoate (3)

The compound was prepared according to McCombie's directions (2) in 11% crude yield. In accordance with these directions, purification was effected by a lengthy extraction with diethyl ether. A simpler purification method was recrystallization from *N,N*-dimethylacetamide (27 ml/g). Infrared spectra of both samples were identical and the absence of a carbonyl absorption band is evident from Fig. 2.

Alternatively, the benzoate (**3**) can be prepared from the chloride (**4**). The chloride (**4**) (0.400 g, 0.00083 moles) was dissolved in a boiling mixture of 15 ml of *N,N*-dimethylacetamide and 4 ml of water. Silver benzoate (5) (0.195 g, 0.00085 moles) dissolved in 10 ml of hot *N,N*-dimethylacetamide was then added. After boiling briefly, the mixture was filtered, the filtrate was evaporated, and the brownish crystalline residue (0.415 g, 86% crude yield) recrystallized from 15 ml of *N,N*-dimethylacetamide to give 0.262 g of 1,2,3,4,5-pentaphenylimidazolium benzoate (**3**). The infrared spectra of the crude and the purified benzoate (**3**) were identical with that of the material prepared using McCombie's method.

1,2,3,4,5-Pentaphenylimidazolium Chloride (4)

A reference sample was prepared according to the published procedure (3). Purification was effected by recrystallization from ethanol or from *N,N*-dimethylacetamide containing 20% water (26 ml/g).

Alternatively, 0.570 g (.001 mole) of the benzoate (**3**) and 0.212 g (.005 mole) of lithium chloride were heated in 10 ml of *N,N*-dimethylacetamide to reflux for 5 min. The mixture was cooled and filtered to give 0.472 g (97% yield) of the chloride (**4**). Recrystallization was effected from 15 ml of *N,N*-dimethylformamide containing 10% water. The i.r. spectra of both the crude and recrystallized material were identical with that of the reference sample (**4**).

The benzoate (**3**) (0.150 g, 0.00026 moles) was refluxed

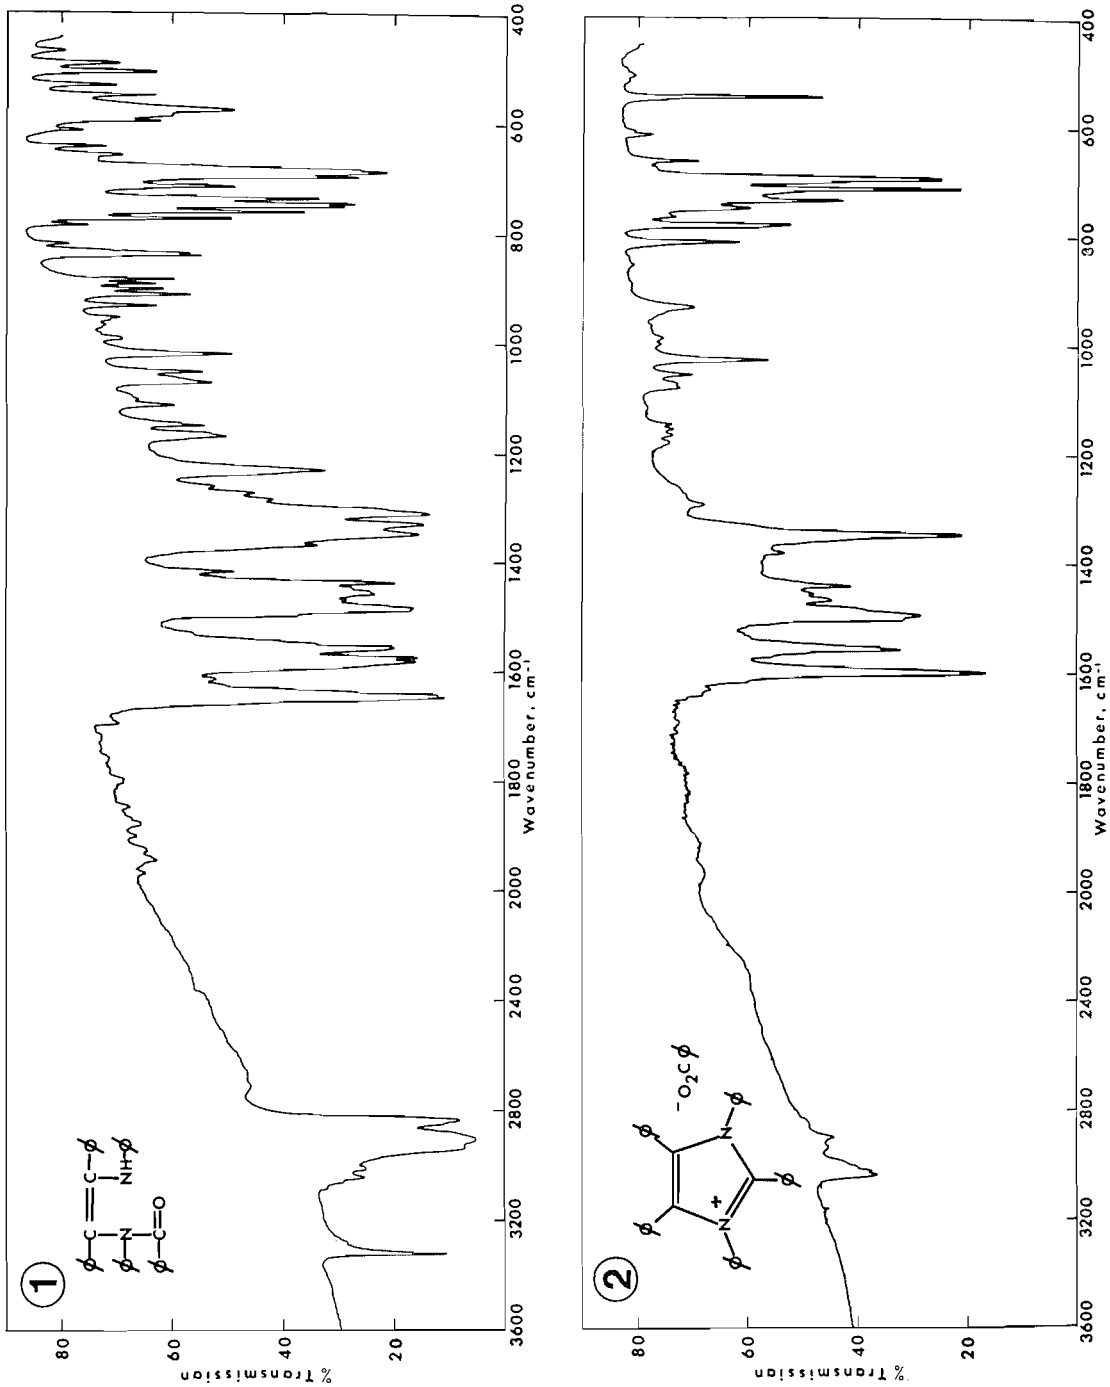

FIG. 1. Infrared spectrum of *N*-benzoyl-*N*,*N*′-diphenylstilbene-α,α′-diamene (**1**).
FIG. 2. Infrared spectrum of 1,2,3,4,5-pentaphenylimidazolium benzoate (**3**).

with 6 ml of thionyl chloride for 45 min. The clear solution was poured onto ice and the precipitate which separated was filtered, washed with water, and dried; weight: 0.097 g (76% yield). This material was recrystallized from 6 ml of *N,N*-dimethylacetamide containing 10% water to give 0.034 g of solid having an i.r. spectrum identical with that of the chloride (**4**). The i.r. spectrum of the crude material contained a strong band in the 1200–1300 cm^{-1} region which was attributed to sulfate or sulfite impurities.

Hydrolysis of 1,2,3,4,5-Pentaphenylimidazolium Chloride

The chloride (**4**) (0.25 g, 0.00056 moles) was dissolved in 20 ml of hot ethanol and 0.25 g of sodium hydroxide in 10 ml of ethanol was added. A yellow color developed and after boiling for 5 min the solution was treated with 50 ml of water. A yellow solid separated and was filtered, washed with water, and dried; weight 0.183 g (70% yield). This solid had a m.p. of 210–215° (with decomposition) and an i.r. spectrum identical to *N*-benzoyl-*N,N'*-diphenylstilbene-α,α'-diamine (**1**) prepared by a similar hydrolysis (2) of 1,2,3,4,5-pentaphenylimidazolium benzoate (**3**).

1,3-Diaryl-2,4,5-triphenylimidazolium Benzoate

These were prepared by the method described by Bailey and McCombie (4) in rather poor yields: 1,3-di-*m*-tolyl-, 0.7% yield, m.p. 370–375°, 1,3-di-*m*-chlorophenyl-, 4% yield. Both were purified by dissolving in boiling benzene containing sufficient methanol to solubilize the compound, filtering with decolorizing charcoal, and boiling the filtrate so as to distill off the methanol and precipitate the imidazolium salt. Neither the crude nor the purified products showed a carbonyl band in their i.r. spectra.

Azaindoles. Part II. The proton magnetic resonance spectra of 5-azaindoles[1]

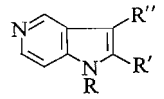
P. G. Riley and B. Robinson
Department of Pharmacy, University of Manchester, Manchester 13, England

Received March 27, 1969

The proton magnetic resonance (p.m.r.) spectra of 5-azaindole and 5-aza-1- and 3-methylindoles have been recorded and analyzed. It has been shown that in the spectrum of 5-azaindole, 3,7- coupling occurs but 1,3- coupling is not observed. In none of the spectra were any 2,6- or 4,6- couplings observed.

Canadian Journal of Chemistry, 47, 3257 (1969)

The p.m.r. spectra of 5-aza-2,3-dimethylindole (**1**; R = H, R' = R'' = Me) (1) and 5-azaindole (**1**; R = R' = R'' = H) (2) have been reported.



1

The doublet of doublets centered at 3.30 τ in the spectrum of 5-azaindole has been assigned (2) to the 3-proton (H-3) which, it is suggested (2), is coupled with H-2 ($J_{2,3}$ = 3.2 Hz) and the *N*-proton ($J_{1,3}$ = 1.0 Hz). The possibility that this latter fine coupling was not caused by 1,3- but by 3,7- coupling was not considered, probably because the H-7 signal was detected (2) only as a doublet of doublets centered at 2.61 τ ($J_{7,4}$ = 1.0 Hz, $J_{7,6}$ = 5.6 Hz). However, such 3,7- coupling or its equivalent is well-established in indole and many other polynuclear aromatic systems (3, 4). Also, the spectrum of 5-azaindole in DCl/D_2O (in which the *N*-proton will be completely exchanged for deuterium) still shows such coupling (2), and in the spectrum of 7-azaindole such coupling is absent (2, 5). We have now reinvestigated the p.m.r. spectrum of 5-azaindole (6) and have also analyzed the p.m.r. spectrum of its 1- and 3-methyl derivatives (**1**; R = Me, R' = R'' = H and R = R' = H, R'' = Me, respectively). The results of these studies have established that in the 5-azaindole

TABLE I

Analysis of the p.m.r. spectrum of 1-methyl-5-azaindole

Proton	Signal	Center of signal (τ)	Coupling constants (Hz)	Effect of double irradiation of signal
H-2	d	2.98*	$J_{2,3} = 3.0$	d^2(H-3) → d ($J = 0.8$ Hz)
H-3	d^2	3.46*	$J_{3,2} = 3.0, J_{3,7} = 0.8$	d (H-2) → s,d^3(H-7) → d^2 ($J = 6.0$ and 0.8 Hz)
H-4	d	1.11	$J_{4,7} = 0.8$	d^3(H-7) → d^2 ($J = 6.0$ and 0.8 Hz)
H-6	d	1.70	$J_{6,7} = 6.0$	d^3(H-7) → d^2 ($J = 0.8$ and 0.8 Hz)
H-7	d^3	2.83	$J_{7,6} = 6.0, J_{7,4} = J_{7,3} = 0.8$	d^2(H-3) → d ($J = 3.0$ Hz), d(H-4) and d(H-6) → s
NCH_3	s	6.27		

NOTE: s, singlet; d, doublet; d^2, doublet of doublets; d^3, doublet of doublets of doublets.
*cf. the signals of the 2- and 3-protons in the p.m.r. spectrum of 1-methylindole which are doublets centered at 3.18 and 3.52 τ, respectively (9).

system 3,7- coupling occurs and 1,3- coupling is absent.

The spectrum of 5-azaindole has a doublet centered at 1.02 τ ($J_{4,7} = 1.0$ Hz) (H-4), a doublet centered at 1.72 τ ($J_{6,7} = 6.0$ Hz) (H-6), a doublet of doublets centered at 3.38 τ ($J_{3,2} = 3.1$ Hz, $J_{3,7} = 0.9$ Hz) (H-3) and a broad singlet between −2.40 and −1.40 τ (NH). The signals caused by the H-2 and H-7 protons were superimposed to give a 2-proton multiplet between 2.56 and 2.78 τ. The chemical shifts for all these protons are in keeping with those previously (2) reported. Both they and the assigned couplings were verified by double irradiation of the (H-2 + H-7) multiplet, which caused the H-3, H-4, and H-6 signals to collapse to singlets, and by exchange of the *N*-proton with deuterium which had no observable effect on the spectrum other than eliminating the NH-signal.

Further evidence that 1,3- coupling was not contributing to the doublet of doublets signal of H-3, but that the couplings in this signal are caused by 3,2- and 3,7- couplings, was obtained by analysis (Table I) of the spectrum of 5-aza-1-methylindole, prepared by the reaction of 5-azaindole (6) with sodamide followed by methyl iodide (7, 8).

The H-7 signal in the spectrum of 5-aza-3-methylindole (8) appears as a doublet of doublets centered at 2.75 τ ($J_{7,6} = 5.7$ Hz, $J_{7,4} = 0.8$ Hz), as would be expected since now 3,7- coupling has been eliminated. The H-4 and H-6 protons give rise to doublets centered at 1.09 and 1.73 τ ($J_{4,7} = 0.8$ Hz, $J_{6,7} = 5.7$ Hz), respectively, as does the H-2 proton whose doublet signal is centered at 2.96 τ ($J = 0.8$ Hz). This latter doublet is caused by coupling of H-2 with the *N*-proton (a broad signal between −0.98 and −0.58 τ), since after exchange of this proton with deuterium the H-2 doublet collapses to a singlet.

Surprisingly, in spectra recorded in $CDCl_3$, 1,2- coupling is not observed in 7-azaindole (2) although it is observed (2) in 4-, 5-, and 6-azaindoles. The reason why such coupling should still be observed (2) in the spectra of 5- and 6-azaindoles recorded in DCl/D_2O solution remains obscure and is worthy of further investigation.

In none of the spectra described in the present studies were any 2,6- (4) (cf. ref. 2) or 4,6- (2) couplings observed.

Experimental

Proton magnetic resonance spectra were recorded in deutero-chloroform solution on a Varian HA 100 spectrometer, tetramethylsilane being used as internal standard; unless otherwise stated, all signals referred to integrated for one proton. Exchanges of *N*-protons for deuterium were effected by shaking the deutero-chloroform solutions with D_2O.

5-Azaindole and 5-Aza-3-methylindole

These were prepared as described in the literature (refs. 6 and 8, respectively).

5-Aza-1-methylindole

To liquid ammonia (20 ml) was added sodium (1 g) and a few crystals of anhydrous ferric chloride. After stirring for 1¼ h the original blue color of the mixture disappeared. Finely powdered 5-azaindole (5) (1.0 g) was then added, stirring continued for 1½ h, methyl iodide (2.5 ml) added, and stirring continued a further 4½ h. The excess ammonia and methyl iodide were then allowed to evaporate at room temperature overnight, and the residual traces of these reagents removed by heating on a steam-bath. The residue was shaken with water, strongly basified by the addition of sodium hydroxide and the liberated oil extracted with chloroform (3 × 25 ml). The combined chloroform extracts were washed with water (2 × 25 ml), dried (magnesium sulfate), and evaporated to afford a yellow-green oil which after distillation [b.p. 180–190 °C (bath temperature)/0.1 mm] gave a colorless oil which rapidly crystallized.

Recrystallization of the product could not be satisfactorily effected and therefore it was subjected to column chromatography in ether on grade "H" alumina. Upon evaporation of the ether eluates, colorless crystals were

Nuclear magnetic resonance spectrum and deuteration of porphobilinogen lactam and its derivatives[1]

Y. C. Kim[2]

Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received May 21, 1968

Derivatives of porphobilinogen are distinguished from those of its lactam in that the C_4- and C_7-protons of the latter show homoallylic coupling, $J_{4,7} = 2.5$–3.0 Hz (150°) and the C_4-protons are exchangeable in alkaline solution.

Canadian Journal of Chemistry, 47, 3259 (1969)

As will be reported elsewhere (1), the very labile dipyrryl-methane **1** was synthesized for biogenetic studies as a reasonably stable potassium salt. As obtained by the hydrolysis of **8**, it was difficult to characterize, and the usual methods did not clearly show that the lactam ring had been opened. We now report an examination of model porphobilinogen derivatives **2–10** (1–3) showing that, in lactam but not in open forms, the C_4- and C_7-protons show homoallylic coupling, $J_{4,7} = 2.5$–3.0 Hz (150°) and the C_4-protons are exchangeable; in alkaline D_2O, this exchange is faster than ring-opening.

*All signals were triplets.
†The chemical shift of the HOD signal (assigned 5.30) was used as an internal standard.
‡Protons on the propionic methylenes.
§Potassium salt in D_2O.
‖Sodium salt in D_2O.

The nuclear magnetic resonance (n.m.r.) spectra of the lactams **2–8** suggested homoallylic coupling between the C_4- and C_7-protons. These appear as broad singlets, $w_{1/2}$ = 7–9 Hz at 35°, and as well-resolved triplets, $J_{4,7}$ = 2.5–3.0 Hz at 150° (Table I). Analogous homoallylic coupling had been noted (4,5), particularly in **11** (6) which had $J_{2,5}$ = 3.0 Hz. In contrast to these signals for the C_4- and C_7-protons in **4** and **5**, those for the corresponding protons in the open forms **9** (K salt in D_2O: C_4- and C_7-protons at τ 6.63 and τ 5.90) and **10** (Na salt in D_2O: C_4- and C_7-protons at τ 6.80 and τ 6.49) were all sharp singlets indicating no homoallylic coupling.

After the lactam **2** had stood for one week in DMSO-d_6/KOBu^t at 50°, its spectrum at 150° showed no C_4-proton signal at τ 6.73 and the triplet at τ 5.67 for the C_7-protons had collapsed to a singlet. As this could only be ascribed to deuteration at C_4, it established both the assignments for the C_4- and C_7-protons and also the homoallylic coupling. Again the open analogues **9** and **10** differed, showing no exchange in alkaline D_2O.

In 2 *N* KOD/D_2O, **4** was rapidly deuterated at C_4 and more slowly hydrolyzed to largely C_4-deuterated **9**. Here the C_4-proton signal at τ 6.90 was largely eliminated in 7 min, completely in 1 h, and the appearance of a small sharp singlet at τ 6.75 indicated some hydrolysis to **9** prior to the deuteration. Concurrently, the C_7-proton signal of **4** at τ 6.02 first sharpened, then was replaced by the sharp singlet at τ 6.52 representing C_7-protons of **9**, whether or not deuterated at C_4. At the same time, the signal for the propionic methylenes of **4**, a poorly-resolved multiplet at τ 7.57, became a well-resolved multiplet at τ 7.45, identical with that observed in the spectrum of the potassium salt of **9**. The spectrum of the recovered deuterated **9** in CF_3COOH was identical with that of **9** except that the 2H singlet at τ 6.02 (C_4-protons) had almost disappeared. Here the C_7-protons of **9** appear as a quartet (τ 5.33, J = 5.5 Hz) in CF_3COOH but as a singlet in CF_3COOD; evidently the quartet arises from coupling of the C_7-protons with those of the protonated amino group.

In 1 *N* NaOD/D_2O, **5** behaved analogously. Within 15 min it was deuterated on C_4 then converted into C_4-deuterated **10**, a little undeuterated **10** being formed also.

The same homoallylic coupling and deuterium exchange was found in the less closely related lactam **12**, which was prepared for the purpose. Its n.m.r. spectrum in $CDCl_3$ showed the C_4-protons as a poorly resolved triplet (τ 6.47, J = 1.5 Hz) and the C_1-protons as a broad singlet (τ 5.57, $w_{1/2}$ = 5.0 Hz). The spectrum in DMSO-d_6 at 130° was no better resolved. After **12** was deuterated by leaving it in CH_3ONa/CH_3OD for 3 days at 20°, its spectrum showed no signal at τ 6.47 and that at τ 5.57 was sharper ($w_{1/2}$ = 3.3 Hz).

Experimental

Compounds **2,4,5** and **10** (2), **3** (3) and **6–8** (1) were obtained by literature methods.

1,4-Dihydro-3[2H]-isoquinolone (12)

In a 250 ml flask fitted with a magnetic stirrer, condenser and drying tube, were placed 150 ml of THF and 1 g of 2-thiohomophthalimide (7). Two teaspoons of Raney Nickel (Grace No. 28) were added as a slurry in 50 ml of THF and the mixture was stirred and refluxed for 3 h. The nickel was filtered off within an hour for, if the mixture first stood overnight, an unidentified com-

*Compounds with the structure  .

reaction of **1** (R = CH_3 or C_6H_5) under the same conditions with *p*-nitrofluorobenzene proceeded directly to **4** (Ar = *p*-$NO_2C_6H_4$) and none of the normal product (3) of the type **3** could be isolated.

The reaction of **1** (R = C_6H_5) with *p*-fluorobenzaldehyde gave the ester **5**, the type of product normally obtained from the reaction of an aldehyde with **1**, indicating that the formyl group did not activate the halogen sufficiently to allow arylation to take place in preference to the reaction of **1** at the carbonyl carbon. The halogen was also not sufficiently activated in 2-bromopyridine and the only product from the reaction of this compound with **1** (R = C_6H_5) was 1-benzoylisoquinoline, the normal base-catalyzed rearrangement product of **1**.

Extension of this arylation to the quinoline series through reaction of **2** with *p*-nitrofluorobenzene gave 2-cyano-4-(*p*-nitrophenyl)quinoline (**6**). It is of interest to note that the use of *p*-fluoronitrobenzene in the isoquinoline series led to complete hydrolysis in the reaction or reaction work up to yield **4** and not **3** while the similar reaction in the quinoline series led to partial hydrolysis with the removal of the benzoyl group but not the cyano group. The reaction might be expected to take place in the 2-position of **2**, as is the case with aldehydes or in the 4-position of **2** as is the case with methyl iodide (2). That the product had the structure indicated, (**6**), and was not 2-cyano-2-(*p*-nitrophenyl)-1,2-dihydroquinoline was indicated by the mass spectra which had a strong molecular ion at 275 indicating the structure **6** and not the dihydro structure which would have arisen from reaction at the 2-position.

Experimental[3]

Arylation of Isoquinoline Reissert Compounds

To a mixture of 0.01 mole of the benzoyl or acetyl isoquinoline Reissert compound and 0.01 mole of 2,4-dinitrofluorobenzene or 3-nitro-2-bromopyridine dissolved in dimethylformamide was added 0.80 g (0.01 mole) of sodium hydride (30% in oil). The mixture was stirred for 1.5 h, poured over 500 g of ice, filtered, and recrystallized from ethanol to give the materials in Table I.

Use of *p*-nitrofluorobenzene with either of the Reissert compounds in the above procedure gave a quantitative yield of 1-(*p*-nitrophenyl)isoquinoline (**4**, Ar = *p*-$NO_2C_6H_4$), m.p. 151–152° (reported (4) m.p. 155°).

Anal. Calcd. for $C_{15}H_{10}N_2O_2$: C, 71.99; H, 4.03; N, 11.20. Found: C, 71.87; H, 4.04; N, 11.08.

Use of *p*-fluorobenzaldehyde with the benzoyl isoquinoline Reissert compound in the above procedure gave a 31% yield of **5**, m.p. 150–151°.

Anal. Calcd. for $C_{23}H_{16}FNO_2$: C, 77.30; H, 4.51; N, 3.92. Found: C, 77.47; H, 4.47; N, 3.84.

Hydrolysis of Arylated Reissert Compound

In a typical experiment 1.7 g of **3** (R = C_6H_5; Ar = 2-(3-$NO_2C_5H_3N$)) was dissolved in 25 ml of ethanol and 25 ml of water containing 8.0 g of potassium hydroxide and refluxed for 2 h. The ethanol was removed *in vacuo* and the precipitate was subjected to dry column chromatography on alumina with chloroform. The first fraction was recrystallized from ethanol to give 0.48 g of **4** (Ar = 2-(3-$NO_2C_5H_3N$)), m.p. 169–171°. The same product was also obtained from the acetyl Reissert adduct.

Anal. Calcd. for $C_{14}H_9N_3O_2$: C, 66.93; H, 3.61; N, 16.73. Found: C, 66.99; H, 3.68; N, 16.82.

In a similar manner, **3** (R = CH_3 or C_6H_5; Ar = 2,4-$(NO_2)_2C_6H_3$) gave **4** (Ar = 2,4-$(NO_2)_2C_6H_3$), m.p. 222–223°.

Anal. Calcd. for $C_{15}H_9N_3O_4$: C, 61.02; H, 3.07; N, 14.23. Found: C, 61.12; H, 3.10; N, 14.08.

[3]All melting points are corrected and taken in capillaries. Analyses were determined by Spang Microanalytical Lab., Ann Arbor, Mich; mass spectra were performed by Morgan–Schaffer Co., Montreal.

Branched-chain sugar nucleosides. II. 9-(3-Deoxy-3-*C*-hydroxymethyl-β-D-glucopyranosyl)-adenine[1]

ALEX ROSENTHAL, M. SPRINZL, AND H. J. KOCH
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received March 17, 1969

Application of the oxo reaction to 1,2,4,6-tetra-*O*-acetyl-3-deoxy-α-D-*erythro*-hex-2-enopyranose (**1**), followed by acetylation of the oxo products, gave crystalline 1,2,3′,4,6-penta-*O*-acetyl-3-deoxy-3-*C*-(hydroxymethyl)-α-D-glucopyranose (**2**) in about 30% yield. Conversion of **2** into the branched-chain sugar bromide, followed by condensation of the latter with 6-benzamidochloromercuripurine afforded a blocked branched-chain sugar nucleoside (**5**) in 67% yield based on **2**. The nucleoside (**5**) was deblocked with methanolic sodium methoxide to afford 9-(3-deoxy-3-*C*-hydroxymethyl-β-D-glucopyranosyl)-adenine (**6**) in 75% yield.

Canadian Journal of Chemistry, **47**, 3263 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

From 1966 to the present a number of reports have appeared (1–8) dealing with branched-chain sugar nucleosides. Most of these unusual nucleosides contain the furanosyl moiety (1–5), but a few have the pyranosyl ring system (6–8). The fact that some of the synthetic branched-chain sugar nucleosides (1–3) have been found to exhibit biological activity has helped to focus further attention on these interesting compounds. In this communication we wish to report complete details of a facile synthesis of the branched-chain deoxy sugar 3-deoxy-3-*C*-hydroxymethyl-D-glucopyranose and its conversion into the branched-chain deoxy sugar nucleoside (8).

When 1,2,4,6-tetra-*O*-acetyl-3-deoxy-α-D-*erythro*-hex-2-enopyranose (**1**) (9) was allowed to react with a mixture of carbon monoxide and hydrogen (oxo synthesis) in the presence of preformed dicobalt octacarbonyl at 150–160° for 2 h, a mixture of oxo products was obtained (8). After the products were freed from catalyst, they were fully acetylated using acetic anhydride and pyridine. An attempt to separate the mixture by column chromatography using alumina as adsorbent and ether as developer gave a partial separation of the products. Preparative vapor phase chromatography (v.p.c.) of the mixture of acetates gave compound (**2**) (having the longest retention time), in about 30% yield. A suggested mechanism of the reaction has already been discussed (8). A parallel reaction of **1** with carbon monoxide and deuterium followed by acetylation gave the partially deuterated analogue, namely, 1,2,3′,4,6-penta-*O*-acetyl-3-deoxy-3-*C*-(hydroxymethyl)-α-D-glucopyranose-2,3′,3′,-$^2H_3$ (*cis*) (**7**). The structures of **2** and **7** were readily ascertained from their nuclear magnetic resonance (n.m.r.) spectra and have already been described (8).

The branched-chain sugar (**2**) was converted into 2,3′,4,6-tetra-*O*-acetyl-3-deoxy-3-*C*-(hydroxymethyl)-D-glucopyranosyl bromide (**4**) by the usual method (not isolated because of instability) and immediately condensed with 6-benzamidochloromercuripurine in the presence of cadmium carbonate to afford the crystalline blocked branched-chain sugar nucleoside (**5**) in 67% yield based on the acetate (**2**). Although a

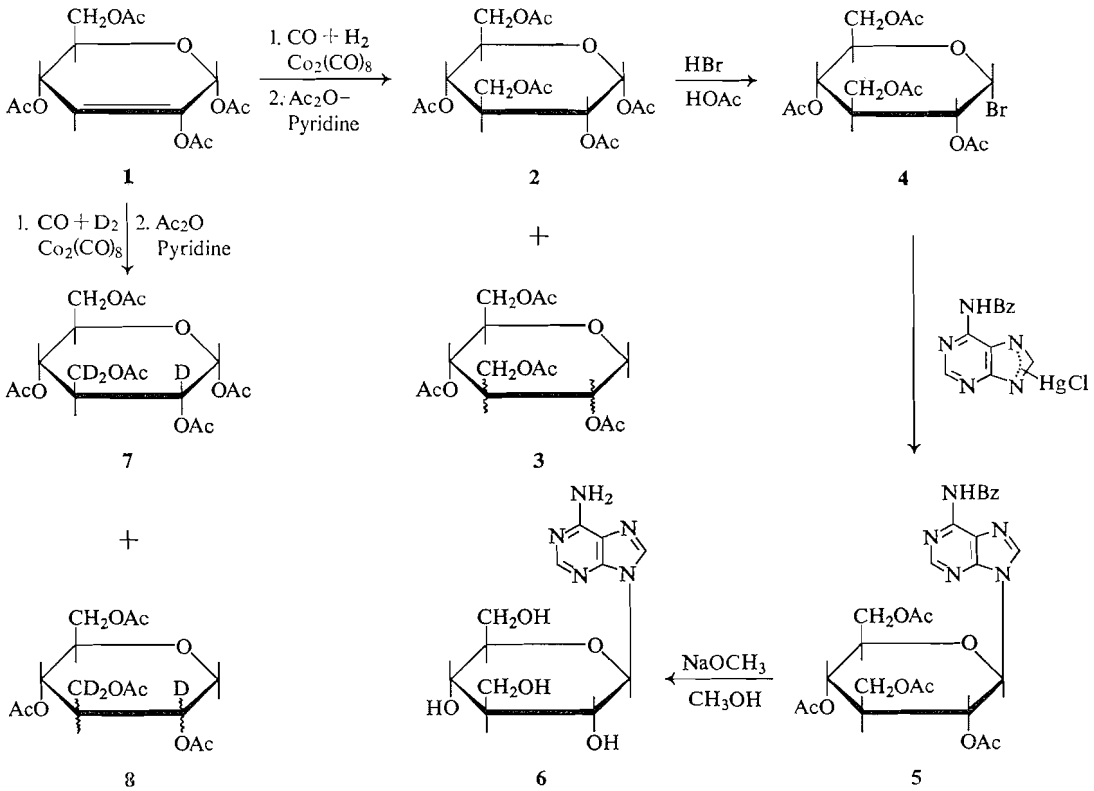
The fact that some of the synthetic branched-chain sugar nucleosides (1–3) have been found to exhibit biological activity has helped to focus further attention on these interesting compounds. In this communication we wish to report complete details of a facile synthesis of the branched-chain deoxy sugar 3-deoxy-3-*C*-hydroxymethyl-D-glucopyranose and its conversion into the branched-chain deoxy sugar nucleoside (8).

When 1,2,4,6-tetra-*O*-acetyl-3-deoxy-α-D-*erythro*-hex-2-enopyranose (**1**) (9) was allowed to react with a mixture of carbon monoxide and hydrogen (oxo synthesis) in the presence of preformed dicobalt octacarbonyl at 150–160° for 2 h, a mixture of oxo products was obtained (8). After the products were freed from catalyst, they were fully acetylated using acetic anhydride and pyridine. An attempt to separate the mixture by column chromatography using alumina as adsorbent and ether as developer gave a partial separation of the products. Preparative vapor phase chromatography (v.p.c.) of the mixture of acetates gave compound (**2**) (having the longest retention time), in about 30% yield. A suggested mechanism of the reaction has already been discussed (8). A parallel reaction of **1** with carbon monoxide and deuterium followed by acetylation gave the partially deuterated analogue, namely, 1,2,3′,4,6-penta-*O*-acetyl-3-deoxy-3-*C*-(hydroxymethyl)-α-D-glucopyranose-2,3′,3′,-$^2H_3$ (*cis*) (**7**). The structures of **2** and **7** were readily ascertained from their nuclear magnetic resonance (n.m.r.) spectra and have already been described (8).

The branched-chain sugar (**2**) was converted into 2,3′,4,6-tetra-*O*-acetyl-3-deoxy-3-*C*-(hydroxymethyl)-D-glucopyranosyl bromide (**4**) by the usual method (not isolated because of instability) and immediately condensed with 6-benzamidochloromercuripurine in the presence of cadmium carbonate to afford the crystalline blocked branched-chain sugar nucleoside (**5**) in 67% yield based on the acetate (**2**). Although a

[1]For part I, see reference 13.



trace of impurity could not be removed from the blocked nucleoside, its analysis (by nitrogen and n.m.r. data) was compatible with the suggested structure. The trace of impurity was readily removed on unblocking **5** using methanolic sodium methoxide to afford the unsubstituted branched-chain sugar nucleoside (**6**) in 75% yield.

The assignment of the structure of **6** was based on the following: (*a*) ultraviolet (u.v.) absorption data of **6** substantiate the site of glycosylation at N-9 (10), (*b*) the *trans* rule (11) indicates that **6** has a β-configuration, (*c*) n.m.r. evidence (H-1′ gave a doublet with $J_{1',2'} = 9$ Hz) clearly corroborates the β-anomeric configuration of **6**.

Experimental

General Considerations

The oxo reaction (8) was performed in an Aminco autoclave. Dicobalt octacarbonyl was purchased from Alfa Inorganics, Inc., Beverley, Massachusetts. Nuclear magnetic resonance spectra were performed on a 100-HMz HA spectrometer, using tetramethylsilane (unless otherwise stated) as the internal standard set at $\tau = 10$. Mass spectra were measured with an A.E.I. M.S.9 spectrometer. Vapor phase chromatography was performed on a Varian Aerograph model 1525 instrument operated at 280° using a 12 ft column of Chromosorb W carrying 10% (by weight) silicone gum rubber SE-52. Detection of nucleosides was performed using a short wave u.v. filter (mineralicht) lamp.

*Reaction of 1,2,4,6-Tetra-O-acetyl-3-deoxy-α-D-erythro-hex-2-enopyranose (**1**) with Carbon Monoxide and Hydrogen to Yield 1,2,3′,4,6-Penta-O-acetyl-3-deoxy-3-C-(hydroxymethyl)-α-D-glucopyranose (**2**)*

A solution of 1,2,4,6-tetra-*O*-acetyl-3-deoxy-α-D-*erythro*-hex-2-enopyranose (8 g) (9) and dicobalt octacarbonyl (3 g) in dry purified benzene (35 ml) was shaken with carbon monoxide (800 p.s.i.) and hydrogen (1400 p.s.i.) in a high-pressure autoclave at a temperature of 150–160° for 2 h. After the gases were vented, 100 ml of petroleum ether (b.p. 35–60°) was added to the reaction mixture. The brown syrup which precipitated was separated from the solution and dissolved in benzene. The benzene solution was decolorized with activated charcoal, filtered, and evaporated under reduced pressure to yield an amber colored syrup (7.7 g). The syrup was acetylated using pyridine (50 ml) and acetic anhydride (50 ml). The acetylation mixture was evaporated to dryness and dissolved in chloroform. The chloroform solution was washed with aqueous sodium bicarbonate followed by water. The dried organic layer was evaporated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

under reduced pressure to yield a syrup (8.8 g). Preparative v.p.c. of the product (in 200 ml of toluene) at 280° gave two major zones, A and B, and traces of five minor zones. The loss due to aerosol formation was considerable. One of the major zones (A) (0.530 g), which had the longest retention time (15.4 min), was readily recrystallized from ethyl ether – light petroleum ether (b.p. 30–60°); m.p. 100°, $[\alpha]_D^{22}$ +58° (*c*, 4 in benzene). The n.m.r. of **2** has been reported previously (8).

Anal. Calcd. for $C_{17}H_{24}O_{11}$ (mol. wt. 404): C, 50.47; H, 5.98. Found (mol. wt. 404 (added 43 to parent peak) (*m/e* 361, loss of CH_3CO)): C, 50.41; H, 5.98.

The second major zone (B) (compound **3**) (1.6 g) was a syrup and had a retention time of 11 min. The v.p.c. rerun of zone B at 180° showed the presence of two zones (never separated in 100% purity); τ ($CDCl_3$) 4.9–5.5 (overlapping multiplets, equal to 2 hydrogens attributed to H-2 and H-4), 5.6 to 6.6 (overlapping multiplets equal to 5 hydrogens, assigned to 2H-6, 1H-5, and 2H-3′) 7.55 (t, assigned to a single H-3a methine hydrogen, with J_{3-4} = 12 Hz), 7.36 (m, assigned to H-3e, 8 (12 acetyl H)). There was no signal that corresponded to the H-1 anomeric proton.

Two mobile zones (retention time 5 min) isolated in low yield (about 5%) were directly compared by v.p.c. with products obtained by carrying out a platinum-catalyzed hydrogenation in ethanol of **1**, whereby two main zones (exhibiting no anomeric hydrogens in their n.m.r. spectra) were obtained with retention times identical with those of the two fast moving minor components in the fully acetylated oxo product of **1**.

*Reaction of **1** with Carbon Monoxide and Deuterium to Yield 1,2,3′,4,6-Penta-O-acetyl-3-deoxy-3-C-(hydroxymethyl)-α-D-glucopyranose-2,3′,3′-$^2H_3$ (cis) (7)*

The unsaturated sugar (**1**) was allowed to react with carbon monoxide and deuterium and the product worked up as described above.

Anal. Calcd. for $C_{17}H_{21}D_3O_{11}$ (mol. wt. 407): C, 50.10; H and D, 6.68. Found (mol. wt. 407 (added 43 to parent peak) (*m/e* 364, loss of CH_3CO)): C, 50.26; H and D, 6.56. The nuclear magnetic resonance spectrum of 7 has been shown previously (8).

The branched-chain anhydroalditols (**8**) were not characterized.

3-Deoxy-3-C-(hydroxymethyl)-α(β)-D-glucopyranose-2,3′,3′-$^2H_3$(cis)

Compound (7) was deacetylated with sodium methoxide in methanol and the product worked up in the usual way. Recrystallization of the product from aqueous methanol gave crystalline 3-deoxy-3-*C*-(hydroxymethyl)-α(β)-D-glucopyranose-2,3′,3′-$^2H_3$(*cis*); m.p. 169–170°, $[\alpha]_D^{22}$ +44° (*c*, 1 in water), R_{G1} 1.65 (ethyl acetate, pyridine, water 5:2:7). Too little compound was available for reliable chemical analysis.

Anal. Calcd. for $C_7H_{11}D_3O_6$: C, 42.64; H, 8.63. Found: C, 41.68; H, 7.24.

6-Benzamido-9-(2,3′,4,6-tetra-O-acetyl-3-deoxy-3-C-hydroxymethyl-α-D-glucopyranosyl)-purine (5)

1,2,3′,4,6-Penta-*O*-acetyl-3-deoxy-3-*C*-hydroxymethyl-α-D-glucopyranose (0.146 g, 0.36 mmole) was allowed to react with 18% hydrogen bromide in glacial acetic acid (1 ml) at room temperature for 2 h under anhydrous conditions. After the solvent was removed under reduced pressure (anhydrous conditions), the residue was treated thrice with 3 ml of freshly distilled anhydrous xylene and the solvent then distilled to remove the hydrogen bromide. To a mixture of 0.24 g of 6-benzamidochloromercuripurine (12), 0.24 g of Celite, and 0.10 g of cadmium carbonate in 15 ml of anhydrous xylene (first dried by distilling off 5 ml under anhydrous conditions and normal pressure) was added a solution of the sugar bromide (0.140 g) in xylene (3 ml). The reaction mixture was heated at 60° for 0.5 h and then refluxed for 5 h. The hot reaction mixture was then filtered, and the precipitate washed with 20 ml of chloroform. After the solvent was removed under reduced pressure, the residue was extracted with 20 ml of chloroform. The chloroform solution was washed with 7 ml of 30% potassium iodide and with 7 ml of water. Concentration of the dried ($MgSO_4$) chloroform layer gave 0.20 g of product which was extracted with 10 ml of petroleum ether (b.p. 60–90°) to remove non-nucleoside material. The remaining solid residue in 5 ml of methanol was decolorized with charcoal, filtered, and the solvent removed under reduced pressure; yield, 0.14 g (67%); the crystalline product was recrystallized from methanol; m.p. 102–104°; $[\alpha]_D^{22}$ +18° (*c*, 2 in chloroform). The substance contained a trace of impurity which could not be removed by thin layer chromatography on silica gel using ethyl acetate–benzene (2:1); R_f = 0.25. τ ($CDCl_3$) 7.9 (12 acetyl hydrogens), 7.65 (H-3′, $J_{3',2'}$ = 12 Hz, $J_{3',4'}$ = 12 Hz), 5.6–6.3 (m, assigned to branched-chain CH_2 and to 2H-6′, H-5′), 4.4–4.9 (m, assigned to H-2′ and H-4′), 4.06 (d, H-1′, $J_{1',2'}$ = 9.0 Hz), 2.5 and 2.0 assigned to phenyl, 1.75 and 1.2 assigned to H-2 and H-8.

Anal. Calcd. for $C_{27}H_{29}N_5O_{10}$: N, 11.98. Found: N, 11.62.

9-(3-Deoxy-3-C-hydroxymethyl-β-D-glucopyranosyl)-adenine (6)

The blocked nucleoside (**5**) (0.53 g) (first dried by azeotroping with anhydrous benzene) was allowed to react with 0.05 *N* methanolic sodium methoxide (5 ml) at 50° for 2 h. The cooled solution was added to a column (1 cm diameter) containing 5 ml of freshly activated Rexyn 102 (H^+) resin and the resin then eluted with 10 ml water. The combined eluate was evaporated to dryness and the residue extracted with ether. The resin was further eluted with 50 ml of 0.7 *N* ammonium hydroxide and the eluate evaporated under reduced pressure. The resulting residue was combined with the residue remaining after the ether extraction (total yield, 0.041 g), and separated by paper chromatography using 1-butanol–ethanol–water (40:19:11) as developer; yield of **6**, 0.021 g (75%) amorphous substance which could not be crystallized from methanol or water. The solid nucleoside appeared to lose water at about 100° and decomposed at 230–235°, $[\alpha]_D^{22}$ +7° (*c*, 2 in water); $\lambda_{max}(H_2O)$ (mμ) 258 (ε 12 600); R_f 0.31; τ (D_2O) (DDS as internal standard) 8.2 (H-3′ signal overlapping with DSS signal), 6.15–6.4 (m, 2H-6′, H-5′, H-4′), 6.05 (d, branched-chain CH_2, *J* = 3 Hz), 5.75 (two d, assigned to H-2′, $J_{2',1'}$ = 9 Hz and $J_{2',3'}$ = 9 Hz), 5.3 (DOH), 4.42 (d, H-1′, $J_{1',2'}$ = 9.0 Hz), 1.9 (s, H-8), 1.75

(s, H-2). Irradiation at τ 8.3 changed the doublet at τ 6.05 to a singlet and altered the multiplet at τ 6.15–6.4. Irradiation at τ 4.4 altered the H-2′ signal.

For analysis compound (**6**) was dried at 60° under reduced pressure for 1 h.

Anal. Calcd. for $C_{12}H_{17}N_5O_5 \cdot H_2O$: C, 43.70; H, 5.75; H, 21.20. Found: C, 43.40; H, 5.60; N, 21.41.

Ring enlargement through acyloin condensation of cycloalkane-1,2-dicarboxylic esters

T. MORI, T. NAKAHARA, AND H. NOZAKI

Department of Industrial Chemistry, Kyôto University, Kyôto, Japan

Received March 26, 1969

Cycloalkane-1,2-dicarboxylic esters of 11-, 12-, and 13-membered rings were prepared from cyclododecanone. Acyloin condensation of these esters in the presence of trimethylchlorosilane followed by acidic hydrolysis afforded 13-, 14-, and 15-membered cycloalkane-1,2-diones in 71–74% yields. The diketones were reduced by treatment with triethyl phosphite and alkali hydroxide into corresponding acyloins.

Canadian Journal of Chemistry, 47, 3266 (1969)

Acyloin condensation in the presence of trimethylchlorosilane was first reported by Schräpler and Rühlmann (1) and later extended to the preparation of four membered cyclic acyloins by Rühlmann (2) and Bloomfield (3). Bloomfield further discussed thermal ring-opening of intermediary cyclobutene-1,2-diol disilyl ethers being controlled by the Woodward–Hoffmann rule.[1]

We now wish to report that this procedure, when applied to large ring cycloalkane-1,2-dicarboxylic esters, constitutes a convenient method for ring enlargement affording cycloalkane-1,2-diones under the incorporation of two side-chain carbons into the rings.[2,3]

Experiments were conducted with 11-, 12-, and 13-membered cycloalkane-1,2-dicarboxylic esters (**6***a–c*), all of which were hitherto unknown compounds and prepared from cyclododecanone (**1**) as a common starting material as shown in Scheme 1. The 11-membered unsaturated ester **2** (7) and the 12-membered unsaturated nitrile **3** (8*b*) have already been obtained from cyclo-

[1]For the valence-isomerization of cyclobutenes, see ref. 4.

[2]Brannock *et al.* (5) and Scharf *et al.* (6) reported similar ring enlargements through thermal ring-opening of bicyclic cyclobutene derivatives.

[3]Dr. Bloomfield kindly suggested to us that the application of this procedure to the diester available from cycloalkanone enamine and dimethyl acetylenedicarboxylate (5) can add four carbon atoms into the starting ring.

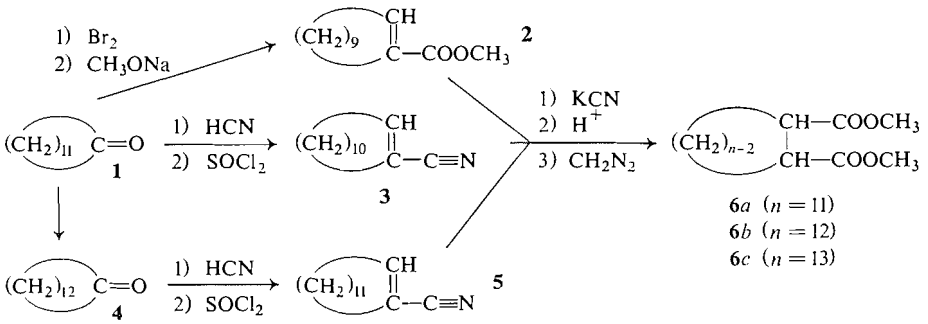

SCHEME 1

dodecanone (**1**) in good yields. Cyclotridecanone (**4**) required in the preparation of 13-membered nitrile **5** is now readily accessible from **1** or its precursor 1,5,9-cyclododecatriene (8).

The α,β-unsaturated ester and nitriles were all converted into corresponding diesters (**6***a–c*) by hydrocyanation, acidic hydrolysis, and final esterification with diazomethane. The diesters (**6**) were characterized by correct elemental analyses, infrared (i.r.) absorption spectra, and nuclear magnetic resonance (n.m.r.) spectra (see Experimental). Each diester would naturally form a mixture of *cis* and *trans* isomers but the separation has not been attempted. As described below, both of the *cis* and *trans* isomers of the intermediates **7** derived from the respective isomers of **6** should be able to undergo ring-opening to **8** to give the same products after hydrolysis, when *n* is sufficiently large.

The acyloin condensation of **6** (see Scheme 2) was performed by following the procedure of Bloomfield (3) in the presence of trimethylchlorosilane in xylene at 110–120°. The reaction was completed by heating to reflux in order to ensure the ring-opening of intermediary cyclobutenes **7** into 1,3-dienes (**8**). Acidic hydrolysis of the reaction mixture gave 1,2-diketones (**9**) in 71–74% yields. The structures of the diketones **9** were ascertained by elemental analyses, i.r., visible absorption spectra, n.m.r., and by reduction to the known cyclic acyloins (**10**).

Reduction of **9** was attained by alkaline hydrolysis of the adducts of **9** with triethyl phosphite in 74–79% yields.

Since the cyclic acyloins (**10**) can be easily reduced to cycloalkanones (9) this reaction sequence would constitute another route to larger ring ketones including cyclotetradecanone and exaltone that are useful as musk odor substances.

Experimental

All temperatures are uncorrected. Nuclear magnetic resonance spectra were obtained on JOEL C-60-H spectrometer in CCl_4 solutions with tetramethylsilane as an internal reference. Chemical shifts are given in p.p.m. from this reference, together with the multiplicity of signals indicated in an abbreviated form: s for singlet, t for triplet, and m for multiplet, respectively. Gas–liquid chromatography was conducted on SE-30 on Chromosorb W (10%) with hydrogen as a carrier gas at 150–190°.

Dimethyl Cycloundecane-1,2-dicarboxylate (6a)

A solution of methyl cycloundecene-1-carboxylate (**2**) (7) (105 g, 0.5 mole) in ethanol (500 ml) was added to potassium cyanide (97.5 g, 1.5 mole) dissolved in water (225 ml) and the whole mixture was heated at reflux for

40 h. After cooling, the mixture was diluted with water (300 ml) and washed with ether. The aqueous layer was acidified with dilute hydrochloric acid and extracted with ether. The organic layer was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residual semisolid was dissolved in acetic acid (830 ml) and concentrated hydrochloric acid (450 ml) and the solution was heated at reflux for 40 h. After cooling and dilution with water, the mixture was extracted with ether several times. The extracts were combined, washed with water, and concentrated *in vacuo*. The resulting solid was immediately esterified with diazomethane to give dimethyl ester (**6***a*). Vacuum distillation gave pure **6***a* (47.3 g, 35% yield based on **2**) as a colorless oil, b.p. 128–134°/0.2 mm Hg. Gas–liquid chromatography showed a single peak. Infrared (neat): 1740, 1190, 1160 cm^{-1} ($COOCH_3$). Nuclear magnetic resonance: δ 3.60 s (6 H), 2.75 m (2 H), 2.0–1.0 m (18 H, a peak at 1.45).

Anal. Calcd. for $C_{15}H_{26}O_4$: C, 66.6; H, 9.7. Found: C, 66.4; H, 9.8.

Dimethyl Cyclododecane-1,2-dicarboxylate (6b)

To a solution of cyclododecene-1-carbonitrile (**3**) (8*b*) (50 g, 0.26 mole) in ethanol (500 ml) was added potassium cyanide (80 g, 1.23 mole) dissolved in water (200 ml) and the whole mixture was heated at reflux for 42 h. After cooling, the reaction mixture was diluted with water. Acidification with dilute hydrochloric acid and salting-out gave white powdery precipitates which were separated by filtration and dissolved in acetic acid (1100 ml) and concentrated hydrochloric acid (750 ml). The resulting solution was heated at reflux for 16 h, cooled, diluted with water, and extracted with ether several times. The extracts were, combined, washed with water, dried (Na_2SO_4), and concentrated *in vacuo* to give solid cyclododecane-1,2-dicarboxylic acid which was esterified with diazomethane without further purification into dimethyl ester (**6***b*). Distillation *in vacuo* afforded pure **6***b* as a colorless solid (57.3 g, 77% yield based on **3**), b.p. 116–118°/0.03 mm Hg, m.p. 54–56°. Gas–liquid chromatography gave a single peak. Infrared (Nujol): 1740, 1190, 1160 cm^{-1} ($COOCH_3$). Nuclear magnetic resonance: δ 3.60 s (6 H), 2.70 m (2 H), 2.0–1.0 m (20 H, a peak at 1.40).

Anal. Calcd. for $C_{16}H_{28}O_4$: C, 67.6; H, 9.9. Found: C, 67.4; H, 9.9.

Cyclotridecene-1-carbonitrile (5)

Hydrocyanic acid (35 ml) was added to a mixture of cyclotridecanone (**4**) (8) (27.5 g, 0.14 mole), triethylamine (3 ml), and ether (50 ml) under stirring in the course of 1 h at room temperature. After stirring at room temperature for 3 h, the mixture was heated at reflux for 1 h. The reaction mixture was cooled, acetic acid (4 ml) added, and the whole washed with water, dried (Na_2SO_4), and concentrated *in vacuo* to give crude cyclotridecanone cyanohydrine (33 g) as a pale-yellow solid. Thionyl chloride (50 g, 0.41 mole) was added dropwise to the crude cyanohydrine dissolved in benzene (70 ml) under stirring at 60° during 2 h. Then the reaction temperature was raised to 75–80° and stirring was continued until no evolution of hydrogen chloride was observed. Vacuum distillation of the reaction mixture gave **5** (24 g, 83% yield based on **4**) as a yellow oil. Redistillation afforded an analytically pure sample as an almost colorless oil, b.p. 102–107°/0.2 mm Hg. Infrared (neat): 2240 cm^{-1} C≡N). Nuclear magnetic resonance: δ 6.05 t (1 H), 2.6–1.9 m (4 H), 1.9–1.1 m (18 H, a peak at 1.30).

Anal. Calcd. for $C_{14}H_{23}N$: C, 81.9; H, 11.3; N, 6.8. Found: C, 81.6; H, 11.2; N, 6.4.

Dimethyl Cyclotridecane-1,2-dicarboxylate (6c)

The unsaturated nitrile **5** was converted into dimethyl ester **6***c* in the same way as described for the preparation of **6***b*. The ester **6***c* was obtained in 56% yield as a colorless solid, b.p. 137–142°/0.08 mm Hg, m.p. 95–97°. Infrared (Nujol): 1740, 1190, 1160 cm^{-1} ($COOCH_3$). Nuclear magnetic resonance: δ 3.65 s (6 H), 2.7 m (2 H), 2.0–1.0 m (22 H, a peak at 1.40).

Anal. Calcd. for $C_{17}H_{30}O_4$: C, 68.4; H, 10.1. Found: C, 68.3; H, 10.2.

Cycloalkane-1,2-diones (9a–c)

General Procedure

A mixture of dimethyl cycloalkane-1,2-dicarboxylate (**6**) (0.04 mole), trimethylchlorosilane (21.7 g, 0.2 mole), and xylene (20 ml) was added dropwise to metallic sodium (5.7 g, 0.24 mole) dispersed in xylene (60 ml) with vigorous stirring at 110–120° under nitrogen atmosphere in the course of 3 h. Stirring was continued at 110–120° for 6 h, and then at reflux temperature for 3 h. After cooling and filtration of inorganic substances, the filtrate was concentrated *in vacuo* to give a viscous oil, which was dissolved in ethanol (140 ml). The resulting solution was added with water (25 ml) and with concentrated hydrochloric acid (4 ml) and the mixture was heated at reflux for 15 min under nitrogen atmosphere. After cooling and dilution with water, the mixture was extracted with ether. The extracts were combined, washed with water, dried (Na_2SO_4), and distilled *in vacuo* to afford **9** as a golden yellow oil or solid. The yields and physical properties were as follows. There was no spectral evidence indicating the presence of enol tautomer.

Cyclotridecane-1,2-dione (9a)

Product was obtained in 71% yield, b.p. 94–97°/2 mm Hg, infrared (neat): 1710 cm^{-1} (C=O), nuclear magnetic resonance: δ 2.70 diffused t (4 H), 2.0–1.0 m (18 H, a peak at 1.25), visible and ultraviolet absorption spectra (in *n*-hexane): log ε_{max} 1.33 (446 mμ), 3.22 (267 mμ). The abnormal absorption in the ultraviolet region might possibly be ascribed to the presence of a trace of inseparable impurity. Biacetyl and cyclodecane-1,2-dione show absorptions of log ε_{max} 1.2 (276 mμ, in cyclohexane) and 1.43 (270 mμ, in ethanol), respectively (10).

Anal. Calcd. for $C_{13}H_{22}O_2$: C, 74.2; H, 10.5. Found: C, 74.4; H, 10.6.

Cyclotetradecane-1,2-dione (9b)

Product was obtained in 73% yield, b.p. 88–93°/0.03 mm Hg, m.p. 37–38° (from *n*-hexane), infrared (Nujol): 1710 cm^{-1} (C=O), nuclear magnetic resonance: δ 2.70 diffused t (4 H), 2.0–1.0 m (20 H, a peak at 1.25), visible and ultraviolet absorption spectra (in *n*-hexane): log ε_{max} 1.37 (443 mμ), 1.53 (278 mμ).

Anal. Calcd. for $C_{14}H_{24}O_2$: C, 75.0; H, 10.8. Found: C, 75.2; H, 10.8.

Cyclopentadecane-1,2-dione (9c)

Product was obtained in 74% yield, b.p. 86–92°/0.02 mm Hg, m.p. 35–37° (from *n*-hexane), infrared (Nujol): 1710 cm^{-1} (C=O), nuclear magnetic resonance: δ 2.75

diffused t (4 H), 2.0–1.0 m (22 H, a peak at 1.25), visible and ultraviolet absorption spectra (in *n*-hexane): log ε_{max} 1.31 (442 mμ), 1.58 (276 mμ).

Anal. Calcd. for $C_{15}H_{26}O_2$: C, 75.6; H, 11.0. Found: C, 75.3; H, 11.0.

*2-Hydroxycycloalkanones (**10a–c**)*

General Procedure

1,2-Diketones (**9**) (0.03 mole) dissolved in benzene (20 ml) was added to a stirred mixture of triethyl phosphite (6.1 g, 0.04 mole) and benzene (16 ml) in the course of 15 min at room temperature under nitrogen atmosphere. The whole mixture was then heated at reflux for 1 h, and concentrated *in vacuo*. The residual oil was mixed with ethanol (75 ml), water (60 ml), and potassium hydroxide (6.7 g, 0.12 mole) and the mixture was stirred at room temperature for 3 h. After dilution with water, the mixture was extracted with chloroform. The extracts were combined, washed, dried and concentrated. Purification of the residual solid by vacuum distillation and recrystallization from *n*-hexane gave analytically pure samples of acyloins **10**. The yields, melting points, etc. were as follows.

*2-Hydroxycyclotridecanone (**10a**)*

Product was obtained in 79% yield, m.p. 44–45° (reported (11) m.p. 45–46°), infrared (Nujol): 3400 (OH), 1710 cm^{-1} (C=O).

Anal. Calcd. for $C_{13}H_{24}O_2$: C, 73.5; H, 11.4. Found: C, 73.5; H, 11.4.

*2-Hydroxycyclotetradecanone (**10b**)*

Product was obtained in 78% yield, m.p. 82–83° (reported (11) m.p. 84–85°), infrared (Nujol): 3530 (OH), 1705 cm^{-1} (C=O).

Anal. Calcd. for $C_{14}H_{26}O_2$: C, 74.3; H, 11.6. Found: C, 74.4; H, 11.5.

*2-Hydroxycyclopentadecanone (**10c**)*

Product was obtained in 74% yield, m.p. 55–56° (reported (11) m.p. 57–58°), infrared (Nujol): 3450 (OH), 1710 cm^{-1} (C=O).

Anal. Calcd. for $C_{15}H_{28}O_2$: C, 75.0; H, 11.7. Found: C, 75.1; H, 11.8.

Separation and identification of methyl ethers of D-glucose and D-glucitol by gas–liquid chromatography[1]

H. G. Jones and J. K. N. Jones

Department of Chemistry, Queen's University, Kingston, Ontario

Received May 5, 1969

The separation by gas–liquid chromatography of the methyl ethers of D-glucose and of D-glucitol is described.

Canadian Journal of Chemistry, **47**, 3269 (1969)

In view of the importance of methyl ether derivatives in the determination of polysaccharide structure it is considered of value to publish details of their separation by gas–liquid chromatography as methyl glycosides and glycitol ethers, and as their acetyl derivative. Details of the separation of methyl ethers of arabinose (1) and of xylose have already been given (2). We now publish details of the separation of the methyl ethers of D-glucose and of D-glucitol.

All separations were made on a Pye–Argon

[1]Abstracted from the Ph.D. thesis of H. G. Jones, Queen's University, Kingston, Ontario, 1964.

TABLE I

The retention times of methyl *O*-acetyl-*O*-methyl-D-glucopyranosides relative to methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-α-D-glucoside (1.0)

Methyl D-glucopyranoside	Retention time 190°
Methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucoside	0.114
Methyl 2,3,4,6-tetra-*O*-methyl-β-D-glucoside	0.085
Methyl 6-*O*-acetyl-2,3,4-tri-*O*-methyl-α-D-glucoside	0.350
Methyl 6-*O*-acetyl-2,3,4-tri-*O*-methyl-β-D-glucoside	0.250
Methyl 4-*O*-acetyl-2,3,6-tri-*O*-methyl-α-D-glucoside	0.390
Methyl 4-*O*-acetyl-2,3,6-tri-*O*-methyl-β-D-glucoside	0.276
Methyl 3-*O*-acetyl-2,4,6-tri-*O*-methyl-α-D-glucoside	0.575
Methyl 3-*O*-acetyl-2,4,6-tri-*O*-methyl-β-D-glucoside	0.38
Methyl 2-*O*-acetyl-3,4,6-tri-*O*-methyl-α-D-glucoside	0.245
Methyl 2-*O*-acetyl-3,4,6-tri-*O*-methyl-β-D-glucoside	0.355
Methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-α-D-glucoside	1.00 (15 min)
Methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-β-D-glucoside	0.725
Methyl 3,6-di-*O*-acetyl-2,4-di-*O*-methyl-α-D-glucoside	0.825
Methyl 3,6-di-*O*-acetyl-2,4-di-*O*-methyl-β-D-glucoside	0.655
Methyl 3,4-di-*O*-acetyl-2,6-di-*O*-methyl-α-D-glucoside	0.890
Methyl 3,4-di-*O*-acetyl-2,6-di-*O*-methyl-β-D-glucoside	0.600
Methyl 2,6-di-*O*-acetyl-3,4-di-*O*-methyl-α-D-glucoside	0.695
Methyl 2,6-di-*O*-acetyl-3,4-di-*O*-methyl-β-D-glucoside	1.08
Methyl 2,4-di-*O*-acetyl-3,6-di-*O*-methyl-α-D-glucoside	0.690
Methyl 2,4-di-*O*-acetyl-3,6-di-*O*-methyl-β-D-glucoside	1.05
Methyl 2,3-di-*O*-acetyl-4,6-di-*O*-methyl-α-D-glucoside	0.685
Methyl 2,3-di-*O*-acetyl-4,6-di-*O*-methyl-β-D-glucoside	0.755
Methyl 2,3,4-tri-*O*-acetyl-6-*O*-methyl-α-D-glucoside	1.10
Methyl 2,3,4-tri-*O*-acetyl-6-*O*-methyl-β-D-glucoside	1.39
Methyl 3,4,6-tri-*O*-acetyl-2-*O*-methyl-α-D-glucoside	2.33
Methyl 3,4,6-tri-*O*-acetyl-2-*O*-methyl-β-D-glucoside	1.56
Methyl 2,4,6-tri-*O*-acetyl-3-*O*-methyl-α-D-glucoside	1.80
Methyl 2,4,6-tri-*O*-acetyl-3-*O*-methyl-β-D-glucoside	2.66
Methyl 2,3,6-tri-*O*-acetyl-4-*O*-methyl-α-D-glucoside	2.05
Methyl 2,3,6-tri-*O*-acetyl-4-*O*-methyl-β-D-glucoside	2.28
Methyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucoside	2.84
Methyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucoside	3.58

TABLE II

The retention times of acetylated methylated glucitols relative to 1,4,5,6-tetra-*O*-acetyl-2,3-di-*O*-methyl-D-glucitol (1.0)

Acetylated methylated glucitol	Retention time
1,5-Di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-D-glucitol	0.244
1,2,5-Tri-*O*-acetyl-3,4,6-tri-*O*-methyl-D-glucitol	0.390
1,3,5-Tri-*O*-acetyl-2,4,6-tri-*O*-methyl-D-glucitol	0.412
1,5,6-Tri-*O*-acetyl-2,3,4-tri-*O*-methyl-D-glucitol	0.468
1,4,5-Tri-*O*-acetyl-2,3,6-tri-*O*-methyl-D-glucitol	0.477
1,3,4,5-Tetra-*O*-acetyl-2,6-di-*O*-methyl-D-glucitol	0.750
1,2,3,5-Tetra-*O*-acetyl-4,6-di-*O*-methyl-D-glucitol	0.795
1,2,4,5-Tetra-*O*-acetyl-3,6-di-*O*-methyl-D-glucitol	0.821
1,2,5,6-Tetra-*O*-acetyl-3,4-di-*O*-methyl-D-glucitol	0.973
1,3,5,6-Tetra-*O*-acetyl-2,4-di-*O*-methyl-D-glucitol	1.00
1,4,5,6-Tetra-*O*-acetyl-2,3-di-*O*-methyl-D-glucitol	1.00 (29 min)
1,2,3,4,5-Penta-*O*-acetyl-6-*O*-methyl-D-glucitol	1.14
1,3,4,5,6-Penta-*O*-acetyl-2-*O*-methyl-D-glucitol	1.60
1,2,4,5,6-Penta-*O*-acetyl-3-*O*-methyl-D-glucitol	1.81
1,2,3,5,6-Penta-*O*-acetyl-4-*O*-methyl-D-glucitol	2.00
1,2,3,4,5,6-Hexa-*O*-acetyl-D-glucitol	2.66

Chromatograph at 190 °C and with a gas flow of 190 ml per min. The methyl glucosides were separated on a column (120 × 0.5 cm I.D.), the packing of which was composed of LAC-4R-886[2] (15%) polyester wax on Chromosorb W(60–80 mesh). The glucitols were separated on a similar column containing LAC-4R-886[2] (10%) polyester wax. Experimental details are given in reference (1).

New synthesis of *S*-alkyl-DL-homocysteines

HAROLD M. KOLENBRANDER
Department of Chemistry, Central College, Pella, Iowa 50219

Received March 27, 1969

A simple method for the synthesis of *S*-alkyl-DL-homocysteines is described. The method involves the reaction of homocysteine thiolactone with a primary alkyl halide in sodium methoxide solution.

Canadian Journal of Chemistry, 47, 3271 (1969)

Ethionine, *S*-ethyl homocysteine, has long been known to be a methionine antagonist in biological systems (1). More recently it has been found capable of lowering the level of activity of rat liver urocanase (2–4). Because we desired to learn whether the effect on liver urocanase could also be produced by other *S*-alkyl homocysteines, it was necessary to prepare these commercially unavailable compounds.[1]

Previously published methods for the synthesis of the homologous series of alkyl homocysteines require the use of liquid ammonia and/or hydrogen cyanide (5, 6). In an attempt to avoid the use of these reagents, we have developed a simple method for the synthesis of alkyl homocysteines giving yields of 75–95%. The method involves the reaction of homocysteine thiolactone[2] (**1**) with a primary alkyl halide[3] (**2**) in sodium methoxide solution. The reaction sequence is outlined in Scheme 1, using the synthesis of methionine as an example.

[1]Recent experiments conducted in our laboratory have demonstrated that the higher alkyl homologues do not affect the level of urocanase activity in rat liver.
[2]Obtained from the Aldrich Chemical Company.
[3]We found that a secondary alkyl iodide can be used, but the yield of final product was significantly reduced. Using 2-iodopropane, we synthesized *S*-isopropyl homocysteine in 20% yield.

Experimental

The purity of each compound whose synthesis is reported was assayed by: *1*) melting points; *2*) thin-layer chromatography (t.l.c.); *3*) infrared (i.r.) spectroscopy; and *4*) nuclear magnetic resonance (n.m.r.) spectroscopy.

Melting points were determined using a Hoover–Thomas capillary melting point apparatus at a heating-rate setting of 7. Each compound was recrystallized until its melting point was constant.

The compounds were examined by t.l.c. on Bio-Sil A[4] using three solvent systems: *1*) $CHCl_3$/methanol/17% NH_4OH (2:2:1, v/v); *2*) *n*-propanol/water (64:36, w/w); and *3*) *n*-butanol/glacial acetic acid/water (60:20:20, w/w). Each compound was chromatographically pure in all three solvent systems. The modified ninhydrin solution described by Moffat and Lytle (7) was used to detect the presence of the amino acids on the thin-layer plates.[5]

The i.r. spectra were obtained with a Perkin–Elmer 337 spectrophotometer using KBr pellets. The spectra were very similar to one another showing strong absorption bands near 1420, 1345, 1282, 1078, 547, and 435 cm^{-1}. The spectra of the DL-methionine and of the DL-ethionine, prepared by using the method outlined below, were identical with those obtained from the respective commercial compounds. The other *S*-alkyl homocysteines are not commercially available.

The absence of absorption bands at 840 and 904 cm^{-1} in the spectra of each compound indicates that neither

[4]Silicic acid, available from Bio–Rad Laboratories.
[5]We also sprayed identical chromatograms with concentrated sulfuric acid in order to detect any non-amino acid impurities. None were found.

Chromatograph at 190 °C and with a gas flow of 190 ml per min. The methyl glucosides were separated on a column (120 × 0.5 cm I.D.), the packing of which was composed of LAC-4R-886[2] (15%) polyester wax on Chromosorb W(60–80 mesh). The glucitols were separated on a similar column containing LAC-4R-886[2] (10%) polyester wax. Experimental details are given in reference (1).

New synthesis of *S*-alkyl-DL-homocysteines

HAROLD M. KOLENBRANDER
Department of Chemistry, Central College, Pella, Iowa 50219

Received March 27, 1969

A simple method for the synthesis of *S*-alkyl-DL-homocysteines is described. The method involves the reaction of homocysteine thiolactone with a primary alkyl halide in sodium methoxide solution.

Canadian Journal of Chemistry, 47, 3271 (1969)

Ethionine, *S*-ethyl homocysteine, has long been known to be a methionine antagonist in biological systems (1). More recently it has been found capable of lowering the level of activity of rat liver urocanase (2–4). Because we desired to learn whether the effect on liver urocanase could also be produced by other *S*-alkyl homocysteines, it was necessary to prepare these commercially unavailable compounds.[1]

Previously published methods for the synthesis of the homologous series of alkyl homocysteines require the use of liquid ammonia and/or hydrogen cyanide (5, 6). In an attempt to avoid the use of these reagents, we have developed a simple method for the synthesis of alkyl homocysteines giving yields of 75–95%. The method involves the reaction of homocysteine thiolactone[2] (**1**) with a primary alkyl halide[3] (**2**) in sodium methoxide solution. The reaction sequence is outlined in Scheme 1, using the synthesis of methionine as an example.

[1]Recent experiments conducted in our laboratory have demonstrated that the higher alkyl homologues do not affect the level of urocanase activity in rat liver.
[2]Obtained from the Aldrich Chemical Company.
[3]We found that a secondary alkyl iodide can be used, but the yield of final product was significantly reduced. Using 2-iodopropane, we synthesized *S*-isopropyl homocysteine in 20% yield.

Experimental

The purity of each compound whose synthesis is reported was assayed by: *1*) melting points; *2*) thin-layer chromatography (t.l.c.); *3*) infrared (i.r.) spectroscopy; and *4*) nuclear magnetic resonance (n.m.r.) spectroscopy.

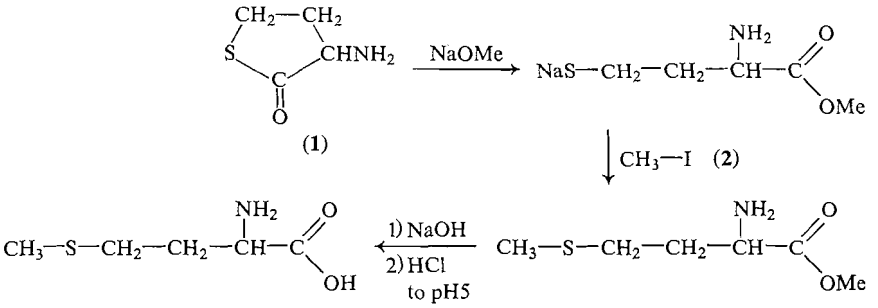
Melting points were determined using a Hoover–Thomas capillary melting point apparatus at a heating-rate setting of 7. Each compound was recrystallized until its melting point was constant.

The compounds were examined by t.l.c. on Bio-Sil A[4] using three solvent systems: *1*) $CHCl_3$/methanol/17% NH_4OH (2:2:1, v/v); *2*) *n*-propanol/water (64:36, w/w); and *3*) *n*-butanol/glacial acetic acid/water (60:20:20, w/w). Each compound was chromatographically pure in all three solvent systems. The modified ninhydrin solution described by Moffat and Lytle (7) was used to detect the presence of the amino acids on the thin-layer plates.[5]

The i.r. spectra were obtained with a Perkin–Elmer 337 spectrophotometer using KBr pellets. The spectra were very similar to one another showing strong absorption bands near 1420, 1345, 1282, 1078, 547, and 435 cm^{-1}. The spectra of the DL-methionine and of the DL-ethionine, prepared by using the method outlined below, were identical with those obtained from the respective commercial compounds. The other *S*-alkyl homocysteines are not commercially available.

The absence of absorption bands at 840 and 904 cm^{-1} in the spectra of each compound indicates that neither

[4]Silicic acid, available from Bio–Rad Laboratories.
[5]We also sprayed identical chromatograms with concentrated sulfuric acid in order to detect any non-amino acid impurities. None were found.



SCHEME 1

TABLE I

Nuclear magnetic resonance spectra of the *S*-alkyl-DL-homocysteines (τ, parts per million)*

S-Alkyl substituent	Homocysteine protons		*S*-Alkyl protons
	C-2 proton	Methylene protons	
Methyl	5.79t	7.07–8.00m	7.88s
Ethyl	5.76t	7.07–8.05m	8.79t
Propyl	5.76t	7.05–8.01m	8.17–8.75m and 8.75–9.30m
Butyl	5.78t	7.08–8.00m	8.15–8.90m and 8.90–9.33m
Pentyl	5.79t	7.06–8.00m	8.10–8.95m and 8.95–9.42m
Hexyl	5.79t	7.08–8.06m	8.06–9.00m and 9.00–9.42m
Benzyl	5.71t	7.05–7.95m	2.58s and 6.16s

*The notations m, s, and t refer to multiplets, singlets, and triplets respectively.

homocysteine nor its thiolactone are significant contaminants of any of the compounds synthesized. Furthermore, none of the spectra had absorption bands in the 1070–1030 cm^{-1} and the 1160–1120 cm^{-1} regions indicating the absence of sulfoxides and sulfones respectively.

The n.m.r. spectra were obtained using a Varian A-60 spectrometer and were entirely consistent with the assigned structures. The spectra of commercial DL-methionine and DL-ethionine could be superimposed exactly on those of the corresponding compounds obtained using the synthetic method described below. Analysis of the integration data indicated that deviations from the expected number of hydrogens relative to the C-2 proton were within ±3%. The data obtained from the n.m.r. spectra are presented in Table I.

Synthesis of DL-*Methionine*

DL-Homocysteine thiolactone hydrochloride (50 mmoles, 7.65 g) was added to a cold solution, 0°, of sodium methoxide in methanol (2.7 g of sodium metal in 210 ml of methanol). After stirring at room temperature for 0.5 h, 50 mmoles (3.11 ml) of iodomethane were added dropwise during 5 min and the stirring continued for 1.25 h. The reaction mixture was then filtered and the filtrate concentrated to 20 ml under reduced pressure. The concentrate was taken up in 300 ml of 1 *N* sodium hydroxide and the resulting solution was heated under reflux for 1.5 h. Following concentration to 40 ml under reduced pressure, the reaction mixture was cooled to 0° and brought to pH 5 by the dropwise addition of concentrated hydrochloric acid with vigorous stirring. The resulting thick suspension was stirred at 0° for 15–20 min and filtered. The precipitate was dissolved in a minimum volume of boiling water and filtered. Four volumes of absolute ethanol were added to the filtrate which was cooled to 0° for 2 h to give 7.05 g of crystals, m.p. 268–270° with decomposition.

*Synthesis of Other S-Alkyl-*DL-*homocysteines*

The ethyl, propyl, butyl, pentyl, and hexyl homocysteines were synthesized by similar procedures. *S*-Benzyl-DL-homocysteine was synthesized by the same procedure except that benzyl chloride was used as the alkylating agent rather than benzyl iodide.

The melting points and other data pertaining to the preparation of DL-methionine and the other *S*-alkyl-DL-homocysteines are recorded in Table II.

Partition coefficients of some *N*-alkyl-and *N,N*-dialkyl-derivatives of some cinnamamides and benzalcyanoacetamides in the system cyclohexane–water

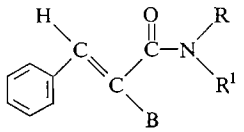
A. D. DELANEY[1], D. J. CURRIE, AND H. L. HOLMES
Chemistry Section, Defence Research Establishment Suffield, Ralston, Alberta

Received August 14, 1968

Substituent constants, π, and substituent interaction constants, π interaction, for the groups —CONHR and —CONRR[1] have been derived which allow the calculation of the partition coefficients of the title compounds.

Canadian Journal of Chemistry, 47, 3273 (1969)

A series of *N*-alkyl and *N,N*-dialkyl derivatives of cinnamamide and α-cyanocinnamamide and their 4-chloro-, 4-methoxy-, and 3,4-methylenedioxy-derivatives, **1**, have been synthesized and



1 *a*) B = H
b) B = CN

their partition coefficients, *K*, determined in the system cyclohexane–water. From these values and eq. [1] (1,2) substituent constants, π, and substituent interaction constants, π interaction, have been determined for the functional groups —CONHR and —CONRR[1]. For —CONHR, π = −4.65 and π interaction = +2.00[2] while for −CONRR[1], π = −4.00 and π interaction = +0.95.

$$[1] \qquad \log K = \Sigma\pi + \Sigma\pi \text{ interaction} - 1.30$$

For cinnamamides and α-cyanocinnamamides with large alkyl groups (e.g. *N*-cyclohexyl, *N,N*-pentamethylene, *N,N*-dipentyl, and *N,N*-dicyclohexyl) the calculated partition coefficients are more positive than those observed. These lower observed values probably result from intramolecular solvation. In contrast to this, the partition coefficients calculated for the *N,t*-butyl derivatives are less positive than those measured indicating that solvation of the nitrogen atom is sterically hindered by the *t*-butyl group.

After excluding these few anomalies, the following correlations were obtained. For 41 *N*-alkyl- and *N,N*-dialkyl-cinnamamides log *K* observed =

[1]Summer student: present address McGill University, Montreal, Quebec.

[2]These values replace those reported (1) for NHCOR.

‡The sign "~" indicates that the variation in the measured log K values exceeded 0.06 log unit.

0.91 log K calculated +0.05. The correlation coefficient, r, is 0.98, the standard error of r, Δr, is 0.03 and the standard error of the estimate, Δ estimate, is 0.24. For 41 N-alkyl- and N,N-dialkyl-α-cyanocinnamamides, log K observed = 0.98 log K calculated +0.04: $r = 0.98$, $\Delta r = 0.04$ and Δ estimate = 0.23.

Benzalcyanoacetic acid (m.p. 181.5–181.8 °C) and its 4-chloro (m.p. 198.0–198.3 °C)-, 4-methoxy (m.p. 228.6–229.4 °C)- and 3,4-methylenedioxy (m.p. 229.8–230.4 °C)-derivatives as well as their acid chlorides were prepared by the method of Synerholm and Hartzell (3). The preparation of these new N-substituted cinnamamides and α-cyanocinnamamides from amines followed established procedures (3, 4) as did the preparation from amine hydrochlorides (5).

The partition coefficients were determined as in the earlier papers (1, 2). Each determination was done at least twice, the phases remaining in contact for 10 and 15 min with periods of shaking of 5 and 10 min respectively. The difference between the log K values from the two determinations rarely exceeded 0.06 log units. The averages of these log K values are listed in Tables I and II. Changes with time in the log K values of the N-alkyl- and N,N-dialkyl-derivatives of 4-methoxy- and 3,4-methylenedioxy – benzalcyanoacetamide were eliminated by partitioning these compounds in the absence of light.

Melting and/or boiling points of the amides and their analytical figures are given in Tables I and II.

Functional group and substituent effects, both steric and electronic, upon the ultraviolet absorption spectra of some *N*-alkyl- and *N,N*-dialkyl-derivatives of some cinnamamides and benzalcyanoacetamides

A. D. DELANEY,[1] D. J. CURRIE, AND H. L. HOLMES
Chemistry Section, Defence Research Establishment Suffield, Ralston, Alberta

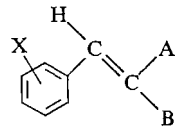
Received August 14, 1968

Conjugative and steric constants for *N*-substituted carboxyamide groups have been derived which allow the calculation of the long wavelength absorption maxima of *N*-alkyl- and *N,N*-dialkyl-derivatives of cinnamamide and benzalcyanoacetamide. Deviations between calculated and observed values indicate that there may be steric interference between bulky *N,N*-dialkylcarboxyamide groups and the benzylic hydrogen atom.

Canadian Journal of Chemistry, 47, 3278 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Ultraviolet (u.v.) absorption spectra have been recorded for a number of *N*-alkyl- and *N,N*-dialkyl-derivatives of cinnamamide and benzalcyanoacetamide and their 4-chloro-, 4-methoxy-, and 3,4-methylenedioxy derivatives. The constancy of the long wavelength absorption maxima for the *N*-alkylcinnamamides, **1**(A = CONHR, B = H), and for the *N*-alkyl-benzal-



1

cyanoacetamides, **1**(A = CONHR, B = CN), and the close approximation of these (Tables I and II) to the respective values for the cinnamamides, **1**(A = $CONH_2$, B = H), and the benzalcyanoacetamides, **1**(A = $CONH_2$, B = CN), indicate that the *N*-alkyl group does not influence significantly the polarization of the conjugated system in these compounds. The effect of two alkyl groups on the carboxyamide nitrogen atom upon polarization of the conjugated system, on the other hand, is much more pronounced especially for bulky alkyl groups. For example, the absorption maximum of *N,N*-diisopropylcinnamamide is at a wavelength 5 mμ shorter than that of the *N,N*-di-*n*-propyl analogue. This probably results from interference between the isopropyl groups and the hydrogen atom on the β carbon atom rotating the *N,N*-diisopropylcarboxyamide group out of the plane of the styrene moiety, thus reducing overlap of the π orbitals. The assumption is made above that, in analogy with the configuration of benzalcyanoacetamide, the CONHR and $CONRR^1$ groups of these compounds are *trans* to the phenyl group.

Equation [1] was developed earlier in these laboratories (1) for calculating the long wavelength absorption maxima for conjugated heteroenoid compounds with the generalized structure **1**.

$$[1]\quad \lambda(X{-}C_6H_4{-}CH{=}C(A)(B)) = \lambda(C_6H_5{-}CH{=}CH_2) + \Delta\lambda_A + \Delta\lambda^1{}_B + \Sigma\Delta\lambda^{11} + D$$

The term $\Delta\lambda_A$ is the conjugative effect (mμ units) of the *trans* group, $\Delta\lambda^1{}_B$ is the inductive effect of the *cis* group in the same units, while $\sum\Delta\lambda^{11}$ is the sum of the steric effects of the A, B, and phenyl groups. *D* quantitates the effect (mμ units) of phenyl substituents, X, upon the absorption maximum (1, 3).

This equation has now been applied to these *N*-alkyl- and *N,N*-dialkyl-derivatives and for CONHR, $\Delta\lambda_A$ is +24 mμ and $\Delta\lambda^{11}$ is −10 mμ, while for $CONRR^1$, $\Delta\lambda_A$ is +31 mμ and $\Delta\lambda^{11}$ is −20 mμ.[2] Using these values, long wavelength absorption maxima have been calculated for the cinnamamides (Table I) and benzalcyanoacetamides (Table II) and compared with the observed

[1]Summer student; present address: McGill University, Montreal, Quebec.

[2]The spectra of cinnamic acid, benzalcyanoacetic acid, and benzalmalonic acid (Table XI) provided values for the carboxyl group of $\Delta\lambda_A = +25.5$ mμ, $\Delta\lambda^1{}_B = +30.5$ mμ, and $\Delta\lambda^{11} = -9.0$ mμ. The conjugative effect ($\Delta\lambda_A \simeq +46.5$ mμ) and the steric effect ($\Delta\lambda^{11} \simeq -7.5$ mμ) for —C(O)Cl are obtained similarly from cinnamoyl chloride and benzalcyanoacetylchloride.

values (Tables III–VI and Tables VII–X respectively).[3] For all the compounds listed λ observed = 0.98λ calculated + 6.3. The correlation coefficient, *r*, is 0.99 and the standard errors of *r* and the estimate are 0.01 and 2.7 respectively.

Substituent X wavelength increments or *D* values (1, 3) were useful in predicting the positions of the long wavelength absorption bands of phenyl-substituted derivatives of the *N*-alkyl- and *N,N*-dialkyl-derivatives of the benzalcyanoacetamides. These *D* values, however, only provided one or two of the multiple absorption bands of 4-chloro-, 4-methoxy-, and 3,4-methylenedioxy-cinnamamides and their *N*-alkyl- and *N,N*-dialkyl-derivatives (Table I). A similar inadequacy of *D* values has been noted for other unifunctional styrene derivatives, e.g. 4-chloro-derivatives of ethyl cinnamate, cinnamanilide and β-nitropropenylbenzene.

The preparation of these compounds is described by Delaney *et al.* (2). Their spectra were determined with a Cary model 15 spectrophotometer using 10^{-3} *M* ethanolic solutions of the

Solvolyse des tosylates des *tert*-butyl-4 diméthyl-2,2 cyclohexanols *cis* et *trans*[1]

JEAN-CLAUDE RICHER ET PATRICE BELANGER[2]
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 29 novembre 1968

La solvolyse des tosylates des *tert*-butyl-4 diméthyl-2,2 cyclohexanols a été effectuée dans diverses conditions expérimentales et la nature des produits obtenus a été établie. Les vitesses de solvolyse dans l'acide acétique ont été déterminées à différentes températures; les facteurs thermodynamiques qui en découlent ont été calculés. Les résultats sont discutés en fonction de la stéréochimie des produits de départ.

Introduction

Plusieurs auteurs (voir réf. 1) se sont penchés sur le problème de la solvolyse des tosylates des *tert*-butyl-4 alkyl-2 cyclohexanols. Dans le cadre de nos travaux (voir réf. 2) sur la *tert*-butyl-4 diméthyl-2,2 cyclohexanone (**1**) et ses dérivés (**2***a* et **3***a*) nous avons examiné les vitesses et la nature des produits de solvolyse des tosylates **2***b* et **3***b*; ces produits pourraient être considérés comme conformationnellement semblables aux dérivés des diméthyl-4,4 stéroïdes examinés entre autres par Levisalles et Pete (3). Les résultats obtenus au cours de cette étude font l'objet de la présente communication.

a) R = H
b) R = SO_2—C_6H_4—CH_3 *p*
c) R = $COCH_3$

Partie expérimentale

Les spectres infrarouges (i.r.) ont été déterminés sur un spectrophotomètre Perkin–Elmer, modèle 21 à double faisceaux avec prisme de chlorure de sodium. Les analyses en chromatographie en phase gazeuse (c.p.g.) sont effectuées sur un appareil KROMO-TOG K-2 de la Compagnie Burrell. Les points de fusion sont pris dans des tubes capillaires à l'aide d'un appareil muni d'un thermomètre calibré avec des standards du bureau de Washington. Les spectres de résonance magnétique nucléaire (r.m.n.) ont été pris avec un spectrophotomètre modèle A-60 de la Compagnie Varian; les déplacements chimiques, δ, sont exprimés en p.p.m. du champ total et se réfèrent au tétraméthylsilane utilisé comme standard interne. Les mesures cinétiques sont faites dans un bain maintenu à température constante, grâce à un thermostat Haake–Universal de la Compagnie Gebruger Haake A. G.

1 Tosylates

1.1 Tosylate 3b du tert-butyl-4 diméthyl-2,2 cyclohexanol trans

Obtenu à la manière habituelle (4) par réaction de 5 g d'alcool **3***a* (5) avec 9 g de chlorure de *p*-toluenesulfonyle, ce dérivé fond à 83–84 °C; son spectre i.r. montre des bandes caractéristiques à 1170 et 1190 cm^{-1} et son spectre r.m.n. présente des pics à 0.82 p.p.m. (*tert*-butyle), à 0.88 p.p.m. (*gem*-diméthyle) et à 4.25 p.p.m. (proton carbinolique).

Anal. calculé pour $C_{19}H_{30}O_3S$: C, 67.86; H, 8.88; S, 9.36. Trouvé: C, 67.41; H, 8.94; S, 9.50.

1.2 Tosylate 2b du tert-butyl-4 diméthyl-2,2 cyclohexanol cis

Obtenu à la manière habituelle (4) par réaction de 5 g d'alcool **2***a* pur par c.p.g., (5) avec 9 g de chlorure de *p*-toluenesulfonyle, ce dérivé fond à 93–94 °C; son spectre i.r. montre des bandes caractéristiques à 1170 et 1190 cm^{-1} et son spectre r.m.n. présente des pics à 0.82 p.p.m. (*tert*-butyle), à 0.80 et 0.90 p.p.m. (*gem*-diméthyle) et à 4.25 p.p.m. (proton carbinolique). L'instabilité de ce dérivé n'a pas permis d'obtenir d'analyses centésimales satisfaisantes.

2 Mesures cinétiques

Les vitesses de solvolyse des tosylates ont été effectuées dans l'acide acétique anhydre et en tubes scellés; la procédure expérimentale de Winstein et ses collaborateurs (6) a été fidèlement suivie. Dans tous les cas les constantes de vitesse de l'acétolyse sont du premier ordre pour plus de 70% de la réaction. Les résultats obtenus sont rapportés au Tableau I, en regard des facteurs thermodynamiques qui peuvent en être déduits utilisant les méthodes décrites par Laidler (7).

3 Solvolyse et identification des produits obtenus au cours de ces réactions

3.1 Dans l'acide acétique

3.11 En présence d'acétate de sodium—D'une manière générale, 500 mg de tosylate et 2 g d'acétate de sodium anhydre dissous dans 15 ml d'acide acétique anhydre sont

[1]Les résultats rapportés dans cette communication sont extraits en partie du mémoire de maîtrise de P. Bélanger, Faculté des Sciences, Université de Montréal, 1963.

			179			

*Dans ces conditions il a été mesuré que les constantes de vitesses d'acétolyse des *tert*-butyl-4 cyclohexanols *cis* et *trans* sont respectivement de 153 et 56.5.
†Les erreurs moyennes sur ces valeurs sont de ±0.2 kcal/mole.
§Les erreurs moyennes sur ces valeurs sont de ±0.2 u.c.

maintenus à 65 °C pendant 9 jours. Le mélange réactionnel est alors neutralisé par une solution glacée de NaOH 20% et extrait à l'éther. La couche éthérée est lavée par de l'eau salée, séchée sur Na_2SO_4 anhydre et évaporée au travers une colonne de Widmer. Le résidu est analysé par c.p.g. à l'aide d'une colonne de 2.5 m contenant 20% de Ucon Polar adsorbé sur du Kromat F.B. L'analyse est effectuée à 150 °C utilisant un débit de 90 ml/min d'hélium. Les pics sont identifiés par leur temps de rétention et par superposition à l'aide de produits authentiques (8). Les résultats obtenus sont résumés au Tableau II. Les pourcentages relatifs qui sont rapportés ont été évalués en faisant l'hypothèse (9) que les surfaces relatives sous les pics peuvent être assimilées aux pourcentages relatifs de produits présents.

3.12 En présence d'acétate de tétrabutylammonium—Les opérations sont comme précédemment (section 3.11) excepté que l'acétate de sodium est remplacé par de l'acétate de tétrabutylammonium.

3.13 Sans base additionnée—Les opérations sont telles que décrites dans la section 3.11 excepté que l'acétate de sodium est omis.

3.2 Dans la N-méthylpyrollidone en présence de l'acétate de tétrabutylammonium

3.21 A 65 °C—La réaction est effectuée sur 500 mg de tosylate, 390 mg d'acétate de tétrabutylammonium dans 15 ml de *N*-méthylpyrollidone dans les conditions décrites dans la section 3.11.

3.22 A 160 °C—La réaction est effectuée comme décrite dans la section 3.21 excepté que le mélange réactionnel est chauffé à 160 °C pendant 4 h plutôt qu' à 65 °C pendant 9 jours.

Discussion

Si l'on examine les vitesses de réactions portées dans le Tableau I, on observe que l'introduction de deux substituants en position adjacente du site réactionnel provoque une accélération de la vitesse de réaction; cette observation est formellement en accord avec la suggestion de Winstein et Hollness (10) qui

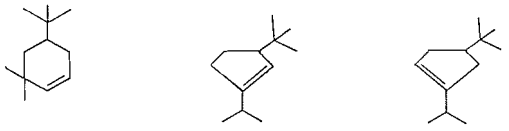
attribuent ces différences de vitesse à la compression stérique. Toutefois l'utilisation des valeurs k_{Me}/k_H rapportées par Sicher et ses collaborateurs (1) permettrait de prévoir, si l'additivité des compressions joue un rôle, que les vitesses de solvolyse des tosylates **2***c* et **3***c* relatives à celle du tosylate dérivé du *tert*-butyl-4 cyclohexanol *trans* devraient être respectivement de 35 et 11; or les vitesses relatives observées sont de l'ordre de 3.8 pour **2***c* et 3.2 pour **3***c*, ce qui indiquerait que les effets de compression ne sont pas les seules causes influençant les vitesses relatives de solvolyse et nous rejoignons alors les conclusions de Sicher et ses collaborateurs (1). Il peut aussi être envisagé que les états de transition des réactions étudiées au cours du présent travail diffèrent de ceux impliqués dans les réactions de solvolyses plus rapides (composés de la série "*cis*") examinées par Sicher et ses collaborateurs (1); en effet des formes non chaises ayant été postulées (1) pour expliquer ces résultats il n'est pas certain qu'il soit nécessaire dans notre cas de faire intervenir ces conformations.

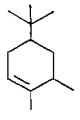
Les résultats rapportés dans le Tableau II font ressortir que les solvolyses des tosylates examinés conduisent principalement aux produits d'élimination plutôt qu'aux produits de substitution et ce, quelles que soient les conditions expérimentales; à la suite des travaux de Henbest et Jackson (11), il avait été espéré que les réactions conduites dans la *N*-méthylpyrollidone conduiraient à des quantités importantes d'acétates **2***c* et **3***c*. Des conclusions importantes peuvent toutefois être tirées de la nature des oléfines produites au cours des solvolyses:



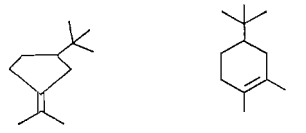
4

5

6



7



8

9

1. Le fait que le tosylate *cis*, **2***b*, ne conduit à aucun produit de contraction de cycle indiquerait que dans l'état de transition, le produit est sous forme chaise et que l'élimination directe (conduisant à **4**) ou le réarrangement (conduisant à **7** et **9**) impliquent respectivement l'hydrogène axial en position-6 et le méthyle axial (*trans* et coplanaire, antiparallèle ou antipériplanaire) en position-2; cette conclusion serait en accord d'une part avec les propositions formulées par Campbell et ses collaborateurs (12) et selon lesquelles "il n'y a aucune preuve expérimentale que la réaction de solvolyse du tosylate du *tert*-butyl-4 cyclohexanol *cis* se produise par l'intermédiaire d'une forme autre que la conformation chaise" et d'autre part avec les hypothèses de Levisalles et Pete (3) et selon lesquelles il est inutile, pour expliquer les réactions de tosylates dérivés du diméthyl-4,4 cholestanol-3α de faire intervenir des conformations différentes de la conformation chaise.

2. Considérant que la solvolyse du tosylate **3***b* conduit à des fortes proportions de produits provenant d'une contraction de cycle, il peut en être déduit que l'état de transition de ces réactions est aussi presque complètement sous forme chaise; toutefois la formation de faibles quantités de l'oléfine **9** permettrait de suggérer à la suite de Shiner et Jewett (13) et Campbell et ses collaborateurs (12) que cette réaction peut procéder par l'intermédiaire d'un état de transition qui n'impliquerait pas une chaise parfaite. Pour expliquer les résultats obtenus avec les tosylates du diméthyl-4,4 cholestanol-3β, Levisalles et Pete (3) invoquent aussi l'intervention de conformations non-chaise.

L'ensemble des résultats rapportés dans le présent travail, tout en montrant que des différences existent entre les réactions de solvolyse des tosylates des méthyl-2 d'une part et diméthyl-2,2 *tert*-butyl-4 cyclohexanols d'autre part, met en évidence un accord général entre les réactions de solvolyse des tosylates **2***c* et **3***c* et les dérivés correspondants dans le domaine des diméthyl-4,4 stéroïdes (3, 14).

Remerciements

Les auteurs remercient sincèrement le Conseil National de Recherches du Canada et le Ministère de la Jeunesse de la Province de Québec pour l'aide financiaire apportée sous forme de subvention de recherche et de bourse de perfectionnement. Les auteurs remercient aussi la Compagnie Dow Chemicals of Canada Ltd.,

Reçu le 13 mars 1969

La stéréochimie de la réduction d'alkyl-2 cyclohexanones par des organomagnésiens a été établie. Les résultats obtenus montrent que l'encombrement stérique présenté par le groupe alkyle en position-2 vis à vis du réducteur est tout à fait comparable à celui des substituants du carbone-3 du noyau cyclohexanique.

Canadian Journal of Chemistry, **47**, 3285 (1969)

Introduction

Dans le cadre de nos travaux (1, 2) sur la stéréochimie des additions nucléophiles sur des dérivés cyclohexaniques substitués, il s'avérait intéressant d'examiner la réduction par des organomagnésiens, d'alkyl-2 cyclohexanones; en effet trois hypothèses ont déjà été formulées pour apprécier l'importance du substituant en position-2 sur la stéréochimie de la réduction du groupement carbonyle. Pour Dauben et ses collaborateurs (3), ce groupement ne devrait pratiquement pas influencer la stéréochimie des réductions puisqu'il se trouve approximativement dans le plan du carbonyle et de ce fait opposerait le même empêchement à une attaque axiale qu'à une attaque équatoriale. Landor et Regan (4) considèrent que la formation de deux alcools *cis* et *trans* résulte uniquement d'une attaque équatoriale soit sur la forme flexible de la cyclohexanone en conduisant à l'alcool *trans* soit sur la forme chaise en conduisant à l'alcool *cis* (Schéma 1);

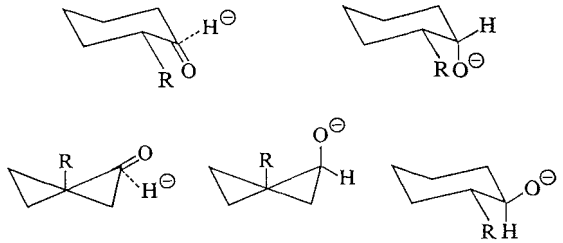

SCHÉMA 1

le groupement alkyle en position-2 devrait aussi être considéré comme ayant une influence négligeable sur la stéréochimie de la réduction puisque

TABLEAU I

Pourcentages normalisés d'alcools *cis* obtenus lors de la réduction d'alkyl-2 cyclohexanones par des organomagnésiens

	RMgCl			
Cyclohexanone	$(CH_3)_3C$—	$(CH_3)_2CH$—	C_6H_{11}—	$(CH_3)_2CH$—CH_2—
Méthyl-2*	36†	38	50	83‡
tert-Butyl-2*	73	68	78	95

*Les pourcentages d'alcools de réduction par rapport au total des produits (réduction, addition et énolisation) de la réduction sont d'environ 50% dans le cas de la méthyl-2-cyclohexanone et d'environ 10% dans le cas de la *tert*-butyl-2 cyclohexanone.
†Un travail de Cornubert (7) d'une époque antérieure à la c.p.g. indiquait la formation exclusive de l'alcool *trans*.
‡Cornubert (7) indiquait la formation exclusive de l'alcool *cis*.

les attaques équatoriales sont peu sensibles à l'empêchement stérique (5, 6). Par contre Kamernitzky et Akhrem (5) considèrent que dans la forme chaise de la cyclohexanone le carbone α, adjacent au carbone-2, des alkyl-2 cyclohexanones joue un rôle comparable à celui des carbones-3 et -5 du noyau cyclohexanique (Schéma 2); on introduit ainsi une nouvelle intéraction 1:3 diaxiale qui défaboriserait les attaques axiales donc la formation de l'alcool *trans*.

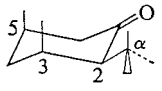

SCHÉMA 2

C'est afin de pouvoir choisir entre ces trois interprétations que nous avons examiné la stéréochimie de la réduction des méthyl-2 et *tert*-butyl-2 cyclohexanones par les magnésiens. Les résultats obtenus font l'objet de la présente communication.

Résultats et Discussion

Les résultats obtenus lors de la réduction des alkyl-2 cyclohexanones par les chlorures d'alkylmagnésium sont consignés dans le Tableau I; ils expriment le pourcentage normalisé d'alcool *cis* (attaque équatoriale) présent dans le mélange réactionnel et sont indépendants de la concentration et de la stoechiométrie des réactifs utilisés.

Ce tableau montre d'une part que la stéréosélectivité de la réduction est beaucoup plus grande pour la *tert*-butyl-2 cyclohexanone. D'autre part, il ressort très bien que la stéréochimie de la réduction dépend beaucoup de l'encombrement présenté par le carbone-2 de l'organomagnésien; ce résultat, en opposition avec les prévisions qui peuvent être formulées grâce aux hypothèses de Dauben (3), nous permet d'écarter ces dernières.

Examinons maintenant les suggestions de Landor et Regan (4). Premièrement, les résultats obtenus par Stolow (8) suggèrent que dans leur état fondamental la *tert*-butyl-2 et la methyl-2 cyclohexanone sont comparables et possèdent la conformation chaise; il est légitime de penser que dans l'état de transition de la réduction ces cétones se comporteront de la même façon. Le parallélisme qui existe entre les résultats obtenus lors de la réduction des deux alkyl-2 cyclohexanone appuie bien cette prévision et permet par ailleurs d'exclure l'hypothèse selon laquelle la méthyl-2 cyclohexanone pourrait être réduite dans sa conformation portant le groupe méthyle axial. Deuxièmement d'après l'hypothèse de Landor et Regan (4), la formation de l'alcool *trans* implique une conformation croisée; cette conformation, d'après les calculs d'Allinger (9) doit être beaucoup plus favorisée pour la *tert*-butyl-2 cyclohexanone que pour la méthyl-2 cyclohexanone ce qui laisserait prévoir que la première cétone devrait conduire à plus d'alcool *trans* que la seconde. Les résultats obtenus sont contraires à cette prévision. Finalement on devrait s'attendre de plus à ce que la stéréochimie des réductions soit indépendante de l'encombrement du réactif réducteur puisque l'attaque équatoriale dépend peu des facteurs stériques (5, 6). Nos résultats sont encore une fois en opposition avec ces prévisions; l'ensemble de cette argumentation tend donc à démontrer que l'hypothèse de Landor et Regan (4) doit être écartée.

Si l'on examine enfin l'interprétation de Kamernitzky et Akhrem (5) pour qui le groupement méthyle en position-2 est équivalent à l'un des carbones-3 ou -5 de la cyclohexanone, on introduit donc avec le méthyle une intéraction 1:3 diaxiale supplémentaire qui va ralentir l'attaque axiale; ce ralentissement sera encore plus accen-

SCHÉMA 3

tué pour la *tert*-butyl-2 cyclohexanone car dans cette molécule le groupement *tert*-butyle amène une intéraction 1:3 diaxiale comparable à celle d'un groupement méthyle axial en position-3 (Schéma 3). Comme l'attaque axiale est sensible à l'encombrement stérique présenté par l'agent réducteur, cette attaque devrait donc diminuer en passant premièrement de la méthyl-2 à la *tert*-butyl-2 cyclohexanone et deuxièmement lorsqu'on augmente le nombre de substituants sur le carbone-2 de l'organomagnésien; c'est effectivement ce qui est observé. Il en ressort donc que la stéréochimie de ces réductions peut être rationalisée en ne faisant intervenir que des facteurs stériques (2, 5) affectant les états de transition.

Le fait que les chlorures de *tert*-butyle et d'*iso*-propyle donnent, comme il a été mis en évidence précédemment (1), une stéréochimie sensiblement la même est compatible avec le mécanisme cyclique de Whitmore (voir Schéma 4) et montre que les substituants du carbone-1 de l'organomagnésien n'ont qu'une influence faible sur la stéréochimie de la réduction.

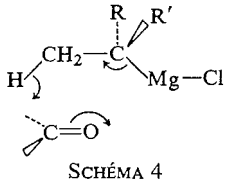

SCHÉMA 4

L'importance de l'encombrement présenté par l'agent réducteur ne se limite pas seulement aux organomagnésiens. En effet la très grande stéréospécificité de la réduction de la méthyl-2 et de la *tert*-butyl-2 cyclohexanone par les dicyclohexyl- et *diiso*pinocamphenylboranes (10 et 11) qui peuvent être rapprochés des additions de borane (12) et de peracides (13) au *tert*-butyl-3 cyclohexène montrent que le groupement alkyle sur le carbone adjacent au site réactionnel ralentit notablement l'attaque axiale.

Partie experimentale

Alcools de références et analyse

Méthyl-2 cyclohexanols

Ces alcools ont été identifiés par c.p.g. à l'aide de témoins préparés par réduction (14, 15) de la méthyl-2 cyclohexanone; ils constituaient un mélange contenant 75% d'alcool *trans* et 25% d'alcool *cis*. Lors de la chromatographie en phase gazeuse à 85 °C, avec un débit d'hélium de 20 ml/min et à l'aide d'une colonne de 1/8 po. × 3 m contenant 20% de glycérol déposé sur du chromosorb W 80/100, les temps de rétention sont de 13 min pour l'alcool *cis* et de 18 min pour l'alcool *trans*.

tert-Butyl-2 cyclohexanols

L'alcool *cis* est préparé à partir de l'acétate correspondant alors que l'alcool *trans* (contenant 10% de son isomère) est obtenu par réduction de la cétone correspondante par le sodium et l'éthanol. Lors de la c.p.g. à 110 °C, avec un débit d'hélium de 35 ml/min et une colonne de 1/4 po. par 8 pi. contenant 15% de diglycérol et 2% d'eau déposés sur du chromosorb W, les temps de rétention des alcools *cis* et *trans* sont respectivement de 9.5 min et de 13 min.

Tous les pourcentages relatifs d'épimères qui sont rapportés ont été déterminés en faisant l'hypothèse qui a été vérifiée pour de nombreux alcools épimères (16) que dans le cas de composés épimères, les surfaces relatives sous les pics peuvent être assimilées aux pourcentages relatifs de produits présents.

Réductions

Les réactifs de Grignard ont été préparés de la façon classique et titrés par iodométrie (17, 18). Les réactions de réduction ont été effectuées sur des quantités de cétone variant de 0.1 à 1 g. L'hydrolyse de ces milieux réactionnels est effectuée par NH_4Cl 10% et les produits bruts, obtenus par extraction à la manière habituelle avec de l'éther, sont examinés par c.p.g. Les résultats obtenus sont rapportés dans le Tableau I; chaque valeur représente la moyenne d'au moins trois expériences.

Remerciements

Les auteurs remercient vivement le Centre National de la Recherche Scientifique (CNRS) de France, le Conseil National de Recherches du Canada et le service de la Coopération avec l'extérieur du Ministère de l'Education de la province de Québec pour l'aide financière apportée sous forme d'octrois de recherches et de bourses d'étude. L'un de nous (J.C.R,) tient â exprimer sa profonde gratitude au Dr. Pierre Maroni et à Mlle Marthe Benoit de la Faculté des Sciences de Toulouse pour l'accueil et l'aide qui lui ont été accordés durant la préparation de ce manuscrit.

N-Chlorination of secondary amides. II. Effects of substituents on rates of N-chlorination

E. W. C. W. THOMM AND M. WAYMAN

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto 5, Ontario

Received February 18, 1969

Various secondary amides have been N-chlorinated, at high and at low pH. The reactivity of the chlorinating reagents with all the amides investigated was found to have the sequence

$$CH_3COOCl > Cl_2 > OCl^- > HOCl$$

The substituent groups R_1 and R_2 of the amide $R_1\overset{\overset{O}{\|}}{C}NHR_2$ were found to have large effects on the rate of chlorination. With the three molecular chlorinating agents, the reactivity of the amides was found to be in the order

$$CH_3\overset{\overset{O}{\|}}{C}NHCH_3 > CH_3\overset{\overset{O}{\|}}{C}ClNHCH_3 > CH_3CH_2\overset{\overset{O}{\|}}{C}NHCH_3 > CH_3\overset{\overset{O}{\|}}{C}NHCH_2CH_3 >$$
$$CH_3\overset{\overset{O}{\|}}{C}NHCH_2CH_2OH > CH_3\overset{\overset{O}{\|}}{C}NHCH_3 > H\overset{\overset{O}{\|}}{C}NHCH_2CH_3 > H\overset{\overset{O}{\|}}{C}NHCH_3 > CH_3\overset{\overset{O}{\|}}{C}NHC_6H_5$$

With hypochlorite ion the reverse order of reactivity was observed. These results are discussed and reaction mechanisms proposed. It is proposed that, when a hypochlorite ion is a chlorinating agent, the primary reaction is hydrogen bond formation between the amido hydrogen and the hypochlorite oxygen atom, but that the donation of electrons from the amido N to the Cl atom is the primary reaction with the molecular chlorinating agents.

Canadian Journal of Chemistry, 47, 3289 (1969)

Introduction

This paper is part of a series intended to shed light on the mechanism of N-chlorination of secondary amides. Interest in this group of compounds arose as a result of the development of chlorine exchange resins (1), which contain amide functional groups of which the nitrogen atoms take up positive chlorine reversibly. The first paper of this series (2) reported rate studies which suggested that the active species in the chlorination of N-methyl acetamide, in acetate buffered hypochlorous acid solutions and in the pH range 3.0 to 6.0, are CH_3COOCl, Cl_2, and HOCl, in order of decreasing reactivity. The apparent activation energy of the N-chlorination of N-methyl acetamide was found to be very low near room temperature, the secondary amide group of N-methyl acetamide being very sensitive to a chlorinating environment. Since secondary amide groups are common in many polymers, including proteins, it was decided to investigate the effects of substituents upon the rates and energies of these reactions. In the present paper 7 other amides were chlorinated, in the pH range 3 to 10.5.

Experimental

Reagents

All of the following amides were purchased from the Eastman Kodak Co.: N-methyl formamide, N-ethyl formamide, N-methyl acetamide, N-ethyl acetamide, N-methyl propionamide, N,N′-dimethyl urea, and

N-(hydroxyl ethyl) acetamide. These were of the purest commercial grade. They were further purified by precipitation from ethanol solutions using ethyl acetate as the non solvent.

Hypochlorous acid was obtained by acidifying sodium hypochlorite solutions (Fisher Scientific Co.) to the appropriate pH.

Experimental Procedure

The kinetic runs were carried out as outlined previously (2). The buffer used at low pH was acetic acid – sodium acetate, and at high pH, disodium hydrogen phosphate – sodium hydroxide. Sodium chloride was added to the reaction mixture in most runs. The working pH ranges were so chosen that in the absence of other additives, either undissociated HOCl or OCl^- ion was the main chlorinating species present (3).

As previously reported (2) in the low pH region 4–6, the pH of the reaction medium did not alter. However, in the high pH region, 10 or above, the pH increased as the reaction proceeded. As an example, in the reaction medium containing 12 m*M* $CH_3CH_2\overset{O}{\overset{\|}{C}}—NH\cdot CH_3$ and 3 m*M* OCl^- initially, the change in pH is shown below.

Buffer concentration $[Na_2HPO_4]$, *M*	pH	
	Initial	Final
0.05	10.0	10.5
0.10	10.0	10.3
0.15	10.0	10.2
0.25	10.0	10.1

Treatment of Data

All results fit the following rate expression

$$\frac{d[R_1CONClR_2]}{dt} = k_{obs}[R_1CONHR_2][ROCl]$$

where R_1CONHR_2 denotes a secondary amide, $R_1CONClR_2$ denotes the corresponding chlorinated amide, and ROCl denotes hypochlorous acid in the pH range 4–6, or the hypochlorite ion at pH 10 or above.

The observed rate constant, k_{obs}, was calculated from the best straight line of the plot of log $[R_1CONHR_2]/[ROCl]$ vs. time. Although in the high pH region, where OCl^- is the dominating species, the pH of the reaction mixture increased as the chlorination reaction proceeded, no deviation from the observed rate law was found.

Results

In our previous communication (2), we found that for N-methyl acetamide chlorination, the observed rate constant, k_{obs}, could be expressed as the sum of three terms. This was also true in acid medium for the secondary amides under study in the present work. In general, in the absence of other additives, the following relationship holds for N-chlorination in acid medium

$$\begin{aligned} k_{obs} &= k_1 + k_2[H^+][Cl^-] + k_3[CH_3COOH] \\ &= k_{HOCl} + k_{Cl_2}K_{Cl_2}[H^+][Cl^-] \\ &\quad + k_{AcOCl}K_{AcOCl}\frac{[CH_3COOH]}{[H_2O]} \end{aligned}$$

where k_{HOCl}, k_{Cl_2}, and k_{AcOCl} are specific rate constants of N-chlorination involving HOCl, Cl_2, and CH_3COOCl, respectively, as the chlorinating species, and the *K*'s are the equilibrium constants of the formation of the subscript species by reacting HOCl and either HCl or HOAc.

As can be noted in Table I, the rate of N-chlorination of secondary amides due to undissociated hypochlorous acid is small, being significant only for the ureas. Various reports (4–6) have confirmed that hypochlorous acid is a rather poor agent for C-chlorination of aromatics. Table I shows that molecular chlorine and chlorine acetate are much more powerful chlorinating agents than HOCl. The k_{Cl_2} values are, however, smaller than the k_{AcOCl} values by a factor of about 100 for all the amides studied. This observation was also made by Mauger and Soper (4) in their study of N-chlorination of N-methyl acetamide and by de la Mare and Hassan (7) for C-chlorination of aromatics. Schilov and Kaniaev (8) noted that the rate of addition of molecular chlorine to carbon–carbon double bonds was some 10^5 times that of HOCl. In the present work, the ratio of the N-chlorination reactivity of chlorine and hypochlorous acid varied within a range of 10^3–10^4, depending on the amide, with the exception that the ratio for the N,N'-dimethyl urea is about 5×10^5.

The order of reactivity of the various amides with molecular chlorine and chlorine acetate was observed as follows

$$\begin{aligned} &\overset{O}{\overset{\|}{C}}H_3NHCNHCH_3 > CH_3N\overset{Cl}{}\overset{O}{\overset{\|}{C}}NHCH_3 > CH_3CH_2\overset{O}{\overset{\|}{C}}NHCH_3 > CH_3\overset{O}{\overset{\|}{C}}NHCH_2CH_3 \\ &> CH_3\overset{O}{\overset{\|}{C}}NHCH_3 > CH_3\overset{O}{\overset{\|}{C}}NHCH_2CH_2OH > H\overset{O}{\overset{\|}{C}}NHCH_2CH_3 > H\overset{O}{\overset{\|}{C}}NHCH_3 \end{aligned}$$

TABLE II

Activation energies of N-chlorination

		25	11.3×10^4	
		40		

*Reference 2.

The literature value (7) for k_{Cl_2} for acetanilide is less than that for methyl formamide. The order of reactivity of these amides with HOCl is essentially the same, although the smallest rate constants shown in Table I are not accurate enough to distinguish between the two formamides and N-methyl acetamide.

The activation energies of Cl_2-chlorination and CH_3COOCl-chlorination of two amides are shown in Table II. The activation energy of N-chlorination by chlorine acetate was found to be lower than that of the reaction with molecular chlorine. Our activation energies are in qualitative agreement with the generally low values found for chlorination of organic compounds. The following activation energies of chlorination were reported by de la Mare and his co-workers.

Compound	Chlorinating species	E_a (kcal/mole)	Reference
Benzene	Cl_2	17	9
Toluene	Cl_2	13	6
Naphthalene	Cl_2	7.5	9
Anisole	HOCl	10	10

The effects of additives on the observed rate constant are presented in Table III. It is obvious from the table that the chloride ion, which participates in the formation of molecular chlorine, has the greatest catalytic effect, while the phosphate and sulfate ions increase the N-chlorination rate only slightly. The nitrate ion exhibits no catalytic activity. Our data are consistent with those of Mauger and Soper (4).

Thus far, we have been reporting data obtained from weakly acidic medium, where the dominant species is undissociated hypochlorous acid. In

an alkaline medium, the acid dissociates according to the following equilibrium

$$HOCl \rightleftharpoons H^+ + OCl^-$$

with the equilibrium constant $K_{OCl^-} = 4.1 \times 10^{-8}$ mole/l at 25 °C (11). At pH higher than 9, practically all the acid is ionized. The N-chlorination of amides would thus involve the hypochlorite ion OCl^- and it was assumed in the present work that the primary chlorinating agent at high pH was the hypochlorite ion

$$R_1\overset{\overset{O}{\|}}{C}NHR_2 + OCl^- \xrightarrow{k_{OCl^-}} R_1\overset{\overset{O}{\|}}{C}NClR_2 + OH^-$$

with the rate law expression

$$\frac{d\left[R_1\overset{\overset{O}{\|}}{C}NClR_2\right]}{dt} = k_{OCl^-}\left[R_1\overset{\overset{O}{\|}}{C}NHR_2\right][OCl^-] = k_{OCl^-}\frac{[OCl^-]}{[HOCl]}\left[R_1\overset{\overset{O}{\|}}{C}NHR_2\right][HOCl]$$

This reaction results in the formation of hydroxyl ion. Indeed, this was observed, as the pH of the reaction medium increased in all cases studied. It was observed that the pH, in the alkaline range studied, did not have any effect on the hypochlorite ion rate constant k_{OCl^-}. Thus, to the general expansion of the observed rate constant, k_{obs}, we must add the term $k_{OCl^-} \cdot [OCl^-]/[HOCl]$ to account for N-chlorination by the hypochlorite ion.

The k_{OCl^-} values for the various amides under study are presented in Table I. Mauger and Soper reported an estimated k_{OCl^-} value of 1.54×10^{-2} (mole/l s)$^{-1}$ for N-methyl acetamide at 25 °C (4). The present determined value was 1.82×10^{-2} (mole/l s)$^{-1}$, in reasonable agreement.

It was noted that the buffer concentration did not influence the specific hypochlorite rate constant, k_{OCl^-}, for all the amides studied. The addition of sodium chloride had no noticeable effect either (Table IV). It is obvious that buffer concentration and the sodium chloride addition would affect the ionic strength of the reaction medium.

TABLE IV

Effect of sodium chloride on the rate of N-chlorination of N-methyl acetamide by hypochlorite ion in 0.15 *M* phosphate buffer at pH 10 and 25 °C

Added NaCl (mole/l)	$10^2 \times k_{OCl^-}$ (mole/l s)$^{-1}$
0.00	1.82
0.01	1.82
0.13	1.78
0.50	1.82
	Mean 1.82

The order of reactivity of the various amides studied with OCl^- is the reverse of that for the molecular chlorinating species hypochlorous acid, chlorine, and chlorine acetate.

The specific rate constants of the various N-chlorinating species are in the order

$$CH_3COOCl > Cl_2 > OCl^- > HOCl$$

with the exception that the two lowest constants were in the reverse order for N-methylpropionamide and N,N′-dimethyl urea. In the chlorination of toluene, de la Mare and co-workers (6) found the same reactivity sequence.

Discussion

Ionic Strength Dependence

For an ionic reaction, the reaction rate constant is related to the ionic strength of the medium by the following expression (12)

$$\log k_I = \log k_{0I} + 1.018 Z_A Z_B I^{1/2}$$

where k_I and k_{0I} are the rate constants at ionic strength I and zero respectively, and Z_A and Z_B are the ionic charges of the ions A and B that enter into the reaction.

The absence of dependence of the reaction rate on ionic strength, both at low and at high pH, leads to the conclusion that at least one of the amide and the chlorinating species is uncharged. Since in the high pH region the dominant chlorinating species is the hypochlorite ion, ClO^-, it can be deduced that the amide or its intermediate remains molecular and uncharged.

Chlorination

(a) Acidic Medium

In an acid medium, where hypochlorous acid exists mainly undissociated, in the absence of buffer or other additives, the rate of N-chlorination of amides was slight. The chlorinating

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

species may be the hypochlorous acid itself or an intermediate. It was proposed by de la Mare and his co-workers (13, 14) that the electropositive chloronium ion, Cl^+, was a possible chlorinating agent. However, the addition of electrolytes should reduce the Cl^+ concentration

$$Cl^+ + Cl^- \rightarrow Cl_2$$
$$Cl^+ + HPO_4^{2-} \rightarrow ClHPO_4^-$$
$$Cl^+ + SO_4^{2-} \rightarrow ClSO_4^-$$

It is inconceivable that such species as $ClHPO_4^-$ and $ClSO_4^-$ should be more reactive than Cl^+ itself, and should increase the reaction rate, as observed, instead of decreasing it. No doubt, Cl^+ would be highly reactive. However, its concentration must be negligibly small. Anbar and Dostrovsky (15) suggested the protonated hypochlorous acid, $ClOH_2^+$, as a likely chlorinating agent

$$H^+ + HOCl \rightarrow ClOH_2^+$$

The absence of dependence of the HOCl reaction rates on pH argues against this formulation. We propose that in the absence of additives, and in the pH region of undissociated hypochlorous acid, the active N-chlorinating species is the acid itself. The absence of influence of changes of pH in this range and of electrolytes upon k_{HOCl} lends support to the molecular HOCl N-chlorination hypothesis.

In the presence of chloride ions, molecular chlorine is generated by the following reaction

$$HOCl + H^+ + Cl^- \rightleftharpoons Cl_2 + H_2O$$

In the presence of acetic acid, chlorine acetate is formed by the following reaction

$$HOCl + CH_3COOH \rightleftharpoons CH_3COOCl + H_2O$$

The protonated chlorine acetate does not exist to any appreciable extent

$$CH_3COOCl + H^+ \rightleftharpoons CH_3.CO^+H.OCl$$

as the N-chlorination reaction involving chlorine acetate was not noticeably affected by the pH of the reaction medium. Again, we are led to the conclusion that the active chlorinating species are molecular chlorine and chlorine acetate.

In general, active N-chlorinating species are generated from hypochlorous acid by reaction either with chloride ion in acidic medium, as follows

[1] $$HOCl + H^+ + Cl^- \rightleftharpoons Cl_2 + H_2O$$

or with a molecular species such as acetic acid, as follows

[2] $$HOCl + HOAc \rightleftharpoons AcOCl + H_2O$$

The catalytic action of phosphates and sulfates, and of other organic acids described by Mauger and Soper (4) appears to result from reactions similar to [1] or [2].

(b) Alkaline Medium

In an alkaline medium, hypochlorous acid reacts to form OCl^- as follows

$$HOCl + OH^- \rightleftharpoons OCl^- + H_2O$$

Neither chloride ion concentration nor hydrogen ion concentration affected the chlorination rate in the ranges studied. We are led to the conclusion that the OCl^- ion takes part directly in the N-chlorination process.

Effect of Substituent Groups

It was suggested in the first part of this discussion that the amide reacts primarily as a molecular entity. The present discussion illustrates the effects of substituents R_1 and R_2 on the reactivity

$$R_1{-}\overset{\overset{O}{\|}}{C}{-}NHR_2$$

of the secondary amides towards the different chlorinating agents. Following Mauger and Soper (4) the reaction may be written

$$R_1{-}\overset{\overset{O}{\|}}{C}{-}\underset{\underset{R_2}{|}}{N}\cdots\overset{\overset{H}{|}}{Cl}\leftarrow X$$

where X may be Cl, HO, AcO, or O^-. Mauger and Soper suggested hydrogen bond formation between the amido hydrogen and the X group. The rate of reaction of the chlorinating agent and the amide is seen as dependent upon the ease of formation of such a bond. It is evident that readiness with which such bonds form would depend on the properties of R_1 and R_2, which determine the electron density about the amide N, and thus the strength of the NH bond, and the chlorinating agent.

The carbonyl group has a high electron affinity. When other effects are equal, the electron-donor properties of the R_1 and R_2 groups would determine the electron density about the amide N. The higher the electron-donating power, the more electronegative the amide N, the stronger the NH bond, and the lower the expected rate of reaction. If the electron-donating power of the

For personal use only.

R_1 or R_2 groups of the amides is measured as the inverse of K_a, the dissociation constants of the corresponding acids, the following order for $1/K_a$ is observed

$$CH_3CH_2COOH > CH_3COOH > HCOOH$$

The specific rate constants for the corresponding amides and the various N-chlorinating species are then expected to be in the reverse order, that is

$$HCNHR_2 > CH_3CNHR_2 > CH_3CH_2CNHR_2$$

and

$$R_1CNHCH_3 > R_1CNHC_2H_5$$

This order is that observed for k_{OCl^-}. The suggestion of Mauger and Soper appears then to be consistent with the observations when the chlorinating agent is hypochlorite ion.

The observed order of reactivity of the amides with the molecular chlorinating agents is just the reverse, that is, the reactions are most rapid when there is the greatest electron density about the amide N atom. In this case it is suggested that the primary reaction is the donation of electrons from the N to the Cl atom, as follows

$$R_1—C(=O)—N(H\ldots X)—R_2 \rightarrow Cl$$

where X is Cl, HO, or AcO. Such a reaction would appear to be most likely if the molecular chlorinating agent were somewhat polarized, with a partial positive charge on the Cl atom, as follows

$$X^{\delta-}—Cl^{\delta+}$$

In this case the order of reactivity would be the same as the degree of such polarization. A measure of such polarization may be the rate or extent of reaction with Cl^- in a slightly acid medium, as follows

[3] $$HOCl + Cl^- + H^+ \rightleftharpoons Cl_2 + H_2O$$

[4] $$Cl_2 + Cl^- \rightleftharpoons Cl_3^-$$

[5] $$CH_3—C(=O)—OCl + Cl^- + H^+ \rightleftharpoons Cl_2 + CH_3COOH$$

At pH near 5, in the presence of low concentrations of Cl^-, very little reaction takes place between HOCl and Cl^-, the equilibrium being far to the left and the equilibrium constant (16) being given as

$$K = \frac{[H^+][Cl^-][HOCl]}{[Cl_2]} = 4.75 \times 10^{-4} \text{ (mole/l)}^2 \text{ at } 25\,^\circ\text{C}$$

The equilibrium constant for the reaction between Cl_2 and Cl^- is given (17) as 1.91×10^{-1} $(\text{mole/l})^{-1}$ at 25 °C.

While again the equilibrium lies to the left, at pH 5 there would be more reaction between Cl_2 and Cl^- than between HOCl and Cl^-.

The equilibrium constant (16, 14) for reaction [5] is

$$K = \frac{[Cl_2][AcOH]}{[AcOCl][Cl^-][H^+]} = \frac{[Cl_2][H_2O]}{[HOCl][Cl^-][H^+]} \times \frac{[AcOH][HOCl]}{[AcOCl][H_2O]}$$

$$= 2.1 \times 10^3 \times 4.0 \times 10^2 \times [H_2O] = 8.4 \times 10^5 \times [H_2O] \text{ (mole/l)}^{-1}$$

The large equilibrium constant suggests a high fraction of positive charge on the Cl of the acetyl hypochlorite, which is consistent with its high reactivity. If we can extend the Hammett equation to the present systems

$$\log (k/k_0) = \sigma\rho$$

where k is the specific rate constant, k_0 is a reference rate constant, σ is the substituent constant independent of the reaction, and ρ is the proportionality constant, then the slope of the

plot log k vs. σ, i.e., ρ, would indicate the electronic interaction between the amide and the chlorinating species. If the substituent groups are electron-withdrawing, ρ should have a positive value; on the other hand, a negative ρ value would indicate facilitation of reaction by electron-releasing substituents.

Taft (18) proposed that σ is made up of two components, the inductive effect σ_I and the resonance effect σ_R, such that

$$\sigma_p = \sigma_I + \sigma_R$$

where σ_p is the σ value for *p*-substituted benzene rings. Table V lists the σ values for R_1 of the amide series

$$R_1\overset{\overset{O}{\|}}{C}NHCH_3$$

and for X of the molecular chlorinating species X—Cl. As can be seen from the X—Cl series, the reactivity is not a function of the inductive effect alone. If it were so, the reactivity of the chlorinating species should be in the order $Cl_2 > CH_3COOCl > HOCl$. However, this was not the observed order.

Figure 1 plots the specific rate constants of the amides against the σ_p values of the substituent X of the chlorinating species. Figure 2 shows the rate constants plotted against σ_p of the substituent R_1 of the amide $R_1\overset{\overset{O}{\|}}{C}NHCH_3$. Both plots exhibit remarkable linearity. It appears that resonance plays an important role in the reaction. It is the combined inductive and resonance effects of the substituents that determine the reactivities of both the amides and the chlorinating species.

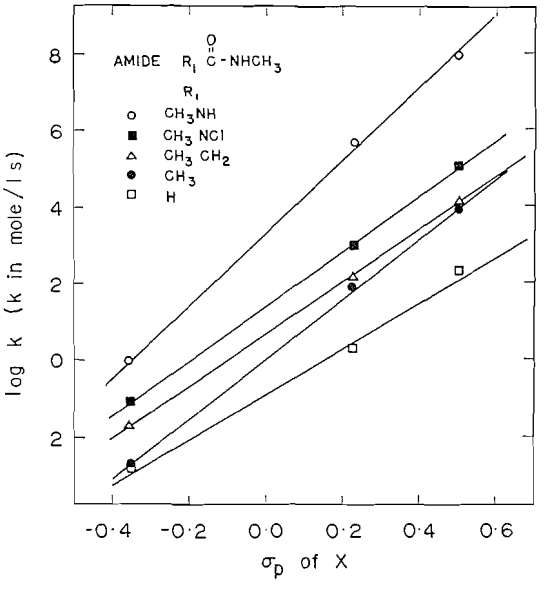

FIG. 1. Effects of the substituents of the chlorinating species X—Cl on the reaction rate constants.

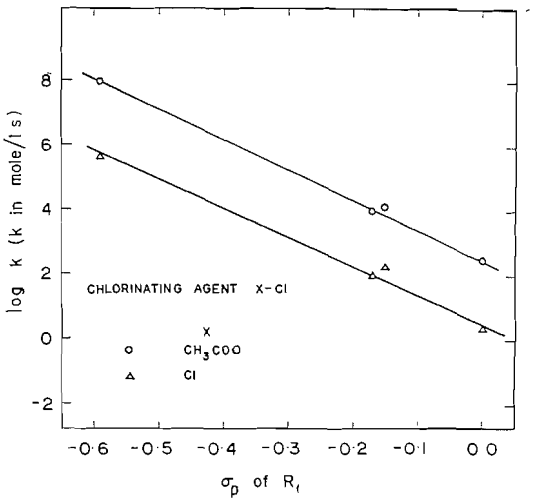

FIG. 2. Effects of the substituents of the amides $R_1\overset{\overset{O}{\|}}{C}NHCH_3$ on the reaction rate constants.

Pauling (22) suggested that amides have two main resonance structures

$$R_1-\overset{\overset{O}{\|}}{C}-N\begin{matrix}H\\ \diagdown\\ \diagup\\ CH_3\end{matrix} \rightleftharpoons R_1-\overset{\overset{O^-}{|}}{C}=N^+\begin{matrix}H\\ \diagdown\\ \diagup\\ CH_3\end{matrix}$$

It is reasonable to suggest that there are similar inductive and resonance effects by the substituent R_1 on the structure of the amide as on the benzene ring.

The positive slopes of Fig. 1 lend support to our hypothesis that the higher the electron-withdrawing power of X, the more reactive the chlorinating species. The negative slopes of Fig. 2 suggest that higher electron density of the amide N facilitates the up-take of positive chlorine. These two observations clearly supplement each other.

Thus, it would appear reasonable to suggest

that the specific rate constants for the reactions between these molecular chlorinating agents and the amides are in the order of the magnitude of the partial positive charge on the Cl atom of the chlorinating species and also of the electron density on the N atom of the amide.

Etude du coefficient d'expansion linéaire de polymères en solution par sédimentation et par viscosimétrie

NGA HO-DUC ET HUBERT DAOUST
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 7 mars 1969

Les coefficients d'expansion linéaire de polyméthacrylate de méthyle en solution dans du tétrachlorure de carbone à 45 °C, dioxanne, benzène et chloroforme à 25 °C et de polyisobutylène en solution dans du caprylate d'éthyle à 10.8 °C, triméthyle-2,2,4 pentane, cyclohexane et heptane à 25 °C ont été étudiés à partir de données expérimentales de sédimentation et de viscosimétrie. Les valeurs des coefficients d'expansion linéaire α_η et α_f sont comparées entre elles et le rapport α_η/α_f trouvé pour les différents systèmes étudiés se situe entre 0.9 et 1.0. Une correction proposée pour la constante de sédimentation, S^0, tenant compte de la variation de α avec la concentration, nous permet de rapprocher davantage les valeurs expérimentales et théoriques de l'exposant δ de la relation entre la viscosité intrinsèque $[\eta]$ et le coefficient de frottement intrinsèque $[f]$. Les valeurs trouvées pour δ se situent entre 2.4 et 3.0 en accord avec la valeur proposée par Stockmayer et Albrecht (2), soit 2.8 et la valeur de 2.7 tirée de la théorie de Ptitsyn (7).

Canadian Journal of Chemistry, 47, 3299 (1969)

Introduction

L'ultracentrifugation offre, en principe, une méthode pour l'étude des dimensions des macromolécules en solution (1). Le coefficient de frottement des particules de soluté à concentration nulle est défini par

$$[1] \qquad f_0 = M(1 - \bar{v}_2\rho)/N_A S_0{}^0$$

où M est la masse moléculaire du soluté, $\bar{v}_2$, son volume spécifique partiel, ρ, la densité du solvant, N_A, le nombre d'Avogadro, et $S_0{}^0$, le coefficient de sédimentation du soluté à concentration nulle et sous 1 atm de pression. Le coefficient de frottement intrinsèque $[f]$ défini par f_0/η_0, η_0 étant la viscosité du solvant, est relié au coefficient d'expansion linéaire d'une chaîne de polymère en solution infiniment diluée α_f, par la relation

$$[2] \qquad [f] = K_f M^{1/2}\alpha_f$$

où K_f est une constante pour un polymère donné. Cette constante est définie par la relation

$$[3] \qquad K_f = P_0(R_0{}^2/M)^{1/2}$$

où P_0 est une constante universelle dont la valeur limite pour un polymère homogène est 5.11 (2); R_θ est la racine carrée de la distance quadratique moyenne entre les bouts d'une chaîne en solvant thêta à concentration nulle. Il existe donc une relation directe entre $[f]$ et la dimension moyenne d'une chaîne de polymère dans un solvant quelconque à concentration nulle définie par R_0. Evidemment, le calcul de R_0 repose sur la détermination de $S_0{}^0$. Cette détermination peut se faire à l'aide de la méthode décrite par Billick (3) dans laquelle le coefficient de sédimentation apparent à une concentration particulière est défini par

$$[4] \qquad S = \frac{\ln (r/r_0)}{\omega^2 t} = S^0\left\{1 - \frac{[m(2a + 1) - a]}{(1 + a)} S^0\omega^2 t - \cdots\right\}$$

où r est la distance radiale de la frontière solvant–solution au temps t, r_0, la valeur au temps zéro, ω, la vitesse angulaire du rotor, S^0, la valeur de S sous 1 atm de pression, m, un paramètre reflétant l'effet de la pression sur la sédimentation et a, un paramètre reflétant l'effet de la concentration. La valeur de $S_0{}^0$ s'obtient par l'extrapolation de la droite obtenue du graphique $1/S^0 = f(c)$.

Une autre méthode grandement utilisée à la détermination des dimensions des macromolécules en solution est la viscosité. La relation classique de Fox et Flory (1) entre la viscosité intrinsèque $[\eta]$ d'un polymère dans un solvant donné et la dimension de la chaîne s'écrit

$$[5] \qquad [\eta] = KM^{1/2}\alpha_\eta{}^3$$

La constante K étant définie par

$$[6] \qquad K = \Phi(R_0{}^2/M)^{3/2}$$

où Φ est un paramètre dont la valeur varie en fonction de la nature du solvant (4).

Les équations données ci-haut pour les deux méthodes de caractérisation reposent sur le

même modèle physique mais la théorie prévoit une différence entre les valeurs de α_η et α_f (2, 4–7). Dans ce travail, nous avons fait une étude comparative des deux méthodes sur des solutions de polyméthacrylate de méthyle (PMM) et de polyisobutylène (PIB).

Partie Expérimentale

La fraction de PMM utilisée est la septième d'un fractionnement simple d'un échantillon préparé d'après la méthode décrite par Fox *et al.* (8). Sa masse moléculaire déterminée par viscosimétrie est 3.91×10^5. La fraction de PIB utilisée vient d'un fractionnement double d'un échantillon commercial connu sous le nom de Vistanex L-100 de Enjay Co., Inc., ayant pour masse moléculaire viscosimétrique 1.17×10^6 (9). Les solvants utilisés sont de qualité réactif analytique.

Les mesures de sédimentation sont effectuées à l'aide d'une ultracentrifugeuse analytique "Spinco" modèle E-HT. La vitesse du rotor est fixée à 59 780 t/min pour tous les systèmes étudiés, soient: PMM–dioxanne, –benzène, –chloroforme, PIB–heptane, –cyclohexane, –triméthyle-2,2,4 pentane à 25 °C, PMM–tétrachlorure de carbone à 45 °C, et PIB–caprylate d'éthyle à 10.8 °C. La température du rotor est maintenue stable à ± 0.2 °C. Le dépouillement des plaques photographiques se fait à l'aide d'un microcomparateur de Nippon Kogaku; la précision de la platine de cet appareil est de ± 0.01 mm. La détermination du "temps zéro" se fait suivant la méthode d'estimation du temps zéro à accélération constante (10). Les graphiques $\ln r = f(t)$ permettent ensuite la détermination précise du temps zéro i.e. à quelques secondes près. Les coefficients de sédimentation S^0 à différentes concentrations sont calculés graphiquement à partir de l'éq. [4] et la valeur de S_0^0 est déduite à partir du graphique $(1/S^0) = f(c)$.

La viscosité intrinsèque est calculée pour chaque système à partir de mesures effectuées, à l'aide d'un viscosimètre Ubbelhode modifié (11), aux températures correspondantes.

Résultats et Discussion

Les Tableaux I et II représentent les valeurs de $1/S_0^0$, α_f et α_η des différents systèmes. Afin d'éliminer les valeurs de M, P_0 et de la constante structurale (R_0^2/M) dans les calculs, nous avons utilisé les relations suivantes

$$[7] \quad \alpha_\eta = ([\eta]\Phi_0/[\eta]_0\Phi)^{1/3}$$

$$[8] \quad \alpha_f = [f]/[f]_0 = (1 - \bar{v}_2\rho)\eta_{00}(S_0^0)_0/(1 - \bar{v}_2\rho)_0\eta_0 S_0^0$$

Nous avons négligé dans ces calculs l'effet de la température sur la valeur de la constante structurale et nous avons utilisé la valeur de 2.48×10^{21} pour la constante Φ pour les bons solvants et 2.87×10^{21} pour les solvants thêta (4). Les différentes constantes physiques des polymères et des solvants sont données dans le Tableau III.

L'analyse des Tableaux I et II permet de constater que le rapport entre α_η et α_f varie entre 0.91 et 1.03, tandis que Kurata et Stockmayer prévoient une valeur de 0.97 (4). Tout le long des études théoriques du coefficient de sédimentation, les auteurs ont tenu compte de l'effet de concentration seulement au point de vue hydrodynamique ou autrement dit de l'effet de

‡Référence 21.

frottement. D'autre part, si on suppose que le coefficient de diffusion est indépendant de la concentration, cela signifie que la dimension de la chaîne est définie par R_0 à toute concentration. Alors, l'éq. [4] suppose que la dimension de la sphère équivalente au volume d'encombrement des chaînes ne change pas avec la concentration. Cependant, il a été démontré théoriquement que le coefficient d'expansion linéaire varie avec la concentration de la solution (13–15). Ainsi, nous pensons qu'il est nécessaire de tenir compte de cet effet et d'apporter une correction sur chaque valeur de S^0. Cette correction pourrait se faire en considérant que le rayon quadratique moyen de la chaîne des polymères est une fonction de la concentration dans la déduction mathématique des équations. Cette nouvelle fonction complique énormément la résolution mathématique de l'équation différentielle de base de la sédimentation.

Pour ne pas se heurter à des difficultés presqu'insurmontables, nous proposons la relation suivante en partant de la loi de Stokes

$$[9] \qquad (1/S_0{}^0)_0 = (1/S^0)_c(\alpha_0/\alpha_c)$$

Cette relation assez rudimentaire amène la valeur de S^0, obtenue à une concentration c pour laquelle le coefficient d'expansion linéaire est α_c, à celle correspondant à la dimension moyenne des chaînes de polymères à concentration nulle comme le suppose la dérivation de l'éq. [4].

La valeur de α à une concentration donnée peut être calculée à l'aide de la relation suivante (13)

$$[10] \qquad \alpha_c = \alpha_0 \exp(-Ac)$$

avec

$$[11] \qquad A = 0.0794(N_A n^2 \beta/2M)\varphi_2(z_0)]$$

où n est le nombre de segments par chaîne, β, l'intégrale obtenue lors du couplage des segments pour former les chaînes de polymères et $\varphi_2(z_0)$ est une fonction dépendant de α_0.

Les Figs. 1 et 2 représentent les courbes moyennes calculées par la méthode des moindres carrés à partir des données expérimentales. Les courbes en traits brisés représentent les pentes limites à dilution infinie de la relation $(1/S^0) = f(c)$ ou en d'autres termes, elles représentent l'allure de cette relation lorsque les dimensions des chaînes sont définies par R_0 à toute concentration. Les courbes en traits continus représentent l'allure des résultats expérimentaux et il est d'usage de définir $1/S_0{}^0$ par l'extrapolation linéaire à concentration nulle des résultats obtenus à des concentrations allant de 0.1 à 1 %. En principe, les deux séries de courbes devraient donner les mêmes valeurs pour $1/S_0{}^0$ mais

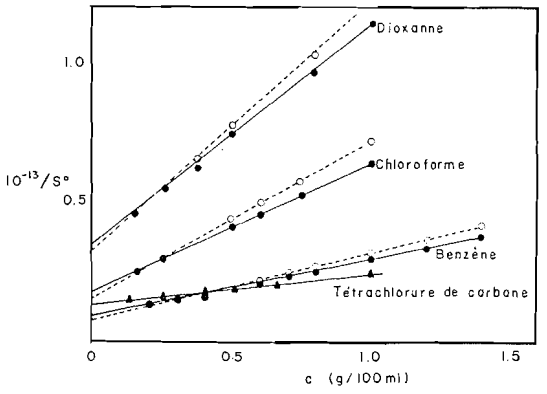

FIG. 1. Variation de $1/S^0$ en fonction de la concentration pour le PMM; traits continus, sans correction; traits brisés, avec correction.

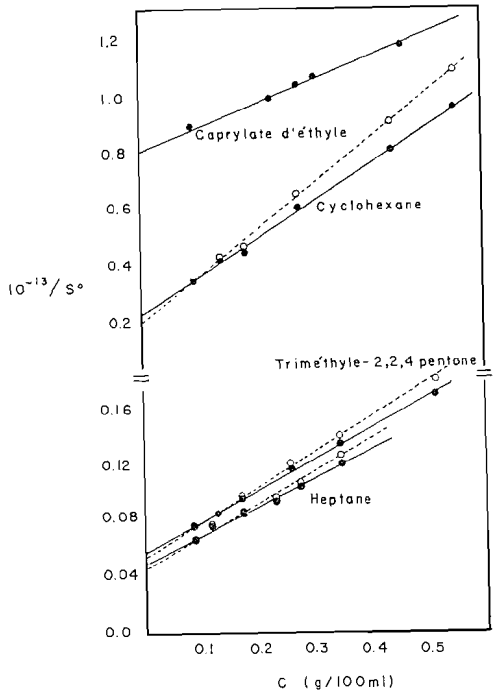

FIG. 2. Variation de $1/S^0$ en fonction de la concentration pour le PIB; traits continus, sans correction; traits brisés, avec correction.

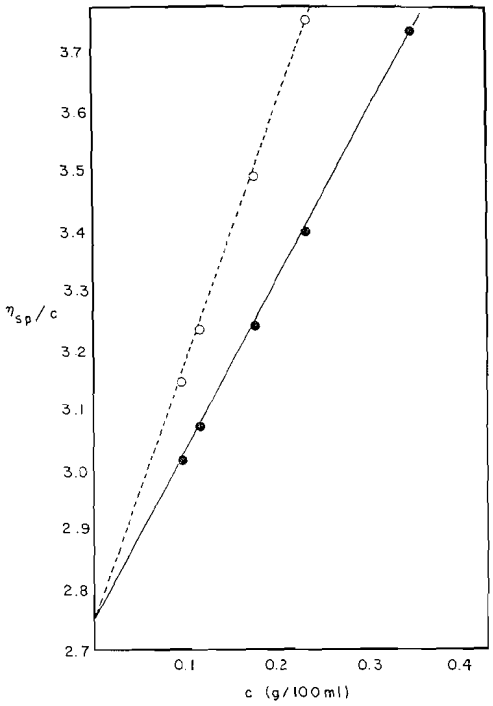

FIG. 3. Variation de la viscosité spécifique réduite en fonction de la concentration pour le système PIB–heptane à 25 °C; trait continu, sans correction; trait brisé, avec correction.

l'imprécision des données expérimentales ne permet pas de conclure à un changement d'allure de la relation $(1/S^0) = f(c)$ à très faibles concentrations. Nous devons donc recourir à la méthode que nous avons utilisée pour arriver au calcul de $1/S_0{}^0$ dans le cas de bons solvants.

Nous avons groupé les résultats finals dans le Tableau IV. Nous constatons qu'avec la correction proposée, la comparaison des valeurs du coefficient d'expansion linéaire calculées à partir des données de l'ultracentrifugation et celles de la viscosimétrie est très avantageuse. Notons que cette conclusion n'est pas du tout justifiée pour les systèmes PMM–benzène et PMM–dioxanne. Nous croyons que ces exceptions pourraient être dues à la différence entre la polarité du polymère et celle du solvant. En effet, il a été démontré (16, 17) que lorsqu'un polymère polaire est en solution dans un solvant de polarité comparable, la polarité n'entre pas en ligne de compte, mais lorsque le solvant possède un moment dipolaire beaucoup plus faible que celui du polymère, alors le paramètre d'interaction polymère–solvant χ_1 augmente avec la dilution. Cette augmentation de χ_1 entraîne une diminution de α avec la dilution et alors la correction suggérée devient difficile à réaliser ou peut-être n'a plus de raison d'être à cause de la cancellation des deux effets opposés.

Nous voudrions faire remarquer qu'en réalité il faut apporter le même genre de correction pour les résultats obtenus à partir des données viscosimétriques car les deux théories traitant de la sédimentation et de la viscosité des polymères en solution sont basées sur le même modèle physique. Nous avons effectué les mêmes calculs afin de corriger le coefficient d'expansion linéaire α_η. Les résultats de ces calculs pour le système PIB–heptane sont représentés dans la Fig. 3 comme exemple afin de montrer que la correction est vraiment négligeable dans le cas de la viscosimétrie. Le changement de la pente est plus accentué que dans le cas de la sédimentation à cause de l'exposant trois de α_η mais l'extrapolation reste pratiquement la même.

Le paramètre δ dont les valeurs sont données dans le Tableau IV vient de la relation

$$[12] \qquad [\eta]/[\eta]_0 = ([f]/[f]_0)^\delta$$

TABLEAU IV

Résumé des résultats finals

Système	A	$1/S_0^0$ ($\times 10^{-13}$) corr.	α_f corr.	α_η/α_f corr.	δ	δ corr.
PMM–dioxanne	8.70	0.330	1.36	1.06	2.8	3.0
PMM–benzène	7.74	0.086	1.36	1.04	2.6	2.8
PMM–chloroforme	13.31	0.156	1.57	0.99	2.3	2.6
PIB–heptane	11.95	0.046	1.37	1.01	2.3	2.7
PIB–cyclohexane	23.5	0.202	1.56	1.00	2.3	2.7
PIB–triméthyle-2,2,4 pentane	6.95	0.053	1.28	1.00	2.1	2.4

Une étude récente de Noda *et al.* (6) a montré que $\delta = 2.4$ pour une série de fractions de poly-α-méthyle-styrène en solution dans le toluène et dans le cyclohexane (solvant thêta). Cette valeur se compare très bien avec celles rapportées dans le présent travail. Cependant, les valeurs de δ corrigées sont plutôt en accord avec la valeur théorique de 2.8 telle que suggérée par Stockmayer et Albrecht (2) et celle de 2.7 tirée du travail de Ptitsyn (7). La correction semi-empirique proposée pour $S_0{}^0$ nous permet ainsi de rapprocher les résultats expérimentaux de ceux prédits par la théorie.

L'application des relations [7] et [8] suppose que les fractions utilisées dans ce travail sont de faible polydispersité, ce qui nous permet d'utiliser les valeurs limites de Φ et de P_0. Dans le cas de la fraction de PIB, des calculs théoriques (18) permettent de prévoir une valeur pour le facteur de polydispersité $h > 10$ donc suffisamment monodisperse (4). Par ailleurs, une valeur de $h = 4$ peut être prévue dans le cas de PMM, ce qui amène une correction due à la polydispersité inférieure à 2% sur le rapport α_η/α_f.

Arrhenius parameters for the reaction of propyl radicals with propane

R. E. BERKLEY, G. N. C. WOODALL, O. P. STRAUSZ, AND H. E. GUNNING
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 19, 1969

The reaction of *n*-propyl radicals from the photolysis of azo-*n*-propane with propane has been studied and Arrhenius parameters for hydrogen atom abstraction relative to the recombination of *n*-propyl radicals determined. From the Arrhenius parameters obtained and the available thermodynamic data, the Arrhenius parameters of the reverse reaction, the hydrogen atom abstraction from propane by *iso*-propyl radicals, have been calculated.

Some complicating factors in the photolysis of azopropane are discussed.

Canadian Journal of Chemistry, 47, 3305 (1969)

The hydrogen abstraction reactions of methyl radicals from alkanes have been extensively studied, but information on the analogous reactions of higher alkyl radicals is scant (1). It has generally been assumed that the reactions of the higher alkyl radicals are very similar to those of methyl except that the activation energy of abstraction would progressively increase as the C—H bond energy of the abstracting radical decreases. This expectation, though trivial, still lacks proof of general validity. The most abundant data for comparison of methyl with higher alkyl radicals are for abstraction of hydrogen from aldehydes. Here, however, the data, if trustworthy, appear to favor an opposite trend. Abstraction of hydrogen for example by Me and *t*-Bu from *t*-BuCHO has activation energies of 10.2 and 4.3 kcal, respectively. For abstraction from *s*-BuCHO by Me and *s*-Bu, the values are 10.4 and 4.9, and from *i*-BuCHO by Me and *i*-Bu 8.4 and 6.5 kcal, respectively (1). The abstraction from *n*-BuCHO and EtCHO by Me, *n*-Bu, and Me and Et exhibits the same trend. On the other hand, abstraction of hydrogen from paraffins (for example from *n*- and *iso*-butane and *cyclo*-hexane) by methyl and ethyl shows the expected trend in that abstraction by ethyl has activation energies about 0.8 kcal larger than by methyl (1).

Hydrogen abstractions by propyl radicals from hydrocarbons have not been reported in the literature. In conjunction with another study, we have determined the Arrhenius parameters for the *n*-propyl-propane reaction.

n-Propyl radicals were generated by the 3660 Å photolysis of azo-*n*-propane. It is generally accepted that photolysis of azo-alkanes in their first absorption band leads to an $n \rightarrow \pi^*$ excitation. The excited molecules may either undergo decomposition into nitrogen and two alkyl radicals or suffer collisional deactivation to the ground state. The decomposition evidently has a small activation energy, and the radicals produced are thermally equilibrated (2–14).

The photolysis of azo-*n*-propane has been carried out in the presence of propane and propane-1,1,1,3,3,3-d_6, and rate constants for the reaction of *n*-propyl radicals with propane relative to the recombination of *n*-propyl have been measured. In the kinetic treatment allowance has been made for the reactions of propyl radicals with the parent azo compound.

Experimental

Small portions of azo-*n*-propane (Merck) were purified by gas chromatography before each run, using the method described below for separation of components of the "heavy fraction". *n*-Propane-azo-isopropane was synthesized according to the method of Spialter and coworkers (15) and was purified in the same manner as the azo-*n*-propane. The propane (Phillips Research Grade) was distilled under vacuum at −131 °C and degassed at −196 °C. It was shown by gas chromatography to contain less than 0.1% ethane and no other detectable impurities. *n*-Hexane, 2,3-dimethylbutane, 2-methylpentane, and propylene used as calibration samples were also shown by chromatography to contain negligible impurities.

Photolyses were carried out in a cylindrical quartz cell equipped with a cold finger and attached to a high vacuum system. The cell was mounted inside an aluminum block furnace. Light was isolated from a Hanovia Utility medium pressure mercury arc by a Kodak Wratten 18A filter. Product analyses were accomplished by low temperature distillation and gas chromatography. The fraction volatile at −210 °C was measured in a gas burette. It was occasionally analyzed by gas chromatography (10 ft 13X molecular sieves, 0 °C) or by mass spectrometry. It consisted of pure nitrogen with the exception of the 232 °C run which showed a trace of methane. The fraction volatile at −131 °C was measured in a gas burette and then analyzed by gas chromatography (15 ft

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

medium activity silica gel, 50 °C). This fraction consisted of propane, propylene, and, occasionally, traces of ethylene. In runs with added propane this fraction was simply discarded. The components of the heavy fraction were separated on a 20 ft 20% SE-30 silicone gum rubber on Chromosorb W.A.W. column at 100 °C. The hexanes were trapped and quantitatively analyzed (24 ft 10% dimethylsulfolane on Chromosorb W.A.W., 0 °C). The dimethylsulfolane column would not resolve 2,3-dimethylbutane and 2-methylpentane, so the proportions of each were calculated, assuming $R_{ab}/(R_{aa}R_{bb})^{\frac{1}{2}} = 2$, where R_{ab} is the rate of cross combination of *n*-propyl and isopropyl radicals and R_{aa} and R_{bb} are the respective rates of autocombination. In the latter part of the investigation the hexanes were analyzed at 25 °C on a 20 ft column packed with 40% isoquinoline on Chromosorb W.A.W. which resolved all three hexane isomers.

Results

Photolyses of pure azo-*n*-propane at 25 °C afforded N_2, propane, propylene, and *n*-hexane, as reported by Calvert and Kerr (4). Upon addition of propane to the system small quantities of 2-methylpentane could be detected. Use of d_6-propane resulted in formation of 2-methylpentane-d_6.

With increasing temperature, many products of lower vapor pressure than azo-*n*-propane began to appear, and the mass balance as calculated from the hydrocarbon products decreased steadily. The heavy products were eluted from the column as very broad peaks with long retention times when the column was operated under conditions optimal for separation of hydrocarbon products, and it was therefore impractical to attempt quantitative analysis of them. Instead account of these products has been taken in the kinetic treatment in terms of the mass balance defect.

The nature of the reactions between alkyl radicals and azoalkanes has been briefly examined in an auxiliary study and the result will be described in another communication (16).

In the azopropane system only the four lightest of the heavy products were trapped, and their identification attempted. One product proved to be propanal propylhydrazone, an isomer of azo-*n*-propane. It was identified by mass spectrometry and nuclear magnetic resonance (n.m.r.). Only mass spectra were obtained for the other three products, since it was too time-consuming to obtain enough sample for n.m.r. spectra. An exact mass measurement indicated that the lightest of these products was a hydrocarbon, or mixture of hydrocarbons, C_9H_{20}. The cracking pattern did not match closely the known cracking pattern of any individual isomer. The other two products both had molecular formula $C_9H_{20}N_2$. The two cracking patterns were virtually identical, except that the product with the shorter retention time had a slightly larger peak at mass 15. The two mass spectra appear closely analogous to that of ethyl 2-butyl diimide (16), and it seems reasonable to suppose that the one with shorter retention time and larger mass 15 peak is propyl 2-methyl-3-pentyl diimide, and that the other one is propyl 3-hexyl diimide. This tentative identification is supported by the fact that the first product is produced in increasing amounts as temperature and isopropyl concentration increase, while the second product is produced throughout the temperature range of the study. The possibility of these products being *cis–trans* isomers of propanal dipropylhydrazone can be dismissed, since dialkyl hydrazones are known not to display *cis–trans* isomerism (16, 17), and the mass spectrum is not analogous to that of ethanal diethyl hydrazone.

The mechanism adapted for the kinetic treatment is summarized below

$$\text{Azo-}n\text{-propane} \xrightarrow{h\nu} 2n\text{-Pr} + N_2$$

[1] $$n\text{-Pr} + C_3H_8 \rightarrow C_3H_8 + i\text{-Pr}$$

[1*a*] $$i\text{-Pr} + C_3H_8 \rightarrow C_3H_8 + n\text{-Pr}$$

[2*a*] $$n\text{-Pr} + i\text{-Pr} \rightarrow \text{2-Methylpentane}$$

[2*b*] $$n\text{-Pr} + i\text{-Pr} \rightarrow C_3H_8 + C_3H_6$$

[3*a*] $$2n\text{-Pr} \rightarrow n\text{-Hexane}$$

[3*b*] $$2n\text{-Pr} \rightarrow C_3H_8 + C_3H_6$$

[4*a*] $$2i\text{-Pr} \rightarrow \text{2,3-Dimethylbutane}$$

[4*b*] $$2i\text{-Pr} \rightarrow C_3H_8 + C_3H_6$$

[5] $$n\text{-Pr} + \text{double bond} \rightarrow \text{Other products or radical}$$

[6] $$i\text{-Pr} + \text{double bond} \rightarrow \text{Other products or radical}$$

The following assumption is made

$$k_{2a} + k_{2b} = 2(k_{3a} + k_{3b}) = 2(k_{4a} + k_{4b})$$

Terry and Futrell (18) have shown that

$$\frac{k_{2b}}{k_{2a}} = 0.41$$

$$\frac{k_{3b}}{k_{3a}} = 0.15$$

$$\frac{k_{4b}}{k_{4a}} = 0.69$$

from which

$$\frac{R_{2a}}{R_{3a}} = 1.63\,\frac{[i\text{-Pr}]}{[n\text{-Pr}]}$$

and

$$r = \frac{[i\text{-Pr}]}{[n\text{-Pr}]} = 0.61\,\frac{R_{2a}}{R_{3a}}$$

The rates of reactions [5] and [6] may be expressed in terms of mass balance

$$R_0 = R_{N_2} - (R_{2a} + R_{2b} + R_{4a} + R_{4b} + R_{3a} + R_{3b})$$

Using the known values of k_d/k_r

$$R_0 = R_{N_2} - 1.41R_{2a} - 1.69R_{4a} - 1.15R_{3a}$$

Since R_0 represents the mass balance defect in terms of radical pairs, while R_5 and R_6 account for the disappearance of single radicals

$$R_5 + R_6 = 2R_0$$

Now k_5 and k_6 will not, in general, be equal. They will be related at a given temperature by

$$q = \frac{k_5}{k_6}$$

Thus

$$\frac{R_6}{R_5} = \frac{k_6[i\text{-Pr}][X]}{qk_6[n\text{-Pr}][X]} = \frac{1}{q}\cdot\frac{[i\text{-Pr}]}{[n\text{-Pr}]} = \frac{r}{q}$$

where [X] represents the collective concentration of double bonds and radicals other than propyl radicals. Steady state assumption for [*i*-Pr] gives

$$\frac{d[i\text{-Pr}]}{dt} = 0 = R_1 - R_{1a} - R_{2a} - R_{2b} - 2R_{4a} - 2R_{4b} - R_6$$

k_1 and k_{1a} are related thermodynamically and from the known entropies and heats of formation of the isopropyl and *n*-propyl radicals (19)

[I] $$k_{1a} = k_1 \exp(0.6 - 3.6/RT)$$

This further leads to the expression

[II] $$\frac{k_1}{k_{3a}^{1/2}} = \frac{1.41R_{2a} + 3.38R_{4a} + \dfrac{2rR_0}{r+q}}{R_{3a}^{1/2}[C_3H_8](1 - r\exp(0.6 - 3.6/RT))}$$

All the unknown quantities in eq. [II] can be evaluated from photolysis of azo-*n*-propane in the presence of propane with the exception of q. At higher temperatures, reactions of radicals with the azo compound and perhaps with propylene formed in the system are evidently of substantial importance, and, in order to evaluate [II], the value of q must be known.

The value of q was determined from the photolysis of *n*-propane-azo-*iso*-propane (under a large pressure of C_3F_8) at several different temperatures. Nitrogen was pumped off at −196 °C and measured. Propane, propylene, and C_3F_8 were removed at −131 °C, and the heavy fraction was analyzed for hexanes as described previously. The ratio of *n*-propyl/isopropyl radicals consumed in

reactions other than combination and disproportionation with each other can be obtained from the mass balance ratio

$$\frac{R_5}{R_6} = \frac{R_{N_2} - (1.41R_{2a} + 2.3R_{3a})}{R_{N_2} - (1.41R_{2a} + 3.38R_{4a})} = M$$

Since $q = r\,R_5/R_6$, one obtains

$$[III] \qquad q = 0.61\frac{R_{2a}}{R_{3a}}M$$

The results are tabulated in Table I. An Arrhenius plot of the data gives a straight line relation corresponding to the equation

$$\log q = -0.011 + 103/T$$

Data obtained from reaction of *n*-propyl radicals with propane are summarized in Table II and the Arrhenius plot is shown in Fig. 1. Least squares treatment gives

$$\log \frac{k_1}{k_{3a}^{1/2}} = 2.60 \pm 0.24 - \frac{7.91 \pm 0.40}{2.3RT} \quad \text{(cc mole}^{-1}\text{ s}^{-1}\text{)}$$

for a 95% confidence limit.

Discussion

In order to derive a value for k_1 one would need to know the value of k_{3a}. The measured value of k_{3a}, reported in the literature (20, 21), exp 15.8 (cc mole^{-1} s^{-1}), however, appears to be too high and cannot be considered reliable. Probably the best one can do is to assume that *n*-propyl radicals recombine with the same rate as ethyl radicals and accept the value for the latter reported by Shepp and Kutschke (22)

$$\log k = 14.2 - (2.0 \pm 1.0)/2.3RT$$

This would lead to a value

$$\log k_1 = 9.7 - 8.9/2.3RT \quad \text{(cc mole}^{-1}\text{ s}^{-1}\text{)}$$

Comparison with the known rate constants of the analogous reactions of the methyl and ethyl radicals; Me + C_3H_8, Me + *n*-C_4H_{10}, and Et + *n*-C_4H_{10}, E_a = 10.2, 9.6, and 11.4 kcal, and log A = 11.87, 11.92, 11.43 (cc mole^{-1} s^{-1}), respectively (1), seems to indicate that our activation energy and A-factor are low with an amount compensating to give approximately the correct rate constant value. Even if allowance is made for the fact that reaction [1] registers the attack of

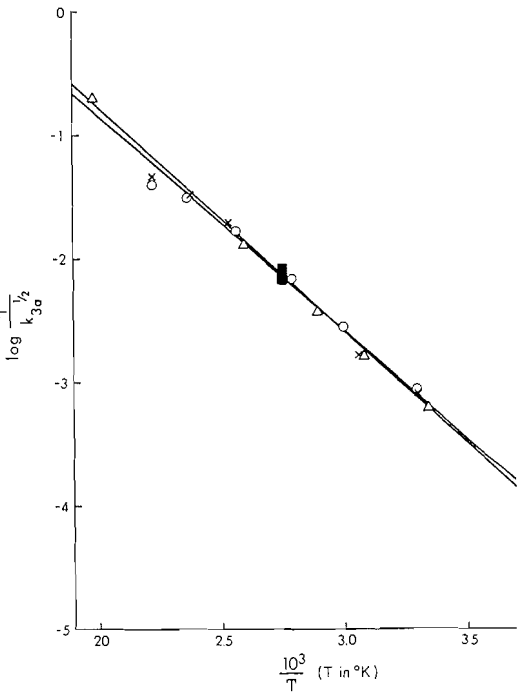

FIG. 1. Arrhenius plot for reaction of *n*-propyl with propane. ○, series 1; ×, series 2; △, series 3. The rectangle represents the mean value of three runs from series 1 and three runs from series 2.

n-propyl radicals only on the secondary hydrogens of propane, the measured activation energy is still about 1 kcal lower than the estimated value of the methyl radical reaction.

As a check on our experimental technique, we have determined the Arrhenius parameters for the hydrogen atom abstraction from azo-*iso*-propane by *i*-propyl radicals. Eight experiments in the temperature range of 27–160 °C gave

$$\log (k_{\text{abstr}}/k_{\text{comb}}^{\frac{1}{2}}) = 4.03 \pm 0.37 - (7.08 \pm 0.61)/2.3RT$$

for a 95% confidence level, which agrees quite well with the literature values of

$$\log (A_{\text{abstr}}/A_{\text{comb}}^{\frac{1}{2}}) = 3.4 \text{ and } 3.5$$

and (5, 13)

$$E_{\text{abstr}} - \tfrac{1}{2}E_{\text{comb}} = 6.5 \text{ and } 6.7 \text{ kcal}$$

A similar study of the abstraction of *n*-propyl from azo-*n*-propane was attempted. However, the temperature range within which reliable data could be obtained for this reaction in our static system was quite narrow due to the low vapor pressure of azo-*n*-propane, and consequently there was a great deal of scatter in the low temperature points. Using six points from the region where the data appeared most reliable, we obtained

$$\log k_{\text{abstr}}/k_{\text{comb}}^{\frac{1}{2}} = 4.8 - 8.0/2.3RT$$

which is consistent with

$$\log (A_{\text{abstr}}/A_{\text{comb}}^{\frac{1}{2}}) = 4.6$$

and

$$E_{\text{abstr}} - \tfrac{1}{2}E_{\text{comb}} = 7.9$$

obtained by Calvert and Kerr (4) in a circulating system.

The most obvious sources of uncertainty in our measurement of k_1 are the processes treated collectively under reactions [5] and [6] which are not directly monitored. These processes include addition and abstraction reactions with propylene and azo-*n*-propane and combination with the resulting radicals. The concentration of propylene should always be very small in the system, and although small quantities of C_9H_{20} hydrocarbons could be detected among the products it is doubtful if radical reactions with propylene are significant. On the other hand, alkyl radicals are known to react very readily with azo-alkanes under the conditions used in this study, and this is undoubtedly the dominant cause of their "disappearance" from the system.

There are two plausible reactions involving the resonance stabilized azo-alkyl radical formed in the abstraction reaction

[7] $n\text{-Pr} + C_3H_7N{=}NC_3H_7 \rightarrow C_3H_8 + CH_3CH_2CH{\cdots}N{\cdots}NC_3H_7$

which are not included in the kinetic treatment; the thermal decomposition and the abstractive attack on propane.

Analogous studies on the reactions of ethyl radicals with azoethane (16) suggest that decomposition of these radicals below 300 °C is unimportant. Also, from a recent study of the pyrolysis of azo-*n*-propane and azo-*iso*-propane, Geiseler and Hoffman (23) have concluded that though reaction [7] is important, the radicals formed in it do not act as chain carriers at temperatures <400 °C.

The abstraction reactions

[8*a*] $CH_3CH_2CH{\cdots}N{\cdots}NC_3H_7 + C_3H_8 \rightarrow$ azo-*n*-propane + *i*-Pr

[8*b*] $\rightarrow$ azo-*n*-propane + *n*-Pr

should have considerable activation energies and the importance of [8*b*] relative to [8*a*] should

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

increase with temperature. Some support for this type of reaction comes from the observation of propanal propylhydrazone among the reaction products. Much of this material may have formed in a heterogeneous reaction, some should have formed through the disproportionation of the azo-alkyl radicals with radicals present in the system, and a small fraction could have arisen by the abstraction reactions

[9a] $CH_3CH_2CH{\cdots}N{=}N{\cdots}C_3H_7 + C_3H_8 \rightarrow CH_3CH_2CH{=}N{-}NHC_3H_7 + i\text{-Pr}$

[9b] $\rightarrow CH_3CH_2CH{=}N{-}NHC_3H_7 + n\text{-Pr}$

The interference by these reactions will tend to be most important under conditions which favor a high rate of abstraction compared to combination. Hence these reactions will be most important in runs with a high value of r, the steady state concentration ratio of isopropyl to n-propyl radicals. We have recalculated the Arrhenius parameters of reaction [1] eliminating the two runs with the highest values of r. Thus, for r less than 1.1, we obtain

$$\log \frac{k_1}{k_{3a}^{1/2}} = 2.83 \pm 0.18 - \frac{(8.25 \pm 0.30)}{2.3RT}$$

for a 95% confidence limit, from which

$$\log k_1 = 9.9 - 9.3/2.3RT \quad (\text{cc mole}^{-1}\ \text{s}^{-1})$$

The activation energy is still 0.6 kcal lower than for the reaction of methyl radicals (1).

Combining the rate parameters with eq. [7] the Arrhenius parameters of the reverse reaction are given by

$$\log k_{1a} = 10.5 - 12.9/2.3RT \quad (\text{cc mole}^{-1}\ \text{s}^{-1})$$

The activation energy for this reaction is 1.3 kcal larger than that measured for methyl radicals.

Acknowledgments

The authors thank the National Research Council of Canada for financial support and Dr. A. M. Hogg for his assistance in the mass spectrometric analyses.

Appendix

Derivation of Expression [II]

$$R_1 = k_1[n\text{-Pr}]\,[C_3H_8] = R_{1a} + R_{2a} + R_{2b} + 2R_{4a} + 2R_{4b} + R_6$$

$$R_{2a} + R_{2b} = 1.41\,R_{2a}$$

$$2(R_{4a} + R_{4b}) = 3.38R_{4a}$$

and

$$k_{1a} = k_1 \exp(0.6 - 3.6/RT)$$

Therefore

$$k_1[n\text{-Pr}]\,[C_3H_8] = k_1 \exp(0.6 - 3.6/RT) \cdot [i\text{-Pr}]\,[C_3H_8] + 1.41R_{2a} + 3.38R_{4a} + R_6$$

Since

$$r = \frac{[i\text{-Pr}]}{[n\text{-Pr}]}$$

$$k_1 = \frac{1.41R_{2a} + 3.38R_{4a} + R_6}{[C_3H_8](1 - r\exp(0.6 - 3.6/RT)[n\text{-Pr}]}$$

R_6 can be expressed in terms of r, R_0, and q, since

$$R_5 + R_6 = 2R_0$$

and

$$R_5 = \frac{q}{r}R_6$$

$$R_6 = \frac{2rR_0}{r+q}$$

Expressing the value of $k_{3a}^{\frac{1}{2}}$ as $R_{3a}^{\frac{1}{2}}/[n\text{-Pr}]$, we obtain for the ratio $k_1/k_{3a}^{\frac{1}{2}}$

$$\frac{1.41R_{2a} + 3.38R_{4a} + \dfrac{2rR_0}{r+q}}{R_{3a}^{1/2}[C_3H_8](1 - r\exp(0.6 - 3.6/RT))} \equiv [II]$$

Nuclear magnetic resonance spectral parameters of α,α,α-trifluorotoluene

R. J. KOSTELNIK, M. P. WILLIAMSON, D. E. WISNOSKY, AND S. M. CASTELLANO
Mellon Institute, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

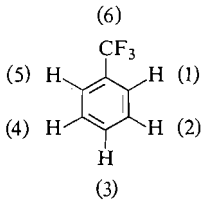
Received March 31, 1969

The 60 and 100 MHz proton spectra of α,α,α-trifluorotoluene have been recorded and analyzed in terms of chemical shifts and coupling constants. The results of the analyses are compared and the values of the spectral parameters discussed. The nuclear magnetic resonance spectral data of 2-chloro-5-nitro-α,α,α-trifluorotoluene are also reported.

Canadian Journal of Chemistry, **47**, 3313 (1969)

Introduction

According to standard nomenclature, the nuclear magnetic resonance (n.m.r.) spectrum of α,α,α-trifluorotoluene (benzotrifluoride), **1**, be-



1

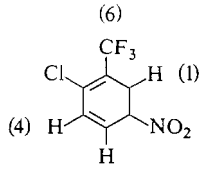
longs to the $AA'BB'CX_3$ type, where the labels A, B, and C refer to the *ortho*, *meta*, and *para* protons, and the label X designates a fluorine nucleus. The problems encountered in the iterative analyses of spectra of this type have already been described in a previous study of the n.m.r. spectrum of toluene (1), where a multi-step procedure for the analysis was also proposed and successfully used. We refer to that paper for any more detailed information on the subject and report here the results obtained by the application of the same procedure to the analysis of the proton spectrum of **1**.

Analysis of the Spectra

The complete analysis of the spectrum of benzotrifluoride involved three successive steps

(*a*) First, 60 MHz, CF_3-decoupled spectra of **1** were recorded and readily analyzed using the LAOCN3 computer program (2). The results of the analyses of these spectra of the AA'BB'C type are reported in entries 1 and 7 of Table I for both the neat liquid and a 10% (wt./wt.) solution in CCl_4. The experimental and calculated CF_3-decoupled spectrum of the neat liquid is shown in Fig. 1.

(*b*) In the second step the proton spectrum of 2-chloro-5-nitro-α,α,α-trifluorotoluene[1], **2**, which



2

belongs to the $ABCX_3$ type, was recorded and analyzed. The resulting spectral parameters are reported in entry 8 of Table I. The analysis of the spectrum of **2** was necessary, since at the time this work was initiated, no reliable values of the long-range CF_3-proton coupling constants had been reported in the literature.

(*c*) The information gathered in (*a*) and (*b*) was then used to initiate the iterative fit of the normal proton spectra of benzotrifluoride. With the aid of the trial calculations, it was possible to dissect the spectrum into two subspectra of the AA'BB'CX type corresponding to the two quantum states ($\pm 1/2$; $\pm 3/2$) of the *z*-component of the total angular momentum of the trifluoromethyl group (1). Each subspectrum was then analyzed independently using the iterative routine of the LAOCN3 program. The results of the complete analyses of the spectra of the neat liquid recorded at 60 and at 100 MHz are reported in entries 2–5 of Table I. For the sake of comparison, the values of the chemical shifts of the 100 MHz spectrum converted to 60 MHz are also presented (in parentheses). The experimental and calculated

[1]The numbering of the magnetic nuclei of **2** corresponds to that used for benzotrifluoride throughout this work and differs from the standard chemical nomenclature.

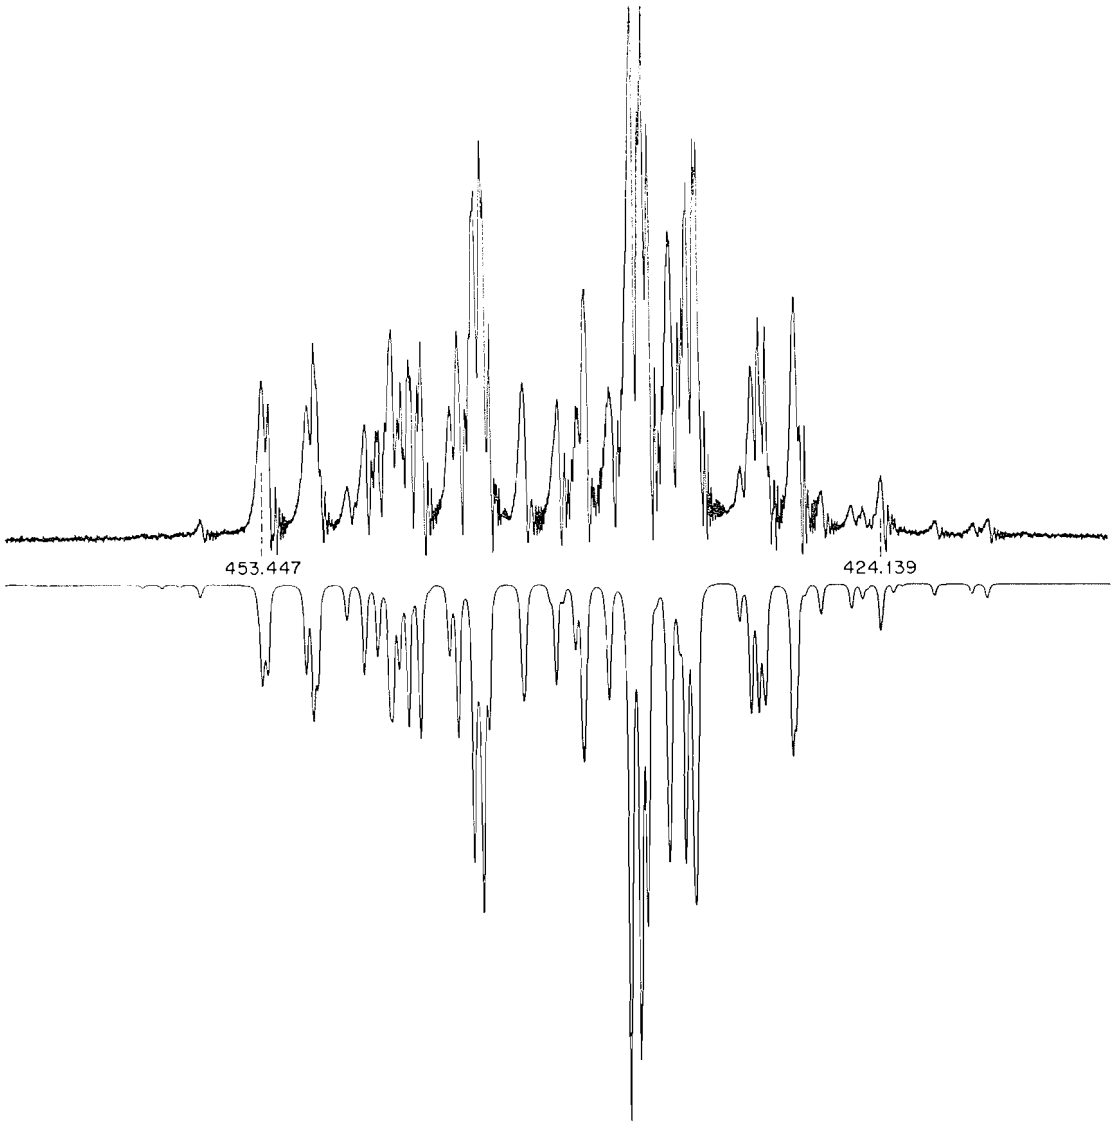

FIG. 1. Experimental and calculated ^{19}F decoupled spectrum of α,α,α-trifluorotoluene at 60 MHz. Frequencies are in Hz from internal TMS.

100 MHz spectrum of benzotrifluoride are shown in Fig. 2.

In Table I all data are reported with three significant decimal digits as obtained directly from the output of the computer. To avoid overcrowding the table, we have not presented the calculated probable errors of the parameters resulting from the fit of each spectrum (2) (or subspectrum) and which, on the average, were always $\leqslant 0.010$ Hz. This value, however, furnishes only a measure of the precision of the experimental determinations but not necessarily their accuracy. The latter can be estimated, in fact, only by comparison of the results of repeated independent measurements. The data in entries 1–5 of Table I are well suited for such a comparison. Their averaged values and standard deviations are reported in entry 6 of Table I. For the coupling constants, the average value (0.013 Hz) of the standard deviations, which were calculated

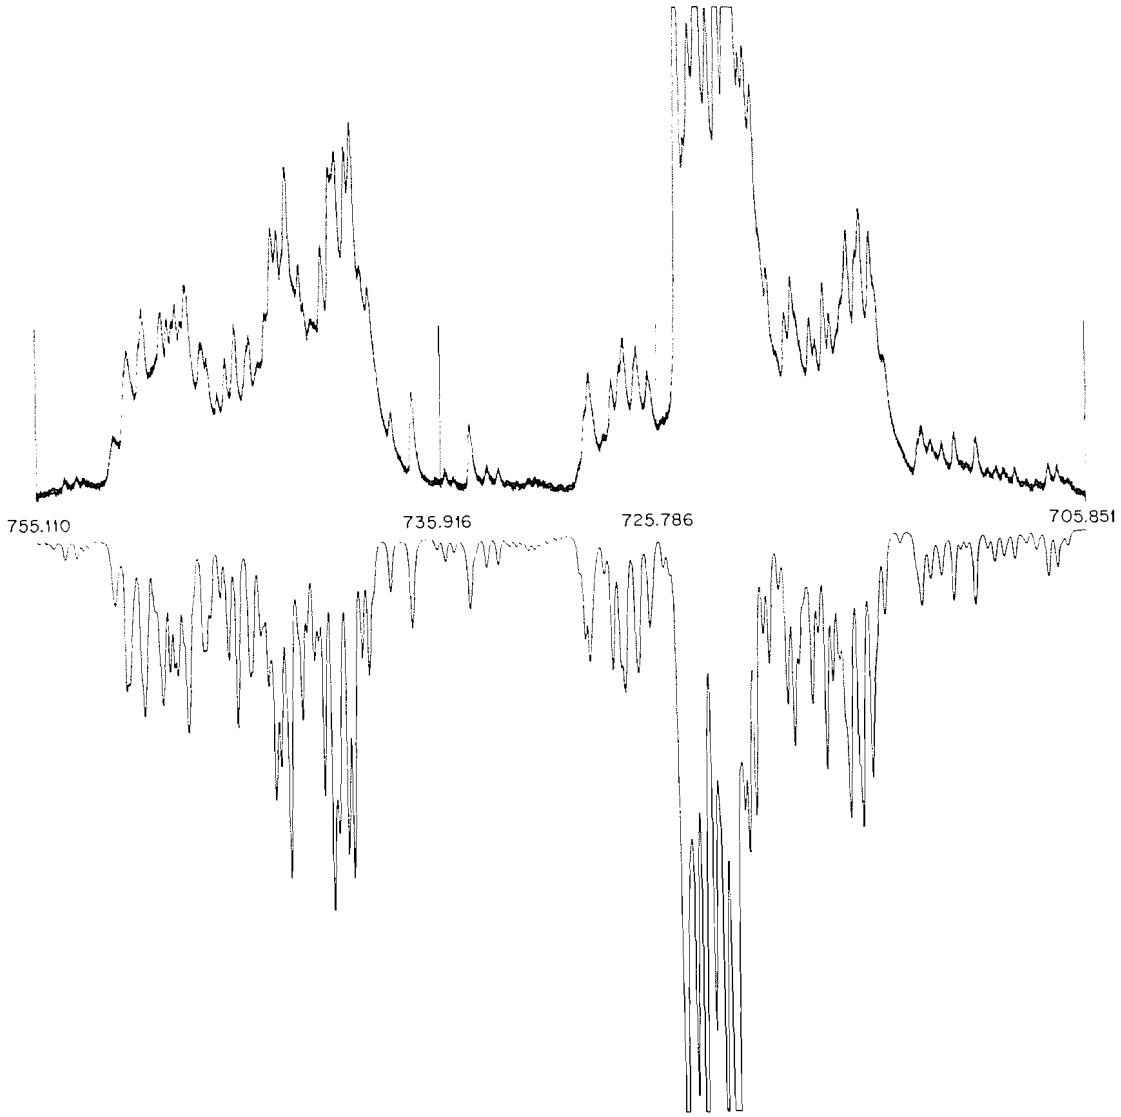

FIG. 2. Experimental and calculated normal spectrum of α,α,α-trifluorotoluene at 100 MHz. Frequencies are in Hz from internal TMS.

using all the data of entries 1–5, indicates that the accuracy of the reported values of the parameters is almost equal to the precision of the fit of the experimental spectra. The same is true for the chemical shifts if the standard deviations of the 60 and 100 MHz results are analyzed independently. A comparison, however, between the averaged values of corresponding parameters of entries 1–3 and of entries 4–5, shows that a systematic deviation of ca. 0.2 Hz is introduced in the measurements by the use of different spectrometers. Since the probe temperatures of the two instruments are sensibly different (see footnotes in Table I), it is most likely that these consistent shifts are entirely due to a temperature effect. We cannot exclude, however, that the observed differences may have, at least in part, some other instrumental origin and, given a choice, we would be inclined to believe that the 60 MHz data are the more reliable.

Discussion

The values of the coupling constants between the aromatic protons of benzotrifluoride are in agreement with the prediction based on the general trends observed for the variations of these parameters with the electronegativity of the substituents (3), i.e., the values of $J(1,2)$ and $J(1,5)$ are larger, and those of $J(1,3)$ and $J(1,4)$ are slightly smaller than the values of the corresponding parameters of benzene; $J(2,3)$ and $J(2,4)$ remain almost unaffected by the presence of the trifluoromethyl group. Qualitatively these variations are similar to those observed in toluene.

TABLE II

Values (Hz) of J_{cis}, $J(1,2)$, and $J(1,5)$ in some monosubstituted ethylenes and benzenes

*All values of J_{cis} taken from ref. 4.
†Reference 5.
‡Reference 6.
§Reference 1.

Perhaps more significant, however, is the comparison of the data (4–6) reported in Table II which shows the effect of some selected substituents on J_{cis} of monosubstituted ethylenes and on $J(1,2)$ and $J(1,5)$ of the corresponding monosubstituted benzenes. The consistent monotonic trend of the variations of the coupling constants in both series of compounds for the substituents of the first four entries of the table is very remarkable. If this trend is interpreted in terms of the general correlations of the coupling constants with the electronegativity of the substituents, it would appear that the cyano and the trifluoromethyl groups behave as if they were less electronegative than the *t*-butyl and the trichloromethyl groups. This surprising result can be rationalized perhaps by reemphasizing once again the primary role of the hyperconjugative mechanism in determining the overall inductive effect of a substituent (7). Most distressing, however, is the lack of any consistent correlation between the data of the last two entries and those relative to the first four substituents. This is an example of the many inconsistencies found within the framework of the general (but always broadly scattered) correlations between the values of the coupling constants and the electronegativity of the substituents and constitutes a warning against overextended generalizations, particularly if based on a limited number of experimental data.

The signs and values of the long-range coupling constants between the trifluoromethyl group and the aromatic protons are also of some interest. In the trial calculations of the spectrum of **2** the signs of $J(1,6)$ and $J(4,6)$ were chosen equal to those of the corresponding parameters of benzoyl fluoride and the sign of $J(3,6)$ was then directly obtained from the complete analysis of the spectrum. The same sign sequence has been obtained by Blears, Danyluk, and Schaefer (8) from "tickling" experiments on the proton spectrum of 2-amino-5-bromobenzotrifluoride, and it is identical to that found in toluene (1). For the sake of comparison, the values of the long-range coupling constants of benzaldehyde, toluene, benzoyl fluoride, and benzotrifluoride have been summarized in Table III. Since the coupling between the methyl (or the trifluoromethyl) group and the *ortho* and *para* aromatic protons is thought to occur primarily through a $\sigma-\pi$ spin delocalization (and/or polarization) mechanism (8), the near identity of the values of $J(1,6)$ and $J(3,6)$ found in toluene and in benzotrifluoride seems to suggest that the hyperconjugation of the CF_3 group with the aromatic ring is, if not equal, at least comparable to that of the CH_3 group[2]. However, the value of $J(2,6)$ in **1** is more than twice as large as the value of the corresponding parameter in toluene. This observation has already been reported by Blears *et al.* (8), who rationalized the experimental results by postulating for **1** larger (as compared with the corresponding ones in toluene) positive σ contributions to $J(2,6)$ and possibly to $J(1,6)$ also. It is, however, not clear from the text why a σ contribution to $J(1,6)$ should be invoked at all. On the basis of the data in Table III, it would appear that the above

[2]It should be pointed out, however, that the CH_3 and CF_3 groups belong to different substituent classes (7): $+I^+$ and $-I^-$, respectively. The shifts (relative to benzene) of the resonances of all the aromatic protons toward higher fields in toluene (1) and toward lower fields in benzotrifluoride indicate, in fact, that the π-electron charge redistributions induced in the phenyl ring by the two groups are almost complementary and in satisfactory qualitative agreement with those expected for substituents of the above classes (7).

‡Reference 1.

assumptions are only partially correct. To the extent, in fact, to which the values of $J(1,6)$, $J(2,6)$, and $J(3,6)$ of benzaldehyde and benzoyl fluoride are indicative of the σ contribution to the long-range coupling, and the almost zero value of $J(3,6)$ in both compounds strongly supports this preposition, it would appear that the latter is indeed larger for the fluorinated compound but that it is positive in the case of $J(2,6)$ and negative in the case of $J(1,6)$. Furthermore, if it is assumed (8) that the σ–π contribution to the long-range coupling is of the same order of magnitude for both $J(1,6)$ and $J(3,6)$, it follows that by the loss of the coplanar conformation characteristic of the carbonyl compounds, the σ contribution to $J(1,6)$ is almost completely removed while that to $J(2,6)$ remains appreciably larger in benzotrifluoride than in toluene. Finally, it is worth reporting that using the additivity relationships of the substituent effects (6) and the values of the spectral parameters of nitrobenzene (9), chlorobenzene (10), and α,α,α-trifluorotoluene, the following values of the proton–proton coupling constants of **2** are obtained: $J(1,3) = 2.580$, $J(1,4) = 0.405$, and $J(2,3) = 7.899$. The agreement between the calculated and experimental values is somewhat less satisfactory than that obtained in other cases (1). Also, the values of the long-range coupling constants of **2** are sensibly different than those of the corresponding parameters of **1**. Both of these results may be indicative of steric (6) and/or mesomeric interactions between the substituents of **2**.

Experimental

All chemicals were of commercial origin (Eastman Organic Chemicals and Aldrich Chemical Co.). The samples of benzotrifluoride and of 2-chloro-5-nitrobenzotrifluoride were distilled, degassed on a vacuum line, and sealed in standard 5 mm NMR tubes after the addition of 3% tetramethylsilane (TMS).

The 100 MHz spectra were recorded on a Varian HA-100 spectrometer which was frequency swept in the HA mode. Two 50 Hz sweep width spectra were recorded for each sweep direction of the magnetic field at a sweep rate of 0.02 Hz/s. Because of the slight nonlinearity of the recorder, the spectra were calibrated by drawing markers approximately every 10 Hz and counting separately the frequencies of the locking oscillator and of the sweep oscillator.

The 60 MHz spectra were obtained on a Varian A-60 spectrometer. Also in this case two 50 Hz sweep width spectra were recorded for each sweep direction, the sweep rate being 0.10 Hz/s. The spectra were calibrated by the standard sideband technique using a Hewlett-Packard 261-A pushbutton oscillator monitored by an Anadex CF-200R counter-timer. The CF_3-decoupled spectra were obtained using an NMR Specialties heteronuclear decoupler (SD-60B).

Experimental line frequencies used in the analysis were the average of four measurements with average standard deviations ≤ 0.025 Hz.

Etude des bandes fondamentale ν_1 et première harmonique $2\nu_1$ des haloformes CHF_3, $CHCl_3$ et $CHBr_3$ à l'état gazeux

INGA ROSSI, MM. NGUYEN-VAN-THANH ET CLAUDE HAEUSLER[1]

Laboratoire d'Infrarouge, Chimie Physique, Faculté des Sciences de Paris, Bâtiment 350.(91)-*Orsay, France*

Reçu le 2 avril 1969

Certaines constantes de vibration–rotation des bandes ν_1(CH) et $2\nu_1$(CH) des molécules CHF_3, $CHCl_3$ et $CHBr_3$ à l'état gazeux ont été déterminées. Les mesures d'intensité de ces bandes ont été effectuées et des anomalies observées dans certaines de ces bandes.

Some rotational and vibrational constants in the ν_1(CH) and $2\nu_1$(CH) bands of gaseous CHF_3, $CHCl_3$, and $CHBr_3$ have been determined. Intensity measurements of these bands are obtained and perturbations in some bands of haloforms are pointed out.

Canadian Journal of Chemistry, 47, 3319 (1969)

Introduction

Dans le cadre général de travaux consacrés à l'étude des interactions moléculaires entre soluté et solvant, nous avons été conduits à analyser le spectre d'absorption infrarouge (i.r.) de molécules de soluté, d'une part à l'état gazeux et d'autre part à l'état dissous. En effet, les théories relatives aux effets de solvant relient les intensités intégrées $\mathscr{A}_{gaz}$ et $\mathscr{A}_{solution}$ et les centres de bandes ν^0_{gaz} et $\nu^0_{solution}$.

Plus précisément dans le présent travail, nous nous proposons d'analyser les bandes fondamentales ν_1 et première harmonique $2\nu_1$ des haloformes CHF_3, $CHCl_3$ et $CHBr_3$ à l'état gazeux, en utilisant les spectromètres de type Pfund et Czerny dont les performances et le système d'étalonnage ont été décrits antérieurement (1, 2).

La bande $2\nu_1$ des molécules CHF_3 et $CHCl_3$ a été analysée en 1953 par Wiggins et coll. (3). Anttila (4) a récemment étudié plusieurs bandes d'absorption i.r. de la molécule $CHCl_3$.

Par ailleurs, les mesures d'intensité des bandes ν_1 et $2\nu_1$ des haloformes ont été effectuées à l'aide de la méthode de Wilson et Wells par Robinson et coll. (5).

L'analyse des bandes ν_1 et $2\nu_1$ des haloformes à l'état dissous fera l'objet d'une publication ultérieure.

Rappels Théoriques

Analyse vibrationnelle et rotationnelle des bandes ν_1 et $2\nu_1$

Nous rappelons que la vibration $\nu_1(A_1)$ totalement symétrique correspond essentiellement à la vibration C—H de valence située vers 3.3 μ (6). Ce qui signifie que pratiquement toute l'énergie de vibration est localisée dans la vibration de la liaison C—H.

L'énergie totale de vibration–rotation d'un rotateur symétrique, pour un niveau vibrationnel non dégénéré, s'écrit

$$E_t = E_v + E_r$$

où l'énergie de vibration E_v et celle de rotation E_r sont données par

$$[1] \quad \frac{E_v}{hc} = \sum_{s=1}^{6} \omega_s\left(v_s + \frac{g_s}{2}\right) + \sum_{\substack{s,s'=1 \\ (s'\geq s)}}^{6} x_{ss'}\left(v_s + \frac{g_s}{2}\right)\left(v_{s'} + \frac{g_{s'}}{2}\right)$$

et

$$[2] \quad \frac{E_r}{hc} = B_v[J(J+1) - K^2] + A_vK^2 - D_JJ^2(J+1)^2 - D_{JK}J(J+1)K^2 - D_KK^4$$

Les nombres d'onde des raies $\nu_{m,K}^{P,R}$ des branches P et R d'une bande parallèle peuvent se mettre sous la forme suivante

$$[3] \quad \nu_{m,K}^{P,R} = a_0 + a_1m + a_2m^2 + a_3m^3$$

avec

$m = -J$ pour la branche P

$(\Delta|K| = 0, \Delta J = -1)$

$m = J + 1$ pour la branche R

$(\Delta|K| = 0, \Delta J = +1)$

et

$$a_0 = \nu^0 + (A' - B') - (A'' - B'')$$

$$a_1 = B' + B'' - D_{JK}K^2$$

[1]L'adresse présente: Laboratoire de Chimie Physique Moléculaire, Faculté des Sciences de Rennes.

$$a_2 = B' - B''$$
$$a_3 = -4D_J$$

Ces dernières expressions sont obtenues en supposant que les constantes de distorsion centrifuge D_J, D_{JK} et D_K sont les mêmes pour les niveaux vibrationnels d'arrivée (′) et de départ (″) de la transition considérée.

Les constantes A_v et B_v sont reliées à celles relatives à l'équilibre A_e et B_e, par les relations

$$[4] \qquad B_v = B_e - \sum_{s=1}^{6} \beta_s\left(v_s + \frac{g_s}{2}\right)$$

$$[5] \qquad A_v = A_e - \sum_{s=1}^{6} \alpha_s\left(v_s + \frac{g_s}{2}\right)$$

Les constantes β_1, ${\omega_1}^0$ et x_{11} s'obtiennent à partir des relations [1] et [4]

$$2\beta_1 = -(B' - B'')$$

$$[6] \qquad {\omega_1}^0 = \frac{4({\nu_1}^0) - (2{\nu_1}^0)}{2}$$

$$x_{11} = \frac{(2{\nu_1}^0) - 2({\nu_1}^0)}{2}$$

où les centres de bandes $({\nu_1}^0)$ et $(2{\nu_1}^0)$ sont définis par

$${\nu_1}^0 = {\omega_1}^0 + x_{11}$$

et

$$2{\nu_1}^0 = 2{\omega_1}^0 + 4x_{11}$$

avec

$${\omega_1}^0 = \omega_1 + x_{11}$$

Mesure d'intensité des bandes

D'après la loi de Lambert, l'intensité lumineuse transmise par un échantillon gazeux $I_t(\nu)$ s'exprime en fonction de l'intensité incidente $I_0(\nu)$ par

$$[7] \qquad I_t(\nu) = I_0(\nu) \exp\,[-k(\nu)l]$$

La variation du coefficient d'absorption $k(\nu)$ s'écrit sous la forme bien connue de Lorentz quand les causes d'élargissement des raies sont dues aux collisions moléculaires. La largeur à mi-hauteur de cette courbe est désignée par 2γ.

Nous définirons la transmission $\eta(\nu)$ par la relation

$$[8] \qquad \eta(\nu) = \frac{I_t(\nu)}{I_0(\nu)} = \exp\,[-k(\nu)l]$$

et le coefficient d'absorption intégré $\mathscr{C}$ d'une raie par l'expression

$$[9] \qquad \mathscr{C} = \int_{\nu_1}^{\nu_2} k(\nu)\,d\nu = \frac{1}{l}\int_{\nu_1}^{\nu_2} \ln \frac{I_0(\nu)}{I_t(\nu)}\,d\nu$$

Dans nos conditions expérimentales $\mathscr{C}$ est proportionnel à la pression $\mathscr{P}$ de sorte que nous pouvons écrire

$$\mathscr{C} = \mathscr{A}.\mathscr{P}$$

ce qui n'est pas nécessairement valable pour les pressions très élevées. La grandeur $\mathscr{A}$, intensité intégrée, (c'est-à-dire le coefficient d'absorption intégré rapporté à l'unité de pression) que nous nous proposons d'évaluer, s'écrit donc

$$[10] \qquad \mathscr{A} = \frac{1}{\mathscr{P}l}\int_{\nu_1}^{\nu_2} \ln \frac{I_0(\nu)}{I_t(\nu)}\,d\nu$$

ν_1 et ν_2 désignent les nombres d'onde qui délimitent l'étendue de la raie d'absorption. L'expression précédente suppose en particulier que la diffusion de la lumière par le gaz est négligeable.

L'intensité transmise observée $I_t'(\nu)$ est différente de $I_t(\nu)$ du fait des déformations qu'introduit le spectromètre; $I_t'(\nu)$ est donnée par

$$[11] \qquad I_t'(\nu_i) = \int_{\nu_i-\Delta\nu}^{\nu_i+\Delta\nu} D(\nu - \nu_i) I_t(\nu)\,d\nu$$

où $D(\nu - \nu_i)$ est la fonction d'appareil de largeur à la base $2\Delta\nu$ et ν_i désigne le nombre d'onde qui correspond au maximum de la fonction D. (Dans le cas d'une fonction d'appareil gaussienne, $2\Delta\nu$ devient infini, et dans le cas d'une fonction d'appareil triangulaire, $2\Delta\nu$ vaut le double de la largeur à mi-hauteur.)

L'expérience nous permet d'atteindre la valeur de la transmission apparente

$$\eta'(\nu_i) = \frac{I_t'(\nu_i)}{I_0'(\nu_i)} = \frac{\displaystyle\int_{\nu_i-\Delta\nu}^{\nu_i+\Delta\nu} D(\nu - \nu_i) I_t(\nu)\,d\nu}{\displaystyle\int_{\nu_i-\Delta\nu}^{\nu_i+\Delta\nu} D(\nu - \nu_i) I_0(\nu)\,d\nu}$$

Considérons maintenant la transmission apparente $\eta'(\nu)$. Si l'intensité de la lumière incidente $I_0(\nu)$ est constante dans l'intervalle spectral $2\Delta\nu$, l'intégrale s'écrit

$$\eta'(\nu_i) = \frac{\displaystyle\int_{\nu_i-\Delta\nu}^{\nu_i+\Delta\nu} D(\nu - \nu_i) \exp\,[-k(\nu)l]\,d\nu}{\displaystyle\int_{\nu_i-\Delta\nu}^{\nu_i+\Delta\nu} D(\nu - \nu_i)\,d\nu}$$

Kostkowski et Bass (7) ont évalué numériquement cette intégrale pour une fonction d'appareil de Gauss, et Montigny (8) l'a réalisé dans le cas d'une fonction d'appareil triangle.

Afin d'obtenir le coefficient d'absorption intégré $\mathscr{C}$, des courbes facilement utilisables expriment la correction qu'il faut apporter à la valeur de $\mathscr{C}'$, mesuré directement sur l'enregistrement d'une raie, en fonction des rapports $I_t(\nu)/I_0(\nu)$ et $\delta\nu/2\gamma$. Dans ce dernier rapport, $\delta\nu$ représente la largeur à mi-hauteur de la fonction d'appareil.

Précisons que la quantité $\mathscr{C}'$ est obtenue en déterminant directement sur l'enregistrement d'une raie la transmission $\eta'(\nu)$, qui permet ensuite d'atteindre la valeur du coefficient d'absorption apparente $k'(\nu)$ et par conséquent celle de

$$\mathscr{C}' = \int_{\nu_1}^{\nu_2} k'(\nu)\, d\nu$$

Dans le présent travail, nous nous proposons de déterminer la quantité $\mathscr{A}_i = \mathscr{C}_i/\mathscr{P}$ des raies d'absorption relatives aux bandes ν_1 et $2\nu_1$ des haloformes à l'état gazeux. Nous connaissons avec suffisamment de précision la fonction d'appareil D des spectromètres utilisés.

Pour le spectromètre du type Czerny utilisé à 1.7 μ, la fonction D est gaussienne. La largeur à mi-hauteur $\delta\nu$ (déterminée en enregistrant une raie d'absorption de largeur très faible) est de 0.15 cm^{-1}, ce qui fournit pour les haloformes un rapport $\delta\nu/2\gamma$ de l'ordre de 0.5, si nous adoptons 0.1 à 0.2 cm^{-1} par atmosphère pour ordre de grandeur de la demi-largeur à mi-hauteur collisionnelle des raies. Par conséquent, pour une raie la correction que l'on doit apporter à $\mathscr{C}_i'$ (donc à $\mathscr{A}_i'$) mesuré directement, est alors selon Kostkowski et Bass de 5% par défaut. Or l'imprécision des mesures due au seul choix de la ligne de base peut atteindre facilement cet ordre de grandeur.

Par ailleurs, on admet que lorsqu'un spectre d'absorption de vibration–rotation, se présente comme un ensemble de raies bien séparées, l'évaluation de $\mathscr{A}$ pour une bande entière s'obtient en faisant la somme des valeurs de $\mathscr{A}_i$ relatives à chaque raie. A la limite pour des raies rapprochées, explorées pour des pressions de gaz suffisamment élevées, le contour d'une bande ne manifeste plus la présence d'une structure de raies. La valeur de $\mathscr{A}$ pour la bande entière peut alors se mesurer directement sur l'enregistrement.

La fonction d'appareil d'un spectromètre résolutif, même si elle est relativement large par rapport à une raie isolée, peut alors être considérée comme étroite par rapport au contour global de la bande dans laquelle la structure rotationnelle a disparu. De sorte que, valablement on peut espérer obtenir par mesure directe une erreur relative de mesure plus faible sur cette bande totale que celle obtenue lors d'une mesure sur une raie isolée en ne considérant que l'effet de déformation $d\hat{u}$ à la fonction d'appareil. On retrouve alors un problème semblable à celui concernant la mesure de l'intensité d'une bande d'absorption d'un liquide avec un spectromètre résolutif (1). Dans les conditions de nos mesures, effectuées sur les bandes ν_1 et $2\nu_1$ des haloformes, nous nous approchons de ce cas limite.

Afin d'évaluer par l'expérience, l'influence de la largeur $\delta\nu$ sur la valeur de $\mathscr{A}$ mesurée directement sur le spectre, nous avons effectué deux mesures d'intensité de la bande $2\nu_1$ du fluoroforme gazeux en utilisant deux spectromètres ayant des fonctions d'appareil de largeur très différente. Dans un cas favorable à la mesure de $\mathscr{A}$, nous avons utilisé le spectromètre du type Czerny, où $\delta\nu$ est égal à 0.15 cm^{-1} à 1.7 μ (la fonction d'appareil D étant gaussienne). Dans un autre cas, défavorable, nous avons utilisé le spectromètre du type Pfund, pour lequel $\delta\nu$ est égal à 1.5 cm^{-1} à 1.7 μ (D étant une fonction triangle). Les deux mesures directes de $\mathscr{A}$ ne diffèrent que de quelques %. L'influence de la valeur de $\delta\nu$ sur celle de $\mathscr{A}$ est donc faible dans les conditions particulières de cette mesure (pression du gaz 760 Torr).

En adoptant des conditions expérimentales (essentiellement pression suffisamment élevée) favorables, nous pouvons appliquer la méthode directe pour la mesure de l'intensité $\mathscr{A}$ des bandes (CH) des molécules CHF_3, $CHCl_3$ et $CHBr_3$.

Nous estimons l'imprécision de mesure sur $\mathscr{A}$ de l'ordre de 8%. Nous exprimons les valeurs de $\mathscr{A}$ en (cm^{-2} atm^{-1}).

Résultats Expérimentaux

Constantes de vibration–rotation des haloformes

Les Figs. 1–3 représentent les spectres de vibration–rotation de la bande $2\nu_1$ des haloformes CHF_3, $CHCl_3$ et $CHBr_3$, obtenus à l'aide du spectromètre du type Czerny vers 1.7 μ.

Considérons la Fig. 1 relative à la molécule CHF_3. Dans les branches P et R de la bande $2\nu_1$ une structure fine en J a pu être observée, mais les raies ne sont pas

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

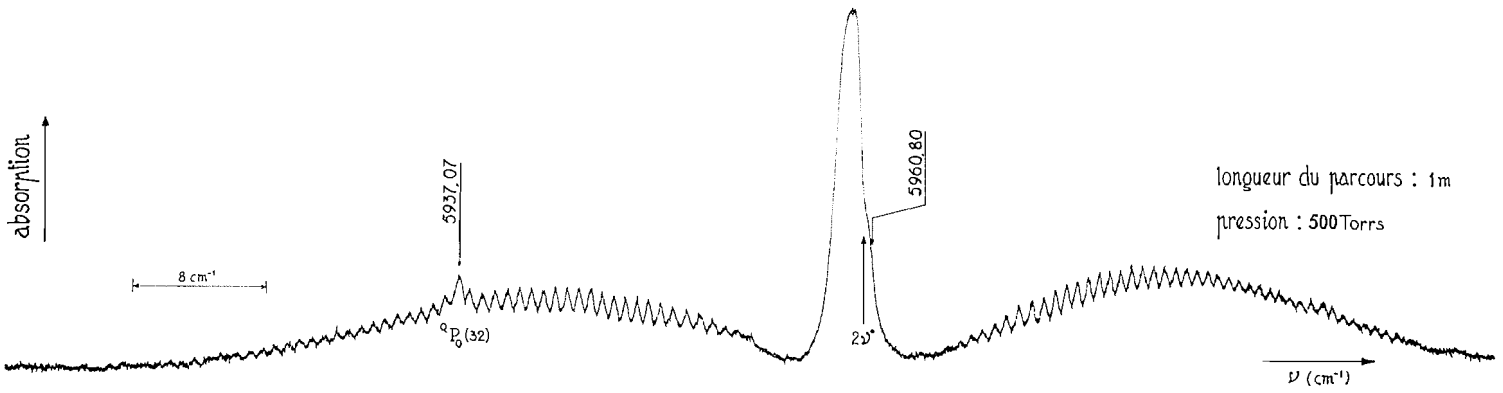

FIG. 1. Spectre de vibration–rotation de la bande $2\nu_1$ de CHF_3 à 1.7 μ.

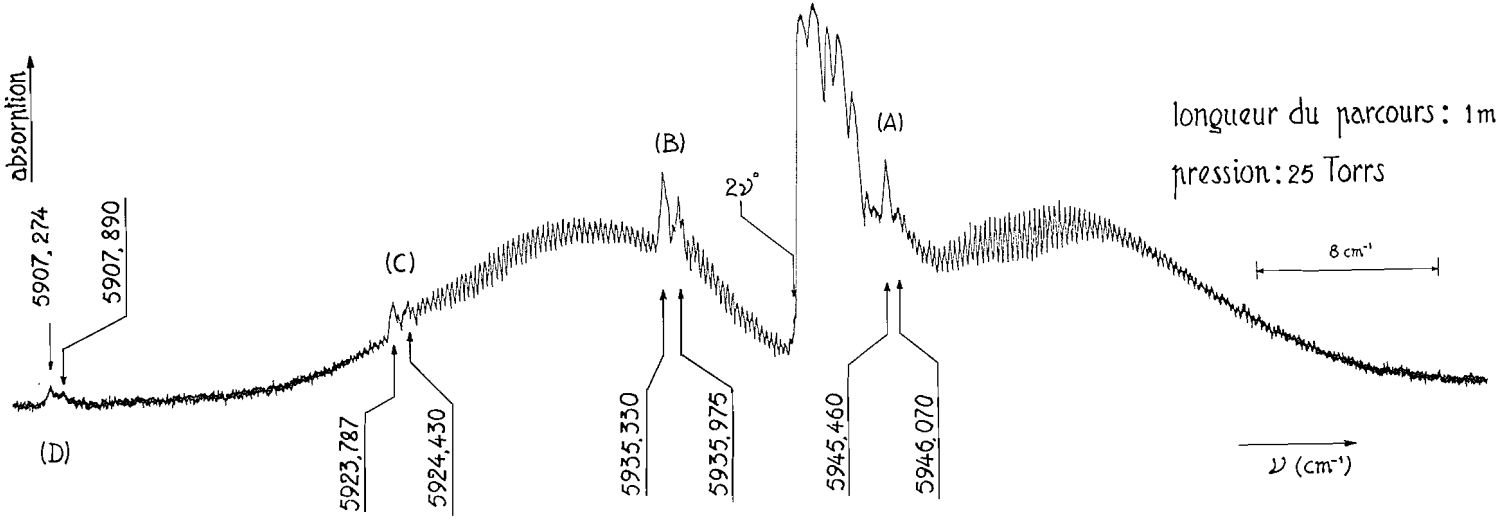

FIG. 2. Spectre de vibration–rotation de la bande $2\nu_1$ de $CHCl_3$ à 1.7 μ.

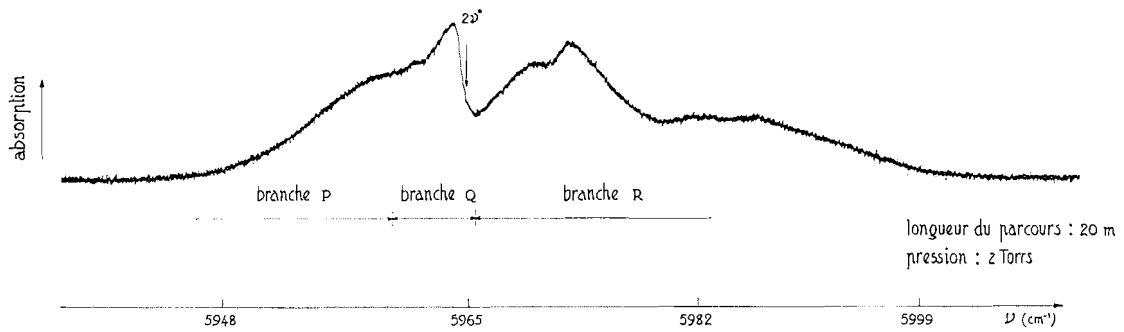

FIG. 3. Spectre de vibration–rotation de la bande $2\nu_1$ de $CHBr_3$ à 1.7 μ.

résolues en K. Les sous-bandes $K = 0$ et $K = 3q$ (q étant un entier) sont théoriquement les plus intenses. En première approximation, nous avons attribué, à la sous-bande $K = 0$, les maximums principaux de la structure observée. On introduit ainsi dans la détermination du nombre d'onde une erreur systématique qui est de l'ordre de l'erreur due au pointé (0.01 cm^{-1}).

La numérotation des branches P et R n'est pas évidente. Nous avons pointé séparément les deux branches. D'après l'aspect de la branche Q (sur un enregistrement à vitesse très lente) dont seule l'enveloppe est observable, on peut prévoir que, (*a*) le centre de bande $2\nu_1^0$ est situé au pied de la branche Q, du côté des nombres d'onde croissants, (*b*) le terme $(A' - B') - (A'' - B'')$ est négatif.

En tenant compte de ces remarques, une numérotation cohérente des branches P et R a été choisie pour définir les nombres d'onde des raies

$$\nu_m^{P,R} = 5959.483 + 0.6905m - 367 \times 10^{-6}m^2 - 16 \times 10^{-7}m^3$$

avec $m = -J$ (branche P), et $m = J + 1$ (branche R). Pour des valeurs de J inférieures à 13, aucune structure fine n'a pu être mise en évidence.

L'existence des bandes étrangères à la bande $2\nu_1$ du fluoroforme se traduit dans le spectre par une anomalie des intensités des raies dans les branches P et Q à $\nu = 5937.07\ cm^{-1}$ (raie P_{32} anormalement large et intense), $\nu = 5960.80\ cm^{-1}$ (raie dans la branche Q).

Les nombres d'onde mesurés, rapportés au vide, sont rassemblés dans le Tableau I. Une méthode des moindres carrés appliqués à la relation [6] donne les valeurs des constantes $2\nu_1^0$, $(B' + B'')$, $(B' - B'')$ et D_J.

La valeur obtenue pour la constante de distorsion D_J est probablement trop élevée, étant donné les simplifications effectuées dans l'expression des nombres d'onde $\nu_m^{P,R}$.

Les valeurs des constantes β_1, ω_1^0, x_{11}, B', B'' et D_J sont relatées dans le Tableau III.

La valeur du centre de bande ν_1^0 est égale à (3034.8 ± 0.2) cm^{-1}, d'après l'enregistrement obtenu à l'aide du spectromètre du type Pfund. La Fig. 4 représente la courbe $k'(\nu)l$ en fonction de ν, déterminée à partir de l'enregistrement.

Considérons maintenant la Fig. 2 relative à la molécule $CHCl_3$. Comme dans le cas du fluoroforme, les branches P et R de la bande $2\nu_1$ du chloroforme présentent une structure fine résolue en J et non en K. En adoptant la numérotation en J de Wiggins et coll. (3), on observe un recouvrement des raies $^QR_K(J)$ par la branche Q pour des valeurs du nombre quantique J inférieures à 20.

Dans la branche Q, sept raies ont été observées (cf. Tableau II). On remarque que, (*a*) l'alternance ternaire

étrangères" a été observé (cf. Tableau II). Les nombres d'onde relatifs à la bande $2\nu_1$ ne sont pas explicités, nos valeurs étant en bon accord avec celles de Anttila (4) à 0.01 cm^{-1} près.

Les valeurs obtenues pour les constantes β_1, $\omega_1{}^0$ et x_{11} sont réunies dans le Tableau III.

La valeur du centre de bande $\nu_1{}^0$ a été obtenue d'après la courbe $k'(\nu)l = f(\nu)$ (spectromètre de type Pfund (Fig. 5)), égale à $(3032.9 \pm 0.2)\ cm^{-1}$.

Considérons enfin la Fig. 3 relative à la molécule $CHBr_3$. On n'observe que l'enveloppe des branches P, Q et R de la brande $2\nu_1$. Le centre de bande $2\nu_1{}^0$ est égal à $(5964.9 \pm 0.1)\ cm^{-1}$. Dans la branche R, on observe une bande étrangère à la bande $2\nu_1$. En prenant pour centre de bande $\nu_1{}^0$, la valeur $(3048.3 \pm 0.2)\ cm^{-1}$, (Fig. 6), nous obtenons les valeurs des constantes $\omega_1{}^0$ et x_{11} (cf. Tableau III).

Intensité des bandes $2\nu_1$ et ν_1 des haloformes

Les Figs. 4–6 représentent les courbes exprimant $\ln(I'_0(\nu)/I'_t(\nu))$ en fonction de ν relatives à la bande ν_1 des haloformes étudiés. Par application de la méthode directe précédemment décrite, les mesures d'intensité intégrée $\mathscr{A}$ des bandes $2\nu_1$ et ν_1 ont été effectuées. Comme nous l'avons dit auparavant, la valeur de la argeur à mi-hauteur $\delta\nu$ de la fonction d'appareil D

†On élimine les bandes dites "étrangères."

influe peu sur la valeur de l'intensité $\mathscr{A}$ dans nos conditions expérimentales. La valeur de $\delta\nu$ était de 0.15 cm^{-1} à 1.7 μ (spectromètre du type Czerny utilisé pour l'étude de la bande $2\nu_1$) et de 0.50 cm^{-1} à 3.3 μ (spectromètre du type Pfund, pour l'étude de la bande ν_1). Les valeurs des intensités obtenues sont relatées dans le Tableau IV.

L'estimation de $\mathscr{A}$ pour la bande ν_1 des haloformes étudiés ne présente pas de difficultés sauf pour la molécule CHF_3 dont le spectre présente des bandes étrangères à la bande ν_1 (Fig. 4). Nous avons dû en tenir compte pour la mesure d'intensité (cf. Tableau IV).

La bande $2\nu_1$ de ces haloformes présente des bandes étrangères. Nous avons déterminé $\mathscr{A}$ d'après le contour global du spectre, ce qui entache ces mesures d'une certaine erreur par excès. Nous n'avons pas pu valablement déterminer cette erreur et nous l'avons estimée inférieure à 10% dans le cas du bromoforme par exemple.

Nous notons que nos valeurs de $\mathscr{A}$ pour les molécules CHF_3 et $CHCl_3$ sont systématiquement inférieures à celles obtenues par la méthode d'extrapolation de Wilson et Wells (5). Par contre, pour la molécule $CHBr_3$, nos résultats sont en assez bon accord avec ceux de Robinson.

A 1.7 μ les bandes étrangères à la bande $2\nu_1$ des molécules CHF_3, $CHCl_3$ et $CHBr_3$ et à 3.3 μ les bandes étrangères à la bande ν_1 de la molécule CHF_3 peuvent être des "bandes chaudes" de la forme $(2\nu_1 + n\nu_6 - n\nu_6)$ et $(\nu_1 + n\nu_6 - n\nu_6)$, n étant égal à 1, 2, ... En effet, les fréquences de vibration les plus basses des haloformes CHX_3 correspondent aux vibrations dégénérées ν_6 de déformation CX_3 (X étant un atome de l'halogène). Par ailleurs, il résulte du calcul de la population relative des niveaux d'énergie ($\nu_6 = n$), que la présence de "bandes chaudes" dans le spectre est probable. Ainsi notamment les bandes A, B, C et D du spectre de $CHCl_3$ à 1.7 μ (Fig. 2) pourraient être du type $(2\nu_1 + n\nu_6 - n\nu_6)$, où n prend les valeurs 1–4.

En outre, un dédoublement (écart $\Delta \simeq 0.6\ cm^{-1}$) de ces mêmes bandes, dans le cas particulier du chloroforme, pourrait s'expliquer par un effet isotopique dans la vibration dégénérée ν_6 de déformation du groupement CCl_3 (9). La molécule $CHCl_3$ est en effet composée essentiellement de deux variétés isotopiques $CH^{35}Cl_3$ et $CH^{35}Cl_2{}^{37}Cl$.

Une bande située normalement hors du domaine spectral étudié pourrait à la suite d'une résonance recouvrir partiellement ou totalement la bande $2\nu_1$ considérée. Nous avons déterminé les niveaux susceptibles de perturber le niveau $\nu_1 = 2$, pour les deux types de résonances accidentelles: résonances vibrationnelles de Fermi et résonances rotationnelles de Coriolis.

Celles-ci n'ayant lieu qu'avec des niveaux de combinaison quaternaire, paraissent d'un ordre trop élevé pour donner lieu à un effet observable.

En considérant la corrélation entre les intensités $\mathscr{A}$ des bandes ν_1 et $2\nu_1$ des haloformes CHX_3, et l'électronégativité du groupe CX_3 (X = F, Cl, Br), on constate que les grandeurs $\mathscr{A}_{1\leftarrow 0}$ et $\mathscr{A}_{2\leftarrow 0}$ présentent respectivement un minimum et un maximum pour la molécule $CHCl_3$.

Le rapport $\rho = \mathscr{A}_{1\leftarrow 0}/\mathscr{A}_{2\leftarrow 0}$ dont la valeur excède en général l'unité, n'est que de l'ordre de 0.2 pour le chloroforme. Cette anomalie ne semble pas pouvoir s'expliquer uniquement par la présence des bandes étrangères à la bande $2\nu_1$ de la molécule $CHCl_3$. Une anharmonicité électrique importante comme celle déjà observée pour la molécule HI (10) pourrait éventuellement en tenir compte.

A study of potential cyclopropyl – silver ion complex formation

B. C. MENON AND RICHARD E. PINCOCK
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received April 16, 1969

The relative abilities of some cyclopropyl derivatives of norbornene and of norbornadiene to form water soluble complexes with 1 *M* silver nitrate at 25° were determined. Equilibrium constants, K_{eq}, for the reaction

$$\text{compound}_{(\text{pentane})} + \text{Ag}^{+}{}_{(H_2O)} \rightleftarrows \text{complex}_{(H_2O)}$$

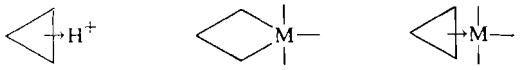
were in the order

norbornadiene > norbornene > *exo*-tricyclo[3.2.1.$0^{2,4}$]oct-6-ene > *endo*-tricyclo [3.2.1.$0^{2,4}$]oct-6-ene
≫ di-*exo*-tetracyclo[3.3.1.$0^{2,4}0^{6,8}$]nonane or 5,5-dimethyl-2-norbornene

Quadricyclene (tetracyclo[3.2.0.$0^{2,7}0^{4,6}$]heptane) is rapidly isomerized to norbornadiene in the presence of silver ion under the equilibration conditions. The relative K_{eq} values are interpretable in terms of steric and inductive effects of cyclopropyl groups on olefin – silver ion complex formation and they give no evidence of a stabilizing cyclopropyl – silver ion interaction.

Canadian Journal of Chemistry, 47, 3327 (1969)

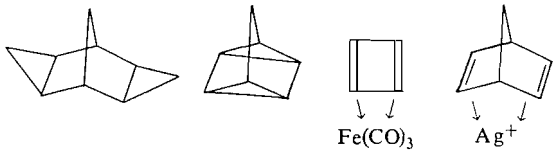
There are many chemical and physical properties which illustrate the close relationships between olefinic double bonds and cyclopropyl bonds. The properties held in common by these compounds arise from their basic similarity in bonding (cf. ref. 1). Just as π electrons of olefins are subject to electrophilic attack, π-like cyclopropyl orbitals (formed from overlap of two sp^5 hybrid bonds) (2) are acted upon by many electrophilic reagents (3). For example, cyclopropyl compounds react readily with acids in a manner similar to that of olefins; an edge protonated cyclopropane intermediate (see structure **1**), where the electrophile adds to the in-plane π-like orbital, has been supported both theoretically (4) and experimentally (5).



1 **2** **3**

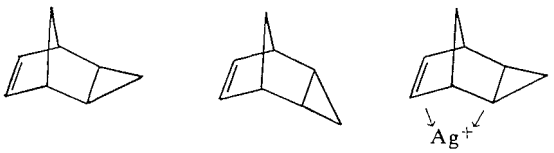
However, one chemical property of a carbon–carbon double bond that has not been found in a cyclopropyl bond is the ability to form relatively weak, but stable complexes with metallic ions. Compounds produced from reaction of cyclopropanes with chloroplatinic acid have been formulated as having two platinum–carbon σ bonds (**2**) (6), while another recent suggestion for these compounds is structure **3** (7). Here the cyclopropyl group retains its ring bonding but donates electrons to the metal in an edgewise manner similar to structure **1**.

The well known existence of olefin – silver ion complexes, the structural similarities of olefin and cyclopropyl groups, and the more recent examples of the ability of cyclopropyl compounds to bond to electrophiles (e.g. ref. 8) all suggest that analogous cyclopropyl – silver ion complexes may exist in aqueous solutions. Following the classical method (9) used to determine the ability of olefins to complex with silver ion, we have studied the relative ability of some cyclopropyl compounds and cyclopropyl olefins to form water soluble complexes in aqueous 1 *M* silver nitrate. The possibility that one of the dicyclopropyl compounds **4** and **5** might have a pair of cyclopropyl orbitals favorably oriented to organometallic bonding was investigated.



4 **5** **6** **7**

Also by further analogy to the proposed bonding in cyclobutadiene – iron tricarbonyl complex **6** (10) or in the norbornadiene – silver nitrate complex **7** (11), the relative complexing abilities of *exo*- and *endo*-bicyclo[3.2.1.$0^{2,4}$]oct-2-enes (**8** and **9**) were studied. It is known that silver nitrate forms a solid complex with *exo* compound **8** but not with the *endo* isomer **9** (12).



8 **9** **10**

This suggested an accentuation, by the *exo* cyclopropyl group, of the ability of the strained double bond in **8** to form a complex; i.e., a structure and interaction shown in **10.** Of related interest is the possibility of isomerization reactions of compounds **4** and **5** (and of **8** and **9**) by silver ion catalysis similar to that recently reported for some rhodium catalysts (13).

Results and Discussion

The method used to determine relative complex formation was similar to that of Winstein and Lucas (9) and Traynham and Sehnert (14). The cyclopropyl or olefinic compound in pentane was equilibrated at 25° with a 1 *M* aqueous $AgNO_3$ solution and the compound remaining in the organic phase was analyzed by vapor phase chromatography. Equilibrium constants, K_{eq}, for the reaction

$$\text{olefin}_{(\text{pentane})} + \text{Ag}^{+}{}_{(\text{H}_2\text{O})} \rightleftarrows \text{complex}_{(\text{H}_2\text{O})}$$

were then calculated from the change in concentration in the pentane phase before and after equilibration and from the known aqueous silver nitrate concentration. For compounds (like the hydrocarbons used) which are essentially insoluble in water or in 1 *M* potassium nitrate, the equilibrium constants obtained are independent of the solubilities of uncomplexed hydrocarbons in water (9). They are therefore the best measures of relative ability to form complexes with silver ion. The results obtained are shown in Table I.

Not surprisingly, the relative equilibrium constants

norbornadiene > norbornene > cyclohexene

for equilibration with pentane solutions (Table I) follow the order previously obtained (15) for equilibrations using carbon tetrachloride as the organic phase. These compounds then provide standards of comparisons for the others in Table I. The data show that the presence of the cyclopropyl groups in either *exo* or *endo* configurations (**8** and **9**) gives compounds with much less ability than norbornadiene to complex with silver ion. Also, the *exo* cyclopropyl compound **8** forms a more stable complex than the *endo* isomer, but neither of these cyclopropyl derivatives of norbornene has as great a tendency to complex with silver ion as norbornene itself. Easy crystallization of the *exo*-silver nitrate complex of

TABLE I

Equilibrium constants for complex formation in aqueous 1.0 *M* silver nitrate at 25°

compound **8**, which allows its convenient separation from *endo* isomer **9**, then appears to be due only to its low aqueous solubility rather than to any especially great tendency of the *exo* isomer to interact with silver ion.

It may be expected that both norbornene and the *exo* cyclopropyl derivative of norbornene (**8**) would have virtually the same steric properties for complex formation from above or below the olefinic bond. Relative to norbornene, the decrease in equilibrium constant brought about by the presence of the *exo* cyclopropyl group in **8** is probably due to the inductive electron withdrawing properties of cyclopropyl groups (e.g. see ref. 16). The further decrease obtained with the *endo* cyclopropyl isomer is possibly due to steric hindrance for complex formation on the "underside" (i.e., *endo* side) of the norbornene structure. Sensitivity to steric effects was shown by the inability of 5,5-dimethyl-2-norbornene to form a measurable amount of complex under the standard conditions used. If *exo* interaction of olefinic bond and silver ion predominated, this dimethyl substituted norbornene derivative would be expected to form a complex to an equal or possibly greater extent than norbornene itself. The absence of complex formation with this compound is taken as evidence that silver ion complex formation in aqueous solution occurs predominantly on the *endo* side of norbornene and of norbornadiene. In the solid state an example of *exo* configuration has been established (17) while *endo* configurations have been favored in other cases (11, 18).

For the cyclopropyl olefins in Table I, the relative equilibrium constant data can therefore be explained in terms of inductive and steric effects of the cyclopropyl group acting on olefin – silver ion complex formation. Potential cyclopropyl – silver ion interaction, which may still account for the greater complex formation from *exo* compound **8** over *endo* isomer **9**, is not required by the data obtained. But a structural study of the solid *exo* complex, which analyzes as a 1:1 complex of $AgNO_3$ with **8**, would be necessary to finally show the position (and indicate the type of bonding) of silver with respect to the π-bonds of olefin and cyclopropyl groups.

With regard to cyclopropyl groups by themselves, it is known that liquid cyclopropane does not form a complex with solid silver nitrate at room temperature (19). Also as reported in Table I, the *exo* cyclopropyl groups in compound **4** do not act to form measurable amounts of complex with aqueous silver nitrate. However, when cyclopropyl groups are suitably arranged (as in the compound quadricyclene **5**), cyclopropyl–metal interaction occurs and a symmetry allowed (13*a*) isomerization to norbornadiene occurs.

When shaken in pentane with aqueous silver nitrate at room temperature under conditions of the equilibrium experiments, quadricyclene is largely rearranged to norbornadiene. Some oxidation was apparent when metallic silver was also deposited. This rapid reaction prevented the determination of an equilibrium constant for quadricyclene – silver ion interaction. Isomerization of quadricyclene catalyzed by rhodium, palladium, or platinum compounds (13*a*), rearrangement of hexamethylprismane by a rhodium catalyst (13*b*) and oxidation and rearrangement of phenylcyclopropane brought about by palladium chloride (20) are recent examples of similar metal cyclopropyl reactions.

A parallel (as in hexamethylprismane) or almost parallel (as in quadricyclene) arrangement of two cyclopropyl rings gives a π orbital system similar to that in cyclobutadiene. Although no stable complexes of silver ion with cyclopropyl groups were found, the isomerization of **5** (but not of **4**) makes it probable that the π-like electrons in two parallel cyclopropyl rings may interact with silver ion in a manner analogous to that in olefin – metal ion complexes like **6** and **7**.

Except for this rather special interaction followed by rearrangement, the general inability (compared to carbon–carbon double bonds) of cyclopropyl groups to complex reversibly with metals is likely due to increased steric effects as well as decreased availability of π-electrons. In olefins the π-electrons are sterically relatively free above the plane of the atoms attached to the double bond, while in cyclopropyl compounds the π electrons in the edge of the ring are closer to atoms attached to the ring carbons. This steric factor, together with smaller p-character of cyclopropyl ring orbitals seems to prevent noticeable complex formation in aqueous solution.

Experimental

The method used was essentially that of Traynham and Sehnert (14), except that the olefinic concentration was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

determined by gas–liquid chromatographic (g.l.c.) analysis of the organic phase. Pentane was used because it allowed g.l.c. separation of all the olefins used. Analyses were carried out using a 20% Carbowax 20-M on 60–80 Chromsorb W (acid washed) column at 100° in an Aerograph model 90-P3 chromatograph. A series of solutions of olefin of varying concentrations in pentane was prepared. These solutions were then analyzed by g.l.c. and a calibration curve of concentration vs. peak area for the olefin obtained. The equilibration was carried out in a two-necked 250 ml flask fitted with a condenser and a mechanical stirrer. Thirty ml of olefin solution (0.1–1.0 *M*) were buretted into the flask, followed by 100 ml of 1.0 *M* $AgNO_3$ solution. The two phases at 25.2 ± 0.1° were rapidly stirred. At the end of 1 h the organic layer was analyzed for olefin by g.l.c. under the same condition employed for the calibration runs. That the equilibration was complete was shown by the fact that the olefin concentration in the pentane phase remained unchanged from 1 to 2 h. The amount of olefin dissolved but not complexed in the water layer was determined by shaking a mixture of 30 ml of olefin solution and 400 ml of 1.0 *M* KNO_3 for 1 h and then analyzing the organic phase. The amount of olefin lost from the organic phase was noticeable but negligible in every case. The equilibrium constants (K_{eq}) for the reaction

$$\text{olefin}_{(\text{pentane})} + Ag^{+}{}_{(H_2O)} \rightleftarrows \text{complex}_{(H_2O)}$$

were calculated from the data given in Table II by the method given in the footnotes. Mixtures of known ratios of *exo* and *endo* isomers (**8** and **9**) were used and the K_{eq} for *exo* compound calculated from the data, and from the K_{eq} obtained from use of pure *endo* isomer.

*Tricyclo[3.2.1.0^{2,4}]oct-6-enes (exo-**8** and endo-**9**) and Tetracyclo[3.3.1.0^{2,4}0^{6,8}]nonane (**4**)*

These compounds were prepared by treating freshly distilled norbornadiene with diazomethane over anhydrous cuprous chloride in ether. (The general method used is given in ref. 21.) The relative proportion of tricyclooctenes and the tetracyclononane was controlled by the time of passage of CH_2N_2 through the ether solution. The *exo* and *endo* monoadducts were not separable by g.l.c.; the mixture showed the properties reported for these compounds prepared by the CH_2I_2–Zn–Cu reaction with norbornadiene (12). The ratio of *exo* to *endo* was determined by the nuclear magnetic resonance (n.m.r.) peaks at 3.55 (for *exo*) and 4.25 τ (for *endo*). The diadduct (4) was separated by g.l.c.; n.m.r. 7.75 (bridgehead), 8.50–9.45 τ. The n.m.r. spectrum and the method of preparation indicated a di-*exo* configuration for this compound (see also ref. 13*c*).

Anal. Calcd. for C_9H_{12}: C, 90.00; H, 10.00. Found: C, 89.52; H, 10.36.

endo-Tricyclo[3.2.1.0^{2,4}]oct-6-ene (**9**) was prepared by the method of Closs and Krantz (22). Quadricyclene (**5**) was prepared by photolysis of norbornadiene (23). 5,5-Dimethyl-2-norborn-2-ene was kindly supplied by McGreer (24). These compounds were purified for use by g.l.c. collections.

The silver nitrate complex of *exo*-tricyclo[3.2.1.0^{2,4}]-oct-6-ene (**8**) was prepared by adding 0.23 g of a mixture of **8** and **9** to 1 ml of 2.5 *M* $AgNO_3$ solution. A white

Etude polarographique des méthoxyhydroperoxydes[1]

JEAN RENARD ET SÁNDOR FLISZÁR
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 18 mars 1969

La réduction polarographique d'une série de α-méthoxyhydroperoxydes, produits par l'ozonation d'oléfines dans le méthanol, a été étudiée. Un mécanisme est proposé pour le processus d'électrode. L'application analytique pour le dosage de ces méthoxyhydroperoxydes et pour l'étude du mécanisme d'ozonolyse des oléfines dissymétriques est exposée.

The polarographic behavior of selected α-methoxyhydroperoxides, produced by ozonization of olefins in methanol, has been studied. A mechanism is proposed for the electrode process. An analytical application for the quantitative determination of these methoxyhydroperoxides and for the study of the mechanism of ozonolysis of unsymmetrical olefins is described.

Canadian Journal of Chemistry, 47, 3333 (1969)

Le comportement polarographique des produits peroxydiques en relation avec l'étude des produits d'oxydation des corps gras, des caoutchoucs, des polymères et des essences, a fait l'objet de nombreuses publications et de plusieures revues (1–3). Kůta et Quackenbush (4) ont signalé les possibilités d'application des techniques polarographiques à l'étude des produits de la réaction d'ozonation, et Slagel (5) a montré l'intérêt de la polarographie pour l'élucidation de la structure d'un produit issu de l'ozonation du 1,2,3,4,7,7-hexachloro-bicyclo-[2,2,1]hepta-2,5 diène. Cependant, aucune étude systématique du comportement polarographique des produits d'ozonation n'a été publiée.

L'ozonation des oléfines en milieu inerte (CCl_4 ou pentane, par exemple) conduit, en général, à la formation de produits carbonylés et de zwitterions (6), selon un mécanisme proposé par Criegee.

Les proportions des 2 voies de clivage (*a* et *b*), qui dépendent de la nature des oléfines soumises à l'ozonation, ont fait l'objet d'études récentes (7), ainsi que la participation possible de zwitterions *syn* et *anti* dans le mécanisme de formation d'ozonides *cis* et *trans* (8).

En présence de méthanol, les zwitterions sont généralement transformés en α-méthoxyhydroperoxydes $R(R')C(OCH_3)$—OOH (6). Dans de nombreux cas il a été vérifié (7) que l'ozonation en présence de méthanol d'une mole d'oléfine conduit à la formation d'une mole du mélange de composés carbonylés prévus par le mécanisme de Criegee, et d'une mole de méthoxyhydroperoxydes. Il a aussi été établi que ces derniers ne réagissent pas avec les produits carbonylés engendrés lors des ozonations si les mélanges réactionels sont conservés pendant 1–2 h à la température de la pièce.

Le but du présent travail est l'étude du mécanisme de la réduction polarographique d'une série de méthoxyhydroperoxydes $RCH(OCH_3)$—OOH, avec R = H, CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *t*-C_4H_9, et phényle (Ph). Une méthode de dosage de ces hydroperoxydes a été élaborée à partir des résultats de cette étude.

Partie expérimentale

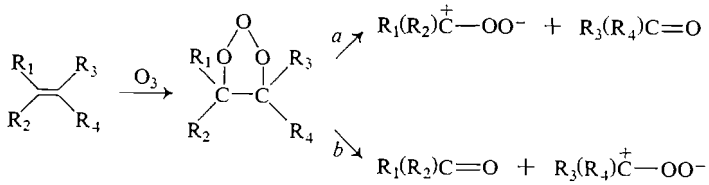
Technique polarographique

Les courbes intensité–potentiel ont été enregistrées à l'aide d'un polarographe Metrohm E-261-R offrant la double possibilité d'une analyse par voltage continu croissant linéairement ou d'une analyse à l'aide d'une tension alternative de faible amplitude, superposée au voltage continu d'analyse (polarographie C.A.) (9, 10). Dans la présente étude, la fréquence de la tension alternative utilisée a été de 60 Mc/s et son amplitude de 50 mV. L'électrode a goutte de mercure était constituée par un capillaire, dont le mouvement commandé par un électroaimant assure un temps de goutte de 1/6 s pour un flux de mercure de 0.9 mg/s. L'électrode de référence était une électrode Ag/AgCl commerciale et l'électrode auxiliaire, une électrode de tungstène.

Les oscillo-polarogrammes $i = f(E)$ ont été obtenus à l'aide d'un oscillo-polarographe Chemtrix SSP-2 utilisant un balayage simple par une tension triangulaire. Les électrodes utilisées étaient les mêmes que celles décrites précédemment. Le temps de goutte avait été ramené à 3 s.

Les électrolyses à potentiel contrôlé ont été effectuées dans une cellule d'électrolyse à 3 compartiments, séparés

[1]Travail présenté en partie au Congrès annuel de l'Association Canadienne-Française pour l'Avancement des Sciences, Ottawa, Novembre 1968, extrait de la thèse de Doctorat de M.J.R.



par des verres frittés. L'électrode de travail était constituée d'une nappe de mercure agitée à l'aide d'un agitateur magnétique. L'électrode de contrôle était une électrode Ag/AgCl, l'électrode auxiliaire un fil de cuivre plongeant dans la solution. Les électrolyses ont été effectuées sur des volumes de 75 ml de solution 10^{-2} *M* de méthoxyhydroperoxydes pendant des durées variant de 1 à 5 h. La tension était appliquée à l'aide d'un potentiostat Tacussel PRT 500 LC. Le courant d'électrolyse était enregistré à l'aide d'un enregistreur potentiométrique Tacussel EPL-1. Les quantités de courant ont été déterminées par des mesures planimétriques des courbes $i = i(t)$ ainsi obtenues. La concentration en dépolariseur a été suivie par polarographie.

Préparation des méthoxyhydroperoxydes

Les méthoxyhydroperoxydes $RCH(OCH_3)—OOH$ (R = C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *t*-C_4H_9, et Ph) ont été préparés par l'ozonation à 0 °C des oléfines symmétriques correspondantes R—CH=CH—R dans le méthanol. Après l'ozonation, le solvant a été évaporé et le résidu a été extrait successivement par l'hexane, l'eau, puis l'éther, en suivant la procédure décrite par Keaveney *et al.* (11). Pour obtenir une plus grande pureté (notamment en vue de l'élimination de restes d'aldéhyde), les échantillons ont été chromatographiés sur une colonne de silica gel Baker (200 g/1 g) en utilisant, comme éluants, le CCl_4 et, ensuite, l'acétone. Lors de la purification du méthoxyhydroperoxyde avec R = Ph, un mélange (1:1) de benzène–hexane a été intercalé entre les éluants précédents.

Les méthoxyhydroperoxydes avec R = H et R = CH_3 ont été préparés par l'ozonation dans le méthanol à 0 °C du 1,1-diphényléthylène et du *trans* β-méthylstyrène, respectivement. Dans ces conditions, 1 mole de 1,1-diphényléthylène engendre 0.33 ± 0.01 mole de $CH_2(OCH_3)—OOH$ et le rendement en $CH_3—CH(OCH_3)—OOH$ est de 0.82 ± 0.02 mole par mole de β-méthylstyrène ozonée (*7a*). Les extractions et purifications par chromatographie sur colonne ont été effectuées selon la procédure exposée ci-haut. Lors du traitement avec l'eau, le méthoxyhydroperoxyde $Ph_2C(OCH_3)—OOH$ obtenu lors de l'ozonation du 1,1-diphényléthylène se décompose très rapidement en engendrant de la benzophénone. Par contre, la décomposition du méthoxyhydroperoxyde R = Ph obtenu lors de l'ozonation du β-méthylstyrène et du stilbène est assez lente pour en permettre la préparation. Cependant, ce même hydroperoxyde est entièrement décomposé dans l'eau, en engendrant de l'aldéhyde benzoïque, après un repos de 1 nuit à la température ambiante, ce qui permet la préparation du méthoxyhydroperoxyde aliphatique à partir du β-méthylstyrène.

Les méthoxyhydroperoxydes avec R = H, CH_3, et Ph ainsi préparés sont en tous points conformes à ceux décrits par Keaveney *et al.* (11). L'identification et les contrôles de pureté ont été effectués à l'aide des spectres de résonance magnétique nucléaire (r.m.n.), enregistrés au moyen d'un spectromètre Jeolco 60 H, des spectres d'absorption infrarouge (i.r.) (Perkin–Elmer 221), et par des dosages iodométriques selon une méthode proche de celle décrite par Lohaus (12). Les méthoxyhydroperoxydes avec R = C_2H_5, *n*-C_3H_7, *i*-C_3H_7, et *t*-C_4H_9 se présentent sous forme d'huiles presque incolores. Leurs spectres r.m.n. sont rapportés dans le Tableau I. Leur pureté est estimée ⩾ 98%.

Procédure polarographique

Le méthanol utilisé a été préalablement chauffé à reflux sur du magnésium pendant 2 h et purifié par distillation. L'acétate d'éthyle employé avait été distillé soigneusement au moyen d'une colonne Ilas de type Todd, garnie d'anneaux de Fenske.

Le pH des solutions tampons a été mesuré à l'aide d'un potentiographe Metrohm E336A, équipé d'une électrode de verre combinée à une électrode de référence Ag/AgCl.

Pour les mesures polarographiques, 1 ml de la solution de méthoxyhydroperoxyde dans le méthanol ou 1 ml de la solution ozonée dans l'acétate d'éthyle – méthanol (1 *M*) a été transféré dans 25 ml de la solution tampon. Les concentrations des solutions de méthoxyhydroperoxydes utilisées étaient comprises entre 0.01 et 0.1 *M*. Lors de l'examen des solutions effectuées dans l'acétate d'éthyle – méthanol, une agitation magnétique rapide est nécessaire pour assurer la miscibilité des deux phases. Le polarogramme est enregistré à 25°, après un dégazage de la solution par un courant d'azote pendant 10 min.

Résultats et Discussion

Stabilité des α-méthoxyhydroperoxydes

Comme l'avaient signalé Subluskey *et al.* (13), ainsi que Keaveney *et al.* (11), les alkylohydroperoxydes R—$CH(OCH_3)$—OOH sont très stables en solution aqueuse jusqu'à pH = 10. En accord avec ces auteurs nous avons également constaté la moindre stabilité du phényl-méthoxyhydroperoxyde Ph—$CH(OCH_3)$—OOH et la décomposition très rapide des dialkyl-méthoxyhydroperoxydes $R(R')C(OCH_3)—OOH$ en solution aqueuse. Par conséquent notre étude a été limitée à 7 méthoxyhydroperoxydes dont la stabilité est suffisante pour permettre un dosage polarographique, et dont les caractéristiques spectroscopiques et polarographiques sont données au Tableau I. Il a été vérifié, pour chacun des

méthoxyhydroperoxydes étudiés, que l'intensité maximum du pic polarographique était constante pendant une période d'au moins 1 h, sauf dans le cas du phényl-méthoxyhydroperoxyde qui, cependant, n'accuse pas une décomposition excédant 5% après 1 h.

Irréversibilité des processus d'électrode

Quelque soit la vitesse de balayage, les oscillopolarogrammes $i = f(E)$ ont montré, pour tous les méthoxyhydroperoxydes étudiés, une complète irréversibilité du processus d'électrode (Fig. 1). Ce résultat est corroboré par l'analyse logarithmique des courbes intensité–potentiel d'après l'équation

$$E = E_{1/2} - (RT/\alpha nF) \ln [I/(I_e - I)]$$

Le coefficient de transfert α qui a été calculé à partir des valeurs des pentes des droites obtenues est, compte tenu des 2 électrons mis en jeu, de 0.2–0.3 pour les méthoxyhydroperoxydes avec R = C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *t*-C_4H_9 et de 0.06–0.07 pour R = H et CH_3.

Nombre d'électrons mis en jeu dans le processus d'électrode

L'électrolyse à potentiel contrôlé du *n*-propyl-méthoxyhydroperoxyde 10^{-2} *M* conduit à une valeur moyenne de $n = 1.9$ électrons (4 déterminations avec *n* compris entre 1.8 et 2.05). Ce résultat est, par ailleurs, confirmé par l'étude des courbes $i = i(t)$ selon la méthode de Gilbert et Rideal (14).

$$\log \bar{i}_{l_0} - \log \bar{i}_I = \bar{i}_{l_0} t/2.3nFC_{t=0}V$$

$\log \bar{i}_I$ est une fonction linéaire de *t*. La pente de la

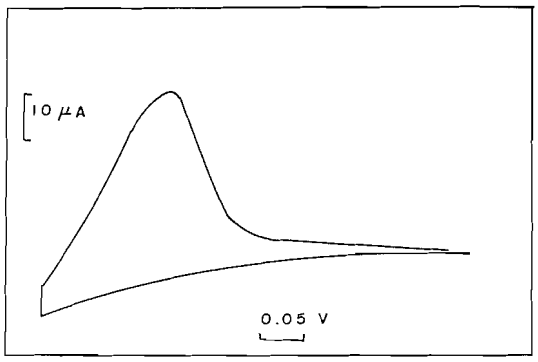

FIG. 1. Oscillo-polarogramme d'une solution 2×10^{-4} *M* de *i*-C_3H_7—$CH(OCH_3)$—OOH dans les tampon Mc Ilvaine, pH = 7; voltage de départ, 0.0 V; domaine de voltage, −0.5 V; vitesse de balayage, 0.5 V s^{-1}.

droite obtenue à partir des valeurs expérimentales $i = i(t)$ conduit au résultat, $n = 1.8$. Ces valeurs trouvées pour n, proches de 2 électrons, sont en bon accord avec la valeur $n = 2$ électrons qui a été déterminée par Skoog et Lauwzecha (15) pour la réduction des alkyl-hydroperoxydes. Contrairement au *n*-propyl-méthoxyhydroperoxyde, le phényl-méthoxyhydroperoxyde subit une décomposition relativement rapide en présence d'une nappe de mercure. On observe, en effet, près de 50% de décomposition en 2 h lorsqu'une solution 10^{-2} *M* de ce méthoxyhydroperoxyde dans l'eau est laissée au contact d'une nappe de mercure. La complexité de cette réaction parallèle à la réaction d'électrolyse rendait difficile toute correction précise des résultats polarographiques. L'ordre de grandeur $n = 2$ a néanmoins pu être vérifié de manière grossière.

Identification des produits d'électrolyse

L'électrolyse de 75 ml d'une solution 10^{-2} *M* de phényl-méthoxyhydroperoxyde dans l'eau a été effectuée à 25°, avec une tension appliquée de −0.4 V par rapport à l'électrode Ag/AgCl. Après 2 h de réaction, le méthoxyhydroperoxyde a réagi dans une proportion estimée à environ 95%, ce qui a été attesté par l'examen polarographique de la solution électrolysée et par le dosage iodométrique de l'oxygène actif. La solution électrolysée a été soumise à une extraction par l'éther, et ce dernier a été ensuite évaporé. Le résidu a été dissous dans 10 ml de CCl_4. L'analyse de cette solution par chromatographie analytique en phase gazeuse, à l'aide d'un appareillage F and M 5750, pourvu d'une colonne "silicone rubber", a permis d'identifier l'aldéhyde benzoïque. Son dosage indique un rendement de production de benzaldéhyde correspondant à 90% par rapport au méthoxyhydroperoxyde initialement mis en jeu.

L'électrolyse de 75 ml d'une solution aqueuse 10^{-2} *M* du méthoxyhydroperoxyde $H_2C(OCH_3)$—OOH, avec une tension appliquée de −1.2 V (par rapport à l'électrode Ag/AgCl), a été effectuée pendant 5 h, c'est-à-dire jusqu'à consommation complète du méthoxyhydroperoxyde. Cette consommation est attestée par l'absence de pic dans le polarogramme de la solution électrolysée. Ce polarogramme ne révèle cependant pas de pic correspondant au formol, qui est le produit attendu de l'électrolyse. Dans le but de mettre le formol engendré en évidence, la solution électrolysée a été additionnée de chlorhydrate de semicarbazide jusqu'à l'obtention d'une concentration 1 *M* de ce réactif, selon une procédure voisine de celle décrite par Souchay et Craizon (16) et Coulson (17). Le polarogramme de cette solution, enregistré après un repos de 30 min, révèle 2 pics à −0.8 V et à −1.05 V qui sont identiques à ceux obtenus à partir d'une solution aqueuse de formol traitée de même manière. D'après les mesures effectuées sur le pic à −0.8 V, le rendement en formol obtenu par électrolyse s'élève à environ 80% par rapport à la quantité de méthoxyhydroperoxyde initialement mise en jeu. En tenant compte de la possibilité de pertes en produits au cours de l'électrolyse, dues, notamment, au courant d'azote employé, il est raisonable de conclure que lors de l'électrolyse de ce méthoxyhydroperoxyde le composé carbonylé est libéré à l'électrode en majeure partie, sinon entièrement, sous forme de son hémiacétal non réductible. Des observations similaires ont déjà été rapportées dans la littérature (18).

Ces expériences confirment ainsi que le produit de l'électrolyse des méthoxyhydroperoxydes est le composé carbonylé correspondant, soit sous forme libre, soit sous forme de son hémiacétal méthanolique, selon la stabilité de l'hémiacétal à l'hydrolyse.

Influence du pH

L'influence du pH sur les potentiels de demi-vague et les courants limités a été étudiée sur des solutions de pH compris entre 3 et 8, réalisées à l'aide d'un tampon universel Mc Ilvaine. Pour les deux premiers termes de la série des méthoxy-

For personal use only.

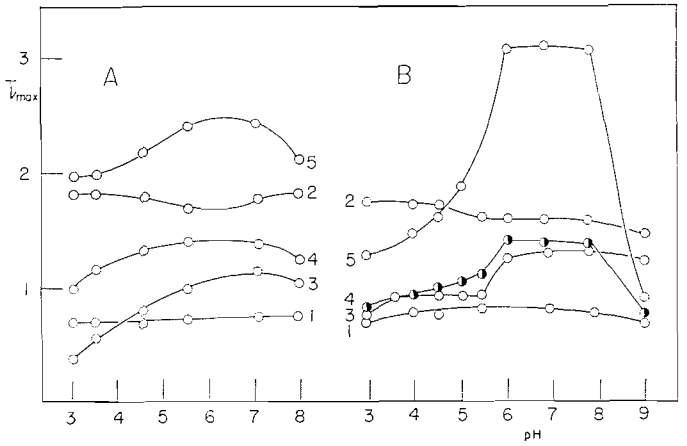

FIG. 2. Variation du courant limite i_{max} (μA) en fonction du pH. A, tampon Mc Ilvaine; B, tampon Clark et Lubs. R = H (1), CH_3 (2), i-C_3H_7 (3), t-C_4H_9 (4), et C_6H_5 (5).

hydroperoxydes étudiés, c'est-à-dire avec R = H et R = CH_3, les potentiels de demi-vague et les courants limites sont indépendants du pH dans le domaine de pH 3 à 8 (Figs. 2 et 3). Les termes supérieurs (R = C_2H_5, et les suivants) montrent un léger déplacement du potentiel de demi-vague vers les potentiels plus positifs lorsque le pH croît, alors que le courant limite passe par un maximum au voisinage de pH = 7. L'étude de l'influence des pH supérieurs, 8.5 et 9, réalisés à l'aide d'un tampon différent (Borax et HCl), indique un déplacement des potentiels de demi-vague vers les potentiels plus négatifs, accompagné d'une diminution des courants limites.

Influence de la composition du tampon

Le domaine de pH compris entre 6 et 8 a été étudié à l'aide (*i*) du tampon Mc Ilvaine et (*ii*) d'un tampon NaH_2PO_4 et NaOH. La comparaison des résultats obtenus à l'aide de ces deux tampons n'indique qu'une faible différence des potentiels de demi-vague, de l'ordre de 50 mV, alors que les courants limites restent du même ordre de grandeur, avec un écart maximum de ±2%, et se comportent de manière similaire lorsque le pH est changé.

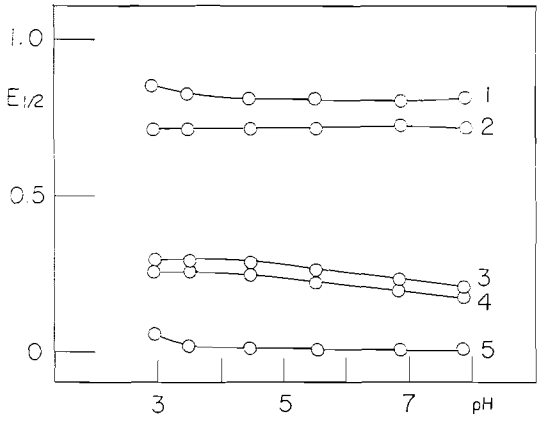

FIG. 3. Variation du potentiel de demi-vague $E_{1/2}$ (V) en fonction du pH (tampon Mc Ilvaine). R = H (1), CH_3 (2), i-C_3H_7 (3), t-C_4H_9 (4), et C_6H_5 (5).

Par contre, le tampon réalisé à base de phtalate acide de potassium, additionné de HCl ou de NaOH, se distingue par son influence des deux tampons précités. Ceci est indiqué par les résultats d'une comparaison entre les tampons phtalate et Mc Ilvaine dans le domaine de pH 3–6. Pour tous les méthoxyhydroperoxydes éxaminés on observe, avec le tampon phtalate, un glissement régulier des potentiels de demi-vague vers les potentiels plus positifs lorsque le pH croît (Fig. 4). Pour les méthoxyhydroperoxydes avec R = H et CH_3, les potentiels de demi-vague observés avec le tampon phtalate diminuent régulièrement et rejoignent, vers pH = 6, les valeurs des potentiels de demi-vague observés avec les tampons NaH_2PO_4 – NaOH et Mc Ilvaine. Avec les autres méthoxyhydroperoxydes (R = C_2H_5 et les suivants), la courbe de décroissance des potentiels de demi-vague (avec les pH croissants) observée en tampon phtalate est pratiquement parallèle aux courbes observées avec R = H et R = CH_3 dans la même région. ($\Delta E_{1/2} \approx 100$ mV entre pH 3 et 5.5.) Contrairement au comportement de ces deux premiers termes, pour R = C_2H_5 (et les termes suivants) le passage à pH = 6

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

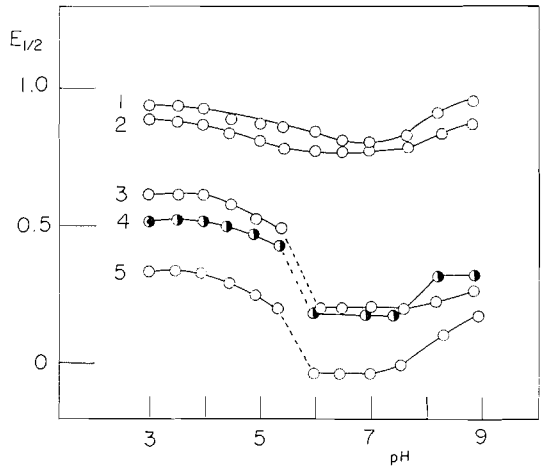

FIG. 4. Variation du potentiel de demi-vague $E_{1/2}$ (V) en fonction du pH (tampon Clark et Lubs). R = H (1), CH_3 (2), i-C_3H_7 (3), t-C_4H_9 (4), et C_6H_5 (5).

en tampon phosphate crée un glissement supplémentaire de 200–250 mV vers les potentiels plus positifs. Les potentiels de demi-vague sont alors à 50 mV près les mêmes qu'en tampon Mc Ilvaine au même pH.

Influence de la vitesse de balayage

Les courants maximum des oscillo-polarogrammes $i = f(E)$ qui ont été observés pour des vitesses de balayage de 0.5 à 20 V/s ont été étudiés en fonction de la racine carrée de la vitesse de balayage. Une relation linéaire est obtenue pour tous les méthoxyhydroperoxydes examinés (Fig. 5). D'après Delahay (19) et Matsuda et Ayabe (20) un tel comportement est caractéristique pour un courant de diffusion d'un processus irréversible

$$i_{max} = k_2 qn(\alpha n_a)^{1/2} CD^{1/2} v^{1/2} \quad (A)$$

Influence de la température

La dépendance de la température du courant maximum obtenu en polarographie en courant alternatif a été étudiée dans le domaine de 10 à 30 °C. Pour les méthoxyhydroperoxydes avec R = H et CH_3, les courants maximum sont pratiquement indépendants de la température. Pour les autres méthoxyhydroperoxydes examinés on observe un coefficient de température moyen de 1.8% par degré, valeur en accord avec celle donnée par Zuman (21) pour un courant contrôlé par diffusion.

Polarographie dans le méthanol–LiCl (M)

Dans ce milieu, l'électrode de référence utilisée

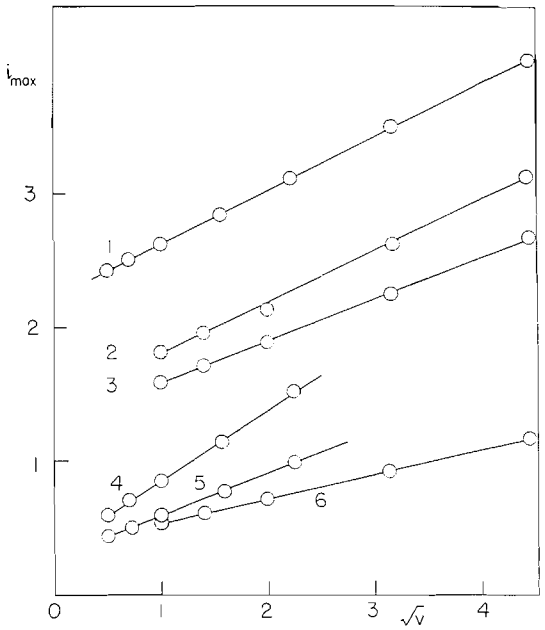

FIG. 5. Variation du courant maximum i_{max} (μA) en fonction de la racine carrée de la vitesse de balayage $(V\ s^{-1})^{1/2}$. R = C_2H_5 (1), H (2), CH_3 (3), n-C_3H_7 (4), i-C_3H_7 (5), et C_6H_5 (6). Les droites 2 et 3 ont été déplacées de 1 μA vers le haut, la droite 1 de 2 μA.

consistait en un fil d'argent plongé dans une solution d'électrolyte saturée en AgCl, séparée de la solution à analyser par un verre fritté fin. On observe, dans ces conditions, un potentiel de demi-vague de −1.54 V pour l'aldéhyde benzoïque; cette valeur est comparable à celle de −1.56 V (vs. calomel saturé) observée par Willits *et al.* (22) dans une solution 0.3 *M* de LiCl dans le benzène–méthanol (1:1). Les potentiels de demi-vague observés sont indiqués au Tableau I. On remarque leur confinement dans le domaine relativement restreint de −1.2 à −0.8 V, c'est-à-dire aux environs du potentiel obtenu dans l'eau pour les deux premiers termes (R = H et CH_3) de la série des méthoxyhydroperoxydes. Ces valeurs sont du même ordre que celles rapportée dans la littérature (4, 22) pour les hydroperoxydes. Ces observations semblent indiquer que la réduction des méthoxyhydroperoxydes avec R = H et R = CH_3 s'effectue dans l'eau selon un mécanisme proche de celui ayant lieu dans le méthanol, ou du mécanisme rapporté pour les hydroperoxydes dans l'eau et dans le méthanol. Les méthoxyhydroperoxydes supérieurs (R = C_2H_5, et les suivants) subiraient, par contre, des phénomènes additionnels dans l'eau, qui auraient

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

pour effet de déplacer les potentiels de demi-vague d'environ 600 mV vers les potentiels plus positifs.

Mécanisme proposé

L'ensemble des observations expérimentales exposées suggère le mécanisme de réaction suivant

Mécanisme A

$$R{-}CH(OCH_3){-}OOH + H^{\oplus} \rightleftharpoons R{-}CH(OOH){-}\overset{\oplus}{O}CH_3 \overset{2e^{\ominus}}{\longrightarrow} CH_3OH + R{-}CHO + OH^{\ominus}$$

Mécanisme B

[1] $$R{-}CH(OCH_3){-}OOH + 2e^{\ominus} \xrightarrow{k_e} R{-}CH(OCH_3){-}O^{\ominus} + HO^{\ominus}$$

[2] $$R{-}CH(OCH_3){-}O^{\ominus} + H^{\oplus} \longrightarrow R{-}CH(OCH_3){-}OH$$

[3] $$R{-}\overset{\overset{OCH_3}{|}}{CH}{-}O^{\ominus} \longrightarrow R{-}CHO + CH_3O^{\ominus}$$

[4] $$\overset{\overset{OCH_3}{|}}{R{-}CH{-}OH} + H^{\oplus} \longrightarrow \left[\overset{\overset{\oplus}{H}\overset{\oplus}{O}CH_3}{\underset{|}{R{-}CH}}{-}OH\right] \longrightarrow R{-}CHO + CH_3OH + H^{\oplus}$$

Le mécanisme A qui considère un transfert de proton précédant le transfert d'électron (ou des transferts simultanés) permet une explication de la dépendance des potentiels de demi-vague en fonction du pH, mais implique la formation de composé carbonylé à l'électrode. L'électrolyse à potentiel controllé a montré de façon certaine que pour R = H le composé carbonylé n'est pas libéré sous forme de H—CHO mais sous forme de son hémiacétal. L'ensemble des résultats, qui démontre la similarité de comportement des composés avec R = H et R = CH_3, paraît indiquer que la formation d'hémiacétal à l'électrode doive être envisagée également avec R = CH_3. Donc, pour R = H et R = CH_3, la réduction semble s'effectuer par les réactions [1] et [2] du mécanisme B. Ceci semble être corroboré par le fait que les potentiels de demi-vague et les courants limites sont indépendants du pH, dans la région de pH 3 à 8.

Les termes supérieurs (R = C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *t*-C_4H_9, et Ph), par contre, conduisent à la formation d'aldéhyde soit à la suite d'un processus d'électrode (A), soit en raison d'une hydrolyse très rapide des hémiacétals. Les mécanismes A et B (réactions [1] et [3] ou [1], [2], et [4]) doivent donc être envisagés. Il convient de souligner que l'irréversibilité des réactions étudiées (démontrée dans le présent travail) concerne le phénomène *global* de la réduction polarographique. Les données expérimentales ne permettent, cependant, pas de conclure à l'irreversibilité complète du processus d'électrode lui-même. Dans l'éventualité d'une quasi-réversibilité de la réaction d'électrode, les réactions subséquentes pourraient influencer les valeurs des $E_{1/2}$. Ainsi, pour ces méthoxyhydroperoxydes, le glissement de 600 mV vers des valeurs plus positives pourrait être attribué en partie à une hydrolyse de l'hémiacétal.

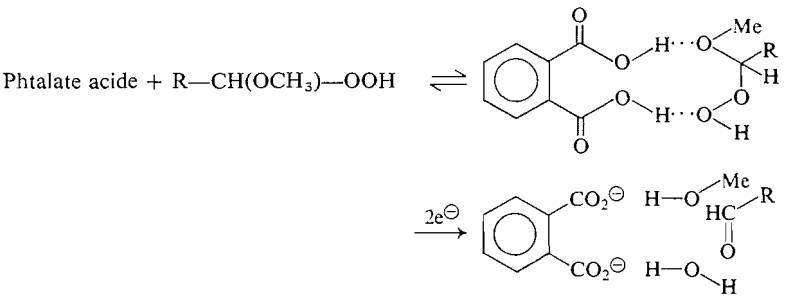
Les résultats précédemment exposés, qui concernent (dans le cas des méthoxyhydroperoxydes supérieurs) la dépendance des courants maximum exprimée en fonction de la température et de la vitesse de balayage, ont permis d'établir clairement l'intervention d'un courant contrôlé par diffusion. Cette observation est en accord avec la théorie des réactions de desactivation de l'espèce réduite consécutives au processus d'électrode (23).

L'effet particulier observé en tampon phtalate peut être expliqué soit par un effet de double couche, soit par une interaction phtalate–hydroperoxyde dans la solution. En l'absence d'autres exemples d'effet de double-couche créé par l'ion phtalate, la deuxième hypothèse semble devoir être retenue de préférence et pourrait être formulée comme suit, d'après une suggestion du Professeur Perrin[2].

Le déplacement des potentiels de demi-vague

[2]Nous tenons à remercier M. le Professeur C. L. Perrin pour cette suggestion, ainsi que pour ses suggestions et commentaires concernant le mécanisme proposé.

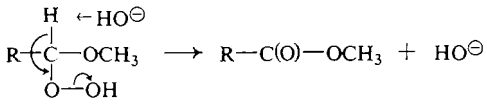
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



vers des valeurs plus négatives et la diminution de courant observés en milieu basique (tampon Borax–HCl) peuvent être interprétés en termes de réactions précédents le processus d'électrode, soit

$$R—CH(OCH_3)—OOH + HO^{\ominus} \rightleftharpoons R—CH(OCH_3)—OO^{\ominus} + H_2O$$

ainsi qu'il a été suggéré par Perrin (24), ou être dus à la décomposition baso-catalysée des méthoxyhydroperoxydes (25)



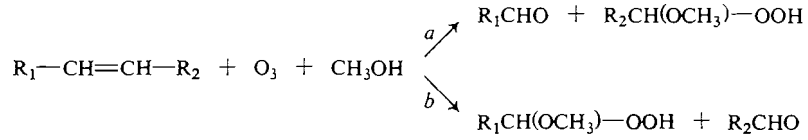
Application analytique

L'étude de l'influence des différents facteurs (pH, tampon, température) sur la position, la forme et l'intensité des pics polarographiques a déterminé le choix du tampon Mc Ilvaine pH = 7 comme électrolyte de support pour les applications analytiques du processus d'électrode étudié. L'étude de la réaction d'ozonolyse dans un solvant participant (CH_3OH) devant être le champ d'application de cette méthode, les conditions opératoires polarographiques devaient être adaptées aux conditions opératoires propres à l'étude de la réaction d'ozonolyse.

L'ozonation des oléfines dissymétriques en présence d'un solvant participant, dans le but de "trapper" les zwitterions de Criegee sous forme d'hydroperoxydes, est fréquemment effectuée dans le méthanol pur (11) ou dans un solvant inerte tel que le CCl_4 contenant une concentration adéquate de méthanol. En général, une concentration 1 *M* de méthanol suffit pour "trapper" quantitativement les zwitterions en les transformant en méthoxyhydroperoxydes (7). Cependant des études récentes (26) tendent à montrer que pour l'étude de certains zwitterions (notamment les zwitterions $R—\overset{+}{C}H—OO^-$ avec R = *i*-C_3H_7 ou *t*-C_4H_9) une concentration supérieure de méthanol (3 *M*) est préférable pour assurer la transformation quantitative des zwitterions en leur méthoxyhydroperoxydes correspondants, à 25 °C.

Il a été vérifié (*7a*) que les méthoxyhydroperoxydes engendrés lors des ozonolyses en présence de méthanol ne réagissent pas, à la température ambiante, avec les produits carbonylés également engendrés lors de l'ozonation. Des bilans d'ozonation ont permis de vérifier que l'ozonolyse, en présence de méthanol, d'une mole d'oléfine engendre 1 mole du mélange de méthoxyhydroperoxydes et 1 mole du mélange de produits carbonylés. Dès lors, l'analyse de ces derniers (notamment par spectroscopie i.r. et chromatographie en phase gazeuse (c.p.g.)) permets de déterminer (*7a*, *7c*) dans quelles proportions les 2 voies de clivage (*a* et *b*) sont suivies. L'analyse des produits carbonylés s'avérant parfois difficile, c'est par l'analyse polarographique des méthoxyhydroperoxydes que ces proportions de clivage (*a* et *b*) pourront être déterminées.

En raison de leur inmiscibilité avec l'eau, les solvants chlorés tels que le chloroforme ou le tétrachlorure de carbone ne peuvent être utilisés. L'acétate d'éthyle, décrit par Greenwood (27) comme étant un bon solvant d'ozonation et qui est miscible à l'eau dans la proportion de 1 ml



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

dans 25 ml d'eau, a été choisi en raison de ces propriétés.

Deux conditions opératoires ont été éxaminées: (*i*) pour des méthoxyhydroperoxydes en solution dans le méthanol et (*ii*) pour des solutions dans l'acétate d'éthyle – méthanol (3 *M*). Les concentrations en méthoxyhydroperoxydes étaient comprises entre 5×10^{-3} et 5×10^{-2} *M*. Ces concentrations sont obtenues par l'ozonation de solutions 0.1 *M* d'oléfine, à des degrés d'ozonation n'excédant pas 50%. Ces faibles degrés d'ozonation permettent de prévenir l'oxydation du solvant, ainsi que l'autoxydation accélérée par l'ozone des produits carbonylés engendrés par l'ozonolyse. En effet, le méthanol ozoné montre un pic polarographique à −1.14 V pouvant affecter la précision de la détermination des méthoxyhydroperoxydes avec R = H et R = CH_3.

En vue de l'analyse polarographique des solutions méthanoliques de méthoxyhydroperoxydes, 1 ml de solution est transféré dans 25 ml de tampon Mc Ilvaine pH = 7. Pour tous les méthoxyhydroperoxydes étudiés, le courant maximum observé est une fonction linéaire de la concentration en méthoxyhydroperoxyde, à 25° C (Fig. 6). La reproductibilité des mesures est alors excellente ($\Delta i_{max} \leqslant 1\%$). La largeur des pics est cependant assez importante. De ce fait la détermination simultanée de deux méthoxyhydroperoxydes des deux groupes, soit (*i*) avec R = H ou CH_3 et (*ii*) avec R = C_2H_5, *n*-C_3H_7, ou *t*-C_4H_9, est difficile (avec précision), voire même parfois impossible, selon les proportions relatives des deux méthoxyhydroperoxydes.

Pour l'analyse des solutions de méthoxyhydroperoxydes dans l'acétate d'éthyle – méthanol (3 *M*), 1 ml de solution est ajouté à 25 ml de tampon Mc Ilvaine pH = 7. Le courant maximum observé est directement proportionel à la concentration en dépolariseur (Fig. 7). La présence d'acétate d'éthyle apporte une modification intéressante aux phénomènes observés. Les potentiels de demi-vague sont déplacés vers des potentiels plus négatifs pour R = H, CH_3 et vers des potentiels lègérement plus positifs pour R = C_2H_5, *n*-C_3H_7, *i*-C_3H_7, et *t*-C_4H_9 (Tableau I). De plus, la largeur des pics est diminuée, de sorte que la détermination simultanée de deux

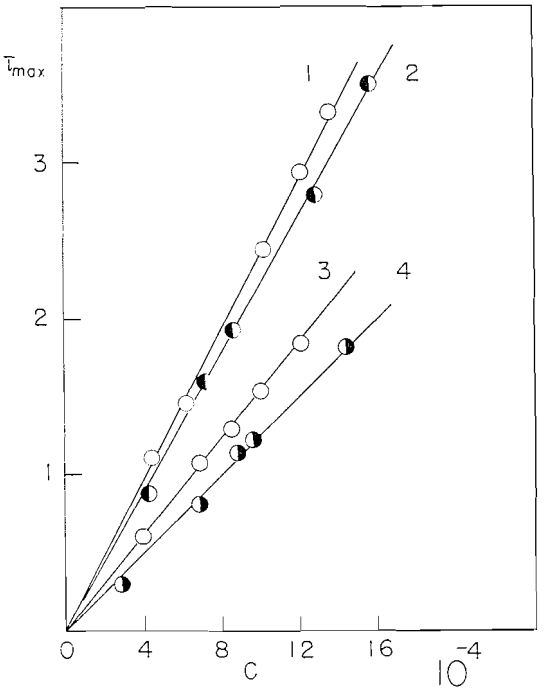

FIG. 6. Intensité des pics polarographiques (μA) vs. concentration *c* (*M*), dans le méthanol, des méthoxyhydroperoxydes. Tampon Mc Ilvaine, pH = 7; température, 25 ± 0.1 °C; R = C_2H_5 (1), *i*-C_3H_7 (2), H (3), et CH_3 (4).

TABLEAU II

Ozonolyse de 1 mmole de *trans* 4-méthylpentène-2, en solution (0.1 *M*) dans l'acétate d'éthyle – méthanol (3 *M*), à 25 °C

O actif mAtome	CH_3—$CH(OCH_3)OOH$ mmole	*i*-C_3H_7—$CH(OCH_3)OOH$ mmole	Hydroperox. total, mmole	% Clivage voie *a*		% Clivage voie *b*
				Méthode 1	Méthode 2	
0.250	0.172	0.074	0.246	69.0	70.0	29.6
0.335	0.240	0.086	0.326	71.6	73.6	26.0
0.420	0.300	0.126	0.426	71.4	70.4	30.0
0.430	0.310	0.120	0.430	72.0	72.1	28.0
0.495	0.350	0.138	0.488	70.8	71.7	28.0

méthoxyhydroperoxydes de chaque groupe devient possible. Dans ces conditions la reproductibilité des mesures est, cependant, plus difficile à atteindre que lors des expériences effectuées en absence d'acétate d'éthyle. Toutes les conditions expérimentales doivent être soigneusement contrôlées, notamment la température, la pureté des solvants (acétate d'éthyle et méthanol), le temps d'agitation (pour la solubilisation), ainsi que le temps de dégazage. Une reproductibilité satisfaisante ($\Delta i_{max} \leqslant 3\%$) peut être atteinte.

L'analyse polarographique des méthoxyhydroperoxydes a été appliquée à la détermination des proportions de clivage selon les deux voies possibles (*a* et *b*) dans le cas d'oléfines pour lesquelles les proportions de clivage avaient été déterminées d'après des dosages des composés carbonylés, effectués par c.p.g. et spectroscopie i.r. (*7a*, *7c*). Le Tableau II rapporte les résultats obtenus lors de l'ozonation du *trans* 4-méthylpentène-2 dans l'acétate d'éthyle – méthanol (3 *M*). On note, qu'aux erreurs expérimentales près, le nombre total de mmoles de méthoxyhydroperoxydes trouvés par voie polarographique correspond bien au dosage iodométrique de l'oxygène actif selon Lohaus (12), qui est une mesure de la quantité totale des hydroperoxydes.

La proportion de clivage selon la voie *a*, qui aboutit à la formation de CH_3—$CH(OCH_3)$—OOH et *i*-C_3H_7—CHO, a été calculée en rapportant la quantité de ce méthoxyhydroperoxyde formé à l'oxygène actif mesuré iodométriquement (méthode 1) et en rapportant la quantité de ce même méthoxyhydroperoxyde à la quantité totale des méthoxyhydroperoxydes formés, d'après leurs dosages polarographiques (méthode 2). Le pourcentage de clivage selon la voie *b*, conduisant à la formation de *i*-C_3H_7—$CH(OCH_3)$—OOH et CH_3CHO, a été calculé d'après le dosage polarographique de ce méthoxyhydroperoxyde, rapporté au dosage de l'oxygène actif. Ces résultats expérimentaux montrent bien que les voies *a* et *b* sont complémentaires. La valeur moyenne déterminée par voie polarographique pour la proportion de clivage selon la voie *a* ($71 \pm 1\%$) se compare bien avec la valeur de $73 \pm 4\%$ trouvée d'après des analyses spectroscopiques et par c.p.g.

Le Tableau III permet, pour quelques oléfines dissymétriques, la comparaison des résultats obtenus pour les proportions de clivage selon les deux voies possibles, ainsi qu'ils ont été obtenus par polarographie et par c.p.g., associée à la spectroscopie i.r.

TABLEAU III

Sens de clivage de quelques oléfines dissymétriques

La polarographie s'avère donc être une méthode satisfaisante pour le dosage des méthoxyhydroperoxydes et, en particulier, pour l'étude de la réaction d'ozonolyse en solvant participant.

Remerciements

Nous tenons à remercier MM. les Professeurs R. L. Benoît et M. Abraham pour toutes les facilités accordées lors de cette étude, ainsi que MM. M. Gauthier et P. Pichet pour leurs conseils. Nous remercions également le Conseil National de Recherches du Canada pour un octroi qui a permis la présente recherche.

Collisional deactivation of singlet methylene in the photolysis of ketene[1]

R. A. Cox[2] and K. F. Preston
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received March 7, 1969

An investigation has been made into the effect of inert gas additions on product quantum yields for the photolysis at 2800 and 2490 Å of mixtures of ketene and oxygen and for the photolysis at 2800 Å of mixtures of ketene and carbon monoxide. Concentration ratios of O_2 (or CO) to CH_2CO were chosen so that the reaction of $CH_2(^3\Sigma_g^-)$ with CH_2CO could be ignored and C_2H_4 formation could be attributed entirely to the reaction

$$CH_2(^1A_1) + CH_2CO \rightarrow C_2H_4 + CO\ (k_1)$$

Quenching of the C_2H_4 quantum yield by inert gases was interpreted in terms of collisional deactivation of $CH_2(^1A_1)$ to the ground state

$$CH_2(^1A_1) + M \rightarrow CH_2(^3\Sigma_g^-) + M\ (k_2)$$

and rate constant ratios k_2/k_1 have been determined for a number of gases: He (0.018), Ar (0.014), Kr (0.033), Xe (0.074), N_2 (0.052), N_2O (0.10), CF_4 (0.047), C_2F_6 (0.11), and SF_6 (0.045). It has been assumed that collision-induced intersystem crossover in excited singlet ketene makes an insignificant contribution to the observed quenching effects, but it has not been possible to verify this assumption experimentally. The mechanism of collision-induced electronic relaxation of singlet methylene is discussed in the light of the results.

Canadian Journal of Chemistry, 47, 3345 (1969)

Introduction

It is established (1–7) that the photolysis of ketene in the wavelength region 2500–3800 Å yields methylene both in the ground triplet state ($^3CH_2$) and in an electronically excited singlet state ($^1CH_2$). These states are believed to correspond to the $^3\Sigma_g^-$ and $^1A_1$ (in C_{2v}) methylene species observed spectroscopically by Herzberg and co-workers (8, 9) during the flash photolysis of diazomethane. It is generally held (1, 7, 10, 11) that the methylenes result from predissociation of excited singlet and triplet ketene molecules, the latter arising by way of intersystem crossover from the excited singlet. The proportion of singlet species in the methylene is determined by the competition between unimolecular dissociation and spin inversion of the excited singlet ketene, and would be expected to increase with increasing energy of excitation of the ketene molecule. This is in accord with the experimental finding (1–3, 5, 7) that the methylene is predominantly (although not entirely) singlet at short wavelengths of photolysis, but mainly triplet at long wavelengths. Since dissociation to methylene and carbon monoxide occurs via an excited molecule of finite lifetime, bimolecular reactions of the excited molecule are a possible complicating feature of studies of methylene reactions based on ketene photolysis as a source. However, the quantum yield of CO formation at short wavelengths shows little or no dependence (2, 12) on pressure or temperature, suggesting that bimolecular reactions of excited ketene molecules may be ignored for $\lambda < 2900$ Å. This is also suggested by the lack of effect (2, 7, 13) of pressure on the estimated relative yields of singlet and triplet methylene. Thus, photolysis of ketene at $\lambda < 2900$ Å approximates a "clean" source of methylene radicals which may be used to investigate the reactivity of singlet methylene when the ground state species is selectively removed by a triplet scavenger.

Two reagents, O_2 (14) and CO (2, 15), appear to be effective triplet methylene scavengers, O_2 being the less discriminating of the two on account of its high reactivity towards radicals and excited molecules in general. Very small additions of oxygen are sufficient to reduce the quantum yield of ethylene formation from the photolysis of ketene at $\lambda < 2900$ Å to a limiting value, approximately 0.65–0.70 which is unaffected by further addition of oxygen (2, 12), and which is close to some estimates (2, 13) of the quantum yield of singlet methylene production at short

For personal use only.

wavelengths. A plausible explanation of these facts and of the results of recent experiments (14) on the photolysis of mixtures of isotopically labeled ketene, olefins, and oxygen is that $^3CH_2$ reacts very much more rapidly with O_2 than with CH_2CO, but the reverse is true of $^1CH_2$. Since it is most unlikely that the products (14) of the reaction of triplet methylene with O_2 will react further with ketene to generate ethylene, the rate of ethylene production from the photolysis of ketene containing oxygen may be used as a measure of the stationary concentration of singlet methylene.

Recently it has been found (2, 15) that $^3CH_2$ reacts more rapidly with CO than with ketene or butene, whereas the reverse is true of $^1CH_2$. When CO is added in sufficient excess, the reactions of $^3CH_2$ in the photolysis of CH_2CO or CH_2CO/butene mixtures may be quenched so that essentially all the products are formed from the reactions of $^1CH_2$. This method of scavenging $^3CH_2$ is perhaps less disputable than the method using O_2, since CO, unlike O_2 (16), is probably inert towards excited ketene molecules.

An essential preliminary to the study of reactions of an electronically excited species which is metastable with respect to the transition to the ground state is the determination of the efficiencies with which molecules effect collisional relaxation of the electronic energy of excitation. Since Herzberg's (8) observation of collisional relaxation of the $^1A_1$ state of methylene to the $^3\Sigma_g^-$ state, several workers (17, 18) have employed inert gases as coolants to ensure the conversion of photolytically generated methylene to the ground state. Their observations of decreasing stereospecificity of addition of methylene to the C=C bond with increasing ratio of inert gas pressure to olefin pressure are consistent with collisional quenching of $^1CH_2$ to $^3CH_2$ by inert gases. However, the quantitative aspects of quenching of $^1CH_2$ have so far been ignored, largely because of uncertainties regarding the contributions of additional quenching processes (e.g. of excited ketene, excited product molecules) to the observed overall effect of added gases on reactions involving methylene. We believe that the photolysis of ketene at $\lambda < 2900$ Å is free of such complications and that in the presence of sufficient oxygen or carbon monoxide the quantum yield of ethylene may be equated with the yield of $^1CH_2$. Accordingly we have undertaken a study of the effects of inert gas additions upon the quantum yield of C_2H_4 formation from the photolysis of mixtures of CH_2CO and O_2 or CO in order to obtain quantitative rate data for the electronic relaxation of $^1CH_2$.

Experimental

Materials

Ketene was prepared and purified by well established techniques (1) and then stored at −196 °C. It contained CO_2 (< 0.01%) as the only detectable impurity. Gases condensable at −196 °C (Xe, SF_6, N_2O, CF_4, C_2F_6; all from Matheson of Canada, Ltd.) were thoroughly degassed at that temperature and distilled through a trap at −78 °C before use. The O_2 contents of cylinder CO (Matheson) and N_2 (Linde) were substantially reduced by passing the gases over hot copper turnings at ~400 °C; after this treatment the N_2 contained < 2 p.p.m. O_2 and the CO contained ~20 p.p.m. O_2. At this O_2 content the contribution of scavenging of $^3CH_2$ by O_2 in experiments using CO as a scavenger could be ignored for the conversions employed. The coincidence of results obtained using extremely pure CO (O_2 content 4 p.p.m.) with the results for the less pure CO confirmed this assumption. Research Grade Kr (Airco) and O_2 (Matheson) were used as such; He (Airco) and Ar (Linde) were taken from cylinders via drying tubes containing molecular sieve 13X.

Apparatus and Procedure

Photolyses were carried out at 27 ± 2 °C in a cylindrical quartz cell of 15 cm length and 306 cc volume, having plane end windows. The cell was connected by a stopcock to a conventional high vacuum apparatus for the preparation and handling of gas mixtures. The light source was an Osram HB200 super pressure Hg lamp coupled to a Bausch and Lomb high intensity monochromator which served to isolate spectral regions centered at 2490 and 2800 Å with a half bandwidth of 50 Å. An RCA 935 phototube was used to monitor the light beam after it had passed through the reaction cell and contents. The voltage drop resulting from passage of the photocurrent through a 10 KΩ resistor was fed directly to a millivolt pen recorder of high input impedance tolerance.

Before each run the reaction cell was evacuated to better than 10^{-4} mm Hg and ketene introduced to the required pressure. After condensing the ketene in a cold finger, O_2 was measured into the cell with the aid of a calibrated Pirani gauge. The mixture of ketene and oxygen was allowed to warm up and inert gas then added to a measured total pressure by expansion from a large storage bulb. A 20 min period proved quite adequate for thorough mixing at the highest total pressure used. The mixtures were normally irradiated for 60 min at 2490 Å and 15 – 30 min at 2800 Å resulting in ~0.2% and ~0.5% decomposition respectively. (Increasing the extent of decomposition to ~1% was without effect on the product quantum yields.) Light transmitted through the reaction cell was recorded continuously throughout each experiment. After irradiation the contents of the cell were allowed to mix for ~10 min. Samples for

For personal use only.

analysis were then taken by direct expansion from the reaction cell into the gas chromatography injection volume.

A thermistor detector and a flame ionization detector were used in conjunction for quantitative analysis of reaction products. Separation of C_2H_4 from other products and reactants was achieved with either a 12 ft column of Porapak Q or a 12 ft column of alumina deactivated with 2% squalane. C_2H_2 was satisfactorily separated from C_2H_4 on the latter column only. Analysis for CO on these columns was possible in the absence of O_2 and other permanent gases; in their presence an 8 ft column of molecular sieve 13X was used to separate CO. Analyses for each run were normally duplicated. The detectors were calibrated frequently with standard mixtures of CO in He, and C_2H_4 in He which were introduced to the sample volume in precisely the same manner as reaction mixtures. The flame ionization detector responses of C_2H_2, C_2H_4, and C_2H_6 were assumed to be identical.

Product quantum yields were based on the time-integrated value of light transmitted I_{trans} through a path length l of ketene at P_k mm Hg. The product $I_{trans} P_k$ was taken as the value of I_{abs} in arbitrary units since the relationship

$$I_{abs} = I_{trans}\, \varepsilon\, l\, P_k$$

held to a good approximation at the wavelengths and pressures used. Conversion of I_{abs} to absolute units was based on the assumption that $\Phi_{CO} = 2.0$ for the photolysis of pure ketene. In a few experiments a second quartz cell was placed in the path of light emerging from the main reaction vessel. Both cells were filled with an identical pressure of ketene, but additives were introduced to the main cell only. The second cell served as a chemical actinometer, CO yields being used to monitor I_{trans}. The overall uncertainty in the measured quantum yields of C_2H_4 and CO was estimated to be of the order of ±7%.

Results

(a) Photolysis of Ketene–Oxygen Mixtures at 2800 Å

Ketene containing a few per cent of oxygen and mixed with varying amounts of inert gas was irradiated at 2800 Å for 15–30 min and the product yields determined. Table I gives the quantum yields of ethylene $\Phi_{C_2H_4}$ and of other products (where measured) calculated from the integrated photometer readings for each run and an assumed value of $\Phi_{CO} = 2.0$ for the photolysis of ketene alone.

The photolysis of pure ketene was frequently carried out as a check on the photometer calibration. It was found that $\Phi_{C_2H_4}$ was consistently close to 0.94 (relative to $\Phi_{CO} = 2.0$) and that this quantum yield was independent of CH_2CO pressure in the range 10–30 mm Hg. Furthermore, the yield of CO per unit light absorbed (absolute

Φ_{CO} values were not determined) did not change appreciably, indicating that the primary dissociation yield from CH_2CO is essentially constant over that range of CH_2CO pressures. Minor products from the photolysis of pure ketene included C_2H_6 ($\Phi_{C_2H_6} \simeq 0.022$) and C_2H_2 ($\Phi_{C_2H_2} \simeq 0.017$) and traces of CH_4, C_3H_8, and C_3H_6.

Addition of oxygen to ketene caused a reduction (Table I) in $\Phi_{C_2H_4}$ from the photolysis to approximately 0.60 and an increase in Φ_{CO} to $\sim$ 3.0. The yields of C_2H_6 and C_2H_2 were reduced to trace amounts. CO_2, which was not formed in the absence of O_2, appeared among the products and its quantum yield was estimated at $\sim$ 0.5. Inert gas additions caused further reductions in $\Phi_{C_2H_4}$. These observations are in agreement with the results of earlier investigations (12, 14).

The final section of Table I shows the results obtained when a reference cell containing ketene only was used as an actinometer. Quantum yields obtained by this method were consistent with the values obtained when using the photometer.

(b) Photolysis of Ketene–Oxygen Mixtures at 2490 Å

The influence of inert gas additions on the quantum yield of C_2H_4 from the photolysis of CH_2CO–O_2 mixtures at 2490 Å was determined. Mixtures of CH_2CO ($\sim$ 25 mm Hg), O_2 ($\sim$ 1 mm Hg), and varying amounts of inert gas were irradiated for 60 min and the C_2H_4 yield measured. Quantum yields of C_2H_4 formation, $\Phi_{C_2H_4}$, were expressed in terms of arbitrary units of light flux. The results are summarized in Fig. 1 in the form of plots of $\Phi_{C_2H_4}{}^0 (\Phi_{C_2H_4})^{-1} - 1$ vs. the concentration ratio [M]/[ketene], where $\Phi_{C_2H_4}{}^0$ is the quantum yield of C_2H_4 formation in arbitrary units for [M] = 0. Frequent checks were made on the value of $\Phi_{C_2H_4}{}^0$ since the photometer arrangement was altered several times during the course of these experiments. It was shown (Table II) that $\Phi_{C_2H_4}{}^0$ was independent of oxygen pressure in the range 0.1–8 mm Hg.

With N_2O as an additive, extremely small amounts of N_2 were produced, but they were not measured quantitatively. For the other additives no additional products were detected with the analytical system used, and it is probable that, except for N_2O, no chemical reaction with the added gases occurred.

TABLE II

Quantum yields (arbitrary units) of C_2H_4 from the photolysis of $CH_2CO - O_2$ mixtures at 2490 Å and 27 °C

25.6	8.6	6.20

(c) Photolysis of Ketene – Carbon Monoxide Mixtures at 2800 Å

Table III gives the quantum yields of C_2H_4 and C_2H_6 formation from the photolysis at 2800 Å of various mixtures of ketene, carbon monoxide, and inert gases. Calculations of the quantum yields were based on the assumption that $\Phi_{CO} = 2.0$ for the photolysis of ketene alone. The reaction of $^3CH_2$ with CO is very slow (2) compared to reaction with O_2, necessitating the use of large [CO]/[CH_2CO] ratios to ensure the complete scavenging of $^3CH_2$. DeGraff and Kistiakowsky's results (2) suggest that a ratio of

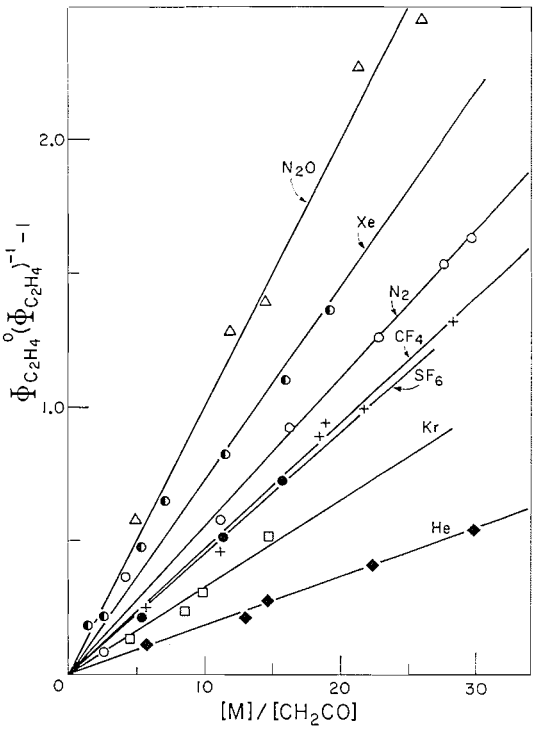

FIG. 1. Plot of $\Phi_{C_2H_4}{}^0 (\Phi_{C_2H_4})^{-1} - 1$ against concentration ratio [M]/[CH_2CO] for the 2490 Å photolysis of mixtures of CH_2CO, O_2, and various added gases, M.

†1.0 mm Hg O_2 added.

at least 4 is necessary to reduce the $^3CH_2$ contribution towards C_2H_4 formation to a negligible level in the photolysis of CH_2CO at 3130 Å. We have used a ratio of approximately 5 (CO = 50 mm Hg, CH_2CO = 10 mm Hg)[3] in examining the effect of inert gas additions on the photolysis at 2800 Å. The quantum yield of C_2H_6 formation (Table III, first section) for that ratio in the absence of additives indicates (2) almost complete removal of $^3CH_2$. Further confirmation of the complete suppression of the reaction of $^3CH_2$ with CH_2CO was provided by the observed lack of effect of O_2 on the value of $\Phi_{C_2H_4}$ for the photolysis of a $CH_2CO/CO/N_2$ mixture (Table III).

At the ratios of $[CO]/[CH_2CO]$ employed some reaction of $^1CH_2$ with CO was unavoidable. The decrease in $\Phi_{C_2H_4}$ with increasing $[CO]/[CH_2CO]$ ratio is a result of this reaction (Table III, first section).

(d) Photolysis of Ketene – Inert Gas Mixtures at 2800 Å

We have examined the effect of inert gas additions on Φ_{CO} and $\Phi_{C_2H_4}$ for the photolysis of CH_2CO at 2800 Å in the absence of $^3CH_2$ scavengers in order to ascertain the importance of the quenching by additives of the primary dissociation yield of CH_2CO. Other workers (2, 10) have shown that at 3130 and 2900 Å large inert gas additions cause only slight reductions in the dissociation yield. Our quantum yield measurements (Table IV) confirm these findings for 2800 Å. Similar results are to be expected for 2490 Å, where the lifetime of the excited ketene molecules is probably even shorter.

TABLE IV

Product quantum yields* for the photolysis of ketene at 2800 Å in the absence of $^3CH_2$ scavengers

Reactant pressures (mm Hg)		Quantum yields	
CH_2CO	M	C_2H_4	CO
11.0	97.0 (N_2)	0.923	nm

10.4	195.2 (")	0.857	1.90
10.8	253.2 (")	0.890	1.91

*Based on $\Phi_{CO} = 2.0$ for photolysis of CH_2CO alone, nm = not measured.

Discussion

The results presented above are readily interpreted in terms of the following simplified

[3]50 mm Hg CO in the reaction cell contained ~.03 μmole O_2; since conversions were such that the C_2H_4 yield was from 0.2–0.4 μmole, the observed quenching effects cannot be ascribed to O_2 in the CO.

reaction scheme for the photolysis of ketene at short wavelengths

$$CH_2CO + h\nu \rightarrow {}^1CH_2 + CO \qquad \phi_s I_a$$

$$\rightarrow {}^3CH_2 + CO \qquad \phi_t I_a$$

[1] $${}^1CH_2 + CH_2CO \rightarrow C_2H_4 + CO \qquad k_1$$

[2] $${}^1CH_2 + M \rightarrow {}^3CH_2 + M \qquad k_2$$

[3] $${}^3CH_2 + CH_2CO \rightarrow CO + C_2H_4, C_2H_6, C_2H_2, \text{etc.} \qquad k_3$$

where M is an inert additive, and ϕ_s and ϕ_t are the primary quantum yields of singlet and triplet methylene, respectively. We have chosen to ignore possible bimolecular reactions of excited ketene molecules, feeling, in view of the results outlined in (*d*) above, that excited molecules generated in the primary process are too short-lived to play a kinetically significant role in the photolysis. Corrections for the slight extent of the quenching of excited ketene that was observed will be considered later. We have also assumed, following other workers (2, 7, 10), that intersystem crossing in excited ketene, which leads to ${}^3CH_2$ formation, is a first order process and is not collision-induced. These two assumptions are equivalent to the postulate that ϕ_s and ϕ_t are pressure independent.

Under conditions where ${}^3CH_2$ is entirely scavenged by the reaction with O_2 (14)

$${}^3CH_2 + O_2 \rightarrow CO, CO_2, H_2, \text{etc.}$$

which we assume does not generate C_2H_4, the quantum yield of C_2H_4 formation for a steady state in the above elementary reactions is given by

$$[i] \qquad \Phi_{C_2H_4}{}^{-1} = \phi_s{}^{-1}\left(1 + \frac{k_2[M]}{k_1[CH_2CO]}\right)$$

This relation may be alternatively expressed in terms of $\Phi_{C_2H_4}{}^0$, the ethylene quantum yield in the absence of inert additives, and relative quantum yield data may be used to test the resulting expression

$$[ii] \qquad \Phi_{C_2H_4}{}^0(\Phi_{C_2H_4})^{-1} - 1 = k_2[M]/k_1[CH_2CO]$$

Figure 1 shows that [*ii*] is obeyed by the quantum yield data (arbitrary units) obtained for the photolysis of CH_2CO–O_2 mixtures at 2490 Å. Reciprocal quantum yields of ethylene formation taken from Table I have been plotted against [M]/[CH_2CO] (Fig. 2) and the resulting plots are linear, in accordance with [*i*]. Values of ϕ_s and k_2/k_1 derived from the slopes and intercepts in Fig. 2 and values of k_2/k_1 obtained from the slopes in Fig. 1 are summarized in Table V.

To account for the influence of CO on ketene photolysis we incorporate the reactions

[4] $${}^1CH_2 + CO \rightarrow CH_2CO \qquad k_4$$

[5] $${}^3CH_2 + CO \rightarrow CH_2CO \qquad k_5$$

into the scheme given above. Total pressures used

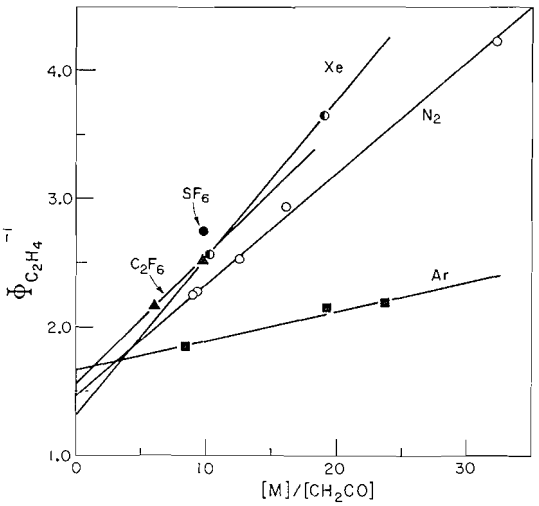

FIG. 2. Plot of reciprocal quantum yield of ethylene from the 2800 Å photolysis of mixtures of CH_2CO, O_2, and additive M against concentration ratio [M]/[CH_2CO].

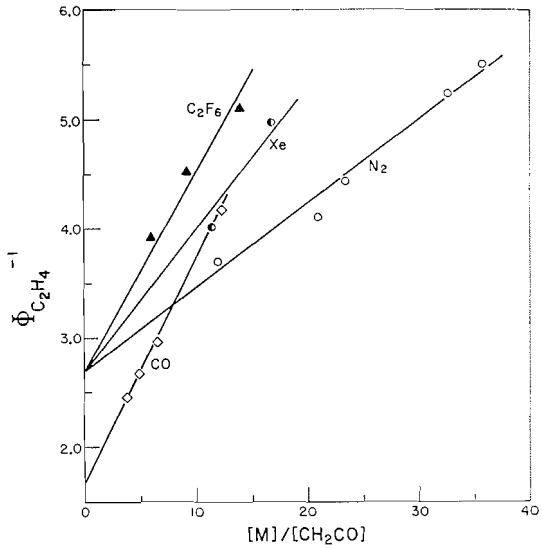

FIG. 3. Dependence of inverse quantum yield of ethylene from the 2800 Å photolysis of mixtures of CH_2CO and CO on the concentration ratios [CO]/[CH_2CO] and [M]/[CH_2CO], where M is an inert additive.

in our experiments were sufficiently high (2) to ensure complete stabilization of the ketene formed in these association reactions. Application of the steady state approximation to the scheme [1]–[5], under conditions where CO is in sufficient excess to eliminate C_2H_4 formation from $^3CH_2$, leads to the following expression

$$[iii] \quad \Phi_{C_2H_4}{}^{-1} = \phi_s{}^{-1}\left\{1 + \frac{k_4[CO]}{k_1[CH_2CO]} + \frac{k_2[M]}{k_1[CH_2CO]}\right\}$$

where k_4 includes a possible contribution from quenching of $^1CH_2$ to $^3CH_2$ by CO. Figure 3 shows that the data of Table III fit the expression [*iii*] satisfactorily. A plot of $\Phi_{C_2H_4}{}^{-1}$ against [CO]/[CH_2CO] at [M] = 0 is linear and from the slope and intercept we obtain $\phi_s = 0.60 \pm 0.02$, $k_4/k_1 = 0.121 \pm 0.005$, in excellent agreement with DeGraff and Kistiakowsky's values (2) for 2900 Å of 0.60 ± 0.03 and 0.12 ± 0.01. Plots of $\Phi_{C_2H_4}{}^{-1}$ against [M]/[CH_2CO] at a fixed [CO]/[CH_2CO] ratio of 5.0 are also linear; values of k_2/k_1 derived from the least squares slopes of the lines and the value $\phi_s = 0.60$ are given in Table V.

The slight reductions in Φ_{CO} and $\Phi_{C_2H_4}$ values (Table IV) caused by inert gas additions to ketene containing no $^3CH_2$ scavenger are suggestive of a small extent of quenching of excited ketene molecules. Assuming (10) that this quenching process does not affect the ratio of singlet to triplet methylene production, the quantum yield $\phi_s{}^M$ of $^1CH_2$ in the presence of additive M is related to the quantum yield ϕ_s in the absence of M by

$$[iv] \quad \phi_s{}^M = \phi_s(\Phi_{CO}{}^M/\Phi_{CO}), \text{ with } \Phi_{CO} = 2.0$$

$\phi_s{}^M$ replaces ϕ_s in expressions [*i*]–[*iii*] above and $\Phi_{CO}{}^M/\Phi_{CO}$ becomes a correction factor to be applied to the $\Phi_{C_2H_4}$ values obtained for photolyses of ketene containing a scavenger of $^3CH_2$. However, the results of Table IV show that even at large pressures of C_2F_6 and Xe the departure of Φ_{CO} from 2.0 is barely significant; at the outside the correction would result in a 10% reduction in the k_2/k_1 values given in Table V. For N_2 additions, analytical difficulties prevented the measurement of CO yields; $\Phi_{C_2H_4}$ values (Table IV) were measured, but these give unreliable indications of variations in the dissociation yield since quenching of $^1CH_2$ to $^3CH_2$ by the additive, even in the absence of a $^3CH_2$ scavenger, contributes to a reduction in the yield of C_2H_4.

Although we favor deactivation of $^1CH_2$ rather than a collision-induced intersystem crossover in excited singlet ketene

$$[6] \quad M + {}^1CH_2CO \rightarrow M + {}^3CH_2CO \rightarrow {}^3CH_2 + CO$$

as the explanation of quenching of ethylene

quantum yields by inert additives, we cannot exclude the latter possibility on the basis of our results alone. Our preference was dictated by the findings and suggestions of other workers (2, 7, 10, 13). If [6] were responsible for quenching, the observed linear dependence of $\Phi_{C_2H_4}^{-1}$ on $[M]/[CH_2CO]$ rather than on $[M]$ would require the introduction into the scheme of a reaction of excited ketene with ground state ketene

[7] $$^1CH_2CO + CH_2CO \rightarrow C_2H_4 + 2CO$$

We have adopted the extreme viewpoint that deactivation of excited ketene molecules makes no contribution to the observed quenching effects of inert gases. While this hypothesis is in keeping with existing experimental evidence, we should stress that it is by no means proved. Strictly, our k_2/k_1 comprises unresolved contributions from reactions of both $^1CH_2$ and $^1CH_2CO$.

Relaxation of the $^1A_1$ state of CH_2 to the ground $^3\Sigma_g^-$ state involves a considerable alteration in electronic structure and presumably occurs efficiently only in the neighborhood of points of intersection or near intersection of singlet and triplet potential energy curves. Theoretical curves for the potential energies of the $^1A_1$ and $^3\Sigma_g^-$ states as functions of the $H\hat{C}H$ bond angle exhibit such a crossing point (19). Since the carbon atom Hamiltonian contains a finite spin–orbit interaction term, the possibility arises of a finite relaxation rate of $^1CH_2$ even in the absence of perturbing collisions.

On the basis of Jordan and Longuet-Higgins' (19) theoretical computations, Bader and Generosa (18) estimate that the crossing point is in the region of the $n = 1$ level of the bending mode of vibration of CH_2 ($^1A_1$), and that for this level the first-order rate constant for electronic crossover is as high as 10^{11} s^{-1}. Since this rate constant will decrease with increasing energy content in the bending mode, they suggest that inert gases promote intersystem crossover through vibrational relaxation of $^1CH_2$ which is vibrationally "hot" when generated photochemically. As evidence for this they offer the order of deactivation efficiencies,

$$CF_4 > N_2, Xe$$

for quenching of $^1CH_2$, deduced by them from experiments on the effect of additives on product yields for the reaction of $^1CH_2$ with *cis*-butene-2. Although we feel that the estimate of Bader and Generosa for the first-order rate constant for crossover is probably much too large[4], we cannot entirely dismiss their explanation of quenching of $^1CH_2$ by added gases on the basis of our results. Certainly we find (Table V) that the polyatomics CF_4, C_2F_6, and SF_6, which should effect rapid vibrational relaxation, all quench efficiently. However, the order of deactivation efficiencies for the monatomic gases (Table V) is the inverse of what one would expect for a simple interchange of vibrational and translational energy. In fact, according to our results, Xe is somewhat more effective in relaxing $^1CH_2$ than CF_4 or SF_6. This indicates that spin inversion may occur via a complex between CH_2 and the inert gas molecule in which the latter contributes to the spin–orbit perturbation necessary for mixing of singlet and triplet states. Large spin–orbit forces present in the collision partner are not the only requisite for rapid electronic relaxation in this case; a large attractive interaction between excited species and quenching molecule is also essential. This is clearly seen from the relative rate data (20) for quenching of O ($^1D_2$) to the ground state, a relaxation process which is believed to proceed through complex formation and potential curve crossing; N_2 and CO_2 deactivate O ($^1D_2$) much more rapidly than Kr in spite of the large spin–orbit coupling constant of the latter. The difference is presumably due to the ability of CO_2 and N_2 to form strongly bound complexes, CO_3 and N_2O, with the excited oxygen atom. The surprisingly large efficiencies of CF_4, C_2F_6, and SF_6 for quenching $^1CH_2$ may then simply reflect a tendency for methylene to complex with the peripheral fluorine atoms in these molecules, a tendency which is in fact not shown by the O ($^1D_2$) atom.

Experiments with N_2O as an additive were undertaken in the hope that N_2 formation could be used to monitor $^1CH_2$ concentrations. The N_2 yield was in fact found to be a very small fraction of the total loss of $^1CH_2$ in reaction with and deactivation by N_2O. Nevertheless, trends

[4]A referee of this paper, Professor G. B. Kistiakowsky, has drawn our attention to the incompleteness of Bader's original argument: fast, first-order crossing processes, being *reversible*, would result in the rapid establishment of an approximately 1:3 equilibrium ratio of singlet:triplet methylene. If such were the case, the observed rates of electronic relaxation would be largely determined by the relative rates of vibrational quenching of singlet and triplet methylene *below* the energy of the crossing point.

in N_2 quantum yields observed[5] for the photolysis of mixtures of CH_2CO, N_2O, and inert additive were completely consistent with the deactivation rate data of Table V.

Our rate constant ratios k_2/k_1 agree reasonably well with the few values which have previously been determined (2) and with values which may be estimated from data in the literature (21, 22). Voisey, in a recent study (23) of the reaction of methylene with methyl ethyl ether, has estimated that the efficiencies of C_3F_8, N_2, and Ar for quenching $^1CH_2$ are in the ratio 1.00:0.42:0.29. This order of deactivation efficiencies is consistent with our data, although we find an appreciably higher efficiency for N_2 relative to Ar.

Oxidation of formaldehyde by copper(II) in aqueous solution

J. J. Byerley and W. K. Teo
Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario
Received August 26, 1968

Copper(II) was found to oxidize formaldehyde in aqueous solutions according to the following reaction

$$2Cu(II) + HCHO + H_2O \rightarrow 2Cu(I) + HCOOH + 2H^+$$

Rates were determined at temperatures between 130 and 166.5 °C. The rate law was found to be of the form

$$\frac{-\,dCu(II)}{dt} = k_1[Cu(II)][HCHO] + k_2\frac{[Cu(II)][HCHO]}{[H^+]}$$

where $k_1 = 1.9 \times 10^{-4}\ M^{-1}\ s^{-1}$ and $k_2 = 2.05 \times 10^{-8}\ s^{-1}$ in 0.125 M acetate solutions at 160 °C. The apparent activation energy is 33 600 cal/mole. The reaction mechanism suggested includes the formation of two bridged intermediates

$$\left(\begin{array}{c} H \\ | \\ Cu—O—CH_2OH \end{array}\right)^{2+} \text{ and } (Cu—O—CH_2OH)^+$$

which account for the acid-dependent and acid-independent reaction paths.

Canadian Journal of Chemistry, 47, 3355 (1969)

Introduction

Aliphatic as well as aromatic aldehydes are readily oxidized in aqueous solution by metal ions and complex metal ions. Among the many reactions of this type which have been reported, the oxidation of formaldehyde by metal ions has received considerable attention. In aqueous solution, formaldehyde under controlled conditions may be converted to formic acid. Under more energetic conditions the oxidation may proceed to completion yielding carbon dioxide. In many cases the final oxidation states of the metal ions involved in the processes are rather unpredictable.

Kinetic and mechanistic data have been reported for the oxidation of formaldehyde by chromium(VI) (1, 2), cerium(IV) (3), vanadium(V) (2), and cobalt(III) (4, 5) in acid solutions. In all cases the reactions were found to be first-order with respect to metal ion and formaldehyde concentrations. On the other hand the acid dependence for these reactions showed little similarity; for example, oxidation by chromium(VI) was second-order with respect to hydrogen ion concentration whereas an inverse dependence was reported for oxidation by cobalt(III).

In general, formaldehyde is more reactive in alkaline solutions, a conclusion that is easily verified by comparing the oxidation potentials for the half cell reaction in alkaline solutions with that in acid media (6). In basic solutions a number of metals including silver, bismuth, copper, mercury, nickel, and gold (7) may be precipitated when subjected to formaldehyde although no detailed kinetic information is available for these reactions.

It is significant that in acid solutions very few examples of oxidation accompanied by metal precipitation have been reported. Generally the reactions result in metal ions of intermediate oxidation states, examples of which have been cited earlier. Gold and platinum apparently are precipitated from their chlorides even in strong acid solutions (8). Copper sulfate is reported (9) not to oxidize formaldehyde even on prolonged heating at 100 °C. In contrast, cupric ions (10) and cuprous oxide (11) are reported to oxidize formaldehyde in alkaline solutions with the evolution of hydrogen.

[1] $2Cu(II) + 2HCHO(aq) + 4OH^- \rightarrow 2Cu^0 + H_2 + 2H_2O + 2HCO_2^-$

[2] $2Cu_2O + 2HCHO(aq) + 2OH^- \rightarrow 2Cu^0 + H_2 + 2HCOO^- + H_2O$

The present paper describes a kinetic and mechanistic investigation of the oxidation of formaldehyde by copper(II) in acetate solutions above 100 °C where reactivity is observed.

Experimental

Materials

All chemicals were reagent grade and used without further purification. Cupric perchlorate stock solutions were prepared by dissolving cupric oxide in perchloric acid and standardizing using EDTA with murexide as indicator. Stock solutions of formaldehyde were prepared by dissolving in water gaseous formaldehyde obtained by heating paraformaldehyde. Concentrations of formaldehyde were established using the sodium sulfite and chromotropic acid methods.

Kinetic Measurements

The kinetic data for the oxidation of formaldehyde by copper(II) were obtained by continuously recording the decrease in optical density of copper(II)–formaldehyde solutions as the cupric ion (absorption peak approximately 7500 Å) was reduced to the colorless cuprous species. Since measurable rates could only be obtained well above 100 °C, a titanium vessel equipped for pressurization was required. This vessel fitted directly into the sample compartment of a Bausch and Lomb Spectronic 505 recording spectrophotometer. The cell used quartz windows and was capable of continuous operation up to 200 °C.

Experimental Procedure

The spectrophotometer was first balanced at zero absorbance with the reaction and reference compartments filled with distilled water. The water in the sample compartment was then replaced by the solution to be studied. Both compartments were closed and pressurized with nitrogen. The vessel was then inserted into a preheated aluminum block and the entire assembly placed in the spectrophotometer. The desired reaction temperature (generally 160 °C) and temperature control (±0.3 °C) were achieved within 7 min. The interval of 7 min during which a record of the reaction progress could not be observed introduced little error into the kinetic data because the reaction is a relatively slow process. Any errors in establishing initial absorbance were overcome by eliminating the formaldehyde from the system and measuring the absorbance of the blank at the reaction temperature.

Experimental Results

Measurable rates of oxidation of formaldehyde by copper(II) were obtained above 160 °C at pH ranging from 4.2 to 5.0. At lower pH the reaction rates were very slow while at pH above 5.0 the reaction was complicated by hydrolysis of cupric acetate with the formation of blue basic cupric salts. These solids interfered with the spectrophotometric analysis.

Under experimental conditions the oxidation product of formaldehyde was identified as formic acid[1], the blue cupric ions being reduced to colorless cuprous species. In the absence of any strong stabilizing ligand in the system, such as in the formation of a cuprous carbonyl (12), the cuprous ion may undergo further reduction to metallic copper or hydrolyze to cuprous oxide. Disproportionation of the cuprous ion was not observed.

The oxidation of formaldehyde in acid media given by Latimer (6) in terms of a half-cell reaction suggests the following stoichiometry for the oxidation of formaldehyde by cupric ion.

$$[3]\quad 2Cu(II) + HCHO + H_2O \rightarrow 2Cu(I) + HCOOH + 2H^+$$

An effort was made to verify reaction [3] by measuring the ratio of cupric ion consumed to the amount of formic acid generated. Data taken from an experiment of this type[2] are given in Table I. As noted in table, a sample taken very early in the reaction period results in the ratio of cupric ion consumed to formic acid generated being approximately 2:1. Samples taken later in the reaction exhibited a tendency for the formic acid concentration to be progressively in excess of the apparent stoichiometric quantity. This behavior was observed repeatedly over a wide range of experimental conditions. The presence of excess formic acid over that required by a stoichiometry described by reaction [3] was attributed to another formic acid generating reaction, the further reduction of cuprous ion to metallic copper

$$[4]\quad 2Cu(I) + HCHO + H_2O \rightarrow 2Cu^0 + HCOOH + 2H^+$$

Although no attempt was made to examine reaction [4], a reddish precipitate was always found on the walls of the vessel after completion of an experiment. This precipitate was identified as a mixture of metallic copper and cuprous oxide.

The reactivity of formic acid towards cupric ion was tested and was found to be equivalent to formaldehyde. Since all kinetic measurements were carried out in excess formaldehyde (the formaldehyde concentration was always at least 60 times greater than the formic acid concentration) any contribution from formic acid oxidation was negligible.

The possibility of formation of carbon dioxide

[1]Formic acid was determined by the mercuric chloride and chromatographic methods.

[2]Stoichiometry measurements were carried out in a 100 ml shaking autoclave.

TABLE I

Oxidation* stoichiometry

Time (min)	[Cu(II)] × 10^3M consumed	[HCOOH] × 10^3M generated	[HCOOH] × 10^3M, reaction [3]	Excess [HCOOH] %
10	1.29	0.78	0.65	20
60	5.49	4.19	2.97	41
120	8.13	6.58	4.17	58

*Conditions: 0.0092 *M* Cu(II), 0.3 *M* HCHO, 0.25 *M* NaOAc, 0.125 *M* HOAc, temperature, 160 °C.

as the final oxidation product was investigated. This reaction, which is the sum of the oxidation reactions of formaldehyde and formic acid, may be expressed as

[5] $4Cu(II) + HCHO + H_2O \rightarrow 4Cu(I) + CO_2 + 4H^+$

Under this condition formic acid would appear only as an intermediate product. Results using a pressure sensitive autoclave system (13) indicated no gas evolution during the reaction nor did chromatographic analysis detect any gaseous products.

Kinetic data were obtained under a variety of initial conditions ranging from 0.01 to 0.001 *M* cupric ion, 0.1 to 0.8 *M* formaldehyde, pH 4.2 to 5.0, and temperature 130 to 166.5 °C. The dependence of the oxidation rate on copper(II) concentration is shown in Fig. 1. These standard logarithmic plots are diagnostic of a first-order reaction with respect to copper(II) i.e.

$$[6] \qquad \frac{-d[Cu(II)]}{dt} = k'[Cu(II)]$$

The effect of formaldehyde concentration is also shown in Fig. 1. When the rate constant k' is determined for each formaldehyde level and plotted vs. the corresponding formaldehyde

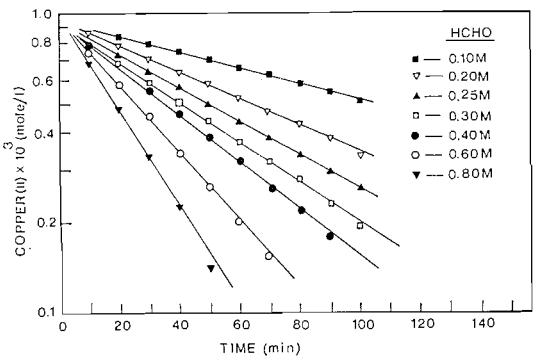

FIG. 1. First-order rate plots at different formaldehyde concentrations: 0.0092 *M* Cu(II), 0.125 *M* NaOAc, 0.25 *M* HOAc; temperature, 160 °C.

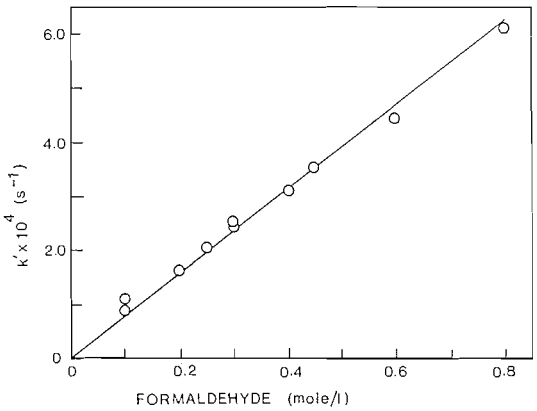

FIG. 2. Effect of formaldehyde concentration on k': 0.0092 *M* Cu(II), 0.125 *M* NaOAc, 0.25 *M* HOAc; temperature, 160 °C.

concentration, the linear relationship shown in Fig. 2 is obtained. The reaction is therefore first-order with respect to formaldehyde concentration with k' being defined in terms of a new rate constant k, given by

$$[7] \qquad k' = k[HCHO]$$

The effect of pH was examined using various acetic acid concentrations while maintaining the sodium acetate level constant. Plots of k vs. the reciprocal of acetic acid at 3 concentrations of sodium acetate are shown[3] in Fig. 3. The result is a set of straight lines with a non-zero intercept. This non zero intercept indicates an acid-independent contribution to the overall reaction rate which may be expressed by a new set of rate constants

$$[8] \qquad k = k_1 + k_2'/[HOAc]$$

[3]The rather sparse and compressed data especially at high pH are the result of the limited pH range available before the onset of complicating reactions such as the hydrolysis of cupric acetate and precipitation of basic cupric salts when heated to the reaction temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

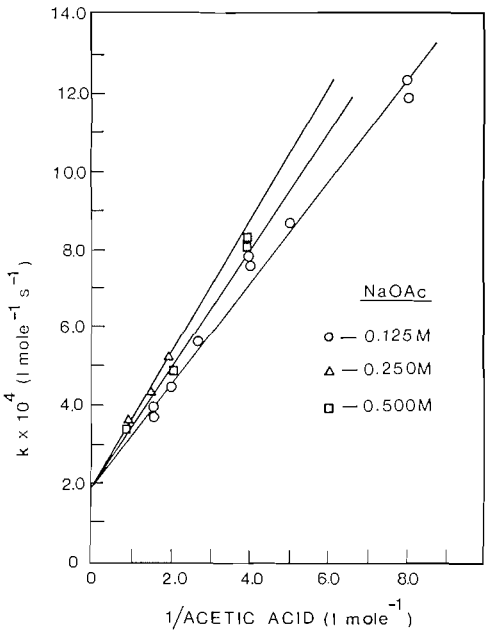

FIG. 3. Dependence of k on 1/[HOAc]: 0.0092 M Cu(II), 0.3 M HCHO; temperature, 160 °C.

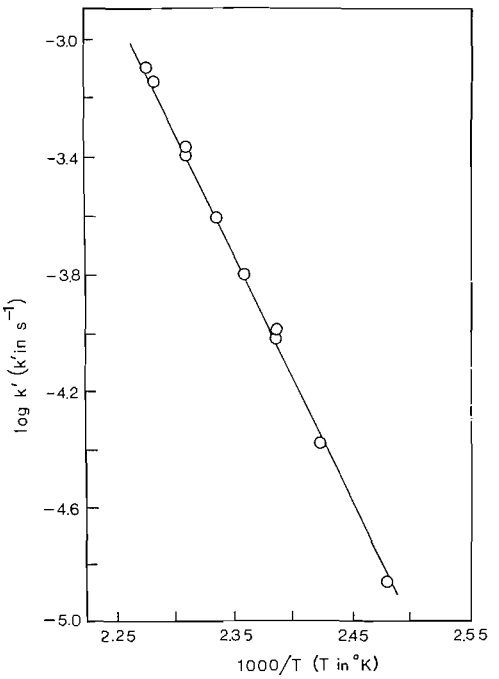

FIG. 4. Arrhenius plot for the oxidation of formaldehyde by copper(II): 0.0092 M Cu(II), 0.125 M NaOAc, 0.25 M HOAc, 0.6 M HCHO.

The hydrogen ion concentration is directly proportional to the acetic acid concentration given by

$$[9] \qquad [H^+] = K_i[HOAc]/[OAc^-]$$

where K_i is the ionization constant of acetic acid and $[OAc^-]$ is assumed to be the total acetate concentration. Using the relationship given in eq. [9] the rate law may be rewritten to include the acid-independent component and the ionization constant K_i

$$[10] \qquad \frac{-d[Cu(II)]}{dt} = k_1[Cu(II)][HCHO] + k_2\frac{[Cu(II)][HCHO]}{[H^+]}$$

where k_2 includes the ionization constant K_i (taking K_i as 1.75×10^{-5}), $k_1 = 1.9 \times 10^{-4}$ $M^{-1}s^{-1} \pm 10\%$, $k_2 = 2.05 \times 10^{-8} M^{-1} \pm 15\%$; conditions: 0.125 M NaOAc, 160 °C.

Although it is clear that the effect of sodium acetate concentration on the reaction rate is directly related to the hydrogen ion concentration through the buffer system, there still remains the question of complexing. Figure 4 may be used to illustrate the inhibiting effect of increasing acetate complexing which has been observed earlier (12, 13) by selecting a point on each line of equivalent [NaOAc]/[HOAc] ratio. Under these conditions the pH is nearly constant and the rate constant is seen to decrease with increasing acetate ligand. No attempt was made to study the effect further and therefore the complexing variable is contained in k_1 and k_2.

Experiments to investigate the effect of temperature on reaction rate produced limited information due to the lack of high temperature equilibrium constant data. Although both k_1 and k_2 were evaluated as functions of temperature the data was not acceptable since the temperature dependence of K_i could not be included in the rate constant calculations. An overall activation energy was obtained using the rate constant k' as defined by eq. [6]. From the Arrhenius plot shown in Fig. 4 an experimental activation energy of 33.6 ± 3.0 kcal/mole was estimated.

Reaction Mechanism

A reaction mechanism which is consistent with the experimental rate law given by eq. [9] may be postulated. This mechanism defines two parallel

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reaction paths for the oxidation of formaldehyde by copper(II). The reaction sequence may be represented as follows (reaction [11])

(*i*) *Path A*

$$[11a]\quad Cu(II) + HCHO + H_2O \underset{}{\overset{K_a}{\rightleftarrows}} [Cu{-}O{-}CH_2OH]^+ + H^+$$

$$[11b]\quad [Cu{-}O{-}CH_2OH]^+ \overset{k_a}{\rightarrow} Cu(I) + \cdot OCH_2OH$$

$$[11c]\quad Cu(II) + \cdot OCH_2OH \overset{\text{fast}}{\rightarrow} Cu(I) + HCOOH + H^+$$

(*ii*) *Path B*

$$[11d]\quad Cu(II) + HCHO + H_2O \overset{K_b}{\rightleftarrows} \left(\begin{matrix} H \\ | \\ Cu{-}O{-}CH_2OH \end{matrix}\right)^{2+}$$

$$[11e]\quad \left(\begin{matrix} H \\ | \\ Cu{-}O{-}CH_2OH \end{matrix}\right)^{2+} \overset{k_b}{\rightarrow} Cu(I) + H^+\dot{O}CH_2OH$$

$$[11f]\quad H^+\dot{O}CH_2OH \overset{\text{fast}}{\rightarrow} \cdot OCH_2OH + H^+$$

$$[11g]\quad Cu(II) + \cdot OCH_2OH \overset{\text{fast}}{\rightarrow} Cu(I) + HCOOH + H^+$$

The rate law derived from this reaction mechanism corresponds to

$$[12]\quad \frac{-d[Cu(II)]}{dt} = k_bK_b[Cu(II)][HCHO] + k_aK_a\frac{[Cu(II)][HCHO]}{[H^+]}$$

Equation [12] is identical to eq. [10] if

$$k_aK_a = k_2 \quad \text{and} \quad k_bK_b = k_1$$

The proposed mechanism is based on the formation of two bridged complexes as reaction intermediates

$$(Cu{-}O{-}CH_2OH)^+ \quad \text{and} \quad \left(\begin{matrix} H \\ | \\ Cu{-}O{-}CH_2OH \end{matrix}\right)^{2+}$$

The former gives rise to a pH-dependent reaction path while the latter results in a pH-independent reaction path. The second term of the rate equation accounts for more than 70% of the overall reaction rate. This would indicate that

$$(Cu{-}O{-}CH_2OH)^+$$

is more reactive than

$$\left(\begin{matrix} H \\ | \\ Cu{-}O{-}CH_2OH \end{matrix}\right)^{2+}$$

a not unexpected result in view of the difference in charge on the two species.

There are many examples of bridged complexes proposed as intermediate in reaction mechanisms describing metal ion oxidation of aldehydes. In the case of the oxidation of benzaldehyde by chromic acid (14) an ester formation mechanism has been suggested

$$[13]\quad \begin{matrix} H \\ | \\ R{-}C{=}O \end{matrix} + H_2CrO_4 \rightleftarrows \begin{matrix} OH \\ | \\ R{-}C{-}OCrO_3H \\ | \\ H \end{matrix}$$

A similar bridged intermediate

$$\begin{matrix} OH \\ | \\ C_6H_5{-}C{-}OMnO_3 \\ | \\ H \end{matrix}$$

has been postulated for the oxidation of aromatic aldehydes by permanganate ions in acid and neutral solutions (15). The oxidation of formaldehyde by cobaltic ion is said to proceed through the formation of two bridged intermediates (4, 5, 16)

$$(Co{-}O{-}CH_2OH)^+ \quad \text{and} \quad \left(\begin{matrix} H \\ | \\ Co{-}O{-}CH_2OH \end{matrix}\right)^{2+}$$

These species which are analogous to those presented in this work account for the observed pH-dependent and pH-independent portions of the reaction.

An interesting parallel may be drawn between the oxidation of carbon monoxide by copper(II) and the present reaction. Both reactions exhibit acid dependence and acid independent components. In the case of carbon monoxide oxidation by copper(II), this observation is accounted for by 2 insertion complexes

$$\left(\begin{matrix} O \\ | \\ Cu{-}C{-}OH \end{matrix}\right)^+ \quad \text{and} \quad \left(\begin{matrix} OH \\ \vdots \\ Cu{-}C{\equiv}OH \end{matrix}\right)^{2+}$$

which form in pre-equilibrium steps. The rate limiting steps are the subsequent decomposition of these intermediates by cupric ions.

In the oxidation of formaldehyde by copper(II) the rate limiting steps are also preceded by pre-equilibria in which 2 bridged intermediates are formed. The spontaneous decomposition of these intermediates is the rate limiting step. It appears that the copper–oxygen bonds are broken, yielding cuprous ions and free radicals. The removal of a hydrogen ion from $H^+\dot{O}CH_2OH$

should be fast in order to satisfy the condition of acid dependence. Final reaction of the $\cdot OCH_2OH$ with cupric ion is regarded as a fast process.

Coordination complexes of acetylene diphosphines. Part III. Silver(I) and mercury(II) complexes

W. A. ANDERSON, A. J. CARTY, AND A. EFRATY
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received March 27, 1969

Complexes of bis(diphenylphosphino)acetylene with silver(I) and mercury(II) are described. Infrared and Raman spectra together with chemical evidence suggest that the compounds AgX(DPPA) (X = Cl, Br, I, SCN, NO_3; DPPA = bis(diphenylphosphino)acetylene), $[AgX]_2(DPPA)_3$ (X = Cl), $AgX(DPPA)_2$ (X = BF_4, PF_6), and $HgX_2(DPPA)$ (X = Cl, Br, I) have polymeric structures with bridging bis(diphenylphosphino)acetylene groups.

Les complèxes de bis(diphénylphosphino)acétylène avec l'argent(I) et le mercure(II) sont decrits. Les spectres Raman, infrarouge et l'évidence chimique suggèrent que les composés AgX(DPPA) (X = Cl, Br, I, SCN, NO_3; DPPA = bis(diphénylphosphino)acétylène, $[AgX]_2(DPPA)_3$ (X = Cl), $AgX(DPPA)_2$ (X = BF_4, PF_6) et $HgX_2(DPPA)$ (X = Cl, Br, I) ont des structures polymèriques dans lesquelles les groupes bis(diphénylphosphino)acétylène forment les ponts entre les atomes des métaux.

Canadian Journal of Chemistry. 47, 3361 (1969)

Introduction

Tertiary phosphines form 1:1, 2:1, 3:1, and 4:1 complexes with silver(I) salts (1–7) as well as a variety of mononuclear or halogen bridged polynuclear complexes with mercury(II) halides (2, 8). Whereas silver(I) is normally 3 or 4 coordinate in these compounds (2, 3, 6), mercury(II) prefers tetrahedral coordination (8). Few diphosphine or diarsine complexes have been described (9–11).

There has been considerable recent interest in coordination compounds of unsaturated phosphines and arsines (12–16), particularly with a view to preparing complexes having coordinated olefinic bonds. In other papers in this series (17, 18) we have shown that the acetylenic diphosphine bis(diphenylphosphino)acetylene **1** (DPPA) forms stable binuclear diphosphine bridged complexes with copper(I), gold(I), palladium(II), and platinum(II), and we have now extended these studies to include silver(I) and mercury(II).

Experimental

The diphosphine $Ph_2PC{\equiv}CPPh_2$ was prepared as previously described (17). Silver and mercury salts were Fisher reagent grade materials and were used without further purification.

Microanalyses were carried out by A. B. Gygli, Toronto and A. Bernhardt, Elbach uber Engelskirchen, Germany. Infrared (i.r.) spectra were recorded on Beckman IR 9 and IR 12 spectrometers. Solid state Raman measurements were made using a Spex Helium–Neon laser equipped instrument. Calibrations were made with the carbon tetrachloride line of shift $\Delta\nu = 459\ cm^{-1}$ and frequencies are accurate to $\pm 2\ cm^{-1}$.

Mercury Compounds

Dichloro[bis(diphenylphosphino)acetylene]mercury(II)

Mercuric chloride (0.2 g) dissolved in ethanol (5 ml) was added dropwise to a warm solution of **1** (0.5 g) in

$$Ph_2PC{\equiv}CPPh_2$$

1

ethanol (70 ml). The white crystalline precipitate was filtered off, washed carefully with ethanol, boiling benzene, and dichloromethane, then dried in vacuo, m.p. 192–194° (decomp.).

Anal. Calcd. for $HgCl_2$(DPPA): C, 46.90; H, 3.0; Cl, 10.64. Found: C, 46.66; H, 3.15; Cl, 10.50.

Dibromo[bis(diphenylphosphino)acetylene]mercury(II)

Prepared as above using mercuric bromide, this had m.p. 191–193° (decomp.).

Anal. Calcd. for $HgBr_2$(DPPA): C, 41.37; H, 2.67; Br, 21.16. Found: C, 41.73; H, 2.31; Br, 21.09.

Diiodo[bis(diphenylphosphino)acetylene]mercury(II)

Mercuric iodide (0.45 g) was dissolved in ethanol (50 ml) in the presence of potassium iodide (0.2 g). This solution was added dropwise to a solution of the ligand (0.4 g) in ethanol (50 ml). The precipitated pale yellow product was purified as described above, m.p. 174–176° (decomp.).

Anal Calcd. for HgI_2(DPPA): C, 36.80; H, 2.37; I, 29.97. Found: C, 36.83; H, 2.56; I, 29.65.

Attempts to prepare zinc and cadmium halide complexes by the same techniques were unsuccessful.

Silver Compounds

Nitrato[bis(diphenylphosphino)acetylene]silver(I)

Reaction of **1** (2.0 g) in ethanol (150 ml) with a saturated solution of silver nitrate (0.9 g) in the same solvent gave a white precipitate which was recrystallized from a large volume of ethanol. The compound explodes at 165–175°.

Anal. Calcd. for $Ag(NO_3)$(DPPA): C, 55.35; H, 3.57; P, 10.96; N, 2.48. Found: C, 55.12; H, 3.63; P. 8.77; N, 2.42.

Thiocyanato[bis(diphenylphosphino)acetylene]silver(I)
Method A

$Ag(NO_3)$(DPPA) (0.3 g) was dissolved in dichloromethane to give a saturated solution. Excess of a warm saturated solution of potassium thiocyanate in ethanol was added and the reaction mixture was left to stir at 50° until all the solvent had evaporated. The resulting white product was washed carefully with water and ethanol and dried at 50°, m.p. 255–257° (decomp.).

Anal. Calcd. for Ag(NCS)(DPPA): C, 57.88; H, 3.60 N, 2.50. Found: C, 57.92; H, 3.76; N, 2.69.

Method B

$Ag(NO_3)$(DPPA) (0.5 g) was suspended in a small volume of ethanol and the solvent heated to boiling. Solid **1** was added gradually to the boiling suspension until all the nitrate had dissolved. Excess of a saturated ethanolic solution of potassium thiocyanate was added and the reaction mixture stirred at room temperature for 5 h. The precipitate was washed thoroughly with acetone and water, then dried in vacuo, m.p. 256–257° (decomp.). Found: C, 58.11; H, 3.77.

Iodo[bis(diphenylphosphino)acetylene]silver(I)
Method A

A similar procedure to *method A* above using potassium iodide gave a white product, m.p. 209–210° (decomp.).

Anal. Calcd. for AgI(DPPA): C, 49.64; H, 3.20. Found: C, 49.33; H, 3.17.

Method B

The same product was obtained using *method B* above.

Anal. Calcd. for $(AgCl)_2(DPPA)_3$: C, 63.74; H, 4.11.

Di[bis(diphenylphosphino)acetylene]silver(I) hexafluorophosphate

$Ag(NO_3)$(DPPA) (0.25 g) was suspended in ethanol (20 ml) and **1** added slowly to the refluxing solvent until a clear solution was obtained. The solution was cooled to room temperature, filtered, and 20 ml of a saturated solution of potassium hexafluorophosphate added. The reaction mixture was left to stir for 2–3 h, and the white precipitate filtered off and washed with small quantities of ethanol, m.p. 168–178°.

Anal. Calcd. for $Ag(PF_6)(DPPA)_2$ (mol. wt. monomer, 1042): C, 59.94; H, 3.87; P. 14.87. Found (mol. wt. (CH_3NO_2) 704): C, 60.45; H, 3.84; P, 13.35.

Di[bis(diphenylphosphino) acetylene] silver(I) tetrafluoroborate

Prepared similarly to the hexafluorophosphate this had m.p. 230–240° (decomp.).

Anal. Calcd: C, 63.48; H, 4.10. Found: C, 63.16; H, 4.29.

Extensive washing of the product with acetone was necessary for purification, m.p. 206–209° (decomp.). Found: C, 48.93; H, 3.43.

Bromo[bis(diphenylphosphino)acetylene]silver(I)

Using *method A*, with potassium bromide replacing potassium thiocyanate gave the pure product in small yield, m.p. 226–228° (decomp.).

Anal. Calcd. for AgBr(DPPA): C, 53.65; H, 3.46; Br, 13.73. Found: C, 52.77; H, 3.45; Br, 13.42.

Treatment of a suspension of $Ag(NO_3)$(DPPA) in ethanol with a large excess of potassium bromide for 48 h followed by boiling of the precipitate in water and ethanol to remove excess KBr and $Ag(NO_3)$(DPPA) gave a similar product. Found: C, 52.68; H, 3.48.

Chloro[bis(diphenylphosphino)acetylene]silver(I)

This compound can be prepared in small yield by *method A* using $Ag(NO_3)$(DPPA) and a saturated ethanolic solution of sodium chloride, m.p. ~200° (decomp.). The compound is very light sensitive. Poor microanalyses were obtained unless reactions were carried out completely in the dark. Halogenated solvents catalyze the decomposition.

Anal. Calcd. for AgCl(DPPA): C, 58.08; H, 3.75; Cl, 6.59. Found: C, 56.26; H, 3.84; Cl, 6.22.

A different compound was obtained by dissolving $Ag(NO_3)$(DPPA) in an ethanolic or methanolic solution of **1** followed by addition of a solution of sodium chloride or aluminum chloride in the same solvent. Decomposition of this compound also occurred on standing in light. Analyses of products gave the following.

$$Ag(NO_3)(DPPA) + DPPA \xrightarrow{\text{ethanol} + NaCl} \text{C, 62.90; H, 4.23}$$

$$Ag(NO_3)(DPPA) + DPPA \xrightarrow{\text{methanol} + NaCl} \text{C, 62.84; H, 4.57}$$

$$Ag(NO_3)(DPPA) + DPPA \xrightarrow{\text{ethanol} + AlCl_3} \text{C, 62.82; H, 4.40}$$

Results and Discussion

Silver Complexes

Silver nitrate reacts with **1** in alcoholic solution to give a colorless, crystalline, diamagnetic complex of empirical formula $Ag(NO_3)$(DPPA). The complex is only slightly soluble in ethanol and dichloromethane, insufficient for molecular weight measurements. The i.r. spectrum (Table I) confirms that the nitrate group is coordinated. $\nu_3(E')$ for $NO_3^-(D_{3h})$ in $AgNO_3$ is at 1378 cm^{-1}. For mono- or bi-dentate nitrate, the degeneracy of ν_3 is removed and the band splits into 2 components, one at higher frequency and the other lower. The magnitude of the band splittings has often been used together with other information as a means of tentatively assigning mono- or bidentate coordination (19). For $Ag(NO_3)$ (DPPA)

the 2 components arising from ν_3 of NO_3^- are at 1412 and 1297 cm^{-1}. The absence of any nitrate absorption above 1412 cm^{-1} argues against a strongly coordinated bidentate or bridging nitrate. Other bands in the spectrum due to coordinated nitrate are at 1034 and 822 cm^{-1}; components arising from a lifting of the degeneracy of the $\nu_4(E')$ bending mode of NO_3^- are, however, obscured by strong ligand absorption in the 700 cm^{-1} region.

$\nu(C{\equiv}C)$ appears at 2097 cm^{-1} (17, 20) in a Raman spectrum of **1** but is i.r. inactive both in **1** and in complexes where the diphosphine is symmetrically bonded to 2 metal atoms via the phosphorus atoms only (20, 21). Conversely, in acetylene complexes of symmetrical disubstituted acetylenes, $\nu(C{\equiv}C)$ appears weakly in the i.r. 200–400 cm^{-1} lower than in the free ligand (22). We were unable to obtain a frequency for $\nu(C{\equiv}C)$ from the Raman spectrum of $AgNO_3$(DPPA) due to decomposition to silver metal in the laser beam. However, a very weak absorption at ca. 2110 cm^{-1} in the i.r. of a strong mull probably arises from $\nu(C{\equiv}C)$. Thus only the phosphorus atoms of the ligand are coordinated (17). Interestingly, no cleavage of the $P{-}C_{sp}$ bond was apparent when **1** reacted with alcoholic $AgNO_3$. This contrasts with the behavior of other non-metal acetylene compounds where the $M{-}C_{sp}$ bond is readily cleaved by this reagent (23). It is likely that $AgNO_3$(DPPA) has a polymeric structure **2** in which bridging DPPA molecules and a monodentate nitrate contribute to a planar geometry around each silver ion. An alternative structure **3**

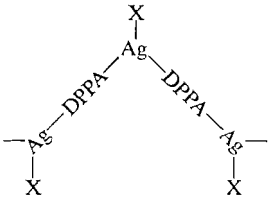
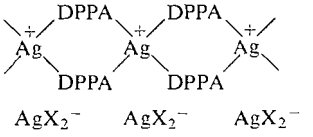
with tetrahedral silver receives some support from the known crystal structures of (cyclooctatetraene)$AgNO_3$ (24) and (norbornadiene)$2AgNO_3$ (25) where bridging nitrate groups are present.

$Ag(NO_3)(DPPA)$ is a useful starting material for the preparation of other silver(I) complexes. The reactions are summarized in Scheme 1.

The halide complexes AgX(DPPA) (X = Cl, Br) are obtained in small quantities from these reactions and are difficult to purify due to their insolubility in suitable solvents. Attempts to prepare larger quantities by *method B* (see Experimental) resulted in products having high C and H analyses. In the case of the chloride, analytical figures for products prepared in 3 different ways using solutions of $AgNO_3$(DPPA) and excess ligand in ethanol, agreed consistently with the formulation $(AgCl)_2(DPPA)_3$. Attempts to purify and characterize both series of compounds by physical techniques were hindered by insolubility in suitable solvents. Solid state i.r. spectra confirmed the bidentate behavior of DPPA (Table I), however, and showed that $\nu(C{\equiv}N)$ of Ag(DPPA)SCN occurred as a strong sharp band at 2084 cm^{-1} suggesting the presence of N bonded thiocyanate (24). Silver complexes of stoichiometry $AgX(L_2)$ (L_2 = chelating diphosphine or diarsine; X = Cl, Br, I) are usually formulated as $[Ag(L_2)_2][AgX_2]$ on the basis of conductivity

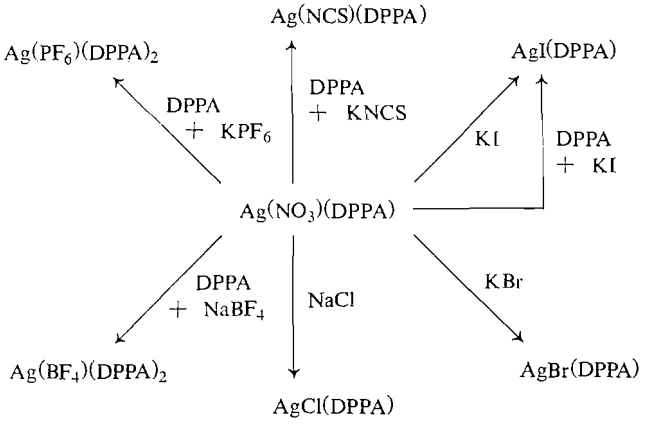


4



5

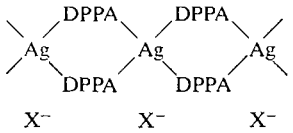
measurements (10, 11). Similar structures are unlikely for AgX(DPPA) since the diphosphine is incapable of chelation (20). Moreover, the insolubility in nitromethane, nitrobenzene, and acetonitrile argues against a simple ionic formulation.



SCHEME 1

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Two structures consistent with the bridging properties of **1**, the i.r. data, and the insolubility of the products are **4** and **5**. A meaningful distinction between these structures cannot be made on the basis of the evidence available. For $(AgCl)_2(DPPA)_3$ a tetrahedral diphosphine bridged structure analogous to that of $(CuX)_2(DPPA)_3$ (X = Cl, Br, I, NCS, BH_4, NO_3) (20) is probable. The compounds $AgX(DPPA)_2$ (X = PF_6, BF_4) contain ionic PF_6^- and BF_4^- respectively, $\nu_3(T_{1u})$ of PF_6^- occurring as a symmetrical absorption at 842 cm^{-1} and $\nu_3(T_2)$ of BF_4^- at 1060 cm^{-1} (Table I). No splitting of these bands as a result of a lowering of symmetry of the ions from O_h or T_d on coordination, was apparent. Both compounds are only sparingly soluble in nitromethane but dissolve in nitrobenzene to give colloidal, conducting solutions. This is in contrast to the analogous gold complexes $AuX(DPPA)_2$ (17) which readily dissolve without decomposition in halogenated solvents as well as nitromethane. Lewis, Nyholm, and Phillips (10) reported similar observations on silver(I) diarsine compounds. Lack of physical evidence again precludes a definite structural assignment. A polymeric structure **6** in which all diphosphine molecules are bridging and silver(I) has its usual tetrahedral coordination agrees with all the available i.r. evidence and is tentatively suggested.

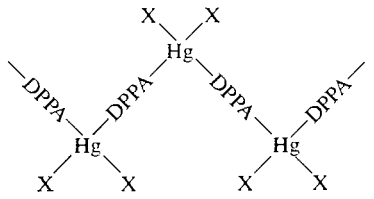


6

The work confirms that silver(I) phosphine complexes are less stable and more difficult to prepare and characterize than the corresponding copper(I) and gold(I) derivatives. This is particularly evident with DPPA, a ligand with apparently higher π acceptor but poorer σ donor properties than alkylene diphosphines (26). The lower effective electronegativity of silver compared with copper and gold (10) implies the necessity of a strongly basic ligand in order to produce a strong Ag—P bond.

Mercury Complexes

Mercuric halides form monomeric tetrahedral $(R_3P)_2HgX_2$, halogen bridged dimeric $(R_3P)_2(HgX_2)_2$, and halogen bridged polymeric $(R_3P)_2(HgX_2)_3$ complexes with tertiary phosphines (8). 1,2-Bis(diphenylphosphino)ethane (diphos) reacts with mercuric bromide to give the expected compound $HgBr_2$(diphos) but gives $(HgCl_2)_2$(diphos) with mercuric chloride (27). Reaction of **1** with mercuric halides in alcohol produces colorless complexes of empirical formula $HgX_2(DPPA)$ which are virtually insoluble in polar and non-polar organic solvents. The compounds are stable in air but decompose on melting. The i.r. spectra (Table I) are virtually identical and changes in the spectrum of the ligand on complexing parallel those reported previously (18). The absence of any i.r. absorption assignable to $\nu(C{\equiv}C)$ of the ligand indicates non-coordination of the triple bond and a symmetrical bidentate ligand. This is confirmed by Raman measurements on the solid complexes. $\nu(C{\equiv}C)$ occurs as an intense absorption at 2123, 2118, and 2115 cm^{-1} for $HgCl_2(DPPA)$, $HgBr_2(DPPA)$, and $HgI_2(DPPA)$, respectively. In the far infrared $HgCl_2(DPPA)$ has a very strong ν(Hg—Cl) absorption at 247 cm^{-1} with a weaker ν(Hg—Cl) mode at 234 cm^{-1}. These values are close to the values reported for ν(Hg—Cl) in the tetrahedral triphenylphosphine complex $(Ph_3P)_2HgCl_2$ (28) and strongly suggest a tetrahedral C_{2v} local symmetry around mercury for which two ν(Hg—X) modes (A_1 + B_1) are expected. The evidence thus points to structure **7** for the mercury complexes in which mercury has its usual tetrahedral configuration and all diphosphine molecules are bridging.



7

All attempts to prepare cadmium and zinc complexes of **1** resulted in failure. Although many cadmium and zinc halide–phosphine adducts are known (28), they are generally less stable than the corresponding mercury compounds. The failure of zinc and cadmium halides to complex with **1** can therefore be attributed to the "*a*" class character of these metals (29) and the weaker σ donor

properties **1** compared with other tertiary alkyl and aryl phosphines.

Methyl "radicals" on doped silica gel surfaces[1]

E. J. Casey, C. W. M. Grant[2], and C. L. Gardner
Defence Research Establishment Ottawa, Defence Research Board, Ottawa, Canada

Received January 8, 1969

Methyl radicals adsorbed on silica gels containing dopings of the semiconductor ZnO were investigated by electron spin resonance at 77 °K. In addition to the normal 4-line "*a*"-spectrum, with hyperfine splitting of 23.3 ± 0.2 G, a second broader 4-line spectrum "*b*" with splitting 18.8 ± 0.6 G appears. Variations in line intensity with extent of doping were measured. Disappearance of the *b*-spectrum when the doped gels were dried under hot oxygen was observed. Partial delocalization of the radical's free electron and mixing into the *doped* surface were clearly indicated.

Satellites ("*c*") to the *a*-spectrum were observed and are discussed.

Canadian Journal of Chemistry, 47, 3367 (1969)

In the present paper we report on an investigation of the effect of the doping of silica gel, with the semiconductor zinc oxide, on the electron spin resonance (e.s.r.) spectrum of adsorbed methyl radicals. Although ion radicals such as O_2^- have been formed (1) by adsorption of O_2 on irradiated semiconductor materials such as ZnO and MgO, and although NO has been detected (2*a*) on MgO, and the spectrum analyzed (2*b*), it is only very recently that adsorbed, e.s.r.-detectable, neutral free-radicals have been directly observed (3–7), in spite of the fact that they are often postulated as intermediates in kinetic schemes. We imagined that this may be due to the electron of the radical being transferred more or less into the semiconductor or conductor material, forming either an undetectable ion or a charge-transfer complex rather than a detectable stabilized free radical. Information about the distribution of the electronic charge of the adsorbed radical is important, for example, in predicting what intermediates may reasonably be expected in catalytic electro-oxidation reactions such as the electro-oxidation of hydrocarbons.

In these experiments we have attempted to change the adsorbent material from an insulating state (pure silica gel) gradually towards a more semiconducting state, by doping the silica gel with increasing amounts of ZnO, and then to examine the nature of the bonding with CH_3 as the doping is increased.

Preparation and Measurements

Since preparation affects the results, details are given as follows. To a 50 ml 1 *M* sodium silicate solution was added 50 ml of water in a beaker. The solution was constantly stirred and concentrated HCl was added simultaneously from a second buret at such a rate as to keep the pH below 3. At this stage varying amounts of 1 *M* $ZnCl_2$ were added, followed by titration of the solution with 1 *N* NaOH to pH 7, at which point gelling occurred rapidly. The gels were dried at room temperature and washed thoroughly with boiling water. The resulting gel was transparent and colorless. In this way gels with up to 11.7% ZnO by weight were prepared, the zinc content having been determined by analysis after the drying step. Several precautions must be taken in preparing the gels this way. (*a*) The neutral region must be approached from the acid side if premature gelling of the SiO_2 is to be avoided. (*b*) If too much $ZnCl_2$ is added, premature gelling of ZnO occurs and a non-homogeneous mixture results. This fact limits the maximum doping to less than 12%. (*c*) Since ZnO and SiO_2 do not gel at precisely the same time or rate, the percentage of doping is not exactly reproducible. Any unattached ZnO formed is washed away in the washing procedure.

X-Ray diffraction by a gel sample known by chemical analysis to be doped with 6.7% Zn showed the sample to be amorphous, indicating that the ZnO was well dispersed in the gel lattice, and not agglomerated as crystalline islands of ZnO.

The samples for use in the e.s.r. measurements were prepared as follows. The doped gels were degassed at less than 10^{-4} mm Hg for approximately 9 h at 300 °C. Some were dried under 1 atm O_2. Methyl iodide (Brickman and Co., reagent grade) was then allowed to adsorb onto the gel at a pressure of ~10 mm Hg. The sample tube was sealed, cooled to 77 °K, and irradiated with an unfiltered GE-UA2 mercury lamp. Electron spin resonance spectra were taken on a Varian V-4500 spectrometer at this temperature.

The a-Spectrum

The 4-line spectrum of methyl radicals adsorbed on pure silica gel is now well known (3–5) and is shown for reference in Fig. 1*a*. (The line S, absorption by a center in irradiated silica gel, usually appears in addition to the 4 lines (a_1 to a_4) of adsorbed CH_3.) The hyperfine splitting constant is 23.3 ± 0.2 G. Little anisotropy is indicated by the line shapes. In our previous work the variation of linewidth of the *a*-spectrum with nuclear spin

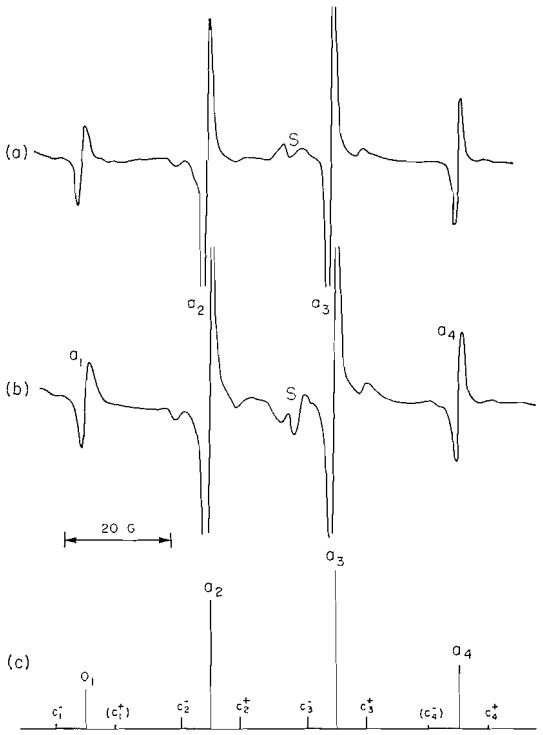

FIG. 1. Electron spin resonance spectra of methyl radicals at 77 °K. (*a*) Undoped silica gel, (*b*) doped silica gel, dried under oxygen, and (*c*) stick spectrum.

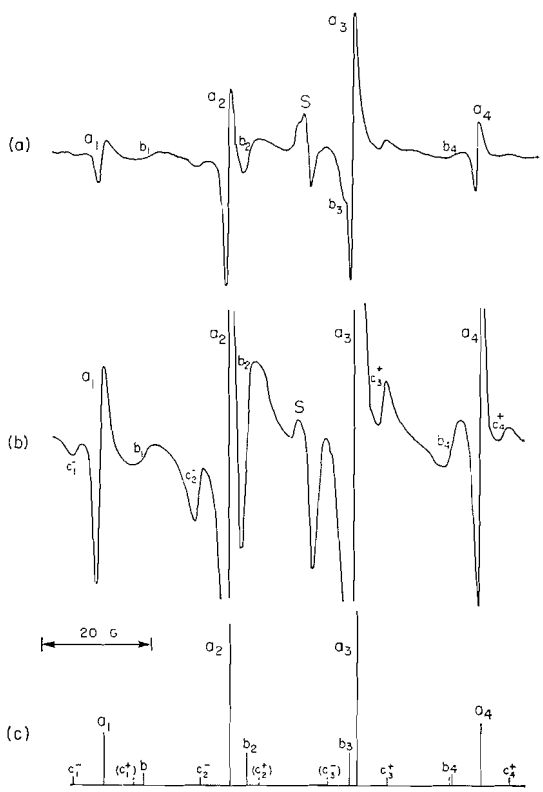

FIG. 2. Electron spin resonance spectra of methyl radicals on ZnO-doped (11.7%) silica gel at 77 °K. (*a*) Low sensitivity, (*b*) high sensitivity, and (*c*) stick spectrum.

quantum number from the predicted 1:3:3:1 was quantitatively interpreted as being due to hindered rotation of the radicals on the surface, and the tumbling frequency was evaluated (6).

By contrast with the pure gel, the e.s.r. spectra observed with the doped gels, Fig. 2 (CH_3 on silica gel with 11.7% ZnO), are more complicated. Furthermore, the intensity of the extra lines depends on the extent of doping. The most intense lines (a_1 to a_4) in the more complex spectra are the same as those of CH_3 on the undoped gels, and although the hyperfine splittings of the *a*-spectrum (23.10, 22.90, 23.18, 22.75, 22.80) observed for 5 doped gels (1 to 11.7%) may be slightly smaller than the splitting we have observed for CH_3 on undoped gels, the difference is very close to the limits of error and is probably not significant.

The b-Spectrum

A second methyl radical spectrum, less intense, and with broader lines and greatly reduced hyperfine splitting (18.8 ± 0.6 G) clearly appears in the doped samples (lines b_1 to b_4). The lines b_1, b_2, and b_4 appear clearly in windows of the *a*-spectrum, and b_3 appears as a shoulder on and a distortion of line a_3, in Fig. 2*a*. Positions of the *a*- and *b*-lines are indicated in the stick spectrum, Fig. 2*c*.

The intensity of the *b*-spectrum relative to the *a*-spectrum increases with amount of ZnO in the gel. Thus the ratio of peak heights for b_1 and a_1 increased with doping as follows: 0.114, 0.136, 0.221, and 0.284 for gels with ZnO present in 4 increasing amounts of about 2, 5, 8, and 11.7%, respectively. We suggest that the *b*-spectrum corresponds to CH_3's adsorbed on "ZnO-sites". These may be faces of silica tetrahedra which have dopant nearby, or real, amorphous ZnO (anhydrous or hydrated?) islands in the substrate. It is obvious that at the molecular level the doping may not be completely homogeneous.

Since the hyperfine splitting shown in the *b*-spectrum is markedly lower than that in the *a*-spectrum, considerably more delocalization of the radical's electron has taken place on the ZnO-sites, approximately 19% more being mixed with the ZnO-site than with the pure silica site.

The marked line-broadening which appeared in these *b*-spectra suggested that considerable variation must exist in the doped sites, possibly in the intensity of the electric field at the adsorbed radical, and possibly due to variation in composition of the ZnO from stoichiometric 1:1. We recall that it is well known (8) that the rate of the homomolecular oxygen reaction varies with ZnO composition. In the present case, the supported ZnO (11.7%), having been dried under vacuum, was probably oxygen-deficient. Therefore, for comparison, a special preparation of the same doped substrate intended to contain oxygen-excess ZnO was made, in which the last stage of drying was done

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

under an atmosphere of oxygen at 300 °C. After drying, the sample was cooled under O_2 and then outgassed at 25 °C under vacuum before admission of the CH_3I. All other steps were the same. Although the resulting spectrum still showed strong *a*-lines, it had no trace of *b*-lines (Fig. 1*b*).

This behavior could occur for several reasons: more complete mixing of the radical's electron with the excess O of an n-type semiconductor, or with a distorted silica tetrahedron nearby, so that it is essentially an ion adsorbed on the O-excess doped sites; partial coverage of the doped sites by chemisorbed oxygen and hence no adsorption at all; rearrangement of adsorbed radicals to (adsorbed) methyl ether; and probably others. In summary, we see that the surface composition can markedly affect the nature of adsorption, and that evidence of partial (Fig. 2*a*), as well as possibly complete (Fig. 1*b*), electron-transfer into the surface during adsorption has been obtained.

The c-Spectrum

On the ZnO-doped silica gel, in addition to the "*a*" and "*b*" sets of spectral lines for adsorbed CH_3 radicals, 4 weak lines (called "*c*") are also evident in Fig. 2. c_1^- is very weak and in about 20 samples was found to lie between 4.0 and 5.5 G downfield from a_1. Likewise c_4^+ lies between 4.0 and 5.5 G upfield from a_4. However, c_2^- and c_3^+ in all samples lie 5.4 ± 0.1 G from a_2 and a_3, respectively. Peak heights of the *c*'s are small, 3–5% of the corresponding *a*'s. The observed 4 may be members of a group of 8 (the others being hidden under the *b*'s) arising from interaction of the radical with the ^{29}Si nucleus, which has a nuclear spin quantum number of 1/2 and a 4.7% natural abundance in the gel. Thus, if we assume that the electron is donated into the sp^3 orbital of silicon, the value (9) of the hyperfine splitting constant of 1160 G for an electron in the 3s orbital of ^{29}Si permits the estimate that only about 4% delocalization is needed to account for the observed splitting of *a*'s. The fact that the ratio of peak heights of the clean c_2^- line to the clean a_2 line shows no systematic variation with doping, from 0 (pure gel) to 11.7% ZnO-doped, seems to strengthen this assignment. The main weakness of this view is that only 4 of the supposed 8 lines consistently appear, although in Fig. 1*b* as many as 7 may be imagined.

Other possibilities exist which cannot be unequivocally eliminated. One is that the gel has not become completely freed of —OH groups by the drying procedure, and that the 4 observed *c*'s are due to proton-splitting. It seems improbable, however, that the *c*/*a* ratio would remain constant throughout the study, including the experiment in which the doped gel was kept under oxygen before and during cooling, if the intensity of the *c*-lines depended upon —OH groups at the adsorption sites. Another possibility is that OCH_2, as well as CH_3, is formed at doped sites. Thus, one could consider c_2^- and c_3^+ to be the outside lines of the 3-line spectrum of partly-delocalized, adsorbed OCH_2 radicals, with the center line obscured by the S lines, normally present in irradiated silica gels. The observed splitting would then be 16.5 G (Fig. 2*b*), which is lower than the reported value of 20.5 for $SiOCH_2$ (10), and about 25% delocalization would thus be required. However, there is no evidence whatsoever for *undelocalized* $SiOCH_2$, at 20.5 G, even on the oxygenated, doped gel; nor would the c_1^- and c_4^+ lines be accounted for in this interpretation. Therefore, we favor the ^{29}Si interpretation over proton-splitting, and consider delocalized oxyradicals only a remote possibility in the present investigation.

Conclusion

The experiments have indicated that increased delocalization of the methyl radical's unpaired electron can occur as silica gel is doped with a semiconductor material such as ZnO. The degree of delocalization in the SiO_2–ZnO system seems to be a *site* property rather than a *bulk* property of the material. Adsorbed free-radicals, some undelocalized and some with at least partial delocalization, and possibly even ions, can form from adsorption of CH_3 on different sites on the same surface. One infers that the phenomenon should be observable by e.s.r. techniques whenever the catalytic surface is only partially semiconducting.

Reactions of diphos and diars with iron carbonyls: a reinvestigation

W. R. CULLEN AND D. A. HARBOURNE
Chemistry Department, University of British Columbia, Vancouver, British Columbia

Received March 27, 1969

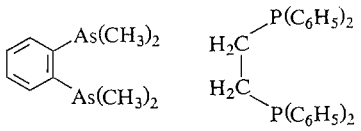
The bidentate ligands diars (**1**) and diphos (**2**) react with iron carbonyls to give the previously known diarsFe(CO)$_3$, diphosFe(CO)$_3$, diphosFe$_2$(CO)$_8$, and the new complex diarsFe$_2$(CO)$_8$. The reactions of diars also yield compounds in which the ligand has been modified. DiarsFe(CO)$_3$ reacts readily with chloroform to give a new paramagnetic iron carbonyl complex.

Canadian Journal of Chemistry, 47, 3371 (1969)

Introduction

The two chelating ligands 1,2-bis(dimethylarsino)benzene, diars (**1**), and 1,2-bis(diphenylphosphino)ethane, diphos (**2**), are well known for their ability to displace carbon monoxide from metal carbonyl compounds (e.g. 1–3).

During the course of our investigation of the complexing abilities of related fluorocarbon-bridged ditertiary phosphines (and arsines) (4–8), it became necessary to reinvestigate the reaction of (**1**) and (**2**) with iron carbonyls. The purpose of this paper is to report these new results which involve (*a*) improved reaction workup procedures which allow a fuller investigation of the products of the reactions, (*b*) improved syntheses of diphosFe(CO)$_3$, diphosFe$_2$(CO)$_8$, and diarsFe(CO)$_3$, (*c*) the characterization of diarsFe$_2$(CO)$_8$, and (*d*) the synthesis of a new paramagnetic iron carbonyl. The structures of most of these compounds have been recently discussed (7) in a paper which describes their infrared (i.r.) spectra in the carbonyl region and their Mössbauer spectra.



1 2

Experimental

The results of some representative experiments are summarized in Table I. All reaction mixtures were treated in a similar manner which consisted of removal of volatiles and solvents followed by chromatography on Florisil *under nitrogen*. Eluants (which may vary a little depending on column conditions etc.) are indicated for each product in Table I. The eluants used in each experiment were in order, petroleum ether (b.p. 30–60°), petroleum ether/benzene mixtures, benzene, petroleum ether/ether mixtures, ether, and acetone. A product given as eluting with 1:1 petroleum ether/benzene was eluted *after* the column had been cleared of earlier bands by the solvents mentioned above. In some cases recrystallization of a chromatographic band was necessary to obtain a pure product.

The spectrometers used in this investigation have been described previously (6). Microanalyses were done by Mr. Peter Borda of this department.

Results and Discussion

Our study of the reactions of fluorocarbon-bridged ditertiary phosphines (and arsines) with the various iron carbonyls (5–8) has shown the products formed to be critically dependent upon the carbonyl and conditions used. A good number of di- and tri-iron derivatives have been isolated. Our reinvestigation of the reactions of diphos and diars with the iron carbonyls has shown a remarkable *independence* of conditions and carbonyl used (Table I) and a lack of any stable products containing iron–iron bonds, apart from this possibility in trace products (less than 1%).

In all reactions of diphos investigated, the major products are invariably diphosFe$_2$(CO)$_8$ and diphosFe(CO)$_3$. This latter compound does not elute significantly from a Florisil column unless nitrogen saturated conditions are used. This is probably the reason that it was not obtained by Manuel (2). Further products were not separated in above trace (below 1%) quantities apart from one pale yellow powdery material which was isolated in small amounts from reactions [1], [2], and [3] (Table I). It was eluted from Florisil, apparently as a single yellow band, with 1:1 benzene/petroleum ether and its carbonyl i.r. spectrum shows bands at 2057s, 1982s, 1947vs, 1940vs(sh), 1895s, and 1885s(sh) cm^{-1}. The first 4 bands are in the same position and have the same relative intensities as those of diphosFe$_2$(CO)$_8$ (Table II, ref. 7). Recrystallization from benzene/heptane or ether/petroleum

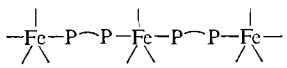
ether did not appear to affect the relative intensities of these bands, although chromatography on alumina (under N_2) suggested the material to be a mixture despite eluting as a single band. Carbon and hydrogen analyses are close to those required for a 1:1 mixture of diphosFe$_2$(CO)$_8$ and diphosFe(CO)$_3$ or a compound (diphos)$_2$Fe$_3$(CO)$_{11}$, possibly **3**.



3

Although mass spectral, Mössbauer, and nuclear magnetic resonance (n.m.r.) data tend to suggest the presence of diphosFe$_2$(CO)$_8$ in the material, none was ever separated as such. However, a compound (diphos)$_2$Fe$_3$(CO)$_{11}$ could possibly give similar spectroscopic results. In addition, in order to satisfy the i.r. spectrum, the diphosFe(CO)$_3$ in a 1:1 mixture would need to be the polymeric *trans*-disubstituted derivative described by Manuel (2) (though not observed in our reaction mixtures) as red–brown, which does not correlate well with the observed pale yellow color of our material. It is not inconceivable that this material does contain some (diphos)$_2$Fe$_3$(CO)$_{11}$.

Another compound formed in these diphos reactions is an unstable and somewhat intractable deep-red material which eluted with 1:1 petroleum ether/acetone (reactions [1] and [2] only). Its Mössbauer spectrum possibly indicates that 3 iron atoms are involved but the compound could not be characterized. Materials similar to this have been noted in reactions of the fluorocarbon-bridged ditertiary phosphine ffos (8).

Mass spectral data of diphosFe(CO)$_3$ and diphosFe$_2$(CO)$_8$ are given in Table III. Their formulation is shown to be correct, although some ambiguity is involved in the cracking pattern as, in low resolution, C_2H_4 has the same *m/e* value as CO and loss of C_2H_4 appears to be an important process.

The reactions of diars (**1**) with iron carbonyls afford one main product, diarsFe(CO)$_3$, although they are not as clean as previously reported (1). Our experience with diarsFe(CO)$_3$ is that the complex is very air sensitive, especially in solution, and that it undergoes an extremely interesting and facile reaction with air-free spectroscopic chloroform, despite the fact that this has been mentioned (3) as a solvent for i.r. studies on this complex. Reaction appears to start almost immediately and deep yellow crystals (only slightly

*All yellow solids.

soluble in chloroform) are produced within 1 day at room temperature. The crystals appear to be air stable and a complete analysis establishes the empirical formula $C_{15}H_{23}Cl_3As_3OFe$. One carbonyl stretching band at 1926 cm^{-1} is observed (KBr disc). The Mössbauer spectrum shows a doublet with a quadrupole splitting ($\Delta = 0.57$ mm/s) much less than that shown by normal 5 coordinate iron complexes. The size of this splitting is consistent with a distorted octahedral environment while the isomer shift value of $\delta = 0.42$ mm/s relative to sodium nitroprusside could indicate an oxidation state of +4 for the iron (9). The complex is also paramagnetic with a gram susceptibility of $7.20 (\pm 0.28) \times 10^{-6}$ c.g.s.e.m.u. Using the above formula and applying the appropriate diamagnetic corrections the estimated $\mu_{eff} = 3.31$ B.M. This value also indicates a high oxidation number for the iron, the iron(IV) compound $[Fe(diars)_2Cl_2][ClO_4]_2$ having a μ_{eff} of 2.98 B.M. (10). It is difficult to reconcile the high oxidation state of the iron and paramagnetism with the observation that the compound contains a carbonyl group. Although single crystals of this complex can be obtained, they have so far proved to be unsuitable for the necessary X-ray investigation.

A second product, $diarsFe_2(CO)_8$, may also be separated with difficulty and in low yield from reactions between diars and iron carbonyls (Table I). As with $diarsFe(CO)_3$, the mass spectrum (Table III), confirms its formulation. It is worth noting that in all of the reactions studied a large proportion of the diars is converted into a viscous yellow oil (e.g. 1.0 g in reaction [7], Table I). This oil chromatographs on Florisil to give what appear to be fairly distinct yellow bands eluting with petroleum ether/benzene mixtures. Their carbonyl i.r. spectra indicate that they are all $LFe(CO)_4$ or $LFe_2(CO)_8$ derivatives. However, n.m.r. studies showed the chromatographic bands to be mixtures. Using an alumina column the tail of the second band eluting with 2% diethyl ether/98% petroleum ether gave a yellow solid. The proton n.m.r. (CS_2 solution, internal TMS) of this material shows ostensibly singlet resonances at 1.84 p.p.m. (area 3), 2.61 p.p.m. (area 1), and 7.68 p.p.m. (area 2). The i.r. carbonyl stretching bands at 2054s, 1984s, 1950vs (C_6H_{12} solution), are characteristic of an $LFe(CO)_4$ or $LFe_2(CO)_8$ derivative. The mass spectrum of the complex indicates it to be an $LFe_2(CO)_8$ complex with *m/e* for the ligand at 270. The above facts are consistent (apart from the n.m.r. *singlet* at 7.68 p.p.m. possibly) with a structure **4**.

A *trans*-derivative is shown as this is compatible with a singlet CH_2 resonance.

It would thus appear that the yellow oil obtained in the diars reactions consists of $Fe(CO)_4$ and/or $Fe_2(CO)_8$ complexes of ligands formed by fragmentation of diars. Diars$Fe(CO)_4$ itself was not isolated but may well exist in the mixture although it is expected to be unstable.

A recent paper describes how a compound originally reported by Nyholm to be $[(diars)_3Ni][ClO_4]_2$ is in fact $[(diars)(triars)Ni][ClO_4]_2$ (11) where rearrangement of the diars has occurred. The related fluorocarbon bridged ligand, ffars (**5**), gives the compound ffars$Fe_3(CO)_9$ in which an As—C bond in the ligand has been broken and an Fe—C bond formed (8, 12). Thus modification of ligands in complex forming reactions may well be more common than generally thought.

Préparation et caractérisation de polymères-modèle à structure en étoile, par copolymérisation séquencée anionique

DENIS J. WORSFOLD[1], JEAN-GEORGES ZILLIOX ET PAUL REMPP
Centre de Recherches sur les Macromolécules (CNRS), 67-Strasbourg, France

Reçu le 20 mars 1969

Des polymères à structure "en étoile" ont été préparés par copolymérisation séquencée anionique de styrène et de divinylbenzène (DVB), la proportion de ce dernier monomère étant de l'ordre de quelques molécules par extrémité vivante. Toutes les opérations ont été effectuées sous vide poussé, et le benzène a été choisi comme solvant. Les échantillons obtenus ont été trouvés quasiment exempts de polystyrène linéaire et leur polydispersité est très faible. Le nombre de branches des étoiles dépend de la concentration globale, de la proportion de DVB mise en jeu et de la masse moléculaire du précurseur linéaire. Les résultats obtenus avec des isomères para et méta du DVB ne diffèrent pas de façon significative, pour ce qui est de la structure des produits obtenus. L'étude spectroscopique de la réaction fait apparaître cependant des différences notables, dues au fait que les 2 doubles liaisons de l'isomère para diffèrent par leurs réactivités, ce qui n'est pas le cas de l'isomère méta.

Star-shaped polystyrene samples have been synthesized by anionic block-copolymerization of styrene and divinylbenzene (DVB), the proportion of the latter monomer being of the order of a few molecules per living end. Vacuum technique was used and benzene was chosen as solvent. The samples were found almost free of linear polystyrene, and of very low polydispersity. The number of branches was found to be a function of the overall concentration, of the amount of DVB, and of the molecular weight of the linear precursor. The results obtained with the meta and the para isomers did not differ significantly, as far as the products themselves are concerned. However, spectroscopic investigations carried out during reaction showed that the reactivity of the 2 double bonds of the para isomer differ significantly, whereas this is not the case with the meta isomer.

Canadian Journal of Chemistry, 47, 3379 (1969)

Introduction

Nous avons décrit récemment (1, 2) le principe d'une méthode originale de préparation de polystyrènes à structure "en étoile", par voie anionique. Rappelons que cette méthode consiste à préparer un polystyrène mono-carbanionique et à en utiliser, dans une seconde phase, les extrémités carbanioniques comme promoteurs pour la polymérisation de divinylbenzène (DVB). Ce dernier monomère se polymérise en donnant naissance à un nodule réticulé, lié simultanément à n chaînes linéaires de polystyrène: on obtient donc un polymère "en étoile", tout au moins lorsqu'on prend soin de limiter la proportion de DVB à une valeur aussi faible que possible.

La plupart des préparations de polystyrènes "en étoile" qui ont été relatées jusqu'ici (1, 2) ont été effectuées sous atmosphère d'argon, essentiellement en solution dans le tétrahydrofuranne (THF), à basse température, avec le cumylpotassium comme promoteur, et avec du DVB commercial. Les produits obtenus étaient fortement polydispersés, et souillés de polystyrène linéaire (3, 4).

Aussi, devant les difficultés que nous avons rencontrées, avons-nous effectué une nouvelle série de préparations dans des appareils scellés, sous vide poussé, en utilisant la technique des joints fragiles et des distillations sur parois froides (5). Il nous a en effet paru indispensable d'étudier les facteurs qui influencent le déroulement de la réaction afin d'en déterminer le mécanisme. Ce sont les résultats de cette étude qui font l'objet du présent mémoire.

Choix des Conditions Expérimentales

Solvant

La presque totalité de nos expériences a été effectuée en solution dans le benzène. L'intérêt de ce solvant pour ce type d'expérience réside dans sa faible polarité qui implique une vitesse de polymérisation assez peu élevée pour le styrène et ses homologues. De ce fait lors de l'addition du DVB, un mélange homogène peut être réalisé par agitation, ce dont on ne peut être assuré en milieu THF.

Promoteur

Le souci d'obtenir une vitesse d'amorçage aussi élevée que possible nous a conduit à choisir le sec-butyl-lithium comme promoteur. En effet si l'amorçage était lent par rapport à la vitesse de propagation, la

For personal use only.

polydispersité du polystyrène qui sert de "précurseur" s'en trouverait accrue (6). Il a été montré (7) que le butyl-lithium secondaire est plus actif que l'isomère normal, c'est ce qui a déterminé notre choix. Les valeurs obtenues du rapport de polydispersité M_w/M_n pour le polystyrène "primaire" sont voisines de l'unité (< 1.1), de sorte qu'en première approximation l'on peut considérer les branches des étoiles comme identiques entre elles.

Divinylbenzène

Toutes les expériences relatées ici ont été effectuées avec les isomères para ou méta purs du DVB. Le *m*-DVB (99%) nous a été aimablement fourni par la Société Pétrofina; quant au *p*-DVB, nous l'avons obtenu à partir du mélange commercial par la méthode au chlorure cuivreux décrite par Rubinstein et Snyder (8). Deux purifications successives suivies d'une cristallisation du produit obtenu, avec élimination de la phase liquide, conduisent à une substance dont la pureté dépasse 99%.

Température

Les expériences ont été réalisées à température ambiante, et se sont prolongées durant plusieurs heures, car à cette température les polymérisations sont lentes en milieu benzénique.

Caractérisation des Polymères "en Etoile" Obtenus

La masse moléculaire du polystyrène utilisé comme "précurseur" est déterminée sur un prélèvement désactivé au méthanol, par diffusion de la lumière, en solution benzénique.

La masse moléculaire du polystyrène "en étoile" est également mesurée par diffusion de la lumière. La présence éventuelle d'homologue linéaire (précurseur) dans l'échantillon est détectée par chromatographie liquide (g.p.c.) et l'on peut ainsi, le cas échéant, corriger la valeur de M_w pour en tenir compte.

Le rapport de la masse moléculaire du polystyrène en étoile à celle de son "précurseur" linéaire conduit au nombre moyen n de branches de l'étoile. Nous avons calculé n à partir des moyennes en poids (et non à partir des M_n) ce qui conduirait à des valeurs trop élevées si les échantillons étaient fortement polydispersés. L'erreur est en fait peu importante: les résultats des fractionnements montrent en effet que la polydispersité de nos échantillons est très peu marquée.

Discussion des Résultats

Les résultats que nous avons obtenus sont présentés schématiquement au Tableau I.

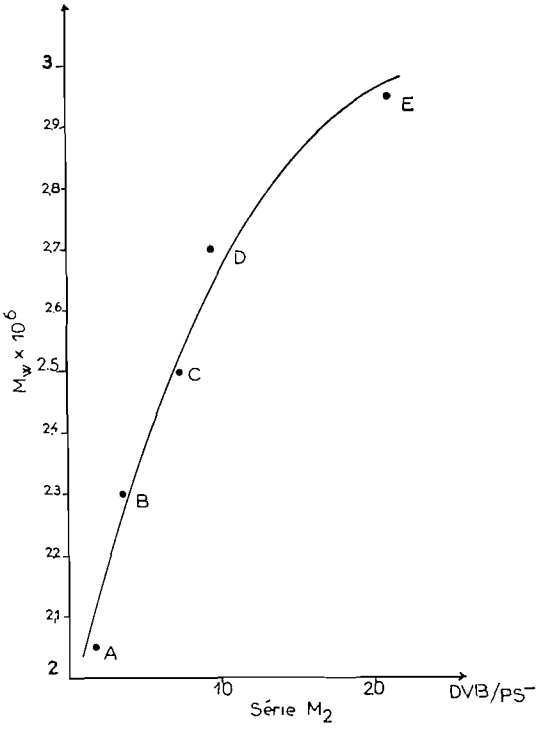

FIG. 1. Variation de la masse moléculaire du polymère en étoile en fonction du rapport DVB/PS⁻.

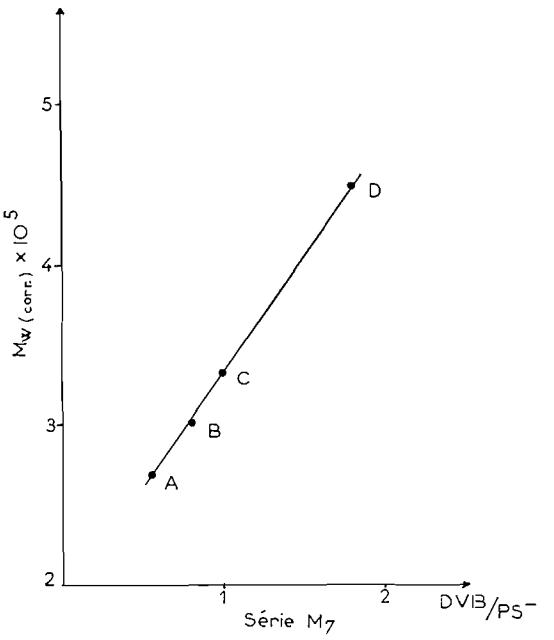

FIG. 2. Variation de la masse moléculaire du polymère en étoile en fonction du rapport DVB/PS⁻.

On peut constater, tout d'abord, que dans la plupart des expériences la proportion de précurseur linéaire dans les échantillons bruts est faible, parfois même indécelable par g.p.c.

L'influence des divers facteurs que nous avons fait varier appelle les commentaires suivants:

(1) Proportion de DVB

Le nombre de branches n des molécules en étoile formées dépend, entre autres, de la proportion de DVB mise en jeu, la concentration globale et la masse moléculaire du précurseur demeurant constantes (exp. 2). La masse moléculaire du produit formé (donc le nombre n de branches) augmente lorsque le rapport du nombre de molécules de DVB au nombre d'extrémités vivantes (DVB/PS⁻) croît de 1.8 à 21 (Fig. 1). La proportion de précurseur linéaire dans les échantillons bruts est très faible.

Lorsque la proportion de DVB est plus faible encore (exp. 7: DVB/PS⁻ variant de 0.55 à 1.8), la masse moléculaire du précurseur et la concentration globale demeurant constantes, la proportion d'homopolymère linéaire dans les échantillons devient plus importante et elle augmente en raison inverse du rapport DVB/PS⁻.

En revanche, la masse moléculaire, et par suite le nombre de branches du polymère en étoile augmente avec la proportion de DVB mise en jeu (Fig. 2). La présence d'un produit de simple couplage du précurseur n'a pu être mise en évidence; ce résultat contredit l'observation effectuée par Baer (9), selon laquelle le produit de couplage constitue l'essentiel de l'échantillon lorsque le rapport DVB/PS⁻ est voisin de 0.5.

(2) Masse Moléculaire du Précurseur

A concentration globale et proportion de DVB constantes, lorsque la masse moléculaire du précurseur linéaire augmente, le nombre de branches décroît, mais cet effet est assez faible (Fig. 3).

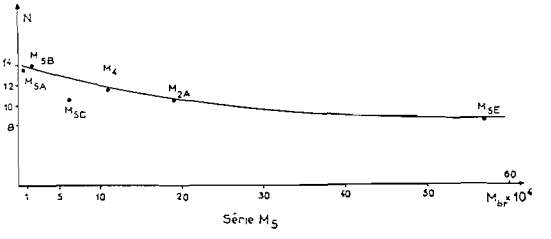

FIG. 3. Variation du nombre de branches du polymère en étoile en fonction de la masse moléculaire de la branche.

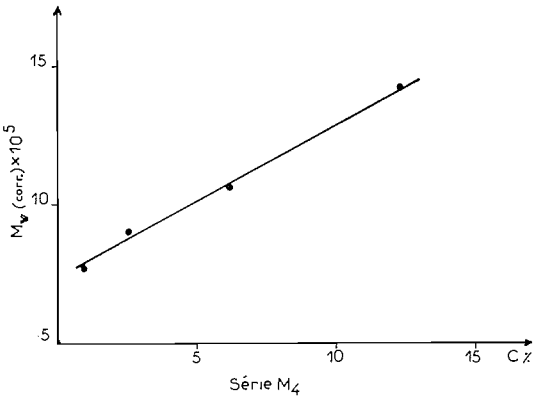

FIG. 4. Variation de la masse moléculaire du polymère en étoile en fonction de la concentration globale.

(3) Concentration Globale

Lorsque la masse moléculaire du précurseur et le rapport DVB/PS$^-$ demeurent constants, la masse moléculaire du polymère en étoile augmente avec la concentration globale du milieu réactionnel, dans le domaine de concentration considéré (exp. 4): Alors que la concentration croît de 1 à 12% la masse moléculaire du produit en étoile double (Fig. 4).

(4) Nature du Solvant

L'expérience 6 ne permet pas de conclure de façon ferme quant au rôle du solvant dans la réaction de formation des étoiles. En milieu THF, les vitesses de polymérisation sont si élevées que l'homogénéité de concentration dans le milieu réactionnel ne peut être assurée de façon satisfaisante, lors de l'addition du DVB. Toutefois la présence de 25% de PS linéaire dans le produit brut M 6 THF peut s'expliquer par des réactions accidentelles de désactivation et/ou d'isomérisation (10) qui se seraient produites pendant l'évaporation du benzène ou lors du processus de redissolution dans le THF. Il n'y en a que 8% dans le produit préparé en milieu benzénique, le précurseur étant le même, la proportion de DVB constante et les concentrations identiques.

(5) Nature de l'Isomère du DVB

La nature de l'isomère utilisé, *p*-DVB ou *m*-DVB n'affecte pas sensiblement la masse moléculaire des polystyrènes "en étoile". Dans des conditions expérimentales identiques, la masse moléculaire du produit obtenu avec le *m*-DVB est légèrement supérieure (exp. 1 et 2). Par contre les 2 isomères se distinguent par la réactivité de leurs doubles liaisons vinyliques, ainsi que le fait apparaître l'étude spectrophotométrique que nous relatons plus loin.

Fractionnement des Produits Obtenus

Nous avons déjà signalé que la présence de polystyrène linéaire dans nos échantillons est le plus souvent indécelable. Mais on peut se demander, d'autre part, si les échantillons de polystyrène "en étoile" obtenus ici sont homogènes en masse et en structure.

Nous avons soumis le produit M 2 B à une précipitation fractionnée (solvant: benzène, précipitant: méthanol) dont les résultats sont rassemblés au Tableau II. Trois fractions, recueillies dans un intervalle de γ très faible, présentent des masses moléculaires presque identiques et constituent la totalité de l'échantillon. Examinées séparément par chromatographie liquide, elles présentent des temps de rétention très voisins. Seule la 3e. fraction contient environ 25% de précurseur linéaire, ce qui correspond à 1% de l'ensemble de l'échantillon. La polydispersité de ce polystyrène "en étoile" est donc suffisamment faible pour que le fractionnement par précipitation s'avère inefficace.

Il est en général admis, que le pouvoir séparateur d'un fractionnement par élution est supérieur à celui d'une précipitation fractionnée. Aussi avons-nous soumis ce même produit (M 2 B) à un fractionnement par élution sur une colonne du type Baker-Williams à cycle de température programmé, réalisée par Koessler *et al.* (11). Le système d'élution utilisé était le mélange benzène–méthanol. Les 8 fractions recueillies ont été précipitées par le méthanol, filtrées et séchées, et elles ont été étudiées par diffusion de la lumière. Ici encore, mis à part la première fraction constituée du précurseur linéaire (3% de l'échantillon) toutes les fractions ont, à peu de chose près, la même masse moléculaire. Ce résultat, confirmé par g.p.c. des fractions, met en évidence la remarquable homogénéité en masse et en structure du polystyrène "en étoile" obtenu ici.

Etude Spectrophotométrique de la Copolymérisation Styrène–DVB

Nous avons vu, dans ce qui précède, que les polymères "en étoile" obtenus avec l'isomère

9	0.471	17.7	2 230 000

*M_{br} = 190 000, M_X = 2 300 000, $PS_{linéaire}$ = 2–3%.

para du divinylbenzène et ceux préparés à l'aide de l'isomère méta diffèrent peu du point de vue de leur masse moléculaire. Il est cependant nécessaire, pour connaître le mécanisme de la réaction, de suivre par voie spectroscopique, dans l'un et l'autre cas, l'évolution de l'absorption au cours du temps, en tachant d'identifier les bandes d'absorption pour les attribuer à tel ou tel des intermédiaires de la réaction.

En solution benzénique le polystyryl-lithium présente une bande d'absorption à 334 mμ. Les isomères para et méta du DVB absorbent respectivement à 314 et 305 mμ.

(1) Réaction du PS "Vivant" avec le p-DVB

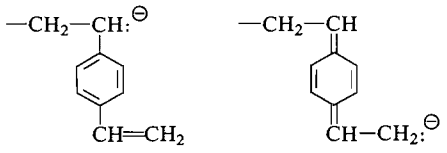
Lorsqu'on ajoute du *p*-DVB à une solution de polystyryl-lithium, en milieu benzénique, on observe la formation instantanée d'une bande d'absorption à 380 mμ. La bande à 314 mμ, correspondant au DVB monomère disparaît complètement en 20 min environ. L'absorption à 380 mμ décroît en intensité au cours du temps pour faire place à une bande située à 345 mμ, cependant qu'une autre absorption importante se situe à 297 mμ. L'assignation probable de ces diverses bandes d'absorption est présentée schématiquement au Tableau III. Il semble donc que le *p*-DVB réagisse séparément par ses 2 doubles liaisons. Cela ressort de l'existence de doubles liaisons pendantes dans le nodule de polydivinyl benzène (297 mμ). L'absorption à 380 mμ, qui concerne le carbanion en résonance avec la double liaison, confirme également ce fait.

(2) Réaction du PS "Vivant" avec le m-DVB

Si l'on effectue la même réaction, dans les mêmes conditions, avec l'isomère méta, on constate la formation immédiate de 2 bandes d'absorption, à 316 et 347 mμ imputables respectivement aux sites carbanioniques *m*-vinyliques et aux sites carbanioniques alkylés en méta, c'est-à-dire aux molécules de DVB dont les 2 groupes vinyle ont participé à la réaction. L'absorption du *m*-DVB, à 305 mμ, de même que celle à 316 mμ, disparaissent peu à peu mais une faible absorption à 297 mμ (doubles liaisons pendantes) subsiste indéfiniment.

A ces commentaires il convient d'ajouter les 2 remarques suivantes:

(*1*) Les bandes d'absorption relatives aux carbanions issus des 2 isomères se différencient nettement: 316 et 380 mμ pour le méta et le para respectivement. Cela traduit les possibilités de résonance qui n'existent que pour l'isomère para:



(*2*) En raison même de cette possibilité de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

TABLEAU III

Assignation des bandes d'absorption des espèces chimiques présentes

Espèce chimique	Assignation (mμ)	Espèce chimique	Assignation (mμ)
	334		
	314		305
	380		316
	345		347
	297 (doubles liaisons pendantes)		297

mésomérie, la réactivité des 2 groupes vinyle est plus nettement différenciée dans le cas de l'isomère para qu'elle ne l'est pour l'isomère méta. Cependant ce résultat n'est que qualitatif et ne résulte pas de l'examen de la cinétique de la réaction, au demeurant difficile à étudier dans le cas présent. Il reste que le nombre de doubles liaisons pendantes, donc inutilisées, est plus élevé pour le *p*-DVB que pour l'isomère méta.

Conclusions

Le choix de techniques expérimentales appropriées—travail sous vide poussé, utilisation du benzène comme solvant—nous a permis de faire progresser sensiblement l'étude de la préparation de polystyrènes en étoile par copolymérisation séquencée anionique de styrène avec le divinylbenzène, la proportion de ce dernier monomère étant limitée à quelques molécules par extrémité carbanionique.

Nous avons ainsi pu préparer de façon reproductible des échantillons de polystyrène en étoile exempts de "précurseur" linéaire et dont l'homogénéité moléculaire est remarquable. Le nombre moyen de branches de ces polymères en étoile dépend de la concentration globale du milieu réactionnel, de la proportion de DVB mise en jeu, par rapport au nombre de sites carbanioniques, et de la masse moléculaire du "précurseur" linéaire. Les masses moléculaires des produits obtenus avec l'un et l'autre isomère du DVB ne diffèrent guère. L'influence du solvant ne se manifeste sur la réaction que dans la mesure où l'homogénéité en concentration du milieu réactionnel ne peut plus être assurée; c'est le cas du THF, mais non celui du benzène, et

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

c'est ce qui nous a fait préférer ce dernier solvant.

L'étude spectrophotométrique de la polymérisation du DVB, amorcée par les sites carbanioniques du polystyrène "vivant" a fait apparaître des différences importantes entre le comportement des isomères méta et para du DVB. La réactivité des 2 doubles liaisons diffère sensiblement dans le cas du *p*-DVB et la proportion de doubles liaisons pendantes est, semble-t-il, bien plus élevée dans les nodules de poly-*p*-DVB que dans ceux constitués d'isomère méta.

Remerciements

Nous tenons à remercier Mme Z. Gallot, MM. A. Kohler, J. Gueguen et E. Schuster pour l'aide qu'ils nous ont apportée.

Electrochemical studies of lanthanum and lanthanum–zinc alloys in fused LiCl–KCl eutectic[1]

JEAN-BAPTISTE P. F. LESOURD AND JAMES A. PLAMBECK
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received April 14, 1969

The electromotive force of cells of the type La(s)/LiCl–KCl (eutectic) + $LaCl_3$/(La + Zn, saturated liquid alloy) has been measured over the temperature range 450–600 °C. Thermodynamic functions for the limiting lanthanum–zinc solid intermetallic compound existing in this range are: ΔG_f^0, −58.8 kcal/mole, ΔS_f^0, −53 cal/deg mole, and ΔH_f^0, −97 kcal/mole at 450 °C. The standard potential (mole fraction scale) of the La(III)/La(0) electrode is −2.883 V with respect to the Pt(II)/Pt reference electrode at 450 °C. The significance of these measurements for the electrochemical separation of lanthanum and uranium is discussed.

Canadian Journal of Chemistry, 47, 3387 (1969)

Introduction

In some methods of processing spent nuclear reactor fuel, the metallic fuel is first dissolved in liquid zinc or bismuth. The separation of fission products from uranium by oxidation–reduction reactions using these solutions has been studied (1–4, and references therein). Studies of dilute solutions of uranium in zinc have been made (4, 5) using electromotive force (e.m.f.) methods, and solubility data for metals in liquid zinc have been compiled (6).

The fission of ^{235}U gives primarily one fragment of 90–100 atomic mass units (a.m.u.) and another of 130–150 a.m.u. (7). In the latter group there are seven isotopes of lanthanum, of which one is stable, and isotopes of many other rare earth metals. Lanthanum can be considered a typical rare-earth fission product impurity, and a study of liquid–metal solutions of it is therefore desirable. A study of the lanthanum–bismuth system by e.m.f. methods has been published (8), and cerium and erbium have been studied in several liquid metals (9) including zinc. The phase diagram of the lanthanum–zinc system has been established by Vogel, Rolla, Iandelli, and Canneri (10). Pascal (11) and Hansen and Anderko (12) point out that there is disagreement on the stoichiometry of the solid compound in equilibrium with the solution in the zinc-rich part of the diagram. According to Vogel *et al.* (10), this would be $LaZn_{13}$, whereas Schramm (13) gives the formula $LaZn_{11}$. Veleckis *et al.* (14) report the existence of both these compounds. For the purpose of this paper, the formula $LaZn_{11}$ will be assumed; the results are essentially unchanged, as will be shown later, as long as the formula includes one lanthanum atom. The aim of this investigation was to study the saturated lanthanum–zinc solution in the zinc-rich portion of the diagram, between 430 and 600 °C, by measuring the e.m.f. of the cell

(−)La(s)/$LaCl_3$–LiCl–KCl/La–Zn (saturated liquid alloy)(+)

Experiments were also made to establish the standard potential of the La(III)/La(0) electrode in the fused LiCl–KCl eutectic at 450 °C.

Experimental

Apparatus

The glassware apparatus used was Pyrex and similar to that used in previous electrode potential studies in molten salts (15–17) and alloy studies by e.m.f. methods involving molten salts (4, 5). The crucible containing the molten salt was a flat-bottomed glass tube. It was contained in an envelope which consisted of a round-bottomed glass cylinder on the wall of which was blown a vacuum-cup stopcock (Corning 7544) connected to a vacuum line. This envelope was closed to the atmosphere by means of a Pyrex cap connected to it with a 75 mm O-ring joint. On this cap were blown five 14/20 female ground-glass joints which were used to insert the thermocouple well, the gas inlet, gas outlet, and the electrodes in the cell. All these were constructed such that the inside of the envelope could be isolated from the outer atmosphere or maintained under vacuum when they had been introduced. This vacuum, of 10^{-2} to 10^{-4} Torr, was maintained inside the envelope by a mercury diffusion pump in series with a mechanical pump.

The thermocouple well consisted of 5 mm glass tubing closed at its lower end, which was below the melt surface, and connected at its upper end to a 14/20 male ground-glass joint. The gas inlet consisted of 5 mm glass tubing

For personal use only.

connected to a 14/20 male ground-glass joint, sealed at its top, on the side of which was blown a vacuum-cup stopcock. Its lower end was above the melt. The gas outlet was a male 14/20 ground-glass joint on the side of which was blown a vacuum-cup stopcock; its upper end was connected to a 14/20 female ground-glass joint into which the inlet was inserted.

Electrodes

In the lanthanum electrode potential measurements, three electrodes were used: (*a*) a lanthanum electrode, which was a $\frac{1}{8}$ in. diameter and 5 in. length 99.9% lanthanum rod (A. D. Mackay, Inc., New York, N.Y.) to which a copper lead was attached well above the melt level, (*b*) a platinum reference electrode, and (*c*) a counter-electrode, each of which consisted of a large platinum flag (platinum wire and sheet from Engelhard Industries of Canada, Ltd., Toronto) welded to a copper lead and sealed to a 5 mm glass insulation tube below the lower end of the lead. These three electrodes were introduced in compartments made of a 12 mm glass tube closed with a fritted glass disc of porosity D or E (Ace Glass, Inc., Vineland, New Jersey). The bulk of the melt acted as a salt bridge. In the lanthanum–zinc alloy studies, two electrodes were used: a lanthanum electrode, as described above, and a zinc pool electrode. The liquid zinc was contained in a tantalum crucible on the bottom of the cell tube. Contact to it was made with a tungsten wire (0.020 in. diameter; A. D. Mackay, Inc., New York, N.Y.) dipped in the liquid zinc at its lower end and welded to a copper lead at its upper end; this wire and the lead were insulated with 5 mm glass tubing, the lower end of which, made of uranyl glass, was sealed to the tungsten wire about 1 cm above its lower end. At their upper end, the copper leads were sealed through a Kovar seal to a 10/30 male feedthrough which was inserted in a joint on the cap using a reducer.

To avoid thermocouple effects, connections between different metals were all made in the hot central region of the furnace.

Instruments

Potentials were measured with a Hewlett–Packard Model 3400A digital voltmeter. A Model IV coulometric current source (E. H. Sargent and Co., Chicago, Illinois) was used for electrodepositions and anodizations. The bottom part of the cell envelope was inserted in a Lindberg Hevi-Duty Type 54381A furnace with a Type 59344 temperature control unit. A constant temperature could be maintained in the cell within 1 °C. Temperatures were measured with a chromel–alumel thermocouple calibrated at the zinc melting point. The thermocouple e.m.f. was measured with the digital voltmeter.

Preparation of Molten Salt

A modification of the method of Maricle and Hume (18) was used. The anhydrous, crystalline, reagent grade lithium and potassium chlorides (The McArthur Chemical Co., Ltd., Montreal) were mixed thoroughly in eutectic portions. About 1 mole % anhydrous lanthanum trichloride (A. D. Mackay, Inc., New York, N.Y.) was added in the case of the lanthanum–zinc alloy experiments. The mixture was progressively heated under vacuum (10^{-3} to 10^{-4} Torr) to 450 °C and maintained under these conditions for 12 h in the crucible and envelope previously described. Then argon was introduced in this envelope and the crucible transferred to a Hevi-Duty Model 80 furnace under the fume hood where chlorine was bubbled through the melt for 1 h. Argon was bubbled through for 4–6 h to remove the chlorine. The melt was then poured into glass tubes that were sealed under argon for storage of the frozen melt.

Preparation of La–Zn Alloys

About 20 g of reagent grade zinc shot (May and Baker Ltd., Dagenham, Essex, England) were melted in a small glass tube under zinc chloride. The zinc piece obtained was carefully washed, dried, and polished in order to eliminate surface zinc oxide and chloride. It was then cut into smaller pieces and introduced in a 1 in. outside diameter × $\frac{7}{16}$ in. deep tantalum crucible (A. D. Mackay Inc., New York, N.Y.) together with several previously polished small pieces of lanthanum, weighing from 0.3 to 1.0 g. The crucible was then set on the bottom of the glass envelope described above, under a flow of purified argon at 500 °C, for 15–20 h. The piece of alloy was easily removed from the crucible after cooling down, owing to its contraction, and was then carefully polished and stored until use.

Procedure

A tube of purified melt was opened. The salt was introduced in the cell under argon and maintained under vacuum (10^{-3} to 10^{-4} Torr) at 400 °C for 12 h. The argon (purified by successive passage over hot copper, magnesium perchlorate, titanium sponge at 900 °C, and magnesium perchlorate) was introduced while the electrode system was set up. The cell was put under vacuum again. In the La(III)/La(0) electrode potential measurements, the platinum reference electrode was first anodized until a mole fraction of 5×10^{-4} to 10^{-3} in Pt(II) was reached in the corresponding compartment. Similarly, mole fractions of La(III) from 10^{-4} to 3×10^{-3} were obtained in successive generations in the lanthanum compartment. After each generation, the lanthanum electrode was rotated in order to obtain a homogeneous concentration of La(III) in the compartment rapidly. Its potential against the platinum reference and the temperature were then taken as a function of time. The mole fractions of ions in the compartments were calculated from the total number of equivalents generated and the total number of equivalents of chloride in these compartments, obtained by Mohr titration as previously described (19).

In the lanthanum–zinc alloy experiments, the potential of the zinc pool against the lanthanum electrode and the temperature were measured as a function of time. Then the temperature was changed and another point taken. No more than two points could be taken in a given experiment, even in evacuated apparatus which behaved better than that held under a positive pressure of purified argon. However, similar difficulties have been encountered previously and might be ascribed to corrosion tending to remove the lanthanum from the alloy (20). Lanthanum metal is such a strong reducing agent that any reducible impurities reaching the pool will react with it preferentially.

All calculations were carried out on the University of Alberta IBM 360 computer. The programs used are available in the thesis of the junior author (J.-B. P. F. L.). Error limits given are the 95% confidence limits.

Results and Discussion

Standard Potential of La(III)/La(0)

After elimination of questionable points, usually at the lower concentrations, 36 data points obtained in 6 different experiments were used. Potentials were measured as a function of La(III) concentration at a constant temperature. The time necessary to reach equilibrium varied from 5–30 min, the potential at equilibrium being constant with random variations of less than 2 mV/15 min, due to temperature fluctuations. Potentials at equilibrium were averaged over these small variations. Temperatures at equilibrium were also averaged for small fluctuations, usually of the order of 1 °C. For all experiments the mean e.m.f. values were corrected to correspond to a standard electrode of unit mole fraction Pt(II) (standard mole fraction platinum electrode, s.m.f.p.e.) as a reference (23) using the mean temperatures for each e.m.f.–concentration point. Plots of these e.m.f. values against the logarithm of the mole fraction of La(III) in the lanthanum compartment were linear (Fig. 1), showing that the lanthanum electrode is Nernstian in this solvent. For each run, the slope and the intercept of the straight lines representing the variation of the corrected e.m.f. with the logarithm of the mole fraction of La(III) were calculated by least-square analysis. The mean number of electrons involved in the lanthanum electrode process as calculated from the Nernst slopes was 3.0 ± 0.7, in agreement with the expected value of 3. One experiment gave only a single point, for which the intercept was calculated using the theoretical slope of the line for a trivalent lanthanum electrode process. These intercepts give a set of values of the standard mole fraction potentials of the lanthanum electrode against the s.m.f.p.e. at various temperatures. Linear interpolation (fitting by least-square analysis the best straight line through the experimental temperature–e.m.f. points) gave a standard potential of the La(III)/La(0) couple at 450 °C of −2.883 ± 0.007 V, on the mole fraction scale. The values obtained for this potential on the molarity and molality scales at 450 °C were −2.848 and −2.853 V, respectively, with the same precision. The temperature coefficient obtained was 4.4×10^{-4} V/°C with a standard error of 2×10^{-4} V/°C. Using the data of Laitinen and Pankey (15) for the chlorine electrode against Pt(II)/Pt(0) and the data of Yang and Hudson (21) for the lanthanum electrode against Cl_2/Cl^-, Plambeck (22) calculated a standard potential for this lanthanum electrode against Pt(II)/Pt(0) of −2.912 ± 0.005 V on the mole fraction scale. A temperature coefficient of 6.4×10^{-4} V/°C can also be calculated from these data. The potential value obtained from the present study is 28 mV more positive than that value. The problems involved in the calculation of potential values at 450 °C from the data of Yang and Hudson (21) have been discussed by Plambeck (17, 22). Plambeck (22) also points out that only a few experimental points are given for each couple (10 for La(III)/La(0)). In a study of the very similar Y(III)/Y(0) couple, Hoshino and Plambeck (23) also find electrode potentials about 30 mV higher than those calculated from the data of Yang and Hudson.

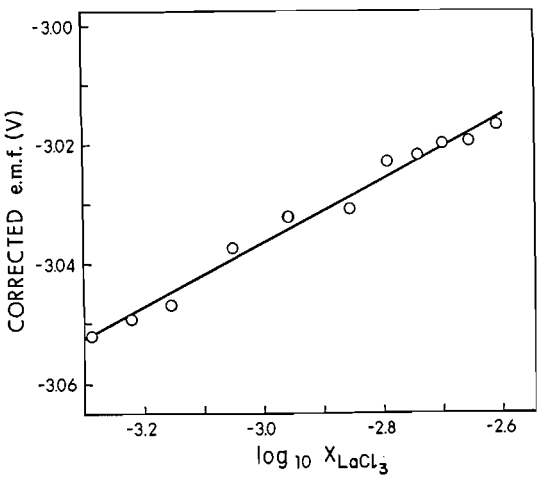

FIG. 1. Nernst plot of typical run, showing e.m.f. of La(III)/La(0) electrode, corrected to s.m.f.p.e., as a function of the mole fraction of $LaCl_3$; temperature 450 °C.

In this work, the temperature coefficient is not known accurately. It agrees satisfactorily with the value calculated from previous work in that this value falls in the range of the rather large experimental error.

Liquid La–Zn Alloy

The equation given by Johnson and Dillon (6) for the solubility of lanthanum in liquid zinc (in g/kg)

$$\log X = 9.573 - 8718/T$$

where T is the absolute temperature, gives a very low solubility of lanthanum in zinc in the range 430–600 °C (0.02 g/kg at 500 °C). It was not possible to prepare unsaturated solutions for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

study due to the extremely small quantities of lanthanum required for saturation. Attempts to prepare the saturated solutions by electrodeposition of lanthanum or by using a quantity of lanthanum slightly in excess of the literature saturation level failed; higher and less stable cell potentials were observed, possibly corresponding to unsaturated solutions. It was found necessary to take a large excess of lanthanum (1 to 5% by weight). When this was done, the potentials were independent of further addition of lanthanum (by electrodeposition on the zinc pool). This shows that saturation had been reached, with the excess lanthanum forming an intermetallic compound assumed here to be $LaZn_{11}$. Therefore at each temperature point, the e.m.f. obtained was that of the cell

$$(-)\text{La(s)/LiCl–KCl–LaCl}_3\text{/La–Zn(saturated)}(+)$$

The activity of lanthanum in this saturated solution is determined by the activity of lanthanum in the solid $LaZn_{11}$ in equilibrium with it, so that the cell can equally well be written as

$$(-)\text{La(s)/LiCl–KCl–LaCl}_3\text{/LaZn}_{11}\text{(s)}$$

A time varying from 1–6 h was found necessary to reach equilibrium, the potential at equilibrium being constant with variations of less than 0.5 mV/30 min in most cases. Potentials at equilibrium were averaged for these small variations. Temperatures were constant within 1 °C as in the La(III)/La(0) potential experiments and were similarly averaged. Thus a set of mean temperature–e.m.f. values was obtained (Table I). The best straight line through these points (Fig. 2) was fitted by least-square analysis, its equation being

$$E = 1.4085 - 7.71 \times 10^{-4}T$$

where E is the e.m.f. (V) and T the temperature

TABLE I

Electromotive force of the cell
$(-)\text{La/LaCl}_3\text{–LiCl–KCl/La–Zn(saturated)}(+)$
as a function of temperature

585.5	0.7479

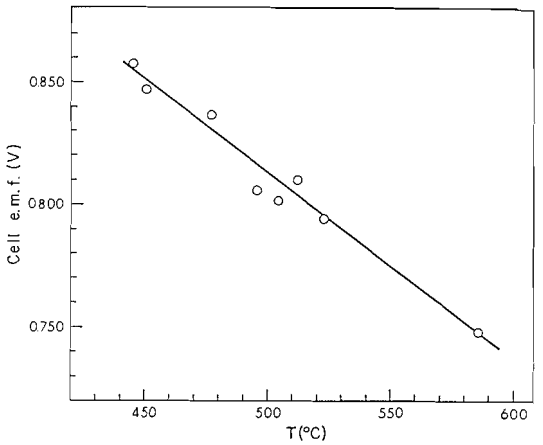

FIG. 2. Behavior of e.m.f. of La(s)/LiCl–KCl–$LaCl_3$/$LaZn_{11}$(s) cell as a function of temperature. Line is least-squares best fit.

(°K). This equation is valid over the range 430–600 °C and gives, at 450 °C, $E = 0.8506 \pm 0.005$ V. The overall process occurring in the cell amounts to the formation of the pure (solid) compound $LaZn_{11}$ from pure (solid) lanthanum and (liquid) zinc saturated with lanthanum. If ΔG is the change in free energy involved, and ΔG_f^0,$LaZn_{11}$ the free energy of formation of $LaZn_{11}$ from pure lanthanum and pure zinc, and a_{Zn} the activity of the zinc in the saturated solution, then

$$\Delta G_f^0,\text{LaZn}_{11}\text{(s)} = \Delta G + 11RT \ln a_{Zn}$$

If one assumes ideal behavior of the zinc, since the solution of lanthanum is very dilute

$$a_{Zn} = 1 - X_{La}$$

where X_{La} is the mole fraction of lanthanum. Then, since X_{La} is very small

$$\Delta G_f^0,\text{LaZn}_{11}\text{(s)} = \Delta G - 11RTX_{La}$$

TABLE II

ΔG_f^0,$LaZn_{11}$
as a function of temperature

Temperature (°C)	ΔG_f^0,$LaZn_{11}$ (kcal/mole)
430	−59.9
450	−58.8
500	−56.2
550	−53.5
600	−50.8

The term $-11RTX_{La}$ is a negligible 0.18 cal/mole at 500 °C. Thus

$$\Delta G_f^0,LaZn_{11}(s) = \Delta G = -nFE$$

where n is the number of electrons involved in the electrode reaction (three). In the same manner, the entropy of formation, $\Delta S_f^0,LaZn_{11}(s)$, is $nF(dE/dT)$, and the enthalpy of formation, $\Delta H_f^0,LaZn_{11}(s)$, can be calculated by extrapolating the free energy to 0 °K. At 450 °C for the free energy and over the temperature range 430–600 °C for the other quantities

$$\Delta G_f^0,LaZn_{11}(s) = -58.8 \pm 0.6 \text{ kcal/mole}$$

$$\Delta S_f^0,LaZn_{11}(s) = -53.4 \pm 8.0 \text{ cal/deg mole}$$

$$\Delta H_f^0,LaZn_{11}(s) = -97.4 \pm 6.0 \text{ kcal/mole}$$

In addition, $\Delta G_f^0,LaZn_{11}(s)$ was calculated at temperatures ranging from 430 to 600 °C (Table II), from the equation

$$\Delta G_f^0,LaZn_{11} = -97.415 + 5.335 \times 10^{-2}T$$

where T is in °K. It appears that these e.m.f. values differ from those obtained in a similar experiment by Johnson (24) by at most 2%. The discrepancies are somewhat greater for the entropy and the enthalpy.

Conclusion

The results of this study show that the compound $LaZn_{11}$ is of much greater stability than $UZn_{8.5}$, the standard free energies of formation at 450 °C being −58.8 and −26.1 kcal/mole, respectively. The standard potentials of pure uranium and pure lanthanum (any scale) differ by 0.630 V, making electrochemical separation of these metals appear quite feasible. Using the free energies given above, however, the difference in standard potentials of uranium (saturated solution of $UZn_{8.5}$ in Zn) and lanthanum (saturated solution of $LaZn_{11}$ in Zn) is only 0.156 V. The effect of alloying with zinc is thus to reduce the feasibility of separating these elements electrochemically by a significant factor.

Electron spin resonance spectra of triple ions: anisotropic effects in the hyperfine splitting patterns of ^{23}Na counter-ions

T. E. GOUGH[1] AND P. R. HINDLE
Department of Chemistry, University of Waterloo, Waterloo, Ontario
Received May 15, 1969

The formation, in tetrahydrofuran, of triple ions of the formula Na_2Q^+ (Q = *p*-benzosemiquinone, 2,3-, 2,5-, 2,6-dimethyl-*p*-benzosemiquinone, durosemiquinone) has been detected by electron spin resonance spectroscopy. The spectra show asymmetric broadening within the ^{23}Na hyperfine multiplets. From the direction of this broadening, it is deduced that the sodium ions lie in the plane of the semiquinone anion, one sodium ion associating with each oxygen.

Introduction

The one-electron alkali metal reduction of duroquinone (D) in ethereal solution forms durosemiquinone (D^-); the electron spin resonance (e.s.r.) spectra of the reaction products indicate extensive ionic association in such media (1–3) though, especially at low temperatures, an equilibrium exists between $M^+ D^-$ and its constituent ions. The reactions which constitute the equilibrium are sufficiently slow that well resolved spectra for $M^+ D^-$ and for D^- are obtained. When the reduction is performed in the presence of an equimolar quantity of sodium tetraphenylboride, the e.s.r. spectra indicate the presence of Na_2D^+, provided that the polarity of the solvent is sufficiently low (4). At higher polarities, e.g. in 1,2-dimethoxyethane, the spectra indicate the presence of intermolecular cation exchange reactions, though a complete interpretation of these spectra has not been achieved.

The polarity of the solvent is not the only factor controlling the formation of triple ions. Listed below are several systems in which strong ionic association occurs, yet triple ions are not observable. All of the following systems contain a semiquinone anion and excess sodium cations dissolved in a solvent of low polarity: 9,10-anthrasemiquinone and sodium iodide in 1,2-dimethoxyethane (5), 9,10-anthrasemiquinone and sodium tetraphenylboride in tetrahydrofuran (6), 2,5-di-*t*-butyl-*p*-benzosemiquinone and sodium iodide in tetrahydrofuran (5), durosemiquinone (7) and 2,6-dimethyl-*p*-benzosemiquinone (8), and sodium *t*-pentoxide in *t*-pentanol.

As part of an experimental survey on the factors governing the formation of triple ions, we report the results of experiments with *p*-benzosemiquinone and its methylated derivatives. The results show that duroquinone is not unique in its ability to form triple ions, and more importantly, provide interesting information concerning the hyperfine splitting of the ^{23}Na nucleus in the triple ions.

Experimental

The experimental techniques for the reduction of quinones and for the recording of their e.s.r. spectra have already been described (3). Addition of sodium tetraphenylboride (Fisher) was performed in two ways; simple addition of equimolar amounts of the salt and the appropriate quinone to the reduction apparatus before sealing was found to be satisfactory. In some cases, a subsidiary vessel containing the salt was joined to the reduction vessel via a high vacuum Teflon needle-valve. The solvent was distilled into this vessel and controlled amounts of the solution of sodium tetraphenylboride added to the system either before or after reduction of the quinone.

Results

When *p*-benzoquinone, 2,3-, 2,5-, and 2,6-dimethyl-*p*-benzoquinone, and duroquinone were reduced by sodium in the presence of sodium tetraphenylboride, the e.s.r. spectra of the reduced solutions indicated the presence of triple ions. In all cases the solubility of the semiquinones was markedly increased by triple ion formation; experiments to prepare sodium–semiquinone ion pairs in tetrahydrofuran were unsuccessful for all but durosemiquinone, because of the low solubility of the ion pairs. However, addition of sodium tetraphenylboride to the sample prior to reduction gave a solution which could be rapidly reduced to give intense e.s.r. spectra of the triple ion.

When controlled amounts of sodium tetraphenylboride were added, after the reduction, to a solution of the ion-pair sodium–durosemiquinone in tetrahydrofuran, well resolved spectra of both the ion pair and the triple ion were observed. The center of the spectrum of the triple ion was 0.28 G higher than that of the ion pair. Increasing the temperature of the sample favored the triple ion at the expense of the ion pair.

The proton hyperfine splitting constants of the triple ion are given in Table I, together with the literature values for the free ions for comparison. For all the triple ions studied, the proton hyperfine splitting constants were insensitive to changes in the temperature of the sample.

For all the triple ions examined, except that of 2,6-dimethyl-*p*-benzosemiquinone, hyperfine interaction with two equivalent ^{23}Na nuclei split each line of the spectrum into a septet. Within this group of the triple ions, that of durosemiquinone is exceptional since it has a positive value of $d|a_{Na}|/dT$, whereas the triple ions of *p*-benzosemiquinone and of 2,3- and 2,5-dimethyl-*p*-benzosemiquinone have negative values of $d|a_{Na}|/dT$. These data are readily accommodated by postulating that the ^{23}Na hyperfine splitting constant of the durosemiquinone triple ion has the opposite sign to that of the other triple ions. With this assumption, all the triple ions were found to have similar values of da_{Na}/dT.

Hyperfine interactions with the cations of the triple ion [2,6-dimethyl-*p*-benzosemiquinone-Na_2]$^+$ generated more complicated splitting of the spectra; depending on the sample temperature, 4, 5, 6, and 7 line patterns were obtained. These patterns were analyzed by assuming the presence of hyperfine interactions with 2 nonequivalent sodium nuclei. Computer simulations of the expected patterns for two $I = 3/2$ nuclei having hyperfine splitting constants of x and $(1 - x)$ units were performed for values of x from 0.00 to 0.50 in steps of 0.01. Each experimental spectrum was matched with the optimum calculated spectrum, and the numerical values of the 2 splitting constants found by normalization with respect to the total spread of the pattern. By analogy with the results for the other triple ions studied, signs were given to these splitting constants so that all values of da_{Na}/dT are similar. The ^{23}Na hyperfine splitting constants of the triple ions are shown diagrammatically as functions of temperature in Fig. 1. The signs of these splitting constants are discussed further below.

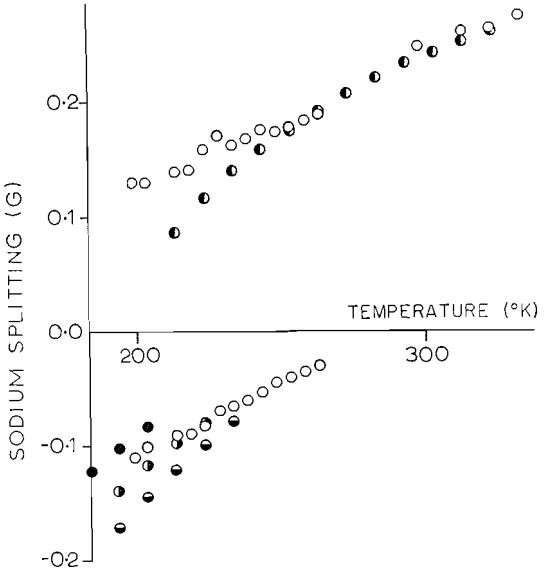

FIG. 1. Experimental ^{23}Na hyperfine splitting constants of the triple ions Na_2Q^+ in tetrahydrofuran plotted as a function of temperature. Q equals: ●, *p*-benzoquinone, ◒, 2,3-dimethyl-*p*-benzoquinone; ◑, 2,5-dimethyl-*p*-benzoquinone; ○, 2,6-dimethyl-*p*-benzoquinone; and ◐, duroquinone.

At reduced temperatures, asymmetric broadening of the ^{23}Na septets was observed. For the triple ion of durosemiquinone, the septets broadened to low field, while for the triple ions of *p*-benzosemiquinone, and of 2,3- and 2,5-dimethyl-*p*-benzosemiquinone, the septets broadened to high field (see Fig. 2). The direction of this broadening for the species [2,6-dimethyl-*p*-benzosemiquinone-Na_2]$^+$ was obscured by overlap of the lines generated by the two nonequivalent sodium nuclei.

Discussion

The e.s.r. spectra of solutions in tetrahydrofuran of *p*-benzoquinone, 2,3-, 2,5-, 2,6-dimethyl-*p*-benzosemiquinone, and duroquinone reduced by sodium in the presence of sodium tetraphenylboride, all indicate the formation of triple ions. With the exception of 2,6-dimethyl-*p*-benzosemiquinone, there is close agreement between the proton hyperfine splitting constants of an unassociated semiquinone anion and of the corresponding triple ion (see Table I), illustrating the symmetrical nature of the latter species. Because of its inherent asymmetry, the proton hyperfine splitting constants of the 2,6-dimethyl-*p*-benzosemiquinone anion are medium dependent, being affected in a complex manner by the polarity and by the molar volume of the solvent (9). Hence, agreement between the proton hyperfine splitting constants of 2,6-dimethyl-*p*-benzosemiquinone and of its triple ion is not to be expected.

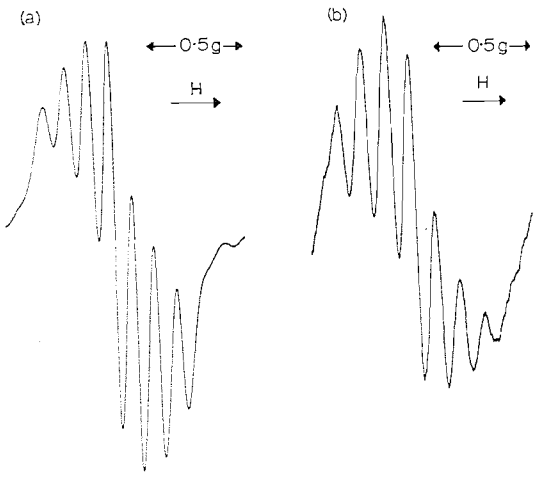

FIG. 2. ^{23}Na hyperfine multiplets of the triple ions (*a*) durosemiquinone-Na_2^+ and (*b*) 2,3-dimethyl-*p*-benzosemiquinone-Na_2^+, showing the asymmetric broadening of the alkali metal splitting.

In Fig. 1, assumptions have been made as to the signs of the sodium hyperfine splitting constants[2]; by analogy with previous studies (11–13), the signs were chosen so as to yield positive values of da_{Na}/dT for the various systems. Experimental support for this positive sign has been provided by measurements of the contact shifts of sodium and rubidium nuclei in alkali metal – aromatic anion ion-pairs (14). In the present cases, there is a correspondence between the signs of the ^{23}Na hyperfine splitting constants and the direction of the asymmetric broadening of the septet pattern, giving further support to the postulate that the spin density at the sodium nucleus may be positive or negative.

Carrington and Longuet-Higgins (15) have shown that for a radical with axial symmetry, provided nuclear relaxation may be neglected, the asymmetric line-width trends within the hyperfine splitting pattern of a nucleus are determined by the sign of the spin density at the nucleus, and by the sign of the product $(g_{\parallel} - g_{\perp})\, t_{\parallel}$ where $t_{\parallel}$ is the principal component of the anisotropic hyperfine interaction in the parallel direction. For *p*-benzosemiquinone the **g** tensor has been shown to be almost axially symmetric (16); assuming that *g* perpendicular to the plane of the ring equals the free spin value of 2.0023, it was shown that *g* along the line joining the oxygens is 2.0091, while the remaining in-plane value is 2.0024. These numerical values probably have little absolute significance, but their general form agrees with the predictions of a more theoretical study (17), and indicates the importance of the nonbonding orbitals on the oxygens in determining the **g**-tensor of a semiquinone.

For the present systems, therefore, the principal direction lies along the line joining the oxygens, and $(g_{\parallel} - g_{\perp})$ is positive: since a positive value of a_{Na} is associated with low-field broadening of the sodium septet (durosemiquinone Fig. 2*a*), and a negative value of a_{Na} with high-field broadening (e.g. 2,3-dimethyl-*p*-benzosemiquinone Fig. 2*b*), following ref. 15, $t_{\parallel}$ must be positive. Thus, the dipole–dipole interaction between the sodium nucleus and the unpaired electron is positive when the polarizing magnetic field is applied along the oxygen–oxygen axis.

[2]These assumptions may be tested by measurements of sodium contact shifts, but the required facilities are not available to the authors.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

A positive value for $t_{\parallel}$ places constraints on the possible location of the sodium ions within the triple ion. Electrostatically, the most stable position for the cations is above the plane of the anion, somewhere between the carbon and oxygen of the C—O bond; however, in this position $t_{\parallel}$ would be negative. If the sodium ions lie in the plane of the ring, the major contribution to $t_{\parallel}$ will be from the unpaired spin on oxygen. Following Slater (18) we may calculate the most probable oxygen-electron distance and then determine that $t_{\parallel}$ will be positive provided that the oxygen–sodium distance is greater than about 0.6 Å. Thus the asymmetric line-width trends observed within the ^{23}Na hyperfine splitting patterns are consistent with a structure for the triple ion in which the sodium ions lie within the plane of the aromatic ring.

To our knowledge, these triple ions are the only species in which asymmetric line-broadening of alkali-metal multiplets has been observed. A combination of factors is probably responsible for the occurrence of the phenomenon for these triple ions; the **g** tensor is, for an aromatic anion, very anisotropic. The presence of 2 sodium nuclei makes the effective nuclear spin high ($I = 3$), while the size of the linear $[NaQ\ Na]^+$ unit, because the sodium ions must retain their solvation shells, is large, causing tumbling to be slow. There is, however, no obvious difference between the extent of asymmetric broadening of the methyl hyperfine multiplets of durosemiquinone-Na and durosemiquinone-Na_2^+, although such comparisons are difficult to make because of the different spin density distributions.

If the sodium nuclei lie completely in the plane of the aromatic ring, overlap between their s orbitals and the π-orbital containing the unpaired electron will be zero, and hence the ^{23}Na hyperfine interaction will be dominated by a negative contribution from excitation of the lone pair electrons on oxygen into the 4s orbital of sodium (11, 19). On increasing the temperature, thermal motion will cause the sodium ions to spend more of their time out of the plane of the aromatic ring thereby increasing the importance of the positive interaction generated by direct overlap between the π-orbital of the unpaired electron and the s orbitals of sodium. Thus the linear model for the triple ions predicts that a_{Na} should be negative and da_{Na}/dT should be positive.

These predictions agree very well with the experimental observations (see Fig. 1) except for the triple ion of durosemiquinone and for one of the sodium ions of the triple ion of 2,6-dimethyl-*p*-benzosemiquinone; it is clear that this sodium must be the one associated with oxygen atom 7, and flanked by 2 methyl groups. Evidently, the steric effects of these flanking methyls are such as to force the sodium ions to spend more of their time away from the plane of the ring, thereby giving a net positive value for a_{Na}.

The agreement between the expected and the observed signs of a_{Na} and da_{Na}/dT may, therefore, be taken as supporting evidence for the assumptions made concerning signs when plotting Fig. 1.

Conclusion

In tetrahydrofuran, triple ions of the formula Na_2Q^+ may be formed for Q^- equal to *p*-benzosemiquinone, 2,3-, 2,5-, 2,6-dimethyl-*p*-benzosemiquinone, and durosemiquinone. One sodium ion associates with each oxygen, and lies in the plane of the aromatic ring unless flanked by two methyl groups in the ortho positions.

Kinetic solvent isotope effect, solvent reorganization, and the S_N1–S_N2 mechanism[1]

L. TREINDL[2], R. E. ROBERTSON, AND S. E. SUGAMORI
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received March 24, 1969

The temperature dependence of the rates of solvolysis have been determined in D_2O for *t*-butyl chloride, 2,2-dibromopropane, 2-bromo-2-chloropropane, and 2-chloro-2-methyl propyl methyl ether, and corresponding values of $\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta C_p^{\neq}$ are derived. Values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ from the solvolysis of seven other halides and two benzenesulfonates have been estimated from rate determinations at two temperatures in D_2O.

A comparison of these values with terms from corresponding experiments in H_2O provides values of $\delta_I\Delta G^{\neq}$, $\delta_I\Delta H^{\neq}$, and $\delta_I\Delta S^{\neq}$ characterizing the kinetic solvent isotope effect.

While $\delta_I\Delta G^{\neq}$ appears to have about the same value for a wide range of halides of different structure irrespective of the probable mechanism of reaction, systematic differences in $\delta_I\Delta H^{\neq}$ and $\delta_I\Delta S^{\neq}$ differentiate those reacting by an S_N2 mechanism from those reacting by an S_N1 mechanism. This difference is in the direction suggesting a loosening of solvent structure in the activation process in agreement with indications obtained from the corresponding values of the heat capacity of activation.

Canadian Journal of Chemistry, 47, 3397 (1969)

One of the surprising facts observed in connection with the kinetic solvent isotope effect (k_{H_2O}/k_{D_2O}, k.s.i.e.) for the hydrolysis of alkyl halides was that those compounds hydrolyzing by an S_N2 mechanism gave no indication of a significant primary isotope effect (1, 2). Equally surprising was the observation that the k.s.i.e. for a series of halides was essentially independent of the size of the displaced ion although there was a clear indication of such a correlation for the transfer energy of the ion from H_2O to D_2O (Table I). Further, it was remarkable, if not frequently remarked on, that the values of k.s.i.e. for hydrolysis by the S_N1 mechanism were just about the same as the corresponding values for the S_N2 mechanism, though all would probably agree that the degree of solvent disruption accompanying the former mechanism was much more extensive than for the latter (3). Few would disagree that primary halides hydrolyze in water by an S_N2 mechanism, or alternatively, tertiary halides hydrolyze by an S_N1 mechanism, the important structural difference in the latter being that charge distribution and steric hindrance preclude nucleophilic interaction. Further, it is reasonable to assume (4) that there will be solute structures which have intermediate requirements with respect to both nucleophilic interaction and solvent reorganization. The secondary halides appear to fall in this grouping for solvolysis in water, the entropy and heat capacity of activation having values which normally lie between those for the primary and for the tertiary halides. If significant differences in the disruption or reorganization of H_2O and D_2O attend the activation process for solvolysis of a series of halides, then these differences should be apparent in the derived terms $\delta_I\Delta H^{\neq}$ and $\delta_I\Delta S^{\neq}$, even though absent in $\delta_I\Delta F^{\neq}$.

There can be little doubt that the k.s.i.e. associated with the solvolysis of alkyl halides in H_2O and D_2O is related in some way to the difference in the structural properties of the solvents. This statement holds whether one favors an explanation based on differences in ion–water interaction at the transition state (5, 6) or alternatively attributes the rate disparity largely to the effect of differences in the work required to disrupt initial state solvent shells of differing sizes and structural stability (7).

In this paper evidence is provided, based on studies of the temperature dependence of the kinetic solvent isotope effect, which supplies a partial answer to some of the questions raised by such observations without pretending to offer final explanations.

Experimental

t-Butyl chloride, 2-chloro-2-methyl-propyl methyl ether, 2,2-dibromopropane, and 2-chloro-2-bromopropane were purified samples which had been used in a previous study (8–10) and kept at low temperatures shielded from the light for the interim. They were redistilled and passed through Al_2O_3 (Fisher, Adsorption) prior to use. All gave strictly first order kinetics. Similar considerations apply to those solutes for which an estimate of $\delta_I\Delta G^{\neq}$, $\delta_I\Delta H^{\neq}$, and $\delta_I\Delta S^{\neq}$ was made from triplicate rate determinations at two temperatures only, i.e.

benzyl chloride, cyclobutyl chloride, methyl and cyclopentyl bromide, and methyl, ethyl, and isopropyl iodide; the purity was checked by vapor-phase chromatography, as well as kinetics where the compound was not purified by the former method.

D_2O was 99.8% pure as obtained from Merck, Sharpe and Dohme, Montreal, and was redistilled through a still of the Stuart–Wormwell design to remove extraneous impurities (11).

Rate determinations were made by a conductance method which has been described in previous work (12). Care was taken to minimize the effect of adsorption of ions at the walls and to avoid supersaturation, these being the major sources of trouble.

Calculations

The extraction of information from a series of rate data determined over a range of temperatures involves a number of assumptions and procedures. The fact that these may be arbitrary or in some measure speculative is of little consequence so long as the results provide a better insight into the nature of the process being investigated and the values are not regarded as ends in themselves.

Recently it has been brought to our attention that an equation of the form we have previously used to express the temperature dependence of the rate of hydrolysis viz.

$$[1] \qquad \log_{10} K = A/T + B \log_{10} T + C$$

is ill conditioned where $T = 0$ °K. This difficulty can be avoided if a simple transformation is made as described by Clarke and Glew (13).

The problem would appear to arise, at least in part because of the limited word length available in machine computation.

Clarke and Glew point out that it is not permissible to avoid this objection by dropping lower terms in T in favor of higher powers, if an attempt is to be made to give physical interpretation to the derived constants. Rather they show that the difficulty can be avoided by an expansion based on the familiar equilibrium relation

$$R \ln K = \frac{\Delta G_T^0}{T} = \Delta S^0 - (\Delta H_T^0)/T$$

if a simple transformation of T is adopted. Restated in terms of the kinetic rate constant, k', the basic assumption of their derivation is that k_T' is a "well behaved function of T which is regular as regards continuity and derivability, so that the changes in the standard thermodynamic functions $\Delta G_T^{\ddagger}$, $\Delta H_T^{\ddagger}$, and $\Delta C_p^{\ddagger}$, which are defined by k_T and its temperature derivatives at T, are similarly well behaved functions of T". This is no more than the implicit assumption of [1]. The gain in their approach comes from the use of the mid-temperature, θ, as the reference temperature for the calculation. By expressing the effect of changing T on the value of H_0 at θ in a Taylor series and combining this with similar derivations of $\Delta S_0^{\ddagger}$ and $\Delta C_{p0}^{\ddagger}$, the Clarke and Glew expression for the temperature dependence of k' can be expressed in the form

$$[2] \qquad R \ln k' = -\frac{\Delta G_0^{\ddagger}}{\theta} + \Delta H^{\ddagger}\left[\frac{1}{\theta} - \frac{1}{T}\right] + \Delta C_{p0}^{\ddagger}\left[\frac{\theta}{T} - 1 + \ln\frac{T}{\theta}\right] + \frac{\theta}{2}\left(\frac{d\Delta C_{p\theta}^{\ddagger}}{dT}\right)_0\left[\frac{T}{\theta} - \frac{\theta}{T} - 2\ln\left(\frac{T}{\theta}\right)\right] \ldots \text{etc.}$$

which will be seen to be equivalent to the equation

$$R \ln k' = A + B/T + C \ln T + DT + \ldots .$$

θ is in the mid-range of the experimental data and $k' = k_{obs}/(kT/h)$, a substitution, in accord with transition state theory, made at this point for computational convenience, where $k = 1.38034 \times 10^{-16}$ ergs/°K, $h = 6.256 \times 10^{-27}$ ergs/s.

For the case where $d\Delta C_p^{\ddagger}/dT = 0$, and for any temperature T

$$RA' = -\Delta G_T^{\ddagger}/T + \Delta H_T^{\ddagger}/T - \Delta C_{pT}^{\ddagger}(1 + \ln T)$$

$$RB' = -\Delta H_T^{\ddagger} + \Delta C_{p\theta}^{\ddagger} T$$

$$RC' = \Delta C_p^{\ddagger}$$

The fourth term expresses the temperature dependence of $\Delta C_p^{\ddagger}$ and requires more accurate data than are presently available to us, hence in our work this term was set equal to zero.

The original paper (13) should be consulted for the details of the method of calculating the derived constants and corresponding errors.

Results and Discussion

The rate data for the solvolysis of 2,2-dibromopropane in D_2O are given in Table I. These are typical of the series[3].

Values of $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ (with corre-

[3]Values of rates included in this study but not reported here have been filed with the Depository of Unpublished Data, from which photocopies may be obtained free of charge, on request, from the National Science Library, National Research Council of Canada, Ottawa, Canada.

sponding errors) calculated by the method outlined by Clarke and Glew (13) are given in Table II, for several temperatures covering the mid-range of the experiments. Empirical constants corresponding to eq. [2] for the interpolative calculation of k_T are given in Table III.

Data for an assemblage of other alkyl halides at two temperatures are given in Table IV. The aim in these cases was to get a wider indication of the values of $\delta_1\Delta H^{\ddagger}$ and $\delta_1\Delta S^{\ddagger}$ with attempting to define these terms as carefully as was done in Table II.

The Kinetic Solvent Isotope Effect

The fact that the values of the k.s.i.e. for the hydrolysis of the majority of alkyl halides whether reacting by an S_N1 or an S_N2 mechanism lie in the range 1.20–1.30 is well established (2, 12, 14). In many cases small differences can be readily attributed to differences in the experimental temperature or to modification of the initial state

solvation shell—a source of difference most evident where corresponding halides and sulfonates are compared (12). The new results reported here merely confirm these generalizations, the values of $\delta_I\Delta G^{\ddagger}$, Table VI, being remarkably similar for all halides.

We cannot disregard the possibility that some of the differences in $\delta_I\Delta G^{\ddagger}$ are caused by initial state differences as was shown to exist for the methyl halides by Thornton and Swain (16, also 21). In so far as these differences arise from size, some compensation is to be expected between initial and transition state solvation.

Clearly, the values of $\delta_I\Delta G^{\ddagger}$ are not dependent in a systematic way on the size of the displaced halide ion, no trend through the series Cl^-, Br^-, I^- being found, such as is evident in ΔG for the free energy of transfer from D_2O to H_2O for the corresponding sodium salts (15), see Table V.

Reference has already been made to the absence of any apparent contribution to the k.s.i.e. in the solvolysis of these halides where some degree of nucleophilic interaction may be assumed. This is not true for all solvolytic displacements.

Thus we know (17) from parallel studies on benzenesulfonyl chloride that when a larger degree of nucleophilic interaction is required at the transition state (as indicated by the high $k_{OH^-}/k_{H_2O} = 10^5$ ratio for the hydrolysis of benzenesulfonyl chloride (18–20)) an indication of a small primary isotope effect is apparent in the k.s.i.e. ($k_{H_2O}/k_{D_2O} = 1.56$). The implication from the $\delta_I\Delta G^{\ddagger}$ values in Table VI is that in the alkyl halide series, where nucleophilic interaction is required, the latter must be small and consequently the k.s.i.e. in the latter cases reflects solvent reorganization only.

$\delta_I\Delta H^{\ddagger}$ *and* $\delta_I\Delta S^{\ddagger}$

Aside from the absence of any notable changes in $\delta_I\Delta G^{\ddagger}$ with a change in mechanism from S_N1 to S_N2 or of any systematic dependence on the size of the displaced ion through the series Cl^-, Br^-, I^-, the large fact apparent in Table VI is that the $\delta_I\Delta H^{\ddagger}$ values for those molecules reacting by an S_N1 mechanism are larger than the corresponding values for those halides which solvolyze by an S_N2 mechanism.

Before examining the mechanistic implications of this apparent grouping of $\delta_I\Delta H^{\ddagger}$ values in

terms of S_N1/S_N2 characteristics, it is important to note that in every case $\Delta H^{\neq}$ is *greater* for solvolysis in D_2O than in H_2O and there is a corresponding *increase* in $\Delta S^{\neq}$. If we bear in mind that D_2O gives evidence of greater structural stability than H_2O (21) both of these facts are consistent with the idea that in all cases the activation process involves the break-down of water structure, the greater degree of structure in D_2O providing a ready explanation for the sign of the difference terms (7).

We note that while $\delta_I\Delta S^{\neq}$ tends to cancel out a part of $\delta_I\Delta H^{\neq}$ for those halides which are considered to hydrolyze by an S_N2 mechanism, there is almost a total compensation for the increase in $\delta_I\Delta H^{\neq}$ which characterizes those halides reacting by an S_N1 mechanism. This would seem to suggest that the solvent reorganization about the developing cation is in some respects different from that which occurs about the developing anion. There will be significant differences in charge density at the surface of the anion and cation and, as Samoilov has shown, these differences can result in positive or negative hydration effects (22). However, the phenomena revealed in the above experiments would seem to be closer to a kind of "melting" of the solvation shell about the cation, with a negligible change in free energy. This effect seems inconsistent with the concept of advanced exothermic solvation of the developing cation at the transition state, however widely this hypothesis has been adopted in theoretical speculations (3, 23, 24).

The possibility that these differences arise as a consequence of initial state differences cannot be excluded on the basis of present information but seems very unlikely in view of the known characteristic of aqueous solutions (25–28).

These results are consistent with the well established observation that the S_N1 mechanism appears to involve a more extensive reorganization of solvent than the S_N2 mechanism, and these differences would appear to provide a quantitative basis for mechanistic distinction, if comparisons are made at the same temperature. The latter requirement will be evident if two related hypotheses are considered. The source of the solvent isotope effect depends on the difference in structural stability of H_2O and D_2O at a given temperature (7). The heat capacity of activation $\Delta C_p^{\neq}$ which characterizes such reactions is attributed to the decrease in the structural stability of the initial state solvation shell with increasing temperature (12). Thus, as the average experimental temperature range from which $\delta_I\Delta H^{\neq}$ is derived increases, the apparent structural stability of the initial state solvation shell decreases both absolutely and differentially as between H_2O and D_2O. The latter decrease may be illustrated[4] by the change in the relative viscosity of H_2O and D_2O with temperature: $k_{D_2O}/k_{H_2O} = 1.305$ at 5°, 1.245 at 20°, 1.202 at 40°, 1.164 at 80° (29). Similar results can be found for the related times of dielectric relaxation (30). Hence the requirement is that comparisons of $\delta_I\Delta H^{\neq}$ refer to the same temperature range, or that some allowance be made for decreasing structure with increasing temperature if this is not practical. Similarly the temperature dependence of $\Delta H^{\neq}$ ($\Delta C_p^{\neq}$) due to the temperature dependence of the structure of water will be greatest at low temperatures and will decrease as the temperature increases, regardless of mechanism. These considerations introduce limitations but do not wipe out the inherent utility of $\Delta C_p^{\neq}$ or, in the present instance, of $\delta_I\Delta H^{\neq}$ as useful indicators of solvent reorganization accompanying ionogenic processes in water. These quantitative indicators are all the more useful at this stage because, as yet, $\Delta S^{\neq}$ has proved to be of little value for this purpose.

Data supporting the above consideration for

[4]Anett and McElvey find a similar evidence of enhancement of structure at lower temperatures (37).

$\delta_I\Delta H^{\neq}$ are given in Table VI. In each example where $\delta_I\Delta H^{\neq}$ values are given at two temperatures for compounds **1**, **2**, and **3**, there is a sharp decrease between values at 20 and 40°, though part of this decrease may be more apparent than real, due to the increase in error at the extremes of the experimental range. When comparisons are made at 40 °C, we note that the values of $\delta_I\Delta H^{\neq}$ for 2-bromopropane, **5**, and for benzyl chloride, **13**, are significantly lower than those for the tertiary halides, **2**, **3**, and **6** which react by an S_N1 mechanism. Cyclopentyl bromide, **7**, in this comparison and also with respect to the corresponding value of $\Delta C_p^{\neq}$ (12), appears to have an intermediate value.

Initially the large difference in the values of $\delta_I\Delta H^{\neq}$ and of $\delta_I\Delta S^{\neq}$ for the hydrolysis of tertiary halides (e.g. **1**, **2**, and **3**) and the primary halides (e.g. **8**, **9**, **10**, and **11**) prompted the hope that a mechanistic distinction could be based on isotopic solvation differences[5]. The accumulation of the data given in Table VI showed that while significant differences do exist in $\delta_I\Delta H^{\neq}$ and $\delta_I\Delta S^{\neq}$ for tertiary and primary halides where the question of mechanistic distinction hardly exists, no such distinction was apparent in the results for the secondary halides where an additional basis for mechanistic distinction was desirable. A hypothesis to account for the intermediate values of $\delta\Delta H^{\neq}$ and $\delta_I\Delta S^{\neq}$ for secondary halides can be found in the consideration that there is less opportunity for charge dispersal in the quasi-cation in the case of secondary than tertiary halides. This hypothesis would also account for the difference in $\delta_I\Delta H^{\neq}$ and $\delta_I\Delta S^{\neq}$ (Table VI) and in $\Delta C_p^{\neq}$ (12) between 2-bromopropane, **5**, cyclopentyl bromide, **7**, and cyclobutyl chloride, **6**. The values of $\Delta C_p^{\neq}$ determined for the hydrolysis of 2-bromopropane and 2-iodopropane are somewhat more negative than those which characterize the hydrolysis of primary halides (12). This is indicative of a more extensive solvent reorganization in the activation process. The same conclusion can be drawn from the value of $\delta_I\Delta H^{\neq}$ for **5** but not for the corresponding value of **12**. We have no explanation for the latter difference. Values of $\Delta C_p^{\neq}$ calculated for allyl iodide, **11**, and benzyl chloride, **13**, are -47 and -39 cal deg^{-1} mole^{-1} while the corresponding values of $\delta_I\Delta H^{\neq}$ are about the same. Benzyl chloride may react by "mixed kinetics". While $\Delta C_p^{\neq}$ would be sensitive to such a mechanistic change, $\delta_I\Delta H^{\neq}$ would not. This lack of sensitivity of $\delta_I\Delta H^{\neq}$ to mechanistic differences for displacement from primary and secondary carbon is further illustrated by the sulfonates, **14** and **15**. Here $\delta_I\Delta H^{\neq}$ and $\delta_I\Delta S^{\neq}$ are both reduced as would be anticipated from earlier discussions (2) and there is no indication of a mechanistic difference.

Rate data for the primary halides **8**, **9**, **10**, and **11** were obtained at higher average temperatures and reflect, in part, a decrease in $\delta_I\Delta H^{\neq}$ due to this fact as well as to the reduced requirement for solvent reorganization in the S_N2 compared to the S_N1 mechanism.

From the above kinetic evidence we must conclude that while large differences in solvent reorganization are found, as between tertiary and primary halides, there is no corresponding differentiation between primary and secondary halides whether the latter react by an S_N1, S_N2, or "mixed" mechanism.

Finally we draw attention to the similarity between the values of $\delta_I\Delta H^{\neq}$ and $\delta_I\Delta S^{\neq}$ for the activated process of liquid flow, **16**, in water and D_2O (36), and the corresponding values determined for the S_N2 process which may be taken as further support that the transition state corresponds to a state of disruption of solvent structure (14).

$\delta_I\Delta C_p^{\neq}$

The change in heat capacity ($\delta_I\Delta C_p^{\neq}$) in a qualitative way is consistent with the idea that structural stability is greater in D_2O than in H_2O and hence will show a greater (negative) temperature dependency. Unfortunately the errors associated with this term in this study are so large as to prevent any useful deductions other than to note that all are more negative than the corresponding term for hydrolysis in H_2O and much larger than the previous value, $\delta_I\Delta C_p^{\neq} = 5$ (Table II) for 2-bromopropane, **5**, or from the ionization of acetic acid $\delta_I\Delta C_p = 3$ cal mole^{-1} deg^{-1} (32), the ionization of phosphoric acid (K_2) (33), ($\delta_I\Delta C_p =$ 4.3 cal mole^{-1} deg^{-1}) and for the autoprotolysis of water, $\delta_I\Delta C_p = 8$ cal mole^{-1} deg^{-1} (34). The differences in our kinetic measurements do not appear to be random since they are all in the same direction, nor have we been able to find any trivial experimental reason which would account for them.

[5]As presented at the 151st meeting of the American Chemical Society, Pittsburgh, Penn. March 22–31, 1966.

TABLE VI

Thermodynamic differences for hydrolysis of a series of halides*

Compound number	Halide	Mechanism	Temperature (°C)	$\delta_t\Delta G^{\ddagger}$	$\delta_t\Delta H^{\ddagger}$ (cal mole^{-1})	$\delta_t\Delta S^{\ddagger}$ (cal deg^{-1} mole^{-1})	$\delta_t\Delta C_p^{\ddagger}$ (cal deg^{-1} mole^{-1})

*Where the rate data for solvolysis in water have been taken from earlier work, the compound and its reference are as follows: 1, (8); 2, (10); 3, (10); 4, (9); 5, (14); 6, (35); 7, (12); 8, (12); 11, (31); 12, (12); 13, (31); 14, (12); 15, (12); 16, (36); 17, (38).

In conclusion we may summarize the above results by the observations that while this study of the temperature dependence of the solvent isotope effect does not require any new hypothesis, it does provide substantial supplementary support for those hypotheses already proposed to account for the nature of solvent reorganization accompanying hydrolysis of alkyl halides in water.

Phosphinohydrazines. Part III. Coordination compounds of N,N-dimethyl,N′-diphenylphosphinohydrazine and N,N-dimethyl,N′-diphenylthiophosphinatohydrazine

E. W. AINSCOUGH, L. K. PETERSON[1], K. I. THÉ, AND G. L. WILSON
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received May 6, 1969

Reactions between N,N-dimethyl,N′-diphenylphosphinohydrazine, $Me_2NNHP(C_6H_5)_2$, (DPH), or N,N-dimethyl,N′-diphenylthiophosphinatohydrazine, $Me_2NNHP(S)(C_6H_5)_2$, (DPS), and appropriate metal salts have yielded the new coordination complexes $Pd(DPH)Cl_2$, $Pd(DPH)_2Cl_2$, $Pd(DPH)_2Cl(ClO_4)$, $Pt(DPH)_2Cl_2$, $Pt(DPH)Cl_4$, $Hg(DPH)Cl_2$, $Pd(DPS)Cl_2$, $Pt(DPS)Cl_4$, $Ag(DPS)NO_3$, $Zn(DPS)Cl_2$, $Cd(DPS)Cl_2$, and $Hg(DPS)Cl_2$. Notably, complexes of 1:1 ligand: metal stoichiometry predominate, the only exceptions being $Pd(DPH)_2Cl_2$ and $Pt(DPH)_2Cl_2$. In reactions between DPH and Zn(II) or Cd(II) salts, ready cleavage of the P—N bond was observed; the metal complexes of dimethylhydrazine were isolated in both instances. With the ligand DPS, however, the P—N bond was consistently stable against cleavage. Many reactions involving Co(II), Ni(II), Ag(I), Au(III), In(III), and Sn(II) resulted in the formation of intractable oils, or in reduction to the metallic state.

Canadian Journal of Chemistry. 47, 3405 (1969)

In previous communications we reported the synthesis and characterization of a series of perfluoroalkyl-phosphino- and arsino-substituted hydrazines, describing these systems as potential polyfunctional Lewis bases with lone pairs of electrons located on each atom of the P—N—N or As—N—N skeleton (1). One would expect different base character at each site, determined by the electronic, steric, and structural environment of the sites in the free and in the complexed molecule. Thus, whereas the N atoms may only exhibit σ donor character, the P or As atoms may function as π acceptors as well as σ donors, particularly when the substituent on P is the electronegative CF_3 group (2). The location of the most basic site in these systems is a problem of some interest to us. Bidentate functionality should lead to the formation of either chelate or polynuclear complexes. The "mixed" nature of the donor sites on the ligand and the presence of an atom other than carbon linking these sites provide additional features of interest in these systems. The functionality of hydrazine, N_2H_4, may be inferred from published reports (3–5). Several interesting examples of chelation by tetramethylhydrazine with alanes have been reported (6*a*, 6*b*), the complexes involving a three membered Al chelate ring, and five-coordinate aluminum. The symmetrical 1,2-bis(diphenylphosphino)-1,2-dimethylhydrazine, $(C_6H_5)_2PN(CH_3)N(CH_3)P(C_6H_5)_2$, however, reacts with 2 moles of trialkyl aluminum, giving complexes for which tetracoordinate aluminum atoms have been proposed, with each phosphorus serving as the donor site (6*c*). The basicity of hydrazines is diminished by alkyl substitution (7), contrary to the trend observed among alkylamines (8). Various adducts of hydrazines are unstable with respect to condensation reaction, leading to the formation of hydrazino-metallanes, such as the reported derivatives of boranes (9), alanes (6*a*, 6*b*, 10), silanes (11), phosphines (12), and arsines (1*a*). While hydrazine forms complexes with most of the elements of the first transition series (13), structural studies, indicating a variety of modes of coordination, have been performed only with $Co(N_2H_4)_6Cl_2$ (14), $Ni(N_2H_4)_3Cl_2$ (15), $Zn(N_2H_4)_2Cl_2$, $Cd(N_2H_4)_2Cl_2$, and $Mn(N_2H_4)_2Cl_2$ (16), and with $Hg(N_2H_4)Cl_2$ and $Hg(N_2H_4)_2Cl_2$ (17). Hydrazine causes reduction of Ti(IV) halides (18), but reasonably stable complexes are formed with Ti(IV) alkoxides (19), and with UCl_4 (20). Substituted hydrazines effect solvolysis of Ti(IV) halides, without reduction. Octahedral structures are proposed for $M(MeNHNH_2)Cl_2$ and $M(MeNHNH_2)_6Cl_2$, M = Co(II) (14), Ni(II) (17); the type $M(MeNHNH_2)_3Cl_2$ is not formed, perhaps because of the greater basicity of the nitrogen atom bearing the methyl group. This paper describes the synthesis of a series of complexes with phosphinohydrazine ligands, as part of a study of the factors determining the functionality of such systems.

Preliminary work with $Me_2NNHP(CF_3)_2$ gave rise to dark brown products, indicative of instability or undesirable side reactions. The diphenylphosphine derivative, $Me_2NNHP(C_6H_5)_2$, however, is more stable, and can be handled quickly in air without serious oxidation (12*d*). In addition, Nielsen *et al.* (21) have already demonstrated that the phosphorus is more basic than either of the nitrogen atoms. Thus with chloramine or methyl iodide, electrophilic attachment occurs on the phosphorus atom. Furthermore, the phosphorylhydrazine $Me_2NNHP(O)(C_6H_5)_2$, DPO, fails to react (at an N center) with methyl iodide or chloramine, indicating a deactivation of both of the nitrogen atoms toward electron acceptor species. The DPO and DPS ligands may provide four- and five-membered chelate ring systems utilizing O (or S) and central N or terminal N coordination. The preferred structure should reflect the combined influence of relative ring strains, steric hindrances, and donor atom basicities, for the various structures.

DPH and $Na_2PdCl_4.H_2O$ react readily in acetone solution, in 1:1 and 2:1 molar ratios, to yield $Pd(DPH)Cl_2$ or $Pd(DPH)_2Cl_2$, respectively. The latter compound was converted into $Pd(DPH)_2Cl(ClO_4)$ by reaction with sodium perchlorate. In similar reactions using DPS, only 1 mole of ligand is taken up, giving $Pd(DPS)Cl_2$. A study of the structural possibilities of mononuclear systems, using molecular models, indicates that a complex containing 2 moles of ligand, i.e. $Pd(DPS)_2Cl_2$, may be constructed with DPS as a monodentate ligand, and with S or N as the donor atom; but if DPS favors chelation, some steric hindrance is indicated for complexes of this type. The complex of platinum, $Pt(DPH)_2Cl_2$, is obtained in the same way as its palladium analogue. It is likely that other members, corresponding to the various palladium compounds, could be synthesized. In its higher oxidation state, Pt(IV) forms both DPH and DPS complexes, without evidence of redox reactions.

Equimolar proportions of mercuric chloride and DPH or DPS yield $Hg(DPH)Cl_2$, a complex which decomposes slowly with liberation of mercury, and stable $Hg(DPS)Cl_2$. Attempts to prepare the complexes containing 2 ligand moieties, using appropriate proportions of reagents, failed in both cases; DPH causes the reduction of $HgCl_2$ to mercury, while DPS yields only $Hg(DPS)Cl_2$, analogous to the DPS–Pd(II) studies. Silver(I) is rapidly reduced by DPH, but it reacts with DPS to form $Ag(DPS)NO_3$. The latter, however, is photosensitive.

For reasons of solubility, methanol was used as the solvent in reactions involving $ZnCl_2$ or $CdCl_2$. Attempts to prepare a series of complexes of DPH yielded derivatives of dimethylhydrazine, DMH, viz., $Zn(DMH)_2Cl_2$ and $Cd(DMH)Cl_2$, indicating solvolysis of the P—N bond. Similar reactions with DPS yielded 1:1 complexes only, $Zn(DPS)Cl_2$ and $Cd(DPS)Cl_2$, the P—N bond remaining intact.

It is evident that phosphinohydrazine systems are effective as ligands with a variety of acceptor species. With DPH, strongly oxidizing conditions must be avoided, since the P(III) atom and the hydrazine moiety are both sensitive to oxidation. DPS, however, is more difficult to oxidize, and may therefore complex with metals in high oxidation states, without the onset of reduction. While the P—N bond in P(III) systems is sensitive to solvolysis, in P(V) systems it is more resistant to cleavage. A study of the physico-chemical properties of the above complexes is in progress.

Experimental

The ligands N,N-dimethyl,N′-diphenylphosphinohydrazine (DPH), and N,N-dimethyl,N′-diphenylthiophosphinatohydrazine (DPS), were prepared by the methods of Nielsen and Sisler (12*d*). The new complexes prepared are given in Table I, together with analytical data[2].

Dichloro(N,N-dimethyl,N′-diphenylphosphinohydrazine) palladium(II), Pd(DPH)Cl₂

Acetone solutions (about 10 ml of each) of DPH (0.122 g) and $Na_2PdCl_4.H_2O$ (0.156 g) were mixed and gently heated on a steam bath until a yellow precipitate was formed. This was collected and recrystallized twice from warm CH_2Cl_2 to remove sodium chloride (yield, 0.12 g, 60%). The compound was soluble in warm acetone, chloroform, and nitrobenzene. The same product was obtained with methanol as solvent.

Dichlorobis(N,N-dimethyl,N′-diphenylphosphinohydrazine)palladium(II), Pd(DPH)₂Cl₂

Acetone solutions of DPH (0.24 g) and $Na_2PdCl_4.H_2O$ (0.156 g, 15 ml) were mixed, causing precipitation of sodium chloride at room temperature. The mixture was filtered and solvent was removed from the filtrate by vacuum distillation, leaving behind an oily residue, which was dissolved in dry CH_2Cl_2 and filtered. A difficult recrystallization was achieved by treating this solution with ether, cooling in an ice bath, and scratching, to yield

[2]Analyses were performed by Pascher, Mikroanalytisches Laboratorium, 53 Bonn, Buschstrasse 54, Germany.

TABLE I

Analytical data for complexes of DPH, DPS, and DMH

Compound*	Color	Analyses					
		Observed			Calculated

$Hg(DPS)Cl_2$	White	30.7	3.18	5.06	30.7	3.12	5.11

*DPH = N,N-dimethyl,N′-diphenylphosphinohydrazine, DPS = N,N-dimethyl,N′-diphenylthiophosphinatohydrazine, and DMH = N,N-dimethylhydrazine.

a pale yellow product (0.210 g, 65%). This substance was slightly soluble in most common solvents.

The corresponding platinum complex, $Pt(DPH)_2Cl_2$, was prepared in a similar way.

Chlorobis(N,N-dimethyl,N′-diphenylphosphinohydrazine) palladium(II)perchlorate, $Pd(DPH)_2Cl(ClO_4)$

Warm acetone solutions of $Pd(DPH)_2Cl_2$ (0.160 g) and excess sodium perchlorate (0.180 g, 15 ml) were mixed and heated until a small volume of solution remained; upon filtering, the filtrate was treated with ether and was cooled at 0 °C to induce precipitation. The pale yellow product was recrystallized twice from CH_2Cl_2 (0.10 g, 60%). It was soluble in several common solvents.

Attempts to replace both chloro groups on $Pd(DPH)_2Cl_2$ by this method were unsuccessful.

Dichloro(N,N-dimethyl,N′-diphenylphosphinohydrazine) mercury(II), $Hg(DPH)Cl_2$

Acetone solutions of DPH (0.24 g, 8 ml) and $HgCl_2$ (0.27 g, 10 ml) were mixed and heated until a small volume of solvent remained. On cooling, a white precipitate was obtained which did not require further purification (0.35 g, 70%). It was sparingly soluble in chloroform, and slowly decomposed on standing, liberating free mercury.

Tetrachloro(N,N-dimethyl,N′-diphenylphosphinohydrazine)platinum(IV), $Pt(DPH)Cl_4$

Acetone solutions of DPH (0.057 g) and Na_2PtCl_6 (0.094 g) were mixed together and heated, resulting in precipitation of sodium chloride. The solution was filtered, most of the solvent was removed, and ether was added to effect precipitation of the product. It was recrystallized from acetone (0.08 g, 70%; color, pale yellow).

The corresponding complex with DPS, $Pt(DPS)Cl_4$, was prepared in a similar way.

Reaction of DPH with $ZnCl_2$ and $CdCl_2 2.5H_2O$

For reasons of solubility, methanol was used as the solvent for the reaction between DPH (0.24 g) and $ZnCl_2$ (0.136 g). The solution was heated to remove most of the solvent, then cooled and diluted with ether to precipitate a white substance with analytical data indicative of bis(N,N-dimethylhydrazine)zinc dichloride, $Zn(DMH)_2Cl_2$ (0.13 g, 50%; DMH = N,N-dimethylhydrazine). This compound was sparingly soluble in acetone and insoluble in chloroform. The same substance was obtained during the attempted synthesis of a bis(DPH) complex of zinc chloride. These results indicate solvolysis of the DPH ligand at the P—N bond, to yield free dimethylhydrazine.

The reaction with cadmium chloride was similar, in that solvolysis of the DPH ligand took place and N,N-dimethylhydrazinecadmium dichloride, $Cd(DMH)Cl_2$, was obtained in 50% yield. This substance was practically insoluble in most solvents.

Dichloro(N,N-dimethyl,N′-diphenylthiophosphinatohydrazine)palladium(II), $Pd(DPS)Cl_2$

Acetone solutions of DPS (0.184 g) and $Na_2PdCl_4H_2O$ (0.209 g) were mixed at room temperature, yielding immediately an orange precipitate which was recrystallized twice from CH_2Cl_2 to remove sodium chloride (0.20 g, 70%).

Attempts to prepare $Pd(DPS)_2Cl_2$ were unsuccessful; the complex described above was obtained in each case.

Nitrato(N,N-dimethyl,N′-diphenylthiophosphinatohydrazine)silver(I), $Ag(DPS)NO_3$

Acetone solutions of DPS (0.069 g) and $AgNO_3$ (0.042 g) were mixed to form a white precipitate which was insoluble in many common solvents (0.08 g, 90%). Attempts to effect dissolution by heating led to decomposition of the complex. This compound turned grey on exposure to light.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The corresponding DPH complex could not be isolated —a reduction reaction resulted in the formation of metallic silver.

Dichloro(N,N-dimethyl,N'-diphenylthiophosphinato-hydrazine)zinc(II), Zn(DPS)Cl_2

Using methanol as solvent, solutions of DPS (0.212 g) and $ZnCl_2$ (0.092 g) were mixed and briefly heated. Upon cooling, a white precipitate was obtained (0.22 g, 70%). This compound was insoluble in common solvents.

Attempts to prepare $Zn(DPS)_2Cl_2$ were unsuccessful.

Dichloro(N,N-dimethyl,N'-diphenylthiophosphinato-hydrazine)cadmium(II), Cd(DPS)Cl_2

Methanol solutions of DPS (0.138 g) and $CdCl_2$-$2.5H_2O$ (0.114 g), corresponding to a 2:1 molar ratio of reactants, were mixed and boiled until only a small volume of solvent remained. On cooling and adding ether, a white precipitate was obtained (0.16 g, 70%). This compound was insoluble in common solvents.

Dichloro(N,N-dimethyl,N'-diphenylthiophosphinato-hydrazine)mercury(II), Hg(DPS)Cl_2

This compound was prepared in the same way as $Zn(DPS)Cl_2$, using DPS (0.184 g) and $HgCl_2$ (0.181 g) in methanol solution (yield, 0.27 g, 75%). It was soluble in acetone and chloroform. Attempts to prepare $Hg(DPS)_2Cl_2$ failed.

Crystal structure of $Cd_2P_2O_7$[1]

C. CALVO AND P. K. L. AU[2]

Department of Chemistry and Institute for Materials Research, McMaster University, Hamilton, Ontario

Received April 17, 1969

Cadmium pyrophosphate forms crystals having triclinic symmetry with the unit cell parameters $a = 6.672(8)$ Å, $b = 6.623(8)$ Å, $c = 6.858(7)$ Å, $\alpha = 95.80(10)°$, $\beta = 115.38(8)°$, and $\gamma = 82.38(8)°$. The space group is $P\bar{1}$ and there are two molecules per unit cell. The structure was refined by least squares methods using 1326 reflections. The pyrophosphate anion, $P_2O_7^{4-}$, has a bent P—O—P bond with a bond angle of 132° and with average inner and outer PO bond lengths of 1.62 and 1.51 Å, respectively. The cations are coordinated to five and six oxygen atoms with average cadmium–oxygen atom bond lengths of 2.33 and 2.31 Å, respectively. This pyrophosphate structure differs from that adopted by other divalent metal ions of small radius in that the ends of the anion are in a nearly eclipsed orientation but shows some similarity to those $A_2B_2O_7$ compounds, where A has a large radius and B a small one.

Introduction

The divalent metal ion pyrophosphates investigated to date fall into two series. The first, characterized by cations of small radii, have closely related structures in all their polymorphs. Included in this group are the pyrophosphates of Mn (1), Cu (2), Mg (3), Co (4), Ni (5), and Zn (6). The second class are those pyrophosphates of the alkaline-earth metals which show four polymorphs, but not all of these occur for each compound. A limited number of structures in this series have been determined. These are: $\alpha Ca_2P_2O_7$ (7), $\beta Ca_2P_2O_7$ (8), and $\alpha Sr_2P_2O_7$ (9). To date no close relationship among those polymorphs of a given compound in this series has been apparent although the structures $\alpha Ca_2P_2O_7$ and $\alpha Sr_2P_2O_7$ are closely related.

The compounds in the first class form structures closely related to that of the mineral thortveitite (10). This structure consists of sheets containing cations octahedrally surrounded by oxygen atoms and each octahedron shares three edges with three neighboring octahedra. The P—O—P part of the anion is accommodated between these sheets, lying opposite empty octahedral sites in the sheets. This structure would be expected to become unstable as the ratio of the cation to anion size diverged from some optimum range. The alkaline earth pyrophosphates seem to have cations too large to be accommodated in this structure. Since $Cd_2V_2O_7$ (11) is known to have the thortveitite structure, it was considered germane to see whether $Cd_2P_2O_7$ formed the upper limit of the thortveitite-like series or the lower limit of the alkaline-earth series.

Experiments

Crystals of $Cd_2P_2O_7$ were prepared by heating stoichiometric amounts of $CdCO_3$ and $(NH_4)_2HPO_4$ until ammonia and carbon dioxide ceased to evolve. The temperature was then raised to beyond 1120 °C, the mixture was melted, slowly cooled across the melting point, and then quenched to room temperature. Clear, colorless parallelopipeds were obtained.

Accurate parameters were obtained from films calibrated with reflections from a crystal of TiO_2 whose lattice parameters were taken as $a = 4.5929(5)$ Å and $c = 2.9591(3)$ Å (12). The values obtained are compiled in Table I along with other crystal data. The density of 4.90 g/cm^3 was measured with a pycnometer.

Intensity photographs of the [100] zone and reflections of the type *hnl* with $n = 0$, 1, and 2 were obtained with MoKα radiation using the Weissenberg camera. The [100], [010], and [101] zones were recorded with the same radiation but taken on a precession camera. The intensities of the reflections were estimated visually, and corrected for absorption, Lorentz, and polarization effects. The former corrections were deemed advisable since the crystals had dimensions of the order of $0.1 \times 0.15 \times 0.2$ mm^3. Thus errors of the order of 20%

could result if this effect were ignored. The crystal was assumed to be spherically shaped for this purpose. Data taken from the same zone but with different cameras were averaged.

The positions of the cations were determined from the Patterson functions calculated from the data taken for the [100], [010], and [001] zones. The Patterson functions indicated that at least the cations were related by a center of symmetry. Further, electron paramagnetic resonance (e.p.r.) experiments on crystals doped with either Cu^{2+} or Mn^{2+} (13) showed, in each case, preferred solubility in one of the cation sites but with no indication of a symmetry lower than $P\bar{1}$, Therefore this space group was selected. As it turned out, the Cd–P interactions were sufficiently distinct in the Patterson functions to permit the determination of the phosphorus coordinates although they were, in fact, obtained from subsequent electron density maps. The structure was refined in stages using difference maps to determine the positions of the oxygen atoms. The final refinement was performed with weights chosen as $\omega = [3 + 0.10\,F_o + 0.009\,F_o^2]^{-1}$ using a full matrix least-squares program written for the IBM 7040 by Stephens. This choice of weights resulted in $||F_o| - |F_c||^2\omega$ being independent of $|F_o|$ (14).

The atomic scattering curves for Cd^{2+}, P, and O^- were taken from the International tables for X-ray crystallography (15) and corrected for dispersion. In the refinement those reflections whose calculated structure factor was less than the local minimum observable value were given zero weight. Individual isotropic temperature factors were used until a minimum value of the residual was obtained and then the anisotropic components of the temperature factors of Cd^{2+} were allowed to vary. Each layer of data was scaled independently. Since the value of the residual, $R_2 = \{(\Sigma\omega||F_o| - |F_c||^2)/(\Sigma\omega|F_o|^2)\}^{1/2}$ changed from 0.18 to 0.12, these changes were regarded to be significant. The final values for $R(= \Sigma||F_o| - |F_c||/\Sigma|F_o|)$ and R_2 are 0.093 and 0.113, respectively. A small number (eight) of intense reflections lying at low angle seemed to suffer from extinction and were left out of the refinement. The final atomic parameters are shown in Table II. The 1326 calculated and observed structure factors are listed in Table III. Of this total 916 had intensities strong enough to be measured.

Description of the Structure

The cations are coordinated to five and six oxygen atoms for site (1) and site (2) respectively. In the former case there are two additional cation–oxygen atom distances at 2.88 and 2.69 Å, but these are beyond the primary coordination sphere. The five oxygen atoms about the first site range in distance from 2.27 to 2.41 Å with a mean of 2.33 Å. The average cation–ligand bond length about site (2) is 2.31 Å with the somewhat smaller range extending from 2.25 to 2.34 Å. Since the estimated standard deviations on these lengths are about 0.02 Å, the difference in these means is not significant. The geometric configuration of the ligands about site (1) is that of a highly distorted trigonal bipyramid with O(4) and O(5) as the apex ligands and O($\bar{4}$), O($\bar{3}$), and O($\bar{6}$) as the equatorial ligands. The average equatorial bond

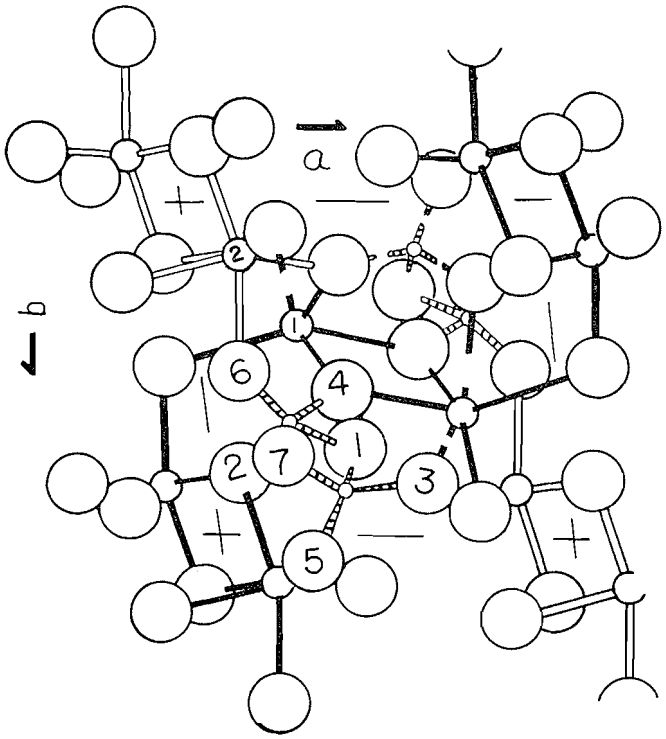

FIG. 1. The structure of $Cd_2P_2O_7$ projected down the *c* axis. The phosphorus atoms, cations, and oxygen atoms are shown as circles of progressively increasing size. The strong bonds between the cations and the oxygen atoms are shown as filled or open bonds. The bonding within the anion is shown cross-hatched.

lengths are larger (2.36 Å) than the average of the axial ones (2.29 Å). Site (2) has an irregular octahedral environment of oxygen atoms. The pertinent bond distances and angles for $Cd_2P_2O_7$ are shown in Table IV.

Cation (1) has two additional oxygen atoms, $O(\bar{2})$ and O(7), lying within 3.0 Å. $O(\bar{2})$ lies on the triangular face formed by $O(\bar{3})$, $O(\bar{5})$, and $O(\bar{6})$ while O(7) lies on the triangular face formed by O(4), O(6), and $O(\bar{4})$. Since these oxygen atoms lie about 0.5 Å beyond the first coordination sphere, they will be regarded as essentially unbonded to cation (1).

Each cation shares a pair of oxygen atoms across a center of symmetry forming groups conveniently called dimers. The O(2)–$O(\bar{2})$ edge is shared by cations of type 2, across the inversion center at 001/2 while the O(4)–$O(\bar{4})$ edge is shared by cations of type 1, across the inversion center at $\frac{1}{2}\ \frac{1}{2}\ \frac{1}{2}$. These dimeric groups are joined by sharing O(6) to form chains running parallel to the $(1\bar{1}0)$ face diagonal of the unit cell. The atoms in the chain are joined with filled bonds in Fig. 1. Parallel chains are bonded by corner sharing $O(\bar{3})$, O(3), $O(\bar{5})$, and O(5). The cations in this structure can be considered to form sheets involving M—O polyhedra with O(6) shared between sheets. These sheets, shown in Fig. 2, parallel the $\bar{1}10$ plane.

The anion, shown with cross-hatched bonds in Fig. 1, consists of two PO_4^{3-} tetrahedra sharing the oxygen atom, O(1). The two tetrahedra on a given anion deviate by 11° from an eclipsed orientation with the central oxygen atom as viewed along the P—P vector. O(3) and O(4) are the oxygen atoms most nearly coplanar with the P—O—P group. The P—O(—P) bond lengths are 1.65 and 1.60 Å on sides 1 and 2 of the anion, respectively. Since the estimated standard deviations for these bond lengths are of the order of 0.02 Å, one must regard these differences as not being significant. On the other hand, the difference between the inner and outer P—O bond lengths is significant. The average values are 1.51 Å on side 1 and 1.52 Å on side 2. One particular P—O short bond, 1.45 Å, involving O(7),

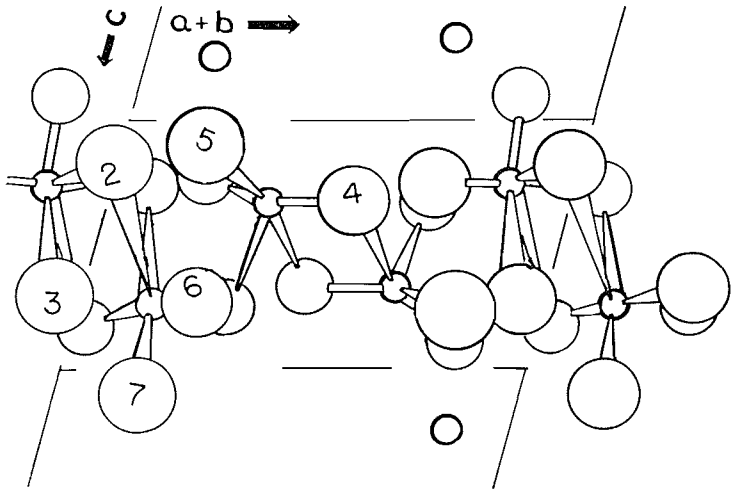

FIG. 2. The bonding near the cation–oxygen atom sheets is shown. The cations are shown as small circles and the anions as large ones. The bonding parallel to the sheet is shown.

involves the terminal oxygen atom ligated to only one cation.

The anion shares O(2) and O(6) from one end of the anion and O(5) and O(7) from the other end with one sheet of cations and O(6), O(4), and O(3) with the adjacent cation sheet. The O(2)—O(5) edge spanning across the two tetrahedra of the anion is shared with one of the cations of type 2. Otherwise, each oxygen atom ligated to a given cation arises from a different anion.

Discussion

The structure of $Cd_2P_2O_7$ differs substantially from that found for other divalent metal ion pyrophosphates although it bears some relationship, in terms of packing, to the $\beta Ca_2P_2O_7$ structure. The cation coordination numbers are the same as in $\alpha Mg_2P_2O_7$ (16) but there the anion has essentially a staggered configuration while in $Cd_2P_2O_7$ it is nearest to an eclipsed configuration. In all the $A_2B_2O_7$ compounds, where the B_2O_7 anion is formed by corner sharing of a pair of tetrahedra, the eclipsed anion configuration appears to be stabilized by having one of the cations sharing oxygen atoms across the anion. In $Cd_2P_2O_7$ this cation is Cd(2) while Cd(1) resides in interstices formed by the terminal oxygen atoms from five anions. It is therefore not unexpected that the solubility of other divalent ions into the two cation sites will differ markedly. In the electron paramagnetic resonance study of Mn^{2+} in $\alpha Sr_2P_2O_7$ (17) it appears that the ion with the larger radius prefers the site bonding across the anion. The occupancy of this site seems to be necessary in order to stabilize the eclipsed anion configuration since point charge calculation suggests about a 5 to 10% greater instability in an anion with the $\alpha Ca_2P_2O_7$ or $Cd_2P_2O_7$ structure over that found for $\alpha Cu_2P_2O_7$, $\alpha Mg_2P_2O_7$, or $\alpha Zn_2P_2O_7$.

The relationship between the $Cd_2P_2O_7$ and $\beta Ca_2P_2O_7$ structures and those of the alkali metal dichromates has been discussed (18). The basic structural unit consists of a pair of anions centrosymmetrically related in contact at the appropriate van der Waals distances. These anions, all in nearly eclipsed orientation, have their B—B vector inclined at about 60° to a plane consisting of these anions pairs at the corners of a pseudosquare. The various members of this series differ primarily in the nature of the packing of adjacent planes. The structure of $Cd_2P_2O_7$ is the simplest of the series and had been predicted by Brown (19) on the basis of his studies of the dichromate series.

The average Cd—O bond lengths found here, 2.33 and 2.31 Å, differ insignificantly from the 2.31 Å found in $Cd_2V_2O_7$ where all cations are octahedrally coordinated and the structure is analogous to thortveitite. The range of bond lengths in the latter case was from 2.24 to 2.39 Å as compared to 2.25 to 2.41 Å in $Cd_2P_2O_7$. The Cd—O bond in the second coordination sphere about cation site 1 in $Cd_2P_2O_7$ are reminiscent

For personal use only.

of those found in $Cd_3(PO_4)$ (20). Here the nine independent cations all show five-fold coordination in the primary coordination sphere, but all cations save one have one additional oxygen atom lying between 2.5 and 3.0 Å. The five strong bonds have average values at each cation lying between 2.25 and 2.30 Å.

The errors on the P—O bonds are too high to make independent conclusions on the basis of this structure. However, in the low temperature phases of the pyrophosphates of Zn (21), Mg (2), and Cu (3), the phosphorus atom is displaced from the center of its tetrahedron toward the terminal oxygen atoms. In addition, when unrestricted by symmetry consideration, the anion becomes dissymmetric in the sense that the bridging PO bonds differ, with the larger bond length on that end of the anion having the shorter PO bond length. This short bond length is invariably related to that oxygen atom strongly bonded to only one cation. All these features also hold in $Cd_2P_2O_7$. In addition, one finds also that the tetrahedron involving the shorter bridging PO bond is the most regular. These results of course imply that the cations are significantly perturbing the π bonding system in the anion. Further, these pyrophosphate anions showing eclipsed configuration have smaller P—O—P bond angles, ranging from 130 to 138°, than are found for anions in the staggered configuration. In the latter case the range is 130 to 157°.

Constitution of magnesium–indium alloys containing 23–100 atomic % indium[1]

K. M. PICKWICK[2], W. A. ALEXANDER, AND R. H. GAMBLE
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received February 3, 1969

A constitutional diagram for magnesium–indium alloys containing between 23.2 and 100 atomic % indium has been established using differential thermal analysis, electrical resistivity, and metallographic methods.

An intermediate solid solution, β, with a wide range of homogeneity, is formed peritectically from the liquid and α, the magnesium primary solid solution. It extends between 23 atomic % indium at 485.3 °C and 86 atomic % indium at 160.2 °C, where it is in equilibrium with γ, the indium primary solid solution. Magnesium has a limited solid solubility in indium of about 6 atomic %.

For alloys containing up to 50 atomic % indium, the derived constitutional diagram is in good agreement with that of a previous investigation (2). Two exceptions are noted: first, there is no evidence of a long period superlattice, β''' of the CuAu II type, and second, a reaction is observed involving a transition between the two ordered phases β′ and β″. For the indium-rich alloys no intermediate or ordered phase formation is observed.

The results have been discussed in terms of the existing phase diagrams.

Canadian Journal of Chemistry, 47, 3417 (1969)

Introduction

Phase relationships in the magnesium–indium system have been the subject of several investigations (1–6). Despite this attention there is disagreement in the literature concerning the form of the equilibrium diagram, especially for alloys containing more than 25% indium[3]. The constitutional diagram of Fig. 1 is derived from the thermal, metallographic, and X-ray diffraction studies of Raynor and co-authors (1–3). At relatively high temperatures alloys which contained more than 23.5% indium consisted of β, a homogeneous face-centered cubic solid solution. Initially the field was thought to extend across the diagram with a gradual transition, though without phase discontinuity, to γ, the face-centered tetragonal indium primary solid solution. A limit of homogeneity was established at 53.5% indium, and the γ solid solution was considered to be formed peritectically from β and the liquid at 333.5 °C (3). However, more recent work has shown single phase alloys beyond this limit (6).

Investigations of intermediate phase formation in the solid solution have revealed similar inconsistencies. Haucke (4) suggested that the system was analogous to that of magnesium–gallium, and contained four intermediate phases Mg_5In_2, Mg_2In, MgIn, and $MgIn_2$ or $MgIn_3$. Subsequently, Raynor (2) showed that the β phase transformed to give two complex phases which were designated β_1 and β_2. The β_1 phase was stable up to 335 °C in a composition range 23.5–25% indium, and the β_2 phase up to 298 °C within a very narrow homogeneity range at an approximate composition of 34.3% indium. The X-ray diffraction study of Schubert *et al.* (5) has since confirmed the existence of the orthorhombic Mg_5In_2 phase, and both β_1 and β_2 were indexed on the basis of a hexagonal unit cell, with compositions corresponding to Mg_3In and Mg_2In, respectively. They also reported two additional phases, Mg_2In_5 and $MgIn_5$, a result at variance with previous work, which had shown extensive solid solubility of magnesium in indium and no indication of intermediate phase formation (3).

Ordering of the β solid solution has been reported over a wide composition range (2, 3, 5, 6). Raynor (2) showed that in alloys containing up to 50% indium, the reactions were analogous to those occurring in the copper–gold system. Alloys containing less than about 35% indium formed β′, a cubic superlattice ($L1_2$ Cu_3Au Type) and β″, an ordered tetragonal structure ($L1_0$ CuAu Type I) for compositions up to 50% indium (8). Between the boundaries of the disordered β and the tetragonal β″, a phase of orthorhombic structure, β''' (CuAu Type II), was observed. Ino *et al.* (6) have questioned the

existence of the β‴ phase in a study which came to the attention of the authors after completion of the present work. Schubert *et al.* (5) detected ordering of the Cu_3Au type near the composition Mg_2In_5 with partial ordering in alloys containing up to 86% indium.

In view of these contradictions, a further investigation of the constitution of magnesium–indium alloys containing more than 25% indium was considered worthwhile. The phase relationships have been studied using thermal, resistometric, and metallographic methods but excluded any X-ray examination of the alloys. Most phase designations used in the text follow those of Raynor (2).

Experimental Procedure

(a) Thermal Analysis

Heating and cooling curves for the 28 compositions investigated were obtained by a standard differential thermal analysis (d.t.a.) technique.

The magnesium used was a high purity distilled sample. Spectrographic analysis indicated copper as the major impurity at a level of less than 50 p.p.m. Other metals checked were: Ca, Al, Mn, Ni, Pb, Si, Sn, and Zn; all were less than 10 p.p.m. The indium used was the "Standard Grade" supplied by the Consolidated Mining and Smelting Co., with their typical analysis of major impurities: Cd, 40; Pb, 30; Sn, 20; Ni, 2; Cu, 1; and Tl, 1 p.p.m. and a claimed minimum purity of 99.97% In.

The alloys were formed from the constituent metals in a stainless steel vessel (7), which was mounted symmetrically with an inert reference specimen within a large cast iron block. The enclosure was initially evacuated, then filled with argon and maintained slightly above 1 atm. Alloy, reference, and differential temperatures were recorded at 2 s intervals by a Hartmann-Braun six-point recorder, at automatically controlled heating and cooling rates. The maximum sensitivity of the differential curve was ±0.02 °C, while that of the direct temperature was ±0.15 °C.

The liquidus/solidus temperatures were taken from the discontinuities in the differential temperature curves. Reliability was based on the reproducibility of the transition temperatures from at least 4 heating and cooling cycles, with rates between 0.5 and 1.0 °C per min. Calibration corrections were carried out for the measuring thermocouple Pt:Pt–13% Rh, during experimentation by comparison with a Cambridge vernier potentiometer and between experiments by standardization against the melting temperatures of pure lead, zinc, and tin.

The liquidus and peritectic arrest temperatures were reproducible to within ±0.1 °C. The absolute accuracy of the arrests is more difficult to estimate, though in consideration of the normal calibration corrections and the interpretation of the differential curves, errors of less than ±0.5 °C are probable. In the case of the solidus and ordering temperatures, the arrests are less distinct than for the liquidus, and additional errors result from their interpretation; thus they are considered correct to within ±1.0 °C.

After each series, the alloy was heated 50–100 °C above the liquidus temperature, and chill cast into a mould contained in a side arm of the vessel. Sections were taken from the top and bottom of the ingot, and analyzed for indium. The compositions of the ingots are listed in Table I*a*.

(b) Electrical Resistivity

Five alloys, R 2, 4, 5, 6, and 7, (Table I*b*), were prepared by melting high purity magnesium and indium in a stainless steel crucible under an atmosphere of purified argon. The magnesium used was the same material mentioned above, but purified by an additional fractional distillation step. The indium used was from the same

supplier as above, but of the "59 Grade", claimed to be at least 99.999% pure. The impurities listed by the supplier are: Pb 2.0, Cd 1.0, Tl 1.0, Cu 1.0, and Sn 1.0 p.p.m. In addition, two specimens, R 1 and 3, of critical composition, were taken from the chill castings of the thermal analysis work. Alloy R 3 was used primarily to study the precipitation of the β_2 phase. The alloys were sealed in evacuated Pyrex tubes, homogenized for 14 days at a temperature between 325–375 °C depending on composition, and then hot extruded in a modified laboratory press to wire of 0.056 in. diameter. An attempt was made at all stages of processing to minimize atmospheric corrosion, which was particularly severe in the alloys of higher indium content. Specimens were stored in evacuated glass tubes and heat treated either under argon or dynamic vacuum ($< 10^{-3}$ Torr).

The resistance was measured using a standard d.c. potential difference comparison method with both temperature and resistance being recorded continuously during the following heat treatments:

(*i*) Slow heating and cooling through the temperature range of the order–disorder transformation.

(*ii*) Annealing to reach equilibrium conditions at various temperatures over a similar temperature range. The specimens were initially homogenized in the disordered condition at 50 °C above T_c, the critical ordering temperatures, determined in (*i*) above. Starting with the disordered specimen, measurements of resistivity were taken by establishing equilibrium at successively lower temperatures, and then similarly for increasing temperatures. The increment between readings was varied from 2 °C close to T_c up to 20 °C for the less critical points on the curve.

(*iii*) Isothermal annealing at temperatures below T_c in specimens quenched from the disordered region.

Chromel–alumel thermocouples were spot welded to the specimens, and over the length between the potential probes (about 10 cm) the temperature variation was less than ±0.25 °C. Errors in the resistivity values were estimated to be less than ±0.03% due to current instability, ±0.25% in the measurement of specimen dimensions, ±0.5% due to temperature measurement, and ±0.5% due to furnace temperature control. The values are reported with errors of less than 3.0%, but may be considered as apparent resistivities, since no correction has been made for thermal expansion of the wires during testing.

(c) Metallography

Metallographic examination of selected alloys was carried out to confirm the phase transformations and locate the intermediate phase boundaries. Following the heat treatments shown in Table III, sections were mounted and polished using conventional techniques. The microstructures were readily revealed by etching with either alcoholic nitric or picric acids, although considerable difficulty was encountered in preserving the surfaces for photomicrography. Conclusive results could not be obtained for alloys containing more than about 60% indium due to this rapid surface deterioration both during and after polishing.

Results and Discussion

The constitutional diagram derived from the heating and cooling curves of the 28 alloys of the thermal analysis study is shown in Fig. 2. Included in the diagram and indicated according to the symbols of the key are confirmatory points from the resistometric and metallographic investigations. The derived diagram does not conform to any one of the previous investigations (2–6). Up to 50% indium, the results are in general agreement with those of Raynor (2), but compare more favorably with the work of Schubert *et al.* (5) beyond this point. For convenience the system can be discussed in terms of three distinct regions, namely, the liquidus/solidus, the ordering reactions, and the intermediate phase formation.

Liquidus/Solidus Region

The β solid solution forms peritectically from the liquid and α, the magnesium primary solid solution. A peritectic horizontal was located from the cooling curves of alloys TA 1 (23.2% In) and TA 2 (24.3% In) at a temperature of about 485.3 °C (Table II). This compares favorably with the previous determination of 484 °C (2), though there are certain differences in the compositional limits of the reaction. Alloy TA 3 (24.8% In) shows only a liquidus arrest at 484.8 °C on cooling and a solidus arrest on heating. The indium-rich limit of the peritectic lies in the region of 24.8% indium compared with Raynor's (2) value of 25.7%. The position of the invariant point at which β decomposes to form α and liquid was determined by extrapolation of the solidus to the peritectic horizontal, and lies in the vicinity of 23% indium.

The alloy compositions for the diagram were taken as the mean of the chemical analyses of the ingot sections following chill casting. There was excellent agreement between the two samples (Table I*a* and *b*) with a maximum variation of 0.5 wt. % (0.8 atm. %) at the composition of TA 16 (52.3%).

The β phase was found to extend beyond the homogeneity limits of Graham and Raynor (3). In alloys containing more than 24.8% indium, single liquidus and solidus arrests were observed up to 84.3% indium. Subsequent microstructural examination of quenched β phase alloys confirmed that the solid solution was continuous at least up to the composition of alloy TA 19 (59.9% In). The β-phase alloys showed the equiaxed grain structure of a normal solid solution, but without the twinning characteristic

of the β′ and β″ ordered solutions. Some difficulty was experienced in observing the microstructures beyond this point and the extension of the β phase field across the composition range of alloys TA 20–25 (62.7–84.3% In) could be shown only from the thermal analysis curves. Therefore, smooth curves are drawn to represent the liquidus between 24.8% indium at 485.3 °C and about 97% indium at 160.2 °C, and the solidus between 23% indium at 485.3 °C and about 86% indium at 160.2 °C (Table II, Fig. 2). In view of the wide temperature range of crystallization for the indium-rich alloys, particular care was taken to ensure alloy homogeneity prior to determining the liquidus and solidus arrests. For the former, the melt was stirred continuously until the arrest was well established, and for the latter, observations were made on heating following a homogenization anneal just below the solidus temperatures. In most cases the discontinuities in the differential temperature curves could be easily interpreted, although special care was required with the solidus arrests for the more indium-rich compositions. The results, however, were reproducible throughout the heating and cooling cycles. Oxidation was considered negligible and both the appearance of the ingot and subsequent micro-examination confirmed this conclusion.

The results for the indium-rich alloys suggest that the β phase comes into equilibrium with the γ indium primary solid solution in the region of 86% indium. Alloy TA 26 (88.9% In) showed a liquidus arrest at 208.8 °C on cooling, followed by a distinct constant temperature evolution of heat at 160.0 °C; no solidus arrest was observed on reheating. At 95.6% indium a liquidus and a constant temperature arrest were observed at 180.0 and 160.4 °C, respectively, and a solidus arrest on heating at 158.0 °C. The peritectic horizontal and solidus arrests were small in both magnitude and duration, but were completely reproducible. Thus, despite the limited number of alloys investigated for this concentration range, the thermal analysis curves are consistent with the peritectic formation of the indium primary solid solution from the β solid solution and the liquid. A two phase region, β + γ, which must therefore be present between about 86 and 94% indium, could not be definitely confirmed from the metallographic studies. This indication of a

limited solubility of magnesium in indium is in general agreement with the results of Schubert *et al.* (5), and similarly with respect to the two-phase field limits.

The liquidus and solidus curves are clearly inconsistent with either the formation of a Mg_5In_2 phase (4) or a peritectic reaction in the vicinity of 53.5–63% indium (3). Regarding the former, the present results show that a phase Mg_5In_2 cannot be formed from the melt as for Mg_5Ga_2, and it must be assumed that if a phase of this composition does exist it must form as a result of a lower temperature transformation. For the latter, the curves run smoothly across that particular composition range. Furthermore, metallographic examination of alloys TA 17 (54.4% In), 18 (58.6% In), and 19 (59.9% In) revealed single phase microstructures, which, in agreement with the thermal analysis, suggests that the β phase is continuous between the points at which it enters into equilibrium with α and with γ, the respective primary solid solutions.

Ordering Reactions

The transformation curve for ordering of the β solid solution is shown in Fig. 2, the critical ordering temperatures (T_c) being taken from both the resistivity/temperature curves of Fig. 3 (*a*, *b*, and *c*) and the thermal analysis heating curves. The results from each technique are fully consistent, with the exception of the T_c values for R 1 and R 2, which are somewhat low. Identical values of T_c were obtained from both the equilibrium and non-equilibrium (slow heating or cooling) resistivity curves. In contrast to Raynor's X-ray diffraction studies, only two ordered phases were detected, namely, β′ for alloys containing up to about 39% indium and β″ for those richer in indium. The transition between the β′ and β″ phases is discussed below. In the region of the β″ reaction, nonequilibrium thermal and resistometric curves showed only a single discontinuity due to the $\beta \rightarrow \beta''$ transformation. Extensive annealing of alloys at subcritical temperatures failed to reveal the $\beta''' \rightarrow \beta''$ orthorhombic/tetragonal transition suggested by Raynor (2), though it is reasonable to assume that such a transition would, from consideration of the crystallographic change, involve a distinct resistivity and specific heat anomaly. Ino *et al.* (6) also failed to find any evidence of the existence of a β‴ phase. Above about 125 °C, the cooling curves of the thermal analysis study show no indication of an ordered phase at the composition Mg_2In_5.

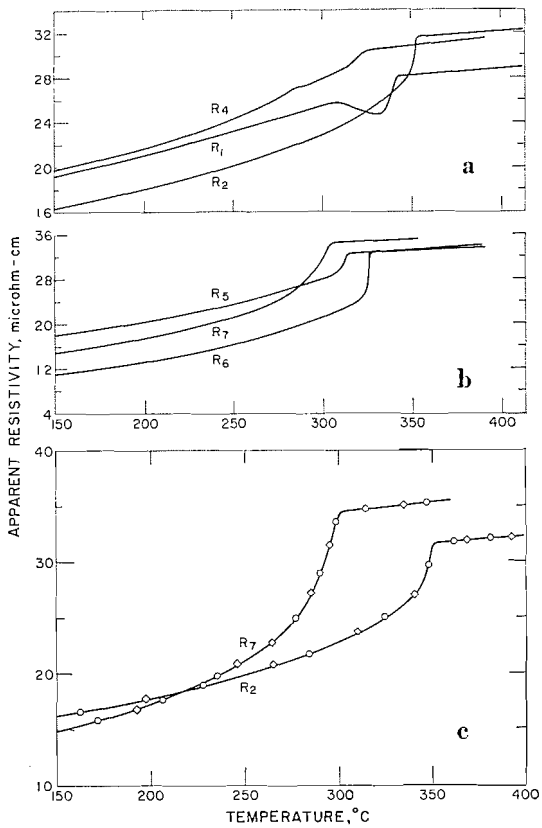

FIG. 3. The variation of apparent resistivity of the specimens with temperature under conditions of continuous heating: (*a*) alloys R 1 (24.8% In), R 2 (27.9% In), and R 4 (37.1% In); (*b*) alloys R 5 (40.0% In), R 6 (48.7% In), and R 7 (52.8% In); and under equilibrium conditions, (*c*) alloys R 2 (27.9% In) and R 7 52.8% In): ○, heating; ◇, cooling.

Simple theoretical calculations usually indicate that there should be a maximum in the ordering transformation curve at or near the stoichiometric composition. For the β′ ordering reaction there is an ill-defined maximum in the region of 29% indium and similarly for β″ near the equiatomic composition. In the latter case the available T_c values favor location of the maximum at a nonstoichiometric composition in the region of 47% indium. Alloys at the compositions of these maxima also exhibited maximum values of electrical conductivity measured at the ambient temperature and maximum heats of transformation (peak area) in the d.t.a. curves. Nonstoichiometric maxima for T_c have been observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

by Raynor (2) for Mg_3In in the present system and in others such as CuPd, Cu_3Pd, CuPt (8), and Pt_2Mo (9). Hirabayashi *et al.* (10) also found from specific heat measurements that the maximum transformation temperature for MgIn was 328 °C at somewhat less than 50% In. It has also been confirmed by the present work that the T_c maximum coincides with a range of composition where the β′ phase is stable at relatively low temperatures (11).

Some contradictory evidence was found concerning the order of reaction for the formation of β′ and β″ and consequently concerning their representation in the constitutional diagram. Empirically, it appears that ordering changes involving a transformation of the close packed lattice, such as $A1$ (β) → $L1_2$ (β′) and $L1_0$ (β″) (2, 5, 6), occur by a first order reaction, and are second order for all others (13). The former predicts a discontinuous change of order: isothermally at the point of univariant equilibrium and over a range of temperature for bivariant conditions. At compositions close to the β′ and β″ maxima, the major part of the ordering or disordering process was in fact completed within a very small temperature range, approxi-

mately 2 °C, but over a considerably wider range on either side of the maxima. This has been shown in Fig. 4 for the $\beta \rightarrow \beta''$ transformation only, where the lower broken line corresponds to points on the d.t.a. heating curves at which significant disordering was detected. Similarly, in the resistivity curves the alloys closest to the T_c maxima, namely R 2 and R 6, (Fig. 3*a* and *b*) show a large and almost discontinuous change of resistivity compared with the more continuous variation of the others. These effects are not due to any variation in reaction rate[4], since both β' and β'' order very rapidly in the composition range of R 1–7. A similar widening of the transformation zone about the composition of the T_c maximum was observed by Ino *et al.* (6) and by Hirabayashi *et al.* (10) for β'' alloys, and was explained in terms of the coexistence of ordered and disordered phases. This conforms with accepted first order reaction characteristics (12–14). However, the equilibrium resistivity curves of alloys R 2 and 7 in Fig. 3*c*, which have compositions in the range of the indicated $\beta + \beta'$ and $\beta + \beta''$ phase regions, respectively, show no sharp discontinuities below T_c due to such two-phase boundaries. Clearly, if ordered and disordered phases are in equilibrium, the range must extend over a very small temperature interval and considerably less than that indicated by the peak widths of the d.t.a. curves. In the absence of unequivocal evidence, the ordering reactions have been represented in Fig. 2 by a single line, showing only the variation of T_c with composition.

Intermediate Phases

Intermediate phase formation was investigated with respect to the system of Fig. 1 and the phase boundaries located by the metallographic examination of several critical alloys. The results shown in Figs. 2 and 4 are clearly in agreement with the boundaries and relationships determined by Raynor (2), with the exception of the β_2 + ordered β phase field on the high indium side. We find a series of arrests at 276 °C in this region which Raynor does not show. Resistivity and thermal measurements could not be used due to the prohibitively long times for the precipitation of the β_1 or β_2 phases from the ordered solid solution at temperatures close to those of the equilibrium phase boundaries. Following the heat treatments of Table III, the microstructures were easily developed using the alcoholic nitric or picric acid etchants. In contrast to the β_1 and β_2 phases, both β' and β'' exhibited characteristic twinning (2), although the main identifying feature was the selective etching of the constituent phases. In the two-phase alloys $\beta_1 + \beta'$ and $\beta' + \beta_2$, the second phase was essentially grain boundary nucleated and formed in proportions approximating to the existing diagram. Between the $\beta'/\beta_1 + \beta'$ and $\beta'/\beta' + \beta_2$ boundaries, in the region of alloy TA 5 (27.1% In) the β' phase was stable at temperatures below 200 °C. The microstructure was unchanged following annealing for times up to 21 days at 150 °C. It is interesting to note that this composition range coincides with Schubert's Mg_5In_2 phase. In addition to the metallographic evidence, resistivity curves of a both slowly cooled and equilibrated alloy, R 2 (27.9% In), Fig. 3*c*, gave no indication of a phase transformation. Thus we have found no evidence for the existence of the Mg_5In_2 phase. The exact composition of β_2 was not determined, although it has been located within a very narrow homogeneity range at Mg_2In (5, 6), which is a slightly lower indium content than the results of Raynor at 34.3% In in Fig. 2. For the β_2 + ordered β phase alloys, discontinuities at 276 °C were observed in the d.t.a. heating curves and also in the resistivity curve of R 4 (37.1% In), Fig. 3*a*. The arrest at 276 °C was essentially independent of composition between 35.5–37.1% indium, and corresponds to the eutectoid horizontal of Ino's diagram (Fig. 4). Subsequent examination of the microstructure of alloy TA 9 (35.5% In) quenched from 320 °C and annealed at 220 °C showed that β_2 precipitation had occurred by a cellular or discontinuous growth. Above 276 °C, the temperature of the arrest, the intermediate phase was precipitated preferentially in the grain boundaries as in the $\beta_1 + \beta'$ and $\beta' + \beta_2$ phase fields. Alloys containing between 32 and 52.5% indium have been investigated by Ino *et al.* (6) and our results agree with their diagram (Fig. 4). The two-phase regions $\beta + \beta'$, $\beta + \beta''$, and $\beta' + \beta''$ in their diagram were based on nonequilibrium thermal curves, and were inferred from the variation of specific heat peak width with composition. A similar effect was shown in the d.t.a.

TA 19	59.9	14 days	280 °C	21 days	200 °C	β

curves of the present work, although it could not be definitely associated with the coexistence of the ordered and disordered phases. Of the two eutectoidal reactions, the $\beta'' + \beta' \rightleftarrows \beta$ could not be confirmed experimentally, but the cellular nature of the decomposition products in alloys TA 9 (35.5% In) and TA 10 (36.2% In) was most probably due to that of $\beta'' + \beta_2 \rightleftarrows \beta'$, at 276 °C. Provided that the two phase regions between β, β′, and β″ do exist, then Fig. 4 represents a probable form of the constitutional diagram.

Addendum

Since the above work was completed and prepared for publication, a paper by Hiraga, Koiwa, and Hirabayashi (15) has come to our attention, in which an investigation of the indium-rich part of the system is reported. Their results approximately confirm our data beyond about 85% In, although the peritectic formation of the indium primary solid solution involves an intermediate solid solution, γ, not β. In this respect they appear to have equated Graham and Raynor's γ phase, which was in fact the face-centered tetragonal indium primary solid solution in the reaction β + liquid $\rightleftharpoons$ γ (3), with their face-centered cubic intermediate solid solution, also designated γ. No experimental evidence is presented to justify the inclusion of this peritectic reaction. The nature of our apparatus made extension of the cooling curves below about 125 °C prohibitive, hence we did not investigate the ordered γ′ range of Hiraga's work.

Initial damage centers in γ-irradiated α-aminoisobutyric acid[1]

DAVID G. CADENA, JR., ROBERT E. LINDER, AND JOHN R. ROWLANDS
Department of Physical and Biological Sciences, Southwest Research Institute, San Antonio, Texas 78228

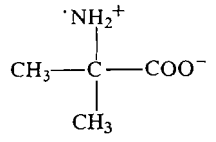
Received March 4, 1969

Electron spin resonance measurements of single crystals of α-aminoisobutyric acid, which are both irradiated and measured at 77 °K, give rise to a strong central absorption line at the center of two weak "satellite" peaks. The species largely responsible for the intensity of the central absorption line has been discussed previously and is considered to be the doubly ionized radical anion. In this paper, evidence is presented which shows that some of the intensity of this central line is contributed by the species giving rise to the satellite lines. Furthermore, this evidence, which is based upon saturation studies, variable temperature measurements, deuteration studies, and complete neglect of differential overlap–self consistent field molecular orbital calculations, suggests that the species giving rise to the satellite spectra is a planar conformation of the radical $(CH_3)_2\dot{C}CO_2H$.

Canadian Journal of Chemistry, 47, 3429 (1969)

I. Introduction

There has been considerable attention focused in recent years upon the identification by electron spin resonance (e.s.r.) of the initial damage centers created by ionizing radiation in organic and biologically important molecules. Recently, there have been two papers published discussing the nature of the initial damage centers formed in α-aminoisobutyric acid by both X- and γ-irradiation. Box and Freund (1) first reported that the e.s.r. spectra of the initial damage centers in single crystals of α-aminoisobutyric acid consisted of a strong central line (considered to arise from the radical $(CH_3)_2C(NH_2^+)CO_2^{2-}$ (1) at the center of two weak satellites, while Fujimoto *et al.* (2) in a more recent publication, report the presence at certain orientations of hyperfine structure on both the central intense line and the satellite peaks. Fujimoto *et al.* assigned the species that gives rise to the satellite lines as one formed by loss of a hydrogen atom from the interacting amino and carboxyl groups, i.e., the radical



1

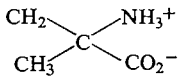
They indicate that the observed hyperfine pattern arises from the interaction of the unpaired electron with the nitrogen nucleus and two hydrogen nuclei. In view of the anisotropic behavior of the spectra obtained in a study of the radical $\cdot\overset{+}{N}H_2SO_3^-$ (3), which is formed by γ-irradiation of sulfamic acid, it is difficult to rationalize the observed isotropic behavior of the satellite absorption (see section III) with radical **1**. The principal values of the nitrogen and hydrogen hyperfine coupling tensors in the radical $\cdot\overset{+}{N}H_2SO_3^-$ were found to be nitrogen (103, 17, 33, iso: 51 Mc/s) and hydrogen (−65, −83, −44, iso: −64 Mc/s) respectively. Both the nitrogen and hydrogen hyperfine interaction tensors would be expected to be similar in magnitude for radical **1**. Neither the observed single crystal spectra nor the spectrum of the polycrystalline sample are consistent with such anisotropic hyperfine coupling.

Furthermore, crystals grown from D_2O containing in excess of 85% $(CH_3)_2C(ND_3)^+CO_2^-$ were observed in our studies to give rise to identical e.s.r. spectra. Since hydrogen deuterium exchange reactions are known to take place in radiation processes (4), some caution has to be exercised in drawing conclusions from deuteration studies. However, consideration of the deuteration studies, together with the known anisotropic behavior of the $\cdot\overset{+}{N}H_2—SO_3^-$ radical, is strong evidence for considering that radical **1** is not the species that gives rise to the satellite spectra.

The possibility that the satellite spectrum arises

[1]This research was supported in part by a grant from the Research Grants Section, National Center for Radiological Health, U.S. Public Health Service, No. RH GM 00384-01, and in part by Southwest Research Institute Internal Project No. 05-9015-01.

from a radical produced by loss of a hydrogen from a CH_3 group to give rise to the species



2

was also considered. Hyperfine coupling to a rapidly rotating $\dot{C}H_2R$ group has been observed in the radical $\dot{C}H_2OC(NH_2)_2{}^+Cl^-$ produced in γ-irradiated O-methylisourea (5). This species gave rise to two exactly equivalent hydrogen couplings at all orientations of the crystal with respect to the magnetic field. The e.s.r. spectra were anisotropic, giving rise to principal values of the hyperfine coupling constants of the indistinguishable hydrogens of −24.5, −67.0, and −73.0. Such anisotropy is not compatible with the e.s.r. spectra of the "satellite" species.

The observed spectra are consistent with an isotropic total splitting of the satellite lines. The extra hyperfine structure, which is resolved on all three lines at certain orientations, may be explained in terms of an anisotropic linewidth combined with some anisotropy in the hyperfine coupling of the nuclei, giving rise to the extra structure. Similar behavior has previously been reported in γ-irradiated DL-methionine (6). The e.s.r. spectra of the room temperature species $CH_3S\dot{C}HCH_2CHNH_3{}^+CO^-$, at most orientations, are the typical eight-line pattern of three interacting protons. At certain orientations, each line is observed to further split into a 1:3:3:1 pattern of the weakly coupling methyl group.

II. Results and Discussion

A. Radical Assignment

An alternative assignment for the observed satellite spectra may be made if one assumes that the appearance and disappearance of the hyperfine structure is due to an anisotropic linewidth variation of the hyperfine components rather than anisotropic variation of the magnitudes of the hyperfine interactions. From a close look at Fig. 1*a* and comparison with a computed spectrum (7) shown in Fig. 1*d*, it may be seen that each of the satellite lines splits into a quintet of approximate intensity distribution 1:4:6:4:1. Such an intensity distribution can arise from the interaction of the unpaired electron with four equivalent hydrogens. This intensity distribution can

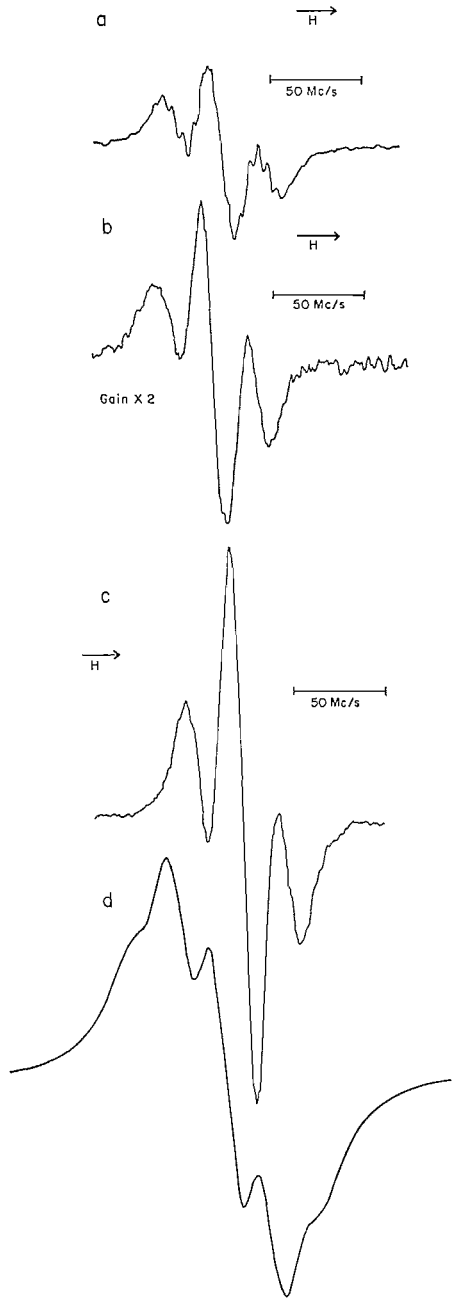


FIG. 1. Electron spin resonance spectra of single crystal α-aminoisobutyric acid (1*a* and 1*b* are different orientations in the *ac* plane), of polycrystalline α-aminoisobutyric acid (1*c*), and of a calculated 1:4:6:4:1 spectrum with a 0.96 linewidth: hyperfine splitting ratio (1*d*).

be obtained if one assumes that the species giving rise to the satellite spectrum is yet another conformation of the room temperature stable radical $(CH_3)_2\dot{C}CO_2^-$, in which both the CH_3 groups are frozen into equivalent configurations in which each gives rise to one large and two small hydrogen hyperfine interactions[2].

Hyperfine coupling constants based upon this analysis are tabulated in Table IV. Exact equivalence of the two methyl groups with respect to the carbon 2pπ orbital containing the unpaired electron was assumed, although small deviations from equivalence would not be detected. This assignment requires that the satellite spectrum consist of a major 1:2:1 isotropic hyperfine pattern, in which the line of intensity 2 is hidden by the strong single line signal of the $(CH_3)_2C(NH_3^+)CO_2^{2-}$ radical.

B. Evidence for Radical Assignment

As already reported by Box and Freund and by Fujimoto *et al.* the e.s.r. spectra of radicals trapped in X-irradiated α-aminoisobutyric acid consist of a strong central line at the center of two weak satellites. In agreement with the latter authors, at certain orientations of the crystals with respect to the applied magnetic field, extra hyperfine splitting is observed on all three lines. Spectra obtained at two crystal orientations, together with the spectrum of a polycrystalline sample, are included in Fig. 1.

1. Saturation Studies

It was also observed in our studies that the relative amplitudes of the satellite lines with respect to the amplitude of the central line were sensitive to the microwave power.

In view of the observed differences in saturation behavior of the satellite lines to the central line, detailed saturation studies were conducted in an effort to determine the contribution of the satellite hyperfine pattern to the central line intensity. The results of saturation experiments were analyzed on the basis of two distinct radicals whose spectra were superimposed at the strong central line. Plots of center line amplitude, satellite line amplitude, center line amplitude minus twice the satellite amplitude, coal standard amplitude, all vs. microwave power, are illustrated in Fig. 2.

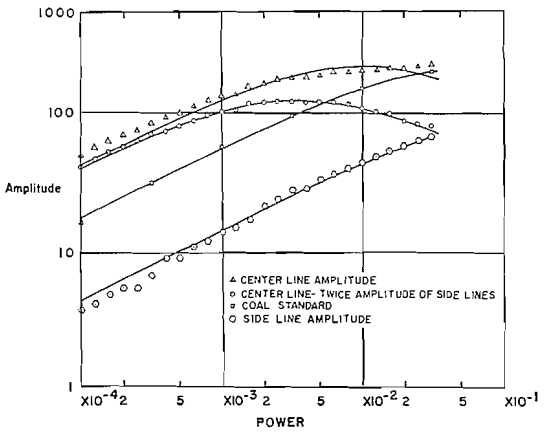

FIG. 2. Power saturation data and the nonlinear least squares fits to the data for the indicated samples.

In the figure, the ordinate gives the peak amplitudes in arbitrary units, while the abscissa gives the microwave power relative to the unattenuated power of 1.0. Also shown in the figure are the calculated least squares best fit of the experimental data.

The saturation behavior was analyzed by assuming that the e.s.r. experiment is described by the steady state Bloch equations (9), with the amplitude at $\Delta\omega$ from resonance being given by

$$[1] \quad \text{Amp.} = \frac{\gamma_e H_1 \tau_2 M_0}{1 + \gamma_e^2 H_1^2 \tau_1 \tau_2 + (\tau_2 \Delta\omega)^2}$$

At resonance ($\Delta\omega = 0$), we have

$$[2] \quad \text{Amp.} = \frac{\gamma_e H_1 \tau_2 M_0}{1 + \gamma_e^2 H_1^2 \tau_1 \tau_2}$$

This curve can be more simply represented by

$$[3] \quad \text{Amp.} = \frac{k_1 H_1}{1 + k_2 H_1^2}$$

taking into account the relative nature of the data. Since the power is proportional to the square of the field amplitude, we finally arrive at

$$[4] \quad \text{Amp.} = \frac{k_1' \sqrt{P}}{1 + k_2' P}$$

where P is the relative power given in Fig. 2.

The amplitude of the absorption peak (Amp.

[2]It should perhaps be noted that the room temperature stable radical has, at 40 °K, a configuration in which one proton has a large hyperfine splitting and the other two are smaller (8). The overall splitting is, however, larger than in the initial damage spectrum.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in eq. [4]) is taken to be the peak-to-peak amplitude of the experimental derivative curve, since the linewidth was found to be constant to within the experimental error.

The fitting procedure was a nonlinear least squares technique based on Levenberg's (10) method. The calculations were performed on a CDC 3600 computer using a program by McKay (11), and the results of the various fits are given in Table I and Fig. 2.

As an indication of the precision of the data and of the applicability of the method, the saturation curve of a coal sample was measured and the best values for k_1 and k_2 were determined. The overall fit and data spread can be judged by observing the average percent error (last column in Table I), and the validity of the values obtained for the constants can be estimated from the t and Δk values. The t values are the normal statistical t's and are given by the value of the number referred to over its standard error. The Δk values give the range for the k with a 95% probability. For coal, which is seen to be only slightly saturated at the maximum power levels used (Fig. 2), the overall fit and k_1 are good, with k_2 being less reliable. These results are taken to mean that the method is a valid procedure, especially in view of the fact that only seven points were used for the coal data.

The results of the saturation experiments are tabulated in Table I. The center peak data were taken from the spectra as the peak-to-peak amplitude of the center line, with no weighting of points. The first analysis of the side peak data (*3a*) was performed with a weighting on the higher power points, while the second (*3b*) was done with no weighting. The data for the triplet analysis (*4*) were obtained by subtracting from the center peak amplitude the amplitude of the side peak for each power level with no weighting. This corresponds to the assumption of a 1:1:1 pattern superimposed on a singlet. The data for the 1:2:1 pattern were obtained in the same way, but subtracting twice the side peak amplitude at each power level.

The sets *1* and *3* show the accuracy of the method for a strong signal (coal), indicating precision in the power measurements, and for a weak signal (side peak), showing the precision of the amplitude measurements, with the weighting showing up errors at low power levels. The sets *2*, *4*, and *5* may be compared directly, with the conclusion being that a much better fit is obtained when a 1:2:1 distribution is assumed for the superimposed pattern. This is shown in the t values, with a consistent improvement being shown as we go from 1:0:1 to 1:1:1 to 1:2:1 and in the average % error. A 1:3:1 distribution gave negative center peak amplitudes at the highest power levels.

2. Variable Temperature Studies

Variable temperature studies were also conducted in an effort to obtain further evidence for the assignment of the satellite spectrum. Polycrystalline samples were used in this phase of the investigation. Spectra were recorded at 77 °K, using a Varian liquid nitrogen Dewar, and variable temperature measurements were made at temperatures between 101 and 133 °K, using the Varian variable temperature accessory.

With constant microwave power, at temperatures between 77 and 120 °K, an increase in the

ratio of the central absorption line relative to the satellite lines caused by a decrease in amplitude and broadening of the satellite peaks was observed. At temperatures above 123 °K, the satellite peaks were observed to move in toward the center and their amplitude began to increase. At temperatures up to 133 °K, these observed spectral changes were shown to be completely reversible. These observations are fully consistent with the type of behavior that one would expect for the temperature dependence of a radical which exhibits hyperfine interactions to two equivalent methyl groups (12). At 77 °K, the rotation of each methyl group is largely restricted ($< 10^7$ c.p.s.), whereas at the higher temperatures, the broadening of the spectra reflects the onset of rotation. Unfortunately, it is not possible to extend these measurements to temperatures greater than 133 °K because of the irreversible changes that take place.

3. CNDO-II Calculations

Hyperfine coupling constants measured from orientations of the single crystal spectra in which the extra hyperfine structure was observed, based upon our assignment, are given in Table II. The analysis is based upon the assumption that the two methyl groups are frozen into equivalent conformations in which the projection of one hydrogen from each methyl is perpendicular to the radical plane. For this analysis to be acceptable, it is further necessary for the radical geometry to be such as to allow extensive delocalization of the unpaired electron. The observed isotropic hyperfine coupling of 63 Mc/s for the strongly coupling protons is approximately one-half of that typically found for β hydrogens frozen into this configuration.

The unpaired electron spin density distribution calculated by the CNDO SCF molecular orbital method is presented in Table IV. Details of the CNDO approximation are given in the original papers of Pople, Segal, and Santry (13, 14). The method is a semi-empirical one with parameters chosen so as to best reproduce the results of a full LCAO-SCF treatment. The program is available in Fortran IV language and was used here as it was received from the Quantum Chemistry Program Exchange, including the semi-empirical parameters.

Since the CNDO method utilizes as a basis set all the valence orbitals, and also uses different molecular orbitals for α and β spins, the unpaired electron spin density distribution is obtained by subtracting the β density from the α density, i.e.

$$[5] \quad \rho_i = \sum_j \underset{\text{(occupied orbitals)}}{C_{ij}^2(\alpha)} - \sum_j \underset{\text{(occupied orbitals)}}{C_{ij}^2(\beta)}$$

or

$$[6] \quad \rho_i = \rho_i(\alpha) - \rho_i(\beta)$$

The radical geometry that was used in the calculations is listed in Table III. No effort was made to optimize this geometry. The choice of both the presence and position of the OH protons represents an attempt to compensate for the effects of proton exchange and hydrogen bonding between nearest neighbors. The methyl hydrogen spin densities were insensitive to the position of these protons. In making the calculations, it was assumed that atoms C_1, C_2, C_3, C_4, O_1, and O_2 are coplanar to ensure maximum delocalization of the unpaired electron and that methyl protons are each frozen into a configuration in which the projections of C_3H_1 and C_4H_4 are perpendicular to the radical plane. The calculated hyperfine coupling constants obtained by multiplying the calculated methyl proton spin densities by the atomic splitting parameters are listed in the last column of Table IV. In view of the many uncertainties involved in such calculations, the agreement between the calculated hyperfine coupling constants to those obtained from an analysis of the spectra must be considered as strong evidence for the correct assignment of the radical as a planar conformation of the room temperature radical $(CH_3)_2\dot{C}CO_2H$.

III. Experimental

Crystals of α-aminoisobutyric acid were grown from saturated aqueous solutions by slow evaporation. Deuterated crystals of α-aminoisobutyric were grown from D_2O solution after three exchanges. The crystals grown in this fashion were shown by infrared analysis to contain in excess of 85% $(CH_3)_2CND_3{}^+CO_2{}^-$. The crystals are of monoclinic symmetry with space group $C2/c$ and contain eight molecules per unit cell (15). In each set of measurements, three separate crystals were chosen and mounted on plastic rods, one on each of the orthogonal a, b, and c^* axes. The crystals were irradiated at 77 °K with 220 kV X-rays. The e.s.r. spectra were recorded every 10° by rotating the crystals about the three orthogonal axes in turn, using a Varian V4500 X-band spectrometer with 100 kc/s magnetic field modulation. Spectra recorded at 77 °K were made using a Varian liquid nitrogen accessory, while variable temperature studies were made using a Varian V4537 variable temperature accessory to control the sample temperature between 101 and 133 °K, with the sample temperature being continuously monitored using a thermocouple and a Hewlett–Packard digital voltmeter.

Saturation experiments were conducted at 77 °K on polycrystalline samples. The spectrometer was used in a low power configuration so that an attenuation of 40 db ($\times 10^{-4}$) could be obtained. Because the Q of the cavity and other factors enter into the calculation of the absolute power at the sample, the power level shown in Fig. 2 is a relative number. (The unloaded Q is 7000, and the klystron power is 0.350 W; however, the loaded Q with the liquid nitrogen accessory is not known.)

IV. Summary

The observed isotropic behavior of the satellite lines has led to a rejection of radicals 1 and 2 as possible species. An alternative assignment has been given which explains the isotropic behavior and which further agrees with the saturation data and with the CNDO-II calculation.

Surface area of cesium perchlorate

P. VENKATARAMANA AND V. R. KRISHNAN[1]
Sri Venkateswara University Chemical Laboratories, Tirupati, India
Received February 4, 1969

Specific surface area of cesium perchlorate has been determined by isotopic surface exchange, air-permeability, and microscopic methods. There is agreement between the values of specific surface area evaluated by air-permeability and microscopic methods. The results obtained by the isotopic surface exchange method are reproducible but are significantly greater than those obtained by the other methods, and the difference is attributed to the fact that while air-permeability and microscopic methods measure the external surface area, the surface exchange method measures the total surface area (external as well as internal) of solids.

Determination of the surface area of solids is important for all quantitative investigations of heterogeneous processes. The measurement is complicated due to the geometrical irregularities with which the solids are always associated. For such estimations numerous methods have been devised, of which the most widely used ones are as follows. (*a*) The gas adsorption method (1), which consists essentially of determining the quantity of gas required to cover the surface of a given weight of powder completely with a monomolecular layer of the gas, with suitable adaptations in cases of multimolecular layer adsorption. (*b*) Air-permeability method (2), which depends upon measurement of the rate of flow of air through a bed of particles, the rate being proportional to factors such as porosity, pressure drop across the bed, area of the bed, thickness of the bed, and the specific surface area of the powder. (*c*) Isotopic surface exchange method (3), which in principle is as follows. When a saturated solution is tagged with an isotopic tracer, a kinetic exchange between the tracer ions in solution and the inactive ions at the solid–solution interface occurs, and if self-diffusion and recrystallization processes are negligible, a pseudo equilibrium is established which enables the evaluation of surface area from the fractions of labelled atoms exchanged. (*d*) The microscopic method (4), which consists essentially of the measurement of the dimensions of the individual particles under a microscope.

One or more of the above procedures has been used to measure the surface areas of anhydrous salts such as $PbSO_4$ (5), $PbCrO_4$ (6), AgBr (7), $CaCO_3$ (8), $BaSO_4$ (9), etc.

In the present investigation, surface exchange, air-permeability, and microscopic methods were employed to measure the surface area of cesium perchlorate.

Experimental

Preparation of Cesium Perchlorate Sample

Cesium perchlorate was precipitated from 1 *M* cesium chloride (thrice recrystallized), by adding slowly 30% perchloric acid. The precipitate was filtered, washed free from chloride ion, and finally dried by drawing dry air through for 48 h. This sample was used in all surface area measurements.

Determination of Solubility

A saturated solution of cesium perchlorate was prepared in 95% alcohol at 30 ± 0.01 °C. An aliquot of the suspension was centrifuged. A known volume of the supernatant liquid was pipetted out into a centrifuge tube and evaporated till it was free from alcohol. The amount of cesium in the remaining aqueous solution was estimated using a Hilger UVISPEK spectrophotometer, with 12-molybdo phosphoric acid (10), at a wave length of 226 mμ.

Determination of Density

The density of cesium perchlorate at 30 ± 0.01 °C was determined by a pycnometric method as described by Weissberger (11). A double stem pycnometer of the type described by Naidu and Krishnan (12) was employed for the purpose. *p*-Xylene was chosen as the displacement fluid.

Determination of Mean Pore Size

The mean pore volume was determined by the method described by Emmett (13), and assuming the pores to be cylindrical, the mean pore radius $\bar{r}$, was calculated using the relation

$$[1] \qquad \bar{r} = \frac{2V}{S_w}$$

where V is the average pore volume and S_w the total surface area per gram of the solid, determined as follows.

[1]Present address: Sri Venkateswara University, Postgraduate Centre, Anantapur, India.

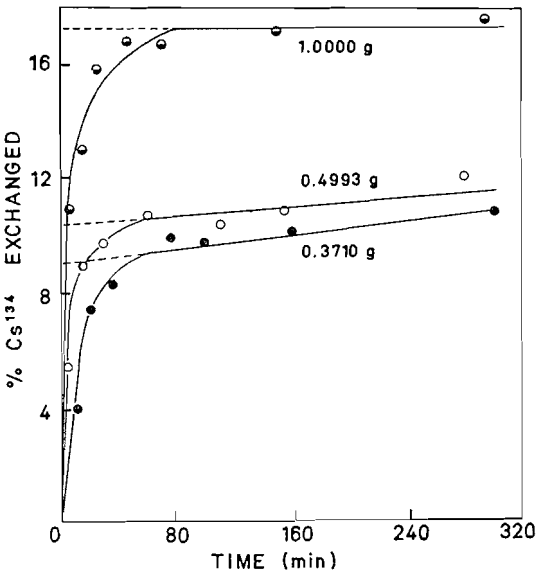

FIG. 1. Plot of % ^{134}Cs exchanged vs. time of shaking in minutes.

Determination of Surface Area

(1) Isotopic Surface Exchange Method

250 ml of a saturated solution of cesium perchlorate was prepared in 95% alcohol and an aliquot of ^{134}CsCl solution was added. This solution was equilibrated for 2 weeks at 30 ± 0.5 °C. (100 λ of this solution gave about 2000 counts per min with a Geiger Müller (G.M.) counter.) 25 ml of the above solution was added to a 100 ml narrow mouthed bottle with a ground-glass stopper, into which a known amount of cesium perchlorate was already weighed. The contents were agitated by an electrical shaker in a thermostat at 30 °C. At desired time intervals, 2 ml of the suspension was centrifuged and 100 λ of the centrifugate was transferred to a stainless steel planchet, by means of a micro-pipette, dried under an infrared lamp, and its beta activity measured with a G.M. counter.

Activity was plotted vs. time of shaking (Fig. 1). This plot was employed to obtain the percentage of ^{134}Cs exchanged at equilibrium, after correcting for recrystallization and self-diffusion by extrapolation to zero time of shaking.

The equilibrium may be represented as

$$[2] \qquad \frac{N_s^+}{N_s} = \frac{N_1^+}{N_1}$$

where N_s^+ and N_1^+ are the number of tracer ions in the solid and solution phases respectively, and N_s and N_1 are the total number of active and inactive species in the corresponding phases.

N_s is readily calculated from the experimentally determined values of solubility (N_1), and N_s^+ and N_1^+. If l^2 is the effective area of the tagged species, the surface area S is given by

$$[3] \qquad S = N_s l^2$$

where

$$[4] \qquad l^2 = \left[\frac{M}{\rho N a}\right]^{2/3}$$

where M is the molecular weight, ρ the density of the powder, a the number of gram ions of the tagged species of ions per mole of the solid, and N, the Avogadro number.

The results are presented in Table I.

(2) Air-Permeability Method

The air-permeability apparatus used was after Lee and Nurse (2) (Fig. 2). The permeability cell had a cross-sectional area of 5.07 sq. cm. A capillary flow-meter 277 cm long with an internal diameter of 0.904 mm was used.

A weight of cesium perchlorate, calculated to give the desired porosity for a predetermined bed thickness, was weighed into the permeability cell and tapped gently to consolidate. A plunger was introduced and the powder was compressed carefully to a bed of known thickness, the knurled flanges having been adjusted to give the desired height. The powder was always compressed to give the same height and the mass of powder in each run was varied to get different porosities. The plunger was twisted clockwise to compress and finally anticlockwise by a half turn so that a uniform surface was obtained. The plunger was finally removed carefully by a twisting action. Air from an air compressor, dried and free from carbon dioxide (by passing through columns of anhydrous calcium chloride and soda lime) was passed through the bed, with the pressure regulated to 60 lb/sq. in. by the two control valves attached to the outlet in the air compressor.

TABLE I

Isotopic surface exchange method

Sample number	Weight of sample (g)	% Exchange of ^{134}Cs	Specific surface area (cm^2/g)
1	0.3710	9.0	9.32×10^3
2	0.4993	10.4	8.21×10^3
3	1.0000	17.2	7.34×10^3
			Mean 8.29×10^3

Solubility of $CsClO_4$ at 30 °C = 0.02273 g/100 ml, density of $CsClO_4$ at 30 °C = 3.286 g/cc.

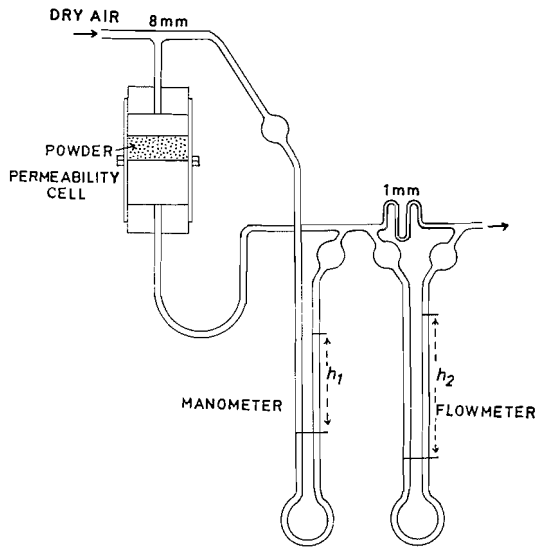

FIG. 2. Permeability apparatus.

For various rates of flow of air, the heights in the manometers across the powder bed (h_1) and the flowmeter (h_2) were recorded. The ratios of the heights in the manometers (h_1/h_2) were then computed and a frequency distribution was made by processing the data to obtain the most probable value.

The most probable value could be considered as the center of gravity of the frequencies (weights) f_1 and f_2 acting at the ends of the modal class i.e. the class of maximum frequency, so that the most probable value is given by the relation

$$[5] \quad \text{Most probable value} = L_1 + \frac{cf_2}{f_1 + f_2}$$

where L_1 is the lower limit of the modal class, f_1 and f_2 are the frequencies of the classes immediately before and immediately after the modal class, and c is the class interval.

The calculations of surface area are based on an equation which was derived by Kozeny and was first applied to surface determinations by Carman (14, 15). The equation is often used in the following form

$$[6] \quad \mu = \frac{\varepsilon^3}{(1-\varepsilon)^2} \frac{g\Delta P}{k\eta L S_w^2 \rho^2}$$

where μ = linear velocity of the fluid, ε = porosity, g = acceleration due to gravity, ΔP = pressure difference across the bed, η = viscosity of fluid, L = thickness of the bed, k = a constant, and ρ = density of powder. Carman found that over a wide range of experimental conditions, $k = 5.0 \pm 0.5$ and this value is almost always used.

The rate of flow of air, Q, through the flow-meter is given by the equation

$$[7] \quad Q = \frac{Ch_2 d}{\eta}$$

where C is a constant for a given capillary, h_2 the difference in the levels in the flowmeter manometer, and d the density of liquid in the manometer. From eq. [7]

$$[8] \quad Q = \mu A = \frac{\varepsilon^3}{(1-\varepsilon)^2} \frac{g\Delta P A}{k\eta L S_w^2 \rho^2}$$

Using the values of $k = 5$ and $g = 980$ cm/s^2, one gets

$$[9] \quad S_w = \frac{14}{\rho(1-\varepsilon)} \left(\frac{\varepsilon^3 A h_1}{C L h_2} \right)^{1/2}$$

where A is the cross-sectional area of the permeability cell and h_1 the difference in the levels of the manometer across the powder bed.

When a gas is used as the permeating fluid, eq. [9] should be modified in order to correct for the "slip" at the walls of the channel where theoretically the gas should be stationary. However, since the pressures used across the powder beds were small, the correction worked out to be negligible.

From the measured values of the area of the bed A, thickness of bed L, porosity of the bed ε, and the density of the powder ρ, the specific surface area was calculated with the use of relation [9].

The flow meter constant C was evaluated by means of the eq. [7]. A calibrated gas-meter was employed to determine Q. The most probable value of C was calculated from over 100 values of flow rates. The value of C obtained was 5.91×10^{-6} c.g.s. units. These results are presented in Table II.

(3) Microscopic Method

Cesium perchlorate powder (of the same sample as above) was mounted and spread out on a perfectly clean and dry object-glass (1 in. × 3 in.) using a fine needle, in such a way that the grains exhibited their outline without aggregation. The glass slide was fixed to an integrating stage with facility for both longitudinal and transverse movement of the slide. In order to determine the grain dimensions, an ordinary eye-piece micrometer, which was calibrated with the help of a stage micrometer, was used. The stage was then mounted on a Leitz polarizing microscope and the maximum length and maximum breadth of each grain were measured and recorded individually. Measurements were carried out for 300 particles at a magnification of 300 times.

The particles were assumed to be parallelepipeds, and the surface area was calculated. The specific surface area was obtained by dividing the area of 300 particles by the mass of the same, obtained in turn by the product of their volume and density. In the above calculations, the thickness and breadth of the particles were assumed to be equal (5). These values are presented in Table III.

Results and Discussion

The values of specific surface area of cesium perchlorate obtained by the three methods are reproducible for each method and satisfactory. The results of specific surface area evaluated in terms of air-permeability agree well with those obtained on the basis of microscopic method. The divergency noticed is within the limitations of the

TABLE II

Air-permeability method

Sample number	Weight of sample (g)	Porosity (void volume/unit volume)	h_1/h_2	Specific surface area (cm^2/g)

†Obtained by calculating the most probable values from the frequency distributions.

experimental procedures. In the air permeability method, specific surface areas for porosity range 0.55–0.49 are constant. (The small decrease in the surface area in the range 0.49–0.45 may be attributed to a decrease in free permeation of air as a result of closer packing.) However, the specific surface area obtained on the basis of isotopic surface exchange procedure is significantly greater than the results of the other methods. This is understandable when we distinguish the internal surface due to the cracks and fissures in the crystals from the external surface (16). It is obvious that the microscopic method would measure only the external surface leaving out the submicroscopic fissures. The air flow method too would not include the internal surface, as air filling in the cracks and fissures would be relatively stagnant. Isotopic surface exchange would measure the total surface (both internal and external) and may well be expected to give specific surface area values of a higher order. The pore radius measured is of the order 1.3 μ, showing that the contribution to the specific surface area estimated by isotopic surface exchange method includes the internal surface due to the porous nature of cesium perchlorate. The surface porosity may be attributed to the method of preparation and also the inherent porous character of cesium perchlorate.

Conclusions

It is concluded from the present work on the specific surface area of cesium perchlorate, that the air-permeability and microscopic methods yield results in agreement with each other and probably measure the external surfaces of solids. The surface exchange method, on the other hand, gives a measure of the total surface, internal and external, of solids. Independent methods for evaluation of internal surface alone are not available at present. The order of difference observed, between the external surface area and the total surface area as measured by these methods, is comparable to the difference recorded in like situations concerning other solids studied (17–20).

Stability of fused rings in metal chelates. VI[1]. Structures and stability constants of the copper(II) chelates of dipeptides containing glycine and/or β-alanine

OSAMU YAMAUCHI, YUMI HIRANO, YASUO NAKAO, AND AKITSUGU NAKAHARA
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka, Japan

Received March 10, 1969

The reactions of the dipeptides containing glycine and/or β-alanine with an equimolar amount of copper(II) nitrate in acid solution were investigated potentiometrically, and the stability constants for the copper(II) chelates formed in acid solution were determined at 25 °C by the method of Datta and Rabin. The chelates with the composition [Cu·peptide(OH_2)] were isolated in the pure state. The dipeptides exhibited analogous reactivities, and the stability constants, log K_1, for the charged chelates, $CuHL^+$, were found to be between 5.5–5.7. Comparison of the values for glycylglycine and β-alanylglycine with those for glycine and β-alanine suggests that these dipeptides act as terdentate ligands forming fused-ring chelates, where the coordinating sites are probably the amino nitrogen, amide nitrogen, and carboxyl oxygen, although the complexing ability of the amide NH group may be weak. The constants, K_c, for the dissociation of the amide hydrogen from the charged chelates to form the deprotonated chelates, CuL, with the rigid 5-5-, 5-6-, or 6-6-membered ring system decrease in the order glycylglycine > β-alanylglycine > glycyl-β-alanine > β-alanyl-β-alanine. The log K_1K_c values indicate that the tendency of forming the deprotonated chelates also decreases in this order.

Canadian Journal of Chemistry, 47, 3441 (1969)

Introduction

The studies on the relative stabilities of the chelates of multidentate ligands are of great importance in finding clues to the subjects relating to the structures and reactions of metal complexes. From this point of view, the relative stabilities of the copper(II)–Schiff base complexes with 5-5-, 5-6-, 6-5-6-, and 5-5-6-membered fused-ring systems[2] were disclosed in the previous investigations on the basis of the numerical results obtained by various physicochemical measurements (1, 2). In order to shed light on the structures and relative stabilities of fused-ring chelates as an extension of the previous studies, investigations have recently been made on the stability constants of the copper(II) chelates formed by the reactions of the dipeptides composed of glycine and/or β-alanine with an equimolar amount of copper(II) nitrate in acid solution, and on the contribution of the peptide bond to the coordination around copper. Although glycylglycine and related peptides were already reported to exhibit quite interesting formation reactions of chelates with copper(II) (3–10), there have been no comparative studies on the structures and stabilities of the copper(II) chelates of glycylglycine (Gly-Gly), glycyl-β-alanine (Gly-β-Ala), β-alanylglycine (β-Ala-Gly), and β-alanyl-β-alanine (β-Ala-β-Ala), which are expected to behave as terdentate ligands forming 5-5-, 5-6-, or 6-6-membered fused-ring chelates with copper(II).

The present paper deals with the determination of the stability constants of the 1:1 copper chelates of the above mentioned dipeptides formed in the pH range 4–7 and discusses their structures and relative stabilities in aqueous solution. These findings may also have a potential significance in the biological field.

Experimental

Reagents

Ligands. Gly-Gly was prepared by the diketopiperazine method. Gly-β-Ala, β-Ala-Gly, and β-Ala-β-Ala were prepared by the carbobenzoxy method. Their purity was checked by the melting points and elemental analyses.

0.01 M $Cu(NO_3)_2$. This was prepared by dissolving copper(II) nitrate in water and was standardized by 0.01 *M* EDTA which had been standardized against standard zinc (99.99% pure).

0.1 N KOH. This was prepared by the method of Armstrong (11) and standardized against potassium hydrogen phthalate.

All the reagents used were of reagent grade, and deionized water was used throughout.

Apparatus

A Yanagimoto Model 66A pH meter with a Horiba 1026-05T glass electrode and a Horiba 2630-05T calomel electrode was used.

pH Titration

Exactly equimolar amounts of a ligand and Cu(II) were mixed in 45 ml of water and to this was added 5 ml

[1]For Part V of this series, see ref. 18.

[2]This type of notation will be used hereafter for the expression of the individual ring size of a fused ring. For example, "5-5-membered" indicates that the fused ring is composed of two 5-membered rings.

For personal use only.

of 1 M KNO_3 to make the concentration 0.004–0.005 M. The mixture was titrated with 0.1 N KOH at 25 °C under a nitrogen atmosphere, and the pH values were measured. The ligands were titrated in the absence of Cu(II) under the same conditions to determine their acid dissociation constants. Conversion of pH to $-\log [H^+]$ and determination of the apparent ion product of water, pK_w', were made by titrating 0.01 N HNO_3 with 0.1 N KOH under the same conditions. Thus, $[H^+] = 10^{-pH}/0.92$; $pK_w' = 13.88$.

Preparation of the Cu(II) Chelates

[*Cu·Gly-β-Ala(OH₂)*]. This was prepared by the method of Manyak *et al.* (4) from Gly-β-Ala (0.005 mole) and a slight excess of freshly prepared $Cu(OH)_2$. After evaporation of the reaction mixture in vacuo, acetone was added, and the mixture was cooled, when a blue crystalline powder, m.p. 193–196 °C (decomp.), separated.

Anal. Calcd. for $C_5H_{10}N_2O_4Cu$: C, 26.62; H, 4.47; N, 12.42. Found: C, 26.33; H, 4.44; N, 12.27.

[*Cu·β-Ala-Gly(OH₂)*]. This was obtained in a similar manner from β-Ala-Gly and $Cu(OH)_2$ as blue prisms, m.p. 205–210 °C (decomp.).

Anal. Calcd. for $C_5H_{10}N_2O_4Cu$: C, 26.62; H, 4.47; N, 12.42. Found: C, 26.44; H, 4.40; N, 12.50.

Results and Discussion

The pH titration curves of the ligands in the absence and presence of Cu(II) are shown in Fig. 1. The dipeptides investigated have analogous titration curves except that precipitation occurred during the titration of the β-Ala-β-Ala-Cu(II) system (curve 5). When Gly-Gly is caused to react with an equimolar amount of Cu(II), the following two reactions have been shown to occur in acid solution (3–7)

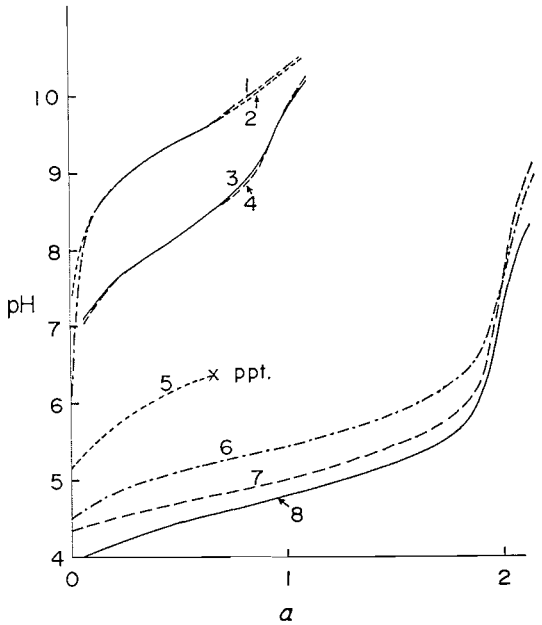

FIG. 1. pH titration curves for the dipeptides at 25 °C (μ = 0.1(KNO_3)): ——— Gly-Gly, – – – Gly-β-Ala, - - - - - - β-Ala-Gly, - - - - - β-Ala-β-Ala; ligands alone (curves 1–4); ligand:Cu(II) = 1:1 (curves 5–8). The term a is the number of moles of KOH added per mole of ligand.

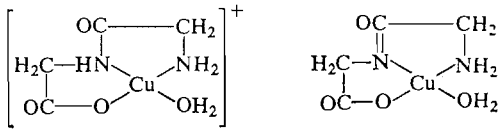
$$[1] \qquad Cu^{2+} + HL^- \overset{K_1}{\rightleftharpoons} CuHL^+$$

$$[2] \qquad CuHL^+ \overset{K_c}{\rightleftharpoons} CuL + H^+$$

where HL^-, $CuHL^+$, and CuL denote respectively the free ligand, the positive chelate **1**, whose structure will be discussed below, and the neutral chelate **2** formed upon the dissociation of the peptide NH of **1**.



$CuHL^+$ **1**

CuL **2**

The equilibrium constants K_1 and K_c are defined as follows

$$[3] \qquad K_1 = \frac{[CuHL^+]}{[Cu^{2+}][HL^-]}$$

$$[4] \qquad K_c = \frac{[H^+][CuL]}{[CuHL^+]}$$

As is apparent from the curves, two acid dissociations were observed to occur in the acid region before the pH jump, and we may assume the reactions [1] and [2] reported for Gly-Gly also in the reactions of Gly-β-Ala and β-Ala-Gly. Following the method of Datta and Rabin (5), we first obtained graphically the approximate value of K_1 with the aid of eq. [5] by assuming $\beta = 1$ and then inserted it into eq. [5] to calculate the corresponding K_c value at each pH and its average value, $\overline{K_c}$

$$[5] \qquad \frac{1}{K_1} = -\frac{K_{a_2}}{[H^+]}\left(\frac{\beta(2C_L + A) - C_L}{A\alpha - \gamma}\right) \times \left(C_L - \frac{A\alpha - \gamma}{\alpha/\beta - 3\alpha + 1}\right)$$

where $A = -[K^+] - [H^+]$, $\alpha = 1 + [H^+]/K_{a_1}$, $\beta = 1 + K_c/[H^+]$, and $\gamma = C_L[H^+]/K_{a_1}$; K_{a_1} and

K_{a_2} are the acid dissociation constants of the carboxyl and amino groups of the dipeptides, and $[K^+]$ and C_L are the amount of KOH added and the total concentration of ligand, respectively. Then, the initial log K_1 value was increased or decreased by 0.05 log unit, and K_c was calculated again. The best set of K_1 and $\overline{K_c}$ corresponded to the minimum point in the plot of the variances of $-\log K_c$ (pK_c) against log K_1. Usually, 20–30 sets of $[K^+]$ and $[H^+]$ were used for the calculations of the pK_a values, and 40–60 sets were used for K_1 and K_c. The constants for β-Ala-β-Ala, whose reactions are assumed to be the same as those of Gly-Gly, may be less accurate because sufficient data were not obtained owing to the precipitation of copper(II) hydroxide. The standard deviations of the log K_1 and pK_c values were within 0.03. The validity of the results was checked by duplicate runs, where the differences in the corresponding constants were less than 0.1 log unit. The amounts of alkali at various pH values were calculated from eq. [5] by using the determined constants and were found to correspond well with the experimental results. Hence, this confirms the assumption that under the conditions employed, the reactions [1] and [2] occur. All the computations were made with the use of a NEAC-2200/500 computer of the Osaka University Computation Center. The pK_a values and the stability constants are listed in Table I along with the constants for the chelates of glycine and β-alanine calculated by the method of Irving and Rossotti (12).

The pK_a values of the glycine residue of the dipeptides are lower than the corresponding values of the β-alanine residue, and this fact can be ascribed to the lower pK_a values of glycine as compared with those of β-alanine. The stability constants for Gly-Gly determined by the present investigation are in good agreement with those reported by Dobbie and Kermack (log K_1 = 5.88; pK_c = 4.25) (3), Datta and Rabin (log K_1 = 5.82; pK_c = 4.25) (5), and Bryce *et al.* (log K_1 = 5.50; pK_c = 4.30) (10). With respect to the charged chelates of the peptides, $CuHL^+$, the log K_1 values for Gly-Gly, Gly-β-Ala, and β-Ala-Gly are between 5.6 and 5.7, the differences being almost negligible, but the value for β-Ala-β-Ala is somewhat lower. On the other hand, the log K_1 for the 5-membered glycine–copper(II) chelate is considerably higher than that for the 6-membered β-alanine–copper(II) chelate. Considering that there is practically no difference between the log K_1 for Gly-Gly and β-Ala-Gly in spite of the large difference in the pK_a values of the two NH_2 groups, there seems to be no distinct correlation between the stability constants and the pK_a values of the coordinating groups. Therefore, we may safely infer that steric effects play an important role in the chelate formations by the peptides.

There have been some ambiguities about the coordination sites of the peptides in acid solution. Freeman *et al.* (13) disclosed by X-ray analysis that, in the solid state, the protonated complex of triglycine, $[CuH_2L]^+Cl^-$, has a polymeric structure with the carboxyl group of a ligand molecule coordinating to the neighboring copper atom which is coordinated by the amino nitrogen and peptide oxygen atoms of another ligand molecule. In dilute aqueous solution, however, we can hardly assume the same structure, because we must take into account the solvation by water molecules and the stabilization due to the so-called "chelate effect." As for Gly-Gly, Rabin (14) and Martell (15), by referring to the stability constants and infrared spectra, preferred the coordination through the amino nitrogen and the amide oxygen, regarding the dipeptides as bidentate ligands. If this is the case and the chelates of the type **3** are formed, the log K_1 values for the glycine and β-alanine chelates would predict on

3

stereochemical grounds that the differences between the values for Gly-Gly and β-Ala-Gly, and for Gly-β-Ala and β-Ala-β-Ala would also be as large as the difference between glycine and β-alanine. On the contrary, the fact is that the differences are very small. On the basis of these observations, we are more in line with the view that the dipeptides, when present in dilute solution, react with copper(II) as terdentate ligands, forming fused-ring chelates of the type **1** with the strain of the individual chelate rings dispersed over the chelate as a whole. Although no positive information has been reported as yet about the contribution of the amide NH group without loss of the hydrogen (16), we may reasonably presume that the coordination is through the amide NH of the peptides when they act as terdentate ligands, because participation of the amide oxygen is sterically almost impossible. Whether or not the hydrogen atom is found on the amide nitrogen is not to be clarified at the present stage. The complexing ability of the amide NH group may be so weak that its contribution to the binding with copper would be feasible only through the coordination of the terminal amino and carboxyl groups. Therefore, the amide oxygen will be the preferred coordination site when the participation of the amide nitrogen is sterically difficult[3].

With the increase of the pH of the solution, dissociation of the amide hydrogen of the chelates occurs to an increasing extent, resulting in the formation of the neutral chelates of the type **2**, where the binding between nitrogen and copper is considered to be much stronger. The structure **2** was proposed for Gly-Gly in solution and has been confirmed also in the crystalline state by X-ray analysis (17). The neutral chelates may be regarded as intrinsic fused-ring chelates belonging to the 5-5-, 5-6-, and 6-6-membered ring systems. The relative stabilities among these chelates can be inferred from the following relationship obtained by combining eqs. [4] and [5]

$$[6] \qquad \frac{[CuL]}{[Cu^{2+}][HL^{-}]} = \frac{K_1 K_c}{[H^{+}]}$$

It is apparent from eq. [6] that the relative degrees of formation of the neutral chelates and their relative stabilities at a constant pH are given by the K_1K_c values. Table I shows that these values decrease in the order Gly-Gly > β-Ala-Gly > Gly-β-Ala > β-Ala-β-Ala with the differences somewhat larger than those observed about the log K_1 values (Scheme 1).

The observed stability sequence is also in agreement with the observations about the isolation of the chelates and their absorption spectra in the visible region. The stable copper(II) chelates of Gly-Gly, β-Ala-Gly, and Gly-β-Ala could be isolated as pure crystals in contrast with the unstable chelate of β-Ala-β-Ala which could not be isolated under the same conditions. As shown in Table II, the absorption maxima of the former chelates are found in the range 632–643 mμ at pH 6.6–7.2, whereas the maximum of the latter is found at 708 mμ at this pH and shifts to 650 mμ only at pH above 8. Such a spectral behavior corresponds to the higher pK_c value of the copper(II) chelate of β-Ala-β-Ala as compared with the corresponding values of the other chelates. The low stability of this chelate is explained as due to the greater steric strain of the fused-ring system. This strain affects the formation of the deprotonated complex, resulting in the extremely high pK_c value, because the strain supposedly becomes more prominent in the rigid neutral complex than in the protonated complex.

The present findings about the relative stabilities might seem to be incompatible with the conclusion which we made about the copper(II) chelate of the Schiff base derived from pyruvic

[3]As Rabin (14) pointed out, the coordination sites of glycylsarcosine are most probably the amino nitrogen and the amide oxygen because the amide nitrogen has a methyl group which sterically impedes the binding of the nitrogen with copper.

coordinating atoms are an azomethine nitrogen and two carboxyl oxygens as compared with an amino nitrogen, an amide nitrogen, and a carboxyl oxygen in the dipeptide chelates. Accordingly, the steric requirements around the copper atom and hence the ring strain therein would also be different in the two series.

It should be emphasized that the comparison of the stabilities of fused-ring chelates is possible only when the systems being investigated are structurally comparable and consist of coordinating groups of the comparable nature.

The above mentioned relative stabilities of the fused-ring chelates may suggest an explanation of the specificity or selectivity of the enzymic reactions where metal ions are indispensable.

Acknowledgments

We wish to thank Mr. Hiroyuki Ishibashi for measurement of some of the constants and Mr. Toshihiko Kohno for preparation of the copper chelates. We are also indebted to Miss Yoshiko Komuro for the elemental analyses and to the members of the Osaka University Computation Center for computations.

Studies on microcapsules. IV. Preparation and some properties of sulfonated polyphthalamide microcapsules

MASUMI KOISHI, NAOKO FUKUHARA, AND TAMOTSU KONDO

Faculty of Pharmaceutical Sciences, Science University of Toyko, Funagawara-machi, Shinjuku, Tokyo, Japan

Received February 3, 1969

Sulfonated polyphthalamide microcapsules were prepared by making use of the interfacial polycondensation reaction between *p*-phthaloyl dichloride and a mixture of diethylenediamine and 4,4′-diaminostilbene-2,2′-disulfonic acid. These microcapsules were found to be fluorescent as well as negatively charged owing to the presence of sulfonated stilbene skeletons chemically bound in the membranes. The electrophoretic mobility measurements in the presence of inorganic electrolytes revealed a strong resemblance between the microcapsules and hydrophobic colloid particles.

Introduction

A previous paper of this series (1) has dealt with the preparation of polyphthalamide microcapsules, based on the interfacial polycondensation reactions between diamines and phthaloyl dichlorides, under various conditions. However, the microcapsules thus obtained had a tendency to form aggregates in water on prolonged storage unless a considerable amount of dispersing agent, such as Tween 20, was present because they were not electrically charged. This has often made the treatment of microcapsules troublesome in later stages.

An attempt has been made, therefore, to prepare the microcapsules stabilized in water by having strongly ionizable groups in their membranes. The microcapsules of this kind could be obtained, as suggested by Chang (2), by using a mixture of sulfonated and unsulfonated diamines. This paper describes the preparation and some physicochemical properties of the charged polyphthalamide microcapsules.

Experimental

Preparation of Microcapsules

(A) Preparation of Sulfonated Polyphthalamide Microcapsules

The preparation of sulfonated polyphthalamide microcapsules was made by utilizing the interfacial polycondensation reaction between diamines and *p*-phthaloyl dichloride. Thus, the procedure consisted of the following 3 steps.

1. To 7.5 ml of aqueous 1% (wt./wt.) polyethylene glycol (polymerization degree: 4000) solution in a 1 l round bottom flask surrounded by ice, was added an equal volume of a 0.4 *M* solution of a mixture of diethylenediamine (DEDA) and 4,4′-diaminostilbene-2,2′-disulfonic acid (DASSA) in varying ratio, in aqueous 0.45 *M* sodium carbonate solution, containing 1% (wt./wt.) polyethylene glycol. To this solution was added 75 ml of mixed solvent (chloroform–cyclohexane 1:3, v/v, containing 5 or 10% (v/v) Span 85 as an emulsifying agent). The mixed solution was then mechanically emulsified with a Model B-100 Chemistirrer (Tokyo Rika Kikai Co.) at 620 r.p.m. for 5 min to yield a water-in-oil emulsion. The alkali served to neutralize hydrogen chloride formed during the polymerization reaction.

2. Without stopping the stirring, 75 ml of *p*-phthaloyl dichloride solution was quickly added to the emulsion, and the stirring was continued for another 3 min. The *p*-phthaloyl dichloride solution was prepared immediately before use by adding 0.6 g of pure *p*-phthaloyl dichloride to 75 ml of the mixed solvent.

3. To this dispersion was added 75 ml of the mixed solvent, and the dispersion was centrifuged at 350–2000 g to separate the newly formed charged microcapsules. To remove the residual organic solvent, the unreacted reagents, and the salt formed during polymerization, the microcapsules separated from the organic phase were washed twice with 80 ml of aqueous 20% (v/v) Tween 20 solution on the centrifuge. The microcapsules were finally suspended in 80 ml of each of aqueous potassium nitrate, barium nitrate, and lanthanum nitrate solutions containing 4% (v/v) Tween 20, the ionic strengths of which were 1×10^{-2}, 1×10^{-3}, and 1×10^{-4}. Tween 20 was added to prevent the aggregation of microcapsules by the electrolytes.

(B) Partition of Diamines between Aqueous and Organic Phases

The competitive transfer of the diamines into the mixed organic solvent from aqueous solution must first be examined to see the tendency of sulfonate groups to be incorporated in the microcapsule membranes. For this purpose the determination was made of the diamine partitions between the aqueous and the organic phase under the same conditions as those in the preparation of microcapsules.

Thus, the partition coefficients were determined by the following method. To 30 ml of a 0.4 *M* solution of DEDA or DASSA in aqueous 0.45 *M* sodium carbonate solution containing 1% (wt./wt.) polyethylene glycol in a 100 ml Erlenmyer flask surrounded by ice, was added an equal volume of the mixed solvent. The mixed liquid was then mechanically agitated with the Chemistirrer at 620 r.p.m. for 5 min. In each case an emulsion was formed, which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was centrifuged to completely separate it into two liquid layers. The concentration of DEDA plus sodium carbonate remaining in the aqueous phase was determined by titration with hydrochloric acid using a piston burette and BCG–BTB mixed indicator. The initial concentrations of the diamine plus sodium carbonate and sodium carbonate alone were also determined by the same procedure. In the case of DASSA, the concentration in the aqueous phase was determined fluorophotometrically by a Hitachi model MPF-2A fluorescence spectrophotometer.

Finally, the transferred amounts of the diamines were calculated from their initial and final concentrations in the aqueous phase, and then the partition coefficients between the aqueous and the organic phase were calculated.

Fluorescence of Sulfonated Microcapsules

The sulfonated polyphthalamide microcapsules were remarkably fluorescent under ultraviolet (u.v.) light, very probably due to DASSA chemically incorporated in the membranes. The fluorescence spectra of DASSA in the microcapsule membranes dispersed in aqueous phase were recorded on the Hitachi model MPF-2A fluorescence spectrophotometer using the light of a wavelength of 360 mμ for exciting the sample.

The microcapsules used for the measurements were washed twice with aqueous 20% (v/v) Tween 20 solution after preparation and then suspended in the same medium.

An Olympus model HLS-II photomicroscope was employed for photographing the fluorescent microcapsules. This instrument was equipped with a high-pressure mercury vapor lamp as the source of u.v. light. A blue filter, BG-370, was also used to delimit the wavelength of radiation reaching the specimen from the light source.

Determination of Size and Size Distribution of Sulfonated Microcapsules

Several samples from each batch of the sulfonated microcapsules were photographed under an ordinary microscope. Calculations were made of the length mean diameter, size distribution, standard deviation, mean surface diameter, and mean volume diameter by using an IBM 1620 computer as described in the previous paper (1).

Electrophoretic Mobilities of Sulfonated Microcapsules

Electrophoretic mobilities of the sulfonated microcapsules were measured in a quartz flat electrophoresis cell of rectangular cross section under a microscope. Necessary precautions were taken so that the measurements could be made at the stationary layer of the cell. For each measurement, 40 microcapsules were timed in each direction to eliminate the polarization effect of the electrodes. The dispersion media were aqueous solutions of potassium, barium, and lanthanum nitrates of various ionic strengths containing 4% (v/v) Tween 20.

Zeta potentials of the microcapsules, ζ, were calculated by the Henry equation (3)

$$\zeta = f\pi\eta u/D$$

where u is the mobility of the microcapsules, D and η are respectively the dielectric constant and viscosity of dispersion medium, and f is the numerical factor depending on the value of the product of the reciprocal of double layer thickness around the microcapsules, κ, and their radius, a. The value of 4 was used for f when κa was larger than 300. In other cases, the values of f were calculated according to Overbeek (4).

The surface conductance effect was found to be negligible because preliminary experiments showed that the product of the specific conductance of dispersion medium and the microcapsule radius was much larger than the surface conductance at the interface of the dispersion medium and the microcapsule. Thus, for example, the surface conductance at the interface of the microcapsule and 1×10^{-4} potassium nitrate solution containing 4% (v/v) Tween 20 was 2.64×10^{-10}, while the product of the specific conductance of the same dispersion medium and the microcapsule radius was evaluated to be 1.06×10^{-8}. This satisfies the condition of particles to be insulating (5).

The relaxation correction was made by Booth's method (6), when the zeta potentials were not very low and κa was less than 100.

Results and Discussion

Formation of Sulfonated Microcapsules

The formation of sulfonated microcapsules was practically not affected by the molar mixing ratio of the diamines. Thus, the quantity of microcapsules obtained was nearly constant over the range from 0 to 85 mole % of DASSA in the diamine mixtures. No polymer particles were formed in the organic phases under the experimental conditions used in this work.

The sulfonated polyphthalamide microcapsules were generally more resistant to centrifugation than the unsulfonated ones, presumably owing to the presence of strongly ionizable groups in the membranes, which are able to prevent the microcapsules from aggregating in water by electrostatic repulsive forces.

The shape of the microcapsules was invariably spherical in all cases studied, probably due to the osmotic pressure exerted by the polyethylene glycol solution encapsulated within the semipermeable polymer membranes. The microcapsules were also quite stable and no appreciable aggregates were found to form even on storage for over a month in distilled water.

Partition of Diamines between Aqueous and Organic Phases

The partition coefficients of the diamines varied with the concentration of Span 85. Thus, the values of the partition coefficients determined at 620 r.p.m. decreased with increasing concentration of Span 85 as given in Table I.

A comparison of the partition of DEDA with

TABLE I

Partition coefficients of the diamines in the presence of Span 85

Diamine	[Span 85], % (v/v)	Partition coefficient, $K(C_{aq}/C_{org})$
DEDA	5	26.00
	10	18.83
DASSA	5	2.93
	10	2.33

that of DASSA clearly indicates an easier transfer to the organic phase of the latter compared to the former. This will ensure that the sulfonated microcapsules can be prepared favorably using the diamine mixture of any ratio lying in the range described before in the presence of either 5 or 10% (v/v) of Span 85.

Fluorescence of Sulfonated Microcapsules

Figures 1 and 2 are typical photomicrographs of the sulfonated microcapsules taken under u.v. light, showing a beautiful blue fluorescence.

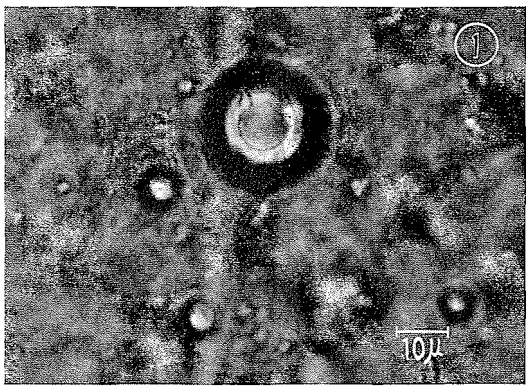

FIG. 1. Photomicrograph of sulfonated polyphthalamide microcapsules taken under ultraviolet light.

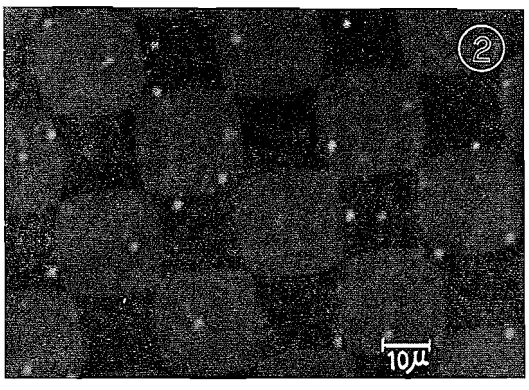

FIG. 2. Photomicrograph of sulfonated polyphthalamide microcapsules taken under ultraviolet light using a yellow filter, FY-4, inserted between the specimen and eyepiece, in addition to the blue one described in text.

The large microcapsules shown in Fig. 1 were specially made by adding sodium methyl sulfate, which is a very effective size controlling agent for microcapsules[1], to the aqueous polyethylene glycol solution to be encapsulated.

The fluorescence spectra of DASSA incorporated in the microcapsule membranes are shown in Fig. 3.

The peak of the spectra appears at about 440 mμ irrespective of the mole percent of DASSA. The fluorescence at this wavelength may arise from the stilbene skeletons of DASSA since some derivatives of DASSA are known to have maximum fluorescence intensity at the same position due to their stilbene skeletons (7, 8).

Size and Size Distribution of Sulfonated Microcapsules

In Fig. 4 is given the size distribution of sulfonated microcapsules in aqueous dispersions in the presence of 10% (v/v) of Span 85. No significant effect is found of varying mole percent of DASSA used on the size distribution curve. This means that the size of the sulfonated microcapsules is mainly determined in the emulsification step of the preparation as in the case of the unsulfonated microcapsules (1).

Table II summarizes the results on the calculations of the length mean diameter, standard deviation, mean surface diameter, and mean volume diameter of the sulfonated microcapsules.

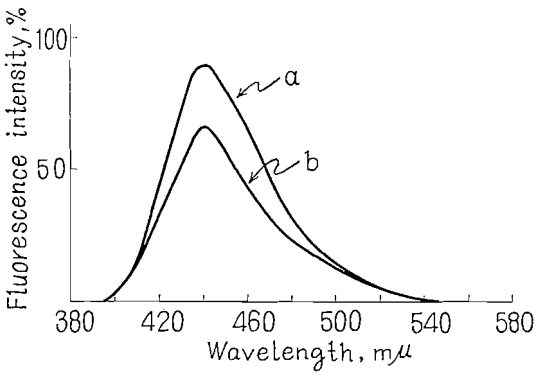

FIG. 3. Fluorescence spectra of DASSA incorporated in the microcapsule membranes prepared at (*a*) 28.6 and (*b*) 23.1 mole % respectively.

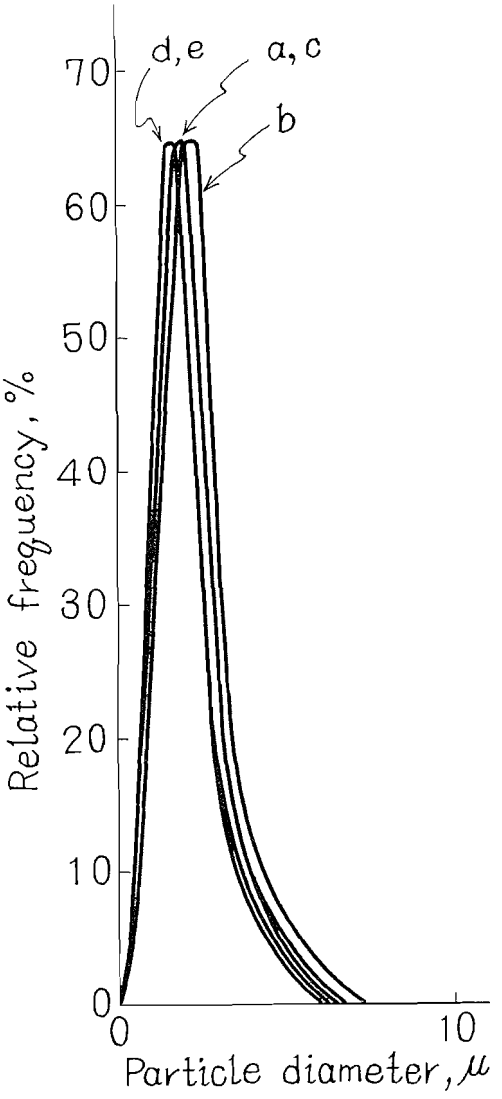

FIG. 4. Size distribution of the sulfonated microcapsules prepared from the mixture of DEDA and DASSA in varying ratio and *p*-phthaloyl dichloride. Mole percent of DASSA: (*a*) 0, (*b*) 28.6, (*c*) 55.6, (*d*) 66.7, and (*e*) 83.3.

TABLE II

Length mean diameter (d_1), standard deviation (δ), mean surface diameter (d_2), and mean volume diameter (d_3) of the sulfonated microcapsules

Mole % of DASSA	d_1(μ)	d_2(μ)	d_3(μ)	δ
0	2.00	2.12	2.25	0.70
28.6	2.32	2.59	2.86	1.15
55.6	2.02	2.26	2.56	1.01
66.7	1.91	2.09	2.33	0.83
83.3	1.89	2.22	2.59	1.17

Electrophoretic Mobilities of Sulfonated Microcapsules

The sulfonated microcapsules always moved toward the anode with a measurable mobility in aqueous potassium nitrate solutions of various ionic strengths, while the unsulfonated microcapsules suspended in the same media had no surface charge detectable by electrophoresis. The presence of Tween 20 did not affect appreciably the values of the zeta potential. The zeta potentials of the microcapsules are plotted in Fig. 5 against the mole % of DASSA in the diamine mixtures used in the preparation.

The absolute value of the zeta potential decreases first as the mole % of DASSA increases and then begins to rise after passing through a minimum at all ionic strengths studied, although the position of the minimum depends slightly on the ionic strength of the medium. The appearance of a minimum was confirmed by separate measurements on several samples of different preparations. This will be interpreted as showing that the increase in the content of sulfonate groups in the membranes facilitates the fixation of counter ions on the left half of the figure, thereby lowering the zeta potentials of the microcapsules, but, on the right half, it tends to exceed the neutralizing effect of counter ions, resulting in an increase of net negative charge of the microcapsules.

Figure 6 shows the effect of counter ion valency

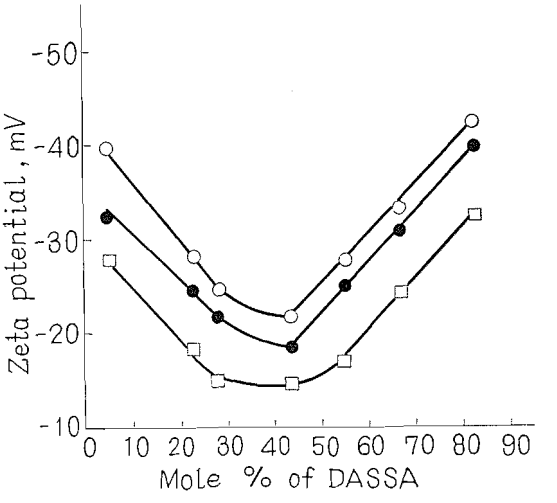

FIG. 5. Zeta potentials of the sulfonated microcapsules in KNO_3 solution as a function of mole % of DASSA. Ionic strength: 1×10^{-2} (□), 1×10^{-3} (●), and 1×10^{-4} (○).

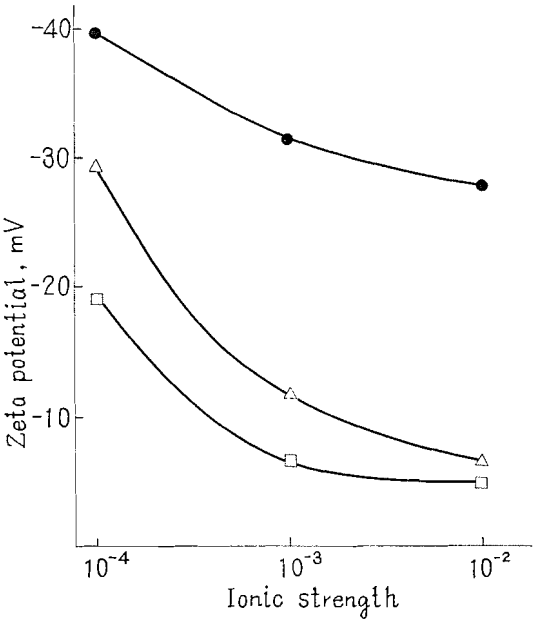

FIG. 6. Effect of potassium, barium, and lanthanum ions on the zeta potentials of sulfonated microcapsules prepared at 4.8 mole % of DASSA. KNO_3 (●), $Ba(NO_3)_2$ (△), and $La(NO_3)_3$ (□).

on the zeta potentials of sulfonated microcapsules. An increasing order, $La^{3+} > Ba^{2+} > K^+$, is evident in the lowering effect of these cations on the zeta potentials. The situation is quite similar to that found in the flocculation of negatively charged hydrophobic colloids by cations of various inorganic electrolytes (9). This will be suggestive in applying the microcapsules to various fields of science and technology.

Microwave spectrum of morpholine

J. J. SLOAN[1] AND R. KEWLEY
Department of Chemistry, Queen's University, Kingston, Ontario

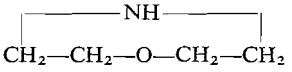
Received May 21, 1969

The microwave spectra of morpholine and N-deuteromorpholine have been investigated within the 8 to 40 GHz region. For both the normal and the deuterated species, strong *a*-type spectra which are due to the chair conformer with an equatorial imino group were recorded. The ground vibrational state rotational constants and quadrupole coupling constants are (in MHz), for normal morpholine, $A = 4924.88 \pm 0.05$, $B = 4625.15 \pm 0.05$, $C = 2684.25 \pm 0.05$, $\chi_{aa} = 2.22 \pm 0.02$, $\chi_{bb} = 2.51 \pm 0.04$, $\chi_{cc} = -4.73 \pm 0.02$, and for N-deuteromorpholine, $A = 4925.39 \pm 0.05$, $B = 4399.67 \pm 0.05$, $C = 2607.09 \pm 0.05$, $\chi_{aa} = 1.92 \pm 0.02$, $\chi_{bb} = 2.59 \pm 0.04$, $\chi_{cc} = -4.51 \pm 0.02$. The r_s coordinates of the imino hydrogen are (in Å) $a_H = 2.373 \pm 0.005$ and $c_H = 0.10 \pm 0.03$. For the normal species the dipole moment components are (in D) $\mu_a = 1.68 \pm 0.01$, $\mu_c = 0.30 \pm 0.01$, $\mu = 1.71 \pm 0.02$. The value of a_H and the direction of μ with respect to the *a* and *c* principal axes confirm that the observed spectrum is that of the chair equatorial conformer of morpholine.

Canadian Journal of Chemistry, 47, 3453 (1969)

Introduction

Morpholine is a member of a class of compounds which have six-membered heterocyclic aliphatic rings. Its formula may be expressed as



Other compounds of this type for which rotational spectra are known are the oblate symmetric top *sym*-trioxane (1), piperidine (2), and tetrahydropyran (3). All three molecules have been shown to have chair form structures.

Such molecules do not easily lend themselves to complete r_s structure determinations because of the low natural abundances of the atoms ^{13}C, ^{18}O, ^{15}N, and D, and the exorbitant cost of most isotopic syntheses involving these rings. Nevertheless interesting information may be derived from their spectra because of the possibilities of both boat–chair and axial–equatorial isomerism, and also of inversion of the whole molecule by chair–chair interconversion. Also in molecules like piperidine and morpholine the r_s method may still be applied in a limited way to gain a knowledge of the position of the imino hydrogen. This assists in assigning a spectrum to either the axial or the equatorial NH conformer.

The present investigation was undertaken in order to extend knowledge concerning this type of ring system, particularly to discover whether or not the boat form is present in an observable amount and to ascertain, if possible, the relative quantities of axial NH and equatorial NH conformers of the expected chair form of the molecule.

Experimental

The spectrum was observed using a 100 kHz Stark modulation spectrometer which has been described previously (3). Recorder traces were taken by driving the klystron mechanical tuning knob with Bristol synchronous motors having speeds of $\frac{1}{3}$, 1, and $3\frac{1}{3}$ r.p.h. so as to obtain sweep rates of about 10 MHz per min. The charts so produced were valuable for surveying ranges of the spectrum from 50–500 MHz but were not used for accurate frequency measurement, which was achieved as described in ref. 3. The recorder used was a Honeywell Electronik 18, modified to allow the display of both lines and Stark lobes when using phase-sensitive detection.

A sample of the normal morpholine was obtained from the Aldrich Chemical Company Inc. and used without further purification. The index of refraction of this sample was determined as $\eta_{20/D} = 1.4547$ which compares well with the tabulated value of $\eta_{20/D} = 1.4545$ (4). The N-deuteromorpholine sample was prepared by the following procedure. A mixture containing equal volumes of normal morpholine and a solution consisting of 10% sodium deuteroxide in deuterium oxide was stirred vigorously under a dry nitrogen atmosphere for 2 days. The morpholine layer was removed and mixed, again in equal volumes, with a fresh sample of the $NaOD/D_2O$ mixture. This was again stirred under dry nitrogen for a 2 day period. At the end of this time the morpholine layer was removed and added to Linde molecular sieve, type 4A, which had previously been treated with D_2O. On account of the hygroscopic nature of morpholine further drying was required. This was carried out using the type 4A molecular sieve in vacuo. The morpholine/molecular sieve mixture was placed on the vacuum system and degassed. After remaining on the molecular sieve for about 4 h, the morpholine was transferred to a second tube containing freshly degassed molecular sieve. The original molecular sieve was then degassed at 400 °C and all material thus

[1]Present address: Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139.

For personal use only.

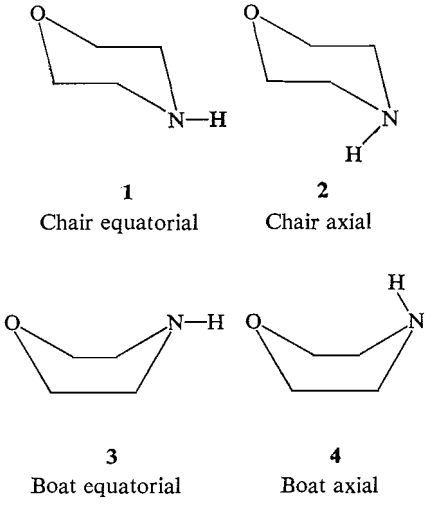
driven off was discarded. The morpholine was then pumped onto the regenerated sieve. After this procedure had been repeated four times, microwave lines were obtained from the N-deuteromorpholine which were of acceptable intensity and width. Even though some of the stronger lines of the normal morpholine spectrum were still visible at this stage and also some lines of HDO, the pressure broadening due to foreign gases was not considered to contribute significantly to the line width in the N-deuteromorpholine spectrum. The completeness of deuteration was also checked by nuclear magnetic resonance (n.m.r.) using 10% solutions of normal and N-deuteromorpholine in $CHCl_3$ and $CDCl_3$, respectively. From the size of the peak at 200 c.p.s. due to the imino hydrogen, it was concluded that over 95% deuteration was achieved.

Sample pressures ranging from about 10–100 μ were used when observing the spectra. All such observations were made at room temperature on account of the small vapor pressure of morpholine at temperatures below its melting point of −4.9 °C.

Rotational Spectrum

General Features

In order that the assignment of the observed rotational spectrum be achieved more easily, preliminary computations were carried out of the spectra expected from the 4 geometrically possible conformers of morpholine.



1 Chair equatorial — **2** Chair axial

3 Boat equatorial — **4** Boat axial

This was done with the aid of an IBM FORTRAN IV program which calculates the atomic cartesian coordinates and spectroscopic parameters by means of Euler's angles transformations applied to the assumed bond lengths and angles input data. The program then calculates the estimated dipole moment components using the atomic coordinates and the Pauling electronegativities of the atoms, which are also supplied as input data. The parameters defining the assumed structures were ∠OCC = ∠CCN = ∠OCH = ∠CCH = 109°28′; ∠COC = ∠CNC = 110°; bond lengths C—O, C—C, C—N, C—H, and N—H of 1.43, 1.54, 1.47, 1.11, and 1.01 Å, respectively. The results of these computations for the conformers **1**–**4** are shown in Table I.

TABLE I

Predicted rotational constants and dipole moment components for conformers of normal morpholine

Parameter	Value in conformer 1	2	3	4
A (MHz)	4927.9	4849.5	4759.9	4847.6
B "	4553.1	4642.4	4730.8	4678.6
C "	2667.9	2722.4	2782.5	2851.6
κ	0.67	0.80	0.97	0.83
μ_a (D)	1.12	0.34	1.35	0.00
μ_c (D)	0.21	1.38	2.85	2.00
μ_{total} (D)	1.14	1.42	3.14	2.00

It may be seen that for all 4 conformers, the resulting rotational constants are those for asymmetric tops having $0 < \kappa < 1$. The dominant feature of the microwave spectrum of this type of oblate slightly asymmetric top is the form of the two strong a-type Q-branches ${}^aQ_{0,-1}$ and ${}^aQ_{2,-1}$, which appear as doublet progressions with frequency spacing between members of a doublet, spacing between successive doublets and line intensities all decreasing as each doublet series approaches its branch head. For a molecule such as conformer **3**, having $\kappa = 0.97$ and large μ_a, the Q-branch heads would be very dense and over 20 strong absorption lines would fall within about 30 MHz of a typical branch head. Such a feature would be unmistakeable. From the μ_a values of Table I it can be seen that conformer **1** is the only other form for which a strong a-type spectrum would be expected.

The observed spectra of normal and N-deuteromorpholine do contain many intense Q-branch lines. However, these lines had to be identified initially by their appearance at fairly low Stark voltages, about 40 V cm^{-1}, and by the large number of rapidly moving Stark components associated with each line. The frequency separations and doublet splittings were much larger than the ones predicted on the basis of the conformer **3** structure. This is illustrated in Fig. 1, a portion of the spectrum of undeuterated

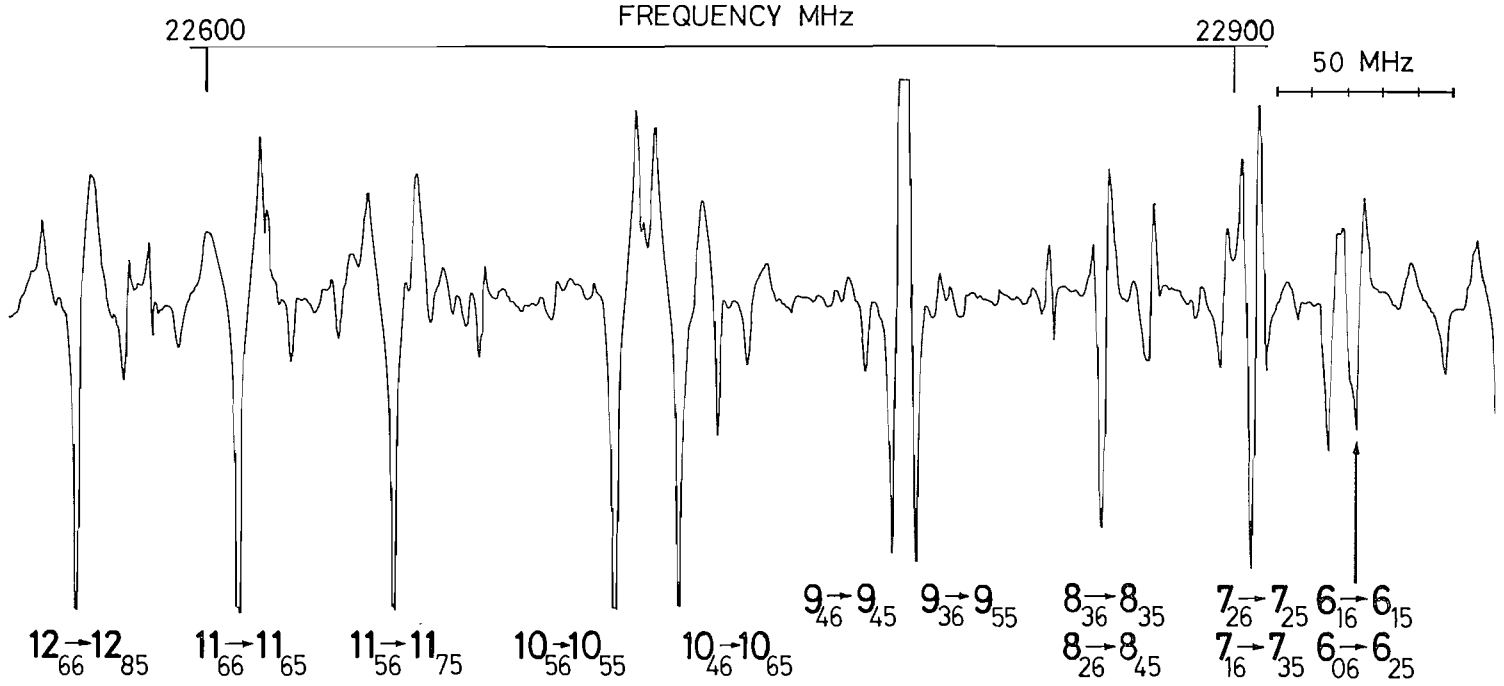

FIG. 1. Recorder trace of the Q-branch doublet series $K_{+1} = 6 \rightarrow 5$ for the ground vibrational state of undeuterated morpholine. For conformers **2** and **4** such a series would not be sufficiently intense to be detectable. For conformer **3** the first 20 lines of the series are predicted to fall within 30 MHz of the $J = 6 \rightarrow 6$ branch head.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

morpholine. Such Q-branch series heads are observed to occur at intervals of slightly more than 4000 MHz for both of the isotopic forms studied. A number of weaker low J a-type R-branch lines were also observed and identified by means of their characteristic Stark patterns. The assignable lines of both isotopic forms in the region studied are therefore to be attributed to the chair equatorial form, conformer **1**. No c-type transitions could be found. This was expected because of the low μ_c estimated for conformer **1**.

None of the lines in any observed region could be positively assigned to the chair axial form. This does not necessarily show that this form is absent, however. As may be seen from the μ_a and μ_c components of conformer **2** in Table I, this form of the molecule is predicted to give rise to a strong c-type spectrum but only a very weak a-type spectrum. A c-type spectrum prediction for J values between 1 and 12 using the computed rotational constants of conformer **2** shows that only 8 R-branch and 5 weak Q-branch lines are expected within the entire attainable frequency range. Because of the extremely rich character of the observed chair equatorial spectrum, it is likely that the 13 lines of the chair axial spectrum are present but cannot be picked out from amongst the many hundreds of strong a-type lines of the chair equatorial form. As indicated above, no spectra due to the much more symmetric boat forms were found.

The observed spectra have many features in common with the spectrum of tetrahydropyran which facilitated the assignment and analysis. An important extra effect in the morpholine spectrum is the hyperfine structure arising from quadrupole coupling of the ^{14}N nucleus. Almost all the assigned lines appear as doublets under high resolution with measurable hyperfine splittings in the range 0.500 to 2.000 MHz. Before precise values of the rotational constants could be evaluated, it was therefore necessary to analyze the small quadrupole splittings and hence calculate the unperturbed line frequencies.

Analysis of ^{14}N Quadrupole Hyperfine Interaction

The effect of quadrupole splitting due to the ^{14}N nucleus was more noticeable for Q-branch than R-branch lines. All Q-branch lines with J less than 8 had measurable splittings, whereas splittings were resolvable only for the $J = 1$–2 and some of the $J = 2$–3 R-branch transitions.

Because of the small values of the ^{14}N quadrupole coupling constants, in no case could more than 2 hyperfine peaks be resolved even though 3 strong hyperfine lines with $\Delta F = \Delta J$ are predicted for a nucleus with spin quantum

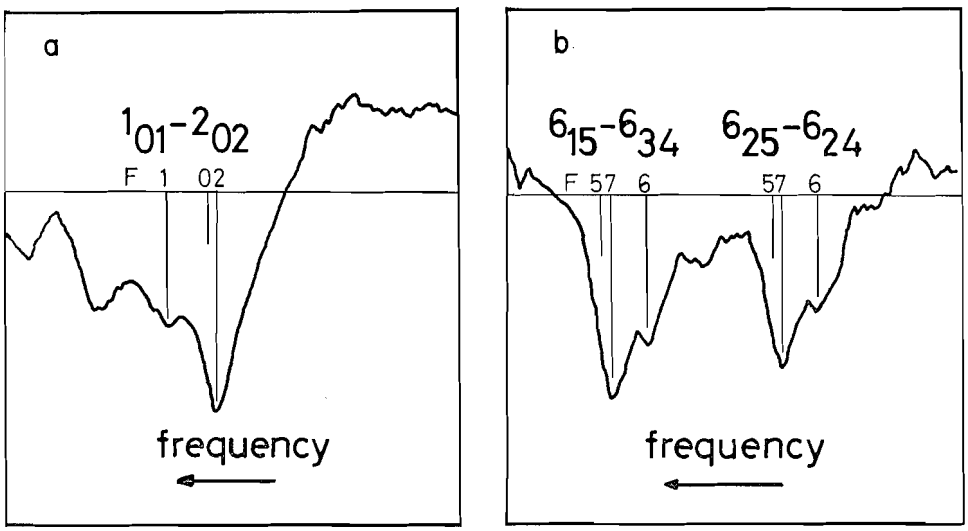

FIG. 2. Oscilloscope photographs showing typical quadrupole hyperfine patterns for a-type R and Q branch transitions. (a) The R-branch transition $1_{01} — 2_{02}$, observed splitting 0.767 MHz. (b) The Q-branch transitions $6_{15} — 6_{34}$ and $6_{25} — 6_{24}$, observed splittings 1.043 and 1.127 MHz, respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

number $I = 1$. For a Q-branch line the component for which $F = J \rightarrow J$ appears as a separately observable peak, whereas the components with $F = J - 1 \rightarrow J - 1$ and $F = J + 1 \rightarrow J + 1$ are contained in the second peak. In such a case the top of the larger resolved peak is taken to correspond to the frequency of the more intense $F = J + 1 \rightarrow J + 1$ hyperfine component. Similarly for a low J R-branch transition the $F = J \rightarrow J + 1$ component is usually separately resolved but the components with $F = J - 1 \rightarrow J$ and $F = J + 1 \rightarrow J + 2$ are coalesced. This is illustrated in Fig. 2.

The elements χ_{aa}, χ_{bb}, and χ_{cc} of the ^{14}N quadrupole tensor, referred to the principal rotation axes of the molecule, were calculated for each of the normal and N-deutero species by the following procedure. The quadrupole energy E_Q may be written as a function of the asymmetry parameter κ and the quantum numbers F and J as

$$[1] \quad E_Q(\kappa, F, J) = \{(\chi_{aa} + \chi_{cc})f_1(\kappa, J) + (\chi_{aa} - \chi_{cc})f_2(\kappa)\} \frac{Y(F)}{J(J+1)}$$

where $Y(F)$ is Casimir's function and

$$f_1(\kappa, J) = J(J+1) - 3\frac{\partial}{\partial \kappa} E(\kappa)$$

$$f_2(\kappa) = E(\kappa) - \kappa \frac{\partial}{\partial \kappa} E(\kappa)$$

The splitting $\Delta\nu$ on a transition between two quadrupole components for which $F_1 \rightarrow F_1'$ and $F_2 \rightarrow F_2'$ can be expressed as a linear equation of the form

$$[2] \quad \Delta\nu = (\chi_{aa} + \chi_{cc})g_1 + (\chi_{aa} - \chi_{cc})g_2$$

where g_1 and g_2 are functions of J, κ, F_1, F_1', F_2, and F_2', which can be evaluated if the asymmetry and the appropriate quantum numbers are known.

The splittings between observed components for 19 transitions in the spectrum of normal morpholine and for 20 transitions in the spectrum of N-deuteromorpholine were measured. The corresponding functions g_1 and g_2 were evaluated for each $\Delta\nu$ and the data were subjected to least squares type fits to obtain $(\chi_{aa} + \chi_{cc})$ and $(\chi_{aa} - \chi_{cc})$ for each species. The calculated and observed splittings are shown in Tables II and III. The variance of least squares residuals was 0.003 MHz in each case.

The values of χ_{bb} were found from the Laplace relation $\Sigma\chi_{mm} = 0$, $m = a, b, c$. The values of χ_{bb} for both isotopic forms of the molecule should be equal on account of the molecular symmetry. From Table IV this may be seen to be the case within experimental error. It would

TABLE IV

Diagonal elements of the ^{14}N quadrupole coupling tensor in the principal molecular axis system

Element	Value	
	Normal morpholine	N-deuteromorpholine
χ_{aa} (MHz)	2.22±0.02	1.92±0.02
χ_{bb} (MHz)	2.51±0.05	2.59±0.05
χ_{cc} (MHz)	−4.73±0.02	−4.51±0.02

be desirable to obtain also the values of χ_{xx}, χ_{yy}, χ_{zz}, the elements of the ^{14}N quadrupole tensor in the quadrupole axis system. However, this requires a precise knowledge of the angle of principal axes rotation on H → D substitution which is not available in the present case because of the very small c coordinate of the imino hydrogen and the very small value of the angle.

The value of χ_{bb}, however, remains unchanged during the transformation of axes becoming equal to χ_{yy}, where y is perpendicular to the single molecular symmetry plane. The average value of 2.55 ± 0.05 MHz observed for the constant is comparable to the value of the coupling constant for the corresponding direction for each of the related molecules: trimethylamine, 2.74 MHz (5); dimethylamine, 3.04 MHz (6); methylamine, 2.12 MHz (7); and ammonia, 2.04 MHz (8).

Rotational Constants and Imino Hydrogen Coordinates

Using the determined values of χ_{aa} and χ_{cc} the unperturbed line frequencies were calculated using eq. [1]. Because only the a-type spectrum was observed, and because the derived value of the rotational constant A is relatively insensitive to small changes in the frequencies of the a-type lines, the following method was adopted for the determination of A, B, and C. For each isotopic species the unperturbed frequencies of 12 a-type R-branch lines were calculated from the observed frequencies of Tables VI and VII. The resulting frequencies were then subjected to least squares fitting to give the final values of B and C. For these calculations the resulting variances were 0.044 MHz for normal morpholine and 0.024 MHz for N-deuteromorpholine. The exact value of A for each species was then obtained by the well known graphical method in which $\frac{1}{2}(A - C)$ is plotted against the asymmetry parameter κ for a series of Q-branch lines. The resulting rotational constants are given in Table V and the calculated and observed frequencies in Tables VI and VII.

TABLE V

Rotational constants (MHz) and principal moments of inertia* (u Å²) of morpholine, ground vibrational state, chair equatorial conformer

Parameters	Value	
	Normal morpholine	N-deuteromorpholine
A ±0.05	4924.88	4925.39
B ±0.05	4625.15	4399.67
C ±0.05	2684.25	2607.09
κ ±0.00011	0.73246	0.54646

The effects of centrifugal distortion were neglected throughout this treatment. The values of $\nu_{obs} - \nu_{calcd}$ for some of the Q-branch transitions indicate, however, that centrifugal stretching becomes noticeable for $J > 8$.

The r_s coordinates of the imino hydrogen were calculated from the observed moments of inertia of Table V using Kraitchman's equations for an asymmetric rotor (9). Because of the symmetry of morpholine the b coordinate is set at zero, the imino group lying in the ac plane. The magnitudes of the a and c coordinates, see Table VIII, confirm that the spectrum is that of the chair equatorial conformer. The large error in the c coordinate is to be expected since the substituted atom lies very close to the c axis of normal morpholine. The angle through which the principal a and c axes rotate on H → D substitution is very small, being estimated at 0.2°.

Dipole Moment

The Stark effect was studied for 3 a-type R-branch transitions in the normal morpholine spectrum. At field strengths above 25 V cm^{-1} some non-quadratic Stark effects were noticed for the $M = 1$ component of the $1_{11} - 2_{12}$ transition. This effect is expected for a near oblate rotor with appreciable a component of the dipole moment and has also been observed in the spectrum of the molecule CH_3CHF_2 (10). This non-quadratic behavior is caused by perturbations between the energy levels 2_{02} and 2_{12}, which are nearly degenerate with a separation of 32 MHz. The $1_{10} - 2_{11}$ transition has a normal Stark behavior. The quadratic behavior at low field strengths was employed in the dipole moment determination. The dipole moment components μ_a and μ_c were obtained by least squares fitting to the observed coefficients $\Delta\nu/E^2$, see Table IX. The value of $\mu_{ocs} = 0.7124 \pm 0.0002$ D (11) was used in calibrating the Stark cell.

An interesting comparison can be made among the dipole moments of tetrahydropyran and the equatorial forms of piperidine and morpholine, see Table X. It may be seen that the a components of the CNC moment and the NH bond moment largely cancel in piperidine to give a small μ_a, so that the larger μ_a in morpholine can be attributed to the COC moment, which is also responsible for the large μ_a of tetrahydropyran. The μ_a values also indicate that in morpholine the NH bond moment is more than the CNC moment. The very small observed value of μ_c for morpholine, which was also predicted for conformer **1**, see Table I, confirms the expectation that the c-type spectrum would most likely be unobservable. The observed angle between the total dipole vector and the principal a axis of normal morpholine is 10°, as shown in Fig. 3, which agrees very closely with that calculated as 10.5° from the estimated dipole moment components of Table I.

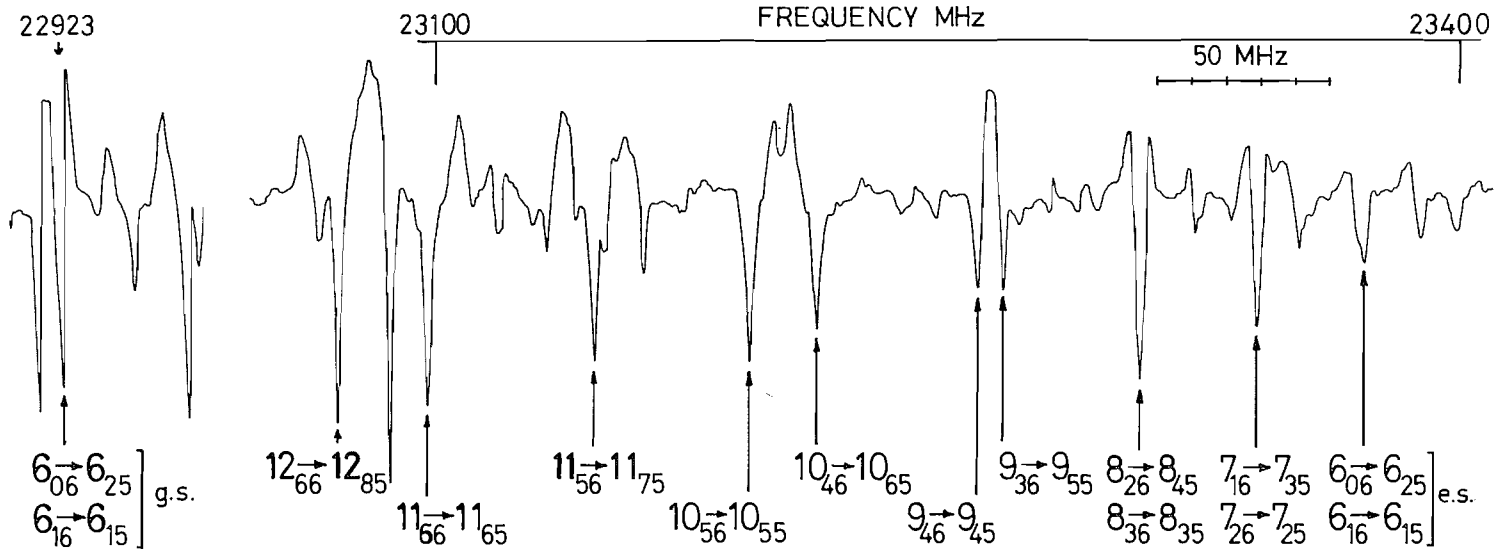

FIG. 4. Recorder trace of the Q-branch doublet series $K_{+1} = 6 \rightarrow 5$ for an excited state (e.s.) of chair equatorial morpholine. The first peak of the corresponding series for the ground state (g.s.) is shown for comparison on the left side of the figure. Because of the relative intensities the vibration is considered to be the lowest energy ring deformation mode.

TABLE IX

Stark effect coefficients and dipole moment components of normal morpholine, chair equatorial conformer

Transition	M	$10^3 \times \Delta\nu/E^2$ (MHz cm^2 V^{-2}) Observed	Calculated
$1_{11} - 2_{12}$	1	0.6277	0.6244
$1_{11} - 2_{12}$	0	0.0519	0.0550
$1_{10} - 2_{11}$	1	−0.3483	−0.3251
$2_{12} - 3_{22}$	2	0.5805	0.5952
$2_{12} - 3_{22}$	1	0.1582	0.1622
$2_{12} - 3_{22}$	0	0.0174	0.0178

Dipole moment	Value (D)
μ_a	1.68 ± 0.01
μ_c	0.30 ± 0.01
μ	1.71 ± 0.02

TABLE X

Dipole moments of tetrahydropyran, piperidine, and morpholine

Dipole moment (D)	Value Piperidine (ref. 2)	Tetrahydropyran (ref. 3)	Morpholine
μ_a	0.195	1.53	1.68
μ_c	0.781	0.82	0.30
μ	0.80	1.74	1.71

Excited Vibrational States

In addition to the ground state spectrum discussed above, a spectrum from a vibrationally excited form of normal morpholine was observed. Satellites of the two Q-branches having $K_{+1} = 6 \rightarrow 5$ were observed with a branch head $6_{06} - 6_{25}$ and $6_{16} - 6_{15}$ 450 MHz above the corresponding ground state lines, see Fig. 4. From the intensity ratios of the excited state to ground state lines the vibrational state was estimated to lie 200 ± 50 cm^{-1} above the ground state. The infrared and Raman spectra of morpholine have not yet been investigated in this region. However, the energy difference is similar to those for the lowest excited states of piperidine, 246 cm^{-1} (12), and tetrahydropyran, 256 cm^{-1} (13); this vibration is therefore most likely the lowest frequency ring deformation mode of morpholine.

Conclusion

The observed rotational spectra are due to the chair equatorial conformers of morpholine and N-deuteromorpholine. The lack of a *c*-type spectrum for either isotopic form can be ascribed to the small value of μ_c. Although the spectrum of the chair–axial conformer has been observed for the similar molecule piperidine, with this conformer being in about 40% abundance, no analogous spectrum was found for morpholine. This is because of the small number of widely distributed *c*-type lines in the expected spectrum of chair–axial morpholine and because of the extreme difficulty of separating these lines from those in the dense spectrum of the chair equatorial form. No spectra due to boat forms were found, which is not unexpected as the boat conformer for molecules of this type lies typically 7 kcal per mole above the chair form in energy.

Acknowledgments

The authors should like to express their gratitude to Dr. R. F. Curl for his assistance in computing the dipole moment of morpholine and to Dr. D. B. McLay for helpful advice and discussions. They would also like to acknowledge the support of the work by the National Research Council of Canada through operating grants and the award of a Studentship.

An infrared transmission cell for ultra-thin liquid films[1]

R. P. YOUNG[2] AND R. N. JONES
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received May 8, 1969

This note describes the design and use of an ultra-thin cell for the quantitative measurement of infrared absorption bands of strongly absorbing liquids or solutions by transmission. From these measurements the optical constants of the absorbing material can be evaluated. The technique is demonstrated by a comparison with the optical constant data reported in the literature for the 1527 cm^{-1} band of hexafluorobenzene as measured by attenuated total reflection.

Canadian Journal of Chemistry, 47, 3463 (1969)

Introduction

The conventional transmission methods of absorption spectrophotometry are unsuitable for strongly absorbing liquids or concentrated solutions because of the low intensity of the transmitted radiation and the lack of adequate means to correct for reflection losses.

The absolute intensity of the band is most meaningfully described in terms of[3] the *absorption coefficient* k, which is defined as the imaginary component of the complex refractive index ($\hat{n} = n - ik$). The relation between k and the more commonly employed decadic absorbance A is given by

$$[1] \qquad k = \frac{2.30258}{4\pi\nu l} \cdot \log (I_0/I)$$

where ν is the wavenumber, l is the path length (cm), and $\log (I_0/I)$ is the decadic absorbance.

Where k_{max} exceeds 0.1 the film thickness must be reduced to below 10 μ to obtain sufficient transmission for efficient measurement, and the absorption spectrum is then superimposed on an underlying fringe pattern. Within the region of absorption the fringes perturb the true band contour. Beyond the wings of the band the fringe pattern can be used to determine the cell thickness, although this is more usually obtained from the fringe pattern generated by the empty cell (1). If k_{max} exceeds 1.0 a film thickness of 1 μ or less is required to allow the transmission of sufficient radiant energy for accurate measurement. Serious problems are then encountered in constructing cells of conventional design, in measuring the thickness of the film, and in controlling its dimensional uniformity. In recent studies of the absolute absorption intensities of strongly absorbing materials these difficulties have been circumvented by the use of techniques based on dispersion (2, 3), reflection (4, 5), or attenuated total reflection (a.t.r.) measurements (6, 7). These methods give an absorption curve only indirectly after considerable computation and, in the case of the reflection and a.t.r. measurements, extensive modification must be made to the spectrophotometer. It is therefore of interest to develop a technique that will permit the absorption coefficient to be obtained directly from transmission measurements through thin films.

These considerations motivated the design of the ultra-thin liquid film cell described here and also the development of a computational technique to correct the observed absorption spectrum for reflection losses, which will be discussed in a later publication. This cell has been used to produce films of accurately controlled thickness of the order of 1 μ. Since the spacing

[3]In the "Manual of symbols and terminology for physicochemical quantities and units" approved by I.U.P.A.C. at the XXVth Conference (Cortina d'Ampezzo, June 30 – July 8, 1969), the expression "absorption coefficient" is used to designate the quantity $\log_{10}(I_0/I)$. This will necessitate a new name for k. Temporarily we shall continue to use the older nomenclature pending the clarification of anomalies of this kind. A joint committee of I.U.P.A.C. Commissions I.1 (Physicochemical Symbols, Terminology, and Units) and Commission I.5 (Molecular structure and spectroscopy) has been established to recommend uniform practice in those areas of symbolism and nomenclature not covered by the Manual. The recommendations of this committee will be published as appendices to the Manual.

of the interference fringe pattern for a cell having an air gap of 1 μ is about 5000 cm^{-1}, the fringes are so extended that no significant fluctuation is induced in the baseline intensity of all but the broadest absorption bands. The elimination of the interference effect in this manner necessitates the use of a different method of measuring the film thickness.

Experimental

The structural details of the cell are shown in Fig. 1. Two potassium bromide plates (40 × 40 mm) are each machined to a uniform thickness of 6 mm ± 20 μ, drilled as shown in (*a*) and (*b*), and polished to an optical flatness of about half a fringe per cm for visible light. A uniform film of aluminum is deposited to the required thickness by evaporation on the inner face of plate (*a*) leaving a rectangular space which is to form the cavity for the liquid. The two plates are mounted together, as shown in (*c*), in a holder designed for use with a Perkin–Elmer Model 521 spectrophotometer.

Before assembly, the thickness of the deposited film is determined interferometrically with an estimated accuracy of ±2% in the range 0.1–5.0 μ. On the basis of the optical flatness of the plates and the evenness of the controlled deposition of the evaporated metal film, it is assumed that the gap thickness of the assembled cell will be the same as the measured thickness of the deposited film. Experimental evidence to support this is given below.

The liquid is introduced into the reservoir cavity R by means of a syringe, with the tube T open. After several minutes the sample space will become filled by capillary action and Teflon stoppers are then inserted at R and T. After the measurements have been made, the liquid is withdrawn from the reservoir and the film space emptied in 10 to 15 min by placing the cell in a vacuum desiccator attached to a rotary oil pump. Cells of this type are unsuited for use with solutions of non-volatile solutes that could deposit the solute in the cell cavity; however, no difficulties have been encountered in maintaining the cells in a clean condition when they are used with volatile solutes, solvents, and pure liquids. The rubber gasket (Fig. 1(*c*)) does not come in contact with the sample liquid and can cause no contamination of the inner cell surfaces. If regular dismantling of the cell is contemplated the surface of the metal film can be protected by an

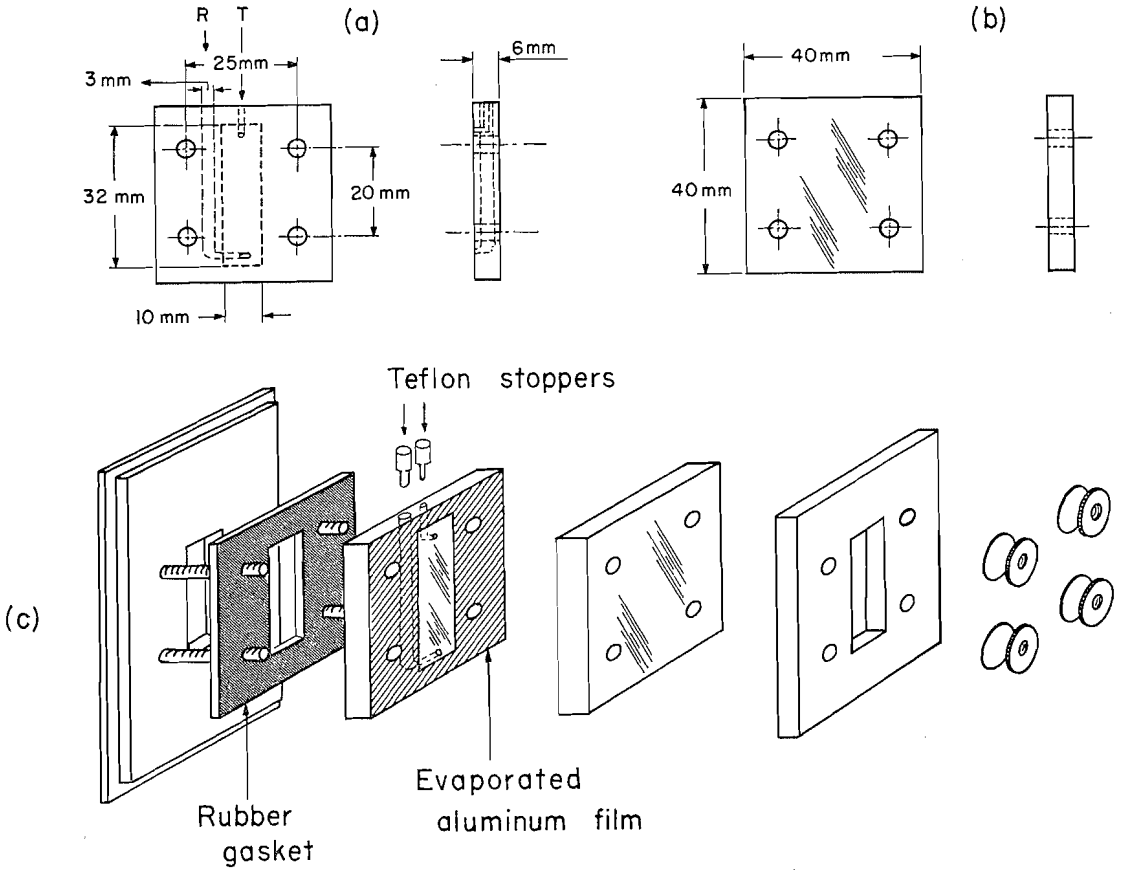

FIG. 1. The two KBr plates (*a*) and (*b*) were drilled as shown before evaporation of the aluminum film on to the inner surface of (*a*). The final assembly is shown in (*c*).

overlay of silica about 0.1 μ thick. In such cases the thickness of the combined metal–silica film would be measured.

The spectra have been recorded on a Perkin–Elmer Model 521 spectrophotometer with digital encoding at 1.0 cm^{-1} intervals on punched paper tape; in regions of atmospheric absorption the instrument is flushed with dry nitrogen. The wavenumber scale is calibrated after each set of measurements against accepted standards; liquid indene, or NH_3, H_2O, or HCN vapor have been used for this purpose (8). High speed rotating sector photometers are used to calibrate the transmission scale of the recording system (9, 10). Computation is performed by an IBM 360(50) computer.

Results

It is well known that the transmission spectra of strongly absorbing materials are distorted by reflection loss effects in regions where the refractive index changes rapidly and it is necessary to correct the observed "apparent" absorption curve for this effect (11, 12). A theoretical analysis of these effects has been made and we have developed a corrective procedure. These corrections have been applied to a number of representative absorption bands and details of the method of computation will be discussed in a separate publication. The practicality of the cell is illustrated by measurements on the band at 1527 cm^{-1} in the spectrum of hexafluorobenzene shown in Figs. 2 and 3. The transmission of an empty cell with a gap thickness of 0.62 μ is shown in Fig. 2(*a*). This curve was obtained without any compensation in the control beam of the spectrophotometer and shows the total radiation loss caused by reflection at the front window surface together with the multiple internal reflections within the two windows as modulated by the interference effects of the air gap, i.e. the cell is functioning as a Fabry–Perot etalon. The absolute transmission in the 1600–1450 cm^{-1} region of the same cell when filled with liquid hexafluorobenzene is shown in Fig. 2(*b*). The dotted curve is the directly measured spectrum

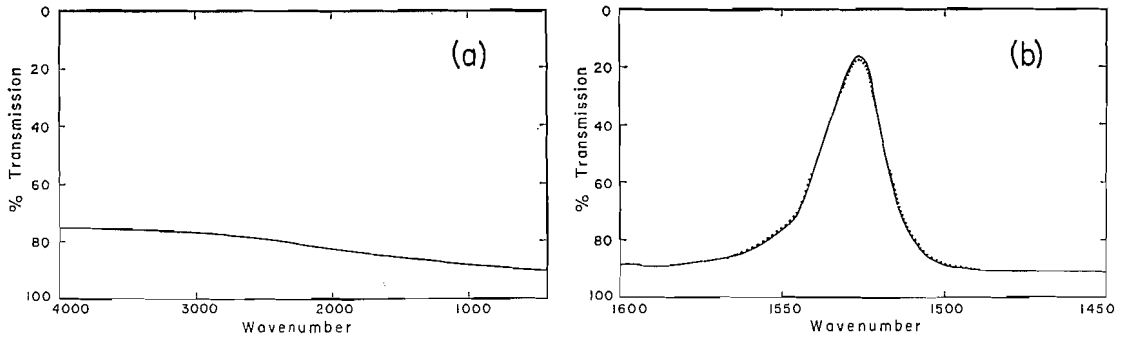

FIG. 2. Absolute transmission spectra after wavenumber and intensity calibration. (*a*) Transmission of the empty cell (0.62 μ air gap between KBr plates). (*b*) Transmission of the cell filled with liquid hexafluorobenzene: ·····, as recorded; and ———, after correction for slit distortion by pseudo-deconvolution.

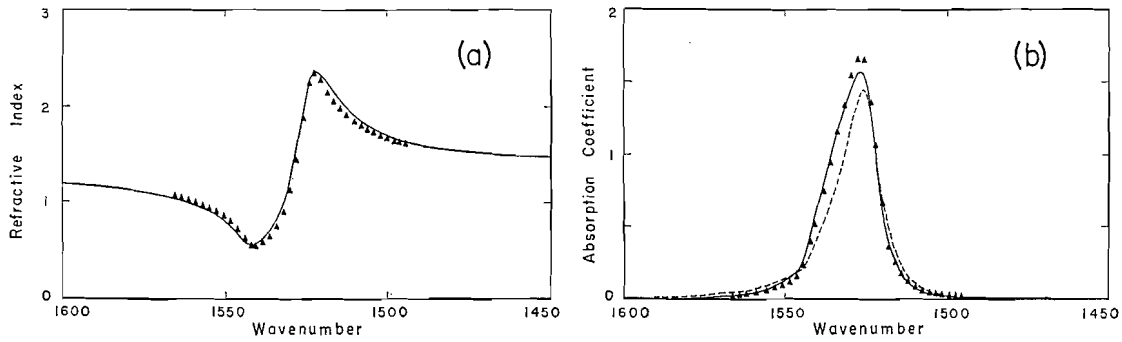

FIG. 3. (*a*) Refractive index curves: ———, calculated from the transmission data after reflection loss correction of the pseudo-deconvoluted spectrum; and ▲, values obtained by the a.t.r. method. (*b*) Absorption coefficient curves; ———, calculated from the transmission data after reflection loss correction of the pseudo-deconvoluted spectrum: ---, experimentally observed pseudo-deconvoluted transmission spectrum without correction for reflection losses; and ▲, values obtained by the a.t.r. method.

and the solid line illustrates the small but significant difference which results from correction for slit distortion by pseudo-deconvolution with a triangular slit function of 3.0 cm^{-1} half width (13). The "apparent" absorption coefficients (k_a) calculated by eq. [1] from the pseudo-deconvoluted spectrum are shown by the dashed line in Fig. 3(*b*). The optical constants (*n* and *k*), obtained from this curve after correcting for the effects of reflection losses, are shown as the solid lines in Fig. 3, together with the values computed from the a.t.r. data by Fujiyama and Crawford (14).

TABLE I

Intensity of the 1525 cm^{-1} band of liquid hexafluorobenzene

	Integrated intensity	
Absorption coefficient	$cm^{-1}\ s^{-1}$ molecule $^{-1}$	$cm^2\ mole^{-1}$
k_a (as measured)	31.58×10^{-4}	41 440
k_a (pseudo-deconvoluted)	31.18×10^{-4}	40 910
k (transmission)	34.08×10^{-4}	44 730
k (a.t.r.)*	34.51×10^{-4}	45 290

*From ref. 14.

In Table I are listed the integrated intensity values calculated both in IUPAC Absolute Units ($cm^{-1}\ s^{-1}$ molecule^{-1}) and in the "absorption cross-section" units (cm^2 mole^{-1}) used by Fujiyama and Crawford. The agreement between the intensity values derived from a.t.r. and transmission data for the absorption coefficient curve (k) is within 2%. The discrepancy of nearly 10% in the "apparent" absorption curve (k_a) results from the reflection distortion losses; it will normally be lower for bands that are less intense. For a series of bands of progressively lower intensity the magnitude of the reflection distortion steadily diminishes so that when k_{max} is less than about 0.1 the discrepancy between the integrated areas of the apparent and reflection-corrected absorption curves is usually between 2 and 5%. However, for very weak bands, where such differences become almost negligible, the film thickness must be increased to obtain accurate transmission data, and care must then be taken to eliminate the interference fringe effects that increasingly perturb the baseline.

Conclusion

The good agreement with the a.t.r. results shown here is well substantiated by measurements on other bands and indicates that the liquid film thickness values derived from the measured thickness of the metal deposit are acceptable. The gap thickness has remained unchanged over many weeks during which the cells have been used extensively, but not dismantled and reassembled. Should frequent dismantling cause the thickness to change, a new value could be readily obtained once some standard bands of known intensity have been established for calibration purposes. The maintenance of the optical flatness of the inner surface of the cavity is readily checked by visual inspection of the empty cell for which the fringe pattern is clearly seen in the natural reflected light of the laboratory.

Acknowledgments

We wish to thank Mr. J. N. Cairns for his invaluable advice and assistance in the construction of these cells in the Optical Shop of the Applied Physics Division of the National Research Council of Canada. We are also grateful to Dr. K. H. Hart of the Optical Physics Section of the same Division for making the interferometric film thickness measurements for us. Finally, we would like to thank Professor B. L. Crawford and Dr. T. Fujiyama of the University of Minnesota, Minneapolis for stimulating discussions on the problem of distortion in infrared transmission spectra.

Received April 9, 1969

The existence of equisorptic solution compositions in reverse osmosis systems is illustrated.

Canadian Journal of Chemistry, 47, 3467 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

The reverse osmosis membrane separation process is a general and widely applicable technique for the separation, concentration, or fractionation of substances in fluid solutions. The technique consists of letting the fluid mixture flow, under pressure, through an appropriate porous membrane, and withdrawing the membrane permeated product generally at atmospheric pressure and surrounding temperature. The product is enriched in one or more constituents of the mixture, leaving a concentrated solution on the upstream side of the membrane. No heating of the membrane and no phase change in product recovery are involved in this separation process.

On the basis of the preferential sorption–capillary flow mechanism an appropriate chemical nature of the film surface in contact with the solution, together with the existence of pores of appropriate size on the area of the porous film at the interface, is an indispensable twin requirement for the success of this separation technique (1). Following this approach, the applicability of the reverse osmosis technique for the separation of a number of organic binary liquid mixtures, including azeotropic and isomeric mixtures, has been illustrated (2, 3).

There are two circumstances under which little or no separation will be obtained in the reverse osmosis process, even when the chemical nature of the membrane surface is such that it has some degree of sorption for each of the components of a binary mixture. When the size of the pores on the membrane surface is too big compared to the thickness of the preferentially sorbed layer, separation will obviously be negligible under the reverse osmosis conditions. Further, preferential sorption is a function of the composition of the solution for any given membrane material. If, at a particular composition of the solution, the membrane material has equal sorption for either component in a binary mixture, then under that condition, preferential sorption is zero, and consequently there can be no separation in reverse osmosis whatever the porous structure of the membrane surface. This note illustrates that such equisorptic compositions exist for membrane material – solution systems in reverse osmosis.

Asymmetric porous cellulose acetate membranes (designated here as CA-NRC-18 type films) made in the laboratory by the method of Sourirajan and Govindan (4) were used in this work with isopropyl alcohol – benzene, and isobutyl alcohol – toluene mixtures as the feed solutions. The reverse osmosis experiments were carried out in a stainless steel static cell as described earlier (2, 3). The separation and membrane permeated product rate data reported below represent steady state values for the particular membrane–solution system under study at the laboratory temperature. Figures 1–3 give the experimental separation and product rate data obtained with membranes of different porosities using different compositions of feed solution. The numbers by the side of the product rate data refer to the order in which the experiments were carried out.

The separation data for both the feed solution systems illustrate the existence of equisorptic compositions in reverse osmosis. On one side of the equisorptic composition, the membrane material has a preferential sorption for the alcohol, and on the other side, it has a preferential sorption for the hydrocarbon. With respect to the particular cellulose acetate membrane material and feed solutions studied, the equisorptic compositions (mole ratios) are 26/74 for

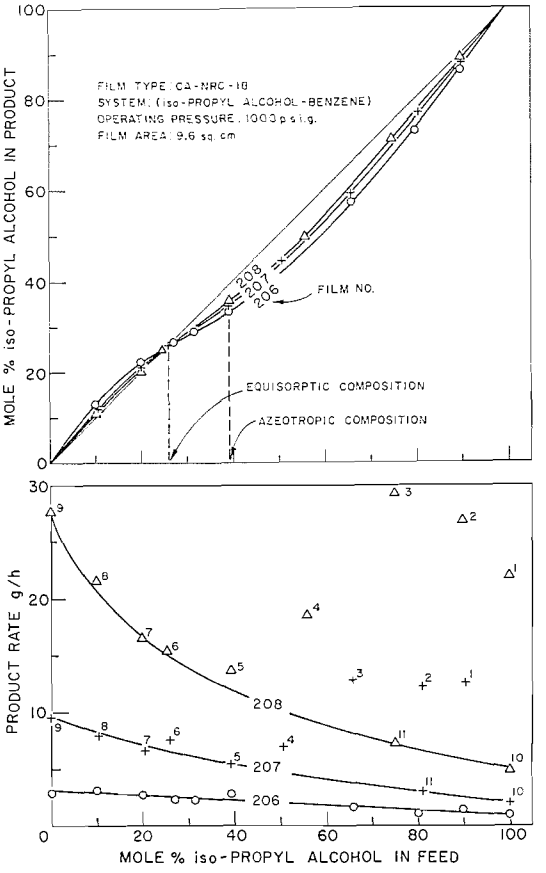

FIG. 1. Separation and product rate data for the system isopropyl alcohol – benzene using porous cellulose acetate membranes.

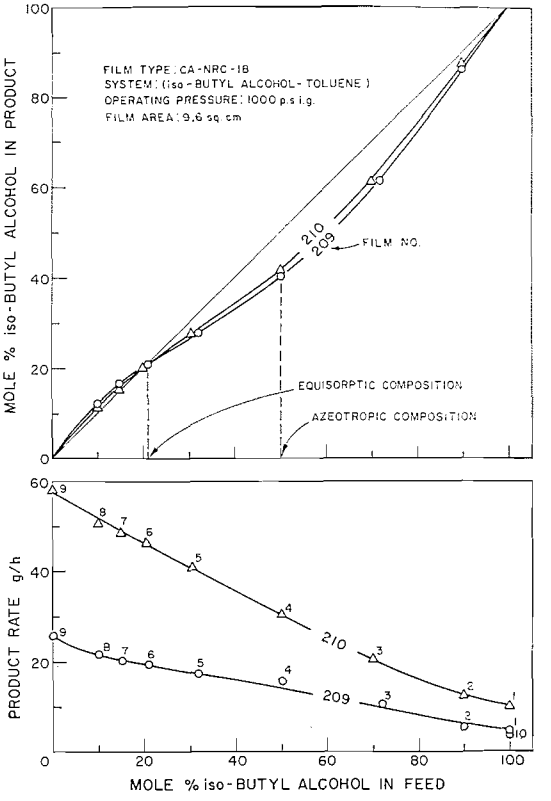

FIG. 2. Separation and product rate data for the system isobutyl alcohol – toluene using porous cellulose acetate membranes.

isopropyl alcohol/benzene, and 21/79 for isobutyl alcohol/toluene systems; for comparison, the azeotropic compositions of the mixtures are 39.3/60.7 and 50/50, respectively. The experimental separation data obtained with different films (Figs. 1 and 2) further show that the equisorptic composition is the same whatever the porous structure of the membrane surface, and, at least for the system isobutyl alcohol – toluene, it is also independent of the operating pressure up to 1000 p.s.i.g. (Fig. 3).

The product rate data for the system isopropyl alcohol – benzene (Fig. 1) illustrate the partial and irreversible collapse of the porous structure of the membrane by feed solutions containing more than about 25 mole % benzene. Such collapse of porous structure did not affect separation data significantly, indicating thereby

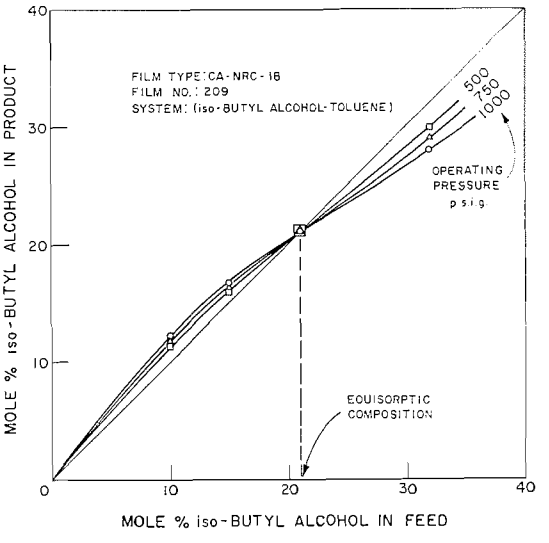

FIG. 3. Effect of operating pressure on equisorptic composition for the system isobutyl alcohol – toluene.

that the porous structure of the dense surface layer of the membrane remained essentially unaffected during the process. The product rate data for the system isobutyl alcohol – toluene (Fig. 2) do not show any indication of irreversible changes in the porous structure of the membrane as a result of changes in the composition of the feed solution. In any case, it is evident that the changes in the porous structure of the membrane brought about by changes in the composition of the feed, do not affect the equisorptic compositions.

At a given operating pressure and temperature, the equisorptic compositions are obviously functions of the chemical nature of the membrane material and that of the feed solution. They are hence significant physical constants in reverse osmosis, analogous to azeotropic compositions in distillation. Their existence adds a new factor in the science and engineering of reverse osmosis.

Thermodynamic properties of ruthenate and molybdate ions

Loren G. Hepler
Department of Chemistry, University of Lethbridge, Lethbridge, Alberta

Received April 3, 1969

Thermodynamic data that have been obtained subsequent to compilations by the U.S. National Bureau of Standards and Latimer now permit calculation of ΔG_f^0, ΔH_f^0, and $\bar{S}_2^0$ values for RuO_4^{2-} (aq) and MoO_4^{2-} (aq). Use of these quantities is illustrated by calculation of thermodynamic properties of Ag_2MoO_4 (c).

Canadian Journal of Chemistry, 47, 3469 (1969)

Data that are now available permit new calculations of the entropy of ruthenate ion and both entropy and free energy of molybdate ion. Both ion entropies are of interest in connection with estimation of entropies of other MO_4^{2-} (aq) ions, and the ΔG_f^0 of molybdate permits direct calculation of some other free energies.

Recent calorimetric measurements by Mercer and Farrar (1) have led them to report $\Delta H_f^0 = -109.4$ kcal/mole for RuO_4^{2-} (aq). Earlier equilibrium investigations (2) have led to $\Delta G_f^0 = -72$ kcal/mole for this ion. These two values now lead to the desired $\bar{S}_2^0 = 11 \pm 3$ cal deg^{-1} mole^{-1} for RuO_4^{2-} (aq).

Calorimetric measurements by Graham and Hepler (3) led to $\Delta H_f^0 = -238.2$ kcal/mole for MoO_4^{2-} (aq). Other calorimetric measurements by Barany (4) led to $\Delta H_f^0 = -369.5$ kcal/mole for $CaMoO_4$ (c) that had been heated at 480–690 °C for 21 days. Earlier calorimetric determination (5) of the heat of precipitation of $CaMoO_4$ (not in a well defined crystalline state) led to $\Delta H_f^0 = -367.3$ kcal/mole. Since the ΔH_f^0 for calcium molybdate in a well defined stable crystalline state is expected to be more exothermic than for the precipitated material, the ΔH_f^0 from Barany (4) is adopted and combined with the third law $S_{298}^0 = 29.3$ cal deg^{-1} mole^{-1} value from Weller and King (6) to obtain $\Delta G_f^0 = -344.0$ kcal/mole for $CaMoO_4$ (c).

The solubility of calcium molybdate (3) led to $K_{sp} = 1 \times 10^{-8}$ and thence to $\Delta G^0 = 10.9$ kcal/mole for solution of $CaMoO_4$ (c). Further combination of this ΔG^0 with the ΔG_f^0 of $CaMoO_4$ (c) given above and the ΔG_f^0 of Ca^{2+} (aq) from Latimer (7) gives us $\Delta G_f^0 = -200.9$ kcal/mole for MoO_4^{2-} (aq). The ΔH_f^0 and ΔG_f^0 values

Thermodynamic properties of ruthenate and molybdate ions

Loren G. Hepler
Department of Chemistry, University of Lethbridge, Lethbridge, Alberta

Received April 3, 1969

Thermodynamic data that have been obtained subsequent to compilations by the U.S. National Bureau of Standards and Latimer now permit calculation of ΔG_f^0, ΔH_f^0, and $\bar{S}_2^0$ values for RuO_4^{2-} (aq) and MoO_4^{2-} (aq). Use of these quantities is illustrated by calculation of thermodynamic properties of Ag_2MoO_4 (c).

Canadian Journal of Chemistry, 47, 3469 (1969)

Data that are now available permit new calculations of the entropy of ruthenate ion and both entropy and free energy of molybdate ion. Both ion entropies are of interest in connection with estimation of entropies of other MO_4^{2-} (aq) ions, and the ΔG_f^0 of molybdate permits direct calculation of some other free energies.

Recent calorimetric measurements by Mercer and Farrar (1) have led them to report $\Delta H_f^0 = -109.4$ kcal/mole for RuO_4^{2-} (aq). Earlier equilibrium investigations (2) have led to $\Delta G_f^0 = -72$ kcal/mole for this ion. These two values now lead to the desired $\bar{S}_2^0 = 11 \pm 3$ cal deg^{-1} mole^{-1} for RuO_4^{2-} (aq).

Calorimetric measurements by Graham and Hepler (3) led to $\Delta H_f^0 = -238.2$ kcal/mole for MoO_4^{2-} (aq). Other calorimetric measurements by Barany (4) led to $\Delta H_f^0 = -369.5$ kcal/mole for $CaMoO_4$ (c) that had been heated at 480–690 °C for 21 days. Earlier calorimetric determination (5) of the heat of precipitation of $CaMoO_4$ (not in a well defined crystalline state) led to $\Delta H_f^0 = -367.3$ kcal/mole. Since the ΔH_f^0 for calcium molybdate in a well defined stable crystalline state is expected to be more exothermic than for the precipitated material, the ΔH_f^0 from Barany (4) is adopted and combined with the third law $S_{298}^0 = 29.3$ cal deg^{-1} mole^{-1} value from Weller and King (6) to obtain $\Delta G_f^0 = -344.0$ kcal/mole for $CaMoO_4$ (c).

The solubility of calcium molybdate (3) led to $K_{sp} = 1 \times 10^{-8}$ and thence to $\Delta G^0 = 10.9$ kcal/mole for solution of $CaMoO_4$ (c). Further combination of this ΔG^0 with the ΔG_f^0 of $CaMoO_4$ (c) given above and the ΔG_f^0 of Ca^{2+} (aq) from Latimer (7) gives us $\Delta G_f^0 = -200.9$ kcal/mole for MoO_4^{2-} (aq). The ΔH_f^0 and ΔG_f^0 values

now lead to $\bar{S}_2^0 = 11 \pm 2$ cal deg^{-1} mole^{-1} for MoO_4^{2-} (aq).

Several earlier thermodynamic calculations for MoO_4^{2-} (aq) and solid molybdates have been based on Latimer's (7) estimated $\bar{S}_2^0 \cong 14$ cal deg^{-1} mole^{-1} rather than experiment-based quantities calculated above.

Combination of the ΔG^0 of solution of Ag_2MoO_4 (c) derived from the solubility product (5) with ΔG_f^0 values for Ag^+ (aq) and MoO_4^{2-} (aq) now leads to $\Delta G_f^0 = -179.5$ kcal/mole for Ag_2MoO_4 (c). Solubility, electrochemical, and calorimetric data gave (5) a "best" $\Delta H_f^0 = -200.4$ kcal/mole for Ag_2MoO_4 (c), which is now used with the ΔG_f^0 above in calculating $S_{298}^0 = 55$ cal deg^{-1} mole^{-1} for Ag_2MoO_4 (c). This value is subject to direct verification by way of heat capacity data and the third law. Similar calculations can be made for other molybdates.

Secondary reactions in the photolysis and pyrolysis of azoethane

O. P. Strausz, R. E. Berkley, and H. E. Gunning
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 19, 1969

A brief study has been made of the secondary reactions occurring in the thermolysis and photolysis of azoethane. In thermolysis the important secondary products found are ethyl 2-butyl diimide and ethanal diethylhydrazone. In photolysis tetraethyl hydrazine has also been detected in substantial yields.

The possible role of secondary reactions in the thermolysis and photolysis of azo compounds is discussed.

Canadian Journal of Chemistry, 47, 3470 (1969)

Azoalkanes are often used as sources of alkyl free radicals for kinetic studies. However, relatively little has been directly observed of their chemistry in photolysis or pyrolysis systems apart from the primary steps. There have been a number of observations which indicate that secondary reactions between azoalkanes and radicals are of potential importance in kinetic systems, and, in a few cases, products from secondary reactions have been tentatively identified (1–5).

We have observed the formation of secondary reaction products in the decomposition of a number of azoalkanes (6). While secondary reactions of the azoalkane molecule are practically negligible at low pressure and room temperature, they become quite important if either the pressure or temperature is increased. Consequently, it is desirable to understand the nature of the more important secondary processes involving azoalkane molecules before they can be used with assurance as sources of alkyl free radicals for radical–molecule reactions. In order to gain an understanding of these processes, we have studied the decomposition of azoethane in both photolysis and pyrolysis systems and have identified the products of the major secondary reactions.

In preliminary experiments, the isomerization of azoethane to ethanal ethylhydrazone in Pyrex vessels at 150 °C was observed. The rate of isomerization was rapid at first, and then, as surfaces became conditioned, the rate decreased until it became quite small. A temperature study of the equilibrium constant for this reaction was carried out, using a KOH lined pyrolysis cell to establish equilibrium rapidly. The results are summarized in Fig. 1. A least-squares treatment of the data indicates $\Delta H = +0.19 \pm 0.08$ kcal/mole and $\Delta S = +2.72 \pm 0.22$ cal/deg mole for a 90% confidence level.

now lead to $\bar{S}_2^0 = 11 \pm 2$ cal deg^{-1} mole^{-1} for MoO_4^{2-} (aq).

Several earlier thermodynamic calculations for MoO_4^{2-} (aq) and solid molybdates have been based on Latimer's (7) estimated $\bar{S}_2^0 \cong 14$ cal deg^{-1} mole^{-1} rather than experiment-based quantities calculated above.

Combination of the ΔG^0 of solution of Ag_2MoO_4 (c) derived from the solubility product (5) with ΔG_f^0 values for Ag^+ (aq) and MoO_4^{2-} (aq) now leads to $\Delta G_f^0 = -179.5$ kcal/mole for Ag_2MoO_4 (c). Solubility, electrochemical, and calorimetric data gave (5) a "best" $\Delta H_f^0 = -200.4$ kcal/mole for Ag_2MoO_4 (c), which is now used with the ΔG_f^0 above in calculating $S_{298}^0 = 55$ cal deg^{-1} mole^{-1} for Ag_2MoO_4 (c). This value is subject to direct verification by way of heat capacity data and the third law. Similar calculations can be made for other molybdates.

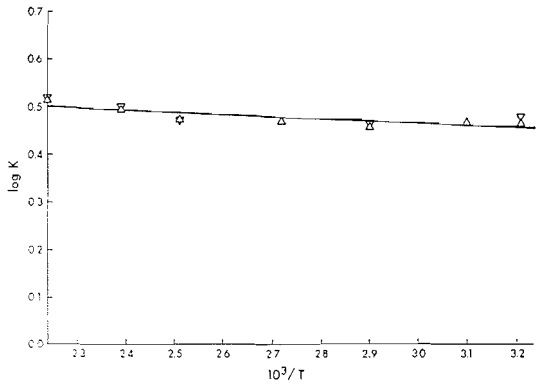

FIG. 1. Plot of log of equilibrium constant vs. $10^3/T$, T in °K; △, runs starting with azoethane; ▽, runs starting with ethanal ethylhydrazone.

Photolysis of azoethane at 100 °C and 5–50 Torr total pressure with 3660 Å light resulted in the formation of 3 major secondary reaction products (see Table I). These were tetraethyl hydrazine, ethanal diethylhydrazone, and ethyl 2-butyl diimide. Some other products also appeared in very small yields. When photolysis was carried out with ~250 Torr added propane, ethanal ethylhydrazone was also formed in low yield. Addition of nitric oxide to the system as a radical scavenger resulted in the complete suppression of heavy products except ethanal ethylhydrazone, a small quantity of which was still formed, probably on the walls.

Pyrolysis of azoethane in the temperature range 240–300 °C yielded, in addition to the expected primary products, more than a dozen secondary products. Most of these were produced in quantities too small to permit identification, and, since their peaks ran together in some regions of the chromatogram, they could not even be accurately counted. These products clearly accounted for a very significant fraction of the azoethane consumed. The 2 major secondary products were ethyl 2-butyl diimide and ethanal diethylhydrazone (see Table II). They were clearly being decomposed as well as formed in the system. When pyrolysis was carried out at 240 °C, where decomposition is fairly slow, with a pressure of about 500 Torr propane, ethanal ethylhydrazone was formed in low yield.

Relative retention times of major products are given in Table III. Molecular structures were determined by mass spectrometry and nuclear magnetic resonance (n.m.r.) spectroscopy. Mass spectral data on the products identified are summarized in Table IV, and n.m.r. spectra are summarized in Table V. Spin decoupling was used to check the apparent positions of the protons. The n.m.r. spectrum of ethanal diethylhydrazone shows no evidence of *cis–trans* isomerism, which is consistent with the results of Stopskii and co-workers (7). A sample of the ethyl 2-butyl diimide produced was irradiated with 3660 Å light. The resulting decomposition

TABLE I

Results of photolysis of 34 Torr azoethane at 97 °C*

Compound	Amount (μmoles)	Compound†	Amount (μmoles)
Azoethane (unreacted)	522

of the molecule yielded the expected hydrocarbon products. Ethanal ethylhydrazone was synthesized by condensation of ethyl hydrazine and acetaldehyde, and the n.m.r. and mass spectra proved identical to those of the compound obtained from isomerization of azoethane. The n.m.r. spectrum is quite similar to that reported by Lemal and co-workers (8).

The detection of ethanal ethylhydrazone produced in photolysis and pyrolysis of azoethane was complicated by the fact that it had the same retention time as ethyl 2-butyl diimide. The peaks at *m/e* 71 and 86 are quite small in the mass spectrum of ethyl 2-butyl diimide produced in low pressure runs. In runs with high pressures of propane and low decomposition rate (which favored abstraction reactions), there was some increase in the *m/e* 71 and 86 peaks relative to the spectrum of ethyl 2-butyl diimide, and this was presumed to be due to formation of ethanal ethylhydrazone.

TABLE III

Relative retention times* for principal secondary reaction products

The products found suggest the following reaction scheme

[1] $EtN{=}NEt \xrightarrow{h\nu \text{ or } \Delta} 2Et + N_2$

[2] $2Et \longrightarrow C_4H_{10}$

[3] $2Et \longrightarrow C_2H_4 + C_2H_6$

[4] $Et + EtN{=}NEt \longrightarrow C_2H_6 + CH_3\dot{C}H{-}N{=}NEt$

[5] $Et + CH_3\dot{C}H{-}N{=}NEt \longrightarrow CH_3CHEtN{=}NEt$

[6] $Et + CH_3\dot{C}H{-}N{=}NEt \longrightarrow CH_3CH{=}N{-}N(Et)_2$

[7] $RH + CH_3\dot{C}H{-}N{=}NEt \longrightarrow R + CH_3CH{=}N{-}NHEt$

[7*a*] $EtN{=}NEt \xrightarrow{\text{wall}} CH_3CH{=}N{-}NHEt$

[8] $RH + CH_3\dot{C}H{-}N{=}NEt \longrightarrow R + EtN{=}NEt$

[9] $Et + EtN{=}NEt \longrightarrow (Et)_2N{-}\dot{N}Et$

[10] $Et + (Et)_2N{-}\dot{N}Et \longrightarrow (Et)_2N{-}N(Et)_2$

Reaction [7*a*] would only be of importance in systems where the walls have not been conditioned. Ethanal ethylhydrazone could possibly be formed by disproportionation as well as by reactions [7] and [7*a*]. The fact that tetraethylhydrazine is not a prominent product in pyrolysis suggests that either the $Et_2N—\dot{N}Et$ radical or the tetraethylhydrazine molecule decomposes rapidly at high temperatures. In either case, formation of ethyl amines would be a possible result. Although no ethyl amines were found in this study, they could well have been present in small amounts as reported by Sandhu (5).

The possibility of a rapid decomposition of the $CH_3CHN_2C_2H_5$ radical has been considered by some authors (4, 5). Our observation of formation of ethyl 2-butyl diimide and ethanal diethylhydrazone in both photolysis and pyrolysis even at 300 °C, however, implies a relatively high stability for this radical.

Gray and Thynne (1) found tetramethyl hydrazine and methyl ethyl diimide in the photolysis of azomethane, but it is notable that they found neither formal methyl hydrazone nor formal dimethylhydrazone. This may mean that the resonance structure $CH_2{=}N{-}N{-}CH_3$ is of less significance in the $CH_2N_2CH_3$ radical than the analogous structure in the $CH_3CHN_2C_2H_5$ radical.

Wacks (2) observed the formation of methyl amine in high temperature pyrolysis of azomethane and suggested that heterogeneous isomerization of azomethane to formal methylhydrazone followed by decomposition of the hydrazone to HCN and methyl amine may occur.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Cohen and Zand (3) reported spectroscopic evidence for the formation of acetone isopropylhydrazone in the pyrolysis of azo-*iso*-propane, but it must be considered that the ultraviolet absorptions of hydrazones are very intense, and very small yields of hydrazones could have been detected. We find that the analogous isomerization of azoethane is not significant in a conditioned reactor unless circumstances extremely favorable to hydrogen atom abstraction by the $CH_3CHN_2C_2H_5$ radical exist.

The reaction scheme indicated in this work differs from that suggested by Cerfontain and Kutschke (4) only in that formation of ethanal diethylhydrazone occurs parallel to formation of ethyl 2-butyl diimide. This could not seriously affect the activation energy values they calculated for the abstraction of hydrogen from azoethane (8 kcal/mole) and the addition of ethyl radicals to the double bond of azoethane (6 kcal/mole).

Sandhu (5) has proposed a general reaction scheme for pyrolysis of azoethane which is similar to the sequence of reactions proposed here. His scheme, however, includes decomposition of the $CH_3CHN_2C_2H_5$ radical, which does not appear to be significant in this work, and he does not include formation of ethanal diethylhydrazone (reaction [6]). It seems likely that much of the complexity of the azoethane pyrolysis system may stem from decomposition of this molecule.

Quantum yield of Hg $6(^3P_1)$ sensitization of hydrogen

T. L. Pollock, E. Jakubowski, H. E. Gunning, and O. P. Strausz
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 31, 1969

The quantum yield for the mercury photosensitized decomposition of hydrogen has been measured using the ethylene scavenging technique and has been found to be equal to unity.

Canadian Journal of Chemistry, 47, 3474 (1969)

The classical experiment of Cario and Franck (1) in 1922 on the mercury photosensitized decomposition of the hydrogen molecule was the first demonstration of the intermolecular conversion of electronic excitation energy into chemical energy. Several studies of this reaction have been reported in the intervening years, but the mechanism and quantum efficiency of the reaction is still a matter of controversy.

Thomas and Gwinn (2) have attempted to measure the quantum yield for the dissociation of hydrogen using copper oxide as a scavenger. By the improbable assumption that the efficiency of the scavenging reaction is unity, the quantum yield of the dissociation reaction was found to be ~ 0.22. Subsequently, Callear and Robb (3) used ethylene as scavenger of hydrogen atoms and obtained a quantum efficiency of unity. From a study of the H + NO reaction Strausz and Gunning (4) also concluded that the primary quantum yield of the dissociation reaction is unity.

More recently Goldschmidt *et al.* (5), employing techniques similar to those of Thomas and Gwinn, have shown that removal of hydrogen atoms from the gas phase by solid molybdenum

oxide is far from being an efficient process and that the quantum yield of dissociation is close to unity.

At this point Yang and co-workers (6) published a theoretical study, based on phase space theory, of the quenching of $Hg(^3P_1)$ atoms by H_2 molecules and concluded that the quantum yields for H atoms, HgH, and undissociated vibrationally excited hydrogen molecules are 0.52, 0.16, and 0.58, respectively. The claim was also made that in mercury-sensitized decompositions, these vibrationally hot H_2 molecules could undergo reactions which were, in the past, attributed solely to H-atom reactions. Since formation of such vibrationally excited H_2 molecules appeared to be an unusual phenomenon, contradicting most experimental results, we have decided to reexamine the quantum yield of hydrogen atom formation in this system, using ethylene as scavenger.

The ratio of the rate of formation of ethane to butane in the mercury photosensitized hydrogenation of ethylene is known to be dependent upon the experimental conditions (3) and is greater than the accepted value of k_d/k_r for ethyl radicals (7). However, under suitable conditions, high H_2-to-ethylene pressure and low light intensities, the deviation is minimal.

LeRoy and co-workers (8, 9) suggested that the excess ethane is formed by recombination of hydrogen atoms with ethyl radicals, while Callear and Pereira (10) proposed an alternative mechanism wherein ethane would be produced via reactions of ethyl radicals with HgH. The intermediacy of HgH has lately been verified by flash mercury photosensitization (11). Neither of these processes would have any effect on the quantum yield determination as measured by the rate of production of ethane plus butane, were it not for the exothermicity of the ethyl radical and hydrogen atom combination reaction. This reaction produces vibrationally excited ethanes which may subsequently dissociate into methyl radicals. These methyl radicals then appear in the products as propane by recombining with ethyl radicals.

[1] $C_2H_5 + H \rightarrow C_2H_6^*$

[2] $C_2H_6^* \rightarrow 2CH_3$

[3] $C_2H_5 + CH_3 \rightarrow C_3H_8$

Further reactions contributing to ethyl loss are the addition of ethyl to ethylene and the combination of the resulting butyl radicals with ethyl to give hexane

[4] $C_2H_5 + C_2H_4 \rightarrow C_4H_9$

[5] $C_2H_5 + C_4H_9 \rightarrow C_6H_{14}$

Experimental

Three cylindrical quartz cells were used as reaction vessels. Their dimensions were 6, 10, and 19 cm in length with a common diameter of 5 cm. Hanovia low-pressure Hg-arcs equipped with Vycor 7910 filters were used as radiation sources. Prior to each experiment a warm-up time of at least 2 h was allowed. All experiments were done at room temperature allowing a minimum of 2 h for mixing of the gases before irradiation.

Light intensities were determined by nitrous oxide actinometry (12).

After irradiation, the noncondensables were pumped off through two traps at −196 °C in series with one at −210 °C. The whole of the condensable products were then admitted to the sample port of a thermal conductivity gas chromatographic unit. A medium activity silica gel column and an alumina column deactivated with 2.5% silicone oil 550 were used to analyze the C_2–C_4 fraction. The presence of hexane was checked using a silicone oil DC200 column.

Ethylene (Phillips Research Grade) was purified by distillation at −160 °C and degassing at −196 °C while the hydrogen (Airco Assayed Reagent) was used without further purification. The butene-1 (Phillips Research Grade) was distilled at −112 °C and degassed at −130°C. Nitrous oxide (Matheson) was purified by distillation at −130 °C and degassing at −160 °C.

Results and Discussion

From the data, summarized in Table I, the combined quantum yield of ethane and butane formation is unity when the ethylene pressure is near 1 Torr. The mean value of the product ratios C_2H_6/C_4H_{10} is 0.166, only slightly higher than the disproportionation to recombination ratio of ethyl radicals, 0.135. If vibrationally excited H_2^* molecules were participating in the reaction, their two conceivable reactions would be

[6] $H_2^* + C_2H_4 \xrightarrow{M} C_2H_6$

[7] $H_2^* + C_2H_4 \longrightarrow C_2H_5 + H$

Reaction [6] can be dismissed on the ground that the ethane in excess of that due to disproportionation of ethyl radicals is negligible, about 2–3% of the total ethyls.

Reaction [7] would require excess energy in H_2^* of at least 65.8 kcal, the endothermicity of the reaction. Since, however, hydrogen atom addition to ethylene has an activation energy of a few kcal, and H_2 addition should have an even

*T = 25 °C.

higher activation energy requirement[1], the minimal excess energy necessary could not be less than about 70 kcal. Now the concentration ratio of H_2 to C_2H_4 in our system was about 880 and the gas kinetic collision ratio $Z(H_2^*\text{–}H_2)/Z(H_2^*\text{–}C_2H_4) \sim 3300$. Unfortunately, vibrational relaxation data for the H_2 molecule are scant. The $Z_{1,0}$ values (ref. 13, p. 202) at 2280 and 2600 °K are 2500 and 3800. Assuming that $Z_{1,0}$ does not increase with decreasing temperature, it can be estimated from the relation $p_{i,i-1} = ip_{1,0}$ (ref. 13, p. 170) that the number of collisions with H_2 necessary to deplete the excess energy of H_2^* below the critical estimate of 70 kcal, which requires the removal of 7 quanta, $v = 15 \rightarrow v = 8$ (14) is not more than about 1500. Thus the fraction of H_2^* which would be relaxed prior to collision with C_2H_4 is

$$\frac{\frac{3300}{1500}}{\frac{3300}{1500}+1} \sim \frac{2}{3}$$

The steric factor of reaction [7] cannot be higher than that of the abstraction reaction by ethyl radicals from H_2, 10^{-2} (9) and therefore practically all H_2^* would be relaxed by collision with H_2 before reaction with ethylene could take place. Consequently, under the prevailing experimental conditions the possibility of reaction [7] can be dismissed.

[1]Reaction [7] can also be compared to the abstraction reaction by ethyl radicals from hydrogen. The Arrhenius parameters of this latter reaction are: $\log A = 9.6$ (l mole^{-1} s^{-1}) and $E_a = 13.7$ kcal (9).

Thus the only conceivable set of elementary steps which can account for the results is

[8] $Hg + h\nu\,(2537\text{ Å}) \rightarrow Hg^*\,6(^3P_1)$

[9a] $Hg^* + H_2 \rightarrow 2H + Hg$

[9b] $Hg^* + H_2 \rightarrow H + HgH \rightarrow Hg + H$

[10] $H + C_2H_4 \xrightarrow{M} C_2H_5$

[11] $HgH + C_2H_4 \rightarrow C_2H_5 + Hg$

[12] $2C_2H_5 \rightarrow C_4H_{10}$

[13] $\rightarrow C_2H_4 + C_2H_6$

with $\Phi([9a] + [9b]) = 1.0$.

The decrease in the overall quantum yield with increasing ethylene pressure is due to polymerization

[14] $C_4H_9 + nC_2H_4 \rightarrow C_{2n+4}H_{4n+9}$

[15] $C_{2n+4}H_{4n+9} + C_2H_5 \rightarrow C_{2n+4}H_{4n+8} + C_2H_6$

Small quantities of polymer formation could be observed in these experiments and at higher ethylene pressures noticeable quantities of *n*-hexane ($\ll 1\%$) were also detected. Reaction [15] could also account for the slight excess of ethane formation.

At low pressures of ethylene, where scavenging of H-atoms by ethylene was incomplete, in agreement with a previous publication (10), small amounts of propane ($\ll 1\%$) were observed which arose from reactions [2] and [3]. Apparently even 800 Torr hydrogen is not sufficient to completely quench the atomic cracking of the hot ethane molecule.

In conclusion, the spin forbidden reaction

$$Hg(^3P_1) + H_2(X^1\Sigma) \rightarrow Hg(^1S_0) + H_2^*(X^1\Sigma)$$

The formation of alkanes in the pyrolysis of *n*-hexadecane: effect of an inert gas on the decomposition of alkyl radicals

François Doue and Georges Guiochon

Laboratoire Professeur L. Jacque, Ecole Polytechnique, 17 rue Descartes, Paris 5°, France

Received June 25, 1968

The rate of formation of alkanes in the pyrolysis of *n*-hexadecane is shown to be drastically reduced in the presence of an inert gas.

The experimental results are in good quantitative agreement with the predictions of a theoretical model, which assumes that the decomposition of alkyl radicals is not monomolecular, because the Maxwell–Boltzmann activation process would be perturbed by a bimolecular reaction having a lower activation energy.

Canadian Journal of Chemistry, 47, 3477 (1969)

In a previous work (1), we have shown that the kinetics of *n*-hexadecane pyrolysis, in the initial stage of the reaction, offered support for the following free radical mechanism

$$C_{16}H_{34} \rightarrow R_i + R_j \qquad \text{Initiation}$$

$$[1]\quad R_1 + C_{16}H_{34} \xrightarrow{k_1} R_1H + \left.\vphantom{\xrightarrow{k_1}}\right\}$$

$$[2]\quad R_2 + C_{16}H_{34} \xrightarrow{k_2} R_2H + \left.\vphantom{\xrightarrow{k_2}}\right\} \quad C_{16}H_{33} \text{ (primary or secondary radicals)}$$

$$[3]\quad R_3 + C_{16}H_{34} \xrightarrow{k_3} R_3H + \left.\vphantom{\xrightarrow{k_3}}\right\}$$

$$[4]\quad R_2 \text{ or } R_3 \xrightarrow{k_4} C_2H_4 + R_i$$

$$[5]\quad R' \xrightarrow{k_5} \text{Alkene} + R_i \quad (R_i \text{ primary radical})$$

$$[6]\quad R_3 \overset{K}{\rightleftharpoons} R' \qquad \text{Isomerization}$$

$$[7]\quad R_i + R_j \rightarrow \text{Products}$$

where $R_1 = CH_3$ or C_2H_5

$R_2 = n\text{-}C_3H_7$ or $n\text{-}C_4H_9$

$R_3 = C_nH_{2n+1}$ $n > 4$ (primary radical)

$R' = C_nH_{2n+1}$ $n > 4$ (secondary radical)

Similar radical mechanisms have been shown by several authors (2–4) to be very useful to account for the kinetics of decomposition of light alkanes.

The reaction was found to be homogeneous, in the following range of experimental conditions: temperature from 380 to 520 °C, pressure from 0.1 to 100 bars, pyrolysis ratio below 5%. The decomposition was performed in small glass tubes, sealed under vacuum (1).

The values derived from this mechanism for the

kinetic parameters and for the composition of the pyrolysis products agree very well with the experimental data (1).

The isomerization reaction via internal transfers of hydrogen atoms was shown to be very fast (1), so that primary and secondary radicals are in thermodynamical equilibrium. K is the average equilibrium constant between C_nH_{2n+1} primary and secondary radicals, where $4 < n \leqslant 16$.

Formation of Alkanes

The amount of alkanes was expressed (1) by the ratio $\theta = y/x$ of the number, y, of alkane molecules with 5 to 15 carbon atoms, to the number, x, of alkene molecules with 3 to 15 carbon atoms which result from the decomposition of ρn_0 molecules of n-hexadecane, where n_0 is the initial number of molecules and ρ is the pyrolysis ratio.

In the initial stage of the pyrolysis, the rate of the reaction is supposed to remain constant. Using a theoretical calculation of the different rate constants and an interpretation of the composition of the pyrolysis products, we have shown (1) that the rate of combination and disproportionation of radicals was comparatively very slow. Then

$$\theta \simeq \frac{k_3}{k_5} \cdot \frac{[R_3]}{[R']} \cdot [C_{16}H_{34}] = \frac{k_3}{k_5 K} p$$

where p is the partial pressure of hexadecane at the beginning of the reaction. From the results already published (1) it can be seen that θ is proportional to p in the pressure range 0.5 to 100 bars (Fig. 1).

Effect of an Inert Gas

In the presence of an inert gas (argon or water), θ is also proportional to the pressure of n-hexadecane in the whole pressure range investigated, but the proportionality coefficient is much lower than in the pyrolysis of pure hexadecane.

Figure 2 shows the results obtained at 420 °C in the presence of water vapor. The partial pressure of water in these experiments was always larger than 2 bars and at least 10 times larger than the pressure of n-hexadecane.

Under these conditions, $\theta \simeq 0.2\theta_0$, where θ_0 is the value of θ observed for pure n-hexadecane; this result does not depend on the partial pressure of water. The same result is observed with argon as the inert gas between 400 and 500 °C.

Interpretation of the Results with the Aid of an Activation–Deactivation Mechanism

At high pressure, the Maxwell–Boltzmann energy distribution is known to be valid for mole-

For personal use only.

cules. This might not be true for radicals at all energy levels, and especially at energies higher than the activation energy of a bimolecular reaction.

The rate constants of steps [3] and [4] are k_3 and k_4, with activation energies $E_3 \simeq 10.5$ and $E_4 \simeq 24$ kcal/mole (1, 2, 5), respectively. Those R_3 radicals with an energy $E(E_3 > E > E_4)$, and called hereafter $R_3{}^*$, can get more energy only via collisions with alkane molecules. Such collisions can also produce the saturation of $R_3{}^*$ via reaction [3]. Then, if the number of collisions necessary for $R_3{}^*$ to reach an energy level greater than E_4 is larger than the reciprocal of the steric factor of reaction [4], this reaction may be supposed to disturb the energy distribution of $R_3{}^*$ radicals.

In the presence of an inert gas A, the mechanism can be written as follows

(*a*) Alkane formation

$$[9] \qquad R_3{}^* + C_{16}H_{34} \xrightarrow{k = aZ} RH + \cdots$$

$$[10] \qquad R_3{}^{\ddagger} + C_{16}H_{34} \xrightarrow{k = a'Z} RH + \cdots$$

where $R_3{}^{\ddagger}$ denotes the R_3 radicals with an energy $E \geqslant E_4$.

(*b*) Radical decomposition

$$[11] \qquad R_3{}^{\ddagger} \xrightarrow{k = \nu} C_2H_4 + \cdots$$

(*c*) Activation–deactivation via two types of collision

1. With alkane molecules

$$[12] \qquad R_3{}^* + C_{16}H_{34} \underset{cZ}{\overset{bZ}{\rightleftharpoons}} R_3{}^{\ddagger} + C_{16}H_{34}$$

2. With molecules of an inert gas A

$$[13] \qquad R_3{}^* + A \underset{c'Z}{\overset{b'Z}{\rightleftharpoons}} R_3{}^{\ddagger} + A$$

where Z is the collision frequency per unit concentration of $R_3{}^*$, $R_3{}^{\ddagger}$, $C_{16}H_{34}$, or A; ν is the frequency factor of the decomposition of $R_3{}^{\ddagger}$ radicals; and a, a', b, b', c, c' are efficiency or steric factors. A is assumed to have roughly the same kinetic properties as $C_{16}H_{34}$ in order to keep the same value for Z in reactions [9], [10], [12], and [13].

With this mechanism, it is possible to calculate the ratio $\alpha = d[R_3H]/d[C_2H_4]$, where α is proportional to θ at a given pressure. As long as the rate of equilibrium between radicals R_3 and R′ is supposed to be very fast, any variation of $[R_3]$ acts on [R′], and so the R_3 and R′ rates of decomposition remain proportional. Thus

$$\alpha = [C_{16}H_{34}] \cdot \frac{Z}{\nu} \cdot \frac{a[R_3{}^*] + a'[R_3{}^{\ddagger}]}{[R_3{}^{\ddagger}]}$$

$$\simeq \frac{ap}{s} \cdot \frac{[R_3{}^*]}{[R_3{}^{\ddagger}]} \quad \text{since } [R_3{}^{\ddagger}] \ll [R_3{}^*]$$

where $s = \nu Z^{-1}$ and $p = [C_{16}H_{34}]$.

The stationary state hypothesis applied to the radicals $R_3{}^{\ddagger}$ allows the ratio $[R_3{}^*]/[R_3{}^{\ddagger}]$ to be calculated. Let $n' = 1/b'$ be the number of collisions of $R_3{}^*$ with the inert molecules A necessary for $R_3{}^*$ to obtain energy E_4. Because of reaction [9] the number $n = 1/b$ of collisions with $C_{16}H_{34}$ molecules necessary to obtain the same energy will be greater than n'. After the $R_3{}^*$ radicals have experienced on the average n' collisions, only a fraction $(1 - a)^{n'}$ of these radicals remain unreacted; the necessary number of collisions to transfer an energy ΔE to the radicals $R_3{}^*$ becomes $n = n'(1 - a)^{-n'}$. If we suppose that a is very small (this will be shown later)

$$[14] \qquad n \simeq n'(1 + n'a) \quad \text{or} \quad b'/b \simeq 1 + a/b'$$

It can be found in the same way that

$$[15] \qquad c'/c \simeq 1 + a'/c'$$

Consequently

$$\alpha = \frac{a}{s} \cdot p \cdot \frac{c'p_A - (c + a')p + s}{bp + b'p_A}$$

with $p_A = [A]$; $p = [C_{16}H_{34}]$.

Semiquantitative Interpretation of the Results

At 400 °C several collisions are most probably necessary to transfer an amount of energy $E_4 - E_3 \simeq 13.5$ kcal/mole. For two collisions we should have $c' = 0.5$ and $b' = c'\exp((E_3 - E_4)/RT) \sim 10^{-4}$. The steric factor, for hydrogen atom abstraction is about 10^{-3} (5, 6) for methyl radicals, and a little lower for larger alkyl radicals. Thus a is about 5×10^{-4} (1) and $a \gg b'$. Equation [14] gives $b' \gg b$.

Therefore the Maxwell–Boltzmann activation process is actually disturbed by reaction [3]. On the other hand, a' cannot be much larger than a. Then $a' \ll c'$ and eq. [15] gives $c \simeq c'$. Since θ is proportional to α at any concentration of

hexadecane, θ/θ_0 can be expressed with the rate constant b' and c' only.

$$\frac{\theta}{\theta_0} = \frac{c'(p_A + p) + s}{p + \left(1 + \frac{a}{b'}\right)p_A} \cdot \frac{p}{c'p + s}$$

For our experimental conditions ($p_A > 2$ bars and $p_A > 10p$)

$$s \ll c'pZ \text{ or } c'p_AZ$$

then

$$\frac{\theta}{\theta_0} \simeq \frac{p_A + p}{p + \left(1 + \frac{a}{b'}\right)p_A}$$

and if $p_A \gg p$

$$\frac{\theta}{\theta_0} \simeq \frac{b'}{a + b'}$$

Consequently, this model shows that (a), θ/θ_0 is independent of the initial concentrations of the alkane and the inert gas as long as they are not too low, and provided that $p_A \gg p$ (b), θ is independent of the nature of the inert gas, and (c), θ is smaller than $\theta_0/5$.

These results are in excellent agreement with the experimental data. This model could be useful to account for other types of reactions where the collisions necessary to activate chemical species can also produce a bimolecular reaction.

On the use of a polyelectrolyte in a thermocell[1]

W. G. Breck and E. King[2]
Department of Chemistry, Queen's University, Kingston, Ontario

Received March 7, 1969

Canadian Journal of Chemistry, 47, 3480 (1969)

Agar's thermocell equations (1) have been applied to experiments involving acid–base (2) and redox (3, 4) electrodes. It is the purpose here to consider applying these relations to a polyelectrolyte such as a polystyrene sulfonic acid or a quaternary ammonium salt. For practical reasons as well as for theoretical simplicity, hydrogen gas electrodes are attractive; with them Lin (5) has obtained satisfactory results using a thermocell for initial values but not for the Soret steady state which is also considered in what follows.

For the use of hydrogen gas with an aqueous solution of a strong electrolyte, HA, the electrode reaction is simply

$$[1] \qquad H^+ - \tfrac{1}{2}H_2 + e = 0$$

Substitution of the coefficients of the terms in reaction [1] into Agar's thermocell equations produces relations for the Soret steady state and the initial state (before any concentration changes have occurred owing to thermal diffusion), respectively, as

$$[2] \qquad F\varepsilon_\infty = -\bar{\bar{S}}_{H^+} + \tfrac{1}{2}S_{H_2} - \bar{\bar{S}}_e$$

$$[3] \qquad F\varepsilon_0 = F\varepsilon_\infty + (1 - t_{H^+})S_{H^+}{}^* + t_{A^-}S_{A^-}{}^* = F\varepsilon_\infty + t_{A^-}S_{HA}{}^*$$

Here F is the faraday; $\varepsilon_\infty = dE_\infty/dT$ is the thermoelectric power or temperature coefficient of electromotive force (e.m.f.) at the Soret steady state; $\varepsilon_0 = dE_0/dT$, the analogous property at the initial condition; t is the Hittorf transport number; $\bar{\bar{S}}$ for a constituent is the transported entropy, being the sum of the usual partial molar entropy, S, and the entropy of transport, S^*; $\bar{\bar{S}}_e$ is thus the

hexadecane, θ/θ_0 can be expressed with the rate constant b' and c' only.

$$\frac{\theta}{\theta_0} = \frac{c'(p_A + p) + s}{p + \left(1 + \frac{a}{b'}\right)p_A} \cdot \frac{p}{c'p + s}$$

For our experimental conditions ($p_A > 2$ bars and $p_A > 10p$)

$$s \ll c'pZ \text{ or } c'p_AZ$$

then

$$\frac{\theta}{\theta_0} \simeq \frac{p_A + p}{p + \left(1 + \frac{a}{b'}\right)p_A}$$

and if $p_A \gg p$

$$\frac{\theta}{\theta_0} \simeq \frac{b'}{a + b'}$$

Consequently, this model shows that (a), θ/θ_0 is independent of the initial concentrations of the alkane and the inert gas as long as they are not too low, and provided that $p_A \gg p$ (b), θ is independent of the nature of the inert gas, and (c), θ is smaller than $\theta_0/5$.

These results are in excellent agreement with the experimental data. This model could be useful to account for other types of reactions where the collisions necessary to activate chemical species can also produce a bimolecular reaction.

On the use of a polyelectrolyte in a thermocell[1]

W. G. Breck and E. King[2]
Department of Chemistry, Queen's University, Kingston, Ontario

Received March 7, 1969

Canadian Journal of Chemistry, 47, 3480 (1969)

Agar's thermocell equations (1) have been applied to experiments involving acid–base (2) and redox (3, 4) electrodes. It is the purpose here to consider applying these relations to a polyelectrolyte such as a polystyrene sulfonic acid or a quaternary ammonium salt. For practical reasons as well as for theoretical simplicity, hydrogen gas electrodes are attractive; with them Lin (5) has obtained satisfactory results using a thermocell for initial values but not for the Soret steady state which is also considered in what follows.

For the use of hydrogen gas with an aqueous solution of a strong electrolyte, HA, the electrode reaction is simply

$$[1] \qquad H^+ - \tfrac{1}{2}H_2 + e = 0$$

Substitution of the coefficients of the terms in reaction [1] into Agar's thermocell equations produces relations for the Soret steady state and the initial state (before any concentration changes have occurred owing to thermal diffusion), respectively, as

$$[2] \qquad F\varepsilon_\infty = -\bar{\bar{S}}_{H^+} + \tfrac{1}{2}S_{H_2} - \bar{\bar{S}}_e$$

$$[3] \qquad F\varepsilon_0 = F\varepsilon_\infty + (1 - t_{H^+})S_{H^+}{}^* + t_{A^-}S_{A^-}{}^* = F\varepsilon_\infty + t_{A^-}S_{HA}{}^*$$

Here F is the faraday; $\varepsilon_\infty = dE_\infty/dT$ is the thermoelectric power or temperature coefficient of electromotive force (e.m.f.) at the Soret steady state; $\varepsilon_0 = dE_0/dT$, the analogous property at the initial condition; t is the Hittorf transport number; $\bar{\bar{S}}$ for a constituent is the transported entropy, being the sum of the usual partial molar entropy, S, and the entropy of transport, S^*; $\bar{\bar{S}}_e$ is thus the

transported entropy of a mole of electrons in the metal leads which are not isothermal.

If some other strong electrolyte, HB (with H^+ in common), is added, eq. [2] is unchanged except in so far as the value of $\bar{\bar{S}}_{H^+}$ changes with possible change in concentration of H^+ or interionic effect. On the other hand, for the initial state

$$[4] \quad F\dot{\varepsilon}_0 = F\varepsilon_\infty + (1 - \dot{t}_{H^+})S_{H^+}{}^* + \dot{t}_{A^-}S_{A^-}{}^* + \dot{t}_{B^-}S_{B^-}{}^* = F\varepsilon_\infty + \dot{t}_{A^-}S_{HA}{}^* + \dot{t}_{B^-}S_{HB}{}^*$$

The subscribed dots indicate values of quantities *in the mixture* of electrolytes (e.g., values of transport numbers will be different in the mixtures of HA and HB from values for HA alone).

If the strong electrolyte, KA (with A^- in common), is added to the solution of HA

$$[5] \quad F\dot{\varepsilon}_0 = F\varepsilon_\infty + (1 - \dot{t}_{H^+})S_{H^+}{}^* - \dot{t}_{K^+}S_{K^+}{}^* + \dot{t}_{A^-}S_{A^-}{}^* = F\varepsilon_\infty + (1 - \dot{t}_{H^+})S_{HA}{}^* - \dot{t}_{K^+}S_{KA}{}^*$$

It is now our purpose to indicate what use can be made of the thermoelectric eqs. [2], [3], [4], and [5] as a basis for experimental work.

(*a*) By measurement of the e.m.f. of a suitable thermocell at the Soret steady state the quantity $F\varepsilon_\infty$ can be evaluated; however, the experimental difficulties are great and only a few such experiments have been carried out successfully. The main troubles are to maintain an invariant temperature gradient over a long period of time and to avoid convection at all times. Also electrode behavior must be highly reproducible. In eq. [2] the value of S_{H_2} is well known (31.21 e.u.) as is also the small value of $\bar{\bar{S}}_e$ for copper leads (−0.045 e.u.). It is apparent then that $\bar{\bar{S}}_{H^+}$ can be evaluated by such experiments at various concentrations. By a suitable extrapolation against a function of ionic strength $\bar{\bar{S}}_{H^+}{}^0$ has been evaluated as 5.1 e.u. with the use of quinhydrone electrodes in a thermocell (2). Here it would be difficult to employ electrodes with hydrogen gas bubbling to follow the thermal diffusion to the steady state because of mechanical disturbance in the cell.

(*b*) If, for an electrolyte such as HA, $F\varepsilon_0$ is also evaluated by measurement of ε_0 it can be seen from eq. [3] that the difference of $F\varepsilon_\infty$ from $F\varepsilon_0$ gives the quantity $t_{A^-}S_{HA}{}^*$. If t_{A^-} is known or measured, $S_{HA}{}^*$ can be found and translated into Soret data.

(*c*) It is interesting to speculate on the significance of making HA a strong polyelectrolyte preferably with water solubility. One of the few available as such (as its Na salt) is polystyrene sulfonic acid which is said to ionize completely (6). Its solubility in water is considerable but presumably decreases with increased molecular weight and degree of cross linkage. As judged by the behavior of other polyelectrolytes it is likely that the transport number of the anion is close to zero. A more physical view of this is that the polyanion framework is a stationary matrix to which the hydrogen ions are held electrostatically. Even for ordinary acid solutions (e.g. HCl) the transport number of the anion is lower than 0.2. The important point is that if t_{A^-} is close enough to zero in eq. [3], then $F\varepsilon_\infty$ is given by $F\varepsilon_0$. This means that in this case lengthy and delicate runs need no longer be done to get $F\varepsilon_\infty$. Furthermore, with convection, no threat electrodes with hydrogen gas bubbling become practicable.

For the polyanion, $S_{A^-}{}^*$ need not be zero nor is it likely so. Measurements on benzene sulfonic acid indicate that its S^* value is comparable to values for other monobasic strong acids. In eq. [3] in writing $t_{A^-}S_{A^-}{}^*$ we have been considering a monovalent anion, A^-. However, with a polyelectrolyte, H_nP, which ionizes according to $H_nP = z^-H^+ + P^{z^-}$, there will be $1/z^-$ mole of P^{z^-} for each mole of H^+. If ionization is complete $n = z^-$ and we write $H_{z^-}P = z^-H^+ + P^{z^-}$. Per equivalent, the entropy of transport of the polyanion is $S_{P^{z^-}}{}^*/z^-$ and

$$[6] \quad F\varepsilon_0 = F\varepsilon_\infty + (1 - t_{H^+})S_{H^+}{}^* + t_{P^{z^-}}S_{P^{z^-}}{}^*/|z^-| = F\varepsilon_\infty + t_{P^{z^-}}S_{H_{z^-}P}{}^*/|z^-|$$

For a mole of polyanion the entropy of transport would be z^- times as large, yielding a large value for a large amount of material.

(*d*) Equations [4] and [5] show that ε_0 can be altered by the addition of other electrolytes (e.g. HB, KA) to give an infinite variety of values of ε_0. Thus thermoelectric powers can be controlled by the selection of added electrolyte(s); this situation can resemble that in polarography where the added electrolyte can flood out the function of the key electrolyte in the bulk of the solution but not at the electrode.

(*e*) Provided that the concentration of H^+ is not changed too much, the addition of another electrolyte allows its Soret data to be evaluated by use of eq. [4] (or eq. [5] as appropriate). Thus the initial condition (and final since these are the same) for the strong polyelectrolyte can be used as a framework on which to base the determination of entropies of transport of added electrolytes without having to do measurements at other than the initial condition.

A new method of synthesis of aldosuloses

D. J. WALTON

Department of Biochemistry, Queen's University, Kingston, Ontario

Received April 16, 1969

As a new approach to the synthesis of aldosuloses (osones), epimeric pairs of the allylic alcohols, **1** and **2**, and **4** and **5**, were oxidized to the corresponding vinyl ketones, **3** and **6**, respectively. Degradation of the latter by reductive ozonolysis and hydrolysis gave D-*glycero*-tetrosulose and D-*arabino*-hexosulose (D-glucosone), respectively.

Canadian Journal of Chemistry, 47, 3483 (1969)

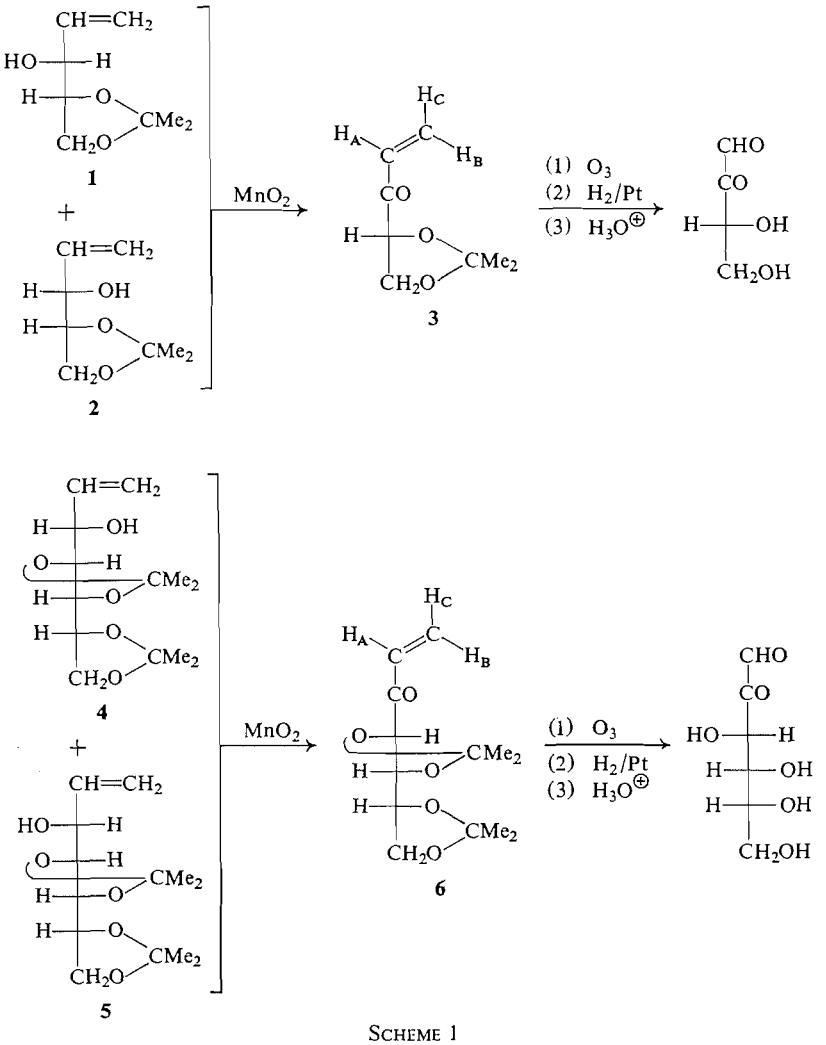
There has recently been renewed biological interest in the aldosuloses, or osones, as 3-deoxy-D-*arabino*-hexosulose is formed when mammalian liver is treated with arsenious oxide (1), and there is probably a connection between mammalian tissue α-keto-aldehyde concentrations and rates of cell division (2). In commencing a study of aldosuloses it was apparent that there are few satisfactory general methods available for their synthesis. Methods of synthesis were reviewed by Bayne and Fewster (3), who mentioned the low yields associated with the oxidation of reducing aldoses, and the deficiencies of the osazone-cleavage method. Subsequent work has included the oxidation of acetone-protected methyl glycosides at C-2, using chromium trioxide (4) or ruthenium tetroxide (5), and the conversion of diazomethyl ketone acetates into the acetates of aldosulose hydrazones (6–8), or into the acetates of aldosulose dithioacetals (9). Most of the derivatives formed in these reactions are not convertible into free aldosuloses, but the aldosulose dithioacetal acetates are exceptional, as they can be successively deacetylated and demercaptalated (9). Hence the diazomethyl ketone → thioacetal route provides a general method of aldosulose synthesis, although little information is available concerning its efficiency.

A new route to the aldosuloses has been devised in this laboratory, and is based on the following sequence of reactions (where R·CHO is an *O*-isopropylidene derivative of an *aldehydo* sugar)

$$\text{R·CHO} \rightarrow \text{R·CHOH·CH=CH}_2 \rightarrow \text{R·CO·CH=CH}_2 \rightarrow \text{R·CO·CHO} \rightarrow \text{aldosulose}$$

A hydroxyl-protected *aldehydo* sugar is vinylated to give a pair of epimeric allylic alcohols as described in previous reports (10, 11). Oxidation of the mixed epimeric alcohols with activated manganese dioxide gives a single vinyl ketone, which is successively ozonolyzed and hydrolyzed to form an aldosulose. The vinyl group, which serves as a potential aldehydo function, makes it possible to obtain the keto group by allylic oxidation, thereby eliminating the need for steps involving aldehyde group protection. Acetal or ketal protecting groups fulfil all the requirements for hydroxyl protection, as they are unaffected by Grignard reagents, manganese dioxide or ozone, but can be removed from a protected aldosulose with acetic acid (12).

The procedure has been used to synthesize D-*glycero*-tetrosulose (see Scheme 1), which cannot be prepared by hydrolysis of D-erythrose phenylosazone (13) and, to the author's knowledge, has not been synthesized previously. The mixed epimeric pentenetriols **1** and **2** were oxidized in 41% yield to 4,5-isopropylidenedioxy-D-*glycero*-1-penten-3-one (**3**). Confirmation of the structure of **3** was obtained from the infrared (i.r.) spectrum, which showed absorption bands



SCHEME 1

due to the conjugated carbonyl group and double bond. The low-field ABX system of the nuclear magnetic resonance (n.m.r.) spectrum was attributed to the vinylic protons. The values of the coupling constants were similar to those reported for vinyl ketones (14, 15; see Table I), and proton H_A resonated at low field as a result of deshielding by the carbonyl group.

Reductive ozonolysis and deketalization of **3** gave a product from which the main component was isolated chromatographically. This substance, a syrup obtained in 18% yield from **3**, was shown by the following methods to be D-*glycero*-tetrosulose. On paper chromatograms it migrated faster than glucose, as a single spot which gave an instant red color with alkaline triphenyltetrazolium chloride, a reagent which is known to react faster with aldosuloses than with aldoses (3). Treatment of the syrup with phenylhydrazine – acetic acid in the cold, or with 2,5-dichlorophenylhydrazine in hot 1-propanol[1] (conditions which preclude conversion of aldoses into osazones) gave D-*glycero*-tetrosulose bis-phenylhydrazone (16) and bis-2,5-dichlorophenylhydrazone (17), respectively. Formation of these derivatives, previously prepared from

[1]Conversion of D-erythrose into D-*glycero*-tetrosulose bis-2,5-dichlorophenylhydrazone requires the inclusion of acetic acid in the reaction mixture (17).

TABLE I

Nuclear magnetic resonance parameters for vinyl groups of vinyl ketones*

Compound	Observed lines (τ)			Chemical shifts (τ)†			Coupling constants (Hz)†		
	H_A	H_B	H_C	H_A	H_B	H_C	J_{AB}	J_{AC}	J_{BC}
3	2.97, 3.12, 3.26, 3.41	3.50, 3.55, 3.79, 3.84	4.15, 4.20, 4.31, 4.36	3.24	3.62	4.25	17.5	10.3	1.8
6	2.95, 3.11, 3.23, 3.38	3.45, 3.52, 3.73, 3.78	4.07, 4.12, 4.22, 4.27	3.23	3.57	4.16	16.8	10.3	1.8
Methyl vinyl ketone (15)‡				3.73	3.82	4.12	17.6	11.0	1.1
Phenyl vinyl ketone (14)‡							18.4	10.8	2.1

*Line assignments were based on the assumption that $J_{trans} > J_{cis} > J_{gem}$.
†Values obtained by second-order analysis. A check of relative line intensities by computer showed that J_{AC} and J_{BC} have the same sign.
‡Values quoted from the literature. Only *relative* shifts are available for phenyl vinyl ketone. Protons H_A, H_B, and H_C resonate at successively higher magnetic fields, the chemical shift differences being Δ_{AB} 0.75, and Δ_{AC} 1.48 p.p.m.

D-erythrose under more drastic conditions, can only be explained by assuming that the hydrazines had condensed with D-*glycero*-tetrosulose.

Borohydride reduction of D-*glycero*-tetrosulose should proceed nonstereoselectively, to give a 1:1 mixture of erythritol and D-threitol. Accordingly, a portion of the syrup was treated with sodium borohydride, followed by acetic anhydride, using the conditions described by Sjöström *et al.* (18). Gas–liquid partition chromatography (g.l.p.c.) of the product revealed the presence of equal weights of two compounds with retention times of erythritol tetraacetate and D-threitol tetraacetate, thus giving further evidence for the tetrosulose structure.

Application of the procedure to the mixed heptenetetrol epimers, **4** and **5**, gave, in 55% yield, vinyl ketone **6**, whose i.r. and n.m.r. spectra had similar characteristics to those of compound **3**. Degradation of **6** afforded chromatographically pure D-*arabino*-hexosulose (D-glucosone) in 37% yield. The identity of the latter was checked by co-chromatography with a reference sample, and by the preparation of two osazones, using the reaction conditions already described for the tetrosulose.

These examples show that allylic oxidation is an effective way of forming the 2-keto group of an aldosulose, in a synthetical route which should be of general applicability.

Experimental

Thin-layer plates, coated with silica gel, were developed with benzene – ethyl acetate 4:1, and sprayed with the alkaline permanganate reagent (19). Paper chromatograms were developed with 1-butanol – acetic acid – water 4:1:5 (solvent system *a*), or phenol – water 4:1 (solvent system *b*), or ethyl acetate – acetic acid – formic acid – water 18:3:1:4 (solvent system *c*). Rates of movement are quoted relative to that of D-glucose (R_G = 1.0). Compounds were visualized with ammoniacal silver nitrate (20) or with alkaline triphenyltetrazolium chloride (21).

Gas–liquid partition chromatography of *C*-vinyl compounds was performed with a column (152 × 0.155 cm) of 10% carbowax 20 *M* terephthalic acid on 70–80 mesh chromosorb W, with a nitrogen flow of 45 ml per min. The oven temperature was 112° at the time of injection, rising to 187° over 11.1 min. Retention times which are shown in Table II are quoted relative to that of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (T = 1.0; retention time 10.6 min). The system used for preparative g.l.p.c. was similar to that described in the last report (11), except that the stationary phase was carbowax 20 *M* terephthalic acid.

Nuclear magnetic resonance spectra of deuterochloroform solutions were obtained at 60 MHz, using tetramethylsilane as the internal standard.

Activated manganese dioxide was obtained from Winthrop Laboratories, New York, and behaved similarly to a sample prepared according to Attenburrow *et al.* (22). Tetrahydrofuran was distilled before use. Epimeric mixtures of **1** and **2**, and of **4** and **5**, were prepared as described previously (10, 11). The ratio of **1** to **2** was 1.0:1.5, and of **4** to **5** was 1.3:1.0. The phenylhydrazine reagent (13) was prepared thus: a solution composed of equal volumes of phenylhydrazine and 50% aqueous acetic acid was diluted with two volumes of water.

4,5-Isopropylidenedioxy-D-*glycero*-*1*-*penten*-*3*-*one* (*3*)[2]

A solution of 1,2-*O*-isopropylidene-D-*threo* (and L-*erythro*)-4-pentene-1,2,3-triol (**1** and **2**, 4.0 g) in tetrahydrofuran (200 ml) was stirred with manganese dioxide (40 g) for 1 h at room temperature. The mixture was filtered on a sintered funnel (M), which resulted in evaporation of ca. 80 ml of solvent. The manganese dioxide filter cake was washed with tetrahydrofuran until the volume of the combined filtrate and washings was restored to 200 ml. The resulting solution was treated with two further batches (40 g each) of manganese dioxide. Each addition was followed by stirring and filtration as before. Analysis of the final solution by g.l.p.c. showed that the proportions of **1**, **2**, and **3** were 2:3:95, respectively. (In separate experiments it was established that these proportions were not altered significantly by further manganese dioxide treatment.) Water[3], which had been adsorbed from the atmosphere during the filtrations, was removed with Na_2SO_4, and the solution was concentrated[4] at 35° and 15 cm to give the product (2.1 g) contaminated with **1** and **2**. Purification was effected by silica gel column chromatography. Elution with benzene – ethyl acetate (94:6) gave the pure product (1.6 g, 41%), a colorless, mobile liquid $[\alpha]_D^{21}$ + 68° (*c*, 2.1 in chloroform). Infrared spectrum (film): 1685 (conjugated CO), 1605 (conjugated C=C), 1395 (vinyl CH in-plane deformation), 1365 and 1375 cm^{-1} (CMe_2 doublet); n.m.r. data: τ 2.97–4.36 (ABX system shown in Table I, vinyl group), τ 5.37–6.13 (3-proton multiplet, H-4, 5, and 5′), τ 8.60 and 8.64 (3-proton singlets, CMe_2). A sample for elemental analysis was obtained by preparative g.l.p.c. at 130°.

Anal. Calcd. for $C_8H_{12}O_3$: C, 61.52; H, 7.74. Found: C, 61.71; H, 7.69.

Samples of compound **3** were stable for several weeks in the refrigerator, but polymerized over a period of several days at room temperature. Distillation of **3** was unsatisfactory as it resulted in formation of impurities, detectable by g.l.p.c.

D-*glycero*-*Tetrosulose*

A solution of **3** (1.5 g) in methanol was held at −40° while a stream of ozonized oxygen (400 ml per min; 0.55 mmoles O_3 per min) was bubbled through for 25 min. Nitrogen was bubbled through the solution while its temperature was brought to 0°, and the flow was continued for a further 10 min. The solution, at 0°, was stirred under hydrogen (atmospheric pressure) in the presence of platinum oxide (50 mg). When gas absorption had ceased the solution was filtered and concentrated to dryness. The residue was heated with 85% aqueous acetic acid (20 ml) for 18 h at 50°. The resulting solution was concentrated, and residual acetic acid was removed by co-distillation with ethanol. The residue, dissolved in water, was passed quickly through Rexyn 203 (OH) resin, and concentrated to a syrup which, after drying over phosphorus pentoxide, weighed 0.39 g. Paper chromatography (solvent *a*) revealed a main component, R_G 2.0, which gave an immediate, permanent, red color with the triphenyltetrazolium spray. Minor impurities, R_G 1.4–2.0, and R_G 3.0, were detectable by silver nitrate. A portion (0.25 g) of the syrup was purified by preparative paper chromatography on Whatman 3MM paper, using solvent *a*. The final product was a syrup (0.13 g, 18%), $[\alpha]_D^{21}$ + 5° (*c*, 4.1 in water), which migrated as a single spot in both system *a* (R_G 2.0) and system *c* (R_G 2.2). In system *b* it moved as a single spot, R_F 0.51, tailing to R_F 0.25.

D-*glycero*-*Tetrosulose Bis*-*phenylhydrazone*

Hydrazine derivatives were prepared from D-*glycero*-tetrosulose which had not been purified by chromatography. To a solution of crude D-tetrosulose (8 mg) in water (1.5 ml) was added 1 ml of phenylhydrazine reagent. After 10 min the osazone (15 mg) was precipitated by addition of water, and had m.p. 164–165°, undepressed when mixed with a sample prepared from D-erythrose; lit. m.p. 164–165° (16).

D-*glycero*-*Tetrosulose Bis*-*2,5*-*dichlorophenylhydrazone*

A solution of crude D-tetrosulose (34 mg) in 95% aqueous 1-propanol (10 ml) was heated on a boiling water-bath for 30 min with 2,5-dichlorophenylhydrazine (200 mg). The solvents were removed and the residue was dissolved in acetic acid (3 ml). Precipitation with water gave the title compound (76 mg), m.p. 208–213°, and m.p. 217–219° after recrystallization from benzene – ethyl acetate (1:1). The m.p. was undepressed on mixing with a sample prepared from D-erythrose; lit. m.p. 219–220° (17).

Tetritol Tetraacetates from D-*glycero*-*Tetrosulose*

Chromatographically pure D-*glycero*-tetrosulose (40 mg) was subjected to the borohydride reduction – acetylation procedure of Sjöström *et al.* (18). Analysis of the final solution by g.l.p.c., using columns 1 and 2 of the previous paper (11) in this series, gave two peaks in a 1:1 ratio, with retention times corresponding to those of erythritol tetraacetate and D-threitol tetraacetate.

4,5:*6,7*-*Bis*(*isopropylidenedioxy*)-D-*arabino*-*1*-*hepten*-*3*-*one* (*6*)[2]

A mixture of 1,2:3,4-di-*O*-isopropylidene-L-*gulo* (and D-*manno*)-6-heptene-1,2,3,4,5-pentol (**4** and **5**, 4.0 g) was oxidized by the method[4] used for compounds **1** and **2**, to give a liquid (2.8 g) which contained compounds **4**, **5**, **6**, and a by-product (*T* 0.41) in the proportions 2:2:90:6, respectively. The pure ketone (2.2 g, 55%) was obtained by column chromatography, and had $[\alpha]_D^{22}$ + 2° (*c*, 5.1 in chloroform). Infrared spectrum (film): 1680 (conjugated CO), 1610 (conjugated C=C), 1395 (vinyl CH in-plane deformation), 1365 and 1375 cm^{-1} (CMe_2 doublet); n.m.r. data: τ 2.95–4.27 (ABX system shown in Table I, vinyl group), τ 5.40–6.12 (5-proton multiplet, H-4,5,6,7, and 7′), τ 8.53, 8.59 (3-proton singlets, CMe_2), and τ 8.64 (6-proton singlet, CMe_2). The analytical sample was obtained by preparative g.l.p.c. at 170°.

Anal. Calcd. for $C_{13}H_{20}O_5$: C, 60.92; H, 7.87. Found: C, 61.13; H, 7.90.

Samples of **6** were stored in the cold. Distillation was unsatisfactory, for the reason given for compound **3**.

[2]Prepared by Miss Margaret Michael.

[3]Traces of water did not affect the efficiency of oxidation.

[4]Smaller pressures resulted in the evaporation of **3**. Solutions of **6** could be concentrated at 1.5–2.0 cm without loss of the product.

D-*arabino-Hexosulose*

Ketone **6** (1.5 g) was subjected to ozonolysis and hydrolysis, as described for compound **3**, but with the omission of any chromatographic purification of the product. The final product, a syrup (0.39 g, 37%), $[\alpha]_D$ − 2° (*c*, 4.4 in water), was chromatographically identical to an authentic sample of D-*arabino*-hexosulose. Chromatograms developed with solvent *a* showed spots at R_G 0.64 and R_G 0.77–1.19, with streaking at R_G 0.41–1.46, as described by Petuely (23). In solvent *b* the product moved as a single spot, R_F 0.25. All the above spots gave the immediate red coloration with triphenyltetrazolium chloride.

D-*arabino-Hexosulose Bis-phenylhydrazone*

The phenylhydrazine reagent (0.5 ml) was added to a solution of D-*arabino*-hexosulose (50 mg) in water (3 ml). The precipitated osazone (90 mg, 89%) was collected after 10 min, and, after recrystallization from aqueous pyridine, had m.p. 206–208°, $[\alpha]_D^{22}$ − 75 → −41° (*c*, 0.7 in pyridine – ethanol 2:3) (2 days); lit. (24) m.p. 208–209°, $[\alpha]_D$ − 40° (equilibrium value, in pyridine – ethanol 2:3).

D-*arabino-Hexosulose Bis-2,5-dichlorophenylhydrazone*

2,5-Dichlorophenylhydrazine (250 mg) was added to a solution of D-*arabino*-hexosulose (50 mg) in 95% aqueous 1-propanol. The mixture was heated for 30 min on a boiling water-bath. The product (78 mg, 56%), m.p. 241–242°, crystallized on cooling, and was washed successively with 50% aqueous acetic acid and water; lit. m.p. 242° (25).

Deamination of two steroidal α-aminoketones[1,2]

O. E. EDWARDS AND T. SANO[3]
Biochemistry Laboratory, National Research Council of Canada, Ottawa, Canada
Received May 14, 1969

The two aminoketones 12α-amino-3α,20β-diacetoxy-11-keto-5β-pregnane and 9α-amino-3β,20β-diacetoxy-11-keto-5α-pregnane were prepared. Deamination of the former could be controlled to give either 12-methyl-18-norpregnane derivatives or *C*-nor-*D*-homo (12,14-cyclo-13,14-secopregnane) derivatives. Deamination of the 9α-aminoketone gave a series of 9β-methyl-19-norsteroids.

Canadian Journal of Chemistry, 47, 3489 (1969)

For personal use only.

The nitrous acid deamination of α-aminoketones (1) and the protonation of an α-diazoketone (2) led to unexpected products including cyclopropyl ketones (1) and a cyclobutanone (2*a*). This seems to be a consequence of carbon–carbon bond participation in the C—N bond cleavage, thus by-passing the high energy α-keto carbonium ion (1). By analogy the deamination of 9-amino and 12-amino-11-keto steroids appeared to provide possible routes to 9,11-cyclosteroids (e.g. buxus alkaloids (3)), 9-methyl-19-nor-11-keto steroids (e.g. cucurbitacins (4)), 12-methyl-18-norsteroids, and *C*-nor-*D*-homo 11-keto-steroids (jervine, veratramine (5)).

We had hoped to prepare both 12α- and 12β-amino-11-ketopregnane derivatives.[4] However, the 12β isomer eluded us. Products derived from the corresponding diazonium ion were only formed by protonation of the diazoketone which was a transient intermediate under some deamination conditions.

12α-Amino-3α,20β-diacetoxy-11-keto-5β-pregnane (**3**) was prepared from the known (6) 12α-bromo-3α,20β-diacetoxy-11-keto-5β-pregnane (**1**) by way of the 12α-azido derivative **2**.[5] The reduction of the azide group was accomplished using stannous chloride in ethanol. The ultraviolet (u.v.) absorption of **1** (λ_{max} 317 mμ, ε 145), **2** (λ_{max} 321 mμ, ε 145), and **3** (R = H) (λ_{max} 310 mμ, ε 190) was consistent with the axial 12α orientation in each case (7), as was subsequent reaction of the amino ketone. Most probably the 12α-bromoketone was in equilibrium with the 12β-bromoketone under the reaction conditions. A much more rapid displacement of the β-bromo group relative to the α-bromo would be expected on steric grounds, thus accounting for the formation of the 12α-azide.[6] Lithium aluminum hydride reduction of **2** followed by acetylation in pyridine led to an acetamido alcohol (**4**, R = H). The small coupling constant (2.5 Hz) for the 12-hydrogen in the corresponding fully acetylated compound was consistent with it being 12α-acetamido-3α,11β,20β-triacetoxy-5β-pregnane (**4**, R = Ac). Reduction of **3** by lithium aluminum hydride followed by acetylation also gave **4** (R = H), confirming that the amino and azido groups had the same configuration.

The synthesis of 9α-amino-3β,20β-diacetoxy-11-keto-5α-pregnane (**10**) proceeded from the known 3β,20β-diacetoxy-5α-pregn-9(11)-ene (**5**) (8). The olefin was converted to the rather unstable 9α-bromo-11β-hydroxy derivative **6**, and thence to the β-oxide **7**. The oxide was opened by heating with lithium azide in dry dimethylformamide. The oxidation of the azido alcohol **8** to the keto azide **9** was accomplished efficiently by the use of acetic anhydride and *p*-toluenesulfonic acid in dimethyl sulfoxide (9). In this series the azido ketone could be reduced in good yield to the aminoketone **10** by hydrogen over palladium on charcoal.

Deamination of 3

The aminoketone hydrochloride in aqueous acetic acid was treated with excess sodium nitrite. The major product was a non-conjugated

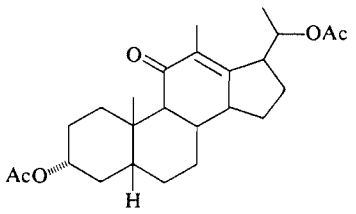
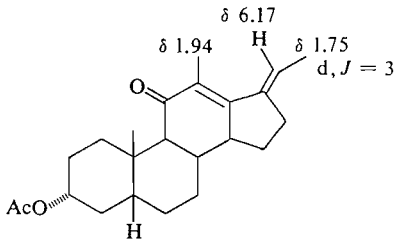
11 12

unsaturated ketone, whose properties corresponded to the 12-methyl-18-nor compounds **11** or **12.**

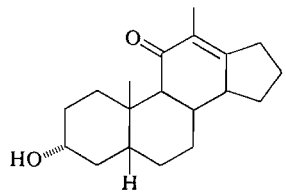
Attempts to purify the product on alumina led to a complex mixture from which a 22% yield of a crystalline mixture of the conjugated ketones **13**



13



14



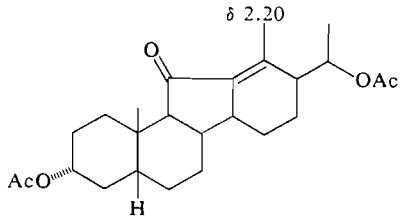
15

(3α,20β-diacetoxy-11-keto-12-methyl-19-nor-5β-pregn-12-ene) and **16** (ratio 4:1 respectively) was obtained. A third product was the dienone **14** (3α-acetoxy-11-keto-12-methyl-19-nor-5β-pregna-12,17(20)-diene). Pure **13** was isolated from the reaction of the hydrochloride of **3** with isoamyl nitrite in chloroform. Its absorption spectra (λ_{max} 250 mμ, ν_{max} 1738, 1665, and 1650 cm^{-1}), and its nuclear magnetic resonance (n.m.r.) spectrum (see formula) were consistent with the structure assigned. Hydrogenation converted it to a dihydro compound with ν_{max} 1730 and 1710 cm^{-1} (shoulder) confirming the ring size of the ketone. The action of hydroxide ion on **13** produced a retroaldol reaction. A 37% yield of **15** (3α-hydroxy-11-keto-12-methyl-19-nor-5β-androst-12-ene) was obtained. This had λ_{max} 248 mμ and ν_{max} 1650 and 1630 cm^{-1}.

The structure of the dienone **14** followed from its λ_{max} at 292 mμ and its n.m.r. spectrum (see formula).

An attempt to form the 12,13-epoxide from **13** using alkaline hydrogen peroxide failed. When a benzene solution of the mixture of non-conjugated ketones from the deamination in protic solvents and dichlorodicyanoquinone was refluxed for 20 h, no aromatization of ring C was observed.

No 12,18- or 12,14-cyclosteroids were detected among the products of deamination of **3** in protic solvents. Since the "aprotic" deamination conditions of Bayless *et al.* (10) generally gave higher yields of cyclopropanes from carbonium ions than aqueous deamination, we submitted **3** to the action of amyl nitrite in benzene. Again no cyclosteroids were detected. Instead the least polar product was now a *C*-nor-*D*-homosteroid. This was characterized as 3α,20β-diacetoxy-11-keto-12,14-cyclo-13,14-seco-5β-pregn-12-ene (**16**) by its absorption spectra (λ_{max} 252 mμ, ν_{max} 1740, 1710, and 1636 cm^{-1}) and its n.m.r. spectrum (see formula). When it was hydrogenated and hydrolyzed, the carbonyl frequency became 1724 cm^{-1}, confirming that the carbonyl was on a five-membered ring.

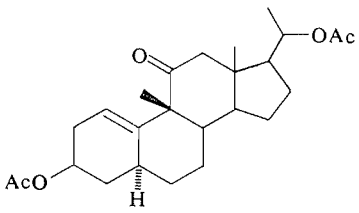


16

The table summarizes the results from deamination of **3** under various conditions. The other products produced were more strongly adsorbed on alumina, and appeared to be ketols and nitrite esters. These were not further characterized.

Deamination of ***10***

In this case, only methyl migration occurred. Three major products were characterized, 3β,20β-diacetoxy-11-keto-9β-methyl-19-norpregn-1(10)-ene (**17**), its $\Delta^{5(10)}$ isomer (**18**), and 3β,20β-diacetoxy-10α-hydroxy-11-keto-9β-methyl-19-norpregnane (**19**). Deamination in aqueous acetic gave 75% of **18** and 5% of **19**.



17

Amyl nitrite in benzene and acetic acid gave 42% of **17**, 31% of **18**, and 11% of **19**, while amyl nitrite in benzene gave an equimolar mixture of **17** and **18**. The structures of **17** and **19** follow

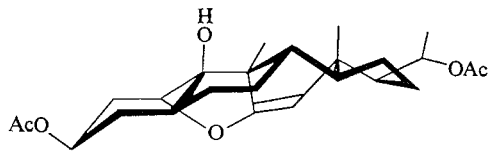
21



from their n.m.r. spectra and reactions. Thionyl chloride in pyridine dehydrated **19** cleanly to **17**. This is only consistent with an α-orientation of the 10-hydroxyl since it is then *cis* to the 5α-hydrogen. Treatment of **17** with *m*-chloroperbenzoic acid gave a mixture of epoxides. When this was warmed with acetic acid, one oxide was converted to a hydroxy enol ether. On the assumption of favored *trans* diaxial opening of the oxide by the 11-oxygen, we consider that the β-oxide **20** reacted, and that the structure and stereochemistry of the enol ether are correctly represented by **21**. When the enol ether was treated with hydrogen chloride in ethanol, ring A was aromatized, giving 20β-hydroxy-11-keto-9β-methyl-19-nor-5α-pregna-1,3,5-triene (**22**). As

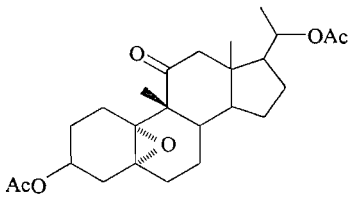
required for this structure it had four aromatic hydrogens in its n.m.r. spectrum.

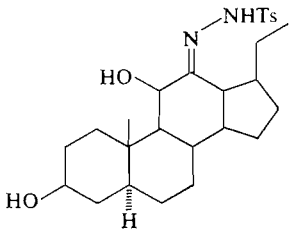
m-Chlorobenzoic acid converted **18** to a single monoxide, probably the α-oxide **23**. This too was aromatized by hydrogen chloride in ethanol. The product was identical with that obtained from **21**.



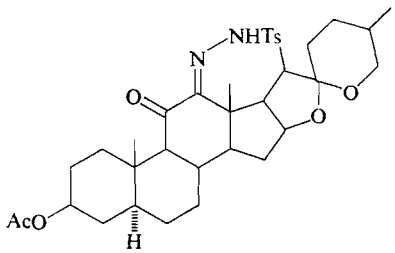
23

Discussion

The *C*-nor-*D*-homo steroid skeleton has been prepared previously in several ways from the normal steroids. The action of base on the 12-tosylhydrazones **24** (11) and **25** (12) gave the corresponding *C*-nor-*D*-homo derivatives.

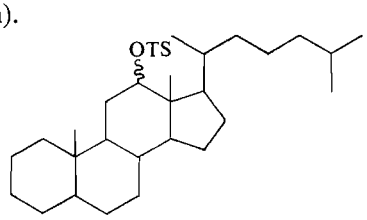


24

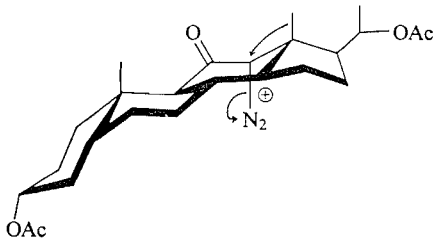


25

Surprisingly, both the 12α and 12β tosylates **26** gave mainly *C*-nor-*D*-homo olefins under solvolytic conditions (13), (presumably largely S_N1 reaction).



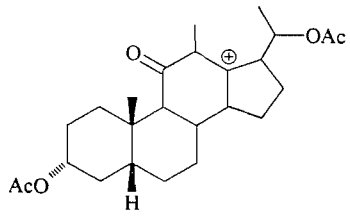
26



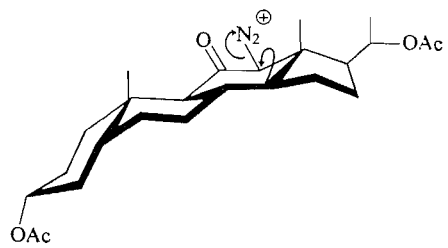
27

A number of cases of migration of C-18 onto C-12 have been reported, initiated by action of hydrogen fluoride on a 9α,11α-oxide (14) dehydration of a 12-hydroxy-7,9(11)-diene (15) and dehydrobromination of a 7,11-dibromo-8-ene on alumina (16).

The deamination of the 12α-aminoketone **3** in protic solvents led predominantly to methyl migration. This is consistent with a concerted migration and nitrogen elimination (see **27** and comments in the introduction). If the cation **28** had been an intermediate, the conjugated olefin should have been a major product, whereas none was formed under essentially neutral conditions.



28

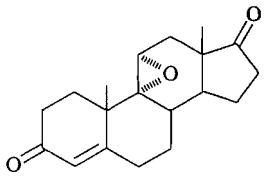


29

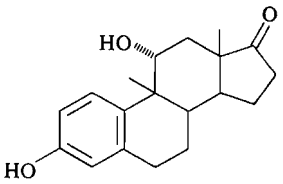
The axial nature of the developing electron deficiency on C-12, the methyl group, and the hydrogens on C-14 and C-17 all contribute to the synchronous processes leading to **11** and/or **12**.

On the other hand, the products from aprotic deamination of **3** correspond to formation of the

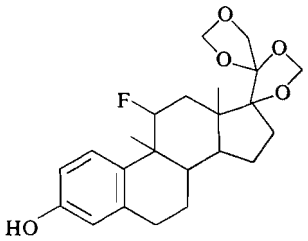
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



30



31



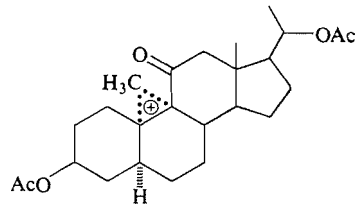
32

diazoketone, followed by axial protonation[7] to give the 12β-diazonium ion **29**. In support of this interpretation, diazoketone (ν_{max} 2090 cm^{-1}) was detected as a transient product of these deaminations.

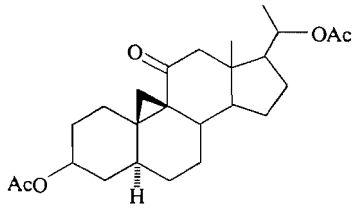
The Lewis acid-catalyzed rearrangement of the 9α,11α-oxide **30** to give **31** (17), the formation of the fluoro compound **32** (18), and the acid-catalyzed rearrangement of 3,16 diketo-17a,17a-dimethyl-18-nor-D-homoandrost-13-ene(19) seem to be the only previously recorded cases of formation of 19-nor-9β-methyl steroids.

In the deamination of **10** the migration of the 10-methyl group is probably synchronous with the loss of the 9α-diazonium group. An initial methyl bridged ion **33** or protonated cyclopropane could then be stabilized by loss of the 1α-hydrogen to give **17**, of the 5α-hydrogen to give **18**, or by reaction with water to give **19**. A compelling argument for the methyl participation in the deamination is the absence of any $\Delta^{8,9}$ olefin among the products.

Much to our disappointment, a fourth possibility, the loss of a proton from **33** to give the 9,19-cyclo compound **34**, was a minor event if it happened at all under our deamination conditions. It appears likely that the *in vivo* formation of 9,19-cyclosteroids involves a strategically placed basic site on an enzyme, which aids



33



34

removal of a proton from the methyl-bridged ion.

Attempts are underway to duplicate the 10-methyl migration in the lanostane series.

Experimental

Infrared spectra were determined using a Perkin–Elmer model 257 grating spectrometer and n.m.r. spectra using a Varian A-60-A spectrometer. Rotations were measured on solutions in 95% ethanol. Thin layer chromatograms (t.l.c.) were done on silica gel plates and column chromatography on Woelm neutral alumina, with activities according to Brockmann and Schodder (20).

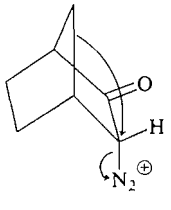
12α-Bromo-3α,20β-diacetoxy-5β-pregnan-11-one (1)

This was prepared as described by Jones and Wenka (6). It had λ_{max} 317 mμ (ε 145) and n.m.r. signals at δ 0.73 (s, 3H) (C-18); 1.12 (s, 3H) (C-19); 1.19 (d, 3H) (C-21); 2.02 (s, 6H) (OAc); 4.03 (s, 1H) (12 βH); and 4.70 (2H) (CHOAc).

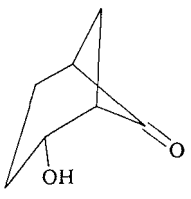
12α-Azido-3α,20β-diacetoxy-5β-pregnan-11-one (2)

A solution of 6.37 g of bromoketone (**1**) and 3.58 g of lithium azide (18) in ml of dry dimethylformamide was maintained at 125–130° under nitrogen for 4 h. After cooling the solution was poured into ice water then extracted with *n*-hexane. The hexane solution was washed with water, dried, and distilled, giving 6.27 g of

[7]The protonation of 3-diazonorbornan-2-one appears to be equally stereospecific, leading to the *endo*-diazo compound (*a*), and thence to the cyclobutanone (*b*) (2*a*).



(*a*)



(*b*)

For personal use only.

crystalline solid. This was recrystallized from methanol, to give 3.1 g of **2** as needles, m.p. 162–165°. It had $[\alpha]_D$ +167.5 (*c*, 0.67); λ_{max} 321 mμ (ε 145); ν_{max} 2115 (—N_3), 1730, and 1250 cm^{-1}; and n.m.r. signals at δ 0.63(C-18); 1.17(C-19); 1.22(d, J = 7)(C-21); 2.02; 2.03(two OAc); 3.66(s, 1H)(CH—N_3); and 4.75(multiplet, 2H) (CHOAc). The signal for the 12-hydrogen shifted downfield by 2.5 c.p.s. in benzene solution.

Anal. Calcd. for $C_{25}H_{37}N_3O_5$: C, 65.33; H, 8.12; N, 9.14. Found: C, 65.15; H, 8.30; N, 9.30.

A solution of 12α-azido ketone **2** (146 mg) in 4 ml of methanol and 1 ml of water containing 300 mg of potassium hydroxide was heated briefly, then left at room temperature for 64 h. The amorphous neutral product (ν_{max} 3610, 3410, 2120, and 1710 cm^{-1}) was reacetylated, giving 136 mg of crystalline product. Its n.m.r. spectrum indicated the presence of 70% 12α-azido ketone (>CHN$_3$ at δ 3.63) and 30% of 12β-azido ketone (>CHN$_3$ at δ 3.37). More drastic treatment (potassium *t*-butoxide in *t*-butyl alcohol at reflux under nitrogen) destroyed the azido group of **2**.

12α-Amino-3α,20β-diacetoxy-5β-pregnan-11-one (3, R = H)

A mixture of 2.29 g of azidoketone **2**, 2.3 g of stannous chloride monohydrate in 150 ml of absolute ethanol was refluxed for 2 h. It was then taken to small volume *in vacuo*. The residue was taken up in water and the product extracted into ethyl acetate using a continuous extractor. The 2.17 g of product was adsorbed from benzene onto 30 g of alumina, activity IV. The fraction eluted with benzene gave 450 mg of **3**(R = H). The mother liquors gave 594 mg of the hydrochloride of **3**(R = H) when treated with ethyl ether saturated with hydrogen chloride. The base had m.p. 189–192°, $[\alpha]_D$ +81° (*c*, 0.71); λ_{max} 310 mμ (ε 190); and ν_{max} 1730, 1260(OAc), 1710(C=O) (shoulder). Its n.m.r. spectrum had signals at δ 0.62(3H); 1.12(3H, d, J = 6.5 c.p.s.); 1.17(s,3H); 1.85 (s, 2H) (NH); 1.97(s, 3H); 2.00(s, 3H); 2.10(s, 2–3H); 3.90(s, 1H) (12βH); and 4.70(m,2H). The 12-hydrogen signal was displaced to δ 3.88 in benzene (5 c.p.s. downfield).

Anal. Calcd. for $C_{25}H_{39}NO_5$: C, 69.25; H, 9.07; N, 3.23. Found: C, 69.44; H, 9.15; N, 3.13. The hydrochloride of **3** had m.p. 203–206°, $[\alpha]_D$ +78° (*c*, 0.57); and ν_{max} (Nujol) 3510, 1735, 1716, and 1240 cm^{-1}.

Anal. Calcd. for $C_{25}H_{40}ClNO_5 \cdot H_2O$: C, 61.50; H, 8.62; N, 2.88. Found: C, 61.78; H, 9.01; N, 3.09.

12α-Acetamide-3α,20β-diacetoxy-5β-pregnan-11-one (3, R = Ac)

The aminoketone 3(R = H) was heated at 100° in 1:1 pyridine – acetic anhydride mixture for 2 h. The mixture was poured into water and the amide collected. After recrystallization from acetone – hexane it formed needles with m.p. 238–242°; $[\alpha]_D$ +135° (*c*, 0.76); λ_{max} 312 mμ (ε 147); and ν_{max} 3450, 1720, and 1680 cm^{-1}. Its n.m.r. spectrum had peaks at δ 0.70(s,3H); 1.18(d, J = 6.5 c.p.s., 3H); 1.23(s,3H); 2.04 (s,6H); 2.10(s,3H); 4.00(d, J = 7 c.p.s., 1H); 4.70(m,2H); and 5.92(broad, 1H).

Anal. Calcd. for $C_{27}H_{41}NO_6$: C, 68.18; H, 8.69; N, 2.95. Found: C, 67.94; H, 8.77; N, 2.87.

The *N*-acetyl ketone **3** (R = Ac) was recovered unchanged after 45 h in acetic acid containing boron trifluoride etherate. Hydrolysis of **3** (R = Ac) using 8% potassium hydroxide in refluxing 80% methanol – water gave a dihydroxy keto azide which crystallized as needles from chloroform, m.p. 240–243°. That this was 12α-acetamido-11-keto-5β-pregna-3α-20β-diol was shown by reacetylation to **3** (R = Ac). Hence the 12α configuration seems to be the stable one.

12α-Acetamido-3α,20β-diacetoxy-11β-hydroxy-5β-pregnane (4, R = H)

(*a*) A solution of 100 mg of azido ketone **2** and 200 mg of lithium aluminum hydride in 30 ml of ether was refluxed for 5 h. The product was acetylated at room temperature in 1:1 acetic anhydride – pyridine during 16 h. The mixture was poured into water and the product collected. It was purified by chromatography on a 20 fold ratio of neutral alumina of activity II. The fraction eluted with chloroform formed prisms (41 mg) from ether – hexane with m.p. 254–258°. This had $[\alpha]_D$ +137° (*c*, 0.75); and ν_{max} 3450, 1720, 1678, and 1720 cm^{-1}. Its n.m.r. spectrum had signals at δ 1.00(s,3H); 1.13(3H, d, J = 7.5 c.p.s.); 1.17(s,3H), 2.01(s,3H); 2.05(s,6H); 2.56(s,2H, disappearing when D_2O added); 3.91; 4.00(2H, collapsing to a signal at δ 3.91 when D_2O added); and 4.75 (multiplet, 2H).

Anal. Calcd. for $C_{27}H_{43}NO_6$: C, 67.89; H, 9.07; N, 2.93. Found: C, 67.99; H, 9.19; N, 3.07.

(*b*) A solution of 245 mg of aminoketone **3**(R = H) and 204 mg of lithium aluminum hydride in 30 ml of ether was refluxed for 3 h. The product was acetylated at room temperature in 1:1 acetic anhydride – pyridine (2 ml) during 16 h. The acetate was recrystallized from ether to give 185 mg of prisms m.p. 254–258°. This proved identical to the product from (*a*).

12α-Acetamido-3α,11β,20β-triacetoxy-5β-pregnane (4, R = Ac)

The hydroxyamide **4**(R = H) (62 mg) was fully acetylated by treatment with acetic anhydride (1 ml) containing 15 mg of *p*-toluenesulfonic acid monohydrate for 16 h at room temperature. The crude product was adsorbed from hexane on 1 g of neutral alumina (activity I–II). Benzene eluted 51 mg of a colorless gum which was homogeneous according to t.l.c. and its n.m.r. spectrum. It had $[\alpha]_D$ +105° (*c*, 0.66); and ν_{max} 3450, 1720, and 1680 cm^{-1}. Its n.m.r. spectrum had peaks at δ 0.90 (s,3H); 0.96(s,3H); 1.12(d, J = 6.5 c.p.s., 3H); 2.04(s,6H); 2.07(s,6H); 4.12(q, J_1 = 9 c.p.s., J_2 = 2.5 c.p.s. which collapsed to a doublet with J = 2.5 c.p.s. when D_2O and *p*-toluenesulfonic acid were added); 4.75(multiplet, 2H); 5.04 (multiplet, 1H, $w_{\frac{1}{2}}$ 6 c.p.s.); and 5.65 (broad doublet, J = 9 c.p.s., which disappeared when D_2O and *p*-toluenesulfonic acid were added). A sample was distilled at 180°, 1 × 10^{-3} mm.

Anal. Calcd. for $C_{29}H_{45}NO_7$: C, 67.02; H, 8.73. Found: C, 66.80; H, 8.56.

Deamination of 3(R = H)

1. Protic Solvents

(*a*) Sodium nitrite (1.43 g) was added to a solution of the hydrochloride of **3** (R = H) (566 mg) in 50 ml of 3% hydrogen chloride in methanol at 5 °C. After 1.5 h stirring at 5°, the mixture was diluted with water and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

product (426 mg) extracted into chloroform and the organic layer washed with sodium carbonate solution. Its u.v. and i.r. spectra showed the absence of conjugated ketone. The n.m.r. spectrum had no signals above δ 0.9. The product was adsorbed onto 15 g of alumina (activity III) from hexane. Hexane eluted 15 mg of dienone **14** (λ_{max} 290 mμ, ν_{max} 1660 and 1650 cm^{-1}) and 39 mg of a mixture of **14** and enones **13** and **16**. More hexane and 10–50% benzene in hexane eluted 165 mg of a mixture of enones **13** and **16**. Benzene eluted 150 mg of hydroxylic products (ν_{max} 3470, 1740, 1720 (shoulder), 1670, and 1555 cm^{-1}) and chloroform eluted 57 mg of similar material. The enone mixture had $\nu_{max}(CCl_4)$ 1740 (OAc), 1710, 1668, 1650, and 1635 cm^{-1}. The ratio of **13** to **16** was estimated from this spectrum to be 3–4:1. Extensive chromatography of this mixture on alumina failed to separate these.

(*b*) A solution of 597 mg of sodium nitrite in 5 ml of water was added to a solution of 180 mg of the hydrochloride of **3**(R = H) in 15 ml of 30% water in acetic acid at 0°. The mixture was stirred at 0° for 1 h, then diluted with water, and extracted with methylene chloride. The organic layer was washed with sodium carbonate solution and water, dried, and distilled, giving 163 mg of product. No conjugated ketone was present (i.r. and u.v. spectra) and its n.m.r. spectrum had no signal above δ 0.9. Chromatography on alumina as for (*a*) separated a 25% yield of the mixed enones **13** and **16**.

2. In Aprotic Solvents

(*a*) Isoamyl nitrite (0.5 ml) was added to a solution of 250 mg of the hydrochloride of **3**(R = H) in 10 ml of chloroform. After 30 min the solvent was removed under reduced pressure. The residue had ν_{max} 1665 and 1650 cm^{-1} corresponding to a cyclohexenone. This was adsorbed on 5 g alumina, activity IV. Hexane – benzene (1:1) eluted 175 mg of crystalline solid. When recrystallized from acetone – hexane this gave 128 mg of needles, m.p. 160–163° identified as **13**. Benzene eluted nothing, while chloroform eluted 45 mg of a complex mixture.

(*b*) One ml of amyl nitrite was added to a solution of 210 mg of **3**(R = H) in 10 ml of benzene containing 0.1 ml of acetic acid. After 30 min at room temperature the solvent was removed *in vacuo*. The residue had absorption characteristic of a cyclopentenone (ν_{max} (CCl_4) 1710 and 1636 cm^{-1}). Chromatography on 4 g of florisil (60–100 mesh) and elution with benzene gave 140 mg of a crystalline compound. Recrystallization from acetone – hexane gave 102 mg of needles m.p. 166–168°, which was characterized as **16**.

(*c*) A solution of **3**(R = H) (66 mg) in 5 ml of benzene to which was added 0.5 ml of isoamyl nitrite was left at room temperature for 10 min. The i.r. spectrum of the mixture showed the pressure of diazo ketone (ν_{max} 2090 cm^{-1}). After 1 h this band had disappeared. Chromatography as for (*b*) gave 41 mg of the conjugated enone **16**.

(*d*) To a solution of 70 mg of **3**(R = H) in 5 ml of benzene containing 150 mg of powdered calcium carbonate was added 0.5 ml of isoamyl nitrite. Nitrogen evolution appeared slow, hence the mixture was left overnight. Evaporation of the solvent and adsorption on 7 g of florisil (60–100 mesh) and elution with benzene gave 51 mg of crystalline solid. On recrystallization from acetone – hexane, this gave 30 mg of **16**.

(*e*) Isoamyl nitrite (1.5 ml) was added to a suspension of 415 mg of the hydrochloride of **3**(R = H) in 30 ml of benzene. After 3 h stirring the solution became clear. The solvent was evaporated under reduced pressure, then the residue adsorbed on 5 g of neutral alumina (grade IV). A 1:1 mixture of hexane – benzene eluted 345 mg of crystalline solid which by its i.r. spectrum appeared to be an approximately 1:1 mixture of **13** and **16**. This could only partially be separated by chromatography on alumina.

3α,20β-Diacetoxy-12-methyl-18-nor-5β-pregn-12-en-11-one (13)

This crystallized from acetone – hexane as needles with m.p. 160–163°, $[\alpha]_D$ −42° (*c*, 0.56); λ_{max} 250 mμ (ε 11 200); and ν_{max} (CCl_4) 1738, 1665, 1650, and 1245 cm^{-1}. Its n.m.r. spectrum had signals at δ 1.00(3H singlet); 1.13(3H doublet, $J = 7$); 1.85(3H, broad singlet); 2.02(6H, singlet); 4.75(1H, multiplet); and 5.26(1H, multiplet).

Anal. Calcd. for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71. Found: C, 72.25; H, 8.89.

The compound was only hydrolyzed by hydrogen peroxide and potassium hydroxide in methanol.

3α,20β-Diacetoxy-12-methyl-18-nor-5β-pregnan-11-one

A solution of 55 mg of **13** in 5 ml of acetic acid was hydrogenated over platinum from 31 mg of Adam's catalyst at one atm during 3 h. A benzene solution of the product was filtered through 1 g of alumina. Evaporation of the benzene left 40 mg of colorless gum with $[\alpha]_D$ +3° *c*, 0.55); and ν_{max} 1730 and 1710 (shoulder) cm^{-1}. It gave n.m.r. signals at δ 0.98(3H, singlet); 1.17(3H, doublet, $J = 7$); 1.21(3H, doublet, $J = 7$); 2.00(3H, singlet); 2.01(3H, singlet); and 4.75(2H, multiplet).

Anal. Calcd. for $C_{25}H_{38}O_5$: C, 71.74; H, 9.15. Found: C, 71.55; H, 9.01.

3α,20β-Diacetoxy-13,14-seco-12,14-cyclo-5β-pregn-12-en-11-one (16)

This crystallized from acetone – hexane as needles with m.p. 166–168°, $[\alpha]_D$ −25° (*c*, 1.21); λ_{max} 252 mμ (ε 14 500); and ν_{max} (CCl_4) 1740, 1710, 1636, and 1245 cm^{-1}. It gave n.m.r. signals at δ 0.97(3H, singlet); 1.10(3H, doublet, $J = 7$); 2.00(3H, singlet); 2.03(3H, singlet); 2.20(3H, broad singlet); 4.75(1H, multiplet); and 5.26(1H, multiplet).

Anal. Calcd. for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71. Found: C, 72.00; H, 8.81.

3α,20β-Diacetoxy-13,14-seco-12,14-cyclo-5β-pregnan-11-one

A solution of 22 mg of **16** in 5 ml of acetic acid was hydrogenated over platinum from 21 mg of Adam's catalyst under 1 atm for 3 h. The residue after filtration and removal of the solvent was dissolved in benzene. The solution was passed through a short column of alumina. The product crystallized from acetone – hexane as needles with m.p. 175–177°, $[\alpha]_D$ +17° (*c*, 0.70); and ν_{max} (CCl_4) 1745 and 1735 cm^{-1}. It gave n.m.r. signals at δ 0.70(3H, doublet, $J = 7$); 0.98(3H, singlet); 1.21(3H, doublet, $J = 7$); 2.00(6H, singlet); and 4.75(2H, multiplet).

Hydrolysis of the diacetate with potassium hydroxide in methanol gave the corresponding diol. It separated from acetone – hexane as needles with m.p. 216–217°, ν_{max}($CHCl_3$) 3600 and 1724 cm^{-1} and $[\alpha]_D$ −14° (*c*, 0.23).

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Found: C, 75.36; H, 10.37.

*3α-Acetoxy-12-methyl-19-nor-5β-pregna-12,17(20)-dien-11-one (**14**)*

This was not obtained crystalline (see deamination 1*a*). It had λ_{max} 290 mμ and ν_{max}($CHCl_3$) 1660 and 1650 cm^{-1}. Its n.m.r. spectrum had signals at δ 1.03(3H, singlet); 1.77(3H, broad singlet); 2.03(3H, broad singlet); 4.75(1H, multiplet); and 6.17(1H, multiplet).

*3α-Hydroxy-12-methyl-18-nor-5β-androst-12-en-11-one (**15**)*

A solution of 115 mg of **13** in 20 ml of 10% potassium hydroxide in methanol was refluxed overnight. The methanol was evaporated then the residue taken up in water and chloroform. The chloroform extracted 105 mg of gum which was adsorbed from benzene onto 3 g of alumina, activity IV. Benzene eluted 50 mg of semi-crystalline product. When recrystallized from hexane this gave 27 mg of needles m.p. 75–79°. It had λ_{max} 248 mμ (ε 12 000); and ν_{max} 1650 and 1630 cm^{-1}. Its n.m.r. spectrum had signals at δ 1.01(3H, singlet); 1.65 (3H, broad singlet); and 3.60(1H, broad multiplet).

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.12; H, 9.79. Found: C, 78.79; H, 9.56.

Attempted Aromatization of Ring C

Crude non-conjugated ketone (210 mg) from deamination of **3**(R = H) in 50% acetic acid using nitrous acid, and 110 mg of dichlorodicyanobenzoquinone in 20 ml of benzene was refluxed for 20 h. No reaction took place according to t.l.c. and the i.r. spectrum of the recovered steroid.

3β,20β-Diacetoxy-9β,11β-oxido-5α-pregnane (7)

N-Bromosuccinimide (516 mg) was added over 10 min to an ice-cold solution of 3β,20β-diacetoxy-5α-pregn-9(11)-ene (**5**) (976 mg) in 7 ml of dioxane and 2 ml of 0.2 *M* perchloric acid. The mixture was stirred for a further 30 min at 5 °C. Saturated sodium hydrogen sulfite (0.5 ml) was added, then the product extracted into ether. After washing with water, then drying over magnesium sulfate the ether was evaporated leaving a pale yellow gum. This was dissolved in 30 ml of acetone, 2 g of fused potassium acetate added, and the mixture refluxed for 17 h. The solvent was removed, the residue suspended in water, and the product extracted into ether. The gum recovered from the ether was adsorbed from hexane onto 15 g of alumina, activity III. Hexane (600 ml) eluted the β-oxide which crystallized as needles from acetone – hexane. Yield 532 mg, m.p. 150–152°, $[\alpha]_D$ +37° (*c*, 0.53); ν_{max}(CCl_4) 1740 and 1250 cm^{-1}. It gave n.m.r. signals at δ 0.83(3H, singlet); 1.00(3H, singlet); 1.13(3H, doublet); 2.00(3H, singlet); 2.02(3H, singlet); 3.38(1H, $w_{\frac{1}{2}}$ 5 c.p.s.); and 4.75(2H, multiplet).

9α-Azido-3β,20β-diacetoxy-11β-hydroxy-5α-pregnane (8)

A solution of 22 g of the β-oxide **7** and 23 g of lithium azide in 400 ml of dry dimethylformamide was heated at 155° for 25 h under nitrogen. The cooled mixture was diluted with water and extracted with ether. The ether solution was washed with water, dried, and distilled. The oily residue was acetylated using 400 ml of pyridine and 50 ml of acetic anhydride for 15 h at room temperature. The product crystallized from *n*-hexane giving 11 g of azido alcohol m.p. 180–185°. The mother liquor was adsorbed from hexane onto 250 g of alumina, activity IV. Hexane eluted 1.9 g of unchanged β-oxide. The benzene eluate (500 ml) crystallized from hexane giving 5.2 g of azido alcohol.

The azido alcohol was recrystallized from hexane to give needles, m.p. 183–186° with $[\alpha]_D$ +103° (*c*, 0.82); and ν_{max}($CHCl_3$) 3600, 2100, 1725, and 1250 cm^{-1}. It gave n.m.r. signals at δ 0.90(3H, singlet); 1.17(3H, doublet, J = 7 c.p.s.); 1.21(3H, singlet); 2.01, 2.05(3H, singlets); 4.33(1H, multiplet $w_{\frac{1}{2}}$ 7 c.p.s.); and 4.75(2H, multiplet).

Anal. Calcd. for $C_{25}H_{39}N_3O_5$: C, 65.05; H, 8.52; N, 9.10. Found: C, 64.92; H, 8.70; N, 9.31.

*9α-Azido-3β,20β-diacetoxy-5α-pregnan-11-one (**9**)*

(*a*) To a solution of 2.06 g of azido alcohol **8** in 25 ml of acetone at 5 °C was added 2.5 ml of Jones' reagent (21). After 2.5 h at this temperature the excess reagent was destroyed using ethanol. The product was isolated by dilution with water and extraction into ether. It was adsorbed from hexane onto 15 g of alumina, activity IV. Hexane eluted 382 mg of the desired keto azide. The products eluted with the benzene had no azide absorption in their i.r. spectra.

(*b*) Azido alcohol **8** (4.71 g) in 31 ml of dry dimethyl sulfoxide and 20 ml of acetic anhydride were maintained at 90° for 72 h. The mixture was poured into ice water and the product extracted into ether. The ether solution was washed with 5% sodium bicarbonate solution then with water, dried, and distilled. By crystallization from hexane, and chromatography of the mother liquors on alumina (activity IV) this was separated into 1.49 g of azido ketone **9** and 2.7 g of azido alcohol.

(*c*) In a comparable experiment to (*b*), but run at room temperature for 3 weeks, 5.02 g of azido alcohol gave 2.01 g of azido ketone **9** and 2.45 g of unchanged azido alcohol.

The azido ketone crystallized as prisms from hexane; m.p. 197–199°; $[\alpha]_D$ +123° (*c*, 0.73); ν_{max}($CHCl_3$) 2095 and 1725 cm^{-1}. It gave n.m.r. signals δ 0.65(3H, singlet); 1.10 (3H, singlet); 1.17(3H, doublet); 2.02; 2.07(3H, singlets); 2.54(2H, singlet); and 5.20(2H, multiplet).

The base gave a hydrochloride which crystallized from acetone – ether as prisms m.p. 163–165°, recrystallizing as needles and remelting at 197–198°. It had $[\alpha]_D$ +62° (*c*, 0.84).

Anal. Calcd. for $C_{25}H_{40}ClNO_5$: C, 63.89; H, 8.52; N, 2.98. Found: C, 64.02; H, 8.69; N, 3.13.

Deamination of ***10***

(*a*) To a solution of 733 mg of **10** in 40 ml of acetic acid and 20 ml of water was added a solution of 4.42 g of sodium nitrite in 20 ml of water—all at 0 °C. The solution was stirred at 0° for 3 h, then poured into ice water, and extracted with ether. The ether solution was washed with aqueous bicarbonate solution then water, dried, and distilled. The 698 mg of gummy residue was adsorbed from benzene onto 11 g of alumina (activity II). Elution with benzene (100 ml) gave 530 mg of crude crystalline olefin **18**. Methylene chloride and methylene chloride – methanol (20:1) eluted 116 mg of crude alcohol **19**.

(*b*) Isoamyl nitrite (358 mg) in 5 ml of benzene was added to a solution of 440 mg of **10** in 20 ml of benzene containing 60 mg of acetic acid. The mixture was maintained at 60–65° for 30 min. A further 0.13 g of isoamyl nitrite was added and the heating continued for 2.5 h. The solvent was evaporated *in vacuo*. The crystalline residue was recrystallized from hexane to give 48 mg of pure olefin **17**. Chromatography of the mother liquors on 5 g of alumina (activity IV) and elution with 1:1 hexane – benzene gave 263 mg of a 1:1 mixture of **17** and **18** which could be separated in part by careful chromatography on a 200 fold ratio of alumina (activity IV). Benzene and methylene chloride eluted 48 mg of crude alcohol **19**.

(*c*) Isoamyl nitrite (323 mg) was added to a solution of 157 mg of **10** in 10 ml of benzene. The mixture was maintained at 60° for 30 min. Evaporation of the solvent left a crystalline residue which was shown by its n.m.r. spectrum to be a 1:1 mixture of olefins **17** and **18**.

*3β,20β-Diacetoxy-9β-methyl-19-norpregn-1(10)-en-11-one (**17**)*

This crystallized from hexane as plates, m.p. 183–186°, $[\alpha]_D$ +150° (*c*, 1.10); ν_{max}(Nujol) 1738, 1700, and 1255 cm^{-1}. It gave n.m.r. signals at δ 0.55(3H, singlet); 1.17(3H, doublet, J = 6); 1.25(3H, singlet); 2.05(6H, singlet); 4.83(2H, multiplet); and 5.25(1H, multiplet).

Anal. Calcd. for $C_{25}H_{36}O_5$ (mol. wt. 416): C, 72.08; H, 8.71. Found (mol. wt. (mass spectrum) 416): C, 71.81; H, 8.83.

*3β,20β-Diacetoxy-9β-methyl-19-norpregn-5(10)-en-11-one (**18**)*

This crystallized from acetone – hexane as prisms, m.p. 174–176°, $[\alpha]_D$ 138° (*c*, 1.15); ν_{max}($CHCl_3$) 1725, 1700, and 1250 cm^{-1}. It gave n.m.r. signals at δ 0.58(3H, singlet); 1.15 (3H, doublet); 1.32(3H, singlet); 2.03(6H, singlet); and 4.83 (2H, multiplet).

When **18** (105 mg) was heated for 2 h at 60° in 10 ml of 2.5% hydrochloric acid in ethanol under nitrogen, then the product reacetylated using 1:1 acetic anhydride – pyridine, unchanged **18** was recovered.

3β,20β-Dihydroxy-9β-methyl-19-norpregn-5(10)-en-11-one

A solution of diacetoxy olefin **18** (320 mg) in 20 ml of 2.5% potassium hydroxide in methanol was refluxed for 2 h. After removal of most of the solvent under reduced pressure and dilution with water, the product was extracted into chloroform. It crystallized from acetone – hexane as prisms (251 mg), m.p. 201–202°, $[\alpha]_D$ +119° (*c*, 0.58).

Anal. Calcd. for $C_{21}H_{32}O_5$: C, 75.86; H, 9.70. Found: C, 75.68; H, 9.90.

On reacetylation using 1:1 acetic anhydride – pyridine pure **18**, m.p. 175–177° was recovered.

*3β,20β-Diacetoxy-10α-hydroxy-9β-methyl-19-norpregnan-11-one (**19**)*

This crystallized from acetone – hexane as needles, m.p. 173–175°, $[\alpha]_D$ +91° (*c*, 0.94); ν_{max}($CHCl_3$) 3590, 1725, 1690, and 1250 cm^{-1}. It gave n.m.r. signal at 0.60(3H, singlet); 1.18(3H, doublet, J = 6 c.p.s.); 1.20 (3H, singlet); 2.07(6H, singlet); and 4.83(2H, multiplet).

Anal. Calcd. for $C_{25}H_{38}O_6$: C, 69.09; H, 8.81. Found: C, 69.07; H, 8.84.

Dehydration of ***19***

Thionyl chloride (0.1 ml) was added to a solution of 30 mg of **19** in 2 ml of pyridine. After standing at room temperature overnight the mixture was diluted with water and the product extracted into methylene chloride. The residue from evaporation of the solvent was adsorbed from benzene onto 1 g of alumina (activity IV). Benzene eluted 20 mg of quite pure crystalline solid. This was recrystallized from acetone – hexane to give needles m.p. 174–175°. It did not depress the m.p. of **17**, and their i.r. spectra in chloroform were identical.

*3β,20β-Diacetoxy-10β-hydroxy-9β-methyl-1α,11-oxido-19-nor-5α-pregn-11-ene (**21**)*

A solution of 108 mg of olefin **17** and 300 mg of *m*-chloroperbenzoic acid (74% peracid) in methylene chloride was left at 5° for 4 days. The acids were removed by a bicarbonate wash. The dried solvent was distilled leaving a gummy product. This was adsorbed from benzene onto 2 g of alumina (activity IV). Benzene eluted 80 mg of crystalline solid, m.p. 139–155°. This gave only one spot of t.l.c., but its n.m.r. spectrum was consistent with it being a nearly equimolar mixture of two epoxides.

The epoxide mixture (120 mg) in 5 ml of acetic acid was heated at 100° for 30 min. After removal of the acetic acid *in vacuo*, t.l.c. showed the presence of at least one major and two minor products. Preparative t.l.c. on silica gel plates and development by acetone – hexane (2:1) gave the major component (middle band) as a gum (63 mg). This crystallized from acetone – hexane as prisms, m.p. 132–135°, and analyzed low in carbon (water solvate ?); hence was sublimed for analysis and spectra. It had ν_{max}($CHCl_3$) 3600, 1740, 1670, and 1250 cm^{-1}, $[\alpha]_D$ +20° (*c*, 1.31); and n.m.r. signals at δ 0.80(3H, singlet); 1.17(3H, doublet, J = 6 c.p.s.); 1.28; 2.01 and

2.05(3H, singlets); 4.30(1H, quartet, $J_1 = 4$ and $J_2 = 2$ c.p.s.); 4.87(2H, multiplet); and 5.43(1H, singlet).

Anal. Calcd. for $C_{25}H_{36}O_6$: C, 69.42; H, 8.39. Found: C, 69.20; H, 8.22.

*20β-Hydroxy-9β-methyl-19-norpregna-1,3,5(10)-trien-11-one (**22**)*

(*a*) A solution of 90 mg of olefin **18** and 210 mg of *m*-chloroperbenzoic acid (74% peracid) in 5 ml of chloroform was left in the dark for 16 h. The mixture was diluted with methylene chloride, and the acids extracted into 10% sodium bicarbonate solution. The organic layer was washed with water, dried, and distilled. The residue (92 mg) was dissolved in 5% hydrogen chloride in ethanol, then stirred for 2 days at room temperature. The solvent was then removed *in vacuo* and the residue chromatographed on 1 g of alumina (activity IV). Benzene eluted 39 mg of crystalline solid. This crystallized from acetone – hexane as prisms, m.p. 201–203°, $[\alpha]_D$ 121° (*c*, 0.91); λ_{max} 260 (ε 428), 267 (ε 526), and 274 mμ (ε 494); $\nu_{max}(CHCl_3)$ 3600 and 1696 cm^{-1}. Its n.m.r. spectrum had peaks at 0.78(3H, singlet); 1.10(3H, doublet); 1.38(3H, singlet); 3.68(1H, multiplet); and 6.75–7.20(4H, multiplet).

Anal. Calcd. for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03. Found: C, 80.64; H, 9.11.

(*b*) Hydroxy enol ether **21** (48 mg) and 3 ml of concentrated hydrochloric acid in 10 ml of ethanol was stirred at room temperature for 3 days. The solvents were evaporated *in vacuo*, and the residue adsorbed from benzene onto 1 g of alumina (activity IV). Benzene eluted 23 mg of crystalline solid, proven by t.l.c., mixed m.p., and i.r. spectrum to be **22**.

Steroids and steroidases. VIII.[1] Further data on the preferred conformations of the cycloheptane rings of A-homosteroidketones

J. Bryan Jones and J. Malcolm Zander
Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received April 28, 1969

The data presented substantiate the conclusions reported previously (1) regarding the applicability of the Hendrickson (2, 3) cycloheptane-based conformational analytical procedure to A-homosteroidketones of the 5α- and 5β- androstane and estrane series. For such cycloheptan*one* derivatives (with no bulky substituents at C-1 to C-5 of ring A) the twist chair conformations with the carbonyl group in the axis or adjacent position appear to be 1–2 kcal mole^{-1} lower in strain energy than predicted from the direct Hendrickson analysis and of these two favored conformers, the former may well be marginally preferred in many cases.

Canadian Journal of Chemistry, 47, 3501 (1969)

Introduction

Previous conformational analyses of the cycloheptane rings of A-homosteroid-3- and 4-ketones showed that, for compounds such as **1**(*a–c*)–**4**(*a–c*), an equilibrium mixture of ring A conformers exists at room temperature and that the main contributors are the twist chairs[2] TC_3, TC_4, and possibly TC_{10} (1). Conformations TC_3 and TC_4 represent those twist chairs in which the carbonyl group is at the axis carbon, or adjacent to it, and of these two carbonyl locations, the previous data indicated that the axis carbon position might be very marginally favored. However, the evidence was not unequivocal, and furthermore, it did not enable the relative importance of TC_{10} to be estimated with any degree of certainty. The investigations described in this paper are an extension of the earlier study (1) and were undertaken in an attempt to define more accurately the conformational preference of the carbonyl group and to clarify the contribution made by TC_{10} to the room temperature equilibrium mixture.

The results reported previously (1) were obtained by application of the conformational analytical procedure described by Hendrickson (2) in 1963 for cycloheptanes. Subsequently Hendrickson has refined the values of the parameters to be used (3)[3] and our current work is based on the revised figures. However, the improved parameters now available do not require any revision of the earlier conclusions (1) and do not remove any of the uncertainties inherent in the application of a substituted cycloheptane-derived analytical procedure[4] to fused ring cycloheptan*one* systems.

As observed previously (1–3) it is difficult to make any quantitative prediction regarding the total effect of inserting a carbonyl group into the seven-membered ring although it is fairly clear that its introduction results in a lowering of the total strain energy. The major factors contributing to this reduction are: (*a*) a reduced torsional barrier for methylene groups adjacent to the carbonyl group (5) and (*b*) the elimination of certain R ↔ H and H ↔ H non-bonded interactions (*cf.* the 3-alkylketone effect (6)). The increased bond angle of the sp^2 carbon is not considered to have a serious effect since it is readily accommodated by an opening of the other bond angles at little energetic expense (2). Nevertheless this effect will distort the geometry of ring A to an unknown extent and accordingly the desirability of applying appropriate physical methods, such as optical rotatory dispersion (o.r.d.) and dipole moment determinations, to check the validity of the conformational predictions made remains unchanged (1).

In order to show how the revised parameters modify the previously calculated energy–pseudorotation functions a comparison of the two curves for the cycloheptane rings of the A-homoandrostanes **1**(*a, c*)–**4**(*a, c*) is reproduced in Fig. 1. This

[1]For Part VII, see ref. 11. Presented in part at the 50th Canadian Chemical Conference, Toronto, June 1967.

[2]The conformational analytical terms and notations used are as defined previously (1, 2).

[3]At about the same time Bixon and Lifson (4) also reported the results of their carefully designed calculations on cycloheptane. Although the energy differences quoted (3, 4) for the cycloheptane conformers are not identical, the deviations are not serious enough to affect the conclusions drawn in this paper.

[4]Discussions regarding the validity of applying this analytical procedure to such complicated systems are summarized in refs. 1–3.

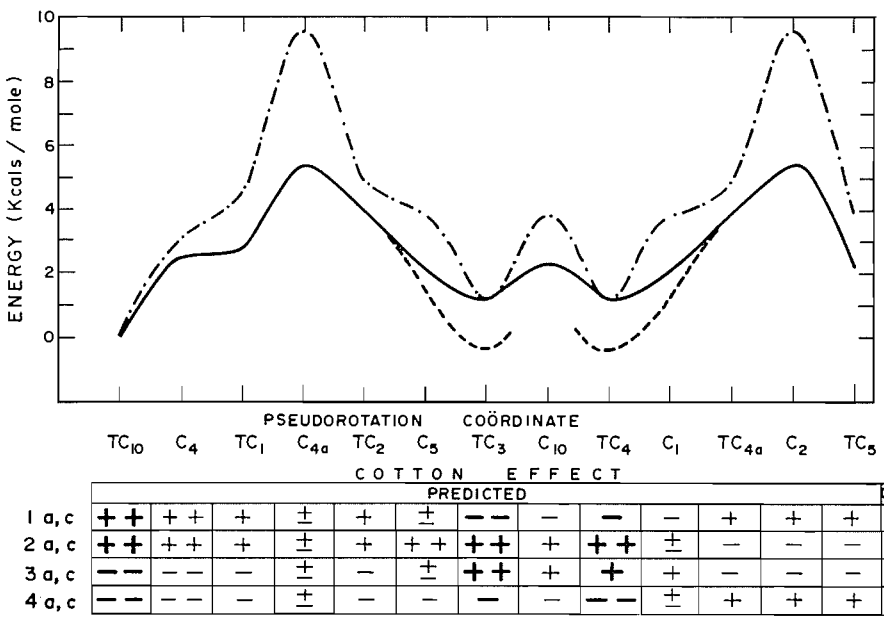

FIG. 1. A comparison of the energy functions calculated for the pseudorotation sequences of the cycloheptanone rings of **1**(*a–c*)–**4**(*a–c*) using the original (2) (—·—·—) and revised (3) parameters (———). These functions were obtained by considering **1**(*a–c*)–**4**(*a–c*) to be substituted cycloheptane derivatives. Previous data (1) have indicated that the introduction of a carbonyl group into the seven-membered ring causes TC_3 and TC_4 (the twist chairs with the carbonyl group at the axis and adjacent carbon respectively) to be reduced in energy by 1.4–2 kcal $mole^{-1}$ as indicated by the broken lines (— — — —). The predicted signs and relative magnitudes of the Cotton effects for each conformation of **1***a*, *c*–**4***a*, *c* were estimated from models (1). The predicted Cotton effects accentuated by heavy lines are those of the preferred conformations.

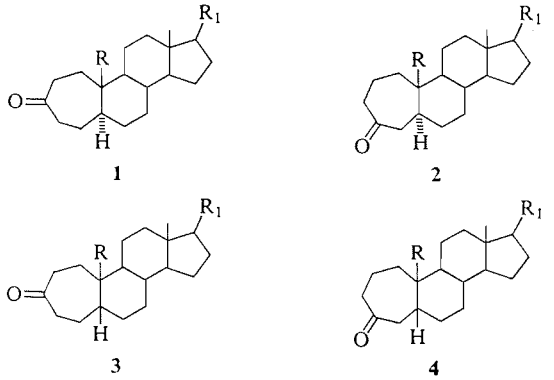
shows that although the old function exaggerated the energy differences by a factor of ~ 2, the preferred conformations predicted are identical using either set of parameters.

Results and Discussion

A-Homoandrostan-3-one and -4-one Derivatives

Previous attempts (1), including low temperature proton magnetic resonance (p.m.r.) spectroscopic analysis, to determine which of the three ring A conformations, TC_3, TC_4, and TC_{10}, of the series of compounds **1**(*a–c*)–**4**(*a–c*) was most preferred had shown that the energy differences involved were small and indicated that twist chairs with an axis carbonyl ($TC_{axis\ CO}$) to be marginally preferred over twist chairs with the carbonyl group adjacent to the axis carbon ($TC_{adj.\ CO}$). However, owing to the closely similar strain energies involved, the minimum temperature (−55°) attainable (due to solubility and instrumental limitations) with the p.m.r. method did not provide sufficient magnification of the conformational energy differences to enable a decision to be made with respect to TC_{10}. Attention was therefore turned to low temperature circular dichroism (l.t.c.d.) in an attempt to overcome the limitations of the p.m.r. technique.[5]



a R = CH_3, R_1 = OH
b R = CH_3, R_1 = =O
c R = CH_3, R_1 = H
d R = H, R_1 = OH
e R = H, R_1 = =O

DIAGRAM 1

[5]For A-homo-B-nor- and A-nor-B-homosteroids the p.m.r. method appears to allow less equivocal conclusions to be drawn (7).

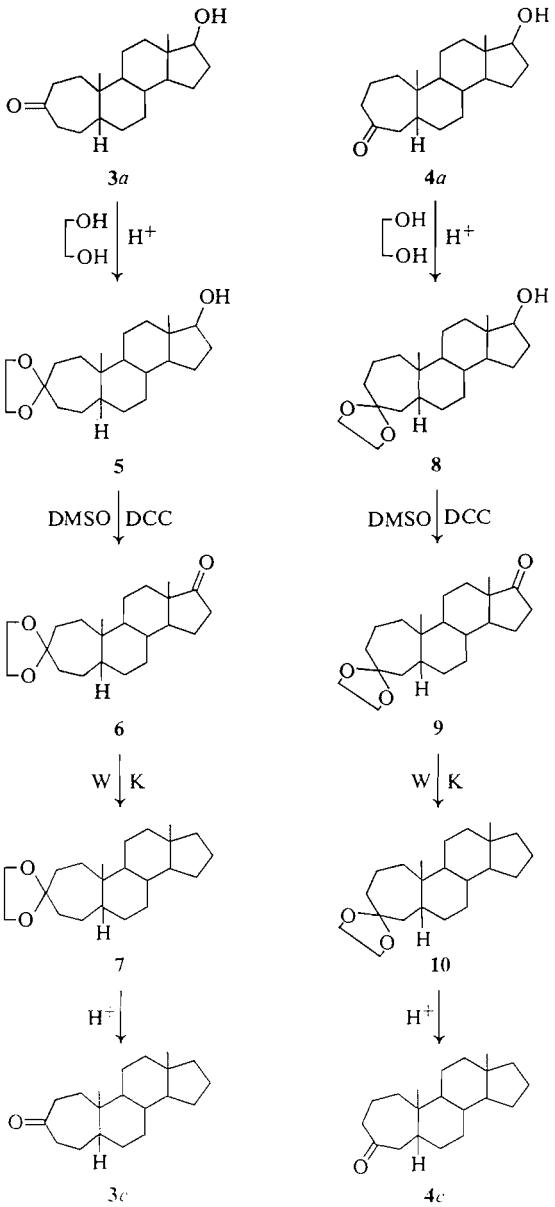

CHART 1

As the temperature of an A-homoketone solution is lowered, the sign and magnitude of its Cotton effect should become increasingly controlled by that of the most preferred conformer. Examination of the predicted and observed signs and relative magnitudes of the Cotton effect for TC_3, TC_4, and TC_{10} (see Fig. 1) showed that if the latter conformer was in fact the most preferred, then the observed Cotton effect should change from − to + for **1**(*a*, *c*) and from + to − for **3**(*a*, *c*) as it came to dominate the mixture. In contrast, if TC_3 and/or TC_4 were more preferred, none of the signs of the Cotton effects would be altered although their magnitude might well vary. The l.t.c.d. method was thus an attractive one since it was felt that the low temperatures (−190°) should ensure a dominant population of the most preferred conformer.

The C-17 oxygenated A-homoandrostanones employed in most of the previous work (1) proved too insoluble to permit satisfactory circular dichroism measurements at the low temperatures required. Accordingly the C-17 desoxy derivatives **1***c*–**4***c* were prepared as outlined for the 5β-series in Chart 1.

The l.t.c.d. spectra obtained are reproduced in Fig. 2 and as the curves show, in no case does the sign of the Cotton effect change in the temperature range +20 to −187° thereby indicating that TC_{10} is not selectively preferred. Closer examination of the spectral changes involved (see Table I) reveals that for **2***c*, **3***c*, and **4***c* the amplitude shifts observed are in a direction compatible with dominance by the conformer previously predicted (1) to be marginally preferred *viz.* the $TC_{axis\ CO}$ species. Unfortunately, for A-homo-5α-androstan-3-one (**1***c*) the positive shift observed is not consistent with the above rationale since the preference for the $TC_{axis\ CO}$ species (TC_3) should have manifested itself in a marked decrease in amplitude at low temperature. The only twist chair conformation compatible with the positive shift actually observed for **1***c* is TC_{10} but in view of the small magnitude of the changes[6] observed for this compound, and for **4***c* also, we would hesitate to place too heavy a weighting on the relevance of the l.t.c.d. amplitude shifts for these two compounds. Overall, however, the l.t.c.d. data do support the conclusion that for A-homoketones such as **1**(*a*–*c*)–**4**(*a*–*c*) the room

[6]Little effort has been put into developing a rationale for the anomalous shift observed for **1***c* since interpretations based on small changes in l.t.c.d. spectra are open to criticism for several reasons. For example, it is well known that differential solvation can cause marked amplitude changes (8) even in conformationally rigid systems. However, it is considered that the data reported in Table I are not due to changes in asymmetric solvation alone since similar results were obtained in two very different solvents, *viz.* methylcycloheptane–isopentane (1:3) (MI) and ether – isopentane – ethanol (5:5:2) (EPA). Furthermore the changes observed are significantly greater than those between the corresponding spectra of analogous six-membered ring A steroids in the same solvent systems (9; G. Snatzke, J. B. Jones, and J. M. Zander. Unpublished observations).

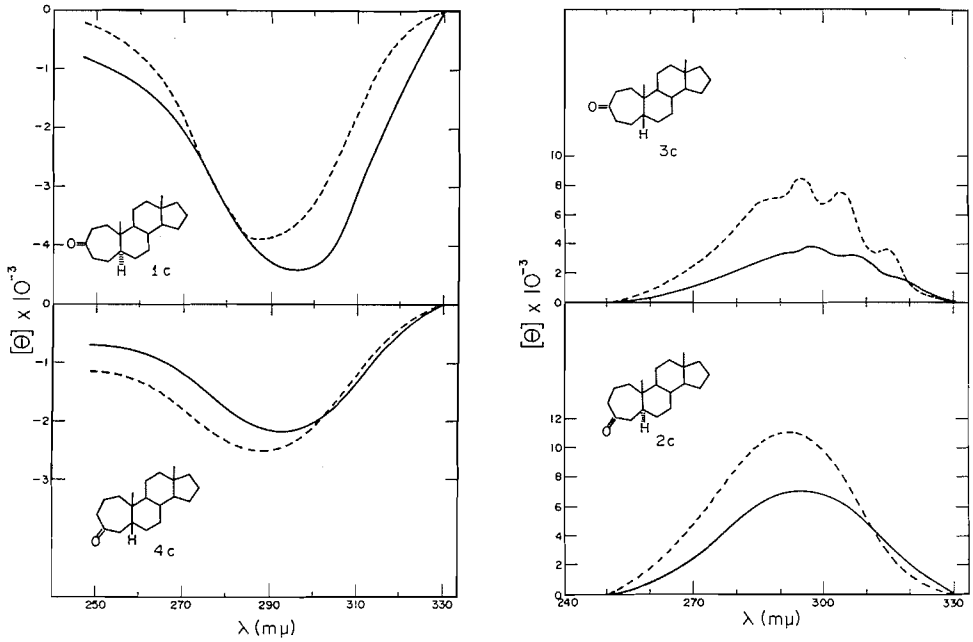

FIG. 2. Circular dichroism spectra at 20° (——) and −187° (— — — —) for solutions of **1***c*–**4***c* in methylcyclohexane–isopentane (1:3).

TABLE I

Correlation of the directions and magnitudes of circular dichroism amplitude shifts observed (Fig. 2) for **1***c*–**4***c* with the preferred twist chair conformations most compatible with the data

Compound	Temperature (°C)	$\Theta \times 10^{-3}$	$\Delta(\Theta_{-187} - \Theta_{+20})$	Most positive rotatory conformation	Most negative rotatory conformation
A-Homo-5α-androstan-3-one (**1***c*)	+20	−4.33	+0.5	TC_{10}	
	−187	−3.86			
A-Homo-5α-androstan-4-one (**2***c*)	+20	+7.03	+4.1	TC_4	
	−187	+11.12			
A-Homo-5β-androstan-3-one (**3***c*)	+20	+3.80	+4.8	TC_3	
	−187	+8.58			
A-Homo-5β-androstan-4-one (**4***c*)	+20	+2.18	−0.4		TC_4
	−187	+2.57			

temperature equilibrium mixtures are dominated by those twist chair conformations with the carbonyl at the axis or adjacent position, with the former probably marginally preferred.

The investigation was then extended to the A-homoestranones **1**(*d*, *e*)–**4**(*d*, *e*). The Hendrickson-derived energy-pseudorotation function for these compounds is reproduced in Fig. 3, and, as a comparison with the curve of Fig. 1 shows, the changes resulting from the absence of a C-10 methyl group are significant. Seven twist chairs are predicted to be equally preferred but in view of the previous evidence (1) that the carbonyl group at the axis or adjacent position reduces the strain energy by 1.4–2 kcal mole^{-1}, one or both of TC_3 and TC_4 should dominate the equilibrium

	COTTON EFFECT PREDICTED										OBSERVED
1 d	+		±		±		∓	−		±	+	− −
2 d	±		±		+		+	+	−		−	+ +
3 d	−		±		+		+	+		±	−	+
4 d	−		±		−		−	∓		+	+	− −

FIG. 3. Energy function for the A-homoestrane-3- and -4-ketones together with the signs and relative magnitudes of the Cotton effects predicted for each preferred conformation of the pseudorotation sequence of **1***d*–**4***d*. The dashed (— — — —) lines indicate the reduction in energy of 1–2 kcal mole^{-1} considered applicable to the most preferred $TC_{axis\ CO}$ and $TC_{adj.CO}$ conformations.

to the extent of > 90% (10). A comparison of the signs and magnitudes of the predicted and observed Cotton effects for each of the compounds **1**(*d*, *e*)–**4**(*d*, *e*) bears this out (see Fig. 3) since only for TC_3 and TC_4 are the data consistently in accord. In fact, when the octant rule projections are examined more closely, the agreements between prediction and observation are seen to be remarkably good and indicate that very small proportions of other conformers are present.

The relevant projections are shown in Fig. 4. For the 5α-A-homoestranes, **1**(*d*, *e*) and **2**(*d*, *e*) the $TC_{axis\ CO}$ and $TC_{adj.\ CO}$ contributors bear an almost perfect mirror image relationship to one another and the o.r.d. spectra of **1***d* and **2***d* reflect this dramatically (Fig. 5*a*).

For the 5β-compounds **3**(*d*, *e*) and **4**(*d*, *e*) the corresponding twist chairs have a similar, albeit somewhat distorted, mirror image relationship and again the o.r.d. curves of **3***d* and **4***d* (Fig. 5*b*) provide support for almost total dominance of the conformational mixture by these two species. However, in view of the difficulties involved in making such quantitative o.r.d. predictions (*cf.* footnote 18 of ref. 1) the excellence of agreement between the predicted and observed spectra may well be, in part, fortuitous.

The data on the A-homoandrostanes had indicated $TC_{axis\ CO}$ conformers to be somewhat more

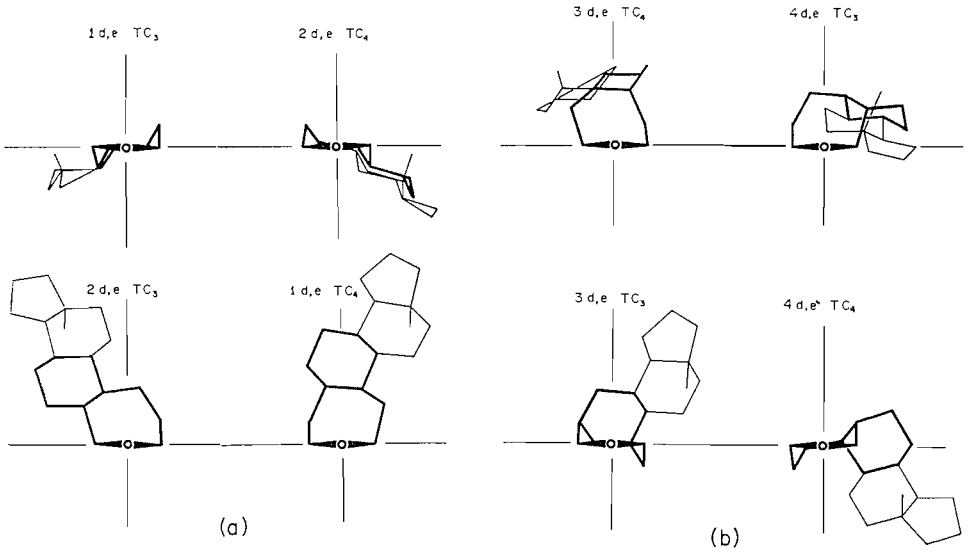

FIG. 4. Comparison of octant-rule projections for the TC_3 and TC_4 conformers of (*a*) A-homo-5α-estran-3- and -4-ones and (*b*) A-homo-5β-estran-3- and -4-ones. Rings A and B, whose atoms and substituents largely control the Cotton effect, are shown in heavy lines; C-17 substituents have been omitted.

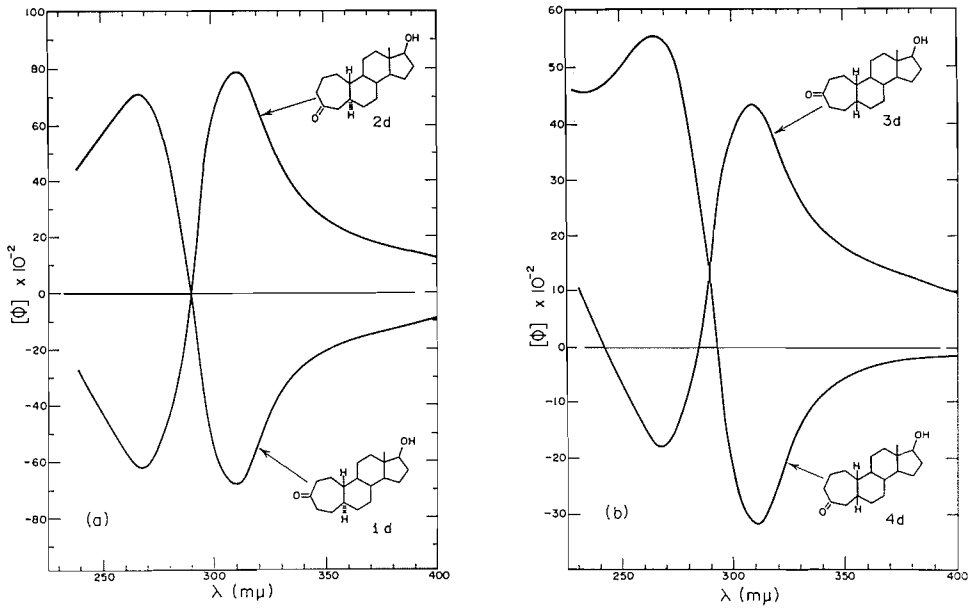

FIG. 5. Optical rotatory dispersion curves obtained in methanol solution for the A-homoestranones **1***d*–**4***d*.

preferred than $TC_{adj.\ CO}$ but the A-homoestrane o.r.d. curves did not give any indication as to which, if either, of the two was favored. In an attempt to clarify the situation the dipole moments of the A-homoestrane diketones **1***e*–**4***e* were determined and the experimental values compared with those predicted for the corresponding $TC_{axis\ CO}$ and $TC_{adj.\ CO}$ conformers.[7]

The data obtained are summarized in Table II and represented graphically in Fig. 6. Although the results are again not unequivocal, they do support the conclusion that $TC_{adj.\ CO}$ and $TC_{axis\ CO}$ are very close in energy and that the latter may well be somewhat favored. Furthermore a comparison of the current dipole moment results with the previous data for the A-homoandrostanes **1***b*–**4***b* (see Fig. 6) indicates that removal of the C-19 methyl group causes the $TC_{axis\ CO}$ conformer to become a slightly more important contributor as evidenced by the observed dipole moment differences between **1***b* and **1***e*, **3***b* and **3***e*, and **4***b* and **4***e*, respectively. Again there is one pair *viz.* **2***b* and **2***e* which does not fit in with this rationale. However, in this case neither of the observed dipole moments is large and it is conceivable that the experimental errors are significantly greater than they were estimated to be (1).

Thus although the l.t.c.d. and dipole moment results each contain one anomaly,[8] the total data now available indicate strongly that the Hendrickson (3) cycloheptane-based conformational analytical procedure is applicable to cycloheptan*one* derivatives provided that it is recognized that a 1–2 kcal mole^{-1} reduction in overall strain energy may well obtain for those twist chair conformations in which the carbonyl group is at the axis or adjacent position.

The original driving force which prompted our interest in this problem arose from the need for information on the preferred conformations of rings A of A-homosteroids as a prerequisite to their evaluation as substrates and inhibitors of a steroid C-1,2-dehydrogenase. In this regard the only conclusion which now seems pertinent is that the energy barriers between the various preferred conformers of the flexible cycloheptanone ring are so low that factors controlling the interaction of the molecule with the enzyme's active center will undoubtedly override many of the conformational analytical criteria developed

[7]The methods used to calculate the dipole moments of the various conformers were as described previously (1).

[8]Unfortunately the anomalies are not of the same series in both cases and it has not proved possible to provide one rationale to account for both deviations.

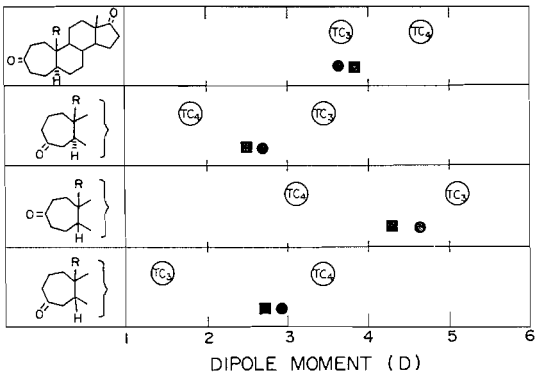

FIG. 6. Comparison of the dipole moments observed ■ (R = CH_3), ● (R = H) for the A-homodiketones **1***b*–**4***b* and **1***e*–**4***e*, respectively with the values calculated for the preferred $TC_{axis\ CO}$ and $TC_{adj.CO}$ conformations.

above and there appears to be little hope that such criteria would be of value in helping to predict the shape of ring A of the A-homosteroids in any enzyme–substrate or enzyme–inhibitor complexes.

Biological testing of a selection of the A-homosteroids prepared in this and previous investigations (1, 11) is in progress.

Experimental

The criteria of purity applied to the A-homosteroids, the analytical instrumentation used, the specifications of the chromatographic supplies, solvents, evaporation methods etc. were as described previously (11). The low temperature circular dichroism data reported in Fig. 2 and Table I were obtained on a Roussel-Jouan Dichrograph.

Compounds

Unless described below the A-homosteroids used in this investigation were prepared as reported in refs. 11 and 12.

*A-Homo-5β-androstan-3-one (**3***c*)*

A solution of 17β-hydroxy-A-homo-5β-androstan-3-one (1.39 g), toluene-*p*-sulfonic acid monohydrate (125 mg), and ethane-1,2-diol (3.0 g) in benzene (110 ml) was refluxed, with magnetic stirring, in a Dean–Stark apparatus for 4 h with periodical withdrawal of the benzene in the side arm. The cooled benzene solution was then washed successively with 10% aqueous sodium carbonate (50 ml) and water (50 ml) and was then dried ($MgSO_4$) and evaporated. The residue (1.6 g) was chromatographed on Florisil (70 g, column packed in *n*-hexane). Elution with ether–*n*-hexane (1:15) gave *3,3-ethylenedioxy-A-homo-5β-androstan-17β-ol* (**5**), which was then obtained as prisms (1.41 g) from *n*-hexane, m.p. 150–151°; infrared (i.r.) ($CHCl_3$): ν_{max} 3600, 1105, and 945 cm^{-1}; p.m.r. ($CDCl_3$): δ 0.72 (3H, s), 0.94 (3H, s), 1.97 (1H, s), and 3.90 (4H, s) p.p.m.; $[\alpha]_D^{23.5}$ +32° (*c*, 1.2 in $CHCl_3$).

A solution of the ketal **5** (1 g), pyridinium trifluoroacetate (316 mg) and dicyclohexylcarbodiimide (2.02 g) in dimethyl sulfoxide (16 ml) (13) was stirred at 55° for 2 h and was then poured into ether (100 ml). The ethereal solution was filtered, washed with water (50 ml), and then dried ($MgSO_4$) and evaporated, and the residue was digested with boiling *n*-hexane (50 ml) for 15 min. The hexane solution was then filtered, concentrated, and applied to a chromatographic column of Florisil (50 g, prepared in *n*-hexane). Elution with *n*-hexane removed the excess dicyclohexylcarbodiimide and further elution with ether–*n*-hexane (1:13) afforded *3,3-ethylene-dioxy-A-homo-5β-androstan-17-one* (**6**), which was then obtained as prismatic needles (833 mg) from *n*-hexane, m.p. 173.5–175°; i.r. ($CHCl_3$): ν_{max} 1725, 1105, and 945 cm^{-1}; p.m.r. ($CDCl_3$): δ 0.87 (3H, s), 0.98 (3H, s), and 3.92 (4H, s) p.p.m.; o.r.d. (*c*, 0.004 in iso-octane): $[\phi]_{326}$ +8700°, $[\phi]_{282}$ −7000° (*a* = +157).

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.26; H, 9.89. Found: C, 76.13; H, 10.05.

The above oxo-ketal **6** (700 mg), potassium hydroxide (1.4 g), and 99% hydrazine hydrate (3.4 ml) were dissolved in diethylene glycol (14 ml) and the solution was refluxed under a nitrogen atmosphere for 3 h. The condenser was then removed and the bath temperature raised gradually to 195° and maintained at this level for 5 h. The mixture was then poured into water (150 ml) and the precipitate filtered and washed with water until the washings were neutral. The dried crude product (637 mg, m.p. 123–123.5°) was dissolved in ether – methanol – 2*N* hydrochloric acid (65 ml, 2:10:1) and the solution was stirred at 25° for 30 min, following which it was poured into water (600 ml), and the mixture extracted with ether (6 × 50 ml). The combined ether extracts were washed with water (50 ml), dried ($MgSO_4$), and evaporated. The oil obtained was chromatographed on Florisil (25 g, prepared in *n*-hexane); ether–*n*-hexane (1:13) elution yielded *A-homo-5β-androstan-3-one* (**3***c*) which was purified by recrystallization from petroleum ether (b.p. 40–60°) followed by sublimation at 100°/0.2 Torr. The pure product (600 mg) had m.p. 51.5–52°; i.r. ($CHCl_3$): ν_{max} 1690 cm^{-1}; p.m.r. ($CDCl_3$): δ 0.70 (3H, s) and 1.03 (3H, s) p.p.m.; o.r.d. (*c*, 0.004 in iso-octane): $[\phi]_{322}$ +3200°, $[\phi]_{310}$ +3300°, $[\phi]_{273}$ −1800° (*a* = +52); (*c*, 0.004 in methanol): $[\phi]_{303}$ +4200°, $[\phi]_{268}$ −2700° (*a* = +69).

Anal. Calcd. for $C_{20}H_{32}O$: C, 83.28; H, 11.18. Found: C, 83.55; H, 11.10.

*A-Homo-5β-androstan-4-one (**4***c*)*

This compound was prepared from 17β-hydroxy-A-homo-5β-androstan-4-one (**4***a*) by a route exactly similar in all details to that described above for **3***c*.

17β-Hydroxy-A-homo-5β-androstan-4-one (680 mg) yielded *4,4-ethylenedioxy-A-homo-5β-androstan-17β-ol* (**8**), as prisms (613 mg) from *n*-hexane, m.p. 134.5–135°; i.r. ($CHCl_3$): ν_{max} 3600, 1100, and 945 cm^{-1}; p.m.r. ($CDCl_3$): δ 0.72 (3H, s), 0.92 (3H, s), 1.91 (1H, s), and 3.90 (4H, s) p.p.m.

Anal. Calcd. for $C_{22}H_{36}O_3$: C, 75.82; H, 10.41. Found: C, 75.47; H, 10.28.

On oxidation with dicyclohexylcarbodiimide – dimethyl sulfoxide – pyridinium trifluoracetate, the above ketal **8** (500 mg) afforded *4,4-ethylenedioxy-A-homo-5β-androstan-17-one* (**9**) which was obtained as prismatic needles

*A-Homo-5α-and 5β-estranediones (**1***e*–**4***e*)*

These compounds were prepared by standard Jones' oxidation (14, *cf.* ref. 12) of the corresponding 17β-hydroxyestranes prepared as described previously (11). The yields and physical characteristics of the diones obtained were:

A-Homo-5α-estran-3,17-dione (**1***e*) (87%), was obtained as prisms from petroleum ether (b.p. 60–70°), m.p. 122–122.5°; $[\alpha]_D^{19}$ +16° (*c*, 1.5 in $CHCl_3$); p.m.r. ($CDCl_3$): δ 0.87 (3H, s) p.p.m.

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.12; H, 9.79. Found: C, 79.29; H, 9.81.

A-Homo-5α-estran-4,17-dione (**2***e*) (87%), was obtained as rhombs from petroleum ether (b.p. 60–70°), m.p. 140°; $[\alpha]_D^{19}$ +255° (*c*, 1 in $CHCl_3$); i.r. ($CHCl_3$): ν_{max} 1730 and 1695 cm^{-1}; p.m.r. ($CDCl_3$): δ 0.87 (3H, s) p.p.m.

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.12; H, 9.79. Found: C, 79.33; H, 9.91.

A-Homo-5β-estran-3,17-dione (**3***e*) (80%), was obtained as prisms from petroleum ether (b.p. 40–60°) m.p. 111–111.5°; $[\alpha]_D^{23}$ +465°; (*c*, 1.5 in $CHCl_3$); i.r. ($CHCl_3$): ν_{max} 1730 and 1695 cm^{-1}.

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.12; H, 9.79. Found: C, 79.25; H, 9.91.

A-Homo-5β-estran-4,17-dione (**4***e*) (75%), was obtained as needles from petroleum ether (b.p. 40–60°), m.p. 135–136°, $[\alpha]_D^{23}$ +111° (*c*, 1.1 in $CHCl_3$); i.r. ($CHCl_3$): ν_{max} 1730 and 1695 cm^{-1}.

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.12; H, 9.79. Found: C, 79.27; H, 9.91.

Dipole moments of the diketones **1***e*–**4***e* were obtained by the procedure outlined in ref. 1 and the relevant data are summarized in Table II and Fig. 6.

Acknowledgments

Financial support by the National Research Council of Canada and the award (to J.M.Z.) of a University of Toronto Open Fellowship are gratefully acknowledged. We also express our appreciation to Dr. G. F Wright and Mr. H. Huber for providing the dipole moment measurement facilities and to Dr. G. Snatzke for the low temperature circular dichroism data and for helpful discussion.

Sur quelques réactions acide-base dans les solvants fortement basiques anhydres. II. Les amino-2 éthylamidures de sodium et de potassium

W. R. HEUMANN, A. BOUCHARD, ET L. ŠAFAŘÍK
Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 13 mai, 1969

Des solutions d'amino-2 éthylamidure de sodium dans l'éthylènediamine anhydre ont été préparées par dissolution d'amidure de sodium ammoniacal $NaNH_2$ dans l'éthylènediamine anhydre et élimination de l'ammoniac formé par le vide. Lorsque ces solutions sont préparées et gardées sous atmosphère d'azote ne contenant pas plus que 5 p.p.m. d'oxygène et 1 p.p.m. d'humidité environ, elles sont incolores et stables. L'amidure pur se sépare de la solution par addition de benzène sous forme d'une poudre blanche grisâtre également stable sous azote pur. L'amino-2 éthylamidure de potassium, qui a été préparé de la même façon en faisant réagir l'hydrure de potassium sur l'éthylènediamine, ressemble à celui de sodium. Le produit pur cristallin est stable, mais ses solutions dans l'éthylènediamine sont peu stables et se colorent assez rapidement en brun foncé à cause d'une polymérisation. Les forces basiques de ces deux amino-2 éthylamidures ont été comparées avec celle de l'amino-2 éthylamidure de lithium, en suivant potentiométriquement la neutralisation de l'acide chlorhydrique, du *p*-méthoxyphénol, de l'eau, et de l'éthanolamine par les trois amidures dans l'éthylènediamine anhydre. Selon les amplitudes des chutes de potentiel aux points d'équivalence, la force basique des trois amidures augmente avec le cation dans l'ordre Na < Li < K.

Solutions of sodium 2-aminoethylamide in anhydrous ethylenediamine were prepared by dissolving ammoniacal sodium amide $NaNH_2$ in ethylenediamine and removing the ammonia formed in vacuum. When these solutions were prepared and kept under nitrogen containing not more than about 5 p.p.m. of oxygen and 1 p.p.m. of moisture, they remained colorless and stable. Upon addition of benzene to these solutions, the pure amide precipitated as fine greyish-white crystals, which were also stable under pure nitrogen. The potassium 2-aminoethylamide was prepared in a similar way from ethylenediamine and potassium hydride. Its solid product resembles that of the corresponding sodium amide, but its solutions in ethylenediamine are less stable, rapidly turning dark brown because of polymerization. The basic strengths of these two 2-aminoethylamides were compared with the corresponding lithium amide by following potentiometrically the neutralization of ethylenediamine solutions of hydrochloric acid, *p*-methoxyphenol, water, and ethanolamine respectively. According to the heights of the potential jumps at the equivalence points the basic strength of the amides was found to increase in the order Na < Li < K.

Canadian Journal of Chemistry, 47, 3509 (1969)

Introduction

Plusieurs auteurs ont déjà tenter de préparer des solutions d'amino-2 éthylamidure de sodium (que nous appellerons dans la suite du texte "amidure de sodium") dans l'éthylènediamine anhydre (EDA). Ces tentatives n'ont réussi que partiellement ou même échoué. Reggel et ses collaborateurs (1) ont chauffé pendant 9 h un mélange de EDA avec une quantité de sodium suffisante pour donner une solution de l'amidure environ 3 *M* et ils ont obtenu une solution visqueuse colorée brun foncé. Bruckenstein et Mukherjee (2) ont tenté d'obtenir l'amidure de sodium par action sur l'EDA du sodium métallique, ou de l'hydrure de sodium ou de l'amidure ammoniacal $NaNH_2$, mais ils finissaient toujours par obtenir des résidus goudronneux noirs. Heumann et ses collaborateurs (3) ont essayé d'appliquer l'échange ionique en faisant passer une solution d'amino-2 éthylamidure de lithium dans l'EDA à travers une colonne échangeuse de cations à sodium en milieu anhydre d'EDA. Cependant, seulement une petite fraction des cations s'échangeait et les concentrations en amidure de sodium atteintes ne dépassaient pas quelques centièmes de mole par litre. Dans des essais analogues avec échangeur à potassium, les solutions obtenues ne contenaient même pas de potassium du tout. Il semble qu'aucune autre tentative de préparation d'amino-2 éthylamidure de potassium ("amidure de potassium" dans la suite du texte) n'ait été décrite dans la littérature.

La présente étude avait pour but la préparation des amidures de sodium et de potassium, ainsi que la comparaison de leurs propriétés basiques avec celles de l'amidure de lithium correspondant, qui avaient été le sujet d'une étude antérieure (4).

Réaction de l'éthylènediamine avec le sodium et le potassium

Nous avons d'abord étudié *l'action du sodium métallique sur l'EDA.* Placé sous forme de petits morceaux dans l'EDA à la température ambiante

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

sous une atmosphère d'azote sec ne contenant pas plus qu'environ 5 p.p.m. d'oxygène, le sodium ne réagit pas de façon perceptible. Seulement aux températures supérieures à 35 °C, la surface du métal se colore légèrement en bleu, mais la solution reste incolore et limpide. Avec du lithium, l'EDA chaude se colore immédiatement en bleu foncé, formant la solution bien connue d'électrons solvatés, qui redevient bientôt incolore par formation de l'amidure de lithium (5). L'EDA a été chauffée à 110 °C avec une quantité de sodium suffisante pour former une solution d'amidure 0.2 *M*, sans que le métal, qui est maintenant liquide, réagisse plus vivement. Après 10 h à cette température, la solution, restée toujours incolore, est refroidie, décantée et titrée avec une solution étalonnée d'acide benzoïque par la méthode décrite ailleurs (4,5). Sa concentration en base n'était que 0.017 *N*, ce qui veut dire qu'environ 8% du sodium avait réagi. Cette basicité a pu être attribuée à l'amidure de sodium et ne pouvait pas être due à une contamination par de l'hydroxyde de sodium, parce que ce dernier est insoluble dans l'EDA. Cette insolubilité a été établie par la constatation, qu'après plusieurs heures d'ébullition en contact avec de l'hydroxyde de sodium solide anhydre, l'EDA ne révélait aucune trace de basicité par titrage avec l'acide benzoïque.

Le *potassium métallique* réagit également peu avec l'EDA. Seulement à des températures légèrement supérieures à celle du point de fusion du métal (62.3 °C), la solution se colorait en bleu foncé. Seulement une fraction de la quantité de potassium suffisante pour former une solution 0.2 *M* d'amidure réagissait à l'état fondu pendant 24 h. Lorsque la réaction se faisait dans une atmosphère ne contenant pas plus qu'environ 5 p.p.m. d'oxygène, la solution chaude de l'amidure, qui était incolore au début, commençait bientôt à se colorer graduellement en brun. Sous une atmosphère plus riche en oxygène cependant, une réaction spontanée, accompagnée d'une effervescence très vive, se déclanchait peu après que la température avait dépassé 60 °C et la solution se transformait rapidement en un liquide visqueux brun foncé. Il est intéressant à noter, qu'un alliage à 78% de potassium et 22% de sodium, liquide à la température ambiante, réagit beaucoup plus facilement avec l'EDA en formant à la température ambiante une solution colorée bleu foncé, qui est stable pendant au moins plusieurs heures. Nous utilisons cette réaction dans la purification de l'EDA pour éliminer des traces d'eau (3).

Contrairement au lithium, le sodium et le potassium ne réagissent donc que peu avec l'EDA. Cependant, l'amidure de sodium se forme facilement par action de l'amidure ammoniacal $NaNH_2$ sur l'EDA et l'amidure de potassium a été préparé par réaction de l'hydrure de potassium avec l'EDA. Les procédés de préparation des deux amidures sont décrits dans la partie expérimentale, tandis que la discussion de leurs propriétés fait partie du chapitre Résultats et discussion.

Nous avons comparé les deux amidures de sodium et de potassium avec celui de lithium, que nous avons déjà étudié dans un travail antérieur (4), en suivant potentiométriquement la neutralisation de plusieurs acides de différentes forces par les trois amidures en solution dans l'EDA.

Partie expérimentale

La préparation de *l'EDA anhydre* a été décrite dans un travail antérieur (3) de même que la préparation de la solution de l'amino-2 éthylamidure de lithium dans l'EDA (5). En opérant soigneusement, nous avons pu maintenir la teneur en eau de l'EDA au-dessous de 5 p.p.m.

Amino-2 éthylamidures de sodium et de potassium

Toute l'opération se fait dans une boîte à gants sous azote pur. Un ballon rond à 3 tubulures est muni de connections pour l'entrée de l'azote, le vide et la vidange par un syphon à pression de gaz. Les joints rodés des cols sont garnis de manchons coniques en Teflon. Pas plus de la moitié du ballon est remplie d'EDA, à laquelle on ajoute une quantité de $NaNH_2$ commercial pur, suffisante pour donner une solution environ 1.5 *M* (par exemple un ballon de 500 ml, 250 ml d'EDA et 15 g de $NaNH_2$). En agitant avec une barre magnétique recouverte de verre ou de polyéthylène, on réduit graduellement la pression jusqu'à environ 100 mm de mercure pour déclencher l'ébullition. Au fur et à mesure que cette dernière diminue, la pression est baissée graduellement jusqu'à environ 1 à 2 mm. Sitôt que tout l'amidure s'est dissout et que l'ébullition a cessé, la pression normale est rétablie avec de l'azote pur. Etant donné qu'une certaine partie du solvant s'est évaporée avec l'ammoniac formé par la réaction, la concentration de la solution aura atteint presque la solubilité de l'amidure de 1.95 à 2 *M*. La solution est syphonnée par pression d'azote dans un autre ballon deux fois plus grand que le premier à l'aide d'un tube descendant au fond du premier ballon. Le bout de ce tube est muni d'un petit filtre en verre fritté de porosité moyenne, lequel retient la petite quantité de NaOH qui a précipité ainsi que l'oxyde ferrique dont l'amidure ammoniacal du commerce est contaminé habituellement. La solution filtrée est additionnée

For personal use only.

lentement de deux à trois fois son volume de benzène pur anhydre et le mélange est agité continuellement par une barre magnétique. L'amidure de sodium $NaHNC_2H_4NH_2$ précipite rapidement en cristaux fins, qui sont séparés par filtration avec suction modérée sur un filtre en verre fritté de porosité moyenne. Le dépôt sur le filtre est lavé plusieurs fois avec du benzène et séché par un courant d'azote. On obtient ainsi une poudre cristalline blanche grisâtre, qui doit être gardée sous azote pur.

L'amidure de potassium est préparé de la même façon que celui de sodium, mais au lieu de l'amidure $NaNH_2$ l'hydrure de potassium KH sous forme d'une suspension poudreuse à 50% dans de l'huile (Metal Hydrides Inc., Beverly, Massachusetts) est ajouté à l'EDA à l'aide d'une pipette.

Solutions des amidures de sodium et de potassium 0.2 M

Ces solutions peuvent être préparées soit comme décrit plus haut, mais sans précipitation par le benzène, ou par dissolution du produit solide qui a été préparé suivant la description du chapitre précédant. Les solutions sont étalonnées potentiométriquement par l'acide benzoïque.

Acides

L'acide chlorhydrique sous forme de chlorure d'éthylènediammonium a été recristallisé à partir de sa solution aqueuse. L'acide benzoïque de qualité "primary standard" a été utilisé tel quel après séchage. Le *p*-méthoxyphénol pur commercial a été recristallisé à partir de sa solution dans le tétrachlorure de carbone et l'éthanolamine pure commerciale a été déshydratée par distillation fractionnée.

Appareil

L'appareil utilisé pour effectuer et suivre potentiométriquement les réactions de neutralisation, était le titreur clos aux électrodes de platine décrit dans un autre mémoire (5). Ce dernier donne aussi la description de la boîte à gants, dans laquelle le titreur était placé et où s'effectuaient aussi les autres manipulations.

Les traces d'humidité dans l'atmosphère de la boîte se déterminaient à l'aide d'un appareil pour la détermination du point de rosé, qui faisait partie du système de purification par recirculation de l'atmosphère. Les traces d'oxygène se déterminaient par chromatographie en phase vapeur sur une colonne de 14 pieds sur 1/4 de pouce contenant des tamis moléculaires (Linde Molecular Sieves 5A). Pour obtenir la séparation entre l'oxygène et l'argon, il fallait maintenir la colonne à une température ne dépassant pas 0 °C.

Mode opératoire

De même que dans notre étude antérieure sur l'amino-2 éthylamidure de lithium (4), nous avons toujours neutralisé 25 ml de solution d'acide 0.065 à 0.066 *N* par une solution étalonnée 0.195 à 0.200 *N* de l'amidure, de sorte qu'aux points d'équivalence les solutions étaient toujours 0.05 *N*.

Résultats et discussion

Les amino-2 éthylamidures de sodium et de potassium

L'amidure de sodium se forme par l'action de l'amidure ammoniacal $NaNH_2$ sur l'EDA lorsqu'on opère sous vide pour enlever l'ammoniac formé par la réaction. A la température ambiante et à la pression normale, $NaNH_2$ se dissout dans l'EDA à raison d'environ 0.2 mole par litre. Aux pressions inférieures à 100 mm de mercure, il y a dégagement de vapeurs d'ammoniac et des quantités beaucoup plus grandes de $NaNH_2$ se dissolvent. L'addition de benzène à une solution débarassée de NH_3 par le vide, entraîne une précipitation d'amidure de sodium sous forme d'une poudre cristalline blanche grisâtre, qui se décompose violemment au contact de l'eau. Le poids moléculaire de l'amino-2 éthylamidure de sodium est 82.1, tandis que celui de l'amidure ammoniacal est 39. Il était donc facile à identifier ce produit par titrage potentiométrique d'une solution dans l'EDA avec une solution étalonnée d'acide benzoïque selon la méthode décrite ailleurs (4,5). De plus, le poids moléculaire a été déterminé par titrage potentiométrique d'une part et conductimétrique d'autre par d'une solution aqueuse obtenue en décomposant le produit par l'eau. Les courbes de neutralisation par l'acide chlorhydrique obtenues par ces deux méthodes sont illustrées dans la Fig. 1. On voit qu'il s'agit d'un mélange de trois bases, c'est-à-dire de l'hydroxyde de sodium et des deux fonctions basiques de l'EDA. Le poids moléculaire trouvé

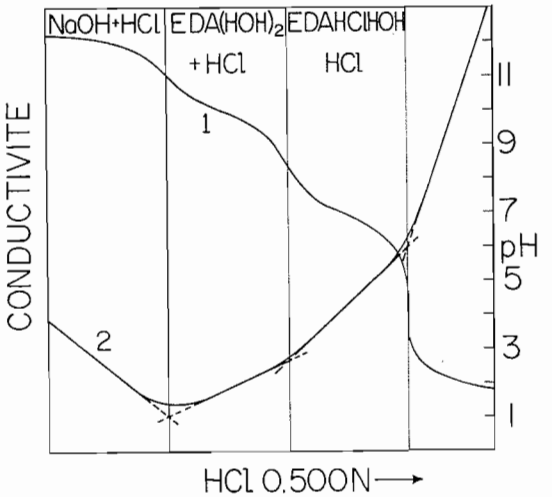

FIG. 1. Titrage de l'amino-2 éthylamidure de sodium. Environ 200 mg (2.5 m.équiv.) d'amidure dans 100 ml d'eau. (1) courbe potentiométrique; (2) courbe conductimétrique.

ainsi dans plusieurs expériences variait entre 80 et 80.6, ce qui confirmait la présence de l'amino-2 éthylamidure de sodium. Pour déterminer sa solubilité dans l'EDA, on a préparé une solution saturée en agitant l'EDA avec un excès de l'amidure en poudre pendant 20 h. Après filtration et dilution de la solution à dix fois son volume avec de l'EDA, on l'a titrée potentiométriquement avec l'acide benzoïque suivant la méthode déjà mentionnée. La solubilité trouvée ainsi était de 1.95 à 2.0 moles ou environ 160 g par litre, ce qui est bien plus que ce qui laissaient prévoir les résultats obtenus par échange ionique (3). Aucune explication de cette divergence ne peut être proposée, mais la valeur présente paraît digne de confiance par la simplicité de sa détermination.

L'amino-2 éthylamidure de potassium a été préparé et identifié de la même façon que celui de sodium, mais on a fait réagir avec l'EDA l'hydrure de potassium au lieu de son amidure KNH_2, parce que celui-ci est difficile à préparer et le produit commercial est rare est très dispendieux. L'amidure de potassium ressemble aux amidures de lithium et de sodium tant par son apparence de poudre cristalline blanche grisâtre stable sous atmosphère inerte que par sa réaction violente avec l'eau.

Quant aux *solutions des amidures* dans l'EDA, il est à noter que contrairement aux résultats des autres auteurs mentionnés au début, les solutions d'amidure de sodium que nous avons préparées, n'étaient pas colorées et il n'y avait pas formation de résidus goudronneux noirs lors de la préparation des solutions. Ces produits foncés se forment sans doute par polymérisation de l'EDA qui probablement n'a lieu qu'en présence d'oxygène moléculaire. Nous avons pu démontrer (5), que la solution pure de l'amidure de lithium dans l'EDA est incolore et stable et que des traces d'oxygène atmosphérique suffissent à provoquer ces colorations allant du rose au bleu–violet et finalement au brun foncé, qui ont été observées dans d'autres travaux (4,6). Les mêmes observations ont été faites avec les solutions incolores de l'amidure de sodium. De plus, il suffit de faire barboter de l'air dans une solution incolore d'un des amidures dans l'EDA, pour provoquer une précipitation immédiate d'un produit brun. Un échantillon d'une solution d'amidure de sodium incolore et limpide, qui avait été gardé dans un tube de verre scellé, ne manifestait aucun changement perceptible pendant un an. Sitôt que le tube fut ouvert et le contenu exposé à l'atmosphère ambiante, la solution se colora immédiatement en bleu pour devenir brun noirâtre peu après. Tenant compte de ces faits ainsi que du comportement du potassium métallique dans l'EDA chaude décrit plus haut, on peut conclure, que l'oxygène est la cause des polymérisations. Les solutions d'amidure de potassium sont particulièrement sensibles. Même sous une atmosphère d'azote ne contenant que quelques parties par million d'oxygène et moins d'une partie par million d'eau, ces solutions se colorent graduellement en brun foncé au cours de quelques heures. Après 2 ou 3 jours un précipité goudronneux commence à se former. Dans les mêmes conditions, les solutions des deux autres amidures sont stables et restent incolores au moins pendant plusieurs semaines.

Nos expériences démontrent, que les amino-2 éthylamidures des métaux alcalins pures et stables peuvent être préparés sous forme solide ou en solutions incolores à conditions qu'on opère en milieux parfaitement inerte, c'est-à-dire un milieu qui contient au maximum quelques p.p.m. d'oxygène, d'eau et de dioxyde de carbone. Les différentes colorations des solutions qui ont été observées, ainsi que la formation de résidus goudronneux qui ont empêché d'autres auteurs de préparer l'amidure de sodium, ne sont pas dues à une instabilité inhérente de ces amidures, mais à des réactions de décomposition avec des petites quantités d'impuretés. Il est donc indispensable d'opérer dans des conditions rigoureusement contrôlées, dont on peut s'assurer seulement par un contrôle analytique assez fréquent de l'atmosphère de la boîte à gants et du solvant. Trop souvent, des expérimentateurs travaillent dans des conditions extrèmes et difficiles à maintenir, comme par exemple un milieu en même temps hygroscopique et anhydre, sans vérifier analytiquement, si la condition qu'ils supposent être réalisée, existe effectivement. Et tout aussi souvent un tel travail produit des résultats expérimentaux faux conduisant à des conclusions erronées.

Forces basiques des amino-2 éthylamidures

La Fig. 2. donne les courbes de neutralisation de l'acide chlorhydrique, du *p*-méthoxyphénol, de l'eau et de l'éthanolamine par les amidures de lithium, de sodium et de potassium. Ces quatres

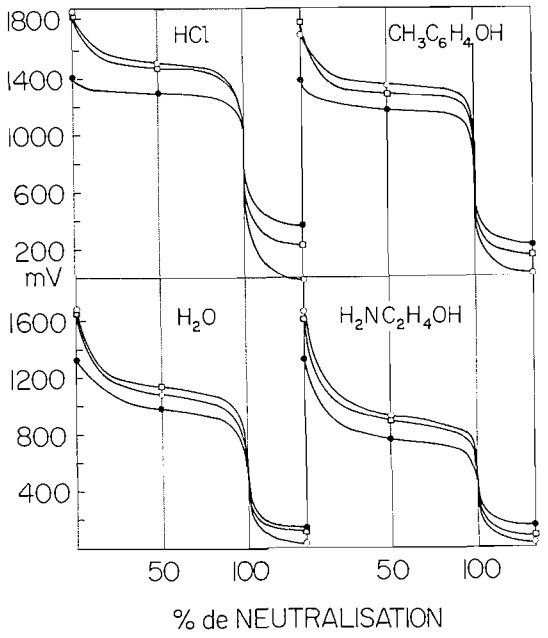

FIG. 2. Courbes potentiométriques de neutralisation de quatre acides par les amino-2 éthylamidures de: ○ potassium; ● sodium; □ lithium.

acides ont été choisis, parce que leurs forces acides sont très différentes et couvrent la majeure partie de la gamme des acidités possibles dans l'EDA.

Les courbes des amidures de lithium et de sodium sont de vraies courbes expérimentales en ce sens que les points de mesures se placent effectivement sur la courbe continue. La reproductibilité des mesures est bonne, les forces électromotrices (f.e.m.) aux points de demi-neutralisation ayant des déviations standards de 10 à 15 mV et aux points d'équivalence entre 5 et 10 mV. Les courbes obtenues avec l'amidure de potassium, cependant, étaient sensiblement moins faciles à reproduire à cause de l'instabilité des solutions de cet amidure. Les solutions fraîchement préparées ne donnaient des mesures potentiométriques exploitables que pendant environ deux jours et les déviations standards des mesures étaient plusieurs fois plus grandes que celles relatives aux deux autres amidures. Les courbes expérimentales étaient donc moins régulières que les courbes "idéalisées" de la Fig. 2., qui représentent les moyennes de trois à quatre essais pour chaque acide.

Notre système potentiométrique à deux électrodes de platine ne donne que des valeurs de repère d'une utilité limitée. Nous avons déjà souligné (4) que les conditions expérimentales de la présente série d'études rendent trop difficile l'usage de l'électrode à hydrogène, mais que ces mesures de repère permettent néanmoins certaines conclusions. Cette étude antérieure a démontré que l'amplitude des chutes de potentiel des courbes de neutralisation par l'amidure de lithium variait directement avec la force des acides. Les courbes de la Fig. 2. permettent par un raisonnement analogue de conclure que les forces basiques des trois amidures doivent être proportionelles à l'amplitude des chutes de potentiel et que par conséquent la force basique augmente avec les cations dans l'ordre Na < Li < K.

Remerciements

Nous remercions sincèrement le Conseil National de Recherches du Canada de l'aide financière sous forme d'octrois de recherches (W.R.H.), qui a rendu possible ce travail.

Nuclear magnetic resonance studies. XVIII.[1] The proton parameters of some bicyclo[2·2·2]octane derivatives

GURUDATA[2] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ontario

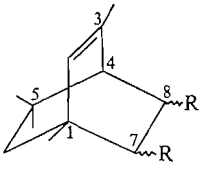
Received May 2, 1969

The high resolution proton spectra of ten substituted bicyclo[2·2·2]octenes and octanes have been analyzed. The proton shieldings and coupling constants are discussed with particular emphasis on the stereochemical dependence of these parameters. Evidence bearing on the anisotropic effect of carbonyl bonds is presented to substantiate other recent findings on these shielding effects. Certain long-range couplings permit stereochemical assignments.

Canadian Journal of Chemistry, 47, 3515 (1969)

Introduction

In the course of an earlier study of maleopimaric acid derivatives by proton spectroscopy (1), certain features of the parameters for the protons associated with the bicyclo[2·2·2]octene moiety were noted. Since the ^1H–^1H spin couplings in this system differ appreciably from those found for the more popular bicyclo[2·2·1]-heptane system it seemed desirable to investigate in more detail the proton spectra of some simpler model compounds having the bicyclo[2·2·2]-octane skeleton. A comparison of the effects of molecular geometry and strain on the vicinal couplings for the two cases appeared worthwhile. A convenient model system was available via the Diels–Alder reaction and consequently a number of 7,8-disubstituted derivatives of 1,3,5,5-tetramethylbicyclo[2·2·2]oct-2-ene (**1**)



1

was prepared by the reaction of maleic anhydride and dimethylfumarate with "1,3,5,5-tetramethylcyclohexa-1,3-diene" **2** as summarized in Scheme 1. The corresponding bicyclooctanes were obtained by catalytic hydrogenation.

Although the stereochemistry of these products follows directly from the geometry of the starting materials, the well-known angular dependence of vicinal proton–proton couplings (2) permits one to distinguish readily between isomers having *cis* and *trans* carbonyl functions. The assignment of the relative orientation of the substituents follows from (*a*) the relative yields of the adducts, (*b*) a consideration of the geometry of the adduct, and (*c*) an analysis of the effect of the olefinic bond on the C-7 and C-8 proton shieldings (3, 4). Further confirmation is provided by the magnitude of the long-range couplings observed for these protons, a subject that has been reviewed recently (5, 6).

In all cases the C-7 and C-8 substituents are carbomethoxyl or carbonyl groups. Thus the proton spectra of the olefins are particularly simple and are readily analyzed, in fact the signals for each proton type appear separately. For the bicyclooctanes, however, a complete analysis is not readily accomplished and only the signals which are unequivocally assignable were analyzed. These data, therefore, may be useful as reference values for protons in related, but more complicated, systems.

Experimental

Spectra

Most of the proton parameters were determined from spectra obtained on a Varian A-60 spectrometer. The chart calibration was checked regularly using audio-frequency sidebands of tetramethylsilane. The decoupling experiments were performed on a Varian A-60A spectrometer using a Varian decoupling accessory.[3] A few double irradiation experiments were carried out using a Varian DP-60 spectrometer in conjunction with either a unit similar to the Varian V3521 integrator or a single sideband homonuclear decoupler Model HD-60 (NMR

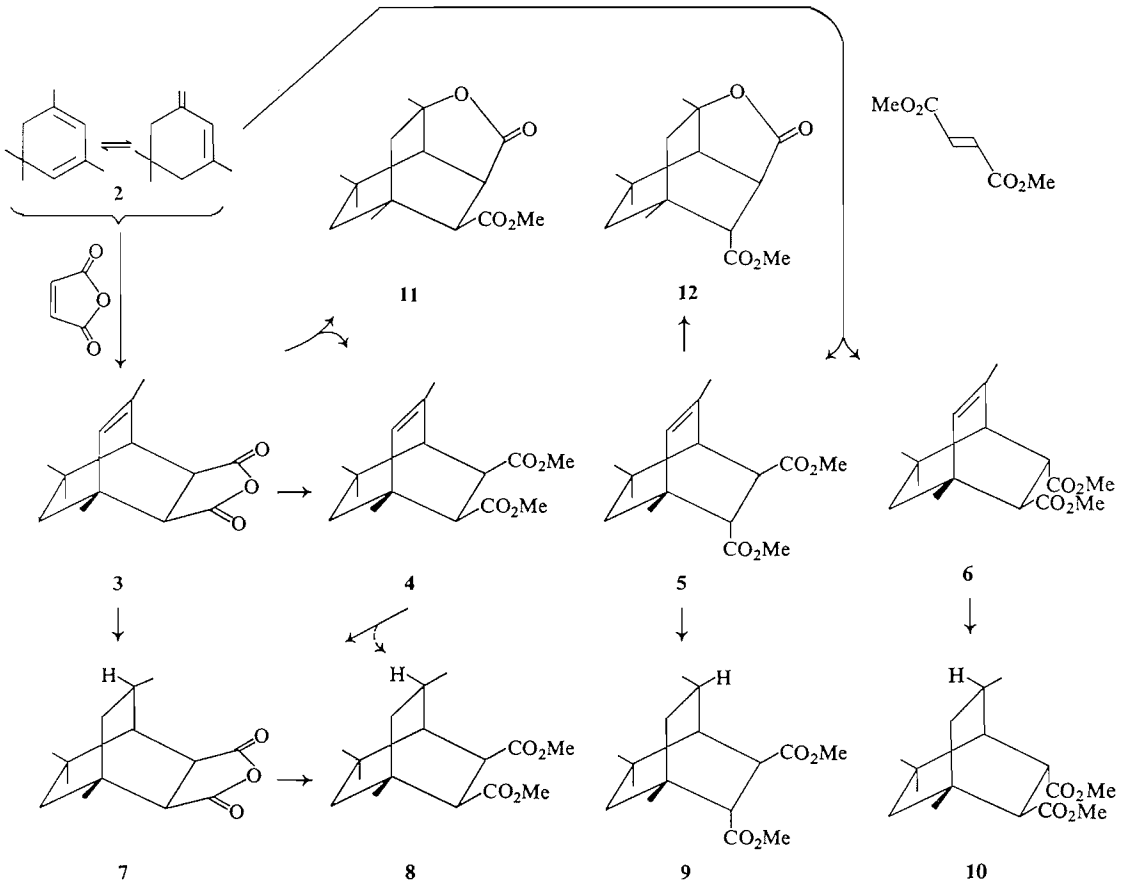

SCHEME 1

Specialties, Inc.). The chemical shifts and coupling constants are judged to have a precision of ±0.01 p.p.m. and ±0.2 Hz, respectively. A few spectra were obtained with Varian HA-60 or HA-100 instruments to check the earlier data and to carry out some nuclear Overhauser experiments. Infrared spectra were recorded on a Beckman IR5A or IR10 spectrophotometer.

Materials

"1,3,5,5-Tetramethylcyclohexa-1,3-diene" (2)

The diene was obtained by a slight modification of the method described by Kharasch (7).

Methyl magnesium iodide, prepared from methyl iodide (114 g) and magnesium turnings (20 g) in 360 ml of ether, was cooled in an ice-bath and a solution of isophorone (96.7 g) in ether (135 ml) was added slowly over 1.75 h. The reaction mixture was allowed to stand for 4 h, refluxed for 1 h, and then allowed to stand overnight. The resulting mixture was poured over 400 g of crushed ice and 46.5 ml of glacial acetic acid was added with stirring. The product was isolated by ether extraction. After evaporation of the solvent, the residual liquid was fractionated on a spinning band column to yield 65 g of **2**, b.p. 45.5–48.0/12 mm [lit. b.p. 151–155/760 mm (7)]; ν_{max} ($CHCl_3$) 1667, 1647, 1616, 900 cm^{-1}; λ_{max} (EtOH) 238, 261 nm.

Maleic Anhydride Adduct of 2 (3)

To 13.6 g of **2** was added a solution of maleic anhydride (9.8 g) in benzene (15 ml). The reaction mixture was warmed until a deep yellow coloration developed at which point heating was discontinued until the reaction slowed considerably. Refluxing the reaction mixture for 1 h resulted in the complete disappearance of the yellow color. Removal of the solvent left a white solid which was recrystallized from a 50/50 mixture of petroleum ether (35–60°) and benzene, to yield 13.1 g of **3**, m.p. 99.5–100.5° [lit. m.p. 98–99° (7)]; ν_{max} ($CHCl_3$) 1855, 1780, 1650 cm^{-1}.

Hydrogenation of 3 (7)

To a solution of **3** (1 g) in 25 ml of glacial acetic acid was added 250 mg of PtO_2 (Engelhard). Three drops of perchloric acid were added and the mixture shaken for ca. 84 h with hydrogen at 50 p.s.i. After removal of the catalyst and solvent, the residue was dissolved in diethyl ether and the solution washed four times with water. After filtration through anhydrous magnesium sulfate, the ether was removed leaving 1.25 g of a syrupy liquid.

Crystallization from methanol yielded 600 mg of a white solid, melting at 72–76°. Recrystallization from chloroform gave **7**, m.p. 76–77°; ν_{max} ($CHCl_3$) 1885, 1775 cm^{-1}.

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53. Found: C, 70.72; H, 8.65.

Esterification of 3 (4)

Adduct **3** (4 g) was dissolved in 100 ml of methanol and 2.4 g of concentrated H_2SO_4 added. The mixture was refluxed overnight.

After removal of most of the excess alcohol, *in vacuo*, the reaction mixture was extracted with diethyl ether. The usual work-up yielded 3.6 g of a colorless viscous liquid, which was chromatographed on silica gel (150 g) with anhydrous ether as eluent. A yield of 3.2 g of **4** was obtained, n_D^{25} 1.4802; ν_{max} ($CHCl_3$) 1740 cm^{-1}.

Anal. Calcd. for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63. Found: C, 68.04; H, 8.77.

Later fractions of the chromatogram crystallized on standing. This material, after recrystallization from anhydrous ether, was identified as the lactone ester **11**, m.p. 87.5–88.5°; ν_{max} ($CHCl_3$) 1780, 1745 cm^{-1}.

Anal. Calcd. for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33. Found: C, 67.97; H, 8.19.

Esterification of **3** with diazomethane, as described for the preparation of **8** below, yielded only **4**.

Esterification of 7 (8)

The saturated anhydride **7** (1.2 g) was dissolved in methanol (30 ml) and an ethereal solution of diazomethane added to the cooled solution. After several hours standing the solvent was removed, leaving a viscous, pale-yellow liquid. To remove traces of unsaturated material which were present in the starting material, the product was dissolved in acetic acid and a few drops of bromine added.

This mixture was allowed to stand for 1 h and then diluted with water and the product isolated by ether extraction. On cooling the residue after removal of most of the ether, a white crystalline solid (216 mg) precipitated. The crystals were separated and the volatile portion of the filtrate evaporated leaving a viscous yellow liquid (0.67 g) whose n.m.r. spectrum showed the absence of unsaturated material. The product was further purified by column chromatography followed by bulb-to-bulb distillation, n_D^{25} 1.4812; ν_{max} ($CHCl_3$) 1730 cm^{-1}.

Anal. Calcd. for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28. Found: C, 67.72; H, 9.09.

Reaction of 2 with Dimethyl Fumarate

Preparation of Dimethyl Fumarate

Dimethyl fumarate was prepared by a method analogous to that described by Vogel (8) for diethyl fumarate.

A mixture of fumaric acid (50 g), methanol (100 ml), benzene (200 ml), and concentrated H_2SO_4 (8 ml) was refluxed for ca. 20 h. On cooling, white crystals precipitated. Recrystallization from chloroform gave 61 g of product, m.p. 101–102° [lit. m.p. 101.2–101.4° (9)].

Diels–Alder Reaction

A mixture of 18.5 g of **2** and 14.5 g of dimethyl fumarate was refluxed for 11 h. The excess diene was removed *in vacuo* (20 mm) and the residue fractionated at 1 mm pressure. The product (20.2 g) distilling between 105–120° was collected.

Isolation of Compound 5

On addition of a small amount of petroleum ether (35–60°) to the distillate, a white crystalline solid precipitated. After several recrystallizations from petroleum ether, the product, **5**, melted at 71–72°; ν_{max} ($CHCl_3$) 1725, 1650 cm^{-1}.

Anal. Calcd. for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63. Found: C, 68.61; H, 8.76.

Conversion of 5 to 12

To glacial acetic acid (50 ml) was added **5** (1 g) and the solution refluxed for 1 h. After cooling and isolation by ether extraction, a white crystalline material **12** was obtained (0.7 g) melting at 100.5–101.0° (from petroleum ether), ν_{max} ($CHCl_3$) 1770, 1735 cm^{-1}.

Anal. Calcd. for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33. Found: C, 67.58; H, 8.06.

Isolation of Compound 6

After the crystallization of **5**, 6.05 g of mother liquor remained. Separation of the components of this mixture was effected by chromatography on alumina (Woelm Neutral, Activity 1). Traces of **5** were eluted with petroleum ether (35–60°), before a new compound, **6**, appeared upon elution with benzene – petroleum ether mixtures. This material was crystallized by cooling to about 10 °C and then adding a small amount of methanol. Recrystallization from petroleum ether gave **6**, m.p. 50–51°, ν_{max} ($CHCl_3$) 1658 cm^{-1}.

Anal. Calcd. for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63. Found: C, 68.00; H, 8.67.

Hydrogenation of Compound 5 (9)

Compound **5** (0.9 g in 25 ml of glacial acetic acid) was hydrogenated over a platinum catalyst (150 mg). A Parr low pressure hydrogenation apparatus was used at a hydrogen pressure of 48 p.s.i. for 36 h. Work-up in the usual way afforded a colorless liquid which was crystallized by cooling to below 0 °C and then adding a small amount of methanol. Recrystallization from petroleum ether (35–60°) gave **9**, m.p. 44.0–45.5°; ν_{max} ($CHCl_3$) 1720 cm^{-1}.

Anal. Calcd. for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28. Found: C, 68.44; H, 9.47.

Hydrogenation of Compound 6 (10)

The diester **6** (450 mg) was dissolved in glacial acetic acid (15 ml) and hydrogenated over a platinum catalyst in the presence of two drops of perchloric acid. A Parr low pressure hydrogenation apparatus was used and the reaction mixture shaken for 72 h at a hydrogen pressure of 58 p.s.i. Work-up yielded 0.45 g of product (**10**).

The saturated diester (**10**) was further purified by column chromatography on silica gel. A sample for analysis was prepared by bulb-to-bulb distillation under reduced pressure, n_D^{25} 1.4742; ν_{max} ($CHCl_3$) 1720 cm^{-1}.

Anal. Calcd. for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28. Found: C, 68.68; H, 8.93.

Results and Discussion

The parent diene was obtained following the method of Kharasch and Tawney from isophorone and methyl magnesium iodide with the subsequent elimination of water from the tertiary alcohol. Although the homoannular diene structure was assigned to **2** by the earlier

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

workers, gas–liquid chromatography indicates the presence of two dienes. The infrared spectrum exhibits three maxima in the C=C stretching region as well as a peak at 900 cm^{-1} suggesting the presence of an *exo*-methylene group. Estimations based on the Woodward rules predict ultraviolet absorption maxima at 236 and 263 nm for the two dienes while the product exhibits maxima at 238 and 261 nm in good agreement with these predictions. The conclusion that the diene **2** is actually a mixture of approximately equal amounts of the two dienes, shown in Scheme 1, is borne out by its proton spectrum, the low-field region of which has four multiplets at 4.62, 4.98, 5.43, and 5.85 p.p.m. (from TMS) in the ratio 2.3 : 1.2 : 1.2 : 1.1. Since the diene mixture **2** was found to undergo the Diels–Alder reaction with maleic anhydride quantitatively, no attempts were made to separate the two dienes, although later it was found that an essentially pure sample of the homoannular diene can be obtained by careful fractional distillation.

Before a detailed discussion of the proton spectra of the bicyclooctane derivatives, their preparation, separation and the elucidation of their gross structures is described.

Since the Diels–Alder reaction of **2** with maleic anhydride proceeds virtually quantitatively to **3** it was assumed initially that the *cis–endo*[4] structure is formed on the basis of the Alder rule (10). It was found that methylation of **3** with methanol in sulfuric acid gave both the expected diester **4** as well as compound **11** which contains a γ-lactone (ν_{max} 1780 cm^{-1}), an ester (ν_{max} 1745 cm^{-1}), no olefinic protons and each methyl proton signal is a singlet. The carboxyl functions are *cis* since $J_{7,8}$ = 9.7 Hz. Presumably the lactone is formed by protonation of the double bond followed by reaction with the C-8 carboxyl function. In addition **3** forms a bromo-γ-lactone quantitatively upon reaction with bromine (11) further confirming the *endo* orientation of the anhydrido function. Each of the unsaturated compounds **3–6** was treated with bromine but since it was found that each reaction follows a different preferred course, a full description of these experiments is deferred for a later report. All attempts to isolate another maleic anhydride adduct or to isomerize **3** to the *cis–exo* form (12) have proved unsuccessful and we are confident that **3** has the *cis–endo* stereochemistry.

Adduct formation of **2** with dimethyl fumarate occurs much less readily but two diesters, **5** and **6**, are obtained in a ratio of ~10:1. Because of the steric hinderance due to the *exo*-methyl group at C-5 it was assumed initially that the major product **5** has an *endo* carbomethoxyl group at C-8. Long-range coupling of the C-7 proton provides additional evidence to support this assignment. Confirmation was obtained by the ready formation of **12**, upon heating in acetic acid, having a γ-lactone (ν_{max} 1770 cm^{-1}), an ester (ν_{max} 1735 cm^{-1}), no olefinic protons and singlet methyl proton signals. Structure **6** is assigned to the second, minor diester since there is no evidence that the bicyclo[2·2·2]octene skeleton has been altered.

The saturated derivatives **7–10** were obtained by catalytic hydrogenation using platinum oxide. The up-take of hydrogen was slow even with the addition of a few drops of perchloric acid in the the case of **3** and **6**, and it was found that hydrogenation of **4** leads preferentially to **7**. Consequently **8** was more readily obtained by methylation of **7** using diazomethane. The orientation of the C-3 methyl group in **7–9** was assigned on the basis of the n.m.r. data and this feature is discussed in a later section.

Proton Spectra

General Comments

To show their relative simplicity, the 60 MHz spectra in $CDCl_3$ solution of the bicyclooctenes are presented in Fig. 1. In the main, the assignment of bands to specific protons is straightforward. For example, the spectrum of the maleic anhydride adduct **3** (Fig. 1*a*) contains a low-field olefinic signal at δ 5.57 coupled to the C-3 methyl (1.80 p.p.m.) J = 1.8 Hz and the C-4 bridgehead proton (2.51 p.p.m.) J = 1.5 Hz. The couplings were confirmed by double irradiation. The larger splitting in the latter signal, 3.5 Hz, represents the coupling to the *exo*-methine proton at C-8 (3.51 p.p.m.) which is also coupled to the C-7 *exo*-proton with J = 8.5 Hz. The C-7 proton at 2.72 p.p.m. gives rise to a simple doublet with no further coupling > 0.3 Hz. The three methyl singlets at 1.37, 1.08, and 0.89 p.p.m. are assigned to the C-1, the *exo* C-5 and *endo* C-5 groups, respectively. Evidence of

[4]The *exo* and *endo* orientations are given relative to the C-2,3 bond.

long-range coupling between the C-5 methyl protons is provided by the fact that their signals are somewhat broader than that for the C-1 group. Proof that the latter is correctly assigned was obtained by a nuclear Overhauser experiment (13) in which the intensity of the 5.57 p.p.m. signal increases by ca. 14 ± 3% upon saturation of the 1.37 p.p.m. signal.[5] In each case one of these three methyl signals is sharper than the others, which allows a ready assignment for the C-1 methyl group. Recent literature provides ample support for the observation of coupling between geminal methyl groups (14, 15). The assignment of the C-5 methyls follows from the assumption that the olefinic bond will tend to shield the *endo*-methyl preferentially (3, 4). Although this is not unequivocal, these assignments do not affect the arguments presented for the other protons. For **3** the signals due to the C-6 methylene protons remain. In Fig. 1*a*, the inner two lines of the AB pattern are discernible on the low-field side of the 1.08 p.p.m. signal. At 100 MHz, three of the four lines of this pattern appear separately and the analysis is straightforward.

The spectral interpretation for the corresponding dimethyl ester **4** (Fig. 1*b*) follows directly from that just described. Apart from the additional signals at 3.57 and 3.54 p.p.m. for the carbomethoxyl protons, the order of the signals is as expected with some change in the relative shifts and small changes in some of the coupling constants. In Fig. 1*b* only the outer pair of lines of the C-6 methylene AB pattern are visible but an expanded sweep reveals one of the inner lines on the high-field side of the 1.08 p.p.m. signal. The bridgehead methyl protons (on C-1) are at significantly higher field in **4** and coincide with, presumably, the *exo* C-5 methyl band.

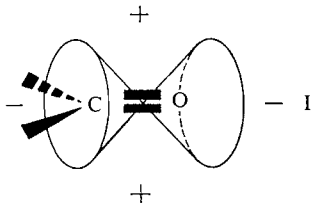
Diester **5** exhibits a readily interpretable pattern (Fig. 1*c*) which has one additional coupling, namely, that between one of the C-6 protons (*endo*, 0.73 p.p.m.) and the C-7 proton (*endo*, 2.60 p.p.m.). The remaining C-6 proton appears as a slightly broadened doublet at 1.51 p.p.m., J = 12.9 Hz. For **6**, the proton spectrum (Fig. 1*d*) differs slightly in that the positions of the C-7 and C-8 protons are reversed and the C-4 proton absorbs very close to these nuclei. A three-spin analysis, allowing for the long range coupling to the olefinic proton, however, was readily accomplished.

The complete set of chemical shift data for compounds **3–6** is collected in Table I while the coupling constants are listed in Table III.

The data for the saturated compounds **7–12** were extracted from the spectra in a similar fashion and the results are collected in Tables II (chemical shifts) and III (coupling constants). Since a number of comparisons failed to show significant solvent effects on the coupling constants only a single set of data is listed for each compound.

Chemical Shifts

Since all compounds were studied in $CDCl_3$ solutions these data are considered first. The olefinic proton (C-2) appears to be deshielded by an *endo* C-8 carbomethoxyl group and shielded by an *endo* C-7 carbomethoxyl group, both effects being ca. 0.1 p.p.m. Presumably this is mainly due to the relative orientation of the > C=O bond with respect to the C-2 proton. The fact that the bridgehead proton at C-4 is different in **4** and **5** suggests that the rotation of the —COOMe moiety is affected by a *cis* vicinal carbomethoxyl. A comparison for this proton in **5** and **6** suggests that the *exo* carbomethoxyl group deshields the bridgehead proton by ca. 0.2 p.p.m., while the same comparison for **9** and **10** yields a smaller difference, 0.12 p.p.m. It seems clear that the orientation of the carbonyl bond in the anhydrides is such that its effect at the bridgehead position is small, 0.1 and 0.2 p.p.m. for the olefins and saturated derivatives, respectively. In the γ-lactones, however, the C-4 proton is deshielded by ca. 0.4 p.p.m. presumably by the carbonyl bond, cf. **11** vs. **8** and **12** vs. **9**. On the other hand, the same comparison indicates that the α-proton on C-8 is *shielded* by the carbonyl bond in the lactones. These observations lend support to the recent proposal of Karabatsos (16) that a model for the anisotropic effect of a carbonyl group such as I serves to explain the observed shifts for neighboring protons more



[5]This experiment was done with a degassed, chloroform solution at ambient temperature.

successfully than that originally suggested (17). According to this model the relatively high-field position of the *endo* C-7 proton in **12** relative to that in **9** must be due in large part to the fixed carbonyl bond in the γ-lactone.

The remaining feature of the data in Tables I and II concerns the effect of solvent on these proton shieldings. It is interesting that there is a general tendency for the proton on or near the olefinic bond or the carbomethoxyl groups to move to higher field in CCl_4 solutions relative to their position in $CDCl_3$ solutions, while the C—Me protons are little affected. In addition, the solvent shifts in benzene are not particularly striking except for those cases having a rigidly fixed carbonyl bond, e.g., the anhydride, **3**, and the γ-lactones, **11** and **12**. This behavior is typical of solutes which tend to associate with aromatic solvents, a subject that has received wide-spread attention and has recently been reviewed (18). In the present system the solvent shifts, $\delta_H^{CDCl_3} - \delta_H^{C_6H_6}$, for these three cases suggest a preferred orientation of the benzene solvent molecules such that certain protons are strongly shielded while others are less affected. For example, in the case of **3**, the protons on C-7 and C-8 are shifted ca. 0.7 p.p.m. to higher field while the others move from +0.15 to +0.43 p.p.m. It is interesting that the C-8 proton shifts +0.47 p.p.m. in **11** but −0.06 p.p.m. in **12** while the C-4 proton is the most shielded, +0.58 and +0.45 p.p.m., respectively. Thus it appears that the solvent molecules are oriented about the carbonyl bond in different ways.

Coupling Constants

(a) Geminal Interactions

Throughout this series the only geminal interaction in common is that for the C-6 methylene protons which is found to be 13.3 ± 0.4 Hz. These values, presumably negative, indicate that there is little strain in the ring system since these differ only slightly from those for methane and other unstrained sp^3-carbons (20). Comparable values, 13.7 ± 0.1 Hz have been reported for similar systems (19).

(b) Vicinal Interactions

A variety of vicinal interactions occurs in the present series and those readily and reliably measured are set out in Table III. These may be considered on the basis of the well-known results of the Karplus treatment (21) for vicinal couplings. While one expects a dependency upon molecular geometry it is well-established that ring-strain and substituent electronegativity also contribute to the magnitude of these couplings (22, 23). Evidence of the effect of ring strain is provided by a comparison of the $J_{7,8}$ values for **3** vs. **4** and **7** vs. **8**. For each, J increases by ca. 1 Hz on opening the anhydride ring. A similar increase is found upon hydrogenation of the double bond, **4** vs. **8**. These changes are comparable to those reported by Tori *et al.* (19) and Roll and Huitric (24) for related systems and to those found for norbornyl systems (22). Presumably these are due to a redistribution of ring strain, assuming that the substituent effect of the anhydrido group is comparable to that of the COOMe. Thus it appears that $J_{7,8} \sim 12$ Hz for a dihedral angle of 0° in this system. The marked decrease in $J_{7,8}$ to 9.7 Hz for the lactone ester **11** must be due in part to the enforced departure from a dihedral angle near 0° because of the formation of the γ-lactone, although part of the decrease may arise from strain.

A dihedral angle of ca. 120° for $J_{7,8}$ is to be expected for **5**, **6**, **9**, **10** but inspection of Table III reveals a range of 4 Hz from 5.9–9.9 Hz. Of the four cases, however, **5** seems the most likely to have a dihedral angle of 120° since in each of the others the C-8 carbomethoxyl group has a "1,3-diaxial" interaction with either a hydrogen atom at C-3 (**9**) or the *exo*-methyl at C-5 (**6** and **10**) while **9** has a similar interaction between the C-3 and -5 methyls as well. Presumably these steric interactions can be reduced by a slight twist of the skeleton. If in a counter-clockwise sense for **9** (as viewed along the C-7,8 bond, Fig. 2) the dihedral angle between the C-7 and C-8 protons will increase from 120° and the dihedral angle between the C-4 and -8 protons will also increase. A comparison of $J_{7,8}$ and $J_{4,8}$ for **5** and **9** shows differences consistent with this rationalization. On the other hand, a clockwise twist of the skeleton for **6** and **10** leads to comparable changes in these dihedral angles. Other evidence to suggest that the *trans* coupling is ca. 6 Hz for the undistorted structure is given by the values for the less cluttered system **13** (1) and **14** (19), both of which have J = 6.0 Hz. Finally, the coupling of 2.1 Hz found for $J_{7,8}$ in **12** is in good agreement with the preceding interpretation since the formation of the γ-lactone between the C-8 carboxyl and C-3 must reduce the dihedral angle

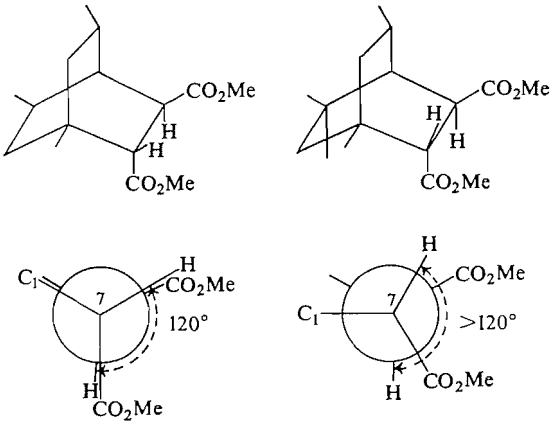

FIG. 2. Diagrammatic representation of the effect of twisting the bicyclo[2·2·2]octane skeleton to reduce non-bonded interactions between neighboring substituents in compound **9**.

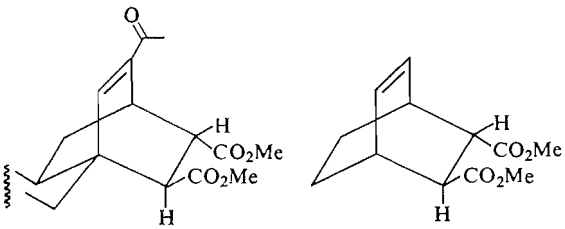

13 **14**

between the C-7 and C-8 protons. As in **11**, however, part of the decrease in the coupling constant may be due to strain.

Dihedral angles near 60° must obtain for the $J_{3,4}$ and $J_{4,8}$ interactions even though these values range from 1.2–4.4 Hz. The larger of these, $J_{4,8}$ for the γ-lactones, are readily rationalized since the formation of the γ-lactone serves to reduce the dihedral angle between the C-4 and *exo* C-8 protons and an inspection of models indicate that it may be as small as 45°. Although models do not reveal an appreciable angle change upon formation of the anhydride the observed $J_{4,8}$ of 3.5 Hz indicates a decrease from 60°. As already noted, the twist illustrated in Fig. 2 tends to increase the dihedral angle between a C-4 proton and an *endo* C-8 proton as in **10** which has $J_{4,8} = 1.5$ Hz. Thus it appears that, for a dihedral angle of 60°, the coupling is ca. 2 Hz in the bicyclooctanes which agrees well with the values found for a number of cases in monocyclic unstrained systems (23). It should be noted that the larger values for $J_{4,8}$ exhibited by the anhydrides and γ-lactones may be reduced somewhat due to a contribution by the strain factor and so it seems unwise to use these couplings to estimate the dihedral angles in these systems.

(c) Long-range Coupling Constants

In the present series two types of long-range interactions are resolved. The first of these is the allylic coupling, H—C—C=C—H, between the C-2 and C-4 protons and between the C-3 methyl protons and the C-2 H. The latter appear to be ca. 0.1 Hz larger. This interaction has attracted many workers and the overall situation was surveyed in 1964 (25). More recently Newsoroff and Sternhell have proposed certain modifications of the current notions on the steric dependence of these couplings (26). The present $J_{2,4}$ values represent examples in which the interacting protons lie in a common plane in a *transoid* configuration. The observed J values of 1.6 ± 0.1 Hz suggest, on the basis of their recent proposal, that the predicted values for this configuration are too low, assuming that the present values are positive, since their curves predict a value of ca. 1 Hz. The present data are in good agreement with those reported by Tori *et al.* (19).

Long-range proton–proton couplings across four single bonds have been recognized for some time and it is well-known that the maximum coupling occurs through a "W" arrangement (5, 6) such that in cyclohexanes 1,3-diequatorial protons are more strongly coupled than either of the corresponding diaxial or axial-equatorial protons. It follows for the bicyclo[2·2·2]octane system that the largest couplings can be expected for an interaction such as that between the 6-*endo* and 7-*endo* protons. The cases in which these 4-bond couplings have been identified are listed in the last four columns of Table III. As mentioned earlier, certain of these permit the assignment of substituent orientation in these derivatives. For example, only one of the bicyclooctenes exhibited a long-range coupling of this type, **5**. This allows an easy distinction between the two *trans* diesters since only the C-7 proton can assume the appropriate orientation. Following a similar argument the fact that the C-8 proton in **7** has a long-range coupling of 1.2 Hz indicates that hydrogenation occurs on the side of the olefinic bond *away* from the *endo*-anhydride grouping. Also the absence of this coupling in **9** indicates that hydrogenation of **5** occurs *anti* to the *endo* C-5 methyl. It seems reasonable to suggest that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

markedly smaller value for $J_{3,8}$ in **7** is a consequence of the strain imparted by the anhydride grouping. Unfortunately the lack of a long-range coupling for the C-8 proton in **10** does not aid the assignment of stereochemistry for the C-3 methyl group. The orientation of the C-3 methyl group for **10** has been assigned on the basis of the pronounced shift for the *endo* C-8 proton upon hydrogenation of **6** relative to that exhibited by the *endo*-C-7 proton for the change **5** → **9**, a difference of > 0.3 p.p.m.

Conclusion

On the basis of the foregoing results, it seems clear that proton spectroscopy can facilitate the elucidation of stereochemistry in the bicyclo-[2·2·2]octane system, but a certain degree of caution is necessary to avoid misinterpretations as the authors of recent reports on the spectra of the bicyclo[2·2·1]heptenes have emphasized (27–29).

Acknowledgments

We wish to thank the National Research Council of Canada and the donors of the Petroleum Research Fund, administered by the American Chemical Society, for financial support of this investigation. We are also indebted to Mrs. Mary Warren for some preliminary experiments and to Dr. G. W. Buchanan for his efforts, albeit unsuccessful, to isomerize adduct **3** to its *cis–exo* form.

Signs of spin–spin coupling constants between aldehydic and ring protons in 2,6-dinitrobenzaldehyde. Evidence for a hyperconjugative contribution to $J_p^{H,CHO}$

C. L. BELL[1,2], S. S. DANYLUK, AND T. SCHAEFER[1,3]
Argonne National Laboratory, Argonne, Illinois 60439

Received May 12, 1969

The spin–spin coupling constant between the aldehydic proton and the proton in the para position, $J_p^{H,HCO}$ is negative in 2,6-dinitrobenzaldehyde. $J_p^{H,CHO}$ is also very likely negative in 2,6-dichlorobenzaldehyde. It is suggested that steric interaction with the ortho substituents forces the aldehyde group out of a coplanar conformation and leads to an interaction of the aldehydic C–H bond with the π system of the ring. Tentative values of θ, a measure of the deviation from coplanarity, are given.

Canadian Journal of Chemistry, 47, 3529 (1969)

Introduction

The negative spin–spin coupling constants, J_o^{H,CH_3} and J_p^{H,CH_3}, between methyl protons and ring protons in the ortho and para positions of toluene (1) and its derivatives (2–4) are apparently dominated by a π electron mechanism (5, 6) and involve hyperconjugation in the ground state of the molecule (7). On the other hand, the positive couplings over five bonds, $J_m^{H,CHO}$, $J_m^{H,OH}$, $J_m^{H,NHX}$, $J_m^{H,CHCl_2}$ in the derivatives of benzaldehyde, phenol, *N*-substituted aniline, and α,α-dichlorotoluene are thought to occur by a different mechanism (8–11). The evidence for this conclusion involves the "CH_3 replacement" technique (12), the fact that the couplings are the largest when the intervening bonds take up a coplanar "zig-zag" arrangement (13, 14), and the surmise that $J_p^{H,CHO}$ is positive in some benzaldehyde derivatives (15).

In benzaldehyde itself $J_p^{H,CHO} = -0.04$ Hz (16). In α,α,2,6-tetrachlorotoluene $J_p^{H,CHCl_2}$ is zero to within experimental error (11). Rate studies by nuclear magnetic resonance (n.m.r.) (11, 17) suggest that in both molecules at room temperature, the C–H bonds of the sidechain flip rapidly between two equivalent conformations in which they lie coplanar with the aromatic ring. Since the π electron mechanism for this coupling predicts that $J_p^{H,XH} \propto \cos^2\theta$, where θ is the angle between the H—X—C_1 plane and the pπ orbital on the C-1 carbon atom of the aromatic ring, the occurrence of small or zero couplings $J_p^{H,CHO}$, $J_p^{H,OH}$, and $J_p^{H,NHX}$ could therefore be a consequence of the preponderance of the coplanar conformations of these groups when bonded to the benzene ring. Coupling of hydroxyl or amino protons to ring protons is observed only when the hydroxyl or amino protons are held in a coplanar conformation by intramolecular hydrogen bonds (10, 18). Otherwise intermolecular proton exchange makes such couplings unobservable in a slow passage experiment.

The aldehydic proton is less easily exchanged and the presence of sufficiently large ortho substituents may well result in a time-averaged nonplanar conformation of the carbonyl groups. Hyperconjugation between the C–H bond of the carbonyl group and the aromatic π system might then lead to a measurable, *negative* value of $J_p^{H,CHO}$.

In this paper the signs of $J_m^{H,CHO}$ and $J_p^{H,CHO}$ relative to J_o^{HH} in 2,6-dinitrobenzaldehyde are determined by double resonance techniques. The results are discussed in terms of the coupling mechanisms indicated above.

Experimental

Sufficient acetone was added to benzene-d_6 to ensure complete solubility of an approximately 20 mole % solution of 2,6-dinitrobenzaldehyde. Proton double resonance experiments (19, 20) on this solution could be interpreted unequivocally because the proton single resonance spectrum was a loosely coupled A_2BX system. A solution of 2,6-dinitrobenzaldehyde in acetone only was also examined in order to determine solvent effects, if any, on the long-range coupling constants. Single proton resonance spectra were also measured on solutions of 2,6-dichlorobenzaldehyde and of 3,5-dichlorobenzaldehyde in benzene-d_6 and in carbon disulfide, respectively.

Tetramethylsilane (TMS) served as an internal reference and as a lock signal in the frequency-sweep mode of a DA-60I Varian spectrometer. Solutions were degassed by the freeze–pump–thaw technique. The benzaldehyde derivatives were obtained from Aldrich Chemical Company.

Results

Signs and Magnitudes of the Long-range Couplings

The proton resonance of 2,6-dinitrobenzaldehyde at 60 MHz is a loosely coupled A_2BX spectrum. For the present purpose the ring proton single resonance spectrum is best displayed schematically, as in Fig. 1. Each of the eight peaks in the A_2B spectrum is split into a doublet by coupling to the aldehydic proton. The 16 transitions in Fig. 1 are labelled with plus or minus signs to indicate the spin states of the other nuclei. A low-field transition of a given nucleus, when labelled with a plus sign for the spin state of another nucleus, corresponds to a positive coupling between these two nuclei.

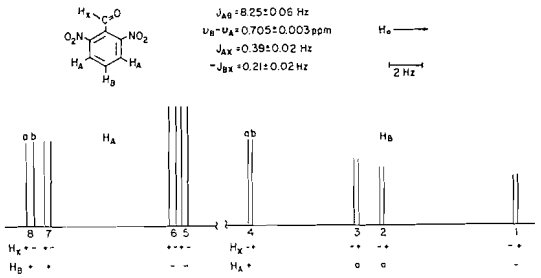

FIG. 1. A stick diagram of the ring proton magnetic resonance spectrum at 60 MHz of 2,6-dinitrobenzaldehyde in a benzene – acetone solvent. The spin states of the coupled protons are indicated by plus and minus signs with the convention that a plus sign under a low-field peak indicates a positive coupling constant to the proton in question.

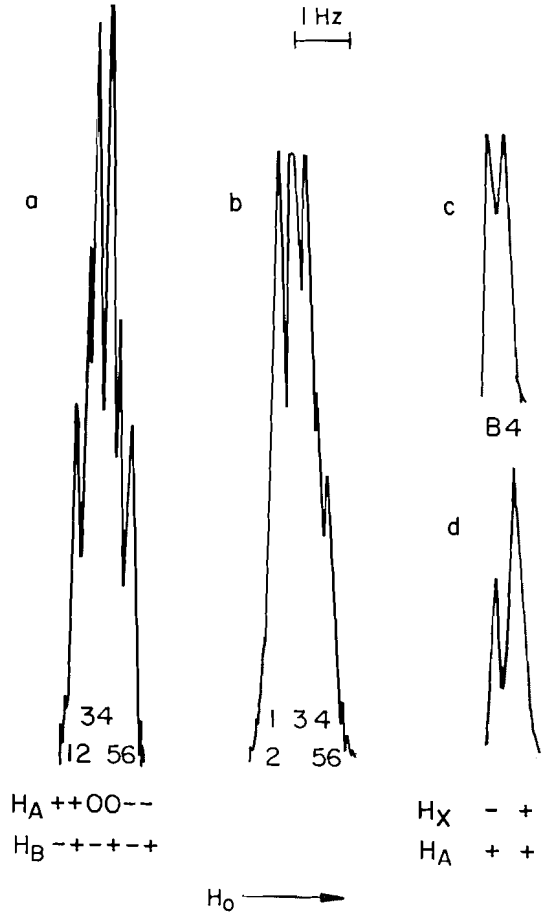

FIG. 2. In *a*) is shown the proton magnetic resonance spectrum of the aldehydic proton of 2,6-dinitrobenzaldehyde under the conditions of Fig. 1. In *b*) the transitions 4*a* and 4*b* of H_B in Fig. 1 are being irradiated leading to collapse of peaks 1 and 2 of the aldehydic proton resonance. In *c*) the single resonance spectrum of transitions 4*a* and 4*b* of H_B is displayed. In *d*) transition 4*a* decreases in intensity when 8*b* of Fig. 1 is weakly irradiated.

In Fig. 2*a*, the single proton resonance spectrum of the aldehydic proton is shown. The triplet of doublets expected for the X part of a loosely coupled A_2BX spectrum is clearly resolved. Simultaneous irradiation of transitions 4*a* and 4*b* in Fig. 1 collapses transitions 1 and 2 of the aldehydic proton resonance as displayed in Fig. 2*b*. This partial decoupling experiment demonstrates that $J_{AB}/J_{AX} > 0$.

In Figs. 2*c* and 2*d* there is shown the result of a generalized Overhauser experiment of the type described by Kaiser (20). This experiment determines the connected transitions in a spin system in a way closely related to the "tickling" experiment originated by Freeman and Anderson (19). In the Overhauser experiment the amplitude of the second radiofrequency field is smaller than in the tickling experiment. As a consequence, the connected transitions change in intensity instead of splitting into doublets. In the present work the Overhauser experiment is more easily performed because γH_2 can be kept small enough so as not to perturb noticeably a transition while its neighbour a few tenths of a Hz away is being irradiated. In Fig. 2*c* the single resonance of transitions 4*a* and 4*b* of H_B is shown while in Fig. 2*d*, the intensity of transition 4*a* of H_B decreases when transi-

For personal use only.

tion 8*b* of H_A in Fig. 1 is weakly irradiated. No change is noted in the signal intensity of 4*b*. Irradiation of 8*a* of H_A on the other hand, causes a decrease in intensity of transition 4*b* of H_B, while 4*a* is unchanged. Hence $J_{AX}/J_{BX} < 0$.

Finally, the A_2BX spectrum was analyzed by the method of effective Larmor frequencies and gave the parameters shown below.[4]

$$\nu_A = 7.958 \pm 0.005 \text{ p.p.m.}$$
$$\nu_B = 7.253 \pm 0.005 \text{ p.p.m.}$$
$$\nu_X = 10.318 \pm 0.005 \text{ p.p.m.}$$
$$J_{AB} = J_o^{HH} = 8.25 \pm 0.06 \text{ Hz}$$
$$J_{AX} = J_m^{H,CHO} = 0.39 \pm 0.02 \text{ Hz}$$
$$J_{BX} = J_p^{H,CHO} = -0.21 \pm 0.02 \text{ Hz}$$

The proton coupling constants of 2,6-dinitrobenzaldehyde are the same within experimental error in the two solvents, benzene and acetone.

2,6-Dichlorobenzaldehyde

In dilute benzene-d_6 solution the proton resonance spectrum is that of a rather tightly coupled A_2BX system with $J_{AB}/(\nu_B - \nu_A) = 0.653$. In this situation the relevant peak spacings are too small to allow for a reliable sign determination by double resonance techniques. However, in a tightly coupled A_2BX spectrum, any asymmetry in the X part of the spectrum indicates that the three coupling constants are not of the same sign (21). The aldehydic proton resonance was not symmetric about its midpoint. Because $J_m^{H,CHO}$ values in 2,6-dichlorobenzaldehyde; 2,6-dinitrobenzaldehyde; 2,4,6-trinitrobenzaldehyde[5]; and in benzaldehyde itself (16) are equal within experimental error, the negative sign is assigned to $J_p^{H,CHO}$ in 2,6-dichlorobenzaldehyde. A normal A_2BX analysis results in the following parameters for 2,6-dichlorobenzaldehyde

$$\nu_A = 6.595 \pm 0.005 \text{ p.p.m.}$$
$$\nu_B = 6.378 \pm 0.005 \text{ p.p.m.}$$
$$\nu_X = 10.130 \pm 0.003 \text{ p.p.m.}$$
$$J_{AB} = J_o^{HH} = 8.46 \pm 0.06 \text{ Hz}$$
$$J_{AX} = J_m^{H,CHO} = 0.40 \pm 0.03 \text{ Hz}$$
$$J_{BX} = J_p^{H,CHO} = -0.15 \pm 0.02 \text{ Hz}$$

3,5-Dichlorobenzaldehyde

A 15 mole % solution in carbon disulfide gives an A_2BX spectrum in which the aldehydic proton resonates as a single peak of line width at half height of 0.21 ± 0.01 Hz. Similarly, the antisymmetric transition of the para proton shows a single peak whose width at half height is equal to 0.20 ± 0.01 Hz. Any observed splitting of this peak is precisely equal to $J_p^{H,CHO}$ (21). From the width of this peak and from its intensity relative to the other resonance peaks of the para proton, an estimate of $|J_p^{H,CHO}| < 0.07$ Hz is obtained.[6] The parameters are then as follows

$$\nu_A = 7.660 \pm 0.005 \text{ p.p.m.}$$
$$\nu_B = 7.489 \pm 0.005 \text{ p.p.m.}$$
$$\nu_X = 9.883 \pm 0.003 \text{ p.p.m.}$$
$$J_{AB} = 1.93 \pm 0.06 \text{ Hz}$$
$$|J_{AX}| = J_o^{H,CHO} \lesssim 0.10 \text{ Hz}$$
$$|J_{BX}| = J_p^{H,CHO} < 0.07 \text{ Hz}$$

Discussion

$J_p^{H,CHO}$ and Hyperconjugation

The sizeable magnitude and negative sign of $J_p^{H,CHO}$ in the 2,6-disubstituted benzaldehyde is in agreement with a hyperconjugative mechanism similar to that proposed for J_p^{H,CH_3} in toluene derivatives (1, 4, 7). It is here suggested that one may write

$$[1] \qquad J_p^{H,CHO} \propto Q_{CH}Q_{CCHO}$$

where $Q_{CH} < 0$ is the hyperfine interaction constant for a C–H bond and $Q_{CCHO} > 0$ is proportional to $\cos^2\theta$ in a manner similar to Q_{CCH} in toluene derivatives (4). The maximum magnitude of Q_{CCHO} (when $\cos^2\theta = 1$) is not known but the value of $J_p^{H,CHO} = -0.04$ Hz in benzaldehyde implies $Q_{CCHO} \approx 0$ when $\theta = \pi/2$ (the lifetime of the CHO group in the planar conformation is some orders of magnitude larger than for nonplanar conformations (17, 22)).

If it is now assumed that Q_{CCHO} is of similar magnitude to Q_{CCH}, an estimate of the mean value of θ in 2,6-dichloro- and 2,6-dinitrobenzaldehyde can be made. In effect we use an equation of the type

$$[2] \qquad \cos^2\theta = (J(\pi/2) - J)/(J(\pi/2) - J(o))$$

where $J(\pi/2)$ and $J(o)$ are the respective J values for coplanar and orthogonal conformations of the formyl group relative to the plane of the aromatic ring. The methyl group in toluene rotates rapidly (23) and hence $\langle\cos^2\theta\rangle = 1/2$.

[4]The shift parameters are those in the mixed solvent of benzene – acetone.

[5]Unpublished work in this laboratory.

[6]In spectra whose linewidths are no smaller than here, a splitting of 0.10 Hz has been easily observed in this laboratory.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

But $J_p^{H,CH_3} = -0.62$ Hz in toluene (1) and therefore $J_p^{H,CH_3} = -1.2$ Hz for $\theta = 0$. If a similar value of $J_p^{H,CHO}$ for $\theta = 0$ is assumed, i.e., $Q_{CCHO} \approx Q_{CCH}$, then it follows that $\theta = 65°$ and 70° in the nitro and chloro compounds, respectively.

Steric hindrance by the ortho substituents would therefore cause a deviation of 20–25° from a planar conformation of the aldehyde groups. The similar magnitude of θ in the two compounds is reasonable because the larger nitro groups can relieve steric strain by twisting out of plane. The present tentative values of θ are in disagreement with a previous assumption, $\theta = 0$, in the dichloro compound (24).

Dipole moment data (25) suggest that while two ortho methyl groups do not hinder the mesomerism of the CHO group, it is almost completely repressed by two ortho bromine substituents. The effective steric sizes of bromine and methyl are here evidently quite different even though their van der Waals radii are considered to be nearly equal (26). The value of $\theta = 70°$ in 2,6-dimethylbenzaldehyde deduced from the electronic spectrum (27) conflicts with the dipole moment data. Consequently, these results cannot be used to confirm or reject the assumptions underlying our values of θ.

On the other hand, ^{13}C chemical shifts of the carbonyl group yield $\theta = 72$–82° in 2,6-dichloroacetophenone and $\theta = 74$–78° in 2-chloroacetophenone (28). On steric grounds smaller values of θ are expected in 2,6-dichlorobenzaldehyde. In that event the θ value obtained by us is presumably a maximum value.

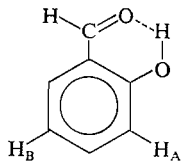
The techniques mentioned above all use equations of the type [2]. Measurements of electrical birefringence do not depend on eq. [2]. These measurements demonstrate that in 9-formylanthracene (29) a value of $\theta = 73°$ is reasonable. The steric interaction here is with the peri hydrogens.

It would clearly be of interest to measure $J_p^{H,CHO}$ and ^{13}C shifts in more strongly hindered benzaldehydes. Kerr effect studies should also prove informative, as would studies of the electron spin resonance spectra of the appropriate ion radicals.

Finally, the implicit assumption that $J_p^{H,CHO}$ is independent of other than steric properties of the substituent is in agreement with the unobservably small values of $J_p^{H,CHO}$ in 3,5-dichlorobenzaldehyde above, in 3,5-dimethoxylbenzaldehyde[7], and in 3,5-dichlorosalicylaldehyde (18), where the CHO group is clearly in a planar conformation for times approaching seconds (18). Also, J_p^{H,CH_3} is independent of substituents in a large number of toluene derivatives.[7]

$J_m^{H,CHO}$ and the Coupling Mechanism

The present results are in accord with earlier multiple resonance (8) measurements which showed that $J_m^{H,CHO}$ is positive. Replacement of the hydrogen atom by a methyl group in CHO leads to a nonobservable value of $J_m^{H,COCH_3}$ and strongly indicates the absence of a π electron contribution to $J_m^{H,CHO}$ (12). Furthermore, $J_m^{H,CHO}$ is stereospecific. Thus, it couples to H_A but not to H_B in **1** where the intramolecular hydrogen bond



1

holds the CHO group in a coplanar conformation. A σ electron mechanism is again indicated. Contributions by σ electrons to proton–proton couplings over five bonds are predicted theoretically (30).

A π contribution to $J_m^{H,CHO}$ cannot be ruled out completely, however, for nonplanar conformations of the CHO group and could account for the similarity of the couplings in benzaldehyde (0.37 Hz), 2,6-dinitrobenzaldehyde (0.39 Hz), 2,6-dichlorobenzaldehyde (0.40 Hz), and 2,4,6-trinitrobenzaldehyde (0.39 Hz).[5] An additional influence upon $J_m^{H,CHO}$ may result from substituent effects (31) acting primarily via the σ electron system. Clearly, the magnitude of $J_m^{H,CHO}$ is affected by a number of factors whose elucidation requires additional studies currently underway.

Calculation of "Dewar" resonance energies in conjugated organic molecules

N. C. BAIRD
Department of Chemistry, University of Western Ontario, London, Ontario.
Received February 3, 1969

Dewar's recent definition of resonance energy (1) for hydrocarbons is extended to molecules containing oxygen, and resonance energy values are calculated from experimental heats of formation for a variety of conjugated organic compounds. A simple additivity scheme is proposed whereby resonance energies and heats of formation can be accurately estimated for benzenoid systems.

Canadian Journal of Chemistry, 47. 3535 (1969)

Introduction

On the basis of semiempirical molecular orbital calculations, Dewar and co-workers (1) have established that the *effective* energies of the "double" and "single" bonds in acyclic conjugated polyenes are independent of the chain length and chain branching. Consequently, Dewar has proposed that these effective bond energies be used in calculating the "expected" bonding energies for the classical structures of cyclic, conjugated hydrocarbons (1). The *Dewar Resonance Energy* (DRE) for a ring system then represents the extent to which conjugation occurs in *excess* of that operative in a corresponding open-chain polyene. If cyclic systems with zero DRE are defined as non-aromatic, then a positive DRE value for a molecule indicates that it is aromatic, and a negative DRE indicates that it is anti-aromatic.

The purpose of this note is to extend Dewar's definition to conjugated molecules containing oxygen, and to indicate that DRE values can be accurately calculated for polycyclic systems by a completely empirical additivity scheme. The additivity scheme should be useful in calculating heats of formation of molecules belonging to homologous series for which insufficient thermochemical data is available to provide an accurate extrapolation.

Calculation of Dewar Resonance Energies

The bonding energies, E, at 25°C of compounds $C_mH_nO_p$ are evaluated using the heats of formation (ΔH_f) of gaseous carbon, hydrogen, and oxygen atoms, and the ΔH_f of the compound:

$$E = m\,\Delta H_f(C^{\cdot}) + n\,\Delta H_f(H^{\cdot}) + p\,\Delta H_f(O^{\cdot}) - \Delta H_f(C_mH_nO_p)$$

Use of the recent JANAF ΔH_f values for atoms (2) leads to the equation (for E in kcal/mole)

$$E = 170.89\,m + 52.10\,n + 59.56\,p - \Delta H_f(C_mH_nO_p)$$

The resonance energies are computed from E by subtracting the sum of the "effective" C=C, C—C, C=O, C—O, C—H, and O—H bond energies evaluated from model acyclic systems (Table I). The C(sp^2)—H and O—H energies in Table I are calculated from the ΔH_f values of +34.1 and −57.8 kcal/mole for the methyl radical (3) and the water molecule (2) respectively. The C=C and C=O energies are then deduced from the ΔH_f's of ethylene of +12.50 kcal/mole (4) and of formaldehyde of −27.7 kcal/mole (5). Finally, the *effective* C(sp^2)—C(sp^2) and C(sp^2)—O single bond energies are computed from the bond energies above and the ΔH_f's for *trans*-butadiene of +26.33 kcal/mole (4) and for divinylether of −3.03 kcal/mole (6). The C=C and C—C bond energies in Table I differ significantly from those determined by Dewar (1*a*), since we consider the methyl radical to belong to the general series of unsaturated hydrocarbons, and hence we derive E(C—H) from its thermochemistry rather than by recourse to a "best fit" procedure.

TABLE I

Effective bond energies (kcal/mole)

Bond	Energy
C(sp^2)—H	97.7
O—H	110.8
C=C	146.9
C—C (polyene)	89.9
C=O	167.0
C—O	89.4

TABLE II

Dewar resonance energies (kcal/mole)

Compound	ΔH_f	Source	Dewar resonance energy: From ΔH_f	Dewar resonance energy: From additivity
Hydrocarbons

tropolone	−39.8	14	+11.8	(0)

*A strain correction of 6 kcal/mole for each five- or seven-membered ring is used in calculation of this value (see text).

†A ring-strain correction may be necessary here, but none is applied (see text).

‡Estimated from the ΔH_f for dimethylfulvene quoted by C. T. Mortimer (12) and corrected for the methyl groups by comparing the ΔH_f of isobutene with that of ethylene.

§Estimated from the heat of hydrogenation for heptafulvene quoted by Mortimer (12), and a heat of formation of methylcycloheptane calculated from the ΔH_f for cycloheptane (15), and the group equivalent values given in (20).

The calculated DRE values in Table II include results for both hydrocarbons and oxygen-containing molecules. The latter series can be included since we have shown elsewhere (7) that C═O and C—O bonds in polyenones and conjugated alcohols and ethers are "localised" according to Dewar's definition (1*a*). Note that the DRE values for molecules containing five- and seven-membered rings are for the "strainless" molecule, since a strain energy correction of 6 kcal/mole (8) per ring has been added to the experimental bonding energies. Small strain energy corrections should probably also be applied to the DRE values for cyclooctatetraene and for [18]-annulene, but have not been applied due to the uncertainty of the magnitude of these effects. Finally, no corrections for steric strain have been attempted.

Results and Discussion

The DRE for the benzenoid hydrocarbons (Table II) parallel their conventional resonance energy values (8) but are significantly smaller. For example, the DRE value for benzene is approxi-

For personal use only.

mately 60% of the 36 kcal/mole usually quoted for its resonance energy. As expected from Dewar's arguments (1), the DRE values for benzenoid ring systems are not increased by the presence of side chains or rings linked by "localized" bonds. For example, the DRE's of styrene, phenol, and benzaldehyde are virtually identical to the value for benzene, and those for stilbene, biphenyl, diphenylether, and benzophenone are all close to twice that of benzene. The DRE for formic acid is substantial, in agreement with the existence of relatively short C—O "single" bonds in such molecules (9). Since the DRE in benzoic acid is close to the sum of that for formic acid and that for benzene (Table II), the conjugation between the ring and the carboxyl group here is very similar to that across the "single" bonds in polyolefins.

Of the cyclic, nonbenzenoid molecules listed in Table II, large, positive DRE's are found only for rings containing $4N + 2\pi$ electrons, or for several rings bonded together containing a total of $4N + 2\pi$ electrons (e.g. azulene). The value for [18]-annulene (i.e. $N = 4$) is quite large, in agreement with the fact that the bonds in this molecule are of aromatic length (10). The value for cyclooctatetraene, a $4N\pi$ electron hydrocarbon, is *negative* due to a loss of conjugation across the single bonds in this nonplanar molecule, angular strain in the eight-membered ring, and the slight anti-aromatic nature of the system.

Additivity of Dewar Resonance Energies

An analysis of the DRE listed in Table II for benzenoid systems indicates that this quantity is *additive* for these molecules in the sense that it can be accurately estimated from their classical structures by the use of a few, simple empirical rules. For neutral, *closed-shell* molecules of this type, the following additive contributions have been derived:

(*i*) Zero from chains containing an even number of conjugated atoms, and similarly for "one-membered" chains.

(*ii*) For rings which contribute 6π electrons and in which the double bonds are conjugated 1,3 (or 1,3,5) to each other, a given double bond contributes to the DRE in *only one ring*, even if it is formally shared between rings in the classical structure. The total DRE of a polycyclic benzenoid compound can be calculated by writing the classical structure with the double bonds "within" one ring or the other, and summing the following contributions:

Benzene ring with 3 double bonds written within it = 21 kcal/mole.

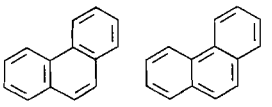
Benzene or furan ring with 2 double bonds written within it = 12.5 kcal/mole.

Benzene or furan ring with 1 double bond written within it = 8 kcal/mole.

Benzene or furan ring with 0 double bond written within it = 0 kcal/mole.

(*iii*) The carboxyl group  contributes 21 kcal/mole.

The DRE values calculated from these group contributions are compared with the experimental values in Table II. In those cases for which more than one nonequivalent classical structure can be written, that giving to the largest DRE is used. For example, the resonance energy for



1*a* **1***b*

phenanthrene structure **1***b* of 12.5 + 21 + 12.5 = 46 kcal/mole is less than that of 21 + 8 + 21 = 50 kcal/mole for structure **1***a*, and consequently the latter value is used.

In almost all the cases listed in Table II, the agreement between the experimental DRE values and those derived from additivity rules is very good. The root mean square (r.m.s.) deviation between these values is only ± 2.2 kcal/mole, which compares very favorably with the r.m.s. error of ± 4.0 kcal/mole[1] by the most accurate molecular orbital theories (1).

Given the DRE contributions for chains and benzene rings, the contributions to the total DRE of a molecule made by rings with $4N + 1$ and $4N + 3\pi$ electrons can be assessed. Such contributions are listed in Table III, and were evaluated by subtracting the additive benzenoid contribution to the DRE (values in brackets in

[1]In computing the r.m.s. values, only benzenoid compounds which are both included in Table II and have been calculated by Dewar and co-workers (1) are included.

TABLE III

DRE contributions from odd-membered rings

Compound	Contribution (kcal/mole)	Double bonds within ring
5-Membered rings		
fulvene	−0.2	2
acenaphthylene	−3.9	1
fluoranthene	−5.3	0
7-Membered rings		
heptafulvene	∼+4	3
tropolone	+11.8	3
5+7-Membered ring		
azulene	+11.1	5

Table II) from the experimental DRE's. Substantial positive contributions are found only in azulene (which has a $4N + 2\pi$ electron perimeter) and in tropolone.[2] Otherwise, five-membered rings make a small *negative* contribution to the overall DRE in molecules, and that for the remaining seven-membered ring is positive but small. These results are in agreement with the nonaromatic behavior of such ring components.

Applications

Using the empirical additivity rules, it is possible to derive accurate values for the DRE, and consequently the ΔH_f value, of various series of benzenoid hydrocarbons. For example, the DRE of linear polyacenes containing N fused benzene rings is equal to $12.5N + 8.5$ kcal/mole, compared to $12.5N + 12.5$ for the corresponding phenanthrene-type isomers, and $12.5N + 13$ for the triphenylene series. In the latter type, the classical structure which yields the largest DRE value is that with no double bonds written within the central triphenylene ring, in agreement with Clar's "hole" hypothesis (11) that such component rings make no contribution to the overall aromaticity of the system.

[2]See page 400 of reference 1*a* for a discussion of the aromaticity of such systems.

Acknowledgments

Cinétique d'oxydation de la cyclohexanedione-1,2 par l'ion thallique[1]

R. Favier et M. Zador
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 24 mars 1969

The kinetics of thallic ion oxidation of 1,2-cyclohexanedione in aqueous perchloric acid solutions lead to the rate expression

$$V = [\text{Enol}](k_{Tl}[Tl^{3+}] + k_{TlOH}[TlOH^{2+}] + k_{TlCl}[TlCl^{2+}])$$

The importance of traces of chloride ions has been shown. Rate constants and activation parameters has been determined and are discussed.

L'étude cinétique de l'oxydation de la cyclohexanedione-1,2 par le Tl(III) en solution aqueuse d'acide perchlorique a conduit à l'équation de vitesse

$$V = [\text{Enol}](k_{Tl}[Tl^{3+}] + k_{TlOH}[TlOH^{2+}] + k_{TlCl}[TlCl^{2+}])$$

L'importance de traces d'ions chlorure a été mise en évidence. Les constantes de vitesse et les paramètres d'activation sont déterminés et interprétés.

Canadian Journal of Chemistry, 47, 3539 (1969)

Introduction

L'oxydation des divers produits organiques par l'ion thallique a été réalisée au cours des dernières années (1).

Du point de vue cinétique, il est à noter le travail de Henry concernant l'oxydation des oléfines en milieu aqueux (2–4). Des essais effectués sur l'oxydation de la cyclohexanone par un excès d'ion thallique en milieu perchlorique nous ont montré qu'en fait, nous avions une série de réactions. Nous avons identifié comme une étape de cette série l'oxydation de la cyclohexanedione-1,2.

Des études cinétiques sur l'équilibre céto-énol de la cyclohexanedione-1,2 ont été effectuées (5); il s'avère de plus qu'à l'état solide la forme énolique est prépondérante. Dans ces conditions la vitesse mesurée est celle de l'oxydation et non pas celle de formation de l'énol comme dans le cas de l'oxydation de la cyclohexanone (6); on peut ainsi étudier le mécanisme de cette réaction.

L'ion thallique se trouve en solution sous forme partiellement hydrolysée et peut également former des complexes avec l'ion Cl^-: les différentes constantes de stabilité sont données dans la littérature (7).

Partie expérimentale

Réactifs

Le solvant est l'eau distillée. La solution thallique a été obtenue par dissolution de l'oxyde thallique (Fairmount Chemical Co. Inc.) dans l'acide perchlorique. Les titres des solutions, environ 0.1 *M*, ont été déterminés par iodométrie. Les solutions de cyclohexanedione-1,2 (J. T. Baker Chemical Co.) ont été fraîchement préparées pour chaque série d'expériences par dissolution du réactif solide dans l'eau distillée; les solutions ont été dosées par spectrophotométrie u.v. à $\lambda = 265$ mμ (5) et par le brome, montrant l'existence de la forme énolique à 95%. Les études infrarouge et r.m.n. des solutions de dione dans le tétrachlorure de carbone confirment la prédominance de la forme énolique.

Stoechiométrie

La stoechiométrie de la réaction a été étudiée en dosant d'une part par spectrophotométrie u.v. l'excès d'énol restant et d'autre part par dosage iodométrique de l'excès d'ions thallique. Dans les deux cas, on observe une stoechiométrie 1:1.

Identification des produits

Pour isoler le produit de la réaction on a procédé comme suit: à 500 ml de solution 0.1 *M* en Tl (III) en milieu acide perchlorique 3 *M*, on ajoute la quantité équivalente de cyclohexanedione-1,2 en gardant toutefois un très léger excès de l'oxydant pour être certain de consommer la totalité de la dione.

A cette concentration et à température d'environ 25 °C la réaction est presque instantanée et le perchlorate thalleux précipite. La solution est ensuite extraite en continu à l'éther ou chloroforme. Etant donné la très grande solubilité du produit dans l'eau même après une semaine on n'a pu extraire la totalité du produit. Les essais de concentration de la solution par distillation de l'eau n'ont pas donné de bons résultats probablement à cause de l'instabilité du produit.

La phase organique à finalement donné une phase liquide brune huileuse et une phase solide blanche dont la quantité variait entre 40–50% suivant le cas.

La phase solide blanche est très instable à l'air, plus stable lorsqu'on la conserve sous atmosphère d'azote.

[1]Présenté au 36ème Congrès annuel de l'Association Canadienne-Française pour l'Avancement des Sciences, Ottawa, Ontario, novembre 1968.

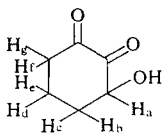
For personal use only.

Compte tenu de son fort degré hydroscopique et de l'impossibilité de le sécher efficacement à cause de son instabilité, l'analyse élémentaire nous fournit des résultats trop grossiers. Après séchage sur plaque poreuse pendant quelques heures, le tout sous atmosphère d'azote, nous avons pu faire immédiatement les études spectrales. Nous l'avons identifié comme l'hydroxy-3, cyclohexanedione-1,2:



Le spectre de masse montre le poids moléculaire à $m/e = 128$ puis le départ du groupement CO nous donne $m/e = 100$ et suite au réarrangement de Mac Lafferty, le pic à $m/e = 55$, (8–10).

Le r.m.n., dans l'acétone deutérée montre un proton hydroxylique (pic aigu) à $\delta = 5.5$ qui disparaît dans D_2O. Puis le proton carbinolique H_a apparaît à $\delta = 2.3$. Les quatre protons H_b, H_c, H_f, H_g apparaissent dans un massif compris entre $\delta = 2.3$ et $\delta = 2$; enfin les protons H_e, H_d apparaissent à $\delta = 1.8$.

L'infra-rouge montre un OH large compris entre 3.200 cm^{-1} et 2.700 cm^{-1}. Les bandes C=O apparaissent à 1710 cm^{-1}, ainsi qu'une bande large à 1.100 cm^{-1} caractéristique de COH.

L'ultraviolet montre une bande d'absorption après quelques jours dans $HClO_4$ à 255 mμ, qui correspondrait à une forme énolique de l'hydroxy-3, cyclohexanedione-1,2.

Nous avons synthétisé un isomère possible du produit de la réaction le dihydroxy-2,3 cyclohexène-2 one-1 (ou dihydropyrogallol) d'après une méthode décrite auparavant (11). La comparaison des spectres de masse, i.r., u.v. et r.m.n. montre que cet isomère n'est pas le produit de la réaction (12). D'autres isomères 1,2,3 ainsi que l'hydroxy-3, cyclohexanedione-1,2 n'ont pas pu être synthétisés dû au manque de données dans la littérature. La phase brune huileuse de poids moléculaire 256 déterminé par osmométrie (301 Vapor Pressure Osmometer Hewlett–Packard, Mechrolab) représente, pensons-nous, le dimère de l'hydroxy-3, cyclohexanedione-1,2; cette tendance à la dimérisation semble être une caractéristique des cyclohexanediones (5). Les méthodes spectroscopiques n'ont pas pu nous conduire à la détermination de sa structure.

Méthodes cinétiques

La réaction a été suivie par enregistrement de l'augmentation de la transmission à la longueur d'onde $\lambda = 265$ mμ. La quantité x d'énol qui a réagi est donnée par l'expression $x = a(D_o - D)/D_o - D_\infty$ ou "a" est la concentration initiale d'énol "D_o", "D" et "D_∞" respectivement les densités optiques aux temps initial, "t" et infini. Les constantes de vitesses et les vitesses initiales ont pu être reproduites à 5% près.

La température a été maintenue constante à ± 0.1 °C et mesurée dans la cellule réactionnelle à l'aide d'un thermocouple.

La vitesse de transformation énol-cétone est négligeable dans nos conditions expérimentales.

L'oxygène de l'air, l'ion Tl (I) n'ont aucune influence sur la réaction.

Les forces ioniques ont été maintenues constantes par $LiClO_4$ (Alfa Organic, Inc.). Compte tenu de l'influence importante des traces d'ions chlorure sur notre réaction, celui-ci a été dosé par la méthode au thiocyanate mercurique (13). Dans nos conditions expérimentales, les solutions de $LiClO_4$ contenaient 1.5×10^{-5} M d'ions chlorure alors que les solutions de perchlorate de sodium (G. Frederick Smith Chemical, Co.) en contenaient 2.10^{-4} M.

Resultats

Equation de vitesse

Notre étude cinétique a permis d'obtenir l'équation de vitesse:

$$[1] \qquad V = k_{exp}[Tl(III)][E]$$

où $[E]$ est l'énol, [Tl(III)] la concentration du thallium à l'état d'oxydation (III). Le graphe de l'équation intégrée est présenté dans la Fig. 1 à plusieurs concentrations en ion thallique et en énol et l'ordre deux global est vérifié. Toutefois, la constante de vitesse d'ordre 2 diminue légèrement avec des concentrations croissantes en ion thallique ce qui nous a amené à penser que cette perturbation était due aux traces d'ions étrangers dans nos solutions. L'étude de l'influence de l'ion Cl^- sur la vitesse de réaction a permis de constater l'effet catalytique mesurable de celui-ci à partir d'une concentration de 10^{-5} M.

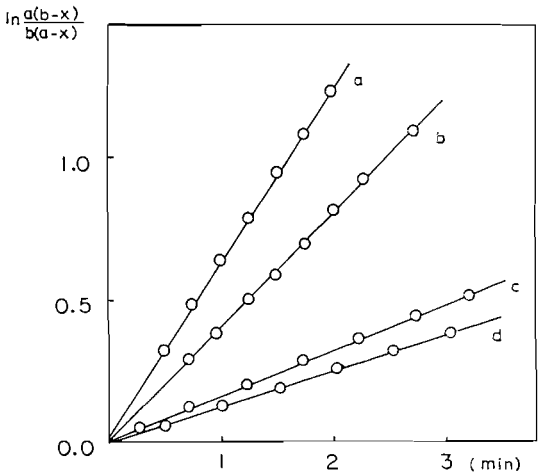


FIG. 1. Equation intégrée d'ordre deux: $T = 25$ °C; $[H^+] = 0.50$ M; force ionique $\mu = 1.0$; a) [Tl(III)] = 7.5×10^{-4} M; [Enol] = 1.0×10^{-4} M; $k_{exp} = 1.0 \times 10^3$ mol^{-1} 1 min^{-1}; b) [Tl(III)] = 5×10^{-4} M; [Enol] = 1.0×10^{-4} M; $k_{exp} = 1.1 \times 10^3$ mol^{-1} 1 min^{-1}; c) [Tl(III)] = 2.5×10^{-4} M; [Enol] = 1.0×10^{-4} M; $k_{exp} = 1.2 \times 10^3$ $mole^{-1}$ 1 min^{-1}; d) [Tl(III)] = 2.5×10^{-4} M; [Enol] = 1.5×10^{-4} M; $k_{exp} = 1.3 \times 10^3$ $mole^{-1}$ 1 min^{-1}.

0.5	250±25	2350±250	0.5	770± 80	4700±500

*[Enol] = 1.0×10^{-4} M; force ionique μ = 1.0.

L'analyse des mélanges réactionnels réalisée dans nos conditions expérimentales a permis d'estimer la concentration en ions Cl^- à 1.5×10^{-5} M.

Ce fait permet d'expliquer la variation de la constante de vitesse. Par la suite, toutes nos solutions ont été analysées quant à leur contenu en ions Cl^-.

Influence de l'ion Cl^-

L'influence de l'ion chlorure est montrée dans la Fig. 2 où on a porté la vitesse initiale, V_i, en fonction de la concentration en ions chlorure.

i) Cas où l'ion thallique est en excès par rapport au chlorure

Dans ce cas d'après les valeurs des constantes de stabilité (7) seul le complexe $TlCl^{2+}$ existe en concentration appréciable et environ 95% de Cl^- se trouve sous cette forme. Dans ce cas, on obtient l'expression de vitesse:

$$[2] \quad V = [E]\{k_0[Tl_0] + k_{TlCl}[TlCl^{2+}]\}$$

où k_{TlCl} et k_0 représentent respectivement les constantes de vitesse de $TlCl^{2+}$ et des espèces sans chlorure, de concentration $[Tl_0]$.

Pour déterminer k_0 on étudie la variation de la vitesse en fonction de la concentration en ion thallique (Tableau I). Dans ce cas, la concentration en $TlCl^{2+}$ demeure constante et à peu près

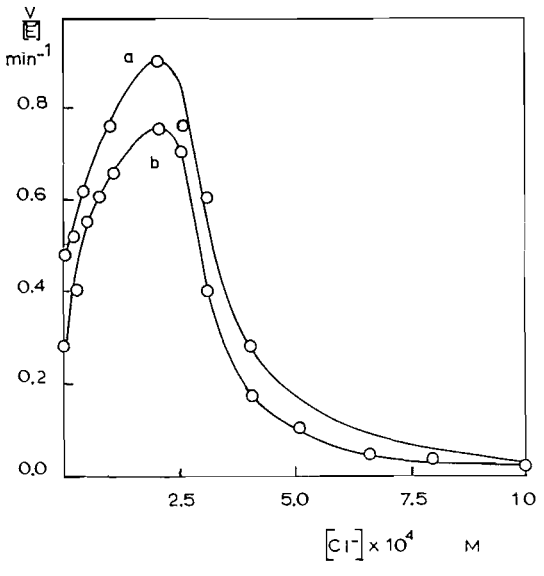

FIG. 2. Influence de l'ion chlorure: T = 25 °C; [Tl(III)] = 2.5×10^{-4} M; [Enol] = 1.0×10^{-4} M; force ionique μ = 1.0 a) $[H^+]$ = 0.1 M; b) $[H^+]$ = 0.5 M.

égale aux traces d'ions Cl^- du mélange réactionnel.

La détermination de k_{TlCl} est faite à concentration en ion thallique constante et en étudiant la variation de la vitesse avec la concentration en ion $TlCl^{2+}$. L'équation [2] devient dans ce cas:

$$[3] \quad V = [E]\{k_0[Tl_0] + (k_{TlCl} - k_0)[TlCl^{2+}]\}$$
où $[TlCl^{2+}] \sim [Cl^-]$.

L'interprétation graphique des courbes de Vi = f(Cl^-) en utilisant l'équation [3] permet de déduire $(k_{TlCl} - k_0)$.

Les valeurs des constantes obtenues sont données dans le tableau I.

On remarque que la valeur de k_0 dépend de l'acidité tandis que k_{TlCl} n'en dépend pas.

D'autre part, la valeur de la concentration des traces d'ions Cl^- dans le mélange réactionnel calculée à partir de l'équation [3] est de 1.5×10^{-5} M aux deux températures en accord avec notre analyse.

ii) Cas où l'ion chlorure est en excès par rapport à l'ion thallique

Lorsque le chlorure est pris en excès par rapport à l'ion thallique, on constate une diminution de la vitesse de réaction (Fig. 2); ceci laisse supposer que les complexes supérieurs Tl (III)-Cl sont relativement inertes. En utilisant les diverses valeurs publiées des constantes de stabilité (7) pour ce système ainsi que nos constantes de vitesse du tableau I, il ne nous a pas été possible d'obtenir un accord parfait entre vitesses calculées et expérimentales et l'étude approfondie se poursuit avec l'étude de l'influence d'autres anions.

L'influence de l'acidité

Contrairement à ce qui a été observé dans l'oxydation de l'éthylène (2), l'acidité a une influence marquée sur la vitesse de réaction.

Les résultats obtenus dans diverses conditions sont présentés au tableau II où k_{exp} est la constante de vitesse définie par l'éq. [1], k_0 est la constante k_{exp} corrigée d'après l'éq. [3] afin de tenir compte de traces de Cl^- et k_0(calc) a été obtenue en tenant compte de l'oxydation par les ions Tl^{3+} et $TlOH^{2+}$ et de l'influence de l'acidité sur leurs concentrations, c'est-à-dire d'après l'expression:

$$[4] \quad k_0 = \frac{k_{Tl} + k_{TlOH} \cdot \dfrac{K_1}{[H^+]}}{1 + \dfrac{K_1}{[H^+]} + \dfrac{K_2}{[H^+]^2}}$$

où k_{Tl} est la constante de vitesse d'oxydation par l'ion Tl^{3+}, k_{TlOH} est celle de $TlOH^{2+}$, K_1 et K_2 sont définies par:

$$K_n = \frac{[Tl(OH)_n^{3-n}][H^+]^n}{[Tl^{3+}]}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

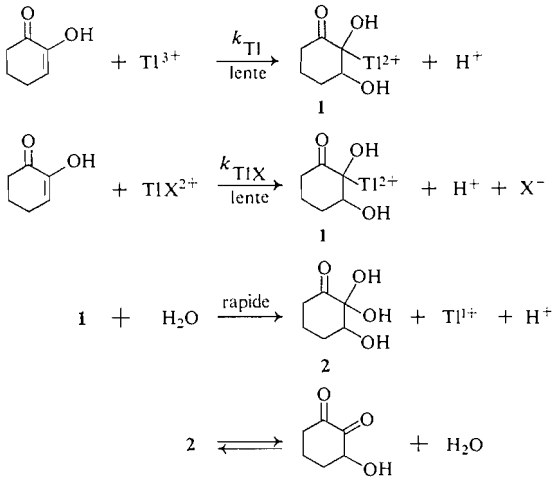
leurs valeurs ayant été calculées pour nos conditions expérimentales d'après (7).

Les valeurs des constantes de l'éq. [4] sont données dans le Tableau II.

L'accord entre les résultats expérimentaux et calculés est bon sauf à très faibles acidités ou $Tl(OH)^{2+}$ prédomine et où l'erreur due à l'incertitude sur K_2 est très importante.

Discussion

L'ensemble de nos résultats peut être interprété par un mécanisme semblable à celui proposé par Henry pour l'oxydation de l'éthylène (2) (14).



où $X^- = Cl^-$ ou OH^-

Les équations [3] et [4] conduisent à l'expression de vitesse globale

$$V = (k_{Tl}[Tl^3] + k_{TlOH}[TlOH^{2+}] + k_{TlCl}[TlCl^{2+}])[E]$$

Il est évident que l'étude cinétique et l'analyse du produit de la réaction ne permettent pas de déterminer sur quel carbone de la double liaison énolique l'ion thallique se fixe initialement; dans les deux cas, le produit final étant identique. Une alternative à ce mécanisme serait la formation lente d'un chélate entre l'ion thallique et les deux groupes fonctionnels du réactif, suivie de l'attaque du carbone 3 par l'eau ce qui donne un mécanisme cinétiquement impossible à distinguer du premier.

Si on compare les résultats obtenus à ceux concernant la réaction d'échange Tl(III)–Tl(I) on constate que l'influence de l'ion Cl^- est contraire à celle que nous avons obtenue. En effet, on a observé la diminution de la vitesse d'échange à faible concentration en ions Cl^-; l'interprétation des résultats a conduit à une constante de vitesse d'échange plus petite pour $TlCl^{2+}$ que pour Tl^{3+} (15, 16). A haute concentration en Cl^- la vitesse d'échange augmente ce qui est dû à l'intervention de complexes supérieurs tandis que dans notre cas la vitesse diminue ce qui tend à éliminer l'oxydation par ceux-là (Fig. 2).

Nos résultats ne sont pas en désaccord avec ceux de Grinstead (1) obtenus dans l'oxydation de l'éthylène: il a rapporté que $TlCl_3$ n'était pas réactionnel. En effet, en utilisant $TlCl_3$, on se trouve à prendre automatiquement un excès de chlorure et donc on favorise les complexes supérieurs en diminuant la concentration des formes réactionnelles Tl^{3+}, $TlOH^{2+}$ et $TlCl^{2+}$.

Henry a rapporté (2) que l'augmentation de la force ionique du milieu avait comme effet l'augmentation de la vitesse de l'oxydation de l'éthylène par l'ion thallique en milieu $HClO_4$–$NaClO_4$. Il a interprété ces résultats en termes de changement d'activité et de changement d'hydratation. Etant donné que nous avons montré l'influence importante de traces d'ions Cl^-, une variation éventuelle de la vitesse avec la force ionique ne peut pas être interprétée d'une manière univoque car elle peut être due à l'augmentation de la concentration en ions Cl^-. Pour cette raison nous n'avons pas envisagé l'étude de l'influence de la force ionique.

TABLEAU III

Paramètres d'activation

Constantes de vitesse	$\Delta H^{\ddagger}_{25°C}$ Kcal/mole	$\Delta S^{\ddagger}_{25°C}$ u.e.
k_{Tl}	24.0 ± 2.5	27 ± 7
k_{TlOH}	7.0 ± 1	-26 ± 4
k_{TlCl}	7.5 ± 1	-24 ± 4

Dans le but d'éclaircir l'influence catalytique des ions OH^- et Cl^- nous avons déterminé les paramètres d'activation des différentes constantes de vitesse. Bien que les résultats du Tableau III soient entachés d'erreurs assez grandes dues à la détermination simultanée des constantes ainsi que des erreurs sur les constantes d'équilibre que nous ne sommes pas en mesure d'évaluer et qui n'ont pas été incluses, ils permettent néanmoins de tirer des conclusions. L'influence catalytique des ions OH^- et Cl^- est reliée à une diminution importante de l'enthalpie d'activation; la valeur élevée du $\Delta H^{\ddagger}$ pour Tl^{3+} montrerait que l'ion

thallique forme un édifice particulièrement stable avec les molécules d'eau de sa sphère de coordination qui serait partiellement détruit lors de la formation du complexe activé, alors que dans le cas de $TlCl^{2+}$ et $TlOH^{2+}$ ce phénomène se produit lors de la formation des complexes avec les anions. Ce genre d'interprétation serait en accord avec les différences notables dans les $\Delta S^{\neq}$. En effet la libération des molécules d'eau lors de l'attaque par l'ion thallique correspondrait à une augmentation d'entropie tandis que, étant donnée la coordination moins importante de $TlOH^{2+}$ et $TlCl^{2+}$ on obtiendrait des valeurs de $\Delta S^{\neq}$ beaucoup plus faibles. Cette interprétation est basée sur la différence significative des résultats plutôt que sur les valeurs individuelles qui incluent d'autres phénomènes.

Remerciements

Nous remercions le Conseil National de Recherches du Canada pour l'octroi grâce auquel ce travail a pu être réalisé ainsi que Monsieur Veschambre Henri pour ses suggestions concernant l'identification des produits.

Reactions of dimethyl acetylenedicarboxylate. III.[1] Reactions with diamines and anthranilic acid

SUSHIL K. KHETAN AND M. V. GEORGE[2]
Department of Chemistry, Indian Institute of Technology, Kanpur, India

Received February 5, 1969

Dimethyl acetylenedicarboxylate reacts with *m*-phenylenediamine, *p*-phenylenediamine and 2,2′-diaminobiphenyl, giving rise to the corresponding bisenamines, having the furmarate geometry. These bisenamines are thermally cyclized to 4(1*H*)-quinolone derivatives and a selective mode of cyclization is observed. Anthranilic acid reacts with dimethyl acetylenedicarboxylate to give an enamine adduct which when heated in diphenyl ether undergoes cyclization to methyl 7-carboxy-3-oxo-2-indolinylidene-carboxylate. Further heating of this product results in the formation of methyl 3-oxo-2-indolinylidene-carboxylate.

Canadian Journal of Chemistry, 47, 3545 (1969)

For personal use only.

The reaction of dimethyl acetylenedicarboxylate with amines has been investigated by several groups of workers. In general, primary amines give rise preferentially to enamines having a fumarate geometry, whereas secondary amines yield either the maleates or a mixture of both maleates and fumarates. Several factors affecting these additions have been studied in detail (1).

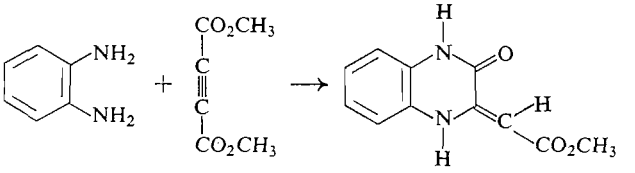
The enamine adducts obtained from the reaction of aromatic amines with dimethyl acetylenedicarboxylate, have been shown to undergo thermal cyclization, yielding 4(1*H*)-quinoline derivatives (2). Thus, when dimethyl anilinofumarate, formed from the reaction of aniline with dimethyl acetylenedicarboxylate, is refluxed in diphenly ether, it undergoes cyclization to give 2-carbomethoxy-4(1*H*)-quinolone (1*a*, 3). The object of the present investigation was to examine the reaction of dimethyl acetylenedicarboxylate with few aromatic diamines and to employ the enamine adducts formed from these reactions for the synthesis of quinoline derivatives.

The reactions of few aromatic diamines are reported in the literature. *o*-Phenylenediamine, for example, reacts with dimethyl acetylenedicarboxylate to give a cyclic product, namely, 2-oxo-3-carbomethoxymethylene-1,2,3,4-tetrahydroquinoxaline (**1**) (4). It is evident that in this reaction, the initially formed intermediate is undergoing cyclization through the attack of the second amino group, present in the starting nucleophile (Scheme I). The reaction of 2,3-diaminonaphthalene with dimethyl acetylenedicarboxylate is analogous to that of *o*-phenylenediamine (5). On the other hand, 1,8-diaminonapthalene reacts with dimethyl acetylenedicarboxylate giving rise to a mixture of products, 2-oxo-3-carbomethoxymethylene-1,2,-3,4-tetrahydronaphtho-[1,8-*ef*]-[1,4]-diazepine (**2**) and 2,3-dicarbomethoxy-1,2,3,4-tetrahydronaphtho-[1,8-*ef*]-[1,4]-diazepine (**3**) (5) (Scheme II).

In the present investigation, we have examined the reactions of *m*-phenylenediamine, *p*-phenylenediamine and 2,2′-diaminobiphenyl with dimethyl acetylenedicarboxylate. *m*-Phenylenediamine reacts with dimethyl acetylenedicarboxylate in methanol medium at room temperature to give a 69% yield of tetramethyl *m*-phenylenediaminobisfumarate (**4**). The nuclear magnetic resonance (n.m.r.) spectrum of **4** showed a sharp singlet at 4.58 τ (2H) due to the two vinylic protons. The observed position of the vinylic proton in **4** is in agreement with the reported values for anilinofumarates (1*a*). Similarly, the reaction of *p*-phenylenediamine with dimethyl acetylenedicarboxylate gave a 62% yield of tetramethyl *p*-phenylenediaminobisfumarate (**7**). Under identical conditions, the reaction of 2,2′-diaminobiphenyl gave a 96% yield of tetramethyl 2,2′-diaminobiphenylbisfumarate (**10**). The n.m.r. spectra of **7** and **10** showed the vinylic proton signals at 4.60 τ and 4.64 τ, respectively, and supports the assigned structures for these enamine adducts.

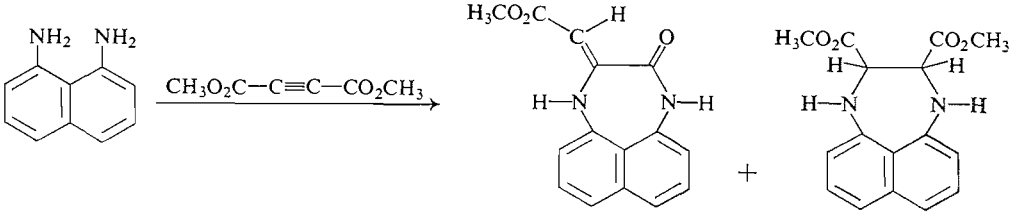
The infrared spectra of the adducts **4**, **7**, and **10** showed the presence of a hydrogen-bonded N—H, absorbing around 3280 cm^{-1}. The chelated ester carbonyl group absorption in these compounds was found to be around 1670 cm^{-1},

[1]For Part II in this series see ref. 10.
[2]To whom enquiries should be addressed.



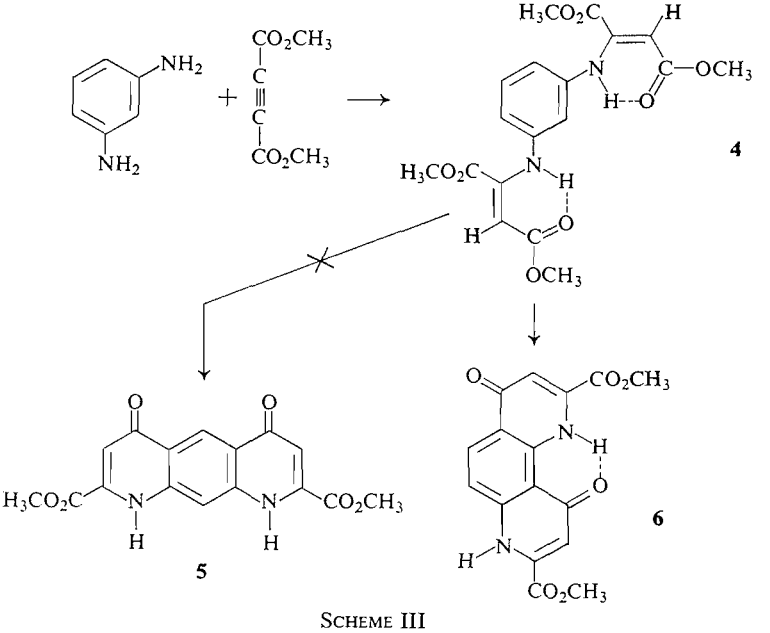
1

SCHEME I



2 3

SCHEME II



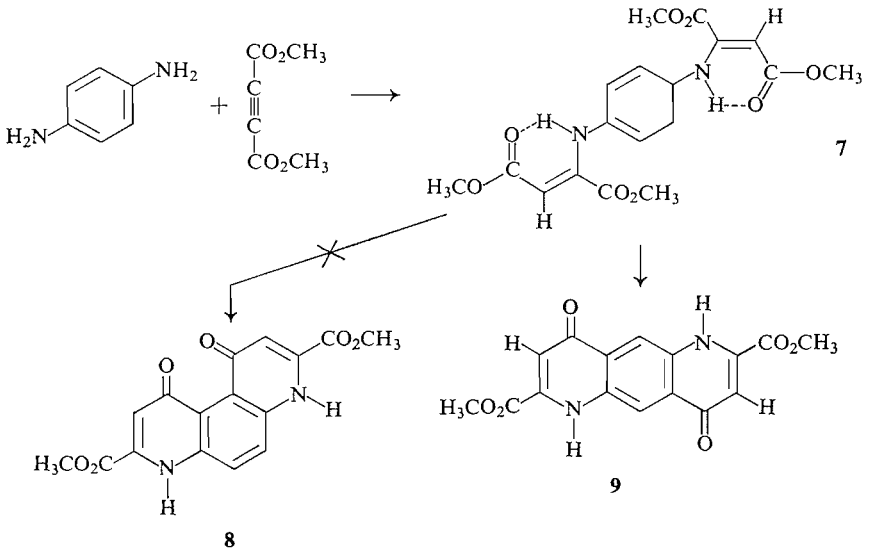
4 5 6

SCHEME III

whereas, the second ester carbonyl group appeared around 1730 cm^{-1}.

A bisenamine adduct like tetramethyl *m*-phenylenediaminobisfumarate (**4**) can undergo cyclization by two different routes giving rise to a linearly fused ring compound, 2,8-dicarbomethoxypyrido-[3,2-*g*]-quinolin-[1*H*, 9*H*]-4,6-dione (**5**) and an angularly fused ring compound, 2,8-dicarbomethoxy-1,7-[1*H*, 7*H*]-phenanthrolin-4,10-dione (**6**) (Scheme III). When the cyclization of **2** was carried out by refluxing it in diphenyl ether for 30 min, a 95% of a single product, melting at 273.5° was isolated. The structure of this product was assigned as **6**, on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



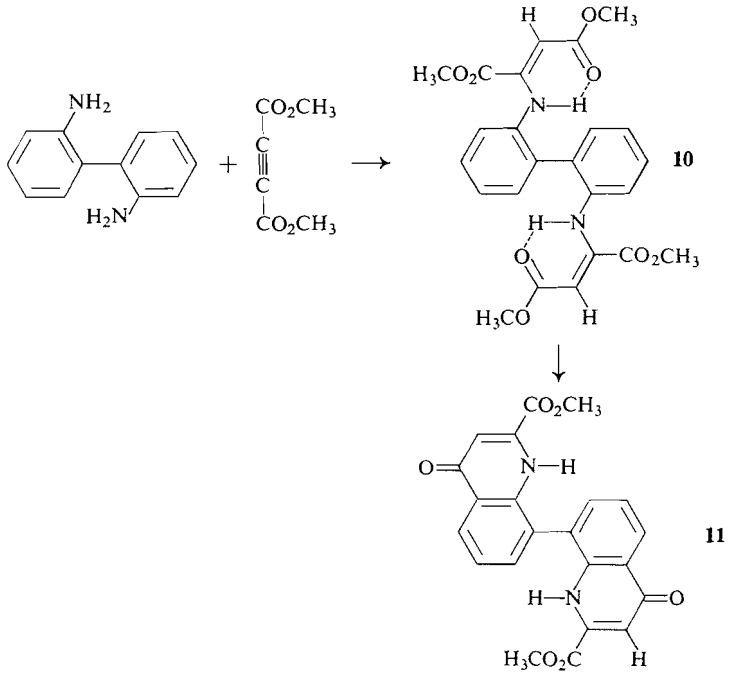
SCHEME IV

the basis of elemental analysis, molecular weight (mass spectral), and spectral evidences. The infrared spectrum of **6** showed two distinctive absorption bands at 3440 cm^{-1} and 3245 cm^{-1}, corresponding to a free and associated NH, respectively. The n.m.r. spectrum of **6**, in trifluoroacetic acid showed signals at 5.79 τ (3H) and 5.94 τ (3H), respectively, due to the ester methyl protons. In addition, the spectrum showed a symmetrical quartet centered around 1.65 τ (2H) of the AB type, with a coupling constant of 9.4 c.p.s. The appearance of this quartet is compatible only with structure **6**, in which there are two ortho protons. A coupling constant of 8–10 c.p.s. is normally observed between the two ortho protons in an aromatic ring (6). The two other olefinic protons present in the pyridone rings of **6**, appeared as two separate singlets at 1.97 τ (1H) and 3.0 τ (1H), respectively. The exact reason for the preferential formation of **6** in the cyclization of the bisenamine adduct **4**, is still not very clear.

Thermal cyclization of tetramethyl *p*-phenylenediaminobisfumarate (**7**), similarly, can give rise to two products **8** and **9**, as shown in Scheme IV. Refluxing a solution of **7** in diphenyl ether resulted in the exclusive formation (97%) of one isomer, namely, 2,7-dicarbomethoxypyrido-[2,3 *g*]-quinolin-[1*H*, 6*H*]-4,9-dione (**9**). The n.m.r. spectrum of **9** showed one singlet at 5.78 τ (6H) due to the ester methyl protons and two separate, sharp singlets at 1.56 τ (2H) and 2.57 τ (2H), respectively, due to the aromatic protons. The spectral data are in full agreement with the assigned structure **9**, for the product. If this compound were to be represented by structure **8**, one would expect the two aromatic ortho protons to appear as a quartet as in the case of **6**. Similarly, the cyclization of tetramethyl 2,2′-diaminobiphenylbisfumarate (**10**), by refluxing in diphenyl ether gave a 95% yield of 8-(2′-carbomethoxy-4′(1′*H*)-quinolonyl)-2-carbomethoxy-4(1*H*)-quinolone (**11**) (Scheme V). Confirmation of the structure **11** was derived from analytical data and spectral evidences. The n.m.r. spectrum of **11** showed a singlet at 5.90 τ (6H), assigned to the carbomethoxyl protons. In addition, the spectrum showed a complex multiplet centered around 1.67 τ (8H), due to the aromatic protons.

In an earlier paper (3), we have reported that ethyl anthranilate reacts with dimethyl acetylenedicarboxylate to give an aminofumarate which on heating undergoes cyclization to give 8-carboethoxy-2-carbomethoxy-4-(1*H*)-quinolone. In the present investigation, we have examined the reaction of anthranilic acid with dimethyl acetylenedicarboxylate with a view to studying the nature of the addition product and also of the mode of cyclization of the enamine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



SCHEME V

adduct formed in this reaction. Treatment of anthranilic acid with dimethyl acetylenedicarboxylate in methanol gave a 78% yield of dimethyl 2-carboxyanilinofumarate (**12**). The infrared spectrum of **12** showed an absorption band at 3247 cm^{-1}, characteristic of the NH group. The two ester carbonyl group absorptions were observed at 1692 cm^{-1} and 1742 cm^{-1} respectively and the C=O absorption of the acid group was observed at 1681 cm^{-1}. The stereochemistry of **12** was inferred to be as that of a fumarate, on the basis of the vinyl proton position at 3.94 τ in its n.m.r spectrum.

When the enamine adduct **12** was heated in refluxing diphenyl ether, it gave rise to a 62% yield of a cyclized product, m.p. 264–265° (decomp.), which has been tentatively assigned the structure **13**, on the basis of analytical results and also of the following evidences. The infrared spectrum of **13** showed an ester C=O band at 1742 cm^{-1}. In addition, the spectrum showed an absorption band at 2500 cm^{-1}, characteristic of an NH_2^+ group and a second absorption band at 1620 cm^{-1}, which could be assigned to a CO_2^- group (7). The mass spectrum of **13** showed a correct molecular ion peak at 247. A second peak was observed at 229, corresponding to the loss of a water molecule from the parent compound. A similar loss of water molecule has been observed when indole-7-carboxylic acid was subjected to electron impact (8). A peak at 187, in the mass spectrum of **13**, could be assigned to the loss of a CO_2CH_3 group from the parent molecule. Other prominent peaks at mass units 171, 170, 143, 115, 114, 103, 75, 63, 39, and 28, were also observed in the spectrum of **13**.

Dry distillation of **13** (230° at 2 mm pressure) resulted in the formation of a small quantity (8.5%) of a product, melting at 137° and identified as methyl 3-oxo-2-indolinylidenecarboxylate (**14**). The yield of **15** could be improved to about 30%, by the direct dry distillation of **12**. The infrared spectrum of **14** showed a carbonyl absorption band at 1689 cm^{-1}, characteristic of a five-membered ring C=O in an indogenide system (9). In addition, the spectrum showed a second C=O absorption at 1709 cm^{-1} and an NH absorption band at 3215 cm^{-1}. The n.m.r. spectrum of **14** showed a broad signal at -1.32 τ (1H), due to the NH proton, a multiplet centered around 2.08 τ (4H) due to the aromatic protons and a sharp singlet at 6.07 τ (3H) due to the

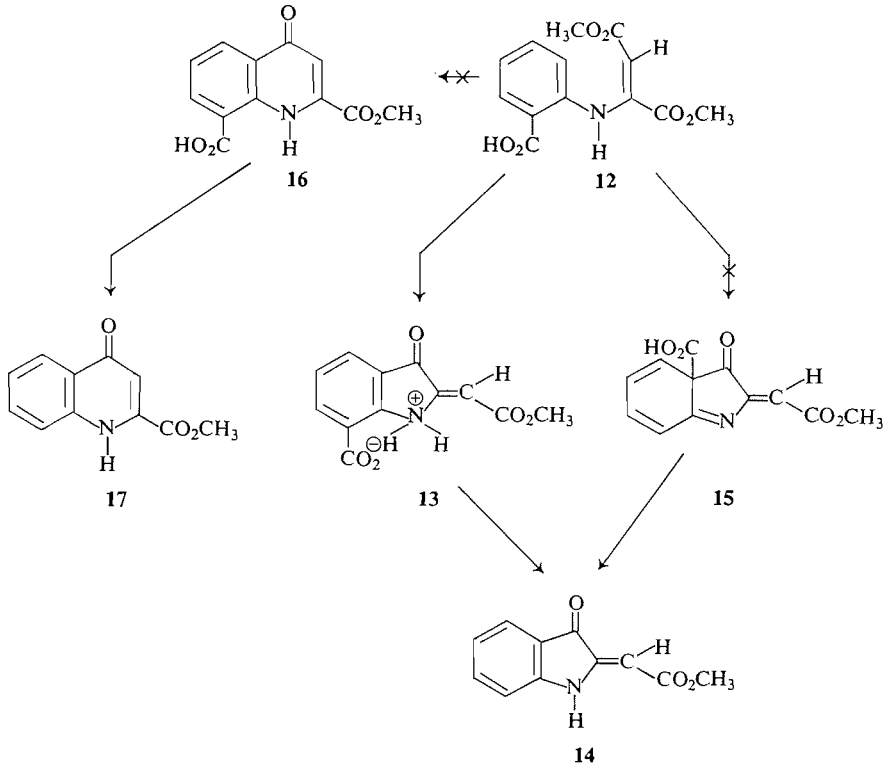

SCHEME VI

carbomethoxy protons. In addition, the spectrum showed a doublet at 3.78 τ (1H) due to the vinylic proton, which was split by the NH proton.

Two other possible structures for the cyclized product obtained from **12** are **15** and **16** shown in Scheme VI. The infrared (i.r.) spectrum of the product which shows the presence of a broad absorption band at 2500 cm^{-1} due to the NH_2^+ group will not favor structure **15**. If structure **16**, on the other hand, correctly represents the product obtained from **12**, then we would expect this product on decarboxylation to give 2-carbomethoxy-4(1*H*)-quinolone (**17**), a known product obtained from the thermal cyclization of dimethyl anilinofumarate (1*a*). The fact that the decarboxylated product (**14**) was not identical with **17**, rules out the possibility of structure **16** for the intermediate, cyclized product.

Experimental

All melting points are uncorrected and were determined in a Thomas–Hoover melting point apparatus. Infrared (i.r.) spectra were determined in a Perkin–Elmer model 137 infrared spectrometer and ultraviolet spectra on a Cary 14-R spectrometer. Nuclear magnetic resonance traces were taken on a Varian HR-100 spectrometer, using TMS as an internal standard.

Reaction of Dimethyl Acetylenedicarboxylate with m-Phenylenediamine

A solution of *m*-phenylenediamine (1.8 g, 0.017 mole) in 10 ml of methanol was treated with a methanolic solution of dimethyl acetylenedicarboxylate (4.9 g, 0.035 mole, in 5 ml). Removal of the solvent under vacuum gave a product which on recrystallization from methanol gave 4.50 g (69%) of tetramethyl *m*-phenylenediaminobisfumarate (**4**), m.p. 146–147°.

Anal. Calcd. for $C_{18}H_{20}N_2O_8$: C, 55.10; H, 5.14; N, 7.14. Found: C, 55.34; H, 5.20; N, 7.51.

Infrared spectrum of **4** (KBr) ν_{max}: 3279 (chelated NH); 3086, 2941 (C—H); 1736 (ester C=O); 1667 (α,β-unsaturated ester C=O); 1603 (C=C), 1435, 1379 (CH_3); 1300, 1264 (C—O—C).

Ultraviolet spectrum of **10** (CH_3OH) λ_{max}: 331 mμ (ε 26 800) and 238 (ε 23 200).

Nuclear magnetic resonance spectrum of **10** ($CDCl_3$): 1.53 τ (NH, 1H); 2.74 τ (phenyl, 8H); 4.63 τ (vinylic, 2H) and 6.40 τ (carbomethoxy, 12H).

8-(2′-Carbomethoxy-4′(1′H)-quinolonyl)-2-carbomethoxy-4(1H)-quinolone

A mixture of tetramethyl 2,2′-diaminobiphenylbisfumarate (**10**) (1.0 g, 0.0026 mole) and diphenyl ether (10 ml) was heated in an oil bath around 250° for 30 min. Removal of the solvent and treatment of the residue with petroleum ether (60–80°) gave a product, which was recrystallized from glacial acetic acid to give 0.80 g (95%) of 8-(2′-carbomethoxy-4′(1′*H*)-quinolonyl)-2-carbomethoxy-4(1*H*)-quinolone, m.p. 225–226°.

Anal. Calcd. for $C_{22}H_{16}N_2O_6$: C, 65.35; H, 3.99; N, 6.93. Found: C, 65.48; H, 4.00; N, 6.52.

Infrared spectrum of **11** (KBr) ν_{max}: 3322 (NH); 2967 (CH); 1730 (ester C=O); 1618 (ring C=O); 1575 (C=C); 1427, 1366 (CH_3); 1261 and 1227 (C—O—C).

Nuclear magnetic resonance spectrum of **11** (CF_3CO_2H): 2.52 τ (aromatic, 8H) and 5.95 τ (carbomethoxy, 6H).

Reaction of Dimethyl Acetylenedicarboxylate with Anthranilic Acid

A mixture of anthranilic acid (13.7 g, 0.1 mole) and dimethyl acetylenedicarboxylate (14.2 g, 0.1 mole) in 50 ml of methanol was stirred for 1 h. The solvent was removed under vacuum to give 21.7 g (78%) of impure dimethyl 2-carboxyanilinofumarate (**12**), which on recrystallization from methanol melted at 138°.

Anal. Calcd. for $C_{13}H_{13}NO_6$ (mol. wt., 279): C, 55.92; H, 4.69; N, 5.02. Found (mol. wt. (vapor pressure osmometry), 275): C, 55.91; H, 4.60; N, 4.97.

Infrared spectrum of **12** (KBr) ν_{max}: 3247 (NH), 1742, 1692 (ester C=O), 1681 (acid C=O), 1577 and 1499 (C=C), 1285, 1249 (O—C—O).

Ultraviolet spectrum of **13** (CH_3OH) λ_{max}: 339 mμ (ε 16 200), 238 (ε 12 800), and 218 (ε 17 900).

Nuclear magnetic resonance spectrum of **12** ($CDCl_3$): −1.11 τ (NH, 1H); 2.07, 2.66, 3.18 τ (aromatic, 4H); 4.32 τ (*trans*-vinylic, 1H); 6.17 τ and 6.22 τ (carbomethoxy, 6H).

Treatment of 2-Carboxyanilinofumarate in Diphenyl Ether at 240°

A mixture of dimethyl 2-carboxyanilinofumarate (2.0 g, 0.007 mole) and diphenyl ether (10 ml) was heated at 240° for 15 min. Removal of the solvent under vacuum and treatment of the residue with petroleum ether (60–80°) gave 1.10 g (62%) of methyl 7-carboxy-3-oxo-2-indolinylidenecarboxylate (**13**), m.p. 264–265° decomp.

Anal. Calcd. for $C_{12}H_9NO_5$ (mol. wt., 247): C, 58.30; H, 3.67; N, 5.67. Found (mol. wt. (mass spectrum), 247): C, 58.72; H, 3.78; N, 5.80.

Infrared spectrum of **12** (KBr) ν_{max}: 3125 (CH); 2500 (NH_2^+); 1742 (ester C=O); 1689 (ring C=O); 1620 (CO_2^-); 1555; 1513 (C=C); 1284, 1212 (C—O—C).

Ultraviolet spectrum of **13** (CH_3OH) λ_{max}: 242 mμ (ε 17 300), 354 (ε 10 000), 373 (ε 11 600), and 219 (ε 24 200).

*Decarboxylation of Methyl 7-Carboxy-3-oxo-2-indolinylidenecarboxylate (**13**)*

Methyl 7-carboxy-3-oxo-2-indolinylidenecarboxylate (**13**) (1.0 g, 0.004 mole) was heated under reduced pressure (2 mm). A compound distilled out around 230° (2 mm), which on purification by chromatography gave 70 mg (8.5%) of methyl 3-oxo-2-indolinylidenecarboxylate (**14**), m.p. 137°.

Anal. Calcd. for $C_{11}H_9NO_3$ (mol. wt., 203): C, 65.02; H, 4.46; N, 6.89. Found (mol. wt. (vapor pressure osmometer), 203): C, 64.83; H, 4.20; N, 6.85.

Infrared spectrum of **14** (KBr) ν_{max}: 3215 (NH-associated); 1709 (ester C=O, associated); 1689 (ring C=O); 1621, 1560, and 1495 (C=C); 1274 and 1110 cm^{-1} (O—C—O).

Ultraviolet spectrum of **14** (CH_3OH) λ_{max}: 352 mμ (ε 10 200), 290 (ε 900), 278 (ε 1 200), and 243 (ε 16 000).

Nuclear magnetic resonance spectrum of **14** (CH_3CN): −1.32 τ (NH, 1H); 1.52, 2.12, and 2.59 τ (phenyl, 4H); 3.78 τ (exo-methylene, 1H) and 6.07 τ (carbomethoxy, 3H).

In a second experiment (4.2 g, 0.001 mole) dimethyl 2-carboxyanilinofumarate (**12**) was directly distilled under reduced pressure (230° at 2 mm) to give 0.90 g (30%) of **14**, m.p. 137° (mixture m.p.).

Reaction of ethanesulfenyl chloride with 2-methoxy-5,6-dihydro-2*H*-pyran[1]

M. J. BALDWIN[2] AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received April 28, 1969

The reaction of ethanesulfenyl chloride with 2-methoxy-5,6-dihydro-2*H*-pyran gives only 4β-chloro-3α-ethylthio-2β-methoxytetrahydropyran. A rationale is presented to explain the observed highly selective reaction.

Introduction

Two recent reports from this laboratory (1,2) have described the reaction of alkane (or aralkane) sulfenyl chlorides with 3,4-dihydro-2*H*-pyran to produce *trans*-2-chloro-3-alkyl (or aralkyl) thiotetrahydropyran which, in the presence of sodium methoxide in methanol, gave *trans*-3-alkyl (or aralkyl)-2-methoxytetrahydropyrans. A rationale was presented to explain the observed highly selective course of the reaction.

The present communication describes the results obtained from the reaction of ethanesulfenyl chloride with 2-methoxy-5,6-dihydro-2*H*-pyran.

Results and Discussion

Addition of an equimolar quantity of ethanesulfenyl chloride to 2-methoxy-5,6-dihydro-2*H*-pyran (**1**) at $-25°$ to $-30°$ gave in good yield a product which was assigned the *trans,trans* structure, 4β-chloro-3α-ethylthio-2β-methoxytetrahydropyran (**2**) (Scheme 1). This assignment was based on the following information. (*i*) All ionic additions of sulfenyl halides to olefins which have been reported to date have led to products in which the alkylthio group and the halogen are *trans* to each other (1–8). (*ii*) The 60 MHz nuclear magnetic resonance (n.m.r.) spectrum in $CDCl_3$ shows a doublet at τ 5.80 ($J_{2,3}$ = 6.5 Hz) which can be assigned to the anomeric proton H-2. The observed chemical shift is very close to that (τ 5.85) found for the C-2 proton of *trans*-3-ethylthio-2-methoxytetrahydropyran (1) and is the same as that (τ 5.80) for the C-2 proton of *trans*-2-methoxy-3-methylthiotetrahydropyran (1), but it is at higher field than that (τ 5.57) for the C-2 proton of *trans*-3-chloro-2-methoxytetrahydropyran. This indicates that the ethylthio group and not the chlorine atom is the substituent at C-3. The relatively large coupling ($J_{2,3}$ = 6.5 Hz) for the anomeric proton also supports the view that the two relevant protons, H-2 and H-3, are *trans* diaxial.

These assignments were corroborated by the 100 MHz n.m.r. spectrum (Fig. 1) and spin decoupling experiments. Irradiation of the nucleus of the proton whose signal is at τ 5.72 (H-2) converted the quartet at τ 7.32 (H-3) to a doublet, $J_{3,4}$ = 7.5 Hz. The magnitude of this coupling clearly shows that H-3 and H-4 are *trans* diaxially disposed. Irradiation at τ 7.32 (H-3) changed the signal at τ 5.72 (H-2) to a "singlet" and simplified the signals in the region τ 6.10–6.40 where the proton (H-4) attached to a carbon bearing a chlorine atom is expected to absorb (9).

The preferred conformation is clearly that of the chair form in which all three groups are equatorially disposed. Although the anomeric effect (10) would tend to favor the alternate chair form, the serious 1,3-diaxial interactions which are present in this alternate conformer would outweigh the stabilizing influence of the anomeric effect.

The exclusive formation of **2** requires comment. It has been suggested (11) that the anomeric effect (10) would favor to the extent of 80–85% that conformer of **1** in which the C-2 methoxy group is *quasi* axial. Also, it has been suggested by Mueller and Butler (7,8) that the first step of the reaction of olefins with ethanesulfenyl chloride is the formation of the episulfonium ion. On the basis of these two observations, in the present case, electrophilic attack of ethanesulfenyl chloride on **1** should occur preferentially from the least hindered side of the molecule, *trans* to the C-2 methoxyl group and result in the formation

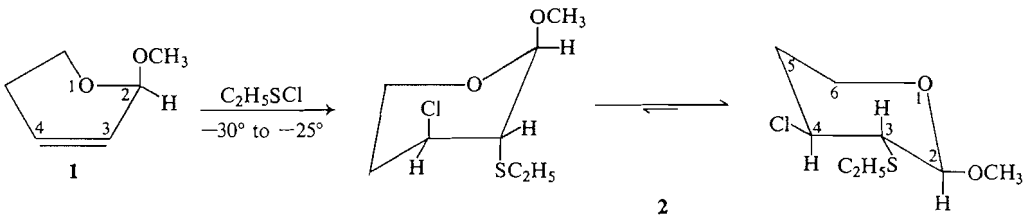

SCHEME 1

of the episulfonium ion intermediate, **3** (Scheme 2). Subsequent attack by the chloride ion could now occur at either C-3 or C-4 with simultaneous opening of the episulfonium ring. Various factors which determine the direction of bond cleavage in such three membered rings have already been discussed (11–13). Keeping these in mind, the course of reaction of the chloride ion with the episulfonium ion **3** can be rationalized. The bulk steric effect of the *quasi* axial methoxy group on C-2, as well as its polar repulsion for the chloride ion, would strongly inhibit attack by the chloride ion at C-3. Both the steric and polar repulsion are minimal or absent when the chloride ion approaches C-4. Furthermore, the preference for a course of reaction in which the negatively charged incoming and "leaving" groups are *trans* diaxial and the six-membered ring assumes the favored chair form (14) will dictate that reaction by the chloride ion occurs at C-4 rather than at C-3.

Another factor which has been considered important in determining the direction of 3-membered bromonium ion ring opening is the inductive effect of the geminal dioxy group at C-2 which would destabilize an incipient positive charge at C-4 less than at C-3, when such a charge is developed by partial C—Br bond breaking (11,15,16). This would favor successful reaction of the chloride ion at C-4 rather than at C-3.

Experimental

All melting points and boiling points are uncorrected. Elemental analyses were made by Mrs. Darlene Mahlow of the Microanalytical laboratory in this Department.

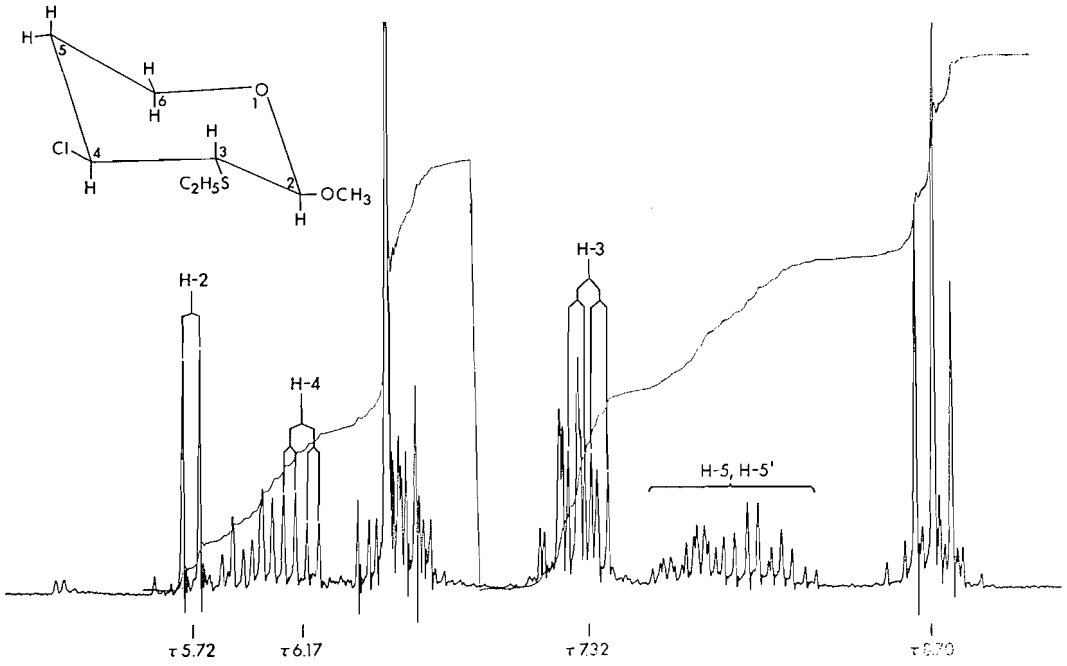

FIG. 1. 100 MHz n.m.r. spectrum in $CDCl_3$ of 4β-chloro-3α-ethylthio-2β-methoxytetrahydropyran.

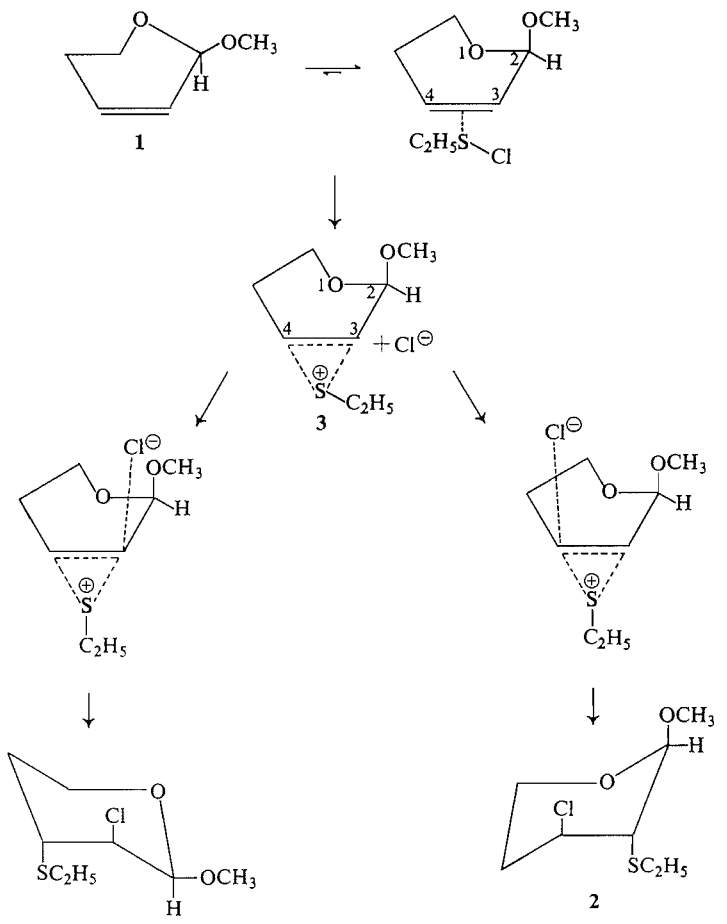

SCHEME 2

The 60 MHz n.m.r. spectra were obtained by Mr. Robert Swindlehurst with a Varian Associates A-60 spectrometer. The 100 MHz n.m.r. spectra and decoupling experiments were made by Mr. Glen Bigham using a Varian Associates HR–100 instrument. The solvent used was $CDCl_3$. The reference material was tetramethylsilane.

Solvents were generally removed by rotary evaporator under vacuum unless otherwise stated.

2-Methoxy-5,6-dihydro-2H-pyran was prepared by a modification (16) of the procedure of Woods and Sanders (17).

Ethanesulfenyl chloride was prepared by the following procedure, based on the general method of Brintzinger *et al.* (18). In an efficient fume hood ethyl disulfide (60 g, 0.4 mole) in a 1 l flask protected with a calcium chloride tube, was cooled to −70° in a dry ice–acetone bath. To this was added sulfuryl chloride (55 g, 0.4 mole) dropwise, with stirring. The solution became orange immediately. During the addition, the solution was allowed to warm slowly to room temperature to prevent precipitation. When the addition was completed, the reaction mixture was heated on a water bath at 45° for 20 min to aid in removal of sulfur dioxide. The mixture was then fractionally distilled under reduced pressure, yielding 51g (66%) of an orange liquid boiling at 40° at 60 mm (lit. b.p. 39° at 58 mm (19)). Ethanesulfenyl chloride was used immediately after its preparation since on standing at room temperature it became dark red within a few hours. Even storage in a freezing compartment failed to prevent its extensive decomposition.

3-Chloro-2-methoxytetrahydropyran was prepared by the method of Riobe (20).

4-Chloro-3-ethylthio-2-methoxytetrahydropyran. To a cold (−30°) stirred solution of ethanesulfenyl chloride (9.6 g, 0.1 mole) in 25 ml of anhydrous methylene chloride was added dropwise 2-methoxy-5,6-dihydro-2*H*-pyran (11.4 g, 0.1 mole). During the course of addition, the yellow color of the sulfenyl chloride slowly disappeared. When the addition was complete, a solution of sodium methoxide (5.4 g, 0.1 mole) in 25 ml of dry methanol was added and the reaction mixture allowed to warm to room

temperature. Removal of the solvents left a sludge which was dissolved in ether. This caused precipitation of dissolved solids. The ether solution was filtered, washed with water, dried ($MgSO_4$) and freed from solvent. Distillation of the residual pale-yellow oil afforded 14 g (67%) of *trans,trans*-4-chloro-3-ethylthio-2-methoxytetrahydropyran; b.p., 77–79° at 0.05 mm; η_D^{26}-, 1.5001.

Anal. Calcd. for $C_8H_{15}ClO_2S$ (mol. wt.: 210): C, 45.61; H, 7.18; Cl, 16.83. Found (208 (by osmometry)): C, 45.70; H, 7.31; Cl, 16.83. The 100 MHz n.m.r. spectrum is shown in Fig. 1 and the significant details are described in the Discussion.

Reaction of 3-aroylaziridines with aryl isothiocyanates

J. W. LOWN, G. DALLAS,[1] AND T. W. MALONEY

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 10, 1969

3-Aroylaziridines react with a variety of aryl isothiocyanates in refluxing benzene to give either (*a*) 4-aroyl-5-arylamino-4-thiazolines by a [2 + 3] cycloaddition and/or (*b*) 2-arylamino-4-aroyl-4-thiazolines. When the *N*-substituent of the aziridine is cyclohexyl or isopropyl the product type (*a*) is isolated in greater quantity, but when the *N*-substituent is methyl, product type (*b*) is isolated in greater quantity. The reactions provide convenient one-step syntheses of new 4-aroyl-4-thiazolines.

Canadian Journal of Chemistry, 47, 3557 (1969)

Recently, interest has been shown in the addition reactions of substituted aziridines involving cleavage of the 2–3 bond to an azomethine ylid and subsequent [2 + 3] cycloaddition to the acetylenic bond and to activated alkenes (1–14). We have reported the analogous addition of 3-aroylaziridines to the polarized carbonyl bond of diphenylcyclopropenone with the formation of novel 4-oxazolines (15, 16). In a continuing study of these addition reactions of 3-aroylaziridines to heteromultiple bonds we now report their addition to aryl isothiocyanates.

Treatment of 1-cyclohexyl-2-phenyl-3-*p*-toluoylaziridine with an equimolar quantity of *p*-nitrophenyl isothiocyanate in refluxing benzene, followed by chromatographic separation on alumina, afforded 3-cyclohexyl-5-*p*-nitrophenylamino-2-phenyl-4-*p*-toluoyl-4-thiazoline **3** (Table I) in 54% yield as orange-red crystals, m.p. 206–207°. The analytical and spectral data on this and similar 4-thiazolines is summarized in Tables I and II and are clearly consistent with structure **3**. In particular the strong hydrogen bonding in a favorable six-membered ring is confirmed by the infrared (i.r.) data, 3050 (broad, bonded NH), 1605(s) (aryl ketone strongly shifted hydrogen bonding), 1589(s) (C=N stretch), and the observation of the low field exchangeable hydrogen bonded NH proton at 13.4 δ in the nuclear magnetic resonance (n.m.r.), spectrum.

This reaction is mechanistically rationalized as involving thermal cleavage of the aroylaziridine to an azomethine ylid and concerted [2 + 3] cycloaddition of this species to the C=S bond of the aryl isothiocyanate and tautomerisation of the product to **3**. It has been observed that the C=S bond of an isothiocyanate will undergo [2 + 3] cycloaddition with diazocompounds, ketocarbenes, alkylene oxides and thioketocarbenes to form five-membered ring heterocycles (17), and that the C=S bond in general displays unusually great activity as a dipolarophile (18).

Huisgen has pointed out that the orientation of 1,3 dipolar additions may not be safely predicted on pragmatic grounds of the assignment of nucleophilic and electrophilic centers in

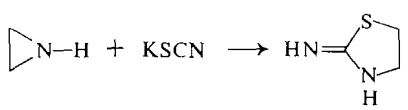
the 1,3 dipole (18). However, in the present reaction, hydrogen bonding of the N—H bond to the carbonyl group uniquely confirms the mode of addition. This reaction therefore provides a useful and facile route to 4-aroylthiazolines and its scope was now explored by examining the reactions of a series of aroylaziridines with a variety of aryl isothiocyanate.

It was anticipated that the above [2 + 3] cycloaddition would in many cases have to compete with nucleophilic attack by the isothiocyanate grouping at the 2-position of the aziridine ring, which Cromwell has pointed out is electrophilic (19).

In the reaction of 3-benzoyl-1-cyclohexyl-2-*p*-biphenylylaziridine with *p*-nitrophenyl isothiocyanate for example products **10** (Tables I and II) and **15** (Tables III and IV) were isolated corresponding respectively to [2 + 3] cycloaddition via the azomethine ylid and to aziridine ring opening at the 2 position and subsequent cyclisation to a 2-arylimino-4-aroyl-4-thiazoline. One of the referees has suggested that compound **15** could also be formed by a [2 + 3] polar cycloaddition.

Gabriel has reported that reaction of aziridine with potassium thiocyanate gives 2-iminothiazolidine (20, 21).



Therefore the initial product of reaction (A) might be expected to be the thiazolidine, and in fact in one example such a thiazolidine was isolated, but in general, the initially formed thiazolidine is dehydrogenated, either during the reaction or in the work-up to the iminothiazoline such as **15**. The iminothiazoline **15** and similar compounds are readily characterized by the observation in the i.r. spectrum of strong C=N stretch and strongly conjugated aryl ketone absorption and the absence of a hydrogen bonded proton characteristic of **10** and similar compounds. In contrast alkyl and aryl isothiocyanates react with aziridines having a free N—H, and gives thioureas (22, 23).

The course of the present reaction of aroylaziridines with aryl isothiocyanates often leads to complex mixtures of oils from which major solid products can be isolated by column chromatography. The data summarized in Table V is given as a preparative guide only, of the dependence of the course of the reaction principally on the nature of the *N*-substituent of the aziridine. While no quantitative conclusions may be drawn from the above observations it is evident in a qualitative sense that when the *N*-substituent of the aziridine is cyclohexyl or isopropyl the [2 + 3] cycloaddition mode is favored in reaction with phenyl isothiocyanate, *p*-nitrophenyl isothiocyanate, *m*-nitrophenyl isothiocyanate, and 1-naphthyl isothiocyanate.

However when the *N*-substituent of the

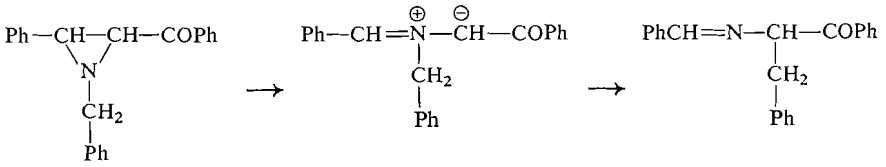
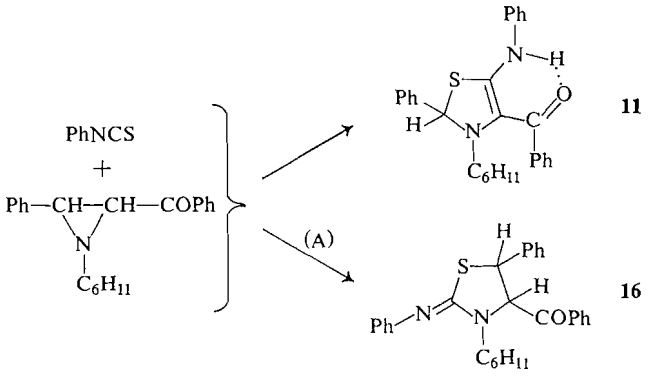
aziridine is methyl, nucleophilic attack at the 2-position of the aziridine is favored leading to the 2-arylimino-4-thiazoline. The yields in Table V represent isolated and purified products after chromatography and no attempt has been made to optimize the yields. *N*-Benzyl substituted 3-aroylaziridines are found to be unsatisfactory in attempted [2 + 3] cycloadditions in this and in other studies (1, 24) where the superior migratory aptitude of the benzyl group favors a Stevens rearrangement of the intermediate azomethine ylid. The thermolysis of 2,3-diphenylaziridine results in a similar rearrangement (5). 3-Benzoyl-1-cyclohexyl-2-phenylaziridine is exceptional in that upon reaction with phenyl isothiocyanate [2 + 3] cycloaddition affords **11** (Table I) and nucleophilic ring opening and subsequent ring closure given the iminothiazolidine **16** (see Experimental) and not the dehydrogenation product.

Compound **16** isomeric with **11** shows an AB quartet due to the 4,5 protons of the thiazolidine ring, the coupling constant of which, 3Hz, corresponds to a *trans* arrangement (8) of these protons in a five-membered ring and confirms, as predicted, that the original 2–3 bond of the aroylaziridine is still intact. Normally dehydrogenation of the initially formed 2-iminothiazolidine to the 2-iminothiazoline occurs during the reaction but **16** proved to be unusually resistant to dehydrogenation, presumably accounting for its isolation in this reaction.

The dehydrogenation of structurally related thiazolines by quinones has been investigated by Kenner and co-workers (25) who found that 9,10-phenanthrenequinone was often satisfactory whereas higher potential quinones such as 2,3-dichloro-5,6-dicyano-1,4-benzoquinone led to more extensive decomposition. Reaction of **16** with 9,10-phenanthrenequinone in acetic acid



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



resulted in dehydrogenative elimination of benzaldehyde to form **17.**

Compound **17** gives correct analytical figures, mass spectral parent peak, the i.r. confirms the absence of an aryl ketone band and the 4-vinyl proton is prominent in the n.m.r. spectrum. The above reaction is analogous to decarboxylative dehydrogenation (26). The abnormal resistance to dehydrogenations of this type has been noted in certain other five-membered ring heterocycles (6).

Treatment of **16** with the higher potential quinone tetrachloro-1,2-benzoquinone in benzene afforded the 2-arylaminothiazole **18.** The [2 + 3] cycloaddition of other reactive hetero-multiple bonds to aroylaziridines is currently under investigation.

Experimental

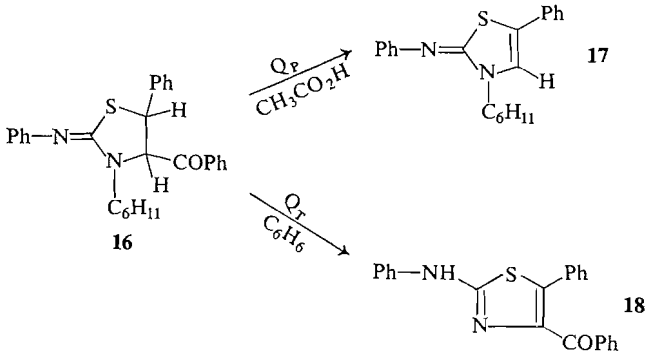
Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. Nuclear magnetic resonance spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in parts per million (p.p.m.) from the reference. Absorption spectra were recorded in 'spectrograde' solvents on a Beckman DB recording spectrophotometer. Mass spectra were determined on an Associated Electrical Industries MS–9 double focusing high resolution mass spectrometer. The ionisation energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for thin-layer chromatography. Microanalyses were carried out by Dr. C. Daesslé, Organic Microanalysis Ltd., Montreal, Quebec and by Mrs. D. Mahlow of this department.

General Preparation of 3-Aroylaziridines

These compounds were prepared by established methods involving aldol type condensations to form the chalcones, then addition of bromine to form the dibromochalcone and treatment of the latter with primary amines to provide the aroylaziridines. Several new aroylaziridines have been prepared by this method exemplified as follows.

Preparation of 3-Benzoyl-1-isopropyl-2-phenylaziridine

Isopropylamine 24 g, (0.407 mole) was added dropwise to a stirred solution of 50 g (0.136 mole) of 2,3-



Q_P = 9,10-phenanthrenequinone
Q_T = tetrachloro-1,2-benzoquinone

dibromo-3-phenylpropiophenone (Eastman Kodak Co.) in 700 ml of dry benzene at 0°, then the solution was stirred for 1 h at 0° and set aside for 24 h at room temperature. The precipitated isopropylamine hydrobromide was collected (34 g; theoretical yield 34 g) and the yellow filtrate washed with water to remove excess amine, dried ($MgSO_4$), and the solvent removed *in vacuo*. The residual oil consisted of an approximately 1:1 mixture of *cis* and *trans* 3-benzoyl-1-isopropyl-2-phenylaziridines (36 g) 100% yield which crystallized partly on chilling. For reaction with the arylisothiocyanates the mixture of isomeric aroylaziridines was used as in previous work (13) but a small quantity was separated into isomers for analytical purposes by preparative thin-layer chromatography on silica with (3:1) benzene:heptane which afforded the pure *cis* isomer and slightly impure *trans*. The latter could be obtained isomerically pure by further chromatography on Fisher alumina in heptane. The stereochemistry was readily assigned by reference to the n.m.r. spectrum (27).

cis-Isomer, pale-yellow crystals m.p. 90–91° (heptane).

Anal. Calcd. for $C_{18}H_{19}NO$ (mol. wt., 265.1467): C, 81.51; H, 7.17; N, 5.28. Found (mol. wt. (mass spectrum) 265.1468): C, 81.32; H, 7.20; N, 5.34.

Infrared spectrum: ν_{max} ($CHCl_3$); 1683 cm^{-1} (aryl C=O). Nuclear magnetic resonance spectrum ($CDCl_3$): 1.22 (doublet, 6H; J = 5.7Hz; $(CH_3)_2CH$—); 1.86 (septet, 1H, $(CH_3)_2$ C*H*), 3.18 (singlet 2H, aziridine ring protons), 7.00–7.50 and 7.80–8.01 (multiplet 10H, aryl protons).

trans-Isomer, low-melting yellow solid, m.p. <25°.

Anal. Calcd. for $C_{18}H_{19}NO$ (mol. wt., 265): C, 81.51; H, 7.17; N, 5.28. Found (mol. wt. (mass spectrum) 265): C, 81.50; H, 7.39; N, 5.05.

Infrared spectrum: ν_{max} ($CHCl_3$) 1662 cm^{-1} (aryl C=O). Nuclear magnetic resonance spectrum ($CDCl_3$): 0.91 (doublet, 3H; J = 6Hz; 1.18, doublet 3H, J = 6Hz; $(CH_3)_2CH$—), 2.19 (multiplet, 1H, $(CH_3)_2CH$—), 3.46–3.66 (AB quartet, 2H, aziridine ring protons); 7.16–7.58 and 7.96–8.16 (multiplets, 10H, aryl protons).

2,3-Dibromo-3-phenyl-p-nitropropiophenone

Styryl-*p*-nitrophenylketone was prepared in 74% yield m.p. 145–147° (lit. m.p. 149–150°) (28) then brominated to give 2,3-dibromo-3-phenyl-*p*-nitropropiophenone in 85% yield, m.p. 210° by the method of Weygand (29).

1-Cyclohexyl-3-p-nitrobenzoyl-2-phenylaziridine

This aziridine was prepared from 2,3-dibromo-3-phenyl-*p*-nitropropiophenone and cyclohexylamine by the standard procedure in 76% yield as an orange solid m.p. 112–113° (hexane).

Anal. Calcd. for $C_{21}H_{22}N_2O_3$ (mol. wt., 350.1630): C, 72.00; H, 6.29; N, 8.00. Found (mol. wt. (mass spectrum) 350.1634): C, 72.10; H, 6.32; N, 7.94.

Infrared spectrum ($CHCl_3$): ν_{max}: 1681, (C=O *cis* aziridine) 1656 cm^{-1} (C=O *trans* aziridine). Nuclear magnetic resonance spectrum ($CDCl_3$): 0.83–2.00 (multiplet, 10H, cyclohexyl CH_2), 2.33–2.76 (multiplet, 1H, cyclohexyl C*H*), 3.22 (singlet, 2H, *cis* aziridine ring protons) (25), 3.57 (singlet, 2H, *trans* aziridine ring protons), 7.18–8.35 (multiplet, 9H, aryl protons).

3-(p-Biphenylyl)-2,3-dibromo-1-phenyl-1-propanone

A solution of 12.6 g (0.0775 mole) of bromine in 50 ml of chloroform was added dropwise to a stirred solution of 22 g (0.0775 mole) of 4-(*p*-phenyl)-styrylphenyl ketone (32) in 100 ml of chloroform during 30 min. The solution was stirred for 15 min, then the solvent removed *in vacuo* to give the dibromo compound as a yellow solid m.p. 180–181°, 34.4 g, (quantitative yield). The product was purified by recrystallization from benzene: hexane as a white solid m.p. 185.5–186°.

Anal. Calcd. for $C_{21}H_{16}Br_2O$: C, 56.75; H, 3.63; Br, 35.99. Found: C, 56.66; H, 3.56; Br, 36.22.

Infrared spectrum ν_{max} ($CHCl_3$): 1690 cm^{-1} (aryl C=O). Nuclear magnetic resonance spectrum ($CDCl_3$): AB quartet centered at 5.76 and 5.92 (2H, J = 11Hz, 2,3 protons); 7.25–8.3 (multiplet, aryl protons).

3-Benzoyl-2-(p-biphenylyl)-1-cyclohexylaziridine

This aziridine was prepared as a *cis–trans* mixture from 22.2 g (0.05 mole) of 2-(*p*-biphenylyl)-2,3-dibromo-1-phenyl-1-propanone and 54.5 g (0.55 mole) of cyclohexylamine by the standard procedure in approximately quantitative yield as a white solid m.p. 127° (MeOH).

Anal. Calcd. for $C_{27}H_{27}NO$: C, 85.00; H, 7.14; N, 3.67. Found: C, 84.90; H, 7.23; N, 3.64.

Infrared spectrum ($CHCl_3$) ν_{max}: 1680 cm^{-1} (C=O). Nuclear magnetic resonance spectrum ($CDCl_3$): 1.0–3.0 (multiplet, 11H, cyclohexyl protons), 3.23 (singlet, 2H, *cis* aziridine ring protons) (27), 3.53 (singlet, 2H, *trans* aziridine ring protons), 7.2–8.3 (multiplet, 14H, aryl protons).

3-Benzoyl-1-methyl-2-phenylaziridine

This aziridine was prepared as a *cis–trans* mixture m.p. 88–89° by the method of Cromwell and co-workers (30).

3-Benzoyl-1-cyclohexyl-2-phenylaziridine

This aziridine was prepared by the method of Cromwell (31) *cis* isomer m.p. 107–109°; *trans* isomer m.p. 99–101°.

1-Methyl-2-phenyl-3-p-toluoylaziridine

This aziridine was also prepared by the above procedure (31) as a *cis–trans* mixture m.p. 76–78°.

1-Cyclohexyl-2-phenyl-3-p-toluoylaziridine

This aziridine was also prepared by the method of Cromwell (31) *cis* isomer m.p. 111–112°; and the *trans* isomer 89–90°.

Reaction of 3-Aroylaziridines with Aryl Isothiocyanates

General Method

The reaction method is exemplified by one reaction of each type in which [2 + 3] cycloaddition and nucleophilic ring opening predominated.

Reaction of 1-Cyclohexyl-2-phenyl-3-p-toluoylaziridine with p-Nitrophenyl Isothiocyanate

A solution of 2.16 g (0.0068 mole) of 1-cyclohexyl-2-phenyl-3-*p*-toluoyl-aziridine and 1.22 g (0.0068 mole) of *p*-nitrophenyl isothiocyanate in 30 ml of dry benzene was heated under reflux for 17 h when a deep orange color developed. The solution was concentrated *in vacuo* to ca. 12 ml and passed down a column of Grade 1 alumina (120 g). Elution with benzene afforded one main fraction which upon evaporation afforded 3-cyclohexyl-5-*p*-nitrophenylamino-2-phenyl-4-*p*-toluoyl-4-thiazoline as deep orange-red crystals 2.1 g (54% yield) m.p. 206–207° from ethyl acetate.

Anal. Calcd. for $C_{29}H_{29}N_3O_3S$ (mol. wt., 499.1930): C, 69.71; H, 5.85; N, 8.41; S, 6.42. Found (mol. wt. (mass spectrum) 499.1931): C, 69.44; H, 5.80; N, 8.38; S, 6.48.

Infrared spectrum: ν_{max} ($CHCl_3$), 1605(s) (C=O), 1589(s) (C=N), 1492(m) 3050 cm^{-1}(m) (broad, chelated hydrogen). Nuclear magnetic resonance spectrum ($CDCl_3$): 0.75–2.15 (11H, multiplet cyclohexyl protons), 2.32 (3H, singlet, aryl methyl), 6.02 (1H, singlet, 4-thiazoline proton), 7.10–8.4 (13H, multiplet, aryl protons), 13.23 (1H, singlet, exchangeable with D_2O, chelated NH proton).

Reaction of 3-Benzoyl-1-methyl-2-phenylaziridine with Phenyl Isothiocyanate

A solution of 1.39 g (0.0059 mole) of 3-benzoyl-1-methyl-2-phenylaziridine and 0.8 g (0.0059 mole) of phenyl isothiocyanate in 20 ml of dry benzene was heated under reflux for 12 h when a deep red-brown color developed. The cooled solution was subjected to chromatography on 70 g of Grade 1 alumina. Elution with benzene afforded one main fraction which upon evaporation of the solvent afforded an orange oil which crystallized upon trituration with ethyl acetate as golden-yellow plates of 4-benzoyl-3-methyl-2-phenylimino-5-phenyl-4-thiazoline, 0.68 g, (31% yield) m.p. 220–221° (from ethyl acetate).

Anal. Calcd. for $C_{23}H_{18}N_2OS$ (mol. wt., 370.1140): C, 74.57; H, 4.90; N, 7.56; S, 8.65. Found (mol. wt. (mass spectrum) 370.1140): C, 74.40; H, 4.69; N, 7.44; S, 8.31.

Infrared spectrum: ν_{max} ($CHCl_3$): 1615(s) (C=O), 1597(s) (C=N), 1497 cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): 3.78 (3H, singlet N—CH_3 group), 7.13–8.40 (15H, multiplet, aryl protons).

Reaction of 3-Benzoyl-1-cyclohexyl-2-phenylaziridine with phenyl isothiocyanate

A solution of 6.35 g (0.0208 mole) of 3-benzoyl-1-cyclohexyl-2-phenylaziridine and 2.8 g (0.0208 mole) of phenyl isothiocyanate in 65 ml of dry benzene was heated under reflux for 7 h when a yellow-orange color developed. The cooled solution was concentrated to ca. 15 ml *in vacuo* and passed down a column of 200 g of Grade 1 alumina. Elution with benzene gave a yellow fraction which upon evaporation of the solvent gave a yellow solid, 1.74 g containing two products. Extraction with hot heptane allowed separation of the products:

(*a*) Insoluble in hexane was 4-benzoyl-3-cyclohexyl-2-phenylimino-5-phenylthiazolidine purified by recrystallization from benzene as pale-yellow crystals, 0.5 g, m.p. 204°.

Anal. Calcd. for $C_{28}H_{28}N_2SO$ (mol. wt., 440.1923): C, 76.33; H, 6.41; N, 6.36; S, 7.28. Found (mol. wt. (mass spectrum) 440.1927): C, 76.57; H, 6.78; N, 6.31; S, 7.34.

Infrared spectrum: ν_{max} ($CHCl_3$): 1673(s) (C=O); 1592(s) (C=N) 1490(m) cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): 0.4–3.35 (11H, multiplet, cyclohexyl protons); AB quartet centered at 6.23 and 6.46 δ (J = 3Hz) (2H, 4,5 thiazolidine protons with *trans* geometry); 6.70–8.50 (15H, multiplet, aryl protons).

(*b*) Soluble in hexane was 4-benzoyl-3-cyclohexyl-2-phenyl-5-phenylamino-4-thiazoline 1.2 g, (20% yield) m.p. 156° (from benzene/hexane). Full details on this compound as well as the physical properties, analytical data and spectroscopic properties of the other 4-thiazolines synthesised may be found in Tables I to IV.

Reaction of 4-Benzoyl-3-cyclohexyl-2-phenylimino-5-phenyl-thiazolidine with 9,10-Phenanthrenequinone

A solution of 0.250 g (0.00057 mole) of the thiazolidine and 0.165 g (0.0008 mole) of 9,10-phenanthrenequinone in 3 ml of acetic acid was heated under reflux for 30 min, allowed to cool and diluted with 15 ml of ether and 15 ml of benzene and allowed to stand over 2.98 g of sodium carbonate overnight. The filtered solution was evaporated to dryness and the residual yellow solid taken up in 5 ml of benzene and subjected to chromatography on 15 g of Grade 1 alumina. Elution with benzene afforded two fractions:

(*a*) a white crystalline solid of 3-cyclohexyl-2-phenylimino-5-phenyl-1,3-thiazoline, 0.175 g (92% yield) m.p. 205° (from 1:1 benzene: petroleum ether).

Anal. Calcd. for $C_{21}H_{22}N_2S$ (mol. wt., 334.1504): C, 75.41; H, 6.63; N, 8.38; S, 9.59. Found (mol. wt. (mass spectrum) 334.1509): C, 75.57; H, 6.62; N, 8.41; S, 9.53.

Infrared spectrum: ν_{max} ($CHCl_3$): 1590(s) cm^{-1} (C=N). Nuclear magnetic resonance spectrum ($CDCl_3$): 0.83–2.48 (10H, multiplet, cyclohexyl protons), 4.57–5.19 (1H, broad multiplet, 1-cyclohexyl proton), 6.90 (1H, singlet, 4-proton) 6.8–7.50 (10H, multiplet, aryl protons).

Fraction (*b*) consisted of 9,10-phenanthrenequinone, 0.125 g m.p. 207°, mixture m.p. 207° with authentic material.

Reaction of 4-Benzoyl-3-cyclohexyl-2-phenylimino-5-phenyl-1,3-thiazolidine with Tetrachloro-1,2-benzoquinone

A solution of 0.421 g of the thiazolidine and 0.236 g of tetrachloro-1,2-benzoquinone in 20 ml of dry benzene was heated under reflux for 12 h during which time the red colour of the quinone was discharged. The cooled solution was passed down a column of 25 g of Grade 1 alumina and elution with benzene, affording one bright yellow fraction of 4-benzoyl-2-phenylamino-5-phenylthiazole 0.108 g (31% yield) m.p. 135° (from cyclohexane).

Anal. Calcd. for $C_{22}H_{16}N_2SO$ (mol. wt., 356.0984): C, 74.13; H, 4.52; N, 7.86; S, 9.00. Found (mol. wt. (mass spectrum) 356.0983): C, 73.95; H, 4.52; N, 7.87; S, 9.20.

Infrared spectrum: ν_{max} ($CHCl_3$): 1595 (C=O), 3150 (broad, NH). Nuclear magnetic resonance spectrum ($CDCl_3$): 6.91–8.52 (15H, multiplet, aryl protons), 11.92 (1H, exchangeable with D_2O, NH).

Comparison of proton magnetic resonance spectra of cell-wall mannans and galactomannans of selected yeasts with their chemical structures[1]

P. A. J. Gorin, J. F. T. Spencer, and R. J. Magus
Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received March 3, 1969

Yeasts can often be identified with the aid of the distinctive proton magnetic resonance (p.m.r.) spectra of their cell-wall mannans or galactomannans. Some of the polysaccharides, such as the galactomannan of *Torulopsis gropengiesseri* and the mannan of *Saccharomyces rouxii* give p.m.r. spectra with only slight differences and have closely related chemical structures in terms of main chains and side chains. Other spectrally similar polysaccharides with related chemical structures have also been found. These are firstly the galactomannans of *Trichosporon fermentans* and *Candida lipolytica* and secondly the mannose-containing polysaccharides of *Torulopsis bombi* (*Torulopsis* species PRL 319-67), *Torulopsis magnoliae* and *Torulopsis apicola* (Hajsig strain). The mannans of *Candida catenulata* and *Endomycopsis fibuliger* give p.m.r. spectra with a lesser degree of similarity, but have markedly different chemical structures. These results show that polysaccharides with similar p.m.r. spectra have related chemical structures and may therefore arise from phylogenetically related yeasts.

Canadian Journal of Chemistry, 47, 3569 (1969)

Recently we have isolated mannose-containing polysaccharides from yeast cell-walls by extraction with hot aqueous alkali followed by purification via their insoluble copper complexes. The H-1 portions of proton magnetic resonance (p.m.r.) spectra of the polysaccharides have proved to be of considerable aid in classification and identification of the yeasts from which they originate (1–6). Many spectra can be grouped if they are identical or bear marked similarities to each other and if these similarities reflected resemblances in polysaccharide structure it is then likely that the originant yeasts are related. We therefore determined the chemical structures of three groups of mannose-containing polysaccharides which give similar spectra. These polymers arose from *a*) *Torulopsis gropengiesseri* and *Saccharomyces rouxii*, *b*) *Candida catenulata* and *Endomycopsis fibuliger*, and *c*) *Trichosporon fermentans* and *Candida lipolytica* (Fig. 1). Also the mannan from a glycolipid-producing *Torulopsis* species PRL 319-67 was compared with a spectrally similar galactomannan from *Torulopsis magnoliae*, the mannose-containing polysaccharides of *Torulopsis apicola* (Hajsig strain) and *Torulopsis gropengiesseri*, species which may be related on the basis of biochemical tests.

(i) Mannose-containing Polysaccharides of Torulopsis spp.

Methylation–fragmentation analysis revealed differences between the mannose-containing polysaccharides of PRL 319-67, *T. magnoliae*, *T. apicola* and *T. gropengiesseri*. In particular *T. magnoliae* and *T. gropengiesseri* galactomannans contained galactopyranosyl non-reducing end-units (Table I).

Some dissimilarities between the polysaccharides were found on determination of specific rotations, galactose content, and periodate oxidation characteristics (Table II). On ultracentrifugation *T. magnoliae* galactomannan gave two peaks whereas one peak was obtained from the other polysaccharides.

Significance can be attached to the unit-size distributions of the free oligosaccharides formed following cleavage by partial acetolysis of the α-(1 → 6)-linkages in the polysaccharides. These fragments arise from side-chains of different length. Large fragments of 2–8 hexose units were obtained from the mannan of PRL 319-67, similar to those of *T. magnoliae* galactomannan (2–10 units) and *T. apicola* (Hajsig) mannan (2–6 units) (Table III). Only short fragments of 2 and 3 units were obtained from *T. gropengiesseri* galactomannan. The above fragments were identified as α-(1 → 2)-linked D-mannopyranose oligosaccharides by p.m.r. spectroscopy (2) and their specific rotations (ca. +55°). Each oligosaccharide fraction from *T. magnoliae* galactomannan, although giving a similar type of p.m.r. spectrum gave a trace of galactose on hydrolysis and had slightly higher specific rotations than its mannose-containing counterpart.

It can be seen that the polysaccharides giving closely related p.m.r. spectra have closely related

chemical structures in terms of main-chains and side-chains.[2] The p.m.r. spectrum (Spectrum 1, Fig. 1) and chemical structure of the mannan of *Torulopsis* sp. PRL 319-67 are close to, but not identical to those of the galactomannan of *T. magnoliae* (Spectrum 3, Fig. 1; Tables I, II, III, IV) and the mannan of *T. apicola* (Spectrum 2, Fig. 1; Tables I, II, III, IV). (There is similarity between the p.m.r. spectrum of the galactomannan of *Torulopsis nodaensis* (Spectrum 4*b*, Fig. 1) and that of PRL 319-67, but the former yeast has differences in its sugar assimilation reactions and does not produce glycolipid.) The p.m.r. spectrum and chemical structure of PRL 319-67 mannan bears little resemblance to those of *T. gropengiesseri* galactomannan (Spectrum 4, Fig. 1; Tables I, II, III, IV).

The p.m.r. and chemical results are relevant since they have a bearing on the identity of a yeast *Torulopsis* species PRL 319-67. In 1954 Spencer isolated it from bumblebee nests and the nectar of sow thistle, clover, and dandelions, growing in the area of Saskatoon and in 1960 it was reisolated and reinvestigated since the yeast produces a glycolipid. This metabolite is of interest since it may be useful as a perfume base or a food additive. Its structure has been investigated (7–10). Since the isolation of this yeast a number of suggestions as to its identity

[2]Each of the polysaccharides contain an α-(1 → 6)-linked D-mannopyranose main-chain (16).

TABLE IV

Oligosaccharide fragments formed following partial acetolysis of mannose-containing polysaccharides

Source of mannose-containing polysaccharide	Oligosaccharides formed on partial acetolysis of polysaccharide (Yields in parentheses)
1. *Torulopsis bombi* (PRL 319-67)	(α-(1 → 2)-D-Manp)$_{2-8}$
2. *Torulopsis apicola* (Hajsig strain)	(α-(1 → 2)-D-Manp)$_{2-6}$
3. *Torulopsis magnoliae*	(α-(1 → 2)-D-Manp)$_{2-10}$
4. *Torulopsis gropengiesseri*	(α-(1 → 2)-D-Manp)$_{2-3}$
5. *Saccharomyces rouxii* (14, 15)	(α-(1 → 2)-D-Manp)$_{2-3}$, 7% and 17%, respectively
6. *Trichosporon fermentans* (1)	D-Manp$^{1,2\alpha}$D-Man (4%), D-Galp$^{1,2\alpha}$D-Manp$^{1,2\alpha}$D-Man (25%)
7. *Candida lipolytica*	D-Manp$^{1,2\alpha}$D-Man (12%), D-Galp$^{1,2\alpha}$D-Manp$^{1,2\alpha}$D-Man (36%)
8. *Candida catenulata*	D-Manp$^{1,2\alpha}$D-Man (5%), unidentified 2-*O*- and 3-*O*-linked tri- and tetramannoside fractions (5% and 6%, respectively)
9. *Endomycopsis fibuliger*	D-Manp$^{1,2\alpha}$D-Man (57%), D-Manp$^{1,3\alpha}$D-Manp$^{1,2\alpha}$D-Man (8%)
10. *Torulopsis lactis-condensi*	D-Manp$^{1,2\alpha}$D-Man (11%), D-Galp$^{1,6\alpha}$D-Manp$^{1,2\alpha}$D-Man (3%)
11. *Hansenula subpelliculosa*	D-Manp$^{1,3\alpha}$D-Man (7%), (α-(1 → 2)-D-Manp)$_{2-4}$, (7%, 6%, 9%, respectively), D-Manp$^{1,3\alpha}$D-Manp$^{1,2\alpha}$D-Manp$^{1,2\alpha}$D-Manp$^{1,2\alpha}$D-Man (6%)
12. *Schizosaccharomyces octosporus*	D-Galp$^{1,2\alpha}$D-Man (27%)

have been made. Wickerham in 1961 suggested that its morphology and carbon and nitrogen assimilation reactions correspond to a strain related to *Torulopsis magnoliae* that does not assimilate nitrate. Phaff in 1963 and Scheda in 1964 investigated cultures of the yeast and noted that its characteristics were similar to those of *Torulopsis apicola* (Hajsig strain). A culture was supplied later (1965) to the Pharmaceutical Division, Imperial Chemical Industries (I.C.I.), Cheshire, England, who relayed it to the Brewing Industry Research Foundation, Surrey, England. Based on a limited number of assimilation tests the yeast was thought to be *Torulopsis gropengiesseri*, which prompted D. F. Jones of the I.C.I. (11) to carry out further structural studies on the glycolipid. (However, since then the I.C.I. culture has been returned to us and the p.m.r. spectrum of its cell-wall mannan was found to be identical to that of PRL 319-67.) Since the new yeast has the ability to produce a unique glycolipid, has a regular habitat and has a cell-wall mannan component different from other known yeasts it is suggested that it is a new species, which could be called *Torulopsis bombi* from its association with bumblebees.

(ii) Galactomannans of Trichosporon fermentans and Candida lipolytica

The p.m.r. spectrum of *Trichosporon fermentans* galactomannan (Spectrum 6, Fig. 1) is similar to that of *Candida lipolytica* galactomannan (Spectrum 7) except that the latter contains a much larger signal at τ 4.53.

Partial acetolysis of the *C. lipolytica* galactomannan gave an acetylated mixture, which was deacetylated and *O*-α-D-galactopyranosyl-(1 → 2)-*O*-α-D-mannopyranosyl-(1 → 2)-D-mannose isolated. It had a specific rotation and p.m.r. spectrum (Spectrum 13, Fig. 2) identical to authentic material (1) and on methylation followed by methanolysis methyl 2,3,4,6-tetra-*O*-methylgalactoside and methyl 3,4,6-tri-*O*-methylmannoside were detected by g.l.c. in a ratio of 1:1.9. A methylation–fragmentation analysis carried out on the parent galactomannan gave methyl glycosides of 2,3,4,6-tetra-*O*-methylgalactose and 3,4,6-tri-*O*-, 2,3,4-tri-*O*-, and 3,4-di-*O*-methylmannoses (for ratio see example 7, Table I). The 6-*O*-substituted α-D-mannopyranosyl units, on the basis of this evidence, can be either in the main-chain or the side-chains, but the former structure is more common, since it is analogous to those of other yeast mannans and galactomannans (1, 12, 13; see also *Endomycopsis fibuliger* mannan described below). This type of mannopyranosyl unit is likely responsible for the H-1 signal at τ 4.53 (Spectrum 7, Fig. 1) since partial hydrolysis of a galactomannan from *Schizosaccharomyces octosporus* gives a mannan with α-(1 → 6)-D-mannopyranose units with H-1 signals with a similar chemical shift (13).

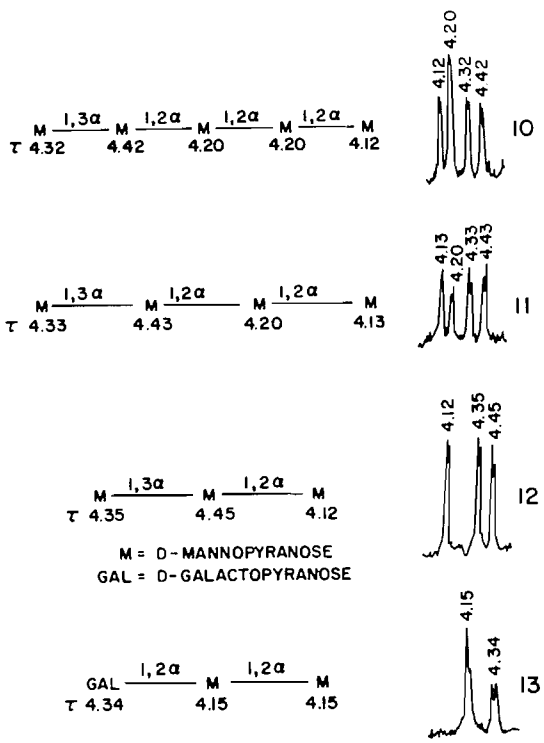

FIG. 2. Proton magnetic resonance spectra of related oligosaccharides from yeast mannans and galactomannan (chemical shifts in τ).

The structural studies, therefore, show that *C. lipolytica* galactomannan contains an α-D-(1 → 6)-D-mannopyranose main-chain which is partially substituted in the 2-positions with *O*-α-D-galactopyranosyl-(1 → 2)-*O*-α-D-mannopyranosyl side-chains (**1**; Fig. 3). The *T. fermentans* galactomannan, on the other hand, contains a similar main-chain and side-chain, except that a higher proportion of main-chain units is substituted with side-chains ((1) **2**; Fig. 3).

(iii) Torulopsis gropengiesseri Galactomannan and Saccharomyces rouxii Mannan

Torulopsis gropengiesseri and *Saccharomyces rouxii* give rise to a galactomannan and a mannan respectively, which provide almost identical p.m.r. spectra (Spectra 4 and 5, Fig. 1, respectively), except for a somewhat broader peak at τ 4.20 in the former spectrum. The two polysaccharides each gave, on acetolysis, α-(1 → 2)-linked D-mannopyranose oligosaccharides of 2–3 units in size (see publication on *S. rouxii* mannan (14, 15), and Table IV). The methylation–fragmentation patterns (Table I), the acetolysis fragments, and enzymolysis data, which show that each polysaccharide contains an α-(1 → 6)-linked D-mannopyranose main-chain (16), show that the galactomannan and mannan are structurally related. Whereas the *T. gropengiesseri* galactomannan has its main-chain substituted in the 2-positions by *O*-galactopyranosyl-*O*-D-mannopyranosyl-(1 → 2)-α-D-mannopyranosyl side-chains, the side-chains in *S. rouxii* mannan are 2-*O*-α-D-mannopyranosyl-D-mannopyranosyl units. (Identical p.m.r. spectra to that of *S. rouxii* mannan have been obtained from those of *Saccharomyces tellustris* CBS 2685, *Saccharomyces elegans* NRRL Y-2228, *Saccharomyces montanus* NRRL 1559, *Saccharomyces mellis* NRRL Y-58, *Saccharomyces pastorianus* NCYC 392, *Saccharomyces acidifaciens* NRRL Y-1011, *Saccharomyces italicus* var. *melibiosi* CBS 2909, *Saccharomyces norbensis* CBS 5378, *Saccharomyces oleaginosus* CBS 3081, and *Saccharomyces oleaceus* CBS 3093 mannans.)

(iv) Mannans from Candida catenulata and Endomycopsis fibuliger

The p.m.r. spectra of mannans from *Candida catenulata* (Spectrum 8, Fig. 1) and *Endomycopsis fibuliger* (Spectrum 9) contain signals with similar chemical shifts, but their proportions are markedly different.

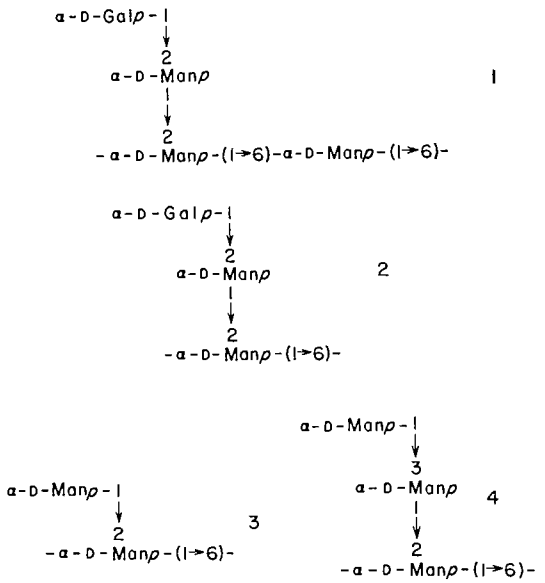

FIG. 3. Structures in some of the yeast polysaccharides.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

E. fibuliger mannan, following partial acetolysis, gave 2-*O*-α-D-mannopyranosyl-D-mannose (57% yield) and *O*-α-D-mannopyranosyl-(1 → 3)-*O*-α-D-mannopyranosyl-(1 → 2)-D-mannose (8% yield). This structure for the trisaccharide is based on the following evidence. It gave the methyl glycosides of 2,3,4,6-tetra-*O*-, 2,4,6-tri-*O*-, and 3,4,6-tri-*O*-methylmannose (1.1:1:1 ratio by g.l.c.) on methylation–fragmentation and was resistant to lead tetraacetate oxidation, consistent with a (1 → 2)-linked reducing end. Its specific rotation, +72°, is indicative of α-D-linkages. Methylation–fragmentation analysis of *E. fibuliger* mannan gave a high proportion of methyl 2,3,4,6-tetra-*O*-methylmannose compared with the methyl glycosides of 2,4,6- and 3,4,6-tri-*O*-methylmannose (Table I). Methyl 3,4-di-*O*-methylmannose was also formed. These data coupled with its specific rotation of +73°, consistent with predominant α-D-linkages, show that the mannan consists of an α-(1 → 6)-D-mannopyranosyl backbone mainly substituted in the 2-positions by single-unit D-mannopyranosyl side-chains (**3**; Fig. 3) and a small proportion of 3-*O*-α-D-mannopyranosyl-D-mannopyranosyl side-chains (**4**; Fig. 3).[3] In accord with this structure only low molecular weight fragments were obtained in partial Smith degradation (compare below). (The mannans from *Endomycopsis capsularis* PRL R_2a and *Endomycopsis selenospora* CBS 2562 give p.m.r. spectra identical with that of *E. fibuliger*.)

Candida catenulata mannan has a specific rotation of +110°, considerably higher than that of *E. fibuliger* mannan. The methyl tri-*O*-methyl and methyl tetra-*O*-methylmannoside fragments obtained on methylation–fragmentation analysis are the same as those from *E. fibuliger* mannan, but the proportion of non-reducing end-units, represented by methyl 2,3,4,6-tetra-*O*-methylmannoside is much lower. Also detected was methyl 2,4-di-*O*-methylmannoside representing structurally different branch points (Table I). Differences were also reflected in the oligosaccharides obtained on partial acetolysis. *C. catenulata* mannan gave rise to 2-*O*-α-D-mannopyranosyl-D-mannose (5% yield) and uncharacterized straight-chain tri- (4%) and tetrasaccharide (6%) fractions, each fraction containing 2-*O*- and 3-*O*-substituted D-mannopyranose units. The fragments obtained by Smith degradations (17) of *C. catenulata* mannan (incorporating mild hydrolytic conditions) were also difficult to characterize. One Smith degradation gave a mannan ($[\alpha]_D$ +55°) which was analyzed by the methylation–fragmentation technique. Gas–liquid chromatography examination of the product indicated the presence of methyl glycosides of 2,3,4,6-tetra-*O*-methylmannose (1 part), 2,3,4-tri-*O*-methylmannose (3.8 parts) and 2,4,6-tri-*O*-methylmannose (6.3 parts) (18). A further Smith degradation on the partially degraded mannan gave a non-reducing fraction with a paper chromatographic mobility close to that of a hexosyl glycerol. Proton magnetic resonance spectroscopy showed that it was a mixture, and hydrolysis gave spots on a paper chromatogram with mobilities equal to mannose and glycerol.

The mannans from *C. catenulata* and *E. fibuliger*, therefore, have widely different chemical structures, but although their spectra (Spectra 8 and 9, respectively; Fig. 1) contain signals with similar chemical shifts, their proportions are different.

(v) Miscellaneous Mannose-containing Polysaccharides from Yeast Cell-walls

A number of mannans and galactomannans, not described in the above presentation, have also been investigated. Since their structures may be of some interest their methylation–fragmentation characteristics, periodate oxidation figures, fragments formed on partial acetolysis, galactose to mannose ratios, and specific rotations are compiled (Tables I, II, and IV).

General Conclusion

In most of the cases examined above, resemblances in p.m.r. spectra of mannose-containing polysaccharides reflect similarities in chemical structure. It seems likely that if two structurally similar polysaccharides are obtained from different species of yeast, then the yeasts possibly have evolved from a common ancestor. Close resemblances in p.m.r. spectra of mannose-containing polysaccharides might therefore suggest a relationship between the parent yeasts.

[3]This type of side-chain is related to that present in baker's yeast mannan, which contains one more (1 → 2)-linked α-D-mannopyranosyl unit (12). Partial acetolysis of *Hansenula subpelliculosa* mannan gives rise to D-Manp^{1,3a}D-Manp^{1,2a}D-Manp^{1,2a}D-Manp^{1,2a}D-Man (Experimental), which arises from a side-chain with two additional (1 → 2)-linked units.

Experimental

The proton magnetic resonance spectra of the mannans and galactomannans were obtained (see Fig. 1) from 20% solutions in D_2O at 70° using a 100 MHz Varian nuclear magnetic resonance spectrometer. Chemical shifts are in τ, based on an external tetramethylsilane standard.

Cultural methods for production of yeast cells and isolation of purified galactomannan or mannan are as previously described (1). Yields of polysaccharide are given in Table II. The polysaccharides were shown to be homogeneous by ultracentrifugation of 0.45% aqueous solutions in 0.1 *M* sodium chloride at 59 000 r.p.m. All of the polysaccharides gave a single peak except those from *T. magnoliae* which gave two peaks.

D-Mannose was isolated from mannans by hydrolysis with *N* H_2SO_4 at 100° for 18 h and characterized by its melting point, mixture melting point, and specific rotation. D-Galactose and D-mannose, similarly obtained from galactomannans, were fractionated by cellulose column chromatography using *n*-butanol–water (9:1 v/v) as eluant, and also characterized by melting point, mixture melting points, and specific rotations. The ratios of galactose to mannose were obtained by the gas–liquid chromatography (g.l.c.) method described previously (1) and are given in Table II.

Methylation of mannose-containing polysaccharides, followed by fragmentation to partially methylated methyl glycosides, was carried out as previously described (1). Gas–liquid chromatographic identification and estimation of the fragments (Table I) are by the method of Bhattacharjee and Gorin (18) following fractionation to tetra-*O*-, tri-*O*-, and di-*O*-methyl derivatives of methyl-mannoside (13).

Partial acetolyses were mostly carried out for 5 days on 2 g samples with the reagent proportions used by Lee and Ballou (12). Following deacetylation in methanolic sodium methoxide the oligosaccharide mixtures were fractionated by cellulose column (40 cm × 4.5 cm diameter) chromatography. Three liters of each of the following acetone–water (v/v) mixtures were used to elute each saccharide fraction. Mono- (10:1), di- (7:1), tri- (4:1), tetra- (7:2), penta- (3:1), hexa- (7:3), hepta- (13:7), octa- (5:3), nona- (3:2), deca- (3:2). Yields are presented in Tables III and IV. Paper chromatography of di- up to pentasaccharide was carried out in *n*-butanol – ethanol – water (2:1:1 v/v/v) using the ammoniacal silver nitrate spray. A 1:1:1 ratio was used for fragments with more than five mannose units.

Characterization of Partial Acetolysis Fragments

2-*O*-α-Linked D-mannopyranoside oligosaccharides gave typical H-1 signals, with τ 4.08 (reducing end), τ 4.40 (non-reducing end) and τ 4.20 (internal units) (2). The proportion of the τ 4.40 signal to other signals showed the unit-size of the fragment. The specific rotations of tri- up to octasaccharide varied from +53° to +57°. The physical constants of various other fragments are given below.

i) Schizosaccharomyces octosporus Galactomannan

2-*O*-α-D-Galactopyranosyl-D-mannose monohydrate (from MeOH–EtOH) had m.p. 105–108° and $[\alpha]_D$ +76° (*c*, 0.6 H_2O).

Anal. Calcd. for $C_{12}H_{22}O_{11}\cdot H_2O$: C, 41.86; H, 7.03. Found: C, 42.0; H, 7.0.

Its resistance to lead tetraacetate oxidation indicated 2-*O*-substitution (19). Hydrolysis gave galactose and mannose and hydrolysis of the sodium borohydride – reduced alcohol gave galactose and mannitol.

ii) Torulopsis magnoliae Galactomannan

The fragments had proton magnetic resonance spectra corresponding to 2-*O*-linked D-mannopyranose oligosaccharides. However, each fraction up to decasaccharide gave on hydrolysis a trace of galactose in addition to mannose. Their specific rotations are higher than expected and are as follows: tri- (+59°), tetra- (+63°), penta- (+52°), hexa- (+65°), hepta- (+72°), octa- (+65°), nona- (+61°), and decasaccharide (+57°) Methylation–fragmentation analysis of the decasaccharide gave mainly methyl 3,4,6-tri-*O*-methylmannoside and a trace of methyl 2,3,4,6-tetra-*O*-methylmannoside as shown by gas–liquid chromatography.

iii) Hansenula subpelliculosa and Endomycopsis fibuliger Mannans

The pentasaccharide from *Hansenula subpelliculosa* had $[\alpha]_D$ +78° (*c*, 1.0 H_2O) and its H-1 p.m.r. spectrum (Spectrum 10, Fig. 2) was similar to that of the D-Manp$^{1,3\alpha}$D-Manp$^{1,2\alpha}$D-Manp$^{1,2\alpha}$D-Man tetrasaccharide (Spectrum 11) except that the signal at τ 4.20 was equivalent to 2 protons rather than 1 proton. This, by analogy with the τ 4.20 signal of (1 → 2)-linked D-mannose oligosaccharides (2) indicates that the pentasaccharide has a D-Manp$^{1,3\alpha}$D-Manp$^{1,2\alpha}$D-Manp$^{1,2\alpha}$D-Manp$^{1,2\alpha}$D-Man structure. The signal at τ 4.32 is due to H-1 of the non-reducing end since it is moved downfield 10 Hz on addition of borate (2).

The trisaccharide from *Endomycopsis fibuliger* ($[\alpha]_D$ +72° (*c*, 0.5 H_2O)) appeared to be D-Manp$^{1,2\alpha}$D-Manp$^{1,3\alpha}$D-Man from its H-1 p.m.r. spectrum (Spectrum 12, Fig. 2). It was methylated and then fragmented to give the methyl glycosides of 3,4,6-tri-*O*-, 2,4,6-tri-*O*-, and 2,3,4,6-tetra-*O*-methylmannose (1:1:1.1 g.l.c. peak ratio). The (1 → 2)-linkage is attached to the reducing end since the trisaccharide is inert to lead tetraacetate oxidation.

iv) Candida catenulata Mannan

The acetolysis fragments consisted of 2-*O*-α-D-mannopyranosyl-D-mannose and tri- and tetrasaccharide fractions. The two latter fractions were each straight chain and contained 2-*O*- and 3-*O*- linked mannopyranose units, as shown by methylation–fragmentation gas–liquid chromatography.

v) Torulopsis lactis-condensi Galactomannan

The hydrated trisaccharide (from MeOH) had m.p. 150–153° and $[\alpha]_D$ +99° (*c*, 0.3 H_2O).

Anal. Calcd. for 2 $C_{18}H_{32}O_{16}\cdot 3H_2O$: C, 40.68; H, 6.64. Found: C, 40.6; H, 6.7.

Methylation – fragmentation – gas–liquid chromatography showed the presence of the methyl glycosides of 2,3,4,6-tetra-*O*-methylgalactose, 2,3,4-, and 3,4,6-tri-*O*-methylmannose (approximately 1:1:1 ratio). The latter fragment arises from the reducing end since the trisaccharide is resistant to lead tetraacetate oxidation and a D-Galp$^{1,6\alpha}$D-Manp$^{1,2\alpha}$D-Man structure is indicated.

vi) Candida lipolytica Galactomannan

The trisaccharide fraction had $[\alpha]_D$ +95° (*c*, 1.0 H_2O)

and an H-1 proton magnetic resonance spectrum (Spectrum 13, Fig. 2) identical to that of D-Galp$^{1,2\alpha}$D-Manp$^{1,2\alpha}$D-Man from *Trichosporon fermentans* (1). Methylation – fragmentation – gas–liquid chromatography gave the methyl glycosides of 2,3,4,6-tetra-*O*-methylgalactose and 3,4,6-tri-*O*-methylmannose (1:1.9 ratio), thus confirming the structure.

Smith Degradations of Candida catenulata Mannan

This procedure first described in a communication by Smith and co-workers (17) has been modified slightly (20). The mannan $[\alpha]_D$ +55° (*c*, 1.0 H_2O) obtained on one Smith degradation using mild hydrolytic conditions was analyzed by the methylation–fragmentation technique. The methyl glycosides of 2,3,4-tri-*O*-, 2,4,6-tri-*O*-, 2,3,4,6-tetra-*O*-methylmannose were identified by gas–liquid chromatography. A further Smith degradation gave a hexosyl glycerol, $[\alpha]_D$ +76° (*c*, 0.3 H_2O), with an R_f equal to mannose on a paper chromatogram (solvent: *n*-butanol – ethanol – water, 40:11:19 v/v/v; spray, ammoniacal silver nitrate). Its p.m.r. spectrum contained several H-1 proton signals which indicates a mixture. Hydrolysis of the material gave hexose and glycerol (paper chromatogram).

Acknowledgments

The authors thank Mr. N. R. Gardner for technical assistance. We also thank Mr. M. Mazurek for preparation of proton magnetic resonance spectra and Mr. W. C. Haid for determination of microanalyses.

Characterization of plant coumarins by combined gas chromatography, ultraviolet absorption spectroscopy, and nuclear magnetic resonance analysis[1]

WARREN STECK AND B. K. BAILEY
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received May 26. 1969

A method for the characterization of sub-milligram quantities of plant coumarins has been devised. Each compound was purified by gas–liquid chromatography, and the collected material analyzed by a combination of ultraviolet absorption and nuclear magnetic resonance spectroscopy. The procedures developed were tested successfully on several plant extracts. Limettin and bergapten were identified in lime peel; angelicin, psoralen, and xanthotoxin in parsnips; and angelicin, xanthotoxin, and bergapten in *Angelica* leaves. Isopimpinellin was found in all three plant materials.

Introduction

The plant coumarins, though widely distributed, seldom occur in high concentrations within plant tissues, so that their isolation and characterization usually require large quantities of starting material. Moreover, since neutral coumarins in particular usually occur as mixtures, lengthy chromatographic procedures may have to be employed to obtain pure components. Today, identification of these constituents usually relies heavily on spectroscopic techniques, particularly nuclear magnetic resonance (n.m.r.).

The use of gas–liquid chromatography (g.l.c.) for separation of coumarins, first reported by Brown and Shyluk in 1962 (1), offered a great simplification of isolation procedures; a number of phenolic (as acetates) and neutral coumarins were successfully eluted and characterized by paper chromatography. Gas–liquid chromatographic separations of coumarin mixtures from lavender, *Angelica archangelica* root, and *Heracleum sibiricum* seeds were demonstrated. These analytical methods were extended somewhat by Furuya and Kojima in 1967 (2) by their work with different columns and additional coumarins. They also stressed the quantitative aspects of the method. Subsequent use of the technique has been limited (3,4), probably because the amounts of pure materials which can be collected conveniently from gas chromatographs have not been considered adequate for structural studies in the absence of matching reference standards. We wish to describe here some of the methods we have used for the characterization of g.l.c. purified coumarins, in particular the application of n.m.r. and ultraviolet (u.v.) absorption analysis to sub-milligram amounts of materials.

Results and Discussion

A number of natural coumarins, along with some other coumarins of structural interest, were chromatographed on several columns under varied conditions. Silicone columns (SE-30), operated near 200°, gave the best separations and offered conveniently short retention times. For most work, a 3 m long column was used, but when compounds of high retention were studied a $1\frac{1}{2}$ m column was preferred. Separations achieved on the longer column are summarized in Table I (the structures of the coumarins are given in Fig. 1). We chose angelicin (**12**) as a standard for measurement of relative retention times (RRT) because it was readily available and because in plant screenings it is frequently the first coumarin of a mixture to elute from the gas chromatograph. It was noted that the phenolic coumarins, umbelliferone (**2**) and scopoletin (**7**) were eluted without difficulty, although 6,7-, 7,8-, and 5,7-dihydroxycoumarin were not recovered from the column. All the simple furanocoumarins (**12–19**, Fig. 1) chromatographed well. The behaviour of prenyl (3,3-dimethylallyl) and related ethers was not consistent; imperatorin (**26**) gave no peaks, undoubtedly because of thermal rearrangement to allo-imperatorin (1), whereas phellopterin (**20**), in which the requisite *ortho–para* positions are blocked, emerged unchanged. More surprisingly, *O*-prenylumbelliferone (**4**) also chromatographed without rearrangement, so that some prenyl ethers can be detected by this method.

[1]Issued as NRCC No. 10860.

TABLE I

Retention and relative retention times of coumarins. Angelicin has been arbitrarily assigned RRT = 1.00

Retention time (min)	RRT	Compound*
2.1	0.35	Coumarin (**1**)
6.0	1.00	Angelicin (**12**)
6.5	1.08	Herniarin (**3**)
6.9	1.15	Psoralen (**16**)
10.2	1.70	6,7-Dimethoxycoumarin (**8**)
10.2	1.70	Umbelliferone (**2**)
10.5	1.75	Limettin (**9**)
11.1	1.85	Scopoletin (**7**)
11.7	1.95	Isobergapten (**13**)
12.0	2.00	Xanthotoxin (**18**)
12.6	2.10	Sphondin (**14**)
13.2	2.20	O-Prenylumbelliferone (**4**)
13.8	2.30	Bergapten (**17**)
15.9	2.65	Pimpinellin (**15**)
15.9	2.65	Osthol (**10**)
16.2	2.70	(**29**)
20.4	3.40	Columbianetin (**28**)
21.6	3.65	Isopimpinellin (**19**)
23.1	3.85	Phellopterin (**20**)
23.1	3.85	Peucedanin (**27**)
26.	4.4	Coumurrayin (**11**)
48. (double peak)	8.0	Oxypeucedanin (**21**)

*Esculetin (5), daphnetin (6), oxypeucedanin hydrate (22), ostruthol (23), ostruthin (24), xanthotoxol (25), and imperatorin (26) did not pass through the column. Chromatographic conditions are given in the experimental section.

Oxypeucedanin (**21**) gave a double peak near RRT 8 which was incompletely resolved. Each portion had the u.v. spectrum of the initial compound. The related diol (**22**) could not be eluted, and neither could ostruthol (**23**), which was surprising since earlier workers had distilled this coumarin (5). The alcohol columbianetin (**28**) behaved normally, and it might be inferred that marmesin and nodakenetin, the linear analogs, would be equally amenable to this type of analysis; this has been confirmed for marmesin (6). The successful chromatography of the synthetic pyronocoumarin **29** similarly implies that this type of natural compound (7, 8) can be detected by g.l.c.

Thus a wide variety of structures may be encountered in practice, and characterization procedures must take this into account. We collected many of the eluted coumarins in small pyrex tubes inserted into the exit port of the chromatograph. The material collected in this way was usually crystalline, but with the exception of coumarin and the sharply-peaking derivatives herniarin (**3**), psoralen (**16**), and angelicin, the melting points were not sufficiently sharp to confirm the identity of the compound. A few micrograms were dissolved in alcohol and the u.v. spectrum measured, while the remainder of the material (about 0.1–1.0 mg) was dissolved in deuterochloroform or deuterodimethylsulphoxide for measurement of the n.m.r. spectrum.

Nuclear magnetic resonance spectra are customarily measured on 10–20 mg pure material, but we soon found that for coumarins in which only a few protons are present satisfactory results (all protons clearly visible) could be obtained with only 1 mg of sample. In favorable cases even half this quantity gave a complete qualitative spectrum. Where multiple signals are involved, as with aromatic methoxyl or aliphatic or vinyl methyl groups, some characterization can be achieved with only 0.1 mg pure sample by noting and comparing the field strengths of these signals. Below 0.5 mg, however, n.m.r. evidence becomes supporting rather than definitive, and in the absence of a reference standard, positive identification of an unknown cannot be made.

Use of a preliminary liquid partition column fractionation (4) has been found to be successful in simplifying mixtures and concentrating minor constituents for gas chromatography, but the procedure is time-consuming and necessitates multiple g.l.c. analyses (of the fractions). We therefore prefer to screen plant materials by g.l.c. initially to see if any coumarins are present, to characterize these on a sub-milligram scale, and then (if interest warrants) to consider the use of a suitable liquid column for the resolution of larger quantities of the coumarin mixtures. In our experience it is usually both quicker and more convenient to collect several g.l.c. passes to obtain sufficient material for n.m.r. analysis than to set up a liquid partition or adsorption column system.

Other methods of extending the range of n.m.r. analysis also seem practicable. For example, if a multiple scanning system were used, a complete spectrum probably could be obtained on about 0.1 mg compound, and the lower limit of analysis would be similarly extended. We did not have such a system at our disposal.

It will be seen at once that a tabulation of n.m.r. signals for the more common coumarins is needed for full exploitation of this micro-method. Data for many derivatives are available in the literature but as these are scattered and incomplete, we had spectra taken of all our chromatographable

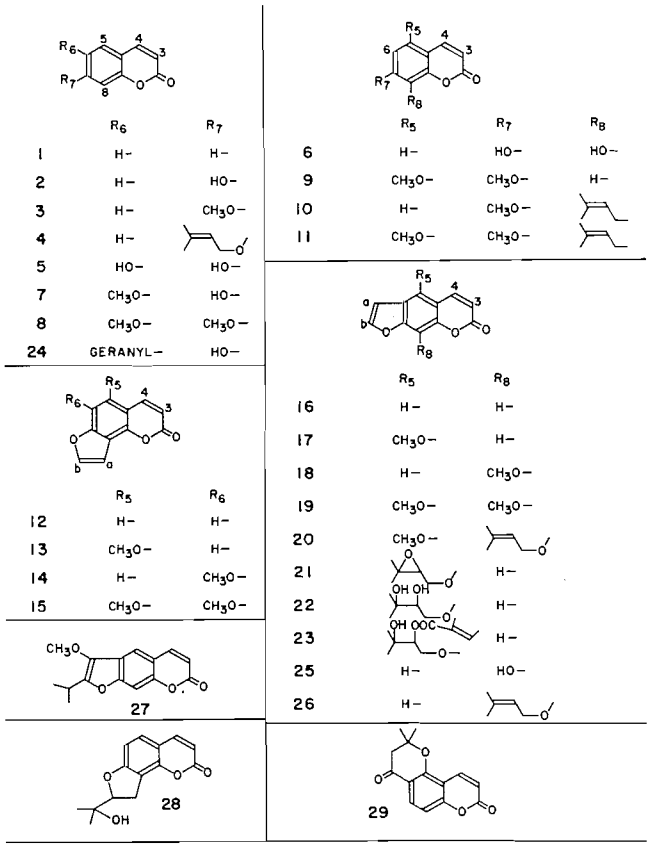

FIG. 1. Structures of some coumarins mentioned in the text. **1** Coumarin; **2** umbelliferone; **3** herniarin; **4** *O*-prenylumbelliferone; **5** esculetin; **6** daphnetin; **7** scopoletin; **8** 6,7-dimethoxycoumarin; **9** limettin; **10** osthol; **11** coumurrayin; **12** angelicin; **13** isobergapten; **14** sphondin; **15** pimpinellin; **16** psoralen; **17** bergapten; **18** xanthotoxin; **19** isopimpinellin; **20** phellopterin; **21** oxypeucedanin; **22** oxypeucedanin hydrate; **23** ostruthol; **24** ostruthin; **25** xanthotoxol; **26** imperatorin; **27** peucedanin; **28** columbianetin.

materials. Table II presents most of these in summary, without comments. The O-methyl and C-methyl signal positions in particular have proved valuable not only for the direct matching of minimal quantities of unknowns with standards, but also for the detection of methyl-bearing sidechains in such unknowns, a feature which u.v. analysis does not show up well.

The u.v. absorption patterns of coumarins are better known, and those of phenolic and neutral derivatives have been discussed elsewhere (e.g. 9,10). In general, 7- and 5,7-hydroxycoumarin derivatives have their strongest absorbance at 320–330 nm, while 6,7- derivatives peak at 340–350 nm; furanocoumarins absorb at 290–310 nm and also in the region of 240–270 nm. The furano compounds possess in general, but not always, a dull yellowish fluorescence under u.v. light, most other coumarins fluorescing violet or blue. Blue fluorescing psoralen and angelicin are notable exceptions.

We tested our methods on several plant materials already reported to contain mixtures of neutral coumarins and obtained good results. Three examples are the analyses of lime peel (*Citrus aurantifolia* Swingle), parsnip root (*Pastinaca sativa* L.) and angelica leaf (*Angelica archangelica* L.). In the first case the peel of one lime was processed to give a lactone fraction (11) and part of this was chromatographed (see Fig. 2*a*). Only one pass was collected. The three major peak fractions, having relative retention times of 1.75, 2.30, and 3.62, were collected and scanned in the n.m.r. machine, then in the u.v. spectrophotometer. The fluorescence of each material was also noted in alcohol in the quartz u.v.

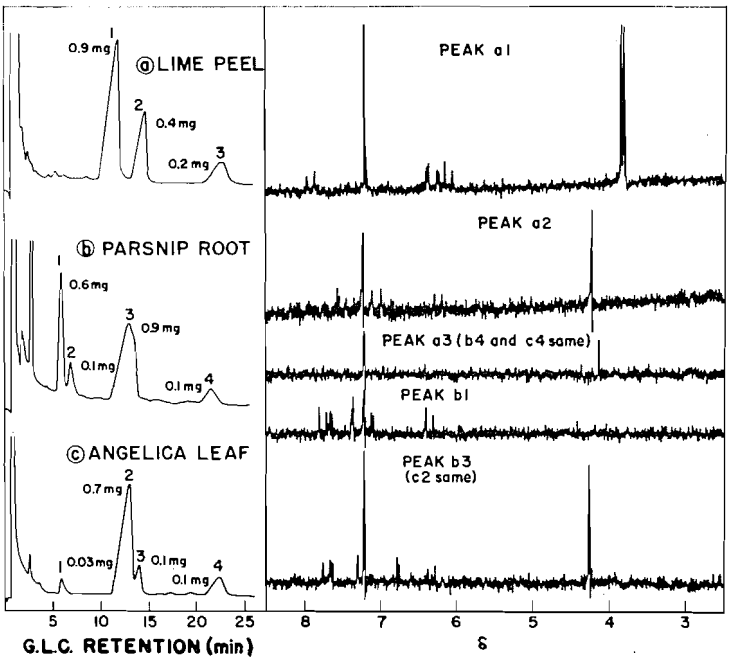

FIG. 2. Gas–liquid chromatography separation and n.m.r. characterization of coumarins from three plant sources. The n.m.r. signals near δ 7.21 are those of chloroform.
(*a*) Lime Peel: Peak 1 = limettin (RRT = 1.75); peak 2 = bergapten (2.30); peak 3 = isopimpinellin (3.62).
(*b*) Parsnip root: Peak 1 = angelicin (RRT = 1.00); peak 2 = psoralen (1.15); peak 3 = xanthotoxin (2.00); peak 4 = isopimpinellin (3.65).
(*c*) Angelica leaf: Peak 1 = angelicin (RRT = 1.00); peak 2 = xanthotoxin (2.00); peak 3 = bergapten (2.26); peak 4 = isopimpinellin (3.68).

cuvettes. The first component's u.v. spectrum suggested an umbelliferone ether (λ_{max} 324 nm, no shift with alkali); the fluorescence was distinctly blue rather than violet, so that a 5-oxygen function seemed likely. The n.m.r. revealed proton signals from two aromatic methoxyl groups and from four other protons, all corresponding to the signals from limettin (**9**). The g.l.c. retention was in agreement. The second component possessed the characteristic u.v. spectrum of bergapten (**17**) (10), and fluoresced dull yellow in u.v. light. The n.m.r. showed a methoxyl signal at δ 4.25 along with five weak aromatic proton signals, all in accord with bergapten. Again the g.l.c. retention was in agreement. The last component had the highly characteristic u.v. spectrum of isopimpinellin (**19**) (10), and this identity was supported by the fluorescence and retention time of the material. The n.m.r. spectrum showed only one sharp signal at δ 4.14, the field strength of the methoxyl six-proton signal of isopimpinellin. Limettin and isopimpinellin are both reported in lime oil (12) and some bergaptol derivatives also (10), but bergapten itself has not been mentioned as an important coumarin of this material.

By similar procedures angelicin (**12**), xanthotoxin (**18**), and isopimpinellin were identified in the lactone fraction of parsnip root (Fig. 2*b*). The minor component, relative retention time 1.15, was not plentiful enough for n.m.r. analysis, but had the u.v. absorption spectrum, violet fluorescence, and typical odour of psoralen (**16**). This identity was confirmed by n.m.r. on combined material from several collections. Bergapten, xanthotoxin, isopimpinellin and the non-chromatographable imperatorin are all reported (13,14) in parsnips but the presence of angelicin and psoralen does not appear to have been appreciated. Chromatography of angelica leaf lactone fraction (Fig. 2*c*), prepared from only a few g of fresh leaves, showed one major peak along with several secondary peaks. Nuclear magnetic resonance showed the main peak was due to

For personal use only.

xanthotoxin and the latest peak to isopimpinellin. The u.v. absorption and fluorescence of the lesser peaks indicated they were angelicin and bergapten. All these components have been reported from this source (3).

Gas chromatography can thus be used for the direct purification of many natural coumarins, and the collected materials, although minute in amount, can be characterized rather fully. The applications of these methods to the screening of unfamiliar plant materials and to the identification of new coumarins are now under study.

Experimental

Chromosorb W-DMCS, acid-washed, 70–80 mesh, impregnated with 5% SE-30 silicone, was packed into a 4.7 mm i.d. × 3.0 m copper column. An Aerograph model A-700 chromatograph with thermal conductivity detection was used. The column temperature was 205°; injector, 252°; detector, 264°; and helium flow 60 ml/min. Materials were injected in chloroform solutions except for phenolic materials, which were dissolved in alcohol. Collected material was dissolved in deuterochloroform for measurement of the n.m.r. spectrum; a Varian model HA-100 machine was used. Tetramethylsilane was the reference standard. Ultraviolet spectra were taken in alcohol with a Bausch and Lomb model 505 recording spectrophotometer.

Materials

Most of the coumarins tested were available in this laboratory. *O*-Prenylumbelliferone (**4**) was prepared from equimolar amounts of umbelliferone, prenyl bromide and anhydrous potassium carbonate in dry acetone by refluxing for 3 h. The filtered acetone solution was evaporated and the solid residue crystallized from aqueous alcohol and from methanol to give white platelets, m.p. 76–77°, in 70–90% yield.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.0; H, 6.1. Found: C, 72.8; H, 6.2.

The n.m.r. spectrum ($CDCl_3$) showed pyrone ring proton signals at δ 6.28 (H_3) and 7.57 (H_4), both doublets (J = 9.5 c.p.s.); benzene ring proton signals at 7.31 (doublet, J = 9.5 c.p.s.) (H_5), 6.80 (multiplet) (H_6), and 6.76 (singlet) (H_8); and prenyl group signals at 5.43 (triplet) (methyne H), 4.54 (doublet) (2 methylene H's), 1.80, and 1.76 (singlets) (6 vinyl methyl H's).

Compound **29**, 3,4-dihydro-2,2-dimethyl-2*H*,8*H*-benzo[1,2-b:3,4-b′]dipyran-4,8-dione, was prepared by heating 0.45 g 3,3-dimethylacrylic acid and 0.60 g resorcinol in 7 ml polyphosphoric acid for 1 h at 75°. The orange–red solution was poured into excess ice and water; the precipitate was broken up, filtered and washed well with cold water. The crude yellow–orange, 2,2-dimethyl-7-hydroxychromanone (0.85 g, 100%) melted at 160–169°; this was raised to 170–171.5° [lit. 172° (15)] by recrystallization from aqueous alcohol. Pechmann reaction of this phenol with malic acid in hot concentrated H_2SO_4 (5–10 min) gave, after workup similar to that for the chromanone, a 45% yield of crystals, m.p. 210–215°. Sublimation gave white needles whose melting point (215–218°) could not be raised or sharpened further.

Anal. Calcd. for $C_{14}H_{12}O_4$: C, 68.8; H, 4.9. Found: C, 68.8; H, 5.0.

The n.m.r. spectrum of this compound ($CDCl_3$) confirmed it was the angular coumarin possible by this Pechmann reaction, and not the known linear isomer (7): α-pyrone ring proton signals at δ 6.33 and 8.01 (doublets, J = 9.5 c.p.s.); benzene ring proton signals at 6.87 and 7.96 (doublets, J = 9.0 c.p.s.); two γ-pyrone ring methylene protons at 2.74 (singlet); and six *gem*-methyl protons at 1.52 (singlet).

*Identification of Limettin (**9**) and Bergapten (**17**) from Lime Peel*

Limettin

The g.l.c. peak fraction emerging at RRT 1.75 was dissolved in deuterochloroform. The n.m.r. spectrum of the solution showed doublets (J = 9–10 c.p.s.) at δ 6.11 and 7.93 (pyrone ring protons H_3 and H_4 respectively); doublets (J = 2–3 c.p.s.) at 6.26 and 6.37 (H_8 and H_6); and three-proton singlets at 3.83 and 3.88. Authentic 5,7-dimethoxycoumarin gave the same spectrum; the u.v. spectra of the isolated compound and authentic limettin also matched.

Bergapten

The second peak fraction (RRT 2.30) gave doublets (J = 9–10 c.p.s.) at δ 6.25 (H_3) and 8.14 (H_4), the latter indistinct; furan ring doublets (J = 2–3 c.p.s.) at 7.0 and 7.6, a singlet at 7.1, and a three proton singlet at 4.25 (aromatic OCH_3). Authentic bergapten gave the same n.m.r. and u.v. spectra (3).

*Identification of Angelicin (**12**) and Psoralen (**16**) from Parsnip Roots*

Angelicin

The g.l.c. peak fraction emerging at RRT 1.00 was crystalline and melted at 136–138° (lit. 138–139° for angelicin). The n.m.r. spectrum of the deuterochloroform solution of these crystals showed aromatic proton signals at δ 6.36 (doublet, J = 9–10 c.p.s.) (H_3); 7.78 (doublet, J = 9–10 c.p.s.) (H_4); 7.4 (singlets?) (H_5 and H_6); 7.12 (doublet, J = 2–3 c.p.s.) (H_a) and 7.67 (doublet, J = 2–3 c.p.s.) (H_b). Authentic angelicin gave the same spectrum, with signals for two protons unresolved at δ 7.38 and 7.40.

The u.v. of the recovered crystals exhibited absorption maxima (ethanol) at 217, 247, and 297 nm; angelicin afforded an identical spectrum.

Psoralen

Crystals from the g.l.c. peak (RRT 1.15) following angelicin showed u.v. absorption (ethanol) at 240 (shoulder), 245, 289, and 327 nm, the absorption maxima of psoralen. The n.m.r. spectrum ($CDCl_3$) on combined material from six passes showed doublets (J = 9–10 c.p.s.) at δ 6.33 (H_3) and 7.75 (H_4) along with a singlet at 7.41 (H_8), a multiplet at 6.8 (H_a), and an unresolved two-proton signal at 7.65 (H_5 and H_b). Authentic psoralen gave the same spectrum.

Acknowledgments

We wish to thank Prof. T. O. Soine for his generous gift of columbianetin and osthol, Prof.

B. A. Bohm for peucedanin and pimpinellin, and Dr. D. L. Dreyer for phellopterin, oxypeucedanin, and oxypeucedanin hydrate. Special thanks are extended to Mr. M. Mazurek, who measured the n.m.r. spectra.

Structure of sibiricine, an alkaloid of *Corydalis sibirica*

R. H. F. MANSKE AND R. RODRIGO

AND

D. B. MACLEAN, D. E. F. GRACEY, AND J. K. SAUNDERS
Department of Chemistry, McMaster University, Hamilton, Ontario

Received April 28, 1969

Structure **1** is proposed for sibiricine, a minor alkaloid of *C. sibirica*. The structural assignment rests on an interpretation of its mass spectrum and its proton magnetic resonance (p.m.r.) spectrum.

Canadian Journal of Chemistry, 47, 3585 (1969)

In 1936 Manske (1) examined *C. sibirica* (L.) Pers. for its alkaloidal content. He found two alkaloids each of the protopine, protoberberine, and phthalide isoquinoline groups. Besides these alkaloids whose constitution was known at that time, he also isolated ochotensine (2), and ochrobirine (3) whose structures have recently been resolved, and two bases, F-15 and F-16, which have not yet been subjected to structural study. Another minor alkaloid has been isolated in the interim from the same species. We designate it sibiricine, and assign to it the molecular formula $C_{20}H_{17}NO_6$. Here we present evidence that sibiricine has structure **1**.

The occurrence of sibiricine in conjunction with ochrobirine **2** and ochotensine **3** suggested that it might be structurally related to these two alkaloids. This relationship was apparent on examination of the 100 MHz p.m.r. spectrum of sibiricine (reproduced in Fig. 1) and comparison of this spectrum with that of the synthetic ketone **4** (4) and the alkaloid fumariline **5** (5–7).

In the p.m.r. spectrum of sibiricine the two signals of area 2 at 5.84 and 6.18 δ are assigned to methylenedioxy groups and that of area 3 at

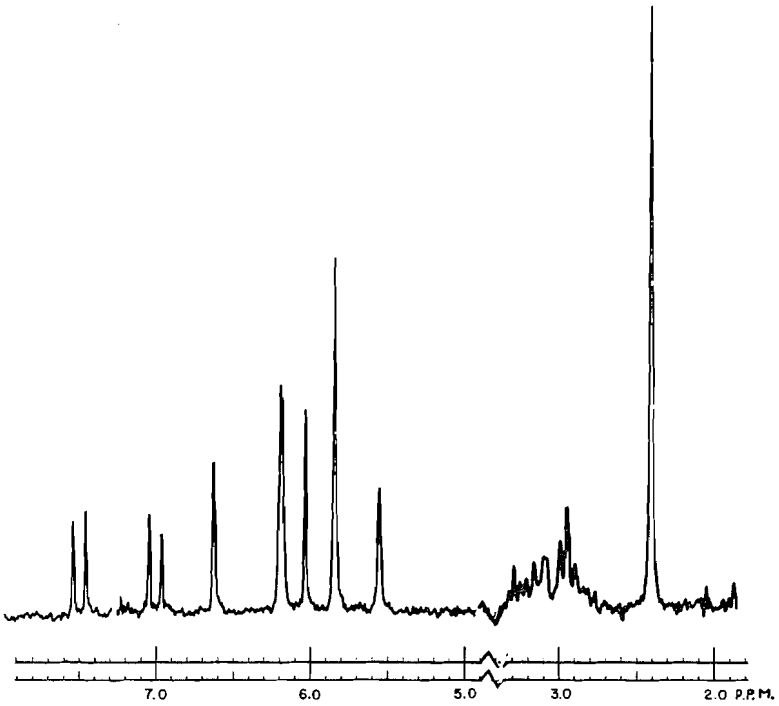

FIG. 1. The 100 MHz p.m.r. spectrum of sibiricine.

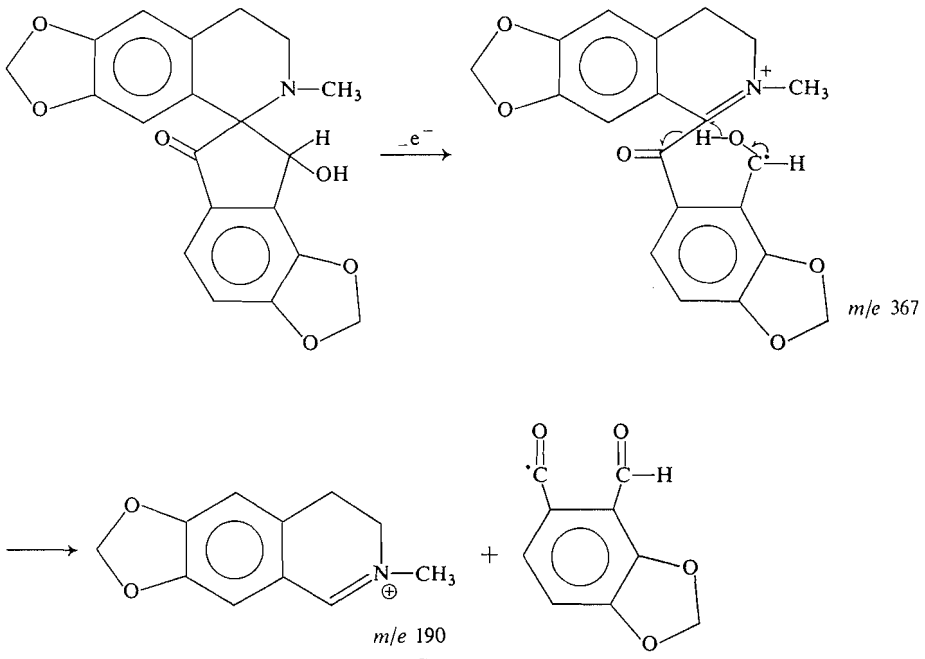
2.43 δ to an N—CH_3 group. In the aromatic region of the spectrum there is an AB quartet assigned to the signals at H-10 and H-11, (δ 7.51 (H-10), 7.01 (H-11); $J_{H_{10},H_{11}}$ = 8.0 Hz). The chemical shifts between these two protons and the corresponding protons in the synthetic ketone **4** are very similar and demonstrate that the carbonyl group of **1** must be adjacent to the proton at H-10. (Compare the spectrum of fumariline where the >C=O is not adjacent to the AB quartet.) The two singlets at 6.04 and 6.54 are assigned to aromatic protons at C-1 and C-4, respectively. The positions of these singlets are virtually identical with those of the corresponding protons in the alkaloid fumariline, **5**. (Spectra of **4** and **5** have been published (6).) There is a broad signal of area 1 at 5.57 δ which becomes a sharp singlet on addition of D_2O. This signal is assigned to a proton geminal to the hydroxyl group at C-14. Analogous behavior has been encountered in the case of ochrobirine (3) and fumaricine (5). The hydroxyl proton has been located as a broad singlet centered near 2.55 δ which disappears on addition of D_2O. The remaining protons yield a complex pattern in the region 2.5–4.0 δ of area 4 and are assigned to the aliphatic protons at C-5 and C-6.

The similarities in the p.m.r. spectrum of this alkaloid to the spectra of the synthetic ketone **4**, to fumariline **5**, and to ochrobirine **3**, leave little doubt that it has the same skeletal structure as these alkaloids and the substitution pattern shown in **1**. The relative configuration of the OH group in **1** is apparent from the large Nuclear Overhauser effect (N.O.E.) (8) of 25% observed at C-14 when the signal at 2.43 δ (N—CH_3) is irradiated. This effect is possible only with the configuration shown.

In the infrared (i.r.) spectrum of **1** there is a band at 1710 cm^{-1} which appears at virtually the same frequency as the carbonyl band of **4** and **5**. The ultraviolet (u.v.) spectrum of **1** is also similar to that of **4**.

The molecular formula of sibiricine was established by high resolution mass spectrometry. The peak of highest mass appeared at *m/e* 367. Accurate mass measurement by the peak matching technique gave a value of 367.1071; calculated



SCHEME 1

for $C_{20}H_{17}NO_6$, 367.1055. Other mass measurements carried out on fragment ion peaks were compatible with this constitutional assignment and the proposed structure. A detailed account of the mass spectrometric work on this and on related alkaloids will be discussed in a subsequent communication. Of particular importance to this investigation, however, is the presence of a fragment ion of *m/e* 190, of composition $C_{11}H_{12}NO_2$ (calculated for $C_{11}H_{12}NO_2$, 190.0868; observed, 190.0864). The formation of this fragment ion is characteristic of alkaloids of this structural type (5) whenever an OH group is present at C-9 or C-14. Its formation may be rationalized as shown in Scheme 1.

Experimental

Methods

The mass spectrum was recorded on a CEC 21-110B double-focussing mass spectrometer. Accurate mass measurements (9) were made by reference to appropriate peaks in the spectrum of perfluorokerosene (10).

The p.m.r. spectrum was recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V 4315 frequency counter incorporated in the instrument. Double irradiation was achieved by employing a Hewlett–Packard 201C audiogenerator at the desired frequency. For N.O.E. measurements degassed solutions were used and a procedure similar to that of Anet and Bourn (8) was employed. A Beckmann IR10 spectrometer was used to record i.r. spectra and a Cary 14 spectrometer was used for the u.v. spectrum.

Isolation of Sibiricine

The mother liquor from the separation of protopine and ochrobirine from the extract of *C. sibirica* (1) was acidified with oxalic acid, exhausted with ether, basified, and then extracted several times with ether again. The residue from the latter extract yielded a small crop of ochrobirine and the mother liquor from this, in the course of several days, deposited a crop of stout prisms which were, however, contaminated with some ochrobirine. The mixture was extracted with several portions of hot methanol and the residue recrystallized from chloroform – methanol, m.p. 225°. Another batch of plant material also yielded the same base.

Anal. Calcd. for $C_{20}H_{17}NO_6$: C, 65.39; H, 4.66; N, 3.81. Found: C, 65.85; H, 4.98; N, 3.62.

Infrared spectrum: $\nu_{OH}(CHCl_3)$ 3560 cm^{-1}; $\nu_{C=O}$ ($CHCl_3$) 1710 cm^{-1}; $\nu_{C=O}$(KBr) 1700 cm^{-1}.

Ultraviolet spectrum: λ_{max} 205, 240, 291, and 313 (sh) mμ; log ε 4.80, 3.94, 3.91, and 3.99.

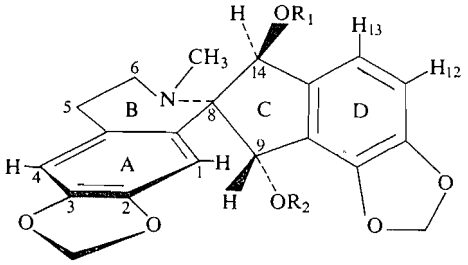
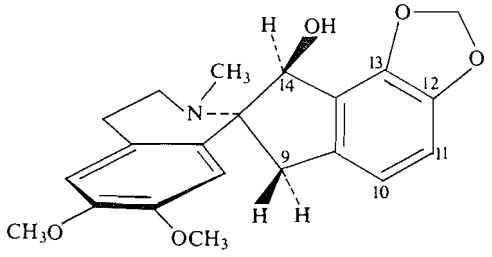
Ochrobirine, $C_{20}H_{19}NO_6$, was first isolated in 1936 from *Corydalis sibirica* (L.) Pers. by Manske (1). It has since been reported in other species of Corydalis (2, 3) but there have been no structural investigations of this alkaloid. Here, we present evidence that ochrobirine has structure **1**.



1 $R_1 = R_2 = H$; Ochrobirine
7 $R_1 = R_2 = CH_3CO$; Diacetylochrobirine



2 Fumaricine

Recently, structures **2** and **3** were proposed for the alkaloids fumaricine and fumariline, respectively (4–6). The structural assignment was based on a comparison of the properties of **2** and **3** with that of the synthetic ketone **4** of established structure (7). Through high resolution proton magnetic resonance (p.m.r.) studies and Nuclear Overhauser effect (N.O.E.) studies (8) the orientation of the substituents of **2** and **3** in rings A and D was established. Sizeable N.O.E.'s were observed between the benzylic protons of rings C and neighboring protons including the adjacent aromatic protons in ring D, the aromatic proton at C-1 in ring A, and the *N*-methyl group. Moreover, there was also a large N.O.E. between the protons at C-5 and the aromatic proton at C-4. An analogous study (9) has been carried out on ochotensimine **5** in which the interactions which were observed in **2**, **3**, and **4** are also present. Thus the N.O.E.'s which have been observed would appear to be characteristic of this ring system.

Ochrobirine occurs in the same plant as ochotensine **6** (10) and its molecular formula led

us to suspect that it might be structurally related to the latter in a manner analogous to **2** and **3**. Accordingly, we examined the 100 MHz p.m.r. spectrum of ochrobirine and its di-*O*-acetate (**7**) and applied N.O.E. studies to ochrobirine. When the results obtained with **1** and **7** were compared with the earlier studies, it was apparent that the ring system of ochrobirine was the same as **2** and **3** and that the position of the substituents and the relative configuration of the alkaloid conforms to that shown in **1**.

The 100 MHz p.m.r. spectrum of ochrobirine (Fig. 1) has singlets of area 1 at 6.04 and 6.62 δ, uncoupled to adjacent aromatic protons, attributed to the protons at C-1 and C-4, respectively. The singlet at 6.62 is broader than that at 6.04 and is long-range coupled to the aliphatic protons at C-5. Two other aromatic protons appear as a signal of area 2 at 6.85 δ. A singlet of area 3 at 2.67 δ is assigned to the *N*-CH_3 group while signals of area 2 at 5.81 and 6.00 δ are attributed to two methylenedioxy groups. There are two signals of area 1 at 4.88 and 5.42 δ which are assigned to aliphatic protons geminal to hydroxyl groups. The higher field peak is a sharp peak while that at lower field is diffuse but sharpens on addition of D_2O. The four remaining protons are spread throughout the region 2.5–3.5 δ and are assigned to the aliphatic protons at C-5 and C-6.

The spectrum of **7**, di-*O*-acetylochrobirine (Fig. 2), lends support to the assignments above. In the high field region there are now three singlets of area 3 at 2.37, 2.12, and 1.89 δ which are attributed to the *N*-CH_3 and to the two acetoxy methyl groups, respectively. One of the latter signals is at higher field than normally expected of an acetoxy methyl group and is apparently shielded by one of the aromatic rings. The four aliphatic protons at C-5 and C-6 appear in an AA′ BB′ pattern centered at 3.00 and 2.72 δ. This is the first instance in this series of alkaloids where a recognizable pattern has been observed for the protons at C-5 and C-6. Its presence may be ascribed to the proximity of one of the two methylene groups at C-5 or C-6 to one or other of the acetoxy groups.

The signal of area 2 at 6.85 δ in **1** is now split into an AB quartet (δ H_{12}, 6.86; δ H_{13}, 6.73; $J_{H_{12},H_{13}}$ = 8.0 Hz) showing that the two aromatic protons are adjacent. The two methylenedioxy signals which appeared as singlets in **1** are shifted slightly downfield and appear as quartets. The protons geminal to the two hydroxy groups of **1** have shifted into the aromatic region where, besides the AB quartet, there are now three signals, one of area 2 at 6.55 δ and two of area 1 at 6.52 and 6.36 δ. Through decoupling experiments it was possible to assign these signals. Irradiation at 2.70 δ sharpened the signal at 6.52 δ and thus this signal is assigned to H-4 (Inset 1, Fig. 2). Irradiation at the $\diagdown\!\!\diagup N—CH_3$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

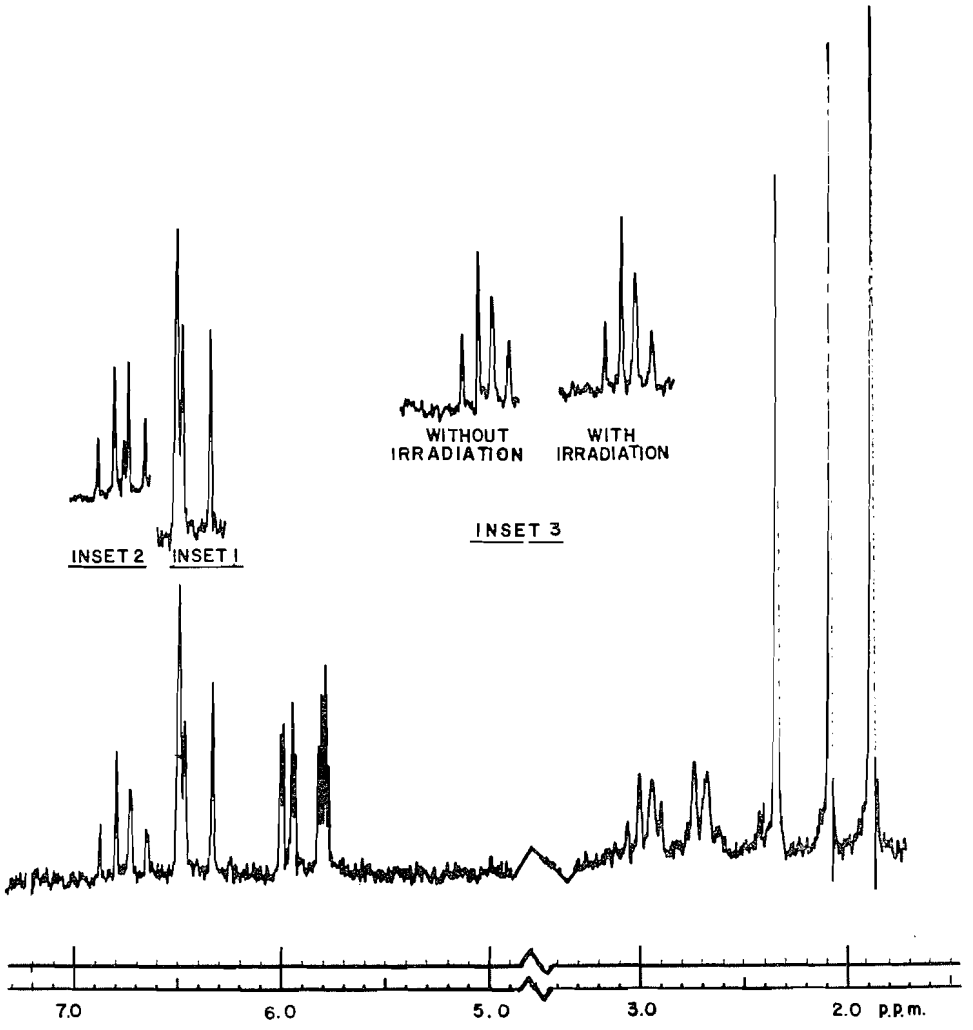

FIG. 2. The p.m.r. spectrum of ochrobirine di-*O*-acetate.

signal increased the area of the signal at 6.55 δ and, therefore, one or both of the protons geminal to the acetoxy groups is present there. Irradiation at 6.55 δ decoupled the higher field proton of the AB quartet but had a negligible effect on that at lower field as expected for ortho and meta benzylic coupling (11) (Inset 2, Fig. 2). We conclude, therefore, that one of the two protons at 6.55 δ is at H-14. Irradiation at 6.36 δ causes the low field doublet of the AB quartet to sharpen relative to the higher field doublet. This is illustrated in Inset 3, Fig. 2 where one can perceive a distinct difference in height of the signals with and without irradiation at 6.36 δ.[1] This behavior would be expected for para and meta benzylic coupling (11) respectively, and, therefore, we assign the signal at 6.36 δ to H-9. By a process of elimination the signal of H-1 is present at 6.55 δ along with that of H-14.

Through N.O.E. studies we were able to confirm the substitution pattern in rings A and D deduced from the decoupling experiments and to arrive at the relative configuration of the molecule. Irradiation of the signal at 2.67 δ in ochrobirine, attributed to the N-CH_3, increased the area of the signal at 5.42 δ by 24% but did not affect the signal at 4.88 δ. Irradiation of the signal at 5.42 δ increased the area of the signal at 6.85 δ by 4% but had no effect on the area of the two aromatic singlets. Accordingly, we assign the proton at 5.42 δ to C-14 and conclude that it is adjacent

[1]The irradiation was carried out several times and in each case the height of the low field doublet relative to that at higher field increased by at least 10%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

to the pair of ortho aromatic protons. Irradiation at 4.88 δ results in an increase in area of the aromatic singlet at 6.04 δ of 13% but does not affect the other aromatic protons. Accordingly we place the irradiated proton at C-9 and the observed proton at C-1. It follows therefore that the OH groups must be *trans* to one another in the five-membered ring. The OH at C-9 is probably internally hydrogen bonded to the nitrogen which may account for the relatively smaller N.O.E. observed between H-14 and H-13 in this system when compared with the earlier systems which were studied.

Attempts to corroborate this structural assignment by chemical degradation were only partially successful. A small yield of noncrystalline ketonic material was obtained by oxidation of ochrobirine with CrO_3 in pyridine but the product would not crystallize. Oxidation of ochrobirine gave 4,5-methylenedioxyphthalic acid identified as its *N*-ethylimide, thus substantiating the assignment of substituents in ring A. The isomeric 3,4-methylenedioxy acid was not, however, found as an oxidation product.

The molecular formula of ochrobirine was confirmed by accurate mass measurement: calcd. for $C_{20}H_{19}NO_6$, 369.1212; found, 369.1204. As expected the ultraviolet (u.v.) spectrum of ochrobirine was similar to that of fumaricine (**2**), (4).

Experimental

Methods

Mass spectra were recorded on a CEC 21–110B double-focusing mass spectrometer. Accurate mass measurements (12) were made by reference to appropriate peaks in the spectrum of perfluorokerosene (13).

The p.m.r. spectrum was recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V4315 frequency counter incorporated in the instrument. Double irradiation was achieved by employing a Hewlett-Packard 201C audiogenerator at the desired frequency. For N.O.E. measurements degassed solutions were used and a procedure similar to that of Anet and Bourn (8) was employed. A Beckmann IR 10 spectrometer was used to record infrared (i.r.) spectra and a Cary 14 spectrometer was used for the u.v. spectrum.

Ochrobirine

The isolation of ochrobirine has been described elsewhere (1–3). Its u.v. spectrum had λ_{max} (MeOH) 205, 240, and 291 mμ; log ε_{max} 4.80, 3.94, and 3.91, respectively. The i.r. spectrum showed two bands in the OH region at 3585 cm^{-1} (sharp) and 3300 cm^{-1} (broad) in CCl_4 solution.

Ochrobirine Di-O-acetate

Ochrobirine (0.1 g) and acetic anhydride (0.6 ml) were heated on a steam bath for 1 h and the cooled solution poured into a dilute solution of sodium carbonate. The crystalline solid which separated was washed thoroughly with water and crystallized twice from methanol after which it melted at 179°. The yield of recrystallized material was 40 mg. The mass spectrum showed a molecular ion at 453.1419; calcd. for $C_{24}H_{23}NO_8$, 453.1423. The diacetate yielded ochrobirine on alkaline hydrolysis showing that the skeletal structure was unaltered during acetylation. This compound is identical with ochrobirine acetate previously reported (2).

Oxidation of Ochrobirine

Ochrobirine (0.2 g) and dilute nitric acid (10 ml) (ca. 15%) were heated for 15 min on a steam bath. The cooled solution was neutralized with sodium hydroxide and extracted with a large volume of ether. The extract was oxidized with potassium permanganate. From the oxidation mixture, after acidification, an acid was extracted which was converted to its *N*-ethylimide. The few mg of imide which were obtained were sublimed and crystallized twice from ether and melted at 129°, either alone, or in a mixture with 4,5-methylenedioxy-*N*-ethylphthalimide.

Received April 28, 1969

The structures of fumaricine, fumaritine, and fumariline, minor alkaloids of *F. officinalis*, have been deduced by spectroscopic methods and by comparison with model systems. Nuclear Overhauser effects observed in these systems aided in the solution of the structural problem. The three alkaloids have a common ring system and are structurally related to ochotensimine.

In 1938 Manske (1) examined *Fumaria officinalis* L. for its alkaloid content. He isolated and identified several isoquinoline alkaloids, namely protopine, cryptopine, ± stylopine, + and ± scoulerine, and sinactine. Besides these alkaloids of established structure he reported the presence of two new alkaloids, F-37 ($C_{21}H_{23}NO_5$) (**1**) and F-38 ($C_{20}H_{19}NO_6$). In the interim Manske (2) has isolated two other minor alkaloids from this source corresponding in composition to $C_{20}H_{21}NO_5$ (**2**) and to $C_{20}H_{17}NO_5$ (**3**). Compound **2** is a lower homologue of **1** since it yields **1** upon methylation with diazomethane. The names, fumaricine, fumaritine, and fumariline have been assigned to **1**, **2**, and **3** respectively.

In two earlier short communications (3, 4) we described briefly the studies which led to the assignment of structures to **1** and **3**. Here we give a full account of our work and provide evidence for the assignment of the hydroxyl and methoxyl groups in **2**.

We were unable to carry out meaningful chemical degradations of these alkaloids and were forced to rely on physical methods for our structural assignments. The infrared (i.r.) spectrum of **3** showed a band at ν_{max} ($CHCl_3$) 1709 cm^{-1} suggesting the presence of a carbonyl group. Its presence was confirmed by reduction of **3** to an alcohol **4** ($C_{20}H_{19}NO_5$) with sodium borohydride or with lithium aluminium hydride. The i.r. spectrum of **4** lacked a band in the carbonyl region but had a band in the hydroxyl region. The ultraviolet (u.v.) spectrum of **4** was virtually superimposable on that of **1** λ_{max} (EtOH) 207, 235, and 288 mμ, (log ε 4.74, 3.94, and 3.74) but distinctly different from that of **3** λ_{max} (EtOH) 203, 237, 263, 294, and 355 mμ, (log ε 4.60, 4.31, 4.05, 3.66, and 3.51). The change in the u.v. spectrum resulting from the reduction suggested that the carbonyl group of **3** was conjugated, probably to an aromatic system. The i.r. spectrum of **1** had no bands in the carbonyl region but had a band in the hydroxyl region, ν_{max} (CS_2) 3560 cm^{-1}, which did not shift upon dilution suggesting that the hydroxyl group was internally hydrogen bonded.

The proton magnetic resonance (p.m.r.) spectra of **1** and **3** showed that both compounds had one *N*-CH_3 group and four aromatic protons, that **1** had two methoxyl groups and one methylenedioxy group, and that **3** had two methylenedioxy groups. The substituents on **2** and **4** follow from their relationship to **1** and **3**, respectively.

From an examination of their mass spectra (Fig. 1) it is apparent that **1**, **2**, and **4** have a common fragmentation pattern. The major fragment ion in each spectrum shows the shift in mass expected for the different substituents in each of them. (That the spectrum of **3** is very different is a consequence of the difference in its functionality from the other alkaloids.) It seems likely, therefore, that **1** and **3** have a common ring system but differ in their substituents and in their oxidation state. The mass spectra, aside from indicating a common ring system for the alkaloids, did not provide much structural information. The spectra were, however, sufficiently different from the spectra of known isoquinoline systems to suggest that the alkaloids belonged to a hitherto unreported structural group. Compound **4** is isomeric with chelidonine (5) but a comparison of its spectrum (Fig. 1*e*) with that of **4** showed that the two compounds must have different ring systems.

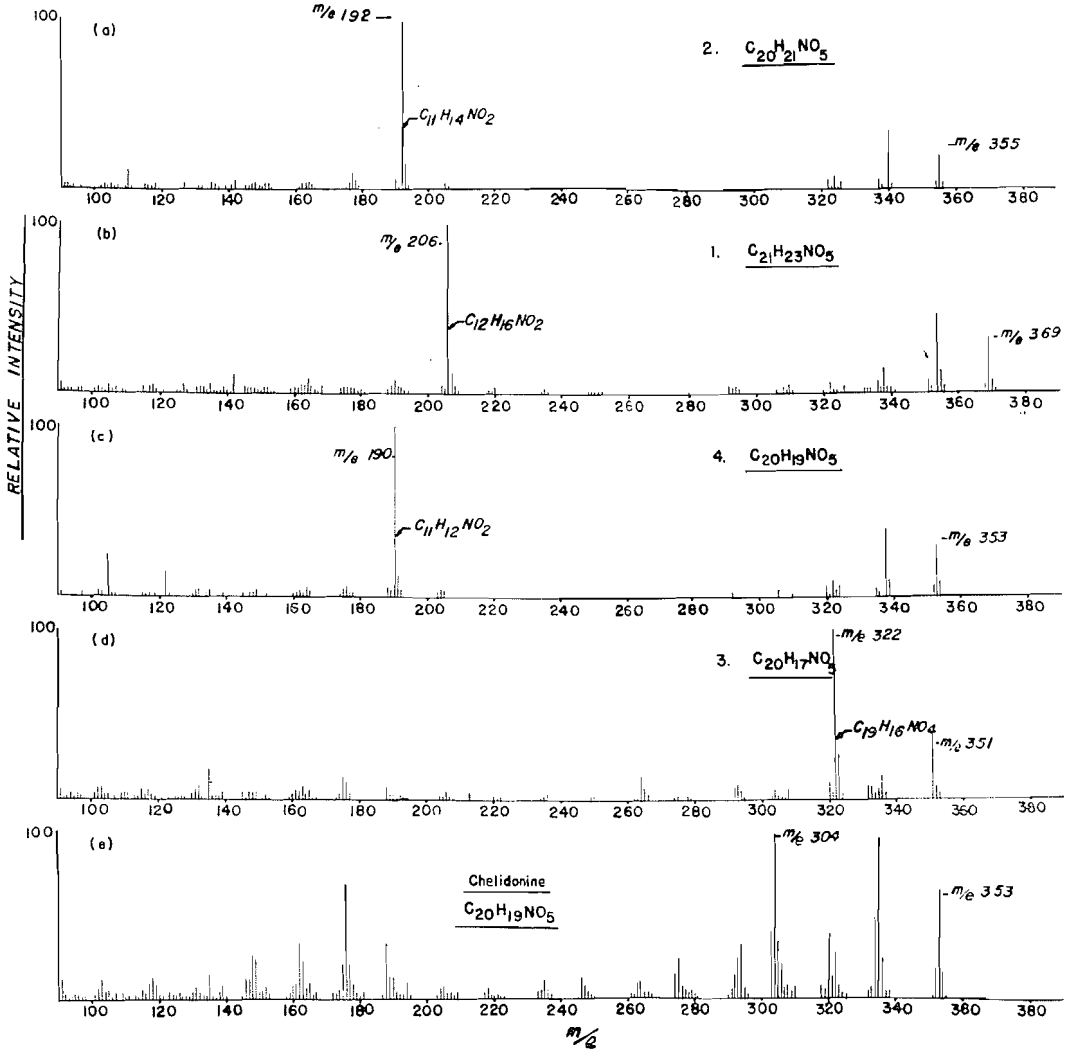

FIG. 1. Mass spectra of (a) fumaritine, (b) fumaricine, (c) dihydrofumariline, (d) fumariline, and (e) chelidonine.

It was through an examination of the 100 MHz p.m.r. spectra of **1**, **2**, **3**, and **4** and an examination of the nuclear Overhauser effects (N.O.E.) (6) in these systems that we were able to arrive at structures for the alkaloids. The salient features of the spectra of **3** and **4** which are discussed first are summarized in Table I. Each spectrum shows four aromatic protons, two ortho and coupled to each other (H-10 and H-11) and two singlets (H-1 and H-4) which are uncoupled. Each has two methylenedioxy groups and one $\diagdown N\text{—}CH_3$. Both show an AB quartet in the region expected of benzylic protons (H-9A, H-9B) which have a large coupling constant but which are uncoupled to neighboring aliphatic protons. In the spectrum of **4** there is a singlet (H-14) attributed to the hydrogen geminal to the hydroxyl group which is absent, as expected, in the spectrum of **3**. This proton is also uncoupled to neighboring aliphatic protons. In each spectrum there are signals corresponding in area to four additional aliphatic protons which lie in the region 2.6–3.6 δ and which are not readily analyzed.

Decoupling experiments carried out on **3** show that H-10 and H-11 are long-range coupled to

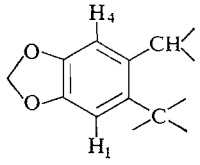
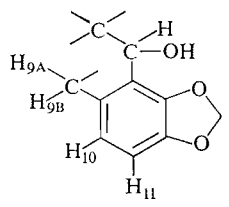
3b



4a



4b

The spectral data suggest the following structural units, *a* and *b*, in **3** and **4**. The carbonyl group is placed in conjugation with the ring carrying H-10 and H-11 since both of these protons undergo an appreciable upfield shift on conversion of ketone **3** to alcohol **4** as does one of the methylenedioxy groups. The carbonyl group is placed adjacent to the methylenedioxy group in **3***b* for the following reasons. The chemical shift difference between H-10 and H-11 is expected of aromatic protons *meta* and *para* to a carbonyl group (7), but is smaller than expected for protons *ortho* and *meta* to a carbonyl group which would be the case if the carbonyl and methylene groups were interchanged in **3***b*. More definitive, however, was the appreciable n.O.e. observed at H-10 in **3** when the protons at C-9 were irradiated (*vide infra*).

The observation that the hydrogen geminal to the OH group of **4***b* at C-4 is uncoupled to neighboring aliphatic protons suggests that a quaternary carbon is adjacent to the >CHOH group

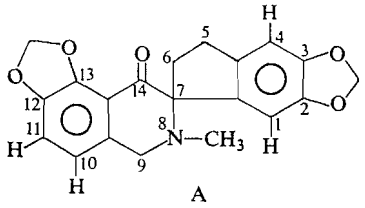
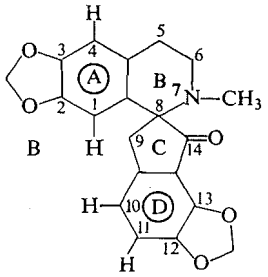
of **4** and to the >=O group of **3**. This conclusion is supported by the fact that **3** did not exchange hydrogen for deuterium in basic or in acidic media. The benzylic methylene protons of **3** and **4** are uncoupled to neighboring aliphatic protons and must, therefore, be adjacent to a quaternary carbon or to nitrogen. There are two



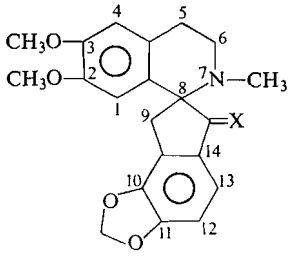
A



B

structures, A and B, into which these structural units can be incorporated and which appear to meet the requirements of the spectral data discussed thus far. Ring system A has not to our knowledge been encountered in nature although this skeleton has been reported as a transformation product of cryptopine (8). Ring system B is related to that found in ochotensimine, **5**, (9).

Structure A contains a substituted 2,3-dihydro-4 (1*H*) isoquinolone system. Derivatives of this system have recently been synthesized by Grethe *et al.* (10, 11). In these compounds the carbonyl absorption for the most part fell in the range 1680–1700 cm^{-1} which is at lower frequency than the carbonyl absorption observed in **3**. In the p.m.r. spectrum (11) of 2-benzyl-2,3-dihydro-7-methoxy-4 (1*H*) isoquinolone, the two sets of benzylic methylene protons absorb at δ 3.75 and 3.85, both of which are at lower field than in our compound **3**. In other isoquinoline alkaloids, for example, chelidonine (12) and the protoberberines (13), the methylene protons lying between nitrogen and phenyl are observed at lower field than we observe in **3**. Thus, the examination of the model systems casts doubt on the validity of structure A.



5. ochotensimine X = CH_2
6. X = O

While this work was in progress the synthesis of ochotensimine, **5**, was reported by McLean *et al.* (14). An intermediate in this synthesis is compound **6** which served as an ideal model of structure B. The carbonyl absorption of **6**, ν_{max} ($CHCl_3$) 1711 cm^{-1}, appears at virtually the same frequency as that of **3**. The 100 MHz p.m.r. spectrum of **6** shows a marked similarity to that of **3**. The spectra were reproduced in our earlier communication and need not be repeated here. The major difference in the two spectra, aside from the differences arising from the substituents, lies in the chemical shift of the low-field proton of the aromatic AB quartet. In **6** this proton is centered at 7.46 δ, in **3** at 7.07 δ. In **6** the low-field proton is *ortho* to the carbonyl group. It appears, therefore, that in **3** the low-field proton is *para* to the carbonyl group and such a difference is expected (7). The proton *meta* to the carbonyl has approximately the same chemical shift in each, at 6.86 and 6.91 in **3** and **6**, respectively, as do the aromatic protons at C-1 and C-4 which appear at 6.16 and 6.54 in **3** and at 6.11 and 6.57 in **6**. Similarly, we found the same chemical shift for the protons of the benzylic AB quartet in each of **3** and **6**. The remarkable similarity in the spectral properties of the two compounds leads us to the conclusion that B and not A is the proper formulation of **3**.

In order to substantiate our conclusions regarding the structure of **3**, and at the same time to ascertain the substitution pattern of **1**, we examined **1**, **3**, and **6** for N.O.E. The potential of N.O.E. in structural and stereochemical studies was pointed out by Anet and Bourn (6) who were the first to use the method in this sense. It has since been applied successfully in the examination of other systems (15). Examination of a model of **6** showed that there were a number of uncoupled

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

protons lying within 3.0 Å of one another for which N.O.E. should be observed. (There is no ambiguity with respect to the structure of **6** since it has been converted in a single step to ± ochotensimine; the structure of natural ochotensimine was established by X-ray analysis (9).) We, therefore, measured N.O.E. in **6** and wherever possible, measured the same interactions in **1** and **3**.

Model studies on **6** showed that irradiation of the protons at C-9 or the methoxyl protons at C-2 should increase the area of the proton at C-1. Similarly, irradiation at the C-3 methoxyl or at the C-5 protons should affect the proton at C-4, and irradiation of the N-CH_3 should affect one of the protons at C-9. In all cases these predictions were borne out experimentally and the results were reported previously (4). It is important to note that irradiation at C-9 should not and did not affect either of the protons of the aromatic AB quartet. Similar effects have also been observed in ochotensimine (16).

With these results at hand for **6** we looked for similar effects in **3**. We found all that were possible in the light of the altered substitution pattern and, in addition, we observed a sizeable effect (4) at the aromatic proton C-10 when the protons of C-9 were irradiated, thereby confirming the assignment of the substituents in ring D which we had drawn from chemical shift data.

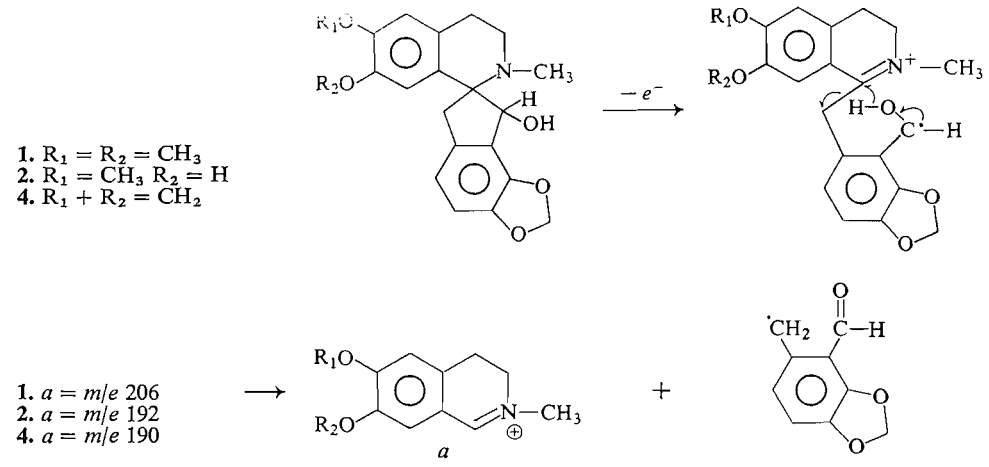
Turning now to fumaricine, we stated earlier that its i.r., u.v., and mass spectra suggested that it has the same ring system as **4**. Its p.m.r. spectrum is compared in Table I with that of **4** and the two spectra are also remarkably similar. Nuclear Overhauser effects measured on **1** were similar to those in **6** except that irradiation at C-9 resulted in an increase in area of the signal attributed to H-10. This finding led us to assign the same substitution pattern to **1** as to **3** and **4**. In our original paper we concluded that the —OH group of **1** was internally hydrogen-bonded to the nitrogen, on the basis of its i.r. spectrum and coupling constant to the hydroxyl proton. We have since found that there is an observable N.O.E. (14%) for the proton at C-14 when the signal due to the N-CH_3 group is irradiated. We must, therefore, revise our original assignment and place the OH group *trans* to the N-CH_3 group. Apparently the hydroxyl group of **1** is π-bonded to the aromatic ring (17) and not to nitrogen as we originally suspected. Since the signal of the proton at C-14 of **4** has the same chemical shift as that of **1** and shows the same behavior, namely, a broad signal which sharpens on addition of D_2O, it seems probable that the configuration of **4** at C-14 is identical with **1**.

Since **2** is converted to **1** by treatment with diazomethane there is only one structural feature of **2** which remains to be resolved, namely the assignment of the OCH_3 group to C-2 or C-3. This assignment was readily made by ascertaining which of the protons, at C-1 or C-4, exhibits an increase in area when the —OCH_3 group of **2** is irradiated. The resonances of the protons of **2** are recorded in Table I. The lower-field and broader signal observed at 6.59 δ has been assigned to C-4 by analogy with the spectra of **1**, **3**, **4**, and **6** and it is this signal which increases in area by 24% when the —OCH_3 group is irradiated. We, therefore, assign the —OCH_3 to C-3 and the OH group to C-2 in **2**.

In the mass spectra of **1**, **2**, and **4** there is only one intense fragment ion, designated *a*, which is found at *m/e* 206 in **1**, at *m/e* 192 in **2**, and at *m/e* 190 in **4**. Exact mass measurements have confirmed the composition of this ion in **1**. A mechanism for the formation of ion *a* is shown in Scheme 1. Compound **4**, deuterated at C-14, was prepared by the reduction of **3** with sodium borodeuteride and its spectrum examined. It was found that *a* still appeared at *m/e* 190 although the molecular ion was at *m/e* 354. When, however, the hydroxyl hydrogen of **4** was exchanged with deuterium it was found that ion *a* was partially shifted to *m/e* 191 in the spectrum of the deuterated compound. These deuteration studies lend support to the mechanism proposed in Scheme 1.

The spectrum of **3** is distinctly different from **1**, **2**, and **4** in that it does not show an intense ion in the low mass region. The major fragment ion appears at *m/e* 322. High resolution mass spectrometry has shown that this peak is a singlet and that it corresponds in composition to $C_{19}H_{16}NO_4$. It is apparently formed by loss of CO followed or preceded by loss of H. The OH function in the five-membered ring appears to be a necessary structural feature for fragmentation leading to ions of type *a*. Their presence in **1**, **2**, and **4** lends further support to that already given for a tetrahydroisoquinoline system in these alkaloids.

Ions of type *a* are also characteristic of the benzylisoquinoline (18) and phthalide isoquinoline alkaloids (19). In these systems the molecular ion is of very low intensity and thus they are



SCHEME 1

readily differentiated from fumaricine and its analogues.

The spectrum of chelidonine is worthy of comment. The major fragment ions appear at *m/e* 335, 320, and 304. That at *m/e* 335 is formed through loss of H_2O, that at 320 through loss of CH_3 from *m/e* 335, and surprisingly that at *m/e* 304 through loss of CH_3NH_2 from *m/e* 335. The composition of these ions has been confirmed by exact mass measurement.

Experimental

Materials and Methods

The isolation and properties of the alkaloids used in this investigation have been described elsewhere (1, 2).

The mass spectra were recorded on a Hitachi Perkin–Elmer RMU-6A mass spectrometer. Samples were introduced through the direct inlet system. Accurate mass measurements (20) were carried out on a CEC-21-110B double-focussing mass spectrometer. The measurements were made by reference to appropriate peaks in the spectrum of perfluorokerosene (21). Observed values agreed with calculated values within ± 0.005 mass units. Exchange of the OH group of **4** was carried out using CH_3OD.

The p.m.r. spectra were recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V4315 frequency counter incorporated in the instrument. Double irradiation was achieved by employing a Hewlett–Packard 201C audio generator at the desired frequency. For N.O.E. measurements degassed solutions were used and a procedure similar to that of Anet and Bourn (6) was employed. A Perkin–Elmer 521 spectrometer was used to record i.r. spectra and a Cary 14 spectrometer was used for u.v. spectra.

Reduction of 3 with Lithium Aluminium Hydride

Compound **3** (58 mg) was dissolved in dry ether and added to an excess of $LiAlH_4$ in dry ether and the mixture heated under reflux for 20 min. Excess hydride was destroyed with water, the ether layer separated, and the aqueous layer extracted several times with fresh ether. The combined ether extract was evaporated to dryness yielding a residue which was recrystallized from ether, m.p. 129–133° (45 mg). The i.r. spectrum showed the presence of hydroxyl absorption but there was no band in the carbonyl region. The mass spectrum showed a molecular ion at *m/e* 353.1248; calcd. for $C_{20}H_{19}NO_5$, 353.1263. The compound showed a single spot on thin-layer chromatography.

Reduction of 3 with Sodium Borohydride

Compound **3**, dissolved in methanol, was added to a solution of sodium borohydride in methanol and the mixture allowed to stand at room temperature for several hours. The solution was evaporated to dryness, water was added to the residue, and the aqueous suspension extracted into chloroform. Evaporation of the chloroform extract gave a residue which had spectroscopic properties identical with the product of $LiAlH_4$ reduction of **3**.

Reduction with sodium borodeuteride was carried out in an analogous manner.

^{13}C Nuclear magnetic resonance studies. XIII. ^{13}C Carbonyl carbon shieldings of some β,γ-unsaturated ketones[1]

GURUDATA[2] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ontario

Received April 16, 1969

The 15.1 MHz ^{13}C nuclear magnetic resonance spectra of 13 aliphatic and alicyclic ketones having an olefinic bond in the β,γ position with respect to the carbonyl group have been recorded and the carbonyl shieldings measured. The major aim of this study was to investigate the possibility of detecting homoconjugative interactions between the π-systems by comparing the carbonyl shieldings with those for the corresponding saturated and α,β-unsaturated systems. Some evidence of homoconjugation is presented on the basis of our previous interpretation of the factors governing carbonyl shieldings. A qualitative assessment of the observed geometrical dependence of the effect is offered.

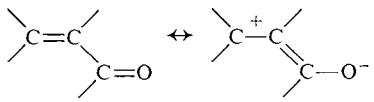
Canadian Journal of Chemistry. 47, 3601 (1969)

Introduction

From our earlier studies of aliphatic and alicyclic ketones (1, 2) it was found that the ^{13}C nuclear shieldings of carbonyl carbons are not nearly so sensitive to alkyl substitution as the saturated carbons in hydrocarbons (3). For the latter it is established that the replacement of an α- or β-hydrogen by a methyl group deshields the carbon nucleus by −9 p.p.m. (i.e., —CH—* CH → —CMe—* CH— or —CH—* C—Me). With the carbonyl compounds, this effect is attenuated to ca. −5 p.p.m. for the α-substitution, e.g. RCHO → $RCOCH_3$, and the changes for more remote substitutions are much smaller (1). A significant shielding effect, however, is found for conjugated systems in which either an olefinic bond (2) or an aryl ring (4) is in the α,β-position. This change is typically 10–12 p.p.m. by comparison with the corresponding saturated system. A rationalization of this trend follows from the consideration of the principal contributing resonance forms in each case. For the saturated systems, forms I and II dominate such that polarization of the π-cloud toward oxygen diminishes the electron density at carbon and accounts for the low field position of these nuclei relative

I II

to other sp^2-hybridized carbons. In conjugated systems, the electron withdrawing effect of oxygen at the carbonyl carbon is partially offset by contributions from forms such as IV and it follows, therefore, that the carbonyl carbon shielding will increase relative to that of a saturated system. Factors which interfere with this conjugative interaction would be expected to reduce the carbonyl shielding and several examples have been presented (2, 4). Support for the present interpretation which assumes a predominant electron density contribution is given by the current theoretical notions of carbon shieldings as well as the data for a variety of systems (5).



III IV

The total shielding constant, σ, for a carbon nucleus can be viewed as a summation of three major factors,

$$[1] \qquad \sigma = \sigma_d + \sigma_p + \sigma'$$

which include a diamagnetic term, σ_d, a paramagnetic contribution σ_p and a neighbor-atom, or group, factor, σ′. The latter includes effects due to neighboring anisotropic atoms or bonds whose small effects are operative through space and which, as a first approximation, can be neglected. The diamagnetic term depends directly on electron density and has an estimated maximum value of ca. 14 p.p.m. (6) for the addition of a 2p electron. Since the total range of carbon shieldings is more than 300 p.p.m., it is generally

[1]For Part X, see ref. 14; Part XI, see ref. 15; Part XII, see ref. 16.

recognized that the paramagnetic term, σ_p, dominates. Karplus and Pople (6) and Pople (7) have developed an expression having the form,

$$[2] \quad \sigma_p = -\frac{k}{\Delta E}\langle r^{-3}\rangle_{2p}\{Q_{AA} + \Sigma Q_{AB}\}$$

where ΔE represents the excitation energies for transitions between the ground and excited states, which is usually replaced with a mean value for particular classes of compounds. The Q terms contain the elements of the charge density and bond order matrix of the unperturbed molecule and $\langle r^{-3}\rangle_{2p}$ is the mean inverse cube radius of the carbon 2p orbitals. The local electron density on the carbon atom of interest is manifested in the latter term and in the atomic term in Q_{AA}. As the total charge on A increases, the orbitals expand, $\langle r^{-3}\rangle_{2p}$ decreases and σ_p becomes less negative. For carbon no large changes are expected for Q_{AA} (7). Maciel has discussed this theoretical approach with respect to the carbonyl group and has shown that the shieldings correlate with the C=O π-bond polarity (8). Thus, our earlier interpretation of the effect of conjugation is consistent with current theory.

In view of the pronounced effect of an adjacent conjugated π-bond on carbonyl carbon shieldings it seems reasonable to expect that any factor tending to increase its local electron density could be expected to shift the carbonyl absorption to higher field. One such factor is a homoconjugative interaction between a carbonyl group and a more remote olefinic bond which can adopt a geometry to permit overlap of the π-systems. The extent of interaction should be reflected in the observed carbonyl ^{13}C shielding. We would predict, therefore, that the position of the carbonyl absorption should vary with the stereochemistry of β,γ-unsaturated ketones and should lie between that of the corresponding saturated and α,β-unsaturated analogues of the system of interest. To test this proposal we have measured the carbonyl carbon shieldings of a series of thirteen β,γ-unsaturated ketones. In this paper we compare these values with those for the corresponding α,β-unsaturated isomers and the saturated analogues.

Experimental

^{13}C Spectra

The carbonyl carbon absorptions were detected using rapid-passage techniques at 15.1 MHz and their positions measured by interpolation using the audio side-bands of the reference signals which were in most cases those of external, enriched methyl iodide. Most of the data were obtained on the neat liquids, while solids were run as concentrated solutions in carbon disulfide. The data are judged to have a precision of ca. ±0.3 p.p.m. and no bulk susceptibility corrections were made. The results are reported relative to CS_2 (δ_c = 0 p.p.m.).

Materials

With the exception of 1-cyclohexenylacetone, obtained from K & K Laboratories, the β,γ-unsaturated ketones were prepared for this work. All of the materials have been described previously in the literature and samples were obtained having essentially the same physical constants. In addition, proton and infrared spectra were determined for each compound to ensure its identity. For the few α,β-unsaturated ketones which were not included in our earlier work (3) samples were prepared by standard methods. The saturated ketones for the most part are commercially available and the remaining examples were prepared by catalytic hydrogenation of the unsaturated analogue.

Results and Discussion

The carbonyl carbon shieldings for the β,γ-unsaturated ketones examined in this study are

TABLE II

^{13}C Carbonyl shieldings of some bicyclic β,γ-unsaturated ketones (p.p.m. from CS_2)

	Compound	δ_c	$\Delta\delta_c(\beta)$
10	Bicyclo[2·2·2]oct-5-en-2-one	−20.2	− 0.2
11	Bicyclo[2·2·1]hept-5-en-2-one	−20.4	+ 1.4
12	Bicyclo[3·2·1]oct-2-en-8-one	−22.0	+ 4.0
13	Bicyclo[2·2·1]hept-2-en-7-one	−10.5	+10.6

given in Tables I (aliphatic and monocyclic examples) and II (bicyclic systems) and the differences relative to the corresponding saturated ketones are listed as $\Delta\delta(\beta)$. In addition the differences in the carbonyl shieldings between the saturated and α,β-unsaturated isomers, $\Delta\delta(\alpha)$, are given in Table I for most of the aliphatic and monocyclic skeletons. It is evident that the β,γ-ketones exhibit carbonyl absorption at somewhat higher fields than their saturated derivatives with the observed differences ranging from 0.8 to 10.6 p.p.m. with one exception, compound **10**. It follows that the effect of the β,γ-double bond is not primarily operative through the bonding network but, instead, through space and therefore depends on molecular geometry.

It is known that π-electron systems situated beta to a developing carbonium ion center can significantly influence the course and the rate of reaction at that center. This anchimeric acceleration of rate has been ascribed to delocalization of the neighboring π-electron cloud in the rate-determining step. Simonetta and Winstein (9) employed a semi-empirical M.O. approach to calculate stabilization energies of such systems and found values which follow the same trend as the rate-enhancing effects in solvolysis. For a variety of systems undergoing solvolysis, anchimeric assistance factors have been estimated (10) to compare the relative extent of overlap between the neighboring π-bonds and the cationic centers. These factors, expressed as the logarithm of the rate difference (observed–calculated), for acetolysis of the tosylates are 12.9, for the *anti*-7-norbornenyl, 6.0, for *anti*-8-bicyclo[3·2·1]oct-2-enyl and 3.8, for *exo*-2-norbornenyl systems which may be compared with the $\Delta\delta(\beta)$ values of 10.6, 4.0 and 1.4, for the corresponding ketones, respectively.

For α,β-conjugated systems, a maximum interaction is expected if the nodal planes of the two π-bonds are coplanar so that 2pπ overlap is at a maximum. For β,γ-unsaturation, however, a different relationship is to be expected and can be considered in terms of simple models for the overlap between the 2p-orbitals (11).

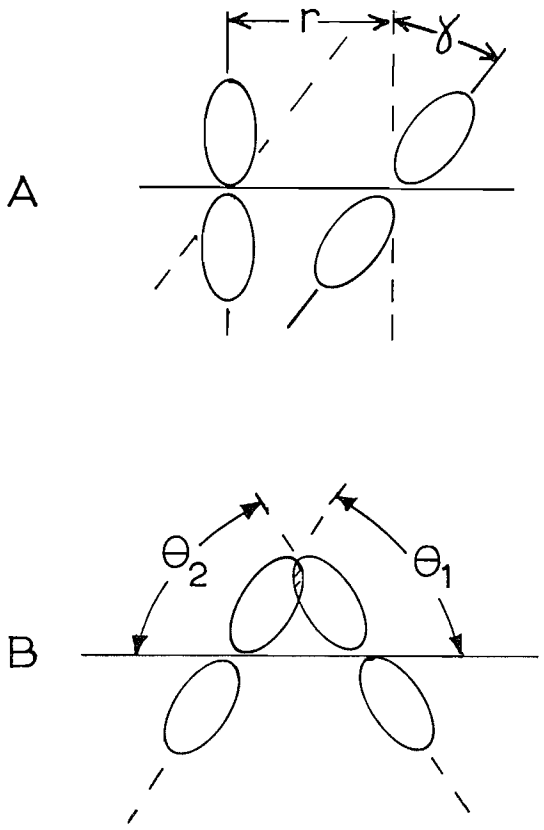

FIG. 1. Modes of overlap for p-orbitals of neighboring atoms.

If the axes of the 2p-orbitals lie in parallel planes at a distance r the overlap integral S_{ij} is given by

$$[3] \qquad S_{ij} = S_{\pi\pi} \cos\gamma$$

where γ is the angle between the axes (Fig. 1*a*). If the axes of the p-orbitals lie in a plane ($\gamma = 0$)

but are tilted towards one another at angles Θ_1 and Θ_2, relative to the internuclear axis (Fig. 1*b*), the overlap can be resolved into $\sigma\sigma$ and $\pi\pi$ contributions, for which

$$[4] \quad S_{ij} = S_{\sigma\sigma} \cos \Theta_1 \cos \Theta_2 + S_{\pi\pi} \sin \Theta_1 \sin \Theta_2$$

If, in addition, γ is non-zero the second term will include a cos γ factor. For the case of two directly bonded sp^2-hybridized carbons, Θ_1 and Θ_2 are 90° and the overlap integral is simply eq. [3] from which it is clear that as γ increases from zero S_{12} decreases. This is the basis for our interpretation of the effects of steric hindrance on carbonyl shieldings in α,β-unsaturated systems (4) and we have previously correlated the δ_c values with the angle γ, which was termed the "angle of twist, Θ".

For the case of two sp^2-carbons separated by one sp^3-carbon, however, it is apparent that little π overlap is possible in a planar arrangement. In non-planar conformation with the p-axes aligned (i.e. $\gamma = 0$) the overlap integral S_{13} is given by eq. [4]. For β,γ-unsaturated ketones in which the 1,3 internuclear distance is ca. 2.5 Å, and Θ_1 and Θ_2 are ca. 55° it can be seen that $S_{\sigma\sigma}$ exceeds $S_{\pi\pi}$ by a factor of ca. 3. Thus, $S_{\sigma\sigma}$ can be expected to make a significant contribution to S_{13}.

On the basis of the foregoing arguments it is expected that interactions between the non-conjugated π systems will be maximal in non-planar configurations (or conformations) and that the effect at the carbonyl carbon will be in the direction of increased shielding. These expectations appear to be supported by the present data. The largest effect, 10.6 p.p.m., found for **13** may be compared, for example, with that for 3-cyclopentenone, **7**, 1.3 p.p.m. which can be taken as representative of the nearly, if not exactly, coplanar cases while the former is restrained to a geometry which yields a substantial value for $S_{\sigma\sigma}$. The geometric parameters, $\Theta_1 = 58°55'$, $\Theta_2 = 68°10'$, $\gamma = 17°29'$, $r = 2.296$ Å yield $S_{ij} = 0.08$, $S_{\sigma\sigma} \approx 0.2$ and $S_{\pi\pi} < 0.06$ (11).

While it is clear that this simple approach is qualitative it does account for the stereochemical dependence and gives a basis for the difference between the geometrical dependence in the β,γ- and α,β-unsaturated systems.

Ketone **13** was included in an earlier study of carbonyl shieldings by Savitsky *et al.* (12), who attributed the difference in carbonyl shielding for **13** and 7-ketonorbornane to the difference in λ_{max} values for the $n \rightarrow \pi^*$ transition. These authors assumed (*a*) that the ΔE term in eq. [2] plays a dominant role in the carbonyl shieldings and (*b*) that the $n \rightarrow \pi^*$ transition energies are proportional to ΔE. For the compounds included in their study, an approximately linear relation was found for $\delta^{C=O}$ vs $\lambda_{max}^{n\rightarrow\pi^*}$. The inclusion of other ketones, however, has clearly shown that a good linear correlation of these parameters does not exist (2*b*). We have recently found that, although the carbonyl oxygen-17 shieldings are grossly correlated with their $n \rightarrow \pi^*$ transition frequencies, within a series of closely related ketones the correlation does not hold (13) but the observed trends correlate nicely with variations in the local electron density. At the present time it appears that the available ^{13}C results are readily interpreted in a similar fashion in terms of variation in the local electron density which are manifest in both the σ_d and σ_p contributions to the total shielding constant.

^{13}C Nuclear magnetic resonance studies. XIV.[1] Conformational effects on carbinyl carbon shieldings in cyclohexanols and derivatives

G. W. BUCHANAN[2] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Canada

Received May 20, 1969

The ^{13}C shieldings of the alicyclic carbons bearing oxygen in several cyclohexanols, their acetates and methyl ethers depend on the orientation of the oxygen functions. The compounds examined include the *cis*- and *trans*-4-alkyl derivatives in which the alkyl groups are *t*-butyl, *i*-propyl, ethyl and methyl, as well as the 3-*t*-butyl isomers. The results for the parent compounds are employed for the estimation of the conformational free energies of the hydroxyl, acetoxyl, and methoxyl groups, and serve to establish that ^{13}C magnetic resonance (c.m.r.) spectroscopy offers a new approach to conformational analysis. The data were obtained using the decoupling technique and materials containing ^{13}C in natural abundance.

Canadian Journal of Chemistry, 47, 3605 (1969)

Introduction

Over the past few years sufficient evidence has been accumulated to establish that carbon shieldings depend, at least in part, on molecular geometry and conformation (1–6). From our investigations of certain alicyclic systems (7, 8) by carbon magnetic resonance (c.m.r.) spectroscopy we were led to an examination of the alicyclic alcohols in which were included the *cis*- and *trans*-4-*t*-butylcyclohexanols. The shieldings of the carbinyl carbons in these isomers were found to differ by *ca.* 5 p.p.m. (3) indicating that c.m.r. techniques have promise as an additional tool for conformational analysis. In fact, the method constitutes a new approach to this aspect of stereochemical studies because the pronounced differences observed are a function of substituent orientation entirely since the position of the carbon nucleus of interest is unchanged relative to the other atoms in the molecule for both epimers. Since the difference is relatively large, its measurement with refined techniques may be superior to other nuclear magnetic resonance (n.m.r.) methods.

To determine the utility of the approach for conformational analysis and to confirm that the shielding differences are primarily due to conformational effects we examined the 4-alkyl series including the isopropyl, ethyl, and methyl derivatives as well as the 3-*t*-butyl isomers. The acetates and methyl ethers were also measured to assess the importance of hydrogen bonding contributions to these shieldings. We describe these results in the present paper to amplify the data presented in our preliminary communication (3). All of the earlier results have been redetermined using the more precise "proton-decoupling" technique originally described by Paul and Grant (9).

Experimental

Spectra

The natural abundance ^{13}C spectra were obtained at 15.1 MHz on a Varian DP-60 system which included a NMR Specialties SD-60 Spin-decoupler operating at a nominal frequency of 60 MHz. The proton-decoupling technique (9) was used throughout for the ^{13}C measurements, which are given relative to CS_2 as described previously (6). A H–P 5245L counter was employed for all frequency measurements.

The proton spectra were obtained with a Varian A60 spectrometer using the usual audio side-band technique to determine peak positions to better than 0.5 Hz.

For the most part the compounds were examined as the neat liquids, while solids were run in carbon disulfide and dimethylsulfoxide solutions.

Materials

The alcohols are known compounds and were obtained from commercial sources or by standard methods. Treatment of these alcohols with acetic anhydride and sodium acetate gave the desired acetates. Physical constants and analytical data for the new compounds are given in Table I. The methyl ethers were prepared by either of two methods: (A) treatment of the corresponding sodium alkoxide with methyl iodide or (B) treatment of an ethereal solution of the alcohol and $BF_3 \cdot Et_2O$ with diazomethane at 0°. Data for the new ethers are collected in Table I. The purity of all materials was checked by infrared (i.r.) and proton spectroscopy. Liquid samples for ^{13}C spectra were obtained by fractional distillation through a spinning-band column.

Results and Discussion

The shielding data are collected in Tables II–V, in which the results for the alkylcyclohexanols,

the corresponding methyl ethers and acetates, and the parent systems are separately presented.

As a starting point for discussion it seems reasonable to consider the 4-*t*-butyl substituted systems as the base cases. With the assumption that this alkyl group exerts a negligible effect on the C-1 shielding we can designate the carbinyl shieldings for the *cis*- and *trans*-isomers as the "true" shieldings for carbons bearing these axial and equatorial oxygen functions, respectively. The original basis for this assumption is the fact that alkyl substitution in hydrocarbons has little effect (i.e. < 0.3 p.p.m.) on the shieldings of carbons separated by more than three σ-bonds from the substituent (1). Experimental proof of this is provided by the data for the series of *trans*-4-alkyl derivatives listed in the Tables. For example, the carbinyl shieldings for the series of methyl ethers (Table III) exhibits a total range of 0.21 p.p.m. while the corresponding acetates (Table IV) have a spread of only 0.08 p.p.m. Unfortunately the 4-*t*-butylcyclohexanols are solids and must be examined in solution. Consequently the somewhat larger difference between their carbinyl shieldings and those of the 4-methyl, -ethyl, and isopropyl derivatives may be due in part to a solvent effect. The fact that the shielding differences in CS_2 and DMSO solutions are dissimilar for the

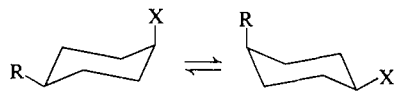
3-*t*-butyl	119.61 ± 0.10	4.62	123.13 ± 0.07	5.11

cis- and *trans*-4-*t*-butyl isomers offers supporting evidence for this. In any event, the solvent effects are small and, as a first approximation, may be neglected. Since the differences, $\delta_C^{cis} - \delta_C^{trans}$, for the 4-*t*-butylcyclohexanols and their methyl ethers are virtually the same, hydrogen-bonding of the hydroxyl grouping has a negligible effect on the carbinyl carbon shieldings. It is interesting that the difference of *ca.* −9 p.p.m. between the alcohols and their methyl ethers is almost identical to the effect found for replacement of a β-hydrogen by methyl in a hydrocarbon chain, viz. −9.1 p.p.m. (1). This "β-effect" has so far eluded attempts to account for its origin (10). Nevertheless, the change is invariably found in ^{13}C spectra. On the other hand, acetylation of the hydroxyl group results in a very much smaller change in the carbinyl carbon shielding, namely *ca.* −2.5 p.p.m. Thus it is clear that the "β-effect" for a carbonyl carbon is very different from that for methyl or methylene carbons.

In the *cis*-4-alkyl isomers, the oxygen function is primarily in the axial orientation and it is apparent that the carbinyl carbon shieldings move to progressively lower field as the alkyl group decreases in size. This is readily explained in terms of the conformational equilibrium **1** ⇄ **2** in which the relative contribution of the equatorial form **2** increases with decreasing bulk of the substituent alkyl group. For the *cis*-4-*t*-butyl derivative one can assume that the equilibrium is almost entirely on the left while **2** would



1 **2**

be expected to make an appreciable contribution for the equilibrium of the *cis*-4-methyl derivative. For the simplest related case, methylcyclohexane, **1** (R=Me, X=H), a recent estimate of the conformational free energy of the methyl group (11) indicates that **2** constitutes *ca.* 8% of the mixture. In the present series with X = OR′ the proportion of **2** will be larger since $-\Delta G_{OR'}$ values are *ca.* 0.7 kcal/mole (see below). While there is evidence that the relative spatial orientation of alkyl carbons is an important factor governing carbon shieldings *if those carbons are within three bonds* of each other, the so-called γ-effect (1,10), no appreciable effects have been observed for

	DMSO*	122.90 ± 0.15	3.47
Cyclohexyl acetate	nil	120.49 ± 0.10	4.73
Cyclohexyl methyl ether	nil	114.18 ± 0.10	3.08

*3 *M* Solutions.

carbons further separated. Thus it follows that the sequential replacement of hydrogen atoms on the δ-carbon will exert no appreciable shielding influence on the carbinyl carbon. This corresponds to the 4-alkyl series, methyl, ethyl, isopropyl, *t*-butyl.

A similar argument applies for the *cis*-3-*t*-butyl derivatives for which the carbinyl shieldings of the ether and acetate are within experimental error of those for the *trans*-4-alkyl cases. The difference between the value for the *cis*-3-*t*-butyl and *trans*-4-*t*-butyl isomers may be due in part to solvent effects. It is interesting that the carbinyl carbon shieldings for the *trans*-3- and *cis*-4-*t*-butyl alcohols and acetates are the same within our limits of measurement, lending support to the notion that the orientation of the oxygen function is the major factor governing the carbinyl carbon shieldings in these compounds.

In contrast the equatorial carbinyl proton on the carbinyl carbon absorbs at consistently lower field (*ca.* 0.15 p.p.m.) in the *trans*-3-*t*-butyl derivatives relative to the *cis*-4-*t*-butyl isomers, whereas the axial protons have similar shifts in both series of alcohols and ethers. Apparently the proton shieldings are more sensitive to small changes in ring geometry. Differences in the deformations of 3- and 4- alkylcyclohexanols have been discussed recently and a tentative explanation presented (12). It was proposed that the tendency of an axial oxygen to reduce its *syn*-diaxial interactions leads to an uneven flattening of the ring such that the flattening is more severe about the C-1, -2, and -6 centres than at C-3, -4, and -5 and eclipsing interactions between C-3 substituents and C-2 hydrogens will affect the extent to which the *syn*-diaxial interactions can be relieved (i.e. the former will reduce the twisting about the C_1—C_2 and C_1—C_6 bonds). If this is valid, it follows that the equatorial C-1 proton may be in a different magnetic environment than the corresponding proton in the 4-alkyl isomer and, therefore, the shieldings may differ. Although a comparable difference may also obtain for the carbinyl carbon shieldings the present experimental method lacks the precision required for its detection. In any event it is clear that the proton shieldings for the 3-*t*-butyl series cannot be employed for conformational energy estimations in the way that has become popular for the 4-*t*-butylcyclohexyl derivatives.

In the axial orientation the oxygen atom will experience non-bonded interactions with the *syn*-axial protons on C-3 and C-5. It seems reasonable to suggest that the carbinyl carbon shielding is affected by steric perturbation of its local electron distribution because of these non-bonded interactions. Evidence of this effect has been presented for a variety of hydrocarbons (2,5,10,13) and other oxygenated cyclohexane derivatives (6). Preliminary results on a quantitative interpretation of the steric perturbation of carbon shieldings in these and related oxygenated compounds have been presented (14). A similar examination of these functional groups in bicyclic systems of known geometry is in progress with the intention of developing a generalized relation between non-bonded interactions and carbon nuclear shieldings.

With the present results, however, it is possible to examine their use for estimating conformational free energies, $-\Delta G°$, for the hydroxyl, methoxyl, and acetoxyl groupings. Two of these have been the subject of several investigations and a large body of data exists (15). Thus, these groups provide a reasonable test of the validity of the ^{13}C approach for conformational analysis. To this end the carbinyl carbon shieldings of

cyclohexanol, cyclohexyl methyl ether, and cyclohexyl acetate were determined and the data are collected in Table V.

Comparison of the results in the Tables reveals that for each case the shielding of the carbinyl carbon for the simple cyclohexyl derivatives lies between those of the *cis*- and *trans*-4-*t*-butyl analogs. Since it appears that the orientation of the oxygen function is the major factor governing these shieldings, it follows that the data can be used to estimate equilibrium constants for the conformational equilibria, **1** ⇄ **2** (R=H, X= OH, OMe, OAc), according to the expression,

$$K = \frac{\delta_{ax} - \delta}{\delta - \delta_{eq}} \qquad [1]$$

where δ_{ax} and δ_{eq} are the shieldings for the "fixed" axial and equatorial forms (taken as the *cis*- and *trans*-4-*t*-butyl derivatives) and δ is the value for the equilibrating system. With these data, the conformational free energy is calculated directly from, $\Delta G^\circ = RT\ln K$. The results are collected in Table VI which also lists the range of $-\Delta G^\circ$ values previously reported as well as the "best" values according to Hirsch (15) and Eliel (16). It is evident that the ^{13}C results agree very well with the currently accepted values although the experimental error is rather large. As noted above, the 3-*t*-butyl group does not appear to affect the carbinyl carbon shieldings and, therefore, it is of interest to compare the $-\Delta G^\circ_{OR}$ values obtained from these data. These are 0.74, 0.58, and 0.68 kcal/mole, for the OH, OMe, and OAc groupings, respectively, which are the same as those listed in Table VI from the 4-*t*-butyl models. In principle, the data for the *cis*-4-methyl, -ethyl, and isopropyl derivatives could be employed to compute the conformational energies of these alkyl groups, assuming additivity of $-\Delta G^\circ$ values for the individual substituents. While this assumption is apparently valid (12), the equilibria favor conformer **1** so heavily that the uncertainty in the calculated $-\Delta G^\circ_R$ values is too high (± 0.7 kcal/mole) to be useful. In fact, calculations lead to averages of 1.34, 1.45, and 1.53 kcal/mole, for methyl, ethyl, and isopropyl groups, respectively, compared to the recently reported values of 1.56, 1.67, and 1.90 kcal/mole (11). Although the order is retained, the ^{13}C results are 0.2–0.4 kcal/mole lower, but the discrepancy may be due entirely to the relatively low precision of the measurements. With the newer instrumentation (17) much higher precision is attainable and the ^{13}C method promises to be valuable. In addition, the enhanced sensitivity provided by "field-locked" spectrometers will permit measurements at high dilution so that solvent effects can be examined in detail.

Recent studies by Jensen, Bushweller, and Beck (18) on the validity of the assumption that the 4-*t*-butylcyclohexyl derivatives are good models for the axial and equatorial conformers require comment. Their results show that the popular method of estimating $-\Delta G^\circ$ values from proton data in a manner analogous to that used here, can lead to erroneous results. These workers have proposed an alternate method which is based on the proton chemical shift measurements but allows for the temperature dependence of these shifts. Of the groups included in the present study only the acetoxyl function was examined by Jensen *et al.* Their value of 0.71 ± 0.05 kcal/mole is further evidence that our ^{13}C result is satisfactory. The trideuteriomethoxyl function was also studied by the Jensen group (18) who found $-\Delta G^\circ_{OCD_3} = 0.547 \pm 0.019$ kcal/mole, which seems to be slightly lower than the value assigned

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

by Eliel (16) for OCH_3. Since the precision of the published data, apart from that of Jensen (18), is *ca.* $\pm$ 0.1 kcal/mole it is not possible to decide whether or not there is an isotope effect on the $-\Delta G^\circ_{OMe}$ value but it would be interesting to check this point since the relatively high precision of the Jensen, Bushweller, and Beck method may be sufficient to reveal it. In view of these findings for the proton results, however, it is essential that the ^{13}C method be checked in a similar manner. We hope to be able to report on this aspect of the problem in the near future.

In any event it is clear that ^{13}C n.m.r. spectroscopy offers a new approach to the evaluation of conformational energies and, since the shieldings of the carbon nuclei bearing substituents depend on the orientation of those substituents, the ^{13}C method should provide a means of examining a variety of groupings which are difficult to study by the other more established methods.

Mass spectra and fragmentation mechanisms of some nitrophenylhydrazines and nitrophenylhydrazones

F. BENOIT AND J. L. HOLMES
Chemistry Department, University of Ottawa, Ottawa 2, Canada
Received April 30, 1969

The mass spectra and fragmentation mechanism of 2- and 4-nitro and 2,4-dinitrophenylhydrazines and their *N,N'* trideutero analogues are discussed with respect to the operation of an "ortho effect". The mass spectra of nitrophenylhydrazones of cyclohexanone, methyl cycolhexanones, and their deuterated analogues are discussed with reference to the fragmentation of the ketone portion of the molecule.

Canadian Journal of Chemistry, 47, 3611 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

The mass spectra of aldehyde and ketone derivatives of 2,4-dinitrophenylhydrazine (1–5) and *N,N*-dimethylhydrazine (4) have been reported previously. The results were mainly interpreted with respect to McLafferty rearrangements (4) and the sequential losses of water and a hydroxyl radical from the molecular ions (6*a*). Little attention has been given to the fragmentation of the aldehyde or ketone moiety of the molecule. Seibl and Völlmin (1) and Seibl (5) noted that the migration of a hydroxyl radical from the ortho–nitro position produced a fragment ion corresponding to the protonated form of the aldehyde. The operation of an "ortho effect" in aromatic nitro compounds has been considered by Harley–Mason *et al.* (7). We report here on the fragmentation mechanism of 2- and 4-nitro- and 2,4-dinitrophenylhydrazines and also on cyclohexanone and methylcyclohexanone nitrophenylhydrazones. The fragmentations of the ketone moiety of the molecules are discussed with respect to the possible use of the mass spectra of these derivatives in identifying structural features in new keto compounds.

Transitions that are supported by a metastable peak are indicated by an asterisk. Where the deuterated compound has also been investigated, the masses of the deuterated fragment ions are shown in parentheses beside the appropriate species in the fragmentation schemes of the undeuterated compound. It should be emphasized that many of the ion structures presented in the fragmentation schemes are necessarily hypothetical.

Results and Discussion

2,4-Dinitrophenylhydrazine

The mass spectrum of 2,4-dinitrophenylhydrazine **1** (Fig. 1*a*) may be interpreted by invoking an "ortho effect".

The mass spectrum of the *N,N'* trideutero analogue was obtained (Fig. 1*b*) and results therefrom used to support the fragmentation mechanism shown as Schemes I and II.

In Scheme I, two H atoms are shown as migrating from the hydrazine function to the *o*-nitro group and the subsequent loss of water produces fragment ion *a*, *m/e* 180 which further dissociates *via* the successive losses of N_2, NO, and NO to produce fragment ions *b*, *c*, and *d*. The fragment ion *d*, *m/e* 92 then dissociates further to produce the peaks *m/e* 64 and 63 by loss of CO or ·CHO, as is found in the case of aryl oxygen compounds (6*b*). A fragment ion of some interest in the above sequence is *b*, *m/e* 152. Upon deuteration of the hydrazine function (Fig. 1*b*), *m/e* 152 is shifted to *m/e* 153 (2% b.p.) and *m/e* 155, *e*, (1% b.p.) (Scheme II), the former arising by loss of D_2ON_2 (either as D_2O and N_2 successively or as $[D_2ON_2]$) from the molecular ion while the latter arises by loss of NO_2 from the molecular ion. The nitro group lost is believed to be from the ortho position because *e* does not show the loss of D_2O or ·OD that could be expected from interaction of an ortho–nitro group with the hydrazine function. Fragment ion *e* then successively loses ND_2 and NO to yield fragment ions *f* and *g* (corresponding to *f'* and *g'* in Scheme I). Fragment *g'* can then undergo the loss of HCN, CO, or HCO· to produce fragments of *m/e* 79, 78, and 77 respectively. It should be noted that *m/e* 79 is not shifted upon deuteration while *m/e* 78 is shifted to *m/e* 79. Thus the intensity of the latter peak is increased sufficiently for it to become base peak while in the undeuterated compound, *m/e* 51 is base peak.

para- and ortho-Nitrophenylhydrazine

The mass spectra of **1** and *p*-nitrophenylhydrazine **2** are superficially similar, except that in the

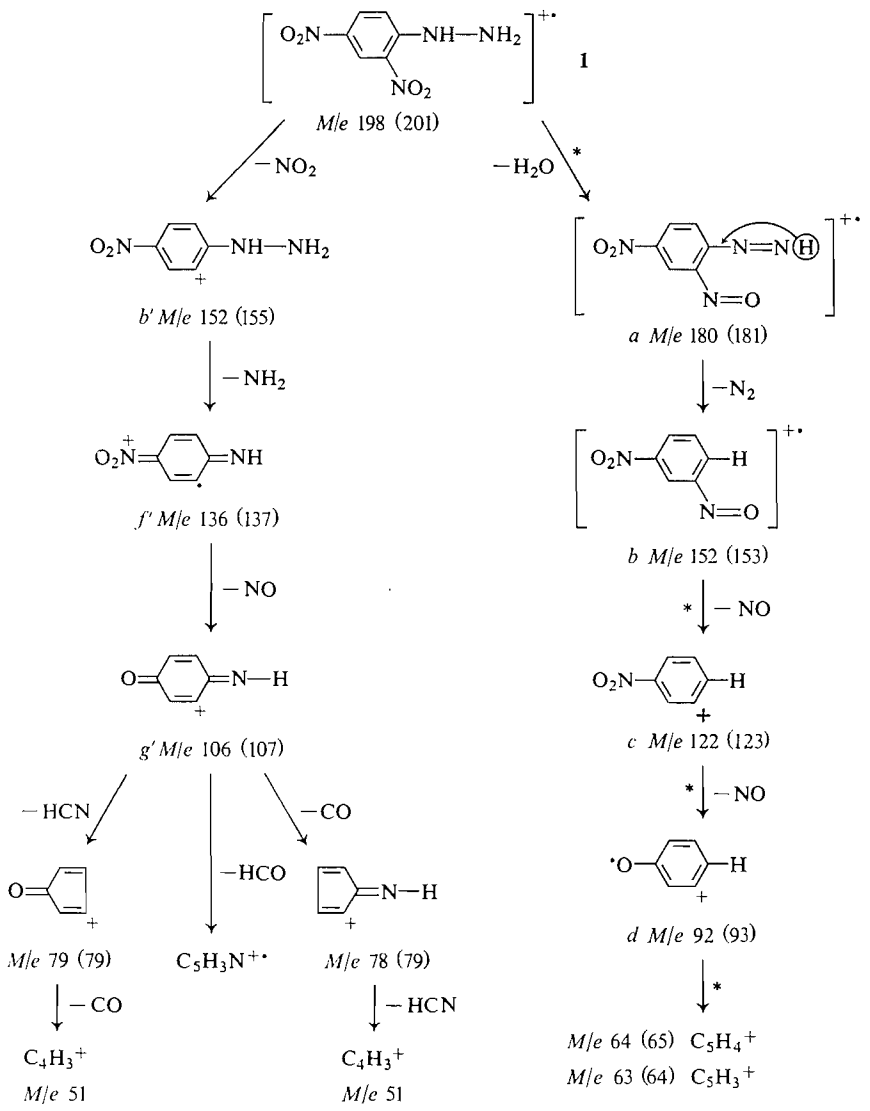
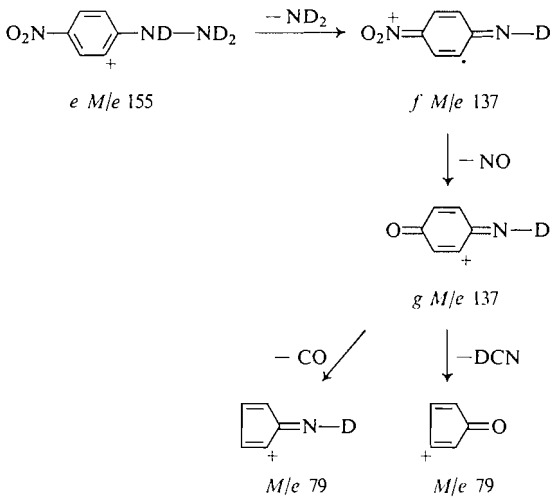


SCHEME I

Fragmentation mechanism of 2,4-dinitrophenylhydrazine.

latter many fragment ions appear at one mass unit higher. For example, peaks at *m/e* 152, 122, 106, and 79 in **1** are observed at *m/e* 153, 123, 107, and 80 in the mass spectrum of **2** which is shown as Fig. 2*a*. One peak prominent in Fig. 2*a* which does not appear strongly in the mass spectrum of **1** is that at *m/e* 90. In the *N,N'*-trideuterated analogue of **2**, the peaks at *m/e* 107 and 90 are shifted to *m/e* 110 and 91 respectively. These can be explained if the loss of NO_2 from the molecular ion is followed by ring opening together with migration of NH_2· to the ortho position, yielding the fragment ions *h* and *h'* shown in Scheme III. The linear structure *h'* would be better able to carry two positive charges than the cyclic form and indeed a small peak (0.1%) is found at *m/e* 53.5. Fragment *h'* can lose either HCN or NH_3 to give ions *m/e* 80 and 90 respectively; the latter pair can undergo conjugate losses as shown, to produce the ion *m/e* 63. It is noteworthy that the ion *m/e* 107 is *not* the analogue of *m/e* 106, *g'* (which contained oxygen) in the mass spectrum



SCHEME II

Fragmentation mechanism of fragment *e* formed in the mass spectrum of *N,N'-d*$_3$-2,4-dinitrophenylhydrazine.

of **1**. This explains the lower intensities of peaks at *m/e* 78 and 79 in **2**; these were found to arise by loss of HCO· or CO from *g'* in **1**.

The mass spectrum of *o*-nitrophenylhydrazine **3** (Fig. 2*b*) is appreciably different from that of the para isomer. This is due to the "ortho-effect" described in the fragmentation of **1**. The ortho isomer sequentially loses H_2O and NO from the molecular ion to give fragment ion *k* as shown in Scheme IV. The loss of N_2 or NH· from *k* to produce ions *m/e* 77 and 90 respectively could occur readily from a cyclic entity. To explain the loss of HCN or CN· from *k* we again propose ring opening following migration of NH· to the ortho position to produce *k'*. The latter can sequentially lose CN· and HCN (or *vice versa*) yielding *m/e* 79, 78, and 52. Thus the ortho isomer, whose mass spectrum is superficially different from that of **2**, fragments by a closely similar mechanism.

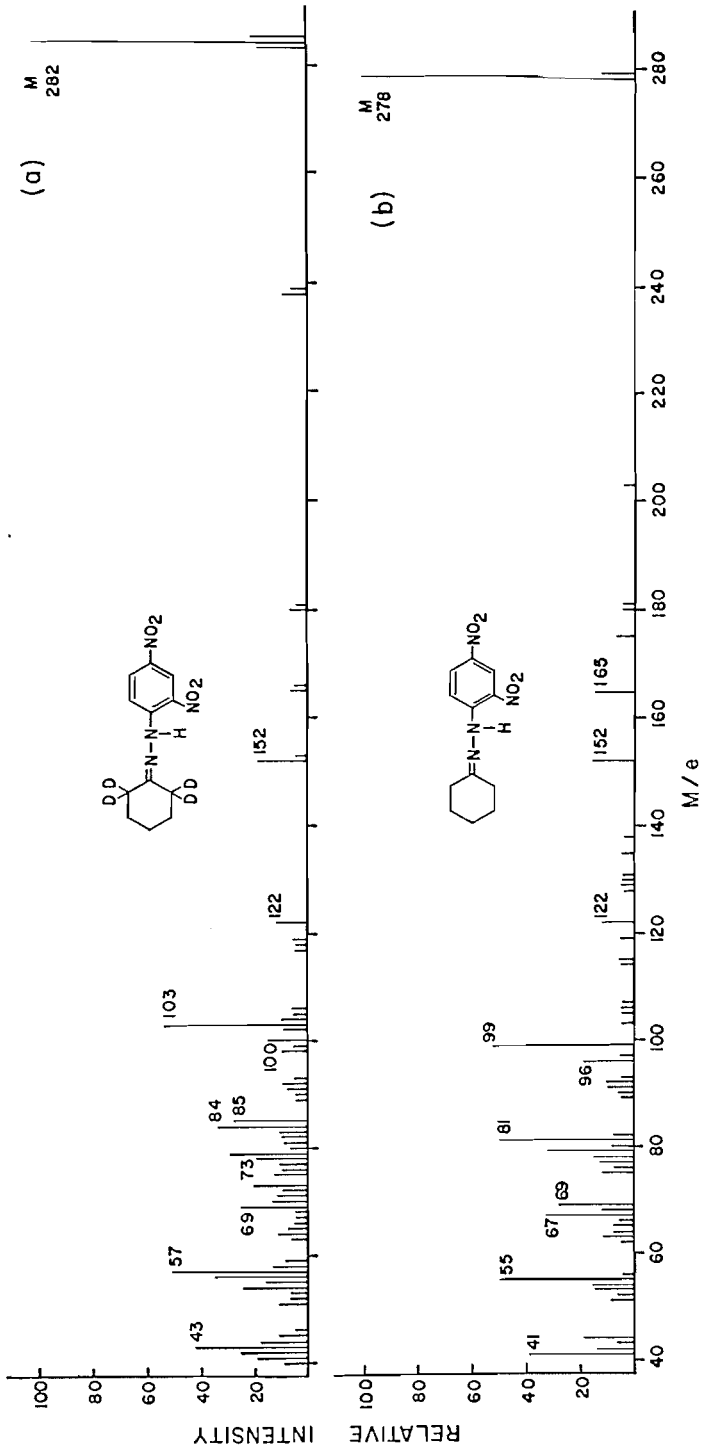

FIG. 3. Mass spectra of (*a*) cyclohexanone-2,4-dinitrophenylhydrazone and (*b*) its α-d_4-analogue.

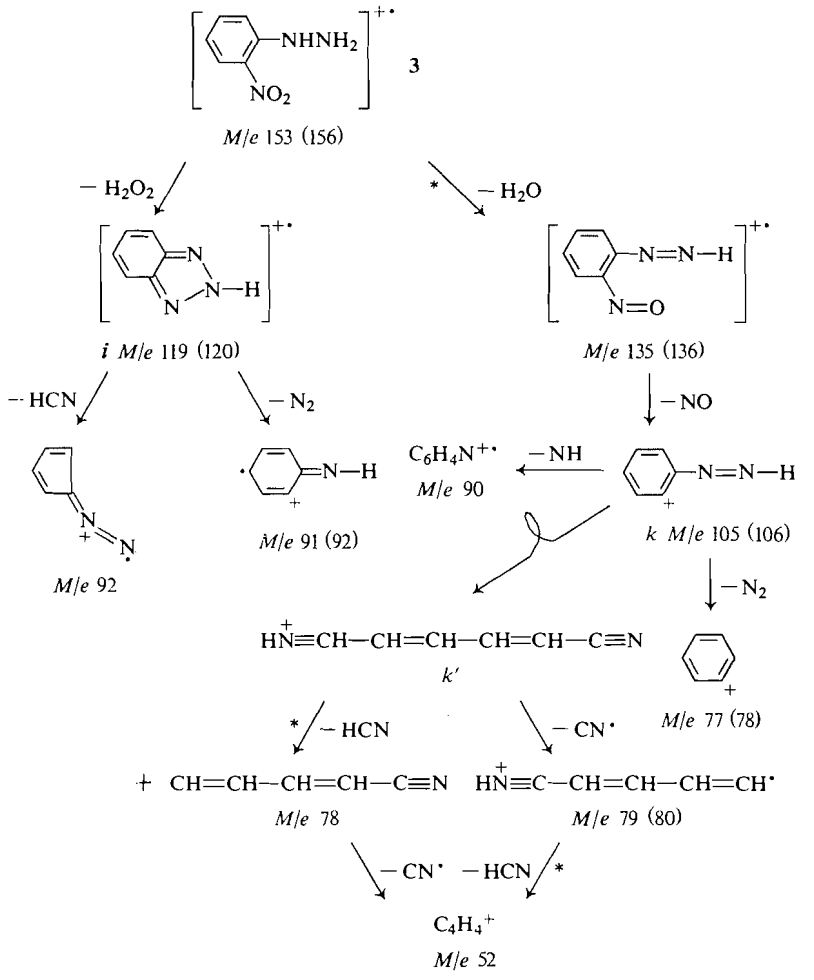

SCHEME IV

Fragmentation mechanism of *o*-nitrophenylhydrazine.

The loss of H_2O_2 from the molecular ion is not widely encountered and deserves mention; the transfer of two H atoms to different oxygen atoms on the nitro group with subsequent loss of H_2O_2 could yield the stable entity **1**, which can further lose either N_2 or HCN to produce *m/e* 91 and 92 respectively as shown in Scheme IV.

Cyclohexanone 2,4-DNP

The mass spectra of ketone 2,4-DNP's show peaks similar to those found in the mass spectrum of 2,4-dinitrophenylhydrazine. Since these fragment ions give little or no information as to the structure of the ketone moiety they will not be discussed further.

A prominent feature in the mass spectrum of cyclohexanone 2,4-DNP (**4**) (Fig. 3*a*) is the intense peak at *m/e* 99 (fragment-*m*). This peak arises from migration of a hydroxyl group from the ortho–nitro group to the ketone moiety to yield the protonated ketone (Scheme V)[1]. This is supported by the observation that the *m/e* 99 peak is shifted to *m/e* 100 in the *N*-deuterated analogue and to *m/e* 103 in the α-d_4 compound (Fig. 3*b*). The structure of *m* is a matter for conjecture but incorporation of the oxygen into a ring (*m'*) is feasible (as shown in Scheme V). Fragment *m'* is then seen to lose water, yielding *m/e* 81; the latter remains in the spectrum of the *N*-deuterated

[1]This migration has been independently suggested by Seibl and Völlmin (1) and Seibl (5).

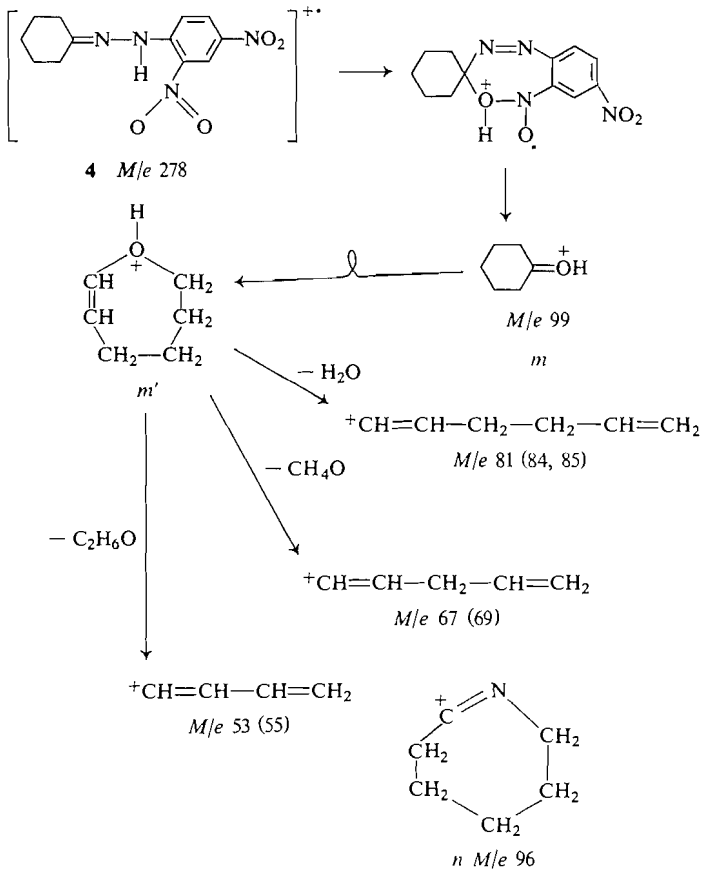

SCHEME V

Fragmentation mechanism of cyclohexanone-2,4-dinitrophenylhydrazone.

species while being shifted to *m/e* 84 and 85 in the α-d_4 compound. This indicates that water loss from *m'* occurs equally by a 1,2 and 1,3 and/or 1,4 elimination. Fragment *m* corresponds to either "protonated cyclohexanone" or the "(M-1) ion of cyclohexanol" and could be expected to show cleavages similar to those observed in the mass spectra of cyclohexanone and cyclohexanol. In cyclohexanol the H atom involved in the loss of water was found to come from either the 3 or the 4 carbon position (6*c*). H_2O loss in cyclohexanone involved H atoms from the 2 or 3 carbon positions (6*d*). The suggested mechanism for the loss of water is shown in Scheme V. Fragment *m'* also loses CH_4O and C_2H_6O. These neutral fragments, corresponding to CH_3OH and C_2H_5OH are believed to be lost by the mechanism shown in Scheme V. The determining factor seems to be the carbon position from which the H atom is transferred. Thus migration of a H atom from the 3 position induces loss of H_2O, from the 4 position loss of CH_4O and from the 5 position loss of C_2H_6O. The fragmentation of the deuterated species supports this dissociation mechanism. Migration of a H atom from the 2 position also gives rise to loss of H_2O and is observed as the loss of HDO from the α-d_4 analogue of *m*.

Even though migration of a H atom from the 4 and 5 positions induces loss of CH_4O and C_2H_6O respectively, water loss may also occur. All the features described above are present in the mass spectrum of cyclohexanone *o*-nitrophenylhydrazone (Fig. 4*a*), but are absent in the *p*-nitro analogue (Fig. 4*b*). The latter fragments differently, *via* cleavage of the central *N-N* bond to produce fragment ion *n*. This species has also been observed in cyclohexanone-*N*,*N*-dimethylhydrazone (4).

Fragment ion *n* may be represented by many structures; one of these is shown in Scheme V, i.e. with the nitrogen atom incorporated into a ring. Fragment *n* behaves similarly to fragment *m*; H atom migrations from the various ring positions are associated with losses of HCN, CH_3CN, and C_2H_5CN to yield the species *m/e* 69, 55, and 41. High resolution measurements on *m/e* 69 and 55 showed that these are $C_5H_9^+$ and $C_4H_7^+$ respectively. The charge appears to remain with the aliphatic fragments rather than with the cyanide entity. That H atom migration from the 2 position is associated with the loss of HCN is shown by the loss of DCN in the α-d_4 species.

The mass spectrum of cyclopentanone 2,4-DNP showed peaks corresponding to fragmentations analogous to those described above for cyclohexanone 2,4-DNP and thus a similar mechanism presumably operates.

Methylcyclohexanone Nitrophenylhydrazones

The mass spectra of the three isomeric methylcyclohexanone-2,4-DNP's were found to be very similar. The only differences observed lay in the relative intensities of the major peaks. The presence and position of the methyl substituent does not appear to exert any significant influence on the fragmentation of the ketone moiety of the molecule which behaves similarly to cyclohexanone-2,4-DNP. The similarity is not surprising since the three isomeric methylcyclohexanones (6*e*) and the methylcyclohexanols (6*f*) are not readily distinguishable by means of their mass spectra. The mass spectra of 4-methylcyclohexanone-2,4-DNP and its *p*-nitrophenylhydrazone are shown in Figs. 5*a* and 5*b*. The substituent position in molecules known to be isomeric could be determined (with some uncertainty) from relative intensities of fragment ions in their mass spectra but these alone would be of little aid in structural determinations of unknown molecules.

Experimental

All mass spectra were measured on a Hitachi–Perkin Elmer RMU-6D mass spectrometer using the direct sample inlet system. The 2,4-DNP's were run at an inlet temperature of 250 °C while *o*- and *p*-nitrophenylhydrazine were run at room temperature. The spectra were measured at electron energy 70 eV.

The nitrophenylhydrazones were prepared by reaction of the appropriate nitrophenylhydrazine and the ketone in acid medium with 95% ethanol as solvent. Deuteration of the hydrazine function was carried out by recrystallization of the sample from a mixture of D_2O and dioxane.

Conformational studies of some 5,9-dimethyl-6,7-benzomorphan diastereoisomers and related compounds

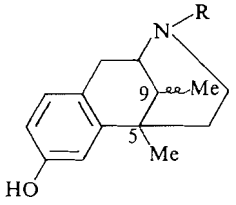
A. F. Casy and A. P. Parulkar
Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alberta

Received January 10, 1969

The proton magnetic resonance characteristics of some α/β diastereoisomeric 5,9-dimethyl-6,7-benzomorphans are reported for free base, hydrohalide, and methiodide forms, and differences between α- and β-signals are interpreted in terms of the piperidine ring fragment of the β-salts adopting skew-boat conformations. The steric course of quaternization of benzomorphan isomers is discussed from results of alkylations using trideuteriomethyl iodide and other experiments. A possible correlation between conformational and potency differences in analgesically active benzomorphan diastereoisomers and related compounds is discussed.

Canadian Journal of Chemistry, 47, 3623 (1969)

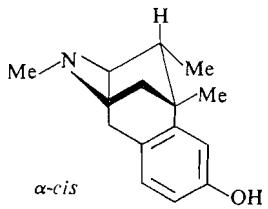
This paper reports a comparative conformational study of some 6,7-benzomorphan derivatives **1** that are diastereoisomeric with respect to the C-5 and C-9 alkyl substituents. The relative



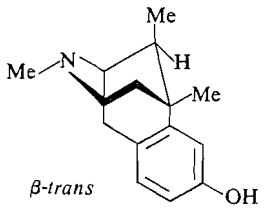
1

5,9-dialkyl configurations of several pairs of benzomorphan isomers are known (α-*cis* and β-*trans* with reference to the hydroaromatic ring) from rates of quaternization and proton magnetic resonance (p.m.r.) data (1), and a recent X-ray analysis of the α-*N*-allyl derivative **1** (R = CH_2-$CH{=}CH_2$) supports these assignments (2). Stereochemical data upon these compounds are of interest in view of the marked analgesic properties found in this class and because of the influence of the 5,9-dialkyl geometry upon analgesic potency (3) (β-diastereoisomers are generally more active than the α-forms).

Evidence of conformation, as in related work upon other classes of analgesic (4*a–c*), has been derived from p.m.r. data, characteristics of two α/β benzomorphan pairs (**1**, R = H and Me) in free base, hydrohalide, and quaternary salt forms being compared. Most of the data refer to solutions in DMSO-d_6 because this was the only convenient solvent which dissolved all forms, and chemical shift values (recorded at 60 MHz) are given in Hz from TMS. Stereochemical information of most value derives from the 5,9-dimethyl and *N*-methyl p.m.r. signals; this information is given in Table I. Differences between α- and β-signals are initially interpreted in terms of the piperidine-chair forms **2** and **3** respectively.



2



3

Bases

The chemical shifts of the α- and β-5-methyl signals are similar and their low field values (near 70 Hz) compared with the usual *t*-methyl positions near 54 Hz (5) are consistent with both groups lying near the plane of, and fairly close to, the 6,7-fused benzene ring (as in **2** and **3**), a position in which they are subject to aromatic deshielding (6). In the case of the 9-methyl signals, however, α-signals are higher field by over 20 Hz, β-signals being near-coincident with the 5-methyl resonance position. May's group (1*a*) obtained similar results for the *N*-methyl pair in $CDCl_3$ and interpreted differences in terms of differential aromatic shielding (α-9-methyl is shielded because it lies within the diamagnetic screening zone, whereas the β-group is too far removed to be affected by phenyl). The proximity of the nitrogen lone-pair to the

β-9-methyl group in benzomorphan bases is probably also of significance in regard to the α/β 9-Me chemical shift difference in view of demonstration of the greater deshielding influence of the lone-pair orbital upon axial than upon equatorial 3-methyl substituents in *trans* quinolizidines (7).

Hydrohalides

Both α- and β-5-methyl signals move downfield by about 6 Hz when basic centers are protonated. Lower field positions (relative to free base signals) also occur for α- and β-9-methyl signals in the protonated bases, the β-shift (7–11 Hz) being a few cycles larger than the α-value (5–5.5 Hz) in DMSO-d_6. 9-Methyl signals of α- and β-hydrohalide salts in D_2O show little difference from corresponding base resonance positions in $CDCl_3$.

9-Methyl-nitrogen geometry in α/β benzomorphans is analogous to that of 3-methyl-nitrogen in α- and β-prodine, (α- and β-**4**) respectively. In these and related compounds, the α-3-methyl signal suffers only a small change when the base is protonated (2–3 Hz downfield shift) while pronounced shifts (14–18 Hz) are observed for the β-signals *in the feebly polar solvent* $CDCl_3$. These differences have provided some of the evidence for the preferred chair conformations of both α- and β-prodine etc. in $CDCl_3$, 3-methyl being close to the deshielding $\overset{+}{N}H$ function in protonated β-**4** but further removed in α-**4** (4*a*). Hence the differences between the α- and β-

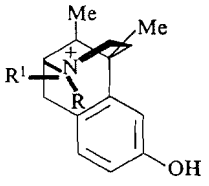
downfield shifts of the 9-methyl groups of the benzomorphans (induced on protonation) are smaller than those expected on the basis of the chair conformations **2** and **3**. The energy of the β-chair **3** will be raised when the base accepts a proton in a polar solvent through 1,3-diaxial non-bonded interactions between the solvated charged nitrogen and the 9-methyl group (axial with respect to the piperidine chair).[1] This interaction may be relieved in flexible conformations such as the skew-boat **5** and an increase in the population of such forms would explain the reduced influence of $\overset{+}{N}H$ upon the 9-methyl chemical shift since these two functions are further removed in **5** than in the chair **3**. There is similar evidence that skew-boat conformers



5

are preferred for hydrochlorides of β-prodine (and related esters) and its parent alcohol (β-prodinol) when dissolved in D_2O (4*b*) or DMSO-d_6.[2] In these cases solubility properties of the salts allowed measurements to be made in the feebly polar solvent $CDCl_3$ when clear evidence for chair conformations was obtained (4*a*, *b*). It is probable that greater 9-methyl salt–base chemical shift differences might have been observed in the β-benzomorphans if $CDCl_3$, rather than DMSO-d_6, could have been used as solvent. A further assessment of conformational, solvent, and anion influences upon the chemical shifts of methyl substituents in these piperidine and benzomorphan salts will be given elsewhere.

Further evidence for skew-boat conformations in β-benzomorphans has been obtained by a study of $\overset{+}{N}H$ and $\overset{+}{N}$—Me p.m.r. signals in hydrochloride and quaternary salts. If skew-boat populations are significant in the β-secondary base **1** (R = H) hydrochloride, the difference between the chemical shifts of the two $\overset{+}{N}$—H protons would be expected to be greater than that between the α-$\overset{+}{N}H_2$ pair since one of the β-$\overset{+}{N}H$ protons (R = H in **5**) falls close to and above the plane of the aromatic ring in the skew-boat **5** (R = R′ = H). A shielding factor difference of about 0.8 p.p.m. (48 Hz at 60 Hz) between pseudo-*a* and *e*-$\overset{+}{N}H$ (or $\overset{+}{N}$Me) groups in **5** (R = R′ = H or Me) is anticipated on the basis of Johnson and Bovey's table of aromatic shielding values (6).[3] In fact, while the α-$\overset{+}{N}H_2$ signal formed a two proton multiplet centered at 570 Hz, the β-salt showed two distinct $\overset{+}{N}H$ signals, at 571 and 525 Hz, the latter, higher field value, being consistent with the aromatic screening of one of the protons, as anticipated for **5** (R = R′ = H). The broad nature of these signals (α-w_H 14, β, 24 and 26 Hz) differentiated them from the sharper phenolic OH signals. The latter fell within the aromatic multiplet in bases and hydrohalide salts as confirmed by comparing spectra of salts of α-**1** (R = H) and the corresponding *O*-methyl ether but were moved downfield in methiodides (forming isolated singlets) possibly as a result of hydrogen bonding of OH to iodide. $\overset{+}{N}H$ signals in the α/β *N*-methyl salts (**1**, R = Me) could not be clearly resolved.

Quaternary Salts

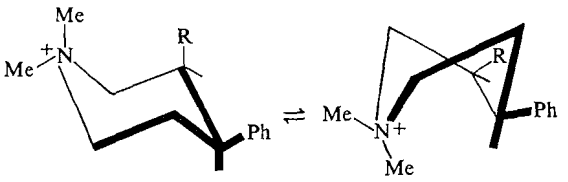
Non-chair conformations of the piperidine ring in methiodides of β-benzomorphans **1** (R = alkyl) are even more probable than in corresponding hydrohalide salts because of the axial 1,3-dimethyl interactions which must arise in the chair forms. This expectation is given point by the case of the 4-phenylpiperidine methiodides **6***a* and *b* where separation of the *N*-Me p.m.r. signals in $CDCl_3$ is reduced from 12 (**6***a*) to 3.5 Hz (**6***b*) when an axial 3-methyl substituent is present.[4] This result demonstrates the smaller environmental difference between

[1]Although no previous studies have been reported in DMSO-d_6, there is evidence that the effective size of $\overset{+}{N}H$ protons is increased by the presence of tightly held water molecules of hydration (8).

[2]Chemical shift differences (salt–base) for the prodinols in DMSO-d_6 are 7 Hz for the α- and 11 Hz for the β-isomer (unpublished results).

[3]$\overset{+}{N}H_2$ chemical shifts are unlikely to be averaged through proton exchange because the rate of this process is slow in hydrogen bonding solvents such as DMSO-d_6 (9).

[4]A. F. Casy and A. P. Parulkar. Unpublished results.



R = (*a*) H; (*b*) Me

6 7

the *N*-Me groups in the 3-methyl derivative as would result from comparable populations of the *e*-Ph chair **6***b* and skew-boat **7***b* (the population of the inverted chair form of **6***b* is likely to be low because of the large $-\Delta G_x^0$ value of phenyl) (10).

Methyl iodide rapidly methylated the α-benzomorphan **1** (R = Me), but a much longer reaction period was required to quaternize completely the corresponding β-isomer, as expected from reported reaction rates (1). The p.m.r. spectrum of the α-methiodide displayed distinct *N*-methyl signals at 202 and 194.5 Hz, whereas that of the β-isomer showed *N*-methyl bands at 188 and 170 Hz (Fig. 1A and D). The greater separation of the β-signals (18 compared with 7.5 Hz for α-) and the unusually high field position of one of the signals is consistent with the β-methiodide having the skew-boat conformation **5** (R = R′ = Me) in DMSO-d_6 with one *N*-methyl group falling well within the aromatic shielding zone. The deshielding influence of charged nitrogen upon the β-9-methyl signal is only a little greater than upon the α-9-methyl resonance ($\nu_{methiodide} - \nu_{base}$: α, 8 Hz; β, 11 Hz), again a result expected for a favored skew-boat rather than piperidine chair β-conformation (cf. argument relating to the conformation of the β-hydrochloride salts).

Quaternization of the α- and β-bases **1** (R = Me) was also carried out using trideuteriomethyl iodide to aid spectral analysis and provide evidence of reaction stereochemistry. In the α-series, the lower field *N*-methyl signal was absent in the mono-*N*-CD_3 iodide, while ring proton signals, hidden in the *N*,*N*-dimethyl form, were revealed in the *N*,*N*-di-CD_3 derivative (Fig. 1, B and C). Identification of the *N*,*N*-dimethyl signals of the β-methiodide itself is equivocal because more than two signals fall in the *N*—Me resonance region (Fig. 1D). One must be the unusually broad 170 Hz band because of its complete absence in the mono-*N*-CD_3 compound, while the other is the 188 Hz signal, as both this and the 170 Hz signal are missing from the spectrum of the *N*,*N*-di-CD_3 derivative (Fig. 1, E and F). Signals near 192 Hz which remain in the last spectrum must be due to ring protons.

There is good evidence that axial rather than equatorial approach is the preferred reaction pathway for the quaternization of cyclic nitrogen compounds, provided the group already attached to nitrogen is not markedly smaller than the incoming group (11, 12). Hence the *N*-methyl signal in the α-*N*-Me,*N*-CD_3 salt is probably due to an equatorial group. This is the higher field member of the *N*,*N*-dimethyl quaternary salt (Fig. 1, A and B), thus the lower field signal (202 Hz) is assigned to axial *N*-methyl. In monocyclic *N*,*N*-dimethyl piperidine salts, the axial *N*-methyl group generally has the *higher* field position (11, 12), and anisotropic effects of the fused hydroaromatic system (influencing *e*- rather than *a*-*N*-methyl) are most probably responsible for the reversal noted in the α-benzomorphan case. In the β-series the lower field methyl signal of the *N*,*N*-dimethyl salt remains in the *N*-Me,*N*-CD_3 salt.[5] This result further supports a radical conformational difference between the methiodide of α- and β-**1** (R = Me) since, if the β-chair **9** were favored, the *higher* field *N*-methyl signal should persist in the mono-*N*-CD_3 compound (as it does in the corresponding α-isomer).

Taking the skew-boat **5** (R′ = R = Me) as the favored β-methiodide conformation, two reaction pathways for quaternization of the β-base **1** (R = Me) with CD_3I may be formulated:

1) axial approach of CD_3I upon the chair conformation **8** and subsequent conformational change of the quaternary chair **9** to the skew-boat **10**;

2) pseudo-axial approach of CD_3I upon the

[5]Hence, assuming the skew-boat conformation **5** (R = R′ = Me), relative positions of pseudo-axial and pseudo-equatorial *N*-methyl chemical shifts are as seen in monocyclic piperidines. The pseudo-equatorial group still falls under the influence of the fused aromatic system (it has a chemical shift close to *e*-*N*-methyl in the α-salt) but the pseudo-axial group is even more subject to the same screening influence.

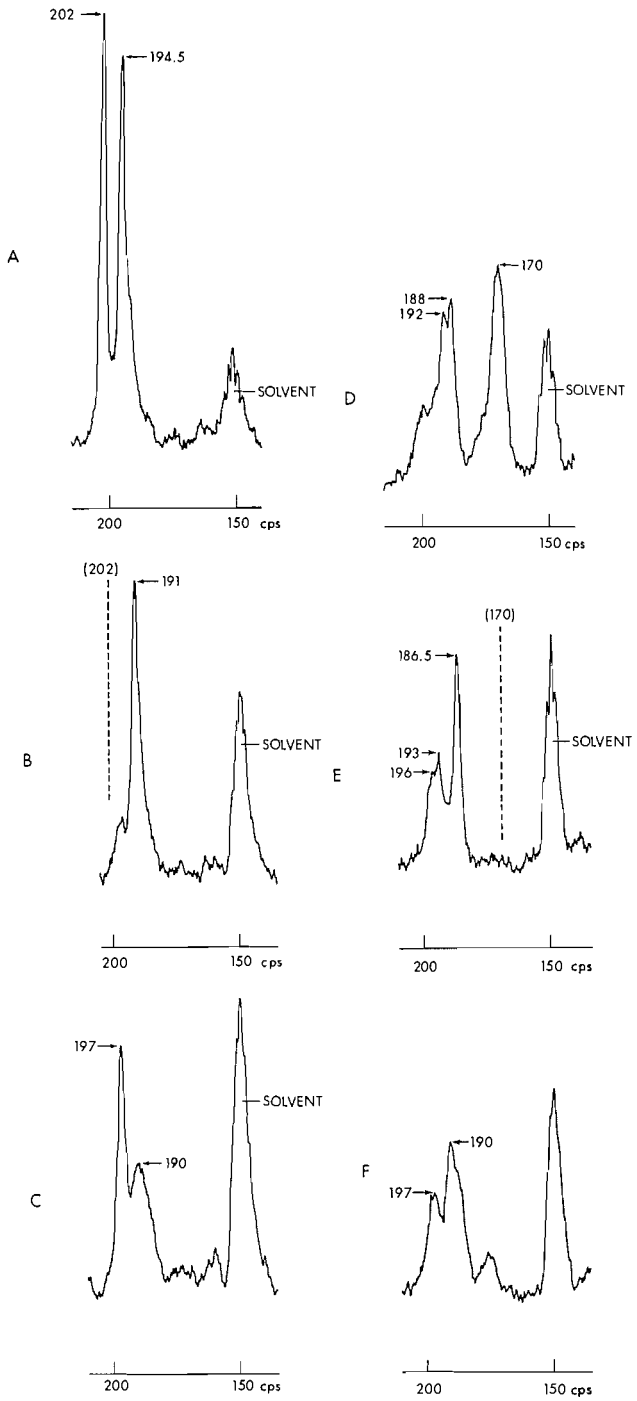

FIG. 1. Part of the proton magnetic resonance spectra of A, *N*,*N*-di-Me; B, *N*-Me,*N*-CD_3; C, *N*,*N*-di-CD_3 iodide salts of α-5,9-dimethyl-2′-hydroxy-6,7-benzomorphan in DMSO-d_6. D, E, and F are spectra of the corresponding salts of the β-isomer. Spectral amplitudes are 12.5 (A), 25 (D), 32 (B and E), and 80 (C and F). Relative signal intensities may be gauged by comparison with solvent signals near 150 Hz. Chemical shifts are in Hz from TMS at a 60 MHz frequency.

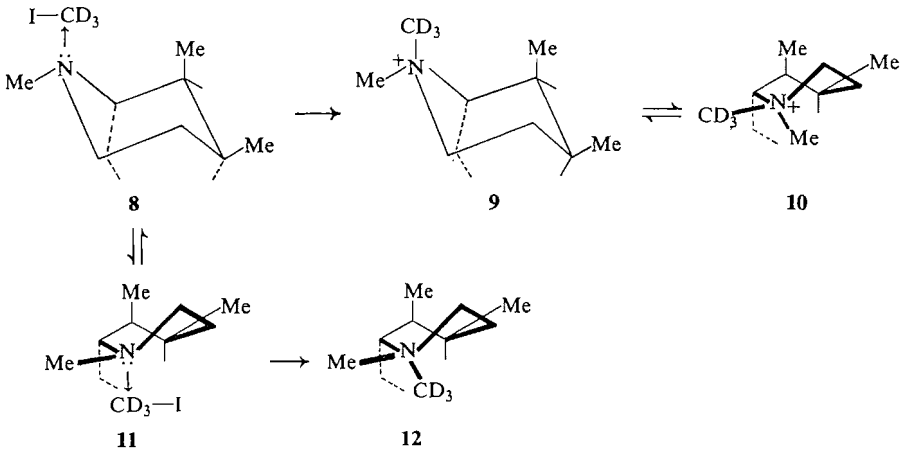
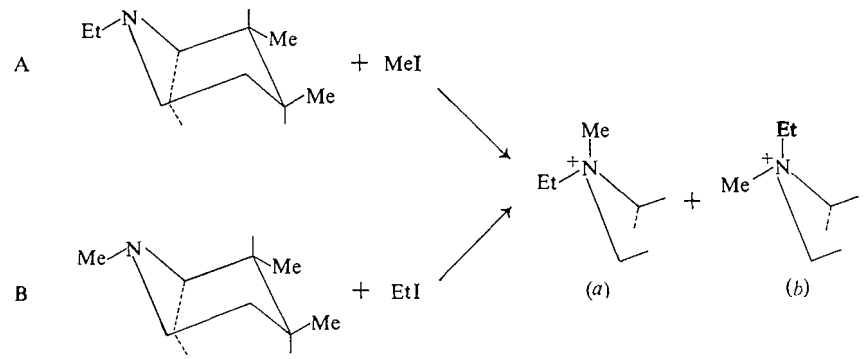


skew-boat conformation **11** of the β-base with direct formation of the favored quaternary salt conformer **12.**

In the former case, the *higher* field *N*-Me signal will remain whereas in the latter, the *lower* field signal; results obtained thus support pathway *2*.

Further evidence for axial *N*-methyl having a lower field chemical shift than equatorial *N*-methyl in α-benzomorphan methohalides was obtained from the results of the methylation of α-**1** (R = Et) (reaction A), and the ethylation of α-**1** (R = Me) (reaction B). Two isomers may result in each case; viz.,



Only one *N*-Me signal (201 Hz) was resolvable in the total product of reaction A and the minor *N*-Me signal (185 Hz) was identified in the spectra of recrystallized samples. The same *N*-Me signals were found for the total product of reaction B but major and minor values were reversed. Hence assuming axial approach of quaternizing reagent (11, 12), the major product of reaction A is the axial *N*-methyl isomer (*a*) (lower field) while that of reaction B is the equatorial isomer (*b*) (higher field).

Ethylation of the β-*N*-methylbenzomorphan **1** (R = Me) (complete only after a 14 day reflux period) gave a total product showing sharp *N*-Me signals at 203 and 184 Hz (a broad band at 195 Hz situated between these signals is provisionally assigned to ring protons) of separation comparable with that found for the *N*-Me signals of the β-**1** (R = Me) methiodide.

The morphinan **13***a* and isomorphinan **13***b* derivatives are close analogues of the α- and β-benzomorphans **1** (R = Me) and similar evidence for favored skew-boat conformations in **13***b* methiodide (in the chair conformation, the 8-methylene group bears a 1,3-diaxial relationship to an *N*-methyl group) derives from

13*a* 14-H *cis* to nitrogen bridge
13*b* 14-H *trans* to nitrogen bridge

N–Me p.m.r. signals. In the methiodide of 3-hydroxy-*N*-methylmorphinan **13***a* (no 8-methylene – *N*-Me interaction), *N*-Me signal separation (8 Hz) approximates to that found in the α-benzomorphan **1** (R = Me) methiodide, whereas a separation of 13.5 Hz (closer to that of the β-benzomorphan analogue) is obtained for the isomorphinan derivative. However, the NMe_2 chemical shift separation of the isomorphinan is not as large as that of the β-benzomorphan methiodide and the higher field member is not moved upfield so markedly; these facts indicate skew-boat conformers to be less favored in **13***b* methiodide than in the corresponding β-benzomorphan salt.

It is attractive to speculate upon a possible correlation between α/β benzomorphan conformational differences and variations in isomeric analgesic potencies, which may arise as a result of the influence of conformation upon drug–receptor interactions and/or processes governing the transport and distribution of isomeric pairs. In the α-derivatives, 9-alkyl groups enhance activity in the 5-methyl series but reduce it in 5-ethyl and 5-propyl analogues (1). In β-derivatives, 9-Me, Et, and Pr substituents yield analgesics of high potency in all examples studied (1, 13). From the present evidence, skew-boat populations are probably high in all the β-derivatives when protonated in aqueous media and it is possible that conformers of this type allow a more effective drug–receptor association than do the chair forms of the α-benzomorphans or are subject more readily to processes governing the transport and distribution of isomeric pairs. These considerations may also be important in regard to the higher potency of isomorphinan over morphinan derivatives (14) and to the remarkably high potency of certain 14-acyloxycodeinones (15).

Experimental

The p.m.r. spectra were recorded on a Varian A-60 spectrometer operating at the normal running temperature with TMS as standard (internal with $CDCl_3$ and DMSO-d_6 and external with D_2O as solvent). Supply of the following chemicals is gratefully acknowledged: α- and β-**1** (R = Me) (Dr. E. L. May, National Institutes of Health); α- and β-**1** (R = H) and the *O*-methyl ether hydrochloride of α-**1** (R = H) (Dr. N. F. Albertson, Sterling Winthrop Research Institute, Rensselaer, New York); dextrorphan (Roche Laboratories, Welwyn Garden City, Herts); (−)-3-hydroxy-*N*-methylisomorphinan (Dr. M. Gates, University of Rochester, Rochester, New York).

The α- and β-benzomorphans **1** (R = H) gave hydrochlorides, m.p. 292–295° decomp. (lit. (16) 290–294° decomp.) and 312–314° decomp., respectively.

Anal. Calcd. for $C_{14}H_{20}ClNO$: C, 66.25; H, 7.9. Found: C, 66.15; H, 7.6.

*Isomeric 2,5,9-Trimethylbenzomorphans **1** (R = Me) and Derivatives*

A mixture of α-**1** (R = H) (3.27 g), 40% formaldehyde solution (2.25 ml), 5% palladized charcoal (0.6 g), and EtOH (20 ml) was shaken with hydrogen (atmospheric pressure and room temperature) until gas absorption ceased. The product was filtered and the filtrate concentrated to give α-**1** (R = Me), m.p. 231–233° from EtOH, lit. 228–233° (17). Reductive methylation of β-**1** (R = H) gave β-**1** (R = Me), m.p. 220–221.5°, lit. 215–217.5° (17), hydrochloride, m.p. 313–315°, lit. 269–272° (17).

Anal. Calcd. for $C_{15}H_{22}ClNO$: C, 67.3; H, 8.3; N, 5.2. Found: C, 67.0; H, 7.9; N, 5.3.

Methiodides

A mixture of α-**1** (R = Me) (0.2 g), MeI (1 ml), and $CHCl_3$ (300 ml) was stirred at 38° (±2°) under reflux for 5 days (solid separated after 8–9 h), then concentrated to 25 ml, and diluted with ether. The solid which separated was recrystallized from EtOH–ether to give α-**1** (R = Me) *methiodide*, m.p. 268–268.5°.

Anal. Calcd. for $C_{16}H_{24}INO$: C, 51.5; H, 6.5; N, 3.75. Found: C, 51.2; H, 6.3; N, 3.5.

β-**1** (R = Me) *methiodide* (it separated from the reaction mixture after 2–3 days) had m.p. 279–281°. Found: C, 51.3; H, 6.4; N,3.7.

N-Trideuteriomethyl Derivatives

A mixture of α-**1** (R = Me) (0.15 g), CD_3I (0.11 g), and $CHCl_3$ (100 ml) was stirred at 33° (±2°) under reflux for 4 days. The methiodide of α-**1** (R = CD_3) which separated had m.p. 250–254°. Similar treatment of β-**1** (R = Me) gave the methiodide of β-**1** (R = CD_3), m.p. 118°. Treatment of α-**1** (R = H) (0.11 g) with CD_3I (0.2 g) gave the trideuteriomethiodide of **1** (R = CD_3), m.p. 254–258° decomp. after a 7 day reaction period. The β-*N*,*N*-di-CD_3 analogue had m.p. 287–288° from EtOH. The p.m.r. spectra of these products closely resembled those of the corresponding *N*,*N*-dimethyl derivatives in all respects save those of the *N*-Me resonance region (Fig. 1).

*N-Ethyl-N-methyl Quaternary Salts of **1** (R = H)*

A mixture of α-**1** (R = Me) (0.4 g), EtI (2 ml), and $CHCl_3$ (250 ml) was heated under reflux for 4 days. The solvent was evaporated and the residue recrystallized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

from EtOH–ether to give an isomeric mixture of *N*-ethyl-*N*-methyl **1** (R = H) iodides, m.p. 265–266.5° decomp.

Anal. Calcd. for $C_{17}H_{26}INO$: C, 52.7; H, 6.8; N, 3.5. Found: C, 52.4; H, 6.5; N, 3.6.

Reductive ethylation of α-**1** (R = Me) using MeCHO instead of formaldehyde gave **1** (R = Et), m.p. 155–157° from $CHCl_3$–ether, lit. m.p. 158–160° (18). The *hydrochloride*, m.p. 166–168° displayed duplicate *N*-CH_2Me (quartets centered on 212 and 217 Hz from TMS, $J = 7$ Hz) and *N*-CH_2Me (triplets centered on 65.5 and 67 Hz, $J = 7$ Hz) p.m.r. signals in DMSO-d_6, indicative of similar populations of $\overset{+}{N}$—H epimers (unfavorable 1,3-diaxial interactions of an *a*-*N*-Et group must be balanced by interactions between *e*-*N*-Et and one of the C-8 methylene protons).

Anal. Calcd. for $C_{16}H_{24}ClNO \cdot H_2O$: C, 64.1; H, 8.7; N, 4.7. Found: C, 64.3; H, 8.4; N, 4.3.

The α-base **1** (R = Et) with MeI gave a quaternary salt mixture, m.p. 165° whose p.m.r. spectrum closely resembled that of the mixture obtained from **1** (R = Me) in all respects save the *N*-Me resonance region (see text). *N*-Ethylation of β-**1** (R = Me) (complete after a 14 day reflux period) gave an *N*-ethyl-*N*-methyl quaternary mixture, m.p. 241–242° from EtOH–ether. Found: C, 52.8; H, 6.9; N, 3.6.

Morphinan and Isomorphinan Methiodides

Dextrorphan (**13***a*) (0.1 g), MeI (2 ml), ether (200 ml), and EtOH (15 ml) were stirred under reflux at 35° (±2°) for 4 days. The solid which separated was recrystallized from $CHCl_3$–EtOH to give *dextrorphan methiodide*, m.p. 285–286°.

Anal. Calcd. for $C_{18}H_{26}INO$: C, 54.1; H, 6.6; N, 3.5. Found: C, 53.75; H, 6.6; N, 3.7.

The analogue derived from (−)-3-hydroxy-*N*-methylisomorphinan (**13***b*) had m.p. 248–250°. Found: C, 53.9; H, 6.6; N, 3.2. *N*-Methyl p.m.r. characteristics in DMSO-d_6 of **13***a* methiodide: singlets at 195.5 and 187.5 Hz from TMS; and **13***b* methiodide: singlets at 184 and 197.5 Hz.

Diprotonation equilibria involving 4-hydroxyazobenzene and 4-hydroxyazobenzene-4′-sulfonic acid[1]

W. M. J. Strachan, A. Dolenko, and E. Buncel
Department of Chemistry, Queen's University, Kingston, Ontario

Received April 14, 1969

4-Hydroxyazobenzene and 4-hydroxyazobenzene-4′-sulfonic acid, which are known to be protonated in dilute acid on the azo function, are shown through spectroscopic studies to undergo a second equilibrium protonation in the 100% H_2SO_4 region. The pK_a[2] values are −10.2 and −11.1 respectively. The spectral evidence suggests that with both substrates the second protonation occurs on the phenolic oxygen site, rather than on carbon.

Canadian Journal of Chemistry, 47, 3631 (1969)

The present work was undertaken as a preliminary to the study of the Wallach rearrangement of azoxybenzene in the 100% H_2SO_4 region. Extension of the kinetic and spectral studies (1,2) beyond 96% H_2SO_4 was desirable for a number of reasons, one being the possibility that the postulated dicationic intermediate (3) might be stabilized in anhydrous acid. However, prior to such a kinetic–spectral study with azoxybenzene, it was required to have full understanding of the spectral behavior in such media of 4-hydroxyazobenzene, the normal product of rearrangement (4). The results recorded here reveal a rather complex pattern of spectral changes, which can be dissected into a second equilibrium protonation of 4-hydroxyazobenzene, a fairly rapid sulfonation process to give 4-hydroxyazobenzene-4′-sulfonic acid, as well as a second equilibrium protonation and the much slower sulfonation of this sulfonic acid derivative.

Results

4-Hydroxyazobenzene

The protonation behavior of 4-hydroxyazobenzene in dilute acid has been examined previously (5,6). In aqueous sulfuric acid a pK_a of −0.93 was reported by Klotz *et al.* (5)[2] for ionization of the conjugate acid, corresponding to 50% protonation in about 20% H_2SO_4. In aqueous sulfuric acid containing 20% ethanol a pK_a of −1.02 was found by Yeh and Jaffé (6)[3]. These data were confirmed in the present work using the medium[4] 5% dioxane–95% aqueous H_2SO_4. For the neutral form λ_{max} was found to be 348 mμ ($\varepsilon = 2.18 \times 10^4$), while for the protonated form λ_{max} was 460 mμ ($\varepsilon = 3.96 \times 10^4$), with pK_a −0.99 in this medium. Beyond 45% H_2SO_4 (corresponding to about 99% protonation) no changes were observed in either λ_{max} or in ε_{max} until about 90% H_2SO_4[4], and the spectral absorption was also time invariant.

4-Hydroxyazobenzene in 90–100% H_2SO_4 has been observed to undergo further spectral changes which are time-dependent. In the region 90–96% H_2SO_4 the initial λ_{max} is unchanged at 460 mμ, but with time this absorption grows in intensity and simultaneously shifts to 465 mμ. In the 96–100% H_2SO_4 region, the initial absorption shifts gradually to shorter wavelengths until it reaches 426 mμ. In these acidities the growth in peak height is more rapid: the product spectra exhibit a concurrent gradual shift to 450 mμ. The above time-dependent spectral changes are shown to be the result of the conversion of 4-hydroxyazobenzene to the 4′-sulfonic acid and are dealt with in detail subsequently (see Experimental and reference 11). The immediate (zero time) spectral shifts are due to a protolytic equilibrium which was characterized as follows.

Initial 4-hydroxyazobenzene spectra were obtained for the 90–100% H_2SO_4 region by extrapolation over 400–480 mμ; some of the

[1]Part VI in series on the Wallach rearrangement (Part V: Can. J. Chem. **47**, 911 (1969)).

[2]These authors used the acidity scale of Michaelis and Granick (7) and strictly a minor correction to the pK_a should be applied on conversion to the Hammett acidity scale (8,9).

[3]For the 20% ethanol–80% aqueous H_2SO_4 medium the appropriate acidity function (6) was used.

[4]The appropriate acidity function for this medium (10) was used. Beyond 70% H_2SO_4, where the solubility of 4-hydroxyazobenzene becomes appreciable, a purely aqueous medium was used. The change in medium had no measurable effect on the absorption being monitored. While use of different media by different workers is disadvantageous from the point of view of inter-comparison, it is generally dictated by various practical considerations.

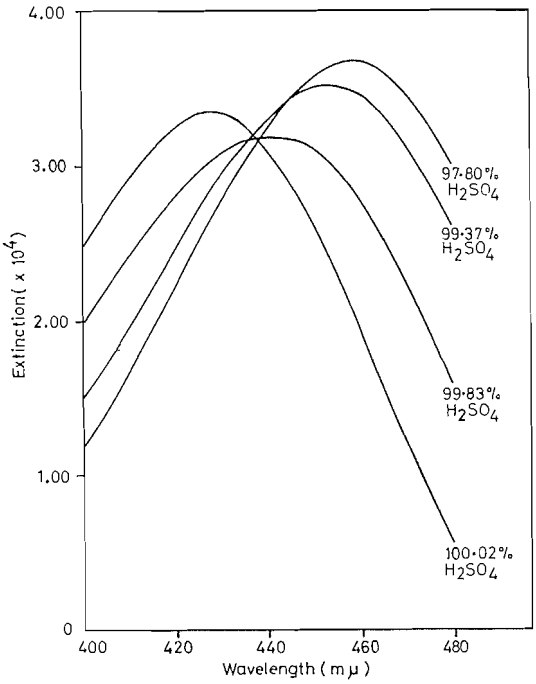

FIG. 1. Spectra of 4-hydroxyazobenzene (reconstituted to zero time) near 100% H_2SO_4 showing mono- and diprotonation.

reconstituted zero-time spectra for the upper acid region are shown in Fig. 1. These have the general character that results from a protonation process, in which medium effects (in addition to errors in extrapolation) may be responsible for the poorly defined isosbestic point (9,12). The 426 mμ absorption is ascribed to diprotonated 4-hydroxyazobenzene.

In order to obtain a pK_a value corresponding to this second equilibrium protonation, the absorbances at 460 mμ were extrapolated to zero time over 90–100% H_2SO_4. The absorbance data are given in Table I. These data when plotted against H_0 (9)[5] give a typical sigmoid curve. From the inflexion point, the pK_a^2 value of −10.1 is obtained as a first approximation.[6] Application of the convergence method of Arnett and Wu (15) to these data yields a pK_a^2 of −10.19, ε_{BH^+} (460 mμ) 3.95×10^4, and $\varepsilon_{BH_2^{++}}$ (460 mμ) 1.05×10^4.

4-Hydroxyazobenzene-4′-sulfonic Acid.

The protonation behavior of 4-hydroxyazobenzene-4′-sulfonic acid in the dilute acid region has been examined by Reeves (16). The pK_a for protonation of the azo function is reported as −1.45, λ_B is 350 mμ ($\varepsilon = 2.54 \times 10^4$) and λ_{BH^+} is 464 mμ ($\varepsilon = 5.08 \times 10^4$), in aqueous medium. In the present work spectral examination of this compound was extended to the 90–100% H_2SO_4 region. The spectra were stable except in the highest acid concentrations, where slow changes were observed which can be ascribed to a second sulfonation process. This is described in detail subsequently (11). Initial, zero-time, spectra could hence be obtained with good precision with this substrate. Some of the resulting spectra are reproduced in Fig. 2 and are seen to exhibit reasonably good isosbestic point behavior (442 mμ). The 420 mμ absorption at the highest acid concentration is ascribed to the diprotonated species.

For determination of the pK_a^2, absorbance data were measured at 465 mμ and at 420 mμ as a function of acid concentration. These data are

[5]Since the equilibrium measured here is between a monoprotonated and a diprotonated species, the H_+ acidity function should, strictly, be used. H_+ data in the 100% H_2SO_4 region are apparently not available but indicator measurements in 30–55% and 75–95% H_2SO_4 (13*a*) indicate that the two acidity functions are parallel over these acid regions (see also reference 13*b*). However other work (14) suggests that there may be no unique H_+ function applicable to the protonation of all monocationic substrate types. In the present study a test for Hammett base behavior was made by means of log [ionization ratio (I)] vs. H_0 plots. (I values were calculated using extinction coefficients ε_{BH^+} and $\varepsilon_{BH_2^{++}}$ given by the Arnett–Wu (15) procedure; the log I vs. H_0 plots excluded points falling outside the limits log $I = \pm 1$). For 4-hydroxyazobenzene the slope of the log I vs. H_0 plot was 1.3. In the case of 4-hydroxyazobenzene-4′-sulfonic acid the corresponding slope was 1.2. The deviation of these slopes from unity suggests that these substrates may not be ideal Hammett bases (see also reference 16).

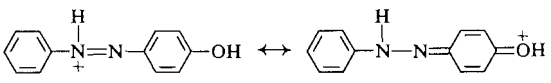
given in Table II. The plot of the extinctions as a function of H_0[5] gives rise to typical sigmoid curves, from which a visual value of pK_a^2 −11.0 is obtained.[6] Application of the Arnett–Wu method (15) to the 420 mμ data gave pK_a^2 −11.11, ε_{BH^+} 2.10 × 10^4 and $\varepsilon_{BH_2^{++}}$ 3.87 × 10^4.

Discussion

The basic centre in the first protonation of 4-hydroxyazobenzene and related compounds is generally (5,17,18) taken to be the β-nitrogen, in accord with resonance stabilization of charge at that position:



The second equilibrium protonation which is observed in concentrated acid media may occur

[6]The figure showing molar extinction as a function of H_0 is deposited with the Depository of Unpublished Data, National Science Library, National Research Council, Ottawa, Canada. Photocopies may be obtained upon request.

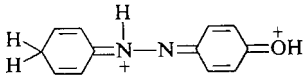
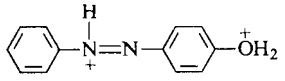
*With these exceptions, all determinations were done from the same stock solution as described in Experimental. (The exceptions noted were determined on individually prepared substrate solutions.)

on aromatic carbon, to give a delocalized structure such as **1**, or on the phenolic oxygen in which case the localized structure **2** results.

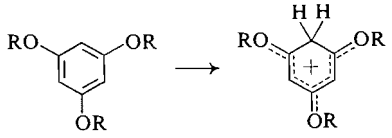


1



2

Aromatic ring protonation of alkyl benzenes such as mesitylene in HF—BF_3 (19) or HSO_3F (20) is well established. Carbon protonation is also observed with phloroglucinol (and its alkyl ethers) in fluorosulfonic acid or aqueous perchloric acid (21,22):



The site of protonation in these instances is given by nuclear magnetic resonance (n.m.r.) evidence. These processes are also characterized by the appearance in the ultraviolet (u.v.) spectrum of a new absorption at ca. 350 mμ. For phenol, anisole, and the dialkoxy analogues the protonation process in aqueous acid is less clear and both O- and C- protonation have been suggested to occur by different workers (14,21,23,24).

If the second protonation of 4-hydroxyazobenzene had occurred on carbon to give (**1**) then

TABLE III

Spectral relationships for first and second protonation equilibria*

Substrate	λ_B mμ	pK_a^1	λ_{BH^+} mμ	pK_a^2	$\lambda_{BH_2^{++}}$ mμ

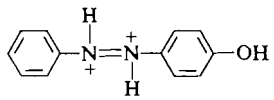
	322	−3.13	418	—	—
	348	−0.93	460	−10.19	426
	350	−1.45	465	−11.11	420

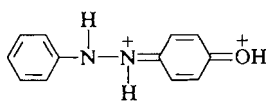
*The origin of the pK_a^1 data in this Table has been given in the main text. The λ values corresponding to these pK_a^1 data are from the same references or were redetermined in the present work.

the π-electron distribution should have been perturbed considerably and one would have expected a spectral shift in the u.v.–visible region to longer wavelength, by analogy with the other aromatic compounds discussed above. On the other hand protonation of the phenolic oxygen, by removing the p-electrons of oxygen from the aromatic resonance system, should result in a dicationic species (**2**) which is iso-π-electronic with the protonated azobenzene cation. The absorption of the latter (424 mμ) is in fact very close to the absorption of the observed diprotonated species (426 mμ). This is taken as evidence that the second conjugate acid of 4-hydroxyazobenzene has structure **2**.[7]

[7]The possibility that the second protonation occurs on the azo group, to give structure **3**, may also be considered. However in that case, structure **4** should be an important contributor, by analogy with monoprotonated 4-hydroxyazobenzene. Consequently one would expect



3



4

diprotonated 4-hydroxyazobenzene to have its absorption maximum largely unchanged from the monoprotonated form, which is not the case. A noteworthy point is that azobenzene itself apparently does not undergo a second protonation even in 100 % H_2SO_4, which suggests that protonation of both nitrogens of the azo function is relatively unfavorable.

The introduction of a sulfonic acid group into an aromatic nucleus generally affects only slightly the longer wavelength absorption of the parent compound (16,25). This is borne out in the present series by the absorptions of azobenzene and its para sulfonic acid derivative, both in the neutral and in the protonated states (Table III). Consequently, the spectral behavior of 4-hydroxyazobenzene and of 4-hydroxyazobenzene-4′-sulfonic acid on protonation is also expected to be similar. The data of Table III show that there is in fact such similarity in the absorptions of the corresponding neutral, the monoprotonated, and the diprotonated species. In view of the previous discussion and by analogy with the iso-π-electronic system of monoprotonated azobenzene, the site of the second protonation in 4-hydroxyazobenzene-4′-sulfonic acid is also indicated to be the phenolic oxygen.

The magnitude of the various pK values, as well as the differences therein, may be commented on briefly. The relevant data are given in Table III. Comparison of azobenzene with its para sulfonic acid derivative shows that introduction of the sulfonic acid group leads to a decrease in the pK_a ($\Delta pK_a^1 = 0.65$). For the 4-hydroxy analogues there is a similar decrease in the first protonation equilibria ($\Delta pK_a^1 = 0.52$), but a slightly larger decrease in the second protonation equilibria ($\Delta pK_a^2 = 0.92$). The larger difference in the pK_a^2 values is presumably the result of the lower overall electron densities corresponding to the second protonation. Perhaps the most striking result of the present data is that in order to effect a second protonation of these substrates the acidity of the medium must be increased, over

that required for the first protonation, by some 9–10 H_0 units (see also references 14,26).

Experimental

Materials

4-Hydroxyazobenzene (Eastman) was recrystallized from 40 % ethanol, m.p. 154.5–155.5°, lit. (6) 155–156°. The spectrum in 95 % ethanol showed: ε (348 mμ) = 2.50×10^4; ε (236 mμ) = 1.23×10^4. 4-Hydroxyazobenzene-4′-sulfonic acid (Eastman) was recrystallized from 75 % ethanol and dried over P_2O_5 at 120°/0.1 mm for 24 h, m.p. above 200° (decomp.)

Anal. Calc. for $C_{12}H_{10}N_2O_4S$: C, 51.80; H, 3.60; S, 11.51. Found: C, 51.92; H, 3.90; S, 11.50.

The aqueous spectrum showed: ε_{max} (350 mμ) = 2.40×10^4; lit. (15), ε_{max} (350 mμ) = 2.54×10^4.

Analytical Method

Sulfuric acid solutions less concentrated than 96% were obtained by dilution of 96% Fisher Reagent Grade acid. More concentrated acid solutions were prepared by addition of Fisher 30% SO_3 fuming acid to the 96% H_2SO_4. Concentrations in the 90–100% region were determined by the conductivity method described by Gillespie (27) and Lichty (28), at 25.00 ± 0.02°. The solutions were stored and transferred under nitrogen. Acids of concentration less than 90% were standardized volumetrically. Acid concentrations were expressed as per cent by weight.

pK_a Determinations

The spectral measurements were made on a Unicam SP800B or on a Bausch and Lomb Spectronic 600 spectrophotometer. The latter instrument was used mainly for absorbance measurements at constant wavelength, as recorded on a Sargent SRL Recorder. Absorbance measurements for pK determinations were taken in thermostated cells at 25°.

For determination of the first equilibrium protonation of 4-hydroxyazobenzene, solutions were prepared by addition of 1.25 ml aliquots of a 1.80×10^{-3} M solution of 4-hydroxyazobenzene in dioxane into 25 ml volumetric flasks followed by dilution with acid solutions of appropriate strengths. Absorbance data at 348 mμ and at 460 mμ were taken over the range 0.53–53.2% H_2SO_4 and plotted against H_0 to give the pK_a. The Table of data and resulting plots are deposited and available on request.[6]

Study of the second equilibrium protonation of 4-hydroxyazobenzene was complicated by the concurrent sulfonation which occurs in the 90–100% H_2SO_4 region. The extent to which this rate process interferes is seen by the following times for one half-life of reaction: 38 h in 91.66% H_2SO_4; 160 min in 97.80% H_2SO_4; 4.5 min in 100.02% H_2SO_4. Solutions were generally prepared by addition of 0.1–1.0 mg samples of substrate, weighed on a Cahn M-10 Electrobalance, to 25–100 ml of sulfuric acid. For the reconstituted curves (Fig. 1) spectral sweeps between 400 and 480 mμ were extrapolated at 10 mμ intervals to zero time. For the pK_a determination the absorbance at 460 mμ was followed with time in the various acid media and extrapolated to zero time.

Determination of the second equilibrium protonation of 4-hydroxyazobenzene-4′-sulfonic acid was not appreciably affected by sulfonation, since the highest rate of this process in 100.79% H_2SO_4 corresponded to a half-life of 200 min. While some of the measurements with this substrate were made on individually weighed samples as previously, the general method was as follows. Standard solutions of this substrate were obtained by evaporation to dryness of 1.00 ml samples of a 1.78×10^{-3} M ethanolic solution in 50 ml volumetric flasks followed by addition of acid. The spectra of the various acid solutions were recorded within 5 min over the region 375–480 mμ (Fig. 2) and treated in the manner indicated.

The reversibility of the second equilibrium protonations was tested as follows. A 0.10 ml portion of a 9.52×10^{-3} M solution of 4-hydroxyazobenzene in ethanol was placed in a 25 ml volumetric flask and evaporated to dryness. The residue was dissolved in 25 ml of 100.02% H_2SO_4 at 25°, the resulting solution quickly transferred to a 10 mm cell and the spectrum recorded (1.25 min after the initial mixing): λ_{max} = 424 mμ, $\varepsilon_{max} = 3.08 \times 10^4$. Simultaneously (2.5 min after the initial mixing), 3 ml of the solution of 4-hydroxyazobenzene in 100.02% H_2SO_4 was added with a pipette to 3 ml of 78.5% H_2SO_4 contained in a 20 mm cell and the spectrum taken: λ_{max} = 461 mμ, $\varepsilon_{max} = 3.85 \times 10^4$. Noting that 4-hydroxyazobenzene undergoes a sulfonation reaction in the 100.02% H_2SO_4 medium with a half-life of 4.5 min, one can estimate thatabo ut 15% reaction has occurred by the time the first spectrum was run and about 30% reaction by the time the dilution was made. Allowing for these extents of reaction, the λ_{max} and ε_{max} values obtained agree satisfactorily with those expected on the basis of about 90% diprotonation of 4-hydroxyazobenzene in the 100.02% H_2SO_4 solution and less than 10% diprotonation in the 90% H_2SO_4 solution obtained on dilution (Fig. 1, Table I).

The reversibility test with 4-hydroxyazobenzene-4′-sulfonic acid was performed similarly but was not complicated by a sulfonation process, which is relatively much slower with this substrate. The dilution was performed on a solution of the substrate in 100.71% H_2SO_4 (λ_{max} = 419 mμ, $\varepsilon = 3.32 \times 10^4$ in 10 mm cell), using 89.3% H_2SO_4 as the diluent (1:1). The resulting solution (run in 20 mm cell) had its absorption shifted to 464 mμ ($\varepsilon = 4.59 \times 10^4$), in accord with a shift in equilibrium on dilution to the monoprotonated form (Fig. 2, Table II).

Alkylation of solid sodium and lithium 2,6-dimethylphenoxide with methyl halide vapor[1]

DAVID Y. CURTIN AND ALLAN R. STEIN[2,3]

Department of Chemistry and Chemical Engineering, University of Illinois, Urbana, Illinois, 61801

Received May 20, 1969

The generally accepted hypothesis that the alkylation of metal phenoxides is forced to occur at the *ortho*-carbon in heterogeneous reactions was investigated. Methyl iodide and bromide vapor reacts with crystalline sodium and lithium 2,6-dimethylphenoxides to give *ortho*-carbon/oxygen alkylation ratios not unlike those obtained in sealed tube reactions with an excess of methyl iodide or with added toluene as solvent. However, an unprecedented amount of *para*-methylation also occurred. The implications of these and related observations in other systems are discussed.

The reaction of alkyl halides with the sodium or lithium salt of 2,6-dimethylphenol (**1**) has been found to provide a practical single-step synthesis of certain cyclohexadienones (1, 2). The reaction has the disadvantage that the dienone formed by C-alkylation is accompanied by large amounts of the alkyl aryl ether formed by O-alkylation. Kornblum and Lurie (3) explained alkylation on carbon by postulation of a reaction of alkyl or benzyl chloride at the surface of solid sodium or potassium *p-t*-octylphenoxide.[4] Alkylation of dissolved or dissociated phenoxide would be exclusively at oxygen. This postulate has been accepted by other authors (4) without further experimental verification.

This explanation for carbon versus oxygen alkylation suggests that synthetically useful control of reaction products might result if the reaction could be carried out under conditions that would favor reaction at crystal surfaces to the greatest possible extent. Thus, we were led to examine the reaction of methyl iodide vapor with the solid lithium and sodium salts of 2,6-dimethylphenol, in the hope that, under these extreme conditions, there would be a "pure" heterogeneous reaction giving exclusively or predominately 2,6,6-trimethylcyclo-2,6-hexadienone (**2**). Such a study might also, we felt, shed light upon the validity and applicability of the explanation (3).

Experimental

Lithium and sodium 2,6-dimethylphenoxides (**1**) were prepared by reacting the appropriate metal with the phenol in stirred toluene at reflux (2). After removal of the toluene at 100° (18 mm pressure), the salt was ground in an agate mortar (in a dry box with a nitrogen atmosphere) and the resulting fluffy white solid stored in the dry box in a flask wrapped in aluminum foil to exclude light.

In order to favor heterogeneous reaction to the greatest possible extent, methyl iodide vapor had to be brought into contact with the phenol salt **1** under conditions in which the alkylation products would be vaporized, that is with a temperature greater than about 100° at 15 mm pressure. This was accomplished with an 8" heated column which was packed in a dry box with the phenol salt dispersed either among 12–14 small wads of oven dried glass wool or glass helices.

The column, which had been loosely packed to permit passage of vapor, was equilibrated at the desired temperature in a nitrogen atmosphere and then was attached at one end to a flask containing the methyl iodide or bromide cooled in dry ice–isopropyl alcohol and at the other to an empty flask.

After evacuation the system was sealed and the cooling bath moved to the empty flask. The methyl halide then evaporated, passed through the heated column of phenol salt and condensed again in the cold flask. In addition alkylation products passed from the heated zone and accumulated in the cold flask. This process could be repeated indefinitely by changing the cooling bath from one flask to the other. At the temperature of the column, the vapor pressure of methyl iodide was about 10^4–10^5 times the measured pressure in the system.

Reaction mixtures were analyzed by evaporation of the methyl iodide or bromide from the alkylation products and analysis by vapor phase chromatography (v.p.c.) employing an Aerograph model A–350–B dual column instrument with a 10 ft column packed with Apiezon 1 (distributed by Shell Oil Co.) on silanized Chromosorb

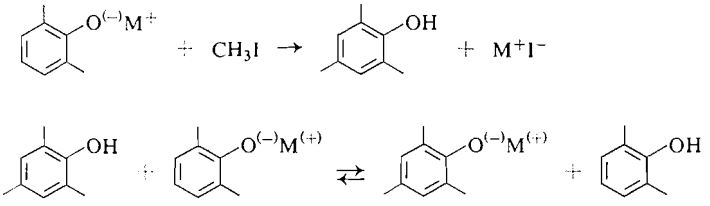
*Based upon analysis of the residue from the methyl iodide flasks (see Experimental).
†*Ortho*-Carbon/Oxygen alkylation ratio. (Where determined, the *para*-C/O ratio appears in brackets).
‡This is the minimum *para*-C/O ratio based upon the amount of 2,4,6-trimethylphenol in the residue from the methyl iodide. Because of the reaction sequence shown in Scheme 1, much of the *para*-methylated product would remain in the column. Since considerable charring and decomposition had occurred at this high temperature, no attempt was made to recover the phenols from the column. An upper limit on the *para*-C/O ratio of 6.5 can be calculated on the assumption that no moisture entered the system so that any 2,6-dimethylphenol in the methyl iodide residue would have arisen from the above phenoxide exchange.
§Methyl bromide replaced methyl iodide.



SCHEME 1

W (distributed by Johns Manville Co. Ltd.) at 173° and with a helium flow rate of 60 cm^3/min. Quantitative estimates were made by comparison of peak areas and retention times with those of authentic samples of the products.[5]

In a number of cases, the residual phenoxide salt was removed from the column materials by washes of aqueous base, and the phenolics recovered by ethereal extraction after acidification. The concentrated extracts were analyzed in the same way as the residue from the methyl iodide or bromide.

Description of the sealed-tube reactions in which excess methyl iodide, either neat or diluted with toluene, was reacted with metal phenoxides was given in previous papers (1,2).

Some data are reported in Table I.

[5]Additional details are reported in the Thesis of Dr. A. R. Stein[1] available on microfilm from University Microfilms, Ann Arbor, Michigan.

Results and Discussion

At temperatures above 150°, the sodium salt of 2,6-dimethylphenol reacted quite readily to give an *ortho*-carbon/oxygen methylation ratio of 0.06 ± 0.02. Even at 250°, the lithium salt reacted more slowly than the sodium salt did at 180° and at this high temperature considerable charring of the salt occurred. For the lithium salt the *ortho*-C/O ratio changed from 0.43 at 175° to 0.78 at 250°.

For the sodium salt, the *ortho*-C/O values of 0.06 ± 0.02 over a hundred degree temperature range are equivalent to the 0.04–0.1 values obtained in the sealed-tube reactions of excess methyl iodide with solid sodium 2,6-dimethylphenoxide (**1**), despite the change in medium and of "concentration" of methyl iodide.

Sealed-tube methylations of the lithium salt gave the following *ortho*-C/O ratios at the temperatures indicated (1): 130°, 0.50; 180°, 0.39; 200°, 0.15.[6] These values are not radically different from those we report for the vapor–solid reaction: 175°, 0.43; 190°, 0.50; 226°, 0.74; 250°, 0.78. Synthetically, then the vapor–solid alkylation of phenoxides has little advantage over the much more convenient sealed-tube reaction for the preparation of dienones.

In the methylation of the lithium salt, the unexpected (1–3) *para*-alkylation is a major competing reaction. While with the sodium salt at 195°, no 2,4,6-trimethylphenol was detected, even at 175°, the lithium salt gives a *para*-C/O ratio of 0.23 (vs the *ortho*-C/O ratio of 0.43). Also the *para*-C/O ratio increases much more rapidly with temperature than does the *ortho*-C/O ratio so that its value is more than two and one half times the *ortho*-value at 226°. In the earlier sealed-tube studies, no *para*-alkylation had been detected but in most cases no attempt was made to detect such products. For comparison purposes we repeated the sealed-tube reaction of excess methyl iodide with lithium 2,6-dimethylphenoxide at 200 ± 5° for 25 h. The *ortho*-C/O was 0.126[6], the *para*, 0.30, so that in the sealed-tube liquid–solid phase reactions as well as in the vapor–solid phase reactions reported here, *para*-methylation is a major reaction at higher temperatures.

We have no direct evidence that the reaction was, in fact, heterogeneous and cannot exclude the possibility that it occurred in microscopic pockets of a condensed phase. Similarly it is not clear how much, if any, of the alkylations carried out with suspensions of phenol salts in non-polar solvents proceeds by a heterogeneous path.[4]

The conclusion which seems inescapable however, is that either reaction at the crystal surface is so slow that it is not able to compete with reaction in the condensed phase or else it leads to product ratios which are not dramatically different from the ratios obtained from the reaction of simplet ion aggregates such as ion pairs.

The study by Labes and Blakeslee (5) of the isomer distribution formed in the halogenation of solid sodium phenoxide with gaseous chlorine and bromine is of interest. They found that, as in our study, the isomer distribution was not significantly different from that obtained in solution. Again it could not be ascertained whether the reaction occurred in a liquid phase existing at the surface or whether a solid–gas reaction occurred and gave the same ratio as that in solution. Another interesting attempt to find evidence for control of the direction of a reaction by carrying it out at a crystal surface of the reaction of asymmetric crystals of methanesulfinic acid with diazomethane (6). The desired asymmetric induction which might have been found if methylation had occurred in the asymmetric environment of the crystal surface was not obtained.[7]

These accumulated examples of the difficulty of diverting the course of a reaction by inducing it to occur at a crystal surface suggest that the postulation of such an effect (3) in the alkylation of phenol salts in a heterogeneous medium should be treated with caution. This conclusion is reinforced by the demonstration by Smith and Milligan (7) that results of product studies in the alkylation of oxime salts which had previously been attributed to heterogeneous reaction (8) could quite satisfactorily be accommodated by homogeneous reaction involving no aggregates larger than ion pairs.

[6]The *ortho*-C/O methylation ratio reported is a minimum value for the sealed-tube reactions, because, especially at the higher temperatures, considerable resinification occurred. The dienone (**2**) would be expected to be the least thermally stable of the major reactants and products present. Such resinification probably explains the lower *ortho*-C/O ratio for the sealed-tube reactions since here, the dienone would be held at the reaction temperature for the duration of the reaction and not removed as it formed. The dienone losses in resinification, are, of course, more significant at higher temperatures and account for the apparently decreasing C/O ratio as the temperature increases.

[7]We have had a similar lack of success in attempts to obtain optically active products from the reaction of an asymmetric crystal of benzil with lithium reagents or metal hydrides (P. E. Bender, unpublished work).

Condensation de la poly-L-lysine et de la poly-L-ornithine avec des dérivés de bases puriques et de sulfamides[1]

LOUIS BERLINGUET ET JACKY GAUTIER
Département de Biochimie, Faculté de Médecine, Université Laval, Québec, Québec

Reçu le 24 février 1969

Free ε-amino groups of poly-L-lysine and poly-L-ornithine were alkylated in aqueous solution with 6-chloropurine and 6-chloropurine-riboside, were acylated with 4-acetylamino benzene sulfonyl chloride, and were condensed with *N*-(4-acetylamino benzene sulfonyl)-glycine using carbodiimide method. Approximately 50% of the free amino groups of the basic polypeptides were substituted. The same method was used to prepare poly-α-amino acids bearing radioactive substituants.

Les groupements ε-aminés des chaînes latérales de la poly-L-lysine et de la poly-L-ornithine ont été: alkylés en milieu aqueux par la 6-chloropurine et la 6-chloropurine riboside; acylés par le chlorure de l'acide 4-acétylamino benzène sulfonique; et condensés avec la *N*-(4-acétylamino benzène sulfonyl)-glycine par la méthode du carbodiimide. Ces analyses subséquentes montrèrent que la substitution s'opérait sur environ 50% des ε-NH_2 des polymères basiques. Nos méthodes ont été adaptées à des micro quantités pour la préparation de ces mêmes poly-α-amino acides porteurs de substituants radioactifs.

Canadian Journal of Chemistry, 47, 3641 (1969)

Introduction

La polymérisation des anhydrides de Leuch (1) dans des conditions variées (2) permet d'obtenir des acides poly-α-aminés possédant des propriétés biologiques remarquables (3). Nous avons pensé fixer sur ces macromolécules des composés doués d'activités pharmacologiques; aussi, avons-nous retenu des polymères formés à partir d'acides aminés basiques (lysine et ornithine), puisque les groupements ε-NH_2 de leurs chaînes latérales peuvent être facilement alkylés ou acylés par des dérivés halogénés de purines ou par des dérivés de sulfamidés. La synthèse de telles macromolécules ainsi modifiées présente un grand intérêt théorique, car, en plus de leur action pharmacologique propre, nous pouvons espérer que la coupure progressive des liens peptidiques puisse libérer, de façon lente, des courts peptides et des molécules possédant des propriétés biologiques différentes de celles des composés de départ.

Résultats et discussion

Condensation de la L-lysine et de la L-ornithine avec les dérivés halogénés de bases puriques

Carter (4) avait déjà préparé la ε,*N*-(6-purinyl)-L-lysine par condensation directe de la L-lysine avec la 6-chloropurine dans un tampon carbonate; il avait montré que la substitution portait surtout sur le groupement ε-NH_2 de l'acide aminé, cependant un fort pourcentage de L-lysine restait inchangé. Lettré (5) reprit cette synthèse en protégeant au préalable les groupements α-aminés par formation du dérivé dicétopipérazine de la L-lysine et de la L-ornithine, suivant la méthode de Fisher (6).

Afin d'avoir des produits de référence en vue de l'identification par chromatographie sur papier des produits d'hydrolyse de nos polymères, nous avons synthétisé la ε,*N*-(6-purinyl) et la ε,*N*-(6-purinylriboside) dérivant de la L-lysine et de la L-ornithine suivant une méthode inspirée de Ward *et al.* (7). Nous avons de plus fait cette synthèse en utilisant soit les chélates cuivriques des acides aminés (8, 9), soit les dérivés α,*N*-carbobenzoxy, dont l'obtention est plus facile que celle des dérivés dicétopipéraziniques. Ces synthèses nous ont permis d'obtenir de très bons rendements, bien qu'il subsistât toujours dans nos préparations, des traces d'acide aminé non substitué; une purification subséquente par passage sur colonne Dowex-2-X-8 est nécessaire pour obtenir les dérivés purs (7).

La condensation des poly-α-aminoacides basiques avec des dérivés halogénés de purines présente peu de difficultés. En effet, seuls les groupements ε-aminés des monomères sont libres et peuvent être substitués. En procédant en milieu aqueux à pH 9, dans le tampon carbonate, nous avons réussit à condenser la 6-chloropurine et la

[1]Une partie de ce travail a été présentée sous forme de note préliminaire dans réf. 16.

For personal use only.

6-chloropurineriboside avec la poly-L-lysine et la poly-L-ornithine. Par dialyse, on récupère la totalité du polymère, mais il se pose cependant un problème théorique quant à l'homogénéité des produits obtenus.

A la limite, on pourrait obtenir un mélange de deux polymères, l'un étant le produit de départ, l'autre le polymère totalement substitué. L'analyse d'un tel mélange donnerait des valeurs de pourcentage d'azote identiques à celles obtenues pour un polymère dont 50% des ε-NH_2 seraient substitués. L'analyse chimique, par la seule détermination du pourcentage d'azote, n'apporte donc pas la mesure de l'homogénéité des polymères résultants de la condensation de la poly-L-lysine ou de la poly-L-ornithine avec des dérivés halogénés de bases puriques. Deux mesures, cependant, nous apportent la certitude que les produits d'alkylation ne sont pas des mélanges mais bien des composés incomplètement substitués:

a) L'électrophorèse sur papier, permet de montrer que le comportement électrophorétique de nos produits est très différent des polymères de départ, et on ne décèle pas la moindre trace de ceux-ci.

b) Une preuve, plus sensible, nous est fournie par des essais biologiques. Il a en effet été démontré (3) que les poly-α-aminoacides de départ s'avèrent très toxiques chez les souris. Nos produits alkylés ont une toxicité beaucoup plus faible, environ cinq fois inférieure à celle des polymères de départ.

Condensation de la L-*lysine et de la* L-*ornithine avec des dérivés de sulfamides*

En protégeant les α-NH_2 de la L-ornithine et de la L-lysine par formation des chélates cuivriques (8, 9), nous avons opéré la condensation directe en milieu aqueux des groupements ε-NH_2 libres avec le chlorure de l'acide 4-acétylaminobenzène sulfonique, suivant une méthode inspirée de Normand (10). Le rendement obtenu pour cette condensation a été faible, environ 60% de la L-lysine restant sous sa forme initiale.

Nous avons effectué la condensation, en milieu aqueux (10), des acides poly-α-aminés avec le chlorure de l'acide 4-acétylaminobenzène sulfonique. Cette condensation s'effectue avec de bons rendements, et si l'on base les calculs sur la quantité de polymère modifié obtenue, environ 45% des groupements ε-NH_2 ont été acylés. Cette méthode a été adaptée pour la condensation du dérivé sulfamidé marqué au ^{14}C sur le noyau benzènique.

Nous avons aussi condensé la poly-L-lysine et la poly-L-ornithine avec la *N*-(4-acétylaminobenzène sulfonyl) glycine par la méthode du *N*,*N*′-dicyclohexylcarbodiimide (11). Ici encore, environ 55% des ε-NH_2 du polymère de départ ont été condensés avec le dérivé sulfamidé de la glycine. La même méthode a été employée pour la condensation avec la *N*-(4-acétylaminobenzène sulfonyl) glycine marqué au ^{14}C sur le noyau benzènique.

Lors des hydrolyses effectuées en vue d'identifier les produits de dégradation des polymères substitués, nous avons constaté une fois de plus, la grande résistance aux ions H^+ du lien sulfanilamide (—SO_2—NH—). C'est ainsi que l'hydrolysat acide de la poly-ε,*N*-(4-acétylaminobenzène sulfonyl)-L-lysine contient un mélange de L-lysine et du chlorhydrate de la ε,*N*-(4-aminobenzène sulfonyl)-L-lysine. Ce dernier composé ne peut être hydrolysé qu'en présence d'acide phosphorique pur à 100 °C. Avec la poly-ε,*N*-(4-acétylaminobenzène sulfonyl-*N*-glycyl)-L-lysine, l'hydrolyse par HCl 6 *N* fournit de la L-lysine et le chlorhydrate de la *N*-(4-aminobenzène sulfonyl)-glycine, mais on ne peut déceler la présence de glycine.

Essais biologiques des polymères substitués

Les études biologiques de ces poly-α-aminoacides basiques substitués sur les bactéries, les tumeurs (Sarcoma 180 et Erhlich) ainsi que leur hydrolyse par divers systèmes enzymatiques seront rapportés dans une publication ultérieure.

Partie expérimentale

Produits de départ

Le bromhydrate de la poly-L-lysine a été synthétisé dans nos laboratoires par polymérisation de l'anhydride de la ε,*N*-carbobenzoxy-α-*N*-carboxy-L-lysine suivant la méthode de Katchalski (12). Avant la condensation, le bromhydrate a été neutralisé et dialysé pendant 3 jours contre H_2O avant d'être lyophilisé. Le poids moléculaire moyen de la poly-L-lysine (2), déterminé par viscosimétrie, est d'environ 12 000.

La poly-L-ornithine a été synthétisée dans nos laboratoires par polymérisation de l'anhydride de la δ,*N*-trifluoroacétyl-*N*-carboxy-L-ornithine suivant la méthode de Ariély *et al.* (13). Le poids moléculaire moyen a été calculé à environ 17 500 (viscosimétrie).

Anal. calc. pour $(C_5H_{10}N_2O)_n$: N, 24.5. Trouvé: N, 24.3.

La 6-chloropurine et la 6-chloropurine riboside ont été obtenues de K and K Laboratories.

Le chlorure de l'acide *N*-acétyl sulfonique a été obtenu de Matheson, Coleman and Bell Laboratories.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

La *N*-(4-acétylaminobenzène sulfonyl)-glycine a été synthétisée dans nos laboratoires suivant la méthode de Boganz (14).

L'aniline ^{14}C (u.m.) a été obtenue de New England Nuclear Corporation (act. spé. 4 mC/mmole).

Chromatographie

Dans toutes ces expériences, l'analyse des produits d'hydrolyse a été faite par chromatographie descendante sur papier Whatman No. 4 dans le solvant butanol – acide acétique – H_2O (2:1:1).

Synthèse

Condensation de la L-*lysine avec la 6-chloropurine*

À 267 mg de α,*N*-Cbz-L-lysine (10^{-3} mole) dissous dans 30 ml d'eau ajusté à pH 5 par addition de KOH on ajoute 500 mg (0.004 mole) de carbonate de sodium et 232 mg (1.5×10^{-3}) mole de 6-chloropurine (**3**). Le mélange réactionnel est ensuite chauffé à reflux pendant 3 h. Après refroidissement, le pH de la solution est ajusté à 2 par addition d'acide formique et le produit est recueilli par filtration.

On dissout ensuite le produit sec dans 50 ml d'acide acétique glacial et l'on fait barboter HBr sec pendant 5 min à 40 °C et on laisse à température ambiante pendant 6 h. Le produit est précipité par addition d'éther anhydre, filtré et repris dans un minimum d'eau puis reprécipité dans l'alcool.

Une purification subséquente par passage sur colonne Dowex-2-X-8 est nécessaire pour obtenir le dérivé pur (**7**): rendement 104, 7 mg (42%) λ_{max} 273-274 mμ.

Anal. calc. pour $C_{11}H_{16}N_5O_2$: N, 35.59. Trouvé: N, 35.42.

*Chlorure de l'acide 4-acétylaminobenzène sulfonique marqué au ^{14}C sur le noyau benzènique (**9**)*

L'aniline ^{14}C (13 mg, 0.5 mC) est dissout dans 0.4 ml d'eau contenant 0.02 ml de HCl concentré; on y ajoute 0.05 ml d'anhydride acétique et 20 mg d'acétate de sodium anhydre préalablement dissous dans 0.1 ml d'eau, en agitant vigoureusement pendant 15 min dans un bain de glace. Au mélange ainsi obtenu, on ajoute 97 mg d'aniline non radioactive fraîchement distillée et dissoute dans 6 ml d'eau contenant 0.09 ml de HCl concentré et l'on répète les opérations précédentes. L'addition de 20 ml d'eau contenant 2 ml d'alcool précipite l'acétanilide: rendement 104 mg (72%) p.f. 113–114°.

La chlorosulfonation s'opére dans un erlenmeyer de 5 ml suivant Fieser (15). A 100 mg d'acétanilide ^{14}C, on ajoute 0.25 ml d'acide chlorosulfonique et on laisse la réaction s'opérer à température ambiante pendant 10 min, puis, le mélange réactionnel est chauffé dans un bain-marie à 100° pendant 10 min. Après refroidissement, on ajoute 5 ml d'eau glacée en agitant vigoureusement. Le produit est recueilli par filtration sur büchner: rendement 127.4 mg (68%); act. spé. 3.93 mC/mmole. Le produit obtenu ne donne par chromatographie qu'un seul spot radioactif qui absorbe dans l'ultraviolet.

*Poly-ε,N-(6-purinyl)-*L-*lysine (**7**)*

Après avoir dissous 128 mg de poly-L-lysine (10^{-3} mole équivalent de lysine), dans 30 ml d'eau ajustée à pH 9.5 par addition de KOH, on ajoute 500 mg (0.004 mole) de carbonate de sodium et 232 mg (1.5×10^{-3} mole) de 6-chloropurine (**3**). Le mélange réactionnel est ensuite chauffé à reflux pendant 3 h. Après refroidissement le pH de la solution est ajusté à 2 par addition d'acide formique. Le mélange est ensuite dialysé pendant 3 jours contre l'eau pure et lyophilysé: rendement 148 mg (79%), λ_{max} 203–204; 268–269 mμ.

Anal. calc. pour $(C_{11}H_{14}N_6O)_n$: N, 34.14. Trouvé: N, 28.03.

Anal. calc. pour $(C_6H_{12}N_2O)_n$(poly-L-lysine initiale): N, 21.88. Trouvé: N, 21.77.

L'hydrolyse par HCl 6 *N* pendant 5 h donne un mélange de L-lysine, R_f 0.20 et de ε,*N*-(6-purinyl)-L-lysine, R_f 0.57. Un aliquot de l'hydrolysat a été analysé par chromatographie sur un analyseur d'acides aminés "Technicon". Le dosage quantitatif de la lysine résiduelle montra qu'environ 50% des ε-NH_2 avait été substitués; le calcul fait à partir des pourcentages d'azote nous indiquait une substitution de 55%.

Homogénéité des polymères obtenus

Afin de prouver que les produits obtenus sont homogènes et ne contiennent pas de poly-α-aminoacides initiaux, nous avons utilisés l'électrophorèse sur papier et des essais biologiques.

L'électrophorèse dans le tampon B_2 (pH 8.2) sous une intensité de 10 mA pendant 2 h 30 min (figure 1) nous montre que les polymères obtenus après alkylation ont un comportement électrophorétique très différent des polymères basiques de départ. L'électrophorèse de nos produits nous a permis d'obtenir des bandes révélables aussi bien à la nihydrine qu'á l'ultraviolet (u.v.) et qui restent très près de l'origine, indiquant ainsi que la substitution diminue fortement le caractère basique de la poly-L-lysine ou de la poly-L-ornithine. A aucun moment, nous n'avons pu déceler la présence des deux produits de départ sur les électrophorégrammes des polymères substitués. L'étroitesse des bandes obtenues nous permet de croire à la grande homogénéité de nos produits.

Nous avons aussi déterminé, chez la souris, les LD_{25} de nos produits (tableau I). La poly-L-lysine et la poly-L-ornithine s'avèrent entièrement toxiques chez l'animal, ceci étant plus particulièrement du à la présence des charges résiduelles de ces poly-α-aminoacides. Nous avons vérifié que les réactions d'alkylation qui diminuent le nombre de charges positives des polymères de départ, diminuent fortement la toxicité.

L'électrophorèse et les essais de toxicité réalisés avec nos polymères de condensation confirment ce que l'analyse chimique laissait entrevoir. Les réactions d'alkylation portent sur environ 50% des εNH_2 des poly-α-aminoacides de départ et dans nos préparations il ne subsiste pas de poly-L-lysine ou de poly-L-ornithine inchangées.

*Poly-ε,N-(6-purinyl)-*L-*ornithine (**5**)*

En procédant de la même façon avec 114.16 mg de poly-L-ornithine (10^{-3} mole-équivalent ornithine) on obtient 131 mg de poly-ε,*N*-(6-purinyl)-L-ornithine (76%); λ_{max} 205–206; 272–273 mμ.

Anal. calc. pour $(C_{10}H_{12}N_6O)_n$: N, 36.20. Trouvé: N, 30.72.

Anal. calc. pour $(C_5H_{10}N_2O)_n$(poly-L-ornithine initiale): N, 24.5. Trouvé: N, 24.3.

Par hydrolyse acide, le polymère donne la L-ornithine, R_f 0.22 et la ε,*N*-(6-purinyl)-L-ornithine, R_f 0.62.

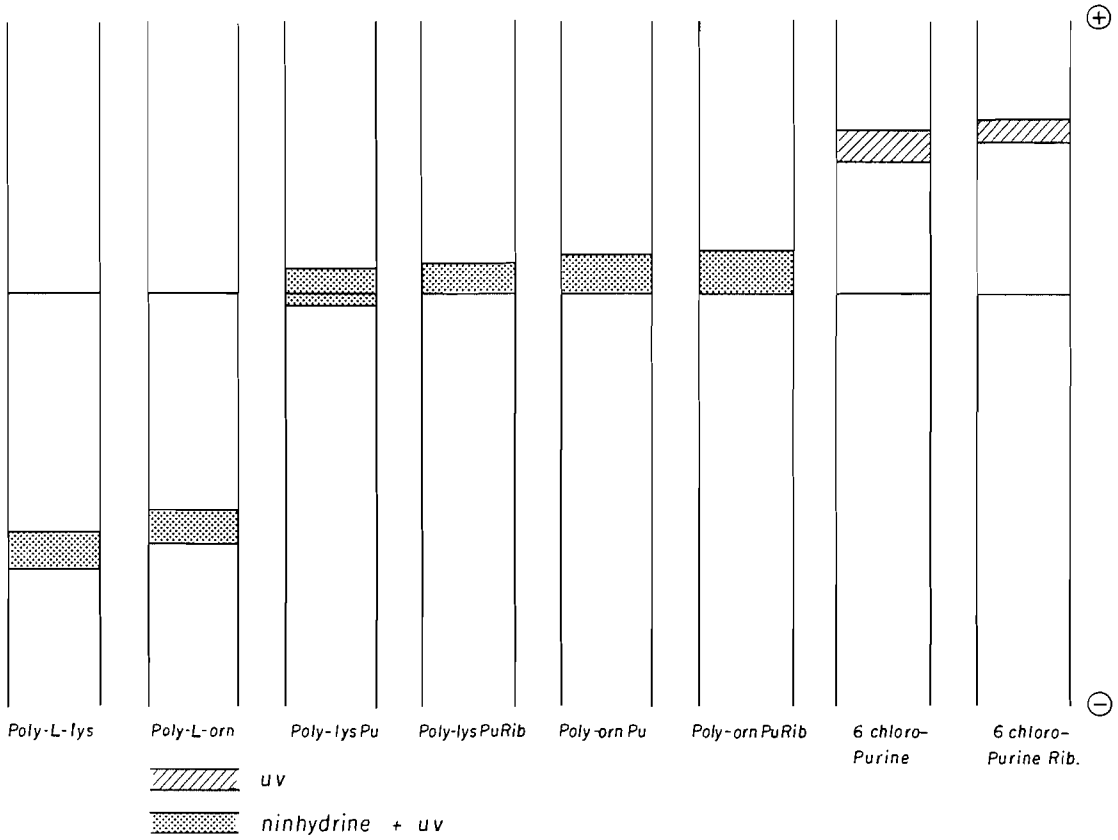

FIG. 1. La migration éléctrophorique des polymères.

L'analyse quantitative d'un aliquot de l'hydrolysat montre qu'environ 55% des ε-NH_2 ont été substitués; le calcul d'après l'analyse en azote donne 53% de substitution.

Poly-ε,N-(6-purinyl riboside)-L-lysine (8)

Avec le même protocole que pour la poly-ε,*N*-(6-purinyl)-L-lysine, mais en ajoutant 582 mg (0.0015 mole) de 6-chloropurine riboside au lieu de la 6-chloropurine, on obtient 177 mg (70%) de poly-ε,*N*-(6-purinyl riboside)-L-lysine; λ_{max} 205–206; 264–265 mμ.

Anal. calc. pour $(C_{16}H_{22}N_5O_5)_n$: N, 19.23. Trouvé: N, 21.42.

Anal. calc. pour $(C_6H_{12}N_2O)_n$(poly-L-lysine initiale): N, 21.8. Trouvé: N, 21.77.

La chromatographie de l'hydrolysat donne deux spots se révélant à la ninhydrine, l'un correspondant à la L-lysine, R_f 0.20, l'autre à la ε,*N*-(6-purinyl riboside)-L-lysine, R_f 0.55. La présence de ribose dans le polymère obtenu fut mis en évidence par la réaction avec l'α-naphtol dans H_2SO_4 concentré. L'analyse quantitative d'un aliquot de l'hydrolysat montre qu'environ 57% des ε-NH_2 ont été substitués; le calcul d'après le pourcentage d'azote trouvé indique une substitution à 54%.

Poly-ε,N-(6-purinyl riboside)-L-ornithine (6)

En employant 114.16 mg de poly-L-ornithine (0.001 mole résidus ornithine) et 582 mg (0.0015 mole) de 6-chloropurine riboside, par le même protocole que celui utilisé pour la synthèse de la poly-ε,*N*-(6-purinyl)-L-lysine, on obtient 163 mg (68%) de poly-ε,*N*-(6-purinyl riboside)-L-ornithine; λ_{max} 204–205; 267–268 mμ. La réaction du polymère avec une solution alcaline d'α-naphtol à 0.3% dans H_2SO_4 concentré donne un anneau violet caractéristique de la présence de ribose.

Anal. calc. pour $(C_{15}H_{20}N_5O_5)_n$: N, 20. Trouvé: N, 21.98.

Anal. calc. pour $(C_5H_{10}N_2O)_n$(poly-L-ornithine initiale) N, 24.5. Trouvé: N, 24.3.

La chromatographie de l'hydrolysat dans HCl 6 *N* donne 2 spots se révélant à la ninhydrine, l'un correspondant à la L-ornithine R_f 0.22, l'autre à la ε,*N*-(6-purinyl riboside)-L-ornithine, R_f 0.54. L'analyse quantitative des produits d'hydrolyse montre une substitution des ε-NH_2 de la poly-L-ornithine d'environ 54% alors que le calcul d'après les pourcentages d'azote indique 56% de substitution.

Poly-ε,N-(4-acétylaminobenzène sulfonyl)-L-lysine (11)

A 50 mg de poly-L-lysine (P.M. 11 000) dissous dans 5 ml d'eau, on ajoute lentement, mais simultanément 100 mg de 4-acétylaminobenzène sulfonyl chloride et 2.5 ml de NaOH 0.2 *N* en gardant une agitation constante. Après 5 h de réaction à température ambiante, on porte le mélange réactionnel à pH 7 par addition de HCl

†LD_{50}.

dilué et l'on dialyse pendant 3 jours contre l'eau pure; rendement: 74.18 mg (60%).

Anal. calc.: N, 12.84. Trouvé: N, 17.87.

Anal. calc. pour $(C_6H_{12}N_2O)_n$(poly-L-lysine initiale): N, 21.88. Trouvé: N, 21.77.

La chromatographie de l'hydrolysat par HCl 6 *N* révèle 2 spots se colorant à la ninhydrine, l'un correspondant à la L-lysine de R_f 0.20, l'autre au chlorhydrate de la ε,*N*-(4-aminobenzène sulfonyl)-L-lysine de R_f 0.30. Une analyse quantitative des produits d'hydrolyse au "Technicon" montre qu'environ 42% des ε-NH_2 ont été acylés; le calcul basé sur les pourcentages d'azote indique 44% d'acylation.

*Poly-ε,N-(4-acétylaminobenzène ^{14}C sulfonyl)-L-lysine (**11**)*

Le même protocole est employé pour l'acylation de la poly-L-lysine par le chlorure de l'acide 4-acétylaminobenzène sulfonique marqué au ^{14}C sur le noyau benzènique (act. spé. 3.93 mC/mmole). On obtient ainsi 79.68 mg de poly-ε,*N*-(4-acétylaminobenzène ^{14}C sulfonyl)-L-lysine (act. spé. 0.00827 mC/mg); ce qui indique qu'environ 43% des ε-NH_2 de la poly-L-lysine ont été acylés. La chromatographie et l'électrophorèse dans le tampon pH 8.6 (Spinco), sous une intensité de 10 mA, ne révèlent qu'un seul spot radioactif se colorant à la ninhydrine et dont les R_f correspondent à ceux du polymère froid de référence (**11**).

*Poly-ε,N-(4-acétylaminosulfonyl-N, glycyl)-L-lysine (**14**)*

A 128 mg de poly-L-lysine (0.001 mole équivalent lysine) suspendus dans 10 ml de tétrahydrofuranne, on ajoute 309.5 mg (0.0015 mole) de *N,N'*-dicyclohexylcarbodiimide et 400 mg (0.0015 mole) de *N*-(4-acétylaminobenzène sulfonyl) glycine (**12**). Après 5 h d'agitation vigoureuse à température ambiante, on ajoute 3 ml d'acide acétique pour décomposer le réactif en excès, et l'on dialyse pendant 3 jours contre H_2O contenant 20% d'alcool; rendement: 229 mg (57.97%).

Anal. calc. pour $(C_{16}H_{22}N_4O_5S)_n$: N, 14.66. Trouvé: N, 18.82.

Ceci indique qu'environ 42% des ε-NH_2 de la poly-L-lysine ont été acylés.

La chromatographie d'un hydrolysat par HCl 6 *N* indique la présence de L-lysine de R_f 0.20 (coloration à la ninhydrine) et du chlorhydrate de la *N*-(4-aminobenzène sulfonyl)-glycine de R_f 0.41 (absorption dans l'u.v. et coloration jaune pâle à la ninhydrine). L'analyse quantitative des acides aminés au "Technicon" montre qu'environ 40% des ε-NH_2 ont été acylés.

*Poly-ε,N-(4-acétylaminobenzène sulfonyl-N, glycyl)-L-ornithine (**13**)*

Suivant un protocole semblable au précédent, **13** fut obtenu avec un rendement de 60% et un pourcentage d'acylation, calculé par les pourcentages d'azote ainsi que par l'analyse quantiative des produits d'hydrolyse, d'environ 47%.

Derivatives of 2,3-benzo-1-azabicyclo[2·2·1]hept-2-ene

STEWART MCLEAN, A. L. FALLAS, U. O. TROTZ, AND W. F. REYNOLDS
Department of Chemistry, University of Toronto, Toronto 5, Ontario

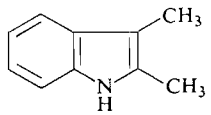
Received April 9, 1969

2,3-Benzo-1-azabicyclo[2·2·1]hept-2-ene derivatives have been prepared by the introduction of a two-carbon bridge between positions-1 and -3 of the indole ring in 2,3-dimethylindole and tetrahydrocarbazole. In the former case both C-7 epimers were isolated and identified, and their nuclear magnetic resonance spectra were analyzed in detail. In the tetrahydrocarbazole series only one product was obtained and some ambiguity remains concerning the stereochemistry of this material. The physical properties of these compounds are of interest because the lone pair electrons on nitrogen are not able to overlap with the aromatic π system; the chemical properties are characterized by a facile cleavage of the tertiary amine under acylating conditions.

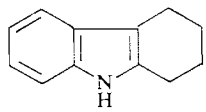
Canadian Journal of Chemistry, 47, 3647 (1969)

In the course of our studies directed towards the synthesis of naturally occurring indole derivatives we have synthesized several compounds which are 2,3-benzo-1-azabicyclo[2·2·1]hept-2-enes. The parent 1-azabicyclo[2·2·1]heptane and some of its derivatives have been described previously (1*a*, *b*, *c*), and the benzo derivative has also been described recently (1*d*). Our synthetic route does not, however, appear to have been used previously and some of the chemistry we have uncovered in this investigation is worth recording at this stage.

Our first synthetic goal was the development of a general method for preparing indolenines substituted as in **2**, where X is a replaceable substituent such as Br, by the introduction of the CH_2CH_2X unit into the disubstituted indole precursor (**1**). The alkylation of indolyl Grignard derivatives has been studied previously (2) and we elected to attempt to apply this method to effect the reaction of the model precursors 2,3-dimethylindole (**1***a*) and tetrahydrocarbazole (**1***b*) with a bifunctional molecule XCH_2CH_2Y. Rather surprisingly, we found conditions under which we could use 1,2-dibromoethane in this reaction and convert the model indoles into the indolenines (**2**; X = Br) in yields in excess of 50%. In agreement with previous workers, we found that the outcome of the reaction was extremely dependent on the precise conditions used; success required the use of reagents and solvents that were very pure and dry, the exclusion of air and moisture during the reaction, care to ensure that the heterocyclic Grignard derivative had completely formed (all unreacted ethyl bromide having been removed before the introduction of the indole into the reaction vessel), and the rapid isolation of the air-sensitive indolenines. Some product in which alkylation had taken place at the nitrogen was also obtained, but in amounts considerably less than that of the 3-substituted indolenine and separation was readily achieved on the basis of the higher base strength of the indolenine.

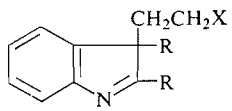


1*a*



1*b*

a R = Me
b R+R = $(CH_2)_4$



2

The indolenines **2***a* and **2***b* (X = Br) showed absorption near 6.32 μ in the infrared, a position we have found to be characteristic of the N=C stretching vibration in this class of compounds although a somewhat shorter wavelength has been associated with it previously (3). In their nuclear magnetic resonance (n.m.r.) spectra no signals appeared in the region normally associated with CH_2Br, and although the spectra were not analyzed in detail, it was clear that these signals were at higher field than anticipated and were part of the complex pattern above τ 7. This high-field shift, which appears to be associated with the shielding of the Ar—N=C grouping, was confirmed when the corresponding 3-ethylindolenines (**2***a*, *b*; X = H) were also prepared; the

TABLE I

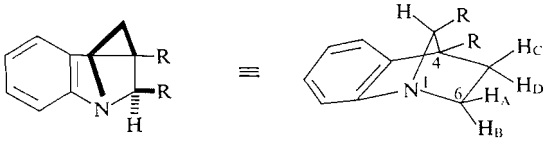
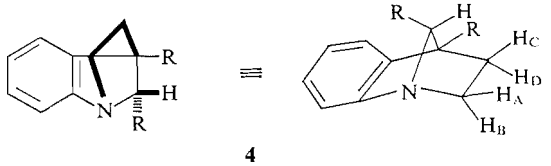
†Reference 4.

corresponding methyl signal in **2***a* (X = H) was at τ 9.65 and in **2***b* (X = H) it was at τ 9.69.

Reduction of the indolenines **2***a* and **2***b* (X = Br) either by sodium borohydride or by catalytic hydrogenation over a platinum catalyst in methanol (and subsequent basification), led to bromine-free products which, on the basis of their mode of formation, their composition, and their physical properties, were considered to have arisen by spontaneous ring closure leading to 1-azabicyclo[2·2·1]heptane derivatives (**3**, **4**). The products were relatively strong bases (pK_a ca. 7.5), the ultraviolet spectra of which showed only a group of three fairly low intensity bands (ε, 300–800) in the 255–270 mμ region. These properties are very similar to those of 2,3-benzo-1-azabicyclo[2·2·2]octane (pK_a 7.79 (4)) and the rather close correspondence between the ultraviolet spectra of these heterocyclic compounds and their carbocyclic analogues is shown in Table I. In both series the benzenoid chromophore (^1L_b) is slightly more intense and at slightly longer wavelength in the benzobicycloheptene than in the benzobicyclo-octene; in the carbocyclic series this has been associated with the effect of strain on the chromophore (5) and it seems reasonable and sufficient to attribute the difference in the heterocyclic series to the same cause, although some of the difference in the latter case may arise because the lone pair orbital on nitrogen in the benzoazabicycloheptene is not completely orthogonal to the π system as it is in the benzoazabicyclooctene. It is not clear why the extinction coefficients are lower in the heterocyclic compounds than in their carbocyclic analogues.



3

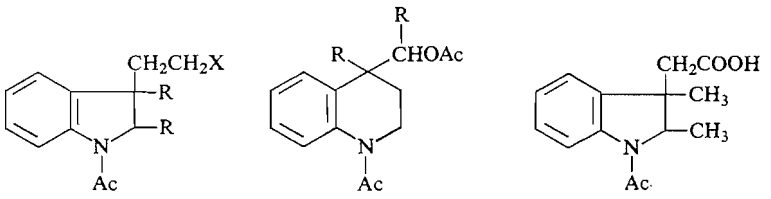


4

When the reduction product of the indolenine **2***a* was examined more closely it became apparent that it consisted of a mixture of isomers, presumably **3***a* and **4***a*. Vapor-phase chromatography showed that the oil initially obtained either by borohydride reduction or catalytic hydrogenation was a mixture of two components in the ratio 19:1. It was possible to induce the major component to separate from pentane as white crystals, m.p. 50–51°, but it was necessary to use vapor-phase chromatography of the material recovered from the mother liquors in order to isolate the minor component. Because it is to be expected that hydrogenation would take place from the less hindered side of the indolenine, the more abundant isomer produced should be **3***a*, and this assignment was supported by a detailed examination of the n.m.r. spectra of the two isomers (*vide infra*).

In the tetrahydrocarbazole series, the product of reduction of **2***b* was an oil which could not be induced to crystallize. No evidence was obtained for the presence of a mixture of isomers and, indeed, the n.m.r. spectrum, although more complex than those just described because of the presence of the methylene protons on the cyclohexane ring, was compatible with the presence of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



5 6 7

only one isomer, the stereochemistry of which will be discussed below.

The benzoazabicycloheptenes in both series reacted with acetic anhydride under the conditions normally employed to acetylate amines and were converted in good yield to products carrying both *N*-acetyl and *O*-acetyl groups. It was clear that the products arose from a reaction in which the *N*-acetylammonium intermediate, formed by reaction of the tertiary amine with acetic anhydride, underwent nucleophilic attack by an acetate ion and concomitant ring opening. There are two sites adjacent to nitrogen where this attack could take place, C-6 and C-7; the first would lead to the opening of the bridge originally closed in the formation of the bicyclic system and result n a dihydroindole (**5**; X = OAc) as the product, and the second would lead to the opening of the one-carbon bridge and the formation of a tetrahydroquinoline (**6**). The products formed appeared to be those arising from the first process, but since some ambiguity remained about this we have established more rigorously that the products are **5***a* (X = OAc) in the dimethylindole series, and **5***b* (X = OAc) in the tetrahydrocarbazole series. In the first case, **5***a* (X = OAc) was selectively hydrolyzed to the alcohol **5***a* (X = OH) which was then oxidized to a carboxylic acid, the composition and spectroscopic characteristics of which were in accord with structure **7**, thus ruling out **6** as a possible structure for the acetate. It was of particular significance and interest that the CH_2 protons α to the carboxylic acid group in **7** were coupled only to each other (J = 17.5 Hz); they were significantly magnetically non-equivalent, one appearing at τ 7.01 and the other at τ 7.19. In the second case, **5***b* (X = OAc) was converted after selective hydrolysis to the tosylate **5***b* (X = OTs) which was then converted to **5***b* (X = Br) by displacement of tosylate with bromide; this product was identical with that obtained when the original tetrahydrocarbazolenine **2***b* (X = Br) was hydrogenated in acetic anhydride. It follows that in both series the ring opening occurs predominantly if not exclusively in the direction resulting from attack of the acetate ion at C-6, and most probably has the characteristics of an S_N2 process, the unusual facility of the process being a result of the ring strain in the *N*-acylammonium intermediate.

The Nuclear Magnetic Resonance Spectra and Stereochemistry of Isomers 3a and 4a

Both isomeric azabicycloheptanes in the dimethylindole series produced remarkably clean, well resolved nuclear magnetic resonance spectra which in gross appearance were very similar but in detail were characterized by several critical differences in chemical shifts and coupling constants which allowed us to assign with complete confidence formula **3***a* to the major component of the original mixture and **4***a* to its isomer.

The chemical shift evidence concerns the substituents at C-7 (the one-carbon bridge): in **3***a* the methyl group appears as a doublet at τ 9.026 while in **4***a* it is more highly shielded and appears at τ 9.319; the reverse holds true for the C-7 hydrogens, that in **3***a* being at higher field, τ 7.381, than that in **4***a* which appears at τ 7.221. These chemical shift differences, which are almost certainly due to the anisotropic diamagnetic susceptibility of the benzene ring, are compatible with the stereochemical assignments made to **3***a* and **4***a*.

Furthermore, the C-7 hydrogen in **4***a* produces a simple quartet (by coupling to the C-7 methyl) but the corresponding quartet in **3***a* is broadened and spin decoupling experiments have established that this arises from long range coupling to protons B and D on the two-carbon bridge (to be discussed presently). It has generally been found in σ-bonded systems coupling through four bonds is appreciable only when the bonds form a W shape (6). Consequently, the fact that long range

			J_{BD}	+ 8.42
			J_{CD}	−10.88

coupling is observable in **3***a* but not **4***a* confirms the stereochemical assignments based on chemical shift data.

The four non-equivalent protons on the two-carbon bridge in each isomer gave rise to a simple or slightly perturbed ABCD spectrum; in **3***a*, the protons designated B and D (see Table II for listing) were split further by the long range coupling already referred to. In each case the ABCD spectrum was analyzed by Bothner-By and Castellano's iterative computer program LAOCN3 (we are very grateful to Professor Bothner-By for letting us have the listing of this program); the rest of the spectrum was analyzed in each case by first order procedures, and the complete analysis is shown in Table II. The labelling (ABCD in order of increasing field) was based on chemical shifts and was supported by the magnitude of the coupling constants associated with each proton; protons that are structurally equivalent received the same label in both isomers. It was assumed that the two low-field protons, A and B, were those adjacent to nitrogen, and, of this pair, the assignment of B was made on the grounds that it should experience some shielding because of the anisotropic diamagnetic susceptibility of the benzene ring. Protons C and D were assigned on the same basis. The assignment is supported by the observation of long range coupling to protons B and D.

The magnitudes of the computed coupling constants fall into the expected range if it is assumed that the methylene groups are eclipsed or nearly eclipsed. The magnitudes of J_{AB} and J_{CD} (see Table II) are consistent with their being geminal coupling constants; the coupling constants assigned to pairs of vicinal protons agree well with values predicted from the modified Karplus equation (7) and have magnitudes similar to those found in a number of model compounds (8). The signs chosen here are also consistent with those obtained in a great number of similar systems (8); other solutions can be obtained with different combinations of signs of coupling constants but their absolute values are only slightly altered. The magnitude of the long range coupling is unexceptional but its sign is undetermined.

Stereochemistry in the Tetrahydrocarbazole Series

Because we have isolated only one azabicycloheptene in the tetrahydrocarbazole series, we have had more difficulty in deciding which stereoisomer it is. A rationale based on its mode of formation would suggest, as with the dimethylindole

product, that **3***b* should be the stereoisomer isolated, but the spectroscopic results, while not yet conclusive, favor **4***b*.

The appearance of the n.m.r. spectrum of the product indicates that the material is essentially homogeneous. The protons on the two-carbon bridge again give rise to a distinctive pattern. The proton (H_A) at lowest field appears as a very clean octet centered at τ 6.73; the next octet (from H_B) near τ 7.6 is confused to some extent because it overlaps another multiplet, presumably that arising from the C-7 hydrogen, but it is clear on careful examination that none of the peaks of the octet is split by long range coupling. The signals from H_C and H_D are part of a complex pattern at higher field which includes the cyclohexane ring protons and the octets cannot be described with confidence although it is probable that parts of each one can be recognized. In the absence of the second isomer, no weight can be put on assignments based on chemical shifts (i.e. by comparisons with **3***a* and **4***a*) and the absence of long range coupling is the firmest piece of evidence available here; this indicates that the isomer is **4***b*, but we recognize that the distortion introduced into the molecule by the extra six-membered ring could be sufficient to remove the long range coupling, and the assignment is not rigorous.

When the bridge has been opened by acetylation, the C-2 proton of **5***b* appears in the n.m.r. as a multiplet near τ 5.9, the appearance of which has a strong temperature dependence. Below 0° four peaks are resolved and these appear to be the X part of an ABX system with $|J_{AX} + J_{BX}| \sim 16$ Hz indicating that the C-2 proton is axially oriented and coupled with one adjacent axial proton and one adjacent equatorial proton. This would be compatible with a *trans*-fused ring system or with a *cis*-fused system which exists predominantly in the conformation with the C-2 hydrogen axial. At low temperature an additional smaller signal near τ 5.6 becomes apparent which may be indicative of the presence of a second conformational isomer; as the temperature rises both signals broaden and the smaller signal eventually can no longer be seen. Most significantly, the appearance and temperature dependence of this part of the spectrum is remarkably similar to that of the *N*-acetyl derivative of *cis*-hexahydrocarbazole, if the extra equatorial–axial coupling in the latter case is allowed for. The spectra can, therefore, be explained in terms of a conformationally mobile *cis*-fused system in **5***b*, derived therefore from **4***b*, but the situation is complicated by the conformational mobility of the *N*-acetyl group which also has a temperature-dependent influence on the C-2 proton (9). Further work, which we are presently undertaking, will be required to remove this uncertainty.

Experimental

Melting points were determined on a Thomas–Kofler micro hot stage. Spectrometers used were: Beckman IR8 and Perkin–Elmer model 257 Infracord for infrared (i.r.) spectra, Bausch and Lomb Spectronic 505 for ultraviolet (u.v.) spectra, Varian A60 and Varian HA100 for nuclear magnetic resonance (n.m.r.) spectra; for detailed spectral analysis of **3***a* and **4***a*, n.m.r. spectra were recorded at a sweep rate of 0.05 Hz/s on the HA100 operated in frequency sweep mode at a probe temperature of 30° and each peak position was determined from the average of at least four measurements.

3-(2′-Bromoethyl)-2,3-dimethylindolenine (2a; X = Br)

Magnesium turnings (4.8 g; 0.2 mole) were placed in a one-1 flask equipped with a mercury-sealed stirrer, a dropping funnel, a condenser and an inlet system for maintaining a nitrogen atmosphere. A small amount of ethyl bromide was allowed to fall on the magnesium, and when the reaction began, a solution of ethyl bromide (22 g; 0.2 mole) in 50 ml ether was added at a rate suitable to maintain a steady reaction. When addition was complete, 250 ml anisole were added and the solution warmed and stirred vigorously. Further ethyl bromide was added at this point if necessary to consume any unreacted magnesium. Further anisole (150 ml) was added and any excess ethyl bromide was removed by distillation. The solution was cooled to 0°, stirred, and a solution of 2,3-dimethylindole (29 g; 0.2 mole) in 50 ml anisole was added over a period of 30 min. The solution was allowed to come to room temperature, excess 1,2-dibromoethane (113 g; 0.6 mole) was added, and the reaction mixture was stirred at 90° for 18 h. The flask was then cooled in an ice-bath, 15 ml saturated aqueous ammonium chloride were added dropwise, and any solid material was removed by filtration. The filtrate was extracted five times with 100 ml portions of 2 *N* hydrochloric acid, and the aqueous extract was washed with 100 ml ether and made basic with 4 *N* sodium hydroxide solution, whereupon a yellow oil began to separate. This mixture was thoroughly extracted with ether, and the ether extracts, after they had been washed with water and dried over potassium carbonate, afforded a dark oil (18–27 g; 35–55% yield). This material, which was extremely sensitive to air, could be purified by rapid chromatography on neutral alumina (British Drug Houses) with elution by 50:50 benzene–ether, when it was obtained as a pale oil which darkened rapidly in air; i.r. λ_{max}(film) 6.22 (w), 6.33 (s) μ; u.v. λ_{max}(MeOH) 260 mμ (ε, 4600); n.m.r. (τ, CCl_4) 2.4–3.2 (4 H; complex), 7.3–7.8 (4 H; complex), 7.85 (3 H; singlet); 8.80 (3 H; singlet). Alternatively, the product could be converted to a picrate (from which the base could be recovered by treatment

For personal use only.

with aqueous lithium hydroxide) which, on recrystallization from methanol, afforded yellow–orange needles, m.p. 170–172.5°.

Anal. Calcd. for $C_{18}H_{17}N_4O_7Br$: C, 44.92; H, 3.56; N, 11.64; Br, 16.61. Found: C, 45.25; H, 3.50; N, 11.96; Br, 16.65.

The anisole solution from which the indolenine had been removed by extraction into acid, was reduced to dryness by distillation at reduced pressure. 2,3-Dimethylindole was recovered from the residue by chromatography on neutral alumina (British Drug Houses) by elution with benzene; up to 40% of starting material could be recovered in this way.

2,3-Dimethyl-3-ethylindolenine (2a; X = H)

The Grignard complex prepared as described above was allowed to react with ethyl bromide in place of dibromoethane. The crude base (28% yield) was isolated in the manner described above and purified as its picrate, m.p. 149–151° (lit. (12) 153°).

The free base was regenerated by treatment of the picrate with saturated aqueous lithium hydroxide and isolated as an unstable pale-yellow oil; i.r. λ_{max}(film) 6.20 (w), 6.32 (s) μ; u.v. λ_{max}(MeOH) 255 mμ (ε, 6600); n.m.r. (τ, CCl_4) 2.4–3.0 (4 H; complex), 7.88 (3 H; singlet), 8.22 (quartet J = 7.2 Hz with further fine structure), 8.79 (3 H; singlet), 9.65 (3 H; triplet, J = 7.2 Hz).

4a-(2′-Bromoethyl)-1,2,3,4-tetrahydrocarbazolenine (2b; X = Br)

Replacement of 2,3-dimethylindole by tetrahydrocarbazole in the above preparation led to the isolation of the tetrahydrocarbazolenine as an oil in about 45% yield. After chromatography (1:3 ether–hexane on neutral alumina) the product (33% yield from tetrahydrocarbazole) was obtained as colorless crystals, m.p. 80–81°; (picrate, m.p. 158–160°).

Anal. Calcd. for $C_{14}H_{16}NBr$: C, 60.45; H, 5.78; N, 5.04; Br, 28.73. Found: C, 60.48; H, 5.48; N, 5.10; Br, 28.83.

Infrared λ_{max}($CHCl_3$) 3.10 (w), 6.32 (s) μ; u.v. λ_{max} (MeOH) 257 mμ (ε, 8000); n.m.r. (τ, CCl_4) 2.4–3.1 (4 H; complex); 7.0–9.2 (12 H; complex).

The anisole solution afforded *9-(2′-bromoethyl)-1,2,3,4-tetrahydrocarbazole* in 8% yield. From hexane it formed white prisms, m.p. 71–72°; (picrate, m.p. 94–95°).

Anal. Calcd. for $C_{14}H_{16}NBr$: C, 60.45; H, 5.78; N, 5.04. Found: C, 60.90; H, 5.66; N, 5.20.

Infrared λ_{max}($CHCl_3$) 6.24 (m) μ; u.v. λ_{max}(MeOH) 230 mμ (ε, 25 800), 286 mμ (ε, 6700), 293 mμ (inflect.); n.m.r. (τ, $CDCl_3$) 2.4–3.1 (4 H; complex), 5.82 (2 H; triplet, J = 7.0 Hz), 6.67 (2 H; triplet, J = 7.0 Hz), 7.15–7.65 (4 H; unresolved peak), 7.95–8.45 (4 H; unresolved peak).

4a-Ethyl-1,2,3,4-tetrahydrocarbazolenine (2b; X = H)

The Grignard complex of tetrahydrocarbazole was allowed to react with ethyl bromide (in place of dibromoethane) and the crude base (55% yield) was isolated in the manner described above. The picrate was prepared and obtained, after recrystallization from ethanol, as yellow needles, m.p. 153–155° (lit. (3*a*) 148–150°).

Anal. Calcd. for $C_{20}H_{20}N_4O_7$: C, 56.07; H, 4.71; N, 13.08. Found: C, 55.97; H, 4.61; N, 12.90.

Treatment of the picrate with saturated aqueous lithium hydroxide afforded the free base as a very pale yellow sweet-smelling oil; i.r. λ_{max}(film) 6.20 (w), 6.32 (s) μ-u.v. λ_{max}(MeOH) 256 mμ (ε, 6400), shifted by hydrochloric acid to λ_{max} 231 mμ (ε, 6600), 276 mμ (ε, 5500); n.m.r. (τ, CCl_4) 2.3–3.0 (4 H; complex), 7.0–9.1 (10 H; complex), 9.69 (3 H; 1:2:1 triplet, J = 7.5 Hz).

4,7-Dimethyl-2,3-benzo-1-azabicyclo[2·2·1]hept-2-enes (3a; 4a)

Preparation A

A solution of the indolenine (**2***a*; X = Br) (13.4 g; 52 mmole) in 250 ml methanol was stirred for 2 h with excess sodium borohydride (20 g) dissolved in 100 ml *N* sodium hydroxide. The solution was cooled on ice and acidified with 2 *N* hydrochloric acid. Most of the methanol was removed by distillation under reduced pressure, and the aqueous solution that remained was made basic with 4 *N* sodium hydroxide and then thoroughly extracted with ether. The extract afforded a yellow sweet-smelling oil (9.62 g), which was distilled under reduced pressure (b.p. ca 50°/0.05 mm). A colorless oil (6.2 g; 36 mmole) was obtained, which was a mixture of two components in the ratio 19:1 as determined by analytical v.p.c. on a Versamid column. A solution of the oil in pentane deposited white crystals which, on repeated fractional crystallization from the same solvent, afforded a homogeneous sample of the major component (**3***a*) m.p. 50–51°; (picrate, m.p. 171–172°).

Anal. Calcd. for $C_{12}H_{15}N$: C, 83.22; H, 8.73; N, 8.01. Found: C, 83.10; H, 8.63; N, 8.00.

The pK_a by potentiometric titration in water with 0.01 *N* hydrochloric acid was determined as 7.47. Spectroscopic data: i.r. λ_{max}(CCl_4) 6.32 μ(w); u.v. λ_{max}(MeOH) 257 mμ (ε, 590), 263 mμ (ε, 790), 270 mμ (ε, 780) and on addition of hydrochloric acid λ_{max} 253 mμ (ε, 320), 259 mμ (ε, 360), 265 mμ (ε, 350); for n.m.r. see text.

The mother liquors afforded material in which the proportion of the minor component had increased, but it was not possible to isolate this isomer by further fractional crystallization. Material enriched in the minor component was subjected to vapor-phase chromatography on a 20 ft × 1/4 in. column of 2% Versamid on 60/80 mesh Chromosorb G at 160°; the minor component had retention time 9 min, the major component 10.8 min. The minor component **4***a* was obtained as a colorless oil which eventually formed crystals, m.p. 48.5–50°.

Anal. Calcd. for $C_{12}H_{15}N$: C, 83.22; H, 8.73; N, 8.01. Found: C, 83.21; H, 8.65; N, 8.19.

Preparation B

A solution of the indolenine (5.24 g; 21 mmole) in 50 ml ethanol was hydrogenated at room temperature and atmospheric pressure in the presence of pre-reduced platinum oxide. After 14 h, 20 mmole hydrogen had been consumed and no further reaction was observed. The brown oil obtained by filtration and evaporation of the solvent was dissolved in chloroform and shaken with excess *N* sodium hydroxide. The chloroform solution afforded a yellow oil (3.17 g; 18 mmole) that had, by v.p.c. analysis, the same composition as the product in Preparation A above.

1,2,3,4,4a,9a-Hexahydro-4a-9-ethanocarbazole

Preparation A

A solution of 4a-(2′-bromoethyl)-1,2,3,4-tetrahydrocarbazolenine (7.85 g; 28 mmole) was reduced with sodium borohydride in the manner described above. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

crude product, a yellow, sweet-smelling oil (5.49 g) was treated with a slight excess of picric acid in hot ethanol. The picrate which precipitated was recrystallized from methanol and obtained as bright yellow crystals (8.13 g; 19 mmole), m.p. 198–200°.

Anal. Calcd. for $C_{20}H_{20}N_4O_7$: C, 56.07; H, 4.67; N, 13.08; O, 26.17. Found: C, 55.94; H, 4.66; N, 13.35; O, 26.64.

A solution of the picrate in carbon tetrachloride was treated with saturated aqueous lithium hydroxide to liberate the free base which was obtained as a pale-yellow oil (3.46 g; 18 mmole); this was purified by distillation under reduced pressure (ca. 85° at 0.05 mm) and isolated as a colorless oil.

Anal. Calcd. for $C_{14}H_{17}N$: C, 84.37; H, 8.60; N, 7.03. Found: C, 84.79; H, 8.41; N, 7.10.

The pK_a by potentiometric titration in water with 0.01 *N* hydrochloric acid was determined as 7.55.

Infrared $\lambda_{max}(CCl_4)$ 6.22 μ (w); u.v. λ_{max}(MeOH) 257 mμ (ε, 500), 266 mμ (ε, 560), 273 mμ (ε, 560) which, when hydrochloric acid was added, gave λ_{max} 256 mμ (ε, 200), 261 mμ (ε, 220), 268 mμ (ε, 210); n.m.r. (τ, $CDCl_3$) 2.9–3.2 (4 H; complex), 6.73 (1 H; octet), 7.4–7.8 (2 H; complex), 8.2–9.2 (10 H; complex); also see text.

Preparation B

The tetrahydrocarbazolenine (1 g; 3.6 mmole) was catalytically hydrogenated in the manner described for indolenine. The product, a yellow oil (0.61 g; 3.1 mmole) afforded after distillation a material, apparently identical with that described in Preparation A, which formed a picrate, m.p. 198–200° alone or on admixture with the picrate described above.

*1-Acetyl-3-(2′-acetoxyethyl)-2,3-dimethylindoline (**5a**; X = OAc)*

A solution of **3***a* (385 mg; 2.2 mmole) in 10 ml acetic anhydride containing a little pyridine was refluxed for 9 h and the mixture was then left at room temperature for a further 18 h. The acetic anhydride was removed by distillation under reduced pressure and the residue was shaken with water and ether. The ether extract afforded a brown oil which was dissolved in benzene and chromatographed on neutral alumina (British Drug Houses); elution was carried out with a benzene–ether mixture in which the proportion of ether was gradually increased and fractions that showed essentially identical i.r. spectra were pooled. A pale yellow oil (543 mg; 2.0 mmole) was obtained and recrystallized from pentane; **5***a* (X = OAc) was obtained as colorless crystals, m.p. 72.5–73.5°.

Anal. Calcd. for $C_{16}H_{21}O_3N$: C, 69.79; H, 7.69; N, 5.09. Found: C, 69.74; H, 8.03; N, 5.08.

Infrared $\lambda_{max}(CCl_4)$ 5.74 (s), 6.01 (s) μ; u.v. λ_{max}(MeOH) 250 mμ (ε, 12 300), 280 mμ (shoulder), 286 mμ (ε, 6500); n.m.r. (τ, CCl_4) 2.3 (1 H; broad), 2.7–3.1 (3 H; complex), 5.76 (3 H; complex), 7.77 (3 H; singlet), 7.98 (3 H; singlet), 7.8–8.1 (2 H; complex), 8.81 (6 H; probably 3 H singlet and 3 H doublet, J = 7 Hz).

*9-Acetyl-4a-(2′-acetoxyethyl)-1,2,3,4,4a,9a-hexahydrocarbazole (**5b**; X = OAc)*

The ethanocarbazole was acetylated in a manner corresponding to that described above with the difference that the reaction was carried out by heating the acetic anhydride solution on a steambath for 3 h. The product was a colorless oil which distilled at 140–150° at 10^{-3} mm.

Anal. Calcd. for $C_{18}H_{23}NO_3$: C, 71.73; H, 7.69; N, 4.65. Found: C, 71.82; H, 7.62; N, 4.73.

Infrared $\lambda_{max}(CCl_4)$ 5.75 (s), 6.03 (s) μ; u.v. λ_{max}(MeOH) 252 mμ (ε, 12 000), 285 mμ (ε, 2450); n.m.r. (τ, $CDCl_3$) 2.0 (1 H; ca. 20 Hz wide), 2.7–3.1 (3 H; complex), 5.95–6.3 (2 H; 7 lines resolved), 7.79 (3 H; singlet), 8.16 (3 H; singlet), 7.8–9.2 (12 H; complex).

*1-Acetyl-3-carboxymethyl-2,3-dimethylindoline (**7**)*

Selective Hydrolysis

A solution of **5***a* (X = OAc) (290 mg; 1.05 mmole) in 15 ml methanol was stirred overnight at room temperature with 3 ml 10% aqueous sodium hydroxide. This solution afforded a pale-brown oil after the usual work-up. Purification was effected by chromatography on silica gel and the major component (**5***a*, X = OH) was eluted with 2:1 chloroform–methanol. This was a colorless oil (140 mg), which showed i.r. $\lambda_{max}(CCl_4)$ 2.71 (m), 2.87 (m), 6.02 (s) μ; u.v. λ_{max}(MeOH) 252 mμ (ε, 7400), 286 mμ (infl.), 276 mμ (infl.); n.m.r. (τ, $CDCl_3$) 2.2 (1 H; broad), 2.85 (3 H; complex), 5.75–6.10 (3 H; complex), 6.54 (1 H; exchanged in D_2O), 7.60 (3 H; singlet), 7.90 (2 H; complex), 8.75 (6 H; probably doublet superimposed on singlet).

Oxidation

To a stirred solution of **5***a* (X = OH) (116 mg; 0.5 mmole) in 5 ml acetone, 0.1 ml Jones reagent (10) was added slowly through a microsyringe. The mixture was stirred for a further 15 min and then diluted with 20 ml water and extracted with methylene chloride. The extract afforded a brown oil (127 mg) which was partitioned between chloroform and aqueous sodium bicarbonate; acidification of the bicarbonate solution and extraction with chloroform yielded, by the standard work-up, white crystals (91 mg; 0.37 mmole), m.p. 84–86°, which had to be sublimed in order to obtain an analytical sample of 7, m.p. 154–155°.

Anal. Calcd. for $C_{14}H_{17}NO_3$: C, 68.01; H, 6.88; N, 5.67. Found: C, 68.23; H, 6.99; N, 5.65.

Infrared $\lambda_{max}(CCl_4)$ 2.75–3.2, 5.82, 6.1 μ; u.v. λ_{max} (MeOH) 251 mμ (ε, 14 700), 278 mμ (shoulder) 286 mμ (ε, 5000); n.m.r. (100 MHz; τ, $CDCl_3$) 1.2 (1 H; broad), 1.8 (1 H; broad) 2.7–2.9 (3 H; complex), 5.5 (1 H; broad), 7.10 (2 H; AB quartet; J = 17.5 Hz; int. chem. shift 0.18 p.p.m.), 7.62 (3 H; singlet) 8.66 (3 H; singlet), 8.77 (3 H; doublet; J = 6.5 Hz).

*9-Acetyl-4a-(2′-bromoethyl)-1,2,3,4,4a,9a-hexahydrocarbazole (**5b**; X = Br)*

Preparation A

Selective hydrolysis of **5***b* (X = OAc) (5.32 g; 17.7 mmole) in the manner described above for **5***a* (X = OAc) converted it to a pale-yellow oil (4.02 g; 15.5 mmole) which could be crystallized from hexane and **5***b* (X = OH) was obtained as a white solid, m.p. 94.5–95.5°.

Anal. Calcd. for $C_{16}H_{21}NO_2$: C, 74.10; H, 8.16; N, 5.40. Found: C, 74.22; H, 7.91; N, 5.65.

Infrared $\lambda_{max}(CCl_4)$ 2.74, 2.80, 6.03 μ; u.v. λ_{max}(MeOH) 254 mμ (ε, 14 750), 280 mμ (ε, 4200), 288 mμ (ε, 3400); n.m.r. (τ, $CDCl_3$) 1.90 (1 H), 2.8–3.0 (3 H; complex), 5.8 (1 H), 6.3–6.6 (2 H; multiplet), 7.10 (1 H; singlet; exchangeable in D_2O), 7.78 (3 H; singlet), 7.8–9.0 (10 H; complex).

The *p*-toluenesulfonate (**5***b*, X = OTs) was prepared

by treatment of the alcohol (1.24 g; 4.8 mmole) in 25 ml pyridine at 0° with *p*-toluenesulfonyl chloride (2.29 g; 11.5 mmole); the reaction was allowed to proceed at 0° for 36 h, the reaction mixture was poured over ice, and the product was extracted into ether. The ether extract afforded a gummy material (3.8 g) which was crystallized with some difficulty from light petroleum ether. The white crystals obtained rapidly became gummy in air at room temperature.

The bromide was prepared by stirring together the tosylate (2.1 g; 5.1 mmole) with sodium bromide (1.0 g; 10 mmole) in 16 ml dimethyl sulfoxide at room temperature for 84 h. The reaction mixture was extracted with ether, the ether extract was washed with dilute sulfuric acid and then water, and the product, obtained in the usual manner, was a white solid (0.44 g; 1.4 mmole) which was recrystallized from hexane. This product, m.p. 95–96°, was identical in every way with the bromide obtained in the following way.

Preparation B

4a-(2′-Bromoethyl)-1,2,3,4-tetrahydrocarbazolenine (**2***b*, X = Br) (2.33 g; 8.38 mmole) in 15 ml acetic anhydride was hydrogenated in the presence of prereduced platinum oxide at room temperature and atmospheric pressure. Reaction ceased after 6 h when 8.17 mmole hydrogen had been consumed. The solution was diluted with water, made basic with sodium carbonate, and extracted with chloroform. The chloroform extract afforded a pale-brown oil (2.6 g) which was purified by chromatography on neutral alumina. The fraction (1.93 g; 6.2 mmole) eluted by 1:1 hexane–ether was solid and, when recrystallized from a mixture of iso-octane and benzene, formed colorless crystals, m.p. 95–96°.

Anal. Calcd. for $C_{16}H_{20}NOBr$: C, 59.64; H, 6.26; N, 4.35; Br, 24.79. Found: C, 59.75; H, 6.15; N, 4.75; Br, 24.91.

Infrared $\lambda_{max}(CHCl_3)$ 6.26 (m) μ; u.v. λ_{max}(MeOH) 252 mμ (ε, 13 100), 286 mμ (ε, 2700); n.m.r. (τ, CCl_4) 1.8–2.3 (1 H; broad), 2.5–3.1 (3 H; complex), 5.8–6.3 (1 H; unresolved), 6.90 (2 H; triplet J = 8.3 Hz, but showing signs of further complexity), 7.79–9.0 (10 H; complex).

A nuclear magnetic resonance study of hydrogen bonding of δ-valerolactam

J. M. PURCELL, H. SUSI, AND J. R. CAVANAUGH

Eastern Utilization Research and Development Division, Agricultural Research Service, U.S. Department of Agriculture, Philadelphia, Pennsylvania 19118

Received February 19, 1969

The association of amide groups of δ-valerolactam through hydrogen bonding has been investigated by means of high resolution nuclear magnetic resonance spectroscopy in CCl_4 and $CDCl_3$ solutions. Chemical shifts of the NH proton signal were measured over a wide range of temperatures and concentrations. Thermodynamic properties associated with the N—H·····O=C hydrogen bond formation were evaluated from a least squares analysis by a direct search procedure with a digital computer. The obtained enthalpy values for hydrogen bond formation are in general agreement with results obtained by other methods.

Canadian Journal of Chemistry, 47, 3655 (1969)

Introduction

The application of nuclear magnetic resonance (n.m.r.) spectroscopy to the study of hydrogen bonding equilibria has been extensive and relatively successful (1–4). Our own interest in interamide interactions (5, 6) has prompted us to investigate the utility of n.m.r. for systems involving N—H·····O=C hydrogen bonding. Many systems involving amide-to-amide hydrogen bonding have been previously investigated by infrared (i.r.) spectroscopy (5–10). The purpose of the present study was to examine a model system which has been thoroughly studied by another technique and thus to obtain some information regarding the applicability of n.m.r. spectroscopy to problems involving amide-to-amide hydrogen bonding.

Accordingly, we have investigated the dimerization of δ-valerolactam through hydrogen bonding in CCl_4 and $CDCl_3$ at various temperatures. *cis* Amides, such as lactams, are conformationally not as closely related to polypeptide chains as *trans* amides, such as *N*-methylacetamide. However, the *cis* amides do offer some distinct advantages. It has been shown that polymers higher than dimers are not formed in appreciable amounts (5, 8, 9). This simplifies considerably the interpretation of spectroscopic data and facilitates thermodynamic computations. Furthermore, there are indications that thermodynamic parameters, particularly bond-enthalpies, are quite similar for hydrogen bonds between *cis* amides and between *trans* amides, as evidenced by a comparison of work on *N*-methylacetamide (9) and the latest results on lactams (6).

Experimental

δ-Valerolactam, obtained from the Aldrich Chemical Company,[1] was purified by vacuum distillation. It was stored under nitrogen in the dark at less than 10°. Sample preparation was performed in a nitrogen atmosphere. Carbon tetrachloride, Baker-Analyzed, obtained from the J. T. Baker Company, was dried over Linde type 4A molecular sieve. No differences were observed between the NH chemical shifts of lactam in specially dried CCl_4 and in CCl_4 used without further purification. Chloroform-*d*, obtained from NMR Specialties Company, was also dried over Linde type 4A molecular sieve. It was stored in a nitrogen atmosphere in the dark over molecular sieve. Prior to the preparation of each sample the purity and dryness of the chloroform-*d* were determined by careful observation of the near infrared region where OH groups absorb. Samples were prepared gravimetrically.

The n.m.r. spectra of solutions of δ-valerolactam in CCl_4 and $CDCl_3$ were obtained with a Varian DP-60 and a DA-60 IL spectrometer, respectively. Tetramethylsilane, obtained from NMR Specialties Company, was used as an internal reference. The Varian V-4340 variable temperature apparatus was used with the DP-60. Temperature measurements were made by means of a copper–constantan thermocouple situated just inside the Dewar probe insert in the incoming gas stream. Calibration was performed using a similar thermocouple placed directly in a sample tube at the receiver coil. The Varian V-4343 variable temperature apparatus was used with the DA-60 IL. The Varian charts for the temperature variation of the OH proton resonance of ethylene glycol and of methanol were used to calibrate the apparatus. Accuracy of the temperature measurements was ±1°.

Each solution of δ-valerolactam in CCl_4 and in $CDCl_3$ displayed only one proton resonance which could be assigned to the NH proton. The midpoint of the broad NH line was considered as the chemical shift, δ, of the NH resonance. Line positions, observed with

the DP-60, were determined by interpolation between calibration side bands. Line positions, observed with the DA-60 IL, were determined by interpolation between two values of the frequency difference of the fixed and swept oscillators. All chemical shifts in Hz downfield from tetramethylsilane are the averages of at least four measurements made with the DA-60 IL with alternate up and downfield sweeps. At least fourteen measurements were made with the DP-60 due to its lesser stability. The least accurate values are precise to within 3 Hz on the basis of 2σ (twice the standard deviation) values. Such error is largely the consequence of the uncertainty of locating the midpoint of the broad NH line, especially for the more dilute solutions. The observed NH chemical shifts are given in Tables I, II, and III.

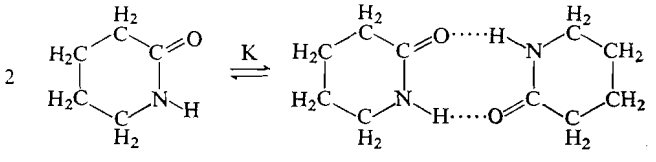
Treatment of Data

Previous careful studies strongly indicate that δ-valerolactam forms only cyclic dimers with two N—H·····O=C hydrogen bonds per dimer (6, 8, 9). If we assume that in dilute solution only hydrogen bonding occurs among lactam molecules to form cyclic dimers and that the solvent does not compete with the solute in the formation of hydrogen bonds, then dimerization can be represented by the simple equilibrium:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The dimerization equilibrium constant in reciprocal mole fraction (mf^{-1}) units is

$$[1] \quad K = \frac{[D]}{[M]^2} = \frac{\frac{XS}{(1-X)S}}{\left[\frac{S(C-2X)}{S(1-X)}\right]^2} = \frac{X(1-X)}{(C-2X)^2}$$

where C = initial mole fraction of δ-valerolactam in terms of monomer, S = total number of moles in the system in terms of lactam monomer and of solvent, and X = equilibrium number of moles of the dimer divided by S. At equilibrium the total number of moles equals the sum of the moles of lactam monomer, lactam dimer, and solvent.

$$[2] \quad (C-2X)S + SX + (1-C)S = S(1-X)$$

The observed chemical shift, δ, for the NH resonance is expressed as the weighted average of the contributions of the two NH-containing species

$$[3] \quad \delta = \left(\frac{C-2X}{C}\right)\delta_M + \left(\frac{2X}{C}\right)\delta_D$$

where δ_M = chemical shift of the NH resonance of the lactam monomer and δ_D = chemical shift of the NH resonance of the lactam dimer. The factor 2 results from the presence of two hydrogen bonds in the cyclic dimer. Solving eq. [1] for X, the physically meaningful root is

$$[4] \quad X = \frac{1}{2}\left\{\frac{(4KC+1) - (-4KC^2 + 8KC + 1)^{\frac{1}{2}}}{4K+1}\right\}$$

As shown in Fig. 1, the variation of the NH chemical shift with concentration of lactam in CCl_4 does not increase monotonically but passes through a maximum at approximately 0.04–0.08 mf. Apparently the dimerization equilibrium given above is insufficient to explain all the data. Perhaps at higher concentrations in CCl_4 a different kind of interaction also occurs which influences the NH chemical shift.[2] It is conceivable that models including other equilibria (e.g., stacking of the lactam rings or hydrogen bonding among higher polymers of lactam) could be devised that would fit the experimental data over a wider range of concentration. However, in view of the increase in the number of adjustable parameters, the results of such treatments admit a variety of interpretations. The important aspect regarding dimerization through hydrogen bonding interaction is the variation of the NH chemical shift with concentration in dilute solution. (The dimerization in CCl_4 is virtually complete at the maxima of the experimental curves, e.g., approximately at 0.07 mf at 33° (6, 7).)

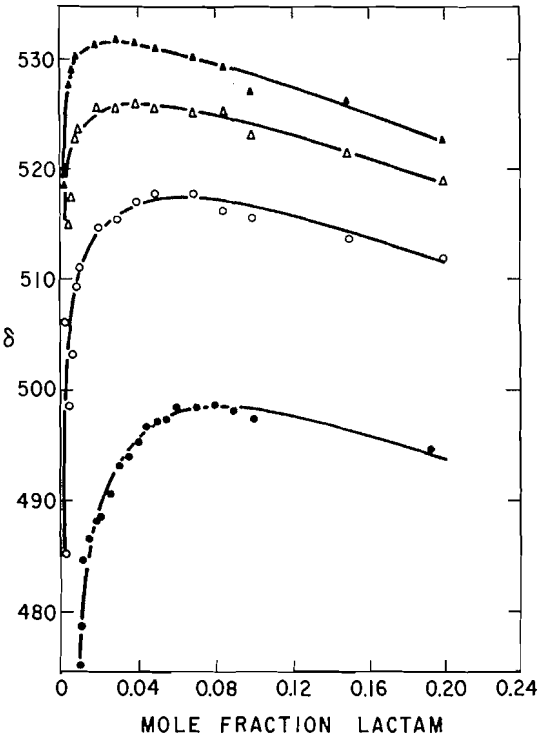


FIG. 1. Variation of δ with concentration in CCl_4 at various temperatures: ▲, −20°; △, −10°; ○, 5°; ●, 33°.

The experimental curves obtained for $CDCl_3$ solution are given in Fig. 2. Slight solvent–solvent hydrogen bonding is possible, but there is reason to believe that hydrogen bonded solvent aggregates are present in very low concentration (12–14). However, in chloroform solution, solvent to solute hydrogen bonding involving the lactam carbonyl group is appreciable. It has been shown (6, 7, 10) that such a system can be treated on the

[2]Yonezawa and Morishima compared the *cis* *N*-methyl proton chemical shifts of neat *N,N'*-dimethylformamide, *N*-methyl-γ-butyrolactam, and *N,N'*-dimethylacetamide with those of 0.1 mf CCl_4 solutions. In each case they observed an upfield shift for the neat liquid relative to the 0.1 mf CCl_4 solution. This observation has been explained in terms of an intermolecular dipolar interaction (association) between the nitrogen and the oxygen (N·····O) of different molecules (11).

assumption that essentially all lactam monomers are specifically solvated. The equilibrium constant and the ΔH value then pertain to the formation of dimers from solvated monomers. The interaction of $CDCl_3$ with lactam monomer will, in fact, be reflected in the differences in the calculated equilibrium constants and enthalpy values for the two systems, as described by Klemperer *et al.* (10) and others (6, 7).

Methods of Calculation

The relationship between the NH chemical shift and lactam concentration is a function of three parameters: the chemical shifts of lactam monomer, δ_M, and lactam dimer, δ_D, and the dimerization equilibrium constant, K. If the monomer and dimer shifts are known, then either the observed NH chemical shift at any given concentration or the slope of the NH chemical shift – concentration curve at any given point is sufficient to determine K. The dimer shift can be estimated from the maximum of the curve. If the limiting slope at low concentration is known, δ_M can be determined by extrapolation. As shown in Figs. 1 and 2, the slope of the experimental curves continuously increases as the concentration approaches zero. Consequently, no graphical extrapolation can be attempted with a reasonable degree of accuracy.

In order to carry out a more thorough analysis of the experimental data, a numerical method was used. Arbitrary values of δ_M were chosen, and values of K and δ_D were determined from a least squares analysis by a direct search procedure (15).[3] The search procedure involves the independent variation of arbitrary initial values of δ_D and K until the root mean square (r.m.s.) error between the calculated and observed curves reaches a minimum for a given value of δ_M. For the $CDCl_3$ system all the experimental data points (Table III) were used in the calculation. For the CCl_4 system only those data points

[3]The computations were carried out on an IBM-1130 computer.

(see Tables I and II, the Experimental section, and footnote 2) pertinent to the dimerization equilibrium were used. The results are shown in Tables IV and V.

Results and Discussion

All the calculated curves based on preset values of δ_M fit the observed data with a relatively small degree of error (r.m.s. error of 1–2 Hz for CCl_4 and 3–5 Hz for $CDCl_3$ which are of the same order of magnitude as experimental error). For the lactam–CCl_4 system, only the low concentration portion of the experimental curves was considered, as discussed in previous sections. The observed and some of the calculated curves for the lactam–$CDCl_3$ system are given in Fig. 3. The calculated dimer shift is nearly independent of the preset monomer shift used in the calculation. The calculated equilibrium constant increases as the preset monomer shift decreases. On this basis, no one value of the monomer shift and the corresponding equilibrium constant can be taken as more realistic than any other.

In general, the information that can be obtained from the chemical shift – concentration curves depends primarily on the value of the equilibrium constant. We have examined the theoretical curves obtained from the treatment given above on the basis of a unit chemical shift difference between the monomer and dimer species. Several values of the equilibrium constant over a wide range were included in the calculations. On this basis certain limitations of the n.m.r. method seem to be indicated. If K is large, the slope at low concentrations is sufficiently steep that no meaningful extrapolation to infinite dilution is possible. On the other hand, if K is very small, the curve is nearly linear; only two of the necessary three parameters can be determined. If K lies in an intermediate range close to unity, the system is amenable to complete analysis. In the lactam systems studied, K lies to the high side of this range.

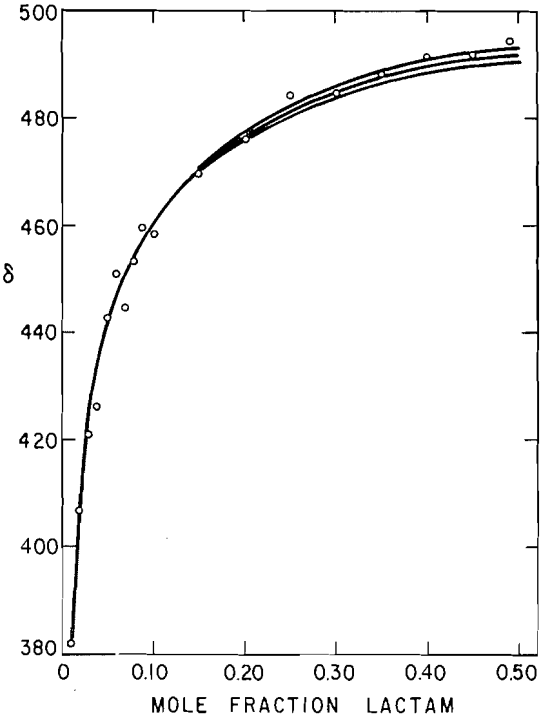

FIG. 3. Comparison of observed and calculated data for lactam in $CDCl_3$ at 33°. Solid lines are calculated curves for various values of δ_M. Upper curve, δ_M = 300 Hz; middle curve, δ_M = 250 Hz; lower curve, δ_M = 200 Hz.

Even though accurate extrapolation cannot be made, one can set limits to the possible choices of δ_M. The downfield limit is given by the lowest

†Calculated.

value of the observed shift. The upfield shift can be set by the chemical shift of a nonhydrogen-bonded N—H proton, e.g., that of piperidine monomer (16, 17) at approximately $\tau = 8.9$. This range, in fact, guided the choices for δ_M used in the calculations described above.

Despite the inability to fix precisely the value for K, ΔH can be more closely estimated. With the assumption that δ_M and δ_D are temperature independent, ΔH can be calculated for a given δ_M using the van't Hoff equation with the calculated values for K as given in Tables IV and V. The results are shown in Table VI. Regardless of the appreciable variation of K corresponding to possible choices of δ_M, the calculated values for ΔH fall in a relatively narrow range. Therefore, a reasonable estimate of ΔH can be obtained even though a full analysis of the experimental data cannot be made. The results obtained for ΔH are in essential agreement with those from i.r. measurements as shown in Table VII. Note that the difference in ΔH between the CCl_4 and $CDCl_3$ systems is ~5 kcal/mole. This difference reflects the specific solvation of lactam monomer and amounts to a ΔH of solvation of ~ -2.5 kcal/mole of monomer, close to the value of −2 kcal/mole estimated for $CDCl_3$–amide interactions by Klemperer *et al.* (10).

Conclusion

Dimerization equilibria described by equilibrium constants on the order of unity are ideally suited to n.m.r. investigation. For such systems, the chemical shift of both monomer and dimer can be precisely obtained and a value of K readily calculated. For the hydrogen bonding of δ-valerolactam, K is large. Nevertheless, even in this system for which the monomer shift cannot be reasonably estimated, a value for ΔH may still be obtained because of its slow variation with assumed values of the monomer shift.

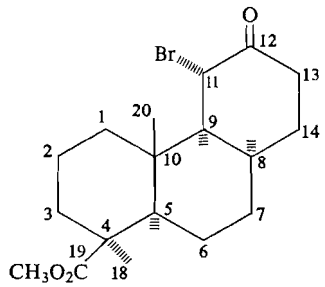
Dehydrobromination of methyl 11α-bromo-12-oxopodocarpan-19-oate

R. A. Bell and M. B. Gravestock
Department of Chemistry, McMaster University, Hamilton, Ontario
Received May 5, 1969

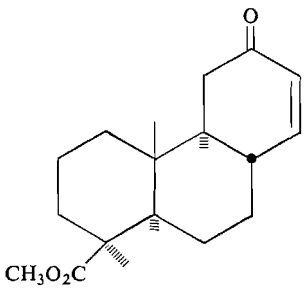
The configuration and stereochemistry of methyl 11α-bromo-12-oxopodocarpan-19-oate **1** have been determined by application of the nuclear Overhauser effect. The dehydrobromination of **1** with dimethylacetamide – calcium carbonate results in a predominant 1,4-elimination process which for short reaction periods yields the non-conjugated ketone **8** and for long reaction periods yields the conjugated ketone **2**. The 1,2-elimination of hydrogen bromide is a minor process and takes place to the extent of 20–22%. The ketone **8** has been oxidatively cleaved to the keto-acid **11**, a valuable intermediate for the synthesis of bicyclic diterpenoids.

Canadian Journal of Chemistry, **47**, 3661 (1969)

Dehydrohalogenation by high-boiling, aprotic solvents was first introduced in 1953 by Holysz (1). Since that time the reaction has proved to be remarkably useful in organic synthesis (2). The particular dehydrobromination of the bromo-ketone **1** by refluxing dimethylformamide in the presence of lithium chloride – lithium carbonate has been reported (3) to furnish the unsaturated ketone **2** as the sole isolable product. Since this compound is of interest as a potential intermediate in the synthesis of bicyclic diterpenes, we undertook a careful scrutiny of the stereochemistry of the bromo-ketone **1** and a detailed analysis of its dehydrobromination products.

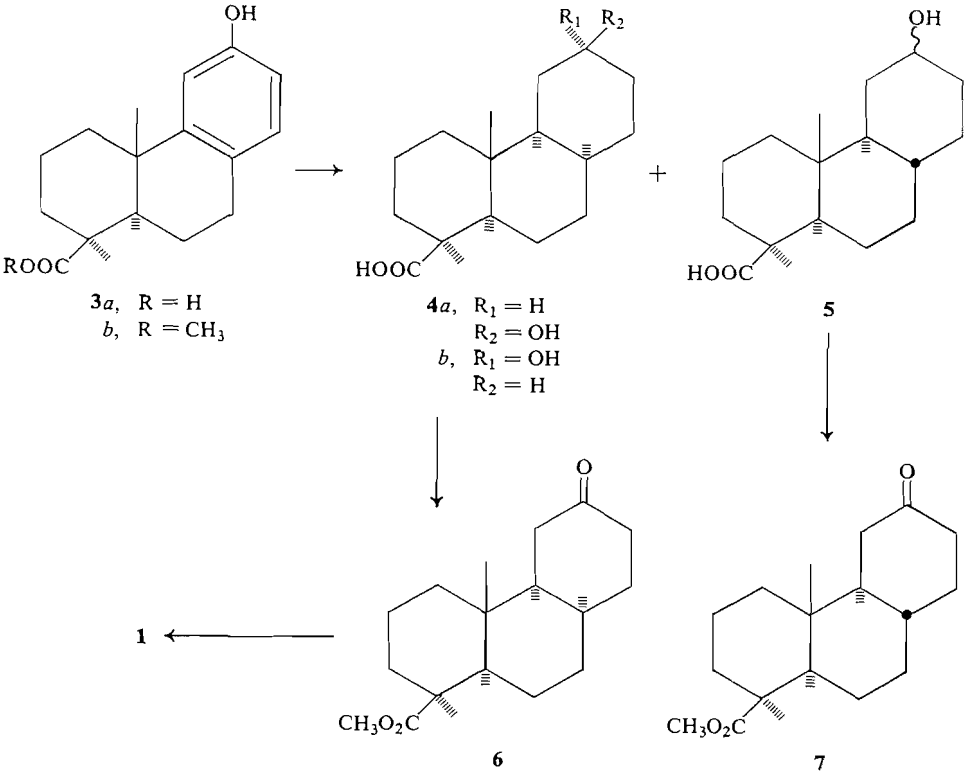


1



2

The bromo-ketone was prepared by a modification of the procedure adopted by Bible and Burtner (3). Experimental conditions were devised which resulted in a greatly improved overall yield of **1** (see Scheme 1). The saturation of the aromatic ring of podocarpic acid **3***a* by hydrogenation over platinum in acetic acid was noted by Bible and Burtner (3) to produce a high % of 12-deoxy material resulting from the hydrogenolysis of the 12-hydroxyl group. In the present study, hydrogenation of **3***a* with a rhodium-on-alumina catalyst (4) proceeded rapidly and resulted in no observable loss of the 12-hydroxyl group. The proton magnetic resonance (p.m.r.) spectrum of the crude rhodium catalyzed hydrogenation product showed that, although the 12β-hydroxy-B/C-*cis* compound **4***a* was the principal product (55%), there was also 30% of the 12α-hydroxy-B/C-*cis* compound **4***b* and 15% of the 12α- and 12β-hydroxy-B/C-*trans* derivatives **5** present. The product composition was further confirmed by p.m.r. analysis of the mixture of the acetates derived from the crude hydrogenation product and also by p.m.r. analysis of the mixture of the ester-ketones, **6** and **7**, obtained by direct oxidation and methylation of the crude hydrogenation product. The predominance of the B/C-*cis* ring juncture is expected on simple steric grounds, the α-face of the molecule being less sterically congested than the β-face. The minor formation of the B/C-*trans* ring juncture during hydrogenation is explicable if it is assumed that part or whole of the hydrogenation of the aromatic ring is a stepwise process and that the most difficult bond to saturate is the Δ-8(9)-double bond. A number of other Δ-8(9)-olefinic diterpenoids have been noted to yield B/C-*trans*



SCHEME 1

products either predominantly (5) or exclusively on catalytic hydrogenation (6).

In practice, isolation of the pure *cis*-keto-ester **6** was best accomplished by methylation of the crude hydrogenated podocarpic acid with diazomethane, oxidation with Jones' reagent (7) and separation of the mixture of **6** and **7** by fractional crystallization from ethyl acetate – hexane. In this manner **6** could be obtained in 70% overall yield from podocarpic acid **3***a*.

The *cis*-bromo-ketone **1** was obtained in 60% yield (isolated) by bromination of **6** with *N*-bromosuccinimide in dilute solution in carbon tetrachloride. Examination of the p.m.r. spectrum of the crude bromination products indicated that the principal component comprised *ca.* 90% of the product. The 11α-configuration assigned (3) to the bromine atom in this bromo-ketone was based on the long wavelength absorption at 310 mμ (ε 130) in the ultraviolet (u.v.) spectrum, which is indicative of an axial bromine (8), and the strong positive Cotton effect observed in the optical rotatory dispersion curve. However, the inspection of a molecular model and application

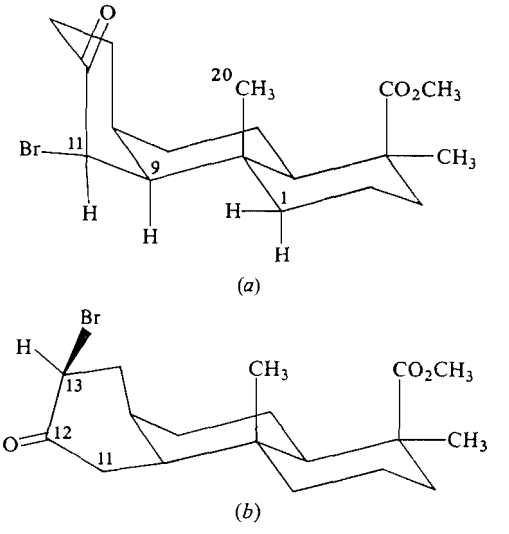


FIG. 1. Possible configurations of **1** showing positive Cotton effect.

of the Octant Rule (9) (see Fig. 1) shows that these spectroscopic properties can be satisfied by an 11α-bromine substituent with ring C in a chair

conformation (*a*), or by a 13β-bromine with ring C in a twist conformation (*b*). To clearly distinguish between these two possibilities the nuclear Overhauser effect (N.O.E.) (10) properties of the proton adjacent to the bromine atom and carbonyl group (signal at 4.37 p.p.m.) were examined (see Table I). The basis for the intramolecular N.O.E. lies in the contributions which neighboring protons make to the longitudinal relaxation time T_1 of the proton of interest. As a general, qualitative rule (11), if the nearest neighboring protons are within 3.0 Å of the proton of interest, then saturation of any (or all) of these protons with a second *rf* field will result in an area increase for this proton.

The 11-proton of the bromo-ketone showed a 7% area increase[1] when the C-20 methyl group[2] was saturated. This clearly implies that the 11-proton and the C-20 methyl protons must be within 3.0 Å of one another. Measurement of this distance with the aid of a molecular model (Fig. 1) for an 11α-bromine substituent showed a separation of 2.8 Å, whilst measurement of the equivalent distance for a 13β-bromine substituent, placed the 13α-proton and the C-20 methyl 3.6 Å apart. It must, therefore, be concluded that the bromo-ketone possesses the 11α-configuration as in **1** and the original assignment of Bible and Burtner is correct.

On the basis of the structure **1** for the bromo-ketone, the chemical shifts for the other neighboring protons of the 11β-proton can be assigned from the N.O.E. data. It is possible to distinguish between the H-1 and H-9 protons by virtue of the coupling ($J_{9,11}$ = 1 Hz) which exists between H-9 and H-11. Thus an *rf* field which was sufficient to saturate H-9 was also sufficient to decouple (12) H-9 from H-11, and the signal from H-11 not only increased in area but also decreased in line width (13). The coupling constant, $J_{11,13}$ = 1.0 Hz, was now also clearly visible by the splitting of the H-11 signal into a doublet. The numerical values for the N.O.E.'s observed for the axial and equatorial protons at C-1 are subject to some doubt since the strong coupling between these 2 protons means that saturation of one of them will result in significant saturation of the transitions of the other (14). However, it is possible to assign their chemical shifts accurately.

Dehydrobromination of 1

The unequivocal establishment of the stereochemistry of **1** meant that the formation of the products from the dehydrobromination experiments could be rationalized on a firm basis. Dehydrobromination of **1** for 30 min (Table II)

TABLE II

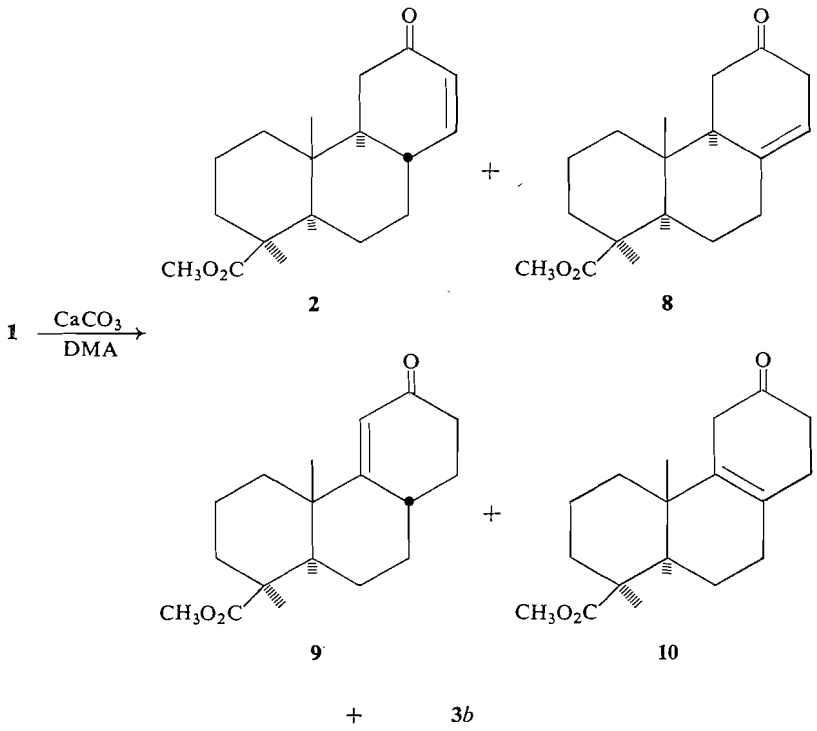
gave as the principal product the α,β-unsaturated ketone **2** (Scheme 2) which resulted from the elimination of hydrogen bromide in a 1,4-manner. Whilst such 1,4-eliminations have ample precedent (15) in the dehydrobromination of many bromo-ketones there are relatively few examples where the 1,4-elimination product is the principal product[3] (16). The predominance of a 1,4-elimination over the normal 1,2-elimination pathway is usually a simple consequence of the 1,2-elimination being a high energy process because of steric or stereoelectronic reasons. In this respect the bromo-ketone **1** is no exception, for

[1]We have found area increases down to as low as 3% to be quite reproducible with current instrumentation. Many of these small area increases have been noted in compounds of unequivocal structure (11) giving increased confidence in the application of the method in the present study.

[2]The numbering system employed is that proposed by the Committee on Diterpene Nomenclature (IUPAC), July 1968.

[3]Except of course in situations where 1,2-elimination is rendered impossible by complete substitution of the β-carbon. See ref. 17.



SCHEME 2

the inspection of a molecular model (see Fig. 1 (*a*)) shows that the dihedral angle between the C-9 H bond and the C-11 Br bond is approximately 60–90° and ring C cannot achieve coplanarity of these 2 bonds without undergoing severe distortion. Thus, the activation barrier for a 1,2-elimination will be high (18) and the alternative 1,4-elimination will be open to the molecule. An analogous situation is to be found in Reichstein's (19) work on 11α- and 11β-bromo-12-keto steroids. Dehydrobromination of 11β-bromo-ketones (a *trans* elimination with the C-9 α-proton) was dramatically more facile than dehydrobromination of the 11α-bromo-ketones. In these examples only 1,2-elimination is possible.

Since the unsaturated ketone **2** possesses a *trans* B/C ring juncture, **2** cannot be the primary product of a 1,4-elimination process. In an attempt to find the B/C *cis*-fused ketone **14**, (Scheme 3), which would be the presumed initial product, **1** was exposed to refluxing dimethylacetamide (DMA)/$CaCO_3$ for increasingly shorter periods of time. The appearance of a highly shielded C-20 methyl group at 0.33 p.p.m. in the p.m.r. spectra of the products was observed as the reaction period was decreased. This compound was the predominant product (60%, see Table II) after a reaction period of 10 min. Shorter reaction times down to a period of 5 min resulted in the recovery of unreacted bromo-ketone and no distinguishable change in the composition of the dehydrobromination products. When the principal product from the 10 min reaction was isolated via silica gel or Florisil chromatography and its spectral properties examined, it was clear that it was not the *cis*-fused ketone **14** but the non-conjugated ketone **8**. Thus **8** showed only one vinylic proton at 5.44 p.p.m. in its p.m.r. spectrum, a carbonyl absorption at 1712 cm^{-1} in its infrared (i.r.) spectrum, and only a weak absorption at 282 mμ (ε 100) in its u.v. spectrum. Moreover, on treatment with alumina or dilute acid, **8** was transformed into a mixture consisting of 95% of **2** and 5% of **8**. This equilibrium composition indicates that **2** is thermodynamically more stable than **8**.[4] To firmly secure the structure

[4]The equilibrium composition of 4-alkylcyclohexenones, however, favors the β,γ-form as the size of the alkyl substituent increases (20).

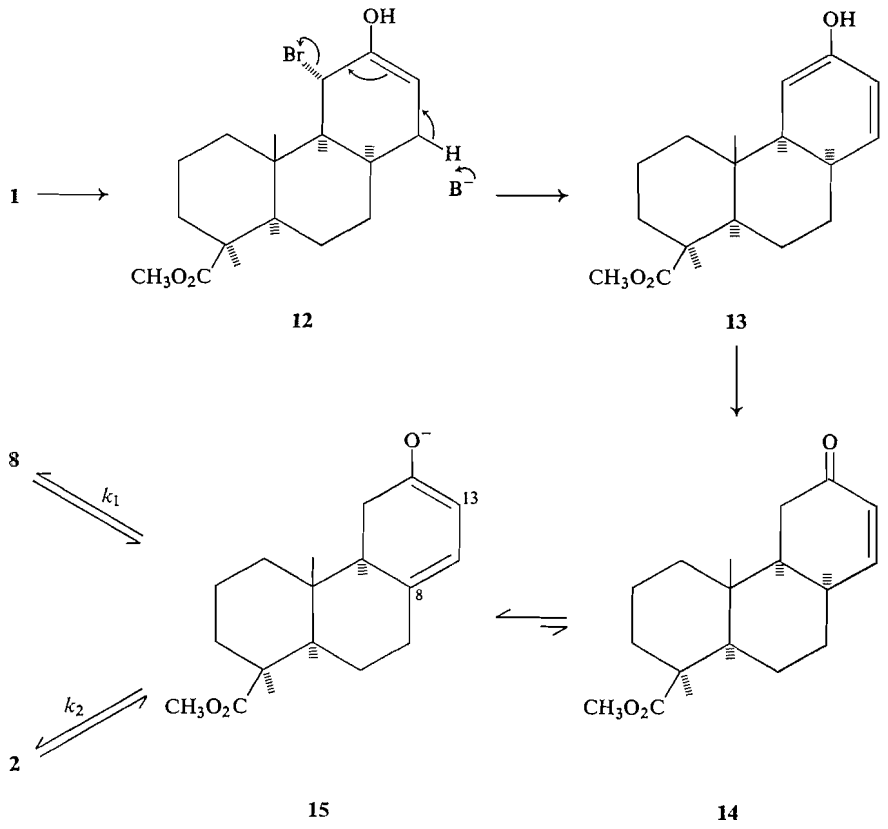
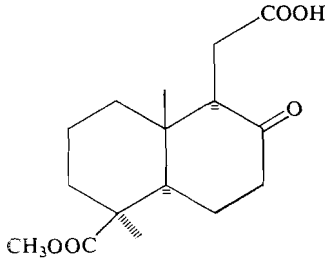


SCHEME 3

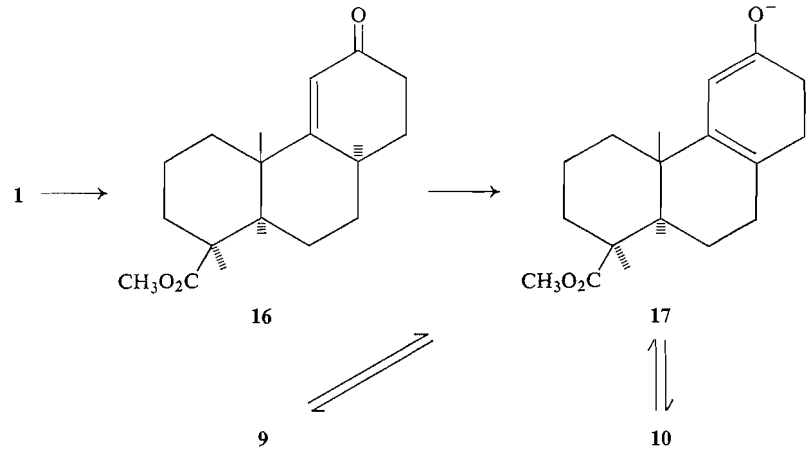
assigned to **8**, the compound was oxidized in excellent yield with either potassium permanganate – sodium periodate or ozone to the known keto-acid **11**. This ketone possessed properties and derivatives which were completely consistent with the keto-acid reported by Erdtman *et al.* (21). It is notable that **11** is potentially an exceptionally useful intermediate in the synthesis of bicyclic diterpenoids (22).

A mechanism for the formation of **2** and **8** is shown in Scheme 3. Although a number of mechanisms may be written for the initial steps of the 1,4-elimination (16*c*), the most straightforward is shown since this dehydrobromination offers no new information on this aspect of the process. The enol **12** can, therefore, be considered to furnish the unsaturated enol **13** by 1,4-elimination. Proton transfer to C-11 of **13** via the enolate then leads to the elusive B/C *cis*-ketone **14**. However, the severe steric interaction between the C-20 methyl group and the C-14 carbon provides a strong driving force for base abstraction of the C-8 proton to give the conjugated enolate **15** where this steric interaction is completely removed. In addition the C-8 hydrogen of **14** is pseudo-axial with respect to ring C and therefore its removal by base should be further facilitated for stereoelectronic reasons (23). Because of these two factors, the C-8 hydrogen appears to be more acidic than normal and even a weak base (24) such as DMA can rapidly abstract it although of course it is not necessary that DMA should be the only basic species involved in this proton removal. In



11

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



SCHEME 4

other decalin systems, where excessive steric interactions are absent, the removal of a γ-hydrogen by DMA or other bases present appears to be a comparatively slow process and little or no isomerization of the ring junction is observed (25).

The enolate **15** can undergo protonation at either C-13 or C-8. Under conditions of kinetic control, protonation will take place preferentially at the site of highest electron density (26), that is at C-13 (with the second order rate constant $k_1 > k_2$) and the non-conjugated ketone **8** will be formed. Under conditions of thermodynamic control, that is if there is an equilibrium between **8** and **2** the more stable ketone **2** will be formed. The predominant formation of **8** during the short reaction period shows that the reaction is largely kinetically controlled over this period. The longer, 30 min reaction period results in principally thermodynamic control. Since the product ratio of **2** and **8** did not change appreciably for more extended reaction periods the observed ratio of 60:14 for **2**:**8** probably represents the ratio of their stabilities in refluxing DMA.

Although the rate of the 1,2-elimination process is slow, as is noted above, it still occurs to the extent of 20% and, as in the case of 1,4-elimination, the intermediate 8α-conjugated ketone **16** (Scheme 4) possesses only a fleeting existence and is rapidly transformed by enolization and protonation into the 8β-conjugated ketone **9** and the non-conjugated ketone **10**. The ratio of **9** to **10** showed only a slight change with increasing reaction period (see Table II) and this is indicative of a situation which is approaching thermodynamic control very quickly. To achieve this, either the ketones **9** and **10** must be in equilibrium or the rate of protonation at C-11, must be comparable with the rate of protonation at C-8. The latter is considered more reasonable here for, despite the high electron density at C-11, the 11-position suffers steric interactions from both the C-20 methyl group and the C-1 hydrogens, whilst the 8-position suffers only an interaction from the C-20 methyl. It is interesting to note that in contrast to the ratio of about 5:1 for **9**:**10** in refluxing DMA, the equilibrium in either acidic or basic media at room temperature is overwhelmingly in favor of **9** (3).

The only other product aside from the ketones **2**, **8**, **9**, and **10**, obtainable from the dehydrobromination of **1** was methyl podocarpate **3***b*. It appeared to have its origin in the air-oxidation of the unsaturated ketones, since experiments performed with the reaction mixture open to the air resulted in greatly increased yields of **3***b* as well as polymeric materials. A consistent 4–7% yield of **3***b* appeared to be a lower limit and is probably a consequence of the experimental technique employed (see Experimental).

Summary

Improved experimental conditions have been developed for the preparation of the bromoketone **1** and its configuration and stereochemistry have been unequivocally determined by application of the N.O.E. The dehydrobromination of **1** with DMA/calcium carbonate results in a predominant 1,4-elimination process which

for a short reaction period takes place under conditions of kinetic control and furnishes the non-conjugated ketone **8** in 60% yield. Reaction periods of 30 min or longer give the conjugated ketone **2** as the principal 1,4-elimination product in 60% yield. The 1,2-elimination of hydrogen bromide from **1** is a minor process and takes place to the extent of 20–22%. It yields a mixture of the unsaturated ketones **9** and **10** which appear to be the products of a thermodynamically controlled process. The non-conjugated ketone **8** is a useful precursor to the keto-acid **11** which is a potential intermediate for the synthesis of a variety of diterpenoids.

Experimental

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Infrared spectra were obtained in chloroform solution unless otherwise noted and u.v. spectra obtained in methanol. Proton magnetic resonance spectra were recorded using Varian Associates HA-100 and A-60 spectrometers in deuteriochloroform solution with tetramethylsilane as internal reference. Mass spectra were recorded with an Hitachi Perkin–Elmer RMU-6A spectrometer at 80 eV.

12β-Hydroxy-8α-podocarpan-19-oic Acid (4a)

The general procedure of Meyers *et al.* (4) was used. Fifty grams (0.182 mole) of podocarpic acid (recrystallized from 10% aqueous methanol and dried *in vacuo* at 80° for 24 h to remove methanol of crystallization) was added to a mixture of 12.5 g of 5% rhodium-on-alumina (Engelhard Industries Inc.) and 200 ml of 95% ethanol containing 1% acetic acid, and the mixture shaken under hydrogen (40–50 p.s.i.) at room temperature in a Parr apparatus. Uptake of hydrogen effectively ceased after 48 h. The reaction mixture was filtered under reduced pressure, the filter pad being washed well with methanol, and the filtrate evaporated to dryness *in vacuo* to give 50.5 g of crude hydroxy-acid as a colorless solid. Two recrystallizations from ethyl acetate gave 25.0 g (50%) of the *cis*-hydroxy-acid **4a**, m.p. 230–234° (lit. (3), m.p. 234.5–236°); p.m.r. (pyridine/CS_2): δ 0.97 (s, 3H, C-20 CH_3), 1.26 (s, 3H, C-18 CH_3), 3.68 p.p.m. (s, broad, 2H, COOH and OH).

Analysis of the Crude Hydrogenation Product

(*i*) Methylation with diazomethane followed by oxidation with Jones' reagent (see below) gave a mixture of keto-esters which by p.m.r. analysis proved to be a mixture of 85% *cis*, and 15% *trans* B/C ring juncture isomers.

(*ii*) Acetylation. The crude hydroxy-acid mixture was methylated and acetylated in pyridine yielding the *cis*-12α- and *cis*-12β-acetates in an approximate ratio of 3:5, respectively. These acetates were identified by their p.m.r. spectra from an independent synthesis (27).

Methyl 12-Oxo-8α-podocarpan-19-oate (6)

A slurry of 50.5 g of the crude hydroxy-acid **4a** in methanol–ether was treated with portions of ethereal diazomethane at room temperature until the yellow color of excess reagent had been present for 15 min. The solvent was then removed *in vacuo* to give 53.0 g of the crude hydroxy-ester as a pale yellow gum. The gum was dissolved in 500 ml of acetone and Jones' reagent added dropwise to the well stirred solution maintained at 10–25° with an ice-bath. When excess of reagent was visible as a permanent orange coloration, the reaction was arrested by the addition of isopropanol and the bulk of the acetone removed *in vacuo* at 30–40°. The residue was diluted with 500 ml water and extracted with ether (2 × 200 ml) and benzene (1 × 100 ml). The combined organic extracts were washed with water and brine, filtered through sodium sulfate and evaporated *in vacuo* to give 52.0 g (98%) of the mixture of B/C *cis* and *trans* keto-esters **6** and **7** as pale yellow-green crystals. Washing through 300 g of alumina in benzene removed the majority of the color and any non-oxidized material giving 50 g (95%) of the crystalline mixture of **6** and **7**. Integration of the areas of the absorptions at 3.63 and 3.66 p.p.m. ($COOCH_3$) showed that this mixture consisted of 85% **6** and 15% **7**.

Separation of the Ketone Isomers

The above mixture of keto-esters (50 g) was dissolved in 200 ml of boiling ethyl acetate – hexane (1:3) and the solution seeded with pure *cis*-keto-ester and cooled slowly to room temperature. After standing for 48 h at room temperature, 33 g (62% from podocarpic acid) of the *cis*-keto-ester **6** was obtained as colorless crystals, m.p. 120–122° (lit. (3), m.p. 120–121.5°); p.m.r.: δ 0.65 (s, 3H, C-20 CH_3), 1.16 (s, 3H, C-18 CH_3), 3.63 p.p.m. (s, 3H, $COOCH_3$). The mother liquors, after evaporation and dissolution in 50 ml ether – 5 ml ethyl acetate – 15 ml hexane at the boiling point and seeding and standing at room temperature, yielded a further 4.2 g of the *cis*-keto-ester **6** (8% from podocarpic acid), m.p. 118–120° (purity 95% by p.m.r.).

The mother liquors from the above crystallizations contained approximately 60% of the *trans*-ketone **7**. In one experiment, careful seeding with a sample of pure **7** obtained from the hydrogenation of **2** (3) gave **7** as colorless crystals, m.p. 110–115° (>90% pure by p.m.r. spectroscopy) (lit. (3), m.p. 116–121.5°); p.m.r.: δ 0.68 (s, 3H, C-20 CH_3), 1.15 (s, 3H, C-18 CH_3), 3.66 (s, 3H, $COOCH_3$).

Separation by selective reaction with Girard's "T" reagent gave variable results and was of no use as a practical method of separating large quantities of the mixed keto-esters.

12-Oxo-8α-podocarpan-19-oic Acid

Twenty-five grams of the hydroxy-acids **4a**, **4b**, and **5**, obtained from the hydrogenation of podocarpic acid as described above were dissolved in 1.2 l of acetone at 10° and oxidized by the dropwise addition of Jones' reagent (7) until a permanent yellow coloration remained. Excess reagent was then destroyed with isopropanol and the bulk of the acetone removed *in vacuo*. The keto-acid was isolated via ether extraction and on crystallization from ether–hexane yielded 18.3 g (73%) of 12-oxo-8α-podocarpan-19-oic acid as colorless crystals, m.p. 165–170° (lit. (3), m.p. 168–174°); p.m.r.: δ 0.79 (s, 3H, C-20 CH_3), 1.25 (s, 3H, C-18 CH_3), 10–11 p.p.m. (s, 1H, COOH).

Methyl 11α-Bromo-12-oxo-8α-podocarpan-19-oate (1)

The method of Bible and Burtner (3) was used with some modification.

To a solution of 39.3 g (0.135 mole) of methyl 12-oxo-8α-podocarpan-19-oate, m.p. 120–124°, in 1500 ml of dry carbon tetrachloride (molecular sieves) was added 25.5 g (0.140 mole) of *N*-bromosuccinimide and one drop of 48% hydrobromic acid. An immediate red coloration developed which vanished after 30 s. The reaction was over in 2–4 h as evidenced by the supernatant succinimide present and the absence of any *N*-bromosuccinimide. The solution was washed free of succinimide and hydrogen bromide by shaking with water (3 × 300 ml), filtered through anhydrous sodium sulfate, and evaporated *in vacuo* at 40°. Drying at 0.5 mm overnight gave *ca.* 50 g (100%) of crude bromo-ketone. The p.m.r. spectrum of the crude reaction product showed the presence of 85–90% of the desired compound together with 5% unreacted starting material and 5–10% other stereoisomeric bromo-ketones. Crystallization from hexane–ether at 0° yielded 35.0 g (70%) of **1** as colorless prisms, m.p. 145–150°. A second crystallization gave 30 g of **1**, m.p. 151–152° (lit. (3), m.p. 152–153°); p.m.r.: δ 0.68 (s, 3H, C-20 CH_3), 1.17 (s, 3H, C-18 CH_3), 3.1 (m, 1H, C-13 axial H (28)), 3.57 (s, 3H, $COOCH_3$), 4.37 (s, broad, $W_{h/2}$ = 4 Hz, 1H, C-11 equatorial H). The concentrated mother liquors afforded additional quantities of crystalline **1**, but of poor purity. No attempts were made in this study to isolate the small quantities of other stereoisomeric bromo-ketones which were present.

The N.O.E. measurements were obtained on a carefully degassed 0.16 *M* solution of **1** in deuterioacetone. The experiments were performed at 100 MHz in frequency-sweep mode. The second saturating *rf* field applied was of the order of 0.75–1.0 mG (29) and area integrations were repeated at least 25 times for each signal. The mean area increases observed (see Table I) were reproducible to within 1%.

Dehydrobromination of 1

The general procedure of Green and Long (2) was used throughout. To determine the change in product composition with the time of reaction, a number of small scale runs were carried out. Two grams of methyl 11α-bromo-12-oxo-8α-podocarpan-19-oate, m.p. 151–152°, were added portionwise over 2 min to 40 ml of refluxing dimethylacetamide (dried over calcium hydride) containing 4 g of precipitated calcium carbonate. The boiling solution was protected from atmospheric oxygen by a positive pressure of dry nitrogen. Further reflux was continued for 3, 8, 18, 28, and 48 min in 5 successive runs. Each run was quenched by cooling rapidly in an ice-bath, filtering under pressure with the filter-pad being well washed with ether, the filtrate diluted with twice its volume of water, and the whole extracted with ether. The dried and evaporated extracts yielded pale yellow oily or crystalline products which were examined by p.m.r. spectroscopy. The components were identified by the chemical shifts of their C-20 methyl absorptions which were assigned from the p.m.r. spectra of authentic samples of each compound and which are recorded in Table III. The individual compounds were either prepared by reported methods or, as in the case of the Δ-8(14)-ketone, obtained by direct isolation from the reaction products. The differences between the chemical shifts of the C-20 methyls were sufficient to permit the determination of the product composition either by direct integration or by simple triangulation. The presence of the bromo-ketone itself was readily determined from the signal for the C-11 proton at 4.37 p.p.m. The product composition results were found to be reproducible to within ±3% and are shown in Table IV.

Methyl podocarpate *3b*	0	4	6	7	10

Methyl 12-Oxopodocarp-8(14)-en-19-oate 8

Ten grams (27.0 mmoles) of the bromo-ketone **1**, m.p. 147–152°, were added portionwise over a period of 2 min to a mixture of 200 ml of dry, refluxing DMA and 20 g of precipitated calcium carbonate, and the whole refluxed for a further 8 min. The products were isolated via ether extraction as described above and upon evaporation of the solvents yielded 7.72 g (99%) of a pale yellow oil, the composition of which is recorded in Table II (10 min reaction). The material was transferred onto 400 g of silica gel (11-200 mesh, Davidson Chemical Co.) in 1:1 benzene – petroleum ether (30–60°). The chromatogram was developed with 500 ml of the same solvent and 1000 ml of benzene. Elution with 1% ethyl acetate in benzene afforded 50 mg of unreacted bromo-ketone and elution with 2% ethyl acetate yielded 4.6 g (60%) of the Δ-8(14)-ketone **8** as a colorless crystalline solid (purity > 90%). Two recrystallizations from 10% ethyl acetate in hexane gave an analytical sample of **8** as colorless prisms, m.p. 99–100°; i.r. ν_{max}: 2940, 2850 (C—H), 1712 cm^{-1} ($COOCH_3$ and saturated CO); u.v. λ_{max}: 282 mμ (ε 100);

Methyl 12-Oxopodocarp-13-en-19-oate (2)

The crude dehydrobromination product obtained by refluxing 10.0 g of **1** in a mixture of 200 ml of DMA and 20 g of calcium carbonate for 30 min and isolated in the same manner as described above was dissolved in 250 ml of acetone containing 25 ml of 3*N* hydrochloric acid and refluxed under nitrogen for 2 h. The majority of the acetone was removed *in vacuo*, the residue extracted with ether and the washed and dried extracts (anhydrous sodium sulfate) were evaporated in vacuo to give 7.7 g of a pale yellow crystalline solid, containing 70% **2**, 6% **8**, 15% **9**, 2% **10**, and 7% methyl podocarpate **3***b*. Chromatography on silica gel in 1:1 benzene – petroleum ether (30–60°) and elution with 2% ethyl acetate in benzene gave the majority of **8**, **10**, and some of **3***b*. Further elution with 5% ethyl acetate in benzene gave crystalline **2**, 4.5 g (58%), m.p. 120–123°. Recrystallization from methanol gave the conjugated ketone as glistening plates, m.p. 127–130.5° (lit. (3), m.p. 126.5–129°); u.v. λ_{max}: 230 mμ (ε 10 500) (lit. (3), λ_{max} 230 mμ (ε 8 710)); p.m.r.: δ 0.715 (s, 3H, C-20 CH_3), 1.15 (s, 3H, C-18 CH_3), 3.64 (s, 3H, $COOCH_3$), 5.85 (quartet, 1H, $J_{13,14}$ = 10 Hz, $J_{14,15}$ = 2.6 Hz, C-13 H), and 6.65 p.p.m. (quartet, 1H, $J_{13,14}$ = 10 Hz, $J_{11,13}$ = 1.6 Hz, C-14 H).

Oxidative Degradation of Methyl 12-Oxopodocarp-8(14)-en-19-oate (8)

Two methods, ozonolysis and potassium permanganate – sodium periodate oxidation, were employed to degrade **8** to the keto-acid **11**. Both methods gave yields of **11** of the same order of magnitude but the permanganate periodate reagent gave inconsistent results whereas ozone gave reasonably reproducible yields.

A solution of 1.60 g of Δ-8(14)-ketone **8**, m.p. 95–98°, in 80 ml of dry methanol (molecular sieves) was treated with ozone (Welsbach T-408 ozonizer) at −65–75° until the solution assumed a pale blue color. Nitrogen was bubbled through to remove excess ozone and the solution transferred to a 500 ml flask in a total volume of 200 ml methanol. This solution was then refluxed with 20 ml of 30% hydrogen peroxide and 50 ml of 10% sodium hydroxide for 30 min under nitrogen. The majority of the methanol was then removed *in vacuo* and the residue diluted with 300 ml of water and ether extracted. The ethereal extracts were counter-washed once with water and the combined aqueous phases acidified to pH 1 with 2*N* sulfuric acid. The liberated acidic product was extracted with a benzene – ether mixture (3 × 100 ml), the extracts washed with water, saturated brine, and filtered through anhydrous sodium sulfate to yield, on evaporation *in vacuo*, 1.40 g of **11** as an oil which crystallized on standing. The p.m.r. spectrum of this crude product indicated that the desired keto-acid was present in approximately 80% yield. Recrystallization from 10% ethyl acetate – hexane gave 0.84 g (52%) of *8-oxo-(13 → 17)-pentanorlabdan-12,19-dioic acid 19-methyl ester* **11** as colorless needles, m.p. 168–170° (lit. (21), m.p. 170–172°); p.m.r.: δ 0.55 (s, 3H, C-20 CH_3), 1.25 (s, 3H, C-18 CH_3), 3.70 (s, 3H, C-19, $COOCH_3$), 10.6 p.p.m. (s, 1H, broad $W_{h/2}$ = 15 Hz, C-12 COOH).

In another experiment 1.60 g of **8** was ozonized and the crude product directly esterified with diazomethane. Chromatography on 50 g of Florisil in 1:1 benzene – petroleum ether and elution with benzene yielded 1.25 g (73%) of the methyl ester of **11** which was crystallized from 5% ethyl acetate – hexane to give 0.95 g (56%) of the *diester* as colorless prisms, m.p. 96–97° (lit. (21), compound reported only as an oil); p.m.r.: δ 0.54 (s, 3H, C-20 CH_3), 1.27 (s, 3H, C-18 CH_3), 3.60 (s, 6H, $W_{h/2}$ = 1.0 Hz, two $COOCH_3$); mol. wt. 310, mass spectrum. The 2,4-dinitrophenylhydrazone of the diester crystallized from aqueous ethanol as yellow needles, m.p. 161–163° (lit. (21), m.p. 161–163°).

Ring openings of γ- and δ-lactones to form γ- and δ-hydroxyamides. Cyclodehydration. Mass spectra of δ-hydroxyamides[1]

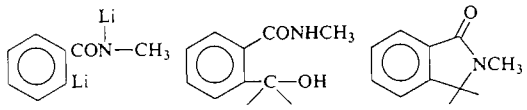
EARL M. LEVI, CHUNG-LING MAO, AND CHARLES R. HAUSER
Department of Chemistry, Duke University, Durham, North Carolina 27706

Received April 25, 1969

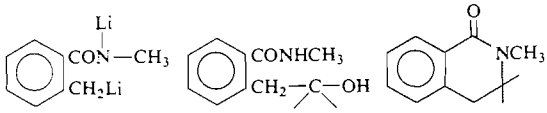
Ring openings of γ- and δ-lactones were effected with potassium amide or hydrazine to form γ- and δ-hydroxyamides, which were cyclodehydrated with sulfuric acid to give γ- and δ-lactams, respectively. These products are, respectively, phthalimidines and 3,4-dihydroisocarbostyrils having no substituent on nitrogen or having the N—NH_2 group. The possible linear dehydration of the δ-hydroxyamides was not observed. The δ-hydroxyamides exhibited, on mass spectrometry, a type of carbon–carbon cleavage that has apparently not been reported for ordinary alcohols. An example of the "*ortho* effect" in mass spectra of *o*-disubstituted benzene derivatives is also discussed.

Canadian Journal of Chemistry, 47, 3671 (1969)

Dilithiations of *N*-methylbenzamide (1) and *N*-methyl-*o*-toluamide (2) have previously been accomplished with *n*-butyllithium to form dilithioamides **1** and **4**, which were condensed with ketones or aldehydes to give γ- and δ-hydroxyamides **2** and **5**, respectively. These compounds have been cyclodehydrated with sulfuric acid to afford γ- and δ-lactams **3** and **6**, respectively (3).



1 **2** **3**



4 **5** **6**

However, similar dilithiations of benzamide (1) and *o*-toluamide[2] have failed. Thus, the above method has not been applicable to preparations of γ- and δ-hydroxyamides and γ- and δ-lactams having no substituent on the nitrogen atom.

We have now prepared such compounds by ring opening of γ- and δ-lactones with potassium amide, followed by ring closure with acid; similarly, hydroxyamides and lactams having the N—NH_2 group were synthesized employing hydrazine. The γ- and δ-lactones were readily obtained by thermal cyclodeamination of γ- and δ-hydroxyamides of types **2** and **5**, respectively (1, 2).

Results with γ-Lactones

γ-Lactone **7** underwent ring opening with potassium amide in tetrahydrofuran (THF) and with hydrazine (neat) to form γ-hydroxyamide **8** and hydrazide **9**, which underwent cyclodehydrations with cold, concentrated sulfuric acid to give γ-lactams **10***a* and **10***b*, respectively.

Crude hydroxyamide **8** and hydrazide **9** were employed in these reactions, since attempted purification of them resulted in reconversion to lactone **7**. The overall yields of **10***a* and **10***b* from lactone **7** were 25 and 20%, respectively.

Similarly, treatment of γ-lactone **11** with hydrazine afforded γ-lactam **12** in 4% yield; this yield might be improved since most of lactone **11** was recovered. The intermediate hydrazide was not isolated. γ-Lactone **11** has previously been

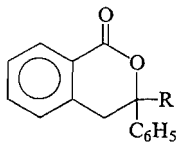
shown to undergo ionization of its benzhydrylic hydrogen atom with potassium amide to form a carbanion which can be alkylated (4).

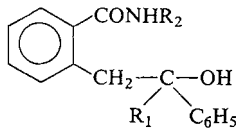
Attempts to prepare γ-hydroxyamides by the action of potassium amide on the γ-lactones obtained from dilithioamide **1** and cyclohexanone or fluorenone were unsatisfactory. Apparently these lactones underwent ring opening but were again regenerated on work-up.

Results with δ-Lactones

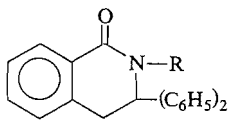
δ-Lactone **13** underwent ring opening with potassium amide in THF and with hydrazine (neat) to form δ-hydroxyamide **14** and the corresponding δ-hydroxyhydrazide (isolated as its acetone derivative **15**) in yields of 69 and 45%, respectively. These compounds were cyclodehydrated with cold, concentrated sulfuric acid to give the 3,4-dihydroisocarbostyrils **16***a* and **16***b* in yields of 89 and 53%, respectively. Interestingly, the possible linear dehydration was not observed.



13, R = C_6H_5
22, R = H



14, $R_1 = C_6H_5$, R_2 = H
15, $R_1 = C_6H_5$, $R_2 = N{=}C(CH_3)_2$
23, $R_1 = R_2$ = H



16*a*, R = H
16*b*, R = $N{=}C(CH_3)_2$

Similarly, δ-lactone **17** underwent ring opening with potassium amide to form δ-hydroxyamide **18** in 82% yield. This compound may have undergone cyclodehydration with cold, concentrated sulfuric acid to give δ-lactam **19** but, surprisingly, olefin-amide **20** was obtained on attempted distillation. That the olefinic product was **20**, and not the possible **21**, was supported by the nuclear magnetic resonance (n.m.r.) spectrum with the vinyl proton absorption at δ 5.28 p.p.m.[3] Had the product been **21**, this absorption should have appeared at lower field. In addition, this n.m.r. spectrum shows benzylic methylene protons at δ 3.47 p.p.m. The infrared (i.r.) spectrum is characteristic of a benzamide and the mass spectrum resembles that of the unsubstituted δ-hydroxyamides in that the most abundant fragment ion appears at *m/e* 135 (see below). The base peak in this spectrum is the molecular ion (*m/e* 215). One might expect to observe the formation of **21** as well as **20**; however, none was isolated.

Likewise, δ-lactone **22** underwent ring opening with potassium amide to form δ-hydroxyamide **23** in 78% yield. Such ring openings appear to be quite general and, in contrast to corresponding γ-lactones, uncomplicated by ring closure during work-up.

It should be mentioned that δ-lactone **13** also underwent ring opening with lithium methylamide in THF to form the corresponding δ-hydroxyamide of type **5**. However, this compound can be prepared more conveniently from dilithioamide **4** and benzophenone (2).

The present method of synthesis of 3,4-dihydroisocarbostyrils having no substituent on nitrogen appears more convenient than earlier ones, which have involved cyclizations of urethanes with polyphosphoric acid (6) and of isocyanates with aluminum chloride (7).

Mass Spectra of δ-Hydroxyamides

These hydroxyamides exhibited, on mass spectrometry, a type of cleavage that appears not to have been observed previously (Schemes 1 and 2). Thus, compounds **14**, **18**, and **23** underwent not only a normal alcohol cleavage (course *a*), but also an abnormal one (course *b*) that involves migration of hydrogen from oxygen to nitrogen accompanied by carbon–carbon bond cleavage. The latter cleavage gave the base peak at *m/e* 135, the molecular ion of a toluamide, common to the three spectra (see Scheme 1). A minor fragmentation observed in all 3 spectra is the loss of 17 mass units from the molecular ion. This fragmentation, in the case of **23**, was shown by high resolution to be due to the loss of *ammonia*,[4] and not to loss of *hydroxyl radical*. This is due to either

[3]The positions reported for vinyl protons of similar type lie between δ 5.36–5.43 p.p.m. (5).

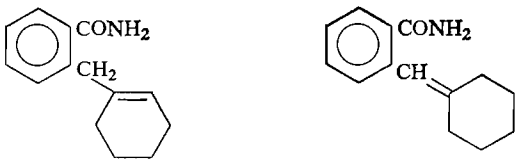
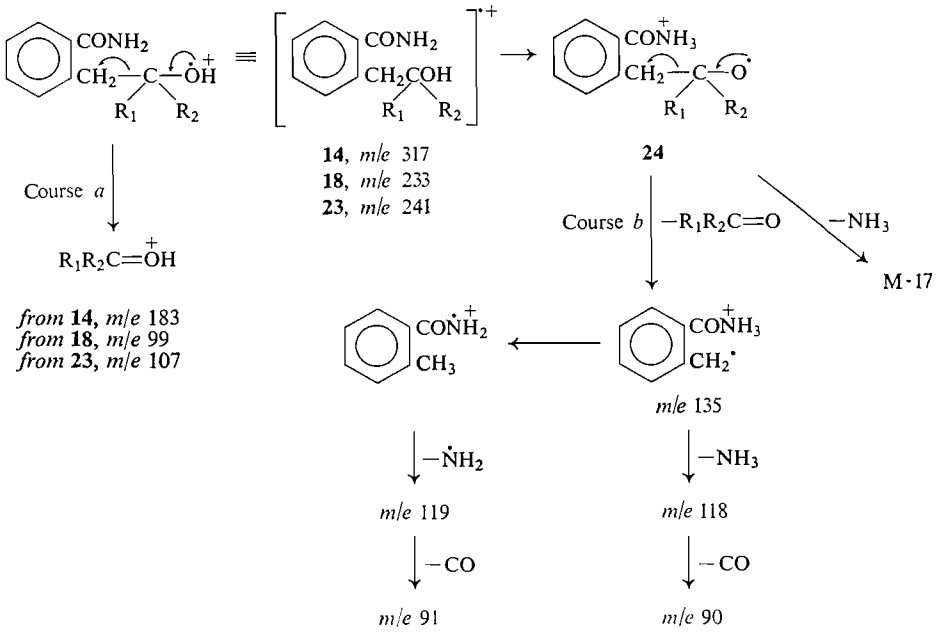
17 18 19



20 21

cyclodeamination before ion impact, loss of ammonia from ion **24** (Scheme 1), or a combination of these effects. The fragmentation from the base peak ion is interesting in that it is another example of the "*ortho* effect" in *o*-disubstituted benzene derivatives. This effect has been observed in the mass spectra of *o*-ethoxybenzamide (8) and *o*-methylbenzoates (9) when compared to the spectra of the *meta* and *para* isomers. The "normal" fragmentation of a toluamide would be expected to follow the pathway *m/e* 135 to *m/e* 119 to *m/e* 91; i.e. loss of an amine radical, followed by loss of carbon monoxide (10). In the mass spectra of the δ-hydroxyamides, part of the fragmentation occurs *via* the pathway *m/e* 135 to *m/e* 118 to *m/e* 90; i.e. loss of ammonia followed by loss of carbon monoxide, as well as following the "normal" pathway.

These rationalizations of the fragmentation pathways are supported by the mass spectra of the *N*-methyl and *N*-phenyl substituted derivatives **25** and **26** (Scheme 2). In these spectra, as in the spectrum of **14**, the major fragmentation follows the abnormal course described above and



SCHEME 1

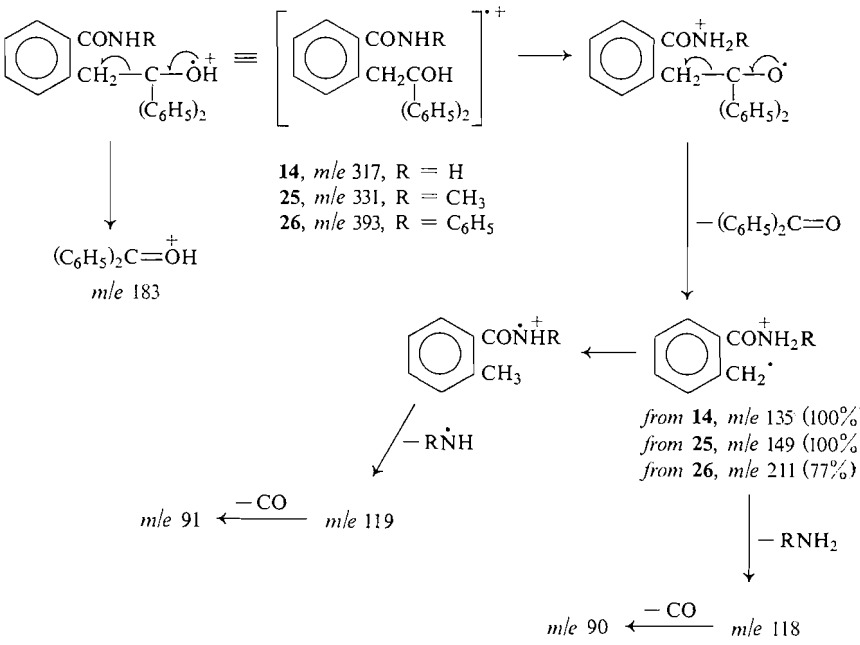

SCHEME 2

is confirmed by shifting of the toluamide peak to *m/e* 149 and *m/e* 211, respectively. The normal elimination of the protonated benzophenone ion is also observed, but to a much lesser extent. The fragmentation from the toluamide ions again follows both the "normal" and the "*ortho* effect" routes. These latter 2 pathways are roughly comparable in terms of ion current carried for all of the 5 spectra examined. The supporting metastable peaks for all of the fragmentations were observed (see Experimental), although not all were observed in each spectrum.

Experimental

Melting points are uncorrected. Infrared spectra were recorded on a Perkin–Elmer Model 137 Infracord and were calibrated against the 6.24 μ band of polystyrene. Nuclear magnetic resonance spectra were taken on a Varian A-60 instrument, operating at 60 MHz, and are reported as downfield shifts in p.p.m. for tetramethylsilane employed as an internal standard.[5] Mass spectra were obtained on an Associated Electrical Industries MS-902 at 70 eV.[6] Tetrahydrofuran (THF) was dried at reflux temperature over lithium aluminum hydride and was freshly distilled before use. Analyses were performed by M-H-W Laboratories, Garden City, Michigan.

2-[(Diphenylhydroxy)methyl]benzamide (8)

A solution of 14.3 g (0.05 mole) of 3,3-diphenylphthalide (**7**) (1) in dry THF (50 ml), was slowly added to a solution of potassium amide prepared from 7.8 g (0.2 g-atom) of potassium in *ca.* 250 ml of liquid ammonia. The reaction mixture was stirred at the b.p. of ammonia for 3 h, 150 ml of dry THF was added, and the ammonia was removed under a slow stream of nitrogen. After stirring for an additional 18 h at room temperature, the reaction mixture was poured into iced hydrochloric acid. The resulting mixture was filtered, and the solid washed well with water, then with acetonitrile to remove lactone **7**. The crude hydroxyamide (10.0 g, 65%), m.p. 170–162° decomp., was recrystallized twice from acetonitrile to give, apparently, pure **8**, m.p. 168–170° decomp.; λ_{max} ($CHCl_3$): 2.90, 3.00, and 6.02 μ.

The analytical data for this compound were unsatisfactory because of the ease with which it decomposed. On standing for about 1 week at room temperature, it was quantitatively reconverted to lactone **7**.

3,3-Diphenylphthalimidine (10a)

Freshly prepared, crude hydroxyamide **8** (10 g) was slowly added to 50 ml of cold (0°), concentrated sulfuric acid (50 ml), giving a dark red solution which was stirred at 0° for 3 h. The reaction mixture was poured onto ice. The resulting mixture was filtered and the solid washed well with water, then with ether to remove lactone **7**. The remaining crude hydrogen sulfate salt of lactam **10***a* was stirred with 20% aqueous sodium

[5]In n.m.r. descriptions: s = singlet, d = doublet, m = multiplet, and b = broad.

[6]We thank Dr. David Rosenthal for the mass spectral determinations, which were done at the Research Triangle Mass Spectrometry Center Supported by Special Facility Grant No. FR-00330-01, National Institutes of Health.

hydroxide for 2 h. The resulting precipitate was collected and treated with aqueous hydrochloric acid to give 4.05 g (38%) of the hydrogen chloride salt of lactam **10***a* which, after washing with ether to remove traces of lactone 7 still present, was stirred with aqueous sodium hydroxide solution for 1 h. The precipitate was collected to give lactam **10***a*, m.p. 105–109°. Two recrystallizations from acetonitrile afforded pure **10***a*, m.p. 125–126°; λ_{max} ($CHCl_3$): 3.03 (NH) and 5.97 μ (C=O); n.m.r. ($CDCl_3$): δ 6.82 (b, 1H, NH), 7.30–7.75 (m, 13H), and 7.75–7.95 p.p.m. (m, 1H).

Anal. Calcd. for $C_{20}H_{15}NO$: C, 84.18; H, 5.30; N, 4.91. Found: C, 84.02; H, 5.26; N, 4.93.

*2-Amino-3,3-diphenylphthalimidine (**10b**)*

A solution of γ-lactone **7** (2.0 g) and hydrazine (95%, 10 ml) was refluxed for 5 days. Hydrazide **9**, m.p. 105–107°, separated on cooling. On standing for 24 h at room temperature, the product had m.p. 115–117°. The odor of hydrazine was detected emanating from the sample and the i.r. spectrum was that of lactone **7**. Attempted crystallization of crude hydrazide **9** also led to lactone **7**. Compound **9** was therefore used immediately upon isolation without further purification.

Freshly-prepared crude hydrazide **9** (from 2 g lactone **7**) was stirred with concentrated sulfuric acid to 0° for 6 h. The solution was poured onto ice, and the crude aminolactam **10***b* was recrystallized twice from ethanol to give 0.42 g (20%) of pure **10***b*, m.p. 174.5–176° decomp.; λ_{max} ($CHCl_3$): 2.90, 3.00 (NH_2), and 5.95 μ (C=O); n.m.r. ($CDCl_3$): δ 3.95 (b, 2H, NH_2), 7.0–7.3 (m, 13H), and 7.7–8.0 p.p.m. (m, 1H); mass spectrum, *m/e* (relative intensity): 300 (67), 223 (100), 130 (11).

Anal. Calcd. for $C_{20}H_{16}N_2O$: C, 79.98; H, 5.37; N, 9.33. Found: C, 79.97; H, 5.07; N, 9.27.

*2-Amino-3-phenylphthalimidine (**12**)*

A solution of 10 g of 3-phenylphthalide (4) (**11**) in hydrazine (95%, 20 ml) was refluxed for 4 days. The reaction mixture was cooled overnight to give 0.5 g of white needles, m.p. 150–155°. Two recrystallizations from ethanol gave 0.4 g (4%) of pure **12**, m.p. 155–156°; λ_{max} ($CHCl_3$): 2.90, 3.00 (NH_2), and 5.94 μ (C=O); n.m.r. ($CDCl_3$): δ 3.83 (b, 2H, NH_2), 5.47 (s, 1H, ArCH), and 7.0–8.0 p.p.m. (m, 9H).

Anal. Calcd. for $C_{14}H_{12}N_2O$: C, 74.99; H, 5.38; N, 12.49. Found: C, 75.05; H, 5.10; N, 12.65.

The original reaction mixture was evaporated to an oil. The i.r. spectrum of the residue was indistinguishable from that of lactone **7**.

Reactions of 3,4-Dihydroisocoumarins with Potassium Amide

These δ-lactones (2) were converted to δ-hydroxyamides in the following manner. A solution of the lactone (1 equivalent) in dry THF was added to a solution of potassium amide (4 equivalents) prepared from potassium (4 equivalents) in liquid ammonia (200–300 ml) under dry nitrogen. The ammonia was removed under dry nitrogen, additional dry THF was then added, and the resulting mixture was stirred overnight. The reaction mixture was poured into iced concentrated hydrochloric acid. The product was collected by filtration and recrystallized.

*A. 2-(β,β-Diphenyl-β-hydroxy)ethylbenzamide (**14**)*

This compound was prepared from 4.5 g (0.015 mole) of δ-lactone **13** and 0.06 mole of potassium amide in 250 ml (total volume) of dry THF. The crude product was recrystallized from benzene–heptane to give 3.27 g (69%) of hydroxyamide **14**, m.p. 132–135° decomp. Two additional crystallizations from benzene–heptane gave the analytical sample of **14**, m.p. 134–135° decomp.; λ_{max} ($CHCl_3$): 2.87 (sh), 2.96 (sh), 3.03 (NH_2 and OH), and 6.06 μ (amide C=O); n.m.r. ($CDCl_3$): δ 3.72 (s, 2H, $ArCH_2$), 6.1–6.4 (b, 2H, NH_2), 6.72 (b, 1H, OH), 7.0–7.6 (m, 14H); mass spectrum, *m/e* (relative intensity): 317 (7), 300 (2), 223 (2), 183 (28), 135 (100), 119 (21), 118 (22), 91 (6), 90 (4), 77 (4), metastable peaks, m* (parent, daughter), 283.9 (317, 300), 105.6 (317, 183), 103.1 (135, 118), 69.6 (119, 91), 68.6 (118, 90), 57.5 (317, 135).

Anal. Calcd. for $C_{21}H_{19}NO_2$: C, 79.47; H, 6.03; N, 4.41. Found: C, 79.55; H, 5.97; N, 4.24.

*B. 2-(1-Hydroxycyclohexyl)methylbenzamide (**18**)*

This compound was prepared from 10.80 g (0.05 mole) of lactone **17** and 0.20 mole of potassium amide in 250 ml (total volume) of dry THF. Crude hydroxyamide **18** (10.05 g, 82%), m.p. 182–183° decomp., was recrystallized twice from acetonitrile to give the analytical sample, m.p. 184–185° decomp.; λ_{max} ($CHCl_3$): 2.89 (sh), 2.96 (sh), 3.04 (NH_2 and OH), and 6.05 μ (amide C=O); mass spectrum, *m/e* (relative intensity): 233 (2), 216 (8), 173 (7), 160 (8), 135 (100), 119 (35), 118 (35), 99 (2), 91 (10), 90 (5), 81 (4), 77 (3), metastable peaks, m* (parent, daughter), 200.2 (233, 216), 118.5 (216, 160), 104.9 (135, 119), 103.1 (135, 118), 78.2 (233, 135), 69.6 (119, 91), 68.6 (118, 90).

Anal. Calcd. for $C_{14}H_{19}NO_2$ (mol. wt. 233.1416): C, 72.07; H, 8.21; N, 6.00. Found (mol. wt. 233.1415, mass spectrum): C, 72.44; H, 8.14; N, 5.91.

*C. 2-(β-Hydroxy-β-phenyl)ethylbenzamide (**23**)*

This compound was prepared from 2.24 (0.01 mole) of lactone **22** and 0.04 mole of potassium amide in 150 ml (total volume) of dry THF. Crude hydroxyamide **23** (1.85 g, 78%), m.p. 145–147° decomp., was recrystallized 3 times from acetonitrile to give the analytical sample of **23**, m.p. 149–150° decomp.; λ_{max} ($CHCl_3$): 2.84 (sh), 2.97 (sh), 3.03 (NH_2 and OH), and 6.06 μ (amide C=O); mass spectrum, *m/e*, (relative intensity): 241 (1), 224 (2), 178 (2), 146 (1), 135 (100), 119 (34), 118 (31), 107 (4), 105 (3), 91 (10), 90 (6), 77 (8), 51 (6), metastable peaks, m* (parent, daughter), 208.2 (241, 224), 104.9 (135, 119), 103.1 (135, 118), 75.6 (241, 135), 69.6 (119, 91), 68.6 (118, 90).

Mol. Wt. Calcd. for $C_{15}H_{15}NO_2$: 241.1103. Found: 241.1104.

*N-[2-(β,β-Diphenyl-β-hydroxy)ethyl]benzoyl Acetone Hydrazone (**15**)*

A solution of 5 g of lactone **13** in 20 ml of hydrazine (95%) was refluxed for 3 days. The reaction mixture was evaporated at reduced pressure to leave an oil. Acetone (50 ml) was added to precipitate 2.8 g (45%) of the crude acetone derivative **15**, which was collected by filtration. This compound, m.p. 232–234° decomp., was washed well with benzene and acetonitrile, and a sample recrystallized from chloroform to give the analytical sample

For personal use only.

of **15**, m.p. 242–244° decomp., λ_{max} ($CHCl_3$): 3.16 (NH) and 6.15 μ (C=O).

Anal. Calcd. for $C_{24}H_{24}N_2O_2$: C, 77.39; H, 6.50; N, 7.21. Found: C, 76.94; H, 6.58; N, 7.17.

Cyclodehydration of δ-Hydroxyamides

The compound was dissolved in 25 ml of concentrated sulfuric acid that had been cooled to 0°. The solution was stirred for 3 h at 0° and then poured onto ice. The product was isolated as described below.

A. 3,3-Diphenyl-3,4-dihydroisocarbostyril (16a)

Crude δ-lactam **16***a*, prepared from 2.38 g (0.075 mole) of δ-hydroxyamide **14**, was collected by filtration and recrystallized from acetonitrile to give 1.98 g (89%) of pure **16***a*, m.p. 243–245°; λ_{max} ($CHCl_3$): 2.98 (NH) and 6.05 μ (C=O); n.m.r. ($CDCl_3$): δ 3.28 (s, 2H, ArCH), 6.5–6.7 (b, 1H, NH), 7.3–7.5 (m, 13H), and 7.9–8.1 p.p.m. (m, 1H); mass spectrum, *m/e* (relative intensity): 299 (34), 271 (4), 270 (14), 223 (17), 222 (100), 204 (6), 203 (10), 195 (3), 194 (6), 179 (4), 178 (5), 165 (4), 119 (13), 118 (81), 104 (6), 90 (27), 89 (8), 77 (8), 57 (7), 55 (5), metastable peaks, m*, (parent, daughter), 269.0 (271, 270), 245.6 (299, 271), 187.5 (222, 204), 177.0 (179, 178), 171.2 (222, 195), 164.8 (299, 222), 144.3 (222, 179), 68.6 (118, 90), 57.0 (104, 77).

Anal. Calcd. for $C_{21}H_{17}NO$: C, 84.25; H, 5.72; N, 4.68. Found: C, 84.24; H, 5.71; N, 4.78.

B. 2-(2-Propylideneamino)-3,3-diphenyl-3,4-dihydroisocoumarin (16b)

Crude δ-lactam **16***b*, prepared from 1.75 g of δ-hydroxyhydrazide **15**, was collected by filtration and recrystallized 3 times from acetonitrile to give 0.90 g (53%) of analytically pure **16***b*, m.p. 197–199°; λ_{max} ($CHCl_3$): 6.06 μ (C=O); n.m.r. ($CDCl_3$): δ 1.82, 1.85 (2s, 6H, $2CH_3$), 3.77 (s, 2H, $ArCH_2$), 7.0–7.5 (m, 13H), and 7.7–8.1 p.p.m. (m, 1H).

Anal. Calcd. for $C_{24}H_{22}N_2O$: C, 81.32; H, 6.26; N, 7.90. Found: C, 81.38; H, 6.56; N, 7.90.

C. 2-(1-Cyclohexenyl)methylbenzamide (20)

δ-Lactam **19**, prepared from 9.1 g of δ-hydroxyamide **18** was apparently present as its hydrogen sulfate salt in the aqueous acidic solution. Extraction of the acidic solution with ether gave 0.95 g of a mixture of lactone **17** and δ-hydroxyamide **18**. The aqueous acidic solution was made basic with solid sodium hydroxide, and the resulting mixture was extracted with ether, dried, and evaporated. The residual oil (6.35 g, 75%) had λ_{max} (CCl_4): 3.06 (NH) and 6.14 μ. Attempted purification by distillation (>200°) gave the olefinic product **20**, which did not distil and solidified on cooling. Crystallization from carbon tetrachloride gave 5.25 g (70%) of pure **20**, m.p. 130–131°; λ_{max} ($CHCl_3$): 2.87, 2.97 (NH_2), and 6.02 μ; n.m.r. ($CDCl_3$): δ 1.4–2.2 (m, 8H, cyclohexyl protons), 3.47 (s, 2H, $ArCH_2C{=}C$), 5.28 (b, 1H, $CH_2C{=}CH{-}CH_2$), and 7.0–7.7 p.p.m. (m, 4H); mass spectrum, *m/e* (relative intensity): 215 (100), 198 (57), 172 (35), 170 (15), 135 (75), 119 (27), 118 (24), 91 (14), 81 (21), metastable peaks, m* (parent, daughter), 197.0 (199, 198), 182.3 (215, 198), 170.0 (172, 171), 169.0 (171, 170), 137.6 (215, 172), 104.9 (135, 119), 103.1 (135, 118).

Anal. Calcd. for $C_{14}H_{17}NO$: C, 78.10; H, 7.96; N, 6.51. Found: C, 78.38; H, 7.85; N, 6.39.

Reaction of δ-Lactone 13 with Lithium Methylamide

n-Butyllithium (34 ml of 2.35 *M*, 0.08 mole) in hexane[7] was slowly added to a solution of methylamine (*ca.* 40 ml) in dry THF (100 ml) under nitrogen and the excess amine was then removed under nitrogen. A solution of 6.0 g (0.02 mole) of lactone **13** in dry THF (100 ml) was added and the resulting mixture was stirred at reflux overnight. The crude mixture was cooled and poured onto iced concentrated hydrochloric acid. The precipitate was collected and recrystallized from 95% ethanol to give 4.5 g (66%) of δ-hydroxyamide **25**, m.p. and mixture m.p. 190–191° (lit. (2), m.p. 190–191°); mass spectrum, *m/e* (relative intensity): 331 (1), 283 (1), 183 (7), 182 (1), 149 (100), 148 (13), 134 (4), 119 (37), 118 (13), 105 (15), 91 (9), 90 (2), 77 (12), metastable peaks, m* (parent, daughter), 147.0 (149, 148), 120.5 (149, 134), 93.4 (149, 118), 60.5 (182, 105), 69.6 (119, 91).

N-Phenyl-2-(β,β-diphenyl-β-hydroxy)ethylbenzamide (26)

The mass spectrum of δ-hydroxyamide **26** was obtained on a sample prepared from *N*-phenyl-*o*-toluamide by a method similar to that previously described (2); mass spectrum, *m/e* (relative intensity): 393 (1), 300 (13), 283 (8), 223 (3), 211 (77), 194 (13), 183 (12), 119 (85), 118 (100), 105 (23), 93 (37), 91 (11), 90 (17), 77 (20), metastable peaks, m* (parent, daughter), 113.5 (393, 211), 66.0 (211, 118), 69.6 (119, 91), 68.6 (118, 90), 67.1 (211, 119).

Amination of tetrazoles with hydroxylamine-*O*-sulfonic acid: 1- and 2-aminotetrazoles

R. RAAP
R and L Molecular Research Ltd., 8045 Argyll Road, Edmonton 82, Alberta

Received March 17, 1969

1-Aminotetrazoles and 2-aminotetrazoles can be prepared by reacting tetrazoles with hydroxylamine-*O*-sulfonic acid in weakly alkaline aqueous solutions. The nuclear magnetic resonance spectra and some of the properties of these aminotetrazoles are described.

Canadian Journal of Chemistry, 47, 3677 (1969)

Of the aminotetrazoles, the 5-aminotetrazoles have received by far the most attention in the literature. The synthesis of 5-aminotetrazole itself was described as early as 1892 by Thiele (1). Only a few reports have been published on 1-aminotetrazoles. Stollé and co-workers (2) have prepared some 1-amino-5-aryltetrazoles and the hydrochlorides of 1,5-diaminotetrazole and 1-amino-5-hydrazinotetrazole. Recently Hagedorn and Winkelmann (3) described a synthesis of 1-aminotetrazole itself. As hydroxylamine-*O*-sulfonic acid had been successfully employed as a reagent for the amination of several substances, such as amines (4), alkylboranes (5), benzotriazoles (6), and benzoxazolin-2-one (7), we investigated its reaction with tetrazoles as a possible route to 1-aminotetrazoles and the (thus far) unknown 2-aminotetrazoles.

When a mixture of tetrazole and sodium carbonate in water was treated with hydroxylamine-*O*-sulfonic acid a 2:1 mixture of 1-aminotetrazole (**1***a*) and 2-aminotetrazole (**2***b*) could be isolated in a total yield of 38%. In the same manner were also prepared the compounds **2**–**5**. The isomers were separated by fractional distillation, fractional crystallization, or by elution chromatography on alumina or silica gel. The yields, some physical constants, and nuclear magnetic resonance (n.m.r.) data of the thus prepared *N*-aminotetrazoles are given in Table I.

The identity of **1***a* was confirmed by comparison with an authentic sample prepared by the procedure of Hagedorn and Winkelmann (3). The other isomer assignments are based on the difference in physical behavior and n.m.r. spectra of the isomer pairs. It has been shown that 2-substituted tetrazoles have lower boiling points and better solubilities in organic solvents than the corresponding 1-isomers (8–13) and with a few exceptions (10, 11, 13), the 2-isomers are also the lower melting ones. There have been several reports in the literature on the use of n.m.r. spectroscopy in assigning structural isomers (12–17, 23), and it has been clearly established that a *N*-substituent is more deshielded in the 2-isomer than in the corresponding 1-isomer. As Table I

*All the yields given refer to the actual isolated amount of pure isomer. The yields for compounds **2**, **3**, and **4** are based on unrecovered starting material (respectively 61, 67, and 71% of the starting materials were recovered). In the case of compounds **1** and **5** no attempt was made to recover starting material.

†The spectra were taken in DMSO-d_6, except for compounds 3*a* and 3*b* where $CDCl_3$ was used as solvent.

‡Some of the aminotetrazoles were analyzed in the form of a more stable derivative (Table II).

§Reported b.p. 118–120 (0.01 mm) (3).

‖Reported m.p. 155° (2*a*).

¶The furyl protons in 4*a* appeared as doublets at τ 1.92 (J = 2 c.p.s.) and 2.44 (J = 3.5 c.p.s.) and a quartet at τ 3.16; in 4*b* these τ values were 2.03, 2.81, and 3.25 respectively.

**The HCl salt decomposed at 175–176°; reported decomposition point 176° (2*b*).

††The HCl salt decomposed at 120°.

shows, there is indeed a substantial difference in chemical shift of the *N*-amino group between isomer pairs ($\Delta\tau$ 0.8–1.0). Compounds **1** and **5** also show the expected difference in chemical shift of the 5-hydrogen and the 5-amino group between two isomers (13, 14, 16).

Whereas heating 1-aminotetrazole with acetic anhydride results in ring opening and the formation of 2-acetylamino-1,3,4-oxadiazole (3), 1-amino-5-phenyltetrazole under these conditions gives 1-diacetylamino-5-phenyltetrazole (2*c*). 1,5-Diaminotetrazole upon heating with acetic anhydride gave a triacetyl derivative, believed to be 5-acetylamino-1-diacetylaminotetrazole as 5-amino-tetrazoles are reported to give only the monoacetylated derivatives under these conditions (17–19). Both the 1- and 2-aminotetrazoles could readily be condensed with aromatic aldehydes. The derivatives thus prepared are listed in Table II. In the case of the diaminotetrazoles the question arose which of the two amino groups reacted; from the position of the amino signals in the n.m.r. spectra (Table III) it could be concluded, however, that the 1- and 2-amino groups underwent reaction in preference to the 5-amino group.[1]

The explosive character of 1-aminotetrazole has already been mentioned (3). The 2-aminotetrazoles appear to be distinctively more explosive than their corresponding 1-isomers, and 2-aminotetrazole and 2,5-diaminotetrazole especially were able to produce devastating explosions.[2] Great care should therefore be exercised in handling the lower members of the *N*-aminotetrazoles. Aryl substitution, and to a lesser extent also alkyl substitution, appears to stabilize the *N*-aminotetrazoles considerably.

[1]Another indication of the higher reactivity of the 1-amino group over the 5-amino group was obtained when an equimolar mixture of 1-amino-5-*n*-propyltetrazole and 5-amino-1-*n*-propyltetrazole was allowed to react with only 0.5 equivalent of anisaldehyde (THF, room temperature). The only product isolated was 1-*p*-methoxybenzylideneamino-5-*n*-propyltetrazole (67% yield) whereas 76% of the 5-amino-1-*n*-propyltetrazole was recovered.

[2]Even a 4 mg sample of 2-aminotetrazole produced a very loud explosion when rapidly heated to 250–300°. 2,5-Diaminotetrazole not only detonated upon impact but when a small sample in a capillary tube was rapidly heated in a pre-heated Gallenkamp melting point apparatus, it detonated already at 210°, with sufficient force to break the bulb of the thermometer. With 1,5-diaminotetrazole on the other hand, no detonation could be affected.

Experimental

All melting points and boiling points are uncorrected. The n.m.r. spectra were measured using a Varian Associates model A-60 spectrometer with tetramethylsilane as a reference. Microanalyses were performed by Dr. G. Weiler and Dr. F. B. Strauss, Microanalytical Laboratory, Oxford, England.

Tetrazoles

The tetrazoles were prepared by literature procedures. Tetrazole itself was obtained by a reductive deamination of 5-aminotetrazole (9, 20) which in turn was obtained from dicyandiamide (21). 5-*n*-Propyltetrazole and 5-phenyltetrazole were prepared by the procedure of Finnegan *et al.* (22) from propionitrile and benzonitrile respectively. In the same manner 5-(2′-furyl)tetrazole, m.p. 198–200° (decomp.), could be prepared from 2-furylcyanide (92% yield).

Anal. Calcd. for $C_5H_4N_4O$: C, 44.12; H, 2.96; N, 41.16. Found: C, 44.26; H, 3.11; N, 40.98.

N-Aminotetrazoles

These were all prepared by essentially the same procedure, the only difference being in the work-up. The procedure is illustrated by the preparation of 1-aminotetrazole (**1***a*) and 2-aminotetrazole (**1***b*) as follows. Tetrazole (28.0 g, 0.40 mole) and sodium carbonate (46.4 g, 0.44 mole) were dissolved in 300 ml of water and the resulting mixture was heated to 75°. A solution of hydroxylamine-*O*-sulfonic acid (54.4 g, 0.48 mole) in 240 ml of water was added dropwise, with stirring, over a period of 20 min, the temperature of the reaction mixture being kept at 70–75°. Throughout the reaction a pH of 7–8 was maintained by the periodic addition of a saturated aqueous sodium bicarbonate solution. When the addition was completed the reaction mixture was heated under reflux for 20–30 min. After cooling the mixture was adjusted to pH 8 and then continuously extracted with ethyl acetate for 16 h. The ethyl acetate extract was dried and concentrated. The colorless residual oil was distilled *in vacuo* to give 4.3 g (13%) of 2-amino-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

tetrazole, b.p. 89–91° (0.3 mm). The distillation residue consisted of only 1-aminotetrazole (8.4 g, 25%) which could be distilled only in small quantities without appreciable decomposition, b.p. 137–142° (0.7 mm); reported b.p. 118–120° (0.01 mm) (3). The infrared and n.m.r. spectra of 1-aminotetrazole were superimposable with the corresponding spectra of an authentic sample (3).

The *N*-amino-5-*n*-propyltetrazoles **2***a* and **2***b* were prepared in the same manner. When after continuous extraction of the products with ethyl acetate the solution was acidified and again continuously extracted with ethyl acetate, 61% of 5-*n*-propyltetrazole being recovered. In the preparation of **3** and **4**, the products were extracted with 3–6 portions of ethyl acetate, then the reaction mixture was acidified to give respectively 67 and 71% of unreacted starting material. Isomers **3***a* and **3***b* were separated by elution chromatography on alumina; **3***b* was eluted with a 1:1 benzene – ether mixture, **3***a* was eluted with ether. Isomers **4***a* and **4***b* were separated by recrystallization of the crude mixture from ethyl acetate, which provided pure **4***a*; the residue obtained from the filtrate was then chromatographed on alumina and **4***b* eluted with a 1:1 ether – ethyl acetate mixture. The diaminotetrazoles **5***a* and **5***b* were isolated by continuous extraction with ethyl acetate. The extract was dried, concentrated, and cooled. The precipitated 1,5-diaminotetrazole was then recrystallized from water. The residue obtained from the filtrate was chromatographed on silica gel and 2,5-diaminotetrazole eluted with ethyl acetate. The yields, physical constants, n.m.r. spectra, and analytical data are listed in Table I.

1-Diacetylamino-5-phenyltetrazole

A mixture of 1-amino-5-phenyltetrazole (0.35 g, 2.17 mmole) and acetic anhydride (5 ml) was heated under reflux for 4 h. Removal of the excess acetic anhydride and recrystallization of the residue from methanol gave 0.42 g (79%) of product, m.p. 88–89°; reported m.p. 90° (2*c*). The n.m.r. spectrum ($CDCl_3$) contained a multiplet at τ 2.0–2.4 and a sharp singlet at τ 7.62 with an integrated area ratio of 5:6.

Anal. Calcd. for $C_{11}H_{11}N_5O_2$: C, 53.87; H, 4.52; N, 28.56. Found: C, 53.95; H, 4.53; N, 28.80.

5-Acetylamino-1-diacetylaminotetrazole

A mixture of 1,5-diaminotetrazole (0.40 g, 4.0 mmole) and acetic anhydride (6 ml) was heated under reflux for 2 h. The mixture was cooled and the white crystalline product, m.p. 186–188° (decomp.), collected by filtration. Yield, 0.48 g (53%). The n.m.r. spectrum (DMSO-d_6) contained singlets at τ 7.65 and 7.78 with an integrated area ratio of 2:1.

Anal. Calcd. for $C_7H_{10}N_6O_3$: C, 37.16; H, 4.46; N, 37.15. Found: C, 37.18; H, 4.36; N, 36.91.

Reaction of N-Aminotetrazoles with Aldehydes

Equimolar amounts of the aminotetrazole and the aldehyde were dissolved in benzene, tetrahydrofuran, or dimethylformamide, depending on the solubility of the aminotetrazole. A trace of *p*-toluenesulfonic acid was added and the reaction mixture was left at room temperature overnight. The product was isolated by removal of the solvent and recrystallization of the residue or by the addition of ether to the tetrahydrofuran or dimethylformamide solutions. In many instances the product crystallized from the reaction mixture. The yields amounted to 50–90%. The derivatives prepared are listed in Table II.

Permanganate–periodate oxidation. Part VIII. The oxidation of some cyclic mono-olefins and monoterpenes[1]

T. SUGA[2] AND E. VON RUDLOFF
Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received November 5, 1968

The reaction of cyclic mono-olefins with the permanganate–periodate reagent was investigated. 4-Terpinenol and its acetate, and to a lesser degree α-terpineol and camphene gave in addition to the expected products, several neutral and acidic products. In contrast, α-pinene, β-pinene, sabinene, pulegone, and several cyclo-olefins which can be considered as simple analogues of these monoterpenes, afforded the predicted products in high yield. Cyclo-hexanone and menthone, though saturated, were oxidized extensively, enolization offering a plausible pathway for this result. Saturated terpene alcohols reacted only very slowly indicating that attack at a tertiary hydrogen is not a significant part of the permanganate–periodate reaction.

Introduction

Recently we have shown that the common acyclic monoterpenes may be oxidized by the permanganate–periodate reagent in high yield to predicted end products (1). In a preliminary experiment it was found that α-terpineol did not give a high yield of the expected product, homoterpenyl methyl ketone. In view of this, and of the different behavior of some dienes as reported recently by Klein and Rojahn (2), Apsimon *et al.* (3), and von Rudloff (4), the oxidation of some cyclic monoterpenes and related cyclo-olefins was studied with the specific purpose of determining whether or not the cyclic mono-olefins, and in particular monoterpenes, would react as predicted with the permanganate–periodate reagent.

Daly and co-workers (5) have employed the reagent in a preparative oxidation of sabinene to yield sabina ketone. We reported briefly (6) on the excellent yields of sabina ketone and nopinone which may be obtained from sabinene and β-pinene respectively, and that the oxidation proceeds at a satisfactory rate in aqueous suspension. Our previous studies (1, 7–12) have shown that the oxidation of an olefinic double bond proceeds in a predictable manner, involving hydroxylation of the double bond by a permanganate ion (via a π complex and hypomanganate ester (13) (see also Wiberg and Geer (14)), followed by periodate cleavage of the diol or ketols thus formed, and subsequent slower oxidation of the resulting aldehydes. Ketones and esters were found to be stable towards the reagent (at pH 7 to 8), whereas alcohols reacted slowly (12). With water-insoluble olefins good results were obtained when the reaction was carried out in aqueous *tert* butyl alcohol solutions (10–50%) (1, 11, 12).

In a few instances, the reaction with mono-olefins did not proceed to the predicted end products. Thus Lin and Cheng (15) reported that 1-cyclopentene-, 1-cyclohexene-, and 1-cycloheptene-carboxylic acids were oxidized to the next lower dicarboxylic acid rather than the expected keto-dicarboxylic acids. We found that carboxylic acids, including pyruvic acid, are not oxidized, although malonic acid was degraded slowly (12). In the same study we found that tetrahydrofurfurol was oxidized to succinic acid rather than to tetrahydro-2-furoic acid. Thus, in certain instances at least, over-oxidation of the type reported by Lin and Cheng must be considered as a possible side reaction.

Experimental

All compounds investigated were of commercial origin (Aldrich Chemical Co., unless otherwise stated). Sabinene was isolated from the oil of Savin (16). If the purity was satisfactory (see Tables I and II) these compounds were used as such. Impure ones were purified as described.

The purity of the starting materials was determined by gas–liquid chromatography (g.l.c.), employing temperature-programming or isothermal conditions and a flame ionization detector. Stainless steel columns, 0.3 cm outer diameter and 2–3 m long, and helium flow rates of 25–40 ml per min were employed. Of the many liquid phases and solid supports tested, polyethyleneglycol (Carbowax 20 *M*, 2%) on Porasil D, 100–150 mesh (17) was found to give the highest degree of separation of cyclo-olefins. For the oxygenated terpenes a standard 5% polyethylene

For personal use only.

glycol column on Aeropak 30, 70–80 mesh (1, 18) was employed. The quantitative area measurements were obtained with a model 471 Varian Aerograph digital integrater. No correction factors were applied. The standard run was from 55° to 200° at 4° per min (18), but for the lower boiling olefins, a lower starting temperature (40°–50°) and lower rate of heating (2° per min) or isothermal conditions were employed.

Melting points were recorded on a Leitz hotstage microscope and these are uncorrected. Infrared (i.r.) spectra were obtained as films between sodium chloride plates or as potassium bromide disks, using a Perkin–Elmer model 21 double beam spectrophotometer. Nuclear magnetic resonance (n.m.r.) spectra were obtained in carbon–tetrachloride solution with tetramethylsilane as internal standard, using a Varian model HA-100 MHz spectrometer.

The quantitative and preparative oxidation procedures were described in detail previously (1, 7, 12). Tables I and II list the purity of the starting materials as determined by g.l.c., the amount of *tert* butyl alcohol used, the results obtained after 1, 6, 24, 144, and 196 h reaction time (the data obtained after 0.5, 2, 3, 48, 72, 96, and 120 h are not included), as well as the products obtained in the preparative oxidations. Neutral products were recovered by extracting the oxidation mixture with ether and removing the solvents as far as possible by fractional distillation. The weakly alkaline aqueous residue was evaporated to a small volume, the distillate being used for formaldehyde determination by the chromotropic acid method (8). The residual aqueous concentrate was acidified and extracted continuously (1–5 days) with ether to recover the acidic oxidation products. A small aliquot was methylated by the addition of freshly distilled diazomethane (best results were obtained by passing the vapors into a concentrated solution of the acidic product) and the resulting methyl esters were analyzed by g.l.c. (5% SE-30). The balance of the acidic product was used for recrystallization or the preparation of suitable crystalline derivatives. The experimental data for those compounds which gave the expected products in high yield have been placed into the Depository of Unpublished Data.[3]

Allyl Cyclohexane

The commercial sample was found to have a purity of 99.9% by g.l.c. (see, however, below). Preparative oxidation (248 mg, 2 mmoles; 20% *tert* butyl alcohol, 24 h) gave formaldehyde and a liquid acidic product (222 mg, 78%, ν_{max} (liquid) 1703, 1293, and 929 cm^{-1}), the methyl ester of which showed only a single peak with the retention time of the methyl ester of cyclohexane acetic acid. The identity was confirmed by conversion to the amide, m.p. 169–170° (lit (19) m.p. 169–171°). In a repeat experiment the neutral fraction (mainly *tert* butyl alcohol) was analyzed by g.l.c. and a peak with the retention time of allyl cyclohexane was recorded. Fractional distillation gave a small amount of a saturated hydro-carbon which had an i.r. spectrum that differed from that of allyl cyclohexane, but *tert* butyl alcohol was an impurity.

(±)-Camphene

The commercial sample (Lights and Co., England) was purified by preparative g.l.c. to give 98.0% pure camphene. Preparative oxidation (544 mg, 4 mmoles, 5–10% *tert* butyl alcohol, 24 h) afforded a neutral (530 mg) and an acidic (12 mg) product. Analysis by g.l.c of the neutral product showed the presence of *tert* butyl alcohol, unchanged camphene, and a major peak with the retention time of camphenilone. The identity of camphenilone was confirmed by conversion to the crystalline semicarbazone, m.p. and mixed m.p. 221.5–223° (lit. (20) m.p. 224°).

Anal. Calcd. for $C_{10}H_{17}N_3O$: C, 61.51; H, 8.78; N, 21.52. Found: C, 61.52; H, 8.77; N, 22.0.

When the reaction was carried out in 30% *tert* butyl alcohol solution, virtually all the camphene reacted but in addition to camphenilone, a neutral compound of much higher retention time (not the same as the derived diol or ketol) and a larger amount of acidic products were obtained.

α-Terpineol

The commercial sample (Eastman Organic Chemical) was found to be 98.6% pure; m.p. 33.5–34.5°. In the preparative oxidation (310 mg, 2 mmoles; 10% *tert* butyl alcohol, 48 h) the neutral product (247 mg, 67%) was extracted with chloroform instead of with ether. Although the i.r. spectrum, ν_{max} (liquid) 1760 cm^{-1} (γ-lactone) and 1708 cm^{-1} (carbonyl), was in good agreement with that of homoterpenyl methyl ketone, g.l.c. analysis showed that at least 3 major and 3 minor impurities as well as some unchanged α-terpineol were present. The retention times of the major impurities (5% SE-30 at 120°; 8.7, 10.5, and 11.5 min) were higher than that of α-terpineol (3.5 min) but lower than that of homoterpenyl methyl ketone (18.0 min). Homoterpenyl methyl ketone semicarbazone, m.p. and mixed m.p. 204.5–205.5°, was obtained in fairly good yield from the crude product. A small amount of an acidic product (74.2 mg) was also isolated. The chromatogram of the derived methyl esters showed 4 major and 12 minor peaks.

α-Terpinyl Acetate

Commercial α-terpineol was acetylated by heating under reflux with a 6-fold amount of acetic anhydride, an equal amount of sodium acetate, and a 15-fold amount of xylene for 12 h. Crude α-terpinyl acetate was purified by fractional distillation, b.p. 78–78.5° (1 mm), n_D^{25} 1.4621, 95% (g.l.c.).

Preparative oxidation (400 mg, 2.04 mmole; 10% *tert* butyl alcohol, 72 h) gave a small amount of neutral product (24 mg) and a liquid acidic product (489 mg, 98.5% based on the assumption of it being the expected acidic product). The neutral product showed at least 8 peaks in g.l.c. analysis, one of which corresponded to α-terpinyl acetate. Analysis by g.l.c. of the derived methyl esters of the acidic product showed one major peak (95%) and a broad tail (3–5%), indicating an impurity or decomposition. The acidic product was hydrolyzed with sodium ethoxide in excess ethanol. On acidification a neutral product was obtained which had an i.r. spectrum that was superimposable with that of homoterpenyl

methyl ketone. The melting point of the derived semicarbazone, m.p. 202.5–204.5° was undepressed in admixture with the authentic specimen. This confirmed that the oxidation product from α-terpinyl acetate was the acetate of homoterpenyl methyl ketone.

4-Terpinenol

The commercial sample (Lights and Co., England) was found to be 98.5% pure. Preparative oxidation (616 mg, 4 mmoles; 10% *tert* butyl alcohol, 6 h) gave a neutral (62.8 mg) and an acidic (426.7 mg) product. The neutral product showed 5 peaks with higher retention times than 4-terpinenol, and the derived methyl esters of the acidic product 1 major and 10 minor peaks. The spectrum of the crude acidic product ν_{max} (liquid) 1718, 1285, 1205, and 918 cm^{-1} (COOH), confirmed that the major product was a keto acid but no crystalline semicarbazone or 2,4-dinitrophenyl hydrazone could be obtained.

4-Terpinenyl Acetate

This acetate was prepared from 4-terpinenol in the same manner as α-terpinyl acetate (see above); b.p. 71–73° (1.3 mm), n_D^{25} 1.4623; 95% (g.l.c.). Preparative oxidation (785 mg, 4 mmoles; 10% *tert* butyl alcohol, 6 h) afforded a small amount of a neutral product (27.3 mg) and a liquid acidic product (416 mg); g.l.c. analysis of the derived methyl esters showed it to be composed of 3 major and 4 minor components. The i.r. spectrum of the sodium salts, ν_{max} (KBr) 1735 ($OCOCH_3$), 1707 (CO), 1566 and 1398 cm^{-1} ($COO^{\ominus}$) confirmed that the acetate of a keto acid was present, but no crystalline derivatives were obtained.

Results and Discussion

The amounts of oxidant consumed by the cyclic olefins at different reaction times are shown in Table I. Cyclopentene, cyclohexene, the methyl substituted derivatives, and 1-methyl cycloheptene, as well as the cyclohexanes with exocyclic double bonds all reacted in the expected manner and the predicted end products were isolated in high yield. The 1-methyl cyclo-olefins reacted more slowly than the other cyclo-alkenes. Allyl cyclohexane consumed less than the calculated 5 atoms of oxygen per mole and cyclohexane acetic acid was obtained in only about 78% yield. A saturated impurity having the same retention time on the PEG-Porasil column as allyl cyclohexane was found to be present and this can account for the low results obtained. Similarly, 4-vinyl cyclohexene afforded only a 58% yield of the expected butane-1,2,4-tricarboxylic acid.

Several oxygenated cyclohexane derivatives were also oxidized (see Table I). As expected (7, 12) cyclohexanol, cyclohexane–methanol and cyclohexene oxide consumed oxidant only at a very slow rate. Cyclohexanone consumed very little oxidant during the first 6 h, but thereafter a steady increase was measured, which reached the equivalent of 2.60 atoms of oxygen per mole of cyclohexanone after 7 days. Hence, it appeared that cyclohexanone enolized under conditions which did not produce any oxidation with aliphatic ketones (12). Once a double bond is formed, one would expect hydroxylation, cleavage, and further oxidation to proceed in the normal manner. It was confirmed that enolization is involved by employing one-half and twice the normal concentration of potassium carbonate, when a corresponding decrease and increase in the rates of oxidation was obtained (see Table I). 2-Cyclohexen-1-ol consumed the calculated amount of oxidant in about 3 days and the predicted end product, glutaric acid, was obtained in 98% yield. Similarly, the oxidation of 3-cyclohexene-1-carboxylic acid proceeded as expected. This is in contrast to the results reported by Lin and Cheng for the oxidation of 1-carboxyl cyclo-olefins (15), but the latter must be considered a special case because of the conjugated nature for the double bond.

The results obtained in the oxidation of some cyclic monoterpenes are shown in Table II. (−)-α-Pinene was oxidized smoothly to (−)-pinonic acid. The almost quantitative oxidation of β-pinene and sabinene to nopinone and sabina ketone respectively employing the aqueous reagent (6) was confirmed. It is noteworthy that the retentions of nopinone and sabina ketone differ considerably on most g.l.c. columns, whereas β-pinene and sabinene are not easily separated. The facile oxidation of the latter to the corresponding ketones offers a convenient method for detecting one terpene in the other.

Camphene did not react appreciably with the aqueous reagent, presumably because this terpene is a solid at room temperature. The reaction proceeded only at a satisfactory rate when 30% *tert* butyl alcohol was added. The expected product, camphenilone, was obtained in only about 50% yield. In addition to this, a mixture of acidic products and at least one higher boiling neutral compound was formed. Upon reducing the *tert* butyl alcohol content of the reaction mixture, the relative yield of camphenilone increased but the amount of camphene which reacted was reduced. Hence it appears that the presence of *tert* butyl alcohol tends to increase side-reaction and undesirable by-products.

α-Terpineol was oxidized to the predicted homoterpenyl methyl ketone, but g.l.c. analysis of the neutral fraction showed the presence of 3

major and 3 minor compounds. The formation of additional neutral products cannot be explained by over-oxidation, as the amount of oxidant consumed did not exceed the theoretical to any appreciable extent (see Table II). Hence, the possibility of the introduction of hydroxyl groups at tertiary hydrogen atoms by reaction with permanganate as reported by Eastman and Quinn (21) was investigated. Dihydro-α-terpineol, menthol, borneol, and isoborneol were oxidized under the same conditions. These saturated alcohols consumed oxidant at a very low rate (see Table II). Hence, any oxidation of a tertiary hydrogen with the permanganate–periodate reagent proceeds at such a slow rate, if at all, that it cannot account for the formation of the additional neutral products in the reaction with α-terpineol. When α-terpinyl acetate was oxidized, both the rate of oxidation (Table II) and the high yield of a single acidic product, which gave homoterpenyl methyl ketone on hydrolysis and acidification, indicated that the typical route of permanganate–periodate oxidation was followed. It appears likely that the side reactions encountered with α-terpineol are not of a general nature, but rather arise from some specific property of this terpene alcohol. This concept was strengthened by the results obtained in the oxidation of 4-terpinenol and its acetate. Not only did both mono-olefins consume more than the calculated amount of oxidant (Table II, 4.1 and 4.5 respectively instead of 3.0 atoms of oxygen per mole), but both gave a rather large number of neutral and acidic products. With these two terpenes it is possible that a reactive methylene group is produced which is oxidized further and may thus lead to a variety of products. Also, one cannot rule out the formation of oxides, as found by Klein and Rojahn (2) in the permanganate oxidation of 1,5-dienes, by Apsimon *et al.* (3) in the oxidation of methyl pimarate, and by us (4) in the oxidation of occidentalol.

When the oxidation of menthone was carried out with different amounts of potassium carbonate, similar results (Table II) as those with cyclohexanone were obtained (see Table I). Hence, enolization may play a considerable role with saturated cyclic ketones unless the pH is kept below 7.5. The reaction with pulegone proceeded in the typical manner and a high yield of the predicted product, 3-methyl adipic acid, was obtained. Therefore, the hydroxylation of the double bond and subsequent cleavage of the diols and ketols produced proceeds rapidly and without any significant side reaction with a conjugated ketone.

It may be concluded that most cyclic mono-olefins react with the permanganate–periodate reagent as predicted to give high yields of the expected products. However, the side-reactions encountered with 4-terpinenol and its acetate, and to a lesser extent with α-terpineol and camphene, indicate that with certain monoterpenes random degradation may take place to such a large degree that the reagent cannot be used for analytical purposes. The facile enolization of the saturated cyclic ketones is a factor which must also be considered when the reagent is applied in terpene analysis.

Conformational dependence of long-range spin-spin coupling constants in 2,6-dichlorobenzylfluoride

T. SCHAEFER, C. M. WONG, AND K. C. TAM
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received April 17, 1969

Double resonance experiments on the proton magnetic resonance spectrum of 2,6-dichlorobenzylfluoride yield the signs of the long-range coupling constants between the ring protons and the fluorine nuclei and protons in the fluoromethyl group. The signs and magnitudes of the long-range couplings are discussed in terms of their dependence on the conformation of the fluoromethyl group.

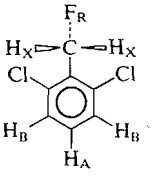
Spectral Parameters of 2,6-Dichlorobenzylfluoride

At 60 MHz the proton magnetic resonance spectrum of an approximately 10 mole % solution of 2,6-dichlorobenzylfluoride, **1**, in benzene-d_6 is the AB_2X_2 part of an AB_2X_2R spectrum in which rapid rotation of the fluoromethyl group



1

ensures the observation of equal coupling from the X_2 protons to the B_2 and A protons, respectively. The properties of such a spectrum are well known (1). However, the AB_2 part is not coupled tightly enough to allow the determination of the relative signs of the long-range couplings from any observed asymmetry in the X_2 resonance peaks (1). Consequently, a series of double resonance experiments under conditions of weak irradiation (2, 3) were performed. In conjunction with the usual analytical procedure (1), these experiments gave the following spectral parameters, where the shifts are quoted in p.p.m. relative to internal tetramethylsilane and coupling constants are measured in Hz.

$$\nu_A = -6.690 \pm 0.003$$

$$\nu_B = -6.927 \pm 0.003$$

$$\nu_X = -5.392 \pm 0.003$$

$$J_{AB} \equiv J_o^{HH} = 8.14 \pm 0.05$$

$$J_{BX} \equiv J_m^{H,CH_2(F)} = 0.34 \pm 0.04$$

$$J_{AX} \equiv J_p^{H,CH_2(F)} = -0.16 \pm 0.02$$

$$J_{XR} \equiv J_g^{CH_2,F} = 47.5 \pm 0.10$$

$$J_{BR} \equiv J_m^{H,C(H_2)F} = 1.25 \pm 0.04$$

$$J_{AR} \equiv J_p^{H,C(H_2)F} = -2.43 \pm 0.02$$

The signs of the proton–proton coupling constants were determined relative to $J_{AB} \equiv J_o^{HH}$ and the signs of the proton–fluorine coupling constants were determined relative to $J_{XR} \equiv J_g^{CH_2,F}$. But J_o^{HH} and $J_g^{H,F}$ are both known to be positive (4, 5).

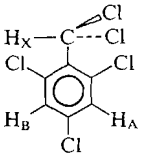
Conformational Dependence of the Long-range Couplings

Conformation of the Difluoromethyl Group

In the ensuing discussion it will be assumed that the most stable conformation of the fluoromethyl is as depicted in **1**, i.e., with the C—F bond directed perpendicular to the aromatic ring on an average. In this conformation steric interactions between the C—F and C—Cl bonds are at a minimum. From a study (6) of the barriers to rotation in α,α,2,6-tetrachlorotoluene it is known that a conformation in which a sidechain C—Cl bond eclipses the aromatic C—Cl bond is at least 12 kcal/mole less stable than a conformation in which these bonds are staggered. It is a reasonable assumption, therefore, that **1** is favored by at least 3 kcal/mole over a conformation in which the C—F bond eclipses a C—Cl bond. In that case the average population of **1** at room temperature is about 150 times as abundant as the eclipsed conformations. Naturally, near room temperature such a barrier will allow oscillations of substantial magnitude about the relevant C—C bond. However, calculations by Stone and Maki (7) suggest that for barriers as high as 3 kcal/mole the following discussion of coupling constants in terms of the rigid conformation **1** is valid to a very good approximation (7).

The Long-range Proton–Proton Couplings

$J_{BX} \equiv J_m^{H,CH} = 0.34$ Hz has the same magnitude within experimental error as the corresponding coupling in toluene (8), 2,6-dichlorotoluene[1] and benzaldehyde (9). From studies on α,α,2,6-tetrachloro- and α,α,2,6-pentachlorotoluene (6, 10) it is known that this five-bond coupling is conformation dependent. Thus in **2**, $J_m^{H_X,H_A} \approx 0.5$ Hz whereas $J_m^{H_B,H_X} < 0.10$ Hz, indicating a preponderant σ electron contribution to J_m^{H,CHX_2}.



2

However, there may also be a finite π contribution to this coupling when the C—H bond takes on a nonplanar conformation which allows hyperconjugation between the C—H bond and the π system of the ring. Therefore, although the σ contribution appears to decrease from a maximum at $\theta = 0°$ to a minimum at $\theta = 180°$ (θ is here the angle between the aromatic plane and the C—C—H plane), the functional form of this θ dependence is unknown. The magnitude of the π contribution for $0° < \theta < 180°$ to this coupling is also unknown. The two contributions can conceivably compensate in such a way as to lead to the same magnitude of $J_m^{H,CH}$ in the above compounds. Further discussion at this time seems inappropriate, particularly in view of the unknown effect of the fluorine substituent on this coupling.

If a negligible σ electron contribution to $J_p^{H,CH}$ is assumed and if the π electron contribution (11–13) is taken as proportional to $\cos^2 \psi$, where $\psi = 0$ corresponds to a conformation in which the C—H bond lies perpendicular to the aromatic plane and therefore to maximum overlap between the C—H bond and the π system (hyperconjugation); the observed $J_p^{H,CH} = -0.62$ Hz in toluene (8) leads to a predicted $J_p^{H,CH} = -1.2$ Hz when $\psi = 0$ (the methyl group rotates rapidly and $\langle \cos^2 \psi \rangle = 0.5$). In the conformation **1**, $\psi = 60°$ so that in **1**, $J_p^{H,CH} = -1.2 \times 1/4 = -0.3$ Hz; approximately twice the observed value of −0.16 Hz. When fluorine in the sidechain is replaced by larger groups of lower electronegativity, e.g. chlorine or methyl,[1] $J_p^{H,CH}$ approaches −0.3 Hz. This observation suggests that the electronegative fluorine atom polarizes the C—H bond, decreases electron density near the proton, and in terms of the simplest group molecular orbitals used to interpret hyperconjugative effects, leads to a less efficient transfer of electron spin polarization information from the π system to the region of the protons in the sidechain.

The Long-range Proton–Fluorine Couplings

$J_{BR} \equiv J_m^{H,CF} = 1.25$ Hz may be compared with the corresponding values of 1.33 Hz in benzoylfluoride and 0.82 Hz in benzotrifluoride (9). If benzoyl fluoride is planar similar remarks apply here as were made above for $J_m^{H,CH}$. Further discussion appears inappropriate.

$J_{AR} \equiv J_p^{H,CF} = -2.43$ Hz compares with the corresponding values of −0.02 Hz in benzoyl fluoride and −0.64 Hz in benzotriflouride (9). If a planar conformation is assumed for benzoyl fluoride and conformation **1** is assumed for 2,6-dichlorobenzylfluoride, arguments similar to those presented for $J_p^{H,CH}$ predict that $J_p^{H,CF} = -2.4 \times 1/2 = -1.2$ Hz in benzotrifluoride; twice the observed magnitude (the barrier to rotation in benzotrifluoride is so small (14) that $\langle \cos^2 \psi \rangle = 0.5$ can be assumed). Again, substitution of two more fluorine atoms may reduce the net hyperconjugation of the C—F bonds with the π system.

There is a need for coupling constant data on benzylfluoride itself and for 2,6-dichlorobenzalfluoride. The spectral analysis of the former is not a simple problem, whereas the synthesis of the latter compound is still being attempted in this laboratory.

Experimental

Preparation of 2,6-Dichlorobenzylfluoride

α-Bromo-2,6-dichlorotoluene (10 g), triethylamine (5 g), and absolute ethanol (5 ml) were mixed and stirred overnight at 50 °C in an oil bath under anhydrous conditions. The mixture was allowed to cool and then anhydrous ether (100 ml) was added to break up the cake formed. The supernatant was decanted through a filtering crucible and the precipitate was stirred with more anhydrous ether (2 × 50 ml). The precipitate was then dissolved in water (50 ml). The solution was stirred with a suspension of powdered silver oxide (10 g) for 1 h and then filtered. This process was repeated twice more. The final filtrate was neutralized with 20% hydrofluoric acid (approximately 4 ml) and concentrated on a steam bath to half of its original volume. The resulting solution was distilled under a water-pump vacuum (20 mm) from a

flask, equipped with a heating mantle, through a condenser into a flask cooled below 0 °C (ice–salt mixture). α-Fluoro-2,6-dichlorotoluene and other impurities were collected as a white solid. The distillate was then exhaustively extracted with ether (5 × 40 ml). The ether extracts were combined, dried (sodium sulfate), and concentrated into a foam (2.2 g). Chromatography (silica gel) of the residue gave a mixture of α-bromo-2,6-dichlorotoluene and α-fluoro-2,6-dichlorotoluene (1.2 g). Rechromatography (silica gel) separated out α-fluoro-2,6-dichlorotoluene as white needles (700 mg), melting point: 58–59 °C.

Proton Magnetic Resonance Spectra

An approximately 10 mole % solution in benzene-d_6 containing internal tetramethylsilane was degassed by the freeze–pump–thaw technique. Spectra were taken on a DA-60I spectrometer in the frequency sweep mode and were calibrated by reading reciprocal frequencies of the sweep and manual oscillators. Weak irradiations under double resonance conditions were performed in the normal way (2, 3).

A new synthesis of poly-γ-D- and L-glutamic acid

J. Kovacs, G. N. Schmit, and B. J. Johnson

Department of Chemistry, St. John's University, Jamaica, New York 11432

Received May 12, 1969

A new synthesis of native polyglutamic acid is described through the polycondensation of γ-glutamylglutamic acid-α,α′-di-*t*-butyl-γ-pentachlorophenyl ester. This route eliminates the possibility of transpeptidation.

Canadian Journal of Chemistry, 47, 3690 (1969)

Degradation (1) of native polyglutamic acids, produced by *B. anthracis* and *B. subtilis*, indicated that they are identical with poly-γ-glutamic acids. The anthrax-polypeptide consists exclusively (2) of D-glutamic acid residues, while the subtilis-polypeptide usually is a mixture (3) of poly-γ-D- and poly-γ-L-glutamic acid.

The synthesis (4) of these polypeptides was achieved by polycondensation of γ-glutamylglutamic acid-α,α′-dimethyl ester through activation of the γ-carboxyl group by various methods used in peptide synthesis. The free poly-γ-glutamic acid was obtained by saponification of the corresponding poly-γ-glutamic acid polymethyl ester. However, under basic conditions transpeptidation (4*a*, 5) could not be completely avoided.

We wish to report a new synthesis of these polypeptides by polymerization of γ-glutamylglutamic acid-α,α′-di-*t*-butyl-γ-pentachlorophenyl ester.[1] Here, the *t*-butyl ester groups can be removed with mild acid treatment of the *C*-protected polypeptide, thus eliminating the possibility of transpeptidation (6). In addition, polymerization through the pentachlorophenyl active ester results in a good yield of high molecular weight polymer (6, 7).

[1]M. Kajtar has applied the method reported here for the synthesis of γ-polyglutamic acids, unpublished work, reported to the authors in a private communication.

flask, equipped with a heating mantle, through a condenser into a flask cooled below 0 °C (ice–salt mixture). α-Fluoro-2,6-dichlorotoluene and other impurities were collected as a white solid. The distillate was then exhaustively extracted with ether (5 × 40 ml). The ether extracts were combined, dried (sodium sulfate), and concentrated into a foam (2.2 g). Chromatography (silica gel) of the residue gave a mixture of α-bromo-2,6-dichlorotoluene and α-fluoro-2,6-dichlorotoluene (1.2 g). Rechromatography (silica gel) separated out α-fluoro-2,6-dichlorotoluene as white needles (700 mg), melting point: 58–59 °C.

Proton Magnetic Resonance Spectra

An approximately 10 mole % solution in benzene-d_6 containing internal tetramethylsilane was degassed by the freeze–pump–thaw technique. Spectra were taken on a DA-60I spectrometer in the frequency sweep mode and were calibrated by reading reciprocal frequencies of the sweep and manual oscillators. Weak irradiations under double resonance conditions were performed in the normal way (2, 3).

Acknowledgments

We are grateful to Dr. S. Castellano for sending us his results prior to publication and to the National Research Council of Canada for financial support.

α-*t*-Butyl-D-glutamic acid methyl ester hydrochloride (**1**), prepared by catalytic hydrogenation of *N*-carbobenzoxy-α-*t*-butyl-D-glutamic acid methyl ester (8), was coupled with *N*-carbobenzoxy-α-*t*-butyl-D-glutamic acid pentachlorophenyl ester (8) to give the dipeptide methyl ester **2**. Saponification of the methyl ester gave the free acid **3**, which was converted directly to the dipeptide active ester **4**. Catalytic hydrogenation of **4** in the presence of HCl yielded α-*t*-butyl-D-glutamyl-α-*t*-butyl-D-glutamic acid pentachlorophenyl ester hydrochloride **5**, which was polymerized (8) in dimethylformamide in the presence of 2.5 equivalents of triethylamine. The resulting polypeptide ester **6** was then treated with trifluoroacetic acid, yielding the desired poly-γ-D-glutamic acid **7** with a mol. wt. 8000 as determined by sedimentation equilibrium (9).

A similar series of reactions, starting with *N*-carbobenzoxy-α-*t*-butyl-L-glutamic acid pentachlorophenyl ester and α-*t*-butyl-L-glutamic acid methyl ester hydrochloride gave poly-γ-L-glutamic acid with a mol. wt. 9000 as determined by sedimentation equilibrium.

Experimental

All melting points are uncorrected. The microanalyses were carried out either by Drs. G. Weiler and F. B. Strauss, Oxford, England, or by Schwarzkopf Microanalytical Laboratory, Woodside, N.Y. Infrared (i.r.) spectra were made in potassium bromide pellets on a Perkin–Elmer model 137 spectrophotometer.

α-t-Butyl-γ-methyl-D-glutamic Acid Hydrochloride (1)

A suspension of 0.8 g of 10% palladium on charcoal in 1 ml of glacial acetic acid and 20 ml of methanol was prehydrogenated for 10 min. A solution of 4.46 ml of 3.5 *N* solution of hydrogen chloride in methanol was added, followed by a solution of 5.27 g (15 mmoles) of *N*-carbobenzoxy-α-*t*-butyl-γ-methyl-D-glutamic acid in 25 ml of methanol. Hydrogenation was continued for 7 min. During this time approximately 200 ml of hydrogen was absorbed. The reaction mixture was filtered and the filtrate was concentrated *in vacuo*. The oily residue was triturated with ether and the crystalline material filtered; yield 85–90%, m.p. 133–134°. A portion of the product was purified by dissolving in water, neutralizing with sodium bicarbonate, and extracting with ether. The ether phase was dried over sodium sulfate and the hydrochloride precipitated by bubbling in hydrogen chloride. This procedure raised the m.p. to 134–135°; $[\alpha]_D^{23}$ −21.7° (*c*, 0.96, ethanol); lit. (10) m.p. 135–135.5°; $[\alpha]_D^{20}$ 21.7° (*c*, 2, ethanol) for the L-isomer.

Anal. Calcd. for $C_{10}H_{20}NO_4Cl$: C, 47.34; H, 7.95; N, 5.52; Cl, 13.97. Found: C, 47.54; H, 8.13; N, 5.70; Cl, 14.20.

N-Carbobenzoxy-α-t-butyl-D-glutamyl-α-t-butyl-D-glutamic Acid Methyl Ester (2)

A mixture of 20.0 g (35 mmole) of *N*-carbobenzoxy-α-*t*-butyl-D-glutamic acid pentachlorophenyl ester, 9 g (35 mmole) of α-*t*-butyl-γ-methyl-D-glutamic acid hydrochloride (**1**), 130 ml of methylene chloride, 3.6 g (35 mmole) of triethylamine, and 3.3 g (35 mmole) of 2-hydroxypyridine was stirred at room temperature for 24 h, then concentrated *in vacuo*. The solid residue was dissolved in ethyl acetate and washed quickly with cold dilute hydrochloric acid, water, 5% sodium bicarbonate, and then water until neutral. The organic phase was dried over magnesium sulfate and the solvent was removed *in vacuo*. The resulting oil was placed on a silica gel column and the pentachlorophenol was eluted with benzene. The desired dipeptide derivative was then eluted with ethyl acetate. The ethyl acetate was removed *in vacuo* and the oily residue was recrystallized from ether – petroleum ether (b.p. 40–60°). The yield was 12 g (58%); m.p. 72–73°, $[\alpha]_D^{24}$ −9.8° (*c*, 1.45, methylene chloride). The i.r. spectrum showed peaks at 5.72, 5.86, 6.03, and 6.46 μ.

Anal. Calcd. for $C_{27}H_{40}N_2O_9$: C, 60.43; H, 7.51; N, 5.22. Found: C, 60.58; H, 7.61; N, 5.02.

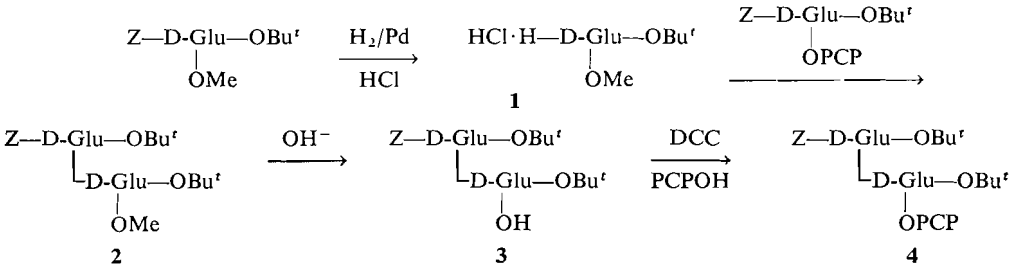
N-Carbobenzoxy-α-t-butyl-L-glutamyl-α-t-butyl-L-glutamic Acid Methyl Ester

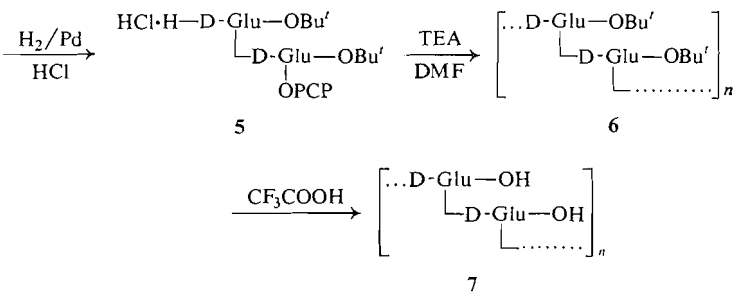
It was prepared similarly in 58% yield. Two recrystallizations from ether – petroleum ether (b.p. 40–60°) gave m.p. 71–72°, $[\alpha]_D^{24}$ 9.9° (*c*, 1.40, methylene chloride). The i.r. spectrum was superimposable on that of the D-isomer.

Anal. Calcd. for $C_{27}H_{40}N_2O_9$: C, 60.43; H, 7.51; N, 5.22. Found: C, 60.34; H, 7.60; N, 5.34.

N-Carbobenzoxy-α-t-butyl-D-glutamyl-α-t-butyl-D-glutamic Acid (3)

A solution of 3.8 g (7 mmole) of *N*-carbobenzoxy-α-*t*-butyl-D-glutamyl-α-*t*-butyl-D-glutamic acid methyl ester (**2**) in 100 ml of methanol and 7 ml of 1 *N* sodium hy-





droxide was kept at room temperature for 30 min and then concentrated *in vacuo*. The residue was diluted with 100 ml of water and extracted with ethyl acetate. The aqueous phase was acidified to pH 3 with dilute hydrochloric acid and extracted twice with 50 ml portions of ethyl acetate. The ethyl acetate phase was dried over sodium sulfate and the solvent removed *in vacuo* to yield 3.5 g (94%) of an oil which was used without further purification.

N-Carbobenzoxy-α-t-butyl-L-glutamyl-α-t-butyl-L-glutamic Acid

It was prepared similarly in 95% yield.

N-Carbobenzoxy-α-t-butyl-D-glutamyl-α-t-butyl-D-glutamic Acid Pentachlorophenyl Ester (4)

To a solution of 3.5 g (6.6 mmole) of free acid **3** in 30 ml of methylene chloride, 1.4 g (6.8 mmole) of dicyclohexylcarbodiimide was added, followed after 20 min by a suspension of 1.8 g (6.8 mmole) of pentachlorophenol in 20 ml of methylene chloride. The reaction mixture was stirred at room temperature for 24 h and then concentrated *in vacuo*. The oily residue was dissolved in ethyl acetate and the solution was washed with 5% sodium bicarbonate and with water, dried over magnesium sulfate, and the solvent removed *in vacuo*. The resulting oil was chromatographed on silica gel, eluted with benzene:petroleum ether (b.p. 40–60°) (1:1), benzene, and finally ethyl acetate. The ethyl acetate eluate was concentrated *in vacuo* and the residue was crystallized from ether – petroleum ether (b.p. 40–60°). The yield was 4.1 g (80%); m.p. 77–78°, $[\alpha]_D^{24}$ −11.7° (*c*, 0.29, methylene chloride). The i.r. spectrum showed peaks at 5.60, 5.79, 6.05, and 6.52 μ.

Anal. Calcd. for $C_{32}H_{37}N_2O_9Cl_5$: C, 49.84; H, 4.84; N, 3.64. Found: C, 49.76; H, 4.83; N, 3.49.

N-Carbobenzoxy-α-t-butyl-L-glutamyl-α-t-butyl-L-glutamic Acid Pentachlorophenyl Ester

It was prepared similarly in an 83% yield, m.p. 77–78°, $[\alpha]_D^{24}$ 11.8° (*c*, 1.51, methylene chloride). The i.r. spectrum was superimposable on that of the D-isomer.

Anal. Calcd. for $C_{32}H_{37}N_2O_9Cl_5$: C, 49.84; H, 4.84; N, 3.64. Found: C, 49.93; H, 4.78; N, 3.89.

α-t-Butyl-D-glutamyl-α-t-butyl-D-glutamic Acid Pentachlorophenyl Ester Hydrochloride (5)

A suspension of 500 mg of 10% palladium on charcoal in 20 ml of methanol and 5 ml of glacial acetic acid was prehydrogenated until no further uptake of hydrogen occurred. A solution of 80 mg (2.11 mmole) of hydrogen chloride in 0.6 ml of methanol was added, followed by a solution of 1.59 g (2.1 mmole) of *N*-carbobenzoxy-α-*t*-butyl-D-glutamyl-α-*t*-butyl-D-glutamic acid pentachlorophenyl ester (**4**) in 20 ml of methanol. Hydrogenation was continued for 2 min until 46.5 ml of H_2 had been absorbed. The mixture was filtered, the filtrate concentrated *in vacuo*, and the residue diluted with ether. The resulting precipitate was filtered and washed with ether. The yield was 1.6 g (81%); m.p. 145° decomp. Recrystallization from methanol – ether raised the m.p. to 152–153° decomp., $[\alpha]_D^{24}$ 18.8° (*c*, 0.82, methanol). The i.r. spectrum showed peaks at 5.59, 5.75, 6.05, and 6.54 μ.

Anal. Calcd. for $C_{24}H_{32}N_2O_7Cl_6$: C, 42.82; H, 4.79; N, 4.16. Found: C, 42.72; H, 4.59; N, 4.01.

α-t-Butyl-L-glutamyl-α-t-butyl-L-glutamic Acid Pentachlorophenyl Ester Hydrochloride

It was prepared similarly in a 76% yield, m.p. 152–153° decomp., $[\alpha]_D^{24}$ −18.4° (*c*, 0.58, methanol). The i.r. spectrum was superimposable on that of the D-isomer.

Anal. Calcd. for $C_{24}H_{31}N_2O_7Cl_5 \cdot HCl$: C, 42.82; H, 4.79; N, 4.16; Cl^-, 5.43. Found: C, 42.57; H, 5.14; N, 4.23; Cl^-, 5.38.

Poly-γ-D-glutamic Acid t-Butyl Ester (6)

The dimethylformamide for this reaction was dried over sodium sulfate; any primary and secondary amines were removed by stirring with *N*-carbobenzoxyglycine *p*-nitrophenyl ester; the solution was filtered and distilled at 33° (0.6 mm). The triethylamine was treated similarly and distilled at 89–90°.

A mixture of 119 mg (0.18 mmole) of α-*t*-butyl-D-glutamyl-α-*t*-butyl-D-glutamic acid pentachlorophenyl ester hydrochloride (**5**), 0.12 ml of dimethylformamide, and 0.06 ml (0.45 mmole) of triethylamine was shaken at room temperature for 3 days. The solid reaction mixture was washed with ether, water, and ether, being centrifuged and decanted after each washing. The polymer **6** was dried overnight *in vacuo* over phosphorus pentoxide; yield 35 mg (51%). The i.r. spectrum showed characteristic peaks at 5.77, 6.03, 6.50, and 11.76 μ.

Anal. Calcd. for $(C_9H_{15}NO_3)_\infty$: C, 58.36; H, 8.16; N, 7.56. Calcd. for $(C_9H_{15}NO_3 \cdot 1/4H_2O)_\infty$: C, 56.97; H, 8.23; N, 7.38. Found: C, 56.77; H, 8.39; N, 7.16.

Poly-γ-L-glutamic Acid t-Butyl Ester

It was prepared similarly in a 57% yield. The i.r. spectrum showed characteristic peaks at 5.73, 6.00, 6.49, and 11.73 μ.

Anal. Found: C, 57.92; H, 7.81; N, 7.39.

Poly-γ-D-glutamic Acid (7)

A solution of 25 mg of polymer *6* in 0.5 ml of 90% trifluoroacetic acid was kept at room temperature for 50 min, then diluted with 10 ml of ether, centrifuged, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the resulting precipitate washed twice with 10 ml portions of ether and dried overnight *in vacuo* over phosphorus pentoxide. Yield 16 mg (89%), $[\alpha]_D^{23}$ 23.6° (*c*, 0.50, water), mol. wt. 8000, determined by sedimentation equilibrium. The i.r. spectrum showed characteristic peaks at 6.06 and 6.45 μ.

Anal. Calcd. for $(C_5H_7NO_3 \cdot 1/4H_2O)_\infty$: C, 44.94; H, 5.66; N, 10.48. Found: C, 44.69; H, 5.56; N, 10.25.

Optical Purity of Poly-γ-D-glutamic Acid

It was determined by hydrolyzing 40.0 mg of a polymer sample, $[\alpha]_D^{22}$ 23.4° (*c*, 0.70, water), for 24 h under reflux in 1 ml of 6 *N* hydrochloric acid and 1 ml of glacial acetic acid. The hydrolysate was diluted to 3 ml with glacial acetic acid, giving $\alpha_D^{23} - 0.441 \pm 0.01°$. A control sample consisting of 44.0 mg of D-glutamic acid of 100% optical purity, $[\alpha]_D^{23}$ −32.0° (*c*, 1.84, 6 *N* hydrochloric acid), was treated under the same conditions, giving α_D^{23} $-0.441 \pm 0.01°$. This would indicate that the polymer is optically pure.

Poly-γ-L-glutamic Acid

It was prepared similarly in an 89% yield, $[\alpha]_D^{23}$ −23.3° (*c*, 0.58, water) mol. wt. 9000 as determined by sedimentation equilibrium. The i.r. spectrum showed characteristic peaks at 6.06 and 6.44 μ.

Anal. Found: C, 44.59; H, 5.20.

Weight average molecular weights were determined in a Spinco Model E analytical ultracentrifuge by the sedimentation equilibrium method in 0.1 *M* aqueous KCl. The calculations used were those given by Schachman. Measurements were made on concentrations in the range of 0.2–0.5% at 25–30°, using a rotor speed of 25 980 r.p.m. and a schlieren angle of 80°. The charge effect, which can lead to low mol. wt. values in water, was assumed to be minimized by using 0.1 *M* aqueous KCl as the solvent.

Acknowledgments

This work was supported by grants from the National Institutes of Health, Public Health Service (GM 06579 and 08795). We wish to thank Professor H. Horan for the infrared spectra. We wish to thank Mr. J. Mongiello for the improvement of the preparation of α-*t*-butyl-γ-methyl glutamic acid hydrochloride reported in this paper.

A steroidal 14β-hydroperoxide

ADRIANO AFONSO

Natural Products Research Department, Schering Corporation, Bloomfield, New Jersey

Received February 26, 1969

Air oxidation of Δ^{14}-androsten-3β-ol-17-one acetate (**1**) was found to afford stereospecifically 14β-hydroperoxy-Δ^{15}-androsten-3β-ol-17-one 3-acetate (**2***a*).

Canadian Journal of Chemistry, 47, 3693 (1969)

A common structural feature of most of the naturally-occurring cardiac-active steroidal lactones is the presence of a 14β-hydroxy substituent (1). The stereospecific introduction of a 14β-hydroxy group into the steroidal nucleus is therefore of interest in synthetic and biosynthetic studies of this class of compounds. A few methods for 14β-hydroxylation of steroids have been described in the literature (2), and in this note we report a new method which makes use of the susceptibility of β,γ-unsaturated ketone systems to undergo oxygenation at the γ-position with simultaneous reconjugation (3).

The oxygenation substrate used in our work was Δ^{14}-androsten-3β-ol-17-one acetate (**1**) (2*b*, 4, 5). This compound has been prepared in less than 5% yield by the dehydrobromination of 16-bromo epiandrosterone acetate with collidine (5);

A control sample consisting of 44.0 mg of D-glutamic acid of 100% optical purity, $[\alpha]_D^{23}$ −32.0° (*c*, 1.84, 6 *N* hydrochloric acid), was treated under the same conditions, giving α_D^{23} $-0.441 \pm 0.01°$. This would indicate that the polymer is optically pure.

Poly-γ-L-glutamic Acid

It was prepared similarly in an 89% yield, $[\alpha]_D^{23}$ −23.3° (*c*, 0.58, water) mol. wt. 9000 as determined by sedimentation equilibrium. The i.r. spectrum showed characteristic peaks at 6.06 and 6.44 μ.

Anal. Found: C, 44.59; H, 5.20.

Weight average molecular weights were determined in a Spinco Model E analytical ultracentrifuge by the sedimentation equilibrium method in 0.1 *M* aqueous KCl. The calculations used were those given by Schachman. Measurements were made on concentrations in the range of 0.2–0.5% at 25–30°, using a rotor speed of 25 980 r.p.m. and a schlieren angle of 80°. The charge effect, which can lead to low mol. wt. values in water, was assumed to be minimized by using 0.1 *M* aqueous KCl as the solvent.

Acknowledgments

This work was supported by grants from the National Institutes of Health, Public Health Service (GM 06579 and 08795). We wish to thank Professor H. Horan for the infrared spectra. We wish to thank Mr. J. Mongiello for the improvement of the preparation of α-*t*-butyl-γ-methyl glutamic acid hydrochloride reported in this paper.

A steroidal 14β-hydroperoxide

ADRIANO AFONSO

Natural Products Research Department, Schering Corporation, Bloomfield, New Jersey

Received February 26, 1969

Air oxidation of Δ^{14}-androsten-3β-ol-17-one acetate (**1**) was found to afford stereospecifically 14β-hydroperoxy-Δ^{15}-androsten-3β-ol-17-one 3-acetate (**2***a*).

Canadian Journal of Chemistry, 47, 3693 (1969)

A common structural feature of most of the naturally-occurring cardiac-active steroidal lactones is the presence of a 14β-hydroxy substituent (1). The stereospecific introduction of a 14β-hydroxy group into the steroidal nucleus is therefore of interest in synthetic and biosynthetic studies of this class of compounds. A few methods for 14β-hydroxylation of steroids have been described in the literature (2), and in this note we report a new method which makes use of the susceptibility of β,γ-unsaturated ketone systems to undergo oxygenation at the γ-position with simultaneous reconjugation (3).

The oxygenation substrate used in our work was Δ^{14}-androsten-3β-ol-17-one acetate (**1**) (2*b*, 4, 5). This compound has been prepared in less than 5% yield by the dehydrobromination of 16-bromo epiandrosterone acetate with collidine (5);

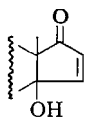
2*a*, R = H
b, R = OAc



3

we obtained higher yields of **1** (42%) by carrying out the dehydrobromination of the same compound with lithium bromide – lithium carbonate in dimethylformamide (6). Exposure of **1** to oxygen led to the formation of a polar product in 82% yield, λ_{max} 212 mμ, which was characterized as 14β-hydroperoxy-Δ^{15}-androsten-3β-ol-17-one 3-acetate (**2***a*). Its acetylation product **2***b* exhibits the acetoxyperoxide absorption at 5.60 μ (3*b*). Reduction of **2***a* with triethylphosphite in pyridine (8) afforded a product which was identical in all respects with Δ^{15}-androsten-3β,14β-diol-17-one 3-acetate (**3**) prepared by the published procedure (2*b*).[1]

In view of the mild conditions under which **1** undergoes stereospecific oxygenation at C-14, a biogenetic origin for the 14β-hydroxy group of cardenolides and bufadienolides may be suggested. Recently it has been demonstrated that C_{21}-steroids are involved in the biogenesis of cardiac active glycosides (9). However, in the alternative C_{19}–C_4 hypothesis (10), the C_{19}-steroidal fragment could be envisioned to acquire the 14β-hydroxy group in a manner analogous to the one described herein.

Experimental

Melting points are uncorrected. Specific rotations were determined on 0.3% solutions in dioxane. Nuclear magnetic resonance spectra in $CDCl_3$ using TMS as the internal standard were determined on a Varian A-60A spectrometer. The author thanks Mr. M. Yudis and his staff for these physical measurements.

Δ^{14}-Androstene-3β-ol-17-one Acetate (1)

A mixture of 16-bromo epiandrosterone acetate (9.9 g) (5), lithium bromide (10 g), and lithium carbonate (10 g) in dimethylformamide (100 ml) was stirred and heated at 180° under argon for 3 h. The reaction mixture was cooled to room temperature, diluted with ice-water, acidified with dilute hydrochloric acid and extracted with ethyl acetate. The organic extracts were washed with water, dried, and evaporated under reduced pressure. The residue was crystallized twice from ether–hexane to afford colorless needles of **1** (3.3 g, 42%), m.p. 152–155°; $[\alpha]_D$ +110° (chloroform) [reported (2*b*): m.p. 154–156°; $[\alpha]_D$ +112°].

14β-Hydroperoxy-Δ^{15}-androstene-3β-ol-17-one 3-Monoacetate (2a)

A solution of Δ^{14}-androstene-3β-ol-17-one acetate (**1**, 1 g) in the minimum amount of chloroform was distributed as a film on the inside walls of a 4-l conical flask which was then filled with oxygen and allowed to stand at room temperature. The disappearance of **1** was followed by thin-layer chromatography and after 5 days the reaction was complete. During this reaction period additional amounts of chloroform were added as required in order to prevent **1** from crystallizing out. The product was transferred to a smaller flask and triturated with ether to afford **2***a* (502 mg). The filtrate was evaporated and the residue was applied on a 20 × 20 × 0.1 cm silica gel plate which was then developed in 10% ethyl acetate–chloroform. The material from the band corresponding to **2***a* was isolated and crystallized from ether (393 mg, 82% total yield). Recrystallization from ethyl acetate–ether afforded **2***a* as colorless needles, m.p. 175–180° (decomp.); λ_{max}(Nujol) 3.08, 5.79, 5.86 μ; λ_{max} (MeOH) 212 mμ (ε 8800); $[\alpha]_D^{26}$ +43.2°; n.m.r. ($CDCl_3$, 60 Mc.p.s.), δ 0.82, 1.22, 2.01 (singlets, 3H each, 19-CH_3, 18-CH_3 and C_3-OCCH_3), δ 6.39, 7.34 (doublets, 1H each, J = 6.5 c.p.s., C-16 and C_{15}-*H*), δ 7.84 (singlet, 1H, 14-OO*H*, exchangeable with D_2O); positive starch iodide test.

Anal. Calcd. for $C_{21}H_{30}O_5$: C, 69.58; H, 8.34. Found: C, 69.62; H, 8.42.

14β-Hydroperoxy-Δ^{15}-androstene-3β-ol-17-one 3,14-Diacetate (2b)

Acetic anhydride (0.7 ml) was added to a cold (0°) solution of **1** (0.34 g) in pyridine (1.5 ml). After 1 h at 0° the solution was allowed to stand at room temperature for 15 min and then diluted with ice-water. The insoluble product was filtered out, washed with water, and dried. The product was crystallized from hexane as colorless needles (**2***c*, 0.232 g), m.p. 125–131° (decomp.); λ_{max}(Nujol) 5.59, 5.79, 5.82 μ; λ_{max}(EtOH) 212 mμ (ε 8300); $[\alpha]_D^{26}$ −98.1°; n.m.r., δ 0.83, 1.20, 1.90, 2.01 (singlets, 3H each, 19-CH_3, 18-CH_3, C_{14}-OOCCH_3 and C_3-OCCH_3), δ 6.33, 7.40 (doublets, 1H each, J = 6.5 c.p.s., C-16 and C_{15}-*H*).

Anal. Calcd. for $C_{23}H_{32}O_6$: C, 68.29; H, 7.97. Found: C, 68.58; H, 7.85.

Δ^{15}-Androstene-3β,14β-diol-17-one 3-Monoacetate (3)

a) From Δ^{14}-Androsten-3β-ol-17-one Acetate (1)

The procedure described in the literature (2*b*) was followed. The product was crystallized from acetone–hexane as colorless plates, m.p. 162–163°; λ_{max}(Nujol) 2.90, 5.78, 5.82 μ; λ_{max}(MeOH) 212 mμ (ε 8000); $[\alpha]_D^{26}$ +103.6°; optical rotatory dispersion in dioxane[2] (*c*, 0.07):

[1]The physical constants reported (2*b*) for **3** are not in complete agreement with those found by us on chromatographically pure **3**. Low values, like ours, for extinction coefficients have been observed in other 14β-hydroxy-Δ^{15}-17-ketones (7). The identity of our **3** was confirmed from its optical rotatory dispersion curve which shows a positive cotton effect and is identical in shape with the published (2*b*) curve.

[2]The author thanks Dr. M. Tanabe of Stanford Research Institute for determining the optical rotatory dispersion curve.

Reductions with sulfurated borohydrides. III. Borohydrides incorporating selenium and tellurium

J. M. Lalancette and M. Arnac
Department of Chemistry, University of Sherbrooke, Sherbrooke, Quebec

Received March 20, 1969

The reactions of selenium and tellurium with lithium, sodium, potassium, and tetramethylammonium borohydrides have been examined, using the hydrogen evolution as a measurement of the replacement of hydrogen by the chalcogen on the borohydride anion. Of all the possible reactions, only the combination of sodium borohydride with tellurium led to a stable compound, easily isolated and of definite stoichiometry. This new borohydride, $NaBH_2Te_3$ offers interesting possibilities as a reducer.

Canadian Journal of Chemistry, **47**, 3695 (1969)

We have reported the sulfuration of sodium borohydride by elemental sulfur, in the presence of organic solvents (1). This reaction gave a new reducer (2, 3), incorporating sulfur, according to eq. [1].

$$[1] \qquad NaBH_4 + 3S \xrightarrow[25°]{THF} H_2 + NaBH_2S_3$$

We had noted from qualitative tests that similar reactions could be obtained with selenium and tellurium. This paper describes the reaction of lower chalcogens with various borohydrides.

Experimental

The reactions were performed with hydrides (British Drug Houses Reagent grade) without purification. Diglyme was used as solvent, after overnight reflux and distillation over sodium. Selenium and tellurium (Fisher Reagent grade) were used in the form of a fine powder, dried in a dessicator under vacuum in the presence of sulfuric acid.

In a typical experiment, a mixture of 0.10 mole (3.78g) of $NaBH_4$ and 0.30 mole (38.4g) of tellurium was placed in a 500 ml, three-neck flask bearing a condenser and an adding funnel. The flask was kept at 40° in a water bath and after flushing with dry nitrogen, 100 ml of dry diglyme was added to the mixture of solids, with stirring. The hydrogen evolved from the system was collected on top of the condenser and measured over water previously saturated with that gas. A drying tube between the gas-collection apparatus and the reacting flask prevented diffusion of water vapors into the reacting vessel.

The infrared (i.r.) spectrum of the borohydride incorporating tellurium was measured in Nujol suspen-

For personal use only.

sion and bands were observed at 1170 (weak), 1080 (weak), and 930cm^{-1} (medium). The very strong bands given by $NaBH_4$ at 2300 (very strong) and 1120 cm^{-1} (very strong) were absent from the spectrum.

When the gas evolution was completed, the reaction mixture was filtered and washed with petroleum ether (b.p. 50–60°) in order to remove diglyme. After drying under vacuum, the black solid was analyzed for Na, B, Te, and H. Determination of boron and sodium was made by flame photometry.

Anal. Calcd.: Na, 5.48; B, 2.63. Found: Na, 5.58; B, 2.68. Sodium borate (analytical) was used as standard. Tellurium was determined by dissolution of a sample in *aqua regia* and subsequent precipitation of tellurium by reduction with SO_2 (4).

Anal. Calcd.: Te, 91.4. Found: Te, 91.1. The hydrogen content of the hydride was obtained by hydrolysis and measurement of the hydrogen evolved. Two hydrogens molecules per mole of hydride were liberated (observed yield of 101%) according to eq. [2]

[2] $$NaBH_2Te_3 + 4H_2O \rightarrow 2H_2 + H_3BO_3 + NaOH + 3Te$$

Selenium and tellurium were allowed to react with lithium, sodium, potassium, and tetramethylammonium borohydrides, using a similar technique to that described above. The kinetics of these reactions and the degree of hydrogen replacement by the chalcogens were ascertained by following the hydrogen evolution. The results of these experiments are reported in Figs. 1, 2, 3, and 4.

Results and Discussion

Selenium

Selenium reacts with all four borohydrides used in our series of experiments. With lithium borohydride, the reaction was extremely brisk with a $Se/LiBH_4$ ratio greater than three and the hydrogen evolution levelled at a $H_2/NaBH_4$ ratio of 1. However, if the $Se/LiBH_4$ ratio was lowered below three, the four hydrogens of the borohydride were evolved. The reaction was somewhat milder with $NaBH_4$, the hydrogen evolution levelling off at a $H_2/NaBH_4$ ratio slightly higher than 1. With potassium borohydride, the reaction was slower and did not level off as the Se/BH_4^- ratio increased. This can be understood either as a decomposition of the seleniated borohydride or a complete replacement of the hydrogen atom of the hydride, at a slower rate, when two hydrogens have been lost. In the case of tetramethylammonium borohydride, the reaction was much slower and did not reach the molar H_2/BH_4^- ratio observed with the other cations.

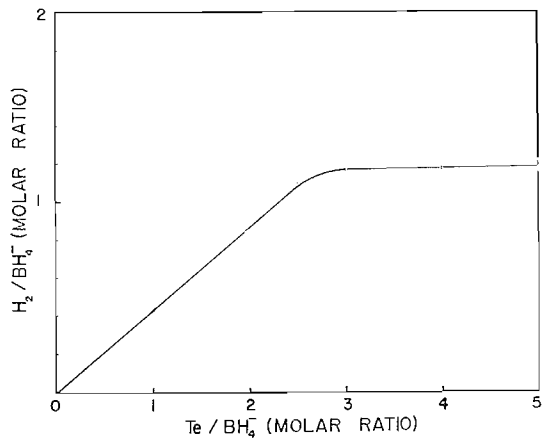

FIG. 1. Variations of the H_2/BH_4^- molar ratio against variations of Te/BH_4^- ratio. Reactions using $NaBH_4$.

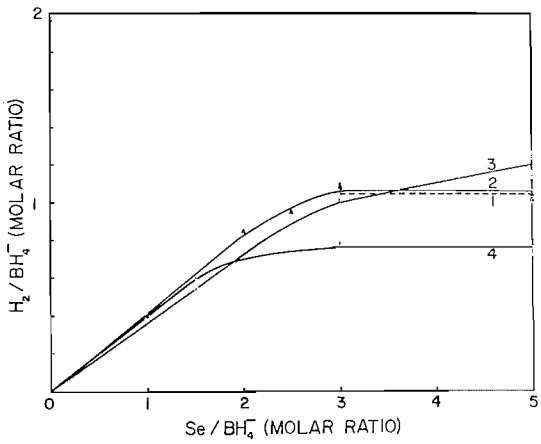

FIG. 2. Variations of the H_2/BH_4^- molar ratio against variations of Se/BH_4^- ratio. Reactions with $LiBH_4$(*1*), $NaBH_4$(*2*), KBH_4(*3*), and $(CH_3)_4NBH_4$(*4*).

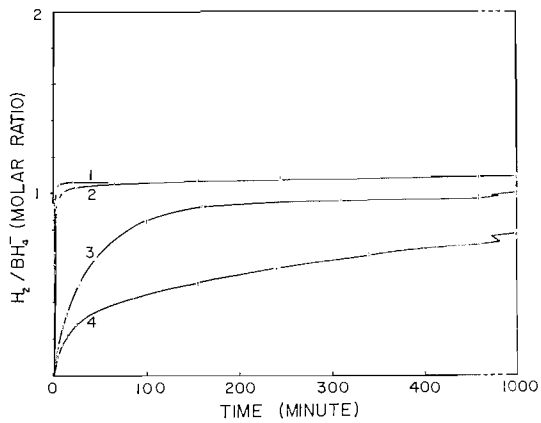

FIG. 3. Corrected volume of hydrogen evolved from a mixture of BH_4^- (0.033 mole) and Se (0.10 mole) in the presence of diglyme, at 25°. Reactions with $LiBH_4$(*1*), $NaBH_4$(*2*), KBH_4(*3*), and $(CH_3)_4BH_4$(*4*).

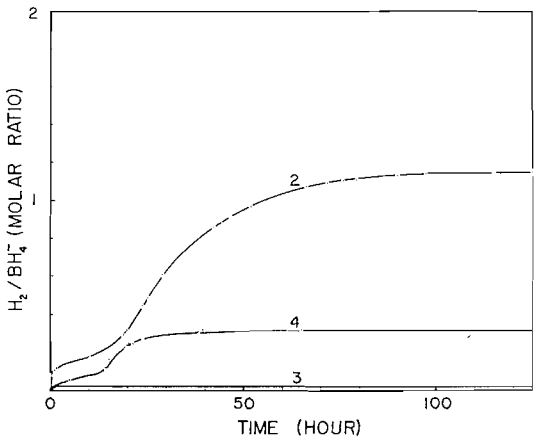

FIG. 4. Corrected volume of hydrogen evolved from a mixture of BH_4^- (0.10 mole) and Te (0.30 mole) in the presence of diglyme, at 56°. Reactions with $NaBH_4$(*2*), KBH_4(*3*), and $(CH_3)_4BH_4$(*4*).

Tellurium

As with selenium, tellurium gave a very fast and even explosive reaction with lithium borohydride in the presence of diglyme. With sodium borohydride, the reaction was very slow but stopped when two hydrogens of the borohydride were replaced by tellurium. Tetramethylammonium borohydride reacted only slightly and potassium borohydride gave no evolution of hydrogen.

These experiments indicate that of the possible combinations of hydrides and chalcogens, only the reaction of sodium borohydride with selenium and tellurium led to relatively stable compounds having the stoichiometry $NaBH_2M_3$ (M = Se, Te). In all other cases, the reaction was either too fast, too slow, or did not stop at a definite level in the course of replacement of the hydrogens by the chalcogens. In the case of $NaBH_2Se_3$, although the hydrogen evolution and subsequent hydrolysis indicated the above formulation, it has not been possible to remove this compound from its solvent, the reddish, rubber like substance retaining important portions of diglyme, even after repeated washings with petroleum ether. This difficulty prevented the elementary analysis as obtained for $NaBH_2Te_3$. The sodium borohydride incorporating tellurium was easily obtained as a black powder, free from diglyme, and showing relative stability for some hours. It is hygroscopic and sensitive to light.

The sodium borohydride incorporating tellurium still retains two hydrogens showing reducing capacity towards organic substrates. Since the anion $BH_2Te_3^-$ is even bulkier than $BH_2S_3^-$, the stereospecificity already observed with the sulfurated borohydride should be enhanced with $BH_2Te_3^-$.

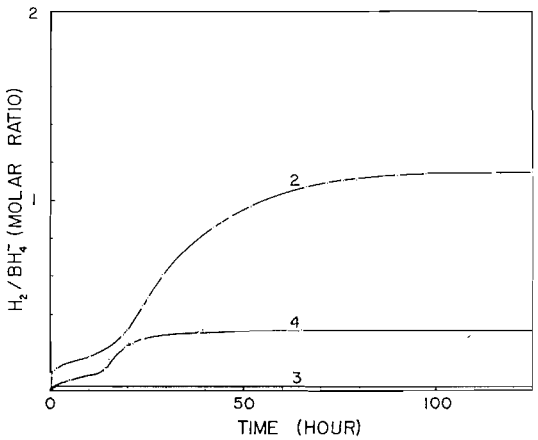

FIG. 4. Corrected volume of hydrogen evolved from a mixture of BH_4^- (0.10 mole) and Te (0.30 mole) in the presence of diglyme, at 56°. Reactions with $NaBH_4$(*2*), KBH_4(*3*), and $(CH_3)_4BH_4$(*4*).

Tellurium

As with selenium, tellurium gave a very fast and even explosive reaction with lithium borohydride in the presence of diglyme. With sodium borohydride, the reaction was very slow but stopped when two hydrogens of the borohydride were replaced by tellurium. Tetramethylammonium borohydride reacted only slightly and potassium borohydride gave no evolution of hydrogen.

These experiments indicate that of the possible combinations of hydrides and chalcogens, only the reaction of sodium borohydride with selenium and tellurium led to relatively stable compounds having the stoichiometry $NaBH_2M_3$ (M = Se, Te). In all other cases, the reaction was either too fast, too slow, or did not stop at a definite level in the course of replacement of the hydrogens by the chalcogens. In the case of $NaBH_2Se_3$, although the hydrogen evolution and subsequent hydrolysis indicated the above formulation, it has not been possible to remove this compound from its solvent, the reddish, rubber like substance retaining important portions of diglyme, even after repeated washings with petroleum ether. This difficulty prevented the elementary analysis as obtained for $NaBH_2Te_3$. The sodium borohydride incorporating tellurium was easily obtained as a black powder, free from diglyme, and showing relative stability for some hours. It is hygroscopic and sensitive to light.

The sodium borohydride incorporating tellurium still retains two hydrogens showing reducing capacity towards organic substrates. Electrolysis in liquid ammonia solution in peptide chemistry

D. A. J. IVES
Connaught Medical Research Laboratories, University of Toronto, Toronto, Canada
Received February 10, 1969

An adaptation of an electrolytic method is suggested for the removal of protecting groups in peptide chemistry. Some initial experiments are reported indicating the scope and possible limitations of the method.

Canadian Journal of Chemistry, 47, 3697 (1969)

Introduction

The benzyl group ($C_6H_5CH_2$—) has had a wide use in peptide chemistry, since its introduction by du Vigneaud *et al.* (1) as a protective function. When it is used to protect the thiol group of cysteine the normal method of removal has been, until recently, reduction by sodium and liquid ammonia (Na/NH_3) (2). In 1965, Sakakibara and Shimonishi (3) found that the benzyl group in *S*-benzyl cysteine peptides could be

removed by the use of anhydrous HF. This reagent also removes other groups such as the *N*-carbobenzoxy, *t*-butyloxycarbonyl, benzyl esters, and benzyl ethers used as protective groups in peptide synthesis (4, 5). Unfortunately anhydrous HF does not remove the benzyl group from im.-benzyl histidine, and where benzyl protected cysteine and histidine occur in the same peptide, Na/NH_3 reduction still has to be used.

Du Vigneaud *et al.* (6) showed that in the removal of *S*-benzyl groups by Na/NH_3 reduction of a protected nonapeptide, high yields of physiologically active oxytocin could be obtained. However, Zahn *et al.* (7) and Katsoyannis (8) have indicated that when Na/NH_3 reduction is used on larger peptides, such as the A and B chains of insulin, low yields of the required products are obtained. To avoid the use of Na/NH_3 reduction many other protecting groups for —SH have been suggested in the literature (4, 5), but the benzyl group still seems the most popular.

The blue color obtained on dissolving alkali metals in liquid ammonia or low molecular weight amines has been suggested (9) as being due to the solvated electron. This species is also credited with being the reducing agent in these solutions. The color can also be obtained by electrochemical methods using these solvents (10). Electrolytic reduction of aromatic hydrocarbons in methylamine solution in the presence of LiCl was observed by Benkeser (10) and a similar reduction of estrone was observed by Fentiman and Poirier (11).

Since it was felt that this alternate method of electrolytically generating the active species in ammonia might find use in the field of peptide chemistry, several experiments were carried out to investigate the usefulness of this method for the removal of the benzyl group usually used to block cysteine peptides. Experimental conditions similar to those in the Na/NH_3 reduction procedure were employed in order that comparison of the results from experiments where both procedures were used could be made.

Experimental

The reductions were conducted in a 250 ml three-necked flask, the two side arms being fitted with coiled platinum wire electrodes and the centre neck being fitted with a soda lime drying tube. Liquid ammonia was collected in the flask by condensation of the gas from a tank, one of the electrodes being removed to allow for the inlet. All the materials used dissolved readily in the ammonia and during the electrolysis the solutions were stirred using a teflon coated magnetic stirring bar. The solutions were kept at acetone/dry ice temperature throughout the period of electrolysis, which was normally 90 min. The reduction could be followed by the decrease in resistance of the solution as evidenced by the increase in current flow at constant voltage. This decrease was complete within the 90 min period.

The materials used were synthesized by established methods and the constants agreed with published figures. The protected nonapeptide was synthesized by the stepwise active ester method (12) and the tetrapeptide by a combination of mixed anhydride and active ester techniques (12). The products of the reactions were usually analyzed by hydrolysis followed by chromatography using a Beckman-Spinco Amino acid analyzer, Model 120C. It was established that under the hydrolysis conditions used there were only trace amounts of cysteine produced from the *S*-benzyl cysteine.

The power source was a Heathkit constant voltage supply unit with a maximum of 400 V D.C. at 100 mA.

Electrolytic Reduction of a Protected Nonapeptide to Oxytocin

The protected nonapeptide Z-*S*-bzl-cys-tyr-ileu-gln-asn-*S*-bzl-cys-pro-leu-gly NH_2 (200 mg) was dissolved in liquid ammonia (125 ml) and electrolyzed for 90 min. The initial current was 20 mA at 400 V D.C. After the 90 min period the current had risen to 75 mA at the same voltage and was constant. The ammonia was allowed to evaporate and the last 10 ml removed under vacuum. The resulting solid was dissolved in water (50 ml) and the pH adjusted to 7.0 with dilute acetic acid. A sample (5 ml) was withdrawn, the solvent removed under vacuum and the product hydrolyzed in 6 *N* HCl (1 ml) for 16 h at 110 °C under vacuum. Analysis of the solution showed cysteine present in the correct ratio, no *S*-benzyl cysteine was observed.

Air was bubbled through the remaining solution (45 ml) for 2 1/2 h and, after the pH had been adjusted to 4.0 with dilute acetic acid, it was filtered. Assay of the solution using the isolated rat uterus method gave 390 IU/ml of oxytocic activity or an adjusted total of 21 400 International oxytocic units from 200 mg of protected nonapeptide.

When the experiment was repeated with the addition of NH_4Cl (1 g) to the liquid ammonia solution the observed current was 100 mA at 40 V D.C. This remained constant for 90 min. No oxytocic activity was found in the product and hydrolysis in 6 *N* HCl and analysis showed that all the cysteine was present as the *S*-benzyl derivative.

In a comparable experiment where the reduction was performed using Na/NH_3 instead of electrolysis, the yield was 20 500 oxytocic units from 200 mg of protected nonapeptide. There was no *S*-benzyl cysteine in an hydrolysate of the product.

Electrolytic Reduction of Protected Tetrapeptide

The protected tetrapeptide, Z-*S*-bzl-cys-pro-leu-gly NH_2 (200 mg) was subjected to the electrolytic reduction detailed above. The current was initially 20 mA at 400 V and rose to 90 mA during the 90 min reaction period. A small amount of the product, which would not

crystallize, was hydrolyzed in 6 *N* HCl and analyzed for amino acid composition. Both cysteine and *S*-benzyl cysteine were present in the ratio of about 7:3. Repetition of the experiment gave the same result. The product of the reaction also gave a positive ninhydrin reaction indicating the removal of the *N*-carbobenzoxy group.

Attempted Reduction of Z-S-Bzl-cysteine

No reduction was observed when Z-*S*-bzl-cysteine was used in the described method. The product obtained after removal of the ammonia could be crystallized from ethyl acetate/petroleum ether and was shown by m.p., mixed m.p., and rotation to be starting material. Hydrolysis and analysis showed only the presence of *S*-benzyl cysteine. The current started at 100 mA at 100 V D.C. and stayed at this level throughout the 90 min period of reaction. Na/NH_3 reduction and hydrolysis of the product showed no *S*-benzyl cysteine.

Attempted Reduction of Z-S-Bzl-cysteine Methyl Ester

When Z-*S*-bzl-cysteine methyl ester was used in the electrolytic method and the product hydrolyzed after removal of the ammonia, all the cysteine was found as *S*-benzyl cysteine. The current started at 20 mA at 400 V and dropped slowly to 10 mA at the end of 90 min. Again Na/NH_3 reduction and hydrolysis gave a product with no *S*-benzyl cysteine.

Discussion

It is apparent from the experimental results, that, with the conditions used, there is electrolytic reduction taking place.

When the protected nonapeptide was used, both the *S*-benzyl and *N*-carbobenzoxy groups were removed, since the product had the same biological activity as that obtained from a Na/NH_3 reduction of the same starting material. With the protected tetrapeptide only partial reduction occurred as evidenced by the presence of some *S*-benzyl cysteine in the hydrolysate, whereas no reduction was found with any of the cysteine derivatives used. The mechanism of the reduction would appear to be different from the Na/NH_3 reduction, since the simpler derivatives of cysteine are untouched by the electrolytic method, but are completely reduced by Na/NH_3. When a protected nonapeptide, obtained by the solid phase synthetic method, was substituted, on one occasion, for the regular nonapeptide, no reduction was observed. The peptide from this method of synthesis differed in having *O*-benzyl tyrosine rather than the free tyrosine as in the regular nonapeptide. This would imply that a partially ionizable group was necessary for reduction to occur. At no time was any blue color observed in the reaction vessel to indicate the presence of solvated electrons, although this does not preclude the reduction proceeding through a very short lived species. The particular electrolytic reduction observed in the above experiments would also appear to have a different mechanism from that observed by Benkeser *et al.* (10), since an introduction of a species designed to increase current flow (NH_4Cl) actually inhibited the reduction.

Future work is planned to widen the scope of the reaction, i.e. the removal of other protecting groups used in peptide chemistry, such as *O*-benzyl, *N*-tosyl, and the nitro group used in arginine. Further information is also required to determine the mechanism of the reaction and whether trace amounts of ions are required.

Addendum: Cryptosporiopsin, an amended structure

G. M. STRUNZ, A. S. COURT, J. KOMLOSSY, AND M. A. STILLWELL
Forest Research Laboratory, Canada Department of Forestry and Rural Development, Fredericton, New Brunswick

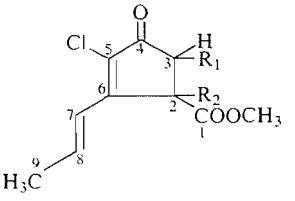
Received May 26, 1969

The structure **1** (R_1 = OH, R_2 = Cl), previously proposed for cryptosporiopsin, has been amended on the basis of new evidence to **1** (R_1 = Cl, R_2 = OH).

Canadian Journal of Chemistry, 47, 3700 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The structure **1** (R_1 = OH, R_2 = Cl) was recently advanced for cryptosporiopsin (1), an antifungal metabolite produced by a species of *Cryptosporiopsis*. The latter is an imperfect fungus isolated from yellow birch, *Betula alleghaniensis* Britt. (2).



1

The skeletal structure and chromophoric system of cryptosporiopsin were established by spectrometric and chemical studies. The secondary nature of the hydroxyl group and its consequent location were inferred principally on the basis of its ready acetylation and the resulting downfield shift of the nuclear magnetic resonance (n.m.r.) signal for the putative geminal proton on carbon 3.

Recent X-ray studies by McGahren *et al.* (3) on a metabolite produced by the coprophilous fungus *Sporormia affinis* Sacc., Bomm and Rouss have shown this compound to have the structure and absolute configuration **1** (R_1 = β-Cl, R_2 = α-OH). The apparent similarity of the *Cryptosporiopsis* and *Sporormia* metabolites has prompted us to re-examine the chemistry of cryptosporiopsin.

In a search for further chemical evidence relating to the environment of the hydroxyl and chlorine substituents of cryptosporiopsin, we have turned our attention to products derived from reductive removal of the labile chlorine atom. We have previously demonstrated that such a reduction can be effected by treatment of cryptosporiopsin with zinc in refluxing ethanol (ester interchange with ethanol also occurring under these conditions) (1). Whereas the n.m.r. spectrum of the zinc–ethanol product was not particularly revealing with respect to the environment of the newly introduced hydrogen, reduction of cryptosporiopsin with zinc in refluxing methanol yielded a product $C_{10}H_{11}O_4Cl$, whose n.m.r. characteristics are in accord with the structure **1** (R_1 = H, R_2 = OH). In particular an AB quartet can be discerned at 7.19 τ in which $|J_{AB}|$ (18–19 c.p.s.) is of the appropriate magnitude for the *geminal* protons on position 3 (4). Thus the zinc-labile chlorine must have been located on carbon 3, and it follows that the structure of cryptosporiopsin is **1** (R_1 = Cl, R_2 = OH). It may be noted that the downfield shift of the signal for the C-3 proton, on acetylation of the hydroxyl of cryptosporiopsin, implies that these groups occupy a *cis* relationship with respect to each other.

Finally, the melting point of cryptosporiopsin was undepressed on admixture with a sample of the *Sporormia* product[1], confirming the identity of the two metabolites.

Experimental

See ref. (1) for general description of instrumentation, etc.

Zinc–Methanol Reduction of Cryptosporiopsin

To cryptosporiopsin (800 mg) in absolute methanol (64 ml) was added zinc dust (1.040 g). The mixture was set aside with stirring at 25° for 15 h and was then refluxed for 2 h. Filtration removed the solid material, which was washed thoroughly with methylene chloride. The filtrates were evaporated to dryness under reduced pressure and the residue was redissolved in methylene chloride. After washing with 2% sulfuric acid followed by water, the solution was dried over magnesium sulfate, and the removal of solvent *in vacuo* yielded 610 mg of pale yellow oil, which crystallized on standing. Recrystallization from cyclohexane afforded pure **1** (R_1 = H, R_2 = OH), melting at 110–112.5°.

Structure of didehydrochelidonine

M. H. Benn and R. E. Mitchell
Department of Chemistry, The University, Calgary 44, Alberta

Received June 2, 1969

Gadamer's didehydrochelidonine is the internal carbinolamine ether **2***c*. The formation of this compound, as also its reduction back to the parent alkaloid, provides chemical proof that the relative stereochemistry of chelidonine is, as previously deduced from spectroscopic studies, that given in **1**.

Canadian Journal of Chemistry, 47, 3701 (1969)

Whilst studying the chemistry of chelidonine J. G. Gadamer observed that mercuric acetate oxidation of this alkaloid yielded a new compound which he named didehydrochelidonine (1).[1,2] Later he and his co-workers discovered that the same compound was obtained in superior yield when the oxidation was performed on chelidonine acetate (3), and that it was also a product of the permanganate oxidation of chelidonine (4).

Didehydrochelidonine was described as a colorless, noncrystalline, basic compound which yielded a number of crystalline derivatives, including a yellow hydrobromide and a colorless pseudocyanide (1, 3). Reduction of didehydrochelidonine, or its hydrobromide salt, with zinc and sulfuric acid was reported to yield unracemized chelidonine (1, 3), and it was also observed that the free base underwent ready dehydration to yield dihydrosanguinarine (**4**) (3).

Gadamer believed that didehydrochelidonine was a carbinolamine (1, 3): in terms of the structure (**1**) subsequently established for chelidonine (without stereochemistry) (5), this would now be formulated as **2***a*(X = OH), and it is in fact commonly so described (6); although others have chosen to represent it as **2***b* (7), presumably to rationalize the dehydration. The salts of didehydrochelidonine have normally been written as **3**, and the pseudocyanide as **2***a*(X = CN) (6*a*).

We anticipated on the basis of experience in the diterpenoid alkaloid field (9) that, *if* the stereochemistry of chelidonine was, as deduced from infrared (8*a*) and proton magnetic resonance (8*b*, *c*) spectroscopic studies, that represented in **1**, didehydrochelidonine would in fact be the internal carbinolamine ether **2***c*. We further anticipated that protic acids would convert **2***c* to acyclic salts (**3**), from which **2***c* would be recovered on basification, except in certain cases, exemplified by basification with cyanide salts, where capture of nucleophile could produce a stable acyclic product (**2***a*) (e.g. X = CN).

Of the other reactions of didehydrochelidonine, the facile reduction to yield chelidonine is in keeping with the known case of reduction of strained carbinolamine ethers (10) and immonium salts, and we visualized the dehydration to

[1]This is one of several historically interesting examples of Gadamer's early use of mercuric acetate oxidations in the structure–determination of alkaloids (2).

[2]In modern terminology the name dehydrochelidonine is to be preferred.

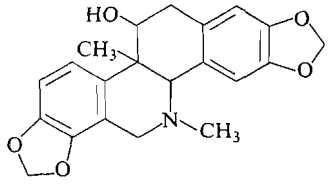
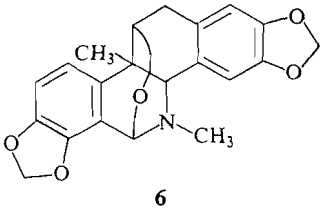
dihydrosanguinarine as proceeding through the sequence **2***c* ⇌ **2***e* ⇌ **2***f* ⇌ **2***g* ⇌ **2***b* → **4**.[3]

We obtained didehydrochelidonine, from the products of the permanganate oxidation of chelidonine, and characterized it as the crystalline hydrobromide and pseudocyanide; like other workers we were unable to persuade the free base to crystallize. Sodium borohydride reduced the free base back to chelidonine.

Prompted by a recent report which describes a permanganate oxidation product of corynoline (**5**) as **6** (12), we record here the evidence which established that **2***c* is indeed the correct structure for didehydrochelidonine.



5



6

The mass spectrum of didehydrochelidonine free base had an apparent M^+ species at *m/e* 351, as required for **2***c*.

Significantly, as judged by the absence of absorption in the 4000–3050 cm^{-1} region of its infrared spectrum, didehydrochelidonine free base did not contain an OH function. (In contrast, the infrared spectrum of didehydrochelidonine hydrobromide had strong absorption at 3300 cm^{-1}.)[4]

[3]The mechanism for the conversion **2***c* ⇌ **2***g* is similar to that proposed for the isomerization of the oxazolidine system in some diterpenoid alkaloids (11).

[4]The infrared spectrum of the hydrobromide also had absorption at 1655 cm^{-1} absent in the spectrum of the free base, which may be ascribed to the C=N$^+$ function. Other evidence which supports **3** (X = Br) as the structure for the hydrobromide includes the ultraviolet light absorption at 397 mμ (ε ~ 7000) consistent with the 3,4-dihydro-2-methyl-6,7-methylenedioxyisoquinolinium chromophone, absent in the spectrum of the parent free base.

The proton magnetic resonance spectrum of didehydrochelidonine free base was most informative. Based on the N—CH_3 signal, the spectrum integrated for 17 protons, a result again in accord with **2***c*, but not with **2***a*(X = OH). An analysis of the spectrum is provided in the Experimental, and we comment here only that it was completely consistent with that required for **2***c*, and excludes structures **2***b* and **2***d*.

We conclude that the structure of didehydrochelidonine is **2***c*, and note that the formation of this compound from chelidonine (as well as its reduction back to chelidonine) constitutes *chemical* proof that the relative stereochemistry of chelidonine is as depicted in **1**.

Experimental

Melting points were determined in capillaries, and are uncorrected. Infrared and ultraviolet spectra were recorded on Perkin–Elmer 337 and 202 spectrophotometers, respectively. Proton magnetic resonance spectra were recorded on Varian HA-100 and A-60 spectrometers, with tetramethylsilane as an internal standard. Optical rotations were measured using a Durrum-JASCO U.V.-O.R.D./5 spectrometer. The mass spectrum was recorded on an AEI-MS9 spectrometer, at the University of Alberta, Edmonton, and we report only ions whose abundance was over 20% of the base peak.

Didehydrochelidonine (2c)

Finely powdered potassium permanganate (360 mg, 2.28 mmoles) was added over the course of 1 h to a stirred solution of chelidonine (500 mg, 1.42 mmoles) in acetone (20 ml). After having been stirred at room temperature for a further hour, the reaction mixture was filtered (Celite) and, after washing the filter-cake with acetone, the yellow filtrate and washings were evaporated to dryness under reduced pressure. The residue was taken up in benzene and chromatographed on a column of Florisil (25 g, 1.8 × 20 cm) packed in benzene. Chelidonine was eluted with benzene–ether (9:1, v/v) followed, as the concentration of ether was increased, by didehydrochelidonine.[5]

The yield of didehydrochelidonine, obtained as an almost colorless glass, contaminated with a very faint trace (t.l.c.) of chelidonine, was 195 mg, and a further 185 mg of material containing slightly more chelidonine was also isolated. The total yield of didehydrochelidonine was 76%: λ_{max} (EtOH) 235 (sh) (ε 8720) and 293 mμ (ε 6000), λ_{min} 257 mμ (ε 1100); on addition of one drop of ca. 1% EtOH–HCl, λ_{max} 241, 302 and 394 mμ, λ_{min} 225 and 253 mμ; ν_{max} (KBr or $CHCl_3$) 1610 cm^{-1} (weak), and nothing in the region 4000–3050 cm^{-1}; τ($CDCl_3$) 3.22 (s) (2H), 3.32 (s) (1H) and 3.37 (s) (1H) (4 aromatic protons, probably those at C-1 and -2, C-5 (or -8), and C-8 (or -5), respectively), 4.02 (s) (2H), 4.07 (d) and 4.11 (d) (AB quartet J = 2 c.p.s.) (2H) (4 methylenedioxy protons, probably those at C-16, and C-15, respectively), 4.69 (s) (1H) (H at C-13), 6.08 (broad multiplet) (a complex quintuplet, possibly made up of overlapping quartets, J = 2 c.p.s.) (1H) (H at C-10), 6.85–7.03 (broad, unresolved, complex multiplet) (4H) (H at C-9, C-11 and C-12), and 7.84 (s) (3H) (protons of *N*-CH_3); *m/e* (rel. intensity) 351 (46), 333 (41), 332 (35), 188 (100), and 43 (32).[6]

Didehydrochelidonine hydrobromide was obtained as yellow needles, from 2-propanol, with no distinct m.p. (sinters and decomposes > 210°); λ_{max} (EtOH) 233 (ε 11 000), 298 (ε 9740) and 397 mμ (ε 1690); ν_{max} (KBr) 3300 (strong), and 1655 cm^{-1} (strong); $[\alpha]_D^{27}$ +390 (±5)° (*c* 0.1, EtOH). Literature (3) $[\alpha]_D$ +412° (*c* 1, EtOH).

Didehydrochelidonine pseudocyanide was obtained as colorless prisms, from ethanol, m.p. 194–196°. Literature (3) m.p. 194–195°.

Sodium Borohydride Reduction of Didehydrochelidonine

Sodium borohydride (2.2 mg, 0.057 mmole) was added to a stirred solution of didehydrochelidonine (40 mg, 0.114 mmole) in ethanol (1 ml). After 30 min the solution was acidified and allowed to stand for a few minutes. The solution was then basified (Na_2CO_3) and extracted with chloroform. The chloroform extracts were dried ($MgSO_4$) and evaporated. The residue, which gave a single spot on t.l.c. identical in R_f to chelidonine, was recrystallized from ethanol, and gave off-white crystals, m.p. 120–130° (30 mg, 75%), undepressed on admixture with authentic chelidonine (which also had m.p. 120–130°); the infrared spectrum of the reduction product was also superimposable on that of chelidonine.

5,5-Disubstituted hydantoins are known to possess hypnotic, anticonvulsant, and hypoglycemic properties (1–5). The introduction of methoxy groups has been reported to increase the anticonvulsant activity (6). Oldfield and Cashin (7) synthesized a number of substituted cycloalkanespiro-5-hydantoins which were reported to potentiate hexobarbital-induced hypnosis. Shaffer *et al.* (8) synthesized *N*-3-propionic acid, its ethyl ester, and *N*-3-(2-cyanoethyl) derivatives of 5,5-disubstituted hydantoin and reported that spontaneous motor activity was depressed by these compounds. Further, Dandiya and coworkers (9) have shown that unsaturation in the side chain is one of the most important factors causing central nervous system depressant effect. This led us to the synthesis of hydantoin and thiohydantoin derivatives possessing the methoxy groups and having unsaturation in the side chain.

Experimental

The thiohydantoin and hydantoin derivatives (Table I) were prepared by the following methods.

2-Thio-5-(2,4,5-trimethoxybenzylidene) Hydantoin (Th-1)

A mixture of 2,4,5-trimethoxybenzaldehyde (2.0 g; 0.01 mole), 3-benzoyl-2-thiohydantoin (2.0 g; 0.01 mole),

TABLE I

NOTE. The compounds listed gave infrared spectra that were in accord with the proposed structures.

fused sodium acetate (1.0 g), and glacial acetic acid (10 ml) was heated in a flask on a hot plate, until the mixture was completely liquidified; the heating was then continued for 2 to 3 h on a steam bath. The reaction mixture was cooled and diluted with cold water. The crystals were collected, filtered, and washed with hot water, and then recrystallized from alcohol, m.p. 227–228 °C, yield 1.2 g.

The other compounds listed in Table I were prepared by the same procedure, using 0.01 molar quantities of the appropriate trimethoxybenzaldehyde and 3-benzoyl-2-thio-hydantoin or hydantoin.

Conversion of Thiohydantoin to Hydantoin

A mixture of 2-thio-5-(trimethoxybenzylidene) hydantoin (2.0 g) and monochloroacetic acid (1.0 g in 10 ml of water) was boiled for 4 h. The mixture was then diluted with alcohol and finally evaporated at 100 °C. The crystals obtained by this process were first washed with cold water and then with boiling water. These were recrystallized from alcohol/or acetic acid.

The hydantoins prepared by both different methods gave exactly the same infrared spectra.

Pharmacological Screening

On pharmacological screening of these compounds, it was observed that the thiohydantoin derivatives protected rats markedly against electroshock-induced seizures. All of the three compounds reduced the duration of the tonic phase of convulsion significantly, but no appreciable effect on clonic convulsion was seen. The compound 2-thio-5-(2,4,5-trimethoxybenzylidene) hydantoin also reduced the duration of the post convulsion coma significantly ($P < 0.05$). Hydantoin derivatives failed to offer any protection against electroshock-induced seizures. These compounds decreased motor activity in mice and blocked conditioned avoidance response in trained rats non-specifically.

Hydrogen transfer reactions. I. Reduction of carbonyl compounds by alcohols catalyzed by alumina

D. V. Ramana and C. N. Pillai[1]

Department of Chemistry, Indian Institute of Technology, Madras-36, India

Received February 25, 1969

Alumina containing about 2.2% by weight of Na^+ has been found to be an effective catalyst for the vapor phase reduction of carbonyl compounds by alcohols and for the reverse reaction, the oxidation of the alcohols by carbonyl compounds. The reduction of a number of aliphatic and aromatic aldehydes and ketones by isopropyl alcohol and the oxidation of a number of primary and secondary alcohols by ketones like acetone and cyclohexanone are reported.

Canadian Journal of Chemistry, 47, 3705 (1969)

Mekhtiev and Narimanbekov (1) have reported the reduction of a number of aliphatic aldehydes and ketones in the vapor phase at 400 °C, catalyzed by magnesium oxide. The use of alumina as a catalyst for the liquid phase reduction of benzaldehydes by methanol at room temperature has also been reported (2). The present communication reports results which demonstrate the use of alumina impregnated with 2.2% by weight of Na^+ as an effective catalyst for the vapor phase reduction of carbonyl compounds by alcohols and for the reverse reaction.

The alumina was prepared by the hydrolysis of

Hydrogen transfer reactions. I. Reduction of carbonyl compounds by alcohols catalyzed by alumina

D. V. Ramana and C. N. Pillai[1]

Department of Chemistry, Indian Institute of Technology, Madras-36, India

Received February 25, 1969

Alumina containing about 2.2% by weight of Na^+ has been found to be an effective catalyst for the vapor phase reduction of carbonyl compounds by alcohols and for the reverse reaction, the oxidation of the alcohols by carbonyl compounds. The reduction of a number of aliphatic and aromatic aldehydes and ketones by isopropyl alcohol and the oxidation of a number of primary and secondary alcohols by ketones like acetone and cyclohexanone are reported.

Canadian Journal of Chemistry, 47, 3705 (1969)

Mekhtiev and Narimanbekov (1) have reported the reduction of a number of aliphatic aldehydes and ketones in the vapor phase at 400 °C, catalyzed by magnesium oxide. The use of alumina as a catalyst for the liquid phase reduction of benzaldehydes by methanol at room temperature has also been reported (2). The present communication reports results which demonstrate the use of alumina impregnated with 2.2% by weight of Na^+ as an effective catalyst for the vapor phase reduction of carbonyl compounds by alcohols and for the reverse reaction.

The alumina was prepared by the hydrolysis of

aluminium isopropoxide and after conversion to 1/8 in. pellets, was calcined at 600 °C in a stream of nitrogen for 6 h. The pellets were then impregnated with a solution of sodium carbonate of sufficient strength to obtain the required catalyst containing 2.2% by weight of sodium ions. This catalyst was calcined at 500 °C for 6 h in a stream of nitrogen and the reactions were carried out in a flow reactor at 300 °C. At higher temperatures, side reactions, especially condensation reactions of the carbonyl compounds became apparent. On alumina catalysts containing lesser amounts of sodium, considerable dehydration of alcohols took place. Some of the typical results are listed in Tables I and II. The products were analyzed by gas–liquid chromatography and were isolated in most cases by distillation.

The reaction is formally similar to the Meerwein–Pondorff reduction and the Oppenauer oxidation and a hydride transfer from the alcohol to the carbonyl group seems to be involved here also. The following surface reaction mechanism can be tentatively proposed for the oxidation reduction process:

Proton magnetic resonance spectrum of 2,6-dichlorobenzaldoxime. Signs and magnitudes of long-range spin–spin couplings. Degree of nonplanarity

T. Schaefer and R. Wasylishen
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received May 7, 1969

From the sign and magnitude of the coupling constant between the C—H proton in the sidechain and the para ring proton in 2,6-dichlorobenzaldoxime it is estimated that the deviation from coplanarity of the sidechain is at least 40°. The hydroxyl proton shift in dimethylsulfoxide solution of −11.7 p.p.m., relative to internal tetramethylsilane, indicates a *cis* arrangement of the hydroxyl and aromatic groups.

Canadian Journal of Chemistry, 47, 3707 (1969)

Spectral Analysis

At 60 MHz the proton magnetic resonance of a 4 mole % solution of 2,6-dichlorobenzaldoxime, **1**, in acetone consists of a tightly coupled AB_2X spectrum (the hydroxyl proton is involved in exchange-averaged hydrogen-bonding equilibria with solvent and solute molecules and is not observed to couple to other protons). Because of

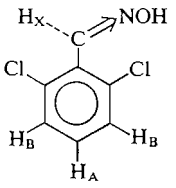
Spectral Analysis

At 60 MHz the proton magnetic resonance of a 4 mole % solution of 2,6-dichlorobenzaldoxime, **1**, in acetone consists of a tightly coupled AB_2X spectrum (the hydroxyl proton is involved in exchange-averaged hydrogen-bonding equilibria with solvent and solute molecules and is not observed to couple to other protons). Because of



1

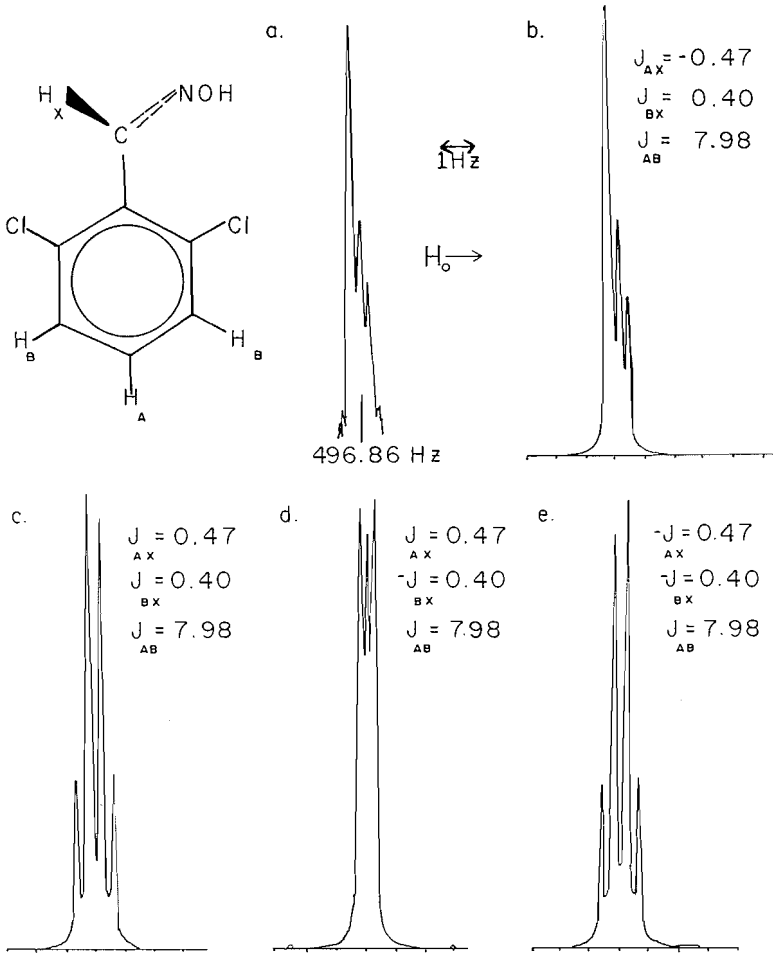


FIG. 1. In *a*, the proton magnetic resonance spectrum of the C—H proton in the sidechain of 2,6-dichlorobenzaldoxime is shown. In *b*, *c*, *d*, and *e*, the computed spectra are shown for various sign combinations J_{AB}, J_{AX}, and J_{BX}. The magnitudes of J_{AB}, J_{AX}, and J_{BX} are in Hz.

the tight coupling between H_A and H_B any asymmetry in the resonance of H_X depends on the relative signs of J_{AB} to J_{AX} and J_{BX} (1,2). In Fig. 1 the observed resonance of H_X is compared with the computed spectra for various combinations of relative signs of the above coupling constants. It is clear that $J_{AX}/J_{AB} < 0$ while $J_{BX}/J_{AB} > 0$. $J_{AB} \equiv J_o^{HH}$ is known to be positive and normal analysis procedures yield the following parameters, where chemical shifts are given relative to internal tetramethylsilane.

$$\nu_A = -7.366 \pm 0.003 \text{ p.p.m.}$$
$$\nu_B = -7.450 \pm 0.003 \text{ p.p.m.}$$
$$\nu_X = -8.283 \pm 0.003 \text{ p.p.m.}$$
$$\nu_{OH} = -10.83 \pm 0.01 \text{ p.p.m.}$$

$$J_{AB} \equiv J_o^{HH} = 7.98 \pm 0.03 \text{ Hz}$$
$$J_{BX} \equiv J_m^{H,CH} = 0.40 \pm 0.02 \text{ Hz}$$
$$J_{AX} \equiv J_p^{H,CH} = -0.47 \pm 0.01 \text{ Hz}$$

Long-range Coupling Constants

At room temperature benzaldehyde flips rapidly between planar conformations (3,4) and $J_p^{H,CHO} = -0.03$ Hz (5), consistent with a σ-π polarization mechanism (6,7) for this coupling. In some ortho disubstituted benzaldehydes the average conformation is nonplanar (8) and leads to larger magnitudes of this negative coupling.

In 2,6-dichlorobenzaldoxime there must also be substantial steric interactions hindering a coplanar conformation of the sidechain and the aromatic ring. An estimate of the deviation from

coplanarity can be made on the unproved assumption that $J_p^{H,CH} = -1.2$ Hz when the C—H bond lies perpendicular to the aromatic ring. The value of -1.2 Hz is derived from $J_p^{H,CH_3} = -0.62$ Hz in toluene (9) where $\langle\cos^2\theta\rangle = 0.5$. The angle θ measures the deviation of the C—H bond from a perpendicular conformation and because the barrier to rotation in toluene is only 0.014 kcal/mole (10), $\cos^2\theta$ may be averaged over the rotation in this simple way. On this assumption a value of $\theta = 50°$ is derived for 2,6-dichlorobenzaldoxime. It may be that in this compound the maximum value of $J_p^{H,CH}$ is less than in toluene, in which case the derived value of θ represents an upper limit. At any rate, it is consistent with a value of $\theta = 70°$ derived by a similar assumption for 2,6-dichlorobenzaldehyde (8), where smaller steric interactions are expected, as well as with a value of $\theta = 71°$ found for the *anti* isomer (aromatic ring and hydroxyl groups in a *cis* arrangement) of *p*-chlorobenzaldoxime in the solid state (11).

Because both σ and π electron contributions to $J_m^{H,CH}$ may exist (12) and because for nonplanar conformations the π contribution possibly compensates for a decreased σ contribution, it is not justified to use the value of $J_m^{H,CH}$ as a check on the degree of nonplanarity derived from the magnitude of $J_p^{H,CH}$. The relative constancy of $J_m^{H,CH}$ which lies between 0.35 and 0.40 Hz in 2,6-dichlorobenzaldoxime, 2,6-dichloro- , and 2,6-dinitrobenzaldehydes (8), benzaldehyde (5), toluene (9), and in 2,6-dichlorobenzylfluoride (13) suggests the presence of a compensatory effect.

Hydroxyl Proton Shift in Dimethylsulfoxide

In a 4 mole % solution in dimethylsulfoxide $\nu_{OH} = -11.71$ p.p.m. This is close to the value of -11.58 p.p.m. found for the *anti* isomer of benzaldoxime (14) and suggests that the present compound has the aromatic ring and the hydroxyl group placed *cis* to one another (the *syn* isomer of benzaldoxime has $\nu_{OH} = -11.2$ p.p.m.). In the same solvent, $\nu_{OH} - \nu_{CH} = -3.04$ and -3.82 p.p.m. for the *syn* and *anti* isomers of benzaldoxime, respectively. For the present compound, $\nu_{OH} - \nu_{CH} = -3.54$ p.p.m. close to the average of these two values. However, strong mean square electric fields arising from the proximate chlorine substituents may well cause a downfield shift of the C—H protons in 2,6-dichlorobenzaldoxime. Hence the value of -3.54 p.p.m. is considered to be consistent with a *cis* arrangement of the hydroxyl group and the ring.

Experimental

2,6-Dichlorobenzaldoxime from the Aldrich Chemical Co., m.p. 149 °C, was studied as 4 mole % solutions in acetone and in dimethylsulfoxide. Lines were considerably narrower in acetone, probably because of differing viscosities, and therefore spectral analysis were carried out on the acetone solution. Samples were degassed by the freeze-pump-thaw technique and proton magnetic resonance spectra were taken in the frequency sweep made on a DA-60I spectrometer. Spectra were calibrated by reading reciprocals of the sweep and manual oscillator frequencies. Computations were performed by hand and checked using the LAOCN3 program (15) on an IBM 360/65 computer. Computed spectral curves were obtained on a Calcomp plotter attached to an IBM 1620 computer.

Substituent effects in the reaction of aromatic amines and peroxydisulfate

N. VENKATASUBRAMANIAN[1] AND A. SABESAN
Department of Chemistry, Vivekananda College, Madras 4, India

Received April 10, 1969

The kinetics of the reaction between aromatic amines and the peroxydisulfate ion in aqueous basic conditions have been investigated. The effect of substituents has been studied by employing about 25 ortho-, meta-, and para-substituted anilines. The reaction is accelerated by electron-releasing substituents and is retarded by electron-withdrawing substituents, pointing to an electrophilic attack by the $S_2O_8^{2-}$ ion. A better correlation between rate and the Hammett constants is obtained for an electrophilic attack at the nitrogen atom of the amine rather than at the carbon atom of the amine. A good correlation also exists between the log k_2 values and the pK_b of the corresponding amines.

Canadian Journal of Chemistry, 47, 3710 (1969)

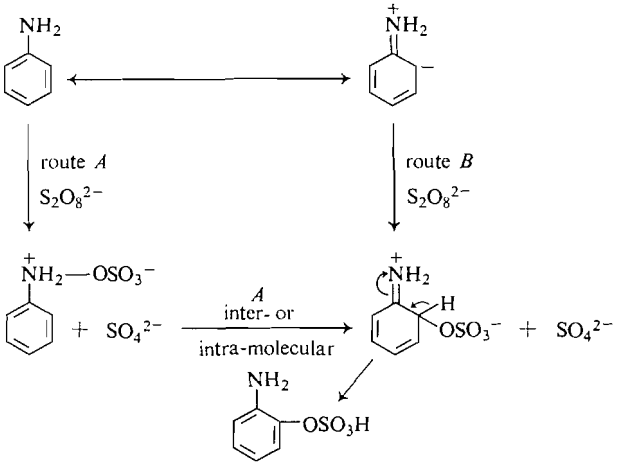
The kinetics of the reaction between aromatic amines and peroxydisulfate in aqueous base, called the Boyland–Sims oxidation (1–4), were recently investigated by Behrman (5) who has proposed a mechanism involving a nucleophilic displacement by the amine nitrogen on the peroxide oxygen to yield the corresponding aryl hydroxylamine *O*-sulfonate (route *A*). This intermediate is then assumed to rearrange to the *o*-amino aryl sulfate.



The alternative possibility of a direct rate-limiting attack at the ortho-carbon (route *B*) was ruled out by a comparison of the rates of oxidation of 2,3- and 2,4-disubstituted anilines. We present in this communication the results of our investigation on this reaction for a series of monosubstituted anilines in order that more extensive substituent effects may be used to test the proposed mechanism (5).

The kinetic studies were carried out in 20% aqueous ethanol[2] (v/v) with a phosphate buffer (pH = 7) under pseudo first order conditions with an amine:peroxydisulfate ratio of 10:1. All the liquid organic compounds were of the extra

pure variety (Fluka AG/Koch-Light/Arapahoe) and were distilled from an all-glass apparatus. Large head and tail fractions were rejected and middle fractions were collected and used. The solid aromatic amines of the extra pure variety (Fluka AG/Koch-Light/Arapahoe) were used without further purification. The reaction was followed by estimating the unreacted peroxydisulfate by the iodometric procedure of Kolthoff and Carr (7). The reaction is of the first order in peroxydisulfate for over 60% of the reaction and also in the neutral amine (Tables I and II; Fig. 1). Allyl acetate, a radical inhibitor has no effect on the rate of consumption of the peroxydisulfate in the present investigations also. The second order rate constants for the oxidation of a number of ortho-, meta-, and para-substituted anilines are presented in Table III. It is evident that electron-releasing substituents on the aniline accelerate the reaction much more when these are para to the $—NH_2$ group than when they are ortho or para to the carbon center where the sulfate group is found ultimately. This, we feel, points to a rate-limiting attack at nitrogen rather than at carbon.

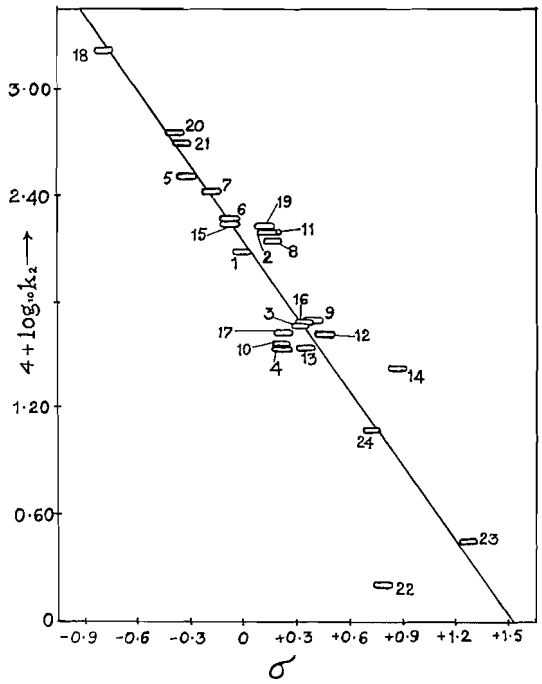

FIG. 2. σ_{p+} values (9) have been used for para substituted anilines, σ_m values for the meta substituted anilines, and σ^* values (14) for the ortho substituted anilines. (*1*) H— (*2*) *p*-Cl (*3*) *m*-Cl (*4*) *o*-Cl (*5*) *p*-CH_3— (*6*) *m*-CH_3— (*7*) *o*-CH_3— (*8*) *p*-Br— (*9*) *m*-Br— (*10*) *o*-Br— (*11*) *p*-I— (*12*) *p*-COOH (*13*) *m*-COOH (*14*) *p*-CH_3CO— (*15*) *p*-F (*16*) *m*-F (*17*) *o*-F (*18*) *p*-CH_3O— (*19*) *m*-CH_3O— (*20*) *o*-CH_3O— (*21*) *o*-C_2H_5O— (*22*) *o*-NO_2— (*23*) *p*-NO_2— (*24*) *m*-NO_2—.

The correlation of these data with the Hammett σ constants (8, 9) is shown in Figs. 2 and 3. The data are plotted in two ways. Figure 2 assumes rate-limiting attack at nitrogen while Fig. 3 assumes a rate-limiting attack at carbon. One might expect that for the meta-substituted anilines, rate-limiting attack at nitrogen should correlate with σ_m while rate-limiting attack at the carbon para to the meta-substituent would give a good correlation of log k_2 for these anilines with σ_{p+} for these substituents. It is already known that the ortho-carbon atom between the NH_2-group and the meta-substituent is not attacked, as steric considerations weigh against this (2) Similarly for *p*-substituted anilines, attack at the nitrogen would be expected to correlate better with σ_{p+} while attack at the carbon should give a correlation with the meta-substitution constants. Further, for the ortho-substituted anilines, nitrogen attack should show a correlation between the logarithm of the rate constants and σ_o while for carbon attack, the same rate constants should be correlated with σ_m for the same substituents. The data displayed in Figs. 2 and 3 show that a good over-all correlation exists only for the plot that assumes attack at the nitrogen rather than at the carbon ortho to the nitrogen. In fact, the points for the second plot for an assumed carbon attack show a random scatter and one cannot discern any linear relationship here. The linear plot in Fig. 2 has a correlation coefficient of 0.9707 (for 22 points excluding the points for *p*-CH_3CO— and *o*-NO_2) which is a fairly satisfactory fit. The Hammett rho for this reaction is −1.41, a value which is nearly the same as was computed by Behrman (5) for the case of the three amines: aniline, *p*-nitro-aniline, and *p*-toluidine (ρ = −1.3). This value compares quite well with the value of −1.86 reported for the reaction of aromatic amines by peroxy acetic acid (10), and of −1.58 for the reaction of nitro-

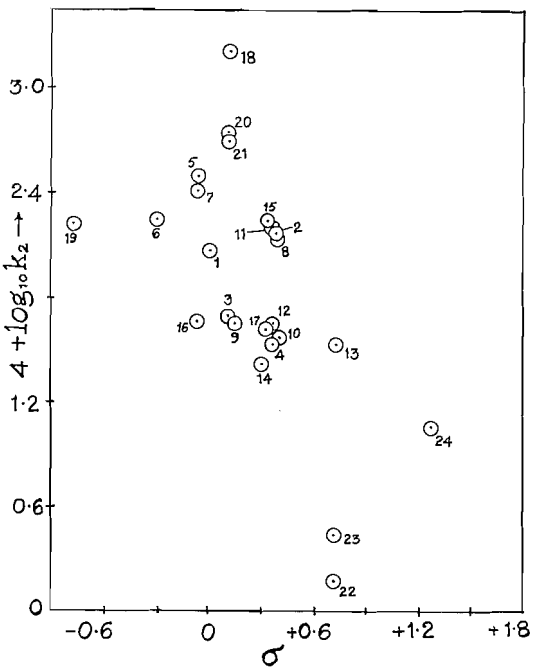

FIG. 3. σ_m values have been used for ortho- and para-substituted anilines and σ_{p+} values for the meta substituted anilines. (*1*) H— (*2*) *p*-Cl (*3*) *m*-Cl (*4*) *o*-Cl (*5*) *p*-CH_3— (*6*) *m*-CH_3— (*7*) *o*-CH_3— (*8*) *p*-Br— (*9*) *m*-Br— (*10*) *o*-Br— (*11*) *p*-I— (*12*) *p*-COOH (*13*) *m*-COOH (*14*) *p*-CH_3CO— (*15*) *p*-F (*16*) *m*-F (*17*) *o*-F (*18*) *p*-CH_3O— (*19*) *m*-CH_3O— (*20*) *o*-CH_3O— (*21*) *o*-C_2H_5O— (*22*) *o*-NO_2— (*23*) *p*-NO_2— (*24*) *m*-NO_2—.

sobenzenes with peroxy acetic acid (11). A good correlation can also be made between log k_2 and the pK_b values of the anilines.

The evidence thus confirms rate-limiting electrophilic attack by the peroxydisulfate ion on the nitrogen of the neutral amine followed by rearrangement to the *o*-amino aryl sulfate. Boyland and Nery (12) have reported that phenyl hydroxylamine *O*-sulfonate rearranges to *o*-amino phenyl sulfate and Behrman (5) has also considered it as a probable intermediate in the reaction between aromatic amines and peroxydisulfate ions.

Initial attack at nitrogen also provides the rationale for the preferential ortho orientation in the Boyland–Sims oxidation as against the preferential para-orientation in the peroxydisulfate oxidation of phenols in alkaline medium (Elbs peroxydisulfate oxidation). The Elbs peroxydisulfate oxidation of phenols further differs from the present work by the fact that in the former case, the use of Hammett correlations as a means of distinguishing the site of attack was indecisive (13).

Adamantanethione and its reduction to 2-adamantanethiol

J. W. GREIDANUS[1] AND W. J. SCHWALM
Department of Chemistry, University of Calgary, Calgary, Alberta

Received July 17, 1969

Reaction of adamantanone with phosphorus pentasulfide affords the corresponding thioketone. This new, comparatively very stable alicyclic thione was also obtained by an indirect route from 2-ethoxy-2-adamantanethiol. Reduction of the thioketone with sodium borohydride yields 2-adamantanethiol.

Canadian Journal of Chemistry, 47, 3715 (1969)

An interest in the properties of non-aromatic thioketones as well as in the chemistry of adamantane has prompted us to prepare adamantanethione (**2**). We expected that this non-enolizable thioketone would be comparatively stable and this was found to be the case.

Few stable non-aromatic thioketones are known and as a result the chemistry of these compounds has not been well investigated. Suitably substituted adamantanethiones might be of considerable interest for optical rotatory dispersion studies of the thiocarbonyl group.

Our initial attempts to obtain the thione from adamantanone (**1**) and H_2S at low temperature (1) gave very unsatisfactory results and we decided to treat the ketone with phosphorus pentasulfide. In the few instances where the latter method has been used by others for the preparation of unsubstituted aliphatic or alicyclic thioketones, either no details for the preparation were given or the results have been considered very doubtful by others, it seems. Several reviews on this topic exist (2).

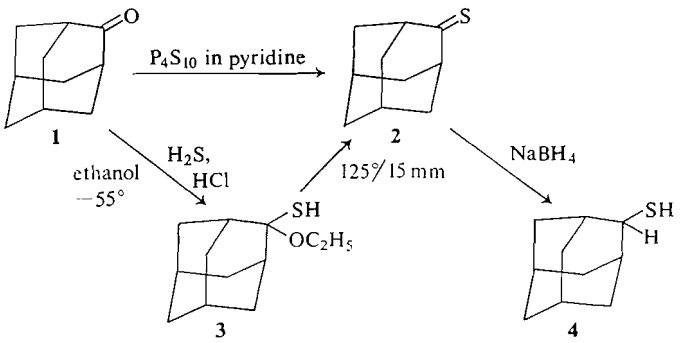
When a solution of 40 mmoles of adamantanone (**1**) and 14 mmoles of P_4S_{10} in dry pyridine was stirred for 96 h at 25° and subsequently added to petroleum ether, adamantanethione (**2**) could be isolated by evaporation of the washed (H_2O) and dried pink–orange supernatant, in 40–55% yield, as a red–orange crystalline[2] solid that could be sublimed readily at 85° and 15 mm, m.p. 173–174°. Its ultraviolet spectrum (*n*-hexane) shows a maximum at 240 mμ (ε with 12 700) a shoulder at 223 mμ; in the visible region (*n*-hexane) it has maxima at 488 mμ (ε 11.3) and 554 mμ (ε 2.7). The band at 488 mμ shows some fine structure as has been observed in the case of other thiones (3). The n.m.r. spectrum of the compound (in CCl_4) shows a broad singlet at τ 6.60 (2H) and a singlet at τ 7.96 (12H). The two bridgehead hydrogens adjacent to the thiocarbonyl group are more strongly deshielded than the corresponding hydrogens in adamantanone, which absorb under identical conditions at τ 7.58. This is another example of the larger anisotropy effect of the thiocarbonyl group as compared to the carbonyl group (4).

Very recently we discovered a new method for the preparation of adamantanethione from the ketone (**1**) via 2-ethoxy-2-adamantanethiol (**3**). The latter compound was prepared according to a reported method (5) and obtained as a colorless solid in a yield of 57%, m.p. 30.5–31.5°. Its infrared (i.r.) spectrum (neat) shows a weak absorption at 2560 cm^{-1} (attributed to the thiol group), its n.m.r. spectrum (in CCl_4) a quartet at τ 6.41 (2H, J = 7 Hz), a triplet at τ 8.84 (3H, J = 7 Hz), a singlet at τ 8.68 (1H) and a complex multiplet between τ 7.5 and 8.6 (14H). When 2-ethoxy-2-adamantanethiol (**3**) was heated for 60 min at 100–130° at 15–100 mm, the colorless liquid turned gradually into a red–orange solid. The product was almost pure adamantanethione (**2**), obtained in yields as high as 93%. The smooth preparation of a thioketone by elimination of an alcohol from a geminal alkoxythiol has not yet been reported to our knowledge.

As it seemed that reduction of the thione might

[1]To whom correspondence should be addressed.

[2]Satisfactory elemental analyses were obtained for all new compounds. Melting points were taken in sealed capillary tubes (liquid bath) and are uncorrected. The nuclear magnetic resonance (n.m.r.) spectra were run at 60 or 100 MHz in the solvent indicated, with tetramethylsilane as an internal standard.



be a convenient route to 2-adamantanethiol (**4**), adamantanethione was treated with an equimolar quantity of sodium borohydride in 1,2-dimethoxyethane. The orange color of the solution disappeared rapidly and 2-adamantanethiol (**4**) was obtained in a yield of 79%. Sublimation in a vacuum (15 mm) at 85° was a convenient method of purification, giving a product with m.p. 160–161°. Its n.m.r. spectrum (CCl_4) shows between τ 7.5 and 8.7 a broad multiplet (14H) with a pattern typical for a 2-substituted adamantane (6), and two doublets at τ 8.53 and 6.68 for the spin-coupled ($J = 7$ Hz) proton of the thiol group and the hydrogen at C-2, respectively. For further characterization of the thiol, 2-adamantyl 3,5-dinitrothiolbenzoate, m.p. 171–172°, and 2-(methylsulfonyl)adamantane, m.p. 113–114°, were prepared. The thiolester shows in the i.r. spectrum (KBr disk) a strong absorption at 1660 cm^{-1} (C=O).

With the methods described a new, comparatively very stable alicylic thioketone and 2-adamantanethiol have become accessible. Further studies of the properties of these and related compounds are in progress.

An estimation of the magnitudes of the contributions from spin polarization and from hyperconjugation to the hyperfine splitting constant of an hydroxylic proton

T. E. GOUGH[1] AND G. A. TAYLOR

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received April 21, 1969

Proton hyperfine splitting constants of monoprotonated *p*-benzosemiquinone are presented for a range of solvents and sample-temperatures. The dependences of these splittings upon temperature, together with the assumption that the hydroxyl group can be described as a torsional harmonic oscillator, are used to evaluate an equation linking a_{OH}, the hyperfine splitting constant of the hydroxylic proton, in gauss, with ρ_O and ρ_C, the spin densities on the hydroxyl oxygen and on the adjacent carbon atoms, and θ, the dihedral angle between the O—H bond and the plane of the aromatic ring.

$$a_{OH} = -19\rho_O + 30\rho_C \langle \sin^2 \theta \rangle$$

Experimental evidence of a positive contribution to a_{OH} is obtained from the spectra of monoprotonated durosemiquinone in tri-*n*-butylphosphate at elevated temperatures.

Canadian Journal of Chemistry, 47, 3717 (1969)

Introduction

Ultraviolet irradiation of neutral solutions of quinones results in the formation of monoprotonated semiquinone radicals, of the general

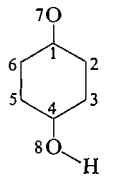

FIG. 1. Structural formula of monoprotonated *p*-benzosemiquinone and the numbering system employed in the present text.

formula shown in Fig. 1, which have been characterized by their electronic (1, 2) and electron spin resonance (3–5) spectra. The latter show that protonation of the semiquinone causes a major redistribution in unpaired electron density; positions ortho to the hydroxyl group carry a small negative spin density (of the order of -0.02) while the meta positions carry an appreciable positive spin density (of the order of $+0.2$). When the medium is sufficiently viscous, the hyperfine splitting pattern of the hydroxylic proton is broadened to high field (see e.g. Fig. 2 of ref. 6), indicating a negative splitting constant for this proton (7).

It is clear (4, 8) that two opposing contributions determine the magnitude and sign of the hyperfine splitting constant of the proton of a hydroxyl group substituted into an aromatic system containing an unpaired electron. Conjugation between the oxygen and aromatic π-systems will place unpaired electron density on the oxygen. This unpaired electron density, ρ_O, will spin-polarize the electrons of the O—H bond, in a manner analogous to that postulated by McConnell for an aromatic CH fragment (9), thereby generating a negative proton hyperfine interaction proportional to ρ_O.

Following the derivation of McConnell and Strathdee (10), Derbyshire calculated a proportionality constant for this interaction of -14 G (11); these calculations involved the assumption that the OH bond has 40% ionic character. However, whenever rotation about the C—O bond places the hydroxylic proton out of the nodal plane of the aromatic π-system, direct

[1]To whom all correspondence should be addressed.

overlap between this system and the proton will result in a positive hyperfine interaction. The size of this interaction will be determined by ρ_C, the unpaired spin density at the substituted carbon, and also by θ, the dihedral angle between the plane of the aromatic ring and the direction of the O—H bond. Quantitatively, for the radical $HO.CH.CO_2^-$ trapped in anhydrous lithium glycollate, $\theta = 56°$, while in lithium glycollate monohydrate, $\theta = 0°$, the corresponding splittings being $+14$ and -2.5 G (12). Taking ρ_C as 0.78 and neglecting spin-polarization in the O—H bond, Whiffen proposed (12) a hyperconjugative interaction of the form

$$[1] \qquad a_{OH} = (-3.2 + 31 \sin^2 \theta)\rho_C \quad \text{G}$$

The small negative term probably reflects the presence of a significant contribution to a_{OH} from a spin-polarization mechanism.

For the experimental determination of these proportionality constants for a radical in solution, it is necessary to allow for torsional oscillations of the OH group which will cause the time averaged value of $|\theta|$ to be non-zero. The effects of torsional oscillations on the ^{14}N and ^1H hyperfine splitting constants of the amino group of the 4-amino-2,6-di-*t*-butylphenoxy radical have been invoked (13) to interpret the temperature dependence (14) of these splitting constants. In this work we apply similar arguments to the hydroxyl group of monoprotonated-*p*-benzosemiquinone, thereby assuming that the equilibrium configuration of the radical is planar, and that the hydroxyl group may be described as a torsional harmonic oscillator, populating all its vibrational states according to Boltzmann statistics.

With these assumptions, it may be shown (13) that

$$[2] \qquad \langle\theta^2\rangle = \frac{h\nu}{2\kappa} \coth\left(\frac{h\nu}{2kT}\right)$$

where ν is the fundamental frequency of the vibration and κ is the associated force constant. Measurement of the temperature dependence of the hyperfine splitting constant of a hydroxyl group, together with calculations of θ, ρ_C, and ρ_O, will therefore allow an evaluation of the magnitudes of the hyperconjugative and spin-polarization mechanisms contributing to this splitting.

Experimental

The apparatus used for the production of semiquinone radicals, and for the observation of their electron spin resonance spectra, has been described previously (6). Solutions were prepared "in vacuo" because the presence of small amounts of water was found to have some effect on the measured hyperfine splitting constants, and on their variations with changes in temperature. *p*-Benzoquinone-$^{13}C_1$ (52% isotopic purity) was purchased from Merck, Sharp, and Dohme.

Results

The general structural formula of the radicals under investigation, and the numbering system used are given in Fig. 1.

Electron spin resonance spectra of monoprotonated *p*-benzosemiquinone, dissolved in a number of solvents, were recorded over as wide a range of temperatures as possible. The maximum attainable temperature was determined by boiling the solvent; lack of resolution of the components of the spectrum at reduced temperatures determined the lower limit at which observations were made.

The experimentally determined hyperfine splitting constants are given in Table I, where numerical subscripts are used to relate splitting constants to the numbering system of Fig. 1. Thus, a_i is the measured hyperfine splitting constant of the hydrogen bonded to atom i of the molecule. In every spectrum a_3 was found to equal a_5; however, at reduced temperatures, when rotation of the hydroxyl group was slow, a_2 and a_6 were found to differ by approximately 0.35 G (6). In all cases, the value reported in Table I for a_2 is the mean meta splitting constant; at high temperatures rotation of the hydroxyl group effected the averaging, while at low temperatures the averaging was performed numerically. The signs given to the hyperfine splitting constants are those determined in a previous investigation of monoprotonated *p*-benzosemiquinone (4).

Experiments using benzoquinone labelled with 52% ^{13}C at position 1 of the parent quinone (26% labelling at either C_1 or C_4 of the radical) were undertaken to obtain further data with which to evaluate the spin density distribution of the radical. However, such experiments were not in general successful; anisotropic effects, as might be expected, were particularly severe for the ^{13}C splittings, yet it was only in viscous solvents that relatively large stationary-state concentrations of radicals were obtained. Table II contains the experimentally determined hyperfine splitting constants; the signs of the splitting constants, and their assignments to position 1 or 4, were determined from the direction of the

anisotropic broadening, in conjunction with the known (3) gross features of the spin density distribution.

Measurements were also made of a_8 for monoprotonated durosemiquinone in *i*-propanol, tetrahydrofuran, and tri-*n*-butylphosphate at various temperatures. The results are given diagramatically in Fig. 2; the signs used for a_8 in these systems are discussed below.

Discussion

Since both spin-polarization and hyperconjugative mechanisms contribute to the hyperfine splitting of the hydroxylic proton of monoprotonated *p*-benzosemiquinone, we may write

$$[3] \qquad a_8 = Q_\pi \rho_8 + Q_\sigma \rho_4 \langle \sin^2 \theta \rangle$$

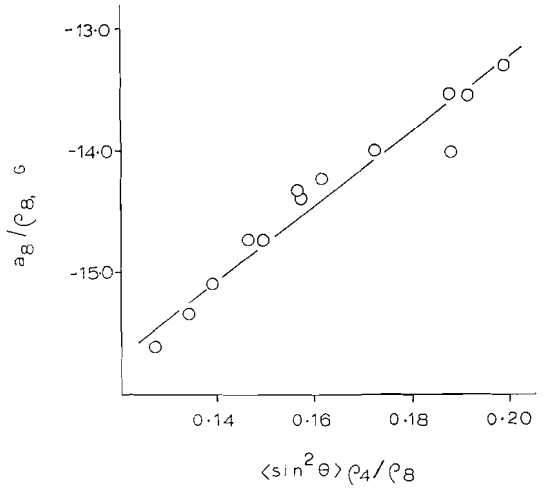

FIG. 3. The plot of a_8/ρ_8 vs. $\langle \sin^2\theta \rangle \rho_4/\rho_8$ for monoprotonated *p*-benzosemiquinone in 2-methyltetrahydrofuran. In generating these points the torsional frequency of the hydroxyl group was taken as 300 cm^{-1}.

or rearranging

$$[4] \qquad a_8/\rho_8 = Q_\pi + Q_\sigma \langle \sin^2\theta \rangle \rho_4/\rho_8$$

where Q_π and Q_σ are the proportionality constants governing the two interactions. Thus a plot of a_8/ρ_8 against $\langle \sin^2\theta \rangle \rho_4/\rho_8$ should be a straight line of slope Q_σ and intercept Q_π. Evaluation of Q_σ and Q_π, therefore, requires knowledge of θ, ρ_4, and ρ_8; evaluation of θ, in turn, requires knowledge of ν and κ (see eq. [2]). The fundamental torsional frequency of the hydroxyl group of phenol has been quoted as occurring at 300 (15), 310 (16), and 320 cm^{-1} (17). We have performed calculations using both extreme values of ν; the corresponding values of κ are 2400 and 2730 cm^{-1} radian^{-2}. In applying these values to the present system, we have assumed that the extra π-electon of the radical does not cause too drastic an increase in ν. Parenthetically, it may be noted that the corresponding value of ν for methanol is 270 cm^{-1} (18).

Calculations of ρ_4 and ρ_8 were performed for each sample, at each temperature, using McLachlan's self-consistent field theory (19). Parameters for the inclusion of the heteroatoms O_7 and O_8 were chosen using methods similar to those already found satisfactory for semiquinone anions (20) and radicals (6). The following parameters, using conventional notation (21), were employed: $\lambda = 1.20$, $h_0 = 1.42$ and 1.17 in protic and aprotic solvents, respectively (22), $k_{C_1O_7} = 1.46 + \Delta$, $k_{C_4O_8} = (1.46 - \Delta)\cos\theta$, where Δ is an adjustable parameter, θ is as defined above, and the value of 1.46 is the optimum value of k_{CO} for symmetrical *p*-benzosemiquinone (22). Thus protonation at O_8 was simulated by increasing the bond order of C_1O_7 and decreasing the bond order of C_4O_8 in keeping with the various valence-bond structures which may be drawn to place high spin density at C_2 and C_6, but not at C_3 and C_5. The factor $\cos\theta$ was applied to $k_{C_4O_8}$ to simulate the decrease in overlap brought about by out-of-plane bending of the hydroxyl group; $\cos\theta$ was evaluated at each temperature, but was assumed independent of solvent.

Once the above numerical constants were fixed, there remained one arbitrary parameter, Δ, with which to describe the effects of solvation upon the spin density distribution (cf. ref. 3). For example, at each temperature Δ was varied, in steps of 0.01, to obtain the optimum agreement between the calculated ratio ρ_2/ρ_3 and the experimental ratio a_2/a_3. In such calculations, a value for $Q_{CH}{}^H$ need not be assigned; however, in all cases the calculated ratio a_2/ρ_2 was found to be close to -24 G, indicating that reasonable spin density distributions were obtained.

From the appropriate calculated and experimental data, numerical values of a_8/ρ_8 and $\langle \sin^2\theta \rangle \rho_4/\rho_8$ were determined and fitted, by the method of least squares, to the straight line represented by eq. [4]. Results for Q_π, Q_σ, and the root-mean-square error (of a_8/ρ_8) are given in Table III. The plot for the results obtained in the solvent 2-methyltetrahydrofuran is given in Fig. 3 ($\nu = 300$ cm^{-1}).

The results for both Q_σ and Q_π fall into two groups, protic and aprotic. It is felt that this difference is to be attributed to the choice of h_0 used for the protic solutions; the value of $h_0 = 1.42$ was derived as the optimum parameter for *p*-benzosemiquinone in a 30–70% water–ethanol mixture (22), a medium of considerably greater solvating power than the three protic solvents used in the current work. Therefore, the value of h_0 used is too high; a value of $h_0 \sim 1.30$ gives good agreement between the results for protic and aprotic solvents. Thus a value of -19 G would seem to be a suitable value for the proportionality constant of the spin-polariza-

tional contribution to the hyperfine splitting constant of a hydroxylic proton. This value is in satisfactory agreement with the calculated value of -14 G put forward by Derbyshire (11). The value of Q_π is not a function of ν (within the error involved in fitting the data) since it is obtained by extrapolation to the point where $\theta = 0$.

The value of Q_σ depends on the choice of ν; however, it would seem that a value of Q_σ between 30 and 40 G would be appropriate. The value suggested by Whiffen is 31 G, an agreement which is noteworthy, since much poorer agreement was obtained for the C—N—H fragment (suggested values of Q_σ: for γ-irradiated glycine 38 G (12); for the 4-amino-2,6-di-*t*-butylphenoxy radical 143 G (13)). Although some of this discrepancy may be due to the difference in charge density between the two systems, it would seem that the assumption of a planar equilibrium configuration for the amino group of the aminophenoxy radical (13) is unjustified, and that, as in aniline (23), the nitrogen is pyramidal. Similarly, the agreement between the presently obtained value and that of Whiffen support the assumption that monoprotonated *p*-benzosemiquinone is planar in its equilibrium configuration.

If the hydroxyl proton of a monoprotonated semiquinone is placed sufficiently far out of the plane of the aromatic ring, then the hyperconjugative mechanism will predominate, and a positive value for a_8 will be observed. Previous experiments (3) have shown that for monoprotonated durosemiquinone the ratio a_8/ρ_8 is extremely sensitive to the solvent employed. The results are consistent with the hypothesis (4) that larger solvent molecules, by reinforcing the steric effects of the *ortho* methyl groups, cause the hydroxyl group to be further from the plane of the aromatic ring. Accordingly, we have examined spectra of monoprotonated durosemiquinone, at high temperatures, in tri-*n*-butylphosphate, which has the largest molar volume of the solvents suitable for the present experiments. As may be seen from Fig. 2, the temperature dependence of $|a_8|$ is the reverse of that observed for all other systems, suggesting that under these extreme conditions a_8 is positive. Confirmation of the postulated positive sign is provided by the fact that, unlike the other systems, the components of the OH doublet broaden to low rather than high field.

The results for Q_σ and Q_π are dependent upon calculations of spin densities, and hence upon the choice of input parameters. A detailed study of the ^{13}C hyperfine splitting constants of positions 1 and 4, over a range of temperatures and solvents, would have allowed us to eliminate our arbitrary assignments of h_0 and k_{CO}, and to replace them by values chosen to give the best fit between calculated and observed hyperfine splitting constants. However, we were unable to obtain a sufficiently comprehensive set of data for this purpose. It is of interest, nevertheless, to calculate, from the spin density distributions used to evaluate Q_σ and Q_π, the expected ^{13}C hyperfine splitting constants, and to compare them with the experimental values. Using standard notation (24)

$$[5]\quad a_1^C = (S^C + 2Q_{CC'}^C + Q_{CO}^C)\rho_1 + Q_{C'C}^C(\rho_2 + \rho_6) + Q_{OC}^C\rho_7$$

a similar equation holding for a_4^C. We take $S^C = -12.7$ G, $Q_{CC'}^C = 14.4$ G, and $Q_{C'C}^C = -13.9$ G (25). The values of Q_{CO}^C and Q_{OC}^C have been shown to be dependent upon the chemical identity of the CO bond; for the *p*-benzosemiquinone anion, values of Q_{CO}^C and Q_{OC}^C of 17.7 and -27.1 G, respectively, have been given (24), while for the phenoxy radical the corresponding values are 8.9 and 16.4 G (26).

The monoprotonated *p*-benzosemiquinone radical may be regarded as the 4-hydroxyphenoxy radical, so that a_1^C may be calculated using $Q_{CO}^C = 8.9$ G, $Q_{OC}^C = 16.4$ G. Unfortunately, similar parameters to allow the evaluation of a_4^C, a more crucial calculation in the present context, are not available.

Calculated and experimental ^{13}C hyperfine splitting constants are given in Table II. The agreement between calculation and experiment is as good as might be expected since the calculation involves the summation of larger terms of opposite signs. Furthermore, the extreme sensitivity to chemical environment of Q_{CO}^C and Q_{OC}^C introduces some uncertainty as to the values to be used for these parameters. Thus the limited data so far available for ^{13}C hyperfine splitting constants indicate that the calculated spin density distributions satisfactorily approximate the actual distributions.

The calculations using $\nu = 300\ cm^{-1}$ more closely approximate the observed ^{13}C hyperfine

splitting constants, indicating that a value of $Q_\sigma = 30$ G (cf. 31 G, ref. 12) is to be preferred. Thus the hyperfine splitting constant of a hydroxylic proton in gauss may be described by eq. [6]

$$[6] \qquad a_{OH} = -19\rho_O + 30\rho_C\langle \sin^2 \theta \rangle$$

Studies on the decomposition of tetra-alkylammonium salts in solution. Part II. Dependence of the activation parameters on the structure of the substrate[1]

J. T. BURNS AND K. T. LEFFEK
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received April 24, 1969

The enthalpy and entropy of activation for the decomposition reaction of seven tetra-alkylammonium iodides in chloroform solution have been measured. All the salts contained the benzyl group attached to the nitrogen atom and decomposed to yield benzyl iodide and a tertiary amine as the only products.

A Hammett free energy correlation is made and used to deduce the nature of the transition state, and a rationalization of the variation of the enthalpy and entropy of activation with the structure of the substrate is given.

Canadian Journal of Chemistry, 47, 3725 (1969)

Introduction

In the first paper of this series (1) the mechanism of the thermal decomposition of phenylbenzylallylmethylammonium iodide in chloroform solution was shown to be a unimolecular decomposition of the ammonium ion, very probably associated with another molecule of the ammonium iodide in the form of a triple ion. The reaction was found to have a high enthalpy of activation and a positive entropy of activation. The present work reports the activation parameters of seven other tetra-alkylammonium iodides, all of which contain the benzyl group and decompose in chloroform to form benzyl iodide, a tertiary amine, and no other product.

Results and Discussion

The products of the decomposition of each iodide were analyzed by vapor phase chromatography (v.p.c.). In each reaction only 2 product peaks were obtained which were identified as benzyl iodide and the aniline, by matching the retention times with those of pure samples under the same chromatographic conditions.

The specific reaction rates were measured conductometrically (1), in duplicate, at 5 different temperatures over a 15–20° range for each compound. Good straight line Guggenheim plots (2) were obtained in all cases, from which first order rate constants were obtained by a least squares analysis.

The first order rate constants are collated in Table I and the activation parameters derived from them, by least squares calculations using the transition state theory equation, are given in Table II.

Hammett Correlation

For the substituted phenyl compounds, a plot of $\log k$ vs. σ yields a ρ value of $+1.4$ for this reaction, confirming that the nitrogen atom has a reduced positive charge in the transition state, but not very much so. Values of ρ, calculated by Jaffé (3) from data by Laidler (4), for the quaternization of N,N-dimethylaniline with methyl iodide in nitrobenzene solution, range from -2.7 to -3.1 for various temperatures. Jaffé also calculated similar negative values from other work for the same reaction in different solvents (5, 6) and further examples were reported by Rossell (7).

In these reactions the movement of electrons is in a direction away from the benzene ring so that electron withdrawing substituents on the ring hinder the reaction. Since such substituents have positive σ values, ρ for these reactions is negative. The magnitude of ρ is similar to that obtained from the equilibrium constants for the protonation of dimethylanilines (8) and therefore indicates that the Menschutkin reaction has a product-like transition state with a large amount of charge development on the nitrogen atom, a conclusion which had been reached earlier (9) by a comparison of the entropy of reaction and the entropy of activation, although Rossell (7) has suggested that the similarity of the two entropies is not a general result. Now for the

reverse Menschutkin reaction, according to the principle of microscopic reversibility, the transition state would be expected to be reactant-like, that is, it should occur before the electrons bonding the benzyl group to the nitrogen have been transferred to the nitrogen to any large extent. Thus the magnitude of ρ should be small and, since the movement of electrons is in the reverse direction to that in the Menschutkin reaction, i.e., towards the phenyl ring, the sign of ρ should be positive. The value of +1.4 obtained for this reaction is in accord with such a transition state.

Activation Parameters

The compounds listed in Table II fall into 2 series, the first with various alkyl groups replacing one of the methyl groups on the nitrogen atom and the second with para-substituted phenyl groups.

In the first series the free energies of activation, which may be assumed to have the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

standard deviations as the corresponding enthalpies of activation, are constant within the experimental error. The enthalpies and entropies of activation do appear to change with the alkyl group attached to the nitrogen atom, but the changes are not large compared to twice the standard deviations so that the interpretation must be cautious. On the other hand, the second para-substituted phenyl series shows definite changes in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ which do not cancel exactly and hence the free energies of activation show a slight change with substrate structure.

Since the free energies of activation for all eight compounds are within a range of 0.9 kcal/mole there is a good correlation between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, but the significance of these correlations is by no means established (10–12). It has been suggested (11) that a relation between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ can be established by plotting the activation energy against the logarithm of the rate constant. Such a graph can be plotted of $\Delta H^{\ddagger}$ (from Table II) against log k, at 35° (from Table I). A reasonable correlation exists, although the points are, of course, more scattered than those for a $\Delta H^{\ddagger}$ vs. $\Delta S^{\ddagger}$ plot. However, little can be concluded from this, other than the reactions of this series all proceed by the same mechanism, which serves only as a confirmation of what has already been assumed implicitly. Therefore, it seems more reasonable to try to interpret the activation parameters directly, in qualitative terms of what factors may be assumed to contribute to their magnitude. Several groups of workers have discussed the Menschutkin reaction in terms of factors arising from within the substrate molecule and those from solvation effects, especially with respect to changes in rate with pressure. These have been summarized recently by Weale (13) who concluded that "bonding" and "solvation" effects were of roughly equal importance for a Menschutkin reaction, but that solvation effects were dominant for the reverse Menschutkin reaction. This may also be inferred simply from the extent of the solubility of these ammonium salts and the ease with which the decomposition reactions proceed in chloroform.

Thus the enthalpy and entropy of activation will be considered to arise from contributions from within the substrate molecule ($\Delta H^{\ddagger}_{\text{int.}}$ and $\Delta S^{\ddagger}_{\text{int.}}$) and from solvent reorganization ($\Delta H^{\ddagger}_{\text{solv.}}$ and $\Delta S^{\ddagger}_{\text{solv.}}$).

With increasing electron release by substituent groups towards the nitrogen atom $\Delta H^{\ddagger}_{\text{int.}}$ should increase, since the electrons from the benzyl carbon atom will be less easily transferred to the nitrogen. $\Delta S^{\ddagger}_{\text{int.}}$ will always be a positive entropy contribution in this unimolecular reaction, but its change in magnitude with substituent group will depend upon the relative extent of bond breaking which cannot be estimated beyond the conclusion reached from the value of ρ.

The contribution $\Delta H^{\ddagger}_{\text{solv.}}$ should decrease with increasing electron release towards the nitrogen atom because greater charge delocalization would yield a weaker solvation shell in the initial state which would require less energy to reorganize it during the activation process. $\Delta S^{\ddagger}_{\text{solv.}}$ may give a negative or positive contribution depending upon whether the positive charge is more or less concentrated in the transition state relative to the initial state. It is possible to imagine that with a strong electron releasing substituent group, the positive charge is extensively delocalized in the initial state and becomes more localized (on the benzyl carbon atom) during activation.

The experimental results may be rationalized to some extent in these terms as it is seen that electron releasing groups in the para position of the phenyl group give low $\Delta H^{\ddagger}$ and negative $\Delta S^{\ddagger}$ values while electron attracting groups give higher $\Delta H^{\ddagger}$ and positive $\Delta S^{\ddagger}$ values, consistent with the postulate that solvation changes are important in these reactions. For the compounds with various alkyl groups substituted on the nitrogen atom, the inductive charge delocalizations would be much less than for the para-substituted series and would change less with change of alkyl group. Thus for these reactions the solvation changes are of lesser importance giving positive $\Delta S^{\ddagger}$ values and generally activation parameters which do not change very much from one compound to the next.

Such a rationalization provides a clearer picture than the various correlations which can be made, and predicts that the relative activation parameters of the para-substituted series should be dependent upon the solvent, which dependence it is hoped to investigate in the immediate future.

In making a rationalization of this sort, attention is focused on one of several contributions

to the activation parameters in the hope that the one, in this case "solvation effects", dominates the others. Although this approach is far from ideal, it is the only practical method of developing theories in kinetic studies.

Experimental

Materials

The quaternary ammonium iodides were prepared by reacting benzyl iodide, which had been purified by distillation at reduced pressure, with the appropriate tertiary amine in equimolar proportions, either with or without a solvent. The reaction mixture was usually allowed to stand several hours at room temperature before the solid product was separated by filtration, washed, dried, and recrystallized from ethanol or a mixture of ethanol and diethyl ether. Table III shows for each salt the yield, melting point, and % purity determined by potentiometric titration of the iodide ion against standard silver nitrate solution. Some of the melting points are a few degrees higher than those in the literature (14–16). N,N-dimethylaniline, N-methyl-N-ethylaniline, *p*-bromo-N,N-dimethylaniline, and *p*-methyl-N,N-dimethylaniline were commercial products purified by distillation.

N-methyl-N-propylaniline was prepared by the method of Claus and Hirzel (17). An equimolar mixture of N-methylaniline and *n*-propyl bromide was heated on a water bath for 5 h and the hard mass which resulted was dissolved in water. The unreacted starting materials were removed by extraction with diethyl ether. After treatment with concentrated NaOH solution the product was distilled twice (boiling range 216–218 °C). The yield was 69%.

p-Methoxy-N,N-dimethylaniline was prepared according to the method of Thomas *et al.* (18). An equimolar mixture of purified *p*-anisidine and trimethyl phosphate was refluxed for 2 h after the initial reaction had subsided. The mixture was then hydrolyzed for $1\frac{1}{2}$ h with NaOH solution, diluted with water, and the amine was isolated by extraction with diethyl ether. After drying and removal of the ether, the amine was twice distilled (239–240 °C) at atmospheric pressure. The yield was 42% and the melting point was 38–39 °C (ref. 18, 37–38.5 °C).

p-Chloro-N,N-dimethylaniline was prepared by the same method in a yield of 55%. The product had a boiling range 240–241 °C at atmospheric pressure and a melting point of 32–33 °C (ref. 18, 32–33.5 °C).

The chloroform solvent was Matheson, Coleman and Bell chromatoquality reagent 99.8%. Analysis by v.p.c. showed that this contained traces of hydrocarbon stabilizer and chlorinated hydrocarbons.

The kinetic measurements were made with 0.05 *M* solutions by the procedure described previously (1) and the duplicate kinetic runs in all cases fitted the Guggenheim equation as well as the run quoted in that paper (1).

Oxidations involving silver. V. The oxidation of primary aliphatic amines

N. A. HAMPSON, J. B. LEE[1], J. R. MORLEY, AND B. SCANLON
Department of Chemistry, University of Technology, Loughborough, Leicestershire, England

Received March 24, 1969

Primary aliphatic amines are rapidly oxidized using a silver electrode at potentials more positive than 0.6 V normal hydrogen electrode (n.h.e.) in aqueous alkali. Primary aliphatic amines with a mono-substituted α-carbon atom give the corresponding nitrile and aldehyde, α,α-disubstituted ones give the corresponding ketone, and α,α,α-trisubstituted ones give the corresponding alcohol, nitro-compound, and unsaturated hydrocarbons. Some evidence for the reaction pathway is presented. The effect of amine on the kinetic parameters for Ag_2O formation is reported.

Canadian Journal of Chemistry, 47, 3729 (1969)

Introduction

In previous papers in the series, studies on the electrochemical oxidation of silver in aqueous alkali using galvanostatic (1) and potentiodynamic techniques (2) have been reported. We now report the results of experiments on the oxidation of primary amines at a silver electrode and the effect of added amine on the potentiodynamic current curves and kinetic parameters.

Barnes and Mann (3) have studied the oxidation of primary amines at platinum electrodes and found the predominant pathway involved breaking the carbon–nitrogen bond. Using different conditions Benkesser *et al.* (4) isolated trimethylhexahydro-*s*-triazine and formamide from the oxidation of methylamine at platinum. The chemical oxidation of primary amines with AgO has been reported (5). The oxidation of aliphatic amines at platinum (6) and carbon (7) has been investigated using cyclic voltammetry.

Experimental

Apparatus

Electrochemical cells made from borosilicate glass were of two types. The cell in which the potential sweep data were obtained has been described (2). Preparative oxidations were carried out in the cell shown in Fig. 1. This consisted of a working compartment (~ 35 ml capacity) which was separated from the counter electrode compartment by a glass frit (porosity 1). The reference electrode (a wick type standard calomel electrode) was contained in the third compartment connected to the working compartment by a horizontal Luggin capillary. Provision was made for N_2 purging of the working electrode compartment.

The working electrodes were made from silver (99.999%, Johnson–Matthey Limited) rod or sheet. The micro-electrodes used in potential sweep experiments have been described (2). Electrodes for preparative oxidations (~ 2.0 cm^2) were made from silver sheet sealed into polythene. The required area was achieved by trimming the polythene support. The counter electrode was silver gauze (~ 2 × 4 cm).

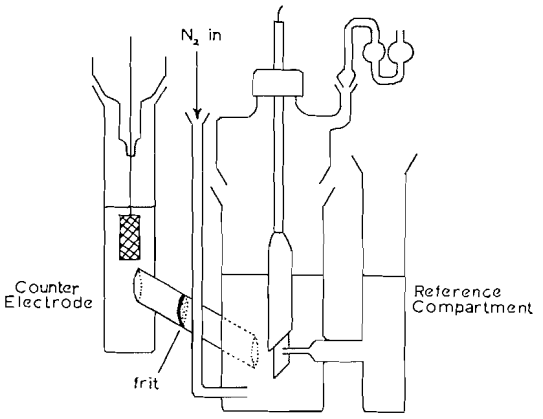

FIG. 1. Electrochemical cell used for preparative oxidations. Vertical plane electrode (2 cm^2) and horizontal Luggin capillary also shown.

The supporting electrolyte was aqueous sodium hydroxide solution prepared from A.R. sodium hydroxide (Fisons Chemicals Limited) and conductivity water.

The amines used were obtained commercially (B.D.H.) and were distilled and analyzed for impurities by gas–liquid chromatography (g.l.c.) immediately before use.

All the preparative experiments were carried out under potentiostatic conditions. Kinetic data were obtained using a fast response potentiostat coupled with either a pulse generator or a linear sweep generator (Chemical Electronics Ltd.). Preparative work was carried out using a potentiostat of higher output (~ 3 A) (Chemical Electronics Ltd.).

Experimental Methods

Potential Sweep Experiments

The general experimental technique has already been described (2). A fixed anodic potential sweep rate of

[1]To whom all correspondence should be addressed.

For personal use only.

5.84×10^{-4} V s^{-1} was used over a potential range of 0.7 V starting at the reversible potential $Ag_2O/Ag/OH^-$ (1*M*). The resultant current–time curve was plotted on a chart recorder (Leeds and Northrup Ltd.).

Preparative Studies

Two main techniques were used. The first involved oxidation at a fixed potential. The effect of OH^- concentration, amine concentration, and electrode potential on the aldehyde/nitrile ratio was examined. The second technique involved the use of a repetitive sequence of square potential pulses (Fig. 2). The effect of pulse frequency, duty ratio, and starting potential on the aldehyde/nitrile ratio was determined.

The products were isolated by extraction of the electrolyte with diethyl ether. The ethereal solution was reduced in volume by distillation, dried over anhydrous sodium sulfate, and examined by g.l.c. (Pye 104) at high and low temperatures. Then the electrolyte was acidified and the analysis repeated. Components were identified by comparison with authentic samples on at least two stationary phases (from dinonylphthalate, silicone oil, carbowax 1500, and polyethylene glycol adipate). Internal standards were used for quantitative determinations.

Galvanostatic Experiments

The technique, cell, and electrodes have been described (1). Additions of amines were made to the electrolyte (1 *M* sodium hydroxide) which was not circulated through charcoal.

Results

At potentials, below that required for the formation of AgO, primary amines are only oxidized very slowly. This reflects the results of chemical oxidations of amines with Ag_2O in alkali which are also very slowly oxidized. Primary amines form a soluble complex with Ag_2O and this leads to the dissolution of the electrode.

The relative oxidation rates for primary amines at platinum and silver electrodes are illustrated by the potential sweeps shown in Fig. 3.

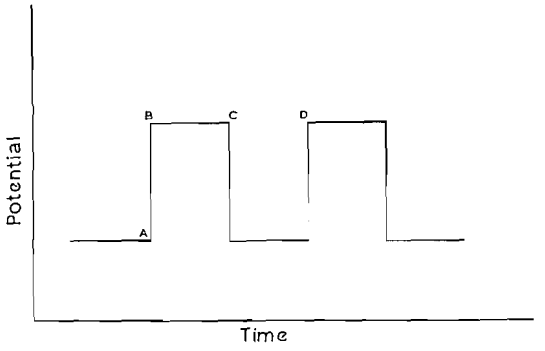

FIG. 2. Potential waveform used in repetitive potential pulse experiments; step height = AB, frequency = 1/BD, duty ratio = BC/BD.

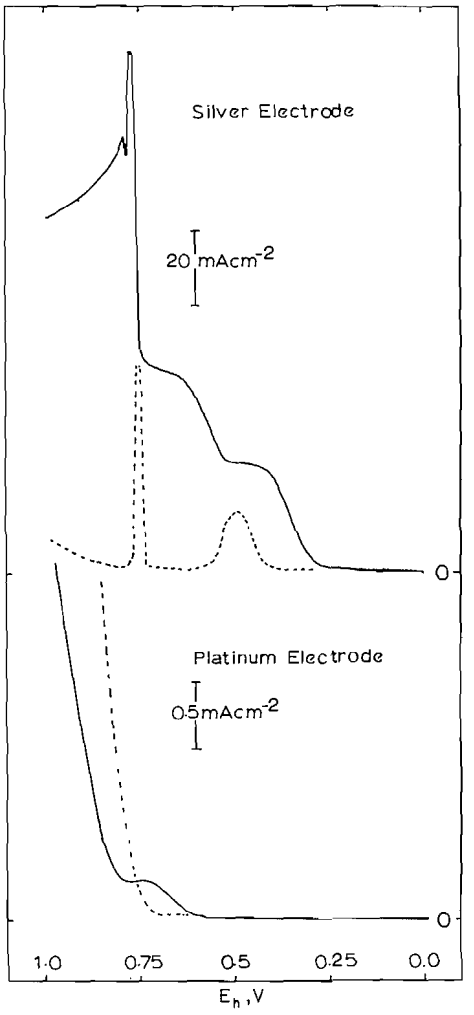

FIG. 3. Effect of electrode material on potentiodynamic current curve for *n*-butylamine in 1 *M* NaOH. Conditions: 4×10^{-1} *M* amine; 23 °C; 5.84×10^{-4} V s^{-1}.

At a silver electrode in aqueous alkali at potentials above 0.6 V n.h.e., primary amines having a mono-substituted α-carbon atom are oxidized to the corresponding nitrile and aldehyde; those having a di-substituted α-carbon atom, to the ketone; and the tri-substituted ones, to alkene, alcohol, and nitro-compounds (Table I). For *n*-butylamine, under conditions where essentially only nitrile is formed, coulombic yields (based on the proposed mechanism) of better than 90% were achieved.

TABLE I

Oxidation of primary amines and oximes in 1 *M* NaOH, (*a*) at silver electrodes at 0.74 V vs. n.h.e., (*b*) with AgO

Amine	Product (relative amounts)	
	Electrochemical oxidation	Chemical oxidation

iso-Butylamine	iso-Butyronitrile, iso-butyraldehyde	iso-Butyronitrile (10), iso-butyric acid (1), iso-butyraldehyde (trace)
sec-Butylamine	Ethyl methyl ketone	Ethyl methyl ketone
t-Butylamine	*t*-Butanol (15), nitro-*t*-butane (10), 2-methylprop-1-ene (25)	*t*-Butanol(10), nitro-*t*-butane (20), 2-methylprop-1-ene (40)
Benzylamine	Benzonitrile	
n-Butyraldehyde oxime	*n*-Butyronitrile (12), nitro-*n*-butane (3), 2-ethylhex-2-en-al (2), *n*-butyraldehyde (trace)	Butyronitrile, butyraldehyde
Ethyl methyl ketone oxime	Ethyl methyl ketone	

Potential Sweep Experiments

The addition of amine causes the peak due to the formation of Ag_2O to become a wave and to shift to a less positive potential (Fig. 4). Depending on the substitution pattern at the α-carbon, further peaks appear at potentials more positive than that at which the formation of AgO takes place (Fig. 5). The wave height (as measured at the first flat portion of the wave) associated with Ag_2O formation varies with concentration of amine as shown in Fig. 6.

In the case of *n*-butylamine the complex was examined a little further. In a series of experiments different amounts of *n*-butylamine were added to a series of suspensions of Ag_2O (in excess) in normal aqueous alkali. After allowing to equilibriate (12 h) the silver ion in solution was determined by Volhard's method. A graph of "soluble" silver concentration against added amine concentration gave a straight line passing through the origin. The slope $d[amine]/d[Ag^+]$ is 4, indicating that each silver ion is complexed with 4 amine molecules. Attempts to confirm that silver was showing a coordination number of 4 by potentiometric and high frequency titrations were inconclusive.

At potentials more positive than that required for AgO formation, the oxidation of *n*-butylamine gave butyraldehyde and butyronitrile in a ratio dependent on OH^- concentration (Table II), amine concentration (Table III), and electrode potential (Table III). Some results of chemical oxidation using AgO are included for comparison.

Tafel Plots: Galvanostatic Experiments

The addition of primary amines to the electrolyte has the effect of lowering the apparent activation overpotential (η_D), at a given current density, for the formation of Ag_2O. The addition of primary amine increases the exchange current (i_0), calculated from the intercept of $\eta_D - \log i$,

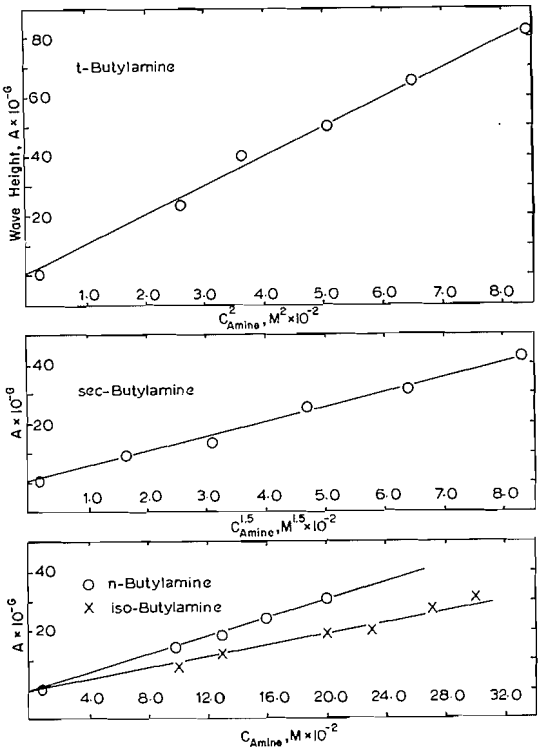

FIG. 6. Effect of concentration of amine on the height of the low potential region wave. Conditions: 1 *M* NaOH; 23 °C; 5.84×10^{-4} V s^{-1}; electrode area = 4.45×10^{-2} cm^2.

while the charge transfer coefficient (α) remains almost constant (Fig. 8).

Discussion

Potential sweep experiments show that at the potential required for Ag_2O formation, the potentiodynamic current curve changes from a peak to a wave (Fig. 4) with increasing amine concentration. At low concentrations of amine the wave height is considerably less than the

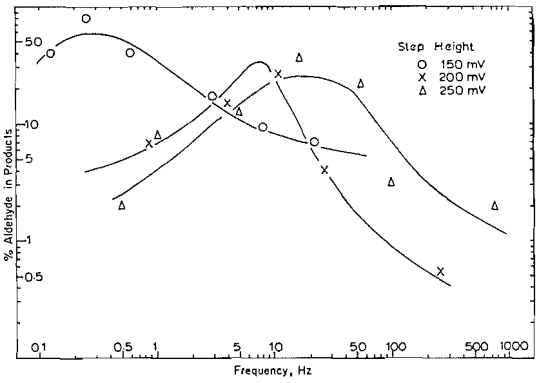

FIG. 7. The effect of pulse frequency and potential step height on the aldehyde:nitrile ratio in the oxidation of *n*-butylamine by repetitive potential pulses. Conditions: 1 *M* NaOH; 4×10^{-1} *M* amine; 23 °C; starting potential 0.600 V (vs. n.h.e.).

Ag_2O peak. This may be the result of the competitive adsorption between amine and hydroxyl ion or a change in mechanism.

The wave results from the formation of a soluble complex between primary amines and Ag_2O. Under alkaline conditions a silver electrode is oxidized to Ag_2O to a depth of about 100 monolayers (2, 9) and then the reaction becomes very slow. In the presence of amine the surface layers of Ag_2O are being continuously removed thus allowing the oxidation to proceed, as the electrode is not oxidized in depth.

The rate of the reaction, as measured by the wave height, is related to the amine concentration. For *n*-butylamine the rate is proportional to $[RNH_2]$; for *sec*-butylamine, to $[RNH_2]^{1.5}$; and for *t*-butylamine, to $[RNH_2]^2$. In each case increasing the agitation of the electrolyte increases the rate of the reaction, indicating that the reactions are, at least in part, controlled by mass transport in solution. The rate is dependent on the slowest step in the reaction sequence below.

$$2Ag + 2OH^- \xrightarrow{-2e} Ag_2O$$

$$RNH_2 \xrightarrow[\text{to electrode}]{\text{diffusion}} n\text{-}RNH_2 + Ag_2O \underset{k'}{\overset{k}{\rightleftharpoons}} [Ag_2O(RNH_2)_n] \xrightarrow[\text{of complex from electrode}]{\text{diffusion}}$$

For *n*-butylamine the reaction rate appears to be controlled by the transport of the amine to the electrode. For *sec*- and *t*-butylamine the reaction rate must be dependent on at least two of the steps in the sequence. The activation energy associated with this reaction for both *n*-butylamine and *t*-butylamine is ~ 1 kcal/mole (as determined from the temperature dependence of

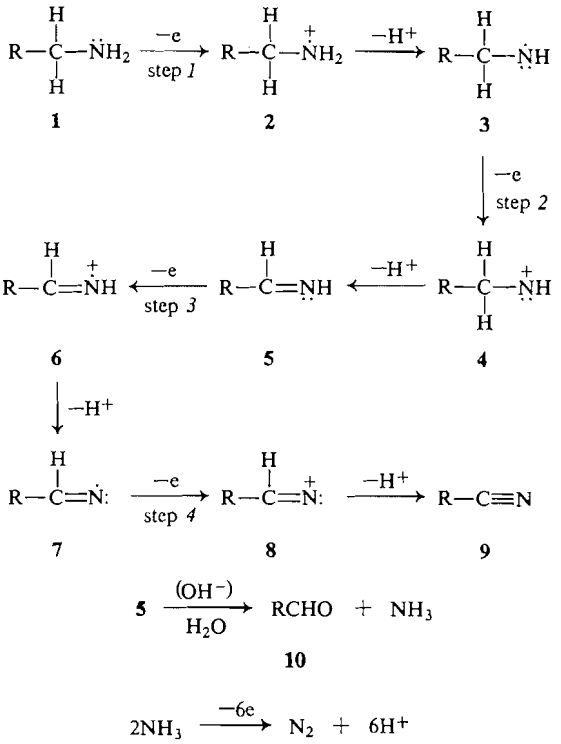
the wave height). Such a low activation energy is characteristic of a diffusion controlled reaction.

The straight line relationship between added amine and the complex formed in the presence of excess Ag_2O indicates that the stability constant of the amine–silver complex is high. Silver is apparently showing a coordination number of 4 instead of 2 which is normally found for amine–silver complexes (8).

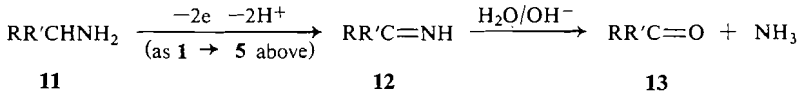
The galvanostatic results for Ag_2O formation (Fig. 8) show that the exchange current (i_0) increases with increasing amine concentration. That the rate of Ag_2O formation increases with amine concentration is borne out by the potentiodynamic results. Although the half-wave potential is difficult to measure precisely (the wave is not symmetrical), it can be seen (Fig. 6) that the wave moves to lower potentials on increasing the amine concentration.

At potentials more positive than that for AgO formation primary amines are oxidized rapidly. The products, which are dependent on the degree of substitution at the α-carbon atom, can be explained by the following reaction scheme.

For compounds of the type RCH_2NH_2



For compounds of the type $RR'CHNH_2$



For compounds of the type R_3CNH_2

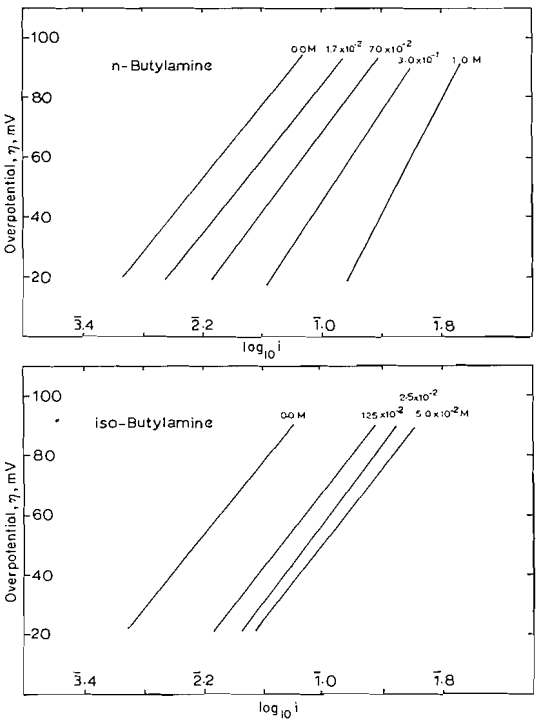

FIG. 8. The effect of added amine on the "Tafel plots" for the formation of Ag_2O. Conditions: 1 *M* NaOH; 23 °C.

Steps *1* and *2* are similar to those proposed by Barnes and Mann (3) for the oxidation of primary amines at a platinum anode. Under the conditions used by these workers (MeCN/$NaClO_3$, Pt at 1.99 V vs. n.h.e.) for saturated primary amines, the major reaction pathway (90–100%) was oxidation step *1* followed by breakdown of the cation radical **2**, to give a carbonium ion and $:\dot{N}H_2$ radical. At a silver electrode at potentials in the range of 0.54–0.74 V, we found no evidence that this pathway was operative. All the evidence indicates that a second oxidation step takes place giving an imine type intermediate.

The oxidation products of the primary amines studied are as predicted by these pathways (Table I).

Typical potential sweeps for the three types of primary amines are shown in Fig. 5. As peaks and not waves are observed above the potential for AgO formation, the reactions are in some way self limiting. In the simplest case, if the oxidation potentials for steps *1–4* increase from left to right, an amine with a mono-substituted α-carbon atom should give four peaks (or waves), a disubstituted one only the first two of these peaks, and a trisubstituted one only the first peak. The potential sweep response for *sec-* and *t*-butylamine approximates to this simple scheme but that for *n*-butylamine is more complex. However, the hydrolysis of the imine is not potential dependent as no charge transfer step is involved, whereas nitrile formation is (see scheme for reactions **5** → **10**, **5** → **9**). Therefore it should be possible to determine the oxidation product by selecting the potential. The direction in which the aldehyde/nitrile ratio changes with the variables discussed below is reproducible. However, individual values of the ratio are more difficult to reproduce as several other variables (such as cell geometry, agitation, and reaction time) affect the result. The oxidation of *n*-butylamine gives a decreasing *n*-butyraldehyde/butyronitrile ratio with increasing potential (Tables II and III). There are two competing reactions for the imine, **5**; it may be oxidized to the nitrile or hydrolyzed to the aldehyde. Increasing the hydroxyl ion concentration at a fixed potential should therefore lead to an increasing aldehyde to nitrile ratio and this is observed (Table II). At a fixed potential and hydroxyl ion concentration the aldehyde/nitrile ratio decreases with increasing amine concentration (Table III). This is explicable if there is competitive adsorption (cf. the competitive adsorption of gases at solids (10)) between amine and hydroxyl ions, and the imine reacts at the surface. Increasing the amine concentration will therefore decrease the hydroxyl ion concentration at the electrode and thus decrease the rate of the hydrolysis reaction **12** → **13**.

The data from the repetitive pulse oxidations for *n*-butylamine show an optimum frequency for the formation of aldehyde. This indicates that the imine concentration is significant. In the long pulses the surface concentration of imine is built up until a "steady state" with respect to imine concentration is achieved. The oxidation then proceeds to give nitrile. In the shorter pulses this "steady state" concentration of imine is not achieved and consequently only a little nitrile is formed. During the rest period the imine is hydrolyzed to give aldehyde. At frequencies higher than the optimum, the reaction cannot

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

follow the potential relaxations and the oxidation tends to approximate to one at constant potential. The optimum frequency is higher with higher potential pulses (Fig. 7) because the "steady state" concentration of imine is achieved in a shorter time.

The reaction scheme would be best tested by studying the oxidation of the imines but, as these are very unstable, this is not possible. Oximes are oxidized to the corresponding nitrile under these conditions (Table I). Control experiments showed that the nitrile did not result from base catalyzed dehydration.

From these observations it is clear that the cleavage of the carbon–nitrogen bond is less favorable at a silver anode than at a platinum anode (3). In the case of primary amines, with only one substituent at the α-carbon atom, the reaction pathway is branched and as only one branch involves charge transfer, the product ratio is potential dependent.

Relative rate constants for reactions of hydroxyl radicals from the reaction of Fe(II) or Ti(III) with H_2O_2[1]

W. A. ARMSTRONG

Defence Research Establishment Ottawa, Defence Research Board, Ottawa 4, Canada

Received March 6, 1969

In an attempt to clarify the reactions of ferrous sulfate and titanous sulfate with hydrogen peroxide, a novel method has been developed to determine the relative rate constants for reactions of the oxidizing species generated in these systems. These species react with hydrogen peroxide to give perhydroxyl radicals which combine with titanium(IV) ions to form the relatively stable $TiOO^{\cdot 3+}$ radical. This radical gives a strong electron spin resonance signal and the competition between hydrogen peroxide and a scavenger for the oxidizing species can be followed by measuring the amplitude of this signal in the presence of various concentrations of scavenger. The relative rate constants calculated in this way for both the Fe(II)–H_2O_2 and Ti(III)–H_2O_2 systems at pH 1.0 agree with those reported for the reactions of hydroxyl radicals in γ-irradiated thymine solutions. This supports the view that hydroxyl radicals are formed in these cases.

Under conditions of acidity favoring the hydrolysis of Fe(II) to $FeOH^+$ ions, hydroxyl radical scavengers do not compete with hydrogen peroxide for the precursors of the $TiOO^{\cdot 3+}$ radical. It is suggested that the $FeOH^+$ ions react with hydrogen peroxide to give a different oxidizing species, possibly the ferryl ion.

Scavengers investigated were thymine, methanol, ethanol, formic acid, acetic acid, chloride ion, and several amino acids.

Canadian Journal of Chemistry, 47, 3737 (1969)

Introduction

There has been much controversy concerning the reaction of hydrogen peroxide with ferrous or titanous ions in acidic aqueous solutions (1–7). It is generally assumed that hydroxyl radicals are formed in both reactions but there is some evidence to suggest that the OH radicals are complexed with titanium in the Ti(III)–H_2O_2 system and that reaction with a scavenger takes place in a $[Ti(H_2O)_4(OH)(scavenger)]^{4+}$ complex (4). Fenton's reagent has been characterized as nucleophilic and Ti(III)–H_2O_2 as electrophilic (2).

The present investigation was designed to measure the relative rate constants for the reactions of a number of solutes with the oxidizing species generated in each of these systems. These constants could then be compared with the reported absolute values obtained by radiolysis experiments (8, 9). Reasonable agreement would indicate that in each case free OH radicals are being scavenged. The method is based on the following reaction scheme

[1] $\text{Fe(II) or Ti(III)} + H_2O_2 \rightarrow \text{Fe(III) or Ti(IV)} + OH^- + \cdot OH$

[2] $\cdot OH + H_2O_2 \rightarrow H_2O + HO_2\cdot$

[3] $\cdot OH + \text{scavenger} \rightarrow X\cdot$

[4] $HO_2\cdot + \text{Ti(IV)} \rightarrow TiOO^{\cdot 3+} + H^+$

The $TiOO^{\cdot 3+}$ radical has a lifetime of several seconds (4) and gives a single electron spin resonance (e.s.r.) line with $g = 2.013$ (5). A second paramagnetic species with $g = 2.012$ is also observed but its identity is in doubt. Fischer (5) suggests it is $TiOOTiOO^{\cdot 5+}$, formed by the reaction of $TiOO^{\cdot 3+}$ with hydrogen peroxide and titanium(IV) ions, but Takakura and Ranby (7) favor the idea of a complex of OH and Ti(IV) ions. However, Arthur and co-workers (10) have observed this species (as well as the $TiOO^{\cdot 3+}$) upon the mixing of a Ce(IV) solution with a solution of H_2O_2 containing Ti(IV) ions and it is unlikely that hydroxyl radicals are produced in this reaction. Under the present experimental conditions the concentration of this second paramagnetic species is small and decreases upon the addition of a scavenger in the same manner as the $TiOO^{\cdot 3+}$ (5). It has, therefore, been ignored. As the lifetimes of most organic radicals are much shorter than the lifetime of the $TiOO^{\cdot 3+}$ radical, the scavenger radicals formed in reaction [3] are not observed.

The e.s.r. spectra observed with the Fe(II)–H_2O_2,Ti(IV) and Ti(III)–H_2O_2,Ti(IV) systems are shown in Fig. 1. For comparison, the spectrum resulting from the illumination of a stream of

[1]Issued as D.R.E.O. Report No. 590.

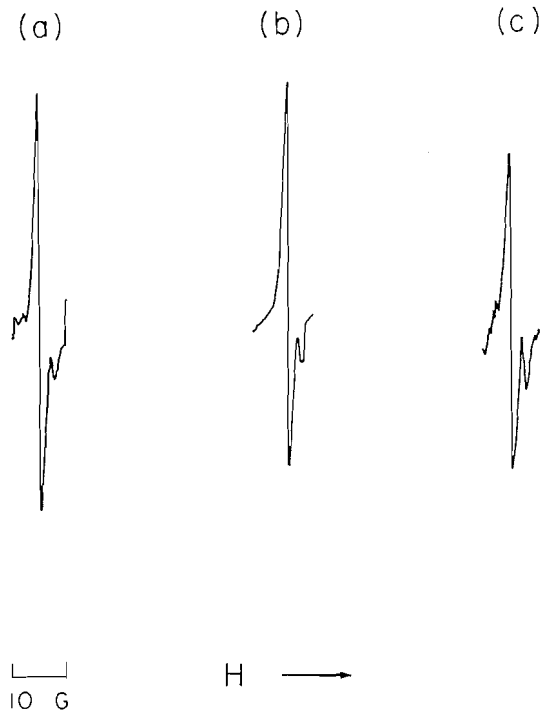

FIG. 1. The e.s.r. spectrum of the $TiOO^{\cdot 3+}$ radical in 0.1 M H_2SO_4. (*a*) 1.0 mM Fe(II) – 80 mM H_2O_2, 30 mM Ti(IV), (*b*) 2.0 mM Ti(III) – 80 mM H_2O_2, 30 mM Ti(IV), (*c*) ultraviolet light, 80 mM H_2O_2, 30 mM Ti(IV).

acidic H_2O_2,Ti(IV) solution with light of 2537 Å (a system which undoubtedly involves the formation of hydroxyl radicals) is included in the same figure. Apparently the same radicals are formed in each system.

If reactions [2] and [3] are the only significant reactions involving OH radicals and all the HO_2 radicals react according to [4], then at a given time of observation and in the absence of a scavenger, $[TiOO^{\cdot 3+}] = [OH]$, the total amount of hydroxyl radicals generated. In the presence of a scavenger

$$[TiOO^{\cdot 3+}] = \frac{k_2[H_2O_2]}{k_2[H_2O_2] + k_3[\text{scavenger}]} \cdot [OH]$$

If A^0 and A are the amplitudes of the $TiOO^{\cdot 3+}$ e.s.r. line in the absence and presence of a scavenger

$$\frac{A^0}{A} = 1 + \frac{k_3}{k_2} \cdot \frac{[\text{scavenger}]}{[H_2O_2]}$$

Thus a plot of A^0/A vs. $[\text{scavenger}]/[H_2O_2]$ should give a straight line with slope $= k_3/k_2$. This approach is similar to that used in the pulse radiolysis experiments where the reaction of OH with I^- or CNS^- was used in the determination of rate constants (11–13).

Experimental

All solutions were prepared immediately before use with triply distilled water which had been saturated with nitrogen. "Low manganese" ferrous sulfate (B and A Laboratories) and "stabilizer-free" 30% hydrogen peroxide (Fisher) were used in the reactant solutions. Both 15% titanous sulfate solution (British Drug Houses, Ltd.) and material prepared in this laboratory by the reduction of titanium basic sulfate in sulfuric acid solution with zinc amalgam (14) were employed. Hydrogen peroxide solutions were standardized by the arsenious oxide method (15). The concentration of titanous sulfate solutions was determined by titration of an aliquot with standardized hydrogen peroxide to a colorless end-point. It was assumed that 1 mole of hydrogen peroxide oxidized 2 moles of titanous sulfate (6). Titanium(IV) sulfate solutions of known concentration were prepared by similar titrations. The acidity of the ferrous and titanous solutions was adjusted with sulfuric acid. The H_2O_2,Ti(IV) solutions for the second stream were prepared by the addition of the desired volume of a 0.4 M titanium(IV) sulfate solution in 2 M sulfuric acid to the aqueous hydrogen peroxide solution. The pH was then adjusted by the addition of either sulfuric acid, sodium monohydrogen phosphate, sodium tetraborate, or sodium hydroxide. At pH > 2.2 titanium hydroxide precipitated.

The e.s.r. spectrometer and flow system have been described elsewhere (16). To permit the accurate adjustment of flow rates, the system was modified to include a flow meter and needle valve in each stream. Normally the flow of each stream was set at 115 ml/min and the radicals were observed about 0.3 s after the mixing of the reactants. Initially, a solution of ferrous or titanous sulfate was mixed with a solution of the same acidity containing the desired amounts of hydrogen peroxide and titanium(IV) sulfate. While these solutions flowed through the mixing chamber and e.s.r. cell, the magnetic field from 5 G below the value for resonance to 5 G above this value was scanned three times. A^0 was the average amplitude of this spectrum. After draining the flow system the process was repeated but with a known amount of scavenger in the Ti(IV)–H_2O_2 solution. Values of A were determined in this way for increasing concentrations of scavenger until $A \approx \frac{1}{3}A^0$. Spectrometer noise prevented the accurate determination of lower values of A. To check the stability of the spectrometer, A^0 was redetermined at the end of each run but for a given set of reaction conditions did not vary significantly over a period of weeks.

ferrous sulfate with various concentrations of hydrogen peroxide and titanium(IV) sulfate. All solutions described in this section were 0.1 *M* in sulfuric acid. Changing the concentration of hydrogen peroxide from 55 to 107 m*M* and that of titanium(IV) from 25 to 49 m*M* did not affect the slope of this straight line. The results are independent of flow rate and hence reaction

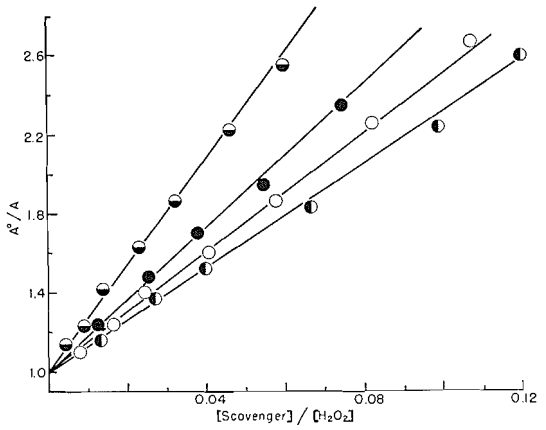

FIG. 3. Competition of scavengers with hydrogen peroxide for OH radicals from Fenton's reagent: 1.2 m*M* Fe(II) plus 60 m*M* H_2O_2, 33 m*M* Ti(IV), scavengers (pH = 1.0): ○, methanol; ◒, acetic acid (multiply abscissa by 100); ◐, l-cystine (multiply abscissa by 0.1); ●, thymine (multiply abscissa by 0.25).

time as shown in Fig. 2*b*. In this instance ethanol was the scavenger and reaction times of 0.021 to 0.065 s were used. Similar linear plots for methanol, acetic acid, cystine, and thymine are given in Fig. 3. Repeated experiments indicated that the measured slope of any plot is accurate to about ±15%.

The slope of each plot should equal k_3/k_2, where k_3 and k_2 are the rate constants for the reactions of hydroxyl radicals with the scavenger and hydrogen peroxide, respectively. However, the literature values of k_2 range from 1.2 to 4.5 $\times 10^7\ M^{-1}\ s^{-1}$ (9). Although less than 2% of the hydrogen peroxide is expended by reaction [1], this does introduce some doubt as to the exact concentration of peroxide which competes for the OH radicals. In view of these factors it was decided to compare all of the results with those obtained with thymine as the scavenger. The rate constant for the reaction of OH with thymine has been determined accurately to be $4.3 \pm 1 \times 10^9\ M^{-1}\ s^{-1}$ and has been used in the determination of the relative reaction rates of OH radicals with many scavengers (8). Assuming this value and employing the measured slope of the thymine plot (72.4), $k_2 = 5.9 \times 10^7$, a value somewhat higher than those quoted above. Results for k_3/k_2 for a variety of scavengers along with rate constants based on the given value for thymine are listed in Table I. For comparison, the rate constants published by Scholes and Willson (8) and derived from studies of the radiolysis of aqueous thymine solutions are also included. Considering the magnitude of the experimental errors, the agreement is good.

A^0/A vs. [scavenger]/[H_2O_2] plots for 1.9 m*M* Ti(III) plus 80 m*M* H_2O_2, 38 m*M* Ti(IV), with formic acid and ethanol as the scavengers are given in Fig. 4. For formic acid, $k_3/k_2 = 1.98$, in excellent agreement with the value obtained with the Fe(II)–H_2O_2 system. Ethanol, however, did not give a straight line plot. As the concentration of the ethanol was increased, the concentration of $TiOO\cdot^{3+}$ decreased to a greater extent than predicted by reactions [2]–[4]. Reaction of the ethanol radicals formed in [3] with the $TiOO\cdot^{3+}$ radicals could explain these results

[5] $\qquad X\cdot + TiOO\cdot^{+3} \rightarrow$ products

The importance of this reaction would depend upon the concentration of $TiOO\cdot^{3+}$ and the reactivity of X·. Under the conditions described

above, the initial concentration of $TiOO^{\cdot 3+}$, as determined by the magnitude of A^0, was more than 100 times as great as that observed with Fenton's reagent. When reactant concentrations were reduced to 0.8 mM Ti(III) plus 60 mM H_2O_2, 3.3 mM Ti(IV), A^0 was reduced by a factor of 20 and the addition of ethanol resulted in the straight line shown in Fig. 4. Thymine, methanol, and acetic acid also gave linear plots. The values of k_3/k_2 are listed in Table I. Cystine and cysteine did not give linear plots (Fig. 4), possibly because the CyS· radical (16) reacts more rapidly with $TiOO^{\cdot 3+}$ than do the other scavenger radicals. Attempts to decrease the concentration of $TiOO^{\cdot 3+}$ to the level attained with the Fe(II)–H_2O_2 system were unsuccessful, as hydrolysis of the Ti(III) prevented any further decrease in its concentration.

The results of the addition of chloride ion to both the Fe(II)–H_2O_2 and the Ti(III)–H_2O_2 reagents are shown in Fig. 5. The initial portion of the plot is linear with a slope of 9.5 which corresponds to

$$k(\mathrm{OH} + \mathrm{Cl}^-) = 5.6 \times 10^9\ M^{-1}\ \mathrm{s}^{-1}$$

The reported values for this constant are 4.0×10^8 at pH 1 and 4.0×10^9 at pH 0 (9). As the chloride concentration was increased the concentration of $TiOO^{\cdot 3+}$ decreased to a lesser extent than predicted by reactions [2]–[4]. The excess chloride ions may complex with the Fe(II) or Ti(III) and be unavailable for reaction with the hydroxyl radicals. An alternative explanation is that the Cl atoms or Cl_2^- radicals formed by the reaction of hydroxyl radicals with chloride ions (17, 18) react with hydrogen peroxide to give perhydroxyl radicals which, by way of [4], form $TiOO^{\cdot 3+}$. The yield of $TiOO^{\cdot 3+}$ would then become independent of the chloride ion concentration. Attempts to observe the e.s.r. spectrum of the Cl_2^- radical were unsuccessful.

The other reactions which might interfere with the proposed mechanism are

[6] Fe(II) or Ti(III) + OH $\rightarrow$ Fe(III) or Ti(IV) + OH^-

[7] $HO_2\cdot$ + scavenger $\rightarrow$ Y·

[8] $TiOO^{\cdot 3+}$ + scavenger $\rightarrow$ Y·

Reaction [6] was minimized by keeping the concentration of H_2O_2 at least 50 times as great as that of the ferrous or titanous ion. To investigate reaction [7], hydroperoxyl radicals were generated in the flow system by the reaction of ceric ammonium sulfate with hydrogen peroxide. Mixing 0.08 m*M* ceric ammonium sulfate in 100 m*M* sulfuric acid with a solution of 16.5 m*M* Ti(IV) and 80 m*M* H_2O_2 in 100 m*M* H_2SO_4 resulted in the formation of an amount of $TiOO^{\cdot 3+}$ comparable with that formed in the Ti(III)–H_2O_2 reagent described above. Addition to the Ti(IV)–H_2O_2 solution of a concentration of scavenger 4 times greater than the maximum amount used in the determination of relative rate constants did not significantly decrease the concentration of $TiOO^{\cdot 3+}$. The first 8 scavengers listed in Table I were investigated and the maximum decrease observed was 3%.

A simple three-stream mixer constructed from 1 mm bore Pyrex tubing was used to investigate reaction [8]. It was arranged so that the third stream entered 0.15 s after the mixing of streams 1 and 2 and, therefore, after the completion of the Ti(III)–H_2O_2 reaction (19). With 3 m*M* Ti(III) – 100 m*M* H_2SO_4 in stream 1, 16.5 m*M* Ti(IV) – 40 m*M* H_2O_2 – 100 m*M* H_2SO_4 in stream 2, and 100 m*M* H_2SO_4 added through stream 3, a concentration of $TiOO^{\cdot 3+}$ radicals 10 times greater than that observed with the Ti(III)–H_2O_2 system was generated. The addition of the same scavengers to the third stream in the same amounts as described in the preceding paragraph did not appreciably affect the concentration of radicals. The maximum decrease observed was <4%. The low reactivity of $TiOO^{\cdot 3+}$ radicals with methanol has been demonstrated previously (19, 20).

Under the present experimental conditions, the most likely path by which the $TiOO^{\cdot 3+}$ radicals disappear is by the relatively slow process of dimerization (19). Increasing the time between the mixing of the reactants and the observation of the radicals from 0.02 to 0.07 s caused a decrease in the measured radical concentration of less than 10%. Only when the concentration of $TiOO^{\cdot 3+}$ was high and the reactivity of the scavenger radical X· great did the addition of a scavenger have any apparent affect on the dimerization reaction.

The Effect of Increasing pH

The results obtained at pH > 1.0 are summarized in Fig. 6. The slope of the plot of A^0/A vs. [ethanol]/[H_2O_2] at pH 1.2 is 30.0 for both

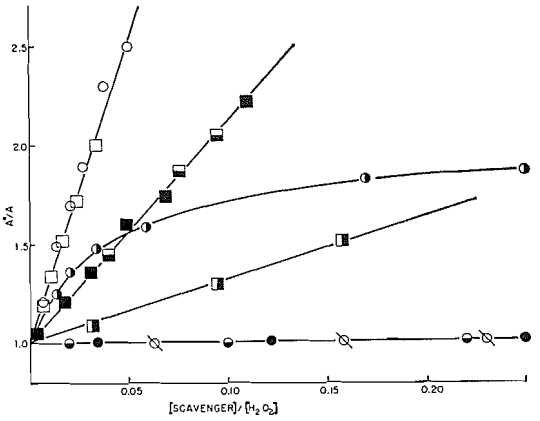

FIG. 6. Competition of scavengers with hydrogen peroxide for oxidizing species at higher pH. (*a*) 0.6 m*M* Fe(II) plus 80 m*M* H_2O_2, Ti(IV), scavenger. For personal use only.

the ferrous and titanous systems, in agreement with the value of 28.9 obtained at pH 1. With the titanous system this slope decreases to 11.3 at pH 2.2. Similarly, when thymine is the scavenger, k_3/k_2 decreases from 71.5 at pH 1.0 to 32.6 at pH 2.2. If the thymine and ethanol results at pH 2.2 are compared and it is assumed that $k(\text{OH} + \text{thymine}) = 4.3 \times 10^9\ M^{-1}\ s^{-1}$, then $k(\text{OH} + \text{ethanol}) = 1.5 \times 10^9\ M^{-1}\ s^{-1}$. This is in agreement with the value measured at pH 1.0. These results may be explained by an increase in k_2 with increasing pH. There is some other evidence suggesting this (9).

The ferrous – hydrogen peroxide system behaves in a different manner. Addition of either thymine or ethanol in concentrations up to 100 times that used at pH 1 to an H_2O_2,Ti(IV) solution of pH 2.2 had no appreciable affect on the amplitude of the $TiOO\cdot^{3+}$ signal observed when this solution was mixed with a ferrous sulfate solution of pH 3.8. The exact pH of the mixture during the reaction is unknown and will be referred to as pH > 2. Under these conditions the scavengers did not compete for the precursors of the $TiOO\cdot^{3+}$ radical.

The mechanism for the reaction of ferrous ions with hydrogen peroxide proposed by Haber and Weiss (21) and modified by Baxendale and co-workers (22) consists of reactions [1], [2], and [6] as well as

[9] $\quad HO_2\cdot + Fe(II) \rightarrow HO_2^- + Fe(III)$

[10] $\quad HO_2\cdot + Fe(III) \rightarrow O_2 + H^+ + Fe(II)$

Baxendale and co-workers (22) examined the change in kinetics of the Fe(II)–H_2O_2 reaction and the evolution of oxygen with changing acidity and found that k_{10}/k_9 increases from 0.14 to 0.70 as the pH is increased from 1.35 to 2.35. To ensure that all the HO_2 reacted according to [4], the concentration of Ti(IV) was raised from 8.3 to 42 mM (as compared with 0.6 mM Fe(II)) with no observable difference in the results. Other evidence that the behavior of the Fe(II)–H_2O_2,Ti(IV) system at pH > 2 is not due to reactions of the Fe(III) species was obtained by the addition of Fe(III) to the H_2O_2,Ti(IV), ethanol solutions. This had no effect on the results when these solutions were mixed with Ti(III) solutions at pH 2.2 (Fig. 6).

The concentration of scavenger radicals formed during the Fe(II)–H_2O_2, scavenger reaction is also dependent on pH. Shiga (1) has shown that the $\cdot CH_2CHOH$ radical is formed by the reaction of Fe(II)–EDTA at pH 7 with H_2O_2 in the presence of ethanol. We have confirmed this and also observed the same radical spectrum when the reaction was carried out at pH 1.2 in the absence of EDTA. However, when a 10 mM $FeSO_4$ solution at pH 3.8 was mixed with a solution 150 mM in H_2O_2 and 400 mM in ethanol, no radicals were detected. Changing reactant concentrations had no effect. When α-alanine was substituted for ethanol, similar results were obtained. The alanine radical was observed in solutions of pH 1.2 but not at pH 3.8. As $k(\text{Fe(II)} + H_2O_2)$ increases with increasing pH (23), it might be expected that the concentration of scavenger radicals available for observation would be greater at the higher pH.

Discussion

The Systems at pH 1.0

From the data obtained at pH 1.0 and presented in Table I it is evident that the relative reaction rates of the oxidizing species from Fe(II)–H_2O_2, Ti(III)–H_2O_2, and the γ-radiolysis of water are identical for a variety of substances. This suggests that the same oxidizing species is produced in each system. A comparison of the Fenton's reagent with the radiolysis of air-saturated aqueous solutions has been made recently by Kraljić (3) .Competition studies with *p*-nitrosodimethylaniline indicated that the OH radical is generated in both systems. The present investigation confirms this conclusion and shows that the Ti(III)–H_2O_2 reaction also produces hydroxyl radicals.

The experimental results fit the mechanism outlined in eqs. [1]–[4]. It is almost identical with that of Fischer (5), the main difference being that reactions [2] and [4] replace

$$OH + Ti(IV)/H_2O_2 \rightarrow TiOO\cdot^{3+} + H_2O + H^+$$

where $Ti(IV)/H_2O_2$ is the titanium – hydrogen peroxide complex and can be written as TiO_2^{2+} (24). Our results indicate that it is the hydrogen peroxide rather than the complex which competes for hydroxyl radicals. Because the Ti(IV) is complexed, it might be more accurate to write eq. [4] as

$$HO_2 + H^+ + TiO_2^{2+} \rightarrow TiOO\cdot^{3+} + H_2O_2$$

Whether the $TiOO\cdot^{3+}$ species is a titanium peroxyl radical or a hydroperoxyl radical com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

plexed by titanium(IV) ions is not material to the overall reaction scheme. The identity of the second paramagnetic species, present in very low concentrations, is of greater importance. As it can be formed under conditions where hydroxyl radicals are not likely to be present (10), the case for a Ti(IV)–OH complex is not completely convincing. However, the occurrence to a small extent of

[11] $$OH + Ti(IV) \rightarrow Ti(IV)\text{-}OH$$

or the back reaction of OH, [6], would not affect the values of the relative rate constants for the reactions of OH radicals with the various scavengers. It would interfere with the evaluation of k_2. That our value of k_2 is somewhat higher than the figure reported previously (5.9×10^7 vs. $4.5 \times 10^7\ M^{-1}\ s^{-1}$) may be related to interference by either reaction [6] or [11].

The suggestion, made by Turkevich and coworkers (4), that the reaction of the hydroxyl radical with the scavenger takes place during the decomposition of a $[Ti(H_2O)_4(OH)(scavenger)]^{4+}$ complex was based primarily on 2 observations. They found that, during the initial reaction period of about 0.01 s, the scavenger radical concentration decreased while the $TiOO^{\cdot 3+}$ signal increased. Although this behavior shows that the signal is not due to free OH radicals, it has been pointed out by Florin *et al.* (6) that it does not require the postulation of this complex. The second observation concerned an increase in the intensity of the $TiOO^{\cdot 3+}$ signal of more than a factor of 2 when small amounts of methanol were added to the hydrogen peroxide solution before it was mixed with a titanium trichloride solution. With higher methanol concentrations, the signal decreased. We repeated this experiment with titanous sulfate instead of titanium trichloride. In all cases the signal intensity decreased with increasing amounts of methanol. Thus the phenomenon they observed is apparently related to reactions of chloride ions. It is evident that the presence of chloride ions greatly complicates any study of the reaction mechanism.

Although the identity of the scavenger radical or radicals resulting from attack by the oxidizing species of Fenton's reagent is often the same as that observed with the Ti(III)–H_2O_2 system (16), there are some exceptions. As the evidence presented here suggests that the oxidizing species is the same in both cases, the differences in spectra may be due to differences in the reactions of the scavenger radicals with Fe(II), Fe(III), Ti(III), or Ti(IV) ions.

The Effect of Increasing pH

It is obvious that reactions [1] to [4] do not explain the results observed with the ferrous – hydrogen peroxide system at pH > 2. Studies with the Ti(III)–H_2O_2 system at the same pH show that changes in k_3/k_2 with pH are not sufficient to account for the decrease in the scavenging ability of ethanol and thymine, and also indicate that reaction [4] occurs at pH > 2. As the pK for the dissociation of HO_2 is 4.4 (25), only reactions of the unionized form are pertinent to this investigation. The results can best be explained on the assumption that hydroxyl radicals are not formed by the reaction of ferrous ions with hydrogen peroxide in solutions of high pH. A possible mechanism is outlined below

[12] $$Fe(II) + H_2O \rightleftarrows FeOH^+ + H^+$$

[13] $$FeOH^+ + H_2O_2 \rightarrow FeO^{2+} + H_2O + OH^-$$

[14] $$FeO^{2+} + H_2O_2 \rightarrow HO_2 + OH^- + Fe(III)$$

[15] $$FeO^{2+} + \text{scavenger} \rightarrow \text{product}$$

All the iron ions are aquated.

It is known that K_h for reaction [12] is about 4×10^{-4} and that the rate of reaction of ferrous ion with hydrogen peroxide increases at pH > 3 (23). The competition studies described in the present investigation were carried out by mixing a ferrous sulfate solution of pH 3.8 with a Ti(IV)–H_2O_2 solution of the highest allowable pH (2.2). Under these conditions reaction [13] could predominate over [1]. The experimental results reported here show that $k_{15}/k_{14} \ll k_3/k_2$. The formation of the ferryl ion, FeO^{2+}, in the reaction

$$Fe(II) + H_2O_2 \rightarrow FeO^{2+} + H_2O$$

was originally proposed by Bray and Gorin (26). Kolthoff and Medalia (27, 28) have pointed out that it is possible to replace the hydroxyl radical by the ferryl ion throughout the Haber–Weiss reaction scheme without altering the kinetics and that reaction with ethanol may take place according to [15]. It is therefore suggested that, under conditions favoring the presence of $FeOH^+$ ions rather than Fe(II) ions, reaction with hydrogen peroxide produces an oxidizing species

which is not the hydroxyl radical and may be the ferryl ion. If the Fe(II) ions are complexed with EDTA, the formation of $FeOH^+$ is prevented and hydroxyl radicals are generated at higher pH.

In addition to providing information about the reaction mechanisms of ferrous and titanous ions with hydrogen peroxide, the technique described offers a novel method for determining the relative rate constants for reactions of hydroxyl radicals with a wide variety of organic compounds in solutions of pH 1.

Etude spectroscopique des dérives du peroxyde d'hydrogène. II. L'oxalate perhydrate, $Na_2C_2O_4.H_2O_2$

JOSÉ L. ARNAU ET PAUL A. GIGUÈRE
Centre de Recherches sur les Atomes et les Molécules, Université Laval, Québec 10, Québec

Reçu le 21 mai 1969

Dans les spectres de vibration du composé d'addition $Na_2C_2O_4.H_2O_2$, les fondamentales actives en infrarouge (i.r.) sont inactives en Raman et vice versa. Cette caractéristique, vérifiée par l'étude du composé partiellement deutérié, est en accord avec les résultats de la diffraction des rayons X et la résonance magnétique nucléaire (r.m.n.), à savoir que la molécule de peroxyde d'hydrogène est plane et centrosymétrique dans ce cristal. Grâce à cette déformation la molécule de peroxyde peut former des liaisons hydrogène très fortes (9 kcal $mole^{-1}$) avec l'anion oxalate, également plan. La majorité des vibrations de réseau prévues par la théorie des groupes ont pu être répérées. Pour fin de comparaison, les spectres du réseau cristallin de l'oxalate de sodium anhydre ont été mesurés en i.r. et en Raman.

The vibrational spectra of the addition compound $Na_2C_2O_4.H_2O_2$ show mutual exclusion of all the fundamentals in infrared (i.r.) and Raman. This feature is confirmed by a study of the partly deuterated compound. It agrees with the conclusion of a previous X-ray and nuclear magnetic resonance study that the hydrogen peroxide molecule in that crystal is planar and centrosymmetric. The two component molecules are held together by strong (9 kcal $mole^{-1}$) hydrogen bonds. Some 20 lattice modes were detected in i.r. or Raman. For comparison purposes, the lattice spectra of anhydrous sodium oxalate were also investigated.

Canadian Journal of Chemistry, **47**, 3745 (1969)

Introduction

Parmi les composés d'addition du peroxyde d'hydrogène l'oxalate perhydrate de sodium est d'un intérêt exceptionnel. En effet, il a été démontré par Pedersen et Pedersen (1) que dans ce cristal la molécule de peroxyde d'hydrogène existe sous la configuration plane *trans*, alors que normalement elle prend la configuration *gauche* (2). A cause de sa symétrie plus élevée, C_{2h}, la molécule plane doit avoir des spectres de vibration quelque peu différents de ceux de la molécule *gauche* (symétrie C_2). Ainsi les modes symétriques seront actifs en Raman seulement et inversement les modes antisymétriques, seulement en i.r. Dans le cadre de ce programme d'études spectroscopiques (3) il nous a semblé intéressant de vérifier ce point ainsi que l'influence de la forte déformation de la molécule sur ses fréquences fondamentales. En cours de route nous avons pris connaissance de la publication récente de Pedersen (4) sur les spectres i.r. des oxalates des métaux alcalins, leurs hydrates et leurs perhydrates. Nos résultats sur les composés du sodium sont cependant plus complets puisqu'ils s'étendent à l'i.r. lointain, jusqu'à 40 cm^{-1}, aussi bien qu'au Raman.

Partie Expérimentale

Le composé a été préparé suivant la méthode originale (1) soit par cristallisation à température ambiante d'une solution saturée d'oxalate de sodium (Baker's, C.P.) dans du peroxyde d'hydrogène (BECCO) à quelque 30%. Après évaporation lente (~20 h) on obtenait de fines aiguilles transparentes. Peu après avoir été séparées de la solution-mère elles se recouvraient d'un film blanc dû à un début de décomposition. Pour le composé deutérié on a utilisé du peroxyde de deutérium de même concentration produit par dissociation de la vapeur d'eau lourde dans une décharge électrique, tel que décrit antérieurement (5). La composition isotopique n'a pas été déterminée avec précision, mais d'après l'intensité des bandes i.r. la concentration de la molécule hybride HDO_2 semblait à peu près la même que celle de H_2O_2, et celle de D_2O_2, de l'ordre de 10 à 15%. La préparation des échantillons ainsi que les conditions d'enregistrement des divers spectres ont déjà été décrites dans le travail précédent (3). Sauf indication contraire les présents résultats se rapportent à la température de l'azote liquide.

Discussion des Résultats

Bandes du Peroxyde

En comparant les spectres du perhydrate avec ceux de l'oxalate anhydre en i.r. (Fig. 1) et en Raman (Fig. 2) on peut identifier tout de suite les bandes dues au peroxyde d'hydrogène (Tableau I). Ainsi dans la région de 3 μ, où l'ion oxalate n'a pas de fondamentales, la forte bande à 2672 cm^{-1} en Raman ne peut être que la vibration de valence O—H symétrique ν_1 et celle à 2605 cm^{-1} en i.r. (2645 cm^{-1} à température ambiante), la vibration antisymétrique ν_5. Cette dernière valeur est la plus basse de toutes celles trouvées jusqu'ici dans les composés d'addition

du peroxyde d'hydrogène. Elle confirme l'existence de ponts d'hydrogène très forts déjà indiquée par les distances O—H...O relativement courtes, 2.588 ± 0.06 Å, entre les molécules de peroxyde et les ions oxalate alternant dans des chaines planes infinies (1). En appliquant la relation de Pimentel et Sederholm (6) à la fréquence observée en i.r., 2640 cm^{-1}, Pedersen (4) est arrivé indirectement à une distance O—H...O un peu plus longue, soit 2.62 Å. Cependant il est plus utile ici de se baser sur la distance expérimentale, connue avec précision, pour évaluer par exemple la force des ponts d'hydrogène, ou encore la longueur de la liaison O—H moins bien connue. Ainsi le modèle de Lippincott et Schroeder (7) conduit à des valeurs d'environ 9 kcal $mole^{-1}$ et 1.05 Å, respectivement pour ces deux quantités. Cette dernière est certainement plus près de la réalité que celle de 0.89 ± 0.05 Å basée sur les diagrammes de densité électronique. Par contre elle est en accord avec celle de 1.1 Å tirée de l'analyse de la structure protonique par résonance magnétique nucléaire (r.m.n.) (1).

Les bandes de déformation OH sont décalées, tout comme les bandes de valence, mais en sens inverse naturellement, par rapport au cristal de peroxyde pur ou de son dihydrate (8). Cet effet est particulièrement marqué dans le cas du mode symétrique ν_2. Vraisemblablement c'est là le résultat combiné de la forte association intermoléculaire et de la haute symétrie, non seulement de la molécule de peroxyde mais encore de son site dans la maille cristalline. La bande de déformation antisymétrique ν_6 vers 1400 cm^{-1} coïncide presque exactement avec une bande faible de l'oxalate. C'est seulement aux basses températures que les deux peuvent être séparées. Effectivement notre interprétation se trouve confirmée par les décalages isotopiques dans les échantillons partiellement deutériés. Par ailleurs la bande d'intensité moyenne à 1475 cm^{-1} dans les spectres des oxalates perhydrates de potassium, de rubidium et de cesium (4) doit être attribuée à ν_6 plutôt qu'à ν_2 vu la faible activité des modes symétriques en i.r. Quant à la forte bande à 828 cm^{-1}, elle appartient au mode fondamental ν_4 dit de torsion interne et non à une combinaison de celui-ci avec un mode de libration présumé de fréquence environ 260 cm^{-1}. Il en est de même de la bande vers 940 cm^{-1} dans des spectres des autres oxalates perhydrates alcalins. Tel que mentionné précédemment (9, 10) cette vibration, à cause de sa faible force de rappel (2), dépend dans une large mesure des interactions moléculaires dans les états condensés. Comme on peut le prévoir la fréquence de ν_4 doit être assez voisine de celle du mode de libration autour de l'axe mineur, ν_{R_x}. Dans le cas de la molécule plane les règles de sélection permettent d'attribuer l'une et l'autre sans ambiguité.

Les spectres i.r. des échantillons partiellement deutériés sont particulièrement révélateurs. Ainsi l'apparition d'une faible absorption à 895 cm^{-1} due à la vibration O—O de la molécule hybride HDO_2 confirme la planéité de la molécule de peroxyde puisque cette fréquence est totalement absente du spectre de H_2O_2. En Raman son intensité n'est pas aussi grande qu'on pourrait le prévoir. Il se peut que le voisinage des fortes bandes de valence C—C de l'ion oxalate conduise à une redistribution d'intensité.

Bandes de l'Oxalate

Les vibrations de l'ion oxalate se retrouvent ici à peu près aux mêmes fréquences que dans le solide anhydre, tant en Raman (11) qu'en i.r. (11–16), sauf pour la vibration C—O antisymétrique dont le doublet à 1648/1618 cm^{-1} est décalé de quelque 40 cm^{-1} vers les basses fréquences. (Les deux faibles bandes vers 1660/1630 cm^{-1} toujours présentes dans nos spectres Raman du perhydrate provenaient sans doute d'une légère décomposition en surface lors du broyage des cristaux.) Six bandes apparaissent dédoublées (surtout dans les spectres à basse température) sous l'effet du champ cristallin dans le cristal anhydre, mais non dans celui du perhydrate. Dans ce dernier, l'insertion alternée de molécules de peroxyde doit amoindrir considérablement le couplage entre les ions oxalate. Les attributions présentes (Tableau II) sont en général les mêmes que celles de Murata et Kawai sauf pour le mode de déformation ν_{10} que nous attribuons à la bande i.r. vers 520 cm^{-1}, tel que proposé par Begun et Fletcher, et non pas à celle de 770 cm^{-1} qui doit appartenir au mode de rotation des groupes CO_2, ν_{12}. La valeur de 295 cm^{-1} calculée pour ce dernier par Murata et Kawai est certainement trop basse. L'attribution des deux fondamentales de basses fréquences ν_8 et ν_4 est conforme à celle de Lorenzelli *et al.* (17).

†La présente notation diffère des précédentes (8–13) en ce qu'elle se rapporte aux axes $0y$ et $0x$, définis suivant la même convention que dans les tables internationales de cristallographie. Les vibrations sont ici numérotées par ordre de fréquence décroissante dans chacune des classes de symétrie successivement, soit Ag, Au, B_{1g}, B_{3g}, B_{1u}, B_{2u} et B_{3u}.

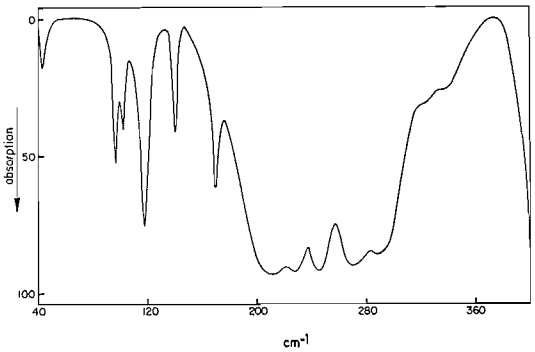

FIG. 3. Spectre d'absorption dans l'i.r. lointain à −190 °C de l'oxalate perhydrate de sodium (suspension dans le Nujol).

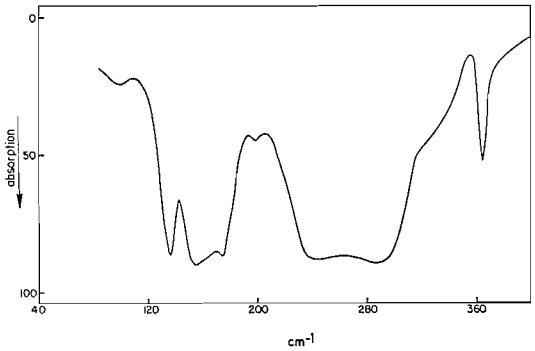

FIG. 4. Spectre i.r. lointain de $Na_2C_2O_4$.

Bandes de Réseau

L'oxalate perhydrate de sodium cristallise dans le système monoclinique (groupe spatial $P2_1/C$) avec deux "molécules" par maille élémentaire. Celle-ci contient donc un total de 8 molécules ou ions individuels: 4 cations Na^+, 2 anions oxalate et 2 molécules de peroxyde, soit un total de 24 degrés de liberté pour les vibrations dans la maille. La représentation réductible pour les translations est donnée par l'expression

$$\Gamma_{réd} = 3A_g + 3B_g + 9A_u + 9B_u$$

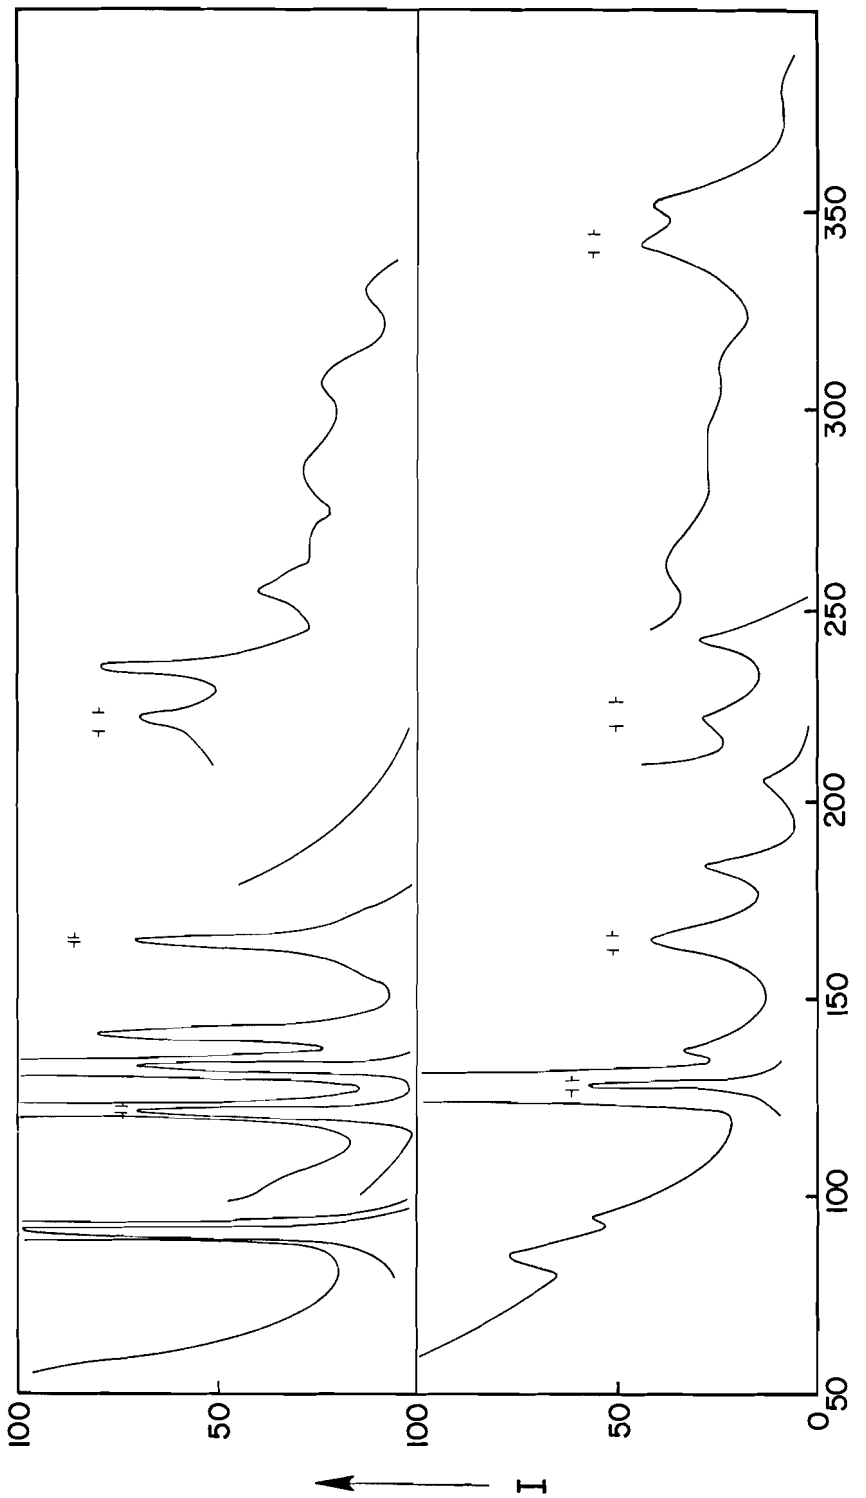

FIG. 5. Spectres Raman de basse fréquence de l'oxalate perhydrate (haut) et de l'oxalate anhydre (bas) à −190 °C.

De ceci il faut soustraire les trois modes $A_u + 2B_u$ appartenant à la branche acoustique; il reste donc un total de 15 modes de translation actifs en i.r. et 6 actifs en Raman (cf. Tableau III).

Quant aux rotations gênées ou librations, les corrélations de symétrie en prévoient 6 chacune pour l'ion oxalate et la molécule de peroxyde, toutes actives en Raman. Les résultats expérimentaux (Tableau IV) concordent assez bien avec ces prévisions puisque l'on trouve 12 bandes dans l'i.r. lointain (Fig. 3) — outre les 2 fondamentales de l'ion oxalate à 260 et 164 cm^{-1} (Fig. 4) — et un nombre égal en Raman des basses fréquences (Fig. 5). A celles-ci il faut ajouter la bande de libration ν_{R_x} à 857 cm^{-1} qui est en fait un mode de réseau. Il serait téméraire de chercher ici une attribution pour chacune de ces bandes de réseau. Notons cependant que celles qui n'ont pas d'équivalent dans les spectres de l'oxalate anhydre (soit à 383, 353 et 342 cm^{-1} en Raman, et à 339 et 228 cm^{-1} en i.r.) doivent être des librations de la molécule H_2O_2. Ces fréquences sont un peu plus hautes que dans le peroxyde cristallin (10) ce qui s'explique par les liaisons hydrogène plus fortes de l'oxalate perhydrate.

Reactions of organotin compounds. X. Reactions of tin hydrides with CF_2=$CFRe(CO)_5$, CF_3CF=$CFRe(CO)_5$, and some fluorinated alkenes

M. AKHTAR AND H. C. CLARK
Department of Chemistry, University of Western Ontario, London, Ontario

Received April 21, 1969

Trimethyltin hydride reacts with CF_2=$CFRe(CO)_5$ under ultraviolet irradiation to give new fluorovinyl derivatives of —$Re(CO)_5$. Similar products were obtained using dimethyltin dihydride, but no reaction occurred between trimethyltin hydride and CF_3CF=$CFRe(CO)_5$. The reactions of trifluoroethylene, 1,1-difluoroethylene, and vinyl fluoride with trimethyltin hydride have been studied, thus completing the sequence of such reactions with fluorinated ethylenes. While both possible addition products were obtained with trifluoroethylene, and also from the corresponding reaction with perfluoropropene, 1,1-difluoroethylene gave only $(CH_3)_3SnCH_2CF_2H$, and with vinyl fluoride only trimethyltin fluoride and ethylene were isolated. Possible explanations are proposed and spectroscopic data for the new compounds are presented.

Canadian Journal of Chemistry, 47, 3753 (1969)

Introduction

Our previous studies established that the addition of trimethyltin hydride to the C=C bonds of perfluorovinyl derivatives of silicon, germanium, and tin (1, 2) occurs by a free radical mechanism and that both possible isomers, $R_3MCF[Sn(CH_3)_3]CF_2H$ and $R_3MCFHCF_2Sn(CH_3)_3$ (M = Si, Ge, or Sn), are formed. These reactions differ from the additions of organotin hydrides to acetylenes where both a polar as well as a radical mechanism are probably involved, and particularly from the non-terminal additions with electrophilic acetylenes which are controlled mainly by polar effects (3–6).

In the present work, the reactivity of some perfluorovinyl derivatives of a transition metal towards organotin hydrides has been studied, as well as the related reactions of trimethyltin hydride with some unsymmetrically substituted fluoro-olefins.

Discussion

Trimethyltin hydride did not react with pentacarbonylperfluorovinylrhenium in benzene at 25° over a long period. At 45° for 48 h in butyronitrile, only a limited reaction occurred with the formation of *cis*-CFH=$CFRe(CO)_5$ and CF_2=$CHRe(CO)_5$ in approximately equal amounts. The reaction therefore occurs much less readily under thermal conditions than the comparable additions of trimethyltin hydride to perfluorovinyl-silicon, germanium, and tin derivatives (1, 2).

When trimethyltin hydride and CF_2=$CFRe(CO)_5$ were exposed to ultraviolet (u.v.) irradiation at 35° for 36 h in benzene, a considerable amount of trimethyltin fluoride was deposited, with *trans*-CFH=$CFRe(CO)_5$ being the main volatile product. The *cis* isomer and CF_2=$CHRe(CO)_5$ were formed in smaller but approximately equal amounts. Similarly, extensive reaction also occurred at 50° in benzene in the presence of azobisisobutyronitrile (AIBN). A considerable amount of trimethyltin fluoride was deposited, and *trans*-CFH=$CFRe(CO)_5$, CF_2=$CHRe(CO)_5$, and *cis*-CFH=$CFRe(CO)_5$ were formed in order of decreasing yield. No addition compounds were isolated, but the nature of the reaction products strongly suggests that addition has occurred, followed by the rapid elimination of trimethyltin fluoride, probably by a β-fluorine elimination process.

$$(CO)_5ReCFHCF_2Sn(CH_3)_3 \rightarrow CF_2{=}CHRe(CO)_5 + (CH_3)_3SnF$$

$$(CO)_5ReCF[Sn(CH_3)_3]CF_2H \rightarrow CFH{=}CFRe(CO)_5 + (CH_3)_3SnF$$

Such a process has already been proposed in connection with the products formed in the addition of trimethyltin hydride to other perfluorovinyl compounds (1, 2), and is also consistent with the formation of *cis*- and *trans*-CFH=$CFMn(CO)_5$ and trimethylfluorogermane or trimethyltin fluoride from the reaction of trifluoroethylene with $(CH_3)_3GeMn(CO)_5$ and $(CH_3)_3SnMn(CO)_5$, respectively (7, 8).

In the present case, *trans*-CFH=$CFRe(CO)_5$ was always more abundant than its *cis* isomer, although in cases reported previously (1, 2), the

For personal use only.

cis isomer was in higher yield. Again, however, it was established that isomerization of *cis* to *trans* occurred under u.v. irradiation; after 6 h under such irradiation, 75% of the *cis* isomer had rearranged to the *trans* form. Seyferth and Vaughan (9) have also reported that the *cis* addition product of trimethyltin hydride and propyne did not rearrange thermally or in the presence of either AIBN or benzoyl peroxide, but did so upon u.v. irradiation. It is also known, however, that such *cis* to *trans* conversion proceeds under the influence of a triorganotin radical (10).

Dimethyltin dihydride did not react with $CF_2{=}CFRe(CO)_5$ in benzene at 25°, but considerable reaction occurred at 25° under u.v. irradiation. Dimethyltin difluoride was deposited, the products being, in order of decreasing yield, *trans*-$CFH{=}CFRe(CO)_5$, *cis*-$CFH{=}CFRe(CO)_5$, and $CF_2{=}CHRe(CO)_5$. This is entirely consistent with the results of other similar addition reactions (1, 2, 11) and with both the greater reactivity of dimethyltin dihydride (12) and the high lattice energy of dimethyltin difluoride (13). It thus appears that a perfluorovinyl transition metal derivative does not differ substantially from its Group IVB analogue in its addition reaction with organotin hydrides, other than showing a somewhat increased reluctance to participate in such reactions.

Introduction of a CF_3 group as a substituent about the vinylic C=C bond, greatly reduced the latter's reactivity. Trimethyltin hydride and $CF_3CF{=}CFRe(CO)_5$ did not react at 45° in butyronitrile, nor under u.v. irradiation in benzene at 40°. In the presence of AIBN in benzene at 45°, complete decomposition of the hydride to hexamethylditin occurred.

The free radical additions of organotin hydrides across the C=C bonds of fluoro-olefins, such as tetrafluoroethylene, have been previously described (14). The unsymmetrically substituted olefin, trifluoroethylene, has now also been found to react with trimethyltin hydride under u.v. irradiation at 25° to give in high yield approximately equal amounts of the two possible addition products, $(CH_3)_3SnCF_2CFH_2$ and $(CH_3)_3SnCFHCF_2H$. A similar reaction involving trimethyltin hydride and perfluoropropene gave $(CH_3)_3SnCF_2CFHCF_3$ and $(CH_3)_3SnCF(CF_3)CF_2H$ in approximately equal amounts. However, when trimethyltin hydride and 1,1-difluoroethylene were allowed to react under u.v. light at 25°, quantitative addition occurred to give only one product, $(CH_3)_3SnCH_2CF_2H$. This preferred formation of just one isomer is possibly due to the presence of the 2 fluorine atoms, as a consequence of which ionic forms, e.g. $F^-(FC{=}CH_2)^+$, have been described (15, 16). Similarly, an increase in the polarity of the C=C bond in $CF_2{=}CCl_2$ has been attributed to the strong inductive effect of the halogens (15, 16) so that RO^- ions attack the carbon atom having the fluorine substituents

$$C_2H_5OH + CF_2{=}CCl_2 \rightarrow C_2H_5OCF_2CHCl_2$$

It appears, then, that the reaction of trimethyltin hydride with 1,1-difluoroethylene might be described in terms of attack of hydride (from $(CH_3)_3Sn^{\delta+}{-}H^{\delta-}$) on the carbon atom bearing the fluorine substituents. Alternatively, the exclusive formation of 1,1-difluoro-2-(trimethylstannyl)ethane may be explained in terms of a free radical mechanism

$$R_3Sn\cdot + CF_2{=}CH_2 \rightarrow \cdot CF_2CH_2SnR_3$$
$$\cdot CF_2CH_2SnR_3 \xrightarrow{R_3SnH} HCF_2CH_2SnR_3 + R_3Sn\cdot$$

The formation of $\cdot CF_2CH_2SnR_3$ will be greatly favored over the formation of $\cdot CH_2CF_2SnR_3$, due to the presence of the fluorine atoms, whereas such exclusiveness is neither expected nor observed in the reaction with the more symmetrically substituted trifluoroethylene.

To complete this sequence of reactions of the hydride with a complete series of substituted olefins, the reaction of trimethyltin hydride with vinyl fluoride was finally studied. Since this olefin contains only one fluorine atom, the configuration of the addition product would be of particular interest. Unfortunately, a stable addition product could not be isolated, the formation of trimethyltin fluoride and ethylene being very rapid even at 25°.

The configurations of the fluorovinyl derivatives of pentacarbonylrhenium have been assigned from the values of the H—F coupling constants observed in their proton magnetic resonance (p.m.r.) spectra, together with the observed frequencies of the C=C stretching absorptions, both of which are consistent with values previously reported for fluorovinyl derivatives of silicon, germanium, and tin (1, 2, 11). The complete spectroscopic data for the fluorovinyl

derivatives of pentacarbonylmanganese (7) and pentacarbonylrhenium are given in Table I.

The addition products obtained from the reactions of trimethyltin hydride with fluoro-olefins were characterized by their ^1H and ^{19}F magnetic resonance studies. From the closely coincident values of H—F coupling constants the ^1H and ^{19}F spectra were matched. The complete nuclear magnetic resonance (n.m.r.) data obtained by normal first order analysis are given in Table II for $(CH_3)_3SnCH_2CF_2H$ and in Table III for $(CH_3)_3SnCF_2CFH_2$ and $(CH_3)_3SnCFHCF_2H$. In these compounds the following ranges of coupling constants were observed

$$J_{(H-F)gem} = 47\text{–}62\ Hz$$
$$J_{(H-F)vic} = 8\text{–}24\ Hz$$
$$J_{(F-F)vic} = 10\text{–}23\ Hz$$

These values are in good agreement with coupling constants observed in similar compounds whose spectra have been discussed in considerable detail (1, 2, 17–19). In the molecule $(CH_3)_3SnCFHCF_2H$ there are 3 different substituents on the C atom α to tin which causes the 2 fluorine atoms in the $—CF_2H$ group to be magnetically non-equivalent, thus giving rise to $J_{(F-F)gem} = 294$ Hz. Two non-equivalent H—F coupling constants are also observed, due to the coupling of these 2 fluorine atoms with one geminal proton. Similarly, 2 non-equivalent coupling constants arise from the coupling of these 2 fluorine atoms with one vicinal proton. Such non-equivalent coupling constants between an alkane proton and 2 magnetically non-equivalent vicinal fluorine atoms have also been observed in other compounds (1, 2, 17, 20).

The values of other coupling constants, for example, arising from the satellites due to ^{119}Sn, ^{117}Sn, and ^{13}C, are consistent with the observed data for other fluorocarbon derivatives of tin (1, 2, 17, 18).

The n.m.r. data for the molecule $(CH_3)_3SnCF(CF_3)CF_2H$ are given in Table II. In both

molecules $(CH_3)_3SnCF(CF_3)CF_2H$ and $(CH_3)_3SnCF_2CFHCF_3$, magnetic non-equivalence of the 2 fluorine atoms of the CF_2 group arises due to the fact that there are 3 different substituents on the adjacent carbon atoms. The spectrum of $(CH_3)_3SnCF_2CFHCF_3$ has already been discussed in detail by Clark *et al.* (17), hence assignments could readily be made for the other molecule $(CH_3)_3SnCF(CF_3)CF_2H$.

Experimental

All general techniques have been described previously (1, 2). Trimethyltin hydride and dimethyltin dihydride were prepared by the procedure of Finholt *et al.* (21), using *n*-butyl ether as solvent. Pentacarbonylperfluorovinylrhenium and pentacarbonylperfluoropropenylrhenium were prepared by the procedure described by Jolly *et al.* (22). Trifluoroethylene, vinyl fluoride, and 1,1-difluoroethylene were obtained from Matheson of Canada, and perfluoropropene from Columbia Organic Chemicals. Proton magnetic resonance spectra were obtained with a Varian A60 spectrometer, and ^{19}F spectra with a Varian HA100 spectrometer operating at 94.1 Mc.p.s.

Reactions of Organotin Hydrides with Pentacarbonylperfluorovinylrhenium and Pentacarbonylperfluoropropenylrhenium

(*a*) Trimethyltin hydride (0.1 g, 0.6 mmole) and $(CO)_5ReCF{=}CF_2$ (0.234 g, 0.57 mmole) were allowed to react in benzene (4 ml) at 25° for 1 week. There was no visible reaction and vacuum fractionation led to complete recovery of the reactants.

A similar mixture, sealed with azobisisobutyronitrile (50 mg) at 50° for 20 h, gave firstly a small amount of a non-condensable gas, some unreacted trimethyltin hydride, and benzene as volatile products.

The remaining solids were washed with tetrahydrofuran and filtered to give a white residue (0.155 g, *ca.* 70% yield), identified spectroscopically as trimethyltin fluoride. Tetrahydrofuran was removed from the filtrate at 0° to give a yellow solid whose infrared spectrum (Nujol mull) showed three new C=C stretching absorptions (cm^{-1}) at 1675 s, 1625 m, and 1615 m in addition to the ν (C=C) for unreacted $(CO)_5ReCF{=}CF_2$ at 1705 cm^{-1}. This solid mixture was dissolved in acetonitrile and its ^1H n.m.r. spectrum recorded (Table I). This confirmed the presence of *trans*-$CFH{=}CFRe(CO)_5$ (60%), *cis*-$CFH{=}CFRe(CO)_5$ (13%), and $(CO)_5ReCH{=}CF_2$ (27%). Acetonitrile was then removed from this mixture at 0°, under vacuum. The remaining solids were sublimed under reduced pressure at room temperature, over a −78° cold probe. During the first 10 min, $(CO)_5ReCF{=}CF_2$ and *cis*-$CFH{=}CFRe(CO)_5$ were collected. The presence of *cis*-$CFH{=}CFRe(CO)_5$ was confirmed by its p.m.r. spectrum and the corresponding C=C stretching absorption at 1625 cm^{-1}. After the removal of *cis*-$CFH{=}CFRe(CO)_5$ from the mixture, *trans*-$CFH{=}CFRe(CO)_5$ and $(CO)_5ReCF{=}CF_2$ were collected on the cold probe for the next 20 min. The p.m.r. spectrum of this fraction corresponded to *trans*-$CFH{=}CFRe(CO)_5$, the C=C stretching absorption being at 1675 cm^{-1}. The i.r. spectrum of the remaining solid material at the bottom of the sublimation flask showed weak absorptions at 1705 and 1675 cm^{-1} and a strong absorption at 1615 cm^{-1}. The p.m.r. spectrum of this material (Table I) showed the presence of only $(CO)_5ReCH{=}CF_2$. Hence the C=C stretching absorption at 1615 cm^{-1} was assigned to $(CO)_5ReCH{=}CF_2$.

The products *trans*-$CFH{=}CFRe(CO)_5$, *cis*-$CFH{=}CFRe(CO)_5$, and $(CO)_5ReCH{=}CF_2$ could not be separated completely from $(CO)_5ReCF{=}CF_2$. Hence, due to the overlapping of absorptions in the CO and C—F stretching region, individual assignments could not be made for the new reaction products.

In the following experiments (*b–e*) the reaction mixtures were worked up as (*a*) above, and the products were identified by their i.r. and p.m.r. spectra.

(*b*) Trimethyltin hydride (0.1 g, 0.6 mmole) and $(CO)_5ReCF{=}CF_2$ (0.237 g, 0.58 mmole) were exposed to u.v. irradiation at 35° for 36 h in benzene. Examination of the reaction mixture gave some unreacted $(CO)_5ReCF{=}CF_2$ and $(CH_3)_3SnH$, along with *trans*-$CFH{=}CFRe(CO)_5$ as the main product and *cis*-$CFH{=}CFRe(CO)_5$ and $(CO)_5ReCH{=}CF_2$ in about equal amounts. From the reaction tube, trimethyltin fluoride (0.049 g) was recovered, corresponding to 47.6% reaction.

A sample (0.15 g) containing $(CO)_5ReCF{=}CF$ and *cis*-$CFH{=}CFRe(CO)_5$ was exposed to u.v. irradiation at 35° for 8 h in benzene. The i.r. spectrum of this mixture showed a strong band at 1675 cm^{-1} (C=C stretch) characteristic of *trans*-$CFH{=}CFRe(CO)_5$, along with the bands at 1705 and 1625 cm^{-1}, corresponding to the starting materials $(CO)_5ReCF{=}CF_2$ and *cis*-$CFH{=}CFRe(CO)_5$, respectively. The band at 1625 cm^{-1} (C=C stretch), characteristic of *cis*-$CFH{=}CFRe(CO)_5$, was about 25% of its original intensity.

(*c*) Trimethyltin hydride (0.1 g, 0.6 mmole) and $(CO)_5ReCF{=}CF_2$ (0.234 g, 0.57 mmole) were allowed to react at 45° for 48 h in butyronitrile. The i.r. spectrum of the reaction mixture showed 2 weak bands of almost equal intensity at 1625 and 1615 cm^{-1} corresponding to the C=C stretching frequencies of *cis*-$CFH{=}CFRe(CO)_5$ and $(CO)_5ReCH{=}CF_2$, respectively. From the reaction tube, trimethyltin fluoride (0.018 g) was recovered, corresponding to 17% reaction.

(*d*) Dimethyltin dihydride (0.2 g, 0.13 mmole) and $(CO)_5ReCF{=}CF_2$ (0.54 g, 1.3 mmoles) did not react in benzene (4 ml) at 25° after 48 h. Considerable reaction occurred when a similar mixture was exposed to u.v. irradiation at 25° for 6 h. Dimethyltin difluoride (0.035 g, *ca.* 14% yield) was deposited, and in addition to small amounts of the starting materials, the reaction products *trans*-$CFH{=}CFRe(CO_5)$, *cis*-$CFH{=}CFRe(CO)_5$, and $(CO)_5ReCH{=}CF_2$ were identified. However, the amounts of these products were too small to be determined quantitatively even by integration of the p.m.r. spectrum.

(*e*) Trimethyltin hydride (0.29 g, 1.75 mmoles) and $(CO)_5ReCF{=}CFCF_3$ (0.8 g, 1.75 mmoles) were allowed to react at 45° in butyronitrile (4 ml) for 1 week. Examination of the i.r. spectrum of the gas phase mixture showed the presence of a non-condensible gas, presumably a mixture of hydrogen and methane, and some unreacted trimethyltin hydride. The i.r. spectra of the involatile compounds in the reaction tube, confirmed the presence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of unreacted $(CO)_5ReCF{=}CFCF_3$ and hexamethylditin (22, 23). The p.m.r. spectrum of this mixture did not show the presence of any vinylic proton. From the reaction tube, a mixture (0.024 g) of metallic tin and a trace of trimethyltin fluoride was recovered.

When similar reaction mixtures were exposed to u.v. irradiation at 40° or allowed to react at 45° in the presence of azobisisobutyronitrile, no reaction products could be identified except from the decomposition of the tin hydride to hexamethylditin and hydrogen.

Reactions of Trimethyltin Hydride with Fluoro-olefins

(*a*) Trimethyltin hydride (0.5 g, 3 mmoles) and 1,1-difluoroethylene (0.2 g, 3 mmoles) were exposed to u.v. irradiation at 25° for 4 h. A small amount of trimethyltin fluoride, identified spectroscopically, was deposited. Vacuum fractionation gave, at −78°, a high yield (0.62 g, 90% yield) of a slightly volatile liquid product. This was identified from its n.m.r. spectra (Table II) to be $(CH_3)_3SnCH_2CF_2H$.

This reaction was repeated, but always the only product obtained in quantitative yields was $(CH_3)_3SnCH_2CF_2H$. This compound slowly decomposed to give visible amounts of trimethyltin fluoride after about 8 h at room temperature. Decomposition to $(CH_3)_3SnF$ and $CH_2{=}$ CFH was complete after 48 h at room temperature.

(*b*) Trimethyltin hydride (0.5 g, 3 mmoles) and trifluoroethylene (0.26 g, 3 mmoles) were exposed to u.v. irradiation at 25° for 6 h. A trace of trimethyltin fluoride, identified spectroscopically, was deposited. Vacuum fractionation gave, at −78°, a high yield (0.69 g, 93% yield) of a liquid product with a vapor pressure of about 1 cm at room temperature. This was identified from its n.m.r. spectra (Table III) as a mixture of 2 addition products, $(CH_3)_3SnCF_2CFH_2$ and $(CH_3)_3SnCFHCF_2H$, in approximately equal amounts.

Anal. Calcd. for $SnC_5F_3H_{11}$: H, 4.89; C, 24.37; F, 23.09. Found: H, 4.56; C, 24.64; F, 23.33.

(*c*) Trimethyltin hydride (0.5 g, 3 mmoles) and perfluoropropene (0.45 g, 3 mmoles) were exposed to u.v. irradiation at 25° for 6 h. Vacuum fractionation gave, at −78°, a high yield (0.897 g, 95% yield) of a liquid product with very low (~ 0.5 cm at 25°) vapor pressure. This was identified from its n.m.r. spectra (Table II) as a mixture of 2 addition products $(CH_3)_3SnCF_2CFHCF_3$ and $(CH_3)_3SnCF(CF_3)CF_2H$ in about equal amounts (17).

Anal. Calcd. for $SnC_6F_6H_{10}$: H, 3.20; C, 22.89; F, 36.20. Found: H, 3.47; C, 22.74; F, 36.52.

(*d*) Trimethyltin hydride (0.5 g, 3 mmoles) and vinyl fluoride (0.138 g, 3 mmoles) were exposed to u.v. irradiation at 25°. After ½ h, substantial amounts of trimethyltin fluoride (0.39 g) had been deposited. Ethylene was the only other reaction product identified, in addition to small amounts of the starting materials.

Reaction of hydrogen atoms with propane: relative Arrhenius parameters for the attack on the 1 and 2 positions

J. M. CAMPBELL, O. P. STRAUSZ, AND H. E. GUNNING
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received May 26, 1969

Arrhenius parameters were measured for the relative rate of attack of hydrogen atom on the primary and secondary C—H bonds of propane. The mercury photosensitization of hydrogen was used as the source of hydrogen atom and the abstraction reactions were monitored by the formation of isomeric hexanes.

Detailed kinetic analysis was applied to assess the importance of secondary reactions.

Canadian Journal of Chemistry, 47, 3759 (1969)

The abstraction reactions of hydrogen atoms with numerous paraffin molecules have been studied and Arrhenius parameters determined (1). In relatively few cases, however, was the site of attack specified. The Arrhenius parameters $\log k = 12.7 - 7400/2.3RT$ cc mole^{-1} s^{-1} reported for the propane reaction, for example (2), refer to the composite sum of the two concurrent reactions

[1] $$H + C_3H_8 \rightarrow i\text{-}C_3H_7 + H_2$$

[2] $$H + C_3H_8 \rightarrow n\text{-}C_3H_7 + H_2.$$

The ratio k_2/k_1 has not been determined directly. An estimate of the ratio can be made if it is assumed that the reactivity of the primary C—H bonds in propane is the same as that of the C—H bonds in ethane. Using the known rate constants, $10^{12.5} \exp(-9000/RT)$ cc mole^{-1} s^{-1} for ethane (2) and $10^{12.7} \exp(-7400/RT)$ cc mole^{-1} s^{-1} for propane (3), one obtains for the ratio

$$k_2/(k_2 + k_1) = 0.63 \exp(-1600/RT)$$

which leads to a value of k_2/k_1 of about 0.8 exp $(-1700/RT)$ between 30 and 200 °C.

In the present article we report an experimental determination of the k_2/k_1 ratio. The triplet mercury photosensitization of hydrogen was used as the source of hydrogen atoms and reactions [1] and [2] were monitored by the rate of formation of the three isomeric hexanes, *n*-hexane, 2,3-dimethylbutane, and 2-methylpentane.

Experimental

The initial experiments were done in a static system. In order to achieve better control of the Hg concentration, further experiments were carried out in a circulating system.

The static system consisted of a 50 mm diameter by 300 mm length cell with a total volume of 524 cc. The valve and cell were enclosed in a close fitting aluminum block furnace with double windows on each end. The furnace temperature was kept constant to within ±0.4 °C. Temperature was read with a calibrated thermocouple.

The circulating system consisted of a 50 mm diameter by 40 mm length quartz cell enclosed in an aluminum block furnace. Heating tape was wrapped for about 6 in. along the tube ahead of the cell to insure that the gas was equilibrated before entering the cell. Both furnace and tape were heated by temperature control units. The gas was circulated by a magnetically operated stirrer which incorporated metal vanes and shaft, teflon bearings, and a glass encased magnet. The gas was passed through a ballast volume, an empty U-trap, and then through one filled with 1/8 in. diameter glass helices before entering the cell. The Hg concentration could then be controlled by the temperature of this trap. The total volume of the system was about 970 cm^3. In reactions done with Hg concentrations corresponding to 0 °C vapor pressure, the gases were circulated for at least 15 min with the trap at −78 °C, then 1 h at 0 °C before each run.

The propane used was Phillips Research Grade and was purified by bubbling it through a 60 cm column of H_3PO_4 in H_2SO_4, then through 120 cm of saturated basic $KMnO_4$ and finally a drierite–ascarite drying column. The propane was then distilled from −130 into −161 °C, saving the middle 2/3 portion. This procedure effectively eliminated all traces of unsaturated compounds (notably propylene) from the propane.

Hydrogen was obtained from a Canadian Liquid Air cylinder. In the initial runs it was first passed through degassed charcoal at −198 °C before pressuring up the reaction system. In later runs, a column of copper turnings heated to about 200 °C to convert the traces of O_2 into H_2O was placed before a molecular sieve column at −198 °C. Both methods seemed adequate to eliminate traces of oxygen and condensable gases.

A Hanovia low pressure mercury lamp #87A-45 was used in all photolyses except the last five where a Hanovia high intensity low pressure quartz spiral mercury lamp was used. This was powered by a 5000 V 120 mA luminous tube transformer and had a 2537 Å line intensity about 30 times greater than that of the low intensity lamp. A Vycor 7910 filter was used to eliminate all wavelengths below 2500 Å.

After irradiation the H_2 was first circulated through the two U-traps at −198 °C to freeze down the condensable

products and then carefully pumped off. The remaining condensable products were distilled at −139 °C. The products not volatile at this temperature (primarily hexanes) were analyzed by gas chromatography on a 20 ft 40% isoquinoline on Chromosorb WAW column at 27 °C. This afforded good separation of all products with the exception of dimethylbutane (DMB) which tailed somewhat into the 2-methylpentane (MP) peak. Since the *n*-hexane (Hx) peak was often too small to measure, it was calculated from the cross-combination ratio (4)

$$\frac{R_{MP}}{(R_{DMB}R_{Hx})^{\frac{1}{2}}} = 2.0$$

The disproportionation to recombination ratios were taken from Terry and Futrell (5) as 0.69 for *i*-Pr + *i*-Pr, 0.408 for *n*-Pr + *i*-Pr, and 0.151 for *n*-Pr + *n*-Pr.

In all experiments the H_2 to C_3H_8 concentration ratio was kept sufficiently high to avoid the mercury sensitized decomposition of propane Quenching of mercury by propane was in the order of 1% or less. The scavenging of H atoms by the propylene product was minimized by limiting the conversion of propane to 0.1% or less.

Results and Discussion

The important reactions taking place subsequent to steps [1] and [2] may be embodied into the following sequence

[3] $n\text{-Pr} + C_3H_8 \rightleftarrows i\text{-Pr} + C_3H_8$

[4] $2\ n\text{-Pr} \rightarrow Hx$

[5] $\rightarrow C_3H_6 + C_3H_8$

[6] $n\text{-Pr} + i\text{-Pr} \rightarrow MP$

[7] $\rightarrow C_3H_6 + C_3H_8$

[8] $2i\text{-Pr} \rightarrow DMB$

[9] $\rightarrow C_3H_6 + C_3H_8$

and the reverse of reactions [1] and [2].

Steady state treatment of this sequence leads to the following expression for the fractional yield of *n*-Pr radicals

$$[10]\quad \frac{R_{(n)}}{R_{(n+i)}} = \frac{k_2[H][C_3H_8]}{(k_1 + k_2)[H][C_3H_8] - \{k_{-2}[n\text{-Pr}] + k_{-1}[i\text{-Pr}]\}[H_2]} - \frac{k_{-2}[H_2][n\text{-Pr}]}{R_{(n+i)}} - \frac{[C_3H_8]\{k_3[n\text{-Pr}] - k_{-3}[i\text{-Pr}]\}}{R_{(n+i)}}$$

$$\equiv Q_1 - Q_2 - Q_3$$

It is now necessary to take into account the fact that the concentration distribution of primary radicals is not homogeneous, but has a more or less steep gradient along the light path in the cell. This is due to the high extinction coefficient of mercury vapor and the consequent attenuation of the light intensity. In this connection Reid and LeRoy (6) have recently developed an explicit correction formula for a light intensity dependence of $-\frac{1}{2}$ power, which has the form

$$\delta = \frac{2(1 - e^{-\varepsilon[Hg]L/2})}{\{\varepsilon[Hg]L(1 - e^{-\varepsilon[Hg]L})\}^{\frac{1}{2}}}$$

where ε is the extinction coefficient of mercury vapor and L is the optical path-length.

In eq. [10] the first term Q_1 is nearly independent of light intensity, while Q_2 and Q_3, which when combined contribute only a few % of that of Q_1, are proportional to the $-\frac{1}{2}$ power of light intensity. Therefore eq. [10] can be written as

$$[11]\quad \frac{R_{(n)}}{R_{(n+i)}} = Q_1 - \delta(Q_2 + Q_3)$$

This can be further rearranged to the form

$$[12]\quad \frac{1}{\dfrac{R_{(n)}}{R_{(n+i)}} + \delta(Q_2 + Q_3)} + \frac{[H_2]\{k_{-2}[n\text{-Pr}] + k_{-1}[i\text{-Pr}]\}\delta}{k_2[H][C_3H_8]} - 1 = \frac{k_1}{k_2}$$

The second term is defined as Q_1'. It will be noted again that the value of k_1/k_2 is determined largely by the ratio $R_{(n)}/R_{(n+i)}$. The other terms having only minor significance can then be evaluated with some approximations.

It will be assumed that Beer's law is obeyed, that

$$k_2[H][C_3H_8] \approx 2I_a \frac{k(H + C_2H_6)}{k(H + C_3H_8)}$$

*High intensity lamp with 40 mm cell and circulating system used.

and that k_{-2} is equal to that of the analogous reaction of ethyl radical, $10^{12.57}$ exp $(-13\ 730/RT)$ cc mole^{-1} s^{-1} (6), and lastly that k_{-1} is equal to $10^{12.57}$ exp $(-17\ 730/RT)$ cc mole^{-1} s^{-1}. Using the recently determined values of k_3 and k_{-3} as $10^{9.9}$ exp $(-9\ 300/RT)$ and $10^{10.5}$ exp $(-12\ 900/RT)$ cc mole^{-1} s^{-1} (7), respectively, and the experimental values of $R_{(n)}$ and $R_{(n+i)}$, the ratio k_1/k_2 can be calculated. The results are given in Table I and plotted against $1/T$ in Fig. 1.

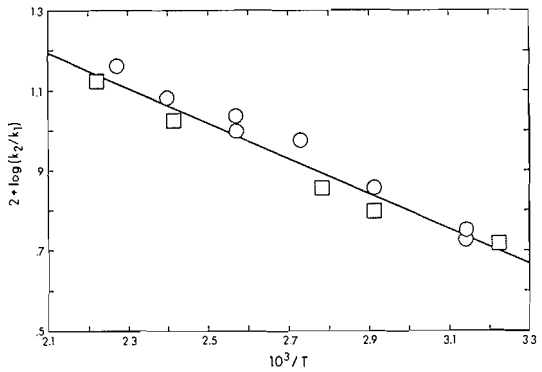

FIG. 1. Arrhenius plot of k_2/k_1: ○, low intensity static system; □, high intensity circulating system.

From least square treatment the Arrhenius parameters are

$$\log (k_2/k_1) = 0.11 \pm 0.11 - \frac{2000 \pm 190}{2.303RT}$$

for 90% confidence limit. Thus

$$k_2/k_1 = 1.29 \exp\left(\frac{-2000}{RT}\right)$$

which is quite close to the value derived from the propane and ethane rate constants (*v.s.*). The normalized A factor ratio A_2/A_1 is 0.43 per C—H bond.

Appendix

Derivation of Eq. [10]

The steady state equations for the reactions [1] to [9] are

$$\frac{d[n\text{-Pr}]}{dt} = 0 = k_2[H][C_3H_8] - k_{-2}[H_2][n\text{-Pr}] - [C_3H_8]\{k_3[n\text{-Pr}] - k_{-3}[i\text{-Pr}]\} - 2(k_4 + k_5)[n\text{-Pr}]^2 - (k_6 + k_7)[n\text{-Pr}][i\text{-Pr}]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$\frac{d[i\text{-Pr}]}{dt} = 0 = k_1[H][C_3H_8] - k_{-1}[H_2][i\text{-Pr}] + [C_3H_8]\{k_3[n\text{-Pr}] - k_{-3}[i\text{-Pr}]\} - (k_6 + k_7)[n\text{-Pr}][i\text{-Pr}] - 2(k_8 + k_9)[i\text{-Pr}]^2$$

If we take the rate of *n*-propyl radicals as observed by the hexane products we have

[A] $$R_{(n)} = 2(1 + k_5/k_4)R_{Hx} + (1 + k_7/k_6)R_{MP}$$
$$= 2(k_4 + k_5)\,[n\text{-Pr}]^2 + (k_6 + k_7)\,[n\text{-Pr}]\,[i\text{-Pr}]$$
$$= k_2\,[H]\,[C_3H_8] - k_{-2}\,[H_2]\,[n\text{-Pr}] - [C_3H_8]\,\{k_3\,[n\text{-Pr}] - k_{-3}\,[i\text{-Pr}]\}$$

Similarly for the sum of the *n*- and isopropyl radicals

[B] $$R_{(n+i)} = 2(1 + k_5/k_4)R_{Hx} + 2(1 + k_7/k_6)R_{MP} + 2(1 + k_9/k_8)R_{DMB}$$
$$= 2(k_4 + k_5)\,[n\text{-Pr}]^2 + 2(k_6 + k_7)\,[n\text{-Pr}]\,[i\text{-Pr}] + 2(k_8 + k_9)\,[i\text{-Pr}]^2$$
$$= (k_1 + k_2)\,[H]\,[C_3H_8] - [H_2]\,\{k_{-2}\,[n\text{-Pr}] + k_{-1}\,[i\text{-Pr}]\}$$

Dividing [A] by [B] gives

$$\frac{R_{(n)}}{R_{(n+i)}} = \frac{k_2[H][C_3H_8] - k_{-2}[H_2][n\text{-Pr}] - [C_3H_8]\{k_3[n\text{-Pr}] - k_{-3}[i\text{-Pr}]\}}{R_{(n+i)}}$$
$$= \frac{k_2[H][C_3H_8]}{(k_1 + k_2)[H][C_3H_8] - [H_2]\{k_{-2}[n\text{-Pr}] + k_{-1}[i\text{-Pr}]\}} - \frac{k_{-2}[H_2][n\text{-Pr}]}{R_{(n+i)}} - \frac{[C_3H_8]\{k_3[n\text{-Pr}] - k_{-3}[i\text{-Pr}]\}}{R_{(n+i)}}$$
$$\equiv Q_1 - Q_2 - Q_3$$

which is eq. [10].

Effect of temperature on the Hg6($^3P_1$) photosensitized decomposition of propane

J. M. CAMPBELL, H. E. GUNNING, AND O. P. STRAUSZ
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received May 26, 1969

The relative yields of *n*-propyl and isopropyl radicals from the primary step of the Hg6($^3P_1$) photosensitization of propane have been measured as a function of temperature between 0 and 202 °C. The ratio of *n*-propyl to isopropyl yield increases with increasing temperature according to the equation

$$\log \frac{k_n}{k_i} = -0.206 \pm 0.041 - \left(\frac{1072 \pm 62}{2.303RT}\right)$$

The primary yields of the propyl radicals were determined from the measured yields of the hexane and pentane products in ethylene scavenging experiments and from the yields of the isomeric hexane products in pure propane, after making proper allowance in the kinetics for all secondary reactions.

Canadian Journal of Chemistry, 47, 3763 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

It is well established that the triplet mercury photosensitized decomposition of simple alkanes proceeds exclusively via carbon–hydrogen bond cleavage (1). With propane, both primary and secondary carbon–hydrogen bond cleavage occur. At room temperature, the ratio of the primary to secondary bond cleavage is 0.10 (1–3). This value seems to coincide with that of the relative quenching efficiency of the two different C—H bonds in the propane molecule, indicating that decomposition occurs at the site of quenching (1).

For the elucidation of the mechanism of the energy transfer reaction a knowledge of the temperature dependence of the various modes of possible decomposition of a paraffin molecule would be of primary importance. Takamuku and Back (4) in a semi-quantitative study have observed that the relative amount of quenching by propane and propane-d_2 in propane–ammonia mixtures varied with temperature. On the other hand, Yang (5) could not detect any effect of temperature on the relative quenching efficiency of propane and propane-d_2 in phosphorescence quenching measurements.

The present article describes a detailed quantitative study of the relative quenching efficiency of the two types of C—H bonds in the propane molecule. The quenching ratio can be determined from the observed yields of *n*-propyl and isopropyl radicals provided all other reactions producing propyl radicals in the system are suppressed, or alternately can be taken quantitatively into account, and the only reactions removing propyl radicals from the system are radical–radical recombination and disproportionation. The important steps in the mercury photosensitization of propane at sufficiently high pressure to make H-atom scavenging complete are as follows

[1] $Hg^* + C_3H_8 \rightarrow i\text{-Pr} + H + Hg$

[2] $\rightarrow n\text{-Pr} + H + Hg$

[3] $H + C_3H_8 \rightarrow i\text{-}C_3H_7 + H_2$

[4] $\rightarrow n\text{-}C_3H_7 + H_2$

[5] $n\text{-Pr} + C_3H_8 \rightleftarrows i\text{-Pr} + C_3H_8$

[6] $2n\text{-Pr} \rightarrow n\text{-hexane (Hx)}$

[7] $\rightarrow C_3H_6 + C_3H_8$

[8] $n\text{-Pr} + i\text{-Pr} \rightarrow \text{2-methylpentane (MP)}$

[9] $\rightarrow C_3H_6 + C_3H_8$

[10] $2i\text{-Pr} \rightarrow \text{2,3-dimethylbutane (DMB)}$

[11] $\rightarrow C_3H_6 + C_3H_8$

Arrhenius parameters for reactions [3], [4], [5], and [−5], and reliable disproportionation–recombination ratios for reactions [6] to [11] have recently become available (6–8), and therefore it is possible to derive the ratio k_2/k_1 from the observed yields of the isomeric hexane products.

Alternately it is possible to scavenge the H atoms by addition of small quantities of an olefin to the system and thereby to eliminate steps [3] and [4] from the sequence. A variation of this technique has been successfully exploited

by Holroyd and Klein (1). Using ethylene, the following sequence prevails

[12] $H + C_2H_4 \rightarrow C_2H_5$

[13] $Et + n\text{-}Pr \rightarrow n\text{-pentane (P)}$

[14] $\rightarrow C_2H_4 + C_3H_8$ or $C_2H_6 + C_3H_6$

[15] $Et + i\text{-}Pr \rightarrow$ isopentane (i-P)

[16] $\rightarrow C_2H_4 + C_3H_8$ or $C_2H_6 + C_3H_6$

[17] $2Et \rightarrow n\text{-butane (B)}$

[18] $\rightarrow C_2H_4 + C_2H_6$

From the measured yields of the pentane and hexane products one can deduce the value of k_2/k_1.

This scavenging technique employing ethylene is particularly useful in room temperature or lower temperature experiments. At elevated temperatures it becomes less practical because of the large concentrations of ethylene required to suppress reactions [3] and [4]. Both techniques were employed in the present study.

Experimental

The circulatory reaction system and photolysis lamps were described in another paper (6). The runs with added ethylene were done in a 50 mm diameter by 99 mm length cell with a total volume of 203 cc.

In the pure propane reactions, the hydrogen was measured volumetrically and analyzed by gas chromatography on a 13X molecular sieve column. Excess propane was distilled off at −139 °C and the condensable fraction, shown to be hexanes and pentanes, was analyzed on 20 ft 40% isoquinoline on Chromosorb WAW.

Results and Discussion

Experiments with added ethylene were done at two temperatures, 0 and 29 °C. In the kinetic treatment it was assumed that all the hydrogen atoms were scavenged by the ethylene, and reactions [5] and [−5] could be neglected. Under these conditions the rates of n-propyl and isopropyl radical formation can be expressed in terms of the hexane and pentane products

$$R_n = 2(1 + k_7/k_6)[\text{Hx}] + (1 + k_9/k_8)[\text{MP}] + (1 + k_{14}/k_{13})[\text{P}]$$

$$R_i = (1 + k_9/k_8)[\text{MP}] + 2(1 + k_{11}/k_{10})[\text{DMB}] + (1 + k_{16}/k_{15})[i\text{-P}]$$

and R_n/R_i is taken as equal to k_2/k_1. The disproportionation to recombination ratios were adopted from the work of Terry and Futrell (8) as $k_7/k_6 = 0.151$, $k_9/k_8 = 0.408$, $k_{11}/k_{10} = 0.69$, $k_{14}/k_{13} = 0.118$, and $k_{16}/k_{15} = 0.306$.

The results are tabulated in Table I. The fractional amount of abstraction from propane by H atom can be estimated from the relation

$$\frac{R_3 + R_4}{R_3 + R_4 + R_{12}} = \frac{1}{1 + \dfrac{k_{12}[C_2H_4]}{(k_3 + k_4)[C_3H_8]}}$$

where $(k_3 + k_4)/k_{12}$ is taken as 1.1 exp $(-4400/RT)$ (9). As seen from the table there is some abstraction occurring, but this has little effect on the deduced value of k_2/k_1. The average of the observed values at room temperature, 0.1009, is in good agreement with that reported by Chesick (3), 0.1010.

The elevated temperature runs were carried out with pure propane. The conversion was always kept small (< 0.04%) to avoid self scavenging of hydrogen atoms by the propylene product. The upper temperature was limited by the thermal decomposition of the n-propyl radical which became noticeable at 220 °C.

Steady state approximation for this system yields the following rate expression

$$[19] \quad \frac{R_{(n)}}{R_{(n+i)}} = \frac{k_2}{2(k_1 + k_2)} + \frac{k_4}{2(k_3 + k_4)} - \frac{R_{\text{DMB}}^{\frac{1}{2}}}{R_{(n+i)}}\left(0.50\frac{R_{\text{MP}}}{R_{\text{DMB}}} - \frac{1}{K_5}\right)\frac{k_5}{k_{10}^{\frac{1}{2}}}[C_3H_8]$$

where $K_5 = k_5/k_{-5} = \exp(3.6/RT - 0.51)$ (7).

To minimize the effect of uneven distribution of radicals on the last term of eq. [19] the mercury vapor pressure in the system was kept low, corresponding to the saturation pressure at 0 °C. The final term in eq. [19] can be calculated taking $k_5/k_{10}^{\frac{1}{2}}$ as $10^{2.91}\exp(-8250/RT)$ (cc mole^{-1} s^{-1})$^{\frac{1}{2}}$ (7). As a check, a series of runs was done at 202 °C and $R_{(n)}/R_{(n+i)}$ plotted against

$$R_{DMB}^{\frac{1}{2}}(0.5R_{MP}/R_{DMB} - K_5^{-1})[C_3H_8]/R_{(n+i)}$$

The slope of this line shown in Fig. 1 is -1.26×10^{-1} (cc mole^{-1} s^{-1})$^{\frac{1}{2}}$, in excellent agreement with $k_5/k_{10}^{\frac{1}{2}}$ calculated at 202 °C of -1.30×10^{-1} (cc mole^{-1} s^{-1})$^{\frac{1}{2}}$. Taking this reported value of $k_5/k_{10}^{\frac{1}{2}}$ (7) and k_4/k_3 as $1.29\exp(-2000/RT)$ (6), k_2/k_1 can be calculated at each temperature. The data are summarized in Table II. An Arrhenius plot for k_2/k_1, including the present results and all those reported earlier for the propane reaction, is shown in Fig. 2. A least-mean-square calculation of these points gives

$$\log k_2/k_1 = -0.206 \pm 0.041 \exp\left(-\frac{1072 \pm 62}{2.303RT}\right)$$

for 90% confidence limits.

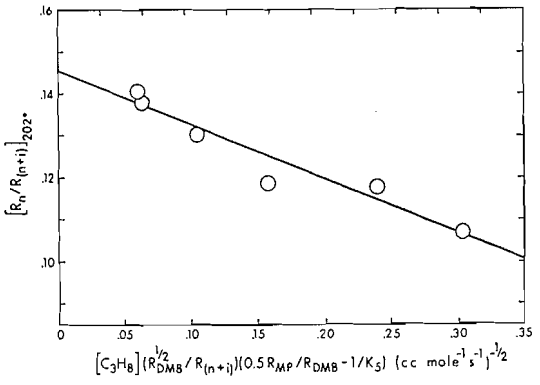

FIG. 1. Plot of $R_{(n)}/R_{(n+l)}$ against $[C_3H_8](R_{DMB}^{\frac{1}{2}}/R_{(n+i)})(0.5\ R_{MP}/R_{DMB} - 1/K_5)$ at 202 °C from Table II.

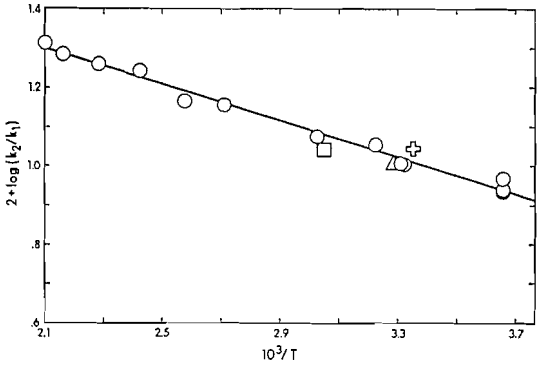

FIG. 2. Arrhenius plot of k_2/k_1: ○, this work; +, Holroyd and Klein (1); △, Chesick (3); and □, Jakubowski *et al.* (2).

This result is significant in that it is the first unambiguous experimental demonstration that the energy transfer reaction from an excited mercury atom to a paraffin molecule possesses an energy barrier. This underlies the analogy between quenching and hydrogen abstraction from paraffins by atoms and radicals. Considering the quenching process as a hydrogen abstraction reaction by an excited mercury atom

$$RH + Hg^* \rightarrow R + HHg$$

a difference in the potential energy of activation, $E_2 - E_1$, of about 1.26 kcal has been calculated recently (10) by the bond-energy–bond-order

method, which is in satisfactory agreement with the experimental value obtained in this work.

Determination of the dipole moments of some polar liquids dissolved in polar solvents

H. A. Rizk, N. Youssef, and H. Grace
Department of Chemistry, Faculty of Science, University of Cairo, Cairo, Egypt, United Arab Republic

Received March 11, 1969

The application of a modified form of the Onsager equation at the condition of infinite dilution of a polar solute in a polar solvent leads to reasonable dipole moments for water, pyridine, acetone, tert-butyl alcohol, *n*-butyl alcohol, and β-octyl alcohol, except in the case of water in tert-butyl alcohol at 30 and 40 °C and the case of acetone in *n*-butyl alcohol at 30 to 50 °C. The initial decrease of the dielectric constant of solvent by addition of solute in each of these two cases is associated with a reduction in the Kirkwood *g*-factor of solute. In all 12 systems investigated, strong hydrogen bonding occurs between solute and solvent molecules and often between solvent molecules themselves. It is thought that this equation must fail when short-range interactions assume predominant importance, but why it works so well for those cases which are also strongly interacting systems is not clear.

In the course of testing the validity of the method suggested in a previous investigation (1) for the determination of the apparent solution moment of a polar solute dissolved in a polar solvent by the use of a modified form of Onsager's equation, a redetermination of the dipole moments of water, pyridine, acetone, tert-butyl alcohol, *n*-butyl alcohol, and β-octyl alcohol, over the temperature range 30 to 50 °C, seemed worthwhile. Thus in the case of water, the polar solvents chosen were pyridine, acetone, and tert-butyl alcohol, and conversely, in the case of each of the latter three compounds, water was used as the solvent. Each of the liquids *n*-butyl alcohol, β-octyl alcohol, and acetone, was used in turn as solute in, and solvent of, the other two liquids.

Experimental and Results

Bidistilled water was purified by the method of Thiessen and Hermann (2). Pyridine, acetone, tert-butyl alcohol, *n*-butyl alcohol, and β-octyl alcohol were purified according to recommended procedures (3). Measurements were made as previously described (4). Calculations of the apparent solution moments with regard to the condition of infinite dilution, within the temperature range 30 to 50 °C, were made using the following equation, which was derived from Onsager's equation (5) as shown in the previous investigation (1)

$$\mu_2^2 = F\frac{d\varepsilon_{12}}{dC_2}\cdot\frac{1}{A_2} + \frac{(A_1\mu_1^2C_1^0V_2 + B_1C_1^0V_2 - B_2)}{A_2}$$

Here C_2 = the number of gram-molecules of solute per liter of solution,

C_1^0 = the molar concentration of pure solvent,

V_2 = the molar volume (in liters) of pure solute, and

$$A_1 = \frac{4\pi N_a}{9000kT}\cdot\frac{(n_1^2+2)^2\,\varepsilon_{12}(2\varepsilon_{12}+1)}{(2\varepsilon_{12}+n_1^2)^2}$$

$$A_2 = \frac{4\pi N_a}{9000kT}\cdot\frac{(n_2^2+2)^2\,\varepsilon_{12}(2\varepsilon_{12}+1)}{(2\varepsilon_{12}+n_2^2)}$$

$$B_1 = 3V_1\frac{\varepsilon_{12}(n_1^2-1)}{(2\varepsilon_{12}+n_1^2)}$$

$$B_2 = 3V_2\frac{\varepsilon_{12}(n_2^2-1)}{(2\varepsilon_{12}+n_2^2)}$$

$$F = 1 - C_2\mu_2^2A_2\frac{n_2^2+4\varepsilon_{12}n_2^2-2\varepsilon_{12}}{\varepsilon_{12}(2\varepsilon_{12}+1)(2\varepsilon_{12}+n_2^2)} - C_1\mu_1^2A_1\frac{n_1^2+4\varepsilon_{12}n_1^2-2\varepsilon_{12}}{\varepsilon_{12}(2\varepsilon_{12}+1)(2\varepsilon_{12}+n_1^2)} - C_2B_2\frac{n_2^2}{\varepsilon_{12}(2\varepsilon_{12}+n_2^2)} - C_1B_1\frac{n_1^2}{\varepsilon_{12}(2\varepsilon_{12}+n_1^2)}$$

The results obtained for the 12 combinations made are summarized in Table I; for ease of comparison, the solution moment values obtained in this way, together with those obtained by previous authors with the aid of usual methods, are given in Table II.

Discussion

It can be seen from Table II that in all cases, except in the case of water dissolved in tert-butyl alcohol at 30 and 40 °C, and also in the case of acetone dissolved in *n*-butyl alcohol at 30, 40, and 50 °C, there exists good agreement between the apparent solution moments obtained by applying the modified form of the Onsager equation at the condition of infinite dilution and those obtained with the aid of the usual Debye equation. Also, the dipole moments obtained this way are in better agreement with the corresponding vapor moments than with the solution values obtained in the usual way.

Surely hydrogen-bonded complexes between solute and solvent molecules and often between solvent molecules exist in all 12 combinations investigated. Since the applicability of the equation to polar solutes in polar solvents appears to be satisfactory in some of these combinations but not in others, one cannot predict a priori the validity of this equation for a given pair of polar substances. It is evidently difficult to understand why water in tert-butyl alcohol at 30 to 40 °C and acetone in *n*-butyl alcohol at 30 to 50 °C give negative dipole moments while correct dipole

moments are obtained when the roles of solute and solvent are interchanged, though complex formation is present in both situations. Curiously also, when the temperature is raised to 50 °C for water in tert-butyl alcohol and when β-octyl alcohol is used instead of *n*-butyl alcohol as a solvent for acetone, correct dipole moments are obtained.

Based on the assumption that hydrogen-bonded complexes exist at all concentration ratios, the question is, therefore, how do these complexes affect the measurements as a function of the concentration ratio. The failures of our equation, which is based on Onsager's model of a spherical cavity of a homogeneous dielectric, are perhaps more easily explained than the successes.
