Synthesis of 9-β-D-arabinofuranosyl-9*H*-purine-6(1*H*)-thione-5′-phosphate[1]

JOHN PERKINS BELL

Life Sciences Research, Stanford Research Institute, Menlo Park, California 94025

Received June 10, 1968

The 5′-phosphate of 9-β-D-arabinofuranosyl-9*H*-purine-6(1*H*)-thione was obtained by selective protection of the 2′- and 3′-positions followed by phosphorylation with β-cyanoethyl phosphate.

Canadian Journal of Chemistry, **47**, 1095 (1969)

Nucleosides possessing D-arabinofuranose in place of D-ribofuranose moieties have received increasing attention (1) as antimetabolites. Of central importance in pharmacological studies of these nucleoside analogues, is the question of nucleotide formation as an activation step *in vivo*. 9-β-D-arabinofuranosyl-9*H*-purine-6(1*H*)-thione(ara-6MP, **1**) has been shown to have metabolic effects (2) which cannot be easily rationalized by its negligible conversion to a "nucleotide-like" metabolite *in vivo* (3). To resolve this problem the synthesis of the 5′-phosphate of **1** was undertaken.

The first approach utilized the direct phosphorylation of the unprotected nucleoside as successfully applied (4) to the 6-amino analogue of **1** using Tener's β-cyanoethyl phosphate(β-CEP) procedure (5). A high yield of a triphosphate of **1** was isolated; however, analyses indicated the absence of labile phosphate which suggested that the phosphorylation had occurred at the 2′-, 3′-, and 5′-positions (6).

A second, more rational approach involved the selective protection of the 2′- and 3′-hydroxyls prior to phosphorylation (7). Thus, reaction of ara-6MP (**1**) with triphenylchloromethane (trityl chloride) at room temperature gave 5′-trityl-ara-6MP (**2**) as the only product as indicated by t.l.c. (thin-layer chromatography) analysis. No evidence for tritylation of the 6-thio group was found; tritylation of 9-β-D-ribofuranosyl-9*H*-purine-6(1*H*)-thione (the ribosyl analogue of ara-6MP) occurs at both the 5′-OH and the 6-thio groups under more forcing conditions (8). One trityl group was revealed in the n.m.r. (nuclear magnetic resonance) spectrum of compound **3**, the acetylated trityl-ara-6MP. Furthermore, as an indication that tritylation occurred only at the 5′-position, the 5′-proton multiplet in the n.m.r. spectrum of **3** shifted 0.3 p.p.m. downfield in the de-tritylated intermediate **4** obtained by mild aqueous acetic acid treatment. In contrast, only minor shifts were observed for the acetate and nucleoside protons. These findings are similar to experiences in the arabinosyl cytosine series (7).

2′,3′-diacetyl-ara-6MP (**4**) underwent phosphorylation by the Tener procedure only with a large excess of reagents. This may be partly explained by the water of hydration found in **4**. The β-cyanoethyl phosphorylated intermediate **5** was not isolated but was directly treated with ammonium hydroxide which removed both the β-cyanoethyl and acetyl protecting groups. The resulting 5′-phosphate **6** was purified by standard procedures, and was found to possess the expected mobilities on paper chromatograms. Analyses revealed one "bound" phosphate group, and compound **6** was found to be a substrate for crude snake venom phosphomonoesterase, yielding only ara-6MP (**1**) under conditions favoring 5′-nucleotidase activity. Radiosulfur labeled ara-6MP phosphate was easily prepared by exchange of the thione group with rhombic sulfur-35.

Studies of the metabolic fate and effects of the labeled ara-6MP phosphate in extracts of mouse ascites tumor cells are now in progress.

Experimental

General

Paper chromatography by the descending technique was performed on Whatman 3 MM paper with the following solvent systems: solvent *a*, isopropyl alcohol – concentrated NH_4OH–H_2O (7:1:2 v/v); solvent *b*, isobutyric acid – concentrated NH_4OH–H_2O (15:1:10 v/v); solvent *c*, 95% ethanol – saturated NaB_4O_7 – 5*M* NH_4OAc – 0.25*M* EDTA (660:240:60:3); solvent *d*, 5% KH_2PO_4.

Thin-layer chromatography (t.l.c.) was performed on microscope slides coated with Silica Gel HF. Spots of tritylated derivatives were located by ultraviolet (u.v.) absorption and coloration with HCl fumes. Spots of phosphate derivatives were located on paper chromatograms with the Hanes–Isherwood spray, followed by u.v. irradiation (9). Paper chromatograms of radioactive compounds were cut into 1 × 3.5 cm strips and counted in a toluene fluor on a Nuclear-Chicago scintillation instrument.

Reagent grade pyridine was stored over KOH pellets before use. Melting points were taken on a Fisher–Johns hot stage and are uncorrected. Elemental analyses were carried out by Stanford Research Institute Analytical Services. Infrared (i.r.) spectra were recorded on a Perkin–Elmer 137 spectrometer, and ultraviolet spectra were recorded on a Gary model 11 spectrophotometer. Nuclear magnetic resonance (n.m.r.) spectra were taken on a Varian instrument at 60 Mc.p.s. with chemical shifts given in p.p.m. relative to external tetramethylsilane. Pertinent n.m.r. data are listed as chemical shift, number of protons, multiplicity (s, d, t, q, and m, indicating singlet, doublet, triplet, quartet, and multiplet, respectively), and coupling constant (*J*) in that order. Compounds were dried by storing *in vacuo* at room temperature over NaOH flakes and concentrated H_2SO_4; pyridine was removed in the same way.

9-(5′-O-Trityl-β-D-arabinofuranosyl)-9H-purine-6(1H)-thione (2)

A solution of 284 mg (1 mmole) of ara-6MP (**1**) and recrystallized (10) triphenylchloromethane (306 mg, 1.1 mmole) in 5 ml of dry pyridine was held at room temperature until t.l.c. analysis of evaporated samples (20% ethanol in chloroform) showed that ara-6MP was replaced by a single faster moving, trityl-positive component in 24 h. The pyridine was removed and the glassy residue triturated in water to remove traces of pyridine and starting material. After thorough drying, the solid was freed of triphenylcarbinol by trituration in ether to afford 413 mg of a white powder (79% yield). For analysis, a sample was recrystallized from methanol–chloroform; m.p. 192–196; i.r. λ_{max} (mull) 3.0–3.2, 6.28, 6.55, and 10.35 μ; u.v. λ_{max} (95% EtOH) 323 mμ (ε 19 500).

Anal. Calcd. for $C_{29}H_{26}N_4O_4S \cdot CH_3OH$: C, 64.50; H, 5.42; N, 10.02; S, 5.74. Found: C, 64.84; H, 5.14; N, 9.97; S, 5.29.

9-(2′,3′-Diacetyl-5′-O-trityl-β-D-arabinofuranosyl)-9H-purine-6(1H)-thione (3)

A solution of 583 mg (1.04 mmole) of crude trityl-ara-6MP (**2**) plus 1.5 ml of acetic anhydride in 8.5 ml of dry pyridine was stirred over night. Evaporation and trituration of the residue in methanol gave 262 mg (38%) of colorless **3** containing traces of triphenyl carbinol and a non-trityl containing component (possibly 2′,3′,5′-triacetytated ara-6MP) as indicated by t.l.c. in 10% ethanol in chloroform. Recrystallization was accomplished by adding $CHCl_3$ to a suspension of **3** in hot methanol until solubilization occurred; partial evaporation initiated crystallization: m.p. 258–263 (dried overnight); i.r. λ_{max} (mull) 5.70, 6.28, 6.37, 8.20, 8.33, and 10.24 μ; u.v. λ_{max} (95% EtOH) 323 mμ (ε 17 850); n.m.r. (DMSO-d_6), 1.7 (3H, s), 2.07 (3H, s), 3.44 (2H, broad s), 4.28 (1H, m), 5.53 (2H, broad m, 5 c.p.s. wide), 6.53 (1H, d, J = 4.5 c.p.s.), 7.32 (15H, broad s), 8.12 (1H, s), 8.22 (1H, s), and 13.8 (0.75 H, broad s).

Anal. Calcd. for $C_{33}H_{30}N_4O_6S \cdot 0.5\ CHCl_3$: C, 60.17; H, 4.59; N, 8.38; S, 4.78. Found: C, 59.68; H, 4.57; N, 8.47; S, 4.51.

9-(2′,3′-Diacetyl-β-D-arabinofuranosyl)-9H-purine 6(1H)-thione (4)

Pure diacetyl-trityl-ara-6MP (**3**) (450 mg, 0.673 mmole) was stirred in 200 ml of 80% aqueous acetic acid at room temperature until t.l.c. analysis (10% EtOH in $CHCl_3$) showed the disappearance of starting material and the appearance of a new, non-tritylated derivative, plus triphenyl carbinol. After 18 h, the clear solution was rotary evaporated *in vacuo* (45° bath) and further dried *in vacuo* at room temperature over night. Trituration of the crystalline residue in boiling ether gave 227 mg of colorless (**4**) (89% yield). A sample was recrystallized from methanol for analysis: m.p. 234–244 (decomp.); i.r. λ_{max} (mull) 2.92, 3.03, 5.70, 6.22, 6.35, 6.51, 8.05, 8.12, and 8.27 μ; u.v. λ_{max} (95% EtOH) 323 mμ (ε 23 100) and λ shoulder 225 mμ (ε 7650); n.m.r. (DMSO-d_6), 1.74 (3H, s), 2.06 (3H, s), 3.70 (2H, m), 4.12 (1H, m), 5.50 (2H, broad m, 7 c.p.s. wide), 6.50 (1H, d, J = 3.5 c.p.s.), 8.22 (1H, s), 8.48 (1H, s).

Anal. Calcd. for $C_{14}H_{16}N_4O_6S \cdot 0.5\ H_2O$: C, 44.56; H, 4.54; N, 14.85; S, 8.50. Found: C, 44.75; H, 4.41; N, 14.99; S, 8.09.

9-β-D-Arabinofuranosyl-9H-purine-6(1H)-thione-5′-phosphate (6)

A mixture of 286 mg (0.76 mmole) of crude 2′,3′-diacetyl-ara-6MP (**4**) and 9.1 ml of β-CEP (4.55 mmole) in pyridine (5) was dried overnight. The residue was stirred with 2.85 g (13.7 mmole) of dicyclohexylcarbodiimide in 38 ml of dry pyridine until t.l.c. analysis (10% ethanol in chloroform) showed that the starting material had disappeared (24 h). Water was added (9 ml) and stirring was continued for another hour. Water was added (20 ml) to precipitate most of the dicyclohexylurea, and after 2 h of stirring, the filtrate was rotary-evaporated under high vacuum to a yellow residue, assumed to be the intermediate **5**. To remove the acetyl and β-cyanoethyl protecting groups, the above residue was stirred in 30 ml of 9 *N* NH_4OH at 55–60° for 1 h. Dicyclohexylurea was filtered off and rotary evaporation of the filtrate carried out under high vacuum (45° bath temp) to a volume suitable for application to a 2 × 7.5 cm Dowex-50-H^+ column. Elution with deionized water until neutral (90 ml) and addition of saturated $Ba(OH)_2$ to attain pH 8 gave a precipitate of barium phosphate which was filtered off after refrigeration overnight. The volume of the filtrate was reduced to 20 ml; adding 2 volumes of ethanol at 0 °C precipitated the crude barium salt of ara-6MP-5′-phosphate (**6**) which was separated by centrifugation and washed with ethanol, acetone, and then ether: 474 mg (> 100% yield) of a white powder. Analysis for inorganic phosphate indicated 0.03% contamination on a molar basis; i.r. λ_{max} (mull) 3.1 (broad), 4.4 (weak, β-CEP), 6.26, 6.5, 8.35 (broad), 9.2 (very broad), and 10.15 (broad) μ; u.v. λ_{max} (pH 1), 324 mμ (ε 7370 assuming a molecular weight of 571.7 (11)). Chromatography in solvents *a* and *b* indicated the presence of β-CEP.

The free phosphate **6** was regenerated from its crude barium salt by absorbing 230 mg on a 1 × 10 cm Dowex-50-H^+ column and eluting at 1 ml/min with deionized water. One-millilitre fractions were collected, and those containing the β-CEP (by analysis of a replicate chromatography of β-CEP) and initial amounts of the desired phosphate **6** (by u.v. analysis) were discarded. Fractions 11 to 30 were pooled and rotary evaporated under high vacuum at 30–40 °C to afford 53 mg of yellow **6**. The analytical sample was recrystallized from water. Analysis for esterified phosphate (12) revealed 1.005 equivalents per mole of ara-6MP-phosphate·$2H_2O$; i.r. λ_{max} (mull) 3.0 (shoulder), 3.2, 6.15, 6.40, 7.95, 8.30, 8.75, 9.30, 9.70, and 10.5 μ; u.v. λ_{max} (pH 7.0) 319 mμ (ε 24 100) and 226 mμ (ε 9 800).

Anal. Calcd. for $C_{10}H_{13}N_4O_7PS \cdot 2H_2O$: C, 30.00; H, 4.28; N, 14.00; S, 8.01. Found: C, 30.23; H, 4.26; N, 13.66; S, 7.69.

Radiosulfur-labeled ara-6MP-5′-phosphate (**6**) was prepared by exchange of its thione group with rhombic sulfur-^{35}S in refluxing pyridine (13) as follows: A suspension of 52.5 mg (0.131 mmole) of **6** and 16 mg (0.5 mmole) of rhombic-^{35}S (The Radiochemical Centre, Amersham, England) in 10 ml of dry pyridine was gently refluxed for 2 h. The pyridine was removed; the residue was taken up in water, filtered to remove the insoluble ^{35}S, and the filtrate was evaporated *in vacuo* at 35°. This process was repeated two more times; 25 mg of the ^{35}S labeled ara-6MP-5′-phosphate **6** crystallized from 3 ml of water as yellow leaflets. The spectral and chromatographic characteristics were the same as those of unlabeled **6**. The specific activity was 1.5 × 10^6 cpm/μmole, and the radiochemical purity was >92%. One-fourth of the impurities was identified as ara-6MP by paper chromatographic analyses in the following solvents.

Solvent	R_f of ara-6MP	R_f of ara-6MP-5′-phosphate
a	0.37	0.05
b	0.47	0.26
c	0.51	0.09
d	0.62	0.73

Following a standard procedure (14), the labeled phosphate **6** (0.3 μmoles) was 20% dephosphorylated with 0.1 mg of crude snake venom phosphomonoesterase and 43% dephosphorylated with 0.2 mg of the enzyme after 1 h incubation at 37 °C in a pH 8.2 buffer containing magnesium chloride (15). Chromatography in solvent *c* revealed ara-6MP (**1**) as the only product.

Acknowledgments

The author wishes to thank Dr. G. A. LePage, in whose laboratory this work was carried out, for helpful discussions, and Dr. Leon Goodman for generous supplies of ara-6MP and for his critique of the manuscript.

Acetoacetyl pyrroles and their boron complexes

M. W. ROOMI[1]

Organisch-Chemisches Institut, der Technische Hochschule, München, West Germany

Received September 19, 1968

Various boron complexes of acetoacetyl pyrrole have been synthesized and their nuclear magnetic resonance and infrared spectra showed that the complexes formed are six member chelate.

Canadian Journal of Chemistry, **47**, 1099 (1969)

Complexes of boron with acetylacetone are well known (1–3). In contrast no studies on boron complexes with acetoacetyl pyrroles have been recorded. This paper describes the preparation of the boron complexes of various 2- and 3-acetoacetyl pyrroles and an investigation of their structures utilizing nuclear magnetic resonance (n.m.r.) and infrared spectroscopy in addition to the chemical degradation. The 2-acetoacetyl pyrroles can form two types of complexes. In one case the complex is formed entirely with the acetoacetyl moiety resulting in the formation of a six member chelate (4–6), while in the other the pyrrole nitrogen participates with the complex formation resulting in a five member chelate (7).

The various acetoacetyl pyrroles used in this investigation were prepared by the reaction of the parent pyrroles with ketene dimer as described by Treibs and Michl (4). The particular pyrroles were chosen to provide three structurally distinct types having functional groups as follows (*i*) a 2-acetoacetyl group and an N—H, (*ii*) a 3-acetoacetyl group and an N—H but with methyl groups at 2 and 5, (*iii*) a 2-acetoacetyl group and an N—CH_3 group.

The infrared spectra of **1–4** showed a sharp band in the 3300 cm^{-1} region and a broad strong band in the 1600–1640 cm^{-1} region characteristic of the N—H and β-diketone function respectively. The spectrum of **5** lacked the N—H absorption but showed an absorption at 1600 cm^{-1} attributed to the free carbonyl.

The n.m.r. spectrum of **1** in $CDCl_3$ showed it to be a mixture of enol **1***ii* or **1***iii* (62%) and keto-1 (38%) tautomers. Similarly **2–5** were observed to be mixtures of enol and keto in the following ratios; 68:22, 62:38, 53:47 and 60:40.

On treatment with boron trifluoride etherate in benzene or ether the acetoacetyl pyrroles **1–5** all gave boron complexes in 80–90% yield. The infrared spectrum of **1***a* has bands at 3378 cm^{-1} (N—H) and 1565 cm^{-1} (chelated carbonyl (8, 9)). It is of special importance to point out that the N—H band showed an increase in frequency and the β-diketone band showed a decrease in frequency relative to those of **1**. This increase in frequency is attributed to the absence of hydrogen bonding to the N—H group in the complex. The N—H is hydrogen bonded in the original compound. The decrease in frequency of the β-diketone is attributed to the coordination of the acetoacetyl group to boron. The decrease in frequency is a measure of the degree of coordination (9) and quite strong coordination is indicated in this case. The infrared evidence points towards a complex involving only the acetoacetyl moiety.

The infrared spectra of **2***a*–**5***a* all resemble that of **1***a* and show the same shift relative to the starting material. That of **5***a* is similar except that it of course lacks the absorption of the N—H at 3200 cm^{-1}. This indicates that they too have structures analogous to **1***a*.

The n.m.r. spectra of **1** (Fig. 1) in $CDCl_3$ exhibit signals at (δ values) 2.05, 2.3, 3.85, 5.9, 6.3, 7.0, and 9.83 p.p.m. with relative intensities of 3:3:2:1:2:1. A comparison of the spectrum with that of the pyrrole leads to the assignment of the signals at 7.0 and 6.3 to the α- and β-hydrogen of the pyrrole ring respectively. The signals at 2.05 and 2.3 are assigned to the protons of the enolic and keto methyl groups, while those at 3.85 and 5.9 are attributed to the —CH= and —CH_2 groups in the keto and enol form.

The n.m.r. spectra of **1***a* (Fig. 2) in $CDCl_3$ exhibit signals at 2.25, 6.2, 6.7, 7.25, and 9.76 p.p.m. with relative intensities of 3:1:1:2:1. A comparison of this with the spectrum of **1** leads to the assignment of the signals at 7.25 and 6.7 to the α- and β-hydrogen of the pyrrole and the signals at 6.2 and 2.25 to the —CH= and methyl protons of the acetoacetyl moiety respectively. The disappearance of the peaks

at 2.3 and 3.85 and a broadening of the signal for N—H at 9.76 p.p.m. in conjunction with the frequency shift observed in the infrared spectra clearly show that the complex has formed on the acetoacetyl moiety in the formation of a six member chelate and does not involve reaction with the nitrogen.

The n.m.r. spectra of the complexes derived from **2**–**5** similarly show only the signals attributed to the enol form of the acetoacetyl groups. This shows they all have the same type of structure as postulated for **1***a*.

Refluxing the boron complexes with aqueous sodium acetate regenerated the starting acetoacetyl pyrroles (10, 11). Similar treatment with aqueous sodium hydroxide gave both the starting acetoacetyl pyrrole and the corresponding acetyl compound, presumably due to ketonic cleavage of the regenerated starting material.

Experimental

All melting points are uncorrected. Nuclear magnetic resonance (n.m.r.) measurements were carried out in $CDCl_3$ containing tetramethylsilane as internal standard using Varian A-60 machine. Infrared spectra were obtained in Nujol on Perkin–Elmer Infracord model 137E.

*1,3-Butanedione-1(2-pyrryl) (**1**)*

This compound was prepared according to the method of Treibs and Michl (4) m.p. 85–87°. Infrared spectrum (Nujol): N—H 3268 cm^{-1}, C=O 1639 cm^{-1}.

Anal. Calcd. for $C_8H_9NO_2$: C, 63.50; H, 6.00; N, 9.27. Found: C, 63.58; H, 5.98; N, 9.23.

*Difluoro[1(2-pyrryl)-1,3-butanediono]borane (**1a**)*

A solution of **1** (75 mg) in benzene (5 ml) was treated with $BF_3{\cdot}Et_2O$ (90 mg) and stirred, the complex separated

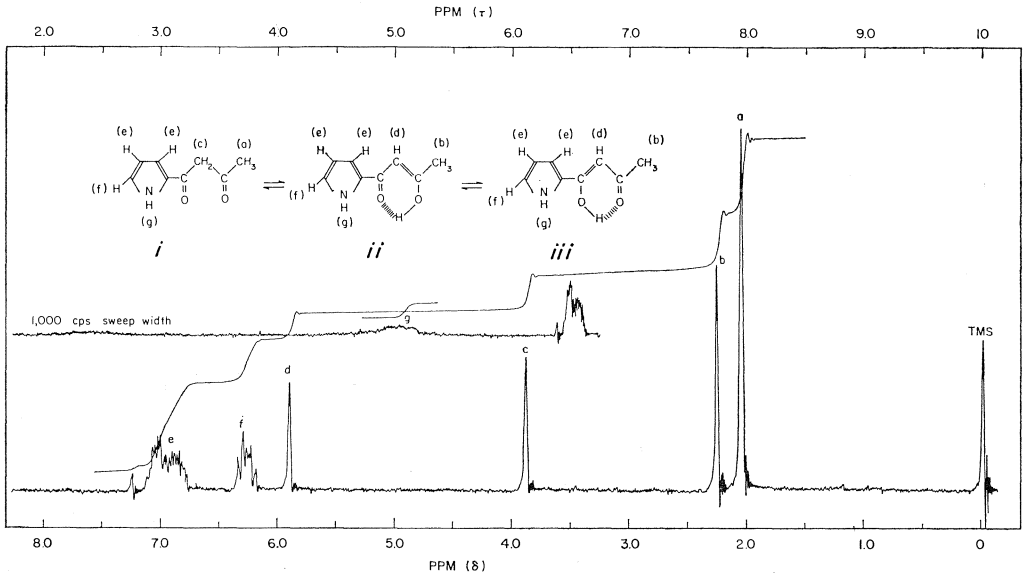

FIG. 1. The nuclear magnetic resonance spectrum of **1** (**1***i*, **1***ii*, and **1***iii*) in $CDCl_3$.

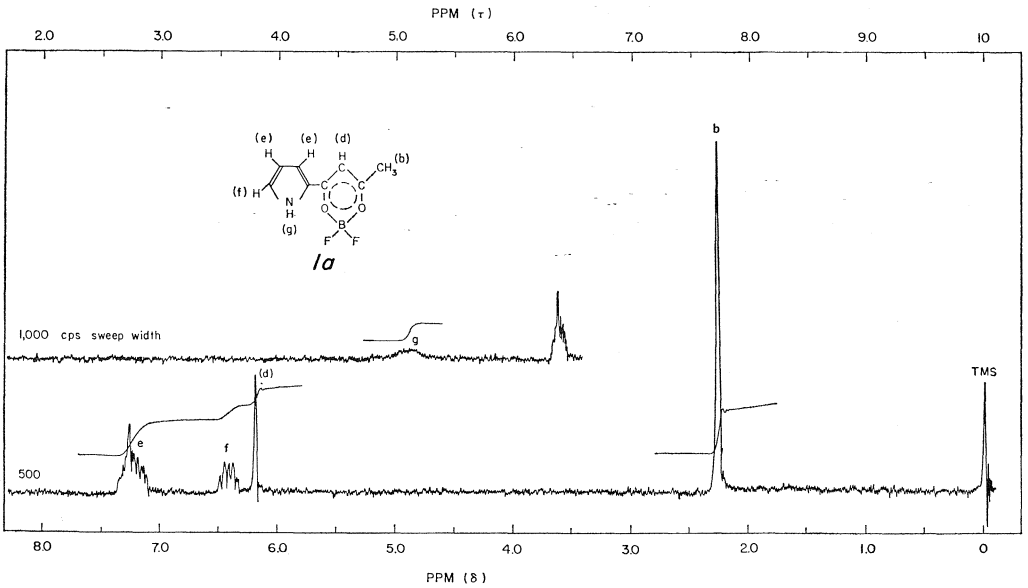

FIG. 2. The nuclear magnetic resonance spectrum of **1***a* in $CDCl_3$.

out, was filtered, washed, dried, and crystallized from benzene gave (75 mg) of the boron complex m.p. 144–146°; infrared spectrum (Nujol): N—H 3378 cm^{-1}, C=O 1565 cm^{-1}.

Anal. Calcd. for $C_8H_8NO_2BF_2$: C, 48.31; H, 4.05; N, 7.03; B, 5.44; F, 19.10. Found: C, 48.24; H, 4.12; N, 7.21; B, 5.24; F, 18.65.

1,3-Butanedione-1(2,4-dimethyl 5-pyrryl) (2)

2 was prepared by reacting 2,4-dimethyl pyrrole with diketene dimer (4) m.p. 106–108°. Infrared spectrum (Nujol): N—H 3279 cm^{-1}, C=O 1639 cm^{-1}. Nuclear magnetic resonance spectrum in $CDCl_3$ showed signals at 2.1, 2.26, 2.3, and 2.35 (singlets, 3H each, enol CH_3, keto CH_3 α- and β-CH_3) 3.9 (singlet, 2H, keto CH_2)

5.86 (broad triplet, enol H and β-H) and 9.83 p.p.m. (singlet, 1H, NH).

Anal. Calcd. for $C_{10}H_{13}NO_2$: C, 67.00; H, 7.31; N, 7.82. Found: C, 66.91; H, 7.23; N, 8.12.

*Difluoro[1(2,4-dimethyl 5-pyrryl)-1,3-butanediono]-borane (**2a**)*

A solution of **2** (1.5 g) in benzene (10 ml) was treated with $BF_3{\cdot}Et_2O$ (1.8 g) the yellow complex separated, was filtered, washed, and crystallized from alcohol (1.9 g) as yellow needles m.p. 216–218°. Infrared spectrum (Nujol): N—H 3367 cm^{-1}, C=O 1575 cm^{-1}. Nuclear magnetic resonance spectrum in pyridine ($CDCl_3$ insoluble) 2.16, 2.26, and 2.33 (singlets, 3H each, enol CH_3, α- and β-CH_3) 5.96 (doublets, β-H), and 6.16 p.p.m. (singlet, enol H).

Anal. Calcd. for $C_{10}H_{12}NO_2BF_2$: C, 52.90; H, 5.29; N, 6.17; B, 4.76; F, 16.76. Found: C, 52.81; H, 5.54; N, 6.23; B, 4.36; F, 15.75.

*1,3-Butanedione-1(2,4-dimethyl 3-ethyl 5-pyrryl) (**3**)*

2,4-Dimethyl 3-ethyl pyrrole was treated with diketene (4) to give **3** m.p. 86–88°. Infrared spectrum (Nujol): N—H 3279 cm^{-1}, C=O 1629 cm^{-1}. Nuclear magnetic resonance spectrum in $CDCl_3$ 6.2 (triplet, 3H, CH_3—CH_2) 2.8, 2.16, 2.26 (singlets, 3H each) 2.5 (quartet, 2H, CH_3—CH_2) 3.86 (singlet, 2H, keto CH_2) 5.83 (singlet, 1H, enol H) and 9.65 p.p.m. (singlet, NH).

*Difluoro[1-(1,2,4-trimethyl 5-pyrryl)-1,3-butanediono]-borane (**5a**)*

A solution of **5** (96 mg) in benzene (5 ml) was treated with $BF_3{\cdot}Et_2O$ (90 mg) and stirred, the complex separated, was filtered, washed, and crystallized from benzene (1.02) as yellow needles m.p. 135–137°. Infrared spectrum (Nujol): C=O 1580 cm^{-1}. Nuclear magnetic resonance spectrum in $CDCl_3$ 2.25, 2.28, 2.36 (singlets 3H each, enol CH_3, α- and β-CH_3) 3.83 (singlet, 3H, N—CH_3) 6.01 p.p.m. (multiplet, 2H, enol and β-H).

Anal. Calcd. for $C_{11}H_{14}NO_2BF_2$: C, 54.80; H, 5.85; N, 5.81. Found: C, 54.72; H, 5.96; N, 5.78.

*Hydrolysis of **2a***

(i) By Sodium Acetate

2*a* (20 mg) was refluxed with 10% sodium acetate (10 ml) for 10 min, allowed to cool, the solid separated, was filtered, washed, dried, and identified as **2** m.p. and mixture m.p. 108°.

(ii) By Sodium Hydroxide

2*a* (20 mg) was heated with dilute sodium hydroxide (5 ml) for 10 min. It was cooled, the colorless crystalline precipitate separated, was filtered, washed, dried and identified as 2,4-dimethyl 5-acetyl pyrrole m.p. and mixture m.p. 120°. The mother liquor was acidified with dilute acetic acid, the precipitate separated, was filtered, washed, dried, and identified as **2** m.p. and mixture m.p. 108°.

Acknowledgments

The author wishes to thank Professor Dr. A. Treibs for his keen interest during the progress of the work and Alexander von Humboldt–Stiftung for the award of the Fellowship.

Alkaloids of fumariaceous plants. LVII. Miscellaneous observations

R. H. F. MANSKE
Research Laboratories, Uniroyal Limited, Guelph, Ontario

Received November 8, 1968

The isolation of a number of new alkaloids from plants previously investigated is reported. Several known alkaloids have been encountered for the first time in plants also previously examined.

Canadian Journal of Chemistry, **47**, 1103 (1969)

A further investigation of plants already reported upon has disclosed a number of new alkaloids and a number of new sources of known alkaloids. These were recovered from new lots of plant material and from a further study of some mother liquors. Several alkaloids which had been given F-numbers have been shown to be mixtures or have been identified with known bases.

Fumaria officinalis L.

This much investigated plant has been subjected to further study in that a new lot of plant material had become available. The alkaloids already reported (1) were again obtained but the combined mother liquors gave the known scoulerine and two new alkaloids, fumariline, $C_{20}H_{17}O_5N$ and F63, $C_{20}H_{21}O_5N$ which may be identical with fumaritine isolated from *F. schleicheri* Soyer-Willem (2). A request to the senior author (P. S. Massagetov) for a specimen for direct comparison remains unanswered. The structures and properties of F37 (fumaricine), fumaritine, and fumariline have been reported (4).

Corydalis ochroleuca Koch (3)

Five alkaloids, none new but, not previously isolated, isocorydine, l-sinactine, *d*-glaucine, l-scoulerine, and adlumidine were obtained.

Corydalis tuberosa DC. (5)

In addition to the alkaloids which had been shown to be elaborated by this plant there were obtained, capnoidine, domestine, and narcotine. There were also obtained a number of fractions of alkaloids of doubtful homogeneity which are currently under study.

Corydalis pallida (Thunb.) Pers. (6)

Corydaline, cryptopine, and *dl*-stylopine were obtained.

Corydalis sibirica (L.) Pers. (7)

The alkaloid F16 proved to be not quite pure adlumidine. After another recrystallization from chloroform it melted sharply at 237° either alone or in admixture with authentic adlumidine.

Experimental

The mother liquors from previous examinations, together with fresh alkaloids from additional plant material, were reworked by the procedure (8) which has been generally satisfactory. The fractions BS and BSE refer respectively to non-phenolic and phenolic bases whose hydrochlorides are *not* extractable from aqueous solution by chloroform. The fractions BC and BCE are respectively non-phenolic and phenolic bases whose hydrochlorides are extractable from aqueous solution by chloroform. All melting points are corrected.

Fumana officinalis

The bases in the filtrate from which alkaloid F37 (fumaricine) had been crystallized were redissolved in dry chloroform and passed through a long column of ca. 250 g neutral alumina. Four eluates of approximately 200 ml each were obtained, pale-yellow, colorless, pale-orange, and colorless. The two last fractions yielded some more F37. The first two fractions were converted to hydrochlorides and yielded a salt from which the free base was regenerated. When recrystallized from methanol, fumariline (F64), obtained in stout prisms, melted at 138°.

Anal. Calcd. for $C_{20}H_{17}O_5N$: C, 68.37; H, 4.84; N, 3.99; NMe, 4.27. Found: C, 68.29; H, 4.93; N, 3.88; NMe, 4.74.

When this alkaloid was treated with carbon disulfide in concentrated ether solution, there was rapid separation of pale-yellow stout prisms which melted at 92° with gas evolution. A test for carbon disulfide was strongly positive (9) and when this compound was admixed with that melting at 138°, the mixture m.p. was 138°, when slowly heated. The infrared (i.r.) and nuclear magnetic resonance (n.m.r.) spectra of the two compounds were superimposable. The yield of this alkaloid was about 0.3 g from 110 kg of dried plant material, and the yields of scoulerine and fumaritine were about 0.1 and 0.5 g respectively.

The total phenolic base fraction from the above amount of plant material weighed only several grams. It was converted to hydrochloride in methanol and then precipitated with excess dry ether with which the pasty residue was repeatedly triturated. When in contact with acetone containing a trace of methanol it became crystalline and was recrystallized from methanol–acetone and then consisted of a mixture of two hydrochlorides.

For personal use only.

The portion very sparingly soluble in water proved to be the hydrochloride of 1-scoulerine (free base, m.p. and mixture m.p. 205°). The very soluble hydrochloride (m.p. 248°) was converted to free base and this crystallized readily from dry ether in fine colorless needles melting at 157°. Fumaritine, so obtained, gave a nondescript dirty green color with concentrated sulfuric acid.

Anal. Calcd. for $C_{20}H_{21}O_5N$: C, 67.60; H, 5.92; N, 3.94; 1 OMe, 8.73. Found: C, 67.87, 68.00; H, 5.32, 5.56; N, 3.83, 4.13; OMe, 9.00, 9.60.

When a solution of fumaritine in methanol was treated with diazomethane there was rapid evolution of nitrogen and the non-phenolic base isolated from the reaction mixture was identical with fumaricine.

Corydalis ochroleuca

The more soluble fraction from which 1-isocorypalmine had been separated was converted to hydrobromide and the base was then regenerated from the sparingly soluble salt. The free base was recrystallized from methanol–ether and then consisted of colorless plates, m.p. 184°, either alone or mixed with *d*-isocorydine.

The fraction from which the 1-tetrahydropalmatine had been separated was dissolved in dry chloroform and passed through a long column of (ca. 250 g) neutral alumina. The base from the front zone of ca. 100 ml solvent was converted to hydrobromide (m.p. 248° decomp.) and the base regenerated again. When recrystallized from methanol it melted at 175–176°. The m.p. was unchanged when admixed with a specimen of 1-sinactine.

The subsequent eluates gave a fraction which yielded a mixture of perchlorates, pale-yellow needles and stout dark polyhedra. The former, more soluble in acetone, proved to be 1-tetrahydropalmatine perchlorate. The less soluble salt was recrystallized from methanol–acetone (m.p. 233°) and the m.p. was not lowered when the salt was admixed with *d*-glaucine perchlorate. The free base, prepared from the perchlorate, was recrystallized from dry ether and then melted at 120° either alone or mixed with *d*-glaucine.

The combined mother liquors from which the protopine and ochroberine had been separated were dissolved in dilute hydrochloric acid and the bases regenerated and dissolved in dry ether. The solution was filtered through a short column of alumina and then deposited a sparingly soluble base which, when recrystallized from chloroform–methanol, melted at 237° either alone or mixed with adlumidine.

The phenolic fraction BSE in contact with methanol yielded some isocorydine. The bases in the soluble fraction were dissolved in dry chloroform and passed through a column of ca. 250 g neutral alumina. When continued percolation with chloroform removed nothing further, the column was eluted with 4% methanol in chloroform. The residue from the eluate crystallized readily when dissolved in hot methanol. It melted at 208° (*in vacuo*) and the m.p. was unchanged when mixed with 1-scoulerine.

Corydalis tuberosa

The somewhat less basic fraction (BC) from which thalictricavine had been separated was converted to perchlorate in methanol. The sparingly soluble salt which separated proved to be the perchlorate of corycavine. The base in the soluble portion was converted to l-tartrate and the sparingly soluble salt thus obtained was recrystallized first from hot methanol (sparingly soluble) and then from water–methanol. The *l*-tartrate then melted at 223° and the base regenerated from it melted at 140° when recrystallized from dry ether in which it was sparingly soluble.

Anal. Calcd. for $C_{20}H_{21}O_4N$: C, 70.80; H, 6.20; 2 OMe, 18.30. Found: C, 71.32, 71.03; H, 6.05, 5.99; OMe, 18.64, 18.39.

The tartrate analyzed satisfactorily for $C_{20}H_{21}O_4N \cdot C_4H_6O_4 \cdot 1/2$ MeOH. The methine, prepared in the usual way from the methiodide, melted at 130° (lit. (10), m.p. 133°) when recrystallized from ether. A specimen of domestine received from Professor Tatsuo Ohta (Tokyo College of Pharmacy, Shinjuku-ku, Japan) melted at 139° and a mixture of it with the above base melted at the same temperature.

The mother liquors from the crystallization of the corydaline were also divided into a number of fractions of progressively weaker bases by successive elution with hydrochloric acid from ether solution. The middle fractions were converted to nitrates in methanol and the salt, which separated and proved to consist largely of corydaline nitrate, was removed. The bases in the soluble portion were regenerated and the portion which then crystallized from ether was recrystallized from chloroform–methanol.

Anal. Calcd. for $C_{22}H_{23}O_7N$: C, 63.91; H, 5.61. Found: C, 64.20, 64.40; H, 5.82, 5.82.

Infrared and n.m.r. spectra showed the presence of a lactone carbonyl, three methoxyls, one *N*-methyl, and one methylenedioxy group. Its m.p. (176°) and the above properties suggest that this alkaloid is narcotine and a mixture m.p. confirmed its identity.

The mother liquors from the separation of the corycavine were converted to oxalates a second time in methanol. The mixture of salts thus obtained consisted largely of the sparingly soluble corycavine oxalate and a second minor component which was removed by warming with water. The base, regenerated from the soluble portion, was recrystallized from chloroform–methanol and then melted at 238°, either alone or mixed with capnoidine. When some of this and an equal weight of adlumidine were recrystallized from chloroform–methanol there was formed *dl*-capnoidine which melted at 206°, either alone or mixed with an authentic specimen.

Corydalis pallida

The mother liquors from which *d*-tetrahydropalmatine had crystallized were converted to hydrochloride and another crop separated. The soluble portion was converted to free base and its solution in ether was dried over potassium hydroxide. Removal of the ether and contact of the residue with methanol yielded a crop of *d*-corydaline which, alone or mixed with an authentic specimen, melted at 135°.

The filtrate from the corydaline was converted to acid oxalate in methanol–acetone. The sparingly soluble salt which slowly separated was washed with acetone and the base regenerated from it crystallized in contact with methanol and proved to be cryptopine (m.p. and mixture m.p., 223°).

The oxalates which remained in solution from the above

experiment were reconverted to the free base mixture. A methanol solution of these yielded a mixture of crystalline bases. The portion sparingly soluble in warm methanol was recrystallized from chloroform–methanol and the resultant *dl*-stylopine (m.p. 220°) was identified by a mixture m.p. determination.

Synthesis of exaltone and *dl*-muscone based on 1,5,9-cyclododecatriene

H. NOZAKI, H. YAMAMOTO, AND T. MORI
Department of Industrial Chemistry, Kyôto University, Kyôto, Japan

Received August 13, 1968

Bicyclo[9·4·1]hexadecan-16-one is prepared from cyclododecanone *via* four steps: ethoxycarbonylation, condensation with 1,4-dibromobutane, saponification, and decarboxylation. Photolysis of the bicyclic ketone yields a ketene which is trapped with methanol to afford methyl cyclopentadecanecarboxylate or alternatively oxidized to exaltone directly. The ester is also converted into exaltone *via* five steps. *dl*-Muscone is prepared by applying the same scheme to cyclotridecanone with 14-methylbicyclo-[10·3·1]hexadecan-16-one as the key intermediate.

Canadian Journal of Chemistry, 47, 1107 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Owing to Wilke's discovery of butadiene-cyclotrimerization, 1,5,9-cyclododecatriene and cyclododecanone (**1**) have become readily accessible. Ohloff, Eschenmoser and others (1, 2) have recently published elegant syntheses of exaltone (cyclopentadecanone) (**12**) and *dl*-muscone (3-methylcyclopentadecanone) (**25**) starting from these 12-membered cyclic compounds. We wish to describe a different route which involves the key intermediates, **4** and **18**, both containing a 15-membered ring bridged by a carbonyl group. Photolysis of **4** and **18** has been shown to afford cyclopentadecanecarboxylates **7** and **20**, which are converted to **12** and **25** in 44 and 19% overall yields based on **4** and **18**, respectively.[1] A similar photolysis of bicyclo[5·2·1]decan-10-one was previously recorded by Gutsche *et al.* (4).

Ethoxycarbonylation of **1** (5) gave **2** which was treated with sodium hydride and 1,4-dibromobutane in toluene to afford the cyclized ketoester **3**. Heating of **3** with sulfuric acid in glacial acetic acid furnished the desired bicycloketone **4** as a sharp melting solid in 72% overall yield based on **2**. Attempted condensation of **1** with 1,4-dibromobutane yielded an approximately 1:1 mixture of **4** and a spiro isomer **5**.[2]

The ketone **4** proved homogeneous upon attempted thin-layer chromatographic (t.l.c.) and gas–liquid chromatographic (g.l.c.) separation and, therefore, is assumed to be the thermodynamically more stable isomer of the possible *cis* and *trans* isomers. The stereochemistry has not been determined yet. Any carbonyl derivatives of **4** could not be obtained and this was ascribed to the steric hindrance around the carbonyl group, as inspection of Dreiding models indicated that the preferred conformation should be the one with the carbonyl group almost buried in the nonamethylene group for either the *cis* or *trans* isomer. The observed inertness of **4** towards ring cleavage by oxidizing agents can be explained in the same way.

The n,π^*-excitation of the hindered ketone **4** was found to cause the ring-cleavage in the desired way. Irradiation of a 3% methanolic solution of **4** was carried out by means of a 200 W high pressure mercury arc with a Pyrex filter for 20–30 h. The volatile product (80% recovery by weight) consisted of a C_{15}-hydrocarbon fraction (32%) and methyl cyclopentadecanecarboxylate (**7**) (68%) by g.l.c. analysis. The hydrocarbon fraction was not investigated in detail.

Irradiation of **4** was examined in several solvents, and the use of halogenated ones such as methylene bromide or carbon tetrachloride was found to decrease the amount of hydrocarbon byproducts remarkably. Thus, irradiation of a 2% solution of **4** in a mixture of methanol and carbon tetrachloride (1:6 by volume) gave **7** as the only distillable product in 73% yield.

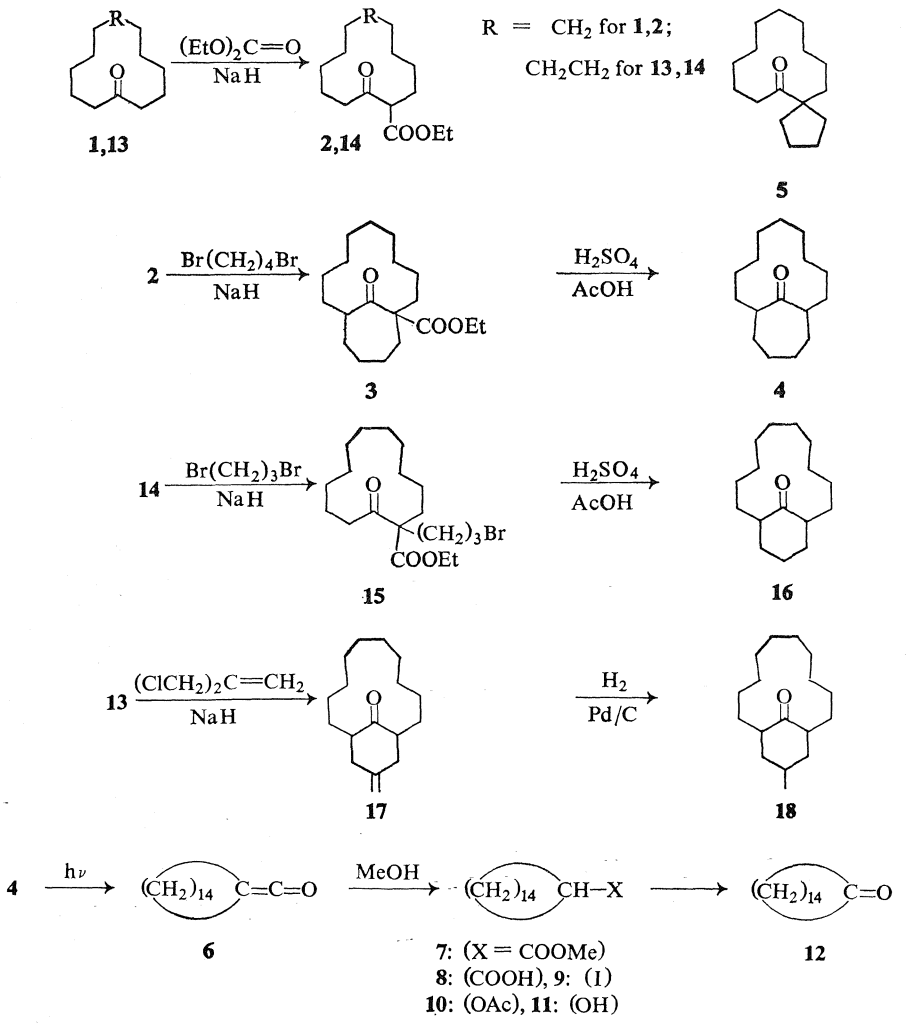
In support of Gutsche's mechanism (4) on this kind of photolytic ring cleavage, irradiation of **4** in cyclohexane gave a solution, whose infrared spectrum (i.r.) showed absorption at 2140 cm^{-1} characteristic of the ketene **6**.[3]

Oxidation of this ketene with oxygen should

[1]The exaltone synthesis has appeared in a preliminary form (3).

[2]Opitz and Mildenberger obtained bicyclic ketones homologous to **4** from the reactions of dihalides with enamines of 5, 6, and 7 membered cyclic ketones (6). We thank one of the referees for this suggestion.

[3]Chapman and Lassila (7) claim the first identification of a ketene intermediate in the type I cleavage of ketone photolysis. See, however, refs. 3 and 4.



furnish exaltone (**12**) directly. Irradiation of a 3% solution of **4** in cyclohexane while bubbling oxygen through the solution afforded **12** in 20–30% yields, but hydrocarbon by-products and polymeric substances were produced together with **12** and separation gave rise to some difficulties. In contrast, the isolated ester **7** gave better yields of **12** by successive treatments mentioned below.

Hydrolysis of **7** followed by decarboxylation according to Barton's procedure (8) gave a mixture of iodocyclopentadecane (**9**) and its acetolysis product **10**. The acetolysis was completed by the action of mercuric acetate in acetic acid, and the resulting acetate **10** was hydrolyzed to cyclopentadecanol (**11**). Oxidation of **11** by Brown's method (9) gave exaltone (**12**) in 61% overall yield based on **7**.

Theoretically *dl*-muscone (**25**) should be obtained by using methyl-substituted **4** as an intermediate. In order to minimize the possibility of obtaining methylcyclopentadecanone having the methyl group at unsuitable positions, it seemed more appropriate to go through **18**. First we prepared the bicycloketone **16** to examine its photochemistry as a model experiment.

Cyclotridecanone (**13**) has been prepared from 1,5,9-cyclododecatriene by several methods (10). Attempted condensation of the ethoxycarbonylated ketone **14** with 1,3-dibromopropane in the presence of 2 mole equivalents of sodium

19 **20**: (X = COOMe) **25**
21: (COOH), **22**: (I)
23: (OAc), **24**: (OH)

hydride failed to afford the desired cyclization product due to side reactions. Condensation in the presence of one mole equivalent of sodium hydride gave the 3-bromopropyl-substituted ketoester **15**, which was not isolated. Treatment of the crude **15** with sulfuric acid was found to effect the cyclization as well as the elimination of the ethoxycarbonyl group simultaneously. The bicycloketone **16** was isolated as a sharp melting solid in a 31% overall yield based on **14** and proved to be homogeneous upon t.l.c. and g.l.c. analyses. This bicycloketone is also assumed to be the thermodynamically more stable isomer. In contrast to **4**, the isomer **16** gave an oxime. Irradiation of **16** in methanolic solution furnished methyl cyclopentadecanecarboxylate (**7**) in a 55% yield.

Attempted synthesis of **18** by means of the reaction of **14** with 1,3-dibromo-2-methylpropane failed, as this halide proved to be inert under the usual conditions for the condensation, possibly due to the steric hindrance of the methyl group (11). Direct condensation of cyclotridecanone (**13**) with 3-chloro-2-chloromethylpropene proceeded smoothly to afford the cyclized product **17** in a 57% yield. Catalytic hydrogenation of **17** gave quantitatively the desired ketone **18**. Both ketones **17** and **18** gave one peak upon g.l.c., but two spots (ca. 1:1) on t.l.c. analysis. The stereochemistry is open to research in the future.

Photolysis of **18** in methanol gave methyl 3-methylcyclopentadecanecarboxylate (**20**) in a 33% yield. This was transformed into *dl*-muscone in a 58% overall yield based on **20** by means of a similar sequence of reactions as used in the exaltone synthesis. The stereochemistry of compounds **20**–**24** has not been determined.

Experimental

All temperatures are uncorrected. Nuclear magnetic resonance (n.m.r.) spectra were obtained on JOEL C-60-H spectrometer in CCl_4 solutions with tetramethylsilane as reference. Chemical shifts are given in p.p.m. from this reference together with the multiplicity of signals indicated in an abbreviated form: s for singlet, d for doublet, t for triplet, and m for multiplet, respectively. Gas–liquid chromatography analyses were performed on a 2 m column of SE 30 on Chromsorb W (10%) with helium as a carrier gas at 160–180°. Thin-layer chromatography analyses were conducted on Silica-gel G with *n*-hexane and ethyl acetate (10:1) as a developing solvent.

Bicyclo[9·4·1]hexadecan-16-one (4)

To a suspension of sodium hydride (7.2 g, 0.3 mole) in anhydrous xylene mixture (30 ml) was slowly added a solution of 2-carbethoxycyclododecanone (**2**) (5) (38.1 g, 0.15 mole) in xylenes (80 ml) with stirring at room temperature under nitrogen atmosphere. After evolution of hydrogen was complete, 1,4-dibromobutane (32.4 g, 0.15 mole) was added in one portion. On heating the mixture at 80–90° another mole equivalent of hydrogen evolved. Heating and stirring were continued until hydrogen evolution had subsided (15 h). After cooling, the mixture was treated with water and extracted with ether. The organic layer was washed with water, dried (Na_2SO_4), and concentrated *in vacuo* to give crude **3** (48.3 g) as a yellow viscous oil. Alkaline hydrolysis of this oily ketoester and subsequent recrystallization from benzene–hexane gave bicyclo[9·4·1]hexadecan-16-one-1-carboxylic acid as colorless crystals, m.p. 141–142° (decomp.). Infrared (Nujol): 3600–2400, 1720–1690 cm^{-1} (C=O, COOH).

Anal. Calcd. for $C_{17}H_{28}O_3$: C, 72.8; H, 10.1. Found: C, 72.3; H, 10.2.

The crude **3** (48.3 g) was dissolved in a mixture of acetic acid (300 ml), water (120 ml), and concentrated sulfuric acid (80 ml), and the solution was heated at reflux for 10 h. After cooling and treatment with water, the mixture was extracted with *n*-hexane. The extracts were combined, washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. Vacuum distillation of the resulting semisolid gave **4** (25.4 g: 72% based on **2**) as a colorless solid, b.p. 110–115°/0.1 mm, m.p. 80–84°. Recrystallization from methanol afforded an analytical sample melting at 86–87°. Infrared (Nujol): 1700 cm^{-1} (C=O). Nuclear magnetic resonance: δ 3.2–2.6 m (2H), 2.3–0.9 m (a peak at 1.25) (26H).

Anal. Calcd. for $C_{16}H_{28}O$: C, 81.3; H, 11.9. Found: C, 81.4; H, 12.2.

In another procedure, a mixture of sodium hydride (4.8 g: 0.2 mole), cyclododecanone (**1**) (18.2 g: 0.1 mole), 1,4-dibromobutane (21.6 g: 0.1 mole), and anhydrous xylenes (50 ml) was stirred at 80–90° under nitrogen

For personal use only.

atmosphere for 40 h, when hydrogen evolution was complete. After cooling and treatment with water, the mixture was extracted with *n*-hexane. The extracts were combined, washed with water, dried (Na_2SO_4), and concentrated. Distillation of the resulting oil gave a colorless oil (10.3 g), b.p. 110–120°/0.15 mm, which solidified on standing, m.p. 40–70°. Fractional recrystallization from methanol gave two crystalline materials, **4** (3.1 g: 13%) melting at 86–87° and a spiroketone **5** (4.5 g: 19%) melting at 50–52°. The structure of **5** was based on the following data. Infrared (Nujol): 1710 cm^{-1} (C=O). Nuclear magnetic resonance: δ 2.5 diffused *t* (2H), 2.3–1.0 m (a peak at 1.25) (26 H).

Anal. Calcd. for $C_{16}H_{28}O$: C, 81.3; H, 11.9. Found: C, 81.1; H, 12.1.

Photolysis of Bicyclo[9·4·1]hexadecan-16-one (4)

A solution of **4** (8.3 g: 0.035 mole) in methanol (280 ml) was well degassed and subjected to irradiation with an immersion type 200 W high pressure mercury arc sealed in a cooling water mantle made of Pyrex glass. The photo-reaction was monitored by means of i.r., and the irradiation was interrupted when the 1700 cm^{-1} band characteristics to the starting bicyclic ketone had disappeared (20–30 h). Evaporation of the solvent followed by vacuum distillation gave a colorless oil (6.6 g), b.p. 70–130°/0.1 mm. Gas–liquid chromatography analysis indicated that this oil consisted of a 32:68 mixture of C_{15}-hydrocarbons and methyl cyclopentadecanecarboxylate (**7**). The mixture was subjected to alkaline hydrolysis, and free carboxylic acid **8** was separated (4.2 g: 47% yield based on **4**), m.p. 65–66° (from ethanol) (reported (12) m.p. 52–54°). Infrared (Nujol): 3300–2400, 1710–1690 cm^{-1} (COOH). The *p*-phenylphenacyl ester of **8** was obtained by the usual method, m.p. 101.5–102° (from ethanol).

Anal. Calcd. for $C_{30}H_{40}O_3$: C, 80.3; H, 9.0. Found: C, 80.3; H, 9.1.

The hydrocarbon mixture, b.p. 70–80°/0.3 mm, consisted of at least three components (g.l.c.) and absorbed about 0.3 mole equivalent of hydrogen on catalytic hydrogenation.

Anal. Calcd. for $C_{15}H_{28}$: C, 86.5; H, 13.5. Found: C, 86.9; H, 13.4.

In another procedure, a solution of the bicyclic ketone **4** (4.7 g: 0.02 mole) in methanol (30 ml) and carbon tetrachloride (180 ml) was similarly photolyzed. Evaporation of the solvent followed by vacuum distillation gave methyl cyclopentadecanecarboxylate (**7**) as a colorless oil (3.9 g: 73%), b.p. 117–120°/0.1 mm, which proved to be homogeneous on g.l.c. and t.l.c. Infrared (neat): 1750, 1195, 1160 cm^{-1} ($COOCH_3$). Nuclear magnetic resonance: δ 3.60 s (3H), 2.5–2.1 m (1H), 1.35 s (28H).

Anal. Calcd. for $C_{17}H_{32}O_2$: C, 76.1; H, 12.0. Found: C, 76.5; H, 11.9.

Direct conversion of **4** to **12** was attained as follows: into a solution of **4** (2 g) in cyclohexane (70 ml) placed in a Pyrex tube, oxygen gas was bubbled through a narrow inlet tube at a rate of 60–70 ml/min at room temperature under external irradiation with a 200 W high pressure mercury arc for 30 h. Distillation of the mixture gave a colorless oil (1.0–1.3 g), b.p. 100–130°/0.3 mm, which was a mixture of several components (g.l.c.). Purification by preparative g.l.c. yielded cyclopentadecanone (**12**) as a colorless solid, m.p. and mixed m.p. 61–62° (reported (13) m.p. 63°), semicarbazone, m.p. and mixed m.p. 187–188° (from ethanol) (reported (13) m.p. 188°). Infrared of **12** was completely superimposable with that of authentic exaltone. The yields ranged from 20 to 30% (determined from the peak area of g.l.c.).

The intermediacy of a ketene in this photolysis was shown as follows. A solution of **4** (1 g) in cyclohexane (70 ml) was irradiated for 20 h with a high pressure mercury arc through a Pyrex filter. The i.r. of the cyclohexane solution showed an absorption band at 2140 cm^{-1}. Attempted isolation of the ketene failed.

Cyclopentadecyl Acetate (10)

A mixture of cyclopentadecanecarboxylic acid (**8**) (5.1 g: 0.02 mole) and mercuric acetate (25.4 g: 0.08 mole) in benzene (200 ml) was heated at reflux with stirring in a nitrogen atmosphere while being irradiated by a 500 W tungsten lamp for 30 min. To this mixture under the same condition was added dropwise a saturated solution of iodine in benzene until the color-discharge was no longer observed (1.5 h). After cooling, the inorganic substances were removed by filtration. The filtrate was washed with aqueous sodium thiosulfate solution and then with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residual oil (5.5 g) gave two spots on t.l.c. and strong i.r. bands at 1750 and 1250 cm^{-1}. This crude oil was dissolved in acetic acid (100 ml), and the solution was heated on a steam bath with mercuric acetate (10 g) for 3 h. After treatment with water, the mixture was extracted with benzene. The extracts were combined, washed with water, dried (Na_2SO_4), and concentrated to about 10 ml. The concentrated solution was passed through a short alumina column and distilled *in vacuo* to give **10** (4.0 g: 74%) as a colorless oil, b.p. 105–108°/0.06 mm. Infrared (neat): 1750, 1250 cm^{-1} (OAc). Nuclear magnetic resonance: δ 5.0–4.5 m (1H), 1.89 s (3H), 1.35 s (28H).

Anal. Calcd. for $C_{17}H_{32}O_2$: C, 76.1; H, 12.0. Found: C, 76.1; H, 12.1.

Cyclopentadecanol (11)

Alkaline hydrolysis of the acetate **10** (2.5 g) in the usual manner afforded cyclopentadecanol (**11**) (2.0 g: 95%) as a colorless solid, m.p. 74–76° (from *n*-hexane) (reported (14) m.p. 81°). The i.r. of **11** was superimposable on that of an authentic sample prepared from exaltone by lithium aluminium hydride reduction. The phenylurethane of **11** was prepared in the usual way and recrystallized from methanol, m.p. and mixed m.p. 102–103° (reported (14) m.p. 104°).

Cyclopentadecanone (12)

To a solution of **11** (1.1 g: 5 mmoles) in ether (20 ml) was added a mixture of sodium dichromate dihydrate (1.0 g: 3.4 mmoles), water (10 ml), and concentrated sulfuric acid (0.8 ml) in the course of 0.5 h under stirring at room temperature. Stirring was continued for an additional 3 h. The ethereal layer was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. Distillation gave **12** as a colorless solid (1.0 g: 91%), b.p. 101–103°/0.2 mm, m.p. 57–60°. Recrystallization from methanol gave an analytically pure sample, m.p. and mixed m.p. 61–62°, semicarbazone, m.p. and mixed m.p. 187–188°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Comparison of i.r. of **12** with that of the authentic exaltone also confirmed the identity.

*2-Carbethoxycyclotridecanone (**14**)*

To a mixture of sodium hydride (4.8 g: 0.2 mole) and diethyl carbonate (150 ml) was added a solution of cyclotridecanone (**13**) (19.6 g: 0.1 mole) in diethyl carbonate (30 ml) in the course of 2 h with stirring under nitrogen atmosphere. Stirring was continued at room temperature until hydrogen evolution had ceased (15 h). After treatment with water and acidification with dilute hydrochloric acid, the mixture was extracted with ether. The organic layer was washed with water, dried (Na_2SO_4), and concentrated. Distillation of the residue gave **14** (25.1 g: 94%) as a colorless solid, b.p. 130–135°/0.15 mm, m.p. 63–66°. Recrystallization from methanol afforded colorless needles melting at 66–67°. Infrared (Nujol): 1750, 1195 (COOR), 1708 cm^{-1} (C=O).

Anal. Calcd. for $C_{16}H_{28}O_3$: C, 71.6; H, 10.5. Found: C, 71.5; H, 10.6.

*Bicyclo[10·3·1]hexadecan-16-one (**16**)*

Condensation of **14** with 1,3-dibromopropane attempted similarly as mentioned for the preparation of **4** gave an intractable oily mixture instead of the desired cyclization product. The following procedure was found to give the best results. A mixture of **14** (20.8 g: 0.0776 mole), sodium hydride (1.87 g: 0.078 mole), and xylenes (35 ml) was stirred until hydrogen evolution was complete, and then 1,3-dibromopropane (47 g: 0.23 mole) was added in one portion. The whole mixture was stirred at 80–90° for 30 h. Treatment with water and extraction with ether followed by concentration of the extracts gave a yellow oil, which was dissolved in a mixture of acetic acid (160 ml), water (80 ml), and concentrated sulfuric acid (80 ml). This solution was heated to reflux for 5 h. After cooling, the mixture was diluted with water and extracted with *n*-hexane. The organic layer was washed, dried (Na_2SO_4), and distilled to give **16** (5.7 g: 31%) as a colorless solid, b.p. 122–126°/0.2 mm, m.p. 49–53°. Thin-layer chromatography and g.l.c. indicated the homogeneity of **16**. Recrystallization from methanol gave an analytically pure sample melting at 54–55°. Infrared (Nujol): 1710 cm^{-1} (C=O). Nuclear magnetic resonance: all protons appeared at δ 3.0–1.0 with poor resolution (a peak at 1.28).

Anal. Calcd. for $C_{16}H_{28}O$: C, 81.3; H, 11.9. Found: C, 81.1; H, 12.2.

The oxime of **16** was obtained in the usual manner, m.p. 143–144° (from ethanol). Infrared (Nujol): 3300 cm^{-1} (OH).

Anal. Calcd. for $C_{16}H_{29}NO$: C, 76.4; H, 11.6; N, 5.6. Found: C, 75.7; H, 11.5; N, 5.5.

The unsatisfactory analysis of carbon might possibly be ascribed to the presence of some impurity, but further purification was impossible due to the lack of material.

*Photolysis of Bicyclo[10·3·1]hexadecan-16-one (**16**)*

A solution of **16** (2.4 g) in methanol (200 ml) was photolyzed as described for the photolysis of **4** while monitoring by g.l.c. The crude reaction mixture was immediately hydrolyzed with ethanolic potassium hydroxide, and the acidic fraction was secured in the usual manner. Reesterification of the latter with diazomethane followed by vacuum distillation gave methyl cyclopentadecanecarboxylate (**7**) (1.5 g: 55%), which was identical with the specimen obtained from **4** upon comparison of i.r., retention time on g.l.c., and m.p. of *p*-phenylphenacyl ester of the free acid (**8**).

*14-Methylenebicyclo[10·3·1]hexadecan-16-one (**17**)*

A mixture of cyclotridecanone (**13**) (19.6 g: 0.1 mole), sodium hydride (4.8 g: 0.2 mole), 3-chloro-2-chloromethylpropene (15) (12.5 g: 0.1 mole), and toluene (30 ml) was stirred at 90–100° after nitrogen flushing, until hydrogen evolution was complete (60 h). The reaction mixture was treated with water and extracted with *n*-hexane. The extracts were combined, washed with water, dried (Na_2SO_4), and concentrated. On vacuum distillation of the residue, cyclotridecanone (**13**) (3.9 g) boiling at 80–100°/0.3 mm was recovered, and **17** (11.3 g: 57% based on consumed **13**) was obtained as a colorless solid, b.p. 115–120°/0.3 mm, m.p. 57–62° which showed a single peak on g.l.c. Recrystallization from ethanol gave a sample melting at 63–66.5°, but further recrystallizations failed to give a sharper melting point. Thin-layer chromatography of recrystallized **17** gave two equal spots. Infrared (Nujol): 3090, 1650, 895 (=CH_2), 1710 cm^{-1} (C=O). Nuclear magnetic resonance: δ 4.79 s (2H), 2.8–1.9 m (6H), 1.6–0.8 m (a peak at 1.25) (20 H).

Anal. Calcd. for $C_{17}H_{28}O$: C, 82.2; H, 11.4. Found: C, 81.9; H, 11.7.

*14-Methylbicyclo[10·3·1]hexadecan-16-one (**18**)*

A solution of the unsaturated ketone **17** (11 g) in ethanol (100 ml) was stirred under an atmospheric pressure of hydrogen in the presence of palladium-on-carbon (10%) (0.5 g). It took 23 h for completion of hydrogen absorption. The catalyst was removed by filtration, and the filtrate was distilled *in vacuo* to give **18** (10.8 g: 98%) as a colorless solid, b.p. 135–137°/0.4 mm, m.p. 49–53°. Recrystallization was not attempted. Infrared (Nujol): 1710 cm^{-1} (C=O). Nuclear magnetic resonance: all protons appeared at δ 3.0–0.8 with poor resolution (peaks at 1.30, 0.98, 0.88).

Anal. Calcd. for $C_{17}H_{30}O$: C, 81.5; H, 12.1. Found: C, 81.5; H, 12.3.

*Methyl 3-Methylcyclopentadecanecarboxylate (**20**)*

A solution of **18** (9.5 g) in methanol (500 ml) was photolyzed as mentioned above. The crude product was hydrolyzed with ethanolic potassium hydroxide and the acidic substance was separated and reesterified with diazomethane to methyl ester, which was distilled *in vacuo* to give **20** (3.5 g: 33%), b.p. 104°/0.04 mm. Gas–liquid chromatography and thin-layer chromatography gave a single peak and spot, respectively. Infrared (neat): 1740, 1195, 1160 cm^{-1} ($COOCH_3$). Nuclear magnetic resonance: δ 3.60 s (3 H), 2.6–2.1 m (1 H), 1.7–1.1 m (a peak at 1.35) (27 H), 0.88 diffused d (3 H).

Anal. Calcd. for $C_{18}H_{34}O_2$: C, 76.5; H, 12.1. Found: C, 76.8; H, 11.8.

The use of halogenated solvents in this photolysis did not improve the yield of **20**.

The methyl ester **20** was hydrolyzed again with ethanolic potassium hydroxide to give free acid **21** (96% yield) as a colorless viscous liquid.

*3-Methylcyclopentadecyl Acetate (**23**)*

The acid **21** (2.68 g: 0.01 mole) was converted into a

mixture of iodide **22** and acetate **23** with mercuric acetate (12.7 g: 0.04 mole) in benzene (100 ml) and a saturated benzene solution of iodine by the method mentioned above for **8**. The mixture was acetolyzed to pure **23** with mercuric acetate (10 g) in acetic acid (100 ml) as before. Vacuum distillation gave **23** (2.3 g: 82%) as a colorless oil, b.p. 107–110°/0.08 mm. Infrared (neat): 1740, 1240 cm^{-1} (OAc). Nuclear magnetic resonance: δ 5.0–4.5 m (1 H), 1.90 s (3 H), 1.8–1.1 m (a peak at 1.34) (27 H), 0.88 diffused d (3 H).

Anal. Calcd. for $C_{18}H_{34}O_2$: C, 76.5; H, 12.1. Found: C, 76.8; H, 12.0.

3-Methylcyclopentadecanol (24)

Alkaline hydrolysis of the acetate **23** (2.0 g) in the usual manner gave crude alcohol **24** (1.6 g: 94%) as an oil, which was subjected immediately to the next oxidation reaction without further purification. Infrared (neat): 3350 cm^{-1} (OH).

3-Methylcyclopentadecanone (25)

To the crude alcohol **24** (0.6 g: 2.5 mmoles) dissolved in ether (10 ml) was added under stirring a mixture of sodium dichromate dihydrate (0.5 g: 1.7 mmoles), concentrated sulfuric acid (0.4 ml), and water (5 ml) in one portion. After stirring the whole mixture for 2 h, working-up followed by distillation gave **25** (0.47 g: 78%), b.p. 106–107°/0.2 mm. Infrared (neat): 1710 cm^{-1} (C=O). Nuclear magnetic resonance: δ 2.6–2.2 m (4 H), 2.1–1.1 m (a peak at 1.30) (23 H), 0.90 diffused d (3 H).

Anal. Calcd. for $C_{16}H_{30}O$: C, 80.6; H, 12.7. Found: C, 80.4; H, 12.8.

The semicarbazone of **25** melted at 130–131° (from methanol) (reported (16) m.p. 131–132°).

Anal. Calcd. for $C_{17}H_{33}N_3O$: C, 69.1; H, 11.3; N, 14.2. Found: C, 68.9; H, 11.3; N, 13.7.

Acknowledgments

On the reduction of the ozonides of selected phenylethylenes by triphenylphosphine

JACQUES CARLES AND SÁNDOR FLISZÁR[1]
Department of Chemistry, University of Montreal, Montreal, Quebec

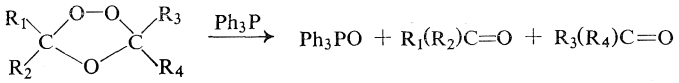
Received November 6, 1968

Triphenylphosphine has been found to reduce ^{18}O labelled ozonides of styrene, stilbene, β-methylstyrene, and triphenylethylene by a very selective attack on the peroxidic oxygen atoms of the ozonides. The presence of an electron withdrawing phenyl group attached to a C atom of the ozonide ring enhances the attack on the peroxidic oxygen adjacent to this C atom, whereas the presence of an electron releasing methyl group enhances the attack on the other peroxidic oxygen atom.

La réduction, par la triphénylphosphine, des ozonides du styrène, stilbène, β-méthylstyrène et du triphényléthylène, marqués par ^{18}O dans la position éther, montre que l'attaque a lieu très sélectivement sur les oxygènes peroxydiques. Le groupe phényle, relié à un atome de carbone du noyau ozonique, favorise l'attaque sur l'atome d'oxygène péroxydique voisin à cet atome de carbone. Le groupe méthyle exerce une influence contraire.

Canadian Journal of Chemistry, 47, 1113 (1969)

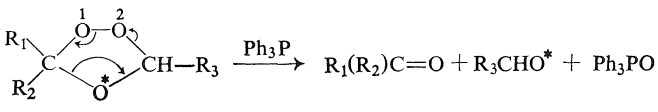
The reduction of ozonides by triphenylphosphine has been investigated by Lorenz and Parks (1, 2). This reaction was found to proceed quantitatively and was thus applicable to the determination of unknown quantities of ozonide (2).

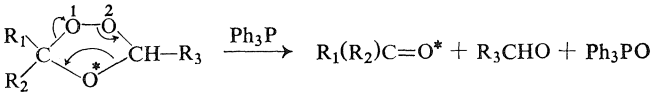


In addition, the nature of the ozonide submitted to this reduction may be determined from the analysis of the carbonyl compounds which are formed during this reduction (1).

In some cases, the reaction proceeds at different rates when *cis*- and *trans*-ozonide isomers are reduced (1). The *cis*-isomer of 2,5-dimethyl-3-hexene ozonide is reduced more rapidly than the *trans*-isomer, whereas, in the case of the 2-butene ozonides, the *trans*-isomer appears to be reduced more rapidly than the *cis*-isomer.

By analogy with the reaction of triphenylphosphine with sulfur (3), the attack of Ph_3P on the ozonide ring is believed to occur via a nucleophilic attack on a peroxidic oxygen of the ozonide ring (1). As no unambiguous experimental proof was available for this hypothesis, this study has attempted to determine the position of attack of the Ph_3P on the ozonide ring. The use of ^{18}O labelled ozonides, in which the isotopic oxygen is situated exclusively in the ether position, has permitted the reaction to be followed and the selectivity of the attack to be determined.





[1]To whom enquiries should be addressed.

*Not determined.

The preparation of the ^{18}O labelled ozonides of styrene, stilbene, β-methylstyrene, and triphenylethylene has been described previously (4–6), and the exclusive location of the oxygen isotope in the ether position has been established (5, 6)[2] by mass spectrometry.

The reduction of these ozonides by Ph_3P was carried out under conditions similar to those indicated by Lorenz and Parks (1). The carbonyl compounds and the triphenylphosphine oxide formed were isolated and purified. The percentage ^{18}O content of these compounds, as determined by mass spectrometry, is indicated in Table I. The percentage labelling of the ozonides submitted to this reduction was determined by mass spectrometry, using the methods described elsewhere (5, 6).

The results indicate that in no case is the triphenylphosphine oxide labelled. This indicates that the attack of triphenylphosphine takes place very selectively on the peroxidic oxygens of the ozonides of those phenylethylenes which have been examined.

The results given in Table I also show that, within experimental error, a satisfactory mass balance for the oxygen isotope is obtained. For example, in the reduction of stilbene ozonide, the expected percentage ^{18}O labelling of the benzaldehyde is half that of the original ozonide, since two molecules of benzaldehyde are formed upon reduction of one molecule of ozonide, one of these molecules retaining a peroxidic oxygen, and the other retaining the labelled ether oxygen of the original ozonide. Similar mass balances for the oxygen isotope are also obtained for the products formed upon reduction of the β-methylstyrene and triphenylethylene ozonides. Within experimental error, the sum of the percentage labelling of the two carbonyl compounds is found, in each case, to be equal to the percentage labelling of the ozonide used.

The reduction of ozonides obtained from unsymmetrical olefins, after examination of the ^{18}O content of the carbonyl compounds formed, also enables the peroxidic oxygen, which is preferentially attacked by the triphenylphosphine, to be determined.

The results obtained with the ozonide of triphenylethylene indicate that most of the ether oxygen is retained in the benzaldehyde formed upon reduction. This indicates that the peroxidic oxygen in position-2 is selectively attacked by the triphenylphosphine. Both electronic and steric factors may be responsible for this selective attack. The steric hindrance contributed by the two phenyl groups (R_1 and R_2) obscures, in this case, the contribution of the electronic effects in distributing the sites of attack of the Ph_3P among the two peroxidic oxygens.

In the reduction of the styrene ozonide, approximately 55% of the attack takes place on the peroxidic oxygen identified by **1**. This is an indication of the participation of the electron withdrawing phenyl group in directing the position of attack of the peroxidic oxygens by triphenylphosphine. In β-methylstyrene ozonide, the electron releasing methyl group tends to increase the electron density at the oxygen identified by **2**. Under the combined influence of the phenyl and the methyl groups, the proportion of attack on the peroxidic oxygen in position-1 is thus favored. This is confirmed by the results given in Table I, which indicate that in the reduction of β-methylstyrene ozonide the positions of attack are distributed as follows: 60% on the oxygen in position-1, and, consequently, 40% on the other peroxidic oxygen.

The present results thus indicate that electron withdrawing groups attached to a carbon atom

[2]The mechanistic implications concerning the formation of ozonides are discussed in refs. 4 and 6.

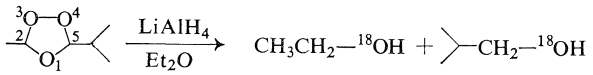
For personal use only.



of the ozonide ring favor the attack by Ph_3P on the peroxidic oxygen adjacent to this carbon atom, whereas electron releasing groups exert the opposite influence.

Similar leaving characteristics of the peroxide-bridge oxygens have been observed by Bishop and Story (7) for the reduction of 1,2-dimethylcyclopentane ozonide by lithium aluminium hydride. This ozonide was labelled exclusively in the ether oxygen by ^{18}O and gave, upon reduction, the 2,6-heptanediol which retained essentially all the isotopic label of the ozonide. Hence the selectivity of attack of the peroxide oxygens by $LiAlH_4$ is clearly established in this case, and it is assumed (7), by extension, that the hydride reduction of other saturated alkyl-substituted ozonides occurs with loss of oxygen only from the peroxide bridge. Their detailed mechanism explains clearly why, with $LiAlH_4$, the peroxide oxygens are favored to leave the ozonide. This selectivity is now found to occur in the ozonide reduction by Ph_3P.

However, little is known about the preferential position of $LiAlH_4$ attack on the peroxidic oxygens of ozonides of unsymmetrical olefins. The most detailed study, by Story *et al.* (8), concerned the hydride reduction of the ^{18}O labelled ozonide of 4-methylpentene-2 (*cis–trans* mixture).

Owing to the mode of preparation of this ozonide from the ozonolysis of *trans* diisopropylethylene in the presence of acetaldehyde-^{18}O, only the oxygen atoms in positions-1 and -3 are labelled. The preferential position of attack (0–3 or 0–4) can be calculated from the published data (8). Let x be the proportion of labelling in 0–3 and, hence, $1 - x$ the proportion of labelling in 0–1. Let y be the proportion of 0–3 abstraction by the reducing agent, and $1 - y$ the proportion of abstraction of 0–4. Thus the labelling of ethanol and isobutyl alcohol, referred to the total ozonide labelling, is expressed by eqs. [1] and [2].

[1] (ethanol) $y(1 - x) + (1 - y)x = 25.4/47.8$

[2] (isobutanol) $(1 - y)(1 - x) = 7.6/47.8$

Owing to the fact that these equations lead to quadratic expressions for x (or y), two solutions are obtained:[3]

(*i*) $x_1 = 0.43$; $y_1 = 0.72$

(*ii*) $x_2 = 0.72$; $y_2 = 0.43$

A consideration of electronic and steric factors favors solution (*i*), which indicates that 43% of the labelling is found in 0–3 and that 0–3 is abstracted in preference (~72%) to 0–4 (~28%).

Electronic factors due to the combined effects of the methyl and the isopropyl groups probably play only a minor role in distributing the sites of attack among 0–3 and 0–4. The results obtained in the reduction of β-methylstyrene ozonide by Ph_3P (Table I) support this view. However, if any small effect occurs, the mechanism of hydride reduction proposed by Story (7) indicates that the attack of H^- on the less negative oxygen atom, i.e. 0–3, and hence its elimination, would be favored.

The steric effects, however, appear to play a more important role in the reduction of ozonides. Story's mechanism predicts that a steric effect should function so as to cause excessive loss of 0–3 rather than 0–4. The results obtained in the reduction of triphenylethylene ozonide by triphenylphosphine also illustrates the significance of the steric effect, since, in this reduction, the peroxidic oxygen adjacent to the carbon atom bearing the two phenyl groups is not attacked by the reducing agent.

Although these limited experimental data do not permit definite conclusions to be drawn, it appears that ozonide rings undergo similar modes of reduction when reacted with lithium aluminium hydride or triphenylphosphine. First, the same selectivity of attack on the peroxide bridge is observed for both reducing agents. Secondly, the electronic effects due to the substituents seem to play a minor role in the distribution of the sites of attack. Story's mechanism

[3]The ^{18}O content of 0–3 calculated here differs from the value (68%) calculated by Story *et al.* (8) because these authors had assumed, to a first approximation, equal proportions of abstraction of 0–3 and 0–4.

for hydride reduction indicates the same trends as those which have been observed for Ph_3P, namely a preferential loss of the least negative peroxidic oxygen atom. Finally, the importance of any steric effect is of equal significance for both $LiAlH_4$ and Ph_3P reduction of the least hindered peroxidic oxygen atom.

Experimental

The preparation of the ^{18}O labelled ozonides, and the determination of the ^{18}O content of the ozonides by mass spectrometry, have been described elsewhere (4–6).

The mass spectra of the compounds obtained upon reduction of the ozonides by triphenylphosphine were recorded using a single focussing Hitachi RMU-6D mass spectrometer, with a direct introduction system MG 158. The vapor pressures of the compounds examined were sufficiently high, so that no external heat on the sample holder was required. The ionization chamber was maintained between 150 and 170 °C, and the ionizing electrons were accelerated by a 70 V potential.

Reduction of the Stilbene Ozonide

Ninety mg of the stilbene ozonide (1:1 *cis–trans* mixture, m.p. 74°) were dissolved, under an N2 atmosphere, in 5 ml of hexane and 150 mg of triphenylphosphine were added. The solution was boiled, under N_2, for 1 h. Cooling to 0° caused the triphenylphosphine oxide (m.p. 160°) to crystallize, and it was isolated by filtration and further purified by recrystallization. The filtrate was distilled under reduced pressure, in N_2 atmosphere, and the benzaldehyde collected. The benzaldehyde was further purified by column chromatography, using Baker Silica-Gel and a benzene–hexane mixture (1:3).

Reduction of Triphenylethylene Ozonide

The procedure is similar to the one described for the stilbene ozonide. One hundred and six mg ^{18}O-triphenylethylene ozonide and 150 mg triphenylphosphine were used. After isolation of the triphenylphosphine oxide and of the benzaldehyde, the benzophenone was isolated from the distillation residue by fractional crystallization in methanol.

Reduction of the β-Methylstyrene Ozonide

One-hundred and twenty-three mg ozonide, 300 mg triphenylphosphine and 5 ml heptane were placed in a "V"-shaped Carius tube and ca. 1 ml of liquid N_2 was added. The Carius tube was sealed, and the mixture was heated at 70° for 1 h. On cooling to room temperature, the mixture was retained in one branch of the "V"-shaped tube. This branch was cooled by a dry ice – acetone bath to collect all the volatile products. After warming to room temperature, the other branch of the tube was cooled rapidly in liquid nitrogen. The acetaldehyde condensed in the cold branch of the Carius tube, which was then cut off. The acetaldehyde was transferred to the mass spectrometer for analysis. The triphenylphosphine oxide was isolated from the heptane solution as described previously by cooling the solution to 0°. By distillation under reduced pressure, the benzaldehyde was isolated, and further purified by column chromatography.

Reduction of the Styrene Ozonide

The work-up procedure for this ozonide was similar to that described for β-methylstyrene ozonide. Seventy mg of ozonide and 200 mg of triphenylphosphine were used. The formaldehyde could not be isolated.

Thiohydantoins. VII. Ionization and ultraviolet spectra of 4-thiohydantoins and 2,4-dithiohydantoins

J. T. Edward and J. K. Liu
Department of Chemistry, McGill University, Montreal, Quebec

Received August 27, 1968

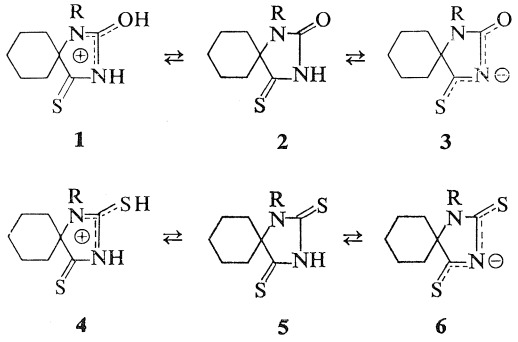
The acid and base dissociation constants of 5,5-pentamethylene-4-thiohydantoin, 5,5-pentamethylene-2,4-dithiohydantoin, and their 1-methyl derivatives, have been determined by ultraviolet studies in basic and acid media. In aqueous sulfuric acid the 4-thiohydantoins are protonated on oxygen at the 2-position, so that the extent of protonation varies with the H_A function of the acid solution, while the 2,4-dithiohydantoins are protonated on sulfur at the 2-position, so that the extent of their protonation varies with H_0'''. The importance of using acidity functions appropriate to the different types of compounds when comparing their basicities is emphasized.

Les constantes d'ionization acides et basiques des pentamethylene-5,5 thio-4 hydantoïne, pentamethylene-5,5 dithio-2,4 hydantoïne, et leur méthyle-1 derivés, ont été déterminés par études d'absorbance ultraviolète dans les milieux basiques et acides. Dans l'acide sulfurique aqueux les thio-4 hydantoïnes sont protonnés sur l'atome d'oxygène à la position-2, parce que le degré d'ionization suit la fonction d'acidité H_A. Les dithio-2,4 hydantoïnes sont protonnés sur l'atome de soufre à la position-2, et le degré d'ionization suit la fonction H_0'''. Ce travail démontre la necessité d'utiliser les fonctions d'acidité appropriées pour des classes différentes de composés, si on veut comparer leurs basicités.

Canadian Journal of Chemistry, **47**, 1117 (1969)

A knowledge of the ionization constants of 2-thiohydantoins and of the changes in their ultraviolet (u.v.) absorption spectra brought about by ionization (1) has proved useful in elucidating the structures of their oxidation products (2). In the present paper we are concerned with extending this knowledge to representative 4-thiohydantoins and 2,4-dithiohydantoins; some use of the results is made in the following paper (3).

The compounds chosen for study were 5,5-pentamethylene-4-thiohydantoin (**2**; R = H), 5,5-pentamethylene-2,4-dithiohydantoin (**5**; R = H), and their 1-methyl derivatives (**2**; R = Me; and **5**; R = Me). The preparation of these compounds has been described by Carrington and Waring (4), who showed that they do not exist, to any appreciable extent, in other tautomeric forms. Their u.v. characteristics in various solvents are listed in Table I; an attempt has been made to classify the absorption bands as Type I, II, or IV, according to a scheme of Janssen (5, 6).



1 **2** **3**

4 **5** **6**

Reaction Scheme 1

For solutions of the neutral compounds in methanol, Carrington and Waring (4) reported the peaks which we classify as Types II and IV. They further reported that the compounds are yellow, but did not observe the Type I peaks responsible for the yellow color. These weak peaks were not observed in water because the compounds are too sparingly soluble, nor in sulfuric acid when they are lost in the trailing edge of the more intense Type II peaks. However, the absorption curve of **5** (R = Me) in 96% sulfuric acid shows an inflexion at about 450 mμ which is probably due to a submerged Type I peak. These peaks are almost certainly the result of $n \rightarrow \pi^*$ transitions of the 4-thiocarbonyl group; $n \rightarrow \pi^*$ transitions of the 2-thiocarbonyl group should take place at shorter wavelengths (6, 7). As expected (6), the Type I peaks of the 2,4-dithiohydantoins are at longer wavelengths than the similar peaks of the 4-thiohydantoins, because the 2-thiocarbonyl group pulls electrons more strongly than the 2-carbonyl group (6). The bathochromic effects of the methyl groups at the 1-position are unexpected and without any obvious explanation.

The Type II bands are undoubtedly due to $\pi \rightarrow \pi^*$ transitions of the thioamide function

(7–9) in the molecules, and the Type IV bands possibly to $n \rightarrow \sigma$ transitions (7).

In sufficiently acid or alkaline solution the compounds **2** (R = H and Me) and **5** (R = H and Me) form the ions shown in Reaction Scheme 1. The ionization can be followed from changes in the spectra of the compounds (see Table I), most conveniently at suitable wavelengths in the neighborhood of the intense Type II peaks.

Ionization of **2** (R = H) in alkaline solution is expected to take place at N_3—H and not at N_1—H (6). In the present instance this view is supported by the similarity of the spectra of the anions **1** (R = H and Me). Similar considerations apply to the ionization of **5** (R = H). The acid strength of **5** (R = H) (Table II), found by the usual spectrophotometric method, proved to be about the same as that of 5,5-dimethyl-2,4-dithiohydantoin (10); the acid-weakening effect of a 1-methyl group (about 0.5 p*K* unit) is about the same as its effect on the acidity of 2-thiohydantoins (1), and has about the magnitude anticipated (11). The ionization constant pK_{HA} of **2** (R = H) (Table II) showed it to be a stronger acid than the corresponding 2-thiohydantoin (1) but (as expected (6)) a weaker acid than the corresponding 2,4-dithiohydantoin (**5**; R = H).

Protonation of **5** (R = H or Me) (B) would be expected to take place on the 2-thiocarbonyl sulfur to give the cation **4** (R = H or Me) (BH^+), because this permits the maximum delocalization of the positive charge (12). The structure **4** (R = H) is supported by the similarity of the spectrum of 5,5-pentamethylene-2,4-dithiohydantoin in 96% sulfuric acid (see Table I) to that of 2-methylthio-5,5-pentamethylene-2-imidazol-4-thione (**7**)[1] in 5% acid (λ_{max} at 263 and 296 mμ; ε_{max} 11 600 and 16 600). Protonation of the latter should give **8**, which differs from **4** (R = H) only in having a S—Me in place of a S—H group; the bathochromic effect of this methyl group on

the Type IV band is large but has many precedents.[2]

The change in spectra of the two compounds **5** (R = H and Me) in different concentrations of acid allowed their ionization to be followed in the usual way (13). The plots of log $[B]/[BH^+]$ against H_0 had slopes greater than unity (Fig. 1*A*), showing that protonation of 2,4-dithiohydantoins does not follow this acidity function. However, plots against H_0''' (15) had slopes close to unity (Fig. 1*B*). It had been shown previously that the ionization of thioamides and thiolactams, which are protonated on sulfur (12), follows H_0''',[2] and it would seem that the same is true for 2,4-dithiohydantoins.

The ionization constants pK_{BH^+} of the 2,4-dithiohydantoins **5** (R = H and CH_3), determined in the usual way from the plots in Fig. 1*B*. are recorded in Table II, and show them to be about ten times weaker bases than the corresponding 2-thiohydantoins,[2] just as they are about ten times stronger acids (1). The difference in both cases depends on the thiocarbonyl group being more polarized, and hence more strongly electron-attracting, than the carbonyl group (6). The base-strengthening effect of the 1-methyl group (about 0.2 pK unit) is the same as that found by Janssen (11) for the methyl groups of *N*,*N*′-dimethylethylenethiourea. Janssen has shown that this effect is probably composite, being made up of an electronic effect (base-strengthening) and a steric effect on solvation (base-weakening). This would explain the greater effect of the 1-methyl group (about 0.5 pK unit) on the basicity of the anion **6** (R = Me), if the methyl group hinders the solvation of this anion less than it does the solvation of the cation **4** (R = Me). This might be expected because of the different distribution of charge in anion and cation.

Lactams are more basic than thiolactams (16), and hence 4-thiohydantoins would be expected to be protonated in strong acid on the 2-carbonyl oxygen to give the cations **1** (R = H or Me). In such a case their ionization would be expected to follow better H_A than H_0; as a parallel case, we have found this to be true for the ionization of *N*-phenylurea (compare Fig. 1*A* and Fig. 1*B*).[3]

[2]J. T. Edward and I. Lantos, unpublished research.

[3]The slope (0.85) of the plot for *N*-phenylurea in Fig. 1*B* shows that the ionization does not follow H_A exactly; however, the deviation of the slope from unity is no worse than in many other cases cited in the literature (18). From Fig. 1*B*, *N*-phenylurea has $pK_{BH^+} = -1.45$.

The ionization of the 4-thiohydantoins (**2**; R = H and Me) takes place only in very strongly acidic solution, beyond the range in which the H_A scale was established by Katritzky *et al.* (17) using amide indicators. However, it can be seen from Fig. 2 that plots of log $[BH^+]/[B]$ against % sulfuric acid for the two 4-thiohydantoins (**2**; R = H and Me) show reasonably good parallelism to the plot for 2,4,6-trinitrobenzamide, the most weakly basic amide indicator acid used by Katritzky *et al.* (17); the parallelism is at least as satisfactory as that of the immediately more strongly basic amide indicators used by these authors, and shown in Fig. 2. Such behavior indicates that the ionization of the 4-thiohydantoins (**2**; R = H and Me) follows H_A, and hence that the compounds are *O*-protonated to give the cations **1** (R = H and Me).[4] Furthermore, the parallelism of the plots of log $[BH^+]/[B]$ with that of phenazine 5,10-dioxide (Fig. 2) is also reasonably good. Johnson *et al.* (18) have recently used this compound as an indicator to extend the H_A scale into higher concentrations of sulfuric acid, justifying its use by the argument that the ionization of more strongly basic *N*-oxides had been found previously to follow the H_A scale reasonably well. The present results with the 4-thiohydantoins (**2**; R = H and Me) support this argument.

The ionization constants pK_{BH^+} of the 4-thiohydantoins, obtained from the plots in Fig. 1*B*, are recorded in Table II, and show them to be considerably stronger bases than the corresponding 2,4-dithiohydantoins. This is to be expected from the greater basicity of lactams as compared with thiolactams (16). A comparison of Fig. 1*B* with Fig. 1*A* shows the dangers of obtaining relative basicities from H_0 values of half-protonation.[5,6] Although the theoretical inadequacy of such a method is well known (19), it continues to be used (e.g. ref. 20). At a more naive level, it is evident from Fig. 1*A* that the 4-thiohydantoins (*a* and *b*) require more concentrated sulfuric acid

[4]This would appear to be the first instance in which the site of protonation in a molecule (frequently a disputed point: see Katritzky and Jones (12)) has been decided on the basis of acidity function behavior.

[5]pK_{BH^+} Values based on H_0 are: *a*, −7.55; *b*, −7.22; *c*, −4.55; *d*, −4.43.

[6]It should be pointed out that a slope s = 1 (as in Fig. 1*b*) is a necessary but not a sufficient condition for the numerical validity of a measured pK_{BH^+} in this region of acidity: see Arnett (19) for a good discussion of this point.

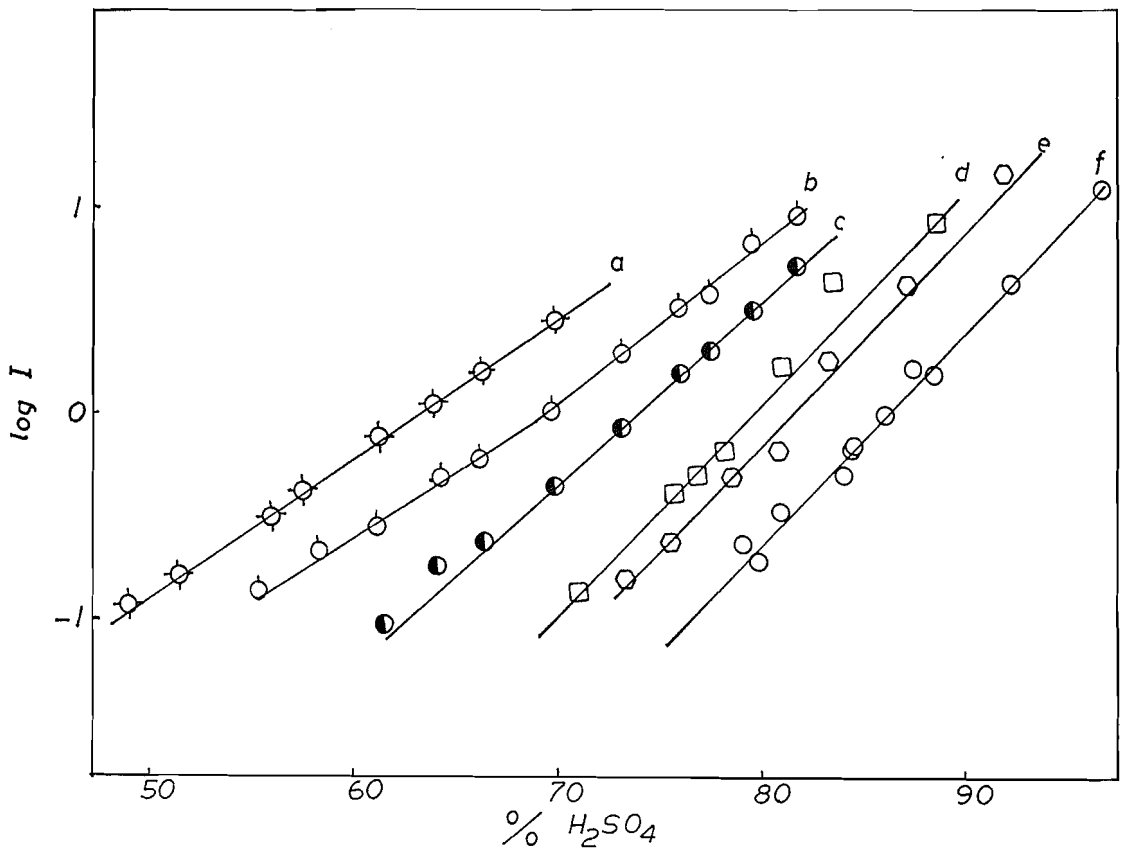

FIG. 2. Plots of log I against % sulfuric acid of the following compounds: *a*: 2,3,6-trichlorobenzamide (ref. 17); *b*: 2,4-dichloro-3,5-dinitrobenzamide (ref. 17); *c*: 2,4,6-trinitrobenzamide (ref. 17); *d*: 1-methyl-5,5-pentamethylene-4-thiohydantoin; *e*: 5,5-pentamethylene-4-thiohydantoin; *f*: phenazine 5,10-dioxide (ref. 18).

to bring about their half-protonation than the 2,4-dithiohydantoins (*c* and *d*), and it might be inferred (erroneously) that for this reason the 4 thiohydantoins are weaker bases. The importance of determining the correct acidity functions for different classes of compounds is apparent.

Experimental

The 4-thiohydantoins and 2,4-dithiohydantoins were prepared according to procedures in the literature (4), and had melting points close to those reported. Spectral measurements for all compounds were made with a Unicam SP 800 spectrophotometer having the cell compartment thermostated at 25.0±0.1°. Ionization constants were obtained by methods described previously (1, 16) and are reproducible to within ±0.05 pK units. The ionic strengths of buffers used in obtaining measurements for pK_{HA} values were about 0.01.

Thiohydantoins. VIII. Structure of the reported 5-phenyl-2,4-dithiohydantoin and its benzylation products

J. T. EDWARD AND J. K. LIU
Department of Chemistry, McGill University, Montreal, Quebec

Received February 23, 1968

The supposed 5-phenyl-2,4-dithiohydantoin (**3**) actually exists as its tautomer 5-mercapto-4-phenyl-4-imidazolin-2-thione (**12**). The reactions of the compound have been clarified by spectral studies of the products; in particular, mono- and dibenzylation have been shown to take place on sulfur and not (as reported) on nitrogen.

Le composé décrit comme phényle-5 dithio-2,4 hydantoïne (**3**) est actuellement son tautomère mercapto-5 phényle-4 imidazoline-4 thione-2 (**12**). Les produits de quelques reactions de ce composé ont été étudiés par spectroscopie. L'action du chlorure de benzyle attache un ou deux groupements benzyliques aux soufres, et non à l'azote.

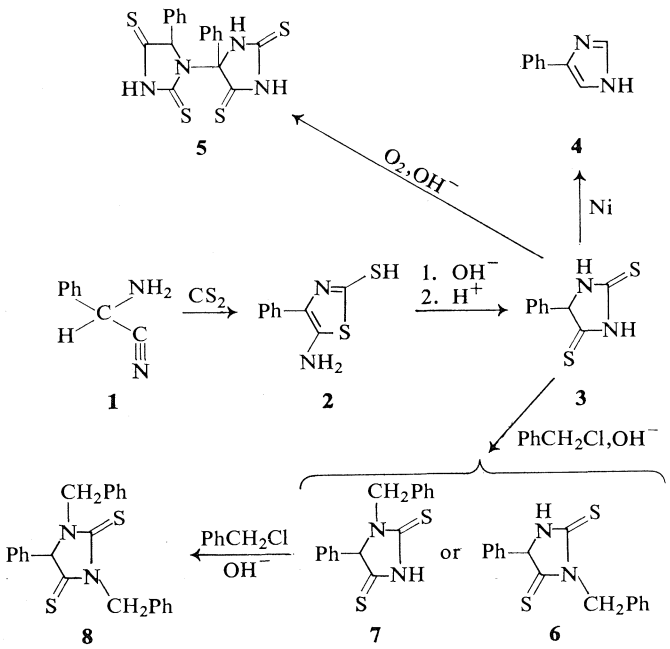
Canadian Journal of Chemistry, **47**, 1123 (1969)

The products formed by the alkylation of ambident ions are generally (but not always (1)) predicted by the theory of Kornblum *et al.* (2). In particular, the theory is in accord with the general tendency of thiohydantoins to be *S*-methylated by methyl iodide in alkaline solution and *N*-methylated by diazomethane in ether solution (3, 4). An apparent exception is provided by the report of Cook *et al.* (5) that 5-phenyl-2,4-dithiohydantoin (**3**) is *N*-benzylated by benzyl chloride in alkaline solution to give a monobenzyl derivative (**6** or **7**) (λ_{max} = 277 mμ) and a dibenzyl derivative (**8**) (λ_{max} = 277 mμ). However, it has already been pointed out (4) that these *N*-benzyl structures are excluded by the ultraviolet (u.v.) absorption spectra which Cook *et al.* reported for their compounds,[1] and by the fact that the dibenzyl compound forms a hydrochloride; the compound **8** would be much too weakly basic to do this (7). Consequently, it became of interest to establish the correct structures of the benzylated compounds.

The procedure followed by Cook *et al.* in preparing 5-phenyl-2,4-dithiohydantoin (**3**) is shown in Reaction Scheme 1. A similar procedure is known to be successful in giving 5,5-disubstituted 2,4-dithiohydantoins (8), and evidence for the structure **3** was obtained by converting the compound by treatment with Raney nickel into 4-phenylimidazole (**4**). On oxidation with air or various oxidizing agents in alkaline solution it gave a compound $C_{18}H_{14}N_4S_4$, assigned the structure **5** by analogy with the structure of the product obtained by oxidizing 5-phenylhydantoin in alkaline solution (9). However, a spectral examination of these various compounds shows the structures assigned to all of them to require modification, except for **1** and **4**.

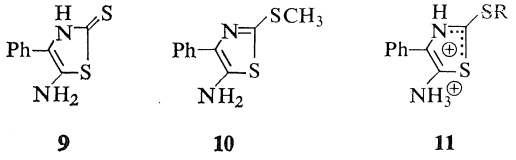
The structure **2** for the compound formed by the reaction of the aminonitrile **1** with carbon disulfide seems much less likely than **9**, in the light of our present knowledge of relative stabilities of thioamides and their iminothiol tautomers (3, 4, 10), and indeed no S—H stretching band (11) could be detected in the infrared (i.r.) spectrum of the compound. Furthermore, in ethanol solution its u.v. absorption spectrum (λ_{max} = 336 mμ, ε_{max} = 10 600) is distinctly different from that of its *S*-methyl derivative **10** (λ_{max} = 296 mμ, 224 mμ; ε_{max} = 12 200, 14 300); the spectra of **2** and **10** would be expected to be fairly similar (10). The compound must consequently exist as the tautomer **9** and not **2**. In sulfuric acid **9** and **10** have similar spectra, protonation of the first compound giving **11** (R = H) (λ_{max} 290 mμ and 245 mμ; ε_{max} 8280 and 11 500) and protonation of the second compound giving **11** (R = Me) (λ_{max} 303 mμ and 248 mμ; ε_{max} = 1.22 × 10^4 and 1.13 × 10^4). The bathochromic shift of 13 mμ on going from **11**

[1]These structures would require strong absorption peaks at about 305 mμ. 2,4-Dithiohydantoins show a strong peak at about 300 mμ (3, 4), and 5-phenyl-2,4-dithiohydantoin would be expected to show a peak at about 305 mμ (6) (cf. 5,5-diphenyl-2,4-dithiohydantoin in ethanol: $\lambda\lambda_{max}$ 410, 310, 235 mμ; $\varepsilon\varepsilon_{max}$ 81, 19 200, 10 900). *N*-Benzylation should have little effect on the ultraviolet absorption of 5-phenyl-2,4-dithiohydantoin (4, 6).

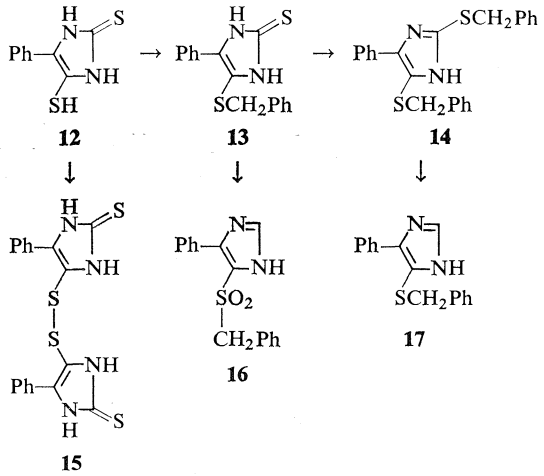


REACTION SCHEME 1

(R = H) to **11** (R = Me) is of the magnitude found for other examples of *S*-methylation,[2] while the strong hypsochromic shift on protonating the thiocarbonyl sulfur of **9** is similar to the shifts noticed on protonating other thiocarbonyl compounds (12).



Cook's second compound (the supposed 5-phenyl-2,4-dithiohydantoin) has the structure **12** (Reaction Scheme 2) and not **3**. Its u.v. spectrum (Table I) does not exhibit a strong peak at about 305 mμ, as would be required by **3**.[1] Its i.r. spectrum showed S—H stretching bands at 2400 cm^{-1} and 2355 cm^{-1} (Nujol). This is lower than the usual frequency for the S—H band (11), but recently we have observed even lower values.[3] The assignment of the band to S—H was



REACTION SCHEME 2

confirmed by treating the compound with deuterium oxide. The peaks at 2400 cm^{-1} and 2355 cm^{-1} disappeared and S—D peaks at 1660 cm^{-1} and 1640 cm^{-1} appeared. The structure **12** also accords with the nuclear magnetic resonance (n.m.r.) spectrum of the compound (Table II), which shows only SH, NH, and aromatic CH peaks. The structure **3** would require a C_5—H singlet at about δ = 5.5 p.p.m.; such singlets are

shown in the spectra of the hydrochloride of **1** (δ = 5.81 p.p.m.) and of 1-acetyl-5-phenyl-2-thiohydantoin (δ = 5.51 p.p.m.), and are unaffected by treating the compounds with deuterium oxide.

The structure **12** is further supported by measurements of the acid and base dissociation constants of the compound (Table III). The acidity (pK_{HA} 8.1) is about that expected for an unsaturated thiol (cf. pK_{HA} of 6.52 for thiophenol, 10–11 for alkane thiols (13)), and the basicity (pK_{BH^+} −3.15, referred to the H_O''' scale (14)), is about that expected for a thiourea.[4] A compound of structure **3** would be a much weaker base, having a pK_{BH^+} of about −6 (7).

TABLE III

Ionization constants

Compound	pK_{HA}	pK_{BH^+}
12	8.15±0.04	−3.16±0.01
13	9.55±0.09	−3.31±0.09
14	10.93±0.15	2.70±0.10
17	11.97±0.03	5.43±0.09
4	12.96±0.04	6.12±0.01*

*Kirby and Neuberger (26) obtained a pK_{BH^+} of 6.00±0.04 (zero ionic strength) from potentiometric measurements.

The occurrence of Cook's supposed 5-phenyl-2,4-dithiohydantoin as its tautomer **12** is interesting in view of the fact that 5-phenylhydantoin and 5-phenyl-2-thiohydantoin, which also have a hydrogen atom at C-5, do not tautomerize in the same way. (The n.m.r. signal in the spectrum of 1-acetyl-5-phenyl-2-thiohydantoin due to this hydrogen has been mentioned above.) It has been

[4]Janssen (15) reported a pK_{BH^+} of −1.9 for ethylenethiourea, the ionization of which he assumed to follow H_O; referred to the H_O''' scale, this would represent a pK_{BH^+} of −2.7.

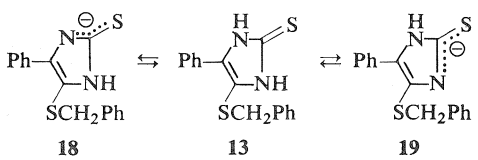
claimed that thiones are more extensively enolized than ketones (16), although quantitative data to support this claim seem to be lacking, and this would seem to be a further example.

The thiol formulation **12** for Cook's second compound makes the disulfide structure **15** more plausible than **5** for its oxidation product $C_{18}H_{14}N_4S_4$. This disulfide structure is supported by the i.r. spectrum, which is similar to that of **12** except for the absence of the S—H band, and the u.v. spectrum, which lacks a peak at about 305 mμ. (The u.v. spectra of this and related compounds will be discussed in detail later.)

The disulfide structure **15** better accommodates some of the properties of the compound (e.g. the formation of 4-phenylimidazole by treatment with Raney nickel) already reported by Cook *et al.* (5). In particular, their report that the compound when treated with alkali gave about 80% yield of 5-phenyl-2,4-dithiohydantoin (**3**) would be most remarkable on the basis of the structure **5**, from which one would expect a maximum yield of 50% (17). It becomes understandable on the basis of **15**, since alkaline hydrolysis of disulfides can give thiols (theoretical yield 75%) and sulfinic acids (18):

$$2RSSR + 2H_2O \rightarrow 3RSH + RSO_2H$$

Benzylation of **12** gives the *S*-benzyl derivative **13**, and not the *N*-benzyl derivative **6** or **7**. The structure **13** is required by the u.v. spectrum (Table I), which, as mentioned above, excludes structures **6** and **7**, by the infrared and n.m.r. (Table II) spectra, which show the thiol group of the starting material **12** to have disappeared, and by the basicity of the compound (Table III), which is about 10^3 times stronger than would be expected for **6** or **7** (7). The absence of the thiol grouping is shown also by the weakened acidity (pK_{HA} 9.5) of the compound, as compared with **12**. The experimental pK_{HA} is probably a composite value, ionization of **13** yielding both **18** and **19**. Because ionization of **12** in basic solution takes place at the SH group, and of **13** at NH groups, their spectra in alkaline solution are different. However, in strongly acidic solution both are protonated on the thiourea sulfur, and have similar u.v. spectra (Table I) and ionization constants (Table III).



18 **13** **19**

Treatment of the monobenzyl derivative with Raney nickel gave 4-phenylimidazole, the product anticipated from **13** but not from **6** or **7**. Treatment with hydrogen peroxide in acetic acid gave the ω-toluenesulfonyl derivative **16**, whose structure follows from its n.m.r. spectrum (Table II) and u.v. spectrum (Table I). The latter shows a fairly strong similarity to that of 4-phenylimidazole. The oxidative removal of sulfur from a thiourea function (as in **13** → **16**) finds ample analogy in the literature (19).

The dibenzyl derivative (pK_{BH^+} +2.70) is about one million times more strongly basic than the monobenzyl derivative, and hence can form a crystalline hydrochloride, as noted by Cook *et al.* (5). Similar changes in basicity have been observed following the *S*-alkylation of thiourea (4), and in the present instance indicate the structure **14** for the dibenzyl derivative. This structure is compatible with the n.m.r. (Table II) and u.v. (Table I) spectra of the compound. The latter shows some similarity to the spectrum of **4**, although the perturbing effect of the two benzylthio groups is perhaps greater than expected.

Treatment of the dibenzyl compound with a deactivated Raney nickel gave 4-phenylimidazole and 5-benzylthio-4-phenylimidazole (**17**). No 2-benzylthio-4-phenylimidazole, a known compound (20), was detected. The preferential removal of the 2-benzylthio group may perhaps be explained by the hindered character of the 5-benzylthio group. The spectral (Tables I and II) and ionization characteristics (Table III) of **17** accord with the structure assigned it. The acidity (pK_{HA}) of the compounds **4**, **17**, and **14** changes in the direction and by about the magnitudes to be expected from the inductive effects of the benzylthio groups. The basicity (pK_{BH^+}) also changes in the direction expected, but the change on going from **17** to **14** (Table III) is unexpectedly large; steric hindrance to solvation of the cation from **14** may be involved (15).

Experimental

General Preparation of Compounds

5-Amino-4-phenyl-2-thiazolin-2-thione (**9**), 4-mercapto-5-phenyl-2-imidazolin-2-thione (**12**), di-(4-phenyl-2-thioxo-4-imidazolinyl) disulfide (**15**), 4-benzylthio-5-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

phenyl-2-imidazolin-2-thione (**13**), 2,4-dibenzylthio-5-phenylimidazole (**14**), and 5-amino-2-methylthio-4-phenylthiazole (**10**) were prepared according to Cook *et al.* (5). 1-Acetyl-5-phenyl-2-thiohydantoin was prepared according to Swan (21). Melting points were in satisfactory agreement with those reported.

5-Phenylmethanesulfonyl-4-phenylimidazole (16)

Hydrogen peroxide (50%; 1 ml) was added dropwise to a solution of 4-benzylthio-5-phenyl-2-imidazolin-2-thione (**13**), (0.5 g) in acetic acid (10 ml) at room temperature. After 1 h the solution was diluted with water (20 ml) and evaporated to dryness at reduced pressure. The residue was crystallized from methanol, giving colorless needles of 5-phenylmethanesulfonyl-4-phenylimidazole (0.13 g), m.p. 212–213°, ν_{max}(KBr) 1330 and 1130 cm^{-1} (sulfonyl: ref. 22).

Anal. Calcd. for $C_{16}H_{14}N_3O_2S$ (mol. wt., 298): C, 64.4; H, 4.7; N, 9.4. Found (mol. wt., 298; mass spectry.): C, 64.1; H, 4.9; N, 10.2.

Desulfurization of 4-Benzylthio-5-phenyl-2-imidazolin-2-thione (13)

The thione (0.32 g) in ethanol (25 ml) was treated with Raney nickel (1.5 g) of W-4 activity (23) for 30 min at 60°. The mixture was filtered, and the filtrate taken to dryness. The residue was extracted with ether, the ether evaporated, and the residue crystallized from benzene, giving colorless plates of 4-phenylimidazole (59 mg; 41% yield), m.p. 133–134°, λ_{max}(EtOH) 258 mμ, ε_{max} = 12 800 (lit. m.p. 133–134° (5), λ_{max}(EtOH) 257 mμ, ε_{max} = 16 000 (24)).

5-Benzylthio-4-phenylimidazole (17)

A solution of 2,4-dibenzylthio-5-phenylimidazole (**14**) (6.3 g) in methanol (100 ml) containing a suspension of deactivated W-2 Raney nickel (23) was refluxed for 4 h. The mixture was filtered, the filtrate evaporated, and the residue chromatographed on neutral alumina. Elution with chloroform–methanol 95:5 (v/v) gave 5-benzylthio-4-phenylimidazole (0.14 g), m.p. 162–163°.

Anal. Calcd. for $C_{16}H_{14}N_2S$: C, 72.2; H, 5.3; N, 10.5. Found: C, 71.7; H, 5.4; N, 10.3.

Conditions for obtaining this compound were extremely critical. Treatment of 2,4-dibenzylthio-5-phenyi-imidazole with W-2 Raney nickel in ethanol, with W-4 nickel in methanol or ethanol, or with deactivated W-4 nickel in methanol gave only low yields of 4-phenylimidazole.

Spectral Measurements

Infrared spectra were obtained with a Perkin–Elmer Infracord 317 instrument, using KBr discs. Nuclear magnetic resonance spectra were obtained with a Varian HA-60 instrument, using tetramethylsilane as an internal standard. Ultraviolet spectra were obtained with a Unicam SP 800 spectrophotometer having the cell compartment maintained at 25.0 ± 0.1°. For u.v. measurements the compounds were dissolved in ethanol, in aqueous sulfuric acid of varying concentration, or in buffer solutions of 0.05–0.1 ionic strength; pH values of the buffer solutions were measured with a Radiometer pH meter No. 23. The spectral characteristics of the un-ionized compound (B or HA), the protonated compound (BH^+), and the deprotonated compound (A^-) were obtained by measurements at appropriate pH or H_O''' values, and the ionization constants pK_{BH+} (= pH or H_O''' + log [BH^+]/[B]) and pK_{HA} (= pH + log [HA]/[A^-]) obtained by absorbance measurements at intermediate pH or H_O''' values according to well-established procedures (25). No correction was made for the effects of ionic strength for compounds ionizing in the pH range 1–14; the pK_{BH+} value of 4-phenylimidazole is in reasonable agreement with the value reported by Kirby and Neuberger (26) when ionic strength is taken into account.

Purine analogues. I. The status of Hückel molecular orbital calculations as predictors of proton shifts, basic strengths, and reactivity[1]

BRIAN M. LYNCH,[2] ALLAN J. ROBERTSON,[3] AND JOHN G. K. WEBB[4]
Organic Chemistry Laboratory, Saint Francis Xavier University, Antigonish, Nova Scotia

Received June 17, 1968

A detailed series of molecular orbital calculations based on the HMO method has been made for the various possible ionic species of purine, pyrazolo(3,4-*d*)pyrimidine, v-triazolo(4,5-*d*)pyrimidine, and pyrazolo(3,4-*b*)pyridine. π-Electron densities and localization and delocalization energies for nucleophilic substitution have been derived.

The results are compared with the observed proton chemical shifts in the conjugate acids of these molecules, with the relative rates of nucleophilic piperidinodehalogenations in the neutral molecules, and with the ionization constants.

It is concluded that it is possible to reconcile the calculations with experimental results for the various positions within a six-membered ring, but that positions in six- and five-membered rings cannot be directly compared. The electron densities seem to be of little value in correlating the observed ionization patterns of purines and their analogues.

Canadian Journal of Chemistry, **47**, 1129 (1969)

Introduction

As a consequence of their involvement as determinants of biological processes, the purine components of nucleic acids and their analogues have received much attention from synthetic organic chemists (1, 2) and from quantum chemists (3). However, there is little constructive interaction between the two groups: uncritical applications of molecular orbital (MO) calculations by synthetic chemists (4) often suggest that the calculations have little value, while defences of the value of simple MO treatments (5, 6) often quote irrelevant or incorrect supporting data. In this paper, we seek to show where simple MO calculations on appropriate ionic species of purines and their analogues are of correlative or predictive value, and also to indicate areas where the simple approach gives predictions at variance with experimental facts.

We have chosen three areas where detailed comparisons between theory and experiment are possible: calculated π-electron densities and observed proton chemical shifts (cf. 7, 8); π-electron densities and ionization constants (cf. 9); and localization energies (10) and delocalization energies (11) for nucleophilic substitution as compared with observed activation parameters for piperidinodehalogenations (cf. 12).

Results and Discussion

Molecular Orbital Calculations

The simple Hückel method (HMO) (13) was used, employing a standard matrix diagonalization program with an IBM 1620 40K computer (14, 15). The following electronegativity parameters h (16) were used: carbon and anionic nitrogen, 0; pyridine-type nitrogen, +0.5; pyridinium- and pyrazole-type NH, +1. All resonance integrals were assumed equal to β_{CC}. The output of the calculations consisted of the orbital energies, π-electron densities, and π-bond orders. ω-Technique calculations (17), using $\omega = 1.4$, were performed using the electron densities from the HMO calculations as input.

Localization energies for nucleophilic substitution at the various positions were evaluated by subtraction of the energies of electrons in the occupied orbitals in the residual systems from those in the parent species, and delocalization energies for nucleophilic piperidinodechlorinations were evaluated following Beltrame *et al.* (11).

The results for purine **1** and the purine analogues 1*H*-pyrazolo(3,4-*d*)pyrimidine **2**, 3*H*-v-triazolo(4,5-*d*)pyrimidine **3**, and 1*H*-pyrazolo-

π-Electron Densities and Proton Chemical Shifts

Previous work has established qualitative and quantitative correlations between proton chemical shifts and HMO π-electron densities for pyridinium and diazolium ions (7), and for the amino protons in carbocyclic and heterocyclic aromatic amines (8), and Black, Brown, and Heffernan (18) have analyzed the proton chemical shifts of a series of heteroaromatic nitrogen compounds, establishing "empirical" electron density distributions after allowing for the effects of ring currents, lone-pair anisotropy, and non-adjacent charges.

Although the proton and carbon-13 magnetic resonance spectra of purine have received considerable attention (19–22), little success has been achieved in correlating electron densities directly with the proton shifts. In view of the fairly wide range of proton shifts available in the series purine, pyrazolo(3,4-*d*)pyrimidine, and v-triazolo(4,5-*d*-)pyrimidine, and also pyrazolo-(3,4-*b*)pyridine (23), we have attempted such a correlation for the protons in the six-membered rings employing the proton chemical shifts observed in trifluoroacetic acid-*d* (in this solvent, many paramagnetic effects of n–π^* transitions will disappear (cf. 7)), and using ring-current corrections of 0.20 p.p.m. for the influence of the five-membered rings at positions α to them, and a further correction of 0.30 p.p.m. for the influence of a pyridine-type nitrogen in a position *peri* to protons α to a five-membered ring. We have used π-electron densities appropriate to models assuming that protonation has occurred at positions analogous to position-1 of purine (which we expect to be the predominant basic site (cf. 9, 21)).

We find that the chemical shifts of the protons in this series of compounds are linearly related to the calculated electron densities, and the correlation coefficient meets the acceptable standard of $r = 0.96$, set by Jaffe (24): the least-squares regression line is defined by

$$\delta = 14.86 - 6.64q\pi \; (r = 0.972)$$

and the average deviation is ca. 0.1 p.p.m. (see Table IV, and Fig. 1).

Thus, the calculated HMO π-electron densities for assumed models of the conjugate acids of purine and purine analogues are excellent predictors for the proton chemical shifts within the six-membered rings. Since very few points are available for correlations within the five-membered rings, no analysis was made in these instances. We point out, however, that the proton shifts are well downfield from the values predicted from the calculated electron densities using the regression line given above, suggesting that the deshielding effect of the ring current in the six-membered ring on protons in five-membered rings is significantly greater than 0.20 p.p.m. (cf. 18).

MO Quantities and Ionization Behavior

As Clark and Perrin (25) have noted, many difficulties beset quantitative correlations of the base strengths of nitrogen heterocycles with MO quantities, although there are correlations between pK_a and electron density at nitrogen with aza-derivatives of alternant hydrocarbons and with polycyclic aromatic amines (26, 27). Thus, although the total HMO π-electron densities at the nitrogen atoms in the pyrimidine rings of the neutral molecules of pyrazolo(3,4-*d*)pyrimidine, purine, and 3*H*-v-triazolo(4,5-*d*)-pyrimidine decrease in the same order as the basic strengths of these compounds (electron densities: 2.491, 2.480, 2.473 (cf. Table I) pK_a of cations: 2.8, 2.4, ca. −0.1), the absolute changes are very small and may have little significance.

Nakajima and the Pullmans (28, 29) have suggested that correlations between relative SCF-MO ionization potentials for the lone-pair electrons on ring nitrogen atoms and pK_a values, which are observed for other nitrogen heterocyclic compounds, allow predictions of the basic strengths of purines and their analogues. We find that these predictions are of very limited

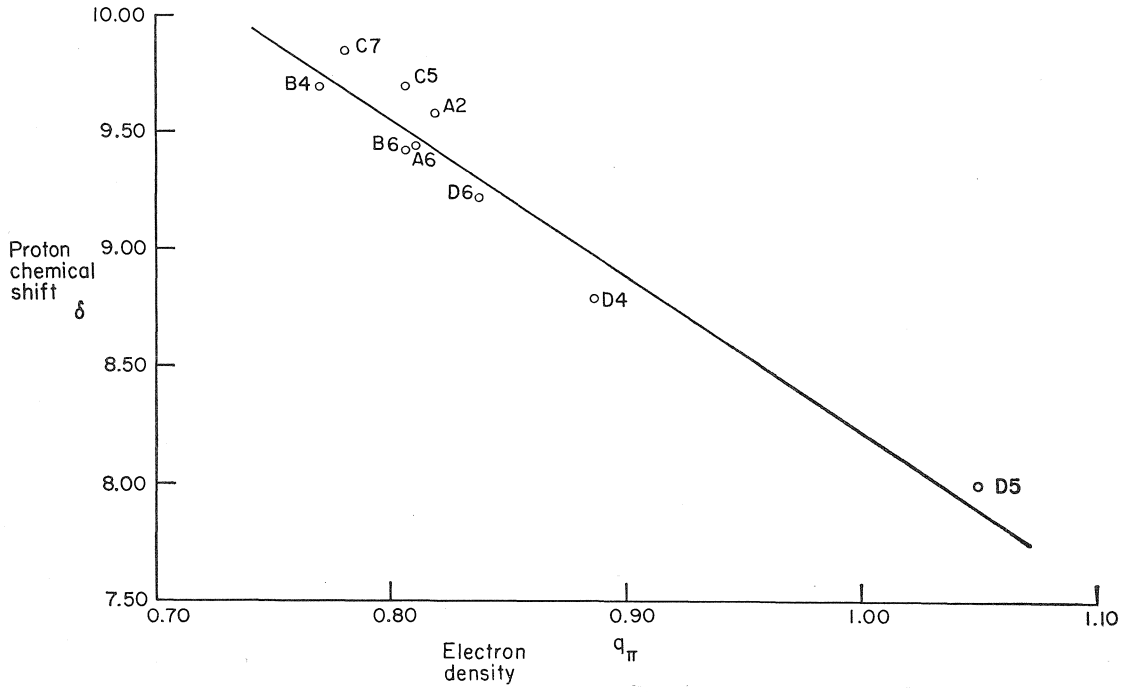

FIG. 1. Plot of π-electron density vs. corrected proton chemical shift. A, Purine; B, 1-methylpyrazolo(3,4-*d*)pyrimidine; C, 3*H*-v-Triazolo(4,5-*d*)pyrimidine; D, 1-methylpyrazolo(3,4-*b*)pyridine. Numerical suffixes refer to positions of protons.

value: although there is a significant correlation between the relative ionization potential and pK_a for purine and some aminopurines ($r = 0.984$) (29), use of the regression line to predict the pK_as of the cations of 4-aminopyrazolo(3,4-*d*)pyrimidine (cf. 9), v-triazolo(4,5-*d*)pyrimidine (30), and its 7-amino derivative results in spectacular failure (the respective values (predicted, found) are: 3.14, 4.59; 1.31, −0.10; 3.05, 2.84). Although the aminopyrazolo pyrimidine and the aminotriazolopyrimidine are predicted to have almost identical pK_a values (their relative ionization potentials are quoted as −1.67 and −1.65 e.V. (29)), the actual values differ by almost two units (see Table V, also (9)).

Further, although it is quite probable that all three basic sites in purine are protonated to some extent (9, 21), the Nakajima–Pullman treatment uses the existence of very small differences in relative ionization potentials to predict preferential basic centers, although as Table V demonstrates, very small differences in relative ionization potentials are accompanied by large variations in actual basic strength.

In view of the failure of the Nakajima–Pullman approach in these examples, we must conclude that calculations in terms of the π-electron approximation do not enable us to predict the base strengths of purines or their analogues (cf. 32).

MO Quantities and Nucleophilic Substitutions

As Pullman (33) has pointed out, π-electron densities in heterocyclic rings often give no indication of the relative reactivities of different positions, and it might be expected that calculations of localization energies would be of greater significance. Pullman and Pullman's calculations of these quantities for the neutral molecules of purine, pyrazolo(3,4-*d*)pyrimidine, and v-triazolo(4,5-*d*)pyrimidine might therefore be expected to be of correlative value for the rates of nucleophilic substitution in such molecules.

One difficulty in a direct correlation has been pointed out by Sutcliffe and Robins (4), since the nature of the reacting species may change with the pH of the reaction medium, and realistic localization energies should take these

variations into account. Robins and Sutcliffe were able to give excellent qualitative explanations of apparent inconsistencies in the order of reactivity of the 2-, 6-, and 8-positions in chloropurines and their 7- or 9-alkyl derivatives by postulating cation or anion formation at the appropriate pH as reactivity-controlling factors. Recent kinetic studies of nucleophilic substitutions in 9-alkylchloropurines and chloropurines by Barlin and Chapman (12*a*) and by Barlin (12*b*) show that these explanations are well founded.

The localization energies for nucleophilic attack at the 6- and 8-positions in neutral purine were evaluated by Pullman (3, 33), and these results (suggesting virtually equivalent reactivities for these positions) are consistent with Barlin and Chapman's findings for the piperidinodechlorinations of 9-methyl-6- and 8-chloropurines (12*a*). It is likely that this agreement is an artifact of the parameters used in the calculation (the localization energy will depend upon the choice of resonance integral for the C_8—N_9 bond), and direct comparison of localization energies for five- and six-membered rings is a risky procedure. Evidence regarding this point is available from Barlin's study (34) of nucleophilic piperidinodebrominations of

C: 3H-v-Triazolo(4,5-d)pyrimidine				
	Position:		7	
Neutral molecule			2.053	

bromoazoles. There is a reasonable correspondence between calculated HMO localization energies (35) and observed activation energies (the ratio is 0.16 ± 0.02), but the ratio for the analogous 2-substitution in pyridine is 0.11. Further, the localization energy for nucleophilic 4-substitution in 2-methyltetrazole is −2.65β and the activation energy 18.7 Kcal, while the localization energy for 2-substitution in pyridine is −2.35β, and the activation energy 21.8 Kcal.

It is therefore probable that direct comparisons in calculated localization energies for 6- and 8-positions are not meaningful.

The changes in relative localization energies accompanying anion formation (see Table II) are as expected, with the value at the 8-position increasing by 0.3β, with little effect at the 2- and 6-positions. Thus, the experimental activation energies for nucleophilic ethoxydechlorination of 9-methyl chloropurines and for the chloropurines (which will exist entirely as anions under the reaction conditions) differ by 11.5 Kcal for the 2-isomer, by 9.8 Kcal for the 6-isomer, but by 17.2 Kcal for the 8-isomer.

TABLE III

Delocalization energies (11) for nucleophilic piperidinodechlorinations*

Compound	Delocalization energy (units of −β)
2-Chloropurine	1.839
6-Chloropurine	1.734
8-Chloropurine	1.826
4-Chloro-1*H*-pyrazolo(3,4-*d*)pyrimidine	1.689
6-Chloro-1*H*-pyrazolo(3,4-*d*)pyrimidine	1.811
7-Chloro-3*H*-v-triazolo(4,5-*d*)pyrimidine	1.680
5-Chloro-3*H*-v-triazolo(4,5-*d*)pyrimidine	1.807

*The following parameters were employed: $h_{NH} = +1$, $h_N = +\frac{1}{2}$, $h_{Cl} = +1$, h for pseudoatom $= -0.4$. All resonance integrals are equal to β_{CC} except $\beta_{C-Cl} = 0.45\ \beta_{CC}$.

Localization energies corresponding to various protonated species (Table II) are relevant to Robins' findings (cf. 2) of selective nucleophilic replacement of 6,8-dichloropurine at the 8-position in aqueous acid solution (where 7-protonation is postulated), and also of 6-amino-2,8-dichloropurine under similar conditions to yield 6-amino-8-chloro-2-hydroxypurine (where 1-protonation seems probable by analogy with adenine).

Within the pyrimidine ring of purine and its aza-analogues, direct comparison of reactivities towards nucleophilic substitution with calculated localization energies should be acceptable. Barlin and Chapman (12*a*) have examined the kinetics of piperidinodechlorinations of 9-methyl-2- and 6-chloropurines in 99.8% ethanol, using classical titrimetry, and we have examined analogous reactions with 1-substituted 4-chloropyrazolo(3,4-*d*)pyrimidine and 3-phenyl-7-chloro-v-triazolo(4,5-*d*)pyrimidine in 99.9% methanol, where we have used ultraviolet spectrophotometry to follow the rates (36). solvents should be closely comparable in their effects, and Table VI shows that the effects of *N*-methyl and *N*-phenyl groups are similar. The effects of substituents in the *N*-phenyl moiety, and the rate-retarding influence of a 6-methyl group, are as expected for a normal nucleophilic substitution. These reactions, therefore, provide a series establishing the effects of annelation of five-membered rings on the reactivity of the pyrimidine ring. The enthalpies of activation for these reactions and the free energies of activation were compared with the following HMO quantities for the relevant positions in the neutral molecules of the three annelated pyrimidines: (*a*) the HMO π-electron

densities q_π (HMO), (*b*) ω-technique π-electron densities (Table I), (*c*) localization energies for nucleophilic substitution (Table II), and (*d*) delocalization energies (11) (Table III) for piperidinodechlorination. Least-squares regression lines were drawn relating the experimental energy parameters to these quantities; slopes, intercepts, and correlation coefficients are given in Table VII, and illustrated in Fig. 2. Significant correlations are found between the free energies of activation or enthalpies of activation and the ω-technique electron densities, and also the localization and delocalization energies. The delocalization energy calculations and the ω-technique electron densities would predict the experimentally observed order of reactivities.

We conclude that simple HMO calculations can mirror reality in nucleophilic substitution reactions in purines and their analogues, providing that comparisons of the same fundamental ring system are being made.

Experimental

General

Melting points were determined using a Fisher–Johns block or a Kofler Heizbank, and are uncorrected. Proton magnetic resonance spectra were recorded for dilute solutions (2% w/w) using a Varian A-60A spectrometer; signals are expressed in parts per million downfield from

*Literature values are given in parentheses.

tetramethylsilane, present as internal reference; signal positions were unaffected by fivefold dilution. Trifluoroacetic acid-*d* was supplied by Merck, Sharp, and Dohme, Montreal. Ultraviolet spectroscopic measurements were made using a Beckman DK-2A ratio-recording spectrophotometer (for pK_a determinations) or a Hitachi Perkin–Elmer model 139 spectrophotometer (for kinetic measurements). A Radiometer model 4 pH meter was used for standardization of buffer solutions.

Sources of Materials

1-Methylpyrazolo(3,4-d)pyrimidine, m.p. 125°, was prepared by desulfurization of the corresponding thio-compound using Raney nickel (37).

1-Substituted-4-halopyrazolo(3,4-d)pyrimidines were prepared *via* cyclization of 1-substituted-5-amino-4-pyrazolo-carboxamides to 1-substituted-4-hydroxypyrazolo(3,4-*d*) pyrimidines followed by treatment with the appropriate phosphorus oxyhalide, using the general method developed by Robins and Cheng (37). The corresponding 1-substituted-4-piperidinopyrazolo (3,4-*d*) pyrimidines were prepared by a standard nucleophilic displacement reaction using an excess of piperidine in methanol solvent, following the general conditions used previously (37, 38). The reaction products were crystallized from methanol. Physical constants for these compounds are given in Table VIII. Proton magnetic resonance signals (in two solvents, deuteriochloroform and trifluoroacetic acid-*d*) were completely consistent with the assigned structures (39), and revealed no impurities. The intensity ratios of the various proton signals, established by electronic integration, were also in agreement with the assigned structures. It is considered that the spectroscopic evidence provides more satisfactory confirmation of structures than conventional element analyses, in view of difficulties in analysis often encountered with polyaza-heterocyclic compounds.

3-Phenyl-7-chloro-v-triazolo(4,5-d)pyrimidine was prepared as follows: 4,6-dichloro-5-aminopyrimidine (Aldrich Chemical Co.) (10 g) was dissolved in acetic acid (75 ml), aniline (6.5 g) was added, and the mixture was heated under reflux for 30 min. After cooling, water (100 ml) was added and the reaction mixture was cooled to 0°. A solution of sodium nitrite (10 g) in water (100 ml), also at 0°, was added rapidly (2 min) and the resulting precipitate was collected and twice crystallized from petroleum (b.p. 27–55°), yielding 3-phenyl-7-chloro-v-triazolo(4,5-*d*)pyrimidine (5.0 g), m.p. 117–118° (lit. 118–119° (40)) (ultraviolet absorption in methanol: λ_{max} 235.5 nm, log ε 4.51).

3-Phenyl-7-piperidino-v-triazolo(4,5-d)pyrimidine, m.p. 85° (ultraviolet absorption in methanol: λ_{max} 246, 308.5 nm; log ε 4.35, 4.28), was obtained by displacement of chlorine from the chloro precursor using piperidine in methanol (cf. 37, 38), and was crystallized from methanol.

Substituted-amino-v-triazolo(4,5-d)pyrimidines listed in Table V were provided through the courtesy of the Cancer Chemotherapy National Service Center.

3H-v-triazolo(4,5-d)pyrimidine, m.p. 174°, was prepared from 4,5-diaminopyrimidine and butyl nitrite (Albert (3)). The proton magnetic resonance spectra of the triazolopyrimidines (39) were consistent with their postulated structures.

1-Methyl-pyrazolo(3,4-b)pyridine, m.p. ca. −10°, was prepared by dediazoniation (41) of the diazonium salt from 1-methyl-3-aminopyrazolo (3,4-*b*) pyridine, prepared by treatment of 2-chloronicotinonitrile with methylhydrazine (42). Its proton magnetic resonance spectrum in trifluoroacetic acid-*d* and in deuteriochloroform was in complete accord with the assigned structure (42).

Molecular Orbital Calculations

Detailed results are available on request, as are listings of the standard HMO programs and the ω-technique program (the averaging method suggested by Ettinger (43) was used).

pK_a Determinations of (substituted amino)triazolopyrimidines

A method based on differential ultraviolet spectrophotometry was used (Lynch *et al.* (9)). Measurements were made at 20°. Although the ionization steps of the triazolopyrimidines overlap significantly, the absorption spectra of the neutral and the anionic species are virtually

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

identical, and differ from those of the cationic species. The spread of pK_a values obtained using buffers of varying pH was 0.20 (i.e. ± 0.10 from the mean). Full details of the ultraviolet absorption spectra of the various ionic species are available on request. The results are assembled in Table V.

Kinetics of Piperidinodehalogenations

The reactions between the various halogen derivatives of pyrazolo(3,4-*d*)pyrimidine and v-triazolo(4,5-*d*)pyrimidine with excess piperidine in methanol (99.9%; Fisher Scientific Co.) were followed by ultraviolet spectrophotometry. The increase in absorbance of the solutions in the region of maximum ultraviolet absorbance of the reaction products was followed as a function of time.

All reactions were carried out in standardized 500 ml flasks immersed in a constant temperature bath regulated to $\pm 0.02°$ using a Bronwill constant temperature circulator–controller. Samples were withdrawn at various times, rapidly diluted to an appropriate concentration and their ultraviolet absorbance was measured. Since all reactions were carried out above 25° and the cell compartment temperature was 20°, cooling accompanied the dilution procedure and reactions were arrested while the absorbance measurements were in progress. For each reaction and reaction temperature, at least ten samples were taken, and in almost all cases reactions were followed to 85% of completion. The "infinite-time" readings (ten half-lives) coincided within 3% with the values expected from the known ultraviolet absorption spectra of the reaction products.

Rate constants were determined from the concentrations of reactants and products (as deduced from their known ultraviolet absorptions) and time measurements using the appropriate second-order reaction expression (12), employing a Fortran II program. The correlation coefficients linking the time and the appropriate term involving the concentrations of the reactants and products exceeded 0.99 in all examples. Typical initial concentrations were: pyrazolopyrimidine, $2 \times 10^{-4} M$; piperidine, $1 \times 10^{-3} M$. Reactions were carried out either in duplicate at three temperatures, or as individual measurements at five temperatures ranging from 25° to 45°.

A Fortran II program was used to establish the activation energies from the linear regression equations linking the logarithms of the rate constants to the reciprocal of the Kelvin temperatures. The correlation coefficients for these regressions exceeded 0.99. The activation parameters $\Delta G^{\neq}$, $\Delta H^{\neq}$, and $\Delta S^{\neq}$ were calculated from the rate constants at 25° and the activation energies, and the values of these parameters, together with the rate constants at 25°, are listed in Table VI. Detailed results, listing the rate constants at various temperatures, are available on request.

Conclusions

Simple HMO calculations are very successful in correlating proton chemical shifts in the conjugate acids of purine and its analogues, and we are currently engaged in further synthetic work to test the scope of these correlations. Further examples of linear relationships linking π-electron densities to corrected chemical shifts have been found for the neutral molecules of several azaindenes prepared in recent years by the research groups of Potts (44) and W. W. Paudler (45) and we hope to present a complete analysis of these results in a later paper in the present series.

In nucleophilic substitution reactions of purine analogues, the correlation coefficients linking activation parameters to the ω-technique electron densities and to the delocalization energies are highly significant, suggesting, for example, that the regression equations could be used with some confidence to predict the rates of nucleophilic piperidinodehalogenations of 1-substituted-6-halopyrazolo(3,4-*d*)pyrimidines and of 3-substituted-5-halo-v-triazolo(4,5-*d*)pyrimidines.

Acknowledgments

We are grateful for support from the National Research Council of Canada through operating and equipment grants to B.M.L., and for a Scholarship to J.G.K.W., and also for grants-in-aid to this university for computing facilities. Supplies of triazolopyrimidines from the Cancer Chemotherapy National Service Center of the National Institutes of Health, Bethesda, Maryland are gratefully acknowledged. It is a pleasure to acknowledge many valuable discussions with Professor Roland K. Robins (University of Utah).

Isolation and characterization of (+)-sesamin and β-cyclopyrethrosin from pyrethrum flowers

RAYMOND W. DOSKOTCH AND FAROUK S. EL-FERALY
College of Pharmacy, The Ohio State University, Columbus, Ohio 43210
Received September 30, 1968

Two compounds isolated from the alcoholic extract of pyrethrum flowers (*Chrysanthemum cinerariaefolium* Visiani) have been characterized as the lignan, (+)-sesamin (**2**) by physical methods and by direct comparison with a known sample and the sesquiterpene, β-cyclopyrethrosin (**3**) by physical methods and conversion to the known ketone **6**.

Canadian Journal of Chemistry, 47, 1139 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

To date, the only reported sesquiterpene from the flowering heads of *Chrysanthemum cinerariaefolium* Visiani is pyrethrosin (**1**) whose gross structure was determined by Barton *et al.* (1) and whose stereochemical assignments were given by Iriuchijima and Tamura (2). We wish to report the isolation and identification of a new natural occurring sesquiterpene that has been known as one of two inseparable isomers obtained from pyrethrosin (**1**) by chemical means. Our study originated in connection with another investigation for which pyrethrosin was required and a fractionation method was devised for its isolation from the natural source. One particular lot of plant material did not yield any of the desired substance but instead gave two crystalline fractions, which are the subject of this note.

The ethanolic residue from the percolation of the flowers was partitioned between chloroform and water, and the chloroform solubles were partitioned between petroleum ether and 10% aqueous methanol. The residue from the methanolic phase was chromatographed on silicic acid with chloroform as the eluting agent. The first crystalline fraction yielded a substance which showed an ultraviolet (u.v.) absorption spectrum typical of an oxygenated benzene derivative and a nuclear magnetic resonance (n.m.r.) spectrum identical to that of (+)-sesamin (**2**) (3). A direct comparison with a sample of (+)-sesamin previously isolated in our laboratory from *Zanthoxylum martinicense* DC. (4) showed them to give superimposable infrared (i.r.) and u.v. spectra and an undepressed mixture m.p. Although (+)-sesamin (**2**) had been isolated from the roots of *Chrysanthemum frutescens* L. (5) it has not been previously obtained from pyrethrum flowers. It is of interest to note that the source of the pyrethrum insecticides also contains a compound known to have an important activity as a pyrethrum synergist (6).

The second crystalline fraction gave a compound, m.p. 166–167° that was shown by the physical and chemical evidence to follow to be β-cyclopyrethrosin (**3**). In the i.r. region it exhibited peaks (see Experimental) for an alcohol, an α,β′-unsaturated-γ-lactone, an acetate, and an unconjugated exocyclic olefin. The n.m.r. spectrum (Fig. 1) showed the presence of a pair of doublets at δ 6.12 (H_e) and 5.45 (H_d) coupled to H_c with constants $J = 3.1$ and 2.9 Hz, respectively. A triplet at δ 5.52 was assigned to the axial H_b proton coupled to two axial protons H_a and H_c (J = 10.3 and 10.3 Hz). The two protons of the isolated exocyclic methylene are found at δ 4.89 and 4.62 as broadened singlets due to allylic coupling. The sextet at δ 4.10 for the axial H_f proton results from interaction with the neighboring two axial and one equatorial hydrogens (J = 11.6, 11.6, and 3.7 Hz). The quartet at δ 3.60 (J = 10.2 and 5.0 Hz) was designated for the axial H_g proton coupled to an axial and an equatorial hydrogen. The alcoholic group must therefore have the β (equatorial) assignment.

The H_c proton located at about δ 2.8 shows clearly only one triplet of a trio of triplets as other protons mask it in that region. The removal of the alcoholic proton absorption at δ 2.59 by exchange with deuterium oxide revealed more clearly the H_c pattern. A first-order analysis of the pattern showed it to be an ABMN type resulting from interactions with the H_b, H_d, H_e, and H_f protons. An acetate methyl at δ 2.06 and a tertiary methyl at δ 0.87 completed the information derivable from the n.m.r. spectrum. The assignments were assisted by double irradiation

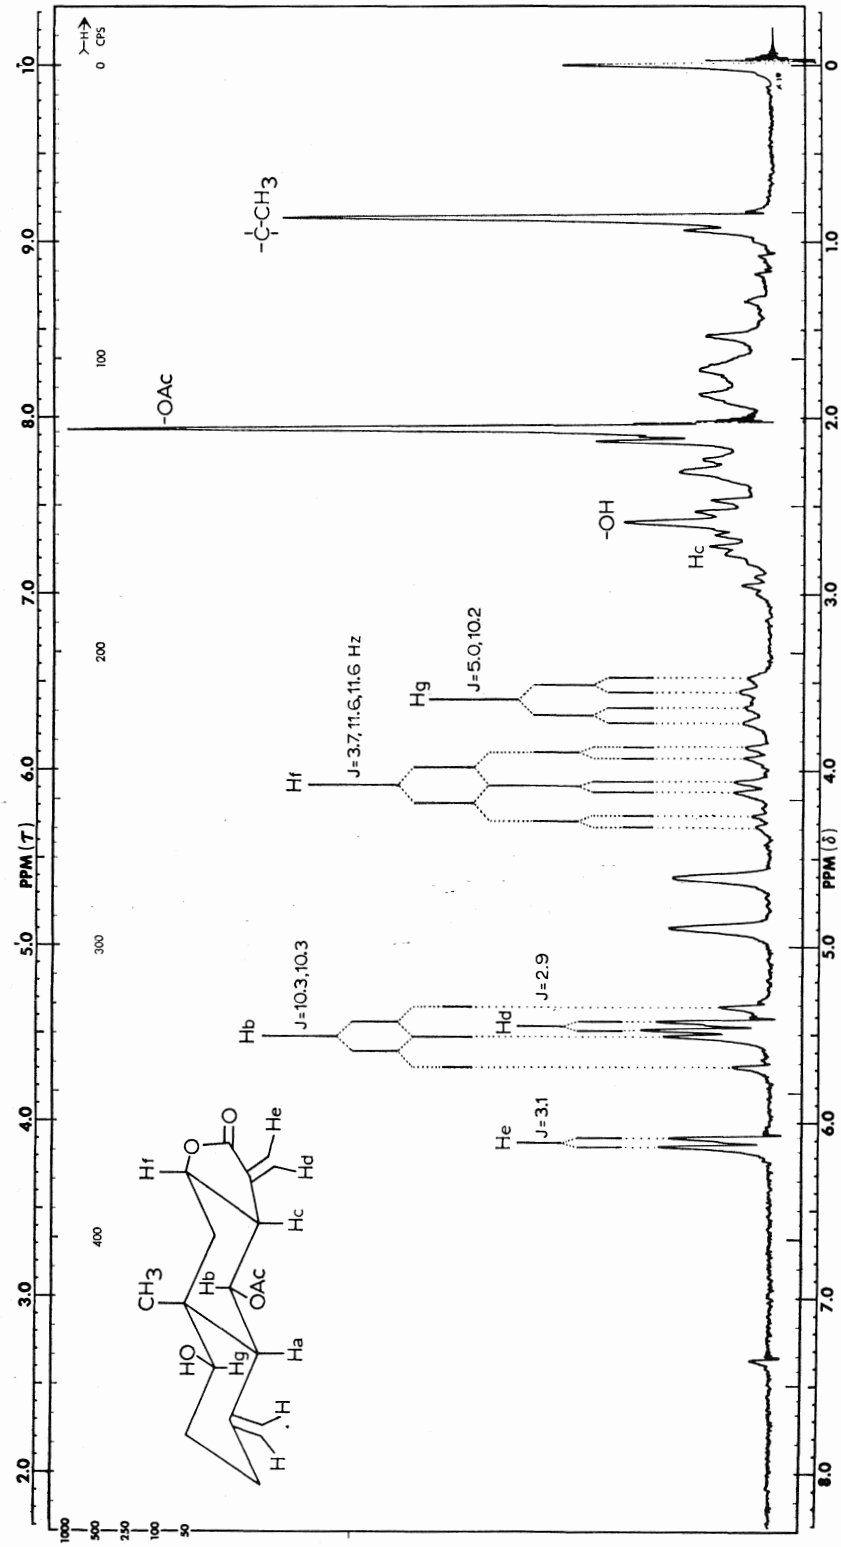

FIG. 1. The nuclear magnetic resonance spectrum of β-cyclopyrethrosin (3).

experiments and previously reported results (2), as well as changes in the spectrum for the derivatives.

The acetate **4** of **3** showed in the n.m.r. spectrum a six-proton singlet at δ 2.08 for the two acetate methyls and also the loss of the alcoholic proton from δ 2.59 and the shift of the quartet for H_g from δ 3.60 downfield to δ 4.84. The H_c trio of triplets became clearly visible in this derivative.

Hydrogenation of **3** over palladium on charcoal as catalyst yielded dihydro-β-cyclopyrethrosin (**5**). The pair of doublets for H_d and H_e were no longer present in the n.m.r. spectrum but a three-proton doublet at δ 1.17 (J = 7.0 Hz) for a secondary methyl appeared. The remainder of the spectrum was relatively unchanged except for the H_c pattern which because of masking by other peaks could not be clearly interpreted.

Oxidation of **5** with Jones' reagent (7) produced the known ketone **6** (2). A comparison of the i.r. and n.m.r. spectra, the optical rotation, and the m.p. of the two, confirmed their identity and established conclusively that the isolated substance was β-cyclopyrethrosin (**3**).

The possibility that the sesquiterpene **3** was an artifact resulting from the cyclization of pyrethrosin (**1**) had to be eliminated. The mixture of α-, β-, and possibly γ-cyclopyrethrosins that is obtained by cyclization with acid was subjected to the same column chromatographic separation as the fraction of the flower extract. No separation of the isomers was observed. β-Cyclopyrethrosin (**3**) is therefore the second reported sesquiterpene elaborated by *C. cinerariaefolium*.

Experimental

Melting points are uncorrected. Elemental analyses were determined by Joseph F. Alicino, Metuchen, New Jersey. Infrared (i.r.) spectra were determined at about 8–10% concentration in chloroform on a Perkin–Elmer Infracord 237 or 257 spectrophotometer. Ultraviolet spectra were obtained in methanol on a Cary model 15 spectrophotometer. The nuclear magnetic resonance (n.m.r.) spectra were obtained in deuteriochloroform with tetramethylsilane as internal standard, signals reported in δ (p.p.m.), and J in Hz units, using a Varian A-60A spectrometer equipped with the model V-6058A spin decoupler. Optical rotations were measured on a Zeiss–Winkel polarimeter or on a Jasco model ORD/UV-5 optical rotatory dispersion recorder in methanol.

Ethanol (95%) was U.S.P. grade; petroleum ether (b.p. 60–68°) was Skellysolve B and other solvents were A.R. grade. Silicic acid (100 mesh) was from Mallinckrodt Chemical Works, St. Louis; Celite 545 from Johns-Manville Corp., New York, and Silica Gel G from E. Merck, Darmstadt, Germany.

Isolation of (+)-Sesamin (2) and β-Cyclopyrethrosin (3)

The flowering heads (2.1 kg) of *Chrysanthemum cinerariaefolium* (Lot. no. LHC 2048, S. B. Penick and Co.) were percolated at room temperature with ethanol to exhaustion. The residue (290 g) remaining after removal of the solvent at reduced pressure and at 40° was partitioned between 1750 ml of chloroform and 500 ml of water. The interfacial solid was discarded and the chloroform phase shaken with 400 ml of water, dried (Na_2SO_4), and evaporated at reduced pressure. The chloroform residue (143 g) was partitioned between 2 l of 10% aqueous methanol and four 500 ml portions of petroleum ether. The combined petroleum ether extract was back-washed with 100 ml of 10% aqueous methanol and the pooled methanolic phase evaporated at reduced pressure to yield 90 g of residue.

A chromatographic column, 7 cm × 52 cm from 1 kg of silicic acid – Celite 545 (4:1), poured as a slurry in chloroform, was loaded with 45 g of the 10% aqueous methanol residue. Elution was with chloroform at a flow rate of 20 ml/h and 80 ml fractions were taken to dryness and weighed.

Fractions 36–38 (110 mg) on crystallization from ethanol gave 43 mg of (+)-sesamin (**2**), m.p. 122–123°; $[\alpha]_D^{25}$ +57.4° (*c*, 0.74 in chloroform); λ_{max}(MeOH) 236 mμ (log ε 4.09), 287 mμ (4.04), (lit. (4) m.p. 124–125°; $[\alpha]_D^{25}$ +57°; λ_{max}(MeOH) 236 mμ (log ε 4.09), 2.87 mμ (log ε 4.04)).

Fractions 65–72 (1.04 g) on crystallization from isopropyl ether – ethanol then 80% aqueous ethanol gave 720 mg of β-cyclopyrethrosin (**3**), m.p. 166–167°; $[\alpha]_D^{25}$ +58.2° (*c*, 0.49); $\lambda_{end\ abs.}$ 210 mμ (log ε 3.94); ν_{max} 3600 and 3490 cm^{-1} (hydroxyl), 1768 and 1674 cm^{-1} (α,β′-unsaturated-γ-lactone), 1734 cm^{-1} (acetate), 1657 and 914 cm^{-1} (olefinic methylene). The C—O—C stretching

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

for the lactone and acetate appears as a broad band between 1200–1260 cm^{-1}. The n.m.r. spectrum is shown in Fig. 1.

Anal. Calcd. for $C_{17}H_{22}O_5$: C, 66.65; H, 7.24. Found: C, 66.35; H, 7.21.

β-Cyclopyrethrosin Acetate 4

β-Cyclopyrethrosin (**3**) (100 mg) was dissolved in 1 ml of pyridine and 2 ml of acetic anhydride and allowed to stand overnight at room temperature. The excess acetic anhydride was decomposed by the addition of water and slight warming. Chloroform was added and the pyridine and acetic acid removed by extraction with water, dilute acid, base, and finally with water. Removal of the chloroform (Na_2SO_4 dried) by evaporation at reduced pressure left a residue (101 mg) which gave from 90% ethanol, 91 mg of colorless needles, m.p. 185–186°, $[\alpha]_D^{25}$ +45.7° (*c*, 0.405). The i.r. spectrum showed a double intensity peak at 1735 cm^{-1} (acetate) and no hydroxyl bands.

Anal. Calcd. for $C_{19}H_{24}O_6$: C, 65.50; H, 6.94. Found: C, 65.40; H, 7.03.

Dihydro-β-cyclopyrethrosin 5

β-Cyclopyrethrosin (**3**) (100 mg) was dissolved in 10 ml of absolute ethanol and added to a suspension of 60 mg of 5% Pd on charcoal presaturated with hydrogen in 10 ml of absolute ethanol. At room temperature and atmospheric pressure the uptake of one mole equivalent of hydrogen was rapid and the reaction was stopped. Removal of the catalyst by filtration and evaporation of the solvent left a crystalline residue (105 mg) that on recrystallization from isopropyl ether – ethanol gave colorless needles, m.p. 212–213°; $[\alpha]_D^{25}$ +72.4° (*c*, 0.235); ν_{max} 3600 and 3485 cm^{-1} (hydroxyl), 1772 cm^{-1} (γ-lactone), 1730 cm^{-1} (acetate), and 1650, 910 cm^{-1} (exocyclic olefin).

Anal. Calcd. for $C_{17}H_{24}O_5$: C, 66.21; H, 7.85. Found: C, 66.00; H, 7.97.

Oxidation of Dihydro-β-cyclopyrethrosin (5) to Ketone 6

Dihydro-β-cyclopyrethrosin (**5**) (80 mg) dissolved in 5 ml of acetone was treated with 1 ml of Jones' reagent (7) for 5 min at room temperature. Methanol was added to destroy the excess reagent and the reaction mixture filtered. The filtrate was treated with 25 ml of 5% $NaHCO_3$ and extracted three times with 50 ml portions of ether. The combined ether extract was washed with water, dried (Na_2SO_4), and evaporated to give an oil (70 mg) that crystallized from 80% ethanol as colorless needles (59 mg). These gave a positive Zimmerman's test (8), m.p. 166–167°, (lit. (2), m.p. 168–168.5°); $[\alpha]_D^{25}$ +135.0° (*c*, 0.10); λ_{max}(MeOH) 270 mμ (ε 62) (as shoulder); ν_{max} 1780 cm^{-1} (γ-lactone), 1735 cm^{-1} (acetate), 1712 cm^{-1} (cyclohexanone), and 1660 and 910 cm^{-1} (exocyclic olefin). A comparison of the i.r. spectrum with the known spectrum[1] (both in Nujol) showed no differences. The n.m.r. spectra were likewise comparable.

Anal. Calcd. for $C_{17}H_{22}O_5$: C, 66.65; H, 7.24. Found: C, 66.66; H, 7.15.

Acid Cyclization of Pyrethrosin 1

Five drops of concentrated hydrochloric acid were added to 70 mg of pyrethrosin (**1**) dissolved in 1 ml of chloroform and diluted with 10 ml of ether and the mixture was stirred 5 min. The solution when analyzed on Silica Gel G t.l.c. plates, employing 5% acetone in chloroform as developing solvent and then spraying with dilute aqueous $KMnO_4$, showed that pyrethrosin (R_f 0.05) was absent. A new single spot at R_f 0.3 (same as β-cyclopyrethrosin) was present. The n.m.r. spectrum of this material showed it to be a mixture. The contribution of β-cyclopyrethrosin to the spectrum was taken as evidence for its presence. Chromatography of the mixture on 10 g of silicic acid – Celite 545 (4:1) with chloroform as eluting solvent resulted in recovery of the unresolved mixture.

Thermal and photolytic decomposition of *N*-benzhydrylidene azidobenzhydrylamine

N. KOGA, G. KOGA, AND J.-P. ANSELME[1]
Department of Chemistry, University of Massachusetts, Boston, Massachusetts 02116

Received November 1, 1968

The thermal and photolytic decomposition of *N*-benzhydrylidene azidobenzhydrylamine (**2**) in aromatic solvents gave *N*-phenyl-*N'*-benzhydrylidene benzamidine (**5**); no benzophenone azine could be isolated. Photolysis in methanol gave no **5** but instead benzophenone dimethylketal and ammonium azide were obtained. Attempts to trap the presumed nitrene intermediate with cyclohexene gave only **5**. Thermal decomposition in decalin gave *N*-benzhydryl benzophenone imine (**9**). The possible mechanisms of these transformations are presented.

Canadian Journal of Chemistry, 47, 1143 (1969)

The formation of *N*-benzhydrylidene azidobenzhydrylamine (**2**) from the reaction of lithio benzophenone imine and tosyl azide has been reported recently (1). This result involves the dimerization of the lithium salt followed by the *diazo transfer* reaction (2) to the resulting dianion (**1**) to give **2**.

The assignment of structure **2** was based on its elemental analysis, its molecular weight, and its reactions (1). We would like to report now its photolytic and thermal decompositions, the results of which confirm further the assigned structure.

Triarylmethyl azides, upon the loss of nitrogen, undergo the Stieglitz rearrangement (3) to give the corresponding imines, possibly via a discrete nitrene intermediate (**3**) or through a concerted displacement (3, 4). Two products **5** and **6** could arise from the rearrangement of **2**. However, when a solution of **2** in benzene was irradiated with a 200 W high-pressure mercury lamp in a quartz apparatus, the only product isolated in 83% yield was a canary yellow solid, m.p. 138–140°. Its identity as *N*-phenyl-*N'*-benzhydrylidene benzamidine (**5**) was proved by its elemental analysis, its infrared (i.r.) spectrum, and by comparison with an authentic sample prepared from *N*-phenyl benzimidoyl chloride and benzophenone imine.

The addition of benzophenone had no effect on the nature or the yield of the products. No evidence for the formation of benzophenone azine

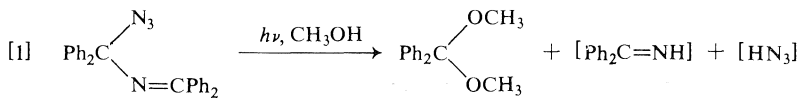
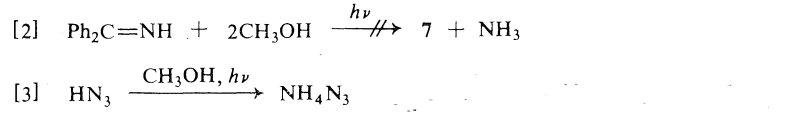
(**6**) could be obtained. The absence of the product resulting from nitrogen migration (hetero rearrangement (5)) recalls the similar behavior of the so-called "rigid" azides (6). An attempt to trap the presumed nitrene intermediate was made by carrying out the photolysis in cyclohexene as solvent. However, **5** was the only product isolated in 79% yield. None of the anticipated bicyclic aziridine could be detected.

When methanol was used as a solvent, the photo-induced decomposition of **2** followed a completely different course. No **5** was formed; instead, benzophenone dimethylketal (**7**) and ammonium azide were formed. Both compounds were identified by the comparison of their i.r. spectra with those of authentic samples. The reaction of **2** with methanol, under identical conditions (time and temperature), in the absence of light gave **7** but in much lower yield; no ammonium azide could be detected. Thus, the effect of light on the course of the reaction is unquestionable although it is difficult at this time to decide in which step it is involved. The absence of ammonium azide in the control run indicates that the light-induced decomposition of hydrazoic acid is the source of ammonium azide (7). The irradiation of benzophenone imine with methanol did not give any appreciable amount of the ketal. A solution of **5** in methanol heated to 40–45° for 6 h did not give any benzophenone dimethylketal (**7**). Irradiation of this solution under the same conditions failed to give any **7**. Irradiation of benzophenone imine (**10**) in methanol also failed to produce any **7**, even in the presence of hydrazoic acid; ammonium azide, traces of benzophenone, and unreacted benzophenone imine were obtained. The formation of **7** and ammonium azide may be summarized as shown in the following equations:



[1] $Ph_2C(N_3)(N{=}CPh_2) \xrightarrow{h\nu,\ CH_3OH} Ph_2C(OCH_3)_2 + [Ph_2C{=}NH] + [HN_3]$

7 **10**

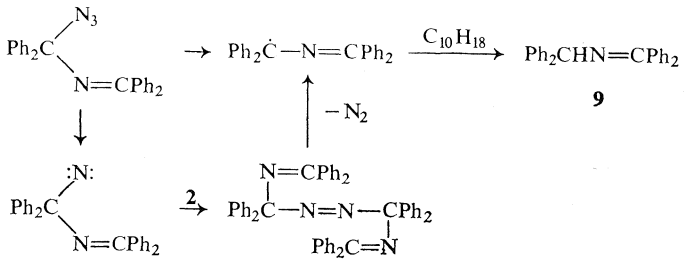


[2] $Ph_2C{=}NH + 2CH_3OH \xrightarrow{h\nu} 7 + NH_3$

[3] $HN_3 \xrightarrow{CH_3OH,\ h\nu} NH_4N_3$

The thermal decomposition of **2** in naphthalene at 190° was not as clean as the photolysis. A black tarry mass was obtained after removal of the naphthalene and only **5** could be isolated in 23% yield; none of the azine (**6**) could be detected. The pyrolysis of **2** in benzophenone azine (**6**) at 190° gave a tarry residue from which **5** and **6** were obtained by chromatography on alumina. The tarry product of the pyrolysis of **2** in **5** did not yield any benzophenone azine. In decalin, the thermal decomposition at 190° followed a different path and from the black tarry pyrolyzate, a 20% yield of a solid was obtained. It was identified as *N*-benzhydryl benzophenone imine (**9**) by comparison with an authentic sample. The formation of **9** may be viewed as arising via the formation of the azo compound **8** or less likely via the homolytic cleavage of the C—N_3 bond of **2** (8). Although the rearrangement product (**5**) is stable thermally up to 200°, the reaction of **5** with **2** at 200° gave a black mass. This may account for the absence of **5** in the thermolysis in decalin and its low yield from the thermolysis in naphthalene.

The fact that *no* benzophenone azine (**6**) was detected from the products of the decomposition of **2** is reminiscent of the failure of *N*,*N*-dialkylcarbonyl azides and of azidoformates to undergo Curtius-type rearrangement (9). In all these cases, the migrating groups are anchored by hetero atoms such as nitrogen or oxygen. The transition state for the migration of a phenyl group to an electron-deficient center such as a carbonium ion has been described (10). A similar picture can be used to rationalize the migration of the phenyl group in the rearrangement of **2** to give **5**. However, a major difference becomes apparent when the transition state for the migration of —N=CPh_2 is visualized. The presence of a nonbonded pair of electrons on the nitrogen may result in the electrostatic repulsion with the non-



8

bonded electrons of the migration terminus. This could slow down the rearrangement and would explain the absence of benzophenone azine.[2]

Experimental

All melting points are uncorrected. Infrared (i.r.) spectra were obtained on a Perkin–Elmer Infracord. The photolyses were carried out under nitrogen in a quartz apparatus similar to that described by De Boer *et al.* (11). A Hanovia 200 W high-pressure mercury lamp was used as the light source.

Photolysis of 2 in Benzene

A solution of 2.0 g (5 mmoles) of **2** in 175 ml of benzene was photolyzed for 6 h. The maximum temperature during the photolysis was 40–45°. Removal of the solvent left a crude oil which crystallized. Recrystallization from cyclohexane gave 1.5 g (83%) of a fine yellow powder, m.p. 138–140°. Its i.r. spectrum exhibited aromatic absorptions at normal positions and a cluster of four closely spaced bands at 1645, 1610, 1585, and 1570 cm^{-1}. It was identical to the spectrum of an authentic sample of **5** (see below) and the mixture m.p. was not depressed.

Anal. Calcd. for $C_{26}H_{20}N_2$: C, 86.66; H, 5.55; N, 7.76. Found: C, 86.76; H, 5.64; N, 7.55.

N-Phenyl-N′-benzhydrylidene Benzamidine (5)

A mixture of 2.1 g (10 mmoles) of benzimidoyl chloride, 1.8 g (10 mmoles) of benzophenone imine, and 5 ml of dry pyridine was heated on a steam-bath for 2h. The reaction mixture was poured into 100 ml of ice water and the organic layer was extracted with two 30 ml portions of ether. The dried ether extract was evaporated to dryness and 3.0 g of crude yellow solid were obtained. One recrystallization from cyclohexane gave 2.4 g (66%) of a yellow powder, m.p. 138–140°. It was identical in all respects with the product obtained from the photolysis of **2** in benzene.

Photolysis of 2 in Cyclohexene

A solution of 3.0 g (7.7 mmoles) of **2** in 175 ml of cyclohexene was photolyzed for 6 h at 40–45°. Work-up of the photolyzate as previously described gave 2.2 g (79%) of **5**, m.p. 137–138°. All attempts to detect the presence of the bicyclic aziridine failed.

[2]The arguments presented here would hold equally well (with minor differences) for a transition state involving the azide (concerted displacement) instead of a nitrene.

Photolysis of 2 in Methanol

A solution of 2.0 g (5 mmoles) of **2** in 200 ml of methanol was photolyzed for 6 h. After removal of the solvent, the residue was extracted with 100 ml of ether. Evaporation of the ether gave 2.0 g (mixture of **7** and **10**) of an oil. Crystallization from methanol gave 0.5 g (45% based on eq. [1] of **7**, m.p. 105.5–106°. Its i.r. spectrum was superimposable on that of an authentic sample of benzophenone dimethylketal. The ether insoluble fraction (0.2 g) was identified as ammonium azide by comparison of its i.r. spectrum with that of an authentic sample.

When **2** was kept for 6 h in methanol, only 40% of **7** was isolated and no ammonium azide was obtained. The irradiation of benzophenone imine in methanol for 6 h did not give **7** in any appreciable amounts.

Thermal Decompositions of 2

(a) In Decalin

A solution of 1.0 g (2.5 mmoles) of **2** in 20 ml of decalin was heated at 190° for 2 h. Removal of the solvent *in vacuo* left a black tar which was chromatographed on Fisher A-540 alumina. Elution with benzene gave 0.17 g (20%) of benzhydryl benzophenone imine (**9**), identical with an authentic sample (12).

(b) In Naphthalene

A mixture of 1.0 g (2.5 mmoles) of **2** in 3 g of naphthalene was heated at 190° for 2 h. The naphthalene was sublimed and the tarry residue was chromatographed as above. Elution with 1:3 *n*-hexane – benzene gave 0.2 g (23%) of **5**, m.p. 136–137°.

Studies in terpenoids. XII.[1] Optical rotatory dispersion and circular dichroism studies on some cyclobutanones derived from α-pinene[2]

L. R. SUBRAMANIAN AND G. S. KRISHNA RAO
Department of Organic Chemistry, Indian Institute of Science, Bangalore-12, India
Received October 23, 1968

The optical rotatory dispersion and circular dichroism studies on the cyclobutanones (**1–5**) are discussed.
Canadian Journal of Chemistry, **47**, 1147 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The octant rule, at first applied to cyclohexanones (1) and later to other systems (2), was successfully extended to cyclobutanones by Conia and Gore (3). The absolute configurations and the preferred conformations of various substituted cyclobutanones were established by these authors from a study of their circular dichroism (c.d.) curves, which clearly demonstrated the puckering of the cyclobutanones investigated by them. Low-temperature c.d. study (4) has also been made use of to investigate the conformational mobility of cyclobutanones (4*a*). The most recent application of the c.d. and the extension of the octant rule for deducing the stereochemistry of optically active cyclobutanones is in the assignment of the absolute configuration of the naturally occurring cyclobutanones, D- and L-filifolones (5).

In the course of our work on the transformation reactions of α-pinene (6), optically active cyclobutanones **1–4** became available. (−)-2,2,3(R)-Trimethylcyclobutanone (**5**) was prepared (*vide* Experimental) from *cis*-(+)-pinonic acid (**6**) (7) by the route: **6** → **7** → **8** → **9** → **5** (Scheme I).

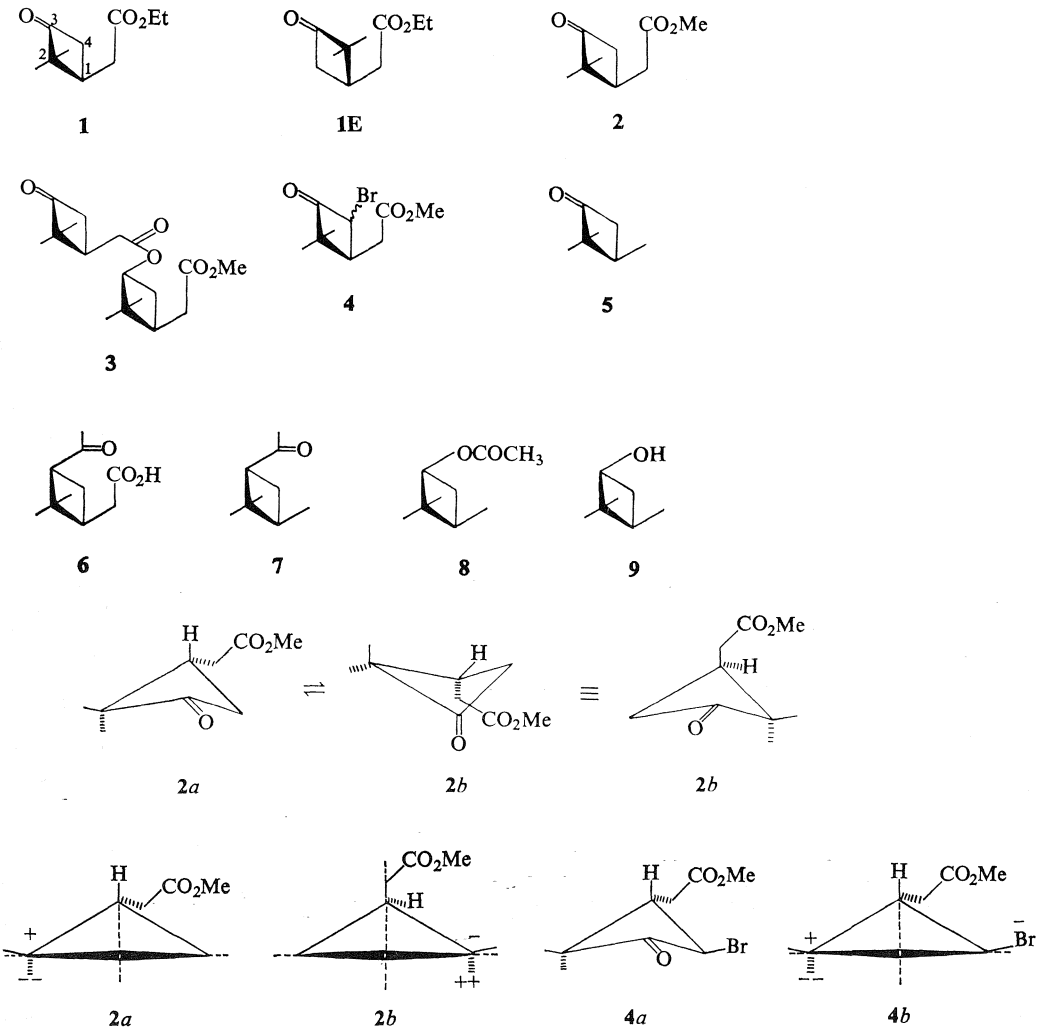
(+)-2,2,3(S)-Trimethylcyclobutanone (**5E**) prepared by Conia and Gore (3) exhibited a positive Cotton effect in c.d. and was also prone to conformational mobility as revealed by the low-temperature c.d. measurement (4*a*). (−)-2,2,3(R)-Trimethylcyclobutanone (**5**) prepared in this study exhibited a single well-defined negative Cotton effect in c.d. (Table I) confirming its antipodal configuration. Since **5** was prepared from *cis*-(+)-pinonic acid (**6**, *ex*.(+)-α-pinene), which in turn was the starting material for the synthesis of methyl (−)-2,2-dimethyl-3-ketocyclobutyl-1(S)-acetate (**2**) (6), the absolute configuration of **2** is correlated with that of **5** and is shown as depicted.

A study of the c.d. curve of the cyclobutanone ester (**2**), however, gave results in contrast with those of the cyclobutanone (**5**) with which it was correlated *via* **6**. In cyclohexane and methanol the cyclobutanone methyl ester (**2**) exhibited multiple Cotton effects in the c.d. curve (a positive extremum at 319–322 mμ, a negative extremum at 302–304 mμ (Table I), and again a positive extremum at 240–248 mμ[3]). Multiple extrema of opposite signs and the change in amplitude with change of solvent from cyclohexane to methanol, as observed from the molecular ellipticity values of the cyclobutanone ester (**2**), (Table I), have been attributed to conformational/solvational equilibria (8). Consider conformers (**2***a* and **2***b*) (Scheme 1) for **2** with the ester side chain equatorial in **2***a* and axial in **2***b*. By the application of the octant rule, conformer **2***a* should exhibit an overall negative Cotton effect and conformer **2***b* a positive Cotton effect and an equilibrium mixture of the two can be expected to show multiple Cotton effects and also an alteration in amplitude from a change of nonpolar to polar solvent.

In the optical rotatory dispersion (o.r.d.) curves the cyclobutanone ethyl ester[4] (**1**, from (+)-α-pinene) exhibited a single positive Cotton effect, the antipodal ester[4] (**1***e*, from (−)-α-pinene) exhibiting a single negative Cotton effect. The negative Cotton effect for **5** (c.d.) and the positive Cotton effect for **1** (o.r.d.) with identical

[1]For Part XI see ref. 18.
[2]Taken from the Ph.D. Thesis of L. R. Subramanian (Indian Institute of Science, 1968).

[3]This positive extremum, also observed in compound **3** (Table I), may be attributed to the $n \rightarrow \pi^*$ transition of the ester carbonyl, the pronounced bathochromic shift observed in the c.d. curve being due to a proximity effect exerted on the ester carbonyl by the cyclobutanone.
[4]The o.r.d. data recorded in Table I for the ethyl esters **1** and **1E** were obtained by us much earlier, while the c.d. data (Table I) for the methyl ester **2**, extending to shorter wavelengths, which enabled us to detect the multiple Cotton effect exhibited by **2**, were obtained recently.



SCHEME I Cyclobutanones **1**–**5** and related compounds.

configurations in both **5** and **1** at the asymmetric center appear to be at variance at first sight. However, the observed reversal in Cotton effects may be ascribed to the preference shown by the freely rotating —CO_2Et group (compound **1**) to one quadrant over the other in a situation of possible steric restriction. The special effect of a β,γ-unsaturated double bond in a cyclobutanone was noted earlier (9). What the effect of a δ-carbonyl (of an ester in a compound like **1**) might be is unknown, but it could be significant.[5]

The dimeric cyclobutanone ester (6) (**3**) exhibited a remarkably similar c.d. curve profile (in dioxan) to that of **2** (in methanol) with positive extrema at 320 and 244 mμ and a negative extremum at 292 mμ (Table I) in conformity with their structural similarity. Methyl (−)-2,2-dimethyl-3-keto-4-bromocyclobutyl acetate (**4**) exhibited c.d. data in agreement with those observed for similar bromocyclobutanones by Conia and Gore (3). Since the bromocyclobutanone ester used in this study consisted of 80% *trans*-isomer,[6] the predominant conformer **4***a* with equatorial bromine (negative octant) satisfies the observed negative Cotton effect for **4**.

[5]We are grateful to one of the referees for this suggestion to explain the observed difference in the Cotton effects.

[6]Deduced from the nuclear magnetic resonance spectrum of **4** (10).

(−)-2,2,3(R)-Trimethylcyclobutanone (5)

(i) Hunsdiecker Brominative Decarboxylation (11) of Pinonic Acid

To *cis*-(+)-pinonic acid (**6**, 40.5 g) (7) in anhydrous CCl_4 (240 ml) was added red oxide of mercury (47.7 g) and the mixture stirred slowly while heating it to gentle reflux for 5 min. The heating was stopped and bromine (13.2 ml) in CCl_4 (80 ml) was added cautiously. The exothermic reaction maintained the reaction mixture boiling for a few min. After addition of bromine was over, the vigor of the reaction subsided. Refluxing was continued for another 3 h. The reaction mixture was cooled and filtered. The filtrate was shaken thrice with 10% $NaHCO_3$ solution and the solvent removed under suction. The crude brownish product (24 g) partially decomposed on distillation, b.p. 105–106°/16 mm; i.r. (neat): 1701 cm^{-1} (>C=O).

(ii) 1-Acetyl-2,2,3-trimethylcyclobutane (Pinonone) (7)

The crude bromide (24 g) was refluxed with water (500 ml) and zinc powder (240 g) (12) for 10 h and the product was steam-distilled to give the ketone **7** (10 g), b.p. 160–162°/690 mm; i.r. (neat): 1706 cm^{-1} (>C=O); nuclear magnetic resonance (n.m.r.) (60 MHz, TMS = 0) 117, CO—*CH*$_3$; 166, *CH*—C(=O)—CH$_3$ (for other proton signals see ref. 10).

Anal. Calcd. for $C_9H_{16}O$: C, 77.1; H, 11.4. Found: C, 77.4; H, 11.2.

The *semicarbazone* had m.p. 210–211° (aqueous MeOH) (lit. (13–15) for the *cis*-, *trans*-isomer mixture, m.p. 197–198°).

Anal. Calcd. for $C_{10}H_{19}ON_3$: C, 60.9; H, 9.7; N, 21.3. Found: C, 60.9; H, 9.6; N, 21.5.

The *2,4-dinitrophenylhydrazone* was prepared by refluxing the above semicarbazone (100 mg) with 2,4-dinitrophenylhydrazine (110 mg) and HCl (2–4 drops) in ethanol for 5 h. The crude product on recrystallization from methanol had m.p. 202.5–204°, (lit. (15), m.p. 202–203°).

Anal. Calcd. for $C_{15}H_{20}O_4N_4$: N, 17.5. Found: N, 17.1.

(iii) 2,2,3-Trimethylacetoxycyclobutane (8)

The ketone (**7**, 14 g) was mixed with standardized, moist $CHCl_3$ solution containing perbenzoic acid (approximately 0.12 mole, 200 ml), and the resulting cloudy solution was swirled at intervals and allowed to stand in the dark at room temperature (16). After the theoretical amount of perbenzoic acid had been consumed (ca. 15 days), the $CHCl_3$ solution was shaken with 10% $NaHCO_3$ solution until free of acid. Distillation after removal of solvent gave the acetoxy compound **8** (13.5 g), b.p. 86–88°/65 mm; n_D^{29} 1.4262; α_D −34.8° (neat): i.r. (neat): 1742 (ester >C=O) and 1242 cm^{-1} (ester —C—O).

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.2; H, 10.3. Found: C, 69.3; H, 10.1.

(iv) 2,2,3-Trimethylcyclobutanol (9)

To a suspension of $LiAlH_4$ (10 g) in ether (100 ml) was slowly added with stirring an ethereal solution of the acetoxycyclobutane (**8**, 36.1 g). After the addition was over, it was gently refluxed for 3 h, cooled, and decomposed with saturated NH_4Cl solution. It was then filtered and the organic matter was extracted with ether. Removal of solvent and distillation furnished 2,2,3-trimethylcyclobutanol (**9**, 23 g), b.p. 108–110°/185 mm; i.r. (neat): 3450 cm^{-1} (O—H).

[7]All m.p.s and b.p.s are uncorrected. The infrared (i.r.) spectra were recorded on a Perkin–Elmer 137 spectrophotometer. All organic extracts were washed neutral and dried (Na_2SO_4) prior to removal of the solvent, unless otherwise stated.

Anal. Calcd. for $C_7H_{14}O$: C, 73.7; H, 12.3. Found: C, 73.8; H, 12.4.

(−)-2,2,3(R)-Trimethylcyclobutanone (5)

To a stirred solution of the hydroxy compound (**9**, 13.5 g) in ether (50 ml) was added dropwise chromic acid solution, prepared from $Na_2Cr_2O_7 \cdot 2H_2O$ (12 g) in 96% H_2SO_4 (9 ml) diluted to 60 ml with water, in about 15 min at 20° (17). After stirring the solution for 2 h, the ether layer was separated and the aqueous layer extracted thrice with ether. On removal of solvent from the combined ether layer and distillation, two fractions were obtained. Fraction 1, b.p. 128°/690 mm was redistilled, b.p. 124–126°/690 mm, to give (−)-2,2,3(R)-trimethylcyclobutanone (**5**, 4 g); n_D^{25} 1.4278; α_D −21.6° (neat); i.r. (neat): 1783 cm^{-1} (cyclobutanone). The i.r. spectrum was superimposable with that of the enantiomeric (+)-2,2,3(S)-trimethylcyclobutanone (**5E**) prepared by Conia and Gore (3).

Anal. Calcd. for $C_7H_{12}O$: C, 74.8; H, 10.7. Found: C, 74.8; H, 10.7.

Fraction 2, b.p. 168°/690 mm proved to be β,γ,γ-*trimethylbutyrolactone* (cf. ref. 6), b.p. 160°/690 mm, n_D^{25} 1.4388; i.r. (neat): 1779 (γ-lactone) and 1418 cm^{-1} (O=C—CH_2—).

Anal. Calcd. for $C_7H_{12}O_2$: C, 65.6; H, 9.4. Found: C, 65.2; H, 9.2.

Acknowledgments

We are indebted to Dr. Sukh Dev for the n.m.r. spectrum of **7**; to Professor Conia for the c.d. curves of **2**, **3**, **4**, and **5** and the i.r. spectrum of **5E**; and to Professor Djerassi for the o.r.d. curves of **1** and **1E**. We thank Professor D. K. Banerjee of this Department for his interest in this work. One of us (L. R. S.) thanks the authorities of the Indian Institute of Science for the award of a scholarship.

Received November 1, 1968

The proton magnetic resonance spectra of several acylamino biphenyls were determined. Evidence was obtained that the proton adjacent to the acylamino group was shifted to lower field relative to the remaining ring protons.

Canadian Journal of Chemistry, 47, 1151 (1969)

In a recent paper, Ribera and Rico (1) described the deshielding of the *ortho* proton in the nuclear magnetic resonance (n.m.r.) spectra of *N*-(2-substituted-phenyl)amides. A low-field shift of the signal corresponding to the *ortho* proton was observed only for those compounds which simultaneously had one free (H) and one occupied (F, Cl, Br, I) position. The magnitude of the chemical shift in this series varied from 0.86 to 1.04 p.p.m. relative to benzene.

The deshielding effect of a proton adjacent to an *N*-acetyl group had been described previously in a number of publications. For instance, it was shown by Carter (2) that the resonance for the *ortho* protons in the spectrum of acetanilide was shifted 0.89 p.p.m. downfield from the corresponding resonance in the spectrum of aniline, by determining the residual proton spectra of the partially deuterated compounds. The low-field shift was attributed primarily to the fact that the anisotropic carbonyl group in acetanilide points towards the aromatic ring, with the plane of the acetamido group and the benzene ring making an angle of approximately 38° (3). A lowering for the *ortho* proton signal was also reported for several *para*-substituted acetanilides (4).

A low-field shift arising from the anisotropic shielding of a neighboring *N*-acetyl group was observed in a number of pyridine derivatives. Brügel (5) showed that acetylation of 2-aminopyridine markedly influenced the resonance of the 3-proton. The chemical shift difference expressed as $\Delta\nu_3 - \nu_4$ relative to pyridine between 2-aminopyridine and 2-acetamidopyridine was approximately 1.1 p.p.m.

Similar effects have been observed for other heterocyclic acylamines in which the *N*-acylamino group is adjacent to a ring hydrogen atom. In the n.m.r. spectra of the *N*-acetyl derivatives of benzimidazoles and purines (6), a constant downfield shift of about 19 c.p.s. (40 Mc.p.s.) of the proton adjacent to the acetyl position had been noted. In 4-*N*-acetylpyrimidine all the remaining ring protons are shifted to lower field relative to the signals for the corresponding 4-amino derivative; however, by far the most striking effect was noticed for the adjacent proton (H-5), which was shifted by 1.5 p.p.m. to low-field (7).

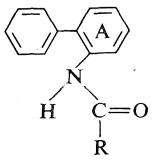
The situation where one of the *ortho* positions is occupied exists also in *N*-acylindoline and compounds related to it. Some years ago it was shown by Anet (8) that the aromatic proton in strychnospermine nearest to the *N*-acyl grouping (H-12)[1] appeared as a doublet at 2.35 τ when the spectrum was taken at about −20°; this corresponded to that conformation in which the carbonyl group was preferentially oriented towards the phenyl ring. The band of the same proton in the opposite conformation was at about 3.25 τ. The low-field position was ascribed to the strong, magnetic anisotropy of the carbonyl group. A similar effect was observed in the n.m.r spectrum of fruticosin (9), and depended on the steric arrangement of the N_a-carbomethoxy group. At −30° two doublets of different intensity at 8.00 p.p.m. and 7.55 p.p.m. (100 Mc.p.s.) for H-17[1] were observed. In fruticosamin the *N*-$COOCH_3$ group is conformationally fixed through hydrogen

[1]This corresponds to H-7 in indoline.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

bonding; this compound shows a normal doublet at 7.54 p.p.m. More recently a detailed study by Nagarajan *et al.* (10) on the configuration of the amide bond in *N*-acylindolines and *N*-acyltetrahydroindolines, clearly indicated that the carbonyl group was oriented towards the phenyl ring as in the case of the low temperature n.m.r. spectrum of strychnospermine; the proton at C-7 was seen as a broad doublet at 8.22 p.p.m. as compared to 6.45 p.p.m. in indoline ($\Delta\delta = 1.77$ p.p.m.!). In compounds in which the carbonyl group is rigidly held in the vicinity of a nearby proton, as in hexahydropyrrolo[1,2-*a*]quinoxaline (11, 12), a pronounced low-field shift was again observed.

In connection with some other studies we had prepared a number of acylamino biphenyl derivatives:



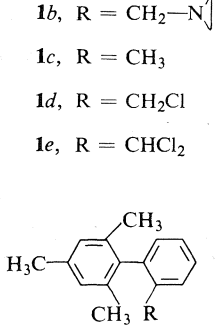
1*a*, R = CH_2—N⟨O⟩ **1***f*, R = CCl_3

1*b*, R = CH_2—N⟨ ⟩ **1***g*, R = CH_2F

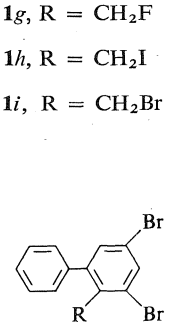
1*c*, R = CH_3 **1***h*, R = CH_2I

1*d*, R = CH_2Cl **1***i*, R = CH_2Br

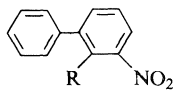
1*e*, R = $CHCl_2$



2, R = $NHCOCH_2Cl$



3, R = $NHCOCH_2Cl$



4, R = $NHCOCH_3$

The n.m.r. spectra of the various amides were determined at 60 Mc.p.s. in chloroform-*d* solution. It was found, that the resonance for one of the protons in compounds (**1***a–i*) was shifted downfield from the corresponding spectrum in 2-amino biphenyl, ranging from 1.40–1.95 p.p.m., (corrected for the diamagnetic anisotropy effect of the vicinal phenyl ring, see below), representing a downfield shift of 1.23–0.68 p.p.m. relative to benzene. Our results are summarized in Table I. The partial n.m.r. spectrum of compound **1***a* is shown in Fig. 1.

TABLE I

Nuclear magnetic resonance data for the *ortho* proton in *N*-acyl biphenyls*

Compound	τ_H†	τ'_H‡	Δ§
1*a*	1.28	1.40	1.23
1*b*	1.39	1.51	1.12
1*c*	1.45	1.57	1.06
1*d*	1.45	1.57	1.06
1*e*	1.56	1.68	0.95
1*f*	1.54	1.66	0.97
1*g*	1.70	1.82	0.81
1*h*	1.73	1.85	0.78
1*i*	1.83	1.95	0.68

*Spectra were determined at 60 M c.p.s., using 0.66 *M* solutions in $CDCl_3$.

‡Adjusted for adjacent ring current effect: $\tau'_H = \tau_H + 0.12$.
§Shift to low field with reference to the chemical shift of benzene, (τ p.p.m. 2.63).

Except for compounds **3** and **4**, all derivatives have one free and one occupied *ortho* position. With regard to the orientation of the carbonyl group, it is clear from our results that this group is oriented towards the aromatic ring as in acetanilide (3), but not necessarily coincident with it and that the adjacent proton lies in the deshielding zone of this group. The *a priori* possibility that the *ortho* position in the neighboring ring might be deshielded because its proximity (cf. 13), was ruled out by the following facts:

a) The spectrum of the mesityl derivative (**2**) clearly showed that the position and the intensity of the low-field signal had not been altered.

b) In the spectrum of **3** the low-field C—H proton signal was absent.

c) In 2-nitro-1-acetamidobiphenyl (**4**) the *N*-acetyl carbonyl group is probably oriented towards the neighboring phenyl ring because of intramolecular hydrogen-bonding between the amido proton and the nitro group.[2] However, the characteristic low-field signal observed for com-

[2]The deshielding of aromatic protons in *ortho*-nitro substituted acetanilides was recently described in great detail (14, 15).

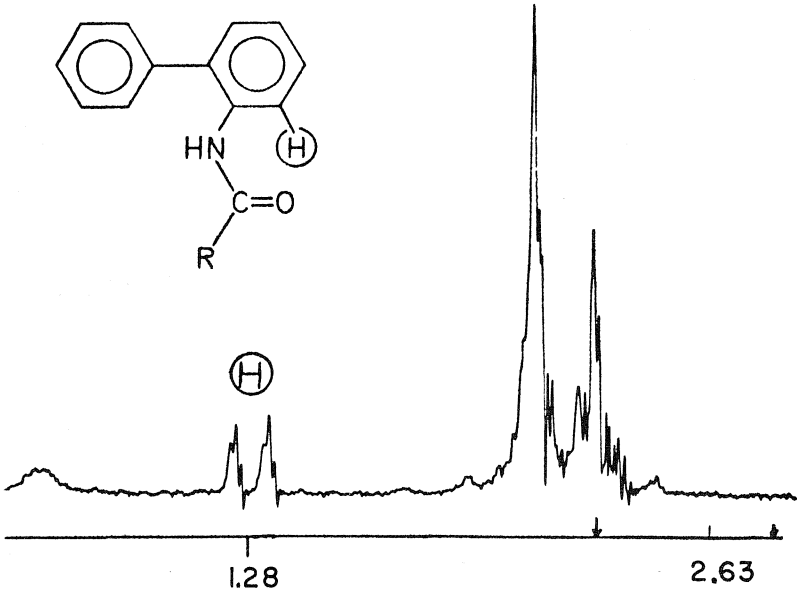

FIG. 1. Partial nuclear magnetic resonance spectrum of **1***a*, R = CH_2-N⟨O⟩, in $CDCl_3$ at 60 Mc.p.s. (numbers are in p.p.m. (τ)).

pounds (**1***a–i*) was absent in the n.m.r. spectrum ($CDCl_3$ and $(CD_3)_2SO$).

It may be concluded, therefore, that it is the proton next to the *N*-acetyl group which resonates at lower field.

In order to correct for the influence of the phenyl substituent on the chemical shift of the protons in ring A we have used the data given in the literature. A correction for the contribution of the halogen atoms to the chemical shift of the *ortho* proton was made by Ribera and Rico (1) using the ^{S}*meta* values given by Diehl (16). Mayo and Goldstein (17), who have carried out a detailed proton resonance investigation of biphenyl, showed that the anisotropic shielding of a given proton is a function of the dihedral angle between the two benzene rings. From their work as well as from a variety of independent evidence cited in their paper these authors suggested, that "the chemical shifts in biphenyl are most plausibly accounted for by a model involving free, or nearly free, rotation of the rings (in solution) and very weak interactions between the phenyl groups". The diamagnetic anisotropic shielding at each position was calculated as a function of the dihedral angle; the corrections were +19.1, +7.2, and +6.0 c.p.s. at 60 Mc.p.s. (determined in $CHCl_3$) for the *o-*, *m-*, and *p*-positions, respectively.[3]

The freely rotating model may not be strictly applicable in our series of biphenyl derivatives since one of the *ortho* positions is occupied by a relatively large group. However, since the shielding of the *meta* protons varies only slightly with the change in dihedral angle as shown by Mayo and Goldstein (17), we have taken the average values of 7.2 c.p.s. for our biphenyl derivatives (**1***a–i*). The correction was not applied for the mesityl compound (**2**), since the values for biphenyl are not necessarily applicable for this case. However, the general trend for the low-field shift was clearly observable (cf. Fig. 2).

The methyl protons in compound **2** give rise to two signals at 2.35 p.p.m. (3 protons) and 2 p.p.m. (6 protons) respectively. The introduction of three large *ortho* substituents in **2** widens the dihedral angle to 70° or greater (18). The effect of twisting the two phenyl rings almost out of plane brings the protons of the *ortho* methyl groups under the influence of the induced field of the adjacent ring which accounts for the observed

[3]An ^{S}*m*-value of -11 ± 2 p.p.h.m. (40 Mc.p.s., CCl_4) was given by Smith (4).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

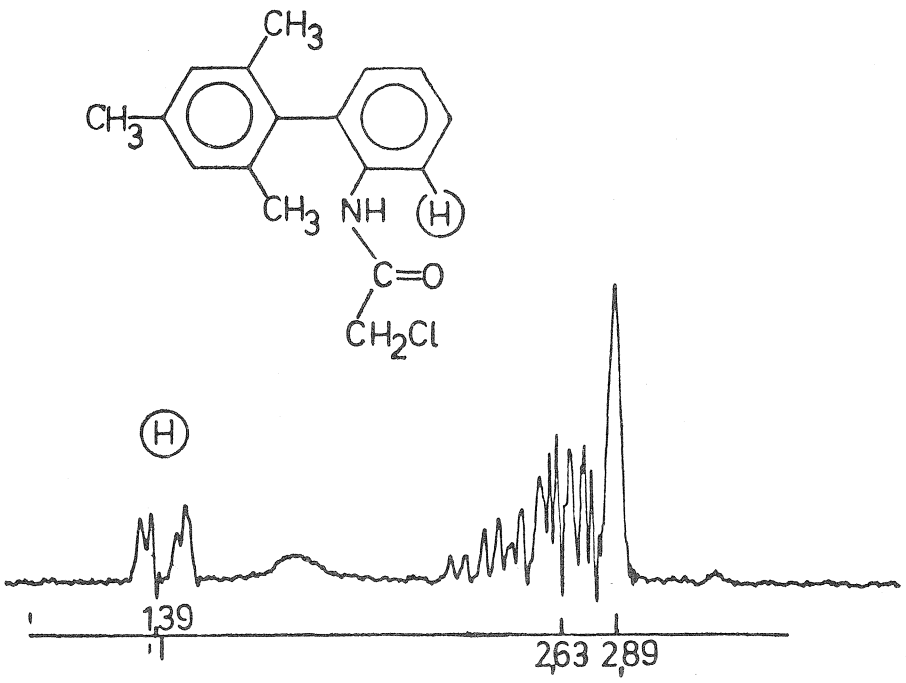

FIG. 2. Partial nuclear magnetic resonance spectrum of **2** in $CDCl_3$ at 60 Mc.p.s. (numbers are in p.p.m. (τ)).

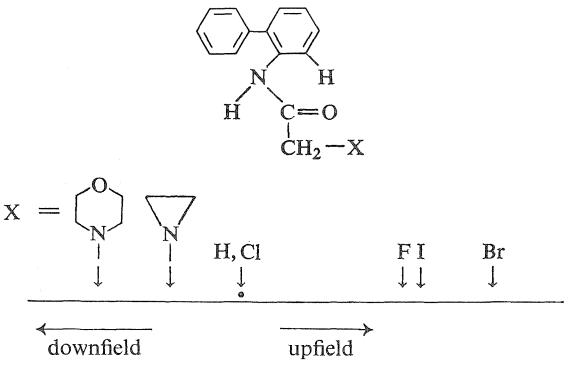
upfield shift of approximately 0.3 p.p.m. For comparison, the signals for the methyl protons in 2,2′,4,4′-tetramethyl biphenyl, occur at 2.37 and 2.03 p.p.m., respectively (19). On the other hand, in 4,5-dimethyl-9,10-tetrahydrophenanthrene the methyl protons give rise to only one signal at 2.29 p.p.m. (20).

From an inspection of Table I, it can be seen that there is a noticeable change in chemical shift values within this series of compounds. This is diagrammatically shown below:



The observed downfield shift of the *ortho* proton is due to a combination of the anisotropic deshielding by the *N*-acetyl carbonyl group as well as to electric and field effects of the amide group, in accord with the general observations cited in this text. This effect is then further modified as shown above. Although there is no observable change for the mono-chloro derivative (**1***d*), additional α-halogenation causes an upfield shift. However, a direct correlation between this upfield shift and the size or the number of the halogen atoms does not exist as shown in Table I; substitution by fluorine, bromine, or iodine results in a noticeable shift to higher frequencies. On the other hand, a shift to lower fields was observed for the two compounds with nitrogen-containing substituents, (**1***a*) and (**1***b*).[4] This variation in chemical shift is rather difficult to assess. Transmission solely through bonds cannot alone account for it; both inductive effects and changes in the magnetic anisotropy of the C—X bond as well as steric differences and

[4]Zanger and co-workers, in a recent publication on the nuclear magnetic resonance spectra of *N*-acylanilines, (21 and cf. ref. 1) also found no change for the monochloroacetyl derivative, and concluded that the nature of the group attached to the acyl carbon atom has relatively little effect on the chemical shift of the aromatic protons.

changes in bond angles are likely contributing factors and are probably interdependent.[5]

Experimental

Elemental microanalyses were provided by Dr. C. Daesslé, Montreal, Quebec, and Dr. A. B. Gygli, Toronto, Ontario. The nuclear magnetic resonance (n.m.r.) spectra were determined as 0.66 *M* solutions in $CDCl_3$ using a Varian Associates model A60-A.

Materials

Compounds (**1***c–f*) and (**1***i*) were obtained by reacting 2-aminobiphenyl (Aldrich Chemical Company) with the corresponding acetyl halides in DMF at 5–10 °C in the presence of K_2CO_3. The mono-iodo compound, (**1***h*), was prepared from the mono-chloro derivative, (**1***d*), by halogen exchange (NaI–acetone).

Monofluoroacetyl chloride was prepared by the method of Truce (22). The fluoroacetyl compound (**1***g*), was then prepared by the method indicated above.

We used the method of Smolinsky (23) for the preparation of 2,4,6-trimethyl-2′-aminobiphenyl; the latter was converted into the monochloroacetyl derivative (**2**) by the previous procedure.

According to the procedure of Scarborough and Waters (24) we obtained 3,5-dibromo-2-aminobiphenyl, which was subsequently converted into the monochloroacetyl compound (**3**) in the usual manner.

For the preparation of 2-nitro-1-acetamidobiphenyl we employed the procedure given by Stepan and Hamilton (25).

The morpholino- and aziridino-compounds (**1***a*) and (**1***b*) were prepared by reacting the monochloroacetyl derivative (**1***d*) with the respective amines.

Characterization data for all compounds are given in Table II.

[5]A correlation with other substituent parameters was not established, because the data are too limited to evaluate the relative importance of these factors accurately.

Conformations and configurations of some chlorosulfated α- and β-D-pentopyranosyl chlorides[1]

H. J. JENNINGS
Division of Biosciences, National Research Council of Canada, Ottawa, Canada
Received November 5, 1968

The conformations of the fully chlorosulfated α- and β-D-xylopyranosyl and lyxopyranosyl chlorides in deuteriochloroform solution have been studied by proton magnetic resonance spectroscopy. The analysis of the spectra indicated that the anomeric effect is a factor in determining the conformational preference of the pentopyranosyl chlorides, as each existed predominantly in the conformation in which the chlorine was axial. A number of factors involving the synthesis of these chlorides have also been elucidated.

Introduction

Previous studies on the proton magnetic resonance (p.m.r.) spectra of the acylpentopyranosyl halides (1–4) have indicated that their conformational preference in solution is influenced to a large extent by the anomeric effect (5). This has been found to be the case with both the thermodynamically more stable and less stable anomers of these halides. The thermodynamically more stable anomers of the acetylpentopyranosyl bromides (1) have been shown by Horton and Turner to exist predominantly in the conformation in which the bromine is axial, and comparisons of both anomers of the tri-*O*-benzoyl-D-ribopyranosyl fluorides, chlorides, and bromides (2) have also shown that in each case, the halogen is predominantly axial. Similar comparisons have been made using the α- and β-anomers of tri-*O*-acetyl-D-xylopyranosyl chlorides (3), and fluorides (4) and again these compounds adopt the conformation in which the halogen substituent is predominantly axial. For the β-D-xylopyranosyl halides this requires that every large substituent group on the pyranose ring be axial and demonstrates the large contribution made by the anomeric effect. We now report an analogous situation for the chlorosulfated α- and β-D-xylopyranosyl and lyxopyranosyl chlorides. The present work reports on the synthesis of these chlorides in both their α-D and β-D configurations and the analysis of their p.m.r. spectra in deuteriochloroform solution. Configurational assignments made previously on both α- and β-D-xylopyranosyl chloride 2,3,4-tri(chlorosulfate) have also been confirmed by p.m.r. spectroscopy.

Discussion

The method of synthesis of β-D-xylopyranosyl chloride 2,3,4-tri(chlorosulfate) (**1**) has been previously described (6), but it has now been established that the conditions of the reaction are such that pure crystalline α-D-xylopyranose yields crystalline **1** in a high degree of purity. This was established by comparison of the p.m.r. spectrum of the crude product with that of pure **1**. The spectra were identical and none of the signals associated with the α-D-chloride (**2**) could be detected. This was also the case when crystalline β-D-lyxopyranose was treated with sulfuryl chloride under identical conditions (6). Only the signals corresponding to those of α-D-lyxopyranosyl chloride 2,3,4-tri(chlorosulfate) (**4**) could be detected in the crude reaction product. This would suggest strongly that 1-chloro substitution occurs via an intermediate 1-chlorosulfate ester, resulting in overall inversion of configuration at the anomeric center. It also demonstrates that anomerization does not occur to any significant extent using these reaction conditions, thus providing a controlled synthesis of the pure anomeric chlorides even in the case of the thermodynamically less stable anomers (**1** and **3**). Further support for this hypothesis was obtained when treatment of an equilibrium mixture of D-xylose with sulfuryl chloride yielded a mixture of chlorides (**1** and **2**) essentially in the same ratio as the original anomeric mixture of reducing pyranoses but with reversed configurations (by p.m.r.). Similar evidence

[1]Issued as NRCC No. 10537.

could not be obtained from the p.m.r. spectrum of the crude reaction product of an equilibrium mixture of D-lyxose with sulfuryl chloride because of the overlap of the anomeric signals of **3** and **4**, but the specific rotation of the crude syrupy mixture in comparison with the specific rotations of pure **3** and **4** did indicate a comparable situation. The synthesis of α-D-xylopyranosyl chloride 2,3,4-tri(chlorosulfate) (**2**) had been previously achieved by the anomerization of **1** using aluminium chloride (6). However, the reported yield was not good and successive repetitions of this reaction have recently indicated that the yields are also very variable. A preferable method is to effect the anomerization of **1** with titanium tetrachloride which gives consistently higher yields of **2**. β-D-Lyxopyranosyl 2,3,4-tri(chlorosulfate) (**3**) was obtained by crystallization from the crude product of the reaction of sulfuryl chloride with an equilibrium mixture of D-lyxose.

Coupling constants were obtained by first-order analysis of the spectra of **1**, **2**, **3**, and **4** and are shown in Table I. The data clearly indicate that all the compounds, regardless of anomeric configuration, exist predominantly in that conformation which places the chlorine at C-1 in an axial position. This requires a predominance of the 1C(D) conformation for **1** and **3** and of the C1(D) conformation for **2** and **4**.

The spectrum of **1** (Fig. 1*a*) gave a narrow unresolved signal at τ 3.74 which was assigned to the anomeric proton (H-1). The fact that the signal was not a simple doublet was due to long-range coupling with H-3 (assigned to the complex multiplet at τ 4.56). This was substantiated when irradiation of H-3 (δ = +48 Hz) resulted in the collapse of the anomeric signal to a doublet ($J_{1,2}$ = 1.4 Hz). This small value of the $J_{1,2}$ coupling constant is consistent with a *gauche* orientation (7) of the H-1 and H-2 protons and a much larger value of $J_{1,2}$ would be required to assign **1** to the C1(D) conformation as in this case the H-1 and H-2 protons would be diaxially oriented (7). The H-5a and H-5e protons were assigned to the quartet and sextet at high field. Irradiation of H-3 (δ = −68 Hz) caused the sextet to collapse to a quartet indicating long-range coupling ($J_{3,5e}$ = 1.4 Hz) of H-3 with one of the H-5 protons. The highest field sextet was thus assigned to the H-5e proton as this type of coupling occurs most frequently when the two protons involved have a diequatorial orientation (8). Similar long-range couplings of the H-3 proton with both H-1 and H-5e have been reported in related pyranose ring compounds (2,3,4,9) and this evidence strongly supports the 1C(D) conformation of **1**. The small values of $J_{4,5e}$ (1.8 Hz) and $J_{4,5a}$ (2.0 Hz) are also in agreement with the *gauche* orientation (7) of H-4 with both H-5e and H-5a.

TABLE I

First-order coupling constants (Hz) of the chlorosulfated α- and β-D-pentopyranosyl chlorides of D-xylose and D-lyxose

Compound	$J_{1,2}$	$J_{2,3}$	$J_{3,4}$	$J_{4,5e}$	$J_{4,5a}$	$J_{5a,5e}$	$J_{3,5e}$
1	1.4*	—	—	1.8	2.0	14.4	1.4*
2	3.8	9.0	9.0	6.0	10.6	11.6	—

4	1.8	—	10.0	6.0	10.2	12.0	—

*Obtained by spin decoupling.
†Not unambiguously assigned.

The spectrum of **3** is shown in Fig. 2*a* and although the H-2, H-3, and H-4 signals were superimposed, there were sufficient similarities between the spectra of **3** and **1** to indicate a β-D-pyranose structure for **3** (see below). Additional proof of this structure was also obtained when **3** was methanolyzed in the presence of silver carbonate to give a syrupy methyl glycoside which on dechlorosulfation, (6) yielded crystalline methyl α-D-lyxopyranoside. The anomeric proton of **3** was assigned to the low-field doublet at τ 3.74 and the small value of the coupling constant ($J_{1,2}$ = 3.9 Hz) is consistent with a *gauche* orientation (7) of the H-1 and H-2 protons. The H-5 protons of **3** gave almost identical signals to the H-5 protons of **1**. The small values of $J_{4,5e}$ and $J_{4,5a}$ are in agreement with the *gauche* orientation (7) of H-4 with both H-5e and H-5a, and the appearance of the H-5e signal of **3** as a high-field sextet indicated a similar situation to **1** with long-range coupling between the diequatorial protons H-3 and H-5e. This evidence supports the 1C(D) conformation of **3** as the alternate C1(D) conformation would require one large coupling constant indicative of the vicinal diaxial H-4 and H-5a protons, and would not be favorable for this type of long-range coupling (8). The $J_{4,5e}$ and $J_{3,5e}$ couplings of **3** were assigned by analogy with those of **1** and could not be confirmed by spin decoupling

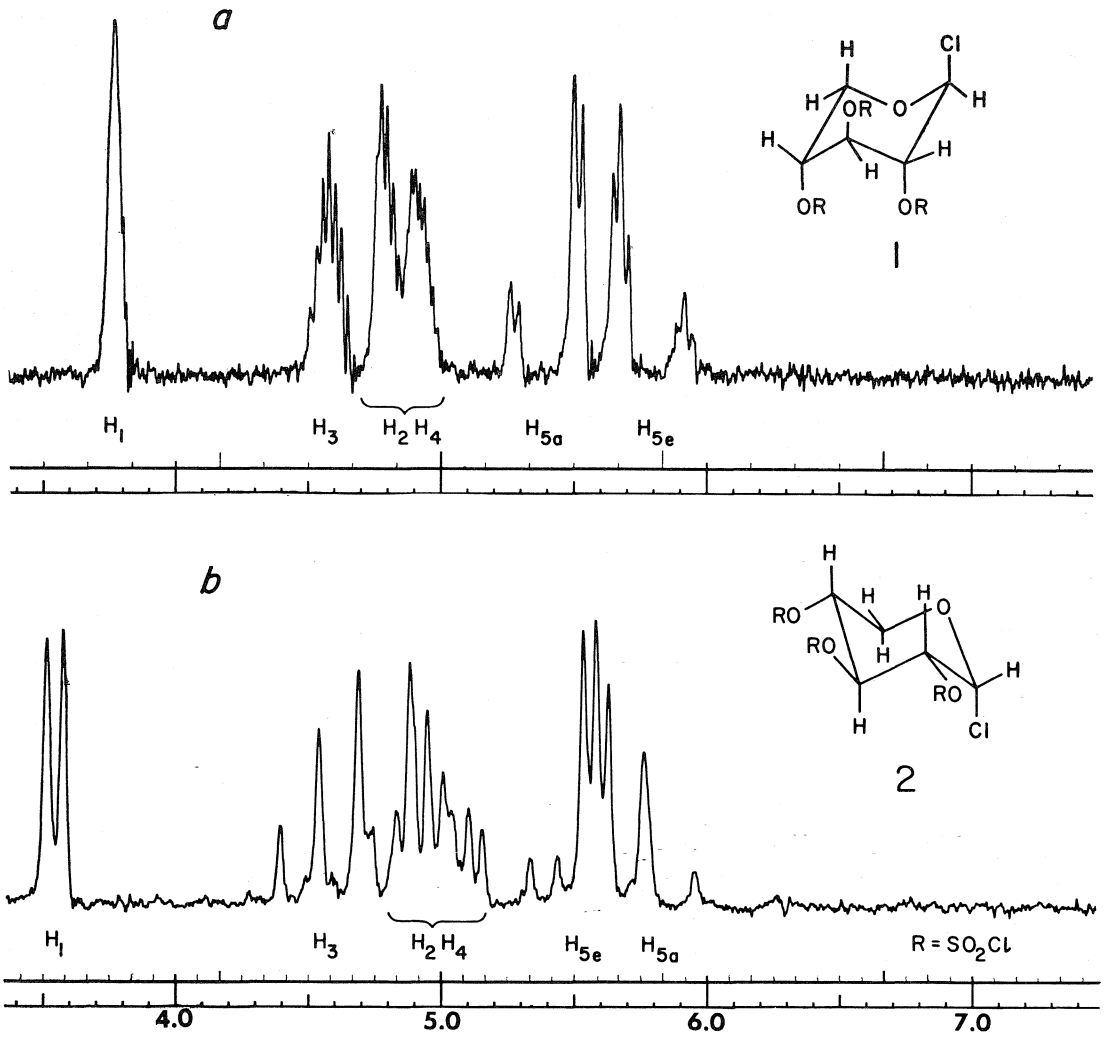

FIG. 1. Proton magnetic resonance spectra at 60 MHz in deuteriochloroform of: *a*) β-D-xylopyranosyl chloride 2,3,4-tri(chlorosulfate) (**1**); *b*) α-D-xylopyranosyl chloride 2,3,4-tri(chlorosulfate) (**2**).

experiments due to the complex overlap of the H-2, H-3, and H-4 signals. However, their small numerical values even if reversed would not affect the conformational deductions.

The p.m.r. spectra of **2** (Fig. 1*b*) and **4** (Fig. 2*b*) are consistent with the existence of both compounds predominantly in the C1(D) conformation. The first-order coupling constants of **2** ($J_{3,4}$ = 9.0 Hz, $J_{4,5e}$ = 6.0 Hz, and $J_{4,5a}$ = 10.6 Hz) are similar to those of **4** ($J_{3,4}$ = 10.0 Hz, $J_{4,5e}$ = 6.0 Hz, and $J_{4,5a}$ = 10.2 Hz) and are consistent with the vicinal diaxial orientation (7) of the H-3, H-4, and H-5a protons of both **2** and **4**. This evidence was also supported in the case of **2** by the fact that equal coupling of the axial H-3 proton with both the axial H-2 and H-4 protons resulted in the appearance of the H-3 signal as a triplet centered on τ 4.52 with $J_{2,3}$ = $J_{3,4}$ = 9.0 Hz. The anomeric protons of **2** and **4** were assigned to the low-field doublets at τ 3.54 and τ 3.69 respectively and the respective coupling constants ($J_{1,2}$ = 3.9 Hz and 1.8 Hz) are

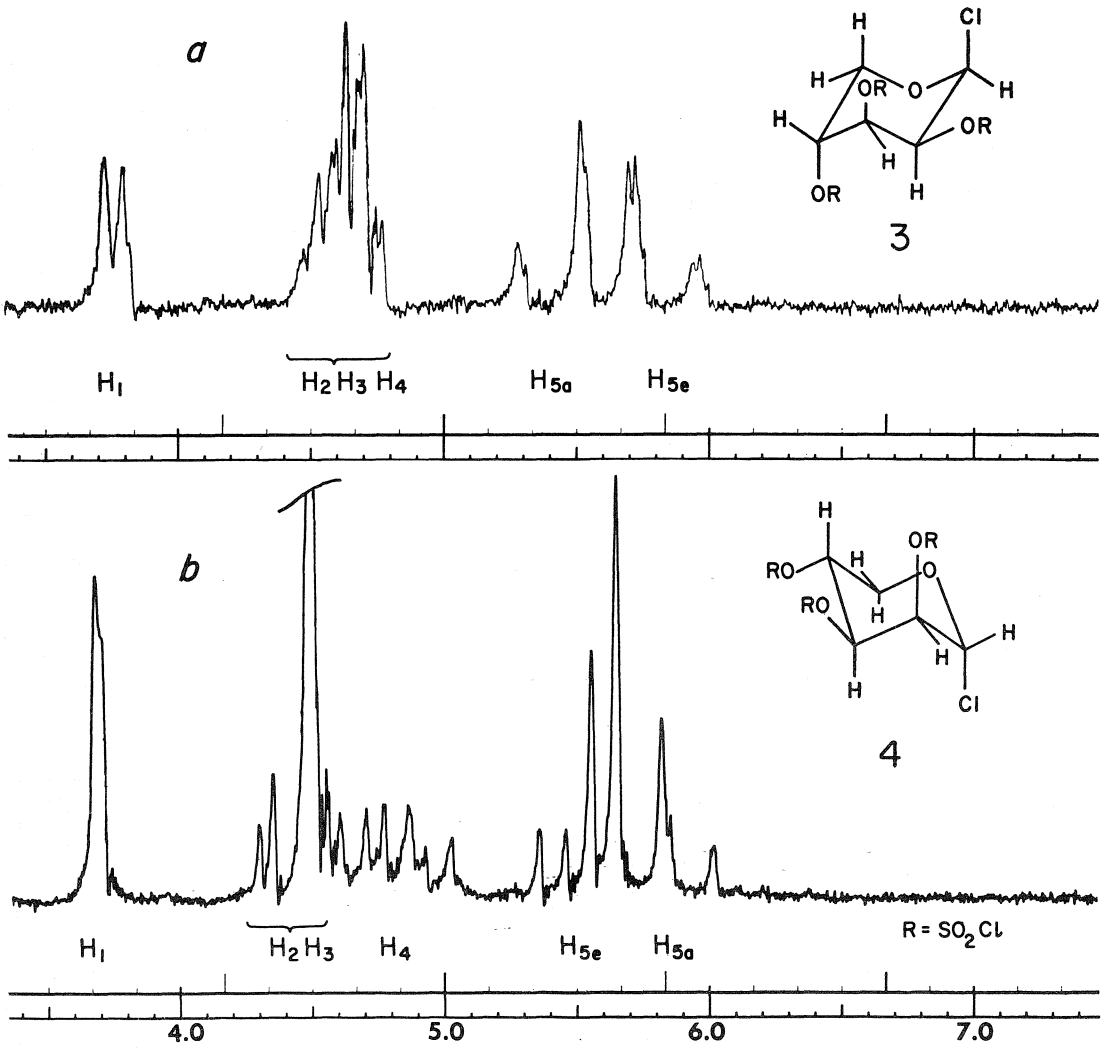

FIG. 2. Proton magnetic resonance spectra at 60 MHz in deuteriochloroform of: *a*) β-D-lyxopyranosyl chloride 2,3,4-tri(chlorosulfate) (**3**); *b*) α-D-lyxopyranosyl chloride 2,3,4-tri(chlorosulfate) (**4**).

consistent with the *gauche* orientation (7) of their H-1 and H-2 protons.

Although the small $J_{1,2}$ values of **1**, **2**, **3**, and **4** are all consistent with a *gauche* orientation (7) of their respective H-1 and H-2 protons, they can be further differentiated as the range of $J_{1,2}$ values of **1** and **4** (1.4–1.8 Hz) are appreciably smaller than those of **2** and **3** (3.8–3.9 Hz). This effect has been previously encountered in pyranose ring systems (9, 10) and in agreement with previous results, these values are typical of J_{ee} coupling for **1** and **4** and J_{ea} coupling for **2** and **3**. A comparison of the geminal coupling constants of **1**, **2**, **3**, and **4** shows that both **1** and **3** have a larger range of values of $J_{5a,5e}$ (14.2–14.4 Hz) than those of compounds **2** and **4** (11.6–12.0 Hz). It has been suggested that the numerical value of $J_{5a,5e}$ is in part dependent on the relative orientation of the vicinal electronegative substituent to the geminal protons (11) the coupling being larger when the electronegative substituent is *gauche* to only one of the geminal protons. The conformations assigned to **1** and **3** (1C(D)) and **2** and **4** (C1(D)) are con-

sistent with this suggestion which is also supported by observations made from the spectra of other pyranose ring compounds (2, 4, 10).

Experimental

Melting points were obtained on a Kofler hot stage and are uncorrected, and optical rotations were measured at 21 ± 3°. The proton magnetic resonance (p.m.r.) spectra were obtained from a Varian A-60A spectrometer at ambient temperature (approximately 30°). The crystalline compounds **1**, **2**, **3**, and **4** were examined as 10–20% solutions in deuteriochloroform using tetramethylsilane (τ 10.0) as the internal standard. Chemical shifts and coupling constants were obtained by first-order analysis and field swept spin decoupling (δ = ±frequency separation in Hz) was carried out using a Varian V-6058A spin decoupler. An equilibrium mixture of each sugar was obtained by concentrating its fully mutarotated aqueous solution to a syrup. The syrup was subsequently treated directly with sulfuryl chloride.

β-D-Xylopyranosyl Chloride 2,3,4-Tri(chlorosulfate) (1)

Crystalline α-D-xylopyranose when treated with sulfuryl chloride as previously described (6) gave a comparable yield of crystalline **1** which had m.p. 84°, undepressed on admixture with authentic **1** (6). The p.m.r. spectrum of **1** (Fig. 1*a*) indicated that **1** was the pure β-D-anomer, and the spectrum remained unchanged after the deuteriochloroform solution had been kept for 24 h at room temperature. The p.m.r. spectrum of the crude reaction product was found to be virtually identical to that of pure **1**.

α-D-Xylopyranosyl Chloride 2,3,4-Tri(chlorosulfate) (2)

Compound **2** was previously synthesized by the anomerization of **1** using aluminium chloride (6). Repetitions of this reaction have indicated that the yields of **2** are poor and unreliable due to the formation of a complex reaction product (p.m.r.). This situation can be improved by using titanium tetrachloride.

Crystalline **1** (3.0 g) was refluxed with titanium tetrachloride (10.2 g) in absolute chloroform (100 ml) solution for 2 h. The mixture was then poured onto crushed ice, and the resultant chloroform phase was separated and washed with sodium bicarbonate solution and water. The chloroform solution was then dried over anhydrous sodium sulfate, filtered, and concentrated to a syrup which rapidly crystallized. Recrystallization from chloroform – light petroleum (b.p. 30–60°) gave crystalline **2** (2.0 g, 60%) of m.p. 98°, undepressed on admixture with authentic **2** (6). The p.m.r. spectrum of **2** (Fig. 1*b*) indicated that **2** was anomerically pure.

An equilibrium mixture of D-xylose (6.0 g) was treated with sulfuryl chloride (6) and yielded a syrupy chloroform soluble mixture (12.0 g) of **1** and **2** (p.m.r.) from which **2** could not be crystallized. Integration of the signals at τ 3.74 and τ 3.54 (anomeric protons of **1** and **2** respectively) indicated that the ratio of α- to β-anomers was 1.6:1 which corresponds roughly to the ratio of β- to α-anomers (D-xylopyranoses) present in the original equilibrium mixture of D-xylose (12).

β-D-Lyxopyranosyl Chloride 2,3,4-Tri(chlorosulfate) (3)

A syrupy equilibrium mixture of D-lyxose (5.0 g) was treated with sulfuryl chloride (6) and the chloroform soluble product was isolated as before (6). The resultant syrup (10.2 g) of $[\alpha]_D$ −60° (*c*, 4.0 in chloroform) slowly crystallized, and recrystallization from chloroform – light petroleum (b.p. 30–68°) gave colorless needles (4.0 g, 26%) of m.p. 78° and $[\alpha]_D$ = −82.8° (*c*, 1.6 in chloroform).

Anal. Calcd. for $C_5H_6Cl_4S_3O_{10}$: C, 13.03; H, 1.30; Cl, 30.55; S, 20.70. Found: C, 13.08; H, 1.53; Cl, 30.41; S, 20.40.

The p.m.r. spectrum of **3** (Fig. 2*a*) indicated that **3** was anomerically pure and the spectrum remained unchanged after the deuteriochloroform solution had been kept for 24 h at room temperature.

The methanolysis of **3** (2.0 g) using silver carbonate was carried out using identical conditions previously described for the methanolysis of **1** (6). The methanolysis produced a syrup (1.8 g) which did not crystallize and which was subsequently dechlorosulfated in aqueous acetone solution with sodium iodide in the presence of excess barium carbonate (6). The aqueous acetone solution was then filtered, and the filtrate was deionized by passage of it through Amberlite I.R. 120 (H^+ form) and Duolite A.4 (OH^- form) ion-exchange resins. Concentration of the deionized solution yielded a syrup which crystallized and recrystallization (two times) from ethyl acetate gave colorless needles (0.21 g, 30%) of $[\alpha]_D$ +57° (1.1 in methanol) and m.p. 109–110°, undepressed on admixture with authentic methyl α-D-lyxopyranoside (13).

α-D-Lyxopyranosyl Chloride 2,3,4-Tri(chlorosulfate) (4)

Crystalline β-D-lyxopyranose (5.0 g) when treated with sulfuryl chloride (6) yielded a syrup which rapidly crystallized. Recrystallization from chloroform – light petroleum (b.p. 30–60°) gave large crystals (9.5 g, 61.3%) of m.p. 92–93° and $[\alpha]_D$ +20.6° (*c*, 1.1 in chloroform).

Anal. Calcd. for $C_5H_6Cl_4S_3O_{10}$: C, 13.03; H, 1.30; Cl, 30.55; S, 20.70. Found: C, 12.80; H, 1.14; Cl, 30.52; S, 20.31.

The p.m.r. spectrum of **4** (Fig. 2*b*) indicated that **4** was anomerically pure and the p.m.r. spectrum of the crude reaction product was virtually identical to that of pure **4**. Compound **4** has been previously isolated in a yield of 52% but the anomeric configuration was not assigned (14); lit. (14) m.p. 94–96° and $[\alpha]_D$ = +20.4° (chloroform).

Cyclic organophosphorus compounds. III. Reactions of nitrosyl chloride with cyclic and open-chain hydrogen thiophosphites[1]

ANDRZEJ ZWIERZAK AND JAN MICHALSKI
Department of Organic Synthesis, Technical University (Politechnika), Łódź 40, Poland

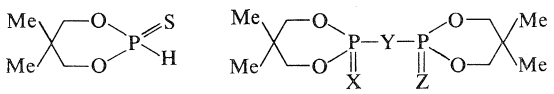
Received September 19, 1968

2-Thiono-5,5-dimethyl-1,3,2-dioxaphosphorinan **1** treated with nitrosyl chloride yields a mixture of asymmetric **2** and symmetric **3** dithiopyrophosphates. Reinvestigation of the reaction of nitrosyl chloride with diethyl thiophosphite showed that, in addition to tetraethyl thiopyrophosphate, the corresponding dithiopyrophosphates are also formed. A mechanism is suggested for the reactions investigated, with nitrosyl chloride as an ambident nucleophile.

Canadian Journal of Chemistry, **47**, 1163 (1969)

Cyclic esters of phosphoric acid with a neopentyl glycol skeleton have recently been extensively applied as model compounds for studying reaction mechanisms (1–4), primarily owing to their relatively high—as compared with acyclic esters—stability and tendency to crystallization. The reaction of dialkyl phosphites with nitrosyl chloride affording pyrophosphate systems was discovered in this laboratory (5). Its mechanistic scheme was supplemented and verified in the elegant studies by Samuel and Silver (6). Almasi and Paskucz (7) claimed that, contrary to the expectations based on the full analogy with dialkyl phosphites, tetraalkyl monothiopyrophosphates are formed in the reaction between dialkyl thiophosphites and nitrosyl chloride. However, no suggestions concerning the reaction mechanism were proposed. The purpose of the present work was to apply the cyclic thiophosphite, 2-thiono-5,5-dimethyl-1,3,2-dioxaphosphorinan **1**, for more detailed studies on the reactions of nitrosyl chloride with thiophosphites.

It was found that **1** reacts with nitrosyl chloride readily in benzene solution at 35–40° to yield a



1

2; X=Y=S, Z=O **4**; X=Z=O, Y=S
3; X=Z=S, Y=O **5**; X=Y=O, Z=S

mixture of asymmetric **2** and symmetric **3** cyclic dithiopyrophosphates.

The reaction proceeds in the presence or absence of pyridine. The overall yield of dithiopyrophosphates **2** and **3** amounts to 60–70%, the **2**:**3** ratio ranging from 1.6:1 in the presence of pyridine to 2.3:1 in the absence of amine, when a ca. 20% benzene solution of nitrosyl chloride was used in the reaction. The **2**:**3** ratio of 3.5:1 was achieved in the presence of pyridine when a ca. 12% solution of nitrosyl chloride in benzene was employed. Compounds **2** and **3** were isolated and purified by crystallization. Their melting points, R_f values (Table I), and infrared (i.r.) spectra, were identical with those of authentic specimens obtained by individual routes. Thin-layer chromatography (t.l.c.) and i.r. spectroscopy revealed that absolutely no monothiopyrophosphates **4** and **5** had formed, a fact in apparent conflict with the results reported by Almasi and Paskucz (7), who claimed that tetraalkyl thiopyrophosphates constitute the major products in the reactions between acyclic thiophosphites and nitrosyl chloride. This observation prompted us to reinvestigate the products of the latter reactions.

The crude[2] and distilled products (R_f values given in Table I) obtained in the reaction between diethyl thiophosphite and nitrosyl chloride, run in the presence as well as in the absence of pyridine, were demonstrated by t.l.c. to be mixtures containing, in addition to *asym* tetraethyl thiopyrophosphate, considerable amounts of the *sym* compound as well as *sym* and *asym* tetraethyl dithiopyrophosphates. Moreover, it was found that the resulting monothiopyrophosphates cannot be the products of subsequent

[1]Paper CXXXVIII on organophosphorus compounds. For Part II see ref. 4.

[2]In this laboratory *sym* tetraethyl thiopyrophosphate was demonstrated to be detectable by t.l.c. On distillation it isomerizes completely to yield the thermodynamically more stable *asym* compound (8).

oxidation of the primarily formed dithiopyrophosphates. Independent experiments revealed that such oxidation does not take place under the conditions of the reaction of dialkyl thiophosphites with nitrosyl chloride.

Kinetic investigations by Samuel and Silver (6) proved that nitrosyl chloride behaves as a typical nucleophile in reactions with dialkyl phosphites. Such behavior may also reasonably be assumed to take place in the reactions with thiophosphites; it is therefore possible to postulate a mechanism for these transformations which would explain the formation of all the products detected. As an ambident nucleophile, nitrosyl chloride can attack the electrophilic phosphorus atom of the thiophosphite, with its softer nucleophilic center located at the nitrogen atom or the harder center situated on the oxygen atom. The two possible reaction sequences are represented by Schemes 1 and 2:

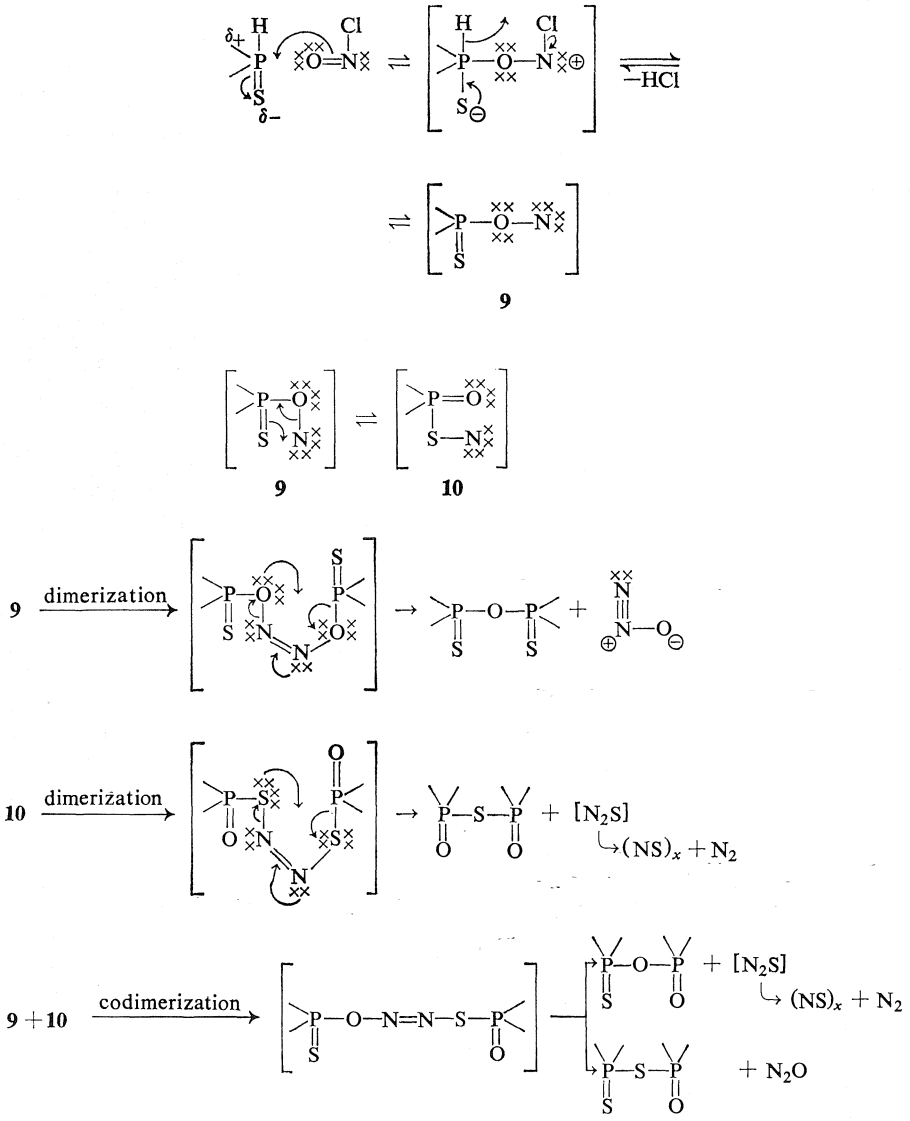

SCHEME 2

While attacking with the nucleophilic nitrogen atom, nitrosyl chloride yields a P-nitroso compound **6**. Its dimer **7**[3] is then intramolecularly rearranged to yield **8** with a phosphorus oxygen bond formed. Samuel and Silver have emphasized (6) that compounds with structures similar to **7** tend to rearrange in order to increase the number of bonds with oxygen. Cyclic rearrangements of oxygen to phosphorus were found in the thermal decomposition of *N*-benzylphosphorimidic trichloride (9) and suggested in the nitrosation of phosphoramides (10). They were also postulated in many reactions of the "Wittig" type (11). A subsequent collapse of the new dimer **8** can account for the formation of asymmetric dithiopyrophosphate (path A) as well as symmetric dithiopyrophosphate (path B). A similar scheme has already been suggested (6) as one of the alternative possibilities of formation of tetraalkyl pyrophosphates in the reactions of nitrosyl chloride with dialkyl phosphites.

[3]Compound **7** is one of the resonance structures of the mesomeric dimer.

*Chromatograms were developed by spraying them with 5% aqueous $AgNO_3$ followed by 2% ethanolic bromothymol blue.

Scheme 2, depicting the consequences of nucleophilic attack by the oxygen atom of the nitrosyl on the electrophilic phosphorus atom of the thiophosphite, attempts to explain the path of formation of tetraalkyl thiopyrophosphates.

The resulting primary unstable compound **9**[4] of a mixed thiophosphoro–hyponitrous anhydride type can dimerize and subsequently split intramolecularly, yielding a *sym* dithiopyrophosphate. The formation of monothiopyrophosphates may be explained only by assuming **9** to exist at equilibrium with the rearrangement product **10**. Such a rearrangement is likely to occur because of the strong p_π—d_π interaction which stabilizes the resulting phosphoryl group. Dimerization of **10**, or codimerization of **9** and **10**, and subsequent intramolecular collapse of the resulting dimers leads to monothiopyrophosphates or possibly to an *asym* dithiopyrophosphate.

The above quoted experimental evidence indicates that the reactions of **1** proceed according to Scheme 1, because no monothiopyrophosphates were found among the products. Such an assumption complies with the predictions, because in this case the softer nucleophilic center on the nitrogen atom of the nitrosyl attacks the relatively soft electrophilic center on the dioxaphosphorinan ring phosphorus atom. Although no direct experimental evidence concerning the electrophilic character of cyclic and open-chain hydrogen thiophosphites is available at present, the latter compounds can be expected to possess a harder electrophilic center at the phosphorus atom. ^{31}P Nuclear magnetic resonance (n.m.r.) data indicate greater electronic shielding of phosphorus in the 1,3,2-dioxaphosphorinan ring ($\delta + 8.13 \pm 1.1$ p.p.m.) (12), than in acyclic phosphate triesters ($\delta + 0.5 \pm 1.5$ p.p.m.) (13). This points to an enhancement in the p_π—d_π double-bond character of the cyclic P—O bonds in the six-membered ring and offers an explanation for the diminished electrophilic reactivity of six-membered phosphate esters as compared with their acyclic analogues. Experimental data bear out this suggestion. The formation of monothiopyrophosphates in the reactions of dialkyl thiophosphites with nitrosyl chloride is explicable only in terms of Scheme 2 which assumes the hard nucleophilic center on the oxygen atom of the nitrosyl to be involved in the attack. However, in terms of the present evidence, the reaction of dialkyl thiophosphites according to Scheme 1 cannot be ruled out as a possibility.

The above presented data reveal a lack of full analogy in the behavior of cyclic and acyclic thiophosphites towards nitrosyl chloride, consequent upon the essential structural differences caused by electronic and steric factors. This indicates that cyclic esters of phosphoric acid

[4]Samuel and Silver (6) have also postulated the formation of intermediates analogous in structure to **9** as one of the alternative possibilities of tetraalkyl pyrophosphates formation in the reactions of dialkyl phosphites with nitrosyl chloride.

are only partially useful as models for mechanistic studies and that the conclusions arrived at should be verified and treated with caution.

Experimental

Solvents were purified by conventional methods. All extracts were dried over $MgSO_4$. Melting points and boiling points are uncorrected. All evaporations were carried out under reduced pressure. Petroleum ether refers to the fraction boiling at 60–80°. Infrared spectra were recorded on a UR-10 spectrophotometer (C. Zeiss). All samples were examined as thin films or Nujol mulls. Thin-layer chromatography (t.l.c.) was carried out on standard glass plates covered with 0.25 mm of Kieselgel G (E. Merck). Samples were analyzed as ca. 5% solutions in benzene or acetone. Two solvent systems (benzene – chloroform – acetone (11:8:1) and benzene–acetone (4:1)) were employed. All chromatograms were developed by spraying them with 5% aqueous $AgNO_3$ followed by 2% ethanolic bromothymol blue solution.

Materials

Nitrosyl chloride was prepared according to Morton and Wilcox (14) by the action of concentrated HCl on an aqueous solution of sodium nitrite, yield 50–60%; benzene solutions (ca. 10 or 20%) of the reagent were used.

2-Thiono-5,5-dimethyl-1,3,2-dioxaphosphorinan **1** was synthesized as described previously (15), yield 90%, m.p. 83.5–84.5°.

Diethyl thiophosphite was prepared by the action of hydrogen sulfide on diethyl phosphorochloridite in the presence of pyridine (16), yield 80%, b.p. 84–86° at 25 mm, n_D^{20} −1.4608.

Reaction of 2-Thiono-5,5-dimethyl-1,3,2-dioxaphosphorinan (1) with Nitrosyl Chloride in the Presence of Pyridine

Nitrosyl chloride (5.9 g, 0.09 mole) in ca. 12% benzene solution was added dropwise for ½ h with stirring and cooling (20–25°) to a mixture of 2-thiono-5,5-dimethyl-1,3,2-dioxaphosphorinan (12.45 g, 0.075 mole), pyridine (5.9 g, 0.075 mole), and benzene (100 ml). Stirring was continued for a further 4 h at 35–40°; the precipitate was then filtered off and washed successively with benzene (2 × 50 ml) and water (2 × 50 ml). The remaining insoluble material (1.9 g, 15%) was dried over P_2O_5 and crystallized from acetone – ethylene chloride (1:1) yielding colorless, long needles of *sym* dithiopyrophosphate **3**, m.p. 228–230°, undepressed on admixture with the specimen prepared by an independent procedure (4) (lit. (4), m.p. 228–230°; (17), m.p. 233°). The infrared (i.r.) spectrum of **3** was identical with that of an authentic sample.

The combined benzene layer and washings were washed successively with water (2 × 100 ml), 5% $NaHCO_3$ solution (2 × 100 ml), and water (2 × 100 ml), before being dried and evaporated. The orange, crystalline residue (9.85 g) was analyzed by the t.l.c. method described and was shown to contain *asym* dithiopyrophosphate **2** contaminated with some amounts of *sym* dithiopyrophosphate **3** and unreacted thiophosphite **1**. *Sym*-monothiopyrophosphate **4** was not found in the mixture, neither did the product contain *asym* monothiopyrophosphate **5** as proved by the absence of the characteristic peak at 733 cm^{-1} in its i.r. spectrum. The spectrum showed bands at 683s, 788s, 824s, 837s, and 864s cm^{-1}, characteristic of **2** and also at 778s and 797s cm^{-1} which indicated the presence of **3**. The crude product was crystallized from benzene – ethyl acetate (1:1) to give slightly yellow prisms (6.75 g, 52%) of *asym* dithiopyrophosphate **2**, m.p. 174–176° (lit. (17), m.p. 171–173°), identical (mixture m.p., i.r. spectrum) with an authentic specimen of **2**.

When a ca. 20% benzene solution of nitrosyl chloride was used in this reaction, more *sym* dithiopyrophosphate **3** (25%) was formed and the yield of *asym* dithiopyrophosphate **2** dropped to 40%.

Reaction of 2-Thiono-5,5-dimethyl-1,3,2-dioxaphosphorinan 1 with Nitrosyl Chloride in the Absence of Pyridine

The reaction was run as described immediately above, starting from **1** (6.23 g, 0.0375 mole) in benzene (50 ml) and nitrosyl chloride (2.95 g, 0.045 mole) in ca. 20% benzene solution. After the mixture had been stirred for 4 h at 35–40°, it was left overnight at room temperature and then degassed and filtered. The solid (1.25 g, 19%) which was washed with benzene (2 × 25 ml) and crystallized from benzene–chloroform (5:2) had m.p. 225–227°. It was identified (i.r. spectrum, mixture m.p.) as *sym* dithiopyrophosphate **3**. Evaporation of the solvent left an orange, crystalline residue (2.8 g, 43%), which was shown (t.l.c., i.r. spectrum) to contain *asym* dithiopyrophosphate **2** contaminated with **3**, unreacted thiophosphite **1**, and two unidentified compounds, possibly decyclization products.

Reaction of Diethyl Thiophosphite with Nitrosyl Chloride in the Presence of Pyridine

A solution of nitrosyl chloride (7.2 g, 0.11 mole) in benzene (30 ml) was added dropwise for ½ h, with stirring and occasional cooling (30–35°) to a solution of diethyl thiophosphite (15.4 g, 0.1 mole) and pyridine (7.9 g, 0.1 mole) in petroleum ether (75 ml). Pyridine hydrochloride precipitated immediately and the mixture acquired a yellow coloration. After the addition had been completed, stirring was continued for 1 h at room temperature; pyridine hydrochloride was then filtered off and washed with benzene. Thin-layer chromatography of the filtrate revealed the presence of *sym* tetraethyl thiopyrophosphate (8). Evaporation of the filtrate and flash distillation of the residue *in vacuo* yielded two fractions: (*a*) 3.0 g, b.p. 52–55° at 0.05 mm (bath temp. 100–105°), n_D^{20} −1.4620 and (*b*) 5.5 g, (36% as calculated for the main component), b.p. 100–102° at 0.01 mm (bath temp. 140–145°), n_D^{20} −1.4614. Fraction (*a*) was identified (t.l.c., i.r. spectrum) as pure, unreacted diethyl thiophosphite. Fraction (*b*) analyzed by t.l.c. was shown to contain *asym* tetraethyl thiopyrophosphate as the main component and *sym* and *asym* tetraethyl dithiopyrophosphates as contaminants.

Reaction of Diethyl Thiophosphite with Nitrosyl Chloride in the Absence of Pyridine

The reaction was carried out as described immediately above, but without pyridine. The same amounts of starting materials were used. A pale-yellow precipitate

(possibly polymeric sulfur nitride) collected on the walls of the reaction vessel during the addition of nitrosyl chloride solution. After the addition had been completed, stirring was continued for 2 h at room temperature. The solution was then filtered, degassed, and evaporated. The residue distilled *in vacuo* afforded two fractions: (*a*) 5.5 g, b.p. 50–60° at 0.05 mm (bath temp. 100–105°), n_D^{20} −1.4614 and (*b*) 4.2 g (28% as calculated for the main component), b.p. 100–103° at 0.01 mm (bath temp. 140–150°), n_D^{20} −1.4694. Fraction (*a*) was identified (t.l.c., i.r. spectrum) as pure, unreacted diethyl thiophosphite. Fraction (*b*) was found (t.l.c.) to contain *asym* tetraethyl thiopyrophosphate contaminated with *sym* and *asym* tetraethyl dithiopyrophosphates. Authentic mixtures of these three components could be resolved and satisfactorily analyzed by the t.l.c. method. The undistilled reaction product (examined by t.l.c.) also revealed the presence of *sym* tetraethyl thiopyrophosphate (8).

Attempted Oxidative Desulfurization of sym and asym Tetraethyl Dithiopyrophosphates by means of Nitrosyl Chloride

Nitrosyl chloride (0.003 mole) in ca. 20% benzene solution was added to *asym* tetraethyl dithiopyrophosphate (0.97 g, 0.003 mole) in petroleum ether (2.5 ml) and the mixture was left for 24 h at 20–25°. After removal of the solvent the residue was shown (t.l.c., i.r. spectrum) to contain only unchanged *asym* tetraethyl dithiopyrophosphate.

No appreciable change was observed when *sym* tetraethyl dithiopyrophosphate was treated with nitrosyl chloride under analogous conditions.

Reaction of dibromocarbene with aromatic ethers

S. D. SARAF
Defence Science Organisation, Chaklala, West Pakistan

Received September 25, 1968

The reaction of dibromocarbene with 1-methoxynaphthalene, 2-methoxynaphthalene, and anisole is discussed. Bromotropones were isolated in good yields in the case of 1- and 2-methoxynaphthalenes. Anisole, on treatment with bromoform and potassium *t*-butoxide gave 4-bromotropone, whereas, on heating with phenyl(tribromomethyl)mercury, *p*-anisic acid and 4,4′-dimethoxybenzophenone were the main products.

Canadian Journal of Chemistry, **47**, 1169 (1969)

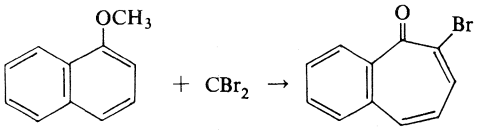
Parham and Reiff (1) have reported that dichlorocarbene reacts with indenes to give cyclopropyl adducts which subsequently afford chloronaphthalenes in high yields by ring expansion and elimination of hydrogen chloride. Birch and Graves (2) have shown that 2,5-dihydroanisole affords tropone and substituted tropones with dichlorocarbene. Parham *et al.* (3) have also reported the formation of chlorobenztropones from 1- and 2-methoxynaphthalenes.

Seyferth *et al.* (4–6) have extensively studied the reaction of phenyl(trihalomethyl)mercury with a large number of carbene acceptors. The yields obtained were good and the neutral conditions could be maintained, since on heating phenyl(trihalomethyl)mercury compounds in benzene, phenylmercury halide is formed.

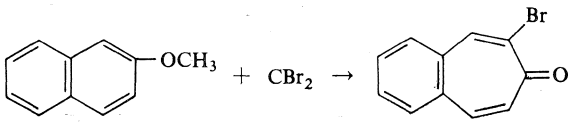
Using this method as a source of carbene, a number of aromatic ethers were studied in the hope of isolating bromotropones, which, on subsequent hydrolysis, would lead to the corresponding tropolones.

1-Methoxynaphthalene on heating with phenyl(tribromomethyl)mercury in dry benzene afforded 7-bromo-2,3-benztropone (**1**, 33%). The ketone was characterized by conversion to the corresponding dinitrophenylhydrazone and by comparison of its infrared (i.r.) and ultraviolet (u.v.) spectra to those of known 7-chloro-2,3-benztropone. The reaction of 2-methoxynaphthalene was effected in the same manner as above. In addition to recovered ether (80%), there was obtained a bromotropone (**2**) in 37% yield. The ketone was characterized by conversion to the corresponding oxime and by its i.r. and u.v. spectra.

Bromotropones proved resistant to acid hydrolysis and were recovered essentially unchanged after reaction with aqueous hydrochloric acid at 120–140° and concentrated sulfuric acid at 0–15°. Similarly, no useful products could be isolated with aqueous potassium hydroxide at 100°.



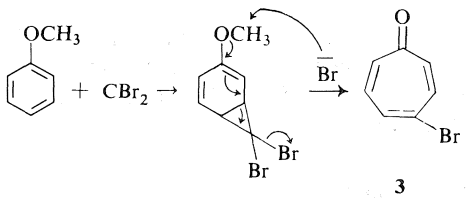
1



2

Anisole showed no reactivity towards dichlorocarbene derived from chloroform and a base (7). Similarly, anisole was recovered unchanged on heating with sodium trichloroacetate in diglyme and with phenyl(trichloromethyl)-mercury in benzene; however, reaction of anisole with bromoform and potassium *t*-butoxide gave 4-bromotropone in low yield. Reaction of anisole with phenyl(tribromomethyl)mercury in benzene at 80° gave none of the tropone but instead, *p*-anisic acid (**4**) and 4,4′-dimethoxybenzophenone (**5**) along with a host of other products.

The formation of 4-bromotropone (**3**) probably involves a similar mechanism to that

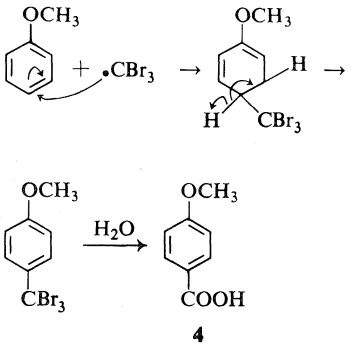


3

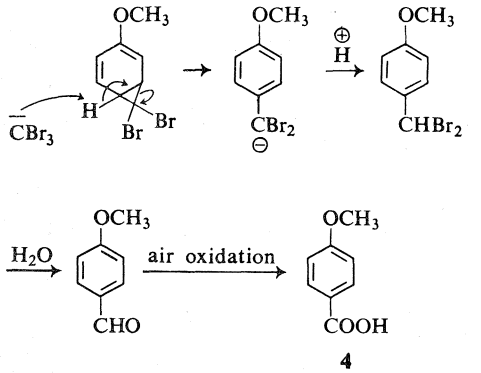
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

involved in the formation of 7-chloro-2,3-benztropone (3) from 1-methoxynaphthalene, i.e. addition of the carbene to the aromatic ring followed by a nucleophilic displacement of a bromide ion, subsequent to a nucleophilic attack on the methyl group.

The formation of *p*-anisic acid (**4**) is difficult to explain. Seyferth and Burlitch (8) have isolated, besides other products, cyclohexyl bromide from a reaction of cyclohexane and phenyl(bromodichloromethyl)mercury, which suggests the possibility of a radical mechanism (9). On that basis the following mechanism may be suggested:



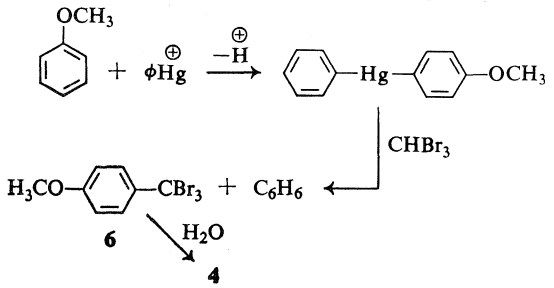
Alternatively, *p*-anisic acid may be formed by an ionic mechanism as shown in Schemes 1 and 2.



SCHEME 1

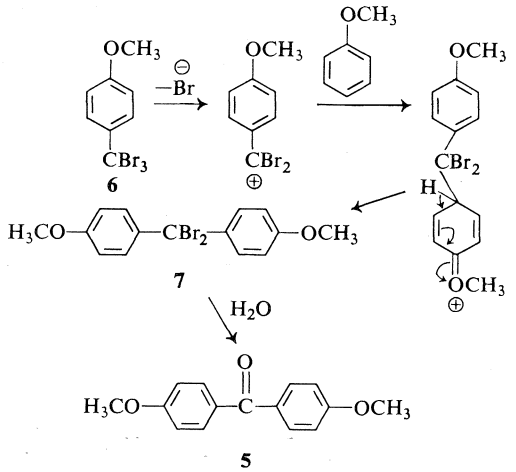
The isolation of diphenylmercury, haloforms, and metallic mercury in such reactions by various research groups (6, 10)[1] supports the above mechanisms.

[1]S. D. Saraf. Unpublished results.



SCHEME 2

The formation of 4,4′-dimethoxybenzophenone may be rationalized by Scheme 3.



SCHEME 3

The above mechanism postulates the formation of **6** as shown in Scheme 2. This may ionize to give an electrophile which would react with anisole to give **8** followed by hydrolysis to the observed product.

Experimental

Reaction of 1-Methoxynaphthalene

A solution of 1-methoxynaphthalene (7 g) and phenyl(tribromomethyl)mercury (8 g) was refluxed with stirring in dry benzene (100 ml) under nitrogen for 2.5 h. The mixture was cooled, filtered, and the residue washed several times with benzene. The filtrate and the washings were combined and distilled *in vacuo* to remove the solvent and the unreacted starting ether (3.5 g). The residue was extracted with boiling petroleum ether (b.p. 40–60°) until no unreacted 1-methoxynaphthalene was recovered and then with 1:1 petroleum ether (b.p. 40–60°) – benzene mixture to give dirty yellow crystals of 7-bromo-2,3-benztropone (**1**) m.p. 94–102°. Recrystallization of this product from petroleum ether (b.p. 60–80°) after sublimation gave white crystals, m.p. 108–109° (1 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

33%). Ultraviolet spectrum (95% ethanol): E_{max} 226 mμ ($\log_e$ 4.2), E_{max} 315 mμ ($\log_e$ 4.1), E_{max} 325 mμ ($\log_e$ 4.1). Infrared spectrum (Nujol): included bands at 1626, 1609, 1594, and 1577 cm^{-1}.

Anal. Calcd. for $C_{11}H_7BrO$: C, 56.17; H, 3.0; Br, 34.0. Found: C, 56.17; H, 2.9; Br, 34.3.

The dinitrophenylhydrazone was prepared in the usual manner and recrystallized from ethyl acetate as red needles, m.p. 232–233°.

Anal. Calcd. for $C_{17}H_{12}N_4O_4Br$: C, 49.15; H, 2.65; Br, 19.3; N, 13.5. Found: C, 49.10; H, 2.90; Br, 19.2; N, 13.5.

Reaction of 2-Methoxynaphthalene

The reaction of 2-methoxynaphthalene (10 g) with phenyl(tribromomethyl)mercury (10 g) in dry benzene (200 ml) was carried out as described above for 1-methoxynaphthalene. Work-up in the usual manner, followed by chromatography on neutral alumina, gave 2-methoxynaphthalene (8 g) and 2-bromo-4,5-benztropone (**2**). The ketone was purified by vacuum sublimation followed by crystallization from petroleum ether (b.p. 60–80°) to give white needles, m.p. 142–143° (1.1 g, 37%). Ultraviolet spectrum (95% ethanol): E_{max} 237 mμ ($\log_e$ 4.4), E_{max} 276 mμ ($\log_e$ 4.6), E_{max} 341 mμ ($\log_e$ 3.6), E_{max} 358 mμ ($\log_e$ 3.3). Infrared spectrum (Nujol): included bands at 1632, 1607, 1558, and 1550 cm^{-1}.

Anal. Calcd. for $C_{11}H_7BrO$: C, 56.17; H, 3.0; Br, 34.0. Found: C, 56.2; H, 3.2; Br, 33.5.

The oxime of **2** was prepared in the usual manner and crystallized from ethanol–water. Light yellow needles were obtained which melted at 201–202°.

Anal. Calcd. for $C_{11}H_8NBrO$: C, 52.3; H, 3.3; N, 5.8; Br, 31.5. Found: C, 52.3; H, 3.2; N, 5.6; Br, 32.0.

Reaction of Anisole with Dibromocarbene

Method A

A stirred solution of anisole (10 g) and potassium *t*-butoxide (20 g) in dry benzene was cooled to −10° and bromoform (15 ml) added dropwise. After 2 h at room temperature, the mixture was filtered, anisole (8 g) recovered by distillation, and the residue was chromatographed on neutral alumina. It was eluted with ether–benzene mixture (1:2) to give a brown solid (132 mg). Repeated crystallizations of this product gave 4-bromotropone (**3**) as colorless needles, m.p. 111–112° (lit. (11) m.p. 112–113°). Ultraviolet spectrum (95% ethanol): E_{max} 230 mμ($\log_e$ 4.12) E_{max} 308 mμ ($\log_e$ 3.72).

Anal. Calcd. for C_7H_5BrO: C, 45.4; H, 2.7. Found: C, 45.6; H, 3.0.

Method B

A stirred solution of freshly distilled anisole (30 g) and phenyl(tribromomethyl)mercury (35 g) in dry benzene (200 ml) was heated at 80° under nitrogen for 2.5 h and the reaction mixture was worked up in the usual manner. Unreacted anisole was distilled and the residue was extracted with boiling petroleum ether (b.p. 40–60°). This extract deposited a solid, which was crystallized from aqueous ethanol to give *p*-anisic acid (110 mg), yield 2%, m.p. 182–184°, undepressed on admixture with an authentic specimen (lit. (12) m.p. 182–183°).

The filtrate was concentrated and chromatographed on neutral alumina with petroleum ether (b.p. 40–60°). The first fraction from the column gave a light-yellow liquid (*a*, 3.2 g). Further elution with benzene gave two solids (*b*, 445 mg) and (*c*, 100 mg).

Fraction a

Thin-layer chromatography showed it to be a mixture of ten compounds but repeated chromatography on alumina resulted in the isolation of only one compound (25 mg) which crystallized from ethanol as colorless needles, m.p. 95–96°. Ultraviolet spectrum (95% ethanol): E_{max} 225 and 312 mμ. The product could not be identified. Fractional distillation of the rest failed to separate the products.

Fraction b

This fraction was rechromatographed on alumina with benzene. The product 4,4′-dimethoxybenzophenone crystallized from petroleum ether (b.p. 60–80°) as long colorless needles, m.p. 145–146.5°, undepressed on admixture with an authentic specimen (lit. (13) m.p. 145–146.5°).

Fraction c

This fraction was rechromatographed on alumina to give a colorless solid, m.p. 151–152.5°, ultraviolet spectrum (95% ethanol): E_{max} 272 and 279 mμ. The molecular weight (Rast) was 226 and an analysis gave: C, 78.6; H, 6.8; OCH_3, 27.6. The product could not be identified.

Reaction of dihalocarbene with *N,N*-dimethylaniline

S. D. SARAF
Defence Science Organisation, Chaklala, West Pakistan

Received September 25, 1968

The reaction of dihalocarbenes with *N,N*-dimethylaniline is discussed. α,α-Dihaloacetanilides and 4,4′-dimethylaminodiphenylmethane were the products isolated.

Canadian Journal of Chemistry, 47, 1173 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

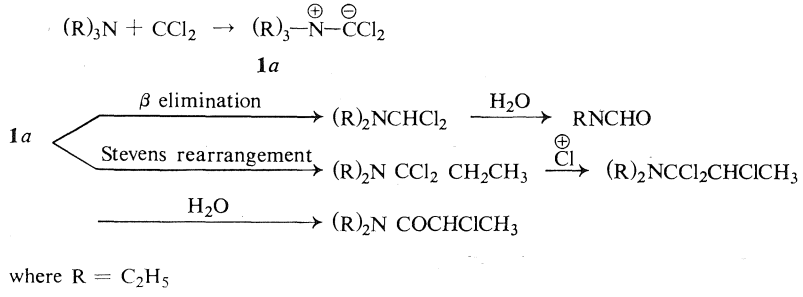
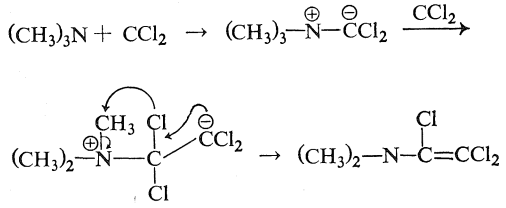
Previous studies of reaction of aliphatic tertiary amines with dichlorocarbene (generated from chloroform and potassium *t*-butoxide) have been reported by Saunders and Murray (1). Dialkyl formamides along with some halogenated amides were the main products isolated.



where R = C_2H_5

Seyferth *et al.* (2) in his studies with phenyl(trihalomethyl)mercury and triethylamine, isolated *N,N*-diethyltrichlorovinylamine in varying yields depending on the reaction conditions. The formation of the product was rationalized by Scheme 1.



SCHEME 1

The object of the present work was to determine the nature of the products resulting from the reaction of dihalocarbenes (from $PhHgCX_3$) with aromatic tertiary amines. *N,N*-Dimethylaniline was heated with phenyl(trihalomethyl)-mercury in benzene at 80° in the hope that ring expansion might lead to the formation of halotropones. However, no tropone like substance was isolated, but instead, *N*-methyldihaloacetanilides, 4,4′-dimethylaminodiphenylmethane and *N*-methylformanilide were the main products of the reaction.

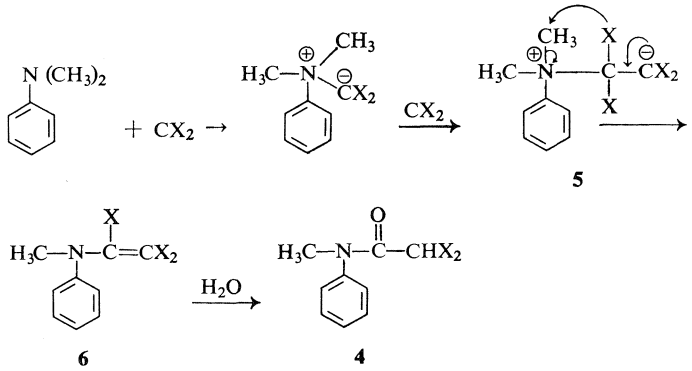
The amide formation can be explained by a mechanism suggested by Seyferth *et al.* (2) as shown in Scheme 2.

The ylid postulated in the above mechanism reacts with one equivalent of dihalocarbene to give **5** followed by the loss of methyl halide to give **6**, which in turn is hydrolyzed to the observed product (**4**).

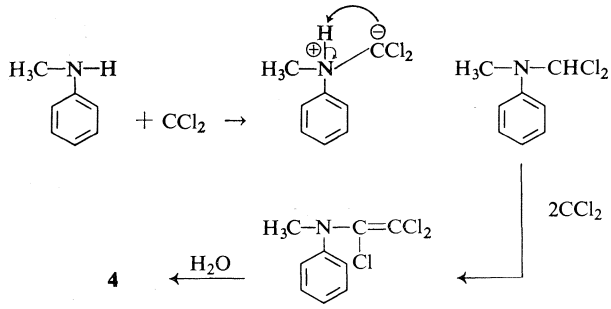
Trihalovinylamines have been shown to be unstable at room temperature and are hydrolyzed in the presence of moisture to the corresponding halogenated amides (3). Water required to hydrolyze **4** may come from the moisture adsorbed on the alumina.

Scheme 4 postulates the formation of *N*-methylanilines as one of the products of this reaction. Parham and Potoski (4) have shown that *N*-methylaniline reacts with phenyl(trichloromethyl)mercury under similar conditions to give *N*-methyl-α,α-dichloroacetanilide as shown in Scheme 3.

This alternative mechanism is probably the most likely one for the formation of **4** and *N*-methylformanilide.



SCHEME 2



SCHEME 3

The formation of 4,4′-dimethylaminodiphenylmethane could easily be explained by Scheme 4.

The above mechanism postulates the formation of an intermediate **7**, which reacts with one equivalent of dimethylaniline to give **8**. Protonation followed by a further reaction with dimethylaniline would lead to the observed product (**9**). This mechanism is similar to that postulated by Parham and Groen (5) for the reaction $\phi S\ CH_3 + CCl_2$.

Experimental

Reaction of N,N-Dimethylaniline with Dibromocarbene

A solution of *N,N*-dimethylaniline (40 g) and phenyl-(tribromomethyl)mercury (45 g) in 200 ml of dry benzene was heated at reflux with stirring under nitrogen for 2.5 h. The mixture was cooled, filtered, and the residue washed several times with benzene. The filtrate and the washings were combined and distilled *in vacuo* to give unreacted *N,N*-dimethylaniline (32 g). The residue was extracted with boiling petroleum ether (b.p. 40–60°) and the extract was chromatographed on neutral alumina. It was first eluted with petroleum ether (b.p. 40–60°) until no unreacted dimethylaniline was recovered, followed by benzene to give slightly yellowish solid (A, 100 mg). Further elution with 25% ether–benzene gave slightly brownish crystals (B, 4.8 g), and a liquid (C, 100 mg).

Fraction A

This fraction was rechromatographed on alumina to give a colorless solid of 4,4′-dimethylaminodiphenylmethane (80 mg), m.p. 89–90° from ethanol, undepressed on admixture with an authentic specimen (lit (6) m.p. 89–90°).

Anal. Calcd. for $C_{17}H_{22}N_2$: C, 80.3; H, 8.6; N, 11.0. Found: C, 80.3; H, 8.4; N, 10.8.

It formed a bis-picrate, which crystallized from methanol as yellow plates, m.p. 183–184°.

Anal. Calcd. for $C_{29}H_{28}N_8O_{14}$: C, 48.9; H, 3.9; N, 15.7. Found: C, 48.9; H, 3.9; N, 15.5.

Fraction B

This fraction was rechromatographed on neutral alumina with 25% ether–benzene to give a colorless solid, m.p. 98–104°. Crystallization of this crude product from petroleum ether (b.p. 60–80°) gave *N*-methyl-α,α-dibromoacetanilide as colorless needles, m.p. 104–105°, undepressed on admixture with an authentic specimen, yield 4.5 g, 26%.

Anal. Calcd. for $C_9H_9Br_2NO$: C, 35.1; H, 3.0; N, 4.6; Br, 52.4. Found: C, 35.0; H, 3.0; N, 4.4; Br, 52.1.

Hydrogenation of this product (**4**) (200 mg) in ethanol

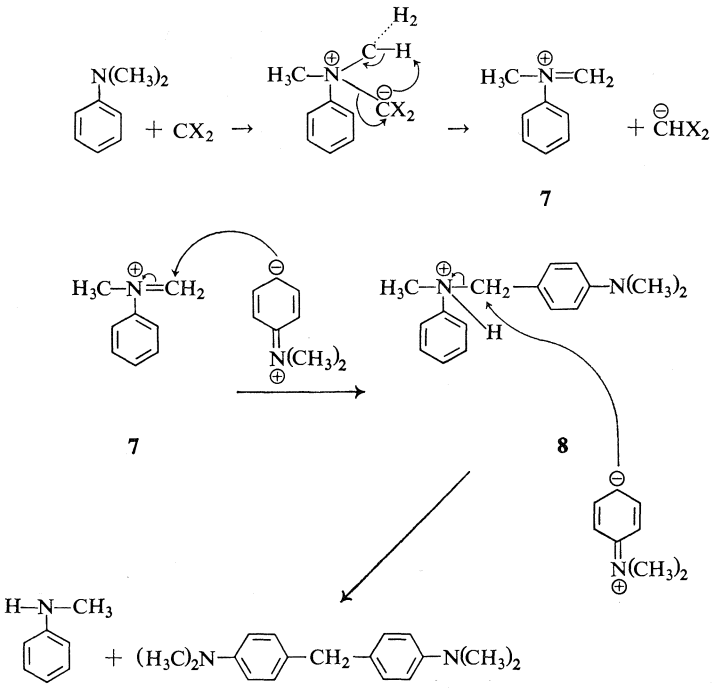

SCHEME 4

(10 ml) with palladium/charcoal (10%, 15 mg) and sodium acetate (120 mg) gave *N*-methylacetanilide (**3**) as a colorless solid, which crystallized from petroleum ether (b.p. 40–60°) and melted at 98–99°, undepressed on admixture with an authentic specimen, yield 82 mg, 85%, (lit. (7) m.p. 100–101°).

Anal. Calcd. for $C_9H_{11}NO$: C, 72.4; H, 7.4; N, 9.4. Found: C, 72.3; H, 7.5; N, 9.5.

N-Methyl-α,α-dibromoacetanilide—To a solution of *N*-methylaniline (2 g) in benzene (10 ml) containing potassium carbonate (2 g) was added dibromoacetyl bromide (1 ml). The mixture was warmed on a water bath for 1 h. Work-up in the usual manner gave a colorless solid, m.p. 100–102°. Crystallization of this product from petroleum ether (b.p. 40–60°) gave *N*-methyl-α,α-dibromoacetanilide as colorless plates, m.p. 105–106°, yield 5 g, 85%.

Fraction C

This fraction was shown to be *N*-methylformanilide by comparison of its infrared (i.r.) spectrum, with that of an authentic specimen.

Reaction with Dichlorocarbene

A solution of *N*,*N*-dimethylaniline (20 g) and phenyl-(trichloromethyl)mercury (8 g) was refluxed with stirring in dry benzene under nitrogen for 44 h. Work-up as described above, left a residue (4 g) which was chromatographed on neutral alumina. It was eluted with benzene to give a brown semi solid (A, 2.3 g). Further elution with 25% ether–benzene mixture gave a yellow solid (B, 900 mg), and a liquid (C, 300 mg).

Fraction A

Crystallization of this fraction from petroleum ether (b.p. 60–80°) gave 4,4′-dimethylaminodiphenylmethane as colorless plates, m.p. 89–90°, yield 1.9 g, 30%.

Fraction B

This fraction on crystallization from petroleum ether (b.p. 60–80°) gave *N*-methyl-α,α-dichloroacetanilide as colorless plates, m.p. 67–68°, undepressed on admixture with an authentic specimen, yield 540 mg, 5%.

Anal. Calcd. for $C_9H_9Cl_2O$: C, 49.5; H, 4.1; N, 6.4; Cl, 32.5. Found: C, 49.7; H, 3.9; N, 6.6; Cl, 32.2.

Hydrogenation of this product in the presence of palladium/charcoal and sodium acetate gave *N*-methylacetanilide (**3**) as a colorless solid, m.p. 98–99°.

N-Methyl-α,α-dichloroacetanilide—A mixture of dichloroacetic acid (1 g) *N*-methylaniline (1 g), and phosphorous pentoxide (5 g) was warmed on a steam bath for 2 h. Work-up in the usual manner gave *N*-methyl-α,α-dichloroacetanilide as a colorless solid, m.p. 67–68°, yield 1.5 g, 75%.

Fraction C

This fraction was shown to be *N*-methylformanilide by comparison of its i.r. spectrum, with that of an authentic specimen.

Synthesis of isomers of acetylcarnitylcholine and other carnitine derivatives

GABOR KATO[1] AND E. A. HOSEIN
Department of Biochemistry, McGill University, Montreal, Quebec

Received April 17, 1968

Carnitine, γ-trimethylammonium-β-hydroxy butyric acid, was synthesized from γ-chloro-β-hydroxy butyronitrile. Acetylcarnitylcholine was prepared either by the esterification of acetylcarnitine or by the acetylation of carnitylcholine.

Canadian Journal of Chemistry, **47**, 1177 (1969)

There is some evidence that acetyl-1-carnitylcholine can be synthesized *in vitro* on the esterification of choline by acetyl-1-carnityl CoA (isolated from fresh rat brain) and choline acetyltransferase (E.C.2.3.1.6) (1). Since acetyl-1-carnitylcholine and/or its precursors *in vivo* would at best be present only in extremely minute amounts (< 1 μg/g fresh brain) the need of larger quantities of such compounds for testing with various chemical, biochemical, physiological, and/or pharmacological systems is apparent. We describe methods for the synthesis of acetylcarnitylcholine, its isomers and various other carnitine derivatives.

Experimental

*Preparation of (±) Carnitine Nitrile Chloride (**1**)*

This material was prepared by the method of Strack *et al.* (2). The infrared spectrum of this compound in Nujol showed the following bands: 3200 cm^{-1} (—OH); 2250 cm^{-1} (—C≡N); 1095 cm^{-1} and 1008 cm^{-1} ($—CH_3$); 964 cm^{-1} and 974 cm^{-1} ($—N^+(CH_3)_3$). The proton nuclear magnetic resonance (n.m.r.) spectrum of **1** consisted of 5 peaks, having areas in the ratio of 1:1:9:1:1 and τ ($≡N^+CH_2—$) – 6.40 and 6.50 p.p.m., τ $(CH_3)_3N^+—$ =6.74 p.p.m., and τ ($—CH_2C≡N$) =7.10 and 7.18 p.p.m. relative to dilute tetramethylsilane (TMS, τ = 10.0 p.p.m.) as external standard.

*Preparation of (−) Carnitine Nitrile Chloride (−**1**) and (+) Carnitine Nitrile Chloride (+**1**)*

Separation of a racemic mixture of **1** was accomplished by the following modification of a procedure by Strack *et al.* (3).

Twenty grams of **1** were changed to the basic form with silver oxide. The aqueous solution was concentrated *in vacuo* to 50 ml with an equimolar amount of *d*-10-camphor-sulfonic acid (**3**) (29.0 g) whereby the crystals came out of solution. These crystals were filtered by suction and washed with absolute alcohol. This will be referred to as *Fraction 1* and contains essentially *d*-carnitine nitrile-*d*-camphorsulfonate, with some contamination of *l*-carnitine nitrile-*d*-camphorsulfonate. The yield was 16.4 g, $[\alpha]_D$ +24.0°.

The mother liquor of *Fraction 1* was concentrated *in vacuo* to dryness, the residue dissolved in boiling 90% ethanol and mixed with sixfold volume of 30% ethanol – HCl mixture, at 0°. The solution was then mixed with an equal volume of anhydrous ether, and allowed to cool at 0°. After 12 h, impure (−**1**) crystallized out of solution, was filtered, and washed with absolute alcohol. The yield was 10.6 g, $[\alpha]_D$ −24.8° (94% optically pure). To obtain optically pure material either one of the following procedures was followed:

(*a*) (−**1**) (10.6 g) obtained above was made into a paste with 75 ml of absolute ethanol at 0°, and converted into the hydroxide with silver oxide previously washed free of water with absolute ethanol. The filtrate and the absolute ethanol extracts of the silver oxide residues were mixed with an equimolar amount of dibenzoyl-*d*-tartaric acid. The total volume was about 150–200 ml from which *l*-carnitine nitrile dibenzoyl-*d*-hydrogentartrate slowly crystallized out. Further fractions were obtained after 24 and 48 h on concentrating the mother liquor. Total yield of *l*-carnitine nitrile-dibenzoyl-*d*-hydrogentartrate was 24.4 g.

The dibenzoyl hydrogentartrate was then converted to the chloride (60% yield) with ethanolic HCl as described earlier. *d*-10-Camphorsulfonic acid and dibenzoyl-*d*-tartaric acid were recovered from the acidic alcohol solution almost quantitatively. Crystallization from absolute ethanol gave 3.9 g of pure (−**1**), melting at 261°, $[\alpha]_D$ −26.2°.

(*b*) An alternative step used in the purification of the optically impure nitrile was to recrystallize this compound ten to fifteen times from absolute ethanol to constant m.p. 261° and constant $[\alpha]_D$ −26.2°. Greater losses were encountered with this process. The final yield of (−**1**) was usually between 2.5 and 4.0 g, $[\alpha]_D$ −26.2°, and m.p. 261°. Infrared bands: 3200 cm^{-1} (—OH); 2254 cm^{-1} (—C≡N); 964 cm^{-1} and 977 cm^{-1} ($—N^+(CH_3)_3$). Its proton n.m.r. spectrum was identical to **1**.

Fraction 1 was converted to the chloride form with ethanolic HCl, and the (+)carnitine nitrile (+**1**) further purified as described above for (−**1**), employing either procedure (*a*) or (*b*). Procedure (*b*) was preferred and typical yield of optically pure (+**1**) was between 4 and 5 g, $[\alpha]_D$ +26.2°, and m.p. 261°. Infrared bands showed identical peaks as **1** and −**1**. Its proton n.m.r. spectrum was also identical with **1** and −**1**.

*Preparation of (±) Carnitine Amide Chloride (**4**)*

This compound was prepared by mild hydrolysis of **1** in HCl. **1** was dissolved in concentrated HCl and stored at room temperature for 2 to 3 weeks. NH_4Cl

was filtered off, the filtrate evaporated *in vacuo* and the residue recrystallized several times from absolute ethanol to give pure **4** melting at 206°. The iodide was obtained by refluxing the chloride in 10% methyl iodide in methanol for 2 h. (±)Carnitine amide iodide melted at 160–162°. The infrared spectrum of **4** showed the following bands: 3300 cm^{-1} (—OH); 1680 cm^{-1} (—C=O); 1620 cm^{-1} (—NH). The n.m.r. spectrum in D_2O showed signals at 6.70 τ (singlet for $-N^+(CH_3)_3$), 6.40 and 6.52 τ ($=N^+CH_2-$), and 7.37 and 7.27 τ ($-CH_2C=O$).

Preparation of (±)Acetyl Carnitine Nitrile Chloride (5)

1 (10 g) was dissolved in minimal amount of glacial acetic acid and an excess of acetyl chloride added. The solution was refluxed for 4 h, cooled, and the solvent mixture evaporated *in vacuo* at 40°. The solid was recrystallized from acetone–ethanol (1:3) mixture to give 8.3 g pure **5** melting with decomposition at 200°. Acetyl carnitine nitrile iodide melted at 180°. Its infrared spectrum in Nujol showed the following bands: 2254 cm^{-1} (—C=N); 1760 cm^{-1} (—C=O); 1015 cm^{-1} and 1240 cm^{-1} (—COC=); 1650 cm^{-1} and 3200–3400 cm^{-1} (H_2O).

Preparation of (±)Acetyl Carnitine Amide Chloride (6)

Compound **4** was acetylated as described above for **1**. The solid product was recrystallized several times from acetone–ethanol (1:3) to yield **6** which melted at 180°. Its infrared spectrum in Nujol showed the following bands: 1750 cm^{-1} (—C=O); 1625 cm^{-1} (—NH).

Preparation of (±)Carnitine Iodide Ethyl Ester (7)

A mixture of 10 g of **10** and 100 ml of ethanol was refluxed with 10 ml of 50% HI for 5 h, cooled and concentrated *in vacuo*. A mixture of 100 g of acetone and 50 g of ether was added slowly to precipitate 6 g of **7** melting at 140°. Its infrared spectrum in Nujol showed the following bands: 3320 cm^{-1} (—OH); 1738 cm^{-1} (—C=O). The n.m.r. spectrum in D_2O showed signals at 6.77 τ ($-N^+(CH_3)_3$), 6.46 and 6.58 τ ($=N^+CH_2$), 7.28 and 7.39 τ ($-CH_2COO-$), 5.62, 5.73, 5.86, 5.96 τ (methylene group in $-CO_2CH_2CH_3$) and 8.63, 8.76, and 8.88 τ (methyl group in $-CO_2CH_2CH_3$).

Preparation of (±)Carnitine Iodide Methyl Ester (8)

The same procedure was employed as above for **7** using methanol instead of ethanol. **8** melted at 120°. Infrared bands were at: 3322 cm^{-1} (—OH); 1740 cm^{-1} (—C=O).

Hydrolysis of (±)Carnitine Nitrile Chloride (1) in Concentrated HCl. Preparation of (±)Carnitine Chloride (10) and Product G_1 (9)

A quantity (17.8 g, 0.1 mole) of **1** was dissolved in 200 ml concentrated HCl and refluxed for 4 h. The reaction mixture was cooled, whereupon a heavy precipitate of NH_4Cl was formed. The slurry was cooled overnight at 5°, the excess NH_4Cl was filtered off and the supernatant kept at room temperature from 5 to 10 days until crystal formation was maximum. Crystallization from absolute ethanol gave 11.5 g of pure **10** which melted at 196°. Its infrared spectrum showed the following major bands: 3255 cm^{-1} (—OH); 1725 cm^{-1} (—COO—); 1056 cm^{-1}, 1069 cm^{-1}, 1097 cm^{-1}, ($-CH_3$); 962 cm^{-1}, 972 cm^{-1} ($-N^+(CH_3)_3$). The proton n.m.r. spectrum

in D_2O showed a singlet at 6.76 τ ($—N^+(CH_3)_3$), 6.45 and 6.56 τ ($=N^+CH_2$), 7.28 and 7.38 τ ($—CH_2COO^-$). When the mother liquor of the NH_4Cl supernatant yielded no more crystalline product (usually after 10 days), the supernatant was evaporated *in vacuo* for 24 h. The oil which separated (3 g), solidified on cooling. This oily solid was called Product G_1 (**9**). It was stored in a desiccator ($MgSO_4$) under reduced pressure. Its infrared spectrum in Nujol showed the following bands: 3250 cm^{-1} (—OH); 1735 cm^{-1} ($—COO^-$); 1050 cm^{-1}, 1069 cm^{-1}, 1099 cm^{-1}, ($—CH_3$); 968 cm^{-1}, 978 cm^{-1} ($—N^+(CH_3)_3$).

*Acetylation of (±) Carnitine Chloride (**10**) and Product G_1 (**9**). Preparation of (±) Acetyl Carnitine Chloride (**12**) and Product G_2 (**11**)*

10 (19.7 g) was acetylated in minimum amount of warm glacial acetic acid and excess acetyl chloride as described for the preparation of **5** and **6**. The solution was refluxed for 4 h, cooled and kept for two days at room temperature when a heavy precipitate (13.2 g) of **12** was formed. Two more crops of crystals of 2.8 and 1.2 g were collected later from the mother liquor. Crystallization from ethanol gave 1.1 g of **10** and 14.8 g of pure **12** (as determined by m.p. and infrared) from ethanol–acetone (3:1) mixture. **12** melted at 188° and showed the following infrared bands: 1720 cm^{-1}, 1745 cm^{-1} (—C=O); 1050 cm^{-1}, 1081 cm^{-1} ($—CH_3$); 1020 cm^{-1} and 1240 cm^{-1} (—COC=); 947 cm^{-1}, 970 cm^{-1} ($—N^+(CH_3)_3$). The proton n.m.r. spectrum in D_2O showed peaks at 6.80 τ ($—N^+(CH_3)_3$), 6.10 and 6.24 τ ($=N^+CH_2—$), 7.12 and 7.23 τ ($—CH_2COO^-$), and 7.86 τ ($—COCH_3$).

The original mother liquor was then evaporated to dryness *in vacuo* in a desiccator for 24 h. Removal of the solvent *in vacuo* led to a colorless thick semisolid gum (4.2 g). Occasionally, the reaction mixture turned pale-yellow. In this instance, the dry gum was dissolved in a minimal amount of ethanol and decolorized with Norit. The product G_2 (**11**) was a clear, colorless sticky material and appeared to be polymeric in nature. Acetylation of **9** by the method described above also gave **11** as determined by infrared. The ester exhibited the following infrared absorption bands: 1725 cm^{-1}, 1745 cm^{-1} (—C=O); 1050 cm^{-1}, 1081 cm^{-1} ($—CH_3$); 1020 cm^{-1} (—COC=); 947 cm^{-1}, 970 cm^{-1} ($—N^+(CH_3)_3$) but several attempts to crystallize this substance were unsuccessful. Consequently the oily ester was employed without further purification in later experiments.

Preparation of the Optical Isomers

The levorotatory and dextrarotatory isomers of most of the compounds shown on Chart 1 from **4** to **12** were also prepared, but since their synthesis were identical to those of their corresponding racemates, only some of their pertinent chemical properties will be given in Table II. Their infrared and proton n.m.r. spectra were virtually identical to their corresponding racemates.

There was, however, a small but significant difference in the absorption of the acetate peaks as shown in Table II.

Isolation of (−)carnitine was accomplished by the method of Friedman *et al.* (4). The total yield from 500 g Difco beef extract was 4.31 g. Its infrared and proton n.m.r. spectra were identical to synthetic (−)carnitine and showed an optical rotation $[\alpha]_D$ −23.7°. It melted at 142°.

*Chemical Properties of (−) Product G_1 (−**9**) and (−) Product G_2 (−**11**)*

It was found in the present investigation that on

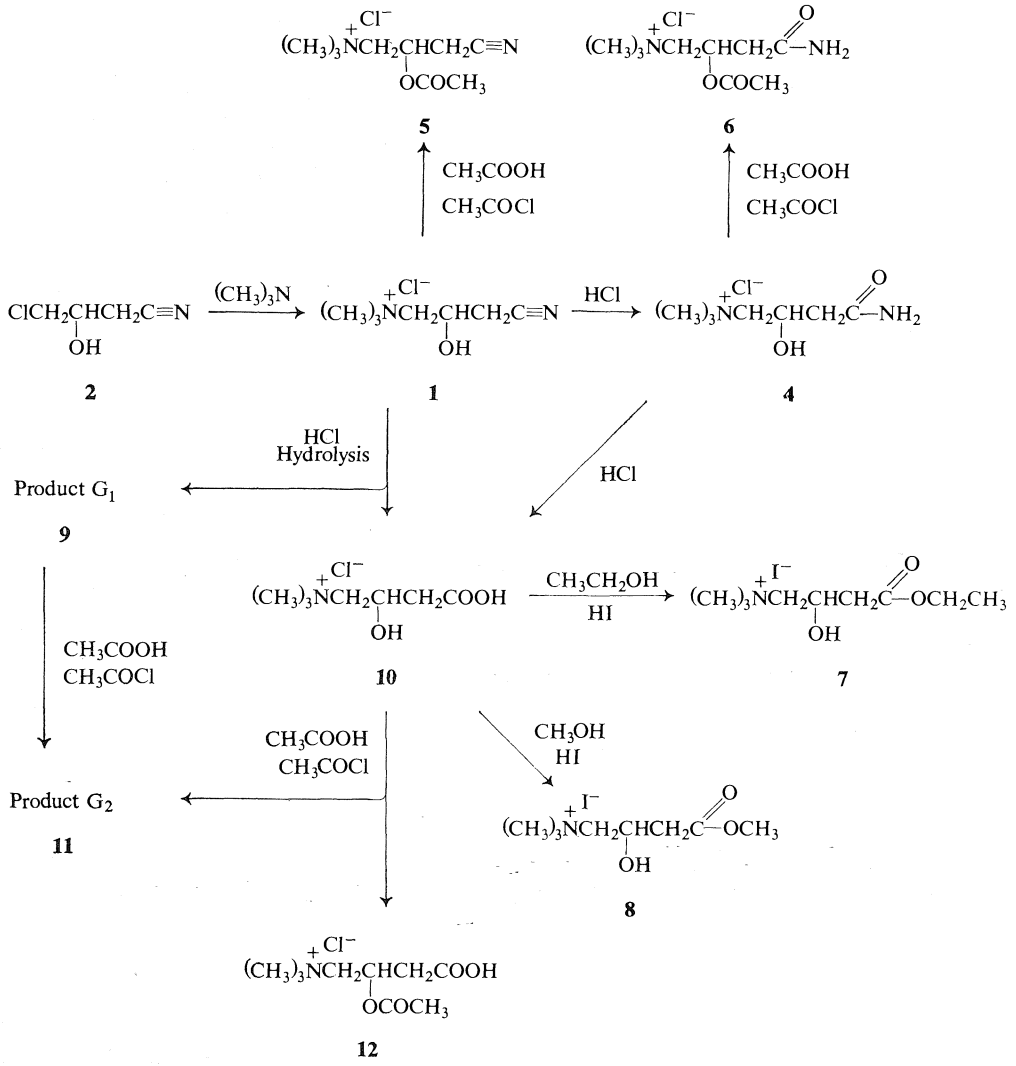

Chart 1

Preparation of certain carnitine derivatives.

reacting −**1** with concentrated HCl two major components (Chart 1) were obtained. One crystalline product was identified as −**10** while the other (−) Product G_1 (−**9**) existed in a gum form, and appeared polymeric. Acetylation of **10** with acetic acid – acetyl chloride mixture also gave two products, one in the crystalline state was identified as −**12** and a second fraction in the gum form referred to as (−)Product G_2(−**11**). Products G_1 and G_2 could not be crystallized and were always obtained as gums. Their n.m.r. and infrared spectra were superimposable upon those of the crystalline products in the same reaction and they appeared to be polymeric as judged by viscosity and dialysis data. Although these products remain to be identified and may be non-homogeneous, it seems that products G_1 and G_2 are apparently polymers of **10** and **12** respectively.

*Preparation of Acetylcarnitylcholine (**18**, Chart 2)*

Method 1

Preparation of 2-Chloroethyl-β-hydroxy-γ-chlorobutyrate

Dry HCl gas (Matheson) was bubbled through a solution containing 250 g of **2**, 180 ml of ethylene chlorohydrin, and 250 ml dry ether for 20 h at −15° according to Braun (5). The thick syrupy product was evacuated overnight at room temperature to eliminate the ether and some of the excess HCl. The imido ester (**13**) was suspended in 500 ml water and allowed to stand at

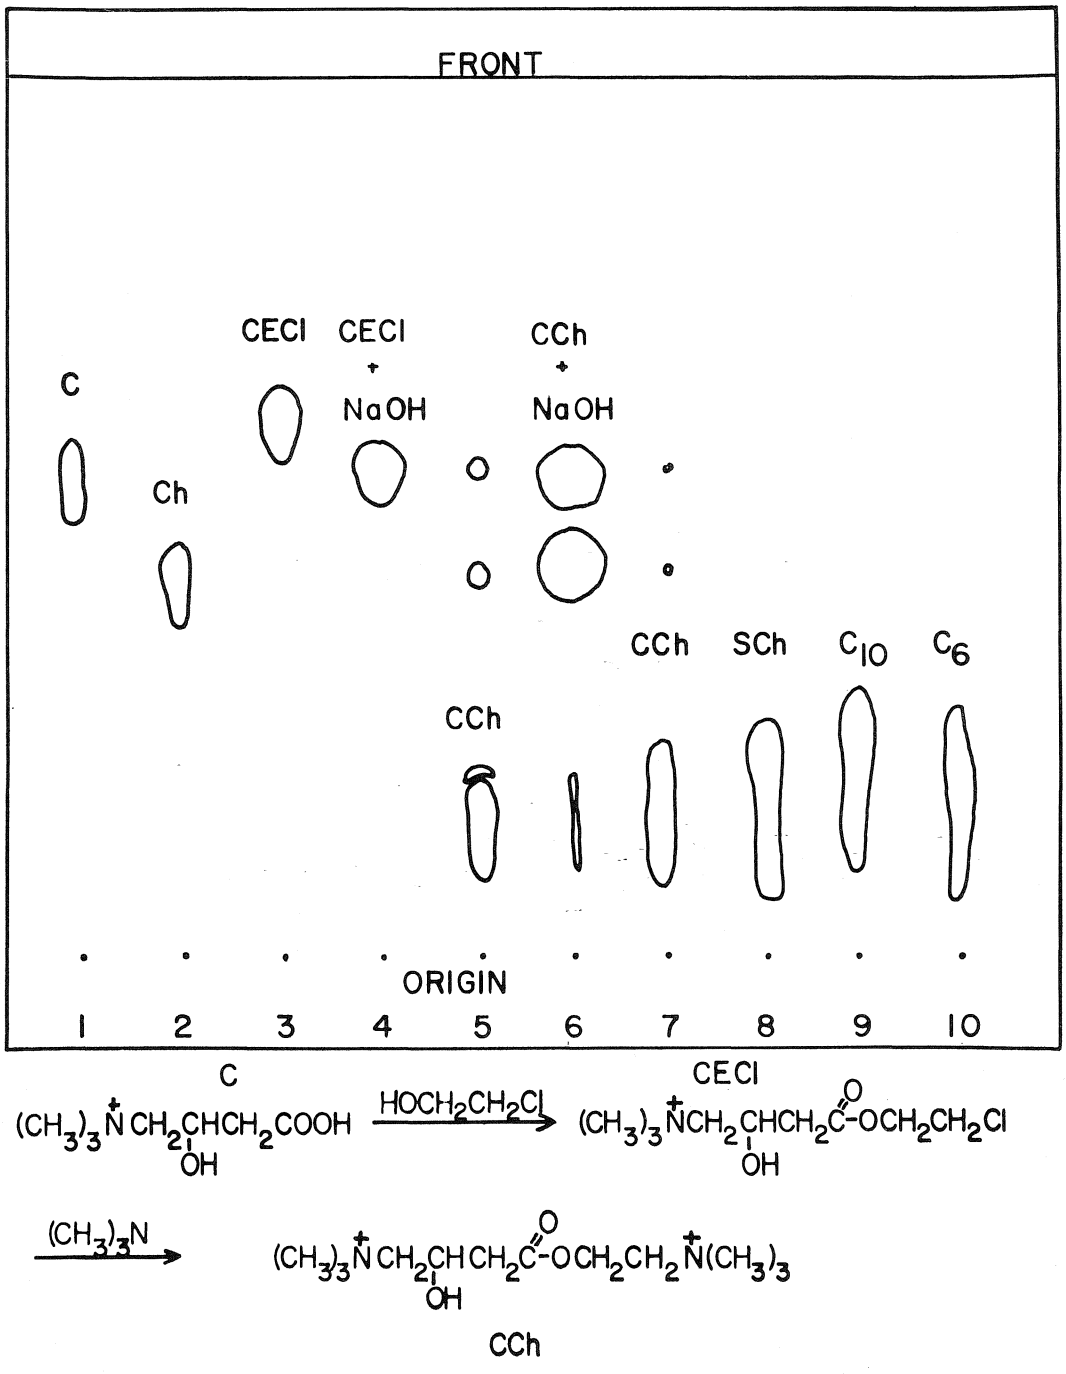

FIG. 1. Thin-layer chromatogram of some related quaternary ammonium compounds: 1, Carnitine (C); 2, choline (Ch); 3, carnitine ethylchloride (CECl); 4, 3 + 1*N* NaOH; 5, carnitylcholine (CCh); 6, 5 + 1*N* NaOH; 7, 5 rechromatographed; 8, succinylcholine (SCh); 9, decamethonium (C_{10}); 10, hexamethonium (C_6). Chromatography was carried out on a 20 × 20 cm plate with a Silica Gel G base, thickness 100 μ.

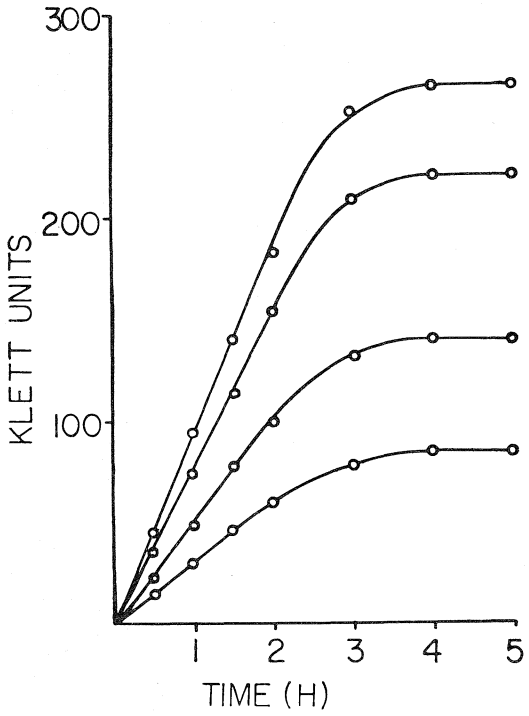

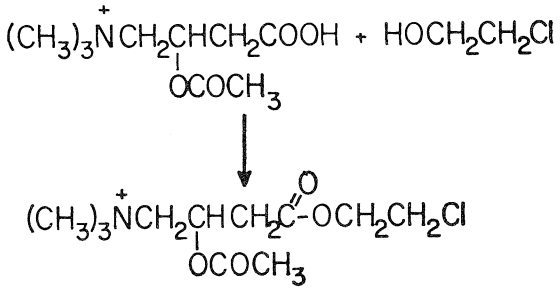

FIG. 2. The curve of ester formation by the reaction of acetyl-*dl*-carnitine chloride with ethylene chlorohydrin at 128°. Aliquots were taken at various intervals for ester determination by the Hestrin method (6). Plots obtained are for increasing initial acetyl-*dl*-carnitine concentrations of 5, 10, and 15 and 20 g/100 ml ethylene chlorohydrin.

45° for 1 h, after which the ester was separated and combined with the etheral extract of the aqueous solution. The combined etheral solution was washed with saturated sodium bicarbonate solution, dried over ammonium sulfate and fractionated by vacuum distillation gave a final yield of 120 g of a colorless sweet smelling ester (**14**) boiling at 140–144° at 7–9 mm Hg.

Anal. Calcd. for $C_6H_{10}O_3Cl_2$: C, 35.82; H, 4.98; Cl, 35.32. Found: C, 36.82; H, 4.37; Cl, 35.72.

The infrared spectrum of **14** showed an alcohol group at 3350 cm^{-1}, an ester group at 1750 cm^{-1} and a chloride group at 667 cm^{-1}.

Preparation of (±) Carnitylcholine Dichloride (17)

Fifty grams of **14** were dissolved in 160 ml of absolute ethanol and treated with 45 g anhydrous trimethylamine in a metallic bomb. After cooling the mixture in a dry ice – acetone bath for 20 min, the bomb was sealed with a clamping device and heated to 60° for 4 h in a water bath. At the end of the reaction, the bomb was cooled in a dry ice – acetone bath, then carefully opened, the excess trimethylamine and ethanol evaporated *in vacuo*, and the solid residue washed with dry ether. Thin-layer chromatography on Silica Gel G of a small quantity (80 mg) of the product in methanol, acetone, HCl (90, 10, 10 v/v) gave two minor bands at R_f 0.48 and one major band at R_f 0.23. Careful removal of the two upper bands and extraction with methanol gave 22 mg of the faster moving material (R_f 0.58) and 14 mg of the slower moving derivative (R_f 0.48). Three recrystallizations of the slower moving component (R_f 0.48) from ethanol–acetone gave crystals melting at 305°. Infrared analysis revealed this substance to be choline. The upper band (R_f 0.58) was recrystallized from ethanol and was found to be carnitine from its melting point (196°) and its infrared spectrum.

The main band (R_f 0.23) was eluted with methanol and converted into its iodo derivative. Three recrystallizations from ethanol gave 12 mg of pure **17** iodide melting at 185°. Upon mild alkaline hydrolysis of **17** with 0.3 *N* NaOH only two major spots were revealed corresponding to carnitine and choline and one minor spot corresponding to unhydrolyzed **17**. Rechromatography of **17** in the same system gave one spot at R_f 0.23. This thin-layer chromatogram along with a number of other bis-quaternary ammonium compounds is shown in Fig. 1. Its infrared spectrum (Fig. 3) showed absorption at 3300 cm^{-1} (—OH); 1735 cm^{-1} (—C=O); 1240 cm^{-1} and 1268 cm^{-1} (—CH_2—); 945 cm^{-1}, 950 cm^{-1}, 962 cm^{-1} (—$N^+(CH_3)_3$). Its proton n.m.r. spectrum in D_2O showed signals at 6.78 τ (—$N^+(CH_3)_3$), 6.45 and 6.55 (=N^+CH_2—), 7.20 and 7.30 τ (—CH_2COO) and 6.16, 6.25, and 6.32 τ (—$COOCH_2CH_2$—).

Preparation of (±) Acetylcarnitylcholine Dichloride (18)

This compound was prepared by the acetylation of **17** in acetic anhydride or acetic acid – acetyl chloride mixture. Excess acetic anhydride (50 ml) was added to 3.2 g of **17** and heated, whereby the crystals dissolved.

The reaction mixture was refluxed for an additional 3 h, then cooled and evaporated *in vacuo*. The precipitate was further dried under P_2O_5, converted to the iodo salt, taken up in absolute ethanol and precipitated with ether. Three recrystallizations from ethanol–acetone (3:1) mixture gave pure **18** iodide melting at 208°. Its infrared spectrum (Fig. 4) had the following bands: 1735 cm^{-1} (—C=O); 1307 cm^{-1}, 1228 cm^{-1}, 1165 cm^{-1}, 1045 cm^{-1} (—CH_3); 971 cm^{-1}, 952 cm^{-1}, 932 cm^{-1} (—$N^+(CH_3)_3$). The proton n.m.r. spectrum of **18** in D_2O showed signals at 6.74 τ (—$N^+(CH_3)_3$), 6.16, 6.22 and 6.29 τ (—$CH_2CH_2N^+$=), 6.96 and 7.06 τ (—CH_2COO—) and 7.81 τ (—$OCOCH_3$).

Method 2

Preparation of (±) Carnitine Ethylchloride Chloride (15)

6 g of **10** were dissolved in 100 ml ethylene chlorohydrin and refluxed at 120°. The progress of the reaction was followed by removing aliquots and reading OD of a ferric hydroxamate complex at 560 mu.

TABLE V

Optical relations and melting points of some carnitine derivatives shown in Chart 2

Derivative		*dl* (±)	*d* (+)	*l* (−)
Carnitine ethylchloride chloride	$[\alpha]_D$	0.00	+19.85	−19.85
Carnitine ethylchloride tetrachloroaurate	m.p.	112°	94°	94°
Carnitylcholine iodide	m.p.	185°	—	—
	$[\alpha]_D$	0.00	+9.32	−9.32
Carnitylcholine tetrachloroaurate	m.p.	122°	—	—
Acetylcarnitylcholine iodide	m.p.	206°	186°	186°
	$[\alpha]_D$	0.00	+9.16	−9.16

In this reaction the excess ethylene chlorohydrin was evaporated *in vacuo* at 45° and the remaining solids were dissolved in boiling ethanol. The solution was cooled and crystals of unreacted carnitine appeared. These were removed by filtration. The supernatant fluid was then evaporated to dryness and recrystallized from an ethanol–ether (3:1) mixture to yield 4.2 g of pure **15**. This product was converted to its tetrachloroaurate derivative which melted at 112°. The n.m.r. spectrum in D_2O showed signals at 6.72 τ ($(CH_3)_3N^+$—), 7.16 and 7.26 τ (—CH_2COO—), 6.40 and 6.50 τ (=CH_2CHOH), 6.04, 6.10, 6.14 and 6.21 τ (—$COOCH_2$—) and 5.42, 5.50, 5.53, and 5.59 τ (—CH_2Cl).

Preparation of (±) Carnitylcholine Iodide

One hundred grams of anhydrous trimethylamine were cooled in an acetone – dry ice bath and carefully poured into a 200 ml capacity metallic container. An amount (usually between 10–15 g) of finely ground **15** was slowly added to the container which was then closed and completely sealed by a clamp. The container was placed on a steam bath for 3 days after which time it was opened and the trimethylamine allowed to evaporate in a fume hood. The hygroscopic residue was washed with ether and converted to its iodo salt and recrystallized three times from ethanol to yield pure (**17**) iodide melting at 185°. Its infrared and proton n.m.r. spectra were identical to (±)carnitylcholine (**17**) prepared by method 1.

Preparation of (±) Acetylcarnitylcholine Iodide

A sample (4.8 g) of acetyl (±)carnitine was dissolved in approximately 150 ml of ethylene chlorohydrin. This solution was then refluxed for 5 h, cooled and the solvent removed under reduced pressure at room temperature. Esterification was again confirmed by removing aliquots and reading OD at 560 mμ. The plot of OD in Klett units (ester concentration) against time for the esterification of acetyl (±)carnitine with ethylene chlorohydrin is shown in Fig. 4.

The crystalline product was dissolved in boiling ethanol and approximately one-third of this volume of acetone was added. After 2 days, the unreacted acetyl (±)carnitine which crystallized out was removed by filtration and the supernatant was removed under reduced pressure. **16** was not isolated but was immediately treated with an excess of anhydrous trimethylamine in a pressure bomb as described earlier for **17**. At the end of the reaction (3 days) the excess trimethylamine was volatilized in a fume hood and any remaining traces were removed by repeated washings with ether. The hygroscopic product was dissolved in distilled water and immediately converted to its iodo salt by conventional methods. After the water was evaporated *in vacuo* at room temperature, a powder was obtained which was recrystallized from ethanol–ether (3:1) to yield 2.3 g of pure **18** iodide which melted at 206°. Its infrared and proton n.m.r. spectra were again identical with **18** iodide prepared by method 1.

Method 3

Preparation of (±) Acetylcarnitylcholine Iodide

The acid chloride (**19**) was prepared by adding 15 ml of thionyl chloride to a suspension of 4.8 g (**12**) in excess chloroform. The solution was heated under gentle reflux on a water bath for 5–10 min until all the crystals

dissolved. The solution was cooled and evaporated under vacuum. The residue was washed several times with dry ether, and the solvent removed. An equimolar amount (2.4 g) of choline chloride was added and the mixture suspended in 100 ml benzene. The reaction mixture was heated under gentle reflux on water bath for 30 min, cooled, and the solvent removed by evaporation under vacuum. The crystalline residue was converted to its iodo salt by interaction with equimolar quantities of KI and recrystallized several times from ethanol–ether (3:1) to yield 3.6 g pure **18** in the iodo form. It melted at 206°.

Preparation of the Optical Isomers

The optically active compounds **15**, **16**, **17**, and **18** were prepared by methods 2 and 3 as for the racemates described above. Since the procedure was identical for their racemates, only certain relevant chemical properties are listed in Tables III, IV, and V. Their infrared and proton n.m.r. spectra were also identical to their corresponding racemates.

Cationic cyclization of deuterated manool[1]

O. E. EDWARDS AND B. S. MOOTOO[2]
Division of Biochemistry and Molecular Biology, National Research Council of Canada, Ottawa, Canada

Received December 10, 1968

A test of the mechanism of acid-catalyzed cyclization of manool to 14α-hydroxyhibane was achieved by synthesis and cyclization of 7,7,9,17,17-pentadeuteriomanool. The reaction involves initial formation of a cyclooctenyl cation, an unusual *in vitro* step. The mass spectrum of the deuterated manool in relation to that of manool was used to analyze its fragmentation.

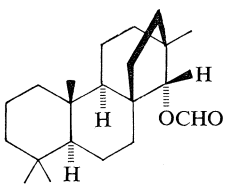
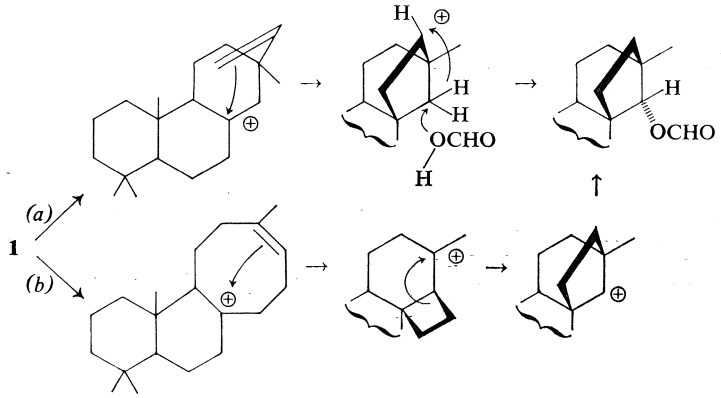
1



2

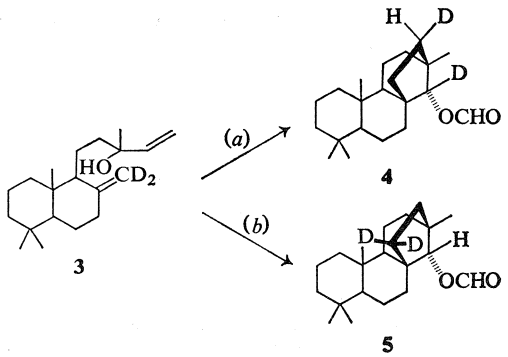
In our recent study (1) of the action of formic acid on manool (**1**), the hoped-for cyclization to a tetracyclic skeleton was observed. However, a completely unexpected feature was the formation of 14α-formyloxyhibane (**2**) rather than 16-formyloxyhibane, hibaene, or kaurane derivatives. This product was also observed by Wenkert and Kumazawa (2). Two mechanisms (*a*) and (*b*) have been considered (1, 2) for the formation of **2**:



A simple way to distinguish these mechanisms appeared to be the preparation and cyclization of 17,17-dideuteriomanool (**3**). The expected location of deuterium in the product is illustrated in **4** and **5**.

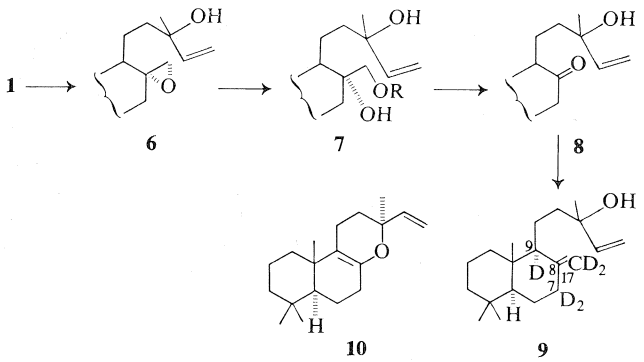
A specifically deuterated manool **9** was prepared as shown on page 1190.

The selective epoxidation has already been described by Jeger and co-workers (3), and by Mousseron-Canet and Mani (4). The epoxide opening to the acetoxy diol **7** (R = Ac) was achieved using anhydrous lithium acetate in dry dimethyl sulfoxide. Traces of water in the dimethyl sulfoxide resulted in opening to the triol **7** (R = H).



3 **4** **5**

[1]Issued as NRCC No. 10574.
[2]NRCC Postdoctoral Fellow, 1966–1968.

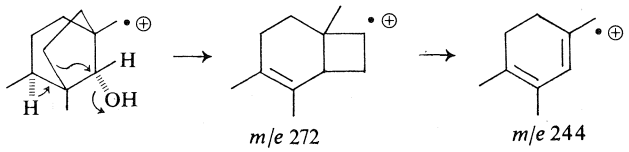


Hydrolysis of the acetoxy-diol gave the triol (**7**, R = H) which was cleaved by periodate under very weakly acidic conditions. At acidities below pH 4 the ketone **8** was largely converted to the enol ether **10**. Ketone **8** had probably previously been prepared in low yield by Wenkert and co-workers (5) by osmium tetroxide – periodate oxidation of manool; however, the cited rotation was of opposite sign.

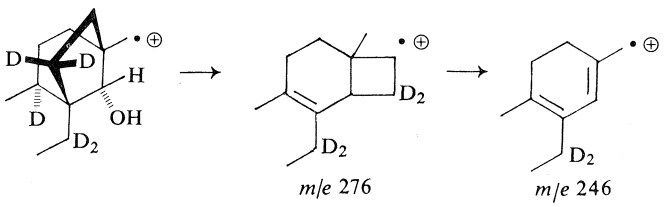
We were unable to prepare dideuteromanool from **8** using dideuteriomethylenetriphenylphosphorane in hexadeuteriodimethylsulfoxide.[3] The hydrogens α to the carbonyl exchanged more rapidly than the Wittig reaction took place. As a consequence the major product was 7,7,9,17,17-pentadeuteriomanool (**9**).

The deuterated manool was treated with formic acid as in our previous work (1). Deuterated 14-hydroxyhibane was produced in ca. 12% yield. Its mass spectrum showed retention of the five deuterium atoms. Its nuclear magnetic resonance (n.m.r.) spectrum had a sharp one-hydrogen signal at δ 2.92 as in the case of the deuterium-free molecule (1). Thus carbon-14 carried a hydrogen instead of the deuterium predicted by mechanism (*a*).

This result eliminates mechanism (*a*) from consideration. Mechanism (*b*) could not readily be confirmed chemically since the deuterium atoms could not be precisely located. However, mass spectrometry provided strong support for it. Two important fragment ions from 14α-hydroxyhibane involved loss of water and ethylene. The composition of these ions and the parent–daughter relations shown below were established by high resolution mass spectrometry:[4]



The pentadeuterio-14α-hydroxyhibane gave ions corresponding exactly with the labelling predicted for mechanism (*b*):



[3]As observed by Atkinson *et al.* (6) this ylid exchanged deuterium rapidly in dimethyl sulfoxide, so that in this solvent only ordinary manool was produced.

[4]We are grateful to Dr. W. D. Jamieson, Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia for these determinations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

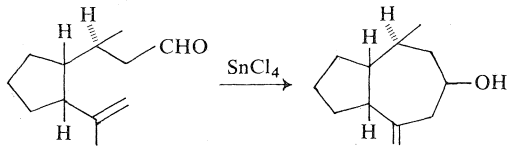
Thus, in the absence of any alternative mechanism consistent with the above facts, we conclude the mechanism (*b*) is correct.

To the best of our knowledge, this is the first *in vitro* cationic cyclization to an eight-membered ring to be observed. However, Marshall and Andersen (7) have recently formed a seven-membered ring by cationic cyclization of an unsaturated aldehyde (**11** → **12**).



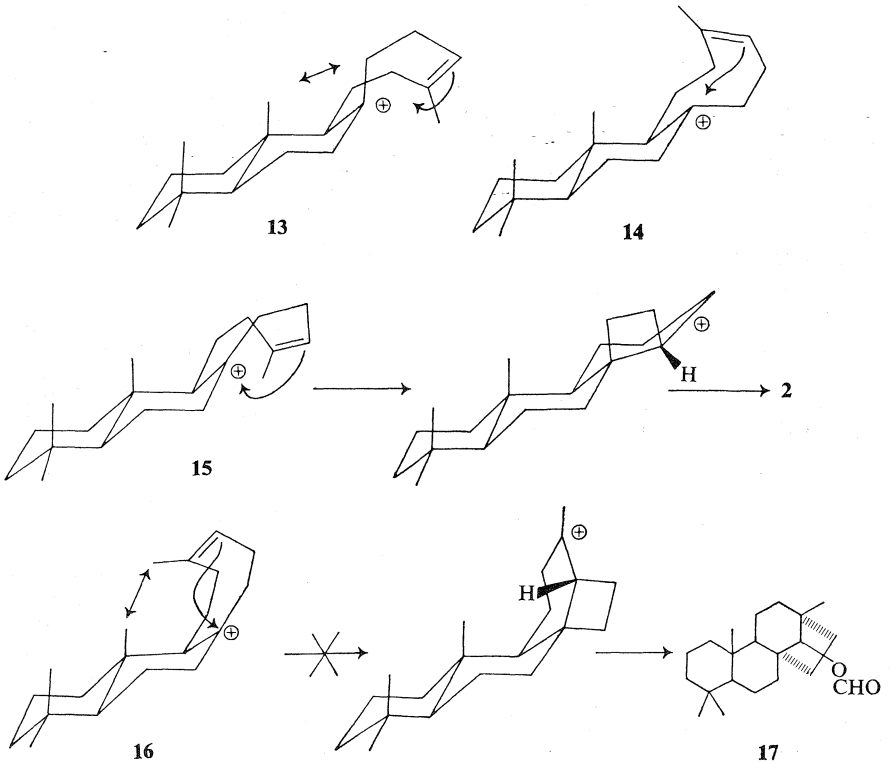
11 **12**

An interesting parallel to mechanism (*b*) is to be found in the postulated route from humulene to α-caryophyllene alcohol (8).

In view of the above results our arguments (1) against the probability of mechanism (*b*) need reexamination. We had assumed that the transition state for formation of the 6–4 ring-fused intermediate would resemble product (nearly tetrahedral C-8). Repulsive interaction developing between the cyclobutane ring and the 10-methyl group (see **13**) would then impede the formation of the hibane skeleton, while the transition state for formation of the isohibane skeleton is quite favorable (see **14**). However, if mechanism (*b*) is correct the transition state must resemble the starting cation (planar C-8). Then the folding leading to **2** (see **15**) would be more favorable than that leading to the isohibane skeleton (**16** → **17**).

It is intriguing that to date no *in vitro* cationic cyclization of the pimarane to hibane systems has been demonstrated, despite the fact that this is such a plausible biosynthetic route to the tetracyclic diterpenes (9). Hence, if this is the *in vivo* route, enzymatic control is vital both for this cyclization step and for the placing of the double bonds of the naturally occurring pimaradienes (ref. 1, page 1115).

The mass spectrum of pentadeuteriomanool (**9**) confirmed some of the assignments made to fragments by Enzell and Ryhage (10). However, others, notably those corresponding to the ions with *m/e* 177, 189, and 204 from manool, require



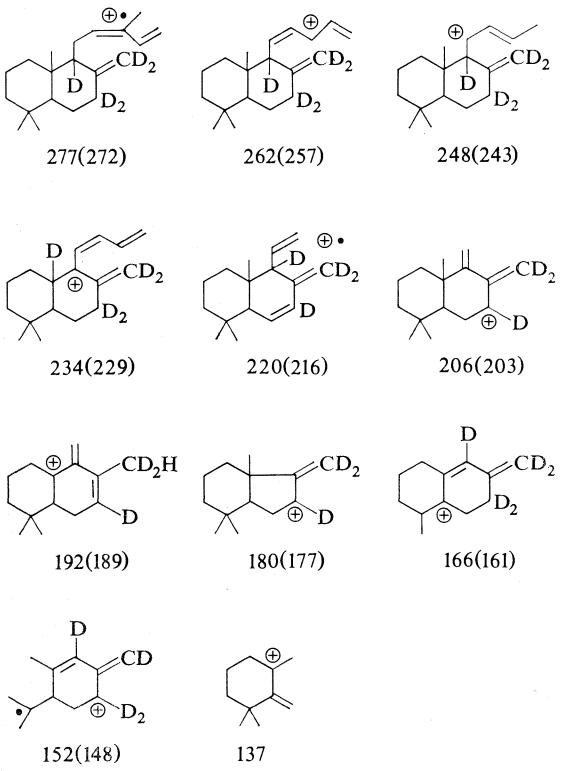


CHART 1

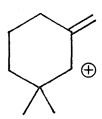
modification. Chart 1 gives our tentative assignments[5] to the most abundant of each of the clusters of ions above *m/e* 137. The least certain of these is the ion with *m/e* 180. The corresponding ions from manool itself are given in parentheses. The main ions below *m/e* 137 contained no deuterium and hence came from the side chain (*m/e* 71) or from ring A.

The most intense peaks below *m/e* 123 in the mass spectrum of 14-hydroxyhibane and the pentadeuterio analogue coincided. Hence these ions originated in ring A. For example, the ion at *m/e* 123 is probably **18** ($C_9H_{15}^+$).



18

[5]The assumption was made that the most abundant ion or the "center of gravity" of each cluster of ions corresponded to the same fragmentation in the deuterated and undeuterated cases.

Experimental

Rotations were of solutions in absolute ethanol. Infrared (i.r.) spectra were of chloroform solutions, measured on a Perkin–Elmer model 257 grating spectrometer, and n.m.r. spectra were of deuteriochloroform solutions with tetramethylsilane as internal reference.

Manool Epoxide

A solution of *m*-chloroperbenzoic acid (9.61 g containing 74% peracid as determined by iodimetry) in chloroform (75 ml) was added dropwise at 0° to a stirred solution of manool (10.99 g) in chloroform (70 ml). Stirring was continued overnight at room temperature. The reaction mixture (containing precipitated *m*-chlorobenzoic acid) was washed thrice with 10% Na_2CO_3 solution. The aqueous washings were grouped and re-extracted with chloroform. The chloroform extracts were washed with water, dried over anhydrous magnesium sulfate, and evaporated to dryness to give 11.2 g of product. Thin-layer chromatography (t.l.c.) (SiO_2, acetone–hexane, 4:1) indicated the presence of a trace of manool and a small amount of a second impurity (possibly β-epoxide; see ref. 3). It was used without further purification.

Reaction of Manool Epoxide with Lithium Acetate

A solution of crude manool epoxide (18 g) and 25 g of anhydrous lithium acetate in 200 ml of dry dimethyl sulfoxide was heated under nitrogen for 35 h at 140–145°. The bulk of the solvent was then removed under 1 mm pressure, the residue diluted with 150 ml of water, and the product extracted into ether (4 × 50 ml). The dried ether solution gave 17.4 g of oil. This was adsorbed on 400 g of neutral alumina, activity 4 from benzene. Methylene chloride – benzene (20:80, 300 ml) eluted the unchanged manool and epoxide (8.17 g). A further 200 ml of this solvent eluted 1.4 g of epoxide and acetoxy diol **7** (R = Ac). Three hundred ml of 50% CH_2Cl_2 in benzene, 100 ml each of 60% and 80% methylene chloride in benzene, followed by 100 ml of methylene chloride, eluted 2.90 g of acetoxy-diol **7** (R = Ac). Methanol in methylene chloride (20:70) eluted a mixture of acetoxy diol and a component with lower R_f on a t.l.c. plate (possibly triol **7**, R = H).

Acetoxy-diol (7, R = Ac)

This crystallized from hexane. After two recrystallizations it had m.p. 106–109° and $[\alpha]_D$ −14.5° (*c*, 1.16). It was sublimed at 100°, 5 × 10^{-4} mm for analysis.

Anal. Calcd. for $C_{22}H_{38}O_4$: C, 72.09; H, 10.45. Found: C, 71.94; H, 10.41.

Its n.m.r. spectrum had peaks at δ 0.81, 0.87, and 1.27 (C—CH_3 groups), 2.11 ($OCOCH_3$), 2.27 (OH), 3.99, 4.07, and 4.26 (CH_2O), 4.91, 4.93, 5.05, 5.12, 5.32, 5.35, 5.73, 5.90, and 6.02 (three vinyl hydrogens).

Triol 7 (R = H)

A solution of 2.9 g of acetoxy-diol **7** (R = Ac) in 60 ml of ethanol was left at room temperature for 5 h, after addition of 10 ml of 10% sodium hydroxide solution. The ethanol was removed under reduced pressure, the mixture diluted with water, and the product extracted into ether. After removal of the ether the triol crystallized. After recrystallization from acetone it formed fine needles, m.p. 145–146°, $[\alpha]_D$ −17° (*c*, 1.27). It was sublimed at 120°, 6 × 10^{-4} mm for analysis.

Anal. Calcd. for $C_{20}H_{36}O_3$: C, 74.02; H, 11.18. Found: C, 74.14; H, 11.08.

Its n.m.r. spectrum had peaks at δ 0.75, 0.81, and 0.87 (C—CH_3 groups) 3.36 (3 OH), 3.7 (CH_2O), 4.91, 4.93, 5.07, 5.11, 5.27, 5.32, 5.36, 5.75, 5.92, 6.04, and 6.11 (three vinyl hydrogens).

Acetylation of the triol at room temperature in 1:1 pyridine – acetic anhydride gave an acetate identical (m.p. and mixed m.p.) with the acetoxy-diol **7** (R = Ac).

*Keto-alcohol **8***

A solution of 2.1 g of sodium periodate in 25 ml of water was brought to pH 6.5 by addition of sodium bicarbonate solution. An ethanol solution of triol **7** (R = H) (2.01 g, in 25 ml) was added slowly with stirring. The pH rose to 7.5 then returned to 7 for the duration of the reaction. After 45 min the reaction mixture was diluted with 25 ml of water then extracted with 4 × 30 ml of ether. The ether yielded 1.66 g of quite pure ketone. This was adsorbed from hexane on to 33 g of neutral alumina, activity 2. A 1:1 hexane–benzene mixture eluted 660 mg of ketone, contaminated with a trace of enol ether **10**. Benzene and methylene chloride eluted 900 mg of pure ketone. Methanol in methylene chloride eluted 83 mg of crystalline impurity.

The ketone would not crystallize. It had ν_{max} 1702 cm^{-1} and n.m.r. signals at δ 0.71, 0.85, 0.97, and 1.26 (CH_3 groups), and a multiplet at δ 4.9–6.2 (three vinyl hydrogens) (see ref. 5 for an alternative preparation). It was distilled for analysis over a short path at 105°, 5 × 10^{-4} mm in ammonia-washed Pyrex bulbs.

Anal. Calcd. for $C_{19}H_{32}O_2$: C, 78.03; H, 11.03. Found: C, 77.88; H, 11.14.

It had $[\alpha]_D$ −43° (*c*, 1.43).

*Enol-ether **10***

To a solution of 120 mg of keto-alcohol **8** in 3 ml of chloroform (¾% ethanol) was added 11 mg of *p*-toluenesulfonic acid hydrate. After 10 min shaking the crystals of acid had nearly completely disappeared, and small liquid droplets had settled on the walls. The i.r. spectrum of the solution now showed no ketone to be present, and a sharp band at 1677 cm^{-1} (enol-ether) had appeared. Solid sodium carbonate was added to the solution, which was then filtered and dried. The oil remaining after removal of the solvent crystallized. After two recrystallizations from methanol it formed stout needles with m.p. 47–48°. It was distilled for analysis at 80°, 5 × 10^{-4} mm. It then had $[\alpha]_D$ +50° (*c*, 0.82).

Anal. Calcd. for $C_{19}H_{30}O$: C, 83.15; H, 11.02. Found: C, 82.91; H, 11.09.

It had ν_{max} 1681 cm^{-1} (vinyl ether) and 1650 cm^{-1} (vinyl group). Its n.m.r. spectrum had peaks at δ 0.85, 0.90, 0.98, and 1.28 (CH_3 groups), 4.87, 4.90, 4.94, 5.11, 5.17, 5.54, 5.70, 5.82, and 6.00 (three vinyl hydrogens). This product proved identical with the readily eluted by-product in the periodate cleavage of triol **7** (R = H).

Manool-d_5

An oil dispersion of sodium hydride (56% hydride) (392 mg) was washed with ether under dry nitrogen to remove the oil. To the hydride was added 10 ml of dry dimethyl sulfoxide-d_6. As soon as the hydride had dissolved, 3.79 g of dry trideuteriomethyltriphenyl phosphonium iodide was added. An orange solution resulted. A solution of 488 mg of keto-alcohol **8** in 6 ml of dimethyl sulfoxide-d_6 was added. The reaction mixture was stirred under nitrogen at room temperature for 14 h, then heated at 65° for 1 h. The cooled mixture was diluted with 20 ml of water, and the product extracted into hexane. The hexane solution was washed with water, dried, and distilled. The residue was adsorbed on 15 g of neutral alumina, activity 2 from hexane. Hexane (20 ml) eluted 4 mg of triphenylphosphine oxide; benzene (10 ml) eluted 53 mg of deuterated manool containing a small amount of triphenylphosphine oxide; benzene, benzene – ether mixtures and ether eluted 395 mg of pure deuterated manool, m.p. after sublimation 50.5–51.5°. Its mass spectrum had intense peaks at *m/e* 277 (12), 262 (30), 248 (2), 235 (2.6), 220 (6), 206 (6), 192 (9), 180 (13), 165 (10), 164 (10), 152 (17), 151 (16), 137 (62), 123 (45), 109 (45), 95 (65), 81 (100), 69 (100), and 55 (80).

Action of Formic Acid on Manool-d_5

To 395 mg of finely divided deuterated manool was added 10 ml of 100% formic acid (dried over boric anhydride). The mixture was shaken vigorously for 20 min, then poured onto a mixture of 90 ml of crushed ice and a concentrated aqueous solution of 15 g of sodium hydroxide. The product was extracted into methylene chloride. The dried solution was concentrated. Its i.r. spectrum had a strong formate ester band at 1715 cm^{-1}.

The methylene chloride was distilled, finally under reduced pressure, giving 385 mg of product. This was dissolved in 5 ml of absolute ethanol. After addition of 200 mg of potassium hydroxide and heating to effect solution, the mixture was left overnight at room temperature. The solution was then boiled for 10 min, then the bulk of the solvent removed under reduced pressure. Water was added and the product extracted into methylene chloride. Evaporation of the methylene chloride left 364 mg of oil. Its i.r. spectrum showed the presence of hydroxyl, but no ester. A hexane solution of 350 mg of the oil was added to a column of 8 g of neutral alumina, activity 3. Hexane (40 ml) eluted 252 mg of pimaradienes; 25% benzene in hexane (20 ml) eluted 4 mg of oil followed by 32 mg of crystals; 50% benzene–hexane (10 ml) eluted 20 mg which crystallized spontaneously. Further elution with 10 ml of 50% benzene–hexane gave 21 mg of oil. Benzene eluted 26 mg which crystallized and ether eluted 26 mg which also crystallized. The 52 mg of less strongly adsorbed crystalline solid was recrystallized from aqueous methanol giving 28 mg of prisms, m.p. 114°. A second crystallization gave pure deuterated 14-hydroxyhibane, m.p. 114–115°. Its mass spectrum had strong peaks at *m/e* 295 (49), 280 (19), 276 (14), 262 (17), 261 (17), 246 (53), 210 (18), 191 (17), 182 (29), 177 (8), 165 (19), 152 (21), 136 (37), 123 (100), 109 (50), 95 (73), 82 (74), 81 (71), 69 (92), and 55 (76).

14α-Hydroxyhibane

Its mass spectrum had prominent peaks at *m/e* 290 (25), 275 (11), 272 (12), 257 (22), 244 (47), 229 (23), 216 (3), 215 (3), 205 (16), 187 (19), 177 (28), 175 (17), 173 (13), 161 (22), 160 (20), 159 (19), 149 (28), 136 (29), 133 (34), 123 (88), 109 (61), 95 (86), 81 (100), 69 (87), 67 (86), and 55 (94). Accurate mass to charge ratios for the ions with *m/e* 290, 272, and 244 were 290.2612 (calcd. for $C_{20}H_{34}O$,

290.26097); 272.2495 (calcd. for $C_{20}H_{32}$, 272.25040); and 244.2188 (calcd. for $C_{18}H_{28}$, 244.21910) respectively.

Acknowledgments

We are grateful to Dr. W. D. Jamieson for accurate *m/e* ratios and parent ion – daughter ion relationships. We thank Mr. A. Knoll and Miss F. Johnson for technical assistance, and Mr. H. Seguin for microanalyses.

Hydrogenolysis of carbohydrate acetals, ketals, and cyclic orthoesters with lithium aluminium hydride – aluminium trichloride[1]

S. S. Bhattacharjee and P. A. J. Gorin
Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received August 19, 1968

The reduction of hexofuranose and hexopyranose acetals with $LiAlH_4$–$AlCl_3$ (1:1, probably AlH_2Cl) to the corresponding ethers proceeds in similar fashion as that of simple acetals and ketals (Scheme I) (refs. 1–7). Certain *O*-methyl and *O*-benzyl derivatives, not readily obtainable otherwise, are conveniently synthesized from appropriate acetals in this way. Cyclic orthoesters of glucofuranose may be selectively reduced to acetals; the steric course of such reduction has been shown unequivocally in the case of orthoformates (Scheme II). Of several cleavable groups, the ease of hydrogenolysis is (*a*) cyclic orthoester > isopropylidene ketal, cyclohexylidene ketal > benzylidene acetal > ethylidene acetal > formal and (*b*) 5,6-*O*-linked or 3,5-*O*-linked acetal or ketal > 1,2-*O*-linked acetal or ketal.

The reductive cleavage of 1,3-dioxolanes, 1,3-dioxanes, 1,3-oxathiolanes, *O*-tetrahydropyran-2-yl, and *O*-tetrahydrofuran-2-yl derivatives to ethers with $LiAlH_4$–$AlCl_3$ has been investigated in detail by several workers, especially in the groups of Eliel (1–3) and Brown (4–7). The effects of various substituents at C-2 and C-4 (Scheme I) on the position of cleavage have been established (4). Although polar effects have been found to predominate, steric factors can also play a role. For example, in **1** electron donor substituents at C-4 result mainly in C_2–O_1 bond cleavage due to the formation of an intermediate ion (**2**) which is partially stabilized, in contrast to the other possible intermediate (**3**). Steric effects arise (8) in the cleavage of compounds that are di-substituted at both C-2 and C-4. In this case scission of the C_2—O_3 bond occurs since the intermediate species is destabilized by non-bonded interactions between the C-2 and C-4 substituents. A rarer type of effect has been observed by Brown and co-workers (9) in hydrogenolysis of compounds in which the approach of reducing species is sterically impeded.

In the light of the existing knowledge of the reductive cleavage with $LiAlH_4$–$AlCl_3$, we were interested in hydrogenolyzing various carbohydrates with the reagent in order to evaluate its synthetic utility and also to test the validity of the reported mechanistic principles in somewhat more complex systems. Various carbohydrates containing cyclic orthoester, *O*-isopropylidene, *O*-cyclohexylidene, *O*-propylidene, *O*-ethylidene, *O*-methylene, and *O*-benzylidene groups were prepared by conventional procedures and each treated with an equimolar mixture of lithium aluminium hydride and aluminium chloride. The condition of hydrogenolysis was generally similar to that used by Brown *et al.* (4–7). The crude reaction products were examined by thin-layer chromatography (t.l.c.) and in some cases by gas–liquid chromatography (g.l.c.) in order to ascertain the number and proportion of various components. The principal reaction product(s) (Table I) obtained from various compounds were isolated and characterized.

The routes of cleavage of *O*-methylene derivatives to methyl ethers are readily predictable, since steric effects should be absent. Hydrogenolysis of methyl 2,3-4,6-di-*O*-methylene-α-D-mannopyranoside (**41**) to methyl 2,6-di-*O*-methyl-α-D-mannopyranoside (**42**) occurs via intermediates which are stabilized by the electron donating environments of C-2 and C-6.[2] The reactions of two moles of the reagent with one mole of 1,2-5,6-di-*O*-substituted glucofuranose ketals or acetal were examined. The main product, in all cases, had the 6-*O*-alkyl group as anticipated by de Belder (10). The 1,2-*O*-isopropylidene or 1,2-*O*-cyclohexylidene group remained intact. The preferential mode of cleavage of the 5,6-*O*-isopropylidene, 5,6-*O*-cyclohexylidene, or 5,6-benzylidene ring follows the

[1]Issued as NRCC No. 10482. Presented at the 51st Meeting of the Chemical Institute of Canada, Vancouver, British Columbia, June 1968.

[2]This method appears to hold promise for preparation of hitherto unsynthesized di-*O*-methyl mannoses, which may be utilized in identification of products obtained by methylation–fragmentation analysis of branched-chain yeast mannans.

polar rule (3, 4), since electrons are likely more available from C-6 than C-5 substituents. Hydrogenolysis of 1,2-5,6-*O*-isopropylidene-α-D-glucofuranose (**12**) and 1,2-5,6-di-*O*-cyclohexylidene-α-D-glucofuranose (**14**) in the presence of copper chromite catalyst gave a similar cleavage pattern (11).

However, hydrogenolysis of methyl 4,6-*O*-benzylidene derivatives of α-galactopyranoside (**24**), α-glucopyranoside (**26**), and α-mannopyranoside (**31**) are less predictable than that of the 5,6-*O*-substituted derivative. The 6-*O*-benzyl derivative (**25**) was obtained preferentially in the case of galactoside; whereas preferential formation of 4-*O*-benzyl derivatives of glucoside (**27**) and mannoside (**32**) was observed. Taking into consideration the yield of the main products and the time of reaction, it is evident that six-membered acetals are more resistant to hydrogenolysis compared to the five-membered ones. This is in accord with previous observations (12, 13) on substituted 1,3-dioxanes and 1,3-dioxolanes.

The hydrogenolysis studies were extended to include the 3,5,6-*O*-substituted orthoesters of α-glucofuranose. The 3,5,6-*O*-orthoformyl derivatives of 1,2-*O*-isopropylidene-α-D-glucofuranose (**5**) and 1,2-*O*-cyclohexylidene-α-D-glucofuranose (**7**) were converted selectively to the corresponding 3,5-*O*-methylene derivatives (**6** and **8**) respectively. Similarly, the corresponding 3,5,6-*O*-orthoacetate (**10**) was converted to the 3,5-*O*-ethylidene (**11**) derivative. The mechanisms of orthoacetate and orthoformate cleavage were studied using proton magnetic resonance (p.m.r.) spectroscopy. 1,2-*O*-isopropylidene-3,5-

SCHEME I. Cleavage of acetals and ketals with $LiAlH_4$–$AlCl_3$.

O-methylene-α-D-glucofuranose contains doublets at τ 5.03 (J = 6 c.p.s.) and τ 5.19 (J = 6 c.p.s.), which are assigned to equatorial and axial *O*-methylene protons, respectively, by analogy with the assignments of Delmau and Duplan (14) in the substituted 1,3-dioxane series. When the orthoformyl derivative was treated with $LiAlD_4$–$AlCl_3$, both the crude reaction product and derived crystals gave one signal at τ 5.18, thus indicating deuteration in the equatorial position (**43**). Interestingly, the product was not equilibrated with approximately 0.1 *N* HCl in chloroform to yield its stereoisomer, and is thus more stable than many other types of acetal and ketal (15, 16, and references therein, 17).

Similar observations on the incorporation of deuterium were made on conversion of 1,2-*O*-cyclohexylidene-3,5,6-*O*-orthoformyl-α-D-glucofuranose (**7**) to a 3,5-*O*-deuteromethylene derivative. Since AlH_2Cl is likely the predominant reactive species in the hydrogenolysis reaction (18), a four-center transition state (19) can be visualized in formation of the specifically labelled 3,5-*O*-deuteromethylene derivatives (Reaction 1, Scheme II).

The hydrogenolysis of 1,2-*O*-cyclohexylidene-3,5,6-*O*-orthoformyl-α-D-glucofuranose (**7**) was less stereospecific when the ratio of $LiAlH_4$–$AlCl_3$ was changed to 1:3. Proton magnetic resonance spectroscopy of the crude reaction product revealed a doublet (τ 4.97: J = 2 c.p.s.; 20% of total methylene signals) with a splitting corresponding to a 5,6-*O*-methylene derivative (**9**) in addition to the quartet of the 3,5-*O*-methylene derivative (**8**). Significantly, isomerization of the 3,5-*O*-methylene derivative to its 5,6-isomer could not be effected using $LiAlH_4$–$AlCl_3$ (1:3) or $AlCl_3$ alone. The mechanism of formation of the 5,6-*O*-methylene derivative appears to involve introduction of a *cis*-hydrogen atom into the 1,3-dioxolane ring since treatment of the orthoester with $LiAlD_4$–$AlCl_3$ (1:3) results in disappearance of the methylene proton at low field.[3]

[3]The position of deuterium labelling of the concomitantly formed 3,5-*O*-deuteromethylene group is the same as the compound formed with $LiAlD_4$–$AlCl_3$ in a 1:1 ratio.

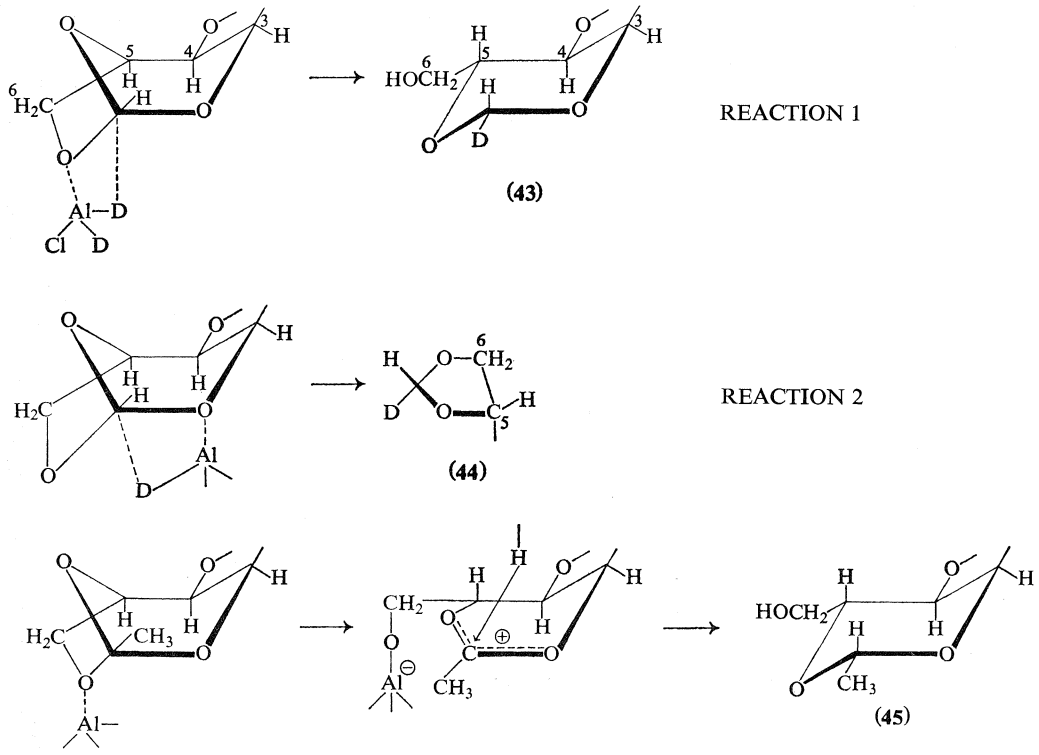

SCHEME II. Conversion of cyclic orthoesters to acetals using $LiAlH_4$–$AlCl_3$.

This proton should be *cis* to the substituent at C-5 since *cis*-ethylidene proton signals in 1,2-*O*-ethylidene glycerol (and its analogues) are at lower field than those of the *trans*-isomer (15). A concerted mechanism involving a four-center transition state (19) similar to that occurring in formation of the 3,5-*O*-deuteromethylene derivative (**44**) therefore occurs (Reaction 2; Scheme II).

Hydrogenolysis of 1,2-*O*-isopropylidene-3,5,6-*O*-orthoacetyl-α-D-glucofuranose using equimolar amounts of $LiAlH_4$ and $AlCl_3$ gave 3,5-*O*-ethylidene-1,2-*O*-isopropylidene-α-D-glucofuranose, which is the thermodynamically stable isomer (**45**, also **11**) since isomerization of acetals may be caused by the reagent when the molar proportion of aluminium trichloride approaches that of lithium aluminium hydride (7). The reaction was repeated using a 1:3 ratio of reagents, respectively. Again the thermodynamically stable isomer was obtained. Unfortunately the possibility of isomeration could not be completely eliminated since we were not able to synthesize the thermodynamically unstable *O*-ethylidene isomer and then test its stability in the hydrogenolysis mixture. The following conclusions should be regarded therefore as tentative. If introduction of an axial hydrogen into the 3,5-*O*-ethylidene group in fact occurred, the four-point attack of the AlH_2Cl species reported in the cleavage of the orthoformates is thus precluded. Instead, the attacking hydride species approaches from the opposite side of the ring from the departing oxygen atom and the reaction is S_N1 in nature (Reaction 3; Scheme II).

In addition to the results reported above on the hydrogenolysis of carbohydrates with $LiAlH_4$–$AlCl_3$, the following observations can be made. The case of hydrogenolysis is comparable to the case of acid hydrolysis of acetals and ketals (10). It occurs in the following order (*a*) cyclic orthoester > *O*-isopropylidene > *O*-cyclohexylidene > *O*-benzylidene > *O*-ethylidene > *O*-propylidene > *O*-methylene, (*b*) 5,6-*O*-

linked or 3,5-*O*-linked acetal or ketal > 1,2-*O*-linked acetal or ketal. No change was observed at the anomeric centers under the described reaction conditions, although minor products in the above reactions were not investigated. Investigations on this topic are proceeding since it is known that anomerization can be effected by using Lewis acid alone (20).

Experimental

Proton magnetic resonance spectra were obtained with a Varian HA-100 spectrometer, using tetramethylsilane as standard and chemical shifts were expressed in τ values. Hydroxyl proton signals were detected in their disappearance on D_2O addition or by variation of chemical shifts with temperature. Characterization of primary, secondary, or tertiary hydroxyls was made according to the method of Chapman and King (21). The g.l.c. unit was of conventional design, with thermal conductivity detectors. The helium pressure was 40 p.s.i. and 2% nitrile silicone gum XE-60 on Chromosorb W (80–100 mesh) (175°) or 2% neopentylglycol succinate on Chromosorb W (190°) in $\frac{1}{4}$ in. × 12 ft columns were used. Thin-layer chromatography was carried out on silica gel G (sulfuric acid spray). Evaporations were performed under reduced pressure and specific rotations were determined at 25°. Infrared spectra were recorded on a Perkin–Elmer instrument. Paper chromatography was carried out on Whatman No. 1 filter paper, solvent: ethyl acetate – acetic acid – water (9:2:2, v/v/v); spray, *p*-anisidine hydrochloride.

General Procedure for Hydrogenolysis with $LiAlH_4$–$AlCl_3$

The starting material (0.5–1.0 g) was added to a stirred suspension of the required amount of lithium aluminium hydride in CH_2Cl_2 – diethyl ether (20 ml). The resulting suspension was stirred magnetically and an ethereal solution of aluminium trichloride, equimolar quantity with respect to lithium aluminium hydride, was added (final ratio of CH_2Cl_2 – ether was generally 1:3, v/v). The reaction mixture was stirred under reflux (anhydrous conditions were maintained) for a definite period as shown in Table I. The reaction was arrested by addition of cold water, the ether layer separated, and the aqueous suspension extracted several times with ether, and then with chloroform. The combined extract was dried (K_2CO_3), filtered, and evaporated to dryness. The mixed product was examined by t.l.c. and in some cases a small aliquot of the product was acetylated and examined by g.l.c. Generally, the principal reaction product crystallized, either directly or after purification by silicic acid column chromatography using an appropriate solvent. The principal reaction products were characterized, but trace components were not further examined. The reaction time, molar equivalents of reagent and yields of principal products are presented in Table I.

Hydrogenolysis of 1,2-O-Isopropylidene-3,5,6-O-orthoformyl-α-D-glucofuranose (5)

Examination of the crude reaction product by t.l.c. (solvent:chloroform–acetone, 1:1, v/v) and g.l.c. (2% nitrile silicone gum) of the acetate showed the presence of one predominant component. Crystallization from chloroform – *n*-hexane, with or without prior chromatography on silicic acid (solvent: chloroform–acetone, 1:1, v/v) gave 1,2-*O*-isopropylidene-3,5-*O*-methylene-α-D-glucofuranose (**6**), m.p. 70–72°; $[\alpha]_D$ +25° (*c*, 1.0 EtOH).

Anal. Calcd. for $C_{10}H_{16}O_6$: C, 51.72; H, 6.89. Found: C, 51.91; H, 6.84.

Proton magnetic resonance data (in $CDCl_3$): 4.00 (doublet, $J_{1,2}$ = 4 c.p.s., anomeric H), 5.03 (doublet, J = 6 c.p.s. equatorial H of —OCH_2O—), 5.19 (doublet, J = 6 c.p.s., axial H of —OCH_2O—), 8.12 (triplet, J = 5 c.p.s., primary OH), 8.48 (singlet, CH_3), 8.64 (singlet, CH_3).

Treatment of the *O*-methylene derivative (50 mg) with trityl chloride in pyridine gave a product (15 mg) which was identical (t.l.c. and mixture m.p.) with 1,2-*O*-isopropylidene-3,5-*O*-methylene-6-*O*-trityl-α-D-glucofuranose prepared in the following manner (22). Potassium *t*-butoxide (1.2 g) was added to a mixture of *t*-butanol (7.5 ml) and toluene (7.5 ml). Subsequent addition of 1,2-*O*-isopropylidene-6-*O*-trityl-α-D-glucofuranose (500 mg), dichloromethane (2 ml), and benzene (50 ml) was made and the mixture refluxed for 72 h under anhydrous conditions. Further addition of potassium *t*-butoxide (1 g) and dichloromethane (2 ml) was made during this period. The reaction mixture was cooled and washed with excess water. The non-aqueous layer was dried (K_2CO_3) and concentrated to a syrup which was chromatographed on a silicic acid column (solvent: chloroform). The faster moving fraction was collected and crystallized from chloroform, m.p. 121°; p.m.r. data (in $CDCl_3$): 2.48–2.80 (multiplet, 15 aromatic H), 4.00 (doublet, $J_{1,2}$ = 3.5 c.p.s., anomeric H), 4.90 (doublet, J = 5.5 c.p.s.; H of —OCH_2O—), 5.18 (doublet, J = 5.5, a H of —OCH_2O—), 8.48, 8.64 (singlets, 2 CH_3).

Preparation of 1,2-O-Cyclohexylidene-3,5,6-O-orthoformyl-α-D-glucofuranose (7)

The procedure for the preparation of 1,2-*O*-isopropylidene-3,5,6-*O*-orthoformyl-α-D-glucofuranose (23) was followed. To a mixture of 1,2-5,6-*O*-cyclohexylidene-α-D-glucofuranose (2.5 g), ethyl orthoformate (3.5 ml), and methanol (1.5 ml), one drop of concentrated hydrochloric acid was added and the mixture stirred for 45 min. Benzene (50 ml) was then added to the resulting mixture, which was shaken with K_2CO_3, filtered, and on concentration 1,2-*O*-cyclohexylidene-3,5,6-*O*-orthoformyl-α-D-glucofuranose (1 g) crystallized. After crystallization from benzene it had m.p. 191° and $[\alpha]_D$ −30° (*c*, 1.0 $CHCl_3$).

For personal use only.

acetate). The reaction product was chromatographed on a silicic acid column (solvent: chloroform–acetone 1:1 v/v) to give (from *n*-hexane) 1,2-*O*-cyclohexylidene-3,5-*O*-methylene-α-D-glucofuranose (**8**) with m.p. 68–70° and $[\alpha]_D$ +22° (*c*, 1.0 EtOH).

Anal. Calcd. for $C_{13}H_{20}O_6$: C, 57.35; H, 7.35. Found: C, 57.26; H, 7.27.

Proton magnetic resonance data (in $CDCl_3$): 3.99 (doublet, $J = 4$ c.p.s. anomeric H), 5.02 (doublet, $J = 6$ c.p.s., equatorial H of —OCH_2O—), 5.20 (doublet, $J = 6$ c.p.s., axial H of —OCH_2O—), 7.16 (triplet, $J = 5$ c.p.s., primary —OH).

*Preparations of 1,2-O-Isopropylidene-3,5,6-O-orthoacetyl-α-D-glucofuranose (**10**)*

A mixture of 1,2-*O*-isopropylidene-α-D-glucofuranose (5 g), ethyl orthoacetate (20 ml), and concentrated hydrochloric acid (3 drops) was shaken for 15 min. On addition of benzene (20 ml) and shaking for another 10 min, complete dissolution occurred. The solution was shaken with K_2CO_3, filtered, and concentrated to a crystalline residue. Recrystallization from benzene gave 1,2-*O*-isopropylidene-3,5,6-*O*-orthoacetyl-α-D-glucofuranose (**10**; 3.5 g) with m.p. 132–134°; $[\alpha]_D$ −41° (*c*, 1.0 in $CHCl_3$).

Anal. Calcd. for $C_{11}H_{16}O_6$: C, 54.09; H, 6.55. Found: C, 54.01; H, 6.46.

Proton magnetic resonance data (in $CDCl_3$): 3.94 (doublet, $J_{1,2}$ = 3.5 c.p.s., anomeric H), 5.48 (doublet, J = 3.5 c.p.s., H_2) 8.38 (singlet, $CH_3C(O)O$—), 8.50, 8.66 (singlets, 2 CH_3).

1,2-*O*-Isopropylidene-3, 5, 6-*O*-orthoacetyl-α-D-glucofuranose was converted to 6-*O*-acetyl-1,2-*O*-isopropylidene-α-D-glucofuranose by treatment with aqueous acid. The orthoester (200 mg) was dissolved in chloroform (15 ml) and 4 drops of 4 *N* HCl added. A crystalline precipitate appeared after 15 min and the reaction was complete in about 30 min (t.l.c.). The crystalline precipitate was dissolved in chloroform, shaken with K_2CO_3, filtered, and concentrated. After recrystallization from chloroform–ether, 6-*O*-acetyl-1,2-*O*-isopropylidene-α-D-glucofuranose (150 mg) with m.p. 146° and $[\alpha]_D$ −5.1° (*c*, 1.0 EtOH) was obtained, (lit. m.p. 146° and $[\alpha]_D$ −6.3° (24).

Anal. Calcd. for $C_{11}H_{18}O_7$: C, 50.38; H, 6.87. Found: C, 50.28; H, 6.98.

The infrared spectrum of this product shows hydroxyl and carbonyl absorptions at 3500 and 1810 cm^{-1}, respectively. Proton magnetic resonance data (DMSO-d_6): 3.85 (doublet, $J = 4$ c.p.s., anomeric H); 4.46, 4.68 (2 doublets, 2 secondary hydroxyls); 7.59 (singlet, CH_3CO—); 8.23, 8.38 (singlets, 2 CH_3).

*Hydrogenolysis of 1,2-O-Isopropylidene-3,5,6-O-orthoacetyl-α-D-glucofuranose (**10**)*

The crude hydrogenolysis product obtained from the orthoacetate consisted of two components (t.l.c. in chloroform–acetone 1:1, v/v, and g.l.c. (silicone nitrile gum) of the acetate). The syrupy minor component comprising about 15% of the mixture is an *O*-ethoxyl derivative of 1,2-*O*-isopropylidene-α-D-glucofuranose as indicated by its p.m.r. spectrum. The major component (80–85%) obtained after silicic acid column chromatography (solvent: chloroform–acetone, 1:1, v/v) was crystallized from chloroform–*n*-hexane and was identified as 3,5-*O*-ethylidene-1,2-*O*-isopropylidene-α-D-glucofuranose (**11**; **45**) with m.p. 101–102° and $[\alpha]_D$ +21° (*c*, 1.0 in ethanol).

Anal. Calcd. for $C_{11}H_{18}O_6$: C, 53.65; H, 7.38. Found: C, 53.87; H, 7.47.

Proton magnetic resonance data (in DMSO-d_6): 3.74 (doublet $J = 4$ c.p.s., anomeric H), 4.62 (quartet, CH of —$OCH(CH_3)O$—), 4.78 (triplet, primary OH) at 70°, 8.20 (singlet, CH_3), 8.34 (singlet, CH_3), 8.49 (doublet, CH_3 of —$OCH(CH_3)O$—).

Treatment of the product with 50% HI (20 min, 100°) gave glucose. The p.m.r. spectrum of the product is identical with that of 3,5-*O*-ethylidene-1,2-*O*-isopropylidene-α-D-glucofuranose prepared by shaking 1,2-*O*-isopropylidene-6-*O*-formyl-α-D-glucofuranose (500 mg) with paraldehyde (10 ml) and 1 drop of concentrated H_2SO_4 for 45 min. Chloroform was added to this mixture, which was then shaken with K_2CO_3, filtered, evaporated to a syrup, and treated with $LiAlH_4$ in ether. The resulting product was purified by silica gel column chromatography (solvent: chloroform–acetone, 1:1, v/v) and crystallization from chloroform–hexane gave 3,5-*O*-ethylidene-1,2-*O*-isopropylidene-α-D-glucofuranose (50 mg).

The 6-acetate was prepared, m.p. 75–76°; p.m.r. data (in $CDCl_3$): 4.00 (doublet, anomeric H); 5.05 (quartet, CH of —$OCH(CH_3)O$—); 7.92 (singlet, —$OCCH_3$); 8.52, 8.68 (singlets, 2 CH_3); 8.72 (doublet, $J = 5$ c.p.s., CH_3 of $CH_3CH(O)O$).

*Hydrogenolysis of 1,2-5,6-Di-O-isopropylidene-α-D-glucofuranose (**12**)*

The crude reaction products obtained by treating the di-*O*-isopropylidene derivative with $LiAlH_4$–$AlCl_3$ had one main component (t.l.c. and g.l.c. of the acetate) which comprised 60–75% of the mixture. It was obtained by fractionation of the reaction product by silica gel column chromatography (solvent: $CHCl_3$–acetone, 1:1, v/v), crystallized from hexane, and identified as 1,2-*O*-isopropylidene-6-*O*-isopropyl-α-D-glucofuranose (**13**) with m.p. 60–63°. After two recrystallizations from hexane the m.p. was 65–66° (lit. 65–67° (25)); $[\alpha]_D$ +5° (*c*, 1.0 $CHCl_3$); lit. +6.6° (25).

Anal. Calcd. for $C_{12}H_{22}O_6$: C, 54.96; H, 8.39. Found: C, 54.68; H, 8.43.

Proton magnetic resonance data (in DMSO-d_6): 4.26 (doublet, $J = 4$ c.p.s., anomeric H), 4.96 and 5.42 (2 doublets, 2 OH), 8.65 and 8.79 (2 singlets, 2 CH_3), 8.91 (doublet 2 CH_3).

A small quantity (50 mg) of the principal product on hydrolysis with *N* sulfuric acid (6 h, 100°) afforded a crystalline compound (20 mg) with m.p. 120–122° (lit. 123° (25)), which was indistinguishable from 6-*O*-iso-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

propyl-D-glucose (11) on a paper chromatogram. Treatment of 1,2-*O*-isopropylidene-6-*O*-isopropyl-α-D-glucofuranose with 50% HI (20 min, 100°) gave glucose.

*Hydrogenolysis of 1,2-5,6-Di-O-cyclohexylidene-α-D-glucofuranose (**14**)*

Silicic acid column chromatography (solvent: chloroform–acetone, 1:1, v/v) of the crude hydrogenolysis product gave a syrupy major component 1,2-*O*-cyclohexylidene-6-*O*-cyclohexyl α-D-glucofuranose (**15**); 70–80% of the crude product) with $[\alpha]_D$ −3.7° (*c*, 0.5 EtOH).

Anal. Calcd. for $C_{18}H_{30}O_6$: C, 63.15; H, 8.76. Found: C, 62.88; H, 8.86.

The syrupy material (80 mg) was hydrolyzed with *N* H_2SO_4 (5 h, 100°), neutralized ($BaCO_3$), filtered, and evaporated to 6-*O*-cyclohexyl-D-glucose (45 mg) which, from methanol–water, had m.p. 111–113° (lit. 115–117° (11)). On oxidation with sodium metaperiodate in D_2O for 16 h, p.m.r. examination indicated 4 formic acid protons (1.16) and 11 cyclohexyl protons (7.4–8.4).

Syrupy 1,2-*O*-cyclohexylidene-6-*O*-cyclohexyl-α-D-glucofuranose was converted to crystalline 1,2-*O*-cyclohexylidene-6-*O*-cyclohexyl-3,5-*O*-methylene-α-D-glucofuranose. A portion (200 mg) was mixed with a solution of anhydrous potassium *t*-butoxide (600 mg) in *t*-butanol (5 ml) and toluene (5 ml). This was followed by the addition of dichloromethane (2 ml) and benzene (50 ml). The resulting mixture was refluxed under anhydrous conditions for 3 days, during which another 5 ml of dichloromethane and potassium *t*-butoxide (800 mg) were added. The mixture was then cooled, washed with excess of water, dried (K_2CO_3), filtered, and evaporated to dryness. The product was chromatographed on a column of silicic acid (solvent: chloroform) and the fast-moving fraction (30 mg) crystallized from chloroform – *n*-hexane. 1,2-*O*-Cyclohexylidene-6-*O*-cyclohexyl-3,5-*O*-methylene-α-D-glucofuranose, thus obtained, had m.p. 86° and $[\alpha]_D$ +23° (*c*, 0.6 $CHCl_3$).

Anal. Calcd. for $C_{19}H_{30}O_6$: C, 64.40; H, 8.47. Found: C, 64.36; H, 8.57.

Proton magnetic resonance data (in $CDCl_3$): 4.00 (doublet, $J_{1,2}$ = 4 c.p.s., anomeric H), 4.83 (doublet, J = 6 c.p.s., H of —OCH_2O—), 5.23 (doublet, J = 6 c.p.s., H of —OCH_2O—), 5.48 (doublet, J = 4 c.p.s. H_2), 8.00–8.80 (21 cyclohexyl protons).

*Hydrogenolysis of 5,6-O-Benzylidene-1,2-O-isopropylidene-α-D-glucofuranose (**16**)*

Reaction with $LiAlH_4$–$AlCl_3$ gave a crude product, which on silicic acid column chromatography (solvent: chloroform–acetone, 1:1, v/v) afforded a fastest-moving fraction (**17**; 55–65% of the crude reaction product). Proton magnetic resonance data (in DMSO-d_6): 2.30 (multiplet, aromatic H), 3.84 (doublet, $J_{1,2}$ = 4 c.p.s., anomeric H), 4.50 (doublet, secondary OH), 4.80 (doublet, secondary OH), 5.10 (singlet, *O*-benzyl), 8.26 (singlet, CH_3), 8.40 (singlet, CH_3).

*Preparation of Methyl 2,3-4,6-Di-O-methylene-α-D-mannopyranoside (**41**)*

To a suspension of methyl α-D-mannopyranoside (4 g) in acetic acid (20 ml), paraformaldehyde (5 g) and concentrated H_2SO_4 (4 drops) were added and the mixture heated at 100° for 1 h. The resulting solution was cooled, mixed with chloroform and cold water, and the aqueous portion extracted with chloroform. The combined extract was washed several times with water, dried (K_2CO_3), and concentrated to a crystalline residue. Three recrystallizations from methanol gave 600 mg of pure di-*O*-methylene derivative. Alternately, silicic acid column chromatography (solvent: chloroform) of the crude reaction product (3 g) afforded a fastest-moving fraction which was crystallized from methanol. The methyl 2,3-4,6-di-*O*-methylene-α-D-mannopyranoside (**41**; 1 g) had m.p. 144–146°, $[\alpha]_D$ +19° (*c*, 1.0 EtOH).

Anal. Calcd. for $C_9H_{14}O_6$: C, 49.54; H, 6.47. Found: C, 49.64; H, 6.54.

Its i.r. spectrum does not show hydroxyl absorption, and g.l.c. (2% neopentyl glycol succinate column) gave a single peak. Proton magnetic resonance data (in $CDCl_3$): 4.75 (singlet, anomeric H), 4.92 and 5.34 (2 doublets, —OCH_2O— protons of six-membered ring). 4.98 (doublet, —OCH_2O— protons of five-membered ring), 6.60 (singlet, OCH_3).

*Preparation of Methyl 2,6-Di-O-methyl-α-D-mannopyranoside (**42**) from Methyl 2,3-4,6-Di-O-methylene-α-D-mannopyranoside (**41**)*

Reaction with $LiAlH_4$–$AlCl_3$ was carried out according to the general procedure. After 3 days another addition of the same amount of reagents was made. The reaction was discontinued after 7 days and worked up in the usual way. Silicic acid column chromatography (solvent: chloroform; followed by chloroform–acetone, 1:1, v/v) on a 1.3 g sample gave three fractions.

Fraction A (500 mg), the fastest moving component, crystallized from methanol and was identified as the unreacted material.

Fraction B (syrup, 300 mg) appeared to be a mixture of two mono-*O*-methylene-mono-*O*-methyl derivatives of methyl α-D-mannopyranoside on the basis of g.l.c. (2% neopentyl glycol succinate column) and its p.m.r. spectrum.

Fraction C (syrup, 330 mg) was homogeneous on t.l.c. and g.l.c. (2% neopentyl glycol succinate at 190°). The consumption of periodate and its p.m.r. spectrum are consistent with a methyl 2,6-di-*O*-methyl-α-D-mannopyranoside structure.

Anal. Calcd. for $C_9H_{18}O_6$: C, 48.64; H, 8.16. Found: C, 48.12; H, 8.16.

Proton magnetic resonance data ($CDCl_3$): 5.23 (doublet, $J_{1,2}$ = 2 c.p.s., anomeric H); 6.56, 6.62, and 6.65 (singlets 3 —OCH_3). The product had $[\alpha]_D$ +71° (*c*, 1.0 EtOH) and on treatment with 50% HI (100°, 20 min) gave mannose.

Hydrogenolysis of Several Methyl O-Benzylidene-hexoside Derivatives

*(1) Methyl 4,6-O-Benzylidene-α-D-galactopyranoside (**24**)*

Reductive cleavage of methyl 4,6-*O*-benzylidene-α-D-galactopyranoside afforded a crude mixture which consisted of one major component and a minor fraction in addition to some unreacted material, as revealed by t.l.c. (solvent: chloroform–acetone, 1:1, v/v). The major component, methyl 6-*O*-benzyl-α-D-galactopyranoside (**25**), was fractionally crystallized from chloroform–acetone (1:1). Two further recrystallizations from

chloroform–hexane gave a product with m.p. 138–140° and $[\alpha]_D$ +116° (*c*, 1.0 EtOH), lit. m.p. 142–144° and $[\alpha]_D$ +113° (26).

Anal. Calcd. for $C_{14}H_{20}O_6$: C, 59.15; H, 7.00. Found: C, 58.81; H, 6.77.

Its p.m.r. data (in DMSO-d_6): 2.25 (multiplet, 5 aromatic H), 5.04 (doublet, J = 3 c.p.s., anomeric H), 5.08 (singlet, 2H, *O*-benzyl), 6.30 (singlet, anomeric OCH_3), OH signals obscured by other signals. Oxidation with sodium metaperiodate in D_2O liberated formic acid (p.m.r. spectrum) consistent with a methyl 6-*O*-benzyl-α-D-galactopyranoside structure.

*(2) Methyl 2,3-Di-O-benzyl-4,6-O-benzylidene-β-D-glucopyranoside (**29**)*

Methyl 2,3-di-*O*-benzyl-4,6-*O*-benzylidene-β-D-glucopyranoside, on treatment with $LiAlH_4$–$AlCl_3$ reagent, gave mainly one reaction product and only traces of another component. The principal component obtained after purification of the crude reaction product by silicic acid column chromatography (solvent: chloroform–acetone, 1:1, v/v) was crystallized from chloroform–hexane to give methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranoside (**30**) with m.p. 74–76°. After being recrystallized from 90% methanol it had m.p. 83–85° and $[\alpha]_D$ +8.5° (*c*, 1.0 $CHCl_3$), lit. m.p. 90–91° and $[\alpha]_D$ +10° (27).

Anal. Calcd. for $C_{28}H_{32}O_6$: C, 72.40; H, 6.94. Found: C, 72.40; H, 6.74.

Proton magnetic resonance data (in $CDCl_3$): 2.70 (multiplet, 15 aromatic H), 5.64 (doublet, J = 7 c.p.s. anomeric H), 6.43 (singlet, anomeric OCH_3), 8.10 (triplet, J = 6 c.p.s., primary OH).

*(3) Methyl 4,6-O-Benzylidene-α-D-mannopyranoside (**31**)*

Hydrogenolysis of methyl 4,6-*O*-benzylidene-α-D-mannopyranoside gave a reaction product containing mainly one component in addition to the unreacted material. After removal of starting material by silicic acid column chromatography (solvent: chloroform–acetone, 1:1, v/v), the main reaction product (syrup) could not be further resolved. Its p.m.r. spectrum (in DMSO-d_6) at room temperature and at 70° showed two doublets and one triplet assigned to three hydroxyl groups. However, the spectrum indicated the presence of a minor component in this syrup. Sodium metaperiodate was added to this sample in D_2O and after 14 h a trace signal at 1.24 for formic acid was observed. Integration and correlation with the aromatic protons with the signal due to formic acid indicates that at least 80% of the syrup was methyl 4-*O*-benzyl-α-D-mannopyranoside (**32**).

*(4) Methyl 2,3-5,6-Di-O-benzylidene-α-D-mannofuranoside (**18**)*

Hydrogenolysis of methyl 2,3-5,6-di-*O*-benzylidene-α-D-mannofuranoside gave a syrup free from any unreacted material. Thin-layer chromatography (solvent: chloroform–acetone, 1:1, v/v) showed the presence of trace amounts of other components which were removed by silicic acid column chromatography. The purified syrupy material did not have any *O*-benzylidene group, as revealed by its p.m.r. spectrum. A portion (30%) crystallized out from the syrup and was recrystallized twice from chloroform – *n*-hexane. The uncharacterized crystalline methyl di-*O*-benzyl-α-D-mannofuranoside had m.p. 74–76° and $[\alpha]_D$ +100° (*c*, 1.0 EtOH).

Anal. Calcd. for $C_{21}H_{26}O_6$: C, 67.37; H, 6.95. Found: C, 67.08; H, 6.90.

*(5) Methyl 2,3-4,6-Di-O-benzylidene-α-D-mannopyranoside (**21**)*

Hydrogenolysis of methyl 2,3-4,6-di-*O*-benzylidene-α-D-mannopyranoside gave a mixture of two compounds which was chromatographed on a silicic acid column (solvent: chloroform–acetone 1:1). The faster moving syrupy component, which comprised 80% of the mixture had $[\alpha]_D$ +38° (*c*, 1.0 EtOH) and p.m.r. data (in DMSO-d_6): 2.1–2.4 (multiplet, 10 aromatic H), 3.86 (singlet, *O*-benzylidene H), 4.40 (doublet, J = 5 c.p.s., secondary OH), 5.00 (superimposed signals, 3H, *O*-benzyl and anomeric H), 6.36 (singlet, anomeric OCH_3). Treatment of the above compound (100 mg) with 3% methanolic hydrogen chloride (reflux 7 h) afforded a syrup (60 mg) which was resistant to periodate oxidation. Proton magnetic resonance data (in DMSO-d_6): 2.1–2.4 (multiplet, 10 aromatic H), 4.74 (doublet, J = 5 c.p.s., secondary OH), 4.88 (doublet, J = 5 c.p.s., secondary OH), 5.18 (triplet, J = 6 c.p.s., primary OH), 5.00 (doublet, *O*-benzyl), 5.07 (doublet, J = 2 c.p.s., anomeric), 6.38 (singlet, anomeric OCH_3). Hydrolysis of the hydrogenolyzed material (N H_2SO_4, 6 h, 100°) gave a product which consumed 0.9 mole/mole of lead tetraacetate after 2, 5, and 10 min reaction (28) thus showing the principal hydrogenolysis product to be methyl 4,6-*O*-benzylidene-3-*O*-benzyl-α-D-mannopyranoside (**22**).

*(6) Methyl 4,6-O-Benzylidene-α-D-glucopyranoside (**26**)*

After removal of the unreacted starting material by silicic acid column chromatography (solvent: chloroform–acetone, 2:1, v/v) the crude reaction product could not be further resolved. On periodate oxidation, the mixture gave 0.4 mole of formic acid per mole of methyl mono-*O*-benzyl-α-D-glucopyranoside corresponding to a 3:2 mixture of the 4-*O*- (**27**) and 6-*O*-benzyl (**28**) isomers, respectively.

*(7) Hydrogenolysis of 3,5-O-Benzylidene-1,2-O-isopropylidene-α-D-glucofuranose (**19**)*

The crude reaction product consisted of one main component (ca. 75%) which was purified through silicic acid column chromatography (solvent: chloroform–acetone 1:1, v/v). Proton magnetic resonance data (in DMSO-d_6) of the purified syrup: 2.15–2.40 (multiplet, aromatic H), 3.78 (doublet, J = 4 c.p.s., anomeric H), 4.84 (*O*-benzyl H), 5.00–5.40 (a doublet and a triplet appeared at 70° corresponidng to a secondary and primary OH respectively), 8.18 (singlet, CH_3), 8.32 (singlet, CH_3). The syrupy material was oxidized completely by periodate indicating a 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose structure (**20**).

*Hydrogenolysis of Methyl 4,6-O-Ethylidene-2,3-O-oxydiethylidene-α-D-glucopyranoside (**34**)*

Two equal fractions were obtained by silicic acid column chromatography (solvent: chloroform–acetone, 1:1, v/v) of the mixed hydrogenolysis product. Fraction *A* could be identified as methyl 4,6-*O*-ethylidene-α-D-glucopyranoside (**35**). The fastest-moving fraction *B*, methyl 3-*O*-ethyl-4,6-*O*-ethylidene-α-D-glucopyranoside (**36**) could be crystallized from chloroform – *n*-hexane, m.p. 136–138° and $[\alpha]_D$ +140° (*c*, 1.0 EtOH).

Anal. Calcd. for $C_{11}H_{20}O_6$: C, 53.22; H, 8.06. Found: C, 53.13; H, 8.01.

Proton magnetic resonance data (in DMSO-d_6): 4.68 (doublet, $J = 6$ c.p.s., secondary OH), 5.08 (doublet, $J = 3$ c.p.s., anomeric H), 4.94 (quartet, CH of $CH_3CH\begin{smallmatrix}O\\O\end{smallmatrix}$), 6.24 (singlet, anomeric OCH_3), 8.44 (doublet, $J = 5$ c.p.s., CH_3), 8.54 (triplet, $J = 7$ c.p.s CH_3).

Treatment of the compound with 3% methanolic hydrogen chloride (reflux 100°, 7 h) afforded methyl 3-*O*-ethyl-α-D-glucopyranoside, crystallized from acetone, m.p. 139–141° and $[\alpha]_D$ +56° (*c*, 1.2 EtOH).

Anal. Calcd. for $C_9H_{18}O_6$: C, 48.64; H, 8.16. Found: C, 49.06; H, 8.55.

It did not consume periodate and the p.m.r. spectrum is consistent with the designated structure. Hydrolysis of methyl 3-*O*-ethyl-α-D-glucopyranoside with *N* H_2SO_4 (6 h, 100°) gave 3-*O*-ethyl-D-glucose which crystallized from acetone with m.p. 134–135° and $[\alpha]_D$ +25 → +60° (*c*, 0.6 H_2O); lit. m.p. 137–138° and $[\alpha]_D$ +26.1 → +55.2° (29). Oxidation of this compound with lead tetraacetate (28) for 5 min and examination by paper chromatography showed a faster-moving pink spot without any starting material.

*Hydrogenolysis of Methyl 4,6-O-Ethylidene-α-D-glucopyranoside (**35**) and of Methyl 4,6-O-Propylidene-α-D-glucopyranoside*

In each case, two components were obtained (approximately in equal amounts) as revealed by t.l.c. No satisfactory fractionation could be achieved in either case, since they had almost identical R_f values. However, small quantities of products were isolated (each was slightly contaminated by the other) by silicic acid column chromatography (chloroform–acetone 1:1, v/v). Tentative structural assignments were made as shown in Table I.

*Hydrogenolysis of 1,2-3,5-Di-O-methylene-α-D-glucofuranose (**39**)*

Thin-layer chromatography (solvent: chloroform–acetone, 1:1, v/v) of the crude reaction mixture after hydrogenolysis revealed the presence of mainly one component along with about 80% of the unreacted material. After being fractionated by silicic acid column chromatography (solvent: chloroform–acetone, 2:1, v/v) the reaction product could be crystallized from hexane with m.p. 90–92°. Proton magnetic resonance data (in DMSO-d_6): 3.82 (doublet, $J = 4$ c.p.s., anomeric H), 4.66 (doublet, $J = 4$ c.p.s., —OCH_2O), 5.02 (doublet, $J = 5$ c.p.s., secondary OH), 5.24 (triplet, $J = 6$ c.p.s., primary OH), 6.24 (singlet, OCH_3). On oxidation with periodate it gave formaldehyde, thus indicating a 3-*O*-methyl-1,2-*O*-methylene-α-D-glucofuranose structure (**40**).

Reaction of 1,2-O-Cyclohexylidene-3,5,6-O-orthoformyl-α-D-glucofuranose with $LiAlD_4$–$AlCl_3$ (1:1)

The crude reaction product consisted of mainly one component as revealed by t.l.c. and g.l.c. The product crystallized from chloroform – *n*-hexane had m.p. 68–70° and $[\alpha]_D$ +23° (*c*, 1.0 EtOH).

Anal. Calcd. for $C_{13}H_{19}DO_6$: C, 57.14; H + D, 7.69. Found: C, 56.96; H + D, 7.23.

Proton magnetic resonance data ($CDCl_3$): 4.00 (doublet, $J_{1,2} = 4$ c.p.s., anomeric H); 5.20 (singlet, *O*-deuteromethylene H); 6.80 (triplet, $J = 5$ c.p.s., primary OH).

Reaction of 1,2-O-Isopropylidene-3,5,6-O-orthoformyl-α-D-glucofuranose with $LiAlD_4$–$AlCl_3$ (1:1)

Equimolar quantities of the starting material, $LiAlD_4$, and $AlCl_3$ were reacted according to the general procedure for 75 min (Table II). Thin-layer chromatography and g.l.c. showed only one principal product (**43**) which was crystallized from chloroform – *n*-hexane with m.p. 66–68° and $[\alpha]_D$ +26° (*c*, 1.0 EtOH).

Anal. Calcd. for $C_{10}H_{15}DO_6$: C, 51.50; H + D, 7.29. Found: C, 51.49; H + D, 6.96.

Proton magnetic resonance data (in $CDCl_3$): 4.00 (doublet, $J_{1,2} = 4$ c.p.s., anomeric H); 5.18 (singlet, *O*-deuteromethylene H); 8.12 (triplet, primary OH); 8.48 and 8.64 (singlets, 2 CH_3).

Identification of di-*O*-, tri-*O*-, and tetra-*O*-methylmannoses by gas–liquid chromatography[1]

S. S. BHATTACHARJEE[2] AND P. A. J. GORIN
Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received November 28, 1968

Some di-*O*- and tri-*O*-methylmannoses which are unknown or difficult to prepare have been synthesized. These and the other isomers, which can arise from methylation–fragmentation analyses of mannofuranose- and mannopyranose-containing polysaccharides can be used as gas–liquid chromatographic (g.l.c.) standards. A system has been devised in which methylation fragments are fractionated on a cellulose column into di-*O*-, tri-*O*-, and tetra-*O*-methylmannose fractions, which are then analyzed individually by g.l.c. following conversion to suitable derivatives.

Canadian Journal of Chemistry, 47, 1207 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In recent studies 88 structurally different mannose-containing polysaccharides have been isolated from 294 yeast species and their proton magnetic resonance (p.m.r.) spectra (1–4) used as an aid in identification of the parent organisms. Since it was felt that further biochemical studies on yeasts containing mannans and galactomannans would be of interest, some of these polysaccharides were selected for structural analysis. Frequent use was made of the methylation–fragmentation technique, in which *O*-methylmannoses were obtained and identified by gas–liquid chromatography (g.l.c.) of suitable derivatives. For this purpose the di-*O*-, tri-*O*-, and tetra-*O*-methyl methylmannosides were used as standards and when they were unknown or not readily available, syntheses were carried out. The syntheses, described in the present publication, make use of lithium aluminium hydride – aluminium trichloride hydrogenolyses in a number of cases. This reagent cleaves *O*-methylene acetals to *O*-methyl ethers and also converts *O*-benzylidene acetals to *O*-benzyl ethers (5, 6), which can be used as intermediates in preparation of partly methylated mannoses.

Preparation of Partly Methylated Methylmannosides

Methyl 2,4-Di-O-methyl-αβ-D-mannopyranoside

Crude 1,6-anhydro-β-D-mannopyranose (7) was converted to its 2,3-*O*-benzylidene derivative (**1**) which was methylated to give 1,6-anhydro-2,3-*O*-benzylidene-4-*O*-methyl-β-D-mannopyranose (**4**). Hydrogenolysis with 1.2 molar equivalents of $LiAlH_4$–$AlCl_3$ (1:1) caused selective cleavage of the *O*-benzylidene ring giving 1,6-anhydro-3-*O*-benzyl-4-*O*-methyl-β-D-mannopyranose (**5**). Successive methylation, debenzylation, and acid methanolysis provided methyl 2,4-di-*O*-methyl-αβ-D-mannopyranoside (**7**) with a retention time (r.t.) of 17.0 min on a neopentyl–glycol succinate g.l.c. column maintained at 190°. The glycoside was separated from a by-product by silicic acid chromatography and since the derived free aldose was not attacked by lead tetraacetate, the possibility of 3,4-di-*O*-substitution was eliminated. Also the glycoside had a different g.l.c. retention time from the 3,4-isomer (8).

The crystalline by-product was unaffected by hot aqueous acid and had an elemental composition and p.m.r. spectrum corresponding to a tri-*O*-methyl derivative of an anhydromannitol. A hydroxyl group at C-3 was indicated by consecutive spin decoupling experiments starting with H-1. In an analogous hydrogenolysis 1,6-anhydro-2,3-*O*-benzylidene-β-D-mannose (**1**) was cleaved by $LiAlH_4$–$AlCl_3$ to 1,6-anhydro-3-*O*-benzyl-β-D-mannopyranose (**2**) and a smaller proportion of 1,5-anhydro-3-*O*-benzyl-D-mannitol (**3**). Structure **2** was assigned since hydrolysis gave 3-*O*-benzyl-D-mannose, which had the same R_f as authentic material on a paper chromatogram (6), and consumed lead tetraacetate, in contrast to the possible 2-*O*-isomer. Compound **3** was not hydrolyzed by hot aqueous acid and was not oxidized with periodate. Since a 1,5-anhydromannitol derivative with this structure is formed on hydrogenolysis of 1,6-anhydro-2,3-*O*-benzylidene-β-D-mannopyranose derivatives the by-product from 1,6-anhydro-2,3-*O*-benzylidene-4-*O*-methyl-β-D-mannopyranose (**4**) is probably 1,5-anhydro-2,4,6-tri-*O*-methyl-D-mannitol (**8**).

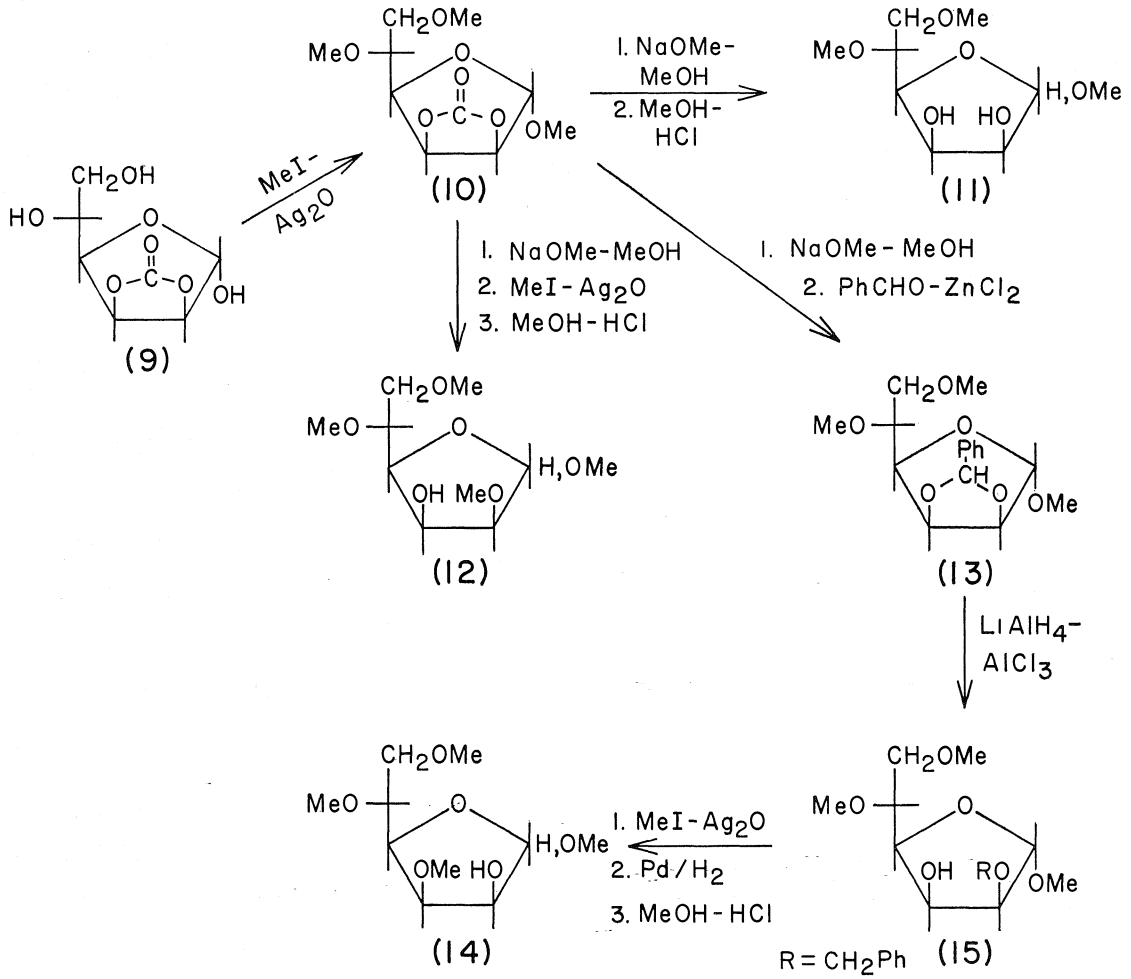
Methyl 5,6-Di-O-methyl-αβ-D-mannofuranoside

Methylation of D-mannose 2,3-carbonate (**9**, 9) with Purdie reagent gave crystalline methyl 2,3-*O*-carbonyl-5,6-di-*O*-methyl-α-D-mannofuranoside (**10**). It has an α-configuration since derived methyl 5,6-di-*O*-methyl-α-D-mannofuranoside has $[\alpha]_D$ +99°. The αβ-anomeric mixture (**11**; r.t. 15.3 min) was obtained from the glycoside by refluxing with methanolic hydrogen chloride. The possibility of 4,6-di-*O*-substitution is eliminated since the retention time of the glycosides on g.l.c. differs from that of methyl 4,6-di-*O*-methyl-αβ-D-mannopyranoside (r.t. 22.3 min).

3,5- and 2,5-Isomers of Methyl Di-O-methyl-αβ-D-mannofuranoside and Methyl 3,6-Di-O-methyl-αβ-D-mannopyranoside

Hydrogenolysis of methyl 2,3-5,6-di-*O*-benzylidene-α-D-mannofuranoside with $LiAlH_4$–$AlCl_3$ gives a crystalline methyl di-*O*-benzyl-α-D-mannofuranoside (**21**, 6). This compound has now been characterized as the 2,6-isomer since treatment with methanolic hydrogen chloride gave a methyl di-*O*-benzyl-αβ-D-mannopyranoside which consumed sodium periodate. The methyl 2,6-di-*O*-benzyl-αβ-D-mannopyranoside structure was confirmed by its conversion to methyl 3,4-di-*O*-methyl-αβ-D-mannopyranoside (g.l.c.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

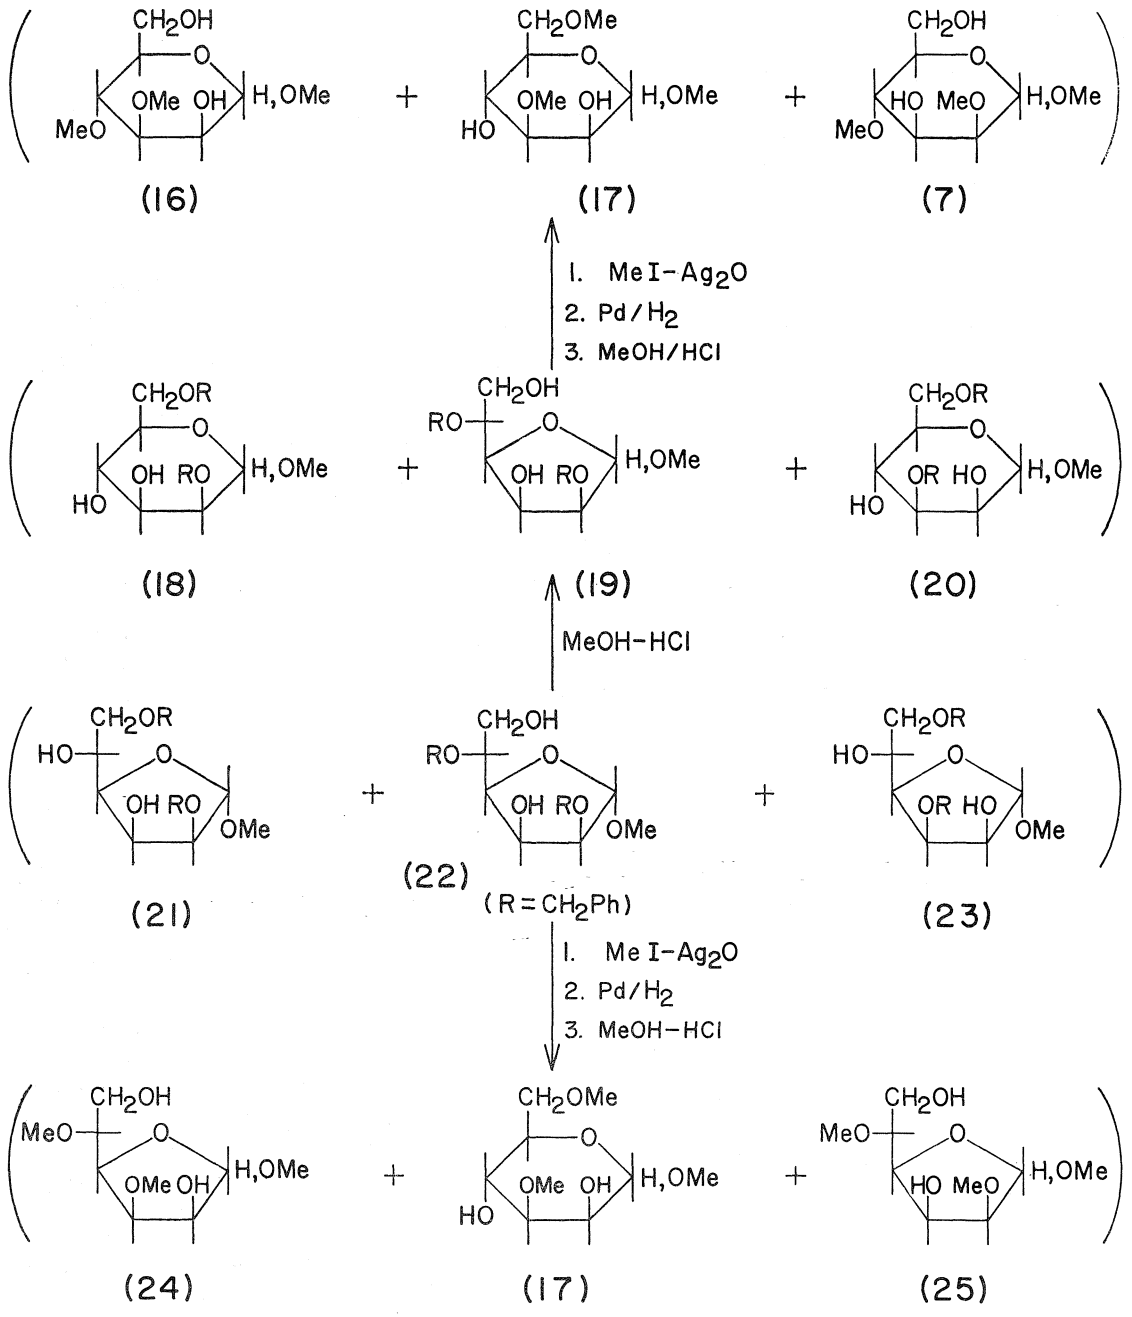


identification; r.t. 15.4 min) by methylation and subsequent debenzylation. Methyl 2,6-di-*O*-benzyl-α-D-mannofuranoside (**21**) was converted by the same procedure to methyl 3,5-di-*O*-methyl-α-D-mannofuranoside (α-anomer of **24**), which was then equilibrated to an αβ-anomeric mixture (**24**; r.t. 18.4 min) with methanolic hydrogen chloride.

The mother liquors, obtained following crystallization of methyl 2,6-di-*O*-benzyl-α-D-mannofuranoside, contained a mixture a portion of which (**21**, **22**, **23**) was treated with methanolic hydrogen chloride (to give **18**, **19**, **20**) and then subjected to methylation and subsequent debenzylation. Examination by g.l.c. showed 3 peaks, two of which corresponded to the 3,4- (**16**; r.t. 15.4 min) and 2,4-isomers (**7**; r.t. 17.0 min) of methyl di-*O*-methyl-αβ-D-mannopyranoside. No 2,6-isomer (r.t. 20.5 min; ref. 6) was detected. The material in the remaining peak (r.t. 14.0 min) was therefore methyl 3,6-di-*O*-methyl-αβ-D-mannofuranoside. The mixture of glycosides was treated with methanolic hydrogen chloride and one of the products, methyl 3,6-di-*O*-methyl-αβ-D-mannopyranoside (**17**; r.t. 19.3 min), could be differentiated from the other components, the 2,4- and 3,4-isomers, by g.l.c.

Another portion of the above mother liquors (**21**, **22**, **23**) was successively methylated and debenzylated yielding 3,6- (r.t. 14.0 min), 2,5- (r.t. 15.5 min), and 3,5-isomers (r.t. 18.4 min) of methyl di-*O*-methyl-α-D-mannofuranoside. The mixture, after reaction with methanolic hydrogen chloride, was resolved into 3 peaks on g.l.c. Two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

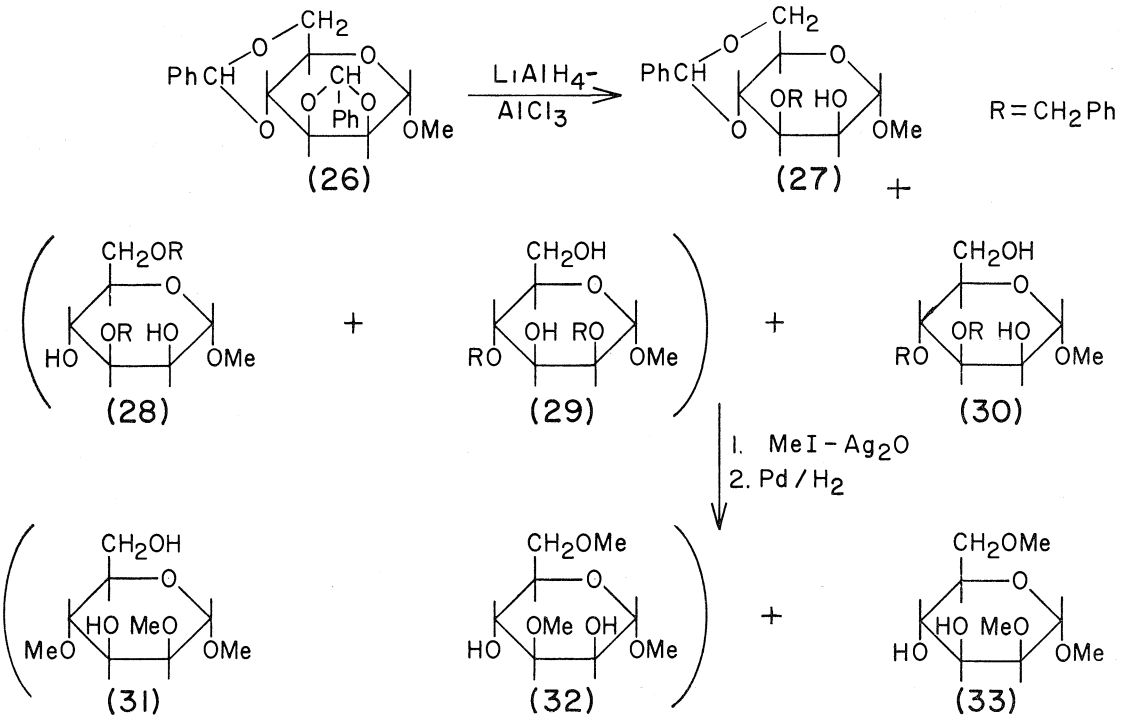


of the peaks were assigned to previously synthesized methyl 3,6-di-*O*-methyl-αβ-D-mannopyranoside (**17**; r.t. 19.3 min) and methyl 3,5-di-*O*-methyl-αβ-D-mannofuranoside (**24**; r.t. 18.4 min). The third peak (r.t. 15.5 min) thus corresponds to methyl 2,5-di-*O*-methyl-αβ-D-mannofuranoside (**25**).

Formation of the 2,6-, 2,4-, and 3,6-Isomers of Methyl Di-O-methyl-α-D-mannopyranoside

Hydrogenolysis of methyl 2,3,4,6-di-*O*-benzylidene-α-D-mannopyranoside (**26**; 6) with $LiAlH_4$–$AlCl_3$ gave a complex mixture from which three main fractions were obtained by silicic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



chromatography. The first fraction was identified as 3-*O*-benzyl-4,6-*O*-benzylidene-α-D-mannopyranoside (**27**) since successive methylation, methanolysis, and debenzylation gave methyl 2-*O*-methyl-α-D-mannopyranoside, which could be oxidized by sodium periodate. The second fraction contained two components, methyl 3,6-di-*O*-benzyl-α-D-mannopyranoside (**28**) and methyl 2,4-di-*O*-benzyl-α-D-mannopyranoside (**29**). Methylation of the mixture, followed by debenzylation gave methyl 2,4-di-*O*-methyl-α-D-mannopyranoside (**31**) and methyl 3,6-di-*O*-methyl-α-D-mannopyranoside (**32**) in a 2:1 ratio (g.l.c.). The last fraction contained methyl 3,4-di-*O*-benzyl-D-mannopyranoside (**30**) since methylation followed by debenzylation gave a product corresponding to methyl 2,6-di-*O*-methyl-α-D-mannopyranoside (**33**; 6) on g.l.c.

*Methyl 2,5,6-Tri-O-methyl-*αβ-D-*mannofuranoside*

Partial methylation of methyl 5,6-di-*O*-methyl-α-D-mannofuranoside (α-anomer of **11**) with Purdie reagent resulted in preferential substitution at OH-2. The product was hydrolyzed and the tri-*O*-methyl fraction separated from 5,6-di-*O*-methyl- and 2,3,5,6-tetra-*O*-methylmannoses by cellulose column chromatography. The tri-*O*-methylmannose fraction consumed 0.14 mole/mole of lead tetraacetate indicating that 2,5,6-tri-*O*- and 3,5,6-tri-*O*-methyl-D-mannose were present in a ratio of 6:1. The 2,5,6-isomer crystallized and was converted to its methyl glycosides (**12**; r.t. at 160°, 18.4 min) by treatment with methanolic hydrogen chloride.

*Methyl 3,5,6-Tri-O-methyl-*αβ-D-*mannofuranoside*

Methyl 5,6-di-*O*-methyl-D-mannofuranoside (α-anomer of **11**) was converted to its 2,3-*O*-benzylidene derivative (**13**) which was hydrogenolyzed with $LiAlH_4$–$AlCl_3$ to methyl 2-*O*-benzyl-5,6-di-*O*-methyl-α-D-mannofuranoside (**15**). This compound was resistant to methylation with the Purdie reagent, but the Kuhn procedure proved successful. The methylated product was debenzylated and the glycoside hydrolyzed giving a mixture of 2,5,6- and 3,5,6-tri-*O*-methyl-D-mannoses, which was fractionated by cellulose column chromatography. The methyl glycosides of the 3,5,6-isomer (**14**) had the same g.l.c. retention time as methyl 2,5,6-tri-*O*-methyl-αβ-D-mannofuranoside (**12**), both as the free glycoside and the trimethylsilyl (TMS) derivative. Fortunately,

*p = pyranoside, f = furanoside.

†The synthesis of methyl 2,6-di-*O*-methyl α-D-mannofuranoside has not yet been published by us.

‡In cases where the methyl α-mannopyranoside derivative was available, no change of retention time was observed on conversion to the αβ-methyl glycosides.

§Since the proportion of α- to β-TMS ether can vary from one experiment to another, it is difficult to detect the furanoside in the presence of the pyranoside isomer. In cases where the furanoside is suspected the formaldehyde produced on periodate oxidation of the parent mannan should be estimated.

however, the TMS derivatives of 2,5,6- and 3,5,6-tri-*O*-methyl-D-mannose could be separated by g.l.c. Our assignments of the g.l.c. peaks of 3,5,6-tri-*O*-methylmannose and its derivatives corresponded to those obtained from another sample of this compound, which has been synthesized by Siddiqui by another route (10).

Gas–Liquid Chromatography Characterization of Di-O-, Tri-O-, and Tetra-O-mannoses and Derivatives

Partially methylated mannoses and their derivatives were gas chromatographed on a column of neopentylglycol succinate (12 ft), a packing used previously in the separation of partially methylated methylmannosides (8). Retention times of (*a*) methyl di-*O*-methylmannosides (190°) and TMS derivatives (136°), (*b*) methyl tri-*O*-methylmannosides (160°) and TMS derivatives (136°), and (*c*) TMS derivatives of tri-*O*-methyl and tetra-*O*-methylmannoses (136°) are recorded in Table I. Using these values a methylation–fragmentation experiment can be carried out on a mannan or mannose-containing polysaccharide

by individual g.l.c. analysis of the di-*O*-, tri-*O*-, and tetra-*O*-methylmannose fractions (obtained by cellulose column chromatography) following their conversion to suitable derivatives. The di-*O*-methylmannoses can be characterized by g.l.c. of both their methyl glycosides and the TMS derivatives of the methyl glycosides.[3] 2,3,4,6- and 2,3,5,6-Tetra-*O*-methylmannoses, although not separated as their methyl glycosides, can be distinguished as their TMS derivatives. All the methyl tri-*O*-methylmannosides that could arise from mannofuranose and mannopyranose units in polysaccharides can be identified by g.l.c. of the methyl glycosides and the corresponding TMS ethers, except for the 2,5,6- and 3,5,6-isomers, which can be distinguished by g.l.c. of the TMS ethers of the free aldoses.

Experimental

Hydrogenolyses with $LiAlH_4$–$AlCl_3$ (in equimolar amounts) were carried out by the general procedure described earlier (6). Methylations were carried out with silver oxide in refluxing iodomethane (13) until the product did not show hydroxyl absorption in the infrared (i.r.) at ca. 3600 cm^{-1}. Infrared spectra were recorded using a Perkin–Elmer Infracord model 21. *O*-Benzyl groups were removed by hydrogenolysis using 5% Pd on charcoal catalyst with ethanol as solvent. Methanolysis was effected by refluxing with 3% methanolic hydrogen chloride for 2 h. Proton magnetic resonance spectra were obtained with a Varian HA-100 spectrometer using tetramethylsilane as external standard and chemical shifts are expressed as τ values. The g.l.c. unit was of conventional design, with thermal conductivity detectors. The helium pressure was 36 p.s.i. and 2% neopentyl glycol succinate on Chromosorb W (80/100 mesh) in $\frac{1}{4}$ in. × 12 ft columns was used. Unless otherwise mentioned, the retention times given in this section refer to the values obtained at 190° for methyl di-*O*-methylmannosides with a flow rate of 55 ml per min, 160° for methyl tri-*O*-methylmannosides, and at 136° for tetramethylsilyl (TMS) ethers, with a flow rate of 60 ml/min at both these temperatures. Thin-layer chromatography (t.l.c.) was carried out on silica gel G (sulfuric acid spray). Evaporations were performed under reduced pressure and specific rotations determined at 25°. Paper chromatography was carried out on Whatman No. 1 filter paper; solvent *n*-butanol – ethanol – water (40:11:19 v/v/v); spray *p*-anisidine hydrochloride. Tetramethylsilyl derivatives were prepared according to the procedure of Sweeley *et al.* (14).

Synthesis of Methyl 2,4-Di-O-methyl-αβ-D-mannopyranoside

Treatment of 1,6-anhydro-β-D-mannopyranose with benzaldehyde and zinc chloride in a conventional manner gave crystalline 1,6-anhydro-2,3-*O*-benzylidene-β-D-mannopyranose (**1**) with m.p. 188–189° (from EtOAc) and $[\alpha]_D$ −78.8° (*c*, 1.0 $CHCl_3$).

Anal. Calcd. for $C_{13}H_{14}O_5$: C, 62.39; H, 5.64. Found: C, 62.5; H, 5.8.

Methylation of the above compound (500 mg) with Purdie reagent gave 1,6-anhydro-2,3-*O*-benzylidene-4-*O*-methyl-β-D-mannopyranose (**4**; 500 mg) which was crystallized from hexane, m.p. 92–93° and $[\alpha]_D$ −92° (*c*, 1.0 EtOH).

Anal. Calcd. for $C_{14}H_{16}O_5$: C, 63.62; H, 6.10. Found: C, 63.3; H, 6.4.

Hydrogenolysis of 1,6-anhydro-2,3-*O*-benzylidene-4-*O*-methyl-β-D-mannopyranose (450 mg) with 1.2 molar equivalents of the $LiAlH_4$–$AlCl_3$ (1:1) reagent for 3 h gave a product (420 mg) which could not be resolved at this stage. Successive methylation, debenzylation, and methanolysis of this material afforded a mixture (180 mg) of two compounds as revealed by t.l.c. (solvent: chloroform–acetone 2:1 v/v). Silicic acid column chromatography (solvent: chloroform–acetone, 2:1 v/v, followed by methanol) gave initially a crystalline minor component (**8**; 25 mg) with m.p. 68–70°.

Anal. Calcd. for $C_9H_{18}O_5$: C, 52.41; H, 8.80. Found: C, 52.7; H, 8.9.

This compound was unchanged by treatment with *N* sulfuric acid (6 h, 100°) and did not react with the *p*-anisidine hydrochloride spray.

The second fraction contained syrupy methyl 2,4-di-*O*-methyl-αβ-D-mannopyranoside (**7**; 70 mg) with $[\alpha]_D$ +47.6° (*c*, 1.0 EtOH). It appeared to be homogeneous by t.l.c. and g.l.c. (r.t. 17.0 min; r.t. of the TMS derivative, 24.6 min). Proton magnetic resonance data (in DMSO-d_6); 5.01 (doublet, J = 2 c.p.s.), anomeric H); 6.26, 6.30, and 6.40 (3 singlets, 3 OCH_3); 4.85 (doublet, secondary OH); 5.10 (triplet, primary OH). A spin decoupling experiment, starting at H-1, showed the absence of hydroxyl group at C-2. On hydrolysis with *N* H_2SO_4 (6 h, 100°) it gave 2,4-di-*O*-methylmannose, which was resistant to lead tetraacetate oxidation (15). It crystallized from EtOAc on seeding with a sample of di-*O*-methyl-D-mannose (11, 12) and had m.p. 120° and $[\alpha]_D$ +13.5° (*c*, 0.6 H_2O). The m.p. was undepressed on admixture with 2,4-di-*O*-methyl-D-mannose, previously considered to be 3,5-di-*O*-methyl-D-mannose by Adams, Bishop, and associates (11, 12). (These workers report $[\alpha]_D$ +14.5°.)

Anal. Calcd. for $C_8H_{16}O_6$: C, 46.15; H, 7.75. Found: C, 46.2; H, 7.7.

Hydrogenolysis of 1,6-Anhydro-2,3-O-benzylidene-β-D-mannopyranose

1,6-Anhydro-2,3-*O*-benzylidene-β-D-mannopyranose (**1**; 50 mg) was treated with $LiAlH_4$–$AlCl_3$ (2.5 molar equivalents) in the usual manner. After 12 h the reaction

[3]During the course of g.l.c. examination of our standards, a crystalline sample of di-*O*-methyl-D-mannose, considered to be 3,5-di-*O*-methyl-D-mannose by Adams, Bishop, and associates (11, 12) was supplied to us. On g.l.c. examination of the methyl glycoside and the TMS derivative of the methyl glycoside, however, it corresponded to 2,4-di-*O*-methylmannose. On further investigation other physical characteristics proved identical to our synthetic material. Our results therefore indicate that the structures of the polysaccharides of birch sap (11) and mannans from several *Candida* spp. (12) should be re-evaluated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

product (40 mg) was isolated and refluxed with 3% methanolic hydrogen chloride for 3 h. After neutralization, the resulting material could not be oxidized by periodate and on hydrolysis with *N* H_2SO_4 (100°, 6 h) two spots were obtained on t.l.c. (solvent: chloroform–acetone 2:1 v/v). The faster moving component (approximately 1 part) was resistant to periodate and did not give any color with *p*-anisidine hydrochloride spray. The slow moving fraction (approximately 4 parts) was identical with 3-*O*-benzyl mannose (6) (paper chromatogram) and could be oxidized by lead tetraacetate.

Hydrogenolysis of Methyl 2,3-4,6-Di-O-benzylidene-α-D-mannopyranoside

Methyl 2,3-4,6-di-*O*-benzylidene-α-D-mannopyranoside (**26**; 1.0 g) was treated with 2.1 molar equivalents of the $LiAlH_4$–$AlCl_3$ (1:1) reagent for 6 days in the usual manner and the resulting product fractionated by silicic acid column chromatography (solvent: chloroform–acetone, 2:1 v/v). Fractions 1 to 4 were obtained consecutively. *Fraction 1* (250 mg) was identified as methyl 3-*O*-benzyl-4,6-*O*-benzylidene-α-D-mannopyranoside (**27**; 6). Successive methylation, methanolysis, and debenzylation of this material afforded methyl 2-*O*-methylmannopyranoside which consumed periodate. *Fraction 2* (200 mg) showed two overlapping spots (**28** and **29**; t.l.c.), which could not be further fractionated. This mixture did not consume periodate. Methylation and subsequent debenzylation afforded a product (92 mg) which was also resistant to periodate. By g.l.c. it was found to contain methyl 2,4-di-*O*-methyl-α-D-mannopyranoside (**31**; r.t. 17.0 min; r.t. of its TMS derivative 24.6 min) and methyl 3,6-di-*O*-methyl-α-D-mannopyranoside (**32**; r.t. 19.3 min; r.t. of its TMS derivative 23.0 min) in a ratio of 2:1 respectively. *Fraction 3* (**30**; 300 mg) with $[\alpha]_D$ +34° (*c*, 1.2 EtOH) was resistant to periodate. Methylation and subsequent debenzylation of a 200 mg portion gave a compound (85 mg) identical (g.l.c. and p.m.r.) with methyl 2,6-di-*O*-methyl-α-D-mannopyranoside (**33**; 6). On hydrolysis with *N* sulfuric acid at 100° 2,6-di-*O*-methylmannose was obtained (paper chromatogram). *Fraction 4* (46 mg) was a mixture of mono-*O*-benzyl derivatives of methyl-α-D-mannopyranoside since a mixture of methyl 2,3,6-, 2,4,6-, and 2,3,4-tri-*O*-methylmannoside (ratio 26:37:2; g.l.c. identification and estimation) was obtained on successive methylation, debenzylation, and methanolysis.

Hydrogenolysis of Methyl 2,3-5,6-Di-O-benzylidene-α-D-mannofuranoside

This reaction was performed in the same way as described earlier (6). The crystalline material with m.p. 74–76° and $[\alpha]_D$ +100°, comprised about 30% of the principal reaction product and was identified as methyl 2,6-di-*O*-benzyl-α-D-mannofuranoside (**21**) since the mannopyranoside obtained by treating the former with methanolic hydrogen chloride (3%, reflux, 2 h) was oxidized by periodate. Methyl 2,6-di-*O*-benzyl-αβ-D-mannopyranoside (**18**) was converted to methyl 3,4-di-*O*-methyl αβ-D-mannopyranoside (**16**; identical with an authentic sample by g.l.c.), by the application of methylation, debenzylation, and methanolysis techniques. 3,4-Di-*O*-methylmannose obtained on hydrolysis was oxidized by lead tetraacetate. By consecutive methylation and debenzylation methyl 2,6-di-*O*-benzyl-α-D-mannofuranoside was converted to methyl 3,5-di-*O*-methyl-α-D-mannofuranoside (α-anomer of **24**) with r.t. 18.4 min (r.t. of its TMS derivative 35.2 min) and $[\alpha]_D$ +63.5° (*c*, 0.5 EtOH).

A portion of the mother liquor, which contained methyl di-*O*-benzyl-mannofuranoside derivatives, was treated with 3% methanolic hydrogen chloride (reflux 2 h) and then subjected to methylation and debenzylation. Gas–liquid chromatography of the reaction product showed three peaks with retention values 14.0, 15.4, and 17.0 min which could be assigned to methyl 3,6-di-*O*-methyl-αβ-D-mannofuranoside, methyl 3,4-di-*O*-methyl-αβ-D-mannopyranoside (**16**), and methyl 2,4-di-*O*-methyl-αβ-D-mannopyranoside (**7**), respectively, in an approximate ratio 1.5:1:1. Methanolysis of the methyl di-*O*-methylmannosides afforded a material which was resistant to periodate and consisted of methyl 3,4-(**16**), 2,4-(**7**), and 3,6-di-*O*-methylmannopyranosides (**17**) with retention values of 15.4, 17.0, and 19.3 min respectively. Another portion of the mother liquor was methylated and then debenzylated. A mixture of methyl 3,6- (r.t. 14.0 min), 2,5- (r.t. 15.5 min), and 3,5- (r.t. 18.4 min) di-*O*-methyl-αβ-D-mannofuranoside, in a ratio of 1.5:1:1, respectively, resulted. On treatment with methanolic hydrogen chloride this mixture gave a periodate-resistant material composed of methyl 2,5-(**25**) and 3,5-di-*O*-methylmannofuranosides (**24**), and methyl 3,6-di-*O*-methylmannopyranoside (**17**; r.t. 19.3 min).

Preparation of Methyl 5,6-Di-O-methyl-αβ-D-mannofuranoside and Methyl 2,5,6-Tri-O-methyl-αβ-D-mannofuranoside

D-Mannose 2,3-carbonate (**9**; 0.30 g, ref. 9) was refluxed overnight in iodomethane (10 ml) containing silver oxide (3 g) and Drierite (3 g). The reaction mixture was filtered, evaporated, and methyl 2,3-*O*-carbonyl-5,6-di-*O*-methyl α-D-mannofuranoside (**10**; 0.19 g) crystallized from ether–*n*-hexane. It had m.p. 85–86° and $[\alpha]_D$ +34° (*c*, 3.2 EtOH).

Anal. Calcd. for $C_{10}H_{16}O_7$: C, 48.38; H, 6.50. Found: C, 48.5; H, 6.6.

Deesterification with methanolic sodium methoxide gave methyl 5,6-di-*O*-methyl-α-D-mannofuranoside (α-anomer of **11**) with $[\alpha]_D$ +99° (*c*, +99° *c*, 1.0 EtOH). The equilibrium αβ-anomeric mixture, obtained with refluxing methanolic hydrogen chloride, had a r.t. of 15.3 min, compared with 22.3 min of methyl 4,6-di-*O*-methyl-αβ-D-mannopyranoside.

Methyl 5,6-di-*O*-methyl-α-D-mannofuranoside (80 mg) was shaken for 6 h in iodomethane (2.5 ml) containing silver oxide (0.5 g). Analysis by g.l.c. showed that the ratio of tri-*O*- to unchanged di-*O*-methyl methyl glycoside was 9:1. The mixture was hydrolyzed (0.1 *N* H_2SO_4, 1 h at 100°) and the product fractionated on a cellulose column using benzene – ethanol – water (500:50:1 v/v/v) as eluant. The tri-*O*-methylmannose fraction (61 mg) consumed 0.14, 0.17, and 0.25 mole/mole of lead tetraacetate (15) after 2, 5, and 15 min, respectively. 2,5,6-Tri-*O*-methyl-D-mannose crystallized from ether–*n*-hexane and had m.p. 92–93° and $[\alpha]_D$ +54° (*c*, 0.6 H_2O; constant value).

Anal. Calcd. for $C_9H_{18}O_6$: C, 48.64; H, 8.16. Found: C, 48.8; H, 8.3.

It was not oxidized by lead tetraacetate. A portion was converted to the methyl glycosides (**12**) with methanolic hydrogen chloride.

*Preparation of 3,5,6- and 2,5,6-Tri-O-methyl-*D*-mannoses*

Methyl 5,6-di-*O*-methyl-α-D-mannofuranoside (200 mg) was shaken with benzaldehyde (2 ml) and anhydrous zinc chloride (150 mg) overnight. The derived methyl 2,3-*O*-benzylidene-5,6-di-*O*-methyl-α-D-mannofuranoside (**15**; 150 mg) was hydrogenolyzed using one molar equivalent of $LiAlH_4$–$AlCl_3$ (1:1) for 5 h. The product was methylated by the Kuhn method (16) and then debenzylated. Hydrolysis with *N* sulfuric acid (100°, 1 h) gave a spot corresponding to tri-*O*-methylmannose and a minor spot corresponding to 5,6-di-*O*-methylmannose. The tri-*O*-methylmannose fraction (25 mg) was purified by cellulose column chromatography using eluants described above. Analysis by g.l.c. of the TMS derivative of the tri-*O*-methylmannose fraction showed that it was a mixture of 3,5,6-tri-*O*-methylmannose (1.5 parts; r.t.'s 36.1 and 30.8 min) and 2,5,6-tri-*O*-methylmannose (1 part, r.t. 28.5 min).

Acknowledgments

The authors would like to thank Mr. R. J. Magus for technical assistance, Mr. M. Mazurek for obtaining p.m.r. spectra, and Mr. W. C. Haid for performing elemental analyses. Also thanks are due to Dr. C. T. Bishop for a sample of 2,4-di-*O*-methyl-D-mannose and Dr. I. R. Siddiqui for 3,5,6-tri-*O*-methyl-D-mannose.

Synthetic reactions by complex catalysts. XII. Copper-catalyzed reaction of isocyanide with alcohol

TAKEO SAEGUSA, YOSHIHIKO ITO, SHIRO KOBAYASHI, KIWAMI HIROTA, AND NOBUYUKI TAKEDA
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto, Japan

Received September 16, 1968

The reaction of alkyl isocyanide with alcohol to produce alkyl formimidate requires catalysis by metal compounds. The catalysts are classified into two groups. The first group includes metallic copper, and the oxides of copper (Cu (I) and Cu (II)), silver, and mercury, which induce the isocyanide reactions of various alcohols including saturated and unsaturated alcohols and amino-alcohol. The second group catalysts are the chlorides of copper (Cu (I)), silver, zinc, and cadmium, which cause the reactions of isocyanide only with special alcohols having strong coordinating tendencies toward the catalyst, as being exemplified by allyl alcohol and β-*N*,*N*-dimethylaminoethanol. Among these catalysts, metallic copper and copper oxides are the most effective and give the products almost quantitatively. The difference in catalyst activity between the two groups of catalysts has been explained by assuming a ternary complex consisting of the catalyst, isocyanide, and alcohol as the site of reaction.

In previous communications (1), we preliminarily reported a new reaction of an isocyanide with an alcohol to produce a formimidate, which was accomplished for the first time by means of catalysts of metallic copper and some copper compounds. This reaction provides a convenient,

$$[1]\quad ROH + :C{\leftrightharpoons}N{-}R' \xrightarrow{\text{Cu catalyst}} \underset{\mathbf{1}}{ROCH{=}N{-}R'}$$

highly selective method for the preparation of formimidates. The product formimidate may be regarded as being derived by the insertion of the isocyanide carbon bearing lone pair electrons between the oxygen and the hydrogen of the alcohol. In the absence of the copper catalyst, alcohol is quite inert toward isocyanides. Alcohol has been employed as an inert solvent in several reactions of isocyanides (2). The activity of copper catalysts is much affected by the valency of copper and the nature of the ligand. Metallic copper and cuprous and cupric oxides are excellent catalysts, which induce the reactions of isocyanides with various alcohols (1*b*). On the other hand, cuprous chloride and cyanide catalyze the reactions with specific alcohols such as β-dimethylaminoethanol and β,γ-unsaturated alcohols (1*a*) including allyl alcohol.

It is well known that isocyanides form complexes with various transition metal salts, especially copper compounds. Therefore, it is suggested that the isocyanide–copper complex plays an essential role in the function of the copper catalyst. In addition, the coordination of alcohol onto copper catalyst is also assumed to be quite important for the reaction. Thus, it seems likely that the reaction has taken place within the ligand sphere of the so-called mixed ligand complex consisting of copper, isocyanide, and alcohol.

The present paper describes the details of the copper-catalyzed reaction of isocyanides with alcohol, as well as some results of infrared spectral studies upon the interactions between copper catalyst and the reaction components.

Results

Reactions of Isocyanides with Alcohols Catalyzed by Metallic Copper and Copper Oxides

Metallic copper and copper oxides (Cu (I) and Cu (II)) catalyzed quite effectively the reactions of cyclohexyl isocyanide with various alcohols (Tables I and II).

*Reaction conditions: cyclohexyl isocyanide, 30 mmoles; alcohol, 34 mmoles; CuO (or Cu_2O), 3 mmoles; 120°; 5 h.
†Boiling point, 93° (19 mm).

Several alkyl *N*-cyclohexylformimidates were produced in almost quantitative yields. In the reactions catalyzed by cuprous and cupric oxides, small amounts of two by-products, *N*-cyclohexylformamide (**2**) and alkyl *N*-cyclohexylcarbamates (**3**) were formed. Compound **2** may possibly have been produced by the hydrolysis of the isocyanide or formimidate (**1**) with water which either was present as an impurity in the initial reaction mixture or was produced *in situ* by the etherification of alcohol. Compound **2** may also be derived from the formimidate according to

$$ROCH{=}N{-}R' + ROH \rightarrow (RO)_2CHNHR' \rightarrow R'NHCHO + ROR$$

The formation of **3** is ascribed to the oxidation of isocyanide to isocyanate by the copper oxide catalysts. The reduction–oxidation between mercuric oxide and isocyanide is known, in which isocyanide is oxidized into isocyanate (3).

As expected, **3** was not formed in the reaction when metallic copper was the catalyst. As to the catalyst activity of metallic copper, it is very important to note that a small amount of metallic copper dissolved in cyclohexyl isocyanide to form a soluble complex. The complex formation from metallic copper and isocyanide will be described later. From these observations, it appears possible that copper oxide catalysts are reduced by isocyanide to form a copper (O)-isocyanide complex which is the actual active species responsible for their catalytic activities. The exact characterization of active species of the metallic copper and copper oxides catalysts is the subject of a future study.

Cuprous Chloride Catalyst in the Isocyanide–Alcohol Reaction

The catalysis of cuprous chloride in the alcohol–isocyanide reaction was somewhat different from that of metallic copper and of copper oxides. Cuprous chloride did not induce the isocyanide reactions with the usual saturated alcohols such as ethanol and *n*-butanol. It catalyzed only the reactions involving β-dimethylaminoethanol and β,γ-unsaturated alcohols such as allyl alcohol. As will be discussed later, these alcohols are characterized by a strong tendency of coordination onto cuprous chloride. The complexes of cuprous chloride and these alcohols are stable and can be isolated. These findings suggest that the coordination of isocyanide as well as alcohol onto cuprous chloride are essential for this reaction.

The reactions of cyclohexyl isocyanide with β,γ-unsaturated alcohols, and β-dimethylaminoethanol by cuprous chloride catalyst are shown in Table III. Benzyl alcohol is among the alcohols which react with isocyanide in the presence of cuprous chloride. Perhaps the phenyl group plays a role similar to that of β,γ-unsaturated group.

In these reactions, *N*-cyclohexylformamide (**2**) and *N*-alkenyl-*N*-cyclohexylformamide (**4**) were produced as the by-products. The amount of **2**, the product of the hydrolysis of cyclohexyl isocyanide, was much higher than that in the reactions with metallic copper and copper oxides

catalysts. It may be attributed to a higher concentration of water formed *in situ* by the etherifications of these alcohols. It is known that β,γ-unsaturated alcohols are easily etherified by cuprous chloride catalyst (4). The by-product **4** was probably produced by the thermal rearrangement (5) of **1** (Chapman rearrangement) which took place, at least partly, during the distillation of the reaction mixture. A higher yield of **4** in the reaction with benzyl alcohol may be due in part to the higher distillation temperature.

In the cuprous chloride catalyzed reaction of cyclohexyl isocyanide with allyl alcohol, the decrease of isocyanide and the increases of the yields of products are plotted against the reaction time (Fig. 1).

There is observed an induction period of 4 h for the formation of **1**. The nature of the induction period has not yet been elucidated. As to the induction period, a possibility that the reaction is autocatalytic may be excluded. The addition of formamide or formimidate to the reaction system did not shorten the induction period. Cuprous chloride catalyst itself was not changed throughout the reaction. The hydrolysis of isocyanide to produce a by-product of **2** starts at the beginning of the reaction. Another by-product of **4**, however, is produced only after the main product of **1** is accumulated in the reaction system.

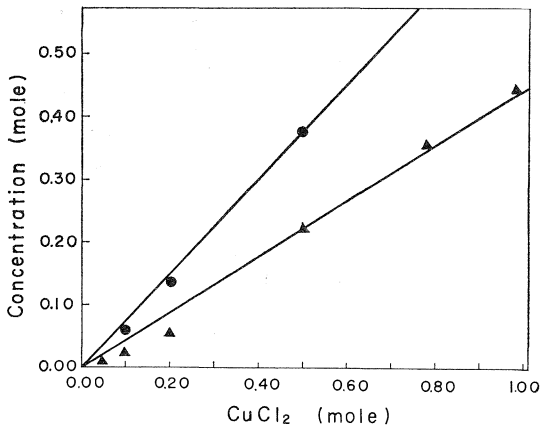

FIG. 2. $CuCl_2$ – cyclohexyl isocyanide reaction in ethanol; ——●——, CuCl (formed by reduction of $CuCl_2$); ——▲——, ethyl *N*-cyclohexylcarbamate.

Catalytic Behavior of Other Copper Compounds

In the cupric chloride catalyzed reaction of isocyanide with saturated alcohols, only small amounts of *N*-substituted carbamate (**3**) and *N*-substituted formamide (**2**) were produced. The carbamate formation suggests the reduction–oxidation reaction between isocyanide and cupric chloride. A series of reactions of cyclohexyl isocyanide with increasing amounts of cupric chloride in the presence of excess ethanol was carried out (Fig. 2).

It was found that cupric chloride was reduced to cuprous chloride, and the molar ratio of cuprous chloride and carbamate was about two. A separate study by us[1] has shown that the isocyanide – cupric chloride reaction in the absence of alcohol produces cuprous chloride and *N*-substituted imidocarbonyl chloride, the precursor of

[2] $2CuCl_2 + RN{\geq}C: \rightarrow 2CuCl + RN{=}CCl_2$

carbamate. The catalytic activity of cuprous cyanide was similar to that of cuprous chloride in the isocyanide–alcohol reaction. Cuprous cyanide induces the isocyanide – allyl alcohol reaction to form allyl formimidate but it does not promote the isocyanide reactions with the usual saturated alcohols.

Catalytic Activities of Other Metal Compounds

Silver oxide and mercuric oxide also catalyzed the reaction of isocyanide with saturated alcohol. Two runs of the cyclohexyl isocyanide–ethanol

[1]T. Saegusa, Y. Ito, and S. Tomita. To be published.

reaction in the presence of silver oxide and mercuric oxide respectively were carried out under the same conditions as Table I, in which ethyl *N*-cyclohexylformimidate was formed in yields of 89 and 51%, respectively. However, oxides of zinc, cadmium, and iron were inactive. Oxides of cobalt and nickel caused only the homopolymerization of isocyanide to produce brown colored, insoluble, and infusible polymers.

Chlorides of silver, zinc, and cadmium caused the reaction of isocyanide with allyl alcohol, but they did not induce that with the usual saturated alcohol. Mercuric chloride did not show catalytic activity even for the isocyanide – allyl alcohol reaction. Chlorides of nickel, cobalt, and palladium did not induce the insertion reaction but caused the homopolymerization of isocyanide.

Mechanisms of Copper Catalysis

According to the catalysis behavior, copper catalysts are divided into two groups. The first group includes metallic copper and cuprous and cupric oxides, which catalyze the reactions of isocyanide with saturated and unsaturated alcohols. The second group of catalysts are cuprous chloride and cyanide which induce the reactions of isocyanide only with β,γ-unsaturated alcohol and β-aminoalcohol. The infrared (i.r.) spectra of mixtures of cyclohexyl isocyanide and copper catalysts showed a new band at a frequency higher than 2140 cm^{-1} of $\nu_{N\equiv C}$ of free isocyanide. The new band has been assigned to $\nu_{N\equiv C}$ of isocyanide coordinating to metal compound (6). From a Hammett relationship of the argentation constant of styrene derivatives (7), it is assumed that the contribution of the back-donation in the complex of d^{10} metal ion is small. The shift of $\nu_{N\equiv C}$ to a shorter wavelength is due to the donation of the electrons of isocyanide to d^{10} metal ion. Therefore, the magnitude of shift of $\nu_{N\equiv C}$ caused by coordination may be utilized as a measure of the strength of the coordination of isocyanide onto copper catalysts. It follows that the coordination of isocyanide with the first group catalysts is weaker than that with the members of the second group.

The cyclohexyl isocyanide – metallic copper system for i.r. diagnosis was prepared at room temperature by the addition of metallic copper powder to liquid cyclohexyl isocyanide under nitrogen. Metallic copper was prepared by the reduction of cupric sulfate with zinc powder in aqueous solution. The copper–isocyanide mixture was centrifuged. The i.r. spectrum of the liquid phase of copper–isocyanide showed a fairly strong absorption at 2180 cm^{-1} as well as the band of $\nu_{N\equiv C}$ of free isocyanide at 2140 cm^{-1}. This finding indicates the formation of a soluble complex from metallic copper and isocyanide. On treating the centrifuged solution with alcohol, the formimidate was produced. This indicates that the metallic copper-catalyzed reaction proceeds in a homogeneous solution phase, and the solid phase is merely the source of soluble catalyst complexes. The band of coordinating species of cyclohexyl isocyanide appeared at 2181 cm^{-1} in the system of cuprous oxide with isocyanide.

On the other hand, the i.r. spectrum of the 1:1 complex of cuprous chloride with cyclohexyl isocyanide showed the band of coordinating isocyanide group at 2192 cm^{-1}. Thus, the magnitude of the shift of $\nu_{N\equiv C}$ caused by cuprous chloride is larger than that caused by metallic copper and cuprous oxide. These findings are taken to indicate that isocyanide coordinates more tightly with cuprous chloride than with the first group catalysts.

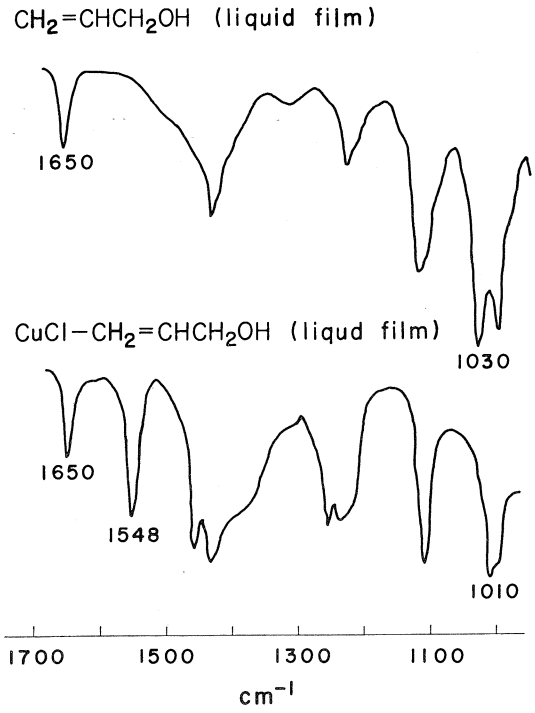

FIG. 3. Infrared spectra of allyl alcohol and CuCl allyl alcohol complex.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

The coordination of alcohol with copper catalysts depends upon the nature of the alcohol and of the copper catalysts. Cuprous chloride is almost insoluble in the usual saturated alcohols, whereas it is quite soluble in allyl alcohol and in β-dimethylaminoethanol. This observation suggests a specific interaction between cuprous chloride and these particular alcohols. The complexing of cuprous chloride with these alcohols was indicated by i.r. spectroscopy. In comparison with the i.r. spectrum of allyl alcohol, the spectrum of cuprous chloride dissolved in allyl alcohol had additional bands at 1548 and 1010 cm^{-1}, which are assigned to the olefin and alcohol groups, respectively, of the allyl alcohol – cuprous chloride complex (Fig. 3) (8). The strong complexing tendency of β-dimethylaminoethanol with cuprous chloride was also demonstrated by i.r. spectroscopy. From cuprous chloride and β-dimethylaminoethanol, a 1:1 complex was successfully isolated, whose i.r. spectrum showed the shift of ν_{C-O} band from 1039 to 1020 cm^{-1} (Fig. 4).

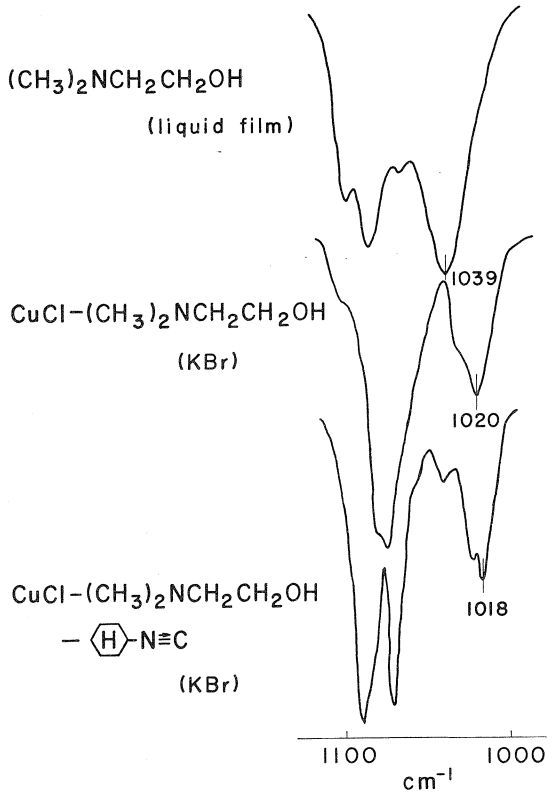

FIG. 4. Infrared spectra of β-*N*-dimethylaminoethanol and its complexes.

On the basis of these i.r. spectroscopic studies, the difference in catalyst activity between the first group catalysts and those of the second group is explained by a hypothesis of mixed ligand complex. Isocyanide is held rather loosely by the first group catalysts, and hence a part of the isocyanide ligand will be replaced by alcohols including saturated alcohols of weak complexing tendency as well as the particular alcohols mentioned above. The first group catalysts will form a ternary, mixed ligand complex consisting of copper, isocyanide, and various alcohols. On the other hand, isocyanide is held tightly by the second group catalyst, and the isocyanide ligand is partly replaced only by the special alcohols of strong coordinating tendencies. The ternary, mixed ligand complexes of the second group catalysts are feasible only for the special alcohols. It is assumed that the reaction between alcohol and isocyanide will take place in the ligand sphere of the mixed ligand complex. Thus, the formation of the mixed ligand complex is a prerequisite for the occurrence of the reaction.

Experimental

(a) Metallic Copper-catalyzed Reaction of Cyclohexyl Isocyanide with Ethanol

Metallic copper was prepared by treating an excess of aqueous solution of cupric sulfate maintained below 70° with zinc powder under a nitrogen atmosphere. The metallic copper precipitate was collected and washed successively with water and dry acetone, and then dried.

A mixture of cyclohexyl isocyanide 3.27 g (0.030 mole), ethanol 1.56 g (0.034 mole), and metallic copper 0.43 g (0.003 g-atom) was heated at 120° for 5 h. After the insoluble catalyst was removed by filtration, the filtrate was subjected to gas–liquid chromatography (g.l.c.) analysis (PEG 20000 on Celite). Two products, **1***a* and **2***a*, were detected. The product **1***a* was also isolated by distillation *in vacuo*, b.p. 54.5° (8mm).

On the basis of the following analyses, **1***a* was identified as ethyl *N*-cyclohexylformimidate.

Nuclear magnetic resonance (CCl_4) of **1***a*: δ 1.21 (3H, triplet), 1.00–2.00 (10H, complex multiplet), 2.70–3.10 (1H, broad singlet), 3.98 (2H, quartet), 7.43 (1H, singlet). Infrared (i.r.) (neat): 1650 (s), 1200 cm^{-1} (s). The structure of **1***a* was further confirmed by comparisons of the g.l.c. retention time and i.r. spectrum with the authentic sample. The authentic sample of **1***a* was prepared as follows (9). *N*-Cyclohexylformamide (0.5 mole) was added dropwise to triethyloxonium fluoroborate (0.5 mole) (10) in ether at room temperature. Ethyl *N*-cyclohexylformimidate hydrogen fluoroborate, which separated as a viscous liquid in the lower layer, was treated with triethylamine to give ethyl *N*-cyclohexylformimidate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Compound **2***a*, b.p. 103° (3mm) was identified as *N*-cyclohexylformamide by comparison with the authentic sample prepared from cyclohexylamine and ethyl formate.

(b) Cuprous Oxide Catalyzed Reaction of Cyclohexyl Isocyanide with sec-Butanol

A mixture of cyclohexyl isocyanide 3.27 g (0.030 mole), *sec*-butanol 2.52 g (0.034 mole), and cuprous oxide 0.43 g (0.003 mole) was heated at 120° for 5 h. After working up the mixture as described above, *sec*-butyl *N*-cyclohexylformimidate, b.p. 90° (21mm) (**1***b*), *N*-cyclohexylformamide, and *sec*-butyl *N*-cyclohexylcarbamate (**3***b*), were detected by g.l.c. and identified.

Nuclear magnetic resonance (CCl_4) of **1***b*: δ 0.87 (3H, triplet), 1.15 (3H, doublet), 1.00–2.00 (12H, complex multiplet), 2.70–3.10 (1H, broad singlet), 4.73 (1H, multiplet), 7.33 (1H, singlet). Infrared (neat) : 1650 (s), 1205 cm^{-1} (s). The authentic sample of **3***b* was prepared by the reaction of cyclohexyl isocyanate with *sec*-butyl alcohol.

(c) Cupric Oxide Catalyzed Reaction of Cyclohexyl Isocyanide with t-Butanol

A mixture of cyclohexyl isocyanide 3.27 g (0.030 mole), *t*-butanol 2.52 g (0.034 mole), and cupric oxide 0.24 g (0.003 mole) was heated at 120° for 5 h. According to the same procedure, *t*-butyl *N*-cyclohexylformimidate, b.p. 93° (10mm) (**1***c*), *N*-cyclohexylformamide, and *t*-butyl *N*-cyclohexylcarbamate (**3***c*) were identified.

Nuclear magnetic resonance (CCl_4) of **1***c*: δ 1.40 (9H, singlet), 1.00–2.00 (10H, complex multiplet), 2.70–3.10 (1H, broad singlet), 7.36 (1H, singlet). Infrared (neat): 1650 (s), 1220 (s), 1170 (s) cm^{-1}.

(d) Cuprous Chloride Catalyzed Reaction of Allyl Alcohol with Cyclohexyl Isocyanide

A solution of cyclohexyl isocyanide 4.36 g (0.040 mole), allyl alcohol 4.06 g (0.070 mole), and cuprous chloride 0.80 g (0.008 mole) was heated at 120° for 5 h. Then the reaction mixture was subjected to g.l.c. analysis and the products were identified. Allyl *N*-cyclohexylformimidate (**1***d*), b.p. 90° (26mm), cyclohexylformamide, and *N*-allyl-*N*-cyclohexylformamide (**4***d*) were the products.

Nuclear magnetic resonance (CCl_4) of **1***d*: δ1.00–2.00 (10H, complex multiplet), 2.70–3.20 (1H, broad singlet), 4.49 (2H, doublet), 4.90–6.20 (3H, multiplet), 7.53 (1H, singlet). Infrared (neat) : 1650 (s), 1190 (s), 990 (m), 910 cm^{-1} (s). The authentic sample of **1***d* was synthesized by the reaction of triallyloxonium fluoroborate with *N*-cyclohexylformamide.

Nuclear magnetic resonance ($CDCl_3$) of **4***d*: 1.00–2.00 (10H, complex multiplet), 2.90–3.50 (1H, broad singlet), 3.84 (2H, doublet), 4.80–6.10 (3H, multiplet), 8.04 and 8.20 (1H, two singlets).

(e) Cuprous Chloride Catalyzed Reaction of Cyclohexyl Isocyanide with Benzyl Alcohol

A solution of cyclohexyl isocyanide 4.36 g (0.040 mole), benzyl alcohol 7.56 g (0.070 mole), and cuprous chloride 0.80 g (0.008 mole) was heated at 120° for 5 h. The whole product could not be analyzed by g.l.c. Distillation of the reaction mixture gave benzyl *N*-cyclohexylformimidate (**1***e*), b.p. 155° (3mm), *N*-cyclohexylformamide, and *N*-benzyl-*N*-cyclohexylformamide (**4***e*), b.p. 133° (3mm).

Nuclear magnetic resonance ($CDCl_3$) of **1***e*: δ 1.00–2.00 (10H, complex multiplet), 2.80–3.20 (1H, broad singlet), 4.49 (2H, singlet), 7.24 (5H, singlet), 7.60 (1H, singlet).

Nuclear magnetic resonance (CCl_4) of **4***e*: δ 1.00–2.00 (10H, complex multiplet), 2.90–3.30 (1H, broad singlet), 4.28 and 4.40 (2H, two singlets), 7.15 (5H, singlet), 8.02 and 8.15 (1H, two singlets).

(f) Cupric Chloride Catalyzed Reaction of Cyclohexyl Isocyanide with Ethanol

A solution of cyclohexyl isocyanide 4.36 g (0.040 mole), ethanol 5.52 g (0.120 mole), and cupric chloride 2.69 g (0.020 mole) was heated at 120° for 5 h. The insoluble matter was separated by filtration, and the filtrate was analyzed by g.l.c. Ethyl *N*-cyclohexylcarbamate (0.0084 mole) was obtained in a yield of 42% (based on $CuCl_2$). CuCl in the insoluble portion was analyzed according to the thiocyanate method. It was found that 76% of $CuCl_2$ was reduced to CuCl (0.0152 mole).

(g) Complex of Cyclohexyl Isocyanide – Cuprous Chloride (1:1)

Cuprous chloride was added slowly to excess cyclohexyl isocyanide at room temperature, and the precipitation was collected by filtration. The white crystalline product was recrystallized from chloroform–ether, m.p. 95–96°. Elemental analysis revealed that the crystalline product consisted of 1 mole cyclohexyl isocyanide and 1 mole cuprous chloride.

Anal. Calcd. for $C_7H_{11}NClCu$: C, 40.40; H, 5.22; N, 6.60; Cl, 17.01. Found : C, 40.40; H, 5.29; N, 6.73; Cl, 17.07.

(h) Complex of β-Dimethylaminoethanol – Cuprous Chloride (1:1)

A dark blue solution of cuprous chloride (0.01 mole) in β-dimethylaminoethanol (0.04 mole) was treated with excess petroleum ether, and the precipitating green crystalline mass was collected and dried, m.p. 144–145°.

NOTES

Metabolites of pathogenic fungi. VII. On the structure and stereochemistry of xanthomegnin, vioxanthin, and viopurpurin, pigments from *Trichophyton violaceum*[1,2]

A. S. NG[3] AND G. JUST
Department of Chemistry, McGill University, Montreal, Quebec

AND

F. BLANK
The Skin and Cancer Hospital, Temple University Health Sciences Center, Philadelphia, Pennsylvania

Received August 30, 1968

Recently, we proposed structure **1** for xanthomegnin (1) and tentatively assigned structures **2** and **3** for vioxanthin and viopurpurin respectively (2). We should now like to present evidence which confirms the structure of vioxanthin (**2**), adds weight to the structure proposed for viopurpurin, and which defines the stereochemistry of the lactone ring in **1** and **3**.

Canadian Journal of Chemistry, 47, 1223 (1969)

Lithium aluminium hydride reduction of **4**, an oxidation product of **1** (1), followed by ozonolysis and oxidation with silver oxide (3), gave β-hydroxybutyric acid, $[\alpha]_D -22.8°$. R-β-hydroxybutyric acid has $[\alpha]_D -24°$ (4). The configuration of the asymmetric center in **4**, and therefore in the lactone ring of xanthomegnin, is R.

[1]This work was supported by United States Public Health Service research grants AI-04050 and 5 ROI AI 05378 from the National Institute of Allergy and Infectious Diseases, and a grant from the John A. Hartford Foundation, Inc., New York.

[2]For part VI in this series, see ref. 9.

[3]Abstracted from part of the Ph.D. Thesis of A. S. Ng, McGill University, 1968.

Oxidation of trimethylviopurpurin (**3***a*) with alkaline hydrogen peroxide gave lactone **6**, identical in all respects with the known lactone obtained by oxidation of floccosin (5). The optical rotatory dispersion (o.r.d.) curves of **4** and **6** are

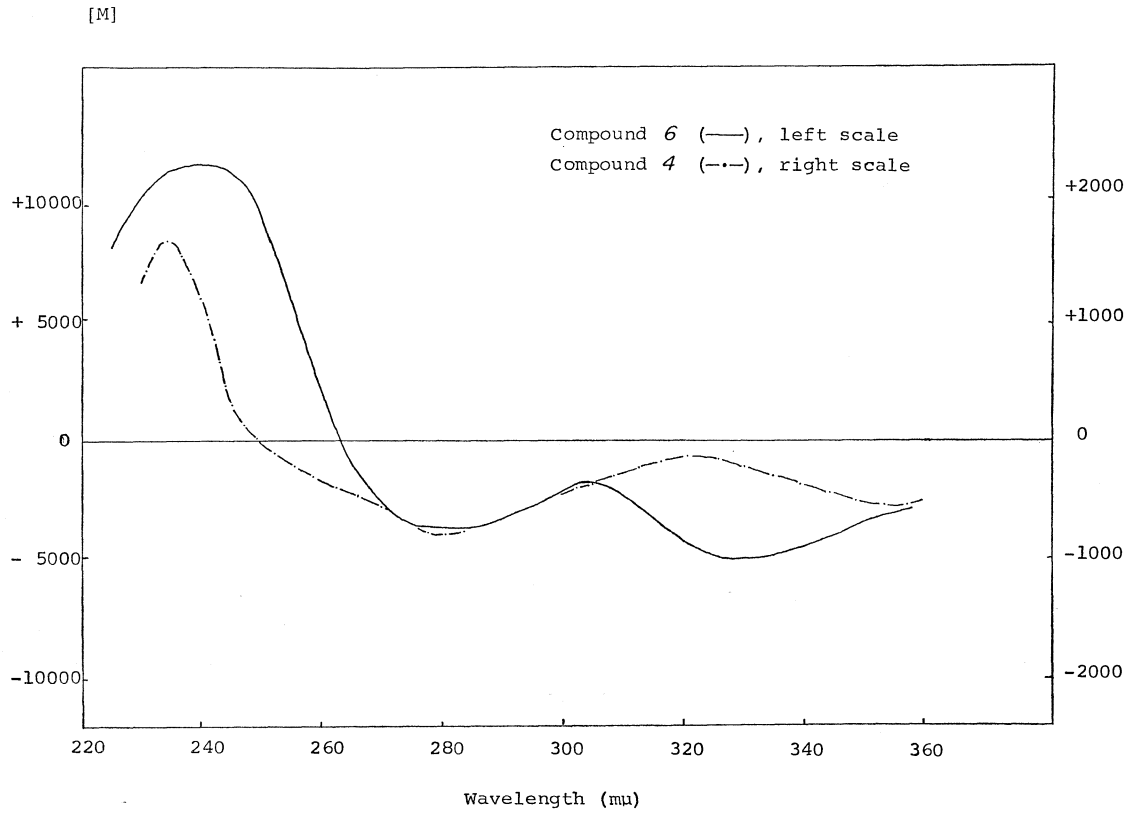

FIG. 1. The optical rotatory dispersion curves of **4** and **6**.

very similar (Fig. 1). It may therefore be concluded that the lactone rings in **4** and **6**, and therefore in **1** and **3**, have the same absolute configuration. This is not unreasonable, especially since both pigments were obtained from the same organism. No degradation product of **2** containing the intact lactone ring could be obtained. It is, however, quite probable that it too has the same absolute stereochemistry.

In our original paper on xanthomegnin (1), we had proposed the S-configuration for the lactone ring, based on an apparently unwarranted extension of the Hudson–Klyne rule (6). It is conceivable that the o.r.d. curve of the acid (or sodium salt) of **1** (see Fig. 3) is sufficiently different from **1** to simulate an apparent reversal of the ΔM_D, (which is taken to reflect the absolute stereochemistry at the asymmetric center) upon opening of the lactone ring.

Vioxanthin has been assigned structure **2**, based mainly on spectroscopic data (2). The linear arrangement of the three rings has now been confirmed by oxidation of **2***a* with alkaline permanganate to the known anisole-2,3,5,6-tetracarboxylic acid[4] and the dimeric nature has been corroborated by mass spectrometry (molecular ion of **2***a*: *m/e* 602).

Biogenetic considerations had governed the assignment of the positions of the dimer linkage and of the methoxy groups in vioxanthin (2). This assignment has now been confirmed by o.r.d. of vioxanthin (**2**) and its tetramethyl ether **2***a* and tetraacetate **2***b* (Fig. 2), which shows a very large Cotton effect (M_D = 480 000) associated with the hindered rotation at the dimer linkage. This large effect cannot be associated with the dissymmetry of the lactone ring (see Fig. 1), and excludes the alternative arrangement in which the

[4]We should like to thank Dr. J. S. E. Holker, Department of Organic Chemistry, University of Liverpool, England, for the infrared spectra of an authentic sample.

For personal use only.

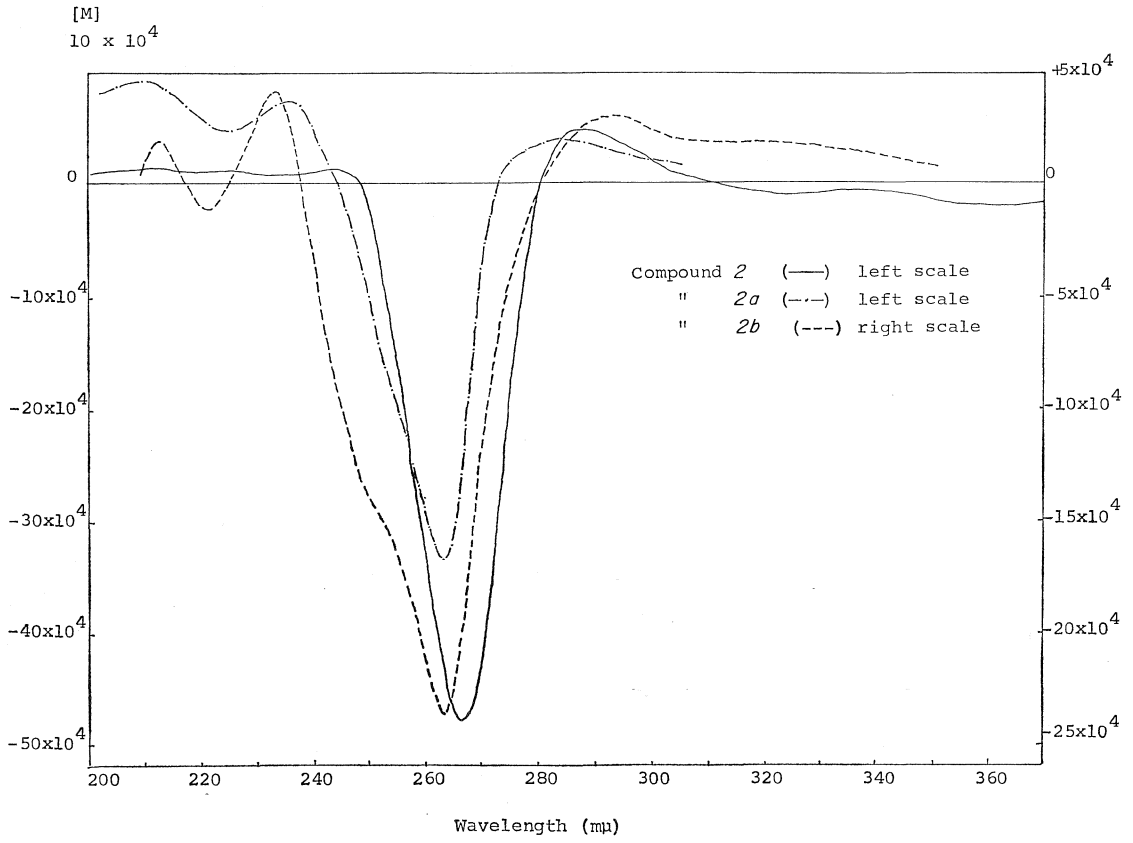

FIG. 2. The optical rotatory dispersion curves of **2**, **2***a*, and **2***b*.

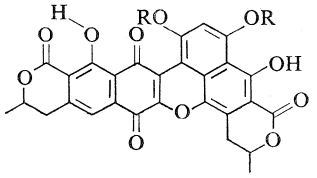
positions of the methoxy group and the dimer linkage are switched, and in which no optical activity due to hindered rotation around the dimer-linkage should be observed.

Not enough model compounds of types **1** and **2** have been described to permit the assignment of the absolute stereochemistry of the binaphthyl linkage in xanthomegnin and vioxanthin (7).

An alternative structure for viopurpurin, which cannot be excluded at the present time, is represented by **7**.



7, R = H,CH_3

Experimental

β-*Hydroxybutyric Acid from Xanthomegnin (**1**)*

Xanthomegnin (500 mg) was dissolved in 50 ml 1% aqueous potassium hydroxide. To the alkaline solution, 10 ml 50% hydrogen peroxide was dropped in slowly with stirring and the solution was stirred for 5 h. The solution was then acidified with concentrated hydrochloric acid to pH 4, and extracted with ether in a liquid–liquid extractor for 48 h.

The oxidation product **4** was then dried *in vacuo*, and dissolved in 50 ml anhydrous tetrahydrofuran. To the tetrahydrofuran solution, 1 g of lithium aluminium hydride was added cautiously, and the mixture stirred for 24 h. The excess reagent was decomposed with 1.6 ml 10% sodium hydroxide and 2 ml of distilled water. After the decomposition was completed, the solution was filtered, the filtrate was taken to dryness, and an oil was obtained. It showed one major spot on thin-layer chromatography (t.l.c.). The crude reduced product was dissolved in 40 ml of chloroform and ozonized at room temperature for 2 h. After the solvent was removed, 20 ml of distilled water and 500 mg of silver oxide were added to the ozonide. The mixture was warmed on a water bath for 20 min at 70°, the oxide was filtered off, and the filtrate acidified

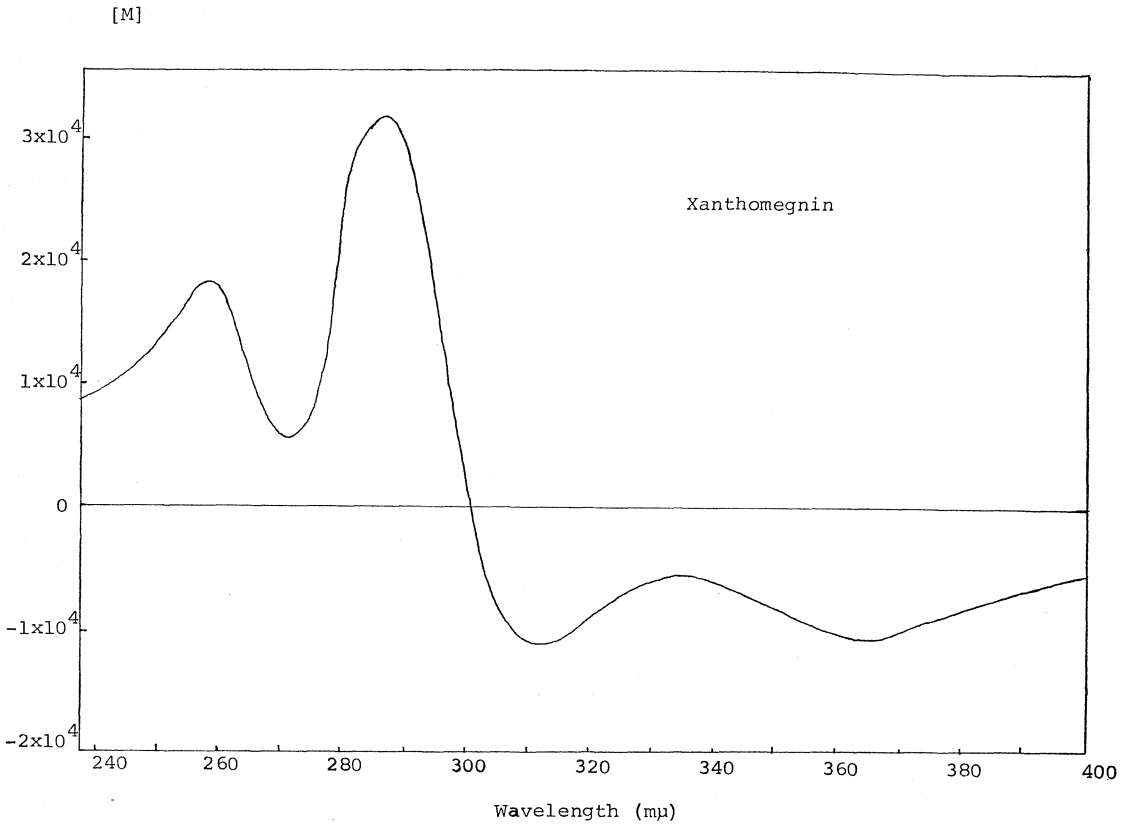

FIG. 3. The optical rotatory dispersion curve of the acid (or sodium salt) of **1**.

with concentrated hydrochloric acid. After removal of silver chloride, the filtrate was extracted with ether; β-hydroxybutyric acid was obtained and identified by t.l.c. The chromatogram was sprayed with methyl orange indicator after developing in acetone. A red spot having the same R_f value as authentic β-hydroxybutyric acid was observed. The acid was further identified by comparison of its retention time with that of an authentic sample on vapor-pressure chromatography (v.p.c.). Optical rotation of the acid was $[\alpha]_D - 22.8°$ ($CHCl_3$).

Tetramethyl Vioxanthin (2a)

To an acetone (20 ml) solution of vioxanthin (50 mg), were added 5 ml of dimethyl sulfate and 2 g of anhydrous potassium carbonate. The mixture was refluxed with stirring for 5 h, cooled, and the solid removed. Acetone was removed by evaporation *in vacuo*. The excess dimethyl sulfate was hydrolyzed with 5% aqueous sodium hydroxide solution. The alkaline solution was acidified with concentrated hydrochloric acid and extracted with chloroform. The chloroform solution was washed with distilled water until free from acid. The pale-colored tetramethyl vioxanthin obtained from the chloroform solution was purified by using t.l.c. (silicagel plates; benzene: hexane, 3:7); 40 mg of pure tetramethyl vioxanthin, m.p. 170–171°, was obtained as a powder and could not be crystallized.

λ_{max} (EtOH) 350 mμ (ε 5380), 320 mμ (ε 8840), 307 mμ ε 9250), 264 mμ (ε 53 000).

Anal. Calcd. for $C_{34}H_{34}O_{10}$ (mol. wt., 602): C, 67.76; H, 5.46; O, 26.60. Found[5] (mol. wt. (osmometric), 583): C, 66.82; H, 5.41; O, 27.69.

Mass spectrum: parent peak at *m/e* 602. The nuclear magnetic resonance (n.m.r.) spectrum differed from that of **2** mainly by the absence of the hydroxyl hydrogens and the presence of methoxy signals at 3.55 and 3.9 p.p.m.

Oxidation of Tetramethyl Vioxanthin

Tetramethyl vioxanthin (20 mg) was suspended in 20 ml of 5% aqueous sodium hydroxide solution. About 20 ml of 5% aqueous potassium permanganate was added portionwise and the solution was heated to reflux for 18 h. Manganese dioxide was removed and the filtrate acidified with dilute sulfuric acid. Sodium bisulfite was added to destroy the remaining manganese dioxide. The acidic solution was then extracted with ether in a liquid–liquid extractor for 48 h. The material obtained (2 mg) from the ether extract showed a spot corresponding to authentic anisole-2,3,5,6-tetracarboxylic acid (8) on t.l.c. Its infrared (i.r.) spectrum was also identical to that of the authentic sample. Crystallization was not possible because of the scarcity of the sample.

[5]Not enough sample to repeat the analysis.

Anisole-2,3,5,6-tetracarboxylic Acid Methyl Ester

The crude anisole-2,3,5,6-tetracarboxylic acid (2 mg) was dissolved in 1 ml of methanol. The solution was methylated with ethereal diazomethane for 30 min. The methylated product was dissolved in ether and injected into a DC 710 v.p.c. column (Model F & M 700, temperature 200 °C). Three peaks appeared with retention times at 0.95, 1.45, and 3.75 min. The retention time of an authentic sample of anisole-2,3,5,6-tetracarboxylic acid methyl ester (8) was 3.75 min.

Trimethyl Viopurpurin (3a)

Viopurpurin triacetate (**3***b*) (40 mg) was dissolved in absolute methanol. A methanol solution of sodium methoxide was added with stirring. The orange colored solution turned blue slowly. After stirring for 2 h, the solvent was removed and methyl iodide added to destroy the excess sodium methoxide. The resulting blue solid was suspended in 20 ml of spectrograde acetone, and 2 g of anhydrous potassium carbonate and 5 ml of dimethyl sulfate were added to the acetone solution. The mixture was refluxed for 8 h. After cooling, the solid was removed. The solvent was taken off by evaporating *in vacuo*. The excess dimethyl sulfate was hydrolyzed by stirring with 5% aqueous sodium hydroxide for 3 h. After the hydrolysis was complete, the alkaline solution was acidified with concentrated hydrochloric acid and extracted with chloroform; 30 mg of red crystalline trimethyl viopurpurin were obtained.[6] Recrystallization from methanol gave blood-red crystals, m.p. 173–174 °C.

λ_{max} (EtOH) 355 mμ (ε 1220), 278 mμ (ε 24 600), 270 mμ (ε 24 000), 218 mμ (ε 14 000); λ_{max} ($CHCl_3$) 455 mμ (ε 1030).

The mass spectrum showed a molecular ion peak at *m/e* 586 (calcd: 586). The n.m.r. of **3***a* showed the following peaks: δ 1.58 (6H, d), 3.10 (4H, d), 4.70 p.p.m. (2H, multiplet), corresponding to $CH_3CH(O)CH_2$—Ar; 7.8 (1H, s), 7.88 p.p.m. (1H, s) corresponding to two aromatic hydrogens; 4.11 (6H, s), 4.15 (3H, s), 4.2 p.p.m. (3H, s) corresponding to four methoxy groups.

[6]The material was used for degradation work. No analysis was obtained.

Alkaline Hydrogen Peroxide Oxidation of Trimethyl Viopurpurin (3a)

Trimethyl viopurpurin (20 mg) was dissolved in 5 ml of methanol and 5 ml of 20% sodium hydroxide was added. To the solution, 10 ml of 50% hydrogen peroxide was added slowly with stirring. Stirring was continued for 5 h, when the intense orange color faded to pale amber. The solution was then acidified with concentrated hydrochloric acid and extracted with ether in a liquid–liquid extractor for 24 h. The ether solution was evaporated to dryness: 3 mg of lactone **6** were obtained which on recrystallization from ether had a m.p. 192–194°. The m.p. was not depressed upon admixture of an authentic sample, and the i.r. spectrum and R_f value (t.l.c.) were identical with those of an authentic sample (5).

Some derivatives of 1-benzazepine

A. H. Rees and K. Simon
Department of Chemistry, Trent University, Peterborough, Ontario

Received September 12, 1968

A new rearrangement of a substituted 5*H*-1-benzazepine-5-one is described. A new route to certain dimethyl-1-benzazepines has been developed and linked up with a known synthesis. Several new derivatives of 1-benzazepine are reported.

Canadian Journal of Chemistry, 47, 1227 (1969)

A number of 1-benzazepines based on the ketolactam **1**, (R = R′ = Me) have been described (1) and screened for pharmacological activity (2). Continuing our studies of this heterocyclic system, although we were unable to prepare analogues **1**, (RR′ = $(CH_2)_3$) and **1**, (R = Cl, R′ = Me) based on 5-acetylaminoindane and 3-methyl-4-chloroacetanilide respectively, we

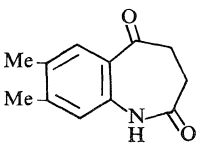
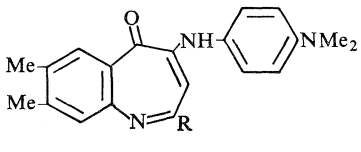
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

were able to make various modifications to the heterocyclic ring.

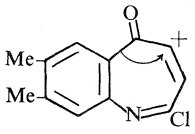


1

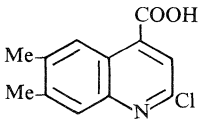


2

7,8-Dimethyl-2-hydroxy-4-(4′-dimethylamino)phenylamino-5*H*-1-benzazepine-5-one (**2**, R = OH) (1) was converted by phosphorus oxychloride into the corresponding 2-chloro-derivative (**2**, R = Cl). Reduction of the latter has so far given only a ring dihydro-derivative still containing the chlorine atom. During removal of the basic sidechain by acid hydrolysis (1), ring contraction occurred (3) to give the known 2-chloro-6,7-dimethylquinoline-4-carboxylic acid (4), presumably via the ion **3**. This is a new reaction of the sensitive "azatropone" system (5).

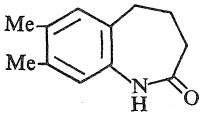


3

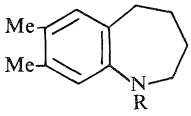


4

We have also developed a new route to 6,7-dimethyl-1-benzazepines based on β-3,4-xyloyl-propionic acid via reduction, cyclization to the tetralone, and Beckmann rearrangement of the ketoxime to give the lactam **5**.



5

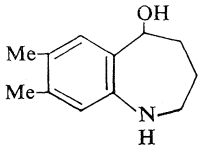


6

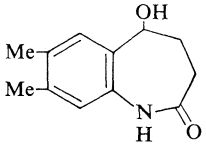
Subsequent hydride reduction gave the amine **6**, (R = H). Dehydration of the known alcohol **7** (1), followed by hydrogenation, gave a product shown to be the amine **6**, (R = H) by m.p., mixture m.p., and infrared (i.r.) spectrum, thus proving that both routes led to the same series of compounds.

The ketolactam **1**, (R = R′ = Me) was reduced by borohydride to the alcohol **8** providing a potential route to still further compounds.

Among variations of our original synthesis (1) of 1-benzazepines, we investigated the use of



7

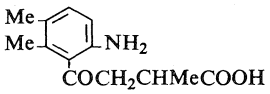


8

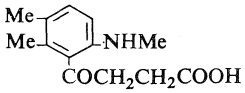
methylsuccinic anhydride and of *N*-methyl-*N*-acetyl-3,4-xylidine. To our surprise, the nuclear magnetic resonance (n.m.r.) spectra of compounds from these series showed the two aromatic protons as AB quartets, (J = 7 c.p.s.), suggesting structures **9** and **10** for the amino-acids isolated. The n.m.r. spectra of lactams **1**, (R = R′ = Me) and **5**, showed the aromatic protons as uncoupled (para-) singlets, confirming their orientation.

Although the amino-acids **9** and **10** might ultimately lead to 1-benzazepines, these were not prepared as they would be 6,7-dimethyl-1-benzazepines, whereas our thesis is (2) that maximum pharmacological activity would lie in the 7,8-dimethyl series.

Further work in this field continues.



9



10

Experimental

7,8-Dimethyl-2-chloro-4-(4′-dimethylamino)phenylamino-5H-1-benzazepine-5-one (2, R = Cl)

The red 2-hydroxy compound **2**, (R = OH), (9.8 g) (1) was heated for 1 h on a steam bath with phosphorus oxychloride (25 ml). The solution was cooled and poured onto ice to decompose excess acid chloride, then filtered to remove a brown substance (0.3 g). On neutralization, the deep-red 2-chloro derivative was precipitated. It was collected and washed with 0.5 *N* carbonate solution, then water, and dried, to give a yield of 8.3 g, m.p. 230° from toluene.

Anal. Calcd. for $C_{20}H_{20}ClN_3O$: C, 67.9; H, 5.7; Cl, 10.0; N, 11.9. Found: C, 68.2; H, 5.8; Cl, 10.2; N, 11.6.

The carbonate washings, on acidification, gave 0.4 g of 7,8-dimethyl-3-hydro-1*H*-1-benzazepine-2,4,5(3*H*)-trione (1).

Catalytic hydrogenation or chromous chloride reduction of compound **2**, (R = Cl), gave the same yellow compound, m.p. 180–200° from aqueous acetic acid. This compound was difficult to purify but analyzed roughly for the acetate monohydrate of the dihydro derivative.

Acid Hydrolysis of the Chloro Compound (2, R = Cl)

The above chloro compound had λ_{max} 395, 280, and 225 mμ, log ε 4.06, 4.34, and 4.71 respectively, in ethanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

but gave an unstable spectrum in acid. On a preparative scale, the chloro compound was boiled with dilute hydrochloric acid until the color had faded. The filtered solution was neutralized, giving a carboxylic acid m.p. 217° from acetic acid, spectroscopically identical with and undepressed in mixed melt by 2-chloro-6,7-dimethylquinoline-4-carboxylic acid, prepared according to the literature (4).

7,8-Dimethyl-3,4,5-trihydro-1H-1-benzazepine-2(H)-one (5)

6,7-Dimethyl-1-tetralone (6) was treated with hydroxylamine hydrochloride in ethanolic pyridine at reflux. Addition of water gave the oxime, m.p. 179°.

Anal. Calcd. for $C_{12}H_{15}NO$: C, 76.15; H, 8.0; N, 7.4. Found: C, 75.75; H, 7.85; N, 7.35.

Beckmann rearrangement (7) of the oxime gave the azepinone (**5**), m.p. 175° from ligroin.

Anal. Calcd. for $C_{12}H_{15}NO$: C, 76.15; H, 8.0; N, 7.4. Found: C, 76.55; H, 8.3; N, 7.4.

7,8-Dimethyl-2,3,4,5-tetrahydro-1H-1-benzazepine (6, R = H)

The azepinone (**5**) gave on hydride reduction (8), the amine **6**, (R = H), m.p. 82° after sublimation.

Anal. Calcd. for $C_{12}H_{17}N$: C, 82.2; H, 9.8; N, 8.0. Found: C, 82.0; H, 9.8; N, 8.0.

The amine was characterized as its picrolonate, m.p. 205°, crystallized from dioxan.

Anal. Calcd. for $C_{22}H_{25}N_5O_5$: C, 60.1; H, 5.7; N, 15.95. Found: C, 60.0; H, 5.7; N, 15.9.

The *N*-acetyl derivative **6**, (R = CH_3CO) had m.p. 90° when crystallized from aqueous ethanol.

Anal. Calcd. for $C_{14}H_{19}NO$: C, 77.4; H, 8.8; N, 6.45. Found: C, 77.05; H, 8.9; N, 6.5.

Dehydration and Subsequent Hydrogenation of 5-Hydroxy-7,8-dimethyl-2,3,4,5-tetrahydro-1H-1-benzazepine (7)

The above azepine (**7**) (1 g) (1) was refluxed with concentrated hydrochloric acid (6 ml). On cooling, crystals of the hydrochloride of the dehydrated base appeared, m.p. 196°.

Anal. Calcd. for $C_{12}H_{16}ClN$: C, 68.7; H, 7.7; N, 6.7; Cl^-, 16.9. Found: C, 68.65; H, 7.5; N, 6.6; Cl^-, 17.0.

This salt was alkalized and a benzene extract washed until neutral, then evaporated, giving the free base, 7,8-dimethyl-2,3-dihydro-1*H*-1-benzazepine (1). This in turn was hydrogenated in ethanol using Adam's catalyst, giving the tetrahydrobenzazepine **6**, (R = H), m.p. 82°, which was undepressed in mixed melt, and the infrared (i.r.) spectrum was superimposable with that of the sample made by the other route.

5-Hydroxy-7,8-dimethyl-3,4,5-trihydroxy-1H-1-benzazepine-2(H)-one (8)

The ketolactam **1**, (R = R′ = Me) in tetrahydrofuran was treated with excess sodium borohydride in water. The mixture was neutralized with dilute acetic acid and extracted with hot benzene giving on cooling, the hydroxy compound (**8**), m.p. 192°. The i.r. spectrum confirmed the structure.

Anal. Calcd. for $C_{12}H_{15}NO_2$: C, 70.2; H, 7.4; N, 6.8. Found: C, 70.5; H, 7.35; N, 6.6.

Friedel–Crafts Reaction of N-Acetyl-3,4-xylidine with Methylsuccinic Anhydride

The above amide (81.7 g) gave (1) the keto-acid (55.4 g) assumed to be the α-methyl isomer (9), m.p. 206°, crystallized from ethanol.

Anal. Calcd. for $C_{15}H_{19}NO_4$: C, 64.95; H, 6.9; N, 5.05. Found: C, 64.85; H, 7.0; N, 5.05.

Hydrolysis with 6 *N* hydrochloric acid yielded the amino-acid hydrochloride, m.p. 143°, crystallized from 2 *N* acid.

Anal. Calcd. for $C_{13}H_{17}NO_3 \cdot HCl \cdot H_2O$: Cl^-, 12.4. Found: Cl^-, 12.1.

Recrystallization from aqueous ethanol resulted in hydrolysis of the salt, giving the free amino-acid, m.p. 173°, crystallized from toluene.

Anal. Calcd. for $C_{13}H_{17}NO_3$: C, 66.4; H, 7.3; N, 6.0. Found: C, 66.4; H, 7.3; N, 6.5.

The nuclear magnetic resonance (n.m.r.) spectrum of the *N*-acetyl derivative showed *ortho* protons indicating structure **9**.

N-Acetyl-N-methyl-3,4-xylidine

N-Formyl-3,4-xylidine (10), b.p. 134°/0.4 mm was reduced by lithium aluminium hydride (8) to *N*-methyl-3,4-xylidine, b.p. 170°/110 mm, n_D^{22} 1.553, lit.(11) 1.558; picrate m.p. 139°, lit. 133–136°. The picrolonate had m.p. 205° decomp., crystallized from ethanol.

Anal. Calcd. for $C_9H_{21}N_5O_5$: N, 17.5. Found: N, 17.6.

The above methylxylidine (20 g), after refluxing for 2 h with acetic anhydride (20 ml) then distilling, gave the *N*-acetyl derivative (23.7 g) b.p. 202°/83 mm which had m.p. 76°, crystallized from cyclohexane.

Anal. Calcd. for $C_{11}H_{15}NO$: C, 74.55; H, 8.55; N, 7.9. Found: C, 74.65; H, 8.65; N, 7.95.

The above methyl-xylidine, after reflux for 1 h with succinic anhydride (1 equivalent) in dioxan, gave on precipitation with water, the *N*-succinoyl derivative, m.p. 102°, crystallized from benzene/cyclohexane.

Anal. Calcd. for $C_{13}H_{17}NO_3$: C, 66.4; H, 7.3; N, 5.95. Found: C, 66.6; H, 7.6; N, 5.8.

Friedel–Crafts Reaction of N-Methyl-N-acetyl-3,4-xylidine with Succinic Anhydride

The above amide (24.3 g) gave (1) the crude keto-acid in benzene solution. After extraction with dilute alkali, starting amide (10 g) remained in the benzene. The alkaline extract was acidified, precipitating the keto-acid as an oil which was triturated with ether leaving insoluble material (2 g). The ether solution was washed with water, dried, and the solvent evaporated leaving a golden brown oil (10.8 g) which did not crystallize. It was therefore hydrolyzed with 6 *N* hydrochloric acid (40 ml) at the reflux (3 h), then concentrated to 20 ml. Neutralization gave an oil which was stored in vacuum until partly solid. After pressing this on a porous plate, a tacky solid remained which was triturated with methanol to give pure amino-acid (1.85 g), m.p. 118°, crystallized from aqueous ethanol.

Anal. Calcd. for $C_{13}H_{17}NO_3$: C, 66.35; H, 7.3; N, 5.95. Found: C, 66.0; H, 7.3; N, 5.85.

The n.m.r. spectrum of the amino-acid revealed *ortho* protons, indicating structure **10**.

Metallation of 5- and 6-membered ring sultones

T. Durst and J. du Manoir

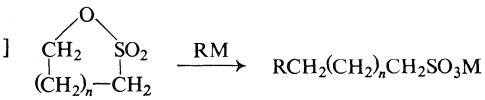
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received September 18, 1968

Treatment of 1,3-propane and 1,4-butane sultone with *n*-butyllithium in tetrahydrofuran at −78° has been shown to result in metallation α to the sulfonyl group. This is in contrast to ring opening which has been observed when the reaction was carried out at room temperature (1, 2). The products obtained from the interaction of the lithio derivatives **3** and **4** with carbonyl compounds and alkyl halides are described.

Canadian Journal of Chemistry, 47, 1230 (1969)

The reaction of 5- and 6-membered ring sultones with a wide variety of nucleophilic reagents such as alcohols, amines, alkoxides, and metal alkyls has been reported to lead invariably to derivatives of sulfonic acids, see eq. [1] (1, 2). This type of reaction has been of considerable industrial importance since it has allowed the introduction of a water-solubilizing group into a variety of organic molecules.



[1] $\xrightarrow{RM}$ $RCH_2(CH_2)_nCH_2SO_3M$

1, $n = 1$
2, $n = 2$

The reactions of **1** and **2** with the organometallic reagents were generally carried out at temperatures above 0° (2). We have found that if the treatment of the sultones with alkyllithiums, e.g. *n*-butyllithium, is carried out at acetone – dry ice temperature in tetrahydrofuran solution, the ring opening reaction is suppressed and metallation occurs α to the sulfonyl group, thereby yielding the lithio salts **3** and **4** as shown by quantitative deuterium incorporation upon hydrolysis with D_2O. The success of the metallation procedure at the low temperature apparently stems from the fact that the ring opening reaction is considerably more temperature dependent than metallation. Metallation α to the sulfonyl groups of aliphatic sulfonic acid esters has recently been reported by Corey and Durst (3).

The lithio derivatives appeared to be stable for at least 3 h in tetrahydrofuran solution at −78°. Decomposition occurred rapidly upon warming to −20° as evidenced by the formation of a colorless water-soluble precipitate. The infrared (i.r.) spectrum (KBr) of this material showed only a few ill-defined bands; its structure has not been further investigated.

Reaction of **3** and **4** with carbonyl derivatives afforded, after hydrolysis, the adducts **5** and **6** in 65–85% yield. The structures of the adducts were assigned on the basis of elemental analyses and spectroscopic properties. The i.r. spectrum of each adduct showed a moderately strong band at about 3550 cm^{-1} due to the newly formed hydroxyl group and strong bands between 1340–1360, 1160–1170, and 980–995 cm^{-1} which indicated that the sultone grouping had been retained. Nuclear magnetic resonance (n.m.r.) data (see Experimental) fully supported the above conclusions.

7 **8** **9** **10**

Dehydration of the hydroxy sultones (benzene-*p*-toluenesulfonic acid) led to the formation of the α,β-unsaturated derivatives **7** and **8** in the case of the benzophenone adducts, and to β,γ-unsaturated sultones **9** and **10** for the acetone and cyclohexanone adducts respectively. The preference of the double bond in the β,γ- rather than α,β-position in the latter two sultones is not unexpected. Similar observations have been made for unsaturated sulfoxides and sulfones (4, 5). The yields of the various dehydrated derivatives were of the order of 75–90%. Analytical and spectroscopic data fully supported the individual assignments.

Reaction of **3** with methyl iodide and benzyl chloride resulted in the formation of the expected alkylation products in 62 and 49% yield respectively. With less reactive alkylating agents, e.g. ethyl bromide or isopropyl iodide, the yields were considerably less. With these reagents no alkylation occurred at −78°. At −20° the decomposition of **3** as judged by formation of the colorless precipitate is apparently more rapid than the alkylation reaction.

It is thus likely that only a limited number of 3-alkylated sultones can be synthesized by the direct alkylation procedure. However, a much larger variety may be obtained in quite reasonable yields by the 3-step sequence involving reaction of the lithio derivatives with the appropriate carbonyl compound, followed by dehydration and hydrogenation.

Experimental

Melting points were determined with a Thomas Hoover apparatus and are not corrected. Infrared spectra were recorded on a Beckman (model IR8) infrared (i.r.) spectrophotometer and nuclear magnetic resonance (n.m.r.) spectra were obtained on a Varian Associates model HA-100 spectrophotometer.

Generation of the Lithio Derivatives 3 and 4

To a rapidly stirred solution of approximately 1 g sultone in 30 ml tetrahydrofuran at −78° under a nitrogen atmosphere, were added dropwise 1.1 equivalents of *n*-butyllithium (1.6 *M* in hexane). The clear solution was stirred for 5 min and then treated with the appropriate reagent. The lithio salt **3** was stable at −78° for at least 3 h. When warmed to −20° decomposition occurred within 10 min and a colorless water-soluble precipitate was deposited. The i.r. spectrum (KBr) of this material showed strong bands at 1280 and 1040 cm^{-1}. Similar stability behavior was noted for **4**.

Reaction of Lithio Derivatives 3 and 4 with Ketones and Aldehydes

The lithio derivatives were prepared as described above. To a solution kept at −78° was added the carbonyl compound, neat if liquid, or as a tetrahydrofuran solution if solid. The reaction mixture was stirred at −78° for a further 10 min and then poured into water and extracted with methylene chloride. The organic extracts were dried over magnesium sulfate and the solvent was evaporated under reduced pressure. Yields were not significantly altered if the reaction mixture was allowed to warm to room temperature prior to the addition of water.

Deuteration of 3

A solution of **3** in tetrahydrofuran at −78° was allowed to react with excess D_2O for 2 min. The reaction mixture was poured into water and extracted with ether. The

For personal use only.

recovery of mono-deuterated 1,3-propane sultone was generally between 65–70%. The n.m.r. spectrum ($CDCl_3$) showed peaks at 2.5–2.8 (m, 2H), 3.1–3.4 (m, 1H), and 4.48 p.p.m. (t, J = 5.5 c.p.s., 2H). In separate experiments it was shown that only approximately 70% of 1,3-propane sultone was recovered under the work-up conditions employed above.

Benzophenone

A solution of 6.6 mmoles of **3** in 30 ml tetrahydrofuran and 1.20 g (6.6 mmoles) of benzophenone gave 1.30 g (65%) of adduct as colorless granules, m.p. 169–171° (decomp.). The i.r. spectrum ($CHCl_3$) showed bands at 3550 (m), 1340 (s), 1162 (s), and 990 (m) cm^{-1}. The n.m.r. absorption ($CDCl_3$) occurred at 2.0–2.4 (m, 1H), 2.6–3.0 (m, 1H), 4.0–4.7 (m, 4H), and 7.2–7.8 p.p.m. (m, 10H).

Anal. Calcd. for $C_{16}H_{16}O_4S$: C, 63.15; H, 5.30; S, 10.52. Found: C, 63.37; H, 5.38; S, 10.90.

The above adduct (2.15 g) and 150 mg of *p*-toluenesulfonic acid in 50 ml of benzene were refluxed for 6 h. The reaction mixture was washed with water. The benzene layer was dried and the solvent evaporated. Recrystallization from methylene chloride – pentane gave 1.76 g (87%) of the unsaturated sultone **7**, m.p. 133–134°. The i.r. spectrum ($CHCl_3$) showed bands at 1620 (w), 1348 (s), 1175 (s), and 997 (m) cm^{-1}. The n.m.r. absorption ($CDCl_3$) occurred at 3.20 (t, J = 7.0 c.p.s., 2H), 4.41 (t, J = 7.0 c.p.s., 2H), and 7.2–7.5 p.p.m. (m, 10H).

Anal. Calcd. for $C_{16}H_{14}O_3S$: C, 67.12; H, 4.93; S, 11.18. Found: C, 67.33; H, 5.27; S, 11.23.

Benzaldehyde

A solution of 11.0 mmoles of **3** in 40 ml of tetrahydrofuran and 1.17 g (11.0 mmoles) of benzaldehyde gave 2.40 g of crude adduct whose i.r. spectrum indicated less than 5% benzaldehyde. The crude product solidified when triturated with 1:1 ether–pentane to yield 2.21 g (88%) of colorless solid. Recrystallization from ether–pentane gave colorless granules, m.p. 83–88°. The i.r. spectrum ($CHCl_3$) showed peaks at 3550 (m), 1348 (s), 1162, and 984 (m) cm^{-1}. The n.m.r. absorption occurred at 2.2–2.5 (m, 1H), 2.6–2.9 (m, 1H), 3.03 (s, 1H), 3.5–3.8 (m, 1H), 4.2–4.7 (m, 2H), 5.50 (d, J = 3 c.p.s., 1H), and 7.40 p.p.m. (s, 5H).

Anal. Calcd. for $C_{10}H_{12}O_4S$: C, 52.63; H, 5.30; S, 14.02. Found: C, 52.81; H, 5.38; S, 14.17.

Cyclohexanone

Addition of 0.60 g cyclohexanone to a solution of 6.0 mmoles of the lithio derivative **3** gave 1.07 g (81%) of crude adduct, m.p. 98–101°. Recrystallization from methylene chloride – pentane furnished colorless plates, m.p. 102–104°. The n.m.r. spectrum ($CDCl_3$) showed a singlet at 2.60 (1H), a pair of doublets at 3.34 (J = 10, 11 c.p.s., 1H), and multiplets at 1.2–2.2 (10H), 2.2–3.1 (2H), and 4.2–4.6 p.p.m. (2H). The i.r. peaks ($CHCl_3$) occurred at 3550 (m), 1342 (s), 1170 (s), 995 (m), and 982 (m) cm^{-1}.

Anal. Calcd. for $C_9H_{16}O_4S$: C, 49.08; H, 7.32; S, 14.53. Found: C, 48.86; H, 7.38; S, 14.73.

Dehydration of the above adduct under the conditions described for the benzophenone adduct gave a 75% yield of **10**, m.p. 66–67°. Three recrystallizations from ether–pentane gave fluffy needles, m.p. 70–71°. Infrared absorptions (CCl_4) occurred at 1357 (s), 1168 (s), and 996 (m) cm^{-1}. The n.m.r. peaks ($CDCl_3$) occurred at 1.5–1.9 (m, 4H), 2.0–2.3 (m, 4H), 2.4–2.9 (m, 2H), 3.85 (t, J = 11.0 c.p.s., 1H), 4.2–4.6 (m, 2H), and 5.9 p.p.m. (broad singlet, 1H).

Anal. Calcd. for $C_9H_{14}O_3S$: C, 53.46; H, 6.98; S, 15.82. Found: C, 53.34; H, 6.93; S, 16.10.

Acetone

Reaction of 10.0 mmoles of **3** in 35 ml tetrahydrofuran at −78° with 580 mg of acetone furnished after recrystallization from ether, 1.11 g (61%) of adduct, m.p. 53–55°. The i.r. spectrum ($CHCl_3$) showed absorption at 3550 (m), 1342 (s), 1162 (s), and 990 (m) cm^{-1}. The n.m.r. peaks ($CDCl_3$) occurred at 1.30 (s, 3H), 1.57 (s, 3H), 2.4–2.9 (m, 2H), 2.99 (s, 1H), 3.35 (doublet of doublets, J = 8.0, 9.0 c.p.s., 1H), and 4.2–4.6 p.p.m. (m, 2H).

Anal. Calcd. for $C_6H_{12}O_4S$: C, 40.00; H, 6.71; S, 17.77. Found: C, 40.50; H, 6.82; S, 17.90.

Dehydration of the acetone adduct in the usual manner furnished a colorless oil (81%) which was homogeneous on thin-layer chromatography (t.l.c.). Spectroscopic properties of this oil were in agreement with its formulation as **9**. Infrared peaks (CCl_4) occurred at 1635 (w), 1355 (s), 1168 (s), 990 (m), and 905 (m) cm^{-1}. The n.m.r. peaks ($CDCl_3$) were at 1.96 (s, 3H), 2.5–2.8 (m, 2H), 3.92 (t, J = 9.0 c.p.s., 1H), 4.3–4.6 (m, 2H), and 2 slightly broadened singlets at 5.18 (1H) and 5.24 p.p.m. (1H).

Reaction of 3 with Benzyl Bromide

To a solution of 7.0 mmoles of **3** in 30 ml of tetrahydrofuran were added 1.20 g (7.0 mmoles) of benzyl bromide. The reaction mixture was stirred at −78° for 30 min and at −20° for 1 h. Work-up yielded 1.42 g of crude product which was purified by preparative t.l.c. The yield of 5-benzyl-1,3-propane sultone was 0.73 g (49%), m.p. 54–55° (colorless needles from ether–pentane). The i.r. spectrum showed bands at 1355 (s), 1168 (s), and 995 (m) cm^{-1}.

Anal. Calcd. for $C_{10}H_{12}O_3S$: C, 56.60; H, 5.70; S, 15.08. Found: C, 56.72; H, 5.70; S, 15.06.

Reaction of 3 with Methyl Iodide

Methyl iodide 1.42 g (10.0 mmoles) was added to a solution of 10.0 mmoles of **3** in tetrahydrofuran at −78°. The reaction mixture was stirred at −78° for 5 min and at −20° for 10 min. The slightly turbid reaction mixture was poured into water and extracted with methylene chloride. The organic phase was dried and the solvent evaporated, yielding 900 mg (67%) of an oil which upon distillation gave 822 mg (62%) of 5-methyl-1,3-propane sultone, $n_D^{25} = 1.4532$; lit.(1, 6) $n_D^{25} = 1.4525$. The n.m.r. spectrum (CCl_4) showed the methyl doublet at 1.48 p.p.m. (J = 7 c.p.s.).

Reaction of 3 with Ethyl Bromide and Isopropyl Iodide

A solution of **3** in tetrahydrofuran was allowed to react with an equimolar amount of alkyl halide, first at −78° for 10 min then at −20° for 2 h. A large amount of colorless precipitate was formed at −20°. The reaction mixture was diluted with water and extracted with ether. The organic layer was dried and the solvent evaporated yielding approximately 25% of crude product which was mainly the 3-alkylated sultone (by n.m.r.).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In other experiments it was shown that virtually no alkylation occurred at −78° and that the precipitate formed at −20° was identical to that formed from **3** at −20° in the absence of alkyl halide.

Reaction of the Lithio Derivative 4 with Benzophenone

To a solution of **4**, generated from 1.00 g (7.35 mmoles) of butane-1,4-sultone in 30 ml of tetrahydrofuran at −78° were added 1.30 g (7.2 mmoles) of solid benzophenone. The reaction mixture was stirred at −78° for 10 min and then worked up as described above. Recrystallization of the crude solid adduct from methylene chloride – pentane gave 1.44 g (63%) colorless needles, m.p. 182–182.5°. The i.r. spectrum ($CHCl_3$) showed peaks at 3550 (m), 1350 (s), 1165 (s), and 955 (m) cm^{-1}. The n.m.r. peaks ($CDCl_3$) occurred at 1.6–2.6 (m, 4H), 4.12 (s, 1H), 4.2–4.7 (m, 2H), and 7.1–7.7 p.p.m. (10H).

Anal. Calcd. for $C_{17}H_{18}O_4S$: C, 64.14; H, 5.70; S, 10.06. Found: C, 64.23; H, 5.87; S, 10.11.

Dehydration of 315 mg of the above adduct under the usual conditions furnished 263 mg (89%) of unsaturated sultone **8**, m.p. 172–173.5° (needles from methylene chloride – pentane). The i.r. spectrum ($CHCl_3$) showed peaks at 1360 (s), 1170 (s), and 970 (m) cm^{-1}. The n.m.r. bands ($CDCl_3$) occurred at 1.9–2.2 (m, 2H), 2.8–3.0 (m, 2H), 4.60 (t, J = 5.5 c.p.s., 2H), and 7.1–7.5 p.p.m. (m, 10H).

Anal. Calcd. for $C_{17}H_{16}O_3S$: C, 67.99; H, 5.37; S, 10.66. Found: C, 68.31; H, 5.45; S, 10.91.

S-[(*N*-Terpenoid carboxamidinium)methyl] thiosulfates (Bunte salts) as potential antiradiation agents

Jerry M. Barton and Ludwig Bauer[1]

Department of Chemistry, College of Pharmacy, University of Illinois (Medical Center), P.O. Box 6998, Chicago, Illinois 60680

Received November 26, 1968

The synthesis of a number of α-acetamidinium Bunte salts, substituted on one of the nitrogen atoms by a terpenoid moiety, is reported.

Canadian Journal of Chemistry, **47**, 1233 (1969)

It has been shown that a number of *S*-[(*N*-substituted carboxamidinium)methyl] thiosulfates, $^{-}O_3SSCH_2C(=NH_2^{+})NHR$, **1**, are promising radiation-protective compounds in mice (1, 2). This paper describes the synthesis of derivatives of **1** in which one of the amidine nitrogen atoms bears a highly condensed aliphatic structure. It has been observed in a series of *N*-(ω-cycloalkane)-alkyl derivatives of **1** [R = *cyclo*-C_nH_{2n-1}—$(CH_2)_m$] that good activity was retained up to R = 4-(cyclohexyl)butyl, (3). In a recent report, it was disclosed that those *S*-2-aminoethyl thiosulfates, $HO_3S_2CH_2CH_2NHR$, bearing similarly constituted (cycloalkane)alkyl substituents on nitrogen, were among the best radiation-protective substances (4). The project described at present was designed to modify the polar character of **1** by introducing highly condensed aliphatic systems into the molecule. By attaching bi- and tricyclic aliphatic ring systems to the amidine function of **1**, it was hoped to impart additional lipid solubility and possibly facilitate transport of these substances through living systems. Toward this end, derivatives of **1** bearing either terpenoid or adamantane substituents were synthesized and their structures are listed in Table I.

The synthesis employed to prepare these compounds was as described previously (1–3). Methyl α-chloroacetimidate is generated *in situ*

[1]The authors gratefully acknowledge support for this project from the Office of the Surgeon General, United States Army Medical Research and Development Command (Contract No. DA-49-193-MD-2047).

In other experiments it was shown that virtually no alkylation occurred at −78° and that the precipitate formed at −20° was identical to that formed from **3** at −20° in the absence of alkyl halide.

Reaction of the Lithio Derivative 4 with Benzophenone

To a solution of **4**, generated from 1.00 g (7.35 mmoles) of butane-1,4-sultone in 30 ml of tetrahydrofuran at −78° were added 1.30 g (7.2 mmoles) of solid benzophenone. The reaction mixture was stirred at −78° for 10 min and then worked up as described above. Recrystallization of the crude solid adduct from methylene chloride – pentane gave 1.44 g (63%) colorless needles, m.p. 182–182.5°. The i.r. spectrum ($CHCl_3$) showed peaks at 3550 (m), 1350 (s), 1165 (s), and 955 (m) cm^{-1}. The n.m.r. peaks ($CDCl_3$) occurred at 1.6–2.6 (m, 4H), 4.12 (s, 1H), 4.2–4.7 (m, 2H), and 7.1–7.7 p.p.m. (10H).

Anal. Calcd. for $C_{17}H_{18}O_4S$: C, 64.14; H, 5.70; S, 10.06. Found: C, 64.23; H, 5.87; S, 10.11.

Dehydration of 315 mg of the above adduct under the usual conditions furnished 263 mg (89%) of unsaturated sultone **8**, m.p. 172–173.5° (needles from methylene chloride – pentane). The i.r. spectrum ($CHCl_3$) showed peaks at 1360 (s), 1170 (s), and 970 (m) cm^{-1}. The n.m.r. bands ($CDCl_3$) occurred at 1.9–2.2 (m, 2H), 2.8–3.0 (m, 2H), 4.60 (t, J = 5.5 c.p.s., 2H), and 7.1–7.5 p.p.m. (m, 10H).

Anal. Calcd. for $C_{17}H_{16}O_3S$: C, 67.99; H, 5.37; S, 10.66. Found: C, 68.31; H, 5.45; S, 10.91.

S-[(*N*-Terpenoid carboxamidinium)methyl] thiosulfates (Bunte salts) as potential antiradiation agents

Jerry M. Barton and Ludwig Bauer[1]

Department of Chemistry, College of Pharmacy, University of Illinois (Medical Center), P.O. Box 6998, Chicago, Illinois 60680

Received November 26, 1968

The synthesis of a number of α-acetamidinium Bunte salts, substituted on one of the nitrogen atoms by a terpenoid moiety, is reported.

Canadian Journal of Chemistry, **47**, 1233 (1969)

It has been shown that a number of *S*-[(*N*-substituted carboxamidinium)methyl] thiosulfates, $^{-}O_3SSCH_2C(=NH_2^{+})NHR$, **1**, are promising radiation-protective compounds in mice (1, 2). This paper describes the synthesis of derivatives of **1** in which one of the amidine nitrogen atoms bears a highly condensed aliphatic structure. It has been observed in a series of *N*-(ω-cycloalkane)-alkyl derivatives of **1** [R = *cyclo*-C_nH_{2n-1}—$(CH_2)_m$] that good activity was retained up to R = 4-(cyclohexyl)butyl, (3). In a recent report, it was disclosed that those *S*-2-aminoethyl thiosulfates, $HO_3S_2CH_2CH_2NHR$, bearing similarly constituted (cycloalkane)alkyl substituents on nitrogen, were among the best radiation-protective substances (4). The project described at present was designed to modify the polar character of **1** by introducing highly condensed aliphatic systems into the molecule. By attaching bi- and tricyclic aliphatic ring systems to the amidine function of **1**, it was hoped to impart additional lipid solubility and possibly facilitate transport of these substances through living systems. Toward this end, derivatives of **1** bearing either terpenoid or adamantane substituents were synthesized and their structures are listed in Table I.

The synthesis employed to prepare these compounds was as described previously (1–3). Methyl α-chloroacetimidate is generated *in situ*

[1]The authors gratefully acknowledge support for this project from the Office of the Surgeon General, United States Army Medical Research and Development Command (Contract No. DA-49-193-MD-2047).

from the base-catalyzed addition of methanol to chloroacetonitrile. Addition of a primary amine hydrochloride leads to the intermediate α-chloroacetimidinium chloride, $ClCH_2C(=NH_2^+)NHR\ Cl^-$. In the present series, only two of these chloroacetamidinium chlorides could be isolated as crystalline solids (see Experimental). The rest were transformed directly by thiosulfate ion to the corresponding Bunte salt. The crystalline *N*-(1-adamantanemethyl)-α-chloroacetamidinium chloride was converted *via* the phosphorothioate method (5) to the corresponding α-mercaptoacetamidinium chloride.

The procedure for ascertaining *in vivo* activity of these compounds in mice was described in detail previously (2, 4, 6). Of the compounds tested, the *N*-bornyl and *N*-(*cis*-myrtanyl) derivatives of **1**, when administered orally or intraperitoneally 15 min prior to irradiation (800–1000 R, X-rays) showed a high survival rate at one-half to one-quarter of the toxic (LD_{50}) dosage.

Experimental

Melting and boiling points are uncorrected. Microanalyses were performed by Micro-Tech Laboratories, Skokie, Illinois. Some nitrogen analyses were obtained by (the late) Mr. Leo Horner in this Department, using a Coleman model D-29. Proton magnetic resonance (p.m.r.) spectra were recorded by means of a Varian A-60 spectrometer, with tetramethylsilane and sodium 3-(trimethylsilyl)-1-propanesulfonate as internal standards in organic and aqueous media, respectively. Chemical shifts are recorded in p.p.m. (δ) downfield from these internal references and multiplicities are indicated by the usual abbreviations.

Starting Materials

The following chemicals were purchased from Aldrich Chemical Co.: chloroacetonitrile, norbornylene, (−)-β-pinene, 2-norbornanecarbonitrile, 1-adamantanecarbonitrile, 2-norboranamine hydrochloride and dehydroabietylamine. 2-Bornanamine [m.p. 159–169°, lit. (7) m.p. 163°] was purchased from K & K Laboratories and converted to the hydrochloride by passing HCl gas through a chilled solution of the amine in dry ether.

exo-2-Norbornanamine Hydrochloride

The procedure to prepare the amine was adapted from a recent literature method (8), except that hydroboration of norbornylene was accomplished here by generating diborane *in situ* (9). The hydrochloride was obtained by adding a slight excess of concentrated HCl to a solution of the free base in methanol, followed by evaporation to dryness. The yield was 25%; p.m.r. (D_2O) δ 3.29 (m, 1, *endo* H), 2.44 (broad s, 2, bridgehead H), 0.97–2.12 (m, 8, methylene H). The *N*-acetyl derivative of the amine melted at 138–140° [lit. (10) m.p. 139°].

The p.m.r. spectrum of commercial 2-norbornanamine hydrochloride (D_2O) was as follows: δ 3.63 (m, 1, *exo* H), 2.42 (m, 2, bridgehead H), 0.87–2.17 (m, 8, methylene H). Since the α-methine and bridgehead hydrogens showed distinct signals from those of the synthetic *exo* compound, it was concluded that the purchased material is the *endo* isomer. There is no indication that either sample was a mixture of isomers.

cis-Myrtanylamine

This amine was prepared by a combination of the literature procedures for hydroboration of (−)-β-pinene (9) and amination of the resulting dialkylborane (8). The free base had b.p. 60–70° at 2–3 mm [lit. (8) b.p. 60–61° at 2 mm]; p.m.r. ($CDCl_3$) δ 2.67 (broad d, 2, J = 6.1 Hz, CH_2N), 1.25–2.50 (m, 9), 1.17 (s, 3, CH_3), 1.05 (s, NH), 0.97 (s, 3, CH_3). The yield was 15%.

The *N*-benzoyl derivative had m.p. 103.5–104.5° [lit. (8) m.p. 105–106°].

endo-2-Norbornanemethylamine Hydrochloride

This compound has previously been obtained from the corresponding phthalimido derivative (11, 12).

A solution of 2-norbornanecarbonitrile (24 g) in dry tetrahydrofuran (40 ml) was added during 1 h to a stirred suspension of $LiAlH_4$ (7.6 g) in dry tetrahydrofuran (350 ml) under a nitrogen atmosphere. The mixture was heated under reflux for 1 h and cooled. The excess hydride was decomposed by the dropwise addition of water (10 ml), and 10% NaOH solution (30 ml) was added with vigorous stirring. The mixture was filtered and the filtrate was dried over anhydrous Na_2SO_4, decanted, and evaporated *in vacuo* at 40–50°. The residual amine was dissolved in methanol and treated with a slight excess of concentrated HCl. Evaporation of the solvents *in vacuo* and recrystallization of the residue from 2-propanol gave 21.3 g of the hydrochloride (64%).

The *N*-benzoyl derivative was prepared directly from the hydrochloride using pyridine as solvent and melted at 99–101.5° [lit. (12) m.p. 99.5–101.5°; the *exo N*-benzoyl isomer reportedly has m.p. 116–117°]. From the m.p. of the derivative it was concluded that the commercially available nitrile used for this reduction was the *endo* isomer.

1-Adamantanemethylamine

This compound has previously been prepared by reduction of 1-adamantanecarboxamide (13).

A suspension of $LiAlH_4$ (4.2 g, 0.11 mole) in dry tetrahydrofuran (200 ml) was stirred in a nitrogen atmosphere and a solution of 1-adamantanecarbonitrile (16.1 g, 0.1 mole) in dry tetrahydrofuran (45 ml) was added during 0.5 h. The mixture was heated under reflux for 2.5 h, cooled, and treated dropwise with water (15 ml) and then 20% NaOH (25 ml). The mixture was filtered, and the filtrate was dried over anhydrous Na_2SO_4, decanted, and evaporated *in vacuo* at 40–50°. The residual amine was distilled to yield 11.6 g (70%) of product, $b.p._{.4}$ 95–97° [lit. (13) $b.p._3$ 83–85°], p.m.r. ($CDCl_3$) δ 2.30 (s, 2, CH_2—N), 1.97 (broad s, 3, bridgehead H), 1.73 (6 H), 1.47 (6 H), 1.10 (s, NH).

The *N*-benzoyl derivative had m.p. 144–145° [lit. (13) m.p. 142°].

S-(Carboxamidinium)methyl Thiosulfates 1

A 1 *M* solution of methyl α-chloroacetimidate was

prepared by adding distilled chloroacetonitrile to the required amount of a stock solution of $NaOCH_3$ (0.1 *N* in methanol), e.g., 20 mmole to 20 ml. Formation of the imidate is readily followed by p.m.r. (14) and was found to be complete in 15 min under these conditions.

One equivalent of the appropriate amine hydrochloride was then added, and stirring was continued for 30–45 min (see below for exception). A solution of one equivalent of $Na_2S_2O_3 \cdot 5H_2O$ in an equal volume of water was then added, and methanol was evaporated *in vacuo* at 25° or under a gentle stream of filtered air at 25°. Some dark tar generally separated, and evaporation was continued until solids began to separate. The supernatant liquid was then decanted and chilled to obtain the product. The tar was extracted once with hot water to recover any product trapped therein, and the combined product was recrystallized either from water, ethanol or a mixture thereof. Details are listed in Table I. Yields are based on chloroacetonitrile.

N-(1-Adamantanemethyl)-α-chloroacetamidine Hydrochloride

1-Adamantanemethylamine (3.3 g, 0.02 mole) was converted to the hydrochloride by treatment with excess concentrated HCl in methanol followed by evaporation of the solvent. Chloroacetonitrile (1.5 g, 0.02 mole) was then stirred for 25 min with $NaOCH_3$ solution (20 ml), and the amine hydrochloride was added. The mixture was stirred for 2 h at room temperature. Some of the product (2.5 g) which had precipitated, was filtered off and the filtrate was diluted with dry ether (100 ml) to yield another 1.4 g of product, m.p. 274–276°. The p.m.r. spectra of the two samples were identical, and the product was recrystallized from absolute ethanol. The total yield was 3.9 g (70%), and the product proved to be sparingly soluble in water; p.m.r. (CF_3CO_2H) δ 4.38 (s, 2, $ClCH_2$), 3.13 (broad d, 2, J = 5.0 Hz, CH_2N), 2.06 (broad d, 2, bridgehead H), 1.80, 1.67 (broad singlets, 12 total, methylene H.)

Anal. Calcd. for $C_{13}H_{22}Cl_2N_2$: C, 56.28; H, 7.97; N, 10.20. Found: C, 56.50; H, 8.06; N, 10.27.

S-[N-(Dehydroabietyl)carboxamidinium)methyl] Thiosulfate

Dehydroabietylamine hydrochloride was precipitated by passing dry HCl through a solution of the free amine (mixed isomers) in dry ether. A solution of the amine hydrochloride (12.2 g) in methanol (50 ml) was added to 40 ml of 1 *M* methyl α-chloroacetimidate (see above). After 45 min, concentrated HCl (1 ml) was added, and most of the solvent was evaporated. Ether was added to precipitate inorganic solids, which were removed by filtration. The solvents were again evaporated, the residue was dissolved in methanol (15 ml), and water was added in small portions until solids began to separate. After several hours, 9.4 g were collected, m.p. 138–146°. The intermediate defied recrystallization from H_2O, organic solvents, and mixtures thereof.

A 2.0 g sample of the solid was dissolved in warm mixture of water (25 ml) and 95% ethanol (5 ml), and $Na_2S_2O_3 \cdot 5H_2O$ (1.25 g) in water (5 ml) was added with stirring. The mixture was cooled, and the precipitate was collected and washed with hot water. The dry weight was 2.0 g. Additional details are listed in Table I.

N-(1-Adamantanemethyl)-α-mercaptoacetamidine Hydrochloride

N-(1-Adamantanemethyl)-α-chloroacetamidine hydrochloride (5.54 g) was suspended in a solution of Na_3SPO_3 (5) (4.0 g) in water (60 ml). The mixture was stirred vigorously for 30 min. The flask was then flushed with nitrogen, and 6*N* HCl (35 ml) and 2-propanol (30 ml) were added. The mixture was stirred, heated to 80–90° for 20 min, and cooled. The product was collected, 5.0 g (91%), m.p. 220.5–222.5° (decomp.). Recrystallization from water did not alter the decomposition range.

Anal. Calcd. for $C_{13}H_{23}ClN_2S$: C, 56.79; H, 8.43; N, 10.19; S, 11.66. Found: C, 56.35; H, 8.36; N, 10.25; S, 11.04.

Coupling of allylic halides promoted by iron metal dispersed in dimethyl formamide

DAVID W. HALL[1] AND EDWARD HURLEY, JR
Denver Research Center, Marathon Oil Company, 7400 South Broadway, Littleton, Colorado 80121

Received July 18, 1968

The coupling reaction of allylic halides to produce non-conjugated dienes was investigated. It was found that iron powder could be utilized, without any special pretreatment, to promote the coupling reaction when a dipolar aprotic solvent was employed as the reaction medium.

Effects of variables such as the nature of the halogen atom in the reactive position of the substrate, substituents on the substrate, presence or absence of organic or inorganic halide catalysts, and solvent type were explored briefly.

Non-conjugated dienes can be prepared in yields which exceed 90% in the more favorable cases. The present procedure avoids many of the difficulties inherent in such previous methods as the Grignard reaction or the nickel carbonyl-promoted reaction.

Introduction

The coupling reaction of allylic halides in the presence of magnesium metal in ether is a well-known side reaction which occurs when one attempts to prepare allylic Grignard reagents (1, 2). The nature of the magnesium-promoted coupling reaction has been investigated by Henne and Chanan (3). These workers utilized the reaction to prepare a series of non-conjugated dienes. The yields were in general around 50%.

Coupling of allylic halides via their reaction with nickel carbonyl has been the subject of considerable study (4–6). A decided inconvenience of this procedure is the care in handling nickel carbonyl which is necessitated by its high toxicity, flammability, and volatility (4*b*).

Though synthetic routes to dimers and polymers of benzylic-type halides by their reactions with free transition metals have been explored in some detail (7–10), relatively little has been done to utilize allylic halides in this manner. Fainberg and Miller have reported that perfluoroallyl iodide reacts with zinc dust in dioxane to give perfluoro-1,5-hexadiene in 83% yield (11). A vapor phase reaction employing allyl chloride and copper deposited on various supporting agents which produces 1,5-hexadiene in 80% yield has been reported (12). Dupont and Zuber obtained 1,5-hexadiene in 70% yield by the reaction of allyl chloride with copper in ethanol (13).

The patent literature contains several reports that coupled products were obtained from allylic halides when iron metal was used as the coupling agent (14–16). A variety of solvents was stated to be effective media for the coupling reaction.

Results and Discussion

Judging from examples given in the patent literature (14–16), the nature of the solvent employed as the reaction medium appeared to us to be a critical variable in the reactions of allylic halides with iron metal, contrary to claims made in the patents. Accordingly, we reinvestigated the effects of using hydrocarbon and alcohol solvents in this reaction. Careful evaluation of the previous studies suggested that acetonitrile, a dipolar aprotic solvent, was superior. Results for these solvent-screening experiments, including data for the dipolar aprotic solvent dimethyl formamide (DMF), are given in Table I.

The data in Table I clearly show that inferior results are obtained when either *n*-heptane or ethanol is used as the solvent for this reaction. Use of the dipolar aprotic solvent DMF leads to high conversions and yields under comparable conditions. The last experiment in Table I shows that addition of benzene to DMF results in decreased reaction rate. This strongly suggests, in contrast to previous reports (14–16) that aromatic hydrocarbons are also poor solvents for this reaction. Presumably, dipolar aprotic solvents other than DMF or acetonitrile would also be suitable for promoting the reaction between allylic halides and iron powder.

Although Dupont and Zuber (13) reported

TABLE I

Solvent effects on the reaction of allyl chloride or bromide with iron powder

Solvent (g)	Allyl halide (moles)	Iron (g-atoms)	Reaction time (h)	Reaction temperature (°C)	Substrate conversion (%)*	Yield (%)*
n-Heptane (77.2)	Chloride (0.55)	0.60	1.0	150†	<5	Trace
n-Heptane (210)	Bromide (0.50)	0.25	9.0	80‡	<2	Zero
Ethanol (150.0)	Chloride (1.0)	1.1	14.0	50‡	Zero	Zero
Ethanol (80.5)	Chloride (0.52)	0.55	1.0	150†,§	56	27
Dimethyl formamide (190)	Chloride (0.50)	0.25	1.0	150†	99+	95.5‖
Dimethyl formamide (95) and benzene (34.5)	Chloride (0.43)	0.22	1.0	150†	66	56.7

*Conversions and yields were based on semiquantitative v.p.c. analyses (see Experimental) done on the reaction mixtures immediately upon the termination of an experiment. Hence, the reported yields are for crude 1,5-hexadiene.
†Conducted in a stirred stainless steel autoclave; reaction time does not include about 1/2 h heat up time and about 1½ h cooling time.
‡Conducted in a baffled glass flask of the Morton type, using a Teflon paddle-blade stirrer.
§Solvent was partially oxidized under the conditions employed.
‖The recovered yield of 99 + % pure 1,5-hexadiene, after a water washing and distillation, was 81%. Iron salts in the DMF residue analyzed 70% Fe^{+2} and 30% Fe^{+3}; the latter presumably was found due to subsequent air oxidation of Fe^{+2} formed initially.

TABLE II

Relative reactivities of allyl chloride and allyl bromide towards iron powder suspended in dimethyl formamide, and catalytic effect of added halides*

Allyl halide	Added halide (g)	Reaction time (h)	Reaction temperature (°C)	Yield of crude 1,5-hexadiene (%)†
Allyl bromide	Zero	24.0	25.0	Zero
Allyl bromide	Zero	2.0	90.0	88.6
		4.0		96.5
Allyl chloride	Zero	4.5	90.0	7.3
		11.5		46.7
		18.5		62.2
Allyl chloride	Sodium bromide (1.0)	2.0	90.0	10.3
		4.0		31.8
Allyl chloride	Allyl bromide (3.3)	2.0	90.0	9.4
		4.0		30.0
Allyl chloride	Sodium iodide (0.7)	2.0	90.0	18.3
		4.0		57.9

*These experiments were conducted in a baffled glass flask of the Morton type, fitted with a Teflon paddle-blade stirrer assembly. In all runs 0.5 moles of benzene was added to the 200 ml of DMF solvent to serve as an internal standard for analysis; 0.50 moles of the allyl halide and 1/4 g-atom of iron were employed. The reaction temperature was maintained within ± 5° of the values listed.
†These yield data have a relative accuracy of about 1%.

that 1,5-hexadiene was formed in 70% yield using pretreated copper powder in ethanol, we found that oxidation of the ethanol occurred with iron at temperatures sufficiently high to promote the coupling reaction. We repeated the work of Dupont and Zuber and found that a long reaction time was required and that a low yield was obtained if the copper powder was not pretreated. At higher temperatures, oxidation of the ethanol became a problem, just as in the case where iron was used. In view of the results we obtained using DMF, there would appear to be little point in employing alcohols as solvents for the coupling reaction.

In most of the experiments conducted in the present investigation the stoichiometry of the coupling reaction was determined by following the conversion of the metal as well as that of the allylic halide. Within a range of about plus or minus 10%, iron was consumed to the extent of about 0.5 g-atom/mole of the allylic halide.

Experiments were carried out to determine the relative reactivities of allyl chloride and allyl bromide towards iron powder suspended in DMF. Effects of several materials added in low concentrations as catalysts were also studied. The results are given in Table II.

The data in Table II show that an added

TABLE III

Reaction of substituted allyl chlorides with iron in dimethyl formamide*

Allyl chloride (moles)	Conversion (%)	Products	Crude yield (%)
Allyl chloride (0.69)	65†	1,5-Hexadiene	61.5†
β-methallyl chloride (0.52)	77†,‡	2,5-Dimethyl-1,5-hexadiene	60.0†
Allyl chloride (0.25) plus β-methallyl chloride (0.25)	98§	1,5-Hexadiene	21.0§
		2-Methyl-1,5-hexadiene	44.8§
		2,5-Dimethyl-1,5-hexadiene	24.1§
2,3-Dichloropropene‖ (0.50)	55§	2,5-Dichloro-1,5-hexadiene + Polymer	35.0§

*These experiments were conducted in a 300 ml stainless steel stirred autoclave using 100 ml dimethyl formamide solvent and 1/2 g-atom of iron per mole of organic substrate. The reaction temperature was 150 °C and the reaction time was 1 h; see footnote † of Table I.

†Benzene equimolar with the allyl chloride substrate, was added as an internal standard for vapor phase chromatographic analysis.

‡Recovered iron corresponded with a substrate conversion of 71%.

§Conversion and yield were determined by vapor phase chromatographic analysis of the crude product after filtration and water washing to remove unchanged iron and most of the dimethyl formamide.

‖A preliminary study with this substrate showed that addition of benzene as an internal standard for vapor phase chromatographic analysis resulted in such a low conversion under the standard conditions that insufficient product could be obtained for characterization.

inorganic bromide or iodide salt, or a labile organic bromide, greatly decreases the required reaction time for coupling allyl chloride, even when a low concentration is employed. Dupont and Zuber found a similar catalytic effect for sodium or zinc bromide on the reaction of allyl chloride with copper in ethanol (13).

Effects of simple substituents such as methyl or halogen in the β position on the course of the reaction of allyl chlorides with iron dispersed in DMF were explored briefly. Table III lists results for experiments on these substrates carried out under standard conditions in a stirred stainless steel autoclave. An experiment employing allyl chloride is included for comparison. Benzene added as an internal standard for vapor phase chromatographic (v.p.c.) analysis in the experiments on allyl chloride and β-methallyl chloride reduced the yield of coupling product formed in the 1 h reaction time at 150 °C.

The yield of 2,5-dimethyl-1,5-hexadiene from β-methallyl chloride is essentially the same as the yield of 1,5-hexadiene from allyl chloride. These data suggest that the substitution of a β-methyl group on allyl chloride changes its reactivity towards iron dispersed in DMF rather little. Additional evidence for this was obtained from mixed-coupling experiments in which equimolar amounts of allyl chloride and β-methallyl chloride were treated with iron in DMF. Two such experiments conducted under quite different reaction conditions gave the following weight percent distributions (weight % in the crude product mixture, as determined by v.p.c. analysis, were normalized to consider only the three coupling products on a 100% basis): 1,5-hexadiene, 21.7 ± 3.0%, 2-methyl-1,5-hexadiene, 49.1 ± 1.2%; and 2,5-dimethyl-1,5-hexadiene, 29.3 ± 1.7%. Theoretical weight percentages for the three products from coupling, presuming equal reactivities for allyl chloride and β-methallyl chloride and an absence of any side reactions, are: 1,5-hexadiene, 21.4%; 2-methyl-1,5-hexadiene, 50.0%; and 2,5-dimethyl-1,5-hexadiene, 28.6%. In the experiment listed in Table III, the combined yields of the three coupling products totalled about 90%. In the second experiment, carried out in glassware at 80 °C using sodium iodide catalyst, the sum of the combined yields was in excess of 95%.

Henne and co-workers (17) reported that equimolar amounts of allyl chloride and β-methallyl chloride reacted with magnesium in ether to give coupling products in the following weight % distributions: 1,5-hexadiene, 13.5%; 2-methyl-1,5-hexadiene, 52.8%; and 2,5-

For personal use only.

dimethyl-1,5-hexadiene, 33.7%. Their yield data were normalized to put the relative percents of the three dienes on a 100% basis for comparison with our own data. The yield of coupled products found by Henne and co-workers was only 40–50%.

Substitution of a halogen atom in the β-position of allyl chloride markedly decreased the reactivity towards iron dispersed in DMF. The last experiment in Table III shows that 2,3-dichloropropene coupled to give 2,5-dichloro-1,5-hexadiene in only 35% yield under the standard conditions of 1 h at 150 °C. A considerable amount of polymer was also produced.

Experimental

Solvents employed in this investigation were commercially available reagent grade materials. They were used as received; no special care was taken to prevent their absorbing atmospheric moisture during storage and handling. Similarly, iron used was commercially available reagent grade of mesh size 200. The only precaution taken was to store the iron under conditions such that undue oxidation of the surface did not occur. Inorganic catalysts were granular reagent grade. All the organic substrates were reagent grade and were readily available from the major suppliers.

The progress of the reactions was followed in many cases by a semiquantitative v.p.c. analysis, and in selected cases by quantitative v.p.c. analysis. In the semiquantitative procedure calibration curves were made up by determining relative response factors of the substrate and product relative to the solvent over concentration ranges corresponding to from 10% up to 90% conversion of the substrate. This method is termed semiquantitative since it presumed no solvent decomposition or mechanical loss occurred during a run. It further presumed that any complexes formed between the metal halides produced and the solvents decomposed very rapidly in the injection port of the chromatograph so that all the solvent value appeared as a single peak in the chromatogram. This latter assumption appears valid when the yield data obtained in this way are compared with isolated yields or yields determined by the quantitative method.

In the quantitative analysis response factors for the substrate, product and solvent were determined over a range, but relative to the added internal standard, benzene. The internal standard was added directly to the reaction mixture at the beginning of an experiment so that any sampling problems arising because of the inhomogeneity of the mixture would affect all components equally. This procedure was followed only after determining that the internal standard was inert under the reaction conditions employed.

Peaks in the chromatograms were assigned by spiking aliquots to be analyzed with authentic samples of the materials in question. Where such standards for comparison were not commercially available, the products of the reaction were carefully purified and their physical properties compared with published values. Retention times under the standard set of v.p.c. analysis conditions were then obtained and compared with the retention times of the various component peaks in the chromatogram obtained from the original analysis of the crude reaction mixture.

Products from all the experiments listed in Tables I–III were isolated and purified in at least one run among a set of related runs so that their identities could be established with certainty. Conversions and yields are reported on a molar basis.

Nuclear magnetic resonance (n.m.r.) spectra were determined on a Varian Associates model A60 spectrometer using tetramethylsilane (TMS) as an internal standard.

Cross-coupling of allyl chloride and β-methallyl chloride

Allyl chloride (2.0 moles), β-methallyl chloride (2.0 moles), iron powder (2.0 g-atom), and sodium iodide (10.1 g) were added to DMF (1000 g) in a conventional glassware apparatus with the reflux condenser open to the atmosphere. The mixture was stirred at 80 °C for 7 h; semiquantitative analysis showed complete conversion of both organic substrates. Volatile components were distilled until the overhead temperature reached that of DMF. Analysis of the crude distillate by the semiquantitative v.p.c. method showed the following weight percentage distribution of coupling products: 1,5-hexadiene, 23.5%; 2-methyl-1,5-hexadiene, 45.8%; and 2,5-dimethyl-1,5-hexadiene, 26.3%. The first and third of these products were identified by spiking with authentic standards. The peak corresponding with 2-methyl-1,5-hexadiene was identified by comparison of its retention time with that of the material subsequently isolated and purified. The sum of the combined yields of the three crude products was 97%.

The distillate was washed with water to remove the small amount of DMF present, dried, and then subjected to a second, more precise, distillation. A center cut (10 g) of the 2-methyl-1,5-hexadiene fraction was collected at 81 °C at a pressure of 623 mm Hg. Analysis (v.p.c.) of this cut showed only a single component present. This very pure material had n_D^{25} 1.4169 and d_{25} 0.7155. Literature values (17) are n_D^{20} 1.4184 and d_4^{20} 0.7198. The infrared and n.m.r. spectra were in accord with the structure and further served to confirm the purity.

Coupling 2,3-Dichloropropene

The conditions for this experiment are outlined in Table III. The product, 2,5-dichloro-1,5-hexadiene, was isolated in the manner described above and purified by distillation through a spinning band apparatus. A center fraction of water-white product was collected at 66 °C at 43 mm Hg. This material had n_D^{25} 1.4695. The n.m.r. spectrum (TMS internal standard) showed a resonance peak for the methylene hydrogens at 7.44 τ and for the vinyl hydrogens at 4.88 τ. The peaks showed no fine structure and were, within the limits of the measurement, in a 1:1 ratio. The n.m.r. spectrum of 2,5-dichloro-1,5-hexadiene was in accord with those of the comparable chloropropenes studied by DeWolf and Baldeschwieler (18).

A molecular weight determination and elemental analysis were not as satisfactory as desired, but in view of

Received September 23, 1968

Reaction of substituted allenes and diazomethane gives rise to optically active methylenecyclopropane and spiropentane derivatives in the presence of dissymmetric copper chelates, bis[*N*-(*R* and *S*)-α-phenethylsalicylaldiminato]copper(II).

Canadian Journal of Chemistry, **47**, 1242 (1969)

Interest in homogeneous catalysis motivated our previous investigation on the decomposition of some diazo compounds by means of *soluble, dissymmetric* copper chelates. The observed asymmetric carbenoid reactions have been ascribed to intermediary chiral carbene–copper complexes (1, 2). The present paper as a continuation of this work refers to the synthesis of certain optically active methylenecyclopropane and spiropentane derivatives which were prepared with great difficulty.

Methylenation of substituted allenes (**1**) with

§Isolated at 135° (Apiezon L 30%, 2m).
‖Measured at 15°.

diazomethane occurred smoothly in benzene solution at 0° in the presence of a catalytic amount of copper chelates, bis[*N*-(*R*)-α-phenethylsalicylaldiminato]copper(II) (*R*-**2**) or its enantiomer (*S*-**2**) to afford mono- and dimethylenated products (**3** and **4**) in good yields. Products were isolated by distillation and purification by gas–liquid chromatography (g.l.c.), and identified on the basis of spectral data (infrared (i.r.) and nuclear magnetic resonance (n.m.r.)). As shown in Table I, all the methylene adducts were obtained in optically active form. The enantiomeric catalysts yielded products with comparable magnitude but opposite sign of rotation. Because of lack of an appropriate resolving group in the hydrocarbon products, the optical yield and absolute configuration have not been determined. In order to transform **3***a* to *trans*-1-methyl-2-phenylcyclopropane whose absolute configuration has been established (2, 3), the reduction was attempted by means of potassium azodicarboxylate. However, the preferential attack of diimide from the sterically less hindered side of the double bond resulted in the formation of the *cis* isomer instead of the desired product.[1]

Monitoring the reaction by g.l.c. indicated that the initial attack of the copper carbenoid occurred almost exclusively at the inner double bond of the allenes as observed in the reaction of other carbenoids (4–7). Thus the asymmetric synthesis of spiropentanes should be attained at the stage of precursory methylenecyclopropane formation.

Finally it should be noted that methylenecyclopropanes **3***a* and **3***b* underwent facile thermal racemization, the half-lives (in $CHCl_3$, 100°) being 22 and 10 min, respectively. However, no signs of rearrangement into benzylidenecyclopropanes could be detected under these conditions.[2] Although further investigations will be required to elucidate the racemization mechanism,

[1]To our knowledge, diimide reduction presents the most effective method for double bond saturation of methylenecyclopropane without concurrent cleavage of the adjacent cyclopropane ring.

[2]For competitive rearrangement and racemization of methylenecyclopropane derivatives, see refs. 8 and 9.

The asterisk represents an odd electron or ± charge.

it may proceed *via* certain concerted bond forming – bond rupture process rather than through distinct planar trimethylene species or corresponding zwitterion (**5**) (8–11).

Experimental

Microanalyses were performed at the Elemental Analyses Center of Kyôto University. All nuclear magnetic resonance (n.m.r.) spectra were taken in 10% CCl_4 solution using tetramethylsilane as an internal standard. Infrared spectra were obtained in neat liquid film.

Reaction of Diazomethane and Allenes in the Presence of Dissymmetric Copper Chelate (2)

Catalysis of diazomethane with copper chelate (*R*-**2** or *S*-**2**) was performed in the previously described manner (2). In the absence of the copper chelate practically no reaction was observed between diazomethane and allenes at 0°.

Gaseous diazomethane generated separately from *N*-methyl-*N*-nitrosourea (27.0 g, 260 mmoles) and KOH in decalin was diluted with dry N_2 and introduced into a solution of phenylallene (**1***a*) (12) (7.0 g, 60 mmoles) and benzene (40 ml) containing a small amount of *S*-**2** (350 mg, 0.69 mmole). The reaction temperature was maintained at 0°. After the introduction was completed, an N_2 stream was bubbled into the mixture for an additional hour. The reaction mixture was fractionated *in vacuo* below 40° at 0.05 mm to give a volatile fraction (3.7 g) which consisted mainly of 2-phenylmethylenecyclopropane (**3***a*) and phenylspiropentane (**4***a*) along with some starting allene. Each component was separated by preparative gas–liquid chromatography (g.l.c.) to yield the analytical samples in optically active form (Table I).

2-Phenylmethylenecyclopropane (**3***a*) (35% yield at 84% conversion): b.p. 35–40° (1 mm); infrared (i.r.) spectrum: 3080, 1750, 890 (=CH_2), 3060 and 1015 cm^{-1} (cyclopropane); n.m.r. spectrum: δ 1.2 (1H, H_2 C-3 *cis* to Ph, multiplet), 1.7 (1H, H_2 C-3 *trans* to Ph, multiplet), 2.5 (1H, PhC*H*, multiplet), 5.6 (2H, =CH_2, multiplet), and 7.2 p.p.m. (5H, Ph, multiplet).

Anal. Calcd. for $C_{10}H_{10}$: C, 92.3; H, 7.7. Found: C, 92.5; H, 7.9.

Phenylspiropentane (**4***a*) (54% yield), b.p. 45–50° (1 mm). Spectral data including i.r. and n.m.r. spectra were quite identical with reported ones (13).

Anal. Calcd. for $C_{11}H_{12}$: C, 91.6; H, 8.4. Found: C, 91.8; H, 8.4.

Formation of benzylidenecyclopropane was not observed.

Decomposition of diazomethane in 1-methyl-1-phenylallene (**1***b*) (12) and *n*-hexylallene (**1***c*) (12) was carried out in the similar manner. The optical data are summarized in Table I. Physical properties of the products are as follows:

2-Methyl-2-phenylmethylenecyclopropane (**3***b*) (44% yield at 97% conversion), b.p. 45–50° (1 mm); i.r. spectrum: 3080, 1735, 880 (=CH_2), 3050, and 1020 cm^{-1} (cyclopropane); n.m.r. spectrum: δ 1.3 (2H, cyclopropane CH_2, multiplet), 1.50 (3H, Me, singlet), 5.5 (2H, =CH_2, multiplet), and 7.2 p.p.m. (5H, Ph, multiplet).

Anal. Calcd. for $C_{11}H_{12}$: C, 91.6; H, 8.4. Found: C, 91.4; H, 8.4.

1-*Methyl*-1-*phenylspiropentane* (**4***b*) (54% yield), b.p. 55–58° (1 mm); i.r. spectrum: 3050, 1025, and 995 cm^{-1} (cyclopropane); n.m.r. spectrum: δ 0.8 (4H, H_2 C-4 and H_2 C-5, multiplet), 1.16 (2H, H_2 C-2, AB quartet, J = 4.5 Hz), 1.45 (3H, Me, singlet), and 7.1 p.p.m. (5H, Ph, multiplet).

Anal. Calcd. for $C_{12}H_{14}$: C, 91.1; H, 8.9. Found: C, 91.3; H, 9.2.

2-*n*-*Hexylmethylenecyclopropane* (**3***c*) (8% yield at 89% conversion), b.p. (bath temperature) 35–40° (1 mm); i.r. spectrum: 3070, 1746, 883 (=CH_2), 3040, and 1018 cm^{-1} (cyclopropane); n.m.r. spectrum: δ 0.5–1.5 (3H, cyclopropane, multiplet), 0.9 (3H, Me, multiplet), 1.3 (10H, CH_2 of *n*-hexyl, multiplet), and 5.3 p.p.m. (2H, =CH_2, multiplet). Reliable optical value could not be obtained because of the low yield, which was ascribed to rapid formation of **4***c*.

Anal. Calcd. for $C_{10}H_{18}$: C, 86.9; H, 13.1. Found: C, 87.0; H, 13.4.

n-Hexylspiropentane (**4***c*) (48% yield), b.p. 38–42° (1 mm); i.r. spectrum: 3070 and 995 cm^{-1} (cyclopropane); n.m.r. spectrum: δ 0.3–1.1 (7H, cyclopropane, multiplet), 0.9 (3H, Me, multiplet), and 1.3 p.p.m. (10H, CH_2 of *n*-hexyl, multiplet).

Anal. Calcd. for $C_{11}H_{20}$: C, 86.8; H, 13.2. Found: C, 86.9; H, 13.3.

Another minor component was detected by g.l.c. (ca. 1%), but not isolated pure. On the basis of the relative retention time and the i.r. spectrum (3070, 3000, 2975, 2950, 2870, 1470, 1380, 1090, 998, 959, 930, 775, 750, 704, and 660 cm^{-1}) it was tentatively assigned to *n-heptylidenecyclopropane*.

Diimide Reduction of **3***a*

To a mixture of **3***a* (1.5 g, 12 mmoles) and potassium azodicarboxylate (14) (4.5 g, 23 mmoles) in methanol (100 ml) was added acetic acid (43 ml) in the course of 3 h under an N_2 atmosphere at room temperature. The mixture was stirred for an additional 12 h and then treated with water, extracted with ether, and dried on Na_2SO_4.

Synthesis of 2-acetamido-2-deoxy-D-gulose, 2-acetamido-2-deoxy-D-idose, and 2-deoxy-D-*xylo*-hexose from 3,4,5,6-tetraacetoxy-D-*xylo*-1-nitro-1-hexene[1]

M. B. PERRY AND ANN C. WEBB

Division of Biochemistry and Molecular Biology, National Research Council of Canada, Ottawa 2, Canada

Received August 23, 1968

3,4,5,6-Tetraacetoxy-D-*xylo*-1-nitro-1-hexene with methanolic ammonia afforded a mixture of 2-acetamido-1,2-dideoxy-1-nitro-D-gulitol and 2-acetamido-1,2-dideoxy-1-nitro-D-iditol which were converted *via* a Nef reaction to 2-acetamido-2-deoxy-D-gulose and 2-acetamido-2-deoxy-D-idose.

Reduction of 3,4,5,6-tetraacetoxy-D-*xylo*-1-nitro-1-hexene afforded 3,4,5,6-tetra-*O*-acetyl-1,2-dideoxy-1-nitro-D-*xylo*-hexitol which was converted *via* the Nef reaction to 2-deoxy-D-*xylo*-hexose.

Canadian Journal of Chemistry, **47**, 1245 (1969)

2-Acetamido-2-deoxy-D-gulose and 2-acetamido-2-deoxy-D-idose were prepared in 32 and 4% yields respectively from 3,4,5,6-tetraacetoxy-D-*xylo*-1-nitro-1-hexene by the general procedure in which polyacetoxy-1-nitro-1-alkenes are treated with ammonia to yield epimeric 2-acetamido-1,2-dideoxy-1-nitroglycitols which may be converted *via* a modified (1) Nef (2) reaction to the corresponding 2-acetamido-2-deoxyglycoses (3–7). This procedure had previously been applied to the preparation of 2-amino-2-deoxy-D-gulose in about 15% yield from the intermediate acetoxylated nitroalkene (8); 2-amino-2-deoxyidose was detected chromatographically in the reaction products.

2-Amino-2-deoxy-D-gulose and 2-amino-2-deoxy-D-idose have been synthesized from D-xylose in 8 and 38% yields respectively by the condensation of D-xylose with hydrogen cyanide and aniline or *p*-toluidine followed by controlled hydrogenation of the products (9). 2-Amino-2-deoxy-D-gulose has been synthesized from 2-amino-2-deoxy-D-galactose by configurational inversion at C-3 (10) and 2-amino-2-deoxy-D-idose has been made by ammonolysis of methyl 4,6-*O*-benzylidene-2,3-di-*O*-*p*-tolylsulfonyl-α-D-galactopyranoside in the presence of sodium methoxide and subsequent *N*-acetylation to yield methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-idopyranoside from which 2-amino-2-deoxy-D-idose could be obtained (11).

3,4,5,6-Tetraacetoxy-D-*xylo*-1-nitro-1-hexene (12) with saturated methanolic ammonia solution gave a mixture of 2-acetamido-1,2-dideoxy-1-nitro-D-gulitol and 2-acetamido-1,2-dideoxy-1-nitro-D-iditol which could not be separated by fractional crystallization. The mixed 2-acetamido-1,2-dideoxy-1-nitroglycitols on treatment with sulfuric acid afforded a mixture of 2-acetamido-2-deoxy-D-gulose and 2-acetamido-2-deoxy-D-idose and a small proportion of the corresponding free aminoglycoses. The product after

treatment with aqueous acetic anhydride, was shown by paper chromatography, to contain only the 2-acetamido-2-deoxygulose and 2-acetamido-2-deoxyidose derivatives in the visual ratio of about 10:1. The mixture was fractionated by cellulose column chromatography to yield pure samples of 2-acetamido-2-deoxy-D-gulose and 2-acetamido-2-deoxy-D-idose. This preparative procedure gives a simple and direct route to the synthesis of the 2-acetamido-2-deoxyglycoses from readily available and inexpensive precursors and should be of practical value.

2-Deoxy-D-*xylo*-hexose was prepared in 25% yield from 3,4,5,6-tetraacetoxy-D-*xylo*-1-nitro-1-hexene by reduction with hydrogen to give 3,4,5,6-tetra-*O*-acetyl-1,2-dideoxy-1-nitro-D-*xylo*-hexitol which underwent the Nef reaction to yield the 2-deoxy-D-*xylo*-hexose. 2-Deoxy-D-*xylo*-hexose which has been reported to be a constituent of a glycoside isolated from *Erysimum perowskianum* (13) has been synthesized from methyl 2,3-anhydro-4,6-*O*-benzylidene-β-D-gulopyranoside by reduction with lithium aluminium hydride to methyl 4,6-*O*-benzylidene-2-deoxy-D-*xylo*-hexopyranoside, which on mild hydrolysis afforded 2-deoxy-D-*xylo*-hexose (14).

Experimental

Paper chromatography was performed by the descending method (15) on Whatman No. 1 filter paper using pyridine – ethyl acetate – water (2:5:5 v/v, top layer) as the mobile phase. The glycoses were detected with (*A*) 2% silver nitrate in acetone followed by 2% sodium hydroxide in ethanol (16), (*B*) 2% *p*-anisidine hydrochloride in ethanol (17), or (*C*) 0.02 *M* sodium metaperiodate followed by ethylene glycol – acetone – sulfuric acid (50:50:0.3 v/v) and 6% sodium 2-thiobarbiturate (18). The rates of movement of the glycoses on the chromatograms are quoted relative to D-galactose (R_{gal}).

Gas–liquid partition chromatography (g.l.c.) was carried out using a Hewlett–Packard 402 chromatograph with a hydrogen flame detector and fitted with glass U tubes (4ft × 6mm × 3mm internal diameter) packed with 10% neopentylglycol sebacate polyester on 80–100 mesh acid-washed Chromosorb W, maintained at 225 °C. Dry helium was used as the carrier gas and retention times of the compounds are quoted relative to 2-acetamido-2-deoxy-1,3,4,5,6-penta-*O*-(trimethylsilyl)-D-glucitol (T_{GN}) or 1,2,3,4,5,6-hexa-*O*-acetyl-D-glucitol (T_G).

Melting points were determined on a Fisher–Johns apparatus and are corrected. Solutions were concentrated under reduced pressure, below 40 °C. Optical rotations were determined at 20 °C using a Perkin–Elmer 141 polarimeter.

2-Acetamido-2-deoxy-D-idose and 2-Acetamido-2-deoxy-D-gulose

A solution of 3,4,5,6-tetraacetoxy-D-*xylo*-1-nitro-1-hexene (20 g) (12), in methanol (150 ml) cooled to 0 °C, was saturated with dry ammonia (about 1 h) and the mixture was then allowed to stand at room temperature for 20 h. The reaction mixture was concentrated to a syrup which was triturated with warm chloroform (4 × 100 ml) to remove acetamide. The residual syrup (13 g) was then dissolved in a solution of $Ba(OH)_2 \cdot 8H_2O$ (16 g) in water (240 ml). This solution was added dropwise with vigorous stirring to a cold mixture of sulfuric acid (14 ml) in water (240 ml) and, after stirring at 10 °C for 2 h the mixture was left at 20 °C for 18 h. The neutralized ($BaCO_3$) reaction mixture was filtered and the filtrate after concentration to about 100 ml was treated with Dowex-1($CO_3^=$) ion-exchange resin (30 ml), methanol (10 ml), and acetic anhydride (0.8 ml). The mixture was then shaken for 30 min. The filtered solution was concentrated to a syrup (11 g) and paper chromatographic examination of the product showed two spots having R_{gal} 1.87 and 2.19 in the visual ratio of 10:1 which corresponded in rates of movement with 2-acetamido-2-deoxygulose and 2-acetamido-2-deoxyidose respectively.

The mixed 2-acetamido-2-deoxyhexoses were separated by cellulose column (4.5 × 85 cm) chromatography using butan-1-ol half saturated with water as the mobile phase. Chromatographically pure 2-acetamido-2-deoxy-D-idose (0.48 g) was eluted first and was followed by 2-acetamido-2-deoxy-D-gulose (3.90 g).

2-Acetamido-2-deoxy-D-idose

The product from the column which could not be crystallized showed a single spot on paper chromatography (R_{gal} 2.19) and had $[\alpha]_D$ −38° (*c*, 2 in water) (lit. (9) $[\alpha]_D$ −45°).

Anal. Calcd. for $C_8H_{15}O_6N$: C, 43.43; H, 6.84; N, 6.33. Found: C, 43.3; H, 6.8; N, 6.3.

The trimethylsilylated (19) 2-acetamido-2-deoxy-D-idose on gas chromatography gave four peaks having T_{GN} 0.58 (4%), 0.87 (48%), 1.06 (18%), and 1.13 (30%).

2-Acetamido-2-deoxy-D-iditol

2-Acetamido-2-deoxy-D-idose (0.1 g) in water (5 ml) was reduced with sodium borohydride (50 mg) for 3 h at room temperature and the isolated 2-acetamido-2-deoxy-D-iditol (65 mg) after recrystallization from ethanol had m.p. 139 °C and $[\alpha]_D$ +25° (*c*, 0.6 in water) and gave a single spot on paper chromatography (R_{gal} 1.13).

Anal. Calcd. for $C_8H_{17}O_6N$: C, 43.05; H, 7.68; N, 6.27. Found: C, 43.1; H, 7.8; N, 6.3.

The fully acetylated hexitol (20) on g.l.c. gave a single peak having T_G 3.23 corresponding in retention time with authentic 1,3,4,5,6-penta-*O*-acetyl-2-acetamido-2-deoxy-D-iditol.

2-Acetamido-2-deoxy-D-gulose

The product obtained crystalline from ethanol solution had m.p. 125–126 °C and $[\alpha]_D$ −66° (*c*, 2.5 in water) (lit. (9) $[\alpha]_D$ −59°) and gave a single spot on paper chromatography (R_{gal} 1.87).

Anal. Calcd. for $C_8H_{15}O_6N$: C, 43.43; H, 6.84; N, 6.33. Found: C, 43.4; H, 6.7; N, 6.4.

The trimethylsilylated crystalline 2-acetamido-2-deoxy-D-gulose on gas chromatography gave two peaks having T_{GN} 1.04 (26%) and 1.16 (74%) and the trimethylsilylated glycose after equilibration in water gave the same two peaks (29 and 71% respectively).

2-Acetamido-2-deoxy-D-gulitol

2-Acetamido-2-deoxy-D-gulose (0.15 g) was reduced as

described above for the preparation of 2-acetamido-2-deoxy-D-iditol to yield 2-acetamido-2-deoxy-D-gulitol which after recrystallization from methanol had m.p. 169–170 °C and $[\alpha]_D$ +6.2° (*c*, 0.5 in water) and gave a single spot on paper chromatography (R_{gal} 1.18).

Anal. Calcd. for $C_8H_{17}O_6N$: C, 43.05; H, 7.68; N, 6.27. Found: C, 43.0; H, 7.8; N, 6.2.

The fully acetylated hexitol on gas chromatography gave a single peak having T_G 3.59.

*2-Deoxy-*D*-xylo-hexose*

*(a) 3,4,5,6-Tetra-O-acetyl-1,2-dideoxy-1-nitro-*D*-xylo-hexitol*

3,4,5,6-Tetraacetoxy-D-*xylo*-1-nitro-1-hexene (10 g) in ethanol (200 ml) was shaken with hydrogen at atmospheric pressure in the presence of palladium black (0.4 g). One mole of hydrogen was absorbed in 20 min. The reaction mixture was filtered and the filtrate was concentrated to a syrup which crystallized. The 3,4,5,6-tetra-*O*-acetyl-1,2-dideoxy-1-nitro-D-*xylo*-hexitol (7.8 g) after recrystallization from ethanol had m.p. 81 °C and $[\alpha]_D$ −5.9° (*c*, 1.5 in chloroform).

Anal. Calcd. for $C_{14}H_{21}O_{10}N$: C, 46.28; H, 5.83; N, 3.86. Found: C, 46.3; H, 6.0; N, 3.8.

*(b) 2-Deoxy-*D*-xylo-hexose*

3,4,5,6-Tetra-*O*-acetyl-1,2-dideoxy-1-nitro-D-*xylo*-hexitol (7.5 g) was dissolved in *N* sodium hydroxide (100 ml) and after 1 h at 20 °C the mixture was added dropwise with stirring to a solution of sulfuric acid (12 ml) in water (20 ml). The neutralized ($BaCO_3$) reaction mixture after filtration, was passed down columns of Rexyn 101(H^+) (200 ml) and Duolite A4(OH^-) (25 ml) ion-exchange resins and the eluate and washings were concentrated to a syrup (2.6 g) which was fractionated on a cellulose column (4 × 35 cm), using butan-1-ol half saturated with water as the mobile phase, to yield chromatographically pure 2-deoxy-D-*xylo*-hexose (1.1 g).

The 2-deoxy-D-*xylo*-hexose on paper chromatography had R_{gal} 2.70 and gave the characteristic red color with the periodate – thiobarbiturate spray reagents. It had $[\alpha]_D$ +9.4° (*c*, 0.5 in water) (lit. (14) $[\alpha]_D$ +12 ± 2°).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 44.0; H, 7.4.

The 2-deoxy-D-*xylo*-hexose (100 mg) on bromine oxidation gave 2-deoxy-D-*xylo*-hexonolactone (90 mg) having $[\alpha]_D$ −56° (*c*, 1.9 in acetone) (lit. (14) $[\alpha]_D$ −57°) which on treatment with phenylhydrazine afforded 2-deoxy-D-*xylo*-hexonic acid phenylhydrazide (38 mg) having m.p. 125–126 °C (lit. (14) m.p. 124–125 °C).

Formation of a C_{22} dihydroxyketo acid by a yeast

Ronald F. Vesonder and Frank H. Stodola

Northern Regional Research Laboratory, Agricultural Research Service, United States Department of Agriculture, Peoria, Illinois 61604

Received December 4, 1968

Saponification of extracellular lipids from the yeast NRRL YB-2501 yielded 8,9,13-trihydroxydocosanoic acid and a new keto dihydroxy acid of melting point 131–132 °C. The keto acid was shown to be 8,9-dihydroxy-13-oxodocosanoic acid by conversion to 5-ketotetradecanoic acid and suberic acid. By means of the method of Ames and Bowman (3), it was established that the vicinal hydroxyls of the new acid have the *erythro* configuration.

Canadian Journal of Chemistry, **47**, 1247 (1969)

In 1965 we reported (1) that 8,9,13-triacetoxydocosanoic acid is produced by a yeast closely related to *Torulopsis fujisanensis*. More recently, in a review (2) on the extracellular lipids of yeasts, we mentioned that this organism also forms at the same time a smaller amount of

Formation of a C_{22} dihydroxyketo acid by a yeast

Ronald F. Vesonder and Frank H. Stodola

Northern Regional Research Laboratory, Agricultural Research Service, United States Department of Agriculture, Peoria, Illinois 61604

Received December 4, 1968

Saponification of extracellular lipids from the yeast NRRL YB-2501 yielded 8,9,13-trihydroxydocosanoic acid and a new keto dihydroxy acid of melting point 131–132 °C. The keto acid was shown to be 8,9-dihydroxy-13-oxodocosanoic acid by conversion to 5-ketotetradecanoic acid and suberic acid. By means of the method of Ames and Bowman (3), it was established that the vicinal hydroxyls of the new acid have the *erythro* configuration.

Canadian Journal of Chemistry, **47**, 1247 (1969)

In 1965 we reported (1) that 8,9,13-triacetoxydocosanoic acid is produced by a yeast closely related to *Torulopsis fujisanensis*. More recently, in a review (2) on the extracellular lipids of yeasts, we mentioned that this organism also forms at the same time a smaller amount of

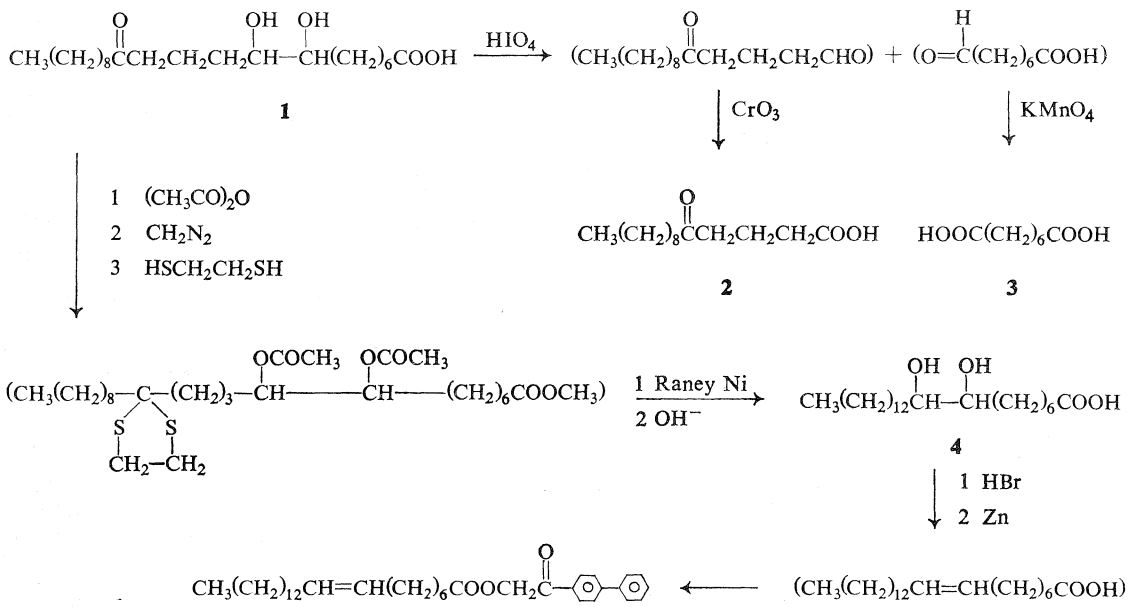
erythro-8,9-dihydroxy-13-oxodocosanoic acid (**1**), presumably in the acylated form; the evidence for the structure of **1** is now presented.

Acid **1** (m.p. 131–132 °C; $[\alpha]_D^{20}$ − 2.8°) was isolated from mother liquors left after the crystallization of 8,9,13-trihydroxydocosanoic acid, obtained by the saponification of the crude lipid excreted by the yeast. The structure and configuration of **1** were established by the following reactions:



Cleavage of **1** with periodic acid gave aldehydes that yielded 5-ketotetradecanoic acid (**2**) and suberic acid (**3**) on oxidation. Configuration of the vicinal hydroxyl groups in **1** was established in the following manner: the diacetyl methyl ester of **1** was converted to 8,9-dihydroxydocosanoic acid (**4**) by way of the thioketal; hydrobromination of **4** according to the method of Ames and Bowman (3), and subsequent debromination yielded a *cis* acid, which indicated an *erythro* configuration of the hydroxyl groups.

In our review (2) we reported the oxidation of 8,9,13-trihydroxydocosanoic acid to acid **1** after protection of the vicinal hydroxyls as an acetonide. A number of unsuccessful attempts to repeat this work, however, have since led us to the conclusion that this oxidation is no value as a structure proof because of very low yields.

Acid **1** is characterized by the following derivatives: methyl ester, m.p. 107–108 °C; *p*-bromophenacyl ester, m.p. 141–142 °C; and the semicarbazone, m.p. 129–130.5 °C.

Experimental

Melting points were determined with a Fisher–Johns apparatus[1] and were not corrected.

*Isolation of erythro-8,9-Dihydroxy-13-oxodocosanoic Acid (**1**)*

Crude lipid (48.3 g), obtained from the yeast NRRL YB-2501 by the procedure already described (1), was heated for 1 h at 95 °C with *N*-methylpyrrolidone (300 ml), *t*-butyl alcohol (250 ml), and 180 ml of water containing 43 g KOH. Acidification of the hot solution with 6 *N* HCl (360 ml), gave 34.0 g of crude 8,9,13-trihydroxydocosanoic acid, which on crystallization from acetic acid yielded 25.2 g of almost pure trihydroxy acid, m.p. 157–158 °C. Dilution of the mother liquor with water gave 7.49 g of crude crystalline acid **1** (m.p. 118–123 °C). Three crystallizations from ethyl acetate gave pure acid **1** with a constant melting point of 131–132 °C; yield, 4.83 g; $[\alpha]_D^{20}$ −2.8° (*c*, 10 in dimethyl sulfoxide).

Acid **1** liquefies in a few days on standing in an evacuated sulfuric acid desiccator, presumably due to ring closure between the hydroxyl and keto groups. Similar

behavior was observed when the acid was boiled for a few hours in petroleum ether (b.p. 93–97 °C).

Anal. Calcd. for $C_{22}H_{42}O_5$: C, 68.35; H, 10.95. Found: C, 68.6; H, 11.0.

Methyl 8,9-Dihydroxy-13-oxodocosanate

Acid **1** (100 mg) was treated with excess diazomethane in methanol–ether. The crude ester was crystallized from methanol-saturated petroleum ether (b.p. 65–68 °C), 75 mg, m.p. 107–108 °C.

Anal. Calcd. for $C_{23}H_{44}O_5$: C, 68.96; H, 11.07. Found: C, 69.1; H, 11.2.

p-Bromophenacyl-8,9-dihydroxy-13-oxodocosanate

Acid **1** (38.6 mg) was converted to the phenacyl ester in a mixture of acetone and *N*-methylpyrrolidone, according to the dicyclohexylethylamine (DICE) procedure (4). The crude product (89%, m.p. 125–130 °C) on crystallization from ethanol gave 38 mg of *p*-bromophenacyl ester, m.p. 141–142 °C.

Anal. Calcd. for $C_{30}H_{47}BrO_6$: C, 61.74; H, 8.12. Found: C, 61.8; H, 8.20.

Semicarbazone of Acid 1

Crude semicarbazone (25 mg) from 31.5 mg of acid **1** was crystallized from ethyl acetate, 16 mg, m.p. 129–130.5 °C.

Anal. Calcd. for $C_{23}H_{45}N_3O_5$: C, 62.27; H, 10.22; N, 9.47. Found: C, 62.6; H, 10.3; N, 9.22.

Periodic Acid Cleavage of Acid 1

A mixture of acid **1** (90 mg), periodic acid (106 mg), water (0.06 ml), and acetonitrile (1 ml) was kept in the dark for 1 h at room temperature. Water (0.5 ml) containing 85 mg $NaHCO_3$ was added, and the reaction mixture was extracted with ether. Removal of ether gave 57.5 mg of pale-yellow solid, which was oxidized with 1.55 ml of 0.91 *M* CrO_3 in acetic acid to 5-ketotetradecanoic acid, m.p. 77.5–79 °C (*p*-bromophenacyl ester, m.p. 83–84 °C).

The aqueous fraction yielded suberic acid after $KMnO_4$ treatment, as described in our earlier work (1).

8,9-Dihydroxydocosanoic Acid (4)

Acid **1** (1 g) was converted to the diacetate with acetic anhydride – pyridine (24 h; room temperature), and the crude diacetate was methylated with diazomethane. The methyl ester was dissolved in a mixture of acetic acid (1.25 ml), BF_3 etherate (0.66 ml), and $HSCH_2CH_2SH$ (0.25 ml). After 20 h at room temperature, the reaction mixture was added to 4 *N* NH_4OH (45 ml). An oil (1.33 g), recovered by ether extraction, was heated at 80 °C for 5 h with Raney nickel in ethanol. Filtration and removal of solvent gave 787 mg of product melting at 128–131 °C, which on crystallization from ethyl acetate yielded 592 mg pure acid **4** (m.p. 132–133 °C).

Anal. Calcd. for $C_{22}H_{44}O_4$: C, 70.92; H, 11.90. Found: C, 70.8; H, 11.8.

p-Phenylphenacyl cis-8-Docosenoate

Acid **4** (50 mg) was dissolved in 25% HBr – CH_3COOH (25 ml) containing 0.2 ml of concentrated sulfuric acid. After standing at room temperature for 20 h, the reaction mixture was heated at 95 °C for 3.5 h. Heating was continued for 4 h more after addition of 0.4 ml of 25% HBr – CH_3COOH. The dibromo compound was isolated by petroleum ether extraction and was esterified with diazomethane. The ester was refluxed under nitrogen for 1 h with ethanol (3 ml) and 30-mesh activated zinc (600 mg). The mixture of *cis* and *trans* esters was recovered by petroleum ether extraction and was shown by infrared absorption to be 93% *cis*. Saponification gave 43.8 mg of colorless crystals, which were converted by the DICE method (4) to crude *p*-phenylphenacyl ester (64.1 mg, m.p. 40–60 °C). Recrystallization from alcohol gave an analytical sample (45.1 mg, m.p. 67–68 °C).

Anal. Calcd. for $C_{36}H_{52}O_3$: C, 81.16; H, 9.84. Found: C, 81.0; H, 9.62.

Monomer and dimer formation in esters of dihydroxyacetone

Lorrin R. Garson, Ronald P. Quintana, and Andrew Lasslo
Department of Medicinal Chemistry, College of Pharmacy, University of Tennessee Medical Units, Memphis, Tennessee 38103

Received January 13, 1969

The monomer (1-undecanoyloxy-3-hydroxyacetone) and dimer (2,5-diundecanoyloxymethyl-2,5-dihydroxy-1,4-dioxane) of dihydroxyacetone monoundecanoate have been characterized, and the conditions associated with their interconversion have been determined. The respective molecular constitutions have been unequivocally documented with ultraviolet and infrared spectral characteristics.

Canadian Journal of Chemistry, **47**, 1249 (1969)

In our preceding communication (1), we reported the synthesis of 1-undecanoyloxy-3-hydroxyacetone (**1**), a compound with potential perdurable insect-repellent efficacy. The data available at that time, however, did not permit us to establish unequivocally whether the compound existed as a monomer or dimer (or as a mixture of these two forms). In order to prepare the substantial quantities of **1** required for the evaluation of its repellent properties, we employed a direct

Monomer and dimer formation in esters of dihydroxyacetone

Lorrin R. Garson, Ronald P. Quintana, and Andrew Lasslo

Department of Medicinal Chemistry, College of Pharmacy, University of Tennessee Medical Units, Memphis, Tennessee 38103

Received January 13, 1969

The monomer (1-undecanoyloxy-3-hydroxyacetone) and dimer (2,5-diundecanoyloxymethyl-2,5-dihydroxy-1,4-dioxane) of dihydroxyacetone monoundecanoate have been characterized, and the conditions associated with their interconversion have been determined. The respective molecular constitutions have been unequivocally documented with ultraviolet and infrared spectral characteristics.

Canadian Journal of Chemistry, **47**, 1249 (1969)

In our preceding communication (1), we reported the synthesis of 1-undecanoyloxy-3-hydroxyacetone (**1**), a compound with potential perdurable insect-repellent efficacy. The data available at that time, however, did not permit us to establish unequivocally whether the compound existed as a monomer or dimer (or as a mixture of these two forms). In order to prepare the substantial quantities of **1** required for the evaluation of its repellent properties, we employed a direct

For personal use only.

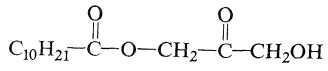
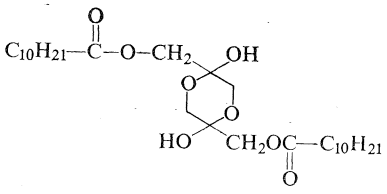
acylation method (2, 3) rather than the method of Schlenk *et al.* (4). The former procedure yielded the desired monoester in considerably higher yield, and with greater facility than the one using the diazoketone intermediate (4).

When compound **1**—prepared by direct acylation—was carefully recrystallized from hexane or chloroform, it afforded a product melting at 96.8–98.3°; recrystallization from ethanol, subsequent to prolonged heating of the solution, yielded a product melting at 44.8–46.1°. Furthermore, when the lower-melting compound was allowed to stand in the crystalline state at room temperature, it slowly reverted to the higher-melting compound; an increase in the melting-point range could be detected even after 24 h.

The data reported below unambiguously indicate that the lower-melting compound is 1-undecanoyloxy-3-hydroxyacetone (monomer, **1***a*) and the higher-melting product is 2,5-diundecanoyloxymethyl-2,5-dihydroxy-1,4-dioxane (dimer, **1***b*).



1*a*



1*b*

The ultraviolet spectrum of a solution of **1***a* in *p*-dioxane reflects the presence of two chromophores; maximum absorption at 274.5 mμ (ε 19.8) is characteristic of a ketone carbonyl function (5), and that at 224 mμ (ε 39.7) is indicative of the ester carbonyl. The ultraviolet spectrum of **1***b* exhibits only a single maximum at 224 mμ (ε 74.5) consistent with the presence of two ester moieties. In the infrared region, apparent molecular absorption coefficients (ε^a) at 1736 cm^{-1} for solutions of **1***a* and **1***b* in chloroform are 330 and 550, respectively, which also substantiate the structural assignments. This observation is consistent with the fact that esters exhibit a higher absorption coefficient than ketones (6); i.e., **1***a* embodying one keto and one ester function has a lower ε^a value than **1***b* with two ester functions.

In addition, the OH stretching frequencies for **1***a* (3509 cm^{-1}) and **1***b* (3571 and 3425 cm^{-1}) are markedly different. The concentration of **1***a*, in carbon tetrachloride, did not affect band intensity at 3509 cm^{-1}; the latter and the relatively low wavenumber reflect an intramolecularly hydrogen-bonded hydroxyl function. Because of the limited solubility of **1***b* in carbon tetrachloride, the latter could not be correspondingly evaluated. Examined in chloroform, however, the band at 3571 cm^{-1} can be attributed to free hydroxyl groups indicative of the dimer (**1***b*); the moderately weak OH vibrational bands 3571 (sharp) and 3425 cm^{-1} (broad) being specifically characteristic of a sterically hindered alcohol (7), evident only in the dimer.

The structure assignments for **1***a* and **1***b* are supported by the findings of Schlenk *et al.* (4); they reported that 1-palmitoyloxy-3-hydroxyacetone can exhibit monomeric (m.p. 63°) and dimeric (m.p. 93°) forms; however, no structure was even suggested for the dimer. Dihydroxyacetone itself is known to exist as a monomer and dimer (8), the latter being 2,5-dihydroxymethyl-2,5-dihydroxy-1,4-dioxane (9, 10).

Experimental

Melting points are corrected; they were determined with a Büchi melting point apparatus. Ultraviolet (u.v.) and infrared (i.r.) spectra were obtained with the Perkin–Elmer model 202 and 137B spectrophotometers, respectively. Combustion analyses were performed by Drs. G. Weiler and F. B. Strauss, Oxford, England.

*1-Undecanoyloxy-3-hydroxyacetone [monomer (**1a**) and dimer (**1b**)]*

A solution of undecanoyl chloride (56.8 g, 0.277 mole) in 555 ml of chloroform (freshly distilled from P_2O_5) was added dropwise, over a period of 2 h, to a stirred solution of 100 g (1.110 mole) of dry 1,3-dihydroxypropanone in 555 ml of dry, freshly distilled pyridine. The temperature of the reaction mixture was maintained at −2 to −6°. After stirring an additional 1.2 h while warming to 18°, the pyridine–chloroform solution was slowly added to 500 ml of cold (−10°) 3 *N* HCl and 1000 g of ice; during the addition, 1 l of 6 *N* HCl was simultaneously added. The aqueous phase was extracted with chloroform (3 × 400 ml) and the combined chloroform phases were dried over anhydrous Na_2SO_4. Removal of the solvent *in vacuo* afforded 78 g of oily crude product. This was dissolved in 95% ethanol, and upon standing, a total of 12.5 g of crystalline material was collected.[1] Ethanol was then removed by distillation

[1]This consisted primarily of 1,3-diundecanoyloxyacetone, the properties of which we described in our preceding paper (1).

in vacuo, the oily residue was treated with benzene (3 × 70 ml), and the solvent was removed *in vacuo* after each addition.

The residue was dissolved in hexane and, upon standing, a crystalline product (23.6 g, m.p. 91.3–93.3°) was collected; a second crop (14.0 g, m.p. 60.3–83.2°) was also obtained. Recrystallization of the first crop from chloroform yielded **1***b*: m.p. 96.8–98.3°;[2] λ_{max} (*p*-dioxane) 224 mμ (ε 74.5); ν_{max} (chloroform) 3571, 3425 (O—H stretching),[2] 1736 cm^{-1} (ester carbonyl).

Anal. Calcd. for $C_{28}H_{52}O_8$: C, 65.09; H, 10.14. Found: C, 65.25; H, 10.27.

After refluxing **1***b* in 95% ethanol for 2 h, and two recrystallizations from the same solvent, **1***a* was obtained: m.p. 44.8–46.1°; λ_{max} (*p*-dioxane) 224 (ε 39.7), 274.5 mμ (ε 19.8); ν_{max} (chloroform) 3509 (O—H stretching), 1736 cm^{-1} (ester and ketone carbonyl).

Anal. Calcd. for $C_{14}H_{26}O_4$: C, 65.09; H, 10.14. Found: C, 65.18; H, 10.27.

Acknowledgments

Nucleophilic displacement of vinylic halogen in fluorinated cycloalkenes. II. Reaction with triphenylphosphine

S. E. Ellzey, Jr.

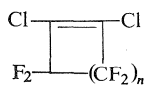
Southern Regional Research Laboratory, Southern Utilization Research and Development Division, Agricultural Research Service, United States Department of Agriculture, New Orleans, Louisiana 70119

Received October 28, 1968

1,2-Dichloroperfluorocyclobutene and the corresponding cyclopentene react with triphenylphosphine under hydrolytic conditions in wet acetic acid to yield novel triphenyl(fluorocycloalkenyl)phosphonium betaines. Structural assignments are made on the basis of elemental analysis, ^1H and ^{19}F nuclear magnetic resonance spectra, infrared spectra, and degradation studies. Triphenylphosphine and 1,2-dichloroperfluorocyclohexene yield triphenylphosphine oxide and a product which appears to be 1-chloro-2-hydrooctafluorocyclohexene.

Canadian Journal of Chemistry, **47**, 1251 (1969)

Displacement of both vinyl chlorines from the olefins **1***a–c* with trialkyl phosphites, phosphonites, and phosphinites yields products substituted in the 1- and 2-positions with phosphorus (1). Depending on the type of nucleophile used, certain secondary phosphines or diphosphines were reported to yield either mono- or disubstitution products (2).



1*a*, $n = 1$
b, $n = 2$
c, $n = 3$

It has now been found that reaction of triphenylphosphine with **1***a* and **1***b* in acetic acid–water yields the triphenylphosphonium betaines **2***a* and **2***b*, respectively, in low yield (3). These are the phosphorus analogues of the quaternary ammonium betaines **3** obtained when the nucleophile is tertiary amino nitrogen (4*a–c*). The structures **2** are assigned on the basis of elemental analysis, molecular weight, infrared, ^1H and ^{19}F

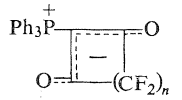
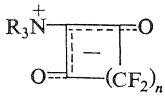
nuclear magnetic resonance spectra, and oxidation of **2***b* to the expected dicarboxylic acid with CrO_3.



2*a*, $n = 1$
b, $n = 2$



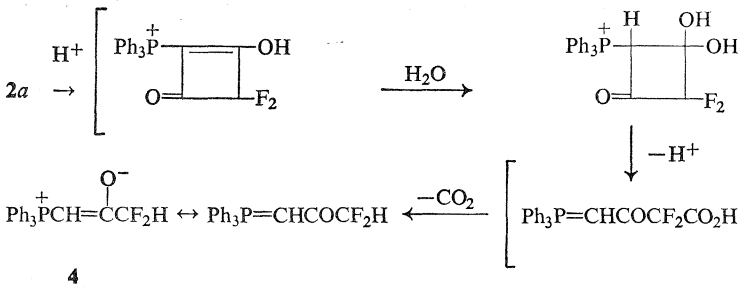
3*a*, R = alkyl, $n = 1$
b, R_3N = , $n = 1,2$

The infrared spectra of the betaines **2** in the 1540–1820 cm^{-1} region were quite similar to those of **3***b* of the same ring size (**4***a*). Strong bands were present in **2***a* at 1779, 1669, and 1637 cm^{-1} for the O⁻C⁻C⁻C⁻O system, while in **2***b* a strong band was present at 1653 cm^{-1}, with much weaker absorption at 1721 and 1686 cm^{-1}.

Absorptions due only to aromatic protons at δ 7.56–7.95 and 7.52–7.95 p.p.m., respectively, were present in the ^1H spectra of **2***a* and **2***b* (acetone-d_6, TMS as internal reference). The ^{19}F spectrum of **2***a* in dimethyl formamide (relative to internal $CFCl_3$) consisted of a doublet at δ +118.1 p.p.m., J_{PF} = 20.5 Hz; the chemical shift for **2***b* in the same solvent was at δ +127.2 p.p.m., J_{PF} = 1.1 Hz. These chemical shifts are very close to those of the corresponding **3***b*[1] and a related system studied by Stockel and co-workers (5). The larger J_{PF} in **2***a* relative to that in **2***b* may result from strong through-space coupling, reflecting the highly strained nature of the four-membered ring (6).

Neither **2***a* nor **2***b* decolorized bromine in CCl_4 or permanganate in acetone, and neither reacted with *m*-nitrobenzaldehyde after 18 h in refluxing tetrahydrofuran. With methyl iodide for 7 h in refluxing acetone **2***a* and **2***b* were unreactive, as was **2***b* with refluxing 50% sulfuric acid for 15 h.

Upon refluxing **2***a* with concentrated HCl for 15 h and recrystallizing the product from ethanol – acetone – water, there was obtained a material of empirical formula $C_{21}H_{17}F_2OP$, to which the structure **4** is assigned on the basis of its infrared and ^1H nuclear magnetic resonance spectra. A pair of strong bands at 1587 and 1562 cm^{-1} is indicative of the proposed betaine structure (7); no absorption due to OH or C=O stretch was evident. In the nuclear magnetic resonance spectrum (dimethyl sulfoxide-d_6), absorption was present at δ 4.12 (PCH, doublet, J_{PH} = 22 Hz) (8), 5.98 (CF_2H, triplet, J_{FH} = 56 Hz), and at 7.38–7.93 p.p.m. (aryl H). The peaks of the doublet and triplet were broad, possibly because of allylic couplings. Integration of the spectrum was in fair agreement with that expected for **4**. Stereochemistry about the C=C bond was not assigned.



4

In contrast to the behavior of **1***a* and **1***b* with triphenylphosphine, **1***c* gave an 81% yield of triphenylphosphine oxide but no product analogous to **2** was isolated. Distillation of the reaction mixture prior to phosphine oxide isolation gave a mixture of acetic acid, unchanged **1***c*, and a material having infrared absorption at 1658 cm^{-1} in CCl_4 and a complex multiplet at δ 6.45 p.p.m. in its ^1H nuclear magnetic resonance spectrum. Although difficulties in separation prevented full characterization, spectral data for the latter compound are in accord with 1-chloro-2-hydrooctafluorocyclohexene, **5**, which reportedly

For personal use only.

has C=C absorption at 1660 cm^{-1} (9). A reason for the apparent change in mode of attack by phosphorus is not known at this time.

Experimental

The olefins **1***a* and **1***c* were obtained from Peninsular ChemResearch, Inc.[2] **1***b* was from either the latter source or Hooker Chemical Corporation. Triphenylphosphine was a product of Eastman Kodak.

Infrared spectra were obtained from KBr disks with a Perkin–Elmer model 137 spectrophotometer (NaCl optics). The nuclear magnetic resonance spectra were recorded on Varian spectrometer models A-60A and HR-60 (56.4 MHz).

Triphenyl(3,3-difluoro-2-hydroxy-4-oxo-1-cyclobuten-1-yl)phosphonium Hydroxide, Inner Salt (2a)

A mixture of 5.85 g (0.03 mole) of **1***a* and 8.66 g (0.033 mole) of triphenylphosphine in 50 ml of acetic acid and 2 ml of water was refluxed for 3 h. The gaseous products gave positive tests for F^- and Cl^-. After refluxing, about 10 ml of the mixture were distilled at 100–116° but gas–liquid partition chromatography (g.l.p.c.) analysis indicated only solvent and traces of other compounds. The remainder of the reaction mixture was poured into about 150 ml of water and ice and the precipitate was filtered and washed with water, 6.71 g, m.p. ca. 120–200°. The solid was washed with two 25 ml portions of ethanol, followed by 25 ml of ether, to give 3.27 g (29%) of **2***a*, m.p. 228–233°. Recrystallization from acetone–water gave an analytical sample, m.p. 230–231°.

Anal. Calcd. for $C_{22}H_{15}F_2O_2P$ (mol. wt., 380): C, 69.47; H, 3.98; F, 9.99; P, 8.14. Found (mol. wt., 375 osmometric in acetone): C, 69.67; H, 3.97; F, 9.59; P, 8.18.

The combined ethanol and ether washes were evaporated and the residue washed with petroleum ether, b.p. 30–60°. The soluble fraction yielded 1.13 g (13% recovery) of triphenylphosphine (mixture m.p. and infrared spectrum); the insoluble fraction yielded 0.56 g of the crude betaine and 0.75 g (9%) of crude triphenylphosphine oxide (m.p. and infrared spectrum).

2*a* could be distilled unchanged (92% recovery) in a sublimation apparatus at 3–3.5 mm, bath temperature 285–295°.

Triphenyl (3,3,4,4-tetrafluoro-2-hydroxy-5-oxo-1-cyclopenten-1-yl)phosphonium Hydroxide, Inner Salt (2b)

A mixture of 7.08 g (0.027 mole) of triphenylphosphine and 6.12 g (0.025 mole) of **1***b* was refluxed for 20 h in 50 ml of acetic acid containing 1 ml of water. Distillation of the reaction mixture until the vapor temperature was about 117° gave no starting material; on g.l.p.c. analysis only acetic acid and an impurity originally present in the olefin were noted. After pouring the distillation residue into water and ice, a dark emulsion formed and was coagulated by heating on a steam cone. The tarry semisolid was recrystallized twice from ethanol–water to yield 3.75 g (35%) of product, m.p. 173–174°. Further recrystallization gave a product melting mostly at 176–178°, but with some melting at 166°. If the melted material was cooled rapidly with ice and then placed in the bath preheated to 165°, it melted at 181–182°. Allowing the melt to cool slowly to room temperature in the bath gave a solid, m.p. 175–176°. The infrared spectra of all the forms were identical.

Anal. Calcd. for $C_{23}H_{15}F_4O_2P$ (mol. wt., 430): C, 64.19; H, 3.51; F, 17.66; P, 7.20. Found (mol. wt., 422 osmometric in acetone): C, 64.34; H, 3.62; F, 17.81; P, 7.34.

The tarry, semisolid residue obtained from the filtrate of the first recrystallization of **2***b* was chromatographed in benzene on a column of Alcoa F-20 alumina and eluted with ethanol and acetone. From the eluate there was obtained 2.15 g of a solid, m.p. 148–153°, which yielded 0.51 g (7%) of triphenylphosphine oxide (infrared spectrum), m.p. 156–157°, and some tar.

Evaporation of the original reaction mixture filtrate gave a few grams of tarry material.

Oxidation of 2b with CrO_3

A solution of 3.01 g (0.007 mole) of **2***b* in acetic acid at 75–80° was treated with a solution of 2.00 g (0.02 mole) of CrO_3 in acetic acid and water and held at 75–80° for 30 min. From this solution was obtained 1.14 g (38%) of recovered **2***b* and 0.54 g (40%) of perfluorosuccinic acid, m.p. 88–90° (from benzene). Identification of this acid was by means of infrared spectrum and neutralization equivalent.

Reaction of 2a with HCl

A stirred slurry of 1.14 g (0.003 mole) of **2***a* in 30 ml of concentrated HCl was refluxed 15 h, cooled, filtered, and the product was washed with tetrahydrofuran and acetone, 0.63 g. It had no sharp melting point and gave a positive test for Cl^- with silver nitrate, but upon recrystallization from ethanol – acetone – water, colorless needles of a chlorine-free product, m.p. 210–211° (decomp.), were obtained.

Anal. Calcd. for $C_{21}H_{17}F_2OP$: C, 71.18; H, 4.84; F, 10.72; P, 8.74. Found: C, 70.89; H, 4.83; F, 10.50; P, 8.63.

The infrared spectrum of the tetrahydrofuran- and acetone-washed product was quite different from that of the recrystallized material. Strong bands at 1587 and 1562 cm^{-1} in the latter were absent in the former; very broad and strong absorption at about 3226 cm^{-1} in the initial product was absent in the recrystallized solid.

Reaction of 1c with Triphenylphosphine

A mixture of 7.38 g (0.025 mole) of **1***c* and 7.08 g (0.027 mole) of triphenylphosphine in 50 ml of acetic acid containing 1 ml of water was refluxed for 43 h. Positive tests for F^- and Cl^- were obtained on the effluent gases. About 20 ml were distilled from the mixture and the distillate was dried over sodium sulfate and redistilled. A fraction weighing 5.68 g was collected at 83–84°. Gas–liquid partition chromatographic analysis indicated about 21% starting olefin and about 75% of an unknown component, in addition to minor peaks. An infrared spectrum of this mixture in CCl_4 showed C=O at 1721 (acetic acid), C=C at 1658 (**5**), and C=C at 1626 cm^{-1} (**1***c*). Further washing with water and redistillation removed the acetic acid; the ^1H nuclear magnetic resonance spectrum (CCl_4) showed a broad multiplet at δ 6.45 p.p.m., in addition to signals due to ether used in the work-up.

[2]Mention of a product or company name does not imply endorsement by the Department to the exclusion of others which may also be suitable.

For personal use only.

The residue from the first distillation was diluted with water to give 6.88 g of solid which yielded 5.63 g (81%) of triphenylphosphine oxide and 0.79 g (11% recovery) of crude triphenylphosphine, both of which were identified by comparison of their infrared spectra with those of authentic samples.[3]

Acknowledgments

^{1}H nuclear magnetic resonance spectra were recorded by Gordon J. Boudreaux of this Laboratory and the ^{19}F spectra were obtained through the courtesy of Dr. Dean F. Keeley and Judith A. O'Connor, University of Southwestern Louisiana, Lafayette, Louisiana. Elemental analyses were by Galbraith Laboratories, Inc., Knoxville, Tennessee.

[3]*Note Added in Proof*: While this note was in press a report (10) appeared which substantially confirmed the present results, although the transformation of **1***c* into **5** went unnoticed. In the present work the formation of **5** was confirmed by analysis of a sample obtained by preparative gas–liquid chromatography.

New nitrochalcones. IX[1]

T. SZÉLL AND I. SOHÁR

Department of Applied Chemistry, University of Szeged, Szeged, Hungary

Received September 5, 1968

A number of new nitrohydroxychalcones are reported. Electron-donating groups in the aldehyde favor condensation by HCl, and electron-withdrawing substituents favor condensation by NaOH.

Canadian Journal of Chemistry, **47**, 1254 (1969)

A number of chalcones have been synthesized from acetophenones and benzaldehydes and the yields compared. Table I lists the results of condensations carried out in the presence of NaOH. The substituents in the aldehyde component increase the yield of chalcone formation in aqueous ethanol in the following way:

2,3-diOMe $\gtrsim$ 2,5-diOMe > H > 2-OMe > 2,4-diOMe

Table II records the results of experiments carried out in ethanol in the presence of HCl. The order of effectiveness of reactants with substituents other than *ortho* can be established as follows:

4-OH $\gtrsim$ 4-OMe $\gtrsim$ 3-OMe-4-OH > 3,4-diOMe $\approx$ 3,4-diOEt $\gtrsim$ 4-Me > H > 4-Cl > 4-NO_2 > 2,4-diNO_2

and for *ortho* substituents:

2,4-diOMe $\gtrsim$ 2-OMe > H > 2,3-diOMe = 2,5-diOMe

The yields show a rough parallelism with Hammett's substituents constants (1), and with basicities (pK_{BH^+}) (2). These results are in accordance with earlier observations (3–5). It can be concluded that electron-donating substituents favor condensation by acid catalysts and that electron-withdrawing groups favor condensation by bases. The choice of condensing agent for the synthesis of chalcones can generally be decided on this basis.

Experimental

Aldehydes and acetophenones were obtained from Aldrich Chemical Co. Inc.; Columbia Organic Chemical Co.; and from Distillation Products. After having checked their purity most of them were used without further purification. Nitrohydroxyacetophenones were prepared as described earlier (4). Syntheses of chalcones in the presence of NaOH were the same as previously reported (4). The acidic condensation was carried out as follows.

An ethanolic solution of the appropriate acetophenone and aldehyde was kept ice-cold while being saturated with HCl gas for 30 min. It was kept in a thermostat at 30° for 1 h, and after allowing it to stand at room temperature

[1]For Part VII see ref. 4*a* and for Part VIII see ref. 10.

On page 1254, in the left-hand column, the order of effectiveness of reactants with substituents should read 4-Cl > H and not H > 4-Cl.

New nitrochalcones. IX[1]

T. SZÉLL AND I. SOHÁR

Department of Applied Chemistry, University of Szeged, Szeged, Hungary

Received September 5, 1968

A number of new nitrohydroxychalcones are reported. Electron-donating groups in the aldehyde favor condensation by HCl, and electron-withdrawing substituents favor condensation by NaOH.

Canadian Journal of Chemistry, **47**, 1254 (1969)

A number of chalcones have been synthesized from acetophenones and benzaldehydes and the yields compared. Table I lists the results of condensations carried out in the presence of NaOH. The substituents in the aldehyde component increase the yield of chalcone formation in aqueous ethanol in the following way:

2,3-diOMe $\gtrsim$ 2,5-diOMe > H > 2-OMe > 2,4-diOMe

Table II records the results of experiments carried out in ethanol in the presence of HCl. The order of effectiveness of reactants with substituents other than *ortho* can be established as follows:

4-OH $\gtrsim$ 4-OMe $\gtrsim$ 3-OMe-4-OH > 3,4-diOMe $\approx$ 3,4-diOEt $\gtrsim$ 4-Me > H > 4-Cl > 4-NO_2 > 2,4-diNO_2

and for *ortho* substituents:

2,4-diOMe $\gtrsim$ 2-OMe > H > 2,3-diOMe = 2,5-diOMe

The yields show a rough parallelism with Hammett's substituents constants (1), and with basicities (pK_{BH^+}) (2). These results are in accordance with earlier observations (3–5). It can be concluded that electron-donating substituents favor condensation by acid catalysts and that electron-withdrawing groups favor condensation by bases. The choice of condensing agent for the synthesis of chalcones can generally be decided on this basis.

Experimental

Aldehydes and acetophenones were obtained from Aldrich Chemical Co. Inc.; Columbia Organic Chemical Co.; and from Distillation Products. After having checked their purity most of them were used without further purification. Nitrohydroxyacetophenones were prepared as described earlier (4). Syntheses of chalcones in the presence of NaOH were the same as previously reported (4). The acidic condensation was carried out as follows.

An ethanolic solution of the appropriate acetophenone and aldehyde was kept ice-cold while being saturated with HCl gas for 30 min. It was kept in a thermostat at 30° for 1 h, and after allowing it to stand at room temperature

[1]For Part VII see ref. 4*a* and for Part VIII see ref. 10.

On page 1254, in the left-hand column, the order of effectiveness of reactants with substituents should read 4-Cl > H and not H > 4-Cl.

*New compounds.
†See ref. 4.
‡C.f. with the same chalcones listed in Table II.
§In runs no. 1, 8, and 15, the concentration of the ketone was 0.1 mole l^{-1}, that of the aldehyde 0.15 mole l^{-1} and the base concentration 1.0 mole l^{-1}. In run 7, the concentrations were 0.17, 0.17, and 1.7 and in all other runs 0.04, 0.04, and 0.5 mole l^{-1} respectively. Yields are reported for crude products, and melting points for the recrystallized materials. Recrystallization was carried out from ethyl acetate, ethanol, or acetic acid. The melting points of the crude products were generally 1–4° below those of the purified materials. The sodium salt of the chalcone was precipitated during the course of each run.

*The acetophenone and aldehyde took part in the condensation in a 0.054 mole l^{-1} concentrated ethanolic solution. Yields are for washed crude products, corrected for the solubility of chalcones; melting points are for recrystallized (using EtOAc, EtOH, or AcOH) materials. The melting points of the crude products were generally 1–4° below those of the purified materials but in some cases the difference was higher and the crude melting point is given in parentheses. In the case of runs 1 and 2 the melting points given in the literature are 220 and 151°, somewhat different from those obtained in this work. In other cases the melting points were practically the same as those given in the literature.

†See ref. 7.
‡See ref. 4.
§New compounds.
‖See ref. 8.
¶See ref. 9.
**See ref. 6.

for a day, the product was precipitated by twofold dilution with water, filtered, and washed with 2 × 1.5 ml of ice-cold ethanol and 2 × 2 ml of water. In runs 8, 23, and 32 the crude products were strongly contaminated with high melting greenish materials and were not easy to purify. These by-products are obtainable alone from the mixture of aldehydes and ketones so that they are not self-condensation products.

Acknowledgments

The generous gift of a number of benzaldehydes from the National Research Council of Canada is gratefully acknowledged. Thanks are due to Mrs. K. Lakos-Láng and Mrs. G. Bartók-Bozóki (University of Szeged) for the microanalyses. The authors are indebted to the Hungarian Ministry of Education for the grant.

Reaction of dialkyl phosphorothioic acids with cyanogen bromide

ROBERT R. ENGEL

Department of Chemistry, Queens College of the City University of New York, Flushing, New York 11367

Received November 5, 1968

Dialkyl phosphorothioic acids (**1**) in benzene solution and in the presence of a tertiary amine react with cyanogen bromide to form the corresponding dialkyl phosphoroisothiocyanatidates (**2**). Under the reaction conditions these are partially decomposed to yield the alkylthiocyanates (**3**) and the alkylmetaphosphates (**4**).

Canadian Journal of Chemistry, **47**, 1258 (1969)

Several years ago Schrader obtained a German patent (1) for the preparation of thiophosphorylcarbimides by the action of cyanogen bromide on *O,O'*-dialkyl thionophosphoric acids. Although Schrader refers to the products as thiocarbimides and writes the structure as containing a P—N=C=S linkage, no evidence is presented which either supports the proposal, or excludes the presence of a P—S—C≡N type linkage. In the present work the reaction of cyanogen bromide with dialkyl phosphorothioic acids (**1**) has been studied under conditions similar to those used by Schrader with the resulting formation of the dialkyl phosphoroisothiocyanatidates (**2**).

$$(RO)_2\overset{\overset{O}{\|}}{P}\text{—SH} + CNBr \xrightarrow{Et_3N} (RO)_2\overset{\overset{O}{\|}}{P}\text{—NCS} + Et_3NHBr$$

(**1**) (**2**)

b, R = Bu

When diethyl phosphorothioic acid (**1***a*) in benzene solution and in the presence of triethylamine is treated with cyanogen bromide, a violent reaction occurs attended by a series of color changes (yellow→green→red→brown) and the formation of a precipitate. Upon removal of the precipitate (triethylamine hydrobromide) and the solvent, ethylthiocyanate (**3***a*), a nondistillable viscous liquid, presumably ethylmetaphosphate (**4***a*), (soluble in benzene and carbon tetrachloride) and diethyl phosphoroisothiocyanatidate (**2***a*) are isolated. Considering the decomposition material isolated, the primary reaction of diethyl phosphorothioic acid with cyanogen bromide proceeded to the extent of at least 60%.

The formation of ethylthiocyanate was confirmed by comparison of infrared (i.r.) and nuclear magnetic resonance (n.m.r.) spectra with those of an authentic sample prepared by the action of potassium thiocyanate on ethyl iodide in acetone solution.

The structure of the viscous residue was deduced as ethylmetaphosphate (**4***a*) from its n.m.r. spectrum (symmetrical triplet at 1.42 δ,

for a day, the product was precipitated by twofold dilution with water, filtered, and washed with 2 × 1.5 ml of ice-cold ethanol and 2 × 2 ml of water. In runs 8, 23, and 32 the crude products were strongly contaminated with high melting greenish materials and were not easy to purify. These by-products are obtainable alone from the mixture of aldehydes and ketones so that they are not self-condensation products.

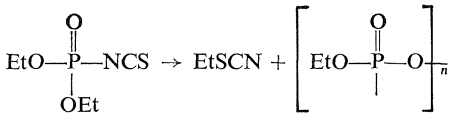
J = 7 c.p.s., area of 3 protons; quintet centered at 4.23 δ, J = 7 c.p.s., area of 2 protons)[1] and its i.r. spectrum which exhibited a phosphoryl band at 1297 cm^{-1} (calculated position: 1308 cm^{-1}) (2). The diethyl phosphoroisothiocyanatidate structure (**2***a*) was assigned to the remaining product after comparison of its spectral and chemical properties with those of an authentic sample prepared by a modification of the method of Kulka (3, 4) in which potassium thiocyanate in acetone solution was allowed to react with diethyl phosphorochloridate. Kulka (3) has shown the compound prepared under his experimental conditions to contain the P—N=C=S linkage by its formation of a thiourea in reaction with a secondary amine. Likewise, the material (**2***a*) reacted violently with secondary amines even at 0°.

The i.r. spectrum of the compound prepared by both routes were identical exhibiting a broad band at 2005 cm^{-1} with a strong shoulder at 2065 cm^{-1}. This type of absorption has been noted (5) for —N=C=S linkages as opposed to the sharp bands for —S—C≡N systems. Also, both exhibited a phosphoryl band at 1290 cm^{-1} and had identical n.m.r. spectra (symmetrical triplet at 1.42 δ, J = 7 c.p.s., area of 3 protons; multiplet centered at 4.20 δ, area of 2 protons).

The diethyl phosphoroisothiocyanatidate is presumably the primary reaction product which undergoes subsequent decomposition under the reaction conditions to yield ethylthiocyanate (**3***a*) and ethylmetaphosphate (**4***a*). This decomposition route has previously been observed for the compound (3). Indeed, further heating of the compound (**2***a*) isolated from the cyanogen bromide reaction yielded additional ethylthiocyanate and ethylmetaphosphate.



(**2***a*) (**3***a*) (**4***a*)

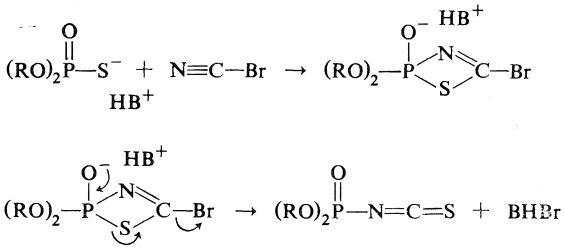
Similarly, upon treatment of dibutyl phosphorothioic acid (**1***b*) with triethylamine and cyanogen bromide, butylthiocyanate (**3***b*), butylmetaphosphate (**4***b*), and the dibutyl phosphoroisothiocyanatidate (**2***b*) were obtained.

Butylthiocyanate (**3***b*) was identified by comparison of i.r. and n.m.r. spectra with those of an authentic sample prepared as above in the ethyl case.

The butylmetaphosphate (**4***b*) was identified by its n.m.r. spectrum (triplet centered at 1.05 δ, J = 6 c.p.s., area of 3 protons; multiplet centered at 1.63 δ, area of 4 protons; multiplet centered at 4.13 δ, area of 2 protons) and the position of the phosphoryl band in its i.r. spectrum (1298 cm^{-1}).

As with the ethyl case, the dibutyl phosphoroisothiocyanatidate (**2***b*) structure was assigned on the basis of its spectral and chemical properties compared with those of an authentic sample prepared by a modification of the method of Kulka (3, 4). Both materials in the i.r. spectrum exhibited a phosphoryl band at 1285 cm^{-1} and a broad band at 2002 cm^{-1} with a strong shoulder at 2065 cm^{-1}. The n.m.r. spectrum showed a triplet centered at 1.05 δ, J = 6 c.p.s., area of 3 protons; a multiplet centered at 1.57 δ, area of 4 protons; and a multiplet centered at 4.04 δ, area of 2 protons.

A mechanism analogous to that proposed by Douglas and Burditt (6) for the reaction of cyanogen bromide with salts of aliphatic acids is presumed to be operating here as shown in the following reaction:



Experimental

Reagents

The dialkyl phosphorothioic acids used were prepared according to the method described by Hoffmann *et al.* (7, 8). The cyanogen bromide was commercial material (Aldrich) and was used without further purification. Benzene solvent was dried by storage over sodium metal.

The Reaction of Cyanogen Bromide with Diethyl Phosphorothioic Acid

To a stirred solution of 4.60 g (0.037 mole) of diethyl phosphorothioic acid and 3.71 g (0.037 mole) of triethylamine in 30 ml of benzene cooled in an ice bath, was added dropwise, over a period of 1 h, 3.93 g (0.037 mole)

[1]All positions given relative to tetramethylsilane observed on a Varian A-60A instrument purchased under NSF Grant GP6926.

of cyanogen bromide, dissolved in 30 ml of benzene. The reaction mixture was allowed to come to room temperature over a period of 1½ h, after completion of the addition of cyanogen bromide. After the precipitate of triethylamine hydrobromide had been removed by filtration, the solvent was removed using a rotary evaporator at room temperature and reduced pressure. Vacuum distillation of the liquid residue yielded 1.73 g (0.010 mole, 28%) of pure diethyl phosphoroisothiocyanatidate and 0.53 g (0.006 mole, 16%) of ethylthiocyanate. Also recovered was 1.22 g (0.011 mole, 31%) of ethylmetaphosphate.

The Reaction of Cyanogen Bromide with Dibutyl Phosphorothioic Acid

To a stirred solution of 10.0 g (0.042 mole) of dibutyl phosphorothioic acid and 4.3 g (0.042 mole) of triethylamine in 40 ml of benzene cooled in an ice bath, was added dropwise, over a period of 1 h, 4.5 g (0.042 mole) of cyanogen bromide, dissolved in 30 ml of benzene. The reaction mixture was allowed to come to room temperature over a period of 2 h, after completion of the addition of cyanogen bromide. After the removal of the triethylamine hydrobromide by filtration the solvent was removed using a rotary evaporator at room temperature and reduced pressure. Vacuum distillation of the residue yielded 2.13 g (0.0085 mole, 20%) of pure dibutyl phosphoroisothiocyanatidate and 0.63 g (0.0055 mole, 13%) of butylthiocyanate. Also recovered was 1.20 g (0.0088 mole, 21%) of butylmetaphosphate.

Hexahalocyclopentadienes. I. A reinvestigation of the reaction of hexachlorocyclopentadiene with fluoro- and chlorosulfonic acids

R. G. PEWS

Hydrocarbons and Monomers Research Laboratory, The Dow Chemical Company, Midland, Michigan 48640

Received August 26, 1968

The reaction of hexachlorocyclopentadiene with chlorosulfonic acid has been reinvestigated and the product found by spectral methods to be the chlorosulfate ester of undecachloropentacyclo[5.3.0.$0^{2,6}$.$0^{3,9}$-.$0^{4,8}$]decan-5-ol. With fluorosulfonic acid, the analogous fluorosulfate ester is formed and not octachloro-3*a*,4,7,7*a*-tetrahydro-4-7-methanoindene-1,8-dione as reported by McBee and Newcomer. A mechanism is proposed for the reaction.

Canadian Journal of Chemistry, 47, 1260 (1969)

McBee and Newcomer (1, 2) have reported that hexachlorocyclopentadiene (**1**) when allowed to react with chlorosulfonic acid yielded a compound (m.p. 146–147°) of molecular formula "$C_{10}H_2OSCl_{12}$" whereas fluorosulfonic acid under similar conditions gave octachloro-3*a*,4,7,-7*a*-tetrahydro-4,7-methanoindene-1,8-dione (**2**). The formation (3) of pentacyclo[5.3.0.$0^{2,6}$.$0^{3,9}$.-$0^{4,8}$] dodecan-5-one (**3**) on hydrolysis of "$C_{10}H_2O_3SCl_{12}$" suggests that the latter had the same pentacyclodecane carbon skeleton. In this note we report, firstly, spectral data which are in agreement[1] with the recently reported X-ray determination (7) of "$C_{10}H_2O_3SCl_{12}$" as the chlorosulfate ester of undecachloropentacyclo-[5.3.0.$0^{2,6}$.$0^{3,9}$.$0^{4,8}$] decan-5-ol (**4***a*), and secondly, results which show that **1** and fluorosulfonic acid yield **4***b* and not compound **2** as reported by McBee and Newcomer.

The mass spectrum of **4***a* showed a parent peak *m/e* 620 and the presence of twelve chlorine atoms. Other ion peaks which support structure **4***a* were found at *m/e* 251 ($C_5Cl_5O^+$) and *m/e* 451 ($C_{10}Cl_9O^+$). In further support of **4***a* no hydrogens were discernible in the nuclear magnetic resonance (n.m.r.) spectrum and the ultraviolet spectrum of the compound was transparent above 215 mμ. In the infrared, the symmetric and antisymmetric stretching vibrations of the sulfonyl group were found at 1431 and 1209 cm^{-1} respectively.

[1]X-Ray crystallographic studies are generally accepted as the ultimate in structural elucidations. The method, however, is not infallible. See for examples the work on triphenylene (4), β-selenium (5), and octaphenylcubane (6).

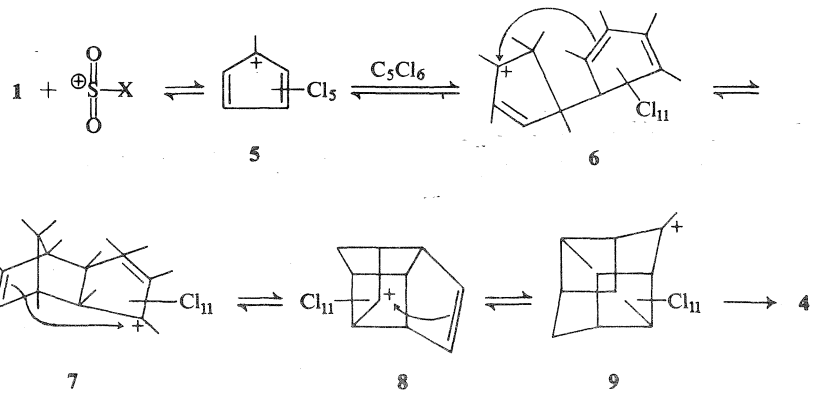
2 **3** **4***a*, X = Cl
4*b*, X = F

In order to clarify the products of the reaction of **1** with halosulfonic acids, fluorosulfonic acid and **1** were allowed to react under conditions identical with those for the preparation of **4***a* from **1** and chlorosulfonic acid. The product, a white crystalline solid, m.p. 222–224°, was characterized by the spectral methods (see Experimental) described for **4***a* and found to be the expected fluorosulfate ester **4***b*. In our laboratory, the reaction of **1** with fluorosulfonic acid, under identical conditions as described by McBee and Newcomer (2) for the synthesis of **2** gave only **4***b* and some unreacted **1**. With a molar excess of fluorosulfonic acid, the yield of **4***b* was 72% with no apparent formation of **2**. The results of the present study suggest that the results of McBee and Newcomer on the reaction of **1** with fluorosulfonic acid may have been due to impurities in the starting materials.

Mechanistically, the formation of **4** can be envisioned as proceeding by the abstraction of a chlorine by the halosulfonium ion to give the pentachlorocyclopentadienyl cation[2] (**5**). Electrophilic addition of the latter to another molecule of **1** would give a new cation **6** which could then undergo cage formation through cationic intermediates **7**–**9** which eventually react with solvent anion to give product (see Scheme 1). Such a mechanism could also apply to the dimerization of **1** to dodecachloropentacyclo[5.3.0.$0^{2,6}$.$0^{3,9}$.$0^{4,8}$] decane (Prins dimer).



SCHEME 1

Experimental

Ultraviolet spectra were determined with a Cary recording spectrophotometer, model 15, and are reported in millimicrons. Infrared spectra were obtained with a Beckmann IR-9 spectrometer. The mass spectra were obtained on a CEC 21-110B (direct probe) instrument. The isotope peaks observed match the relative abundances calculated for the naturally occurring isotopes. The melting points were taken on a Thomas–Hoover melting point apparatus and are uncorrected.

Material

Hexachlorocyclopentadiene was redistilled *in vacuo* and a middle fraction was collected b.p. 92° (5 mm), n_D^{25} 1.5623 [lit. (9) b.p. 92° (5 mm), n_D^{25} 1.5626].

Chlorosulfonic Acid: *Undecachloropentacyclo-*[5·3·0·$0^{2,6}$·$0^{3,9}$·$0^{4,8}$]*decan-5-yl ester (4a)*.

This compound was prepared as described by McBee and Newcomer (1).

[2]Breslow, Hill, and Wasserman (8) have concluded that the ground state of the pentachlorocyclopentadienyl cation is either a triplet or at most 6–8 cal/mole from the singlet ground state in SbF_5 solution. The triplet was not detected with **1** and other Lewis acids in SO_2 solution. For simplicity of discussion, **5** is represented as a classical species.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

*Reaction of **1** with Fluorosulfonic Acid*

The procedure was identical to that described by McBee and Newcomer (2), except that the temperature was controlled at 90° after the addition of the fluorosulfonic acid to **1** at 120°. The white solid obtained after purification had m.p. 222–224°.

Anal. Calcd. for $C_{10}Cl_{11}SO_3F$: C, 19.72; H, 0.00; Cl, 64.02; S, 5.26; O, 7.88; F, 3.12. Found: C, 19.90; H, 0.18; Cl, 64.15; S, 5.02; O, 8.50; F, 3.22.

The mass spectrum gave a molecular ion *m/e* 604, as well as the following: *m/e* 251 ($C_5Cl_5O^+$) and *m/e* 451 ($C_{10}Cl_9O^+$). The compound was transparent in the ultraviolet about 215 mμ and failed to show any absorption in the proton magnetic resonance experiment. The fluorine resonance in CH_2Cl_2 showed a singlet at −51.5 p.p.m. from $CFCl_3$ which is consistent with the proposed —OSO_2F group. The antisymmetric and symmetric sulfonyl stretching vibrations were observed at 1466 cm^{-1} and 1235 cm^{-1} respectively.

Acknowledgments

The author is grateful to Dr. J. Heeschen, Mr. R. Nyquist, and Dr. L. Shadoff for determining the nuclear magnetic resonance, infrared, and mass spectral data respectively. I am also indebted to Mr. J. Simek for the ultraviolet spectra and to Mr. L. Swim and his associates for the elemental analyses reported herein.

Nucleophilic substitution at silicon: the reaction of triphenylsilyl chloride with 2-propanol in CCl_4

A. D. ALLEN AND S. J. LAVERY

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario

Received August 29, 1968

The reaction of triphenylsilyl chloride with 2-propanol in CCl_4 has been reinvestigated and a mechanism proposed. The HCl produced in the reaction is catalytic. The rate of the uncatalyzed reaction, as determined by extrapolations to zero time, increases more rapidly with 2-propanol concentration than would be required for an order of one in the alcohol. The rate of the HCl-catalyzed path is independent of the 2-propanol concentration in the range studied (5 to 15 volume %) but first order in the HCl concentration, suggesting that the reactive alcohol species in this case is of the form ROH...ClH.

Canadian Journal of Chemistry, 47, 1263 (1969)

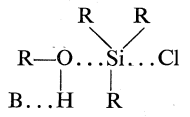
The reactions of triphenylsilyl chloride with H_2O in dioxan (1) and with 2-propanol in CCl_4 (2) are autocatalytic. The reactions may be represented generally by

$$(C_5H_6)_3SiCl + ROH \rightarrow (C_5H_6)_3SiOR + HCl$$

The HCl and chloride ions have been shown to be catalytic species (1, 2).

Petersen and Ross (2) concluded that there was little or no reaction of triphenylsilyl chloride and 2-propanol in the absence of HCl and that the order in the alcohol was one. They interpreted their results as support for a mechanism involving formation of a pentacovalent silicon intermediate followed by HCl-catalyzed decomposition to products.

Allen and Modena (1) assumed that no HCl was present initially in their reaction mixtures and obtained pseudo first-order rate constants for the uncatalyzed reaction of triphenylsilyl chloride and water in dioxan by extrapolation to zero time of plots of log $[R_3SiCl]$ against time. The initial slopes of these plots were constant at any one water concentration. The order in water was greater than one. Multiple orders in alcohol or water have been noted in a number of other systems (3–6) involving substitution at silicon in non-hydroxylic solvents. Allen and Modena proposed that in alcoholysis and hydrolysis, the reactive nucleophilic species is of the form ROH . . . B, where B is any entity that can act as a base and assist proton removal from the OH group.



Transition state

This type of mechanism has been used to explain the action of certain catalysts, the high order in the nucleophile, and temperature effects in a number of systems (1, 3–7).

Analyses of samples of triphenylsilyl chloride, combined with the observation that CCl_4 solutions of the silicon halide failed to show any detectable acid, led us to conclude that the samples used in this work did not contain HCl impurity. This suggested that, contrary to the arguments of Petersen and Ross, it should be possible to determine rate constants for the uncatalyzed reaction of triphenylsilyl chloride and 2-propanol in CCl_4 by extrapolations to zero time, and to determine the order in 2-propanol from the rate constants obtained. We have reinvestigated this reaction using a direct titrimetric method to determine the HCl produced in the reaction.

Results and Discussion

The reaction of 2-propanol and triphenylsilyl chloride in CCl_4 solvent is catalyzed by the HCl produced in the reaction, but HCl need not be present to initiate the reaction. The first-order plot shown in Fig. 1 is typical. Extrapolations to zero time on such plots for runs to which no HCl has been added give pseudo first-order rate constants, k_u, applicable to the uncatalyzed reaction. The results are summarized in Table I. All data were obtained at 25.2°.

From the data in Table I it can be seen that at any one alcohol concentration, k_u is reasonably constant. The rate increases with 2-propanol concentration more rapidly than would be required for an order of one in the alcohol. A plot of log k_u against log (volume % of ROH) is linear with slope equal to 2.4 in the range studied. The multiple order in 2-propanol is consistent with the mechanism proposed by Allen and Modena (1); B is another alcohol molecule. It is known that 2-propanol exists to a large extent as a polymer in CCl_4 (8, 9), and that the pseudo first-order rate constants for the 2-propanolysis of acetyl chloride in CCl_4 are proportional to the concentration of associated alcohol (9).

When HCl is added to the reaction mixtures, the pseudo first-order rate constants obtained by extrapolation, k_1, are higher than the k_u value at the same alcohol concentration. The increments, $k_1 - k_u$, are linear in HCl concentration, but appear to be independent of the alcohol concentration in the range studied (5 to 15 volume % 2-propanol), as can be seen from the k_c entries in column 6 of Table II. Catalysis by HCl is explained in terms of the increased basicity towards silicon of the oxygen of an alcohol molecule hydrogen-bonded through its proton to the chloride of the HCl. If this association of alcohol and HCl is virtually complete, so that the concentration of the reactive alcohol species is equal to the analytical concentration of HCl, then the independence of alcohol concentration shown by k_c is explained.

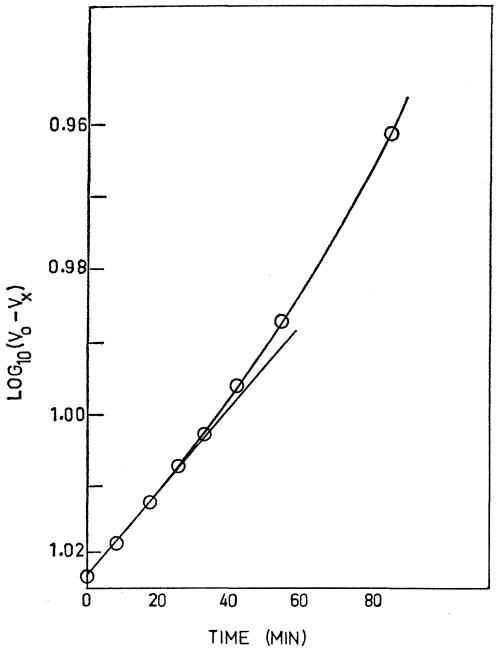

FIG. 1. First-order plot for 2-propanolysis $(C_6H_5)_3SiCl$ in CCl_4 at 25.2°; $[R_3SiCl]_0 = 1.374 \times 10^{-2}$ M, $[ROH]_0 = 10$ volume %, V_0 = volume of Et_3N solution corresponding to the initial silyl chloride concentration, V_x = volume of Et_3N solution corresponding to the HCl produced in the reaction.

The rate equation appears to have the form

$$dx/dt = k_u[R_3SiCl] + k_c[HCl]\,[R_3SiCl]$$
$$= k_u(a_0 - x) + k_c(p_0 + x)\,(a_0 - x)$$

where k_u varies with alcohol concentration but k_c does not. The first term refers to the uncatalyzed path, the second to the HCl-catalyzed path. For runs to which no HCl is added initially, p_0 equals zero. The integrated form of this rate law is

$$\log_e\left[\frac{1-M}{1+M}\right] = (k_c a_0 + k_c p_0 + k_u)t + \log_e\left[\frac{1-B}{1+B}\right]$$

where

$$M = \frac{k_c a_0 - k_c p_0 - k_u - 2k_c x}{k_c a_0 + k_c p_0 + k_u}$$

and

$$B = \frac{k_c a_0 - k_c p_0 - k_u}{k_c a_0 + k_c p_0 + k_u}$$

If values for k_u and k_c are assumed, values of $\log_e [(1 - M)/(1 + M)]$ can be plotted against time for any run. Then the linearity of the plot can be checked and the slope of the least squares straight line through the points compared with the theoretical slope $(k_c a_0 + k_c p_0 + k_u)$. This was done for a wide range of k_c values at each of several k_u values for each run. In general, for each value of k_u there exists a value of k_c at which the theoretical and least squares slopes are essentially equal, and the deviation of points from the least squares straight line is very small. Other values of k_c with this k_u result in much greater deviations. However, for any one run several sets of k_u and k_c with different k_u values meet the requirements given above equally well. Despite this complication, the following points are evident (*a*) for k_u values within ±10% of the values obtained by extrapolation, the best k_c values are close to those calculated from the extrapolation data, (*b*) sets of k_u and k_c values for runs with and without added HCl at the same alcohol concentration show best agreement in the neighborhood of the values obtained by extrapolation, (*c*) the k_c values at any one alcohol concentration are reasonably constant, and (*d*) the k_c values appear to be independent of the alcohol concentration.

Data at various percentages of reaction are, therefore, consistent with the rate law deduced from extrapolations to zero time. Typical results are shown in Table III and a typical plot of $\log_e [(1 - M)/(1 + M)]$ is shown in Fig. 2.

When tetraethylammonium chloride is added to the reaction mixtures, the pseudo first-order rate constants obtained by extrapolation, k_1, are higher than those for the uncatalyzed reaction. The increments to the rate constant appear to be linear in salt concentration, as evidenced by the values of k_s at any one alcohol concentration in column 5 of Table IV. As in all other cases, runs containing Et_4NCl eventually showed autocatalysis by the HCl produced in the reaction.

Pseudo first-order rate constants obtained by extrapolation for runs with both HCl and Et_4NCl added show that the effect of one catalyst is not diminished in the presence of the other. This observation does not agree with the rate law for the

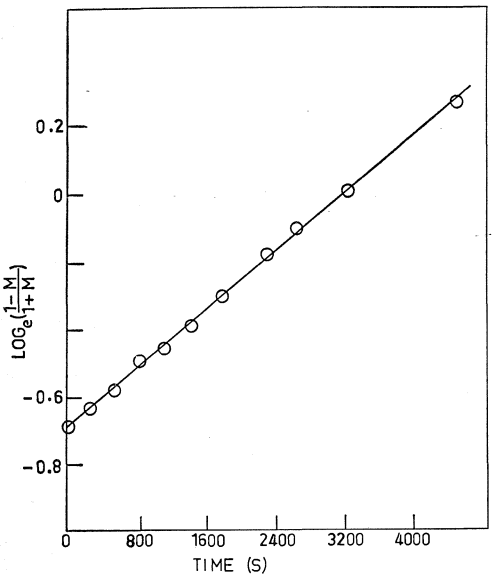

FIG. 2. Plot of $\log_e [(1 - M)/(1 + M)]$ against time with least squares line shown; $[R_3SiCl]_0 = 1.040 \times 10^{-2}\ M = a_0$, $[ROH]_0 = 10$ volume %, $[HCl]_0 = 3.21 \times 10^{-3}\ M = p_0$.

salt-catalyzed reaction proposed by Petersen and Ross (2). The results for samples containing both catalysts are shown in Table V.

Since $k_s > k_c$, Et_4NCl is more effective as a catalyst than HCl. It seems reasonable to conclude that the Cl in both catalysts acts by association with the proton of the alcohol OH group. Such association is known to occur between quaternary ammonium halides and alcohols in CCl_4 (10). The HCl may not be appreciably dissociated (2), while the tetraethylammonium chloride may be present as ion pairs (11).

It is impossible to tell from our kinetic data whether the reaction of the silyl chloride and ROH . . . B proceeds by an S_N2 mechanism or by formation of a pentacovalent silicon intermediate. We favor the former after considering collectively the information dealing with substitution of chloride at silicon by more basic groups as presented in refs. 1, 3, 7, 12–14.

Experimental Details

A. Solvents

Carbon Tetrachloride. Reagent grade CCl_4 was used without further purification or drying. Numerous blanks containing only triphenylsilyl chloride and CCl_4 were run, and in all cases no more than 1% reaction occurred over a 24 h period; there was no detectable acidity produced in the length of time for which normal kinetic runs were followed.

2-Propanol. Molecular sieves were used for drying. The water content was reduced to 0.008% or less (Karl Fisher titration) in 3 to 4 days.

Dioxan. Reagent grade dioxan was refluxed with sodium until formation of resin ceased and the sodium remained shiny. It was then distilled.

Benzene. Reagent grade benzene was dried by distillation from sodium.

Diethyl Ether. Anhydrous diethyl ether was distilled from sodium or used as obtained from Mallinckrodt (A.R., A.C.S., 0.01% H_2O).

B. Preparation of Triphenylsilyl Chloride

$(C_6H_5)_3SiCl$ was prepared by chlorination of $(C_6H_5)_3SiH$ in CCl_4.

The reaction vessel was immersed in an ice-water bath. The CCl_4, Cl_2, and dissolved HCl were pumped off following completion of the reaction. The crude product was recrystallized from benzene and petroleum ether and then distilled at reduced pressure (boiling point 147 °C at 0.01 mm Hg).

Anal. Calcd. for $(C_6H_5)_3SiCl$: C, 73.33; H, 5.12; Cl, 12.03. Found: C, 73.41; H, 5.21; Cl, 11.92.

C. Procedure Followed in Kinetic Runs

Separate solutions of $(C_6H_5)_3SiCl$ and 2-propanol in CCl_4 were made up quantitatively at 25.2° and then mixed. Aliquots were removed from the reaction mixture at intervals, quenched in dry benzene or ether, and titrated immediately for HCl with a dioxan solution of Et_3N. Neutral red dissolved in 2-propanol was used as the indicator. Total acid values were obtained by titration of an aliquot run into 95% ethanol; production of HCl was complete and rapid in the ethanol.

Solutions of HCl in CCl_4 were prepared with HCl which had been passed through a H_2SO_4 drying train.

Tetraethylammonium chloride was dried over P_2O_5 under vacuum at the temperature of boiling methanol for several hours.

Reaction of metallic nitrilotriacetates with histamine

A. L. BEAUCHAMP, J. ISRAELI, AND H. SAULNIER
Département de Chimie, Université de Montréal, Montréal, Québec

Received August 15, 1968

Cu(II), Ni(II), Co(II), and Zn(II) nitrilotriacetates (MeX^-) react with histamine nitrate (LH^+) to form a protonated mixed complex MeXLH where the metal appears to be bound only to the tertiary imidazolic nitrogen of histaminium ion. At higher pH values the proton dissociates to yield a mixed complex ion $MeXL^-$ in which both the imidazolic nitrogen and the terminal amino group are coordinated. The formation constants of these species were calculated from the potentiometric titration curves.

Canadian Journal of Chemistry, 47, 1269 (1969)

Introduction

The reaction of nitrilotriacetate complexes with bidentate ligands was studied previously in this laboratory (1). Mixed complexes of metallic nitrilotriacetates with various mono- and bidentate ligands were also investigated by Mergerum (2) and Angelici (3).

Perrin (4) recently reported on mixed complexes containing histamine. Although this molecule is believed to act in most cases as a bidentate ligand by coordination of both the tertiary imidazolic nitrogen and the terminal amino group (5), coordination through a single nitrogen atom cannot be a priori ruled out. In fact, the present work shows that metallic nitrilotriacetates (MeX^-) of copper(II), nickel(II), cobalt(II), and zinc(II), react with histamine nitrate (LH^+) to form a protonated mixed complex MeXLH in which the metallic nitrilotriacetate is likely to be bound only to the tertiary imidazolic nitrogen atom. At higher pH values, the proton is liberated to yield a mixed complex anion $MeXL^-$ in which coordination of both nitrogen atoms is very probably involved.

Experimental

The metal ions were introduced in solution as perchlorates and standardized by complexometric methods (6, 7). Potentiometric titrations were made with a Radiometer 26 pH meter, with the calomel electrode connected to the solution to be titrated by means of a Fisher bridge 13–639–55 filled with 0.5 *M* $NaNO_3$. Calibration was made to give directly $-\log (H^+)$ (8). All experiments were performed at ionic strength 0.10 ($NaClO_4$) and 25.0 ± 0.1 °C.

Results

Aqueous solutions containing equimolecular amounts of $Me(ClO_4)_2$, Na_2HX, and $LHNO_3$ (where Me = Zn, Cu, Ni, Co) were titrated potentiometrically with sodium hydroxide. Experiments were carried out at three concentration levels (5×10^{-3}, 1×10^{-2}, and 2×10^{-2} *M*) for each metal ion and the results obtained at 2.0×10^{-2} *M* are given in Fig. 1. All curves show two inflection points at $a = 1$ and $a = 2$, respectively, where a is the number of moles of base added per mole of metal ion. The following reaction pathway turned out to explain satisfactorily the essential features of these results.

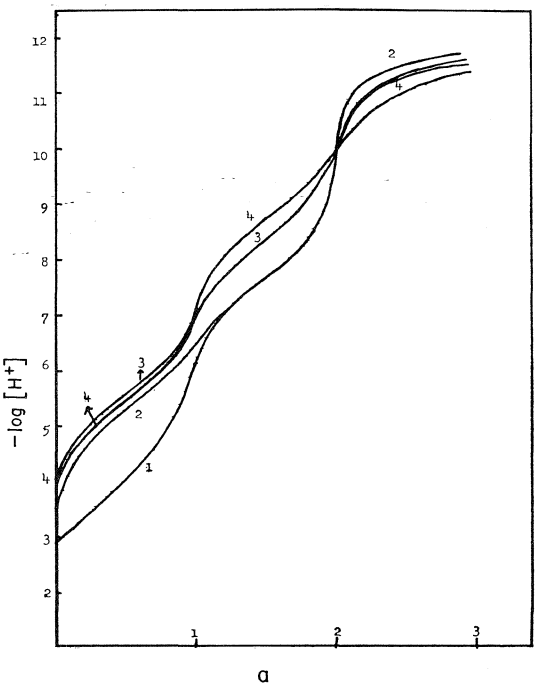

FIG. 1. Potentiometric titration of nitrilotriacetic acid disodium salt (HX^{-2}) 0.02 *M* and histamine nitrate (LH^+) 0.02 *M* in presence of metal ion (Me^{2+}) 0.02 *M*; a = number of moles of sodium hydroxide added per mole of metal; $T = 25.0 \pm 0.1$ °C; $\mu = 0.1$ ($NaClO_4$); 1, Me = Cu; 2, Me = Ni; 3, Me = Co; 4, Me = Zn.

TABLE I

*K_{f1} = [MeXLH]/[MeX$^-$][LH$^+$], μ = 0.1 ($NaClO_4$), T = 25 °C.

The pH value of the first point of each curve shows that histamine nitrate is converted nearly quantitatively to the biprotonated histamine LH_2^{2+} and the formation constants reported elsewhere (9) indicate that the formation of the nitrilotriacetate complex MeX^- is virtually complete. Consequently, mixing equimolecular amounts of the reactants results in the following overall reaction

[1] $Me^{2+} + XH^{2-} + LH^+ \rightarrow MeX^- + LH_2^{2+}$

which involves a proton transfer to the histaminium ion. The first portion of the curve, till a = 1, might then correspond to the neutralization of one proton of LH_2^{2+}.

[2] $$LH_2^{2+} \rightarrow LH^+ + H^+$$

$$K_{a2} = \frac{[H^+][LH^+]}{[LH_2^{2+}]}$$

Although this process actually takes place, the reaction scheme above could only explain the first few points of each curve. It was then assumed that the increasing amount of LH^+ produced by addition of hydroxide would promote the formation of a protonated mixed complex MeXLH, by the reaction

[3] $$MeX^- + LH^+ \rightleftarrows MeXLH$$

$$K_{f1} = \frac{[MeXLH]}{[MeX^-][LH^+]}$$

This reaction would progress till a = 1, after which neutralization of MeXLH takes place to give $MeXL^-$

[4] $$MeXLH \rightleftarrows MeXL^- + H^+$$

$$K_i = \frac{[MeXL^-][H^+]}{[MeXLH]}$$

The formation constant of the unprotonated complex is denoted K_{f2} and defined as follows

[5] $$MeX^- + L \rightleftarrows MeXL^-$$

$$K_{f2} = \frac{[MeXL^-]}{[MeX^-][L]}$$

The constants K_{f1} were obtained from the points in the range a = 0–1 by a graphical method described by Schwarzenbach (10) and Martell (11). The following equations should be valid for the case $C_{Me} = C_X = C_L$, where these symbols denote the total concentrations of metal ion, nitrilotriacetate, and histamine, respectively.

[6] $$C_{Me} \simeq [MeX^-] + [MeXLH]$$

[7] $$C_L = [LH_2^{2+}] + [LH^+] + [MeXLH]$$

[8] $$(1 - a)C_{Me} = [LH_2^{2+}] + [H^+] - [OH^-]$$

From eq. [8], one easily obtains

[9] $$[LH^+] = \frac{K_{a2}}{[H^+]}[(1 - a)C_{Me} - [H^+] + [OH^-]]$$

and from eqs. [6], [7], and [3]

[10] $$K_{f1}[LH^+] + 1 = \frac{C_{Me}}{[LH^+]\left(1 + \frac{[H^+]}{K_{a2}}\right)} = y$$

The dissociation constants of histamine were redetermined and found equal to $pK_{a1} = 9.72 \pm 0.01$ and $pK_{a2} = 6.00 \pm 0.01$. The expected straight lines $y = K_{f1}[LH^+] + 1$ were obtained from the data till $a \sim 0.7$. Severe deviations were obtained at $0.7 < a < 1.0$, due to the fact that reaction [4] cannot be neglected in these conditions. The average values of the formation constants obtained by the graphical method are denoted K_{f1}^0 in Table I.

TABLE II

The formation constants* of the complexes $MeXL^-$

Me	log K_{f2}^0	log K_{f2} $C_M = 5\times10^{-3}$	log K_{f2} $C_M = 1\times10^{-2}$	log K_{f2} $C_M = 2\times10^{-2}$	log K_{f2} (average)
Cu	6.15±0.04	6.14±0.03	6.10±0.03	6.08±0.05	6.11±0.04
Ni	4.88±0.04	4.93±0.04	4.86±0.03	4.86±0.03	4.89±0.04
Co	3.70±0.06	3.75±0.04	3.72±0.04	3.81±0.05	3.76±0.05
Zn	3.57±0.08	3.69±0.08	3.55±0.08	3.58±0.04	3.61±0.08

*$K_{f2} = [MeXL^-]/[MeX^-][L]$, $\mu = 0.1$ ($NaClO_4$), $T = 25$ °C.

The constants K_{f2}^0 were determined from the data after $a = 1$, using the following equations, valid for $C_{Me} = C_X = C_L$

$$[11]\quad C_{Me} = [MeXLH] + [MeXL^-] + [MeX^-]$$

$$[12]\quad C_L = [MeXLH] + [MeXL^-] + [LH^+] + [L]$$

$$[13]\quad (2-a)C_{Me} = [MeXLH] + [LH^+] + [H^+] - [OH^-]$$

Equations [11] and [12] lead to

$$[14]\quad [MeX^-] = [LH^+]\left(1 + \frac{K_{a1}}{[H^+]}\right)$$

while eqs. [3] and [13] give

$$[15]\quad (2-a)C_{Me} = K_{f1}[LH^+]^2\left(1 + \frac{K_{a1}}{[H^+]}\right) + [LH^+] + [H^+] - [OH^-]$$

For each point, the values of $[LH^+]$, $[MeX^-]$, [MeXLH], $[MeXL^-]$, and [L] can be calculated after stepwise substitution from eqs. [15], [14], [3], [11], and [2], respectively, and introducing into eq. [5], we obtained the values of K_{f2}^0 given in Table II.

Computer programs were used to show that the reaction scheme above holds for the entire curves and to refine the results obtained graphically. A program SICOUTIT, adapted by one of us (A.L.B.) from SCOGS (see below), was used to compute a calculated curve $V_c = f(pH)$ for each experiment. In addition to K_{f1}^0 and K_{f2}^0 obtained graphically, three acidity constants for XH_3 and two for LH_2^{2+} were included in the calculation, together with the formation constants of the simple complexes MeL, MeL_2, MeL_3, and MeX^-, assuming the values given in the literature (9).

All equilibrium constants are modified to correspond to the general formula

$$\beta = \frac{[Me_mX_xL_lH_h]^{(3x-2h-2m)-}}{[Me^{2+}]^m[X^{3-}]^x[L]^l[H^+]^h}$$

and the following material balance was used:

$$C_{Me} = [Me^{2+}] + \sum_i m_i\,[Me^{2+}]^{m_i}\,[X^{3-}]^{x_i}\,[L]^{l_i}\,[H^+]^{h_i}\,\beta_i$$

$$C_X = [X^{3-}] + \sum_i x_i\,[Me^{2+}]^{m_i}[X^{3-}]^{x_i}[L]^{l_i}[H^+]^{h_i}\,\beta_i$$

$$C_L = [L] + \sum_i l_i\,[Me^{2+}]^{m_i}[X^{3-}]^{x_i}[L]^{l_i}[H^+]^{h_i}\,\beta_i$$

The experimental value of $[H^+]$ is treated as the independent variable and the roots $[Me^{2+}]$, $[X^{3-}]$, and [L] in the system of material balance equations are obtained by the Raphson–Newton iterative process, the convergence criterion being that the calculated values of C_{Me}, C_X, and C_L are equal to the experimental ones within 10^{-5} %. The values of $[Me^{2+}]$, $[X^{3-}]$, and [L] are then substituted in the electroneutrality equation from which the calculated volume V_c is obtained. The computed curves $V_c = f(pH)$ were found to agree quite satisfactorily with the experimental results and confirmed the proposed reaction scheme.

The formation constants K_{f1}^0 and K_{f2}^0 obtained graphically were then refined by a least-squares technique, using a computer program SCOGS by Perrin and Sayce. This particular program has not been described by the authors but seems to be an adaptation of another program GAUSS by the same authors (12), particularly suitable for the treatment of alkali titration data. The function minimized during the least-squares refinement is $\sum(V_c - V_{exp})^2$.

Since precipitation occurs shortly after the second inflection point for some systems, the data corresponding to $a \leqslant 2$ ($\sim$ 50 points) were used and each titration curve was treated independently. All equilibria mentioned above were included in the calculation and the corresponding constants were fixed to the values of the literature (9), except $K_{f1}{}^0$ and $K_{f2}{}^0$ which were allowed to refine simultaneously. After three or four cycles of refinement, convergence was attained and the refined values of K_{f1} and K_{f2} are given in Tables I and II, together with the initial values. The standard deviation on titre varied between 0.02 and 0.05 ml for a total titre of 5.00 ml. The error given is equal to 4.5 times the standard deviations (σ_{esd}) estimated from the diagonal elements of the least-squares inverse matrix from the last cycle.

The results of Table I and II show that the refined values obtained at three different concentrations for each system are equal within 4.5 times their respective σ_{esd}. Although this appears to be slightly more than the usual criterion ($3 \times \sigma_{esd}$) for a 99% confidence level, the latter criterion implicitly assumes that the fixed constants of the systems (obtained from the literature) are exact, which of course is highly unrealistic in the present case. Average values for each constant are also given in the last column of the tables.

Figure 2 shows the distribution curve for the system cobalt-nitrilotriacetate–histidine. It was calculated from the concentration table computed by the program SCOGS at the end of the last least-squares refinement cycle. This curve shows clearly that the calculation of $K_{f1}{}^0$ from the data corresponding to $a < 0.7$ is fully justified, since the only metallic species present in appreciable concentrations are MeX^- and MeXLH.

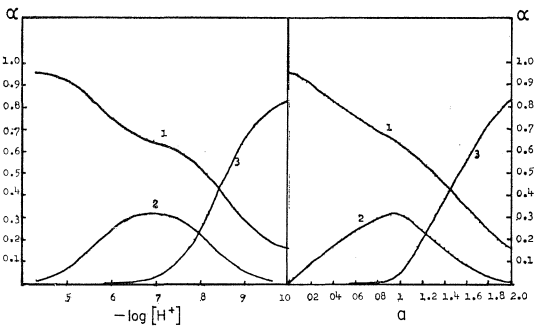

FIG. 2. Distribution curve of metal for the system cobalt-nitrilotriacetate–histamine, each at a total concentration of 0.02 *M*. Curves 1, 2, and 3 correspond to $\alpha_{MeX} = [MeX^-]/C_{Me}$, $\alpha_{MeXLH} = [MeXLH]/C_{Me}$, and $\alpha_{MeXL} = [MeXL^-]/C_{Me}$, respectively.

Discussion

As in previous cases (13, 14), both formation constants K_{f1} and K_{f2} follow the Irving–Williams stability series (15). It is noteworthy that a slight decrease in the relative stability of $CuXL^-$/$NiXL^-$ compared to CuL^{2+}/NiL^{2+} is observed. K_{f2} also conforms to various generalizations frequently observed: for example log K_{f2} is a linear function of log K_1, where K_1 is the formation constant of MeL^{2+}. The overall formation constants $K_s = K_{MeX}K_{f2}$ of the mixed nitrilotriacetate–histamine complex $MeXL^-$ also obey the following empirical relationship observed in previous works (13, 14), K_{MeX} being the formation constant of MeX^-,

$$\log K_s = \alpha \log K_{MeX}K_1 + c$$

In the present case, α assumes a value of 0.70.

It is interesting to note that log K_{f2} is generally greater than log K_{f1} by $\sim$2 log units. In Angelici's work (3) on the reaction of metallic nitrilotriacetates with glycine and glycine esters, similar differences were observed between both types of mixed complexes where the ligands are bi- and monodentate respectively. Although equilibrium constants alone cannot afford direct structural conclusions, the same difference of $\sim$ 2 log units between K_{f1} and K_{f2} might suggest that histamine acts as a monodentate ligand in the protonated mixed complex MeXLH, while the chelate ring is closed in $MeXL^-$.

Furthermore, the tertiary imidazolic nitrogen appears to be the atom actually coordinated to the metal ion in the "open" protonated complex MeXLH; values only slightly higher than those of the present work were obtained for the 1:1 mixed complexes of the same metallic nitrilotriacetates with imidazole which is a monodentate ligand (16). Indeed slightly higher values are expected for the latter system, since the tertiary imidazolic nitrogen of imidazole ($pK_a = 7.0$) is more basic than the one of histamine ($pK_a = 6.0$).

Acid dissociation constants K_i (eq. [4]) of the protonated mixed complex MeXLH can easily be obtained from the results of Tables I and II

$$K_i = K_{f2}\, K_{a1}/K_{f1}$$

TABLE III

Acid dissociation constants* of protonated complexes MeXLH

Me	pK_i
Cu	7.58 ± 0.08
Ni	7.38 ± 0.09
Co	7.93 ± 0.14
Zn	8.41 ± 0.12

*$\mu = 0.1$ ($NaClO_4$), $T = 25$ °C.

The values of pK_i are given in Table III. Assuming the model above, this indicates that the acidity strength of the $-NH_3^+$ group in MeXLH is considerably enhanced by coordination of the tertiary imidazolic nitrogen to the metal nitrilotriacetate. Similar effects on the acidity of unbound groups have been observed for several types of ligands (17, 18) and have been attributed to resonance and inductive effects within the ligands. Although this might act to a certain extent in the present case, we believe that these effects should be small since the amino group is separated from the rest of the molecule by two methylene groups. Therefore the relatively high acidity of the terminal NH_3^+ group would originate to a greater extent from the additional stabilization of the conjugated base $MeXL^-$ by closure of the chelate ring and formation of the mixed complex where both the tertiary imidazolic nitrogen and the terminal amino group are coordinated.

Acknowledgments

We wish to thank the National Research Council of Canada for research grants from which one of us (J.I.) awarded a fellowship to H. Saulnier. We are very thankful to Professor D. D. Perrin who kindly supplied a copy of the computer program SCOGS and for his helpful advice for its utilization, and to Professor R. S. Tobias for detailed information on the least-squares refinement treatment. The use of the CDC 3400 computer of the "Centre de Calcul de l'Université de Montréal" is also acknowledged.

Coordination of silicon tetrafluoride with pyridine and other nitrogen electron-pair donor molecules[1]

JACQUES P. GUERTIN[2] AND MARIO ONYSZCHUK
Department of Chemistry, McGill University, Montreal, Quebec

Received August 22, 1968

Silicon tetrafluoride reacts with pyridine, pyrrolidine, and piperidine forming solid 1:2 complexes. With ethylenediamine, the stable 1:1 complex results. These compounds are easily hydrolyzed and sublimed and have no measurable vapor pressure at 25°. Hydrolysis of $SiF_4 \cdot 2C_5H_5N$ with aqueous HF produces pyridinium hexafluorosilicate (**4**), $(C_5H_5NH^+)_2SiF_6^{2-}$. Ethylenediamine readily displaces pyridine from $SiF_4 \cdot 2C_5H_5N$, forming $SiF_4 \cdot NH_2(CH_2)_2NH_2$. Infrared spectra of the complexes are compared in the 900–280 cm^{-1} region, but it was not possible to decide whether the pyrrolidine and piperidine complexes are *cis*- or *trans*-octahedral.

Canadian Journal of Chemistry, **47**, 1275 (1969)

Introduction

Campbell-Ferguson and Ebsworth (1) recently confirmed that $SiF_4 \cdot 2py$ is the only complex formed between silicon tetrafluoride and pyridine (abbreviated py in formulae), contrary to previous reports of $SiF_4 \cdot py$ (2, 3) and $2SiF_4 \cdot 3py$ (4) complexes. We had also found that under a variety of experimental conditions silicon tetrafluoride and pyridine produce only $SiF_4 \cdot 2py$ (5). Our results are now reported in detail together with data for complexes of silicon tetrafluoride with pyrrolidine, piperidine, and ethylenediamine.

Results and Discussion

Preparation and Properties of $SiF_4 \cdot 2py$

Various methods of preparation always yielded only the 1:2 complex, $SiF_4 \cdot 2py$, when silicon tetrafluoride was mixed with pyridine at 25°, as summarized in Table I. The white solid complex melted at 170–180° (with decomposition), had no measurable vapor pressure at 25°, but could be sublimed in vacuum at 60–80° (without decomposition).

Although the authors' methods were followed carefully, $2SiF_4 \cdot 3py$ (4) and $SiF_4 \cdot py$ (2, 3) could not be synthesized. Schnell (6) and, more recently, Campbell-Ferguson and Ebsworth (1) obtained only the 1:2 complex. The reports of combining ratios other than 1:2 are likely incorrect with the error probably due to loss of pyridine by $SiF_4 \cdot 2py$ on hydrolysis (1).

TABLE I

A summary of analytical data obtained for $SiF_4 \cdot 2py$ prepared by various methods

Method of synthesis	Product mole ratio, py/SiF_4	Fluorine elemental analysis (%)*
Direct gas–liquid, vacuum,		
(*i*) with excess SiF_4 present initially	2.00	28.60
(*ii*) with excess py present initially	2.00	28.60
(*iii*) after sublimation of solid product	†	29.01
py-Diethyl ether solution, stirred in a vacuum	†	28.58
Bubbling SiF_4 into py-diethyl ether solution	†	29.17
Tensimetric titrations,		
(*i*) SiF_4 with py	2.01	28.90
(*ii*) py with SiF_4	2.01	28.85

*Anal. Calcd. for $SiF_4 \cdot 2py$: F, 28.95. Anal. Calcd. for $SiF_4 \cdot py$: F, 41.50.
†In these cases it was not possible to determine combining ratios directly.

Crystalline $SiF_4 \cdot 2py$ reacted with aqueous HF (48%) to produce a colorless solution. Gentle boiling of the resultant solution to dryness yielded a white solid, which after vacuum sublimation at 165° was pure pyridinium hexafluorosilicate (**4**), $(C_5H_5NH^+)_2SiF_6^{2-}$, in 100% yield. This compound was not hygroscopic and melted without decomposition at 154–157°, with some sublimation.

The reaction of $SiF_4 \cdot 2py$ with aqueous HF is similar to a simple hydrolysis using only water, except that in the latter case SiO_2 and pyridine are formed as well as $(C_5H_5NH^+)_2SiF_6^{2-}$. The overall reaction with aqueous HF may be written as follows

[1]This work was supported by a grant from the Defence Research Board of Canada (Grant number 9530-20, Project D-46-95-30-20).
[2]Present address: Bell Telephone Laboratories, Reading, Pennsylvania.

$$SiF_4 \cdot 2py + 2H_3O^+ + 2F^- \longrightarrow 2pyH^+ + SiF_6^{2-} + 2H_2O$$
$$\downarrow -2H_2O$$
$$(pyH^+)_2SiF_6^{2-}$$

The complex $SiF_4 \cdot 2py$ was insoluble in the following solvents: methanol, carbon tetrachloride, benzonitrile, pyridine, benzene, nitrobenzene, monochlorobenzene, chloroform, methyl iodide, thiophene, methylene chloride, methylene bromide, mesitylene, acetonitrile, and a few fluorinated aromatic solvents such as perfluorodecalin, 2-chloro-5-nitrobenzotrifluoride, trichlorobenzotrifluoride, dichlorobenzotrifluoride, meta-nitrobenzotrifluoride, and benzotrifluoride[3]. It appeared to be soluble to the extent of about 5 g/l in nitromethane and bis(2-methoxyethyl)ether. Due to the low volatility of this ether at 25°, it was not possible to evaporate the solvent in order to examine whether the complex would precipitate from solution unchanged; moreover, heating the solution above 25° resulted in the decomposition of the complex.

A careful investigation of the $SiF_4 \cdot 2py$ – nitromethane system revealed that as little as 0.01% water in the nitromethane, present even after it was treated with calcium hydride, could account for the observed "solubility". The solid remaining after evaporation of the solvent contained $SiF_4 \cdot 2py$, $(C_5H_5NH^+)_2SiF_6^{2-}$, and a little SiO_2, indicative of hydrolysis.

Ethylenediamine (abbreviated en in formulae) converted $SiF_4 \cdot 2py$ almost quantitatively into $SiF_4 \cdot en$. The stoichiometry of the reaction was shown by analysis of the amount of pyridine liberated to be

$$SiF_4 \cdot 2py + en \rightarrow SiF_4 \cdot en + 2py$$

The fact that the amount of ethylenediamine consumed was greater than the theoretical value was attributed to some degradation of ethylenediamine during the reaction, as evidenced by a slight yellowing of the product mixture.

Preparation and Properties of $SiF_4 \cdot 2(CH_2)_4NH$, $SiF_4 \cdot 2(CH_2)_5NH$, and $SiF_4 \cdot en$

Direct vacuum synthesis of the complexes at 25° invariably yielded slightly impure pale yellow solids although combining ratios were satisfactory. With pyrrolidine and piperidine the 1:2 complexes, $SiF_4 \cdot 2(CH_2)_4NH$ and $SiF_4 \cdot 2(CH_2)_5NH$, respectively, were obtained; with ethylenediamine, a bidentate ligand, the 1:1 complex, $SiF_4 \cdot en$, resulted. Vacuum sublimation gave analytically pure white solids.

The purest complexes were obtained by bubbling silicon tetrafluoride through precooled solutions of the base in acetonitrile. The precipitated solids were always white, although the solvent had a tinge of yellow, and the solids analyzed to the pure complexes without further purification.

Infrared Spectra of the Complexes

Tables containing infrared (i.r.) absorption band peak positions and suggested assignments in the range 4000–280 cm^{-1} for $SiF_4 \cdot 2py$, $(pyH^+)_2SiF_6^{2-}$, $SiF_4 \cdot en$, $SiF_4 \cdot 2(CH_2)_4NH$, and $SiF_4 \cdot 2(CH_2)_5NH$, all in Nujol and KBr disk form, have been filed with the Depository of Unpublished Data[4]. Spectra in the regions 900–600 cm^{-1} and 600–280 cm^{-1} are reproduced in Fig. 1 in order that band contours and number of bands may be compared.

Previously, Beattie and Webster (7) and Hickie (8) decided that $SiF_4 \cdot 2py$ was *trans*-octahedral on the basis that only a single band was observed in the Si—F bond stretching region, consistent with D_{4h} symmetry of the complex. Although this approach was criticized for valid reasons (9), Bain *et al.* (10) have determined by a three-dimensional X-ray analysis of single crystal $SiF_4 \cdot 2py$ that the complex is molecular with a centrosymmetric *trans* configuration. An X-ray analysis has also confirmed that $SiCl_4 \cdot 2py$ is *trans* octahedral, contrary to earlier i.r. data which, because there were three bands in the Si—Cl stretching region, had been interpreted in terms of *cis* (C_{2v}) configuration (11, 8). After a more complete analysis of the i.r. and Raman spectra of $SiCl_4 \cdot 2py$, Beattie *et al.* (12) were unable to assign the structure decisively even though "the spectroscopic evidence in the 500 cm^{-1} region still looks remarkably *cis*". Coupling of vibrational modes and removal of degeneracies gives the multiple bands in the 300 to 500 cm^{-1} region. This clearly illustrates the danger of

[3]We are very grateful to Professor W. F. Forbes of the Department of Chemistry, University of Waterloo, for having kindly provided purified samples of the fluorinated aromatic solvents.

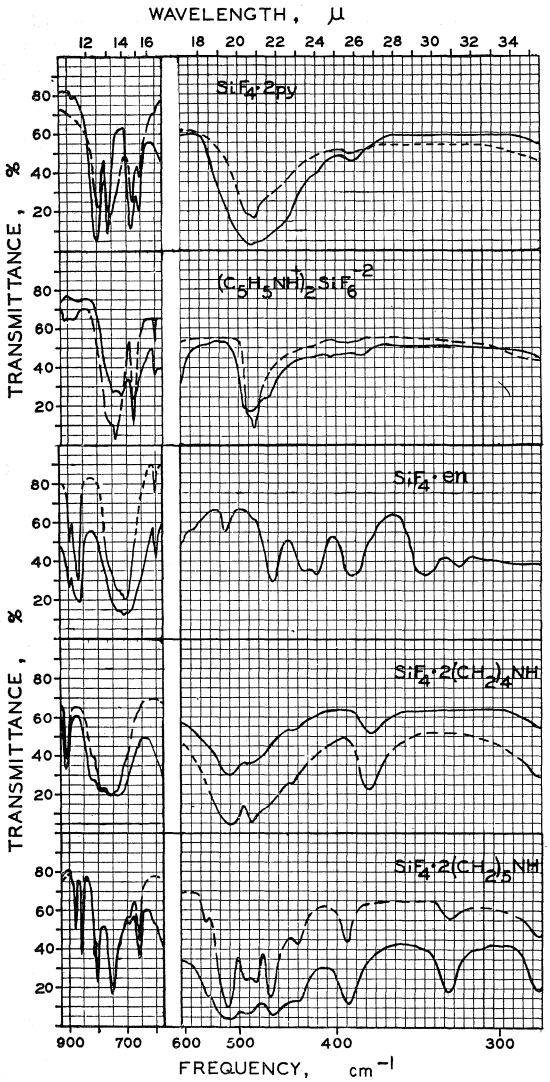

FIG. 1. Infrared spectra of the complexes in Nujol mull (——) and KBr disk (– – – –).

making structural assignments on the basis of the number of bands observed in the solid state spectra of $MX_4 \cdot 2L$ complexes. Accordingly, it is not possible to decide whether the pyrrolidine and piperidine complexes are *cis* or *trans* even though the measured spectra look *cis*.

Experimental

Volatile materials were manipulated in a standard Pyrex glass high-vacuum system which had stopcocks and joints lubricated with No. 90 Kel-F grease. Hygroscopic solids and nonvolatile liquids were manipulated in the dry nitrogen atmosphere of a glove box. Bubbling silicon tetrafluoride through a precooled solution of a base in an inert solvent proved to be the most convenient preparatory method for the complexes. The purity of the volatile compounds was determined by measurements of their vapor pressure, molecular weights, i.r. spectra, and melting points.

Infrared spectra in the range 4000–650 cm^{-1} were recorded on a Perkin–Elmer Model 137 Infracord spectrophotometer equipped with sodium chloride optics. When greater resolution was required, spectra were measured on a grating Perkin–Elmer Model 421 spectrophotometer. This instrument was also used for measurements in the 650–265 cm^{-1} range by replacing the grating with a CsBr prism interchange unit.

Spectra of solids were taken in KBr disks and in Nujol or Fluorolube mulls. The spectra of liquids were taken using fixed or variable space NaCl liquid cells or more simply using a thin film between two NaCl plates. The spectra of gases were taken at known pressures using a cylindrical gas cell (10 cm length and 2.5 cm radius) equipped with Viton O-rings and screw caps for the 7.5 mm thick NaCl windows.

Measurements in the 650–265 cm^{-1} range were made on samples in pure liquid (or in Nujol mull-form) placed between CsBr plates, the delicate surfaces of which were protected by 7.0 μ polyethylene film (Dow Chemical Company "Handi-Wrap"). This film does not absorb in the 650–265 cm^{-1} region. It was found that thin KBr pellets could also be used for measurements to 300 cm^{-1}.

Ultraviolet (u.v.) spectra used in the displacement reaction were recorded on a Perkin–Elmer Model 350 spectrophotometer.

Anhydrous pyridine, nitromethane, acetonitrile, ethylenediamine, pyrrolidine, piperidine (all Fisher reagent grade), and bis-(2-methoxyethyl)ether (Matheson, Coleman and Bell, practical grade) were obtained by refluxing the commercial product over CaH_2 for a few hours and collecting the distillates boiling at 116°/754 mm; 101.5°/757 mm; 82°/760 mm; 117°/751 mm; 86°/748 mm; 106°/756 mm; 163°/750 mm respectively; these compare well with the published normal boiling points (13). Hydrofluoric acid, 48% (Fisher, reagent grade), diethyl ether (Mallinckrodt, reagent grade), and absolute ethyl alcohol (Gooderham and Worts, U.S.P.) were used without further purification. Commercial silicon tetrafluoride (Matheson, 99.5%) was purified by several low-temperature vacuum distillations.

Preparation of $SiF_4 \cdot 2py$

(i) In the direct vacuum synthesis, SiF_4 (35.45 mmoles) was condensed over C_5H_5N (27.12 mmoles) and the mixture slowly warmed to 25°. Distillation at −78° yielded SiF_4 (21.90 mmoles), indicating a combining ratio, 1:2.00, corresponding to the complex, $SiF_4 \cdot 2py$. Fluorine analysis showed that the complex was pure.

Anal. Calcd. for $SiF_4 \cdot 2py$: F, 28.95. Found: F, 28.60.

(ii) The same complex resulted when excess C_5H_5N was used initially. Thus, C_5H_5N (40.40 mmoles), when condensed over SiF_4 (15.00 mmoles) and slowly warmed to 25°, produced unreacted C_5H_5N (10.38 mmoles) recovered by distillation at 25°, and a white solid which contained SiF_4 and C_5H_5N in a mole ratio, 1:2.00, as required for the complex, $SiF_4 \cdot 2py$. Found: F, 28.60.

(iii) Silicon tetrafluoride (15.10 mmoles) was condensed over a 10.5% (by weight) solution of C_5H_5N

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

(12.10 mmoles) in diethyl ether (183.0 mmoles) and the mixture was warmed slowly to 25° and stirred magnetically. The resulting insoluble white precipitate was freed of solvent by vacuum distillation at 25° and an analysis for fluorine confirmed that it was pure $SiF_4 \cdot 2py$. Found: F, 28.58.

(iv) Silicon tetrafluoride was bubbled through solutions of C_5H_5N in diethyl ether (1.5, 3.0, and 6.0% by weight) and C_5H_5N in acetonitrile (10% by weight) with the resultant production of copious quantities of white insoluble precipitates which also proved to be the complex $SiF_4 \cdot 2py$. Found: F, 29.40, 29.09, 29.00 for the diethyl ether solution preparation, and 28.64 for the acetonitrile solution preparation. Extensive pumping under vacuum did not change the composition of the samples.

Tensimetric Titration

In the tensimetric titration of SiF_4 (17.52 mmoles) with C_5H_5N, the plots of which are given in (5), pressures were measured after the temperature of the mixture had been decreased from 25 to −78°. The pressure decreased linearly to zero at a mole ratio, 1:2.01 (corresponding to the addition of 35.25 mmoles C_5H_5N) indicating the formation of only the 1:2 complex, $SiF_4 \cdot 2py$.

In the case of the reverse titration of C_5H_5N (31.02 mmoles) with SiF_4, using the above temperature conditions, the pressure remained zero until the mole ratio had decreased to 2.01 (corresponding to the addition of 15.45 mmoles SiF_4), when it increased rapidly as more SiF_4 was added. This confirmed the formation of only the 1:2 complex.

Displacement Reaction with Ethylenediamine

Under dry conditions, a previously prepared sample of $SiF_4 \cdot 2py$ (0.9103 g) was mixed with $NH_2(CH_2)_2NH_2$ (1.8198 g) and the mixture was kept at 25° for 1 h. The volatile components (2.0845 g) were then distilled from the remaining yellowish nonvolatile residue and condensed into a weighing tube. An i.r. spectrum confirmed that the solid residue was $SiF_4 \cdot en$ free from $SiF_4 \cdot 2py$.

Before the volatile components were analyzed for pyridine by quantitative u.v. spectroscopy, u.v. spectra of ethyl alcohol solutions of pyridine (4.680×10^{-4} g/l, $A = 1.620$) and ethylenediamine (4.028×10^{-2} g/l) were recorded separately and when equal volumes of the two solutions were mixed together. There was no interference between pyridine and ethylenediamine.

An ethyl alcohol solution of the volatile components from the reaction gave a satisfactory absorbance (4.364×10^{-4} g/l, $A = 0.395$) and it contained 1.142×10^{-4} g/l of C_5H_5N, corresponding to an almost quantitative displacement of C_5H_5N from the original sample of $SiF_4 \cdot 2py$.

Anal. Calcd. for 100% displacement: 0.549 g. Found: 0.546 g C_5H_5N.

Calculations were also made of the $NH_2(CH_2)_2NH_2$ consumed but the value found was greater than the theoretical value.

Anal. Calcd. for 100% displacement: 0.2085 g. Found: 0.2798 g.

Reactions of $SiF_4 \cdot 2py$ with Aqueous HF

The complex, $SiF_4 \cdot 2py$ (3.21 mmoles) was mixed with excess HF (48%) in a Pt crucible and the resultant colorless solution boiled gently to dryness. Heating the white solid in an oven at 105° for 2 h did not remove all the unreacted HF.

Anal. Calcd. for $(C_5H_5NH)_2SiF_6$: F, 37.7. Found: F, 39.2.

Vacuum distillation at 165° gave pure $(C_5H_5NH)_2SiF_6$. Found: F, 37.3; in 100% yield (3.21 mmoles).

"Solubility" of $SiF_4 \cdot 2py$ in Nitromethane

A colorless solution and a little insoluble, grey, jelly-like material resulted when $SiF_4 \cdot 2py$ (19.05 mmoles) was mixed with nitromethane (100 ml). After filtering the insoluble material, the i.r. of which showed that it was SiO_2 (0.02 g) (broad ν(Si—O) at 1095 cm^{-1}), the solution was evaporated to dryness at 25° and a white solid remained. Infrared measurement and elemental analysis showed that it was $(C_5H_5NH)_2SiF_6$ (11.88 mmoles) containing a trace of $SiF_4 \cdot 2py$ and/or SiO_2.

Anal. Calcd. for $(C_5H_5NH)_2SiF_6$: F, 37.7; Si, 9.3; N, 9.25; C, 39.7; H, 4.0. Found: F, 36.9; Si, 10.3; N, 8.2; C, 39.1; H, 4.1.

Therefore, the mole ratio of $(C_5H_5NH)_2SiF_6$ formed to $SiF_4 \cdot 2py$ consumed was 1:1.60.

Preparation of $SiF_4 \cdot en$

A mixture of SiF_4 (64.20 mmoles) and $NH_2(CH_2)_2NH_2$ (60.20 mmoles) was slowly warmed from −195 to 25°. Distillation at −78° of the unreacted SiF_4 (5.36 mmoles) indicated that the reaction had occurred in a mole ratio, 1:1.02, corresponding to the complex, $SiF_4 \cdot en$.

The complex was further purified by vacuum sublimation at 120°. Analysis indicated that it was pure.

Anal. Calcd. for $SiF_4 \cdot en$: F, 46.2. Found: F, 46.0.

Since $NH_2(CH_2)_2NH_2$ was found to react with stopcock grease, it was measured and introduced by a syringe (14).

Preparation of $SiF_4 \cdot 2(CH_2)_4NH$

When SiF_4 (5.99 mmoles) was condensed over $(CH_2)_4NH$ (8.63 mmoles) and the mixture slowly warmed from −195 to 25°, a yellow-white solid formed. It was apparent from the amount of unreacted SiF_4 (1.72 mmoles) distilled at −78° that SiF_4 and $(CH_2)_4NH$ had reacted in a mole ratio, 1:2.02, forming the complex, $SiF_4 \cdot 2(CH_2)_4NH$. Further purification by vacuum sublimation at 80° gave the pure, white, 1:2 complex.

Anal. Calcd. for $SiF_4 \cdot 2(CH_2)_4NH$: F, 30.85. Found: F, 30.86.

Using the same "bubbling technique" as that used to prepare $SiF_4 \cdot 2py$, SiF_4 was bubbled through a 10% solution of $(CH_2)_4NH$ in acetonitrile maintained at 0°. Analysis of the resultant white product indicated the formation of pure $SiF_4 \cdot 2(CH_2)_4NH$. Found: F, 30.85.

Preparation of $SiF_4 \cdot 2(CH_2)_5NH$

Again, using the "bubbling technique" and identical conditions as those used for the preparation of $SiF_4 \cdot 2(CH_2)_4NH$, the white solid complex, $SiF_4 \cdot 2(CH_2)_5NH$ was prepared and needed no further purification.

Anal. Calcd. for $SiF_4 \cdot 2(CH_2)_5NH$: F, 27.65. Found: F, 27.56.

Sublimation at 80° did not change its composition. Found: F, 27.60.

Acknowledgments

We thank the National Research Council of Canada and the Defence Research Board for financial assistance in the form of annual grants (to M.O.). We are grateful to G. H. Hickie for his contributions in the interpretation of the infrared measurements.

Infrared spectra of the interactions of aniline and porous glass surfaces

M. J. D. Low and V. V. Subba Rao
Department of Chemistry, New York University, New York 10453

Received August 15, 1968

Infrared spectra were recorded of aniline sorbed on highly dehydroxylated, deuterated, and on fluoridated porous glass as well as on pure and boria-impregnated silica. The results suggest that two types of weak interactions involving the surface SiOH and B—OH groups occurred; the nitrogen atom of the amine was hydrogen bonded to surface OH and there was an interaction between OH groups and the π system of the aromatic ring. Some aniline chemisorbed on surface boron via the nitrogen atom of the amine group. Some aniline chemisorbed dissociatively to form secondary amine structures bonded through the nitrogen to surface boron atoms and new B—OH groups formed. Surface boron impurity acted as an adsorption and dissociation center.

Recent studies have provided evidence that much of the reactivity of porous glass surfaces could be attributed to the presence of impurities (1–7). With NH_3 sorption on highly dehydrated porous glass (4), infrared spectra indicated that residual boron played a role in physical adsorptions, dissociative chemisorption, as well as in an undissociative chemisorption involving the coordination of NH_3 to boron present on the glass. The surface $\equiv B{:}NH_3$ complex was weakly bonded, but may have been the precursor of dissociated, more tightly held species. In order to determine if similar surface complexes were formed with molecules larger than NH_3, we have studied the sorption of aniline on highly degassed, deuterated, and fluoridated porous glass as well as on pure and boria-impregnated silicas.

Experimental

The glass adsorbents were 10 × 25 × 1 mm pieces of Code 7930 porous glass purchased from Corning Glass Works. Silica and 3% $B_2O_3 - SiO_2$ samples were prepared from Cab-O-Sil silica (G. Cabot Co., Boston, Mass.). Most experimental details including the dehydration, deuteration, and fluoridation of specimens have been described elsewhere (1–5). Reagent grade (Matheson Co.) aniline was dried over Na_2SO_4 and distilled 4 times; the final purification was done by repeated freezing and thawing in vacuo. A thermocouple gauge was used to measure the pressure of adsorbate. Spectra were recorded with Perkin–Elmer models 521 and 621 spectrophotometers. The ordinates of spectra shown in the various Figures are displaced to avoid overlapping of traces. The number at the left of each spectrum shows the % transmittance for the particular spectrum at 4000 cm^{-1}.

Results

Trace A of Fig. 1 is a typical "background" spectrum of highly-degassed porous glass; the prominent features are a band at 3748 cm^{-1} due to surface silanols and a smaller but sharp band at 3703 cm^{-1} due to surface B—OH groups (1–5), hereafter termed SiOH and B—OH bands. When such a glass specimen was exposed to aniline vapor at room temperature at increasingly higher pressures from 10 to 200 μ and was then degassed, the surface hydroxyl bands were altered and a series of absorptions caused by sorbed aniline were observed. A typical sorption–desorption cycle is illustrated by the alphabetical sequence of spectra A to L of Figs. 1 and 2 (spectra X and Y were taken from a different sequence and are presented to illustrate intermediate stages). The salient points of the interactions can be summarized as follows.

(*a*) The first bands to appear when a freshly degassed specimen was exposed to aniline were small, sharp bands at 3361 and 3301 cm^{-1} in the N—H region and a small, sharp band at 3050 cm^{-1} in the C—H region. These grew with increasing pressure, and a band near 3440 cm^{-1} with a shoulder near 3420 cm^{-1} appeared. The 3361 cm^{-1} band became slightly asymmetric and a shoulder appeared near 3350 cm^{-1}; similarly, shoulders were observed near 3280 and 3230 cm^{-1} on the 3301 cm^{-1} band, e.g. spectrum B, Fig. 1. The 3050 cm^{-1} band broadened and shifted to 3060 cm^{-1}, and smaller bands appeared at 3030, 3185, 3110, and 3137 cm^{-1}.

(*b*) With increasing pressure, bands grew at 3480–3490, 3410, 3340, and 3245 cm^{-1}; the 3060 cm^{-1} band grew and then the smaller bands near it became difficult to define. The 3361 and 3301 cm^{-1} bands did not shift but were swamped by the broad and strong 3340 and 3245 cm^{-1} bands. Eventually, the entire region from 3500 to

For personal use only.

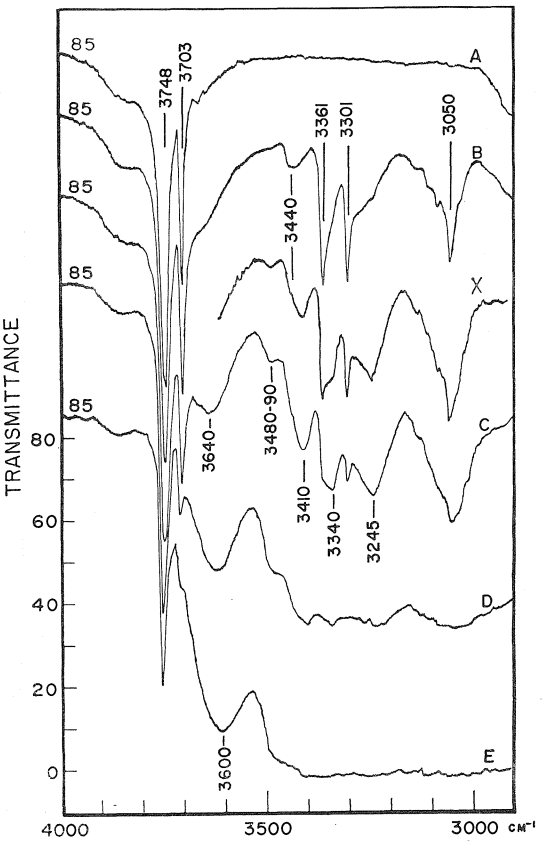

FIG. 1. Aniline sorption: porous glass. After the degassing at 750° for 24 h (spectrum A), the specimen was exposed to aniline at room temperature at the following pressures in μ: B, 13; C, 35; D, 65; E, 150. Spectrum X is taken from a different sequence after exposure to 20 μ aniline.

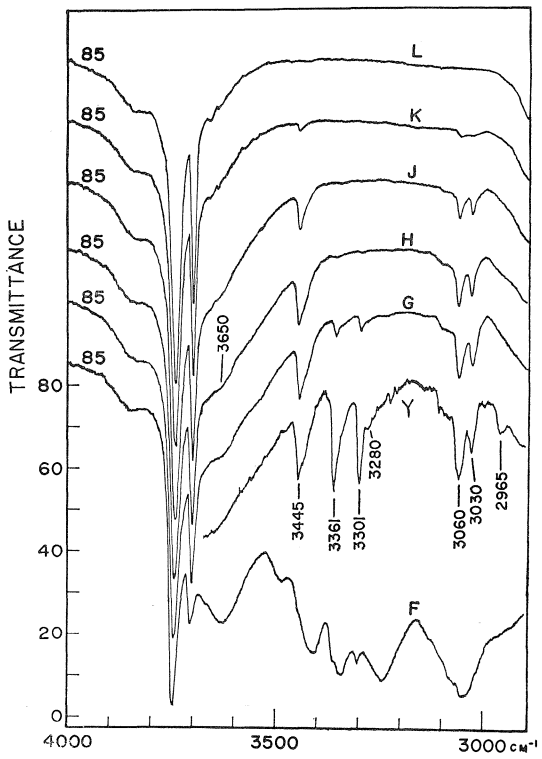

FIG. 2. Aniline desorption: porous glass. Continuation of the sequence of Fig. 1. The temperature (°C) at which the sample was degassed and the time (h) were: F: room temperature, 15; G: 100, 15; H: 150, 15; J: 200, 6; K: 300, 10; L: 400, 3. Spectrum Y was taken from a different sequence after degassing at 100° for 1 h.

3000 cm^{-1} became opaque, there being an intense absorption from 3500 to 2000 cm^{-1}.

(*c*) Pumping at room temperature restored some transmittance below 3500 cm^{-1} but even after long times intense absorptions remained, e.g. spectrum F, Fig. 2. However, degassing at 50 or 100° removed much of the adsorbed aniline. The bands at 3480, 3410, 3340, and 3245 cm^{-1} declined. Bands remained at 3445 and 3361 cm^{-1}, (both asymmetric on the low wavenumber side), and at 3301 cm^{-1} with a shoulder near 3280 cm^{-1}. In the C—H region, the broad and almost structureless 3360 cm^{-1} band declined and split into two bands at 3060 and 3030 cm^{-1}; there were weak absorptions near 3130, 3110–3070, 2965, and 2920 cm^{-1}, e.g. spectrum Y, Fig. 2. All absorptions in the N—H and C—H regions decreased on degassing at higher temperatures. The 3061 and 3030 cm^{-1} bands decreased more rapidly than the 3445 cm^{-1} band and disappeared above 200°. All bands disappeared above 300°, e.g. spectra G–L, Fig. 2.

(*d*) Initial aniline sorption brought about an absorption in the range 3700–3500 cm^{-1}. A definite band formed, grew in intensity, and the band center shifted from about 3650 to 3600 cm^{-1}, e.g. spectra A–E, Fig. 1. The broad absorption, hereafter termed the 3600 cm^{-1} band, decreased in intensity and shifted towards higher wavenumbers on mild degassing (spectrum F, Fig. 2), and declined abruptly along with the removal of much of the sorbed aniline on degassing at higher temperature, e.g. spectra Y, G, Fig. 2. However, even after most of the sorbed aniline had been removed, a weak but definite band remained near 3650 cm^{-1}, e.g. spectra G, H, Fig. 2. The band was hardly noticeable after a 200° degassing and was not detected above 200°.

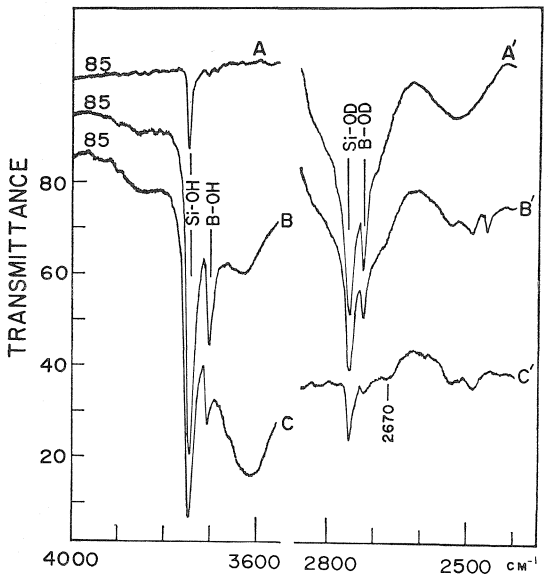

FIG. 3. Aniline sorption: deuterated porous glass. A,A′: after deuteration and degassing; B,B′: after exposure to 27 μ aniline; C,C′: after exposure to 62 μ aniline.

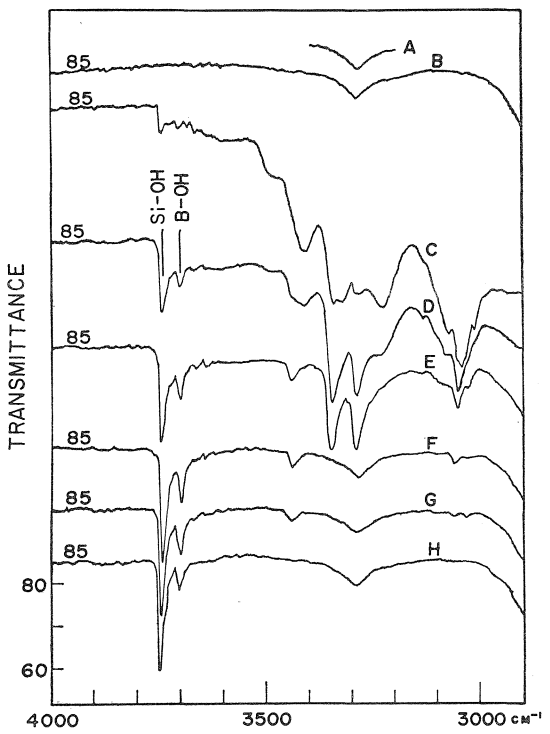

FIG. 4. Reactions on fluoridated porous glass. A: cell windows contaminated by NH_4F; B: fluoridated and degassed specimen; C: after exposure to 170 μ aniline at room temperature. The sample was then degassed at the following temperatures (°C) and times (h): D: room temperature, 12; E: 100, 1; F: 150, 6; G: 200, 15; H: 300, 10.

(*e*) During the sorption part of a cycle the B—OH band broadened, declined, and shifted to lower wavenumbers. At the highest pressures the band frequently disappeared completely. On desorption, the band reappeared near 3700 cm^{-1} and, with progressive degassing, shifted towards 3703 cm^{-1} and increased in intensity. The B—OH band was larger at the completion than at the beginning of a cycle. The SiOH band similarly declined in intensity and shifted to 3745 cm^{-1} with increasing adsorbate pressure, and then regained its original position and intensity upon degassing. However, the increase in transmittance of the sample at wavenumbers higher than the SiOH band and the decrease brought about by the 3600 cm^{-1} band make it difficult to evaluate small changes in the OH bands during a cycle.

Spectra were recorded of the interactions of aniline and deuterated porous glass. Some results are shown in Fig. 3. A deuterated specimen showed bands at 2756 and 2723 cm^{-1} due to surface OD groups (2) and weak bands at 3744 and 3702 cm^{-1} due to residual OH groups. When aniline was sorbed, the OH bands increased and the OD bands declined rapidly. A broad band formed near 2670 cm^{-1}, analogous to the 3600 cm^{-1} band. Small bands formed near 2335, 2490, 2460, and 2400 cm^{-1}, attributed to deuteroaniline. Bands in the N—H and C—H regions were entirely like those found with hydroxylated specimens. On desorption, the small bands in the 2700–2400 cm^{-1} region disappeared and the OD bands declined slightly; other changes in the N—H and C—H regions were similar to those found with hydroxylated specimens.

Figure 4 shows some results obtained with fluoridated porous glass. Spectrum B shows that of the specimen after fluoridation and degassing; all OH groups had been removed. The cell windows were irreversibly contaminated by NH_4F during the fluoridation procedure, leading to a stable band in the 3400–3200 cm^{-1} region. During an adsorption–desorption cycle, the bands and changes in bands below 3500 cm^{-1} found with fluoridated glass were similar to those occurring with hydroxylated specimens. However, the amount of aniline taken up by the fluoridated surface, estimated from the intensity

For personal use only.

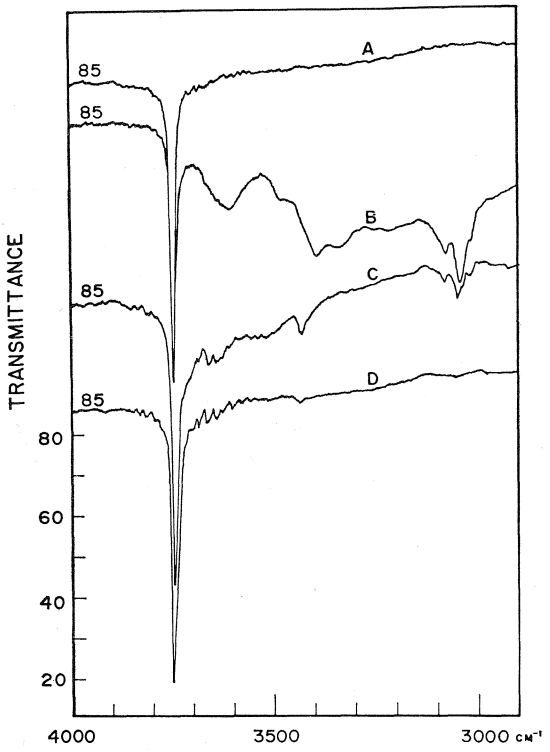

FIG. 5. Aniline sorption: Cab-O-Sil. A: after degassing; B: after exposure to 200 μ aniline at room temperature; C: after degassing at room temperature for 15 h; D: after degassing at 300° for 15 h.

of the bands, was less than that sorbed by a hydroxylated surface. The 3600 cm^{-1} band was not observed. Also, small bands at 3744 and 3700 cm^{-1} were built up.

Some experiments were also carried out with pure Cab-O-Sil silica and with boria-impregnated Cab-O-Sil. Exposure of pure Cab-O-Sil to aniline diminished the 3747 cm^{-1} OH band and caused absorption at 3600, 3470, 3390, 3325, 3070, and 3010 cm^{-1}, e.g. Fig. 5. Evacuation at room temperature restored the OH band and removed other absorptions; small bands remained at 3435 and 3050 cm^{-1}. The two sharp bands at 3361 and 3301 cm^{-1} found with porous glass were not observed.

The results obtained with a Cab-O-Sil – 3% B_2O_3 specimen were quite similar to those obtained with porous glass. Some results are shown in Fig. 6. The sharp 3361 and 3301 cm^{-1} bands were observed, and there was an increase in the B—OH band.

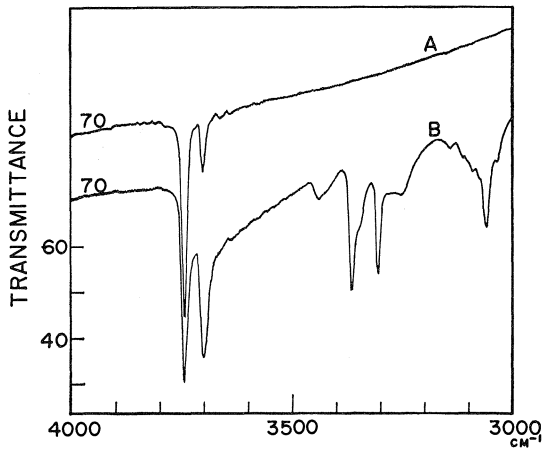

FIG. 6. Aniline sorption: 3% $B_2O_3 \cdot SiO_2$. A: base spectrum; B: after exposure to 15 μ aniline, followed by degassing at room temperature for 15 h.

Discussion

Infrared spectra taken in the overtone region of aniline adsorbed on porous glass have been reported by Yaroslavskii and Terenin (8) and on silica–alumina gel by Filimonov (9). Hydrogen bonding to surface hydroxyls and shifts of N—H bands were found. However, as pointed out by Kiselev and Lygin (ref. 10, p. 213), spectra of the overtone region are limited and difficult to analyze, so that a comparison of overtone spectra with the present data is not attempted. Abramov, Kiselev, and Lygin (11) found the OH groups on Aerosil silica to be strongly perturbed by adsorbed aniline, and that the N—H and C—H stretching frequencies of adsorbed aniline were at 3395, 3330, 3044, and 3078 cm^{-1}, in comparison to 3480, 3394, 3038, and 3075 cm^{-1}, respectively, for aniline in CCl_4 solution. The shift in the N—H bands was ascribed to hydrogen bonding to surface hydroxyls via the nitrogen atom of the amine group. The smaller shift in the C—H bands was taken as an indication that π electrons of the aromatic ring interacted with the surface hydroxyls to a smaller extent than the amine group. More recently (12), spectra recorded in situ of aniline adsorbed on Cab-O-Sil from CCl_4 solution showed N—H bands at 3395 and 3300 cm^{-1}, similarly suggesting hydrogen bonding via the amine group. Also a broad band occurred near 3600 cm^{-1} and was attributed to an interaction of the π system of the adsorbed aniline with SiOH groups. Such π–OH inter-

actions were recently described by Galkin *et al.* (13) for a variety of aromatic compounds adsorbed on silica and are reviewed elsewhere (see ref. 10, p. 309). The present data on porous glass show similar effects.

The broad absorption termed the 3600 cm^{-1} band, which appears in conjunction with the intense N—H and C—H bands of adsorbed aniline and can easily be diminished by mild degassing of the adsorbent, e.g. Figs. 1–3, is attributed to a weak hydrogen bonding involving an interaction of the π system of the aromatic ring of adsorbed aniline and surface OH groups (ref. 10, pp. 213 and 309 and ref. 13). Further evidence indicating that hydroxyls were involved in this comes from the experiments with fluoridated glass (Fig. 4), which showed that the 3600 cm^{-1} band was not produced in the absence of OH groups. With hydroxylated surfaces the 3600 cm^{-1} band was broad and structureless, so that it is not possible to discern individual interactions of the benzene moiety with SiOH or B—OH groups. However, both types of OH groups were diminished by aniline adsorption, so that it is reasonable to assume that each OH species was involved in the same type of interaction.

The spectrum of aniline adsorbed on Aerosil showed a broad absorption near 3600 cm^{-1} which was attributed to bound and intraglobular OH groups; a second, broader absorption near 3200 cm^{-1} was attributed to perturbed hydroxyls (see ref. 11, Fig. 1, spectrum 3). However, the spectrum indicates that the Aerosil sample was hydroxylated to a considerable extent; the 3600 cm^{-1} absorption may well have been caused by the π–OH interaction. A distinct absorption band below 3600 cm^{-1} ascribable to the type of OH perturbation reported for the Aerosil was not found in the present data. However, a series of spectra recorded at increasing aniline pressures, e.g. Figs. 1 and 2, showed that although individual bands did not increase greatly, all bands broadened and the entire region below 3500 cm^{-1} decreased markedly in transmittance, much as if the discrete bands were superimposed on a much broader absorption. In view of the large shifts produced by strongly hydrogen bonded adsorbates (11, 13, and 10, p. 309), the strong absorption below 3500 cm^{-1} can be attributed to SiOH and B—OH perturbed by the hydrogen bonded aniline. However, when appreciable amounts of aniline were adsorbed, the transmittance decreased appreciably not only in the range where a "perturbed OH band" would be expected, but over the entire range from 3500 to 2000 cm^{-1}. This might suggest that a continuous absorption occurred in addition to the absorption produced by direct hydrogen bonding. A similar effect was found with the adsorption of NH_3 on porous glass (4, 14). Cant and Little (14) attributed a continuous absorption to a rapid exchange of the surface hydroxyl proton with the adsorbed NH_3, in analogy to a similar effect found with the polystyrene – sulfonic acid – water system where the continuous absorption was shown to originate in the high exchange probability of a proton in the strongly hydrogen-bonded system (15). Such a mechanism might account for a portion of the intense absorption found with aniline – porous glass. The rapid exchange of adsorbed aniline with surface OD groups, e.g. Fig. 3, would support such a mechanism.

Spectra of aniline adsorbed on pure Cab-O-Sil show bands at 3390 and 3325 cm^{-1} in close agreement with earlier work (11, 12). These bands are assigned to the N—H stretching vibration of adsorbed aniline, shifted because of hydrogen bonding between the hydrogen of SiOH groups and the nitrogen atom of the amine group (8–12). With porous glass, however, comparable bands are observed at 3410 and 3340 cm^{-1} (the absorption at 3245 cm^{-1} is a combination band). The difference in the N—H band positions on pure silica and on porous glass is attributed to the presence of B—OH groups on porous glass. It is considered that absorptions due to hydrogen bonding to B—OH groups contribute to the 3390 and 3325 cm^{-1} absorptions, so that each of the 3410 and 3340 cm^{-1} bands found with porous glass corresponds to two strongly overlapping bands. Support for this view comes from the fact that the 3390 and 3325 cm^{-1} bands with pure silica can be shifted to 3410 and 3340 cm^{-1} by impregnating the silica with boria, thereby producing surface B—OH groups, e.g. Fig. 6. The results thus suggest the existence of 3 types of weak interactions between aniline and surface OH groups. There appear to be somewhat stronger interactions also. Sharp bands occurred at 3361 and 3301 cm^{-1} with porous glass, but not with pure silica. The bands were observed after those due to hydrogen-bonded aniline had been removed, so that the species responsible for the

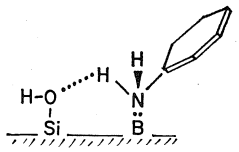
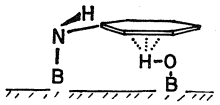
sharp bands was more strongly bonded than most of the adsorbed aniline. The pair of bands agrees well with Bellamy and Williams' relation between asymmetric and symmetric stretching frequencies (16), apparently does not shift with changes in intensity, and is not far from the positions of the N—H stretching frequencies of hydrogen bonded aniline. Also, the bands can be induced with silica by impregnating the silica with boria. The 3361 and 3301 cm^{-1} bands are consequently assigned to the asymmetric and symmetric N—H vibrations of the amine group of aniline, coordinated to surface boron, structure **1**. The slight asymmetry on the low wavenumber side of each band in the absence of physically adsorbed aniline may be caused by interaction with neighboring OH groups.



1



2

A band occurred at 3445 cm^{-1} with porous glass and boria-impregnated silica, but not with pure silica. The 3445 cm^{-1} band appeared at low aniline pressures and remained after other bands had been caused to disappear by degassing, so that the species responsible for the band was more tightly bound to the surface than the hydrogen-bonded species or the chemisorbed structure **1**. The single band is associated with the occurrence of boron on the surface, and its frequency falls in the range found for the single N—H vibrations of secondary amines (17). In analogy to the assignment of a band at 3455 cm^{-1} to a B—NH—B structure found with the reaction of NH_3 with boron-containing surfaces (4), the 3445 cm^{-1} band is assigned to the N—H stretching vibration of a secondary amine, **2**. Such a structure could form through the reaction of aniline with a B—O—B bridge to yield **2** and a B—OH group, leading to an increase of the B—OH band. Such increases occurred with porous glass and boria-impregnated silica but not with pure silica. Also, OH groups formed when aniline reacted with fluoridated glass. The various results thus suggest that surface boron acted as adsorption and dissociation center for aniline in the same fashion found with H_2O (5), NH_3 (4), or HCN (7). It is interesting to note that some traces of the 3600 cm^{-1} band were observed after the weakly held species, which would contribute to the formation of the 3600 cm^{-1} band, had been desorbed, e.g. spectra G, H, J, Fig. 2. As previous work had shown that it is difficult to remove the adsorbed water (2, 3, 5) and the 3600 cm^{-1} band could be removed relatively easily, it is unlikely that the 3600 cm^{-1} remnant was caused by water contamination. Rather, it seems plausible that the aromatic ring of **2** was oriented in such a fashion that some π–OH interaction was possible, thus producing a weak 3600 cm^{-1} band.

Two small bands at 3435 and near 3050 cm^{-1} were observed during the desorption of aniline from silica. The bands are similar, although not identical, to the bands observed with porous glass and may indicate the formation of a surface structure similar to **2**. This could come about through a reaction of aniline with a siloxane bridge or with a SiOH to produce H_2O and the silicon analogue of **2**. Alternatively, there could have been some contamination of the silica by boria evaporated from the all walls (6), but the sharp bands due to **1** were not observed and the single band due to **2** was at a different frequency, so that this alternative seems unlikely.

Microwave spectrum and conformation of tetrahydropyran

V. M. RAO[1] AND R. KEWLEY
Department of Chemistry, Queen's University, Kingston, Ontario
Received October 4, 1968

The microwave spectrum of tetrahydropyran has been recorded in the region 8–40 GHz. The rotational constants of the molecule in its ground vibrational state are, in MHz, $A = 4673.48 \pm 0.05$, $B = 4495.02 \pm 0.11$, and $C = 2601.31 \pm 0.05$. The dipole moment components are, in Debye units, $\mu_a = 1.53 \pm 0.02$, $\mu_c = 0.82 \pm 0.02$, and $\mu = 1.74 \pm 0.03$. The direction of μ with respect to the principal axes of rotation together with the rotational constants show that the observed spectrum is due to the chair form of tetrahydropyran.

Introduction

Tetrahydropyran is a cyclic ether of structure

Other compounds of similar structure for which microwave spectra are known are sym-trioxane (1), which is an oblate symmetric top, piperidine (2), and cyclohexanone (3). All three molecules were shown to have the chair form structure for the ring atoms.

A study of the rotational spectrum of tetrahydropyran was undertaken in order to establish the conformation of the molecule and also to discover whether or not the spectrum showed any unusual effects due to excited vibrational states involving distortion of the ring.

Experimental

The spectrum was recorded using a Stark modulation spectrometer.

Varian klystrons type X13 and X12 were selected to cover the frequency range 8–16 GHz and OKI tubes 17V10, 20V10, 24V10, and 30V11 for the range 16–31 GHz, using an FXR model Z815B power supply. The klystron sawtooth sweep voltage was obtained by amplification of a signal from a Tektronix model 502A dual beam oscilloscope. The oscilloscope was also the display unit for the spectrum and frequency markers. Both the klystron and crystal detector were coupled to the main microwave system through ferrite isolators, giving an improved signal-to-noise ratio.

The 100 kHz Stark modulation and detection was achieved with an Industrial Components Incorporated square-wave generator, preamplifier, and receiver, the latter operating in its phase sensitive detection mode.

Frequency measurements were made by taking the output of a Micronow model 101D frequency standard followed by a Micronow model 301 frequency multiplier, and beating this output with the klyston frequency in the appropriate Micronow model 600 series side arm. The difference in frequency was then fed to a Hallicrafters model SX-62A receiver operating at one of its calibration points. The receiver output was delivered to the oscilloscope, thus providing the frequency marker trace. The marker position was varied by altering the frequency of the model 101D. All frequency measurements were made using both forward and reverse sawtooth sweeps. The 5 MHz fundamental frequency, variable ± 15 kHz, of the model 101D frequency standard was measured by difference using a Micronow model 501 frequency converter. The beat frequency was determined by a Hewlett Packard model 521C 100 kHz counter. The model 501 frequency converter could be checked against the WWV standard 5 MHz signal. Frequency measurements are considered accurate to ± 0.10 MHz.

Sample pressures in the range 10–100 μ were used when recording the spectrum. On account of the very small vapor pressure of tetrahydropyran at dry-ice temperature the measurements were made at temperatures in the range 230–300 °K.

The sample used was obtained from K and K laboratories and was used without further purification.

Results

Rotational Spectrum

Although the spectrum contains many unassigned, presumably high J, lines, it was possible to pick out series of Q-branch absorption peaks with series heads occurring about every 4000 MHz. Each such series is formed from transitions of the ${}^aQ_{0,1}$ and ${}^aQ_{2,-1}$ sub-branches. From these frequencies, given in Table I, approximate values of $(A - C)/2$ and the asymmetry parameter κ were obtained which assisted in the assignment of low J R-branch transitions. The latter were confirmed by their Stark patterns. Both a- and c-type R-branch transitions were observed, as shown in Table II.

The spectrum is that of slightly asymmetric oblate top with the unusual feature that μ_c is the

lesser component of the dipole moment, so that the *a*-type rather than the *c*-type transitions are predominant, see Fig. 1. There is no *b*-component of μ.

The rotational constants were calculated by applying a least squares fit to the 29 lines in Tables I and II, neglecting the effects of centrifugal stretching. The fit was achieved with a standard deviation of 0.29 MHz. The resulting rotational constants are given in Table III.

Dipole Moment

Stark measurements were carried out on both *a*- and *c*-type lines of the $J = 1$–2 transition. The squared dipole moment components μ_a^2 and μ_c^2 were obtained from a least squares fit of the observed coefficients $\Delta\nu/E^2$. The Stark cell was calibrated with carbonyl sulfide using the value of $\mu_{OCS} = 0.7124 \pm 0.0002$ D (4). The Stark measurement data and the dipole moment components are given in Table IV.

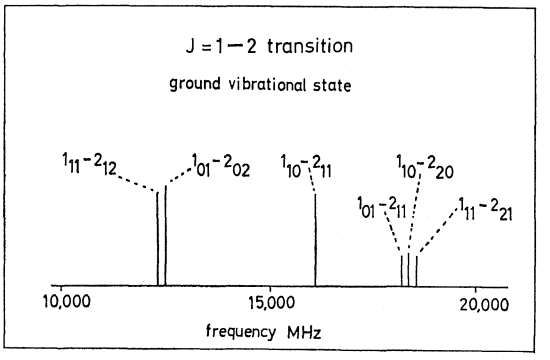

FIG. 1. The $J = 1$–2 transition of tetrahydropyran showing the relative intensities of the *a*-type and *c*-type transitions.

Conformation

To determine the complete r_s structure of tetrahydropyran, it would be necessary to carry out isotopic substitution on the oxygen, three of the carbons, and six of the hydrogen atoms. Since only one isotopic form has been investigated in the present work, detailed structural information cannot be obtained from the observed rotational constants.

The observed constants may, however, be compared with those calculated from reasonable bond lengths and angles assuming that the molecule could exist in either the boat or chair conformation. Taking Hendrickson's values for C—H and C—C of 1.108 and 1.533 Å respectively (5), assuming that all bond angles at carbon are 109° 28′ and that the C—O distance and C—O—C angle are 1.410 Å and 111° 43′ respectively, as in dimethyl ether (6), the calculated rotational constants are as given by Table V.

Comparison of these figures with the observed ones does not allow a clear decision to be made as to which of the two forms gives rise to the observed spectrum, although the chair form is favored. A more detailed consideration of the dipole moment components does enable this to be done. The observed total dipole moment of 1.74 D is very close to the value 1.75 D found for tetrahydrofuran from its microwave spectrum (7), and it can, therefore, be concluded that the main contribution to the molecular dipole moment arises

from the C—O bond moment. Assuming that the total dipole lies along the bisector of the C—O—C angle in the C—O—C plane and using the same assumed structural parameters as above, then it is calculated that for the chair form the μ vector should be inclined at 35° 30′ to the molecular principal *a*-axes, but that in the boat form μ makes an angle 56° with the *b*-axis and that only *b*- and *c*-type transitions would be expected to occur for the boat form, as illustrated in Fig. 2.

The observed angle between μ and μ_a of 28° 22′ is, therefore, in good agreement with the chair structure of tetrahydropyran. Although a search was carried out for a spectrum due to the boat form, no lines could be found due to this isomer.

Excited Vibrational States

Each of the transitions 1_{11}–2_{12}, 1_{01}–2_{02}, and

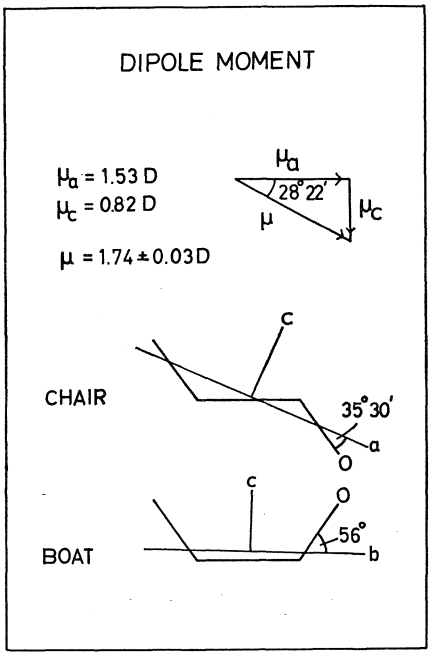

FIG. 2. The relationship between the direction of the total dipole moment vector and the principal axes of tetrahydropyran; 28° 22′ is the observed angle. The figure shows also calculated angles using Hendrickson's values of C—C and C—H (5), tetrahedral carbons and the C—O—C angle, and C—O distance as in dimethyl ether (6).

1_{10}–2_{11} has, associated with the absorption peak due to the ground vibrational state of the molecule, 4 weak satellite lines. No intense satellites of the type characteristic of pseudorotation were present. This phenomenon would not be expected to occur for a molecule that has the relatively rigid chair form structure.

The vibrational satellites can be attributed to 4 of the 6 of the ring deformation frequencies, which are all known to be below 800 cm^{-1} (8). The lowest frequency ring deformation mode occurs in the region of 256 cm^{-1} (8, 9). The first excited state of this vibration is very likely responsible for the lines given in Table VI.

The rotational constants for this state (I) and the other three excited states (II, III, IV) are given in Table VII. For states II, III, and IV the rotational constants were obtained using only lines in the $^aR_{0,1}$ $J = 1$–2 transition.

The next lowest ring deformation frequencies after 256 cm^{-1} are 276, 403, and 434 cm^{-1} (8, 9) which, from the intensities, probably correspond to the states II, III, and IV respectively.

A further ring deformation which might affect the spectrum is the motion

for which nuclear magnetic resonance data (10) give an activation energy or barrier height of 10.5 kcal/mole. This inversion motion causes a reversal of the dipole moment component μ_c and might be expected to cause splitting of the *c*-type transitions. Very few *c*-type lines were recorded and, of those that were, only the 1_{01}–2_{11} and 1_{11}–2_{21} transitions were observed to have pairs of lines, with separations 0.8 Mc. The lines making up these doublets did not show the same intensity relationship for the two transitions and quite possibly could be the unsplit rotational transitions accidentally situated near unidentified high J Q-branch transitions. A doublet was not found for the 1_{10}–2_{20} transition or for any of the other *c*-type R-branch transitions in Table II.

Conclusion

The rotational spectrum of tetrahydropyran shows the molecule to be in the chair form as are the related molecules sym-trioxan (1), piperidine (2), and also cyclohexanone (3). No spectrum from the boat form or any effect that could be definitely attributed to pseudorotation or to inversion of the chair form was found. The observed vibrational satellites are considered to be due solely to deformation modes of the ring with frequencies in the range 250–500 cm^{-1}.

Erratum Pg 1289

When recalibrating the Stark cell during the determination of the dipole moment of 1,3-dioxane, an error was discovered in the earlier calibration, which had been used in the calculations of the dipole moments of tetrahydropyran (1) and morpholine (2). Correcting this calculation error and using the same experimental data (1, 2) the corrected values are:

	μ_a(D)	μ_c(D)	μ(D)
Tetrahydropyran	1.39(0.02)	0.74(0.02)	1.58(0.03)
Morpholine	1.53(0.01)	0.27(0.01)	1.55(0.02)

The μ values agree well with those measured in benzene solution of 1.55 (3) and 1.52 D(4), respectively.

Also in Table IX of the morpholine publication (2), the transition given as 2_{12}—3_{22} is actually 2_{21}—3_{22}.

Effect of solvent and temperature upon the rotationally averaged vicinal coupling constants of some substituted 1,2-dibromoethanes

W. F. Reynolds and D. J. Wood
Department of Chemistry, University of Toronto, Toronto 5, Ontario
Received September 3, 1968

The solvent dependence of vicinal coupling constants has been investigated for (1,2-dibromoethyl)-benzene and three of its 4-substituted derivatives and for threo- and erythro(1,2-dibromopropyl)benzene. The temperature dependence of the vicinal coupling constants of three of the compounds has also been investigated. The difference between the two vicinal coupling constants of (1,2-dibromoethyl)benzene is dependent upon solution dielectric constant (in non-aromatic solvents) while the sum of coupling constants remains constant. The relative stabilities of its three rotamers are deduced from this information. A polar substituent in the 4-position does not affect the rotational equilibrium in any predictable manner. The vicinal coupling constant of threo(1,2-dibromopropyl)benzene is strongly solvent dependent. The relative stabilities of its three rotamers are deduced from the observation that the vicinal coupling constant is temperature independent. The most stable rotamer of erythro(1,2-dibromopropyl)-benzene is deduced from the observation that the vicinal coupling constant is large and independent of solvent. Factors affecting conformational preference are deduced. It is concluded that dipolar interactions are as important as steric interactions.

Introduction

Rotational isomerism in substituted ethanes has been widely investigated by nuclear magnetic resonance (n.m.r.) spectroscopy (1). In the most commonly applied technique (2), energy differences, ΔE, between rotational isomers (rotamers) are estimated from the temperature dependence of averaged vicinal coupling constants, $\langle J_{ij} \rangle$, and chemical shifts. Values of ΔE and the coupling constants for the "frozen" rotamers are determined by a least squares fitting technique. However, it has recently been shown that the value of ΔE and coupling constants for the frozen rotamers of 1,1,2,2-tetrabromofluoroethane measured directly at low temperatures are much different than those obtained from $\langle J_{HF} \rangle$ at high temperatures (3). This was attributed to the insensitivity of the least squares fitting technique. It has also been pointed out that the values of ΔE are temperature dependent (4). Consequently, the above-discussed technique is of doubtful accuracy.

It is well established that for substituted ethanes containing two or more polar groups, the more polar rotamers increase in fractional population upon going from the gas phase to a polar medium (5). Solvent dependent changes in rotationally averaged coupling constants have been noted and interpreted in terms of population changes with change in solvent dielectric constant (6). Recently, Abraham and co-workers have developed a theory which allows one to predict the change in energy difference between rotamers upon going from the gas phase to a solution of dielectric constant ε (4). Then if ΔE is known in the gas phase, ΔE can be determined in the liquid phase. This approach has been successfully applied to a number of simple substituted ethanes (7) and has been extended to include compounds containing three or more polar groups (8).

It is much more difficult to apply this technique quantitatively to the investigation of conformational preference in complex substituted ethanes. Firstly, one generally has no knowledge of the energy differences either in gas phase or in solution; in fact, this is the information one would like to obtain. Secondly, one must also know the molecular volume, polarizability, etc. These quantities are often unavailable. However, it was decided to investigate whether at least semiquantitative information concerning conformational preference could be obtained from an investigation of the effect of ε and, where necessary, temperature upon $\langle J_{ij} \rangle$ for complex substituted ethanes.

A previous investigation of this type had been carried out by Snyder (9). He investigated the effect of a limited number of solvents upon chemical shifts and coupling constants of 12 trisubstituted ethanes (9*a*). He also developed semiempirical relationships which allowed one to estimate ΔE from $\langle J_{ij} \rangle$ (9*c*). It was concluded that changes in energy differences between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

rotamers were only weakly related to the solvent dielectric constant. However, we felt that this conclusion might be incorrect because it was based upon results in a limited number of solvents and because the solutions investigated were very concentrated (40 wt./vol. %).

The initial compounds chosen for this investigation were (1,2-dibromoethyl)benzene and three 4-substituted (1,2-dibromoethyl)benzenes. These compounds were chosen for two main reasons. Firstly, the most stable rotamer of (1,2-dibromoethyl)benzene had been determined by specific deuteration experiments (9*b*). Therefore, it was possible to check the conclusions from the solvent effect investigation. Secondly, it was considered important to determine the effect of the remote dipolar groups. 4-Substituted (1,2-dibromoethyl)benzenes were chosen since the effect of a remote dipole could be determined by direct comparison with the results for the parent compound. In addition, the orientation of the remote dipole with respect to the substituted ethane group would be unaffected by rotation about the carbon–phenyl bond and no additional steric hindrance would be added to the system.

Erythro- and threo(1,2-dibromopropyl)benzene were investigated as examples of substituted ethanes in which there is only one vicinal coupling constant.

In this paper, results are presented for the six compounds mentioned above.

Experimental

(1,2-Dibromoethyl)benzene was prepared by the bromination of styrene in methylene chloride. The corresponding 4-substituted derivatives were prepared by bromination of 4-substituted styrenes in carbon tetrachloride. Erythro(1,2-dibromoethyl)benzene was prepared by bromination of *trans*-propenylbenzene in methylene chloride while the threo isomer was prepared by bromination of *cis*-propenylbenzene in carbon tetrachloride. All reactions were carried out in the dark. The starting materials were obtained commercially and were used without purification. Solid products were purified by recrystallization from methanol–water. The only liquid product, threo(1,2-dibromopropyl)benzene, contained approximately 20–25% of the erythro isomer as an impurity. Attempts to purify this compound by vapor phase chromatography and by low temperature recrystallization were unsuccessful and it was used unpurified.

Spectra were recorded on a Varian HA-100 spectrometer operating in frequency sweep mode at a probe temperature of 30 °C (except for variable temperature experiments). The variable temperature controller was calibrated using standard calibration samples before each variable temperature experiment.

Spectra were recorded at a sweep rate of 0.05 Hz/s. The spectra were recorded twice in each direction for all coupling constant measurements. Spectra were calibrated by measuring the frequency difference between the lock and sweep oscillators, using a Hewlett–Packard 5253B frequency counter in period average mode.

Samples were usually 0.30 *M* in solute. Samples were deoxygenated by bubbling N_2 through them. Five percent tetramethylsilane was added as a lock and reference signal. Any solvents which were not analytical reagent grade were distilled prior to use.

Solution dielectric constants were measured with a W.T.W. DKO3 dekameter.

Results

Spectral analyses of the ABC spectra of the 1,2-dibromoethyl groups of (1,2-dibromoethyl)-benzene and its para substituted derivatives were carried out by the exact method (10), using the computer program EXAN. Iterative analyses were also attempted, using the computer program LAOCN3 (11). The former method was found to be superior for this system. It provided all possible solutions while the iterative method provided only one solution in each case. The latter solution depended upon the choice of approximate input parameters. This is extremely important in this system since in several cases two solutions were obtained with the correct signs for the coupling constant (9*b*), i.e., with both vicinal coupling constants positive and the geminal coupling constant negative. This can be understood by considering that the spectrum is an approximate ABX spectrum. The AB part consists of two quartets or subspectra (12) (see Fig. 1). The two solutions correspond to the two possible signs of the apparent chemical shift (12) of the nearly collapsed quartet. In most cases, the correct solution was chosen on the basis that the vicinal coupling constant in erythro(1,2-dibromoethyl-2-*d*)benzene has a value of 10.5 to 11.0 Hz (9*b*). The correct solution for (1,2-dibromoethyl)benzene in benzene was chosen on a basis which will be discussed later. Results for (1,2-dibromoethyl)benzene are given in Table I while results for its para substituted derivatives are given in Table II.

The 1,2-dibromopropyl groups of erythro- and threo(1,2-dibromopropyl)benzene gave ABC_3 spectra. A complete ABC_3 spectral analysis was carried out for the erythro isomer in carbon tetrachloride, using the computer program LAOCN3. It was found that the doublet splittings of the A proton and the C_3 methyl

*Interference with solvent peak prevented measurement.
†Cell malfunction prevented measurement of the dielectric constants of these solutions.

protons (see Fig. 2) correspond within 0.01 Hz to the calculated values of $\langle J_{AB} \rangle$ and $\langle J_{BC} \rangle$. Consequently $\langle J_{AB} \rangle$ and $\langle J_{BC} \rangle$ were determined by measuring these splittings. Results are given in Table III.

Values of coupling constants for erythro- and threo(1,2-dibromopropyl)benzene are estimated to be accurate within 0.05 Hz. It is more difficult to estimate the accuracy of the coupling constants for the (1,2-dibromoethyl)benzene compounds since the coupling constants do not correspond to first order splittings. "Probable errors" determined by LAOCN3 ranged from 0.01 to 0.1 Hz with the largest errors found when the chemical shift difference of the methylene protons approached zero.

Results of variable temperature experiments are given in Table IV. Results for concentration dependence experiments are given in Table V.

Discussion

A. (1,2-Dibromoethyl)benzene

The three staggered rotamers for (1,2-dibromoethyl)benzene are shown in Fig. 3. There is a bromine–phenyl steric interaction in rotamer **1**, a bromine–bromine steric and a dipolar interaction in rotamer **2**, and two steric and one dipolar interaction in rotamer **3**. On this basis one would expect rotamer **3** to be the least stable. It is difficult to predict the relative stabilities of rotamers **1** and **2**. However, one can make certain predictions concerning the effect of the dielectric constant, ε, upon the vicinal coupling constants. The more polar rotamers (**2** and **3**) should be relatively more stable in solutions of high ε. If rotamer **1** is the most stable rotamer in solutions of low ε, then $\langle J_{AC} \rangle$ should be large but should decrease as ε increases (since protons A and C are *trans* in rotamer **1** and *gauche* in the other rotamers). Correspondingly $\langle J_{BC} \rangle$ should be small but should increase with ε (since protons B and C are *gauche* in rotamer **1** and *trans* in rotamer **2**), i.e., the difference between the coupling constants should decrease as ε increases. On the other hand, the reverse effect would be noted if rotamer **2** is the most stable rotamer. $\langle J_{BC} \rangle$ should be larger than $\langle J_{AC} \rangle$ and the former should increase and the latter should decrease as ε increases, i.e., the difference in coupling constants should increase as ε increases. In rotamer **3** both coupling constants are *gauche*. Consequently any increase in the population of rotamer **3** with ε should lead to a decrease in $(\langle J_{AC} \rangle + \langle J_{BC} \rangle)$[1]. The fractional population of rotamer **3**, p_3, is expected to increase with increasing ε. However, this increase would be negligible if rotamer **3** is considerably less stable than the non-polar rotamer **1**, since p_3 would then be small in all solvents.

[1]This and preceding arguments depend upon the assumption that *trans* proton coupling constants are larger than *gauche* proton coupling constants. Small variations of *gauche* or *trans* coupling constants between different rotamers will not significantly affect these arguments.

Erythro	Chloroform-*d*	4.77	−5	10.39
Erythro	Chloroform-*d*	5.37	−30	10.63
Erythro	Acetone	18.6	+30	10.10
Erythro	Acetone	22.0	−5	10.46
Erythro	Acetone	26.3	−40	10.73

*Dielectric constant measured at 30 °C and calculated at other temperatures assuming the same temperature dependence of ε as for the pure solvent.

The fractional populations of the three rotamers approach equality if the temperature is increased sufficiently. Therefore, the difference between $\langle J_{AC} \rangle$ and $\langle J_{BC} \rangle$ should decrease with increasing temperature regardless of the relative stabilities of rotamers **1** and **2**. Consequently, the temperature dependence of the averaged vicinal coupling constants will not directly give information concerning the relative stabilities of these rotamers. A significant decrease in $(\langle J_{AC} \rangle + \langle J_{BC} \rangle)$ with temperature would suggest that the fractional population of rotamer **3** is not negligible.

From the above discussion it can be seen that it should be possible to determine the relative stabilities of rotamers of (1,2-dibromoethyl)-benzene and similar tri-substituted, dipolar ethanes from solvent effect studies, while variable temperature experiments should yield limited information unless one uses a complicated and probably insensitive curve-fitting procedure.

As can be seen from Table I and Fig. 4, the difference between $\langle J_{AC} \rangle$ and $\langle J_{BC} \rangle$ is significantly smaller in solutions of high ε than in solutions of low ε. The results show a slight anomaly for hexane (although this is barely larger than experimental error) and a major deviation for benzene. Otherwise, a very definite trend is noted. The results strongly suggest that rotamer **1** is the most stable rotamer (since $(\langle J_{AC} \rangle - \langle J_{BC} \rangle)$ decreases as ε increases). This is in agreement with the conclusion reached by Snyder and Buza from their specific deuteration experiments (*9b*). $(\langle J_{AC} \rangle + \langle J_{BC} \rangle)$ remains constant. This indicates that the population of rotamer **3** is small, as expected. It is obvious that measurements of the effect of ε upon averaged vicinal coupling constants can be used to obtain correct predictions of the relative stabilities of the three rotamers of (1,2-dibromoethyl)benzene. Therefore, it is probable that relative stabilities of rotamers of other tri-substituted, dipolar ethanes can be estimated by the same method. A number of compounds of this type are being investigated.

Rotamer **1** will be even more stable with respect to rotamer **2** in the gas phase. The more polar rotamer **2** is apparently significantly more sta-

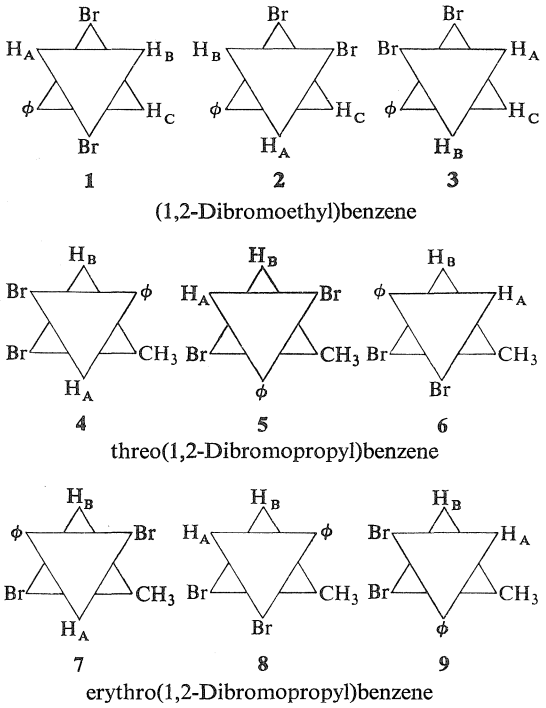

FIG. 3. Staggered rotamers of (1,2-dibromoethyl)-benzene and erythro- and threo(1,2-dibromopropyl)-benzene.

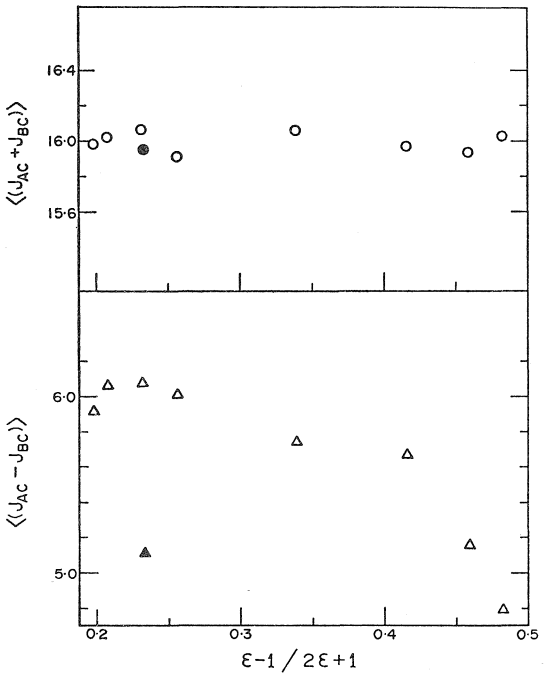

FIG. 4. Plot of $\langle J_{AC}\rangle + \langle J_{BC}\rangle$ and $\langle J_{AC}\rangle - \langle J_{BC}\rangle$ for (1,2-dibromoethyl)benzene versus the dielectric function $(\varepsilon - 1)/(2\varepsilon + 1)$. Filled point represents the benzene solutions.

ble in benzene than in carbon tetrachloride. Similar "benzene" effects have been noted by other investigators, both from vicinal coupling constant measurements (7) and from dipole moment measurements (13). It should be noted that the alternate solution (see Results) gives results which are apparently more consistent with other solvents. However, the first solution was chosen because in the 4-substituted derivatives, the change in $(\langle J_{AC}\rangle - \langle J_{BC}\rangle)$ on going from carbon tetrachloride to benzene was 0.8 to 0.9 Hz. This is more consistent with the first than with the alternate solution.

The conclusion of Snyder that energy differences between rotamers of substituted ethanes are only weakly related to ε was based upon results in a limited number of solvents including benzene. For several of the compounds which he investigated, the apparent discrepancies can be rationalized when it is realized that benzene may give anomalous results. We have noted a very good correlation between ε and $(\langle J_{AC}\rangle - \langle J_{BC}\rangle)$ for (1,2-dibromoethyl)benzene in eight non-aromatic solvents. However, it is only fair to point out that this correlation is probably better than one can normally expect in an investigation of this type. For erythro- and threo(1,2-dibromopropyl)benzene and for the compounds investigated by Abraham and co-workers (4, 7, 8), the variation of vicinal coupling constants with ε is less regular. However, in all cases definite trends can be noticed, provided that enough non-aromatic solvents are used. The most reasonable conclusion appears to be that there is a general relationship between ε and the energy differences of rotamers of substituted ethanes in non-aromatic solvents, but that for any one solvent this relationship may be partially obscured by specific interactions.

The vicinal coupling constants for (1,2-dibromoethyl)benzene are constant over the concentration range 0.15 to 0.60 *M* in both carbon tetrachloride and dimethylsulfoxide (see Table V). Consequently, the coupling constants are assumed to be very close to their infinite dilution values. However, the coupling constants in carbon tetrachloride, deuterochloroform, and acetone differ significantly from those reported by Snyder for 40 wt./vol. % solutions

in the same solvents (9*a*). The value of ε should be significantly different in the more polar solvents and this could lead to population changes. Solute dimerization could also affect the coupling constants at high concentrations. The latter effect has been shown to be important for β-bromopropionitrile at much lower concentrations (7*c*).

($\langle J_{AC}\rangle - \langle J_{BC}\rangle$) decreases with increasing temperature, as expected. ($\langle J_{AC}\rangle + \langle J_{BC}\rangle$) decreases slightly, suggesting that the population of rotamer **3**, while small, is not negligible.

On the basis of the results presented (see Table I), there appears to be a very good correlation between the chemical shift difference for the methylene protons and solvent dielectric constant (except for benzene). However, this is misleading. Measurements were also made in acetonitrile. In this solvent, ($\delta_A - \delta_B$) is very nearly zero and, therefore, would not fit the above mentioned correlation. The coupling constants had approximately the expected values. However, these results have not been reported in detail since the "probable errors" in the vicinal coupling constants were sufficiently large (0.4 Hz) to make the results meaningless. As previously mentioned, this appears to be characteristic of this system as ($\delta_A - \delta_B$) approaches zero.

The observed changes in ($\delta_A - \delta_B$) with solvent appear to be much too large to be explained solely in terms of conformation changes. It appears more probable that they are due to specific solvent effects.

B. 4-Substituted (1,2-Dibromoethyl)benzene

The results for the 4-substituted derivatives are similar to those for the parent compound. The differences between vicinal coupling constants are generally larger in less polar solvents. There is a small but possibly significant concentration dependence for 4-nitro-(1,2-dibromoethyl)benzene. This might be due to the change in solution dielectric constant with solute concentration. Two conclusions can be reached.

Firstly, a remote dipole does not affect relative populations in any predictable fashion. For example, in the case of the 4-nitro derivative, rotamer **1** might be expected to be destabilized with respect to the parent compound, because of an additional dipolar interaction. In fact, the coupling constant difference is larger, indicating an apparent stabilization of rotamer **1**. It is quite possible, however, that the observed difference is due to electronic rather than conformational effects.

Secondly, the remote dipole does not significantly alter the effect of solvent upon rotamer populations. According to the theory for compounds containing three or more polar groups (8), the effect of ε upon energy differences between two rotamers is determined by the difference in net dipole moments and, to a lesser extent, quadrupole moments of the two rotamers. Assuming tetrahedral angles and dipole moments of 4.0 D for the 4-nitro–phenyl group and 2.0 D for C–Br groups, then for the 4-nitro derivative the net dipole moments for rotamers **1** and **2** are, respectively, 4.0 and 2.3 D. Consequently rotamer **1** should be stabilized with increasing ε. In actual fact, the reverse trend is found, suggesting that the remote dipole has little effect[2]. Since the theory assumes a point dipole in the center of a polarizable sphere, a breakdown in the theory for a bulky molecule such as 4-nitro-(1,2-dibromoethyl)benzene would hardly be surprising. The solvent probably tends to solvate the 1,2-dibromoethyl group quite independently of any solvation of the remote dipole, i.e., the effect of ε upon the conformation about the carbon–carbon bond depends only upon the polar groups directly bonded to the carbon atoms.

This conclusion, if correct, considerably extends the usefulness of the technique. For example, it may be possible to investigate conformational preference in low molecular weight polymers which contain many polar groups. It is obviously desirable to determine how close remote dipoles must be before they exert a significant influence. Unfortunately, it is difficult to find a suitable system. 2-Substituted or 3-substituted (1,2-dibromoethyl)benzenes would not be very suitable since the location of the remote dipole would depend upon the orientation of the phenyl group and since a substituent in the 2 or 3 position may cause additional steric hindrance.

---

[2]One might attempt to explain these results by suggesting that the quadrupolar term is more important than the dipolar term. However, nearly identical solvent effects upon vicinal coupling constants are noted for (1,2-dibromoethyl)benzene and its 4-substituted derivatives, in spite of the large differences in dipole and quadrupole moments for these compounds. Therefore, we feel that the explanation presented above is more logical.

C. *Erythro- and Threo(1,2-dibromopropyl)-benzene*

In each of these compounds there are only two protons in the substituted ethyl group and consequently only one vicinal coupling constant which should be solvent dependent owing to conformational changes. It is more difficult to deduce information concerning conformational preference from solvent effect studies on compounds of this type than on compounds with two solvent-dependent vicinal coupling constants. For example, for the threo compound, p_4 and p_6 should increase with increasing ε since rotamers **4** and **6** are polar (see Fig. 3). The protons are *trans* in rotamer **4** and *gauche* in the other two rotamers. Consequently $\langle J_{AB} \rangle$ should increase with increasing ε regardless of the relative energies of the three rotamers. Also, one cannot determine the relative populations of rotamers **5** and **6** since the protons are *gauche* in both rotamers. However, by observing the magnitude of the change in $\langle J_{AB} \rangle$ with ε and temperature, one can deduce much of the desired information.

$\langle J_{AB} \rangle$ for the threo compound increases irregularly with ε (see Table III and Fig. 5). However, a definite trend is noted. The overall change in $\langle J_{AB} \rangle$ is large (nearly twice as large as the changes in the vicinal coupling constants in (1,2-dibromoethyl)benzene for the same range in ε). From this observation one can only deduce that rotamers **4** and **5** must be relatively close in energy. If rotamer **4** is either very stable or very unstable with respect to rotamer **5**, then a small change in ΔE_{4-5} will have little effect upon p_4 (in the limiting case of infinite energy difference there would be no measurable effect). However, if the energy difference is small, then p_4 should be very sensitive to changes in ΔE_{4-5}.

More definite information can be deduced from the variable temperature results (see Table IV). In $CDCl_3$, J_{AB} is constant over a temperature range from −50 to +30 °C. Since the protons are *trans* in rotamer **4** and *gauche* in the other rotamers, one would expect a change in $\langle J_{AB} \rangle$ if there is any change in p_4. Conversely, the constancy of $\langle J_{AB} \rangle$ suggests that p_4 remains essentially constant over this temperature range. This fortuitous constancy can only occur if rotamer **4** is intermediate in energy relative to the other two rotamers. In rotamer **4**, there are two steric interactions and one dipolar interaction. There are three steric interactions in both rotamers **5** and **6** but only the latter has a dipolar interaction. On this basis it is believed that the energy order $E_6 > E_4 > E_5$ is much more probable than the alternate order $E_5 > E_4 \geqslant E_6$.

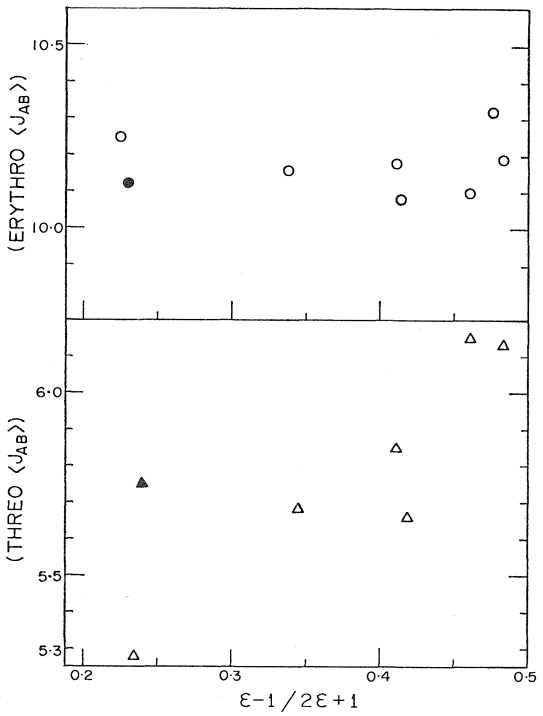

FIG. 5. Plot of $\langle J_{AB} \rangle$ for erythro- and threo(1,2-dibromopropyl)benzene versus the dielectric function $(\varepsilon - 1)/(2\varepsilon + 1)$. Filled points represent benzene solutions.

The conclusion that rotamer **4** must be intermediate in energy can be confirmed by simple calculations. For example, if $E_4 - E_5 = 150$, $E_6 - E_4 = 600$ cal/mole, $J_4 = 12.0$, and $J_5 = J_6 = 1.9$ Hz, then $\langle J_{AB} \rangle = 5.71$ Hz at 30 °C and 5.70 Hz at −50 °C[3]. A similar result can be obtained even if one allows for a slight temperature dependence of ΔE_{4-5} and ΔE_{5-6} (due to the decrease in ε with increasing temperature) and for the fact that J_5 is probably larger than J_6 (a vicinal coupling constant is believed

[3]The normal assumption is made that the entropy difference between rotamers is zero (2). It has been shown that there are small entropy differences between the rotamers of 1,1,2,2-tetrabromo-1-fluoroethane but that if one ignored the entropy difference, one obtained an apparent energy difference between rotamers which is only slightly different from the true energy difference (3).

For personal use only.

to be smaller when one of the protons is *trans* to an electronegative group than when it is *gauche* to that group (7, 14)). For example, if ΔE_{4-5} is 275 cal/mole at -30 °C and 300 cal/mole at $+30$ °C, ΔE_{6-4} is constant at 500 cal/mole, $J_4 = 12.0$, $J_5 = 3.0$, and $J_6 = 1.5$ Hz, then $\langle J_{AB} \rangle = 5.71$ Hz at -30 °C and 5.71 Hz at $+30$ °C. One can obtain the same result for other reasonable choices of ΔE and J. It is impossible to determine from the available data which is the correct choice of parameters. However, any choice of parameters in which rotamer **4** is not intermediate in energy would require that the *trans* coupling constant be smaller than at least one of the *gauche* coupling constants. This would be contrary to all evidence concerning the effect of conformation upon vicinal proton coupling constants. The intermediate size of $\langle J_{AB} \rangle$ is also consistent with the conclusion that rotamer **4** is intermediate in energy.

The relative stability of rotamer **5** should be even greater in the gas phase since this rotamer is non-polar. Consequently, the order of energy levels should be the same in deuterochloroform, in solvents of lower ε, and in the gas phase. However, ΔE_{4-5} should decrease with increasing ε and could possibly change sign at high ε. In any case, relative to rotamer **5**, rotamer **4** should be less stable in carbon tetrachloride and more stable in acetone than in deuterochloroform. Since p_4 is essentially independent of temperature in deuterochloroform, p_4 and $\langle J_{AB} \rangle$ should decrease with decreasing temperature in carbon tetrachloride and increase with decreasing temperature in acetone. This reversal of the sign of the temperature is actually observed (see Table IV).

The above observations are significant since they strongly suggest that the observed solvent dependence of the vicinal coupling constants is due to changes in energy differences and rotamer populations with ε rather than to reaction field effects upon the coupling constants of the individual rotamers. The latter effect has been shown to be important for the ^1H–^{19}F coupling constant in 1-fluoro-1,1,2,2-tetrabromoethane (15). However, it is probable that the reaction field effect is more important for ^1H–^{19}F coupling constants than for ^1H–^1H vicinal coupling constants in substituted alkanes. Previous results support this contention. For example, it has been shown that the averaged vicinal coupling constants for 1-iodo-3,3-dimethylbutane are solvent independent (14). Since this molecule has only one polar group, no change in rotamer population with ε would be expected. Since the coupling constants do not change, it is improbable that there is a significant reaction field effect.

An increased stabilization of rotamer **4** in benzene was noted. It has been suggested that the increased stabilization of the polar forms of 1,2-dihaloethanes in benzene might be due to specific hydrogen bonding of two adjacent benzene protons with the two halogen atoms in a *gauche* conformation (16). An alternate possibility would involve the interaction of the *gauche* halogens with the π electron system of benzene. In an attempt to choose between the two possibilities, we ran the threo compound in *cis*-1,2-dichloroethylene. If the specific interaction is of the former type, one might expect it to occur with *cis*-1,2-dichloroethylene as well. Unfortunately, the results are not entirely conclusive. However, $\langle J_{AB} \rangle$ does have approximately the value which one would expect if no specific interaction occurred. Consequently, it appears probable that the specific interaction with benzene involves the π electron system.

$\langle J_{AB} \rangle$ is, within experimental error, independent of concentration. It was also found that adding pure erythro compound to the impure threo compound did not significantly alter $\langle J_{AB} \rangle$. Consequently, it is believed that our results are not affected by the presence of the erythro compound as an impurity.

$\langle J_{AB} \rangle$ for the erythro compound is independent of ε (see Table III and Fig. 5). There is a considerable scatter of values of $\langle J_{AB} \rangle$ but no trend which could be related to ε. One would expect $\langle J_{AB} \rangle$ to be independent of ε only if one of the rotamers was very much more stable than the other two, or possibly if both rotamers with *gauche* protons were much more stable than the rotamer with *trans* protons. Since $\langle J_{AB} \rangle$ is large (10.2 Hz), the compound must exist predominantly in the rotamer with *trans* protons, i.e., rotamer **7** is much more stable than the other two rotamers. The same order should be found in the gas phase since rotamer **7** is non-polar while the other two rotamers are polar. It is impossible to deduce the relative stabilities of rotamers **8** and **9** from the available information.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The above conclusion is not at all surprising since rotamer **7** has only two steric interactions and no dipolar interaction while both other rotamers have three steric interactions and one dipolar interaction.

The temperature dependence of $\langle J_{AB} \rangle$ is similar to the temperature dependence of the vicinal coupling constants in (1,2-dibromoethyl)-benzene. This suggests that the compound does not exist entirely in the conformation of rotamer **7**. However, this does not necessarily imply that there are appreciable fractional populations for rotamers **8** and **9**. Whitesides *et al.* have noted a similar temperature dependence of averaged vicinal coupling constants for a series of 1-substituted 3,3-dimethylbutanes (14). The larger vicinal coupling constant at room temperature had a value of 10.2 Hz for the cyano derivative and 12.9 Hz for the phenyl derivative, while the corresponding calculated values for J_{trans} were 13.9 and 13.7 Hz. Clearly the simple observation of temperature dependence of an averaged vicinal coupling constant does not provide unequivocal information concerning how close this coupling constant is to a pure *trans* coupling constant.

It is informative to consider the difference in the total number of steric and dipolar interactions for the two most stable rotamers for each of the compounds and to compare this with the observed solvent dependence of the vicinal coupling constants. In threo(1,2-dibromopropyl)-benzene there is a total of three steric and (or) dipolar interactions for each of rotamers **4** and **5**. In (1,2-dibromoethyl)benzene, rotamer **1** has one less (dipolar) interaction than rotamer **2**. In erythro(1,2-dibromopropyl)benzene, rotamer **7** has two less interactions than each of the other two rotamers. The changes in coupling constants (using the larger coupling constant for (1,2-dibromoethyl)benzene) upon going from carbon tetrachloride to acetone are respectively 0.83, 0.49, and 0.15 Hz. Provided that the protons were *trans* in one of the two most stable rotamers, one would expect the largest change in the vicinal coupling constant when the energy difference is smallest and populations are closest to equality. It is apparent that this inverse relationship does exist for the three compounds discussed above. Consequently, it appears that the relative solvent dependence of vicinal coupling constants for a series of closely related compounds can provide meaningful information about relative conformational preference in these compounds.

The value of $\langle J_{AB} \rangle$ for the erythro compound is significantly smaller than the value of the larger vicinal coupling constant in (1,2-dibromoethyl)benzene. This is surprising. On the basis of the previous discussion, one would expect that erythro(1,2-dibromopropyl)benzene would exist predominantly as rotamer **7** while for (1,2-dibromoethyl)benzene there should be appreciable populations of both rotamers **1** and **2**. Therefore, one would anticipate that $\langle J_{AB} \rangle$ for the former compound would be larger than $\langle J_{AC} \rangle$ for the latter compound. We believe that the most probable explanation for this apparent discrepancy is that the *trans* coupling constant in the former compound is significantly smaller than in the latter compound. If this is true, then estimates of conformational preference based only upon the size of a single vicinal coupling constant (17) must be regarded as suspect.

D. Factors Affecting Conformational Preference

Snyder believed that it was surprising that rotamer **1** was significantly more stable than rotamer **2** of (1,2-dibromoethyl)benzene (9). He first considered only steric interactions. Since the phenyl group has a much larger "A" factor (18) than the bromo group, he believed that there should be a much greater steric interaction in rotamer **1** than in rotamer **2**. He then postulated that the additional stability of rotamer **1** might be due to a stabilizing interaction between the phenyl group and the bromine on the β carbon atom. However, it has since been shown that "A" factors (which were determined from substituted cyclohexanes) are not an accurate measure of steric interactions in substituted ethanes (14). In actual fact, bromine has only a slightly smaller steric effect than a phenyl group in substituted ethanes (the energy differences between *gauche* and *trans* rotamers of 1-bromo- and 1-phenyl-3,3-dimethylbutane have been estimated as, respectively, 1.30 and 1.70 kcal/mole (14)). The lower stability of rotamer **2** can then be explained as due to the destabilizing effect of the dipolar repulsion of the *gauche* bromine atoms (if this effect was not important, there would not be any solvent dependence of rotamer population). However, one cannot entirely exclude the possibility of a stabilizing bromine–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

phenyl interaction in rotamer **1** although it is no longer necessary to postulate an interaction of this kind. Indirect support for a stabilizing interaction is provided by the observation of stabilization of polar rotamers by benzene.

As previously discussed, the relative stabilities of rotamers for other compounds can also be rationalized if one assumes that dipolar repulsions are as important as steric interactions in solutions of low ε. Once again, conformational preference might also be affected by stabilizing bromine–phenyl interactions.

There should be considerable decrease of dipolar repulsion by the medium even for solutions of low ε. For example, if the dependence of ΔE upon ε has the form $(\varepsilon - 1)/(2\varepsilon + 1)$ (4), then a medium with $\varepsilon = 2$ will decrease dipolar repulsions 40% as effectively as a hypothetical medium of $\varepsilon = \infty$. Since dipolar interactions are apparently still important in solution, they will obviously be of greater importance in the gas phase.

Summary and Conclusions

The relative stability of the rotamers of (1,2-dibromoethyl)benzene can be deduced from the dependence of the sum and difference of the two vicinal coupling constants upon solution dielectric constant. It should be possible to deduce the relative stabilities of rotamers of other similar tri-substituted dipolar ethanes by a similar technique. A polar substituent in the 4-position of the phenyl group does not affect conformational equilibrium or the effect of solvent upon conformational equilibrium in any predictable manner.

It was not possible to develop a general procedure to deduce the relative stabilities of rotamers of erythro- and threo(1,2-dibromopropyl)benzene. These are examples of substituted ethanes with only one vicinal coupling constant. However, much of the desired information could be determined by specific observations of the sign and magnitude of the change of the coupling constant with solvent and temperature. There appears to be a definite relationship between the magnitude of change of vicinal coupling constants with solvent and the expected energy difference between the two most stable rotamers for a series of closely related substituted dipolar ethanes.

It is possible to rationalize the deduced relative stability of rotamers for the compounds investigated if one assumes that both dipolar and steric interactions determine energy differences. The former appears to be at least as important as the latter in solution and is probably of greater importance in the gas phase.

Kinetic studies of the substitution reactions of the *cis*-dihalotetracarbonylmanganate(I) ions [1,2]

FRANK E. SMITH AND IAN S. BUTLER
Department of Chemistry, McGill University, Montreal, Quebec

Received August 23, 1968

The substitution reactions of $(C_2H_5)_4$[*cis*-$Mn(CO)_4X_2$], where X = Br or I, with a variety of ligands, L, were observed to take place with the loss of halide ion, X^-, to form *cis*-$Mn(CO)_4LX$ and $(C_2H_5)_4NX$. The reaction rates in *s*-tetrachloroethane were first order in substrate, independent of both the nature and the concentration of L, and decreased with increasing atomic weight of the halogen. A dissociative mechanism involving the breaking of a manganese–halogen bond as the rate-determining step is proposed. It is postulated that the order of reactivity of the substrates is most probably the result of an entropy rather than an enthalpy effect. The substitution reactions of $(C_2H_5)_4N$[*cis*-$Mn(CO)_4BrI$] in *s*-tetrachloroethane were also studied kinetically and found to be first order in substrate and independent of the nature and concentration of L. The products of these reactions, however, were mixtures of *cis*-$Mn(CO)_4LBr$ and *cis*-$Mn(CO)_4LI$, and $(C_2H_5)_4NBr$ and $(C_2H_5)_4NI$. A solvent study of the reaction between $(C_2H_5)_4N$[*cis*-$Mn(CO)_4Br_2$] and $P(C_6H_5)_3$ indicated that the rate of reaction tended to increase with increasing polarity of the solvent.

Canadian Journal of Chemistry, 47, 1311 (1969)

Introduction

A large number of detailed kinetic studies have been reported concerning the substitution reactions of neutral metal carbonyl complexes (1). In contrast there have been only two such reports dealing with charged complexes. Hieber and Wollmann (2) investigated the ^{14}CO exchange reactions of $[Mn(CO)_6][AlCl_4]$, $[Re(CO)_6][AlCl_4]$, and $Na[Mn(CO)_5]$; and Allen and Barrett (3) recently published data for the reactions of $(C_2H_5)_4N[M(CO)_5X]$ and $(C_2H_5)_4N$[*cis*-$PR_3M(CO)_4X$] (M = Cr, Mo, and W; X = Cl, Br, and I), with aryl phosphines, PR_3. The Group VII complexes showed no evidence of CO exchange. The $(C_2H_5)_4N[M(CO)_5X]$ complexes apparently reacted by both an S_N1 and an S_N2 mechanism to form $(C_2H_5)_4N$[*cis*-$PR_3M(CO)_4X$] and $PR_3M(CO)_5$, respectively, while the $(C_2H_5)_4N$[*cis*-$PR_3M(CO)_4X$] complexes were believed to react by an S_N1 mechanism to form $(PR_3)_2M(CO)_4$. The effect of solvent on these reactions was not investigated nor were any activation data presented in support of the proposed mechanisms.

The d^6, diamagnetic complexes, $(C_2H_5)_4N$[*cis*-$Mn(CO)_4X_2$] and $(C_2H_5)_4N$[*cis*-$Re(CO)_4X_2$], have been reported (4–6). When the manganese complexes were reacted with phosphines, L, replacement of the halide ion, X^-, occurred (5, 7), see reaction [1].

[1] $(C_2H_5)_4N$[*cis*-$Mn(CO)_4X_2$] + L → *cis*-$Mn(CO)_4LX$ + $(C_2H_5)_4NX$

Angelici estimated the rates of reaction when $L = P(C_6H_5)_3$ and tentatively proposed an S_N1 dissociative mechanism (5). He also discussed the probable importance of the solvent on the reaction rates.

The present study reports kinetic data for the substitution reactions of $(C_2H_5)_4N$[*cis*-$Mn(CO)_4X_2$] and $(C_2H_5)_4N$[*cis*-$Mn(CO)_4BrI$] with a variety of ligands in *s*-tetrachloroethane. Activation parameters have been determined for certain of the reactions, and the reaction of $(C_2H_5)_4N$[*cis*-$Mn(CO)_4Br_2$] with $P(C_6H_5)_3$ was studied in four different solvents.

Experimental

Preparation and Purification of Materials

Chemicals were obtained from the following sources: dimanganese decacarbonyl and triphenylphosphine (Alfa Inorganics, Inc.); tetraethylammonium chloride and bromide, and tri-*n*-butylphosphite (Eastman Kodak Co.); tetraethylammonium iodide (Fluka); trimethylphosphite, triphenylphosphite, tri-*n*-butylphosphine, triphenylarsine, triphenylstibine, triallylphosphite, and triisopropylphosphite (Aldrich Chemical Co.); pyridine, *s*-tetrachloroethane, chloroform, 1,2-dichloroethane, and nitromethane (Fisher Chemical Co.).

The tetraethylammonium salts and all ligands except tri-*n*-butylphosphine were used without further purification. The latter was purified by fractional distillation, under reduced pressure. Solvents were distilled under

For personal use only.

nitrogen from calcium hydride. Before distillation, *s*-tetrachloroethane was shaken with concentrated sulfuric acid and washed with water, and nitromethane was washed twice with aqueous sodium hydrogen carbonate.

The methods described in the literature were used to prepare $Mn(CO)_5Cl$ (8), $Mn(CO)_5Br$ (8), $Mn(CO)_5I$ (9), and $(C_2H_5)_4N[cis\text{-}Mn(CO)_4X_2]$ (5). $(C_2H_5)_4N[cis\text{-}Mn(CO)_4BrI]$, first reported in ref. (4), was prepared by refluxing a mixture of $Mn(CO)_5Br$ (0.2 g, 0.73 mmole) and $(C_2H_5)_4NI$ (0.18 g, 0.7 mmole) in methanol (10 ml) under nitrogen for 1 h. After cooling, the methanol was evaporated off with a water pump. The orange residue was dissolved in CH_2Cl_2 (20 ml) and the solution filtered under nitrogen. The filtrate was slowly added to *n*-hexane (250 ml) and the mixture allowed to stand at room temperature for 24 h. The orange crystals which formed were separated by filtration, washed with *n*-hexane, and dried under vacuum; yield, 0.23 g (65%). All of the anions were recrystallized from CH_2Cl_2 – *n*-hexane mixtures immediately before use.

Determination of Rates

The rates were determined by monitoring the absorbance changes of the reaction mixtures at 450 mμ. Pseudo-first-order conditions were employed in all cases, the substrate concentrations being kept at about 2×10^{-3} *M*. For $(C_2H_5)_4N[cis\text{-}Mn(CO)_4I_2]$ and $(C_2H_5)_4N[cis\text{-}Mn(CO)_4BrI]$, reaction mixtures were prepared in foil-wrapped round bottom (50 ml) flasks fitted with teflon-barrelled stopcocks and neoprene serum caps. This arrangement kept solvent-loss by evaporation to a minimum. The flasks were thermostated in a constant temperature bath (±0.1°). Samples were withdrawn at intervals with a syringe, introduced into an absorption cell, and the spectrum scanned in the region of 450 mμ. A solution containing the same concentration of ligand as in the reaction mixture was used as reference. The presence of a single isosbestic point in every case suggested (10) that the absorbances were due to two species and that the main reactions were proceeding without side-effects. This technique proved too slow to follow the reactions of $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Br_2]$. For these, a single sample was prepared in an absorption cell located in a thermostated block. This block could be mounted in the spectrophotometer and a constant-wavelength scanning device enabled continuous monitoring of the absorbance at 450 mμ. From the absorbance changes, linear plots of $\log(A_t - A_\infty)$ against time were obtained and the pseudo-first-order rate constants were calculated from the slopes of these lines. A_t is the absorbance at time t and A_∞ the absorbance at $t = \infty$. The reactions were assumed to go to completion since the experimental A_∞ values were in agreement with those calculated, and infrared spectra taken at the ends of the runs indicated total disappearance of the substrates.

The reaction of $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Cl_2]$ with $P(C_6H_5)_3$ in *s*-tetrachloroethane was too fast to study kinetically by our methods. Attempts to follow the same reaction in 1,2-dichloroethane by infrared spectroscopy also failed owing to the large number of overlapping bands in the spectrum. The spectrum indicated that the reaction product, $cis\text{-}Mn(CO)_4P(C_6H_5)_3Cl$, was rapidly reacting further with $P(C_6H_5)_3$ to form $cis\text{-}Mn(CO)_3[P(C_6H_5)_3]_2Cl$ (11).

The rate constants were generally reproducible to within 10% or better. A least squares computer program was used to calculate values of the activation parameters. The uncertainties in $\Delta H^\ddagger$ are estimated to be ±2 kcal mole^{-1} and in $\Delta S^\ddagger$, ±4 e.u. mole^{-1}. These uncertainties are somewhat larger for the bromo-iodo complex, viz., $\Delta H^\ddagger$, ±3 kcal mole^{-1} and $\Delta S^\ddagger$, ±5 e.u. mole^{-1}. The calculations were performed on an IBM 7044 computer.

Identification of Products of Reaction [1]

It was not possible to isolate the products from the kinetic runs owing to the dilute solutions used and the very large excess of ligand, L, present. The metal carbonyl products were identified by the similarity of their spectra to those reported for the $cis\text{-}Mn(CO)_4LX$ compounds (12, 13). In the reactions where L was a phosphite, the infrared spectra taken at the end of the kinetic runs indicated that the replacement of a CO group to form the disubstituted product, $cis\text{-}Mn(CO)_3L_2X$, had already begun. In a few cases the reaction products were isolated on a preparative scale.

An equimolar mixture of $(C_2H_5)_4N[cis\text{-}Mn(CO)_4I_2]$ and $P(C_6H_5)_3$ in *s*-tetrachloroethane (20 ml) was allowed to stand at room temperature for 24 h. The solvent was then removed under vacuum and a brown solid remained. This was washed several times with distilled water (taking care to keep the washings) and dried under vacuum. The brown solid was dissolved in *n*-hexane and the solution cooled in a dry-ice – acetone bath. The orange crystals of $cis\text{-}Mn(CO)_4P(C_6H_5)_3I$ which formed were filtered off and dried under vacuum.

Anal. Calcd. for $C_{22}H_{15}O_4PIMn$: C, 47.5; H, 2.7; P, 5.6; I, 22.9. Found: C, 47.9; H, 3.08; P, 5.6; I, 20.6.

The washings were evaporated to dryness on a hot-plate leaving a white residue of $(C_2H_5)_4NI$ which was quickly washed with CH_2Cl_2 (3 × 10 ml) and dried under vacuum.

Anal. Calcd. for $C_8H_{20}NI$: C, 37.4; H, 7.8; I, 49.5. Found: C, 37.5; H, 8.3; I, 49.3.

A similar procedure was used to isolate $cis\text{-}Mn(CO)_4P(C_6H_5)_3Br$ from $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Br_2]$ and $P(C_6H_5)_3$.

Anal. Calcd. for $C_{22}H_{15}O_4PBrMn$: C, 52.0; H, 2.95; P, 6.1. Found: C, 51.9; H, 3.16; P, 5.74.

Reaction of $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Br_2]$ with Pyridine

An orange oil was obtained when $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Br_2]$ was reacted with pyridine in *s*-tetrachloroethane at room temperature. The infrared spectrum corresponded to that reported for $cis\text{-}Mn(CO)_3(C_5H_5N)_2Br$ (12).

Anal. Calcd. for $C_{13}H_{10}N_2O_3BrMn$: C, 41.4; N, 7.4. Found: C, 39.8; N, 7.2.

Reaction of $(C_2H_5)_4N[cis\text{-}Mn(CO)_4BrI]$ with $P(C_6H_5)_3$

The products isolated from preparative scale reactions between $(C_2H_5)_4N[cis\text{-}Mn(CO)_4BrI]$ and $P(C_6H_5)_3$ in *s*-tetrachloroethane at room temperature contained both bromine and iodine. Found for the manganese carbonyl derivative: Br, 4.72 and 4.08; I, 20.09 and 15.08. Found for the tetraethylammonium salt: Br, 24.66; I, 22.61. The infrared spectrum of the carbonyl product showed that it was a mixture of $cis\text{-}Mn(CO)_4P(C_6H_5)_3Br$ and $cis\text{-}Mn(CO)_4P(C_6H_5)_3I$. The near-ultraviolet spectra of the reaction mixtures taken at the end of the kinetic runs

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

for this system indicated that the product was *cis*-$Mn(CO)_4P(C_6H_5)_3Br$. The infrared spectra of these reaction mixtures recorded somewhat later showed the presence of both *cis*-$Mn(CO)_4P(C_6H_5)_3Br$ and *cis*-$Mn(CO)_4P(C_6H_5)_3I$.

Mixed manganese carbonyl products were also formed when $(C_2H_5)_4N$[*cis*-$Mn(CO)_4BrI$] was reacted with other ligands.

Reaction of cis-$Mn(CO)_4P(C_6H_5)_3Br$ with $(C_2H_5)_4NI$

Excess solid $(C_2H_5)_4NI$ was added to a solution of *cis*-$Mn(CO)_4P(C_6H_5)_3Br$ in *s*-tetrachloroethane and the mixture was allowed to stand at room temperature for a few hours. The products were worked up in a manner similar to that described above. Infrared spectra of the manganese carbonyl product indicated the presence of both *cis*-$Mn(CO)_4P(C_6H_5)_3Br$ and *cis*-$Mn(CO)_4P(C_6H_5)_3I$. This was confirmed by halogen analyses. Found for *cis*-$Mn(CO)_4P(C_6H_5)_3X$: Br, 3.82; I, 15.16. The tetraethylammonium salt isolated also contained both bromine and iodine. Found for $(C_2H_5)_4NX$: Br, 8.22; I, 30.5. Since the reaction was carried out in the presence of a large excess of $(C_2H_5)_4NI$, a high iodine analysis would be expected for the tetraethylammonium salt.

The near-ultraviolet spectra of the above reaction mixture was monitored for a number of hours and it was observed that the band maximum gradually began to shift to lower energy and the spectrum corresponded more to that of *cis*-$Mn(CO)_4P(C_6H_5)_3I$ than *cis*-$Mn(CO)_4P(C_6H_5)_3Br$.

Spectra

The infrared spectra were obtained with a Perkin–Elmer 337 grating spectrophotometer equipped with a Texas Servo/Riter Model II expanded-scale recorder. The spectra were calibrated with polystyrene film and are considered to be accurate to at least ± 2.0 cm^{-1}. The near-ultraviolet spectra were recorded on a Unicam SP 800 spectrophotometer using 1 cm quartz cells and are accurate to ± 1.0 mμ.

Results

The substitution reactions of $(C_2H_5)_4N$[*cis*-$Mn(CO)_4Br_2$] in a variety of solvents and those of $(C_2H_5)_4N$[*cis*-$Mn(CO)_4I_2$] and $(C_2H_5)_4N$[*cis*-$Mn(CO)_4BrI$] in *s*-tetrachloroethane were all first order in substrate. The observed pseudo-first-order rate constants for these reactions are listed in Tables I and II. Since the reactions of $(C_2H_5)_4N$[*cis*-$Mn(CO)_4Cl_2$] with $P(C_6H_5)_3$ in *s*-tetrachloroethane were complete in less than 2 min, they were too fast to be measured quantitatively.

Data on the activation parameters for some of the reactions are given in Table III.

The C—O stretching frequencies of the reaction products in *s*-tetrachloroethane are shown in Table IV. The spectra of some of the compounds have been reported previously, but in different solvents (12). Since our measurements show significant differences from these, and the effect of solvent on C—O stretching frequencies in metal carbonyl compounds is well known (14), we feel that their inclusion in the Table is warranted. There is a general increase in the C—O stretching frequencies of the *cis*-$Mn(CO)_4LBr$ compounds with changes in L as, $P(C_6H_5)_3 \sim As(C_6H_5)_3 < P(OCH(CH_3)_2)_3 < P(n\text{-}OC_4H_9)_3 < P(OCH_2CH{:}CH_2)_3 < P(OC_6H_5)_3$. A similar order was given in ref. (12). It is tempting to try and correlate the position of a ligand in the order with its π-bonding ability. However, recent work (15) seems to indicate that C—O stretching frequency shifts may not be as reliable a measure of the π-bonding abilities of ligands in substituted metal carbonyl complexes as was previously believed and such correlations should be viewed with caution.

The near-ultraviolet spectra of the substrates and the reaction products are given in Table V. The near-ultraviolet spectra of *cis*-$Mn(CO)_4LX$ consist of one broad absorption band, the position of which is dependent on both L and X. The absorption maximum in *cis*-$Mn(CO)_4LBr$ moves towards lower energies with changes in L in the order

$$P(OCH_3)_3 > P(n\text{-}OC_4H_9)_3 \sim P(OCH_2CH{:}CH_2)_3 > P(OCH(CH_3)_2)_3 \sim P(OC_6H_5)_3 > P(n\text{-}C_4H_9)_3 > CO > P(C_6H_5)Cl_2 > P(C_6H_5)_3 > As(C_6H_5)_3 > Sb(C_6H_5)_3$$

This is an extension of the order given by Basolo and Angelici (13) who suggested that the higher the energy of the absorption maximum, the better the π-bonding ability of L. A similar, though much less complete series is found for *cis*-$Mn(CO)_4LI$, viz., $P(OCH_3)_3 > P(C_6H_5)_3 > As(C_6H_5)_3$. Keeping L constant and changing X from Br to I causes the band maximum to shift to lower energies. In the case of $P(C_6H_5)_3$ the energy of the band maximum decreases in the order Cl > Br > I. One broad absorption band is also found in the near-ultraviolet spectra of the $(C_2H_5)_4N$[*cis*-$Mn(CO)_4X_2$] and $(C_2H_5)_4N$[*cis*-$Mn(CO)_4BrI$] complexes. The energy of the band maximum decreases as $Cl_2 > Br_2 > BrI > I_2$.

Discussion

Reactions of Tetraethylammonium cis-Dihalotetracarbonylmanganate(I) Complexes

The results of this investigation show that the $(C_2H_5)_4N[cis\text{-}Mn(CO)_4X_2]$ complexes, where X = Br, or I, react with ligands, L, to form $cis\text{-}Mn(CO)_4LX$ and $(C_2H_5)_4NX$. The kinetic data in Tables I and II demonstrate that the rates of substitution of X^- by L are independent of both the nature and concentration of L but decrease with increasing atomic weight of X. This suggests an S_N1 dissociative mechanism involving the slow loss of halide ion in the rate-determining step to form a five-coordinate intermediate, followed by the rapid entry of L (eq. [2])

	$P(OCH_3)_3$	23	

*The activation entropies were calculated from the mean value of the activation enthalpy for each substrate and the mean rate constant at 25.5° for all of the ligands studied with that particular substrate.

Similar S_N1 dissociative mechanisms involving the breaking of a metal–halogen bond as the rate-determining step have been proposed by Allen and Barrett for the substitution reactions of $[cis\text{-}PR_3M(CO)_4X]^-$ (M = Cr, Mo, or W) with phosphines (3), and by Hieber and Wollmann for the halogen exchange reactions of $Mn(CO)_5Br$ and $Mn(CO)_5I$ (16).

Table III shows the activation parameters determined for several of the substitution reactions of $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Br_2]$ and $(C_2H_5)_4N[cis\text{-}Mn(CO)_4I_2]$. The activation enthalpies for the loss of Br^- and I^- are the same within experimental error (mean values of $\Delta H^{\ddagger}$ are 22.3 and 21.7 kcal $mole^{-1}$ for $[cis\text{-}Mn(CO)_4Br_2]^-$ and $[cis\text{-}Mn(CO)_4I_2]^-$ respectively). The activation entropies given were calculated from the mean values of the activation enthalpies for each substrate. They are in the range expected for a dissociative mechanism (1). The activation entropy for the dibromo complex is greater than that for the di-iodo complex.

Correlating the activation data with the relative reaction rates of the two substrates presents some problems. That $[cis\text{-}Mn(CO)_4Br_2]^-$ should lose Br^- almost 100 times faster than $[cis\text{-}Mn(CO)_4I_2]^-$ loses I^- under the same conditions would immediately suggest that the Mn—Br bond is weaker than the Mn—I bond. Such a difference in bond strength would seem entirely reasonable since Mn(I) is classified as a *soft* acid and would be expected to form a weaker bond with the *harder* bromine atom than with the *softer* iodine atom (17). Furthermore, the C—O stretching modes in $[cis\text{-}Mn(CO)_4Br_2]^-$ occur at higher frequencies than those in $[cis\text{-}Mn(CO)_4I_2]^-$ (4, 5) implying a greater C—O

bond strength in the former. This can be interpreted to mean that the bromine atoms give a lower electron density to the central manganese ion than the less electronegative iodine atoms do, and so the Mn—Br bonds should be weaker than the Mn—I bonds. In view of the errors on the activation enthalpies it is, of course, possible that the activation enthalpy for the dibromo complex is significantly lower than that for the di-iodo complex, and this is the reason for the difference in their reactivity. Another possibility is that the bond strengths are comparable and that the difference in the reaction rates arises because of the difference in the activation entropies of the two substrates. An analogous situation has recently been reported for the substitution reactions of the $Re(CO)_5X$ compounds (18). Activation entropies have also been shown to be important in determining the relative rates of the substitution reactions of the Group VI metal hexacarbonyls, $M(CO)_6$, and substituted metal hexacarbonyls such as $M(CO)_4$(*o*-phen) (1).

Why the activated complex formed from $[cis\text{-}Mn(CO)_4Br_2]^-$ should show a greater gain in entropy over its ground state than that formed from $[cis\text{-}Mn(CO)_4I_2]^-$ remains to be explained. It might be expected that since the di-iodo complex is presumably the more constrained in the ground state, it would benefit more in the formation of an activated complex by a dissociation process. The fact that it does not, presumably means that its activated complex is more constrained than that from the dibromo complex. Two possible explanations to account for such a situation come to mind. Firstly, because of the larger halogen atom, the five groups in the intermediate, $Mn(CO)_4I$, have less freedom of movement around the central manganese ion than do those in the other intermediate,

$Mn(CO)_4Br$. Secondly, and more likely, the activated complex consists of a five-coordinated intermediate involved in a weak interaction with the leaving halide ion. The stronger this interaction, the less likelihood of two discrete entities being formed and the lower the activation entropy expected. Since I^- is the larger and more easily polarized of the two halide ions, it might be expected to interact with the intermediate, $Mn(CO)_4I$, to a greater extent than Br^- would interact with $Mn(CO)_4Br$ and hence the di-iodo complex would exhibit the lower activation entropy. The solvent would be expected to play an important part in stabilizing such activated complexes. It should also be pointed out that, from the above discussion, $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Cl_2]$ would be expected to give rise to a larger activation entropy than $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Br_2]$ and therefore to react faster, as was observed. It is planned to determine the activation parameters for the dichloro complex by studying the substitution reactions at low temperatures, to see if the dramatic difference in the reactivity of the substrates is truly the result of the differences in their activation entropies rather than an undetected difference in their activation enthalpies.

The $[Mn(CO)_4X_2]^-$ ions are isoelectronic and iso-structural with the neutral $Fe(CO)_4X_2$ molecules. The latter exchange X with $*X_2$ at a rate which is independent of $*X_2$ (16). The mechanism suggested involves the simultaneous dissociation of both X groups and concomitant X—X bond formation. Unfortunately, the difference in mechanism means that it is impossible to compare the reaction rates of the two systems. The $Mn(CO)_5X$ complexes exchange X with $*X_2$ by an S_N1 dissociative mechanism and at a much slower rate than the substitution reactions of the anions (16). This suggests that the Mn—X bonds are weaker in the anions. In the Introduction it was mentioned that the anionic complexes, $[M(CO)_5X]^-$ (M = Cr, Mo, W), react with phosphines by both an S_N1 and an S_N2 mechanism (3). The relative fraction of the reaction which proceeds by the S_N2 path versus the S_N1 path is larger for the Mo(0) and W(0) complexes than for the Cr(0) complexes. Similar observations have been made for the substitution reactions of the parent hexacarbonyls, $M(CO)_6$, and a variety of substituted hexacarbonyls (1). The occurrence of an S_N2 mechanism in these cases is particularly interesting as there are very few octahedral complexes known to undergo ligand substitution reactions *via* such a mechanism and, from a theoretical standpoint, d^6 metal complexes with filled t_{2g} orbitals would be considered the least likely of all to do so (1). The size of the central atom appears to be a very important factor for d^6, diamagnetic systems. Since Mn(I) is smaller than Cr(0), it comes as no surprise to find that the $[cis\text{-}Mn(CO)_4X_2]^-$ complexes react only by an S_N1 mechanism. We are currently investigating the substitution reactions of the $(C_2H_5)_4N[cis\text{-}Re(CO)_4X_2]$ complexes since, by analogy with Mo(0) and W(0), the much larger Re(I) should react by both an S_N1 and an S_N2 mechanism. Recently it has been reported that the CO substitution reactions of $cis\text{-}Re(CO)_4LX$ take place by both mechanisms (19).

The effect of solvent on the reaction rates has not yet been considered. Because of the ionic nature of the substrates and the release of X^- during the reactions, it was expected that the polarity of the solvent would greatly influence the rates. The reaction of $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Br_2]$ with $P(C_6H_5)_3$ was studied in four different solvents. Unfortunately, the solubility properties of the substrate and ligand precluded the use of solvents covering a wide range of dielectric constants. Table VI indicates that, in general, the rate increases with increasing polarity of solvent. That the solvent has only a slight effect on the rate presumably means that there is very little difference in polarity between the ground state and the activated complex. This might be expected if the activated complex involves the leaving Br^- ion.

The results in Table I show that the reactions of $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Br_2]$ with $As(C_6H_5)_3$ and $Sb(C_6H_5)_3$ in *s*-tetrachloroethane are slower than the reactions with the other ligands under the

same conditions. However, the rates are also independent of ligand concentration. The activation enthalpy for the reaction with $As(C_6H_5)_3$ is 25 kcal mole^{-1}. This is slightly higher than that found for the other ligands and may be responsible for the slower reaction. Another possibility is that the slower rates for $As(C_6H_5)_3$ and $Sb(C_6H_5)_3$ are the result of some specific solvent effects. Similar anomalies were found in the substitution reactions of $Mn(CO)_5Br$ (12).

The reaction of $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Br_2]$ with pyridine went directly to the disubstituted product, $cis\text{-}Mn(CO)_3(C_5H_5N)_2Br$, without giving any evidence for the monosubstituted intermediate. Since the rate constant for the reaction was the same as that found with the other ligands, it is assumed that reaction [2] was rapidly followed by loss of CO and entry of a second pyridine molecule. The same effect was observed when $Mn(CO)_5Br$ reacted with pyridine and other ligands which coordinate through nitrogen (12).

Reactions of Tetraethylammonium cis-Bromoiodotetracarbonylmanganate(I)

It was hoped that by studying the rates of the substitution reactions of the mixed halide complex, $(C_2H_5)_4N[cis\text{-}Mn(CO)_4BrI]$, it might be possible to determine the relative strengths of the Mn—Br and Mn—I bonds, since, if the Mn—Br bond is weaker than the Mn—I bond, reaction [6] would be expected to occur in preference to reaction [7]

[6] $(C_2H_5)_4N[cis\text{-}Mn(CO)_4BrI] + L \rightarrow cis\text{-}Mn(CO)_4LI + (C_2H_5)_4NBr$

[7] $(C_2H_5)_4N[cis\text{-}Mn(CO)_4BrI] + L \rightarrow cis\text{-}Mn(CO)_4LBr + (C_2H_5)_4NI$

The rate of disappearance of $(C_2H_5)_4N[cis\text{-}Mn(CO)_4BrI]$ was found to be independent of the nature and concentration of L. The reactions proceeded with pseudo-first-order rate constants in between the rates for $(C_2H_5)_4N[cis\text{-}Mn(CO)_4Br_2]$ and $(C_2H_5)_4N[cis\text{-}Mn(CO)_4I_2]$ but closer to those of the latter (Table I). The dilute solutions used in the kinetic runs prevented the isolation and analytical identification of the reaction products. The near-ultraviolet spectra of the reaction mixtures taken at the end of the kinetic runs indicated the presence of *cis*-$Mn(CO)_4LBr$. Infrared spectra recorded later showed the presence of both *cis*-$Mn(CO)_4LBr$ and *cis*-$Mn(CO)_4LI$. Preparative scale reactions were carried out with $P(C_6H_5)_3$. The manganese carbonyl derivative and the tetraethylammonium halide isolated proved to be mixtures of *cis*-$Mn(CO)_4P(C_6H_5)_3Br$ and *cis*-$Mn(CO)_4P(C_6H_5)_3I$, and $(C_2H_5)_4NBr$ and $(C_2H_5)_4NI$, respectively. No attempt was made to determine the exact composition of either of these mixtures. The formation of mixed products during these reactions would seem to indicate that both the Mn—Br and the Mn—I bonds are being broken. This would imply that the manganese–halogen bonds are of comparable strength. However, whilst these studies were in progress, the following halogen exchange reaction was observed

[8] *cis*-$Mn(CO)_4P(C_6H_5)_3Br + (C_2H_5)_4NI \rightarrow cis\text{-}Mn(CO)_4P(C_6H_5)_3I + (C_2H_5)_4NBr$

Although no kinetic investigation of this reaction was made, spectroscopic evidence indicated that it was approaching completion at a rate somewhat slower than the substitution reactions of the bromo-iodo complex. The near-ultraviolet spectra taken at the end of the kinetic runs showed the presence of only *cis*-$Mn(CO)_4P(C_6H_5)_3Br$. However, infrared spectra of these reaction mixtures recorded later indicated that both *cis*-$Mn(CO)_4P(C_6H_5)_3Br$ and *cis*-$Mn(CO)_4P(C_6H_5)_3I$ were present. This must mean that the bromo-iodo complex reacts only *via* reaction [7] and that the halogen exchange reaction [8] is responsible for the formation of mixed products. Furthermore, if reaction [8] reaches completion, mixed products would not be expected. It is possible, however, that the spectral studies and product isolation were carried out before the halogen exchange had had chance to reach completion. Another possible explanation for the mixed products is that the exchange reaction reaches an equilibrium rather than going to completion. The halogen exchange reaction is being further investigated at the present time.

It appears then that the rate-determining step in the substitution reactions of the bromo-iodo complex is the rupture of the Mn—I bond. The reactions are faster than those with the di-iodo complex which also take place by the breaking of an Mn—I bond. Recalling our previous discussion, since the mean activation enthalpies for the two substrates are very similar, the faster rate for the bromo-iodo complex is presumably because of the greater activation entropy expected for an

activated complex involving the five-coordinated intermediate, $Mn(CO)_4Br$, than for that involving $Mn(CO)_4I$. Within the experimental errors quoted, the activation entropies for the bromo-iodo and the di-iodo complexes are in agreement with this interpretation. It should be pointed out, however, that it was difficult to obtain satisfactory A_∞ values for the substitution reactions of the bromo-iodo complex at temperatures above 25°, owing to interference from the subsequent reactions of the *cis*-$Mn(CO)_4LBr$ compounds. This interference led to large errors in the activation parameters.

In conclusion, it appears that the substitution reactions of $(C_2H_5)_4N$[*cis*-$Mn(CO)_4BrI$] take place by the breaking of the Mn—I bond and not the Mn—Br bond. The initial products of the reaction appear to be *cis*-$Mn(CO)_4LBr$ and $(C_2H_5)_4NI$. As the result of a halogen exchange reaction, the compounds *cis*-$Mn(CO)_4LI$ and $(C_2H_5)_4NBr$ are also formed. In these substitution reactions and in the analogous reactions of the dibromo and di-iodo complexes there was no evidence of CO substitution by L to form ions of the type $[Mn(CO)_3LX_2]^-$.

^{14}N nuclear magnetic resonance: amines and ammonium ions

M. WITANOWSKI AND H. JANUSZEWSKI
Institute of Organic Chemistry, Polish Academy of Sciences, Warszawa, Poland

Received September 19, 1968

The ^{14}N nuclear magnetic resonance (n.m.r.) signals of alkylamines and ammonium ions are shifted to lower magnetic fields with the increasing number of alkyl groups at the carbon atom directly bonded to the nitrogen atom, and at the nitrogen atom itself. The resonance of an ammonium ion always occurs at a field lower than that for the corresponding amine. It seems that high-lying excited states, not only those corresponding to lowest-wavelength transitions, are important for an explanation of the observed resonance shifts. A downfield shift of the ^{14}N resonance and a substantial increase in signal width, as compared with the spectra of neat amines, are observed for aqueous solutions of amines. There is a very characteristic chemical shift for the $R—CH_2—NH_2$ molecules (R = alkyl, phenyl, vinyl) in the ^{14}N n.m.r. spectra.

Introduction

Correlations between ^{14}N chemical shifts and molecular structure have already been found (1, 2, 4, 5) for various classes of organic compounds that contain sp- or sp^2-hybridized nitrogen atoms. A theoretical explanation of the shifts has been postulated (5, 6) in terms of the linear combination of atomic orbitals (l.c.a.o.), molecular orbitals, and the mean excitation energy approximation. However, there have so far been no satisfactory observations and explanation of the ^{14}N shifts for the nitrogen atoms in saturated systems. The available data (7) for amines and ammonium ions, based on external reference measurements under non-uniform experimental conditions, did not show any obvious dependence of the shift on the structure and the number of alkyl groups at the nitrogen atom. The only exception was the observation of a downfield shift for symmetric ammonium ions, in order NH_4^+, $N(CH_3)_4^+$, $N(C_2H_5)_4^+$. The attempt (7) at finding a relationship between the longest-wavelength transition of the inert electron pair and the ^{14}N chemical shift gave rather unsatisfactory results for saturated amines, while a general correlation of this kind could be observed for large chemical shifts in the spectra of unsaturated molecules.

In this paper, the principal concern is the effect of alkyl groups R in structures $:N(R_1)(R_2)(R_3)$ and $^+N(R_1)(R_2)(R_3)(R_4)$ on the ^{14}N resonances, as can be inferred from a systematic study by internal reference methods (3). Such effects may have diagnostic value for interpretation of ^{14}N n.m.r. spectra. They should also contribute to a better understanding of nitrogen chemical shifts, since only σ-bond and lone-pair effects are involved here. Even if it should not be possible to obtain a complete description of the origin of spectral changes, the observations may be helpful in eliminating non-decisive factors in the theory of ^{14}N chemical shifts.

Experimental

The substances investigated were chemically pure commercial grade. A Varian HA-60 spectrometer operating at 4.33 Mc/s (14 100 G) in the HR mode was used for the measurements of ^{14}N n.m.r. spectra. The samples were placed in 15 mm outer diameter tubes, sealed if neccessary. Both the centerband and the 2 kc/s sideband from the base-line stabilizing system were recorded for calibration purposes, and for optimizing the signal-to-noise ratio of broad and sharp resonance peaks. The latter, particularly those of ammonium ions which showed fine multiplet structure, were measured in the sideband mode. The internal reference methods of calibration followed those suggested in earlier work (3) The results of measurements, given in Tables I and II, are averages of 4–6 runs; maximum experimental deviation is indicated in the Tables. If one or two results happened to differ significantly from the rest, six measurements were carried out, and the average was calculated of the four closest results. The half-height widths were measured under conditions where the power of the radiofrequency was far below the saturation level of the signal. Slight coloration of the samples containing nitromethane was observed after several hours, but the shifts and widths of the resonance signals did not change, at least outside the experimental error.

Results and Discussion

The ^{14}N chemical shifts and signal widths of amines and ammonium ions are given in Tables I and II, respectively. The ^{14}N n.m.r. signals of the aliphatic amines (2–19) occur between +320 and +380 p.p.m., while the amino groups at an

aromatic ring (**20–24**) are characterized by a rather narrow range, +315 to +320 p.p.m. The effect of an aprotic solvent, such as dioxane (Table I), is insignificant, but there is a definite downfield shift of the resonance in aqueous NaOH as well as a remarkable increase in signal width. The spectra of neat amines and their dioxane solutions are not affected by the varying proportion of nitromethane (1–10% v/v). The range of occurrence of ammonium ion resonance peaks overlaps with a large part of that for amines. The reliability of nitromethane as internal standard for concentrated acid solutions of alkylammonium salts was examined in the spectra of tetramethylammonium chloride in concentrated aqueous HCl with a trace of nitromethane, and in neutral aqueous solution with KNO_3 as the internal standard. The difference in the shifts was negligible (Table II).

Mono-alkylamines show a clear dependence of their ^{14}N shifts on the structure of the alkyl group, and a similar downfield shift with the increasing substitution at the α-carbon atom (decreasing electronegativity) is also observed for the corresponding ammonium ions, as shown below.

Compound	R	δ_N (p.p.m.)
$R—NH_2$ (neat)	CH_3	+378
	CH_2CH_3	+355
	$CH(CH_3)_2$	+334
	$C(CH_3)$	+319
$R—NH_3^+$	CH_3	+351
	CH_2CH_3	+336
	$C(CH_3)_3$	+314

Similar trends exist in the shifts of di- and trialkylamines as well as those of di-, tri-, and tetraalkylammonium ions.

The chemical shift of +360 ± 5 p.p.m. is very characteristic of the $R—CH_2—NH_2$ system where R = alkyl, aryl, or vinyl (**3–5**, **14–17**, **19**), since it is out of range of the shifts for di- and trialkylamines and ammonium ions.

A shift to lower field is also observed if the number of alkyl groups at the nitrogen atom increases,

$$RNH_2 \rightarrow R_2NH \rightarrow R_3N$$

$$RNH_3^+ \rightarrow R_2NH_2^+ \rightarrow R_3NH^+ \rightarrow R_4N^+$$

$$\longrightarrow \text{downfield } ^{14}\text{N shift}$$

but the effect is not so large and not so regular as for the substitution at the α-carbon atom. It is possible that steric hindrance and hybridization changes affect the spectra.

The resonance signal of an ammonium ion always occurs at a field lower by 5–30 p.p.m. than that for the corresponding amine. The origin of the low-field shift for aqueous solutions of amines (**1**, **2**, **3**, **8**, **9**, **10**), as compared with neat amines, may be of the same nature.

$$\underset{\text{weak hydrogen bond}}{R—\overset{H}{\underset{H}{N}}: \cdots H—\overset{H}{N}—} \rightarrow \underset{\text{stronger hydrogen bond}}{R—\overset{H}{\underset{H}{N}}: \cdots H—O—} \rightarrow \underset{\text{complete proton transfer}}{R—NH_3^+}$$

$$\longrightarrow \text{downfield } ^{14}\text{N shift}$$

The presence of hydroxyl groups which may be hydrogen-bonded to the amino group results in a large increase in signal width, as can be seen for the aqueous solutions of amines. The viscosity of the solution does not seem to be a dominant factor here, since the dioxane solutions do not show any appreciable broadening of the resonance signals in spite of the higher viscosity of dioxane as compared to water and neat amines.

One should note that the resonance shift between amines and the corresponding ammonium ions is diamagnetic, i.e. to lower fields with the decreasing electron density at the nitrogen atom, while shifts in the other direction are observed within the two groups of molecules. The former may simply be explained as due to a decrease in the diamagnetic term in the expression for the screening constant. However, caution is neccessary here, because of the latter shifts. An alternative explanation of the amine–ammonium ion shift may be found from a consideration of the paramagnetic term. In the mean excitation energy approximation, this is proportional (8) to the mean inverse cube of the 2p-orbital radius, the reciprocal mean excitation energy, and the $\sum Q_{AB}$ term

$$(Q_{AB})_{zz} = P_{x_Ax_B}(2\delta - P_{y_Ay_B}) + P_{y_Ay_B}(2\delta - P_{x_Ax_B}) + 2P_{x_Ay_B}P_{y_Ax_B}$$

with analogous other components of the tensor, where the P terms are p-bond orders and p-charge densities from the l.c.a.o. matrix. For structure $N(R_1)(R_2)(R_3)(R_4)$, where R = H,

an alkyl, or an electron pair (one only), the molecular orbitals may be written as

$$\psi_{NR}^{\sigma} = \frac{1}{\sqrt{2}}[(1 + a)^{1/2}\phi_{N(sp^3)} + (1 - a)^{1/2}\phi_R]$$

where a is the σ-bond polarization parameter. Hence, $Q_{NR,H} = 0$ and $Q_{NN} = 2 - \frac{1}{3}(a_1a_2 + a_1a_3 + a_1a_4 + a_2a_3 + a_2a_4 + a_3a_4)$. This may be simplified, for structures with all groups R identical, to

Group	Q_{NN}
NR_4^+	$2 - a^2$
$:NR_3$	$2 - a - a^2$

The difference in Q_{NN} between NR_4^+ and $:NR_3$ is positive (thus suggesting a downfield shift for the former) if

$$a(NR_3) + a^2(NR_3) - 2a^2(NR_4^+) > 0$$

or else if $a(NR_3) = 0$; 0.05; or 0.10, then $a(NR_4^+) \leqslant 0$; 0.16; or 0.23, respectively. Thus the change in the Q_{NN} term and in the 2p-orbital radius may explain, at least in part, the resonance shift between amines and ammonium ions. However, the shifts within the two groups cannot be explained in this way. The remaining factor in the expression for the paramagnetic term (8) is the mean excitation energy. It is rather difficult to obtain a reliable estimate of the latter. Replacing the mean excitation energy with that of the longest-wavelength transition is a very crude method and gives poor correlation with the ^{14}N shifts of amines; it is better for the nitrogen-containing unsaturated systems (7). However, if the ^{14}N shifts of amines are compared with the available (9) data from vacuum ultraviolet absorption measurements (Table III), the correlation seems to improve for the second band. While the changes in the first band correspond roughly only to the downfield shift with the increasing number of alkyl groups at the nitrogen atom, the changes in the second band reciprocate the shift between the corresponding methyl and ethyl derivatives of ammonia. Nevertheless, the correlation is far from being linear. It is possible, that a still better relationship should be obtained if the next consecutive transition was included into the consideration of the mean excitation energy, but there were no data available.

The effect of delocalization of the lone electron pair at the nitrogen atom is observed on the ^{14}N n.m.r. spectra as a downfield shift (**20–24**) of the resonance. This effect is characteristic of the conjugated amines as a whole, but also shows variations consistent with the degree of delocali-

zation of the lone pair (**22–24**). Most probably, the shift results from an increase in the paramagnetic term due to π-bonding between the nitrogen atom and the aromatic ring. It is analogous to the downfield shift of the ^{14}N resonance of amides (6), where the lone pair is also involved in a delocalized orbital system.

Nuclear recoil reactions in organomanganese compounds. III. $Mn(CO)_5$

I. G. DE JONG, S. C. SRINIVASAN, AND D. R. WILES
Chemistry Department, Carleton University, Ottawa, Canada

Received October 1, 1968

Experimental evidence is presented which shows that upon neutron irradiation of the compounds $Mn_2(CO)_{10}$, $CpMn(CO)_3$, and $CH_3CpMn(CO)_3$ the recoiling ^{56}Mn atom gathers carbonyl radicals to stabilize itself in the group $Mn(CO)_5$, with about 10% radiochemical yield. Basically, the experiments involved addition of iodine to the irradiated compound and identification of the radioactive $IMn(CO)_5$ by carrier techniques. It is suggested that in $Mn_2(CO)_{10}$ targets, the species produced is the $\cdot Mn(CO)_5$ radical itself. Some experimental data are given to show that this radical is stable for over 1 h in the solid at room temperature, but decomposes rapidly above about 60°. The radical decomposes in 20–30 s in solution. In both other target compounds, the species produced is chemically more stable, although it reacts rapidly with iodine. This species is found to be $HMn(CO)_5$, which occurs to the extent of 10–12% in $CpMn(CO)_3$. $CH_3Mn(CO)_5$ was also detected in $CH_3CpMn(CO)_3$ targets, and its yield was found to be a function of the concentration of isooctane used as diluent in the targets.

Results from other studies are discussed in the light of the present data, and it is concluded that in general, in neutron-irradiated metal carbonyl compounds, the recoil atom is able to accumulate carbonyl radicals to a greater extent than is consistent with the composition of the target compound.

Introduction

The various phenomena resulting from the capture of a neutron by a nucleus can be divided into three groups. First, and most obvious, is the nuclear transition itself—in this case we shall consider only radiative capture, or the (n,γ) process.

Second, and much more obscure experimentally, is a group of essentially physical phenomena, which depends mostly on the nature of the nuclear de-excitation process and on the state of aggregation of the target material. These phenomena include high energy (up to several hundred eV) recoil of the product nucleus, or ejection of several (up to 10 or 15) of the atomic electrons, or combinations of these. As a result of this sudden deposition of energy, the region around the product nucleus is presumed to be heated very rapidly to temperatures which are very difficult to estimate but which may be several hundred degrees. The size and duration of this hot zone are also very difficult to evaluate, but current estimates suggest a diameter of some few Å and a lifetime of perhaps 10^{-10} s. A study of these phenomena is made extremely difficult by the short duration of the action and by the fact that invariably the results are severely altered by subsequent reactions.

The third group is one of essentially chemical reactions which depend strongly on the chemical nature of the medium. These reactions include electron capture, electron transfer, ionic diffusion, ligand transfer and exchange, and other reactions in ionic solids, radical diffusion, radical recombination, atom abstraction, group migration, and other reactions in molecular compounds.

It is clear, of course, that the reactions cannot be so neatly categorized in reality, although the reactions which have been studied seem to group themselves roughly along the lines just stated.

Although practical difficulties often interfere, this last group of phenomena is in principle amenable to chemical study. It is these phenomena which we have been studying, in an attempt ultimately to shed light on the nature of the second group of physical processes which precedes and causes the third group.

In previous papers of this series (1, 2) we have discussed studies of recoil reactions in cyclopentadienylmanganese tricarbonyl ($CpMn(CO)_3$) and its homologue methylcyclopentadienylmanganese tricarbonyl ($CH_3CpMn(CO)_3$). While several as yet unexplained phenomena were reported in these and other papers (3) it was established that the important reactions were radical reactions. Perhaps of equal significance, and less predictable, was the discovery and identification (4, 2) of $CH_3Mn(CO)_5$ as one of the products of recoil reactions in $CH_3CpMn(CO)_3$. While not without precedent, since Baumgärtner and Zahn (5) had found considerable chromium hexacarbonyl in neutron-irradiated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

benzenechromium tricarbonyl, this discovery raised the question as to how five carbonyl groups could be collected by a manganese atom, in a milieu of only three carbonyls per molecule. Baumgärtner and Zahn had noted the same anomaly, and attributed the results to the mobility of the carbonyl radical. We conjectured similarly (2, 4) that the molecule was formed largely in the hot zone, but by reactions of a primarily chemical nature. The stepwise nature of such reactions has been suggested by work on the carbonyls of chromium and other Group VI metals (6). Thus, it became possible to pose the question (2) as to which was the final step:

[1] $$\cdot CH_3 + \cdot Mn(CO)_5 \rightarrow CH_3Mn(CO)_5$$

or

[2] $$CH_3\dot{M}n(CO)_4 + \cdot CO \rightarrow CH_3Mn(CO)_5$$

It was evident that the methyl group is the ring substituent, rather than a group reconstituted from ring fragments, since no $CH_3Mn(CO)_5$ was detected in irradiated $CpMn(CO)_3$ (7). Similarly, irradiation of $Mn_2(CO)_{10}$ in benzene solution gave rise to small amounts of phenylmanganese pentacarbonyl, ($C_6H_5Mn(CO)_5$), showing the importance of the available phenyl radicals (7, 8).

Recently, strong evidence was found for the existence of the $Mn(CO)_5$ radical in neutron-irradiated $Mn_2(CO)_{10}$, and the suggestion was made (8) that this radical might provide the mechanism for the formation of $CH_3Mn(CO)_5$ and the other observed manganese pentacarbonyls. Thus, it seemed that reaction [1] was chosen in preference to reaction [2]. This same $Mn(CO)_5$ group is commonly found as an entity forming part of a variety of organometal compounds (9), taking part in photochemical (10) and other reactions. It has been considered as a possible catalytic intermediate (11). Studies of its behavior in a mass spectrometer have been able to lead to determination of some thermodynamic (12) and kinetic (13) properties of $Mn(CO)_5$ in the gas phase. The present paper reports on various studies of the occurrence and behavior of the $Mn(CO)_5$ group in recoil reactions.

Experimental

This work involves experiments which are basically straightforward: a purified target material is irradiated with neutrons, it is dissolved in a purified solvent, macro quantities (e.g. 20 mg) of carriers are added for any suspected products, and the carriers are carefully separated and purified. The purified products are analyzed to determine chemical recovery, and the radioactivity of ^{56}Mn is measured to determine radiochemical yield. The result, after appropriate correction, is expressed as the retention (of the parent compound) or the yield (of all other identifiable products) which is in each case the % of the radioactive ^{56}Mn which is recovered in each of the respective forms.

Target Materials

$Mn_2(CO)_{10}$ was obtained from Strem Chemicals Inc. It was purified before use by chromatography, followed by vacuum sublimation. $CpMn(CO)_3$ was obtained from Ethyl Corporation, and was purified before use by vacuum sublimation. $CH_3CpMn(CO)_3$ was obtained from Ethyl Corporation, and was distilled under reduced pressure before use. In the handling of these materials, care was taken at all stages to avoid strong light, even fluorescent room light, whenever possible. Purified samples were stored in the dark until use.

Carrier Compounds

$IMn(CO)_5$ was prepared by direct reaction of $Mn_2(CO)_{10}$ with I_2 (14) and was purified by column chromatography on silica gel in petroleum ether. $CH_3Mn(CO)_5$ and $HMn(CO)_5$ were prepared by the reactions of CH_3I and of phosphoric acid with $NaMn(CO)_5$ (15). They were purified by high vacuum methods before use.

Chemical Processing

Separation and purification of the various products is done largely by column chromatography on silica gel. $CH_3Mn(CO)_5$ was separated by vapor–phase chromatography (v.p.c.) on Silicone 550 oil, supported on fire brick. $HMn(CO)_5$ was separated in some experiments by v.p.c. and in other experiments by high vacuum transfer techniques. In all cases, it was immediately converted to $IMn(CO)_5$, which was subsequently purified by column chromatography. Except for a few initial experiments, all chemical processing was done under nitrogen, using carefully purified solvents, so as to exclude oxygen and moisture since, as is shown below, some of the compounds are sensitive to the presence of atmospheric oxygen. In all cases the utmost care was taken to avoid severe treatment of the target compound, especially prior to the addition of carriers, since it has been shown (16) that the apparent retention may be affected by such treatment. One frequently used procedure was to dissolve the target compound in a solution of iodine in petroleum ether (8). The iodine was subsequently removed by extraction with an aqueous sulfite solution after the addition of carriers. No evidence has been found to suggest bulk reaction with the target materials, even under conditions much more severe than those actually used in our experiments.

Analysis

Chemical recovery of the carriers was determined by direct weighing whenever possible. Otherwise, spectrophotometric analysis was used, with care taken to minimize photolytic or thermal decomposition within the spectrophotometer.

Irradiations

Irradiations were performed in the Sb–Be neutron facilities of A.E.C.L., Commercial Products Division, in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Ottawa (17) and in the thermal column of the reactor at the Western New York Nuclear Research Center, Buffalo. The thermal neutron fluxes were $\sim 2 \times 10^8$ and $\sim 3 \times 10^9$ cm^{-2} s^{-1}, respectively. The irradiation conditions differed more significantly in the γ flux, which amounted to about 2 Mrads h^{-1} in the Ottawa source, and was very much lower in the thermal column.

Counting Procedure

The 0.84 MeV γ ray from ^{56}Mn was measured using various NaI scintillation counters. The sample geometry was kept constant through all measurements of each experiment. Correction was made for decay of the activity during the experiment.

Results

$Mn_2(CO)_{10}$

The results of various experiments on neutron-irradiated $Mn_2(CO)_{10}$ are shown in Figs. 1–3. The yield of $IMn(CO)_5$ shows a distinct dependence on the presence of atmospheric oxygen, and we accept the data from the nitrogen experiments as representing the more correct value. (The $IMn(CO)_5$ data given in ref. 8 were obtained from experiments done in air, and are thus less accurate than the present data.) The fact that the yield of $IMn(CO)_5$ is insensitive to the concentration of I_2 from very low concentrations, suggests that the scavenging reaction occurs in the solution rather than immediately at the dissolving interface. The evident insensitivity of the retention of $Mn_2(CO)_{10}$ to the iodine concentration, including no iodine at all, shows that the scavenged species does not recombine or exchange to form

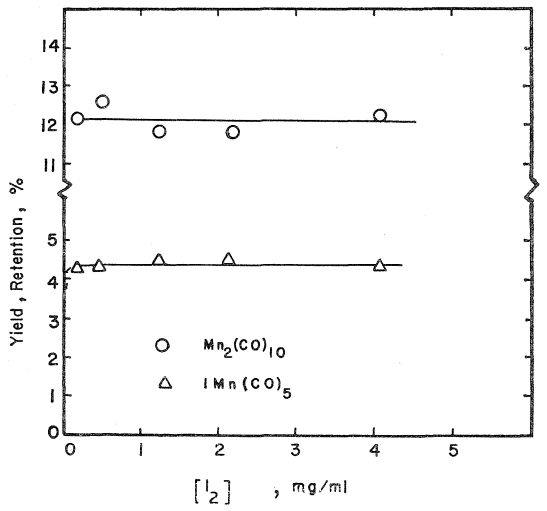

FIG. 1. Retention and yield data in $Mn_2(CO)_{10}$ as a function of iodine concentration.

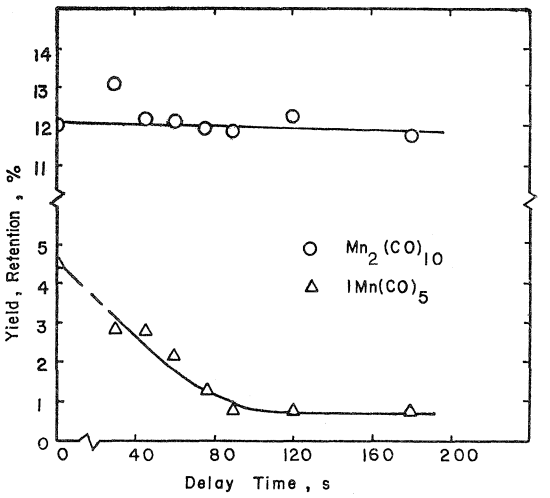

FIG. 2. Retention and yield data in $Mn_2(CO)_{10}$ as a function of the time of delayed addition of iodine (1.2 mg I_2 ml^{-1}). The zero of time is uncertain by about 0.3 min, but the timing of the experiments is consistent to within 2–3 s.

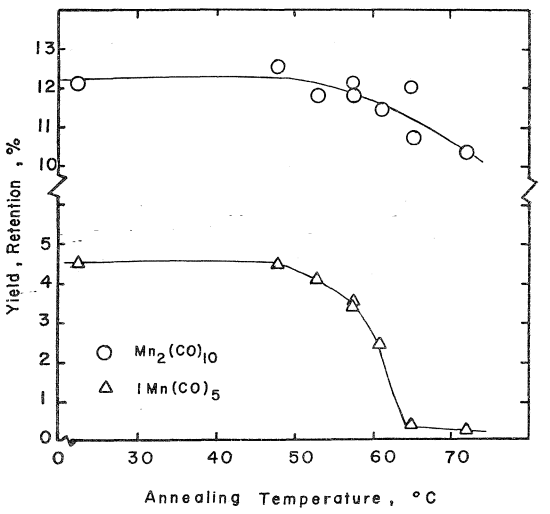

FIG. 3. Retention and yield data in $Mn_2(CO)_{10}$ as a function of temperature of isochronal (6.0 min) annealing.

$Mn_2(CO)_{10}$ in the absence of the scavenger. We have claimed earlier (8) that this species is the $\cdot Mn(CO)_5$ radical. We shall present later in this paper further arguments bearing on this identification.

The stability of the $\cdot Mn(CO)_5$ radical in solution is shown by the data in Fig. 2. The data are somewhat scattered, as one might expect from such an experiment. Nonetheless, it is clear that

the half-time of the radical under these conditions is some seconds—the exact value is not important to this present work. Once again, one sees no effect on the $Mn_2(CO)_{10}$ retention, so it is evident that, whatever their fate, these radicals do not combine or exchange to give $Mn_2(CO)_{10}$.

A very common experiment in the study of recoil reactions in ionic systems is the observation of the effects of heating the solid target material before its chemical processing, so as to learn about reactions which occur in the solid state before the chemical dissolution can have any destructive effect on the various unstable species. Such an experiment was done on the neutron-irradiated $Mn_2(CO)_{10}$, with the results shown in Fig. 3. Here it is quite apparent that the radical is being destroyed—once again without combination or exchange to re-form the target compound. There was no detectable bulk decomposition of the target compound. The fact that the decomposition occurs so abruptly at 55–60° suggests that a single-step reaction is involved. Thus the decomposition is evidently

[3] $$\cdot Mn(CO)_5 \rightarrow Mn(CO)_4 + CO \rightarrow \cdots$$

(We wish to point out here that the usual methods of studying radicals—notably by electron spin resonance—cannot be applied here because of the very small number of these radicals present. We estimate that at the time of our radioactivity measurements we have present about 10^7 $\cdot Mn(CO)_5$ radicals. To scale up the experiments to give a detectable number of radicals would involve the production of very intense radioactivity, which would be awkward to handle. Furthermore, the intense radiation necessary to produce this large an activity would likely cause severe damage to the material, and so obliterate any traces of the radical under study.)

$CpMn(CO)_3$

The results of studies on $CpMn(CO)_3$ are shown in Fig. 4. Only the iodine scavenging experiment was done on this target compound, with heat treatment of the samples prior to their dissolution. Here the behavior is quite different, in that we observe that the species giving rise to $IMn(CO)_5$ is no longer sensitive to the thermal treatment. To be sure, there is a small decrease in the yield of $IMn(CO)_5$, and a corresponding increase in the yield of $Mn_2(CO)_{10}$. If this is not merely coincidence, it may then be that a small

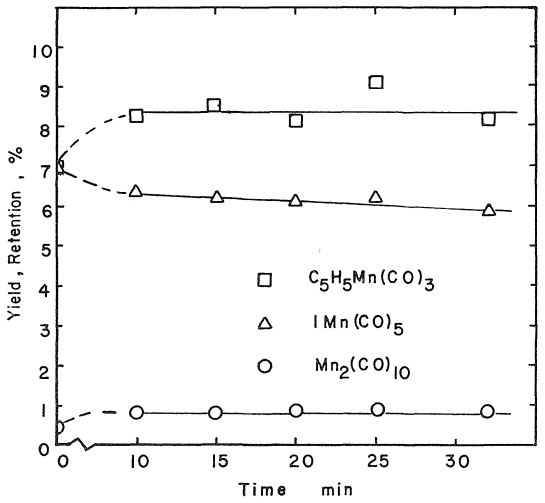

FIG. 4. Retention and yield data in $CpMn(CO)_3$ as a function of time of isothermal (70 °C) annealing.

amount of the species giving rise to $IMn(CO)_5$ is converted to $Mn_2(CO)_{10}$. However, in any case the change is very small, and the bulk of the species remains, at a temperature far higher, and for a time far longer than was the case for the $\cdot Mn(CO)_5$ radical in $Mn_2(CO)_{10}$ targets. This leads us to the conclusion that already in the solid target, long before heat treatment, and thus presumably in the hot or still warm zone, the $\cdot Mn(CO)_5$ radical is scavenged by some internal scavenger to give a stable compound. Again, the retention in the parent compound seems not to be substantially changed in the heating. Specific separation of $HMn(CO)_5$ has been done on samples of $CpMn(CO)_3$ irradiated in the A.E.C.L. neutron source, with the result that 10–12% of the ^{56}Mn was found to be in the form of $HMn(CO)_5$. We take this as satisfactory evidence that the 'stable compound' referred to above is indeed $HMn(CO)_5$. The quantitative discrepancy between these results and those of the iodine scavenging experiments remains unexplained, although it is possible that the reaction of iodine with $HMn(CO)_5$ may not be nearly 100% efficient.

$CH_3CpMn(CO)_3$

In addition to ambient-temperature neutron irradiations carried out in the Sb–Be facility in Ottawa, we have done low-temperature irradiations (using dry ice and liquid nitrogen) and ambient-temperature irradiations in the Western

*Neutron irradiation was done at room temperature in the A.E.C.L. Sb–Be source.

New York Nuclear Research Center's reactor in Buffalo. The results are given in Tables I and II respectively, and are shown in Fig. 5. Here we find that the $CH_3Mn(CO)_5$ yield is a sensitive function of the irradiation conditions and of the physical state of the target. Experiments in which the manganese compound contained added isooctane during the irradiation, showed an increase in the $CH_3Mn(CO)_5$ yield in the Ottawa irradiations and a general decrease in the Buffalo irradiations, when the targets were in the liquid state. This difference of behavior shows a dependence of the yield on the γ dose rate which, in turn, presumably indicates that the reaction leading to the formation of $CH_3Mn(CO)_5$ is dependent on the presence of radiolysis products. However, irradiations at low temperatures show generally higher yields (1–3%) of the same compound. In further experiments, the $CH_3Mn(CO)_5$ yields were lower when iodine was added to the dissolving medium after the irradiations, suggesting that a chemical reaction had taken place between the $CH_3Mn(CO)_5$ produced and the iodine added. This reaction was confirmed in milligram tests which showed that a reaction occurs rapidly in these solutions according to eq. [4]

[4] $$CH_3Mn(CO)_5 + I_2 \rightarrow IMn(CO)_5 \ (+CH_3I \ ?)$$

These iodine scavenging experiments also showed a yield of $IMn(CO)_5$ to the extent of about 10% at low temperatures.

Experiments in which the addition of iodine was delayed by up to 30 min showed no significant variation of the $IMn(CO)_5$ yield, unlike the case of neutron-irradiated $Mn_2(CO)_{10}$ under similar conditions. This suggests once again the presence in the solvent of a stable chemical species which must have undergone reaction with the added iodine to give the ultimate product, $IMn(CO)_5$, but which does not decompose in solution under nitrogen. The general similarity between the two arene target systems is evident. The retentions are similar, the formation of an additional stable species occurs in both, and the only significant

difference appears to be the identity of the additional species, which is $HMn(CO)_5$ in one case and both $HMn(CO)_5$ and $CH_3Mn(CO)_5$ in the other.

Discussion

The identity of the species scavenged in the iodine experiments is perhaps the first thing to discuss. It was suggested earlier (8) that this must be the $\cdot Mn(CO)_5$ radical. From the data shown in Fig. 3, it is evident that in $Mn(CO_2)_{10}$ experiments, the scavenged species is thermally quite unstable, while from Fig. 2 it is apparent that the species has a short but measurable lifetime—some 20 s or so. This is in keeping with its being the $\cdot Mn(CO)_5$ radical, since none of the other expectable compounds of $—Mn(CO)_5$ would decompose so rapidly under such gentle conditions. This conclusion is supported by the data shown in Figs. 4 and 6, showing that in $CpMn(CO)_3$ and $CH_3CpMn(CO)_3$, in which a greater range of reactions are available, the yield of $IMn(CO)_5$ is unaffected by heating and by decomposition in solution. It is evident that in these latter two cases a stable compound is formed already in the solid target—identified as is described above. Thus we conclude that the radical $\cdot Mn(CO)_5$ is indeed formed in $Mn_2(CO)_{10}$ targets, and $HMn(CO)_5$ is produced when hydrogen atoms are available. $CH_3Mn(CO)_5$ is clearly formed only when methyl groups are available, and then not to as great an extent as $HMn(CO)_5$.

It is significant that in $Mn_2(CO)_{10}$ targets, heating does not cause the parent retention to increase in an amount proportional to the decrease in $\cdot Mn(CO)_5$ yield. This shows that the radical cannot combine with other nearby radicals, as in eq. [5], nor does there occur any exchange with nearby $Mn_2(CO)_{10}$ molecules, according to eq. [6].

$$[5] \quad \cdot{}^*Mn(CO)_5 + \cdot Mn(CO)_5 \rightarrow {}^*MnMn(CO)_{10}$$

$$[6] \quad \cdot{}^*Mn(CO)_5 + Mn_2(CO)_{10} \rightarrow {}^*MnMn(CO)_{10} + \cdot Mn(CO)_5$$

Reactions analogous to both of these have been postulated recently to occur in neutron-irradiated iron and ruthenium carbonyls (16).

Perhaps one of the most interesting results is the uniformly high yield of the $—Mn(CO)_5$ products which, in all cases, are *in toto* equal to or greater than the retention in the parent form. These results can be compared with the data from Baumgärtner and Zahn (5) who, on irradiating $C_6H_6Cr(CO)_3$, found a substantially higher yield of ^{51}Cr in $Cr(CO)_6$ than in the parent form. Likewise, it has been shown recently (16) that $Fe(CO)_5$ is formed in quite high yield in neutron-irradiated $Fe_3(CO)_{12}$. All of these results lead us to suggest the following rule (18): *in neutron-irradiated metal carbonyl compounds, the recoil atom is able to accumulate carbonyl radicals to a greater extent than is consistent with the composition of the target compound.* That is to say, the reaction

$$[7] \quad M + nCO \rightarrow M(CO)_x \qquad x = 5, 6$$

is kinetically favored over simultaneous competing reactions.

Several years ago, a paper by Baumgärtner and Zahn (19) showed that in various organochromium systems thermodynamic factors have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

little effect in governing the distribution of recoil atoms among the various products. If that principle is generally valid, it is apparent that kinetic factors must be dominant, as is implied in our postulated rule. Although this postulate requires much wider experimental study than the few systems for which it now appears valid, it seems probable that it carries important implications about the nature of the hot zone surrounding the recoil atom.

Although the evidence is incomplete, it appears that the difference between the $IMn(CO)_5$ and $CH_3Mn(CO)_5$ yields in neutron-irradiated $CH_3CpMn(CO)_3$ (Table II) is entirely accounted for by the presence of $HMn(CO)_5$, and is thus the result of another kinetic competition—between H atoms and CH_3 radicals, competing for the $\cdot Mn(CO)_5$ radicals:

$$[8] \qquad \cdot Mn(CO)_5 \begin{cases} + \cdot H \rightarrow HMn(CO)_5 \\ + \cdot CH_3 \rightarrow CH_3Mn(CO)_5 \end{cases}$$

although one must not ignore the possibility that these reactions involve abstraction rather than radical combination.

The increase in $CH_3Mn(CO)_5$ yield in $CH_3CpMn(CO)_3$ with increasing isooctane concentration (Table I), is evidently the result of increased availability of methyl groups, although the two are not related in a simple way. The difference between these results, obtained at a high γ dose rate, and those of Table II, obtained in a very low γ dose rate, suggests that in these solutions the CH_3 radicals involved are produced radiolytically, not by the recoil action. The ensuing decrease in $CH_3Mn(CO)_5$ yield (Table I) may be attributed, without direct evidence, to the onset of competitive radical reactions which likely affect the availability of CO radicals for the reconstruction of $—Mn(CO)_5$. The decrease in parent retention shown in Table I seems to be related again to the availability of carbonyl radicals.

At this point, when the reactions leading to the observed and identified products are becoming clear, one is impelled to ask about the unidentified 80% of the recoil atoms. It has been common to label this intractable fraction as the 'inorganic' fraction, with the recognition that the only way in which it can be handled is after its conversion to Mn^{++} in aqueous solutions. We are coming to the opinion that this material may more likely be large polymeric species, of perhaps poorly definable composition, which are neither volatile nor soluble in organic solvents. It would be consistent with our observations and with our stated rule for these species to be polymeric carbonyls, $Mn_x(CO)_y$, where $x > 2$. We have no evidence on this point, but hope to make an experimental study of this fraction in the near future.

Acknowledgments

We wish to express our gratitude to Dr. K. E. Collins for extending the hospitality of his laboratory and facilities to one of us for several weeks. We are grateful to the staff of the A.E.C.L. neutron facility for frequent and willing assistance. We also express our thanks to Imperial Oil Ltd., and to the National Research Council of Canada for financial support, and to Carleton University for a Graduate Fellowship to S.C.S.

Reactions of thiyl radicals. VI. Photolysis of ethanethiol[1]

R. P. Steer and A. R. Knight
Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received September 18, 1968

The photolysis of ethanethiol vapor in the pressure range 10 to 350 Torr and the effect of % decomposition, wavelength, and of added inert gas and ethylene on the rate of formation of the products has been determined. In addition, the effect of temperature on the photolysis of methanethiol – ethylene – inert gas and ethanethiol – ethylene – inert gas systems has been studied.

For the pure substrate, the primary process is S—H bond cleavage and the hydrogen atom produced abstracts the sulfyhydryl hydrogen of the substrate. The quantum yield of molecular hydrogen formation is unity, independent of pressure. C_2H_5S radicals, formed either in the primary process or as a result of abstractive attack by H atoms or radicals on the substrate, combine to form an excited disulfide molecule. The major condensable product, $C_2H_5SSC_2H_5$, arises via collisional deactivation of this excited species which can also sensitize the decomposition of the substrate to give C_2H_4, C_2H_6, and H_2S, the other products observed. With added inert gas the rates of formation of the minor products decrease whereas hydrogen and disulfide remain unchanged.

With added ethylene, the major products are H_2, $C_2H_5SSC_2H_5$, and $C_2H_5SC_2H_5$, the addition product. Diethyl sulfide is formed in a chain reaction by the attack of C_2H_5S on the olefinic double bond to form the composite radical, followed by H abstraction from the substrate. The hydrogen rate decreases due to the addition of H atoms to ethylene. The rate constant ratio, k_{22}/k_4, for the reactions [22] and [4], respectively,

$$H + RSH \rightarrow H_2 + RS \qquad H + C_2H_4 \rightarrow C_2H_5$$

is pressure dependent, indicative of the formation of hot hydrogen atoms in the primary process of the photolysis of methanethiol and ethanethiol. The Arrhenius parameters A_{22}/A_4 and $E_{22} - E_4$ for the methanethiol–ethylene and ethanethiol–ethylene systems have been determined. Kinetic treatments of the proposed mechanisms have been undertaken.

Canadian Journal of Chemistry, 47, 1335 (1969)

Introduction

Early investigations (1, 2) of the photolysis of ethanethiol have indicated that the products of the complete photolysis of this compound in the vapor phase are diethyl disulfide and hydrogen, together with a smaller amount of ethane and a trace of unidentified olefin, whereas the only significant gaseous product of the photolysis of liquid ethanethiol at low % conversion is hydrogen. The major products were suggested to arise from the reactions

[1] $$C_2H_5SH + h\nu \rightarrow C_2H_5S + H$$

[2] $$H + C_2H_5SH \rightarrow H_2 + C_2H_5S$$

[3] $$2C_2H_5S \rightarrow C_2H_5SSC_2H_5$$

The photolysis of ethanethiol vapor in the presence of ethylene has been shown (3) to result in a decrease in the rate of hydrogen formation due to the addition of hydrogen atoms to the olefin according to the reaction

[4] $$H + C_2H_4 \rightarrow C_2H_5$$

Using the method of Darwent and Roberts (4), a value of $k_2/k_4 = 1.9 \pm 0.1$ at 24 °C was calculated but was found to be inexplicably pressure-dependent at high total reactant pressures.

Recent work by several groups (5–7) has indicated that hot hydrogen atoms may be produced in the photolysis of H_2S. Preliminary work in this laboratory (8) has shown that hot hydrogen atoms may also be produced in the photolysis of simple alkanethiols. The results of a detailed study of the photolysis of ethanethiol and of the reactions of hot hydrogen atoms in this sytem and in the methanethiol system are presented in this paper as part of a continuing series of investigations (9–12) into the photochemical decomposition of low molecular weight sulfur-containing compounds.

Experimental

Experiments were carried out in a grease- and mercury-free high vacuum system previously described (12). Standard high vacuum techniques were used for handling and storing reactants and products and, when necessary, products were separated by low temperature, high vacuum distillations. Details of these procedures have been given elsewhere (12, 13).

Ethanethiol (Matheson, Coleman and Bell) was purified in the following manner. The thiol (50 ml) was

[1]From the Ph.D. Thesis of R. P. Steer, University of Saskatchewan, Saskatoon, 1968.

TABLE I

Effect of time of exposure on the rates of formation of the products of the photolysis of ethanethiol vapor

Exposure time (min)	Rate of formation of (μmoles/min exposure)				
	H_2	C_2H_4	C_2H_6	H_2S	$C_2H_5SSC_2H_5$
5.0	0.77	0.034	0.16	0.18	0.85
10.0	0.76	—	0.17	0.15	—
10.0	0.71	0.027	0.16	0.16	0.76
10.0	0.76	0.028	0.15	0.17	0.75
30.0	0.70	0.026	0.16	0.18	0.83
60.0	0.67	0.025	0.14	0.16	0.80

fractionally distilled at atmospheric pressure through a 2 ft column of glass helices (b.p. 34.3–34.6 °C/715 Torr), rejecting the first 10 ml of distillate and collecting the next six successive 5 ml fractions. Analysis by gas chromatography showed that fractions 4 and 5 contained the least amount of impurity and these were admitted to the vacuum line for further purification. After degassing, the thiol was vacuum distilled repeatedly from −84 °C (ethyl acetate slush) to −117 °C (ethanol slush), retaining the middle fraction each time. This procedure resulted in material which contained only small amounts of impurities, estimated to be about 0.05%, which were more volatile (on the basis of their gas chromatographic elution times) than ethanethiol but which could not be removed by further distillation. Carbon dioxide was obtained from three sources. Assayed reagent grade carbon dioxide (J. T. Baker Chemical Co. and Air Reduction Corp.) was stated to have no more than 4 p.p.m. impurity (air) and was used without further purification. Cylinder carbon dioxide (Matheson) was distilled once from −130 to −196 °C and was thoroughly degassed before use. Other materials were purified by methods previously given (12).

Light intensities were determined by measuring the rate of CO production from the photolysis of gaseous acetone at 150 °C. For experiments in which the quantum yields of the products of the photolysis of ethanethiol were measured, the absorbed light intensity was $(4.96 \pm 0.08) \times 10^{-2}$ μeinsteins min^{-1}, determined with an interference filter, which passed only the mercury 2537 Å line, in place.

Results

The products of the photolysis of ethanethiol vapor with the mercury 2537 Å line at room temperature were found to be hydrogen, diethyl disulfide, ethane, ethylene, and hydrogen sulfide. In the first series of runs, the rates of formation of these products were measured as a function of the pressure of ethanethiol vapor in the reaction cell. The results are given in Fig. 1.

The rates of formation of the hydrocarbon products, ethane and ethylene, increase rapidly at low ethanethiol pressures, then level off at pressures at which the absorption of 2537 Å light is complete. Hydrogen sulfide exhibits similar behavior, although the yields of this product are somewhat more scattered. The rate of hydrogen production also increases with increasing substrate pressure and levels off in the high pressure region. This behavior is unlike that of the methanethiol system (12) in which the hydrogen rate continues to increase with increasing substrate pressure even after light absorption is complete. Due to mechanical losses of diethyl disulfide in the vacuum line, the yields of this product are extremely scattered. However, within the limits of experimental error, it also increases with increasing substrate pressure and levels off at higher pressures when light absorption is complete.

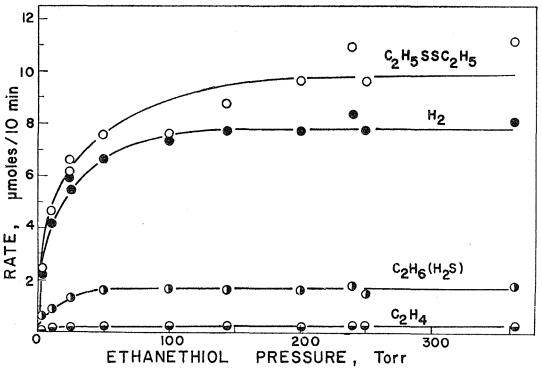

FIG. 1. Rates of formation of H_2, ●; $C_2H_5SSC_2H_5$, ○; C_2H_4, ◒; and C_2H_6 or H_2S, ◑; as a function of substrate pressure for the photolysis of ethanethiol at room temperature. The yields of C_2H_6 and H_2S are so similar that on this scale they can be represented by a single point at a particular thiol pressure.

The effect of increasing exposure time on the rates of formation of the products of the photolysis of 100 Torr of ethanethiol vapor at 25 ± 3 °C was next determined. The results are very similar to those obtained in the methanethiol system (12) and are presented in Table I. The rates of forma-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tion of all the products decrease with increasing exposure time due to increasing absorption by the disulfide product as the % decomposition of the substrate increases. However, the *relative* rates of formation of the products do not change significantly with increasing exposure time, indicating that none of the products measured are produced by secondary photolysis.

To determine whether ethylene in this system is produced by the disproportionation of ethyl radicals, a search for *n*-butane from a reaction in which 26 Torr of ethanethiol was photolyzed for 30 min was conducted. Gas chromatographic analysis of the −117 °C non-condensable product of this reaction indicated that *n*-butane was absent. Because *n*-butane is a product of the bimolecular reaction involving two ethyl radicals, its absence would indicate that neither combination nor disproportionation reactions of ethyl radicals are occurring in this system.

TABLE II

Hydrogen quantum yields for the photolysis of ethanethiol at 2537 Å and 22 °C

$P(C_2H_5SH)$ (Torr)	$\Phi(H_2)$
252.0	0.95
175.0	0.98
132.0	1.01
90.0	0.94
	Average 0.97 ± 0.03

The quantum yields of hydrogen, determined as a function of substrate pressure, are given in Table II. Within experimental error, the quantum yield of hydrogen is unity and, unlike the methanethiol system (12), is independent of pressure in the region of complete light absorption. Using the measured value of $\Phi(H_2) = 0.97$, the quantum yields of the other products may be calculated from their yields relative to that of hydrogen. The results are: $\Phi(C_2H_4) = 0.037$, $\Phi(C_2H_6) = 0.22$, $\Phi(H_2S) = 0.23$, and $\Phi(C_2H_5SSC_2H_5) = 1.26$, assuming that the rates of formation of all these products are independent of substrate pressure for pressures greater than 100 Torr. The mass balances $\Phi(H_2S) = \Phi(C_2H_4) + \Phi(C_2H_6)$ and $\Phi(C_2H_5SSC_2H_5) = \Phi(H_2) + \Phi(C_2H_6)$ hold within experimental error.

The addition of increasing pressures of carbon dioxide produces an effect on the photolysis of

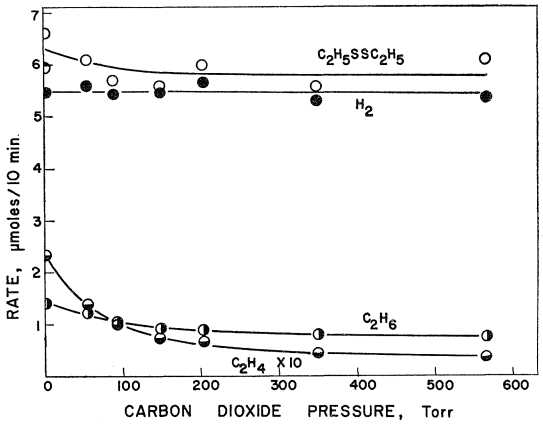

FIG. 2. Rates of formation of H_2, ●; $C_2H_5SSC_2H_5$, ○; C_2H_6, ◑; and C_2H_4, ◒; as a function of the pressure of added CO_2 for the photolysis of 25 Torr of ethanethiol at room temperature.

25 Torr of ethanethiol, which is similar to that observed in the CH_3SH system when CF_4 was used as a deactivating gas (12). The results are presented in Fig. 2. No significant change in the rate of hydrogen production is observed. The yields of the minor products, C_2H_4, C_2H_6, and H_2S (not shown), decrease with increasing inert gas pressure, ethylene decreasing at a faster rate than the others. As the pressure of inert addend is increased it becomes increasingly difficult to determine the yields of these products. Under these conditions, quantitative separation of the large amount of addend from the products and unreacted substrate cannot be easily accomplished. Thus the error in reported yields is highest at the largest pressures of addend used.

Diethyl disulfide also appears to decrease slightly, but again the errors involved in quantitative determination of the yields of this relatively non-volatile product are too large to permit a more definitive statement of its behavior.

To ensure that the pressure effects observed in the presence of CO_2 were actually due to the addend, varying pressures of C_2H_5SH were photolyzed in the presence of a constant CO_2 pressure of 715 ± 5 Torr. The results are given in Fig. 3. A comparison of these results with those for the pure substrate photolysis confirms that the rates of hydrogen and disulfide formation are independent of addend pressure. The rate of formation of minor products, however, apparently depends on the partial pressure of the substrate.

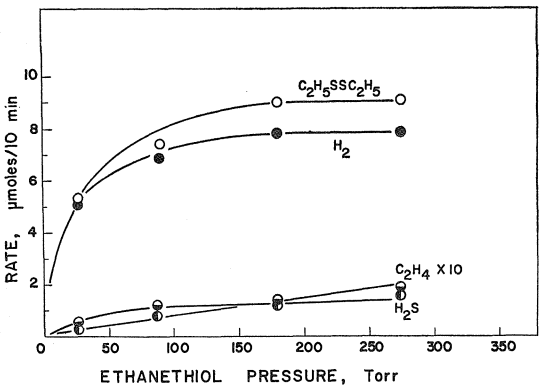

FIG. 3. Rates of formation of H_2, ●; $C_2H_5SSC_2H_5$, ○; C_2H_4, ◒; and H_2S, ◐; as a function of the partial pressure of substrate for the photolysis of ethanethiol in the presence of 715 ± 5 Torr of added CO_2.

The major products of the photolysis of ethanethiol in the presence of ethylene are hydrogen, diethyl disulfide, and diethyl sulfide, the addition product. Their rates of formation in the photolysis of 25 Torr of ethanethiol as a function of ethylene pressure are given in Fig. 4. As with similar experiments with methanethiol (12), an increase in ethylene pressure results in a rapid decrease in the rate of hydrogen formation and a rapid increase in the rate of formation of the addition product, diethyl sulfide. Disulfide decreases only slightly in rate.

From the data of Fig. 4 one may calculate, using the method of Darwent and Roberts (4), that the rate constant ratio, k_2/k_4 for the pure ethanethiol system is 2.03 ± 0.10 independent of ethylene pressure up to 100 Torr. This compares favorably with a value of 1.9 ± 0.1 obtained by Kuntz (3).

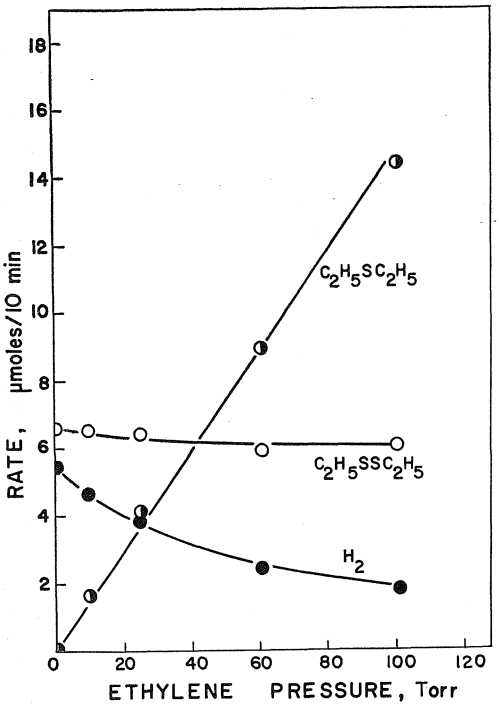

FIG. 4. Rates of formation of H_2, ●; $C_2H_5SSC_2H_5$, ○; and $C_2H_5SC_2H_5$, ◑; as a function of the pressure of added C_2H_4 for the photolysis of 25 Torr of ethanethiol at room temperature.

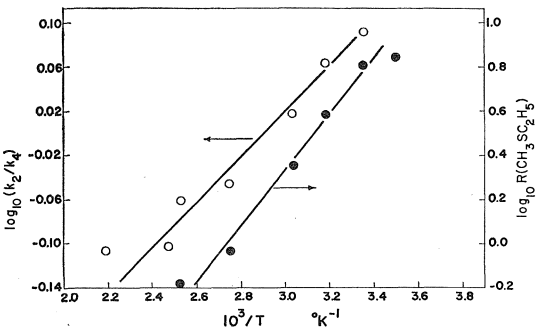

FIG. 5. Graph to determine the Arrhenius parameters of the hydrogen-, ○; and sulfide-, ●; forming reactions for the photolysis of 25 Torr of methanethiol with 25 Torr of ethylene added.

The effects of photolyzing equimolar mixtures of methanethiol or ethanethiol and ethylene in the presence of increasing pressures of inert gas have been previously reported (8). The results are indicative of the formation of hot hydrogen atoms in the primary processes. In order to determine activation energies (or activation energy differences) of reactions in which hydrogen and sulfide are formed, under conditions which would result in the reactions of thermal species only, the effects of varying the temperature of reaction mixtures containing 25 Torr of thiol, 25 Torr of ethylene, and an atmosphere of deactivating gas were studied. Arrhenius activation energy graphs are given in Fig. 5 for the methanethiol–ethylene–deactivator mixture and in Fig. 6 for the ethanethiol–ethylene–deactivator system. The significance of the activation energies obtained will be discussed presently.

The effect of increasing the energy of the photolysis light was briefly studied in a series of experiments in which ethanethiol vapor was photo-

Discussion

Nature of the Primary Process and Fates of the Hydrogen Atom

As in the methanethiol system (12), the only important primary photochemical process in the photolysis of ethanethiol at both 2537 and 2288 Å appears to be S—H bond cleavage,

[1] $$C_2H_5SH + h\nu \rightarrow C_2H_5S + H$$

Hydrogen atoms produced in this process apparently exclusively abstract the sulfyhydryl hydrogen atom of the substrate,

[2] $$H + C_2H_5SH \rightarrow C_2H_5S + H_2$$

as is also the case in the methanethiol system. Thus, the quantum yield of hydrogen is 0.97 ± 0.03, or unity within experimental error. Unlike the methanethiol case, however, the quantum yield of hydrogen in the ethanethiol system is independent of the substrate pressure and the absorbed light intensity.

Direct evidence in support of the suggestions that reaction [1] is the exclusive primary process and that reaction [2] is the sole fate of the hydrogen atoms produced in the ethanethiol system is somewhat sparse. Nonetheless, analogies drawn between the photochemical behavior of methanethiol and ethanethiol are probably quite valid, and thus evidence in favor of processes in the photolysis of methanethiol (12) also lends weight to analogous processes in the ethanethiol system. One should note in this connection that $D(CH_3S—H)$ and $D(C_2H_5S—H)$ are very similar; 88 ± 5 and 88.5 ± 5 kcal mole^{-1}, respectively (14).

The observation that only C_2H_5S radicals are formed on photolysis of ethanethiol in a rigid glass at 77 °K (15) or in a water clathrate at temperatures as high as −20 °C (16) lends support to both reactions [1] and [2], although radicals such as CH_2CH_2SH or CH_3CHSH might not have been found by the spectrophotometric techniques used in these studies. More convincing, however, is the observation by electron spin resonance spectroscopy that only the C_2H_5S radical is formed by ultraviolet irradiation of pure, solid ethanethiol at 77 °K (17). No evidence for any other radical was found in the latter work.

The only possible reaction that hydrogen atoms might undergo in the ethanethiol system that could not occur in the methanethiol system is abstraction of a methylene hydrogen atom from C_2H_5SH,

[4] $$H + CH_3CH_2SH \rightarrow H_2 + CH_3CHSH$$

However, the fact that neither 1,2-dimethyl-1,2-ethanedithiol, the dimer of the radical product of this reaction, nor the mercapto-sulfide from the reaction of C_2H_5S with CH_3CHSH, were observed in the reaction products, even at long exposure times, indicates that reaction [4] is probably not occurring to an appreciable extent.

The fact that ethane, hydrogen sulfide, and ethylene are found as reaction products suggests that alternative primary processes

[5] $$C_2H_5SH + h\nu \rightarrow C_2H_5 + SH$$

[6] $$C_2H_5SH + h\nu \rightarrow C_2H_4 + H_2S$$

might be occurring. However, assuming that hydrogen atoms and ethyl radicals both abstract

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

hydrogen from the substrate efficiently, reactions [5] and [1] cannot both be primary processes, since $\Phi(H_2) + \Phi(C_2H_6)$ is greater than unity. Reaction [6] might be responsible for the production of the small amount of ethylene ($\Phi(C_2H_4) = 0.037$) since $\Phi(H_2) + \Phi(C_2H_4)$ is also unity within experimental error. However, the observations that $\Phi(C_2H_4)$ is dependent on the pressure of added inert deactivating gas but not on the pressure of substrate, would seem to be inconsistent with the formation of an excited ethanethiol molecule in this system. Thus the reaction,

[7] $C_2H_5SH + h\nu \rightarrow C_2H_5SH^* \rightarrow H_2S + C_2H_4$

which would have to be postulated to account for the observed dependence of $\Phi(C_2H_4)$ on the pressure of inert gas, is probably not occurring.

Source of Ethane, Ethylene, and Hydrogen Sulfide

The minor products, C_2H_6, C_2H_4, and H_2S, all appear to be primary products of the photolysis since the rate of their formation does not decrease with decreasing exposure time. If these products do not arise from the initial decomposition process, then reactions involving the decomposition of additional ethanethiol must be occurring.

The observation that the rate of formation for these products decreases with increasing inert addend pressure indicates that they have their origin in reactions involving a species which can be collisionally deactivated. As indicated previously, this species is not involved in the formation of H-atoms. By analogy with the methanethiol system (12), this excited intermediate is proposed to be an excited disulfide molecule, $C_2H_5SSC_2H_5^*$, formed in the reaction

[8] $2C_2H_5S \rightleftarrows C_2H_5SSC_2H_5^*$

The excited molecule will have initially excess energy of at least the bond dissociation energy of the S—S linkage, 69 ± 6 kcal mole^{-1}. This is a minimum value since a fraction of the C_2H_5S radicals formed in the primary process may retain some of the energy excess in that step. As will be demonstrated below, the hydrogen atoms formed in this step have greater than thermal energies.

Considering the relatively large inert addend pressure required for significant deactivation effects, it is highly improbable that the excitation in $C_2H_5SSC_2H_5^*$ is vibrational in nature. Very little information about the excited state of disulfide molecules is known, and their spectroscopy has received only very limited attention. One possibility for $C_2H_5SSC_2H_5^*$ would be a nonspectroscopic electronic excited state. However, until more information is available on the excitation possibilities in disulfide molecules, further speculation is unwarranted. There is, however, experimental evidence that an excited disulfide molecule is also important in the photolysis of pure disulfides (10).

It is suggested that the $C_2H_5SSC_2H_5^*$ molecule participates in the following reactions.

[9] $C_2H_5SSC_2H_5^* + C_2H_5SH \rightarrow C_2H_5SSC_2H_5 + C_2H_5 + SH$

[10] $C_2H_5SSC_2H_5^* + C_2H_5SH \rightarrow C_2H_5SSC_2H_5 + C_2H_4 + H_2S$

[11] $C_2H_5SSC_2H_5^* + C_2H_5SH \rightarrow C_2H_5SSC_2H_5 + C_2H_5SH^*$

[12] $C_2H_5SSC_2H_5^* + M \rightarrow C_2H_5SSC_2H_5 + M$

[13] $C_2H_5 + C_2H_5SH \rightarrow C_2H_6 + C_2H_5S$

[14] $HS + C_2H_5SH \rightarrow H_2S + C_2H_5S$

[15] $C_2H_5SH^*(+M) \rightarrow$ deactivation

Since $D(C_2H_5S—H) = 71 \pm 5$ kcal mole^{-1} (15), reaction [9] should be thermoneutral or slightly exothermic if $C_2H_5S^*$ radicals from the primary process are important. Reaction [10] is highly exothermic with $\Delta H = -50 \pm 6$ kcal. Thus both processes in which $C_2H_5SSC_2H_5^*$ leads to substrate decomposition are energetically possible. The fact that in the absence of deactivator, only ca. 23% of the disulfide molecules formed in the system cause further decomposition may be a manifestation of the rather stringent requirements for this sequence.

Because the yield of ethylene is small compared with that of ethane, reaction [9] must be faster than reaction [10], with $\Phi(C_2H_6)/\Phi(C_2H_4) = k_9/k_{10} = 6$, assuming that no other processes are yielding either ethyl radicals or ethylene and that all of the ethyl radicals produce ethane by reaction [13]. This is not too surprising since the formation of ethylene and hydrogen sulfide via reaction [10] requires a much more drastic rearrangement of the ethanethiol molecule than does simple C—S bond cleavage, and thus reaction [10] might be expected to be somewhat

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

slower than reaction [9]. This may also be consistent with the fact that the rate at which $\Phi(C_2H_4)$ is decreased by the addition of inert gas is greater than the rate of decrease of $\Phi(C_2H_6)$, as shown in Fig. 2.

Combination–Disproportionation Reactions of C_2H_5S Radicals

If the reactions of CH_3S radicals (12) may be used as a model, the relative rates of the combination–disproportionation reactions of C_2H_5S radicals should be pressure dependent, with the combination mode becoming more important with increasing pressure. Unfortunately, the error in the rate of formation of diethyl disulfide is sufficiently large that a definite statement of the behavior of C_2H_5S radicals in the ethanethiol system cannot be made.

It is obvious, however, that the combination reaction of C_2H_5S radicals is much more important than disproportionation at the pressures studied. The mass balance, $H_2 + C_2H_6 = C_2H_5SSC_2H_5$, predicted by the mechanism presented, is satisfied within experimental error at almost all substrate pressures studied, although a deficiency in disulfide *might* be present at lower pressure. Thus, if anything, combination is an even more important mode of reaction of C_2H_5S radicals than for CH_3S radicals.

Reactions of C_2H_5S Radicals with the Substrate

Because the hydrogen quantum yield for the photolysis of ethanethiol is almost equal to unity and is independent of the pressure of substrate and the absorbed light intensity, reactions of C_2H_5S radicals with the substrate to yield hydrogen and disulfide, such as those previously postulated (12) for the methanethiol system, are apparently not occurring to any significant extent. The hydrogen exchange reaction,

$$[16] \quad C_2H_5S + C_2H_5SH \rightarrow C_2H_5SH + C_2H_5S$$

is probably occurring but this process will have no net effect. Thus, unlike the methanethiol photolysis, the quantum yields of hydrogen and disulfide show no apparent pressure or intensity dependence.

Kinetic Treatment of the Mechanism

A kinetic treatment of the mechanism of the photolysis of pure ethanethiol has been attempted, based on reactions [1], [2], [8] to [11], and [13] to [15].

Several assumptions have been made. First, it has been assumed that the only primary process is reaction [1], and that hydrogen atoms react only by reaction [2] even though they may have excess energy. It is also assumed that C_2H_5 or HS radicals react only by reactions [13] and [14], respectively, and that cross-combination or disproportionation reactions of these species are not important. Finally, it is assumed that the self-disproportionation of C_2H_5S radicals is much slower than the self-combination reaction.

Using steady state treatment of the mechanism, the following expressions may be obtained.

$$[I] \qquad \Phi(H_2) = 1.0$$

$$[II] \qquad \Phi(C_2H_6) = \frac{k_9}{k_{10} + k_{11}}$$

$$[III] \qquad \Phi(C_2H_4) = \frac{k_{10}}{k_{10} + k_{11}}$$

$$[IV] \qquad \Phi(H_2S) = \frac{k_9 + k_{10}}{k_{10} + k_{11}}$$

$$[V] \qquad \Phi(C_2H_5SSC_2H_5) = 1 + \frac{k_9}{k_{10} + k_{11}}$$

The mass balances, $\Phi(C_2H_5SSC_2H_5) = \Phi(H_2) + \Phi(C_2H_6)$ and $\Phi(H_2S) = \Phi(C_2H_6) + \Phi(C_2H_4)$ are therefore readily derived. From [II] and [III], $\Phi(C_2H_6)/\Phi(C_2H_4) = k_9/k_{10} = 6$, as previously noted. It is also apparent from these expressions that if the stated assumptions are valid, none of the quantum yields should be dependent on substrate pressure (in the complete absorption pressure range) or on the intensity, as observed.

A kinetic treatment of the mechanism including deactivation by inert addend in reaction [12] indicates that plots of the reciprocal of the quantum yields of ethane, ethylene, and hydrogen sulfide should be linear functions of the ratio $P(CO_2)/P(C_2H_5SH)$. The data from Figs. 2 and 3 have been used to calculate $1/\Phi$ for the minor products, assuming that the quantum yield of hydrogen is unity at all pressures. The results are presented in Fig. 7. The graph of $1/\Phi(C_2H_4)$ vs. $P(CO_2)/P(C_2H_5SH)$ yields the predicted straight line, with slope $k_{12}/k_{10} = 7.5$. Although as predicted qualitatively by the mechanism the yields of ethane and hydrogen sulfide decrease as $P(CO_2)$ increases, Fig. 7 shows that the reciprocal

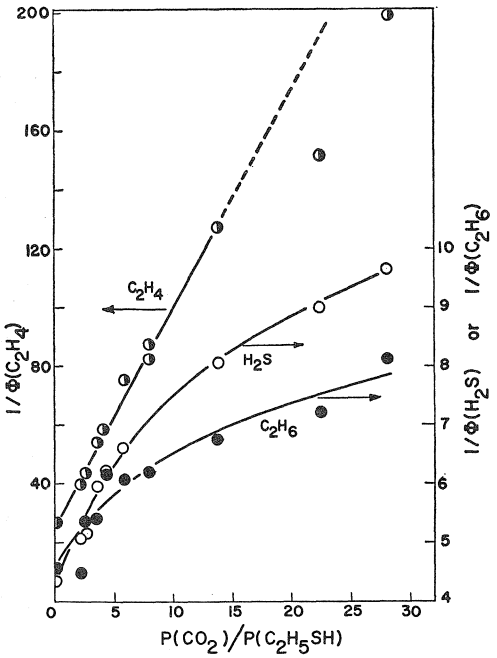

FIG. 7. Graph of $1/\Phi(C_2H_4)$, ◑; $1/\Phi(C_2H_6)$, ●; and $1/\Phi(H_2S)$, ○; versus $P(CO_2)/P$ (C_2H_5SH) for the photolysis of ethanethiol – carbon dioxide mixtures at room temperature.

plots are not linear. This may indicate that additional deactivation reactions involving $C_2H_5SSC_2H_5$* should be included in the mechanism, for example, two excited disulfide states which are deactivated at differing rates. Unfortunately, because of the uncertainties in the small yields of these products at high addend pressures, the data are not sufficient to permit the detailed analysis necessary to examine this possibility. It may be pointed out that in the methanethiol system, the rates of CH_4 and H_2S formation do yield a linear plot when presented in the form of Fig. 7.

Photochemical Addition to Ethylene

The major features of the photochemical addition of ethanethiol to ethylene in the absence of deactivating gas may be explained by the following reaction sequence.

[1] $C_2H_5SH + h\nu \rightarrow C_2H_5S + H$

[2] $H + C_2H_5SH \rightarrow H_2 + C_2H_5S$

[4] $H + C_2H_4 \rightarrow C_2H_5$

[13] $C_2H_5 + C_2H_5SH \rightarrow C_2H_6 + C_2H_5S$

[3] $2C_2H_5S \rightarrow C_2H_5SSC_2H_5$

[17] $C_2H_5S + C_2H_4 \rightleftarrows C_2H_5SC_2H_4$

[18] $C_2H_5SC_2H_4 + C_2H_5SH \rightarrow C_2H_5SC_2H_5 + C_2H_5S$

Here, it has been assumed (*a*) that chain terminations other than reaction [3] are not occurring, (*b*) that the polymerization reaction in which $C_2H_5SC_2H_4$ radicals add to ethylene is unimportant, (*c*) that excited disulfide molecules are deactivated with unit efficiency and without the production of C_2H_5 and HS radicals or ethylene and hydrogen sulfide, and (*d*) that hot ethyl radicals formed in reaction [4] will be efficiently deactivated (18) so that the use of the detailed reaction sequence,

[19] $H + C_2H_4 \rightleftarrows C_2H_5*$

[20] $C_2H_5* \rightarrow C_2H_5$

is unnecessary. The addition to ethylene of ethyl radicals formed in reaction [4] has been ignored, although this reaction is undoubtedly occurring to a significant extent. However, the formation of higher molecular weight alkanes by the process

[21] $C_2H_5 + n C_2H_4 + C_2H_5SH \rightarrow \text{alkanes} + C_2H_5S$

will be kinetically indistinguishable from reaction [13] being the sole fate of C_2H_5 radicals in so far as the rates of formation of hydrogen, diethyl sulfide, and diethyl disulfide are concerned. Each alkyl radical whether it is consumed in reaction [13] or [21] will eventually produce a C_2H_5S radical by reaction with ethanethiol so that the total number of C_2H_5S radicals will remain constant.

Reaction [17] is likely reversible since the analogous reaction of CH_3S radicals with ethylene has been previously shown to be reversible (19, 20). This reversibility is manifested by a negative overall activation energy, $E_{17} + E_{18} - E_{-17}$ for reactions forming diethyl sulfide, as will be shown presently.

The addition product, diethyl sulfide, is formed in the chain propagating reactions [17] and [18]. The order of the sulfide-forming reaction with respect to ethylene may be obtained from the slope of a graph of $\log_{10} R(C_2H_5SC_2H_5)$ versus $\log_{10} P(C_2H_4)$. The formation of diethyl sulfide is observed to have an order of 0.95, or unity within experimental error, with respect to ethylene, in agreement with the analogous reaction in the methanethiol–ethylene system (12).

The fact that the rate constant ratio, k_{22}/k_4, for the competitive reactions,

[22] $\quad H + RSH \rightarrow H_2 + RS$

[4] $\quad H + C_2H_4 \rightarrow C_2H_5$

is dependent on the pressure of added inert gas (3, 8) may be explained by postulating that hot hydrogen atoms are produced in the primary photochemical process. The following reactions are suggested.

[23] $\quad RSH + h\nu \rightarrow RS + H^*$

[22′] $\quad H^* + RSH \rightarrow H_2 + RS$

[4′] $\quad H^* + C_2H_4 \rightarrow C_2H_5$

[24] $\quad H^* + M \rightarrow H + M^*$

[22] $\quad H + RSH \rightarrow H_2 + RS$

[4] $\quad H + C_2H_4 \rightarrow C_2H_5$

Thus, the rate constant ratios, k_{22}'/k_4', which were found to be 2.03 ± 0.11 for ethanethiol and 2.32 ± 0.11 for methanethiol at 25 °C in the absence of deactivating gases are those associated with hot hydrogen atoms. These values may be compared with values of 1.9 ± 0.1 and 1.7 ± 0.2, respectively, obtained by Kuntz (3) under experimental conditions similar to those used in the present study. On the other hand, the values of k_{22}/k_4 equal to 0.96 ± 0.08 for ethanethiol and 1.15 ± 0.10 for methanethiol (8), determined in the presence of a large excess of deactivating gas, are for the reactions of thermal hydrogen atoms.

Values of $E_{22} - E_4$ and A_{22}/A_4 may be obtained from a measurement of the temperature variation of k_{22}/k_4 in the presence of excess inert gas. The values of these parameters may be calculated from the Arrhenius activation energy graphs given in Figs. 5 and 6. The value $E_{22} - E_4$ is -1.0 ± 0.3 kcal mole^{-1} for ethanethiol and -0.94 ± 0.09 kcal mole^{-1} for methanethiol. In each case the error quoted is that estimated by taking the average of the differences between the largest and smallest possible slopes and the actual slope, determined by the least squares method. The points on the graphs are rather scattered and therefore the errors in $E_{22} - E_4$ are somewhat larger than desirable. Nonetheless, within experimental error the difference between the activation energy of abstraction from thiol (reaction [22]) and the activation energy of addition of hydrogen atoms to ethylene (reaction [4]) is the same for both methanethiol and ethanethiol. This should not be surprising since $D(CH_3S—H)$ and $D(C_2H_5S—H)$ are very nearly equal (14). The ratios of the pre-exponential factors, A_{22}/A_4, are found to be 0.18 ± 0.06 for ethanethiol, slightly smaller than the value of 0.24 ± 0.01 for the reactions of thermal hydrogen atoms in the methanethiol system. This is to be expected since ethanethiol should offer somewhat more steric hindrance to an approaching hydrogen atom than methanethiol.

An activation energy difference, $E_{22} - E_4$, of 0.54 ± 0.12 kcal mole^{-1} and a ratio of pre-exponential factors, A_{22}/A_4, of 3.85 ± 0.25 have been obtained by Inaba and Darwent (21) for the undeactivated methanethiol–ethylene system. It may thus be noted that A_{22}/A_4 and $E_{22} - E_4$ decrease from 3.85 ± 0.25 and 0.54 ± 0.12 kcal mole^{-1}, respectively, for hot hydrogen atom reactions to 0.24 ± 0.01 and -0.94 ± 0.09 kcal mole^{-1}, respectively, for reactions involving thermal hydrogen atoms in the methanethiol–ethylene system.

This data would seem to resolve the apparent discrepancy between the observations that thermalizing hot hydrogen atoms by the addition of inert gas (8), and increasing the temperature of the thermalized reaction mixture, both result in a *decrease* in k_{22}/k_4. Using the Arrhenius parameters obtained in the present work and by Inaba and Darwent (21) for the methanethiol–ethylene system, one may calculate that the factor f in the expression

$$[VI] \qquad f = \frac{(k_{22}/k_4)_{\text{hot H}}}{(k_{22}/k_4)_{\text{thermal H}}}$$

is equal to 1.4 ± 0.6, where the error limits are those calculated by using the extremes in the Arrhenius parameters. (Maximum and minimum values of f, 2.0 and 0.8, respectively, vary greatly because of the extreme sensitivity of f to errors in the activation energies.) The data of ref. 8 may then be used to calculate the experimental value of f. Since k_{22}/k_4 is observed to decrease from 2.32 ± 0.11 with no added inert gas to a limiting value of 1.15 ± 0.10 at high pressures, the experimental value of f will be 2.0 ± 0.2. Thus, within the limits imposed by the errors involved in calculating and measuring the theoretical and experimental values of k_{22}/k_4, the observed and theoretical values of f agree. It is, therefore, likely that the observed variation in k_{22}/k_4 with inert gas pressure for the methanethiol–ethylene system

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

can be ascribed to variations in the Arrhenius parameters of reactions [22] and [4] due to hot hydrogen atom effects.

An explanation of why the Arrhenius parameters vary in the observed fashion is hampered by the fact that one may only observe alterations in the *ratio* of A_{22}/A_4 or the *difference*, $\Delta E_a = E_{22} - E_4$. How the individual parameters, A_{22}, A_4, E_{22}, and E_4 change with changing hydrogen atom energy is largely unknown at present. The fact that the value of ΔE_a actually does change with changing energy of the hydrogen atom should not be too surprising, although one might expect that the value of ΔE_a should approach zero as the energy of the hydrogen atoms becomes large relative to the activation energies of reactions [22] and [4]. In fact ΔE_a apparently increases from -0.94 ± 0.09 kcal mole^{-1} for reactions involving thermal hydrogen atoms to $+0.54 \pm 0.12$ kcal mole^{-1} for energetic hydrogen atoms.

The reasons for the change in the pre-exponential factors are somewhat more difficult to envisage, although the observed effects are not unique to thiol–olefin systems. Variations in the pre-exponential factors of reactions involving hot hydrogen atoms from the photolysis of HI and HBr have also been found by Ogg and Russell (22) and by Schwarz, Williams, and Hamill (23). In the HI system, the ratio of the pre-exponential factors, A_{25}/A_{26} for the reactions

[25] $\quad H + I_2 \rightarrow HI + I$

[26] $\quad H + HI \rightarrow H_2 + I$

decreases from a value of 3.8 ± 0.4 for hot hydrogen atoms to a value of about 3×10^{-2} for thermal atoms.

In the methanethiol–ethylene system, A_{22}/A_4 decreases from a value of 3.85 ± 0.25 for hot hydrogen atom reactions to a value of 0.24 ± 0.01 for the corresponding thermal reactions. An explanation of these effects will have to await more information about the general characteristics of hot atom reactions.

A kinetic treatment of the proposed mechanism for the photochemical addition of simple alkanethiols to ethylene has been attempted, based on reactions [4], [4′], [22], [22′], [23], and [24] and

[27] $\quad C_2H_5 + RSH \rightarrow C_2H_6 + RS$

[28] $\quad 2RS \rightarrow RSSR$

[29] $\quad RS + C_2H_4 \rightarrow RSC_2H_4$

[30] $\quad RSC_2H_4 + RSH \rightarrow RSC_2H_5 + RS$

As a simplification, reactions involving excited disulfide molecules have been excluded from this reaction scheme and, as such, only the kinetics of the formation of hydrogen and sulfide will be dealt with here. Also, it has been assumed that the reactions of hot hydrogen atoms may be treated kinetically in the same way as the reactions of thermal hydrogen atoms.

Using a steady state treatment, the following expressions may be derived.

$$[\text{VII}] \quad \Phi(H_2) = \frac{k_{22}'[RSH]}{k_{22}'[RSH] + k_4'[C_2H_4] + k_{24}[M]} + \frac{k_{24}k_{22}[RSH][M]}{\{k_{22}'[RSH] + k_4'[C_2H_4] + k_{24}[M]\}\{k_{22}[RSH] + k_4[C_2H_4]\}}$$

$$[\text{VIII}] \quad \Phi(RSC_2H_5) = \left\{\frac{1}{I_a^{1/2}}\right\}\left\{\frac{k_{29}k_{30}[RSH][C_2H_4]}{k_{28}^{1/2}(k_{-29} + k_{30}[RSH])}\right\}$$

Equation [VII] may be simplified for two special cases. First, for the undeactivated photoaddition of thiol to ethylene $[M] = 0$ and thus,

$$[\text{IX}] \quad \left\{\frac{1}{\Phi(H_2)}\right\}_{[M]=0} = 1 + \frac{k_4'[C_2H_4]}{k_{22}'[RSH]}$$

This equation is identical with that used by Kuntz (3) and Inaba and Darwent (21) for determining the rate constant ratio, k_4'/k_{22}', under experimental conditions which would have resulted in the production and reaction of hot hydrogen atoms.

Second, for the case in which $k_{24}[M] \gg k_{22}' \times [RSH] + k_4'[C_2H_4]$, that is, at very high pressures of deactivator, eq. [VII] may be simplified to give

$$\left\{\frac{1}{\Phi(H_2)}\right\}_{[M]\text{large}} = 1 + \frac{k_4[C_2H_4]}{k_{22}[RSH]}$$

This expression is that which must be used to calculate k_4/k_{22} for thermal hydrogen atoms.

It has been shown previously by Graham *et al.* (19, 20) that for the addition of CH_3S radicals to ethylene, the rate of decomposition of the adduct radical is much faster than its rate of abstraction of hydrogen from the thiol. If this holds true for both methyl and ethyl thiyl radicals, then $k_{-29} \gg k_{30}[RSH]$ and eq. [VIII] may be simplified to give

$$[X] \quad \Phi(RSC_2H_5) = \left\{\frac{1}{I_a^{1/2}}\right\}\left\{\frac{k_{29}k_{30}[RSH][C_2H_4]}{k_{28}^{1/2}k_{-29}}\right\}$$

Thus, measurement of the slopes of the graphs of $\log_{10} R(RSC_2H_5)$ versus $1/T$ for sulfide, given in Figs. 5 and 6 may be used to calculate values of $E_{29} + E_{30} - E_{-29}$, assuming $E_{28} = 0$. Values of -6.5 ± 0.3 kcal mole^{-1} and -6.1 ± 0.3 kcal mole^{-1} for methanethiol and ethanethiol are obtained. Because these values are almost equal, the reaction profiles of the two systems are probably very similar. The value of $E_{29} + E_{30} - E_{-29} = -6.1 \pm 0.3$ kcal mole^{-1} obtained in the methanethiol–ethylene–deactivator system is in reasonable agreement with a value of -5.3 ± 0.1 kcal mole^{-1} obtained by Graham *et al.* (19, 20).

Methyl and trifluoromethyl radical attack on ethers[1]

N. L. ARTHUR[2], PETER GRAY, AND A. A. HEROD[3]
School of Chemistry, Leeds University, Leeds 2, England

Received August 28, 1968

The reactions of CF_3 radicals with dimethylether and diethylether and of CH_3 radicals with dimethylether and diisopropylether have been studied. The photolyses of acetone and hexafluoroacetone were used as radical sources; all rate constants are based on the rate constants for radical dimerization. The Arrhenius parameters measured are as follows

Reactions	$\log_{10} A$ (cm^3 $mole^{-1}$ s^{-1})	E (kcal $mole^{-1}$)
$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_2OCH_3$	11.6	10.0
$CH_3 + (CH_3)_2CHOCH(CH_3)_2 \rightarrow CH_4 + C_3H_6OCH(CH_3)_2$	11.2	7.9
$CF_3 + CH_3OCH_3 \rightarrow CF_3H + CH_2OCH_3$	11.7	6.8
$CF_3 + C_2H_5OC_2H_5 \rightarrow CF_3H + C_2H_4OC_2H_5$	11.9	5.5

Canadian Journal of Chemistry, 47, 1347 (1969)

Introduction

Previous investigations of the hydrogen atom abstraction reactions from ethers by methyl radicals have centered on dimethylether (1–4), with one investigation of diethylether (5), and one of diisopropylether (2). The several dimethylether studies give rate constants which are in fair agreement ($\log_{10} k$ (182 °C) in the range 6.8–6.5 cm^3 $mole^{-1}$ s^{-1}), while the activation energies lie in the range 8.4–10 kcal $mole^{-1}$. The present work on dimethylether and diisopropylether was undertaken to clarify the earlier work and to provide accurate rate constants for comparison with the CF_3 radical work.

The reactions of CF_3 radicals with dimethyl- and diethyl-ethers have not been investigated previously and were studied for two reasons. First, a comparison between CH_3 and CF_3 radical attack on the ethers can be made. Second, although the attack of CF_3 radicals on methanol has been studied (6, 7), the two investigations are in poor agreement (activation energies for attack on the CH_3 group were 4.7 and 8.3 kcal $mole^{-1}$ while $\log_{10} k$ (182 °C) was 7.8 and 8.2 cm^3 $mole^{-1}$ s^{-1}). Since the alkyl groups of ethers and alcohols show the same reactivity to CH_3 radical attack (8, 9) and thus probably also to CF_3 radical attack, this work may shed some light on the conflict over methanol.

Experimental

Materials

Dimethylether

This was obtained from Matheson Co. Ltd. and was fractionated through traps at −78, −96, −150, and −196°. The fraction condensing at −150 °C was collected and stored in a blackened bulb.

Diethylether (A.R. grade)

This was refluxed over sodium, then distilled. A middle fraction was subjected to trap to trap fractionation and stored in a blackened bulb.

Diisopropylether

This was obtained from British Drug Houses Ltd. and was distilled with rejection of large head and tail fractions.

Acetone (A.R. grade)

This was obtained from British Drug Houses Ltd. and was distilled with rejection of large head and tail fractions.

Hexafluoroacetone

This was a gift from Du Pont and was fractionated through traps at −78, −96, −150, and −196°. The fraction collecting at −150° was stored in a blackened bulb.

Apparatus and Procedure

The apparatus and procedure involved in the methyl radical reactions have been described previously (9). With trifluoromethyl radicals, photolysis experiments were carried out in a silica reaction vessel (volume illuminated = 123 ml), fitted with plane parallel windows and housed in an aluminium block furnace fitted with quartz end plates. The furnace temperature was controlled by a platinum resistance thermometer and was measured by three chromel–alumel thermocouples. Photolyzing light (> 3000 Å) was obtained from a Mazda medium pressure mercury lamp and a Chance–Pilkington OX9A filter. Reactants were admitted to the reaction vessel separately.

[1]Complete tables of data upon which the present conclusions are based have been deposited in the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada.

[2]Present address: Mellon Institute, 4400 Fifth Avenue, Pittsburgh, Pennsylvania.

[3]Present address: Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario.

The analysis of reaction products has been described previously (10).

Interpretation

In experiments using CH_3 radicals, acetone was used as the radical source. The photolysis mechanism has been given before (9) and need not be repeated.

The mechanism of the photolysis of hexafluoroacetone may be described by the reactions

$$[1] \qquad CF_3COCF_3 \xrightarrow{h\nu} 2CF_3 + CO$$

$$[2] \qquad 2CF_3 \rightarrow C_2F_6$$

When acetone or hexafluoroacetone is photolyzed in the presence of a substrate RH, the additional reactions [3] and [4] occur

$$[3] \qquad CF_3 + RH \rightarrow CF_3H + R$$

$$[4] \qquad CH_3 + RH \rightarrow CH_4 + R$$

Expressing rate constants relative to those for reactions [2] and [5], ref. (11)

$$[5] \qquad 2\,CH_3 \rightarrow C_2H_6$$

we can write for CF_3 radical reactions

$$k_3/k_2^{1/2} = R_{CF_3H}/R_{C_2F_6}^{1/2}\,[RH]$$

and for CH_3 radical reactions

$$k_4/k_5^{1/2} = R_{CH_4}[4]/R_{C_2H_6}^{1/2}\,[RH]$$

where $R_{CH_4}[4]$ represents that methane formed by reaction [4] alone (allowance must be made to the total methane formed for that arising by attack of CH_3 radicals on acetone itself). The concentrations denote average values.

By carrying out photolyses over a range of initial conditions (temperature, concentration, etc.) the validity of the rate constant expressions may be checked and Arrhenius parameters evaluated.

Kinetic Parameters for Hydrogen Abstraction by CF_3 Radicals

Dimethyl- and Diethyl-Ethers

The temperature dependence of the rate constants (k_3) over the range 60–180 °C can be represented by the equations

$$\log_{10} k\ (\text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1}) = (11.71 \pm 0.03) - (6780 \pm 60)/2.303RT$$

for dimethylether, and

$$\log_{10} k\ (\text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1}) = (11.88 \pm 0.03) - (5550 \pm 60)/2.303RT$$

for diethylether. There are no earlier determinations of these rate constants for comparison.

Kinetic Parameters for Hydrogen Abstraction by CH_3 Radicals

(i) Dimethylether

The temperature dependence of k_4 over the temperature range 135–250 °C may be expressed as

$$\log_{10} k_4\ (\text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1}) = (11.62 \pm 0.08) - (9990 \pm 170)/2.303RT$$

Previous determinations of k_4 are in reasonable agreement; $\log_{10} k$ at 182 °C is 6.80 $\text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1}$ while the previous values (1, 2, 3, 4) are 6.76, 6.74, 6.80, and 6.53, respectively. The Arrhenius parameters agree within experimental errors.

(ii) Diisopropylether

The results for the rate constant between 135–250 °C may be expressed by the equation

$$\log_{10} k\ (\text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1}) = (11.16 \pm 0.01) - (7870 \pm 70)/2.303RT$$

A previous determination of the rate constant (2) is in good agreement with this work.

(iii) Diethylether

The reaction of methyl radicals with diethylether was not studied since a previous determination (5) is available which is in good agreement with our work on ethanol (9). The alkyl groups in each molecule show identical behavior.

Discussion

It is convenient to divide the discussion into three short sections: *(i)* comparing the reactivities of ethers to methyl radicals, *(ii)* comparing the reactivities to CF_3 radicals, and *(iii)* comparing the behavior of the two radicals.

(i) Methyl Radical Attack on Ethers

The order of reactivity of the three ethers is as expected, with diisopropylether the most reactive and dimethylether the least reactive; the relative overall reactivities are 1:3.4:3.7 at 182 °C. The similar reactivities of diethyl- and diisopropylethers is a result of a steric hindrance of the reactive α-CH group of diisopropylether compared with the alcohol (8), an effect noted in the hydrocarbons (13) $(CH_3)_3CH$, $(CH_3)_2CHCH(CH_3)_2$, and $(CH_3)_2CHCH(CH_3)CH(CH_3)_2$ where the rate constant at 182 °C fails to increase, being

n-C_4H_{10}	11.2	5.1	8.74	15
n-C_4H_{10}	11.4	5.3	8.90	17
n-C_4H_{10}	10.8	5.5	8.20	18
n-C_4H_{10}	11.8	6.2	8.80	6

*Abstraction from the alkyl group.

about $10^{7.3}$ cm^3 $mole^{-1}$ s^{-1} for all three compounds. The relative reactivities of the alkyl groups of the alcohols (8) CH_3OD, C_2H_5OD, and i-C_3H_7OD are 1:3.4:8.5. In the alcohols and ethers the activation energies for attack on the alkyl groups are the same (8) and except in diisopropylether where steric hindrance occurs, the rate constant for attack on an alkyl group is identical in the ether and alcohol.

In the series of hydrocarbons (12, 13) C_2H_6, n-C_4H_{10}, and $(CH_3)_2CHCH(CH_3)_2$, the relative reactivities are 1:4.6:18.6; the difference between the ratios for ethers or alcohols and hydrocarbons reflects the activating effect of the oxygen atom on the first members, dimethyl- and diethylethers, of the series compared with ethane and n-butane. This is indicated by the activation energies (Table I) which are the same for diisopropylether and 1,4-dimethylbutane (7.9 kcal $mole^{-1}$), similar for diethylether and n-butane (9.7 and 9.5 kcal $mole^{-1}$ respectively), but different for dimethylether and ethane (10.0 and 11.7 kcal $mole^{-1}$ respectively). The A-factors for the pairs of compounds dimethylether–ethane and diisopropylether–1,4-dimethylbutane are the same within experimental error. For diethylether and n-butane the A-factors are not similar; this may be a result of experimental error.

(ii) Trifluoromethyl Radical Attack on Ethers

No previous work has been done on any of the ethers. In the present work, dimethylether is less reactive than diethylether by a factor 5.7 in the rate constant at 182 °C. The greater reactivity of diethylether is a result of a lower activation energy and a higher A-factor than in dimethylether (see Table II).

The several determinations of the rate constants for attack on ethane and n-butane (6, 14–18) are in poor agreement (see Table II) for either paraffin. One ethane determination (16) may be unreliable (19), while the use of hexafluoroazomethane as a radical source with n-butane (17, 18) may be expected to yield low Arrhenius parameters (20).

Despite the disagreement in the hydrocarbon

TABLE III

Relative reactivity of CF_3 and CH_3 radicals

Substrate	(k_{CF_3}/k_{CH_3}) 182 °C	(A_{CF_3}/A_{CH_3})	$E_{CH_3} - E_{CF_3}$ (kcal mole^{-1})
CH_3OCH_3	46	1.23	3.2
$C_2H_5OC_2H_5$	76	1.32	4.2
C_2H_6	98	0.9	4.2
n-C_4H_{10}	117	2.5	3.3

work, the data indicate that *n*-butane is more reactive than ethane to CF_3 attack by about a factor 6 at 182 °C. Also dimethylether is more reactive than ethane (14) (by a factor of about 3 at 182 °C) while diethylether is more reactive than *n*-butane (6) (by a factor of 2.6 at 182 °C).

Since the alkyl groups of alcohols and ethers show identical behavior to CH_3 attack (8), they might be expected to show identical behavior to CF_3 attack. The attack of CF_3 radicals on methanol has been studied (6, 7), but the rate constants and Arrhenius parameters are not in agreement with expectations. In one case (7) a factor of 2 is apparent between the rate constants for ether and alcohol at 182 °C, but the agreement between this work and the methanol results is not sufficient to support either determination (6, 7).

(iii) Relative Reactivity of CF_3 and CH_3 Radicals

The quotients of *A*-factors and rate constants at 182 °C with activation energy differences for CF_3 and CH_3 radical attack on dimethylether and diethylether and the hydrocarbons ethane and *n*-butane are presented in Table III. It is clear that CF_3 radicals are more reactive than CH_3 radicals with all four compounds. With the exception of *n*-butane the ratio of *A*-factors is close to unity and the greater reactivity of the CF_3 radical is due to an activation energy difference of 3 or 4 kcal mole^{-1}. The CF_3 radical is more reactive than the CH_3 radical by 50–120 times. This is as expected for non-polar molecules (21), whereas for polar molecules, the reactivities of the two radicals are expected to be similar.

In the attack of CH_3 radicals on ethanol it has been shown (9) that the main reaction is with the α-CH_2 group and this is no doubt the case with diethylether. The CH_2 group is presumably also the main center of attack by CF_3 radicals.

An investigation of some iron halide complexes by Mössbauer spectroscopy

T. BIRCHALL
Department of Chemistry, McMaster University, Hamilton, Ontario
Received November 25, 1968

The products of the reaction between iron carbonyls and various ligands have been examined by Mössbauer spectroscopy. With triphenylphosphine and triphenylarsine, complexes of Fe(III) in a tetrahedral configuration are produced. In all other cases the complexes contain Fe(II), and it is suggested that these are not monomeric, but are chlorine bridged complexes.

Canadian Journal of Chemistry, **47**, 1351 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Relatively few tetrahedral complexes of iron(II) are known. The $[FeX_4]^{2-}$ ions exist with large cations where X = Cl^-, Br^-, NCS^-, etc. (1–3). Complexes of the type FeX_2L_2 and $[FeL_4]^{2+}$ are also known (3, 4). The $[FeX_4]^{2-}$ ion in a tetrahedral ligand field has a non-degenerate set of 3d orbitals, with a lower doublet d_γ (d_{z^2}, $d_{x^2-y^2}$) and a higher triplet d_ε (d_{xy}, d_{xz}, d_{yz}). The energy separation (10 *Dq*) between these sets of levels is typically of the order of 4000 cm^{-1} (3). The sixth electron in the Fe(II) 3d orbitals populates essentially only the d_γ levels. When the field at the iron is exactly cubic, then the d_{z^2} and $d_{x^2-y^2}$ energy levels are degenerate. If a tetragonal distortion is introduced, the degeneracy of the d_γ orbitals is removed and a small splitting of these levels occurs. This distortion, while not detected by X-ray crystallography (2), has been detected spectroscopically (3).

More recently, tetrahedral iron(II) compounds have been studied by Mössbauer spectroscopy (5, 6). The quadrupole splitting parameter is an extremely sensitive test for distortions from cubic symmetry, and a study of the variation of this parameter with temperature can lead to more accurate values for the energy separation than can be obtained by other spectroscopic techniques. The recent report by Singh and Rivest (7) on the preparation of some tetrahedral iron(II) complexes was therefore of much interest, and the results of a Mössbauer study of these complexes are reported here.

Experimental

Materials

All solvents were reagent grade and were dried and distilled before use. Iron pentacarbonyl and diiron nonacarbonyl were obtained from Alfa Inorganics and were used without further purification. All of the ligands used were purified by distillation or recrystallization from a suitable solvent.

Preparation

The complexes were prepared according to the method of Singh and Rivest (7), except that no special precautions were taken to exclude air except for the initial deoxygenation of the chloroform. It appears that the CO liberated in the reaction is sufficient to maintain a non-oxidizing atmosphere for the duration of the reaction. With $Fe_2(CO_9)$ as starting material the reaction was complete in approximately 1 h. In the case of $Fe(CO)_5$ the reaction was stopped after 12 h. The products, as finely divided precipitates, were subsequently separated by filtration in an oxygen free dry-box, washed with solvent, and dried in vacuum.

$FeCl_3 \cdot (C_6H_5)_3P$ and $FeCl_3 \cdot (C_6H_5)_3As$ were prepared in an identical manner to that of Singh and Rivest (7). Chloride analyses, infrared spectra, and melting point served to identify the compounds as being identical to those prepared previously (7), except for the benzamide and aniline complexes. The benzamide complex was obtained as a white (not brown) solid, m.p. > 210 °C (not 158 °C), with Cl = 27.8% (not 36.99). The yellow aniline complex (m.p. > 220°) was found to contain 31.68% Cl. The analyses for these compounds do not fit the $FeCl_3L$ formulation but are close to $FeCl_2L$ and are formulated as such in Table I. The fact that different products should be obtained from a preparation essentially the same as that used by the previous workers, seems somewhat surprising. The Mössbauer spectra of the compounds indicated that they contained only 1 kind of iron. No impurity peaks were detected (see Figs. 1–3).

Mössbauer Spectra

Mössbauer spectra were recorded with an Austin Science Associates drive system, used in conjunction with a Victoreen PIP400A multichannel analyzer operating in multiscalar mode. The source was ^{57}Co in a palladium matrix, and the 14.4 keV γ-ray was detected by a thin (1/32 in.) NaI(Tl) activated crystal with matching photomultiplier tube manufactured by the Harshaw Chemical Company. The velocity scale was calibrated with a sodium nitroprusside absorber and all chemical shifts are quoted with respect to the centroid of the sodium nitroprusside spectrum. Samples contained approximately 10 mg cm^{-2} of iron. Spectra were recorded at 295 and 77 °K (liquid nitrogen temperature). The Mössbauer data summarized

TABLE I

Mössbauer data for iron halide complexes

Compound*	Temperature (°K)	Isomer shift δ (mm s^{-1})	Quadrupole splitting ΔE (mm s^{-1})	% Absorption
$FeCl_2 \cdot 2AM$	295	1.39	2.64	5.4

in Table I are thought to be accurate to ± 0.02 mm s^{-1} and typical spectra are shown in Figs. 1–3.

Discussion

The data in Table I clearly separate the complexes examined into 2 classes: those with large isomer shift and quadrupole splitting, and those with small isomer shift and quadrupole splitting. The parameters for the triphenylphosphine and triphenylarsine complexes are typical of high spin iron(III) complexes. Isomer shift values for Fe(III) range generally from ~ 0.5–0.8 mm s^{-1} with the δ value for the $[FeCl_4]^-$ ion being 0.55 mm s^{-1} at liquid nitrogen temperature (8). Since a complex containing Fe(III) in the high spin state would have each d orbital singly occupied, the electric field gradient at the nucleus would be zero and the Mössbauer spectrum would consist of a single unsplit absorption. This is the situation in the $[FeCl_4]^-$ complexes (8). If the cubic field at the iron atom is distorted by replacement of one of the ligands, an electric field gradient will be produced, the degeneracy of the $I = 3/2$ state will be removed, and a quadrupole split doublet will be observed. Distortions arising from non-equivalence of ligands around a high spin d^5 ion are generally small, with the result that ΔE values are small. This is the situation for the $FeCl_3 \cdot TPP$

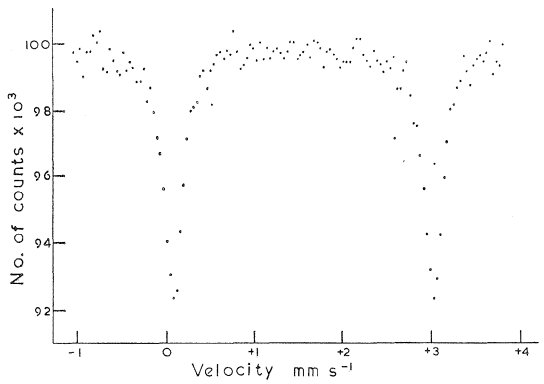

FIG. 2. Mössbauer spectrum of $FeCl_2 \cdot 2FA$ at 77 °K.

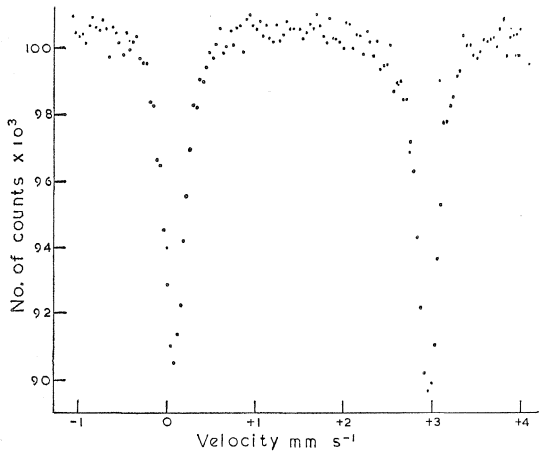

FIG. 3. Mössbauer spectrum of $FeCl_2 \cdot BM$ at 77 °K.

and $FeCl_3 \cdot TPA$ complexes. Support for the tetrahedral arrangement is found in the strong temperature dependence of the Mössbauer absorption. At room temperature, a very weak or negligible absorption is observed which increases in intensity as the temperature is lowered. Tetrahedral compounds of iron generally exhibit weak or undetectable absorption at room temperature (5, 6, 8). All of the Mössbauer evidence, therefore, supports the conclusions of Singh and Rivest (7), that $FeCl_3 \cdot TPP$ and $FeCl_3 \cdot TPA$ are high spin tetrahedral iron(III) complexes.

In sharp contrast are the data for the other complexes listed in Table I. Isomer shifts which are a measure of "s" electron density are markedly influenced by the occupation of d orbitals. An increase in the number of 3d electrons will result in a more efficient screening of the "s" electrons from the nucleus, with the resultant expansion of the 4s electron shell. This reduces the "s" electron density at the nucleus and gives more positive isomer shift values. Iron(II) isomer shifts range from 1.09–1.75 mm s^{-1} (9, 10). The values of $\sim$ 1.4 mm s^{-1} for the amide and aniline complexes fall clearly within this range and all without doubt are complexes of iron(II).

Quadrupole splitting values for d^6 iron in the high spin state vary considerably. The $[FeBr_4]^{2-}$ ion at room temperature has $\Delta E = 0.58$ mm s^{-1} (6), while $FeSO_4 \cdot 7H_2O$ has $\Delta E = 3.20$ mm s^{-1} (11, 12). The magnitude of the quadrupole splitting will be largely determined by the sixth d electron, and the orbital which it occupies. For a tetrahedral arrangement of ligands, the d_γ orbitals lie lowest in energy, with the d_{z^2} and $d_{x^2-y^2}$ being degenerate in an exactly cubic ligand field. Since the contribution to the electric field gradient of an electron in either of these orbitals is equal but of opposite sign (13), the quadrupole splitting would in this case be zero. A small tetragonal distortion lifts the degeneracy of the d_γ pair. The sixth d electron will have a preference for the orbital of lowest energy, an electric field gradient will result, and a quadrupole split absorption will be observed. Distortions of this kind are not large, e.g., 180–135 cm^{-1} for $[FeCl_4]^{2-}$ (5, 6). This is the same order of magnitude as the thermal energy, and the spectrum will therefore show a strong temperature dependence ($(Et_4N)_2FeBr_4$, $\Delta E = 0.52$ at 293 °K and 3.23 at 4.2 °K) (6). The large quadrupole splittings observed for the complexes studied here could, therefore, arise from a tetrahedral arrangement considerably distorted from cubic symmetry.

In an octahedral field the d_ε and d_γ sets are reversed in energy with d_ε lying lowest. As with the tetrahedral case, distortion from cubic symmetry would lift the degeneracy of the lowest lying set of orbitals, which would give rise to a quadrupole split absorption. Some typical parameters for high spin octahedrally coordinated iron(II) compounds are given in Table II. The first 4 compounds in Table I have ΔE values which fall into this range. The quadrupole splitting values for these complexes could, therefore, arise from either a tetrahedral or an octahedral arrangement of ligands.

TABLE II

Mössbauer spectra of some iron(II) compounds

Compound	δ (mm s^{-1})	ΔE (mm s^{-1})	Reference
$FeCl_2$	1.34	0.80	14
$FeCl_2 \cdot 2H_2O$	1.28	2.50	15
$FeCl_2 \cdot 4H_2O$	1.53	3.00	11
$FeSO_4 \cdot 7H_2O$	1.58	3.20	11

Chemical shifts for tetrahedrally coordinated iron(II) complexes are generally less positive than those for iron(II) in an octahedral environment with similar ligands (6). The shifts reported here are significantly more positive than those for the tetrahedral iron(II) complexes reported by Edwards and co-workers, after correcting

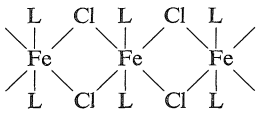
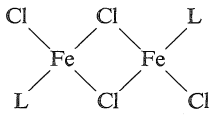
their shifts to sodium nitroprusside as zero (6). Complexes of iron(II) in octahedral environments, such as those listed in Table II, have very similar chemical shifts to those reported here. Anhydrous ferrous chloride has the polymeric $CdCl_2$ structure with all chlorines being shared, while $FeCl_2 \cdot 2H_2O$ has 4 chlorines and 2 water molecules surrounding each iron, with the chlorines bridging to another iron atom (16). A similar structure would be possible for the formamide and acetamide complexes to give the linear polymer **1** having a $FeCl_2L_2$ unit. The polymeric



1

structure is also supported by the relatively strong absorption ($\sim 5\%$) observed at room temperature. Tetrahedral Fe(II) compounds, as stated above, have relatively low Debye temperatures and the absorption is generally $< 1\%$ (6). The Mössbauer nucleus in polymeric compounds will be more rigidly held in the lattice, have a higher Debye temperature, and hence a much stronger absorption.

The structures for the benzamide and aniline complexes are much less certain. While the Mössbauer parameters are similar to those for the acetamide and formamide complexes, the analyses indicate a formulation $FeCl_2 \cdot BM$ and $FeCl_2 \cdot AN$. A chlorine bridged dimer **2** with tetrahedral arrangement about each iron, is one



2 (*cis* or *trans*)

possible structure. One might expect the Debye temperature for such a unit to be higher than for a monomeric species, giving a somewhat more intense absorption. Other arrangements, such as a 5 coordinate polymeric species, can not of course be discounted.

Singh and Rivest (7), on the basis of analytical, infrared, and magnetic evidence, conclude that they are dealing with monomeric, tetrahedrally coordinated compounds of Fe(II) and Fe(III). The triphenylphosphine and triphenylarsine complexes give Mössbauer spectra which are in agreement with the $FeCl_3L$ formulation. Our analytical data for the benzamide and aniline complexes are not in agreement with the results of the above workers, though the mode of preparation was virtually the same. We find no evidence for either $FeCl_3 \cdot BM$ or $FeCl_3 \cdot AN$, and only complexes containing Fe(II) are produced under our reaction conditions with the amide and aniline ligands. The reasons for the different structures found, i.e. $FeCl_2L_2$ and $FeCl_2L$, are not clear, and further work on these and related complexes is continuing.

Electrochemiluminescence of carbazole

K. S. V. SANTHANAM[1], R. N. O'BRIEN[2], AND A. D. KIRK
University of Victoria, Victoria, British Columbia

Received June 6, 1968

Effect of supporting electrolytes in the electrochemiluminescence of carbazole has been studied with a view to understanding more about the mechanism of the chemiluminescence process. Comparison of the emission spectrum with its fluorescence and phosphorescence spectra suggests that the excited state is not carbazole. The intense chemiluminescence observed with tetra-*n*-butyl ammonium iodide as supporting electrolyte has been examined.

Canadian Journal of Chemistry, **47**, 1355 (1969)

Bard *et al.* (1) recently reported the electrochemiluminescence of carbazole in N,N-dimethylformamide (DMF) containing tetra-*n*-butyl ammonium perchlorate as supporting electrolyte, which involved the reduction of carbazole at a mercury electrode apparently followed by a fast chemical reaction resulting in the luminescence process. The chemical reaction may involve the supporting electrolyte or the solvent (DMF), and in the present paper, the reduction of carbazole in different supporting electrolytes is reported.

Experimental

Experiments were conducted by using controlled potential or constant current techniques. The working electrode in both sets of experiments was a mercury electrode. A platinum or silver coil served as the auxiliary electrode. This electrode was placed in a sintered glass disc compartment when a separation from the working electrode was warranted. The reference electrode was an aqueous saturated calomel electrode (s.c.e.) connected through a salt bridge.

The experimental procedure for the controlled potential experiments was essentially the same as that described by Santhanam and Bard (2). Constant current electrolysis was performed in a cell provided with a joint so that it could be connected to a vacuum line. A volume of carbazole solution containing the appropriate supporting electrolyte ($\approx$ 2 ml) was transferred into the cell with a mercury pool at the bottom and a side mounted platinum electrode. After removing dissolved oxygen by evacuation, a constant current was applied to the cell.

A Wenking potentiostat model 61TR was used in all controlled potential experiments. Additional outside currents were superimposed on the built-in static control potential to enable reductions to be carried out at -2.7 V vs. s.c.e. In some cases involving light decay studies, square wave pulses of 5 ms or longer were obtained using a circuit similar to that described by Epstein and Kuwana (3).

Light emission was monitored using an RCA IP28 photomultiplier tube (maximum spectral sensitivity at $\sim$ 3400 Å). Photocurrents were recorded on a Tektronix oscilloscope model 549, by monitoring the potential drop across a 750 kΩ (0.1%) resistor connected between the photoanode and ground. Emission spectra were recorded using a Hilger D292 monochromator with a suitable wavelength drive system.

Carbazole was obtained from the Aldrich Chemical Company and was recrystallized three times in hexane. The purified sample had a melting point of 245 °C. Tetra-*n*-propyl ammonium bromide was obtained from Eastman Organic Chemicals. Tetra-*n*-butyl ammonium iodide and tetra-*n*-butyl ammonium perchlorate were supplied by Southwestern Analytical Chemicals. Tetra-*n*-butyl ammonium perchlorate was dried under vacuum for over 6 h before use. N,N-dimethylformamide (DMF), supplied by Fisher, was purified according to a well established procedure (2).

Results

Carbazole undergoes reduction at a hanging mercury drop electrode (h.m.d.e.) with E_p at -2.71 V vs. an aqueous s.c.e. in N,N-dimethylformamide containing tetra-*n*-butyl ammonium iodide as supporting electrolyte, when the reduction is examined by linear sweep cyclic voltammetry. A typical cyclic voltammogram is shown in Fig. 1. During the reduction process, a faint blue light is given out at the electrode.

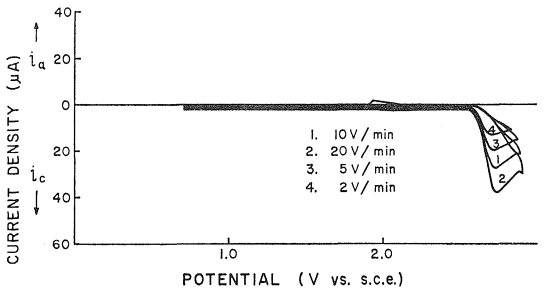

FIG. 1. Cyclic voltammograms.

Since the electrochemical reduction was irreversible (even up to scan rates of 20 V s^{-1}), the E_p or peak potential, value was dependent on the scan rate (4) and the results are shown in Table I. The peak current, i_p, for a diffusion controlled irreversible electron transfer, is given by (4):

$$i_p = 3.01 \times 10^5 n(\alpha n_a)^{\frac{1}{2}} C^\circ v^{\frac{1}{2}}$$

where n is the number of electrons transferred per molecule, α is the transfer coefficient, n_a is the number of electrons in the rate determining step, A is the area of the electrode in cm^2, D is the diffusion coefficient in cm^2/s, C° is the bulk concentration of the electroactive species in mmoles per l, and v is the scan rate in V/s. The value of i_p is directly proportional to the square root of the scan rate and concentration of the electroactive species. The near constancy of the $i_p/v^{\frac{1}{2}}$ values in Table I indicates the absence of any chemical reaction preceding the electron transfer step. Cyclic voltammetric results in other supporting electrolytes such as tetra-*n*-propyl ammonium bromide or perchlorate are essentially the same. Previous work on carbazole has been done with tetra-*n*-butyl ammonium perchlorate (1).

TABLE I

Current function and peak potentials for carbazole at a hanging mercury drop electrode*

E_p (V vs. s.c.e.)	$i_p/v^{\frac{1}{2}}$ μA min V^{-1}	Scan rate V min^{-1}
−2.71	8.4	2.0
−2.72	8.2	5.0
−2.73	8.0	10.0
−2.75	8.1	20.0

*Supporting electrolyte: tetra-*n*-butyl ammonium iodide in DMF.

In order to determine the number of electrons involved in the reduction of carbazole, and to understand more about the electrochemical reduction process, controlled potential coulometric experiments were undertaken using a large mercury pool working electrode (20 cm^2) with its potential controlled at −2.75 V vs. s.c.e. In the absence of any chemical reaction, it has been established (5) that current i_t varies with time as

$$i_t = i_0 e^{-pt}$$

where p represents a constant which is a function of the area of the electrode, solution volume, mass transport, and thickness of the diffusion layer. However, when a chemical reaction occurs leading to the generation of another or the same electroactive species, deviations from the exponential behavior occur. Controlled potential coulometric experiments on carbazole with iodide as supporting electrolyte showed a deviation from the exponential behavior. The current during this reduction decayed with time and reached a constant value higher than the background. For example, in one experiment the value of the current decreased from an initial value of about 32 mA (the solution contained 0.012 g of carbazole in 27.5 ml dimethylformamide) to a steady state constant value of about 1.25 mA. When the electrolysis was resumed after interrupting it for 5 min, the value of the current increased to 3.5 mA (from its steady state value) and subsequently showed a decay to the same steady state value. Interruptions for longer periods gave higher values of the current on resumption of electrolysis. Examination of the solution at the steady state by cyclic voltammetry showed a peak at −2.71 V vs. s.c.e. which agreed with the original carbazole peak. This peak height increased with time, indicating that more carbazole was being generated by a chemical reaction.

Both the results during controlled potential coulometric experiments and the cyclic voltammetric data taken after the electrolysis, suggest that carbazole is being regenerated from the reduced species by a chemical reaction.

When the rate of the chemical reaction is equal to the rate of the electrochemical reduction, a steady state is reached in controlled potential electrolysis. Geske and Bard (6) have studied the case of regeneration by pseudo first order chemical reaction, according to which

$$\frac{k_2}{p} = \frac{C}{C_i - C}$$

where k_2 represents the rate constant for the chemical reaction, p the rate constant for the electrode reaction, C_i the initial concentration, and C the steady state concentration. Using this approach, the rate constant for the regeneration reaction is calculated as 4.8×10^{-4} s^{-1}. It has been shown (6) that the apparent number of electrons involved in the reduction in the presence of a chemical reaction is related to the true number of electrons *(n)* by the equation

$$n_{app} = n\left[\frac{1}{1+\gamma^1} + \frac{p\gamma^1 t}{1-e^{-p(1+\gamma^1)t}}\right]$$

where $\gamma^1 = k_2/p$ and t is the duration of electrolysis. The value of n for carbazole is calculated to be 0.9, which is convincingly close to 1.0.

Electrolysis conducted with a platinum auxiliary electrode in the same compartment where the working electrode was placed, showed a much higher steady state current value of 22 mA.

Electrochemiluminescence and Spectral Properties

During the reduction of carbazole at a mercury electrode, a faint blue light was produced in the solution immediately adjacent to the electrode. The emission spectrum was examined under controlled potential and constant current electrolysis conditions and is shown in Fig. 2. The oscillations

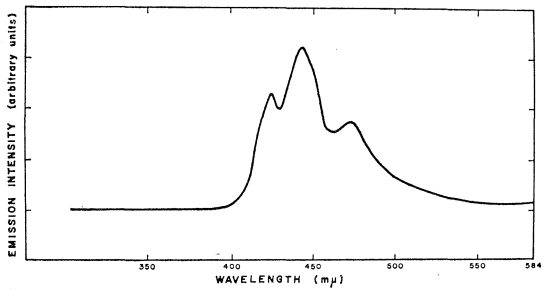

FIG. 2. Emission spectrum at constant current.

of mercury during the electrolysis, and consequently of the emitting zone, limit the precision of measurement of the emission maxima and the relative intensity distributions. Nevertheless, the wavelengths at which intensity maxima occur may be located at about 420, 450, and 470 mμ. Under controlled potential coulometric conditions, using a silver coil as the auxiliary electrode separated from the working electrode in a sintered glass disc compartment, the light intensity showed a decrease with a levelling off at the steady state current. However, under the same conditions, the use of a platinum auxiliary electrode without the sintered glass disc separation gave an increase in the light intensity for the first 20 min (see Fig. 3), decaying to a much higher steady value. Examination of the emission spectrum showed no appreciable change in the relative intensity of the three peaks (1.1:2.0:1) during the development of the emission to full intensity.

Similar results are obtained under constant

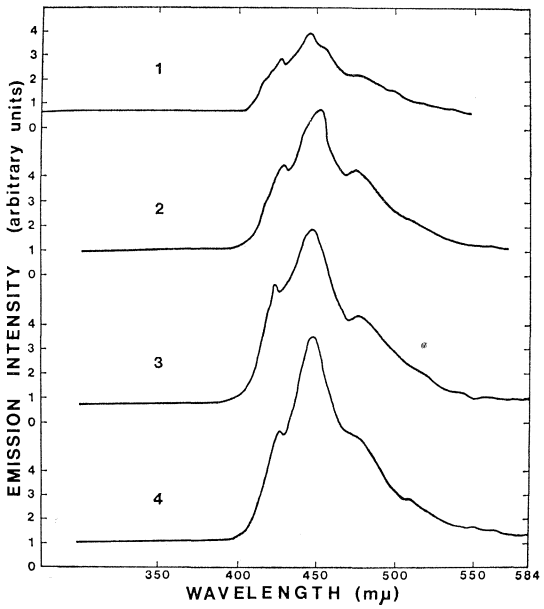

FIG. 3. Increase in emission intensity with electrolysis time.

current electrolysis conditions, realized by applying a current of 15 mA between the mercury pool electrode and a coiled platinum wire in a solution containing tetra-*n*-butyl ammonium iodide. Again, the emission spectrum had maxima around 420, 450, and 470 mμ. With tetra-propyl ammonium bromide as the supporting electrolyte, the light intensity was lower, but the spectrum had the same features. The chemiluminescence of a 5.4 m*M* carbazole solution in iodide medium is visible in an illuminated room with no appreciable decrease in intensity for a period of over 2 h. The emission spectrum does not change during this period. If only carbazole were being irreversibly reduced with this applied current, the electrolysis of the carbazole should have been complete in about 40 s. Spectrophotometric examination of the electrolyzed solution after 4 h of electrolysis showed absorption maxima at 268, 288, 293, 326, and 337 mμ, agreeing well with the carbazole spectrum. Cyclic voltammetric examination of the electrolyzed solution showed the carbazole peak at −2.71 V vs. s.c.e.

Results obtained in experiments conducted with different concentrations of iodide and carbazole are presented in Table II. It is clear that higher concentrations of iodide quench the chemiluminescence process. A similar quenching

TABLE II

Intensity (relative) studies in the reduction of carbazole

$[(C_4H_9)_4NI]$ (M)	[Carbazole] (mM)	Relative intensity
0.096	7.79	2.2
0.46	7.79	2.2
2.7	7.79	1.0
0.096	2.39	0.4
0.096	13.40	3.6
0.096	32.9	1.2

of fluorescence of fluorescein ions by iodide ion has previously been reported (7).

The relative intensities of emission using tetra-*n*-butyl ammonium bromide or perchlorate as supporting electrolytes were approximately equal and were 15 times less than that in iodide medium. Again, however, the luminescence was visible after 2 h of electrolysis. Electrolysis of the supporting electrolyte alone at 15 mA produced either a negligible luminescence or no luminescence. Oxygen (as mentioned) was eliminated on a vacuum line, and when it was bled in, it quenched the luminescence.

Light-Decay Studies

To evaluate the kinetics of the light emission following the reduction of carbazole in I^-, the decay of light intensity was examined after electrolysis was stopped. Such a decay of light intensity is shown in Fig. 4. It is seen that the decay is first order with a rate constant of 3×10^4 s. In controlled potential electrolysis experiments, although the light intensity showed the same type of decay after the termination of electrolysis at the steady state, the regeneration of carbazole continued in solution. Since the emission zone is visibly separated from the electrode, double layer discharge effects could be of only secondary importance in the process.

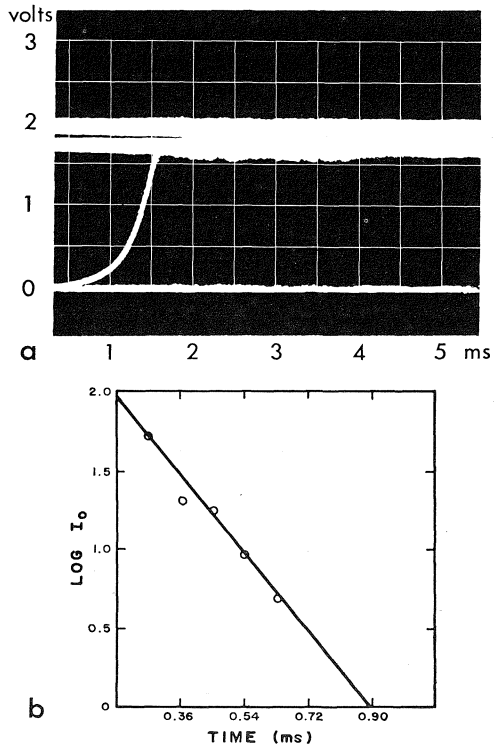

FIG. 4. Decay of light intensity.

Discussion

In the case of several aromatic hydrocarbons, the formation of an electronically excited species proceeds through a radical cation – anion annihilation (8, 9) or annihilation of an anion with an oxidizing agent (10), the reactants being generated by switching the potential from a negative region to a positive region or vice versa. Chemiluminescence of carbazole occurs in the reduction process itself and is more intense than is observed through annihilation processes. The formation of carbazole or carbazole anion in an electronically excited state by processes occurring directly at the electrode surface seems unlikely when one compares the molecular orbital diagram of carbazole with the energy (−2.71 eV) of the electrons available at the electrode surface (11). Both bonding and antibonding levels are full. Furthermore it has already been pointed out that the emission zone is visibly separated from the electrode surface.

It has been shown that carbazole reduces irreversibly at the hanging mercury drop electrode at a potential of −2.71 V vs. s.c.e. The absence of an oxidation wave on reversal of the potential sweep even at fast sweep rates (20 V/s) suggests that the anion produced has a lifetime in the solution of less than a few ms; the lifetime was independent of the nature of the supporting electrolyte.

The coulometric work demonstrates that carbazole is regenerated with a much slower first order rate constant of 4.8×10^{-4} s^{-1}. This result is confirmed by the studies of the recovery

For personal use only.

of carbazole concentration after terminating the electrolysis. The carbazole regeneration is accelerated by the increased steady state current when the auxiliary electrode is in proximity to the mercury pool and also by the marked growth of luminescence intensity as I_2 accumulates in the electrolyzed solution.

Examination of the structure of the chemiluminescence spectrum has shown it to be independent of the nature of the supporting electrolyte. Further, the emission spectrum differed from the fluorescence (maxima at 345 and 373 mμ) or phosphorescence (maxima at 407, 420, and 440 mμ) (12) of carbazole. The lifetime of the chemiluminescent emission is 3×10^{-5} s, which is much shorter than the half-life for regeneration of carbazole. This evidence forces us to recognize that carbazole, while being the species initially reduced, is not the emitting species, but is rapidly converted to a second substance which is either not oxidizable or oxidizes at a potential more positive than Hg. This species leads to light emission with the half-life of 3×10^{-5} s to give the species which returns to carbazole with the much longer half-life of 2×10^{3} s. This latter step is also catalyzed by I_2. To account for all this evidence, we are forced to propose a mechanism of the type

[1]	$R + e^- \rightarrow R^-$	(Electro reduction)
[2]	$R^- + (x) \rightarrow F^*(+x^-)$	Apparent half life ms
[3]	$F^* \rightarrow (F + h\gamma)$	Life time 3×10^{-5} s (not necessarily the radiative life time)
[4]	$F \rightarrow R$	Half life 3×10^{3} s
[5]	$F + I_2 \rightarrow R$	

The data do not enable us to determine the molecularity of step [2]. It may involve the solvent or supporting electrolyte. The latter is unlikely in view of the absence of observable effects due to supporting electrolyte. The nature of the species F is not known definitely. As carbazole is weakly basic (13), it is likely that the carbazole anion would be protonated more easily than carbazole itself. Previous work has shown that anions of this type rapidly protonate even in aprotic solvents such as dimethylformamide (10). Thus, F* may be the protonated carbazole anion in an excited state and F its ground state. It would be surprising, however, if this ground state returned to carbazole as slowly as found here. An alternative possibility is that F* is an excited dimeric carbazole species and F is its ground state. It is hoped to continue this work in an effort to decide between some of these possibilities.

Infrared studies of water in crystalline hydrates: gypsum, $CaSO_4 \cdot 2H_2O$[1]

Received November 5, 1968

Infrared spectra of partially deuterated hydrates yield the fundamental frequencies of isotopically dilute H_2O, D_2O, and HDO molecules. Isotopic dilution eliminates vibrational coupling and allows the determination of the total number of crystallographically distinct water molecules in the crystal. It also yields the number of distinct symmetric (C_{2v}) and asymmetric (C_s) water molecules. The results for gypsum show that all the water molecules are equivalent and that they are asymmetric, in agreement with crystallographic results. The extent of asymmetry is measured by the difference between the two OH stretching frequencies of HDO molecules, which is 90 cm^{-1}. This corresponds to an estimated difference of 0.02 Å in the O···O distances of the two hydrogen bonds. The spectra of partially deuterated gypsum show clearly that spectral features previously explained by the presence of two sets of distinct water molecules or by proton tunnelling, are in fact due to vibrational coupling.

Canadian Journal of Chemistry, **47**, 1361 (1969)

The crystal structure of gypsum has been reported to have the space-group symmetry $C2/c$ $(I2/c)-C_{2h}^6$, with four $CaSO_4 \cdot 2H_2O$ per unit cell (1, 2). The oxygen atoms O_w of the water molecule have been placed in the $8(f)$ equipoint, which has a site symmetry $1-C_1$ (3). The 16 hydrogen atoms must then belong to two non-equivalent sets $8H_1 + 8H_2$. As a consequence there are 8 symmetrically equivalent water molecules in the unit cell, but the two O_w—H distances in each water molecule are non-equivalent and thus, at least in principle, of different length. This asymmetry is connected with the existence of hydrogen bonds between the water molecule and the oxygen atoms O_I of two SO_4 groups (Fig. 1); the sulfate groups are related by a center of symmetry, but the two O_I atoms that are engaged in the hydrogen bonding are not.

The extent of the asymmetry has never been estimated with confidence. An attempt to locate the hydrogen atoms by the most direct method, neutron diffraction, has resulted in these interatomic distances (2)[3]: O_w—H_1, 1.002 ± 0.030 Å; O_w—H_2, 0.981 ± 0.024 Å; Δ, 0.021 ± 0.038 Å; O_w—O_I, 2.816 ± 0.014 Å; O_w—O_I', 2.824 ± 0.015 Å; Δ, 0.008 ± 0.021 Å. It is seen that the differences Δ are absorbed in the corresponding uncertainty intervals, particularly if 3σ limits are used, so that *numerically* the differences have no statistical significance.

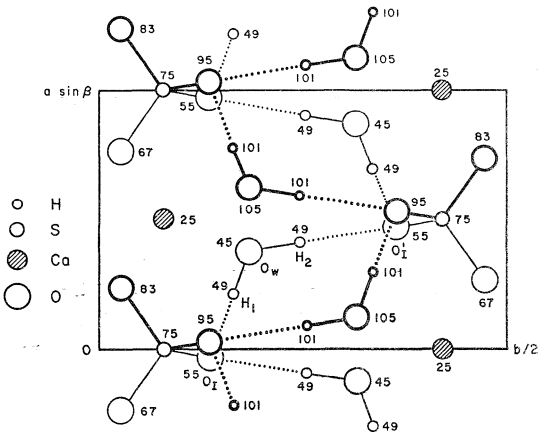

FIG. 1. Schematic projection of one-half of the unit cell of gypsum on the (001) plane (orientation $I2/c$; after ref. 2). The fractional coordinates z have been multiplied by 100.

Raman and infrared (i.r.) *frequencies* of natural (i.e. undeuterated) gypsum[4] cannot establish the

[1]Issued as NRCC No. 10 538.
[2]Killam Post-doctoral Fellow, 1967–1968.
[3]The standard deviations of these distances are based on the 1σ values of the positional parameters given in ref. 2. The distances have not been corrected for thermal motion; isotropic temperature factors were used in the structure refinement.

[4]The i.r. spectrum of undeuterated gypsum has been studied by many investigators (5–12). The spectrum of fully deuterated gypsum has also been reported (8, 9, 11), but not that of partially deuterated gypsum.

For personal use only.

extent, or even confirm the existence, of the asymmetry. The number of normal vibrations and their activities in the i.r. and Raman spectra are the same for an unperturbed (C_{2v}) and a perturbed (C_s) water molecule. Raman and i.r. *intensities* of undeuterated gypsum are of equally little help. If an unperturbed water molecule is assumed, as was done by Cabannes *et al.* (4) in their analysis of the Raman spectrum, and by Hass and Sutherland (5) in their analysis of the i.r. spectrum, gross discrepancies arise between the expected and the observed intensities of the fundamental bands. Whether these discrepancies are due to an unrealistic model or to the contributions of combination modes to the intensities of the fundamentals, is difficult to decide.

When, however, the H_2O molecule in the crystal is replaced by HDO, the existing perturbation from the C_{2v} symmetry caused by asymmetric environment leads to the doubling of all three fundamentals. This doubling, if observed, demonstrates the existence of asymmetry, and its magnitude measures the extent of it. A spectroscopic study of partially deuterated gypsum can thus provide information on the details of geometry of water molecules in gypsum which are not otherwise obtainable.

With this as our main objective we have investigated the spectra of partially deuterated gypsum, paying special attention to the bending and stretching fundamentals of H_2O, D_2O, and HDO dispersed at low isotopic concentrations.

Experimental

A large, colorless, completely transparent crystal of natural gypsum (selenite) from East Milford, Nova Scotia, provided material for some of the experiments. Additional specimens of $CaSO_4 \cdot 2H_2O$ were prepared by precipitation from aqueous solutions of reagent-grade calcium nitrate and sodium sulfate, and in a few experiments commercial reagent-grade $CaSO_4 \cdot 2H_2O$ was also used. The i.r. spectra and X-ray powder diffraction patterns of all these specimens were identical.

Spectra were recorded on a Perkin–Elmer model 521 grating spectrophotometer thoroughly purged with dry nitrogen. Use of an automatic frequency marker and frequent re-calibration of the frequency scale made it possible to measure the frequencies of sharp peaks to within 0.5 cm^{-1}. The effective slit width was about 1 cm^{-1}. Spectra at low temperatures were recorded using a model VLT-2 variable temperature cell (Research and Industrial Instruments Company, London).

Most samples were studied by both the mull and the KBr pellet techniques. The spectra were compensated for absorption by the matrix material by placing suitable films of Nujol or halocarbon oil, or pellets of pure KBr, in the reference beam. The mulls were spread in a 0.1 mm thick layer between NaCl or KBr windows of a demountable cell. The pellets were prepared by pressing mixtures of the finely ground sample and freshly dried KBr in an evacuable die at about 90 000 p.s.i. The pellets had an area of 1.1 cm^2.

The mulls had the advantage that almost no H_2O was introduced in their preparation. On the other hand, sample concentration could not be controlled and the slow agglomeration of the suspended gypsum particles made it necessary to prepare a new mull for each spectrum to be recorded. Also, halocarbon bands completely block the D—O—D bending region of the spectrum, and Nujol bands block the H—O—D bending region. KBr pellets are free from these disadvantages, but small amounts of atmospheric moisture were invariably introduced into the pellets.

Preparation of Deuterated Specimens

Finely ground natural gypsum was soaked in 99.8% D_2O at room temperature or refluxed under exclusion of atmospheric moisture. The rate of exchange at room temperature was very slow and even after two days at the boiling point the deuteration was incomplete. The following two methods proved more satisfactory.

Precipitation

Solutions of calcium nitrate and sodium sulfate in D_2O–H_2O mixtures were prepared and mixed in such a way that the room-temperature solubility of $CaSO_4 \cdot 2H_2O$ was exceeded by a factor of about five. The precipitate consisted of needle-shaped crystals of very good quality. It was filtered, and washed successively with D_2O–H_2O of the desired D:H ratio, acetone, and anhydrous ether. Spectra showed that the precipitates were pure gypsum, without detectable traces of hemihydrate or anhydrous salt[5]. Deuterations up to about 93% were obtained[6].

Rehydration of Anhydrous $CaSO_4$

Reagent-grade $CaSO_4 \cdot 2H_2O$ was dehydrated by heating at 150° *in vacuo* for 24 h and then soaked in D_2O or in D_2O–H_2O mixtures of the desired D:H ratios. The sealed flask was agitated overnight. The samples were filtered, washed with acetone and anhydrous ether, and dried over magnesium perchlorate. Deuterations over 99% were conveniently obtained. Occasionally the spectrum of the product showed traces of hemihydrate.

For low deuterations, precipitation was the only method used. Rehydration was convenient for high degrees of deuteration.

Deuterium Content of Specimens

The D:H ratios were taken to equal twice the ratio of the integrated intensity in the OD stretching region to that in the OH stretching region. This assumes that the

[5]Spectra of $CaSO_4 \cdot \frac{1}{2}H_2O$ and anhydrous $CaSO_4$ have been reported by Morris (11). Our own spectra of these phases were closely similar.

[6]D:H ratios achieved in each deuteration were determined from spectra of mulls. The corresponding spectra of pellets gave considerably lower D:H ratios because of atmospheric moisture introduced in the preparation of the pellets and subsequent H–D exchange.

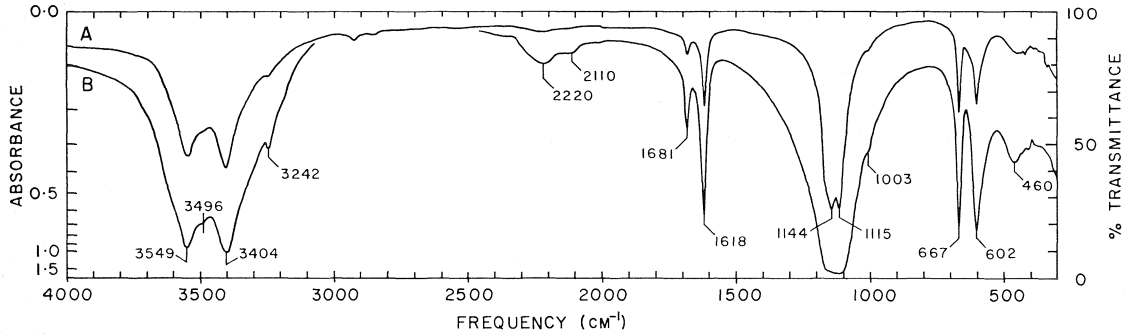

FIG. 2. Spectra of undeuterated gypsum in KBr pellets. *A*, 0.24 mg/200 mg KBr; *B*, 1.00 mg/200 mg KBr.

OD stretching bands have half the integrated intensity of the OH stretching bands (13). For samples of very low deuteration the D:H ratios were taken as those of the parent solution.

The concentrations of the three isotopic species of water were estimated from the molar fractions of hydrogen, x, and deuterium, y

$$[H_2O] : [HDO] : [D_2O] = x^2 : 2xy : y^2$$

This assumes a statistical distribution of deuterium over all the H sites of the crystal. An independent check on whether random distribution had in fact been attained was provided by the relative intensities of the H—O—H, H—O—D, and D—O—D bending bands. These gave a rough measure of the relative concentrations of the three species.

Results

Spectrum of Undeuterated Gypsum

The spectra of gypsum in Nujol and halocarbon oil were identical with those of gypsum in KBr pellets (Fig. 2). The frequencies of the main peaks were averaged from about a dozen spectra and rounded off to the nearest cm^{-1}. The standard deviation was 1.0 cm^{-1} for sharp peaks and 2–5 cm^{-1} for broad peaks and shoulders.

The present peak frequencies agree to within a few cm^{-1} with those reported by Morris (11) and by Wiegel and Kirchner (12). Many published infrared spectra of gypsum indicate the peak frequencies incompletely (8–10) or not at all (6, 7). The extensive set of frequencies obtained by Hass and Sutherland (5) with plane-polarized radiation and single crystals of gypsum is not directly comparable with values such as ours, obtained with unpolarized radiation and polycrystalline material.

The O—H and O—D Stretching Fundamentals of HDO

Figure 3 shows the spectrum in the O—H stretching region for different degrees of deuteration. The broad, complex band in undeuterated gypsum (Fig. 3*E*) becomes simpler and sharper with increasing deuteration (Figs. 3*D*, *C*). The two highest deuterations (Figs. 3*B*, *A*) yield the O—H stretching spectrum of HDO at sufficiently high isotopic dilution to eliminate all contribution from H_2O molecules and HDO–HDO nearest-neighbor pairs. This spectrum consists of two bands of equal intensity, with a separation of 90 cm^{-1}.

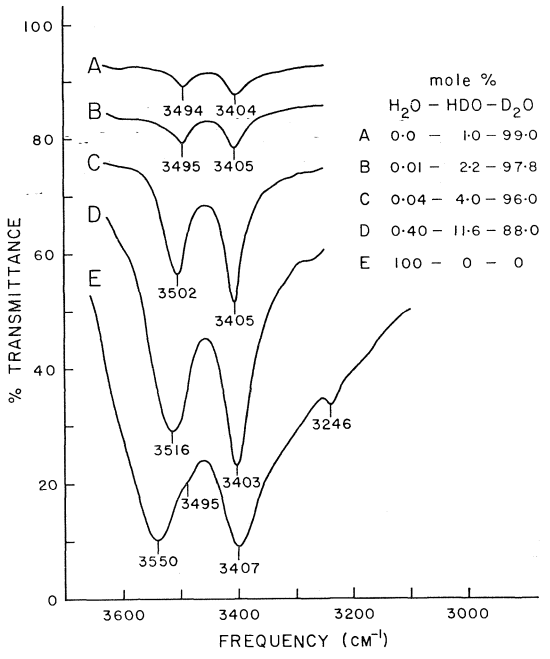

FIG. 3. Spectra of partially deuterated gypsum in Nujol in the OH stretching region. Spectrum *C* has been displaced downward by 15% transmittance, *D* by 18%, and *E* by 4%.

Similarly the O—D stretching band at high deuteration is complex and broad (Fig. 4*F*) but becomes simpler and sharper as the degree of deuteration decreases (Figs. 4*E*, *D*). The lowest deuterations (Figs. 4*B*, *A*) yield a spectrum which, like its O—H counterpart, consists of two bands of nearly equal intensity; their separation is 65 cm^{-1}.

The Bending Fundamental of HDO

At high HDO contents a complex pattern of peaks in the H—O—D bending region occurs (Fig. 5*F*). At lower HDO contents the outer components of this pattern are eliminated. A doublet, with a separation of about 14 cm^{-1}, remains (Fig. 5*C*) and does not change on further dilution (Figs. 5*B*, *A*). An identical doublet appears in the spectra of dilute HDO in highly deuterated samples.

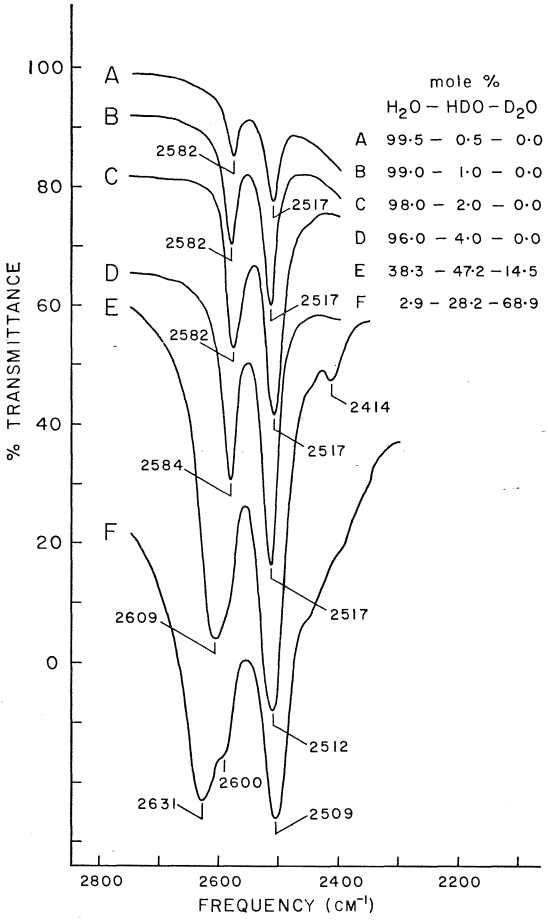

FIG. 4. Spectra of partially deuterated gypsum in KBr pellets in the OD stretching region. The amounts of gypsum used, in mg, were (from *A* to *F*), 4.59, 4.62, 5.00, 2.21, 0.99, and 0.75, respectively. Spectrum *B* has been displaced downward by 6% transmittance, *C* by 13%, *D* by 13%, *E* by 31%, and *F* by 40%.

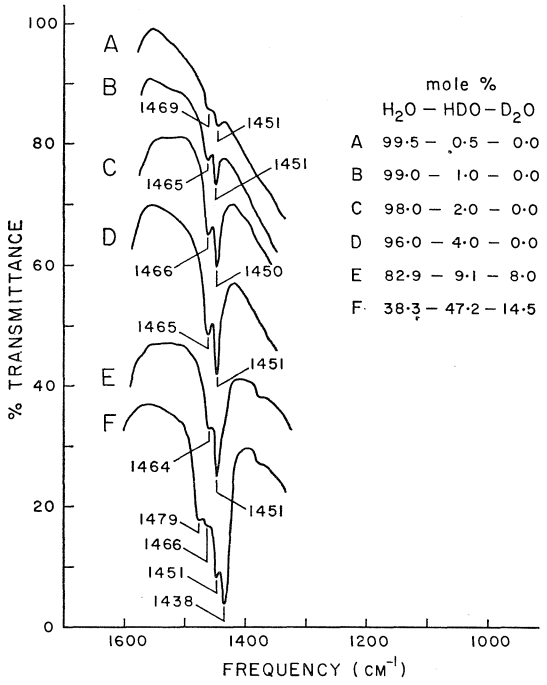

FIG. 5. Spectra of partially deuterated gypsum in KBr pellets in the H—O—D bending region. The amounts of gypsum used, in mg, were (from *A* to *F*) 4.59, 4.62, 5.00, 2.21, 1.02, and 0.99 respectively. Spectrum *A* has been displaced upward by 53% transmittance, *B* upward by 42%, *C* downward by 9%, *E* downward by 35%, and *F* downward by 50%.

The Bending Fundamentals of Isotopically Dilute H_2O and D_2O

At very high deuteration (Fig. 6*A*) the spectrum in the H—O—H bending region has no appreciable contribution from H_2O molecules. The absorption at about 1620 cm^{-1} arises from a weak D_2O band, usually assigned to the combination $\nu_2 + \nu_R$ of the bending vibration ν_2 and restricted rotation ν_R (14). As the deuterium content of the sample decreases, the band due to the bending vibrations of isotopically dilute H_2O molecules appears (Fig. 6*B*). This is a sharp, single band situated at 1654 cm^{-1}. At still lower deuterium contents higher concentrations of H_2O give rise to a more complex spectrum. Undeuterated samples yield the well-known doublet at 1681 and 1618 cm^{-1} (Fig. 6*C*).

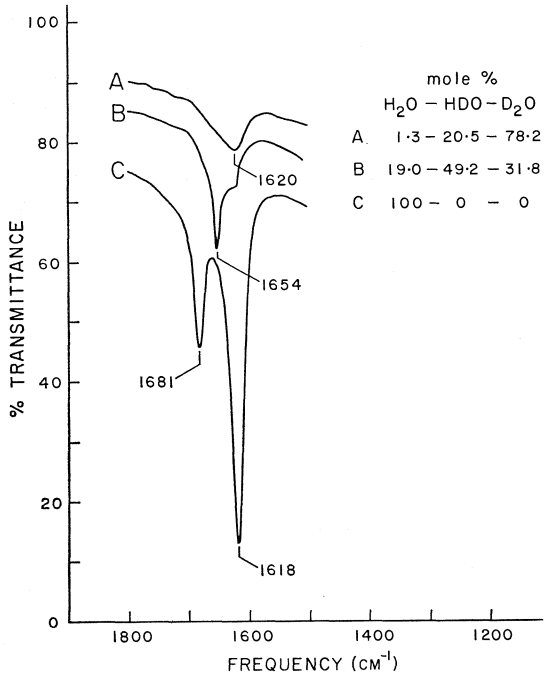

FIG. 6. Spectra of partially deuterated gypsum in KBr pellets in the H—O—H bending region. The amounts of gypsum used, in mg, were (from *A* to *C*) 1.00, 1.01, and 1.00. Spectrum *C* has been displaced downward by 10% transmittance.

The absorption from D—O—D vibrations in gypsum lies on the side of a very intense sulfate band (Figs. 7*B*, *E*). At high deuterium concentrations there are two D_2O peaks in this region, at 1238 and 1194 cm^{-1} (Figs. 7*D*). At lower deuterium concentrations (Fig. 7*A*) the spectrum of dilute D_2O molecules consists of one peak at 1215 cm^{-1}. The D_2O peaks can be seen more clearly in the difference spectra 7*C* and 7*F*, which are compensated for the sulfate group absorption.

Effect of Temperature

The temperature dependence of the frequencies of isotopically dilute HDO molecules is shown in Table I. Temperature shifts are remarkably small. The maximum shift observed was only 7 cm^{-1} for a temperature change of 250°. The half-widths at room temperature were about 30 cm^{-1} for the O—H stretching peaks, 20 cm^{-1} for the O—D stretching peaks, and about 13 cm^{-1} for the H—O—D bending peaks. The half-widths of the stretching peaks decreased on cooling by about 50% over 250°.

Discussion

The water molecules in a unit cell of a crystalline hydrate will be distributed over *n* crystallographically non-equivalent sets; in each of these

HDO	OH stretching	3450	1	2	$n+m$
	OD stretching	2550	1	2	$n+m$
	HOD bending	1460	1	2	$n+m$

*The stretching vibrations of isolated H_2O and D_2O molecules cannot be observed (see text).

sets the molecules are related by symmetry and therefore equivalent[7]. These n sets will give rise to n bending and $2n$ stretching fundamental H_2O vibrations, all of them i.r. active. Partial deuteration will replace some of the H_2O molecules by D_2O molecules and others by HDO molecules. Always assuming that the deuterium atoms are distributed at random throughout the crystal, the D_2O molecules will produce additional $3n$ fundamental vibrations, but the number of HDO fundamentals will depend on the symmetry of the H_2O molecules that the HDO molecules have replaced. A symmetric H_2O molecule on half-deuteration will generate 3 fundamentals, while an asymmetric one will yield either of the two possible distinct HDO species and thus 3 *pairs* of fundamentals. The total number of fundamentals in the partially deuterated hydrate will then be $3n$ from the H_2O molecules plus $3n$ from the D_2O molecules plus $3n + 3m$ from the HDO molecules, m being the number of sets of *asymmetric* H_2O molecules in the undeuterated hydrate. The approximate frequencies at which the absorption bands corresponding to these fundamentals will occur are indicated in Table II.

In principle, n and m can be determined from the study of any one of the H_2O or D_2O fundamentals *and* any one of the HDO fundamentals. In practice, the enumeration of these fundamentals will be complicated by the existence of coupling between vibrations of neighboring molecules which will tend to increase the number of observed bands. To eliminate this complication the fundamentals must be isolated by suitable isotopic dilution. Thus in a highly deuterated crystal the HDO molecules will be surrounded entirely by D_2O molecules as their nearest (water-molecule) neighbors, and the O—H stretching and H—O—D bending vibrations of HDO will be observed in their uncoupled form. Similarly a very low degree of deuteration will yield the frequencies of the O—D stretching and H—O—D bending vibrations of isolated HDO molecules, while intermediate degrees of deuteration may yield bending frequencies of isolated H_2O and D_2O. The *stretching* vibrations of isolated H_2O and D_2O molecules are masked by the stretching bands of HDO and cannot be observed.

Gypsum affords an example of a hydrate in whose spectrum all five observable fundamentals of isolated H_2O, D_2O, and HDO are actually observed. The spectrum of highly deuterated gypsum contains two distinct O—H stretching bands of isolated HDO, while at low deuterations there are two O—D stretching bands. At high and low deuterations there are two bending bands of dilute HDO. Each of these observations corresponds to $n + m = 2$. At intermediate deuterations, only one bending band each is found for isolated H_2O and isolated D_2O, either observation yielding $n = 1$. Consequently all water molecules in undeuterated (or fully deuterated) gypsum are crystallographically equivalent and asymmetric. This conclusion is in complete agreement with the expectations from the space-group symmetry $C2/c$ assigned to gypsum on the basis of X-ray and neutron diffraction studies.

That the asymmetry of the water molecules is appreciable is indicated by the large splittings of the three isolated HDO frequencies: 90 cm^{-1} for O—H stretching, 65 cm^{-1} for O—D stretching, and 14 cm^{-1} for the bending. The hydrogen bonds of the two OH groups must thus differ

[7]Zeolitic water molecules are not being considered here.

considerably in length and strength. The hydrogen-bond lengths can be estimated from the Lord–Merrifield correlation of O—H stretching frequencies and the O···O distances in crystals (15) or from one of its modified versions (16). These correlations are, in the region of interest, at best approximations, and so the two hydrogen-bond lengths in gypsum calculated from them, 2.82 and 2.84 Å, have no claim to accuracy. But they do give the order of magnitude of the *difference* of the two O···O distances, 0.02 Å, and show that the effect of temperature on factors responsible for the asymmetry of the water molecule is small. If a reliable correlation of O—H stretching frequencies with observed O—H distances were available, a similar estimate could be made of the difference of the two O—H bond lengths[8].

The spectroscopic estimate of the difference of two O···O distances in a crystal gives an idea of the accuracy with which such distances would have to be determined by diffraction methods to improve on the reliability of the Lord–Merrifield correlation. In gypsum the difference of the OH frequencies corresponding to the two O···O distances is quite large by spectroscopic standards of resolution, and an accurate determination of the positional parameters of two oxygen atoms in such a crystal ought not to present difficulties. Yet the O_w—O_I and O_w—O_I' distances of ref. 2 differ by 0.008 ± 0.021 Å (or, using 3σ limits, 0.01 ± 0.06 Å) compared with the above estimate, 0.02 Å. Admittedly the accuracy of the determination of the crystal structure of gypsum by neutron diffraction can be improved, but for the results to be useful in the present context the estimated standard deviations of the two distances would have to be of the order of 0.001 Å, i.e. ten times smaller than in ref. 2.

The present results also occasion comment on some of the previous spectroscopic studies of gypsum. Komarov *et al.* (10) interpreted the doublet in the H—O—H bending region at 1620 and 1667 cm^{-1} (1618 and 1681 cm^{-1} in our spectra) as indicating the presence of two types of water molecules in the ratio 3:1. Our spectra show that the H—O—H (and D—O—D) bending doublet reduces to a single peak of intermediate frequency in the spectrum of isolated H_2O (and D_2O). The doublet is thus due to two coupled vibrations of the water molecules present in the unit cell, as correctly assigned by Hass and Sutherland (5).

Stekhanov (18) suggested that the doublet in the O—H stretching region at 3405 and 3495 cm^{-1} in the Raman spectrum is due to the splitting of the energy levels caused by the tunnelling of hydrogen in a double-well potential. Such splitting of energy levels is known to be highly sensitive to the mass of the tunnelling atom; it would be expected to decrease drastically for the O—D stretching vibrations, for which the tunnelling mass doubles (19). Our stretching frequency ratios for isolated O—H and O—D frequencies in gypsum are 3494/2582 = 1.353 and 3404/2517 = 1.352. These ratios are very close to those observed in ice (20) and in $NaCl \cdot 2H_2O$ (21) and show that the two isolated O—H (and O—D) stretching bands originate in distinct OH groups in the crystal. The more complicated pattern of bands in undeuterated (and completely deuterated) gypsum is due to the coupling of these vibrations with those of the neighboring water molecules. There is no anomaly to indicate appreciable tunnelling.

Conclusion

A method is presented for determining the total number n of crystallographically distinct H_2O molecules, and the number m of crystallographically distinct *asymmetric* H_2O molecules, from the spectra of partially deuterated crystalline hydrates. The method is of general applicability. Its limit is set by the ability to resolve closely spaced fundamental bands of the isotopically dilute species of non-equivalent water molecules in the crystal. Whether the method will give the correct values of n and m, or only their minimum estimates, depends on how completely all the fundamentals required by the actual symmetry of the crystal structure are enumerated. There is no difficulty in recognizing as distinct, OH stretching bands 10 cm^{-1} apart ($NaCl \cdot 2H_2O$ at $-170°$; ref. 21). This separation corresponds to a difference of about 0.002 Å in the O···O length. In favorable circumstances, bands lying even closer together should be distinguishable. It is thus possible to detect spectroscopically differences in hydrogen-bonded O···O distances

[8]Mr. R. W. Green of the Department of Chemistry, University of British Columbia, used our frequencies to calculate the approximate ratio of the two O—H distances in gypsum (17). Using a harmonic approximation he found $d(O_w—H') : d(O_w—H) = 0.966$.

which would be difficult to establish by diffraction methods.

Among the experimental difficulties that may arise are (*a*) slow rate of deuteration; (*b*) masking of some of the water-molecule fundamentals by other bands; and (*c*) uncertainty whether vibrational coupling has been reduced to a level where it does not interfere. For gypsum it was possible to deal successfully with each of these problems.

The usefulness of the method is now being tested on several other crystalline hydrates[9].

Acknowledgments

We thank Miss Gwen Thomas for her capable assistance with some of the experimental work and Mr. P. F. Seto for help with the computations; Dr. K. B. Harvey and Mr. R. W. Green for the opportunity to discuss this problem with them; and National Gypsum (Canada) Ltd. for providing a large sample of selēnite.

Effect of pressure on the rates of hydrolysis of allyl chlorides

A. B. LATEEF AND J. B. HYNE
Department of Chemistry, The University of Calgary, Calgary, Alberta

Received October 11, 1968

The pressure dependence of the rates of hydrolysis of allyl chloride and α-, β-, and γ-methyl allyl chlorides has been examined. The significance of the activation volumes, ΔV^*, and their pressure dependence, $d\Delta V^*/dP$, is discussed. These activation parameters indicate an S_N2 mechanism for allyl and β-methyl allyl chloride and an S_N1 or intermediate character mechanism for the other methyl substituted allyl chlorides investigated. The results are compared with the corresponding ΔH^* and ΔC_P^* measurements of Robertson and co-workers. The temperature dependence of the activation volume, $d\Delta V^*/dT$, for the solvolysis of the parent allyl chloride has been measured and found to be small and negative.

Canadian Journal of Chemistry, **47**, 1369 (1969)

Introduction

DeWolfe and Young (1) have reviewed the extensive investigations of various workers on the solvolysis of allylic type halides. It has been suggested (2) that solvolysis reactions of this type represent a continuous spectrum of mechanism, ranging from bimolecular S_N2 to the limiting unimolecular S_N1 type ionization process.

Although the effect of pressure on the rates of reaction in solution has been under investigation for some time, the significance of the activation volume as a mechanistic probe has been recognized only recently (3–5). Whalley (4) has reviewed the significance of activation volumes in the determination of reaction mechanism, and has suggested that the volume of activation is probably easier to rationalize in terms of reaction mechanism than the other important parameters of activation, i.e. the free energy, enthalpy, and entropy. Improvements in the precision with which the pressure dependence of reaction rates can be determined has also permitted the evaluation of the second pressure differential of the rate, namely the pressure dependence of the activation volume, $d\Delta V^*/dP$. Robertson (6) has demonstrated the value of the second temperature differential of the rate, ΔC_P^*, as a measure of reaction mechanism type and it will be shown in this paper that $d\Delta V^*/dP$ may be an equally important and informative activation parameter. Table I summarizes the various activation parameters that may be obtained for a given system by a combination of pressure and temperature effect studies.

There are very few solvolysis reactions for which all of these pseudo thermodynamic activation parameters are available. In order to examine the relative significance of these various activation parameters, as far as reaction mechanism is concerned, it is important to have a complete set for a given system. Robertson *et al.* (7) have examined the solvolysis of methyl substituted allyl chlorides and reported the activation parameters with respect to temperature. The primary purpose of this work was to determine the activation parameters with respect to pressure for this same system, and to illustrate the inter-relationship of all of these activation parameters in indicating the variation of mechanism as the structure of the reacting substrate changes.

TABLE I
Thermodynamic parameters of activation

Variable	First derivative	Second derivative
Temperature	ΔH^* (ΔS^*)	ΔC_P^*
Pressure	ΔV^*	$d\Delta V^*/dP$

Experimental

Kinetic Method

The rate of production of HCl resulting from the hydrolysis of the various allyl chlorides was followed conductimetrically. Details of the in situ conductimetric technique have been reported previously (8). In this work an automatic balancing a.c. conductance bridge with digital print out (GR Type 1680-A) was used, providing improved accuracy and reproducibility, particularly with faster reactions. The high pressure vessel, pressure control, and conductance cell have been described in earlier papers (8). Temperature control was maintained to better than ± 0.01 °C by oil bath thermostating. At temperatures below ambient, an auxiliary refrigerated cooling coil immersed in the oil bath was employed. The temperature sensing device controlled both the cooling unit and the heating element. Pseudo first order rate constants were extracted from conductance/time data by the Guggenheim method (9).

[a]Calculated from the data of Robertson and co-workers (12, 7). N.B. The rate constants reported in Robertson's paper (7) are correct. However the values for the coefficients A, B, and C in the temperature dependence equation for β-methyl allyl chloride are in error. The correct values are $A = -8006.0996$, $B = -23.3571$, and $C = 79.13099$, as obtained from Robertson in a private communication.

Materials

Water

House distilled water was first passed through Ilco-way de-ionizing resin and then redistilled in Pyrex apparatus from which atmospheric carbon dioxide was excluded; storage was in polyethylene containers.

Allyl Chloride

Matheson, Coleman, and Bell material was redistilled at 10^{-3} mm, and the center cut stored for later use. Purity was checked by gas–liquid chromatography (g.l.c.).

β-Methyl Allyl Chloride

Eastman Organic Chemicals sample redistilled in small quantities at 10^{-3} mm, as required. Gas–liquid chromatography indicated no significant impurities.

trans-γ-Methyl Allyl Chloride

The crotyl chloride purchased from Aldrich Chemical Co. was found to be a mixture of *cis*- and *trans*-γ-methyl allyl chloride. The *trans*-γ-methyl allyl chloride was separated by preparative g.l.c. as described by Robertson *et al.* (7). The preparative column used was 9 ft × ⅜ in., packed with 15% β,β′-oxydipropionitrile on Chromosorb P(80–100 mesh), which is capable of separating the *cis* and *trans* isomers. The separation was carried out under the following conditions: injector 100 °C, oven 45 °C, detector 140 °C, flow rate 90 cc nitrogen per min. The purity of the sample of *trans*-γ-methyl allyl chloride was checked on an analytical column of 6 ft × ¼ in. packed with the same material, under the following conditions: injector 100 °C, oven 41 °C, detector 197 °C, nitrogen flow 28 cc per min. The sample of *trans*-γ-methyl allyl chloride was found to have less than 0.3% impurity.

α-Methyl Allyl Chloride

A pure sample of this substrate was kindly provided by R. E. Robertson. The purification method was as described in ref. 7.

Preparation of Working Solutions

All reaction solutions were prepared by weighing required amounts of the various allyl chlorides and dilution in standard flasks to yield 10^{-4} M concentrations. Solutions were degassed by repetitive freezing and melting before being loaded into conductance cells.

Results

Pseudo first order rate constants for the hydrolysis of allyl chloride, β-methyl allyl chloride, and *trans*-γ-methyl allyl chloride at various pressures to 2700 atm are reported in Table II. Attempts to measure the pressure dependence of the rate of hydrolysis of α-methyl allyl chloride were unsuccessful, due to the relatively rapid intramolecular rearrangement of this substrate to a mixture of *cis*- and *trans*-γ-methyl allyl chloride (10). Rearrangements of this kind have been shown (4, 11) to be particularly pressure sensitive and to have rates in excess of the rate of hydrolysis of the parent halide. Accordingly, any attempt to observe the rate of hydrolysis of α-methyl allyl chloride, particularly at elevated pressures, rapidly becomes an observation of the combined rate of hydrolysis of a rearranged mixture of methyl substituted allyl chlorides. The complication is clearly demonstrated by failure to obtain linear first order kinetic behavior in the case of α-methyl allyl chloride.

Allyl chloride and β-methyl allyl chloride were studied at 50.25 °C; at this temperature the reaction proceeded at a rate which permitted considerable pressure variation without increas-

[a]Calculated from ref. 12.

ing the rate beyond a measurable value. *trans*-γ-Methyl allyl chloride, however, hydrolyzes at a considerably faster rate even at room temperature and atmospheric pressure. Accordingly, it was necessary to study the effect of pressure on the hydrolysis of this substrate at 12.02 °C. Since the purpose of this study was to compare the pseudo thermodynamic parameters of activation of the complete set of allyl chlorides, this experimentally dictated temperature difference required that a check of the temperature dependence of the pressure-derived activation parameters be carried out. This was done in the case of allyl chloride. Table III reports the dependence of the rate of hydrolysis of allyl chloride on pressure at four temperatures over the range of 30–60 °C. The activation volume and its pressure dependence derived from these results for each temperature shows a remarkable constancy as the temperature is varied. While this observation in itself is interesting, its main value is to serve as a good indication of the magnitude of any correction that should be applied when comparing the pressure-derived activation parameters obtained from kinetic data at different temperatures.

In any study in which the derivation of the measured rate constants with respect to pressure or temperature is extracted, the error associated with these derived parameters is strictly dependent on the accuracy of the rate determinations themselves. Selected rate data determined at atmospheric pressure in the apparatus used in this work were in excellent agreement with the previously reported values of Robertson and co-workers (7, 12). The values shown at atmospheric pressure in Tables II and III are those calculated from the rate/temperature dependence equation published by Robertson (6). All rate constants reported at elevated pressures are the average values of at least four separate rate determinations. The uncertainties associated with each value were obtained by the method previously described by Golinkin *et al.* (13), and are normally better than ±1.0%. Activation volumes and their pressure dependence were extracted from the rate/pressure data reported in Table II by obtaining a computer best fit to the rate/pressure quadratic equation.

$$\log k = A + BP + CP^2$$

This method has been described in detail in a previous paper (13). Figure 1 is a typical plot of log k vs. pressure for data reported in this paper. The error bars shown on each point illustrate the typical uncertainty associated with the rate

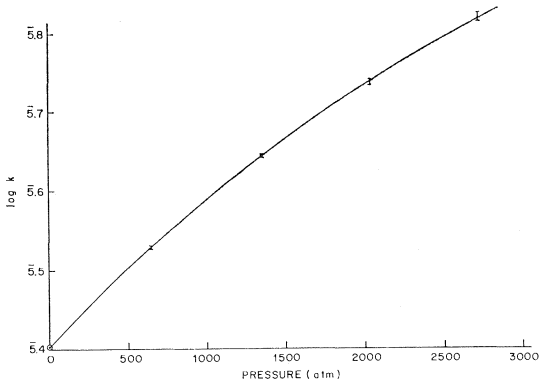

FIG. 1. Plot of log k vs. pressure for the hydrolysis of allyl chloride at 50.25 °C.

TABLE IV

Activation parameters derived from pressure and temperature dependence of rate for the solvolysis of various allyl chlorides

Substrate chloride	Pressure parameters		Temperature parameters[a]	
	ΔV^* (ml/mole)	$(d\Delta V^*/dP) \times 10^4$ (ml/atm mole)	ΔH^* (kcal/mole)	$(d\Delta H^*/dT)\Delta C_P^*$ (cal mole deg)
Allyl-	-11.40 ± 0.13 (50.25°) -8.0 (approx.) (12.0°)	16.11 ± 1.44	21.99 ± 0.01 (50.0°)	-49.6 ± 1.2
β-Methyl allyl-	-10.16 ± 0.21 (50.25°)	9.85 ± 1.03	20.98 ± 0.08 (50.0°)	-48.39 ± 4.5
α-Methyl allyl-			23.87 ± 0.01 (15°)	-91.6 ± 3.1
trans-γ-Methyl allyl-	-14.83 ± 0.05 (12.02°)	46.66 ± 4.69	23.93 ± 0.01 (15°)	-81.6 ± 3.3

[a]Robertson's data, ref. 7.

determinations at pressures above atmospheric, and the plot clearly establishes the non-linearity of the log k vs. pressure relationship. This curvature is reflected in the non-zero valued C coefficient in the quadratic equation used to describe the pressure dependence and yields the $d\Delta V^*/dP$ values shown in Tables II and III.

Discussion

All volumes of activation measured for the allyl halides studied in this work are negative. This observation is in keeping with the fact that where an S_N1 or S_N2 type mechanism is operative, the transition state is normally a more polar species than the initial state. Accordingly, volume reduction by electrostriction of solvent will tend to outweigh any volume increase due to bond extension in the activation process. Furthermore, it might be expected that the ΔV^* associated with the more ion-like transition state of an S_N1 mechanism would be more negative than in the case of an S_N2 mechanism.

Robertson and co-workers (7) have suggested, on the basis of their ΔH^* and ΔC_P^* values (see Table IV), that *trans*-γ-methyl allyl chloride hydrolyzes by a more S_N1 like mechanism while the parent allyl and β-methyl allyl chlorides are more S_N2 type reactions. The ΔV^* values reported in Table II for these three compounds suggest that the two S_N2 type reactions do indeed have volumes of activation somewhat less negative than that for the S_N1 type *trans*-γ-methyl allyl chloride. It is important at this point to recall the temperature dependence of ΔV^* as illustrated in Table III. If the ΔV^* value for allyl chloride is corrected to 12.02 °C a value of approximately -8 ml/mole is obtained, to be compared with a corresponding value for *trans*-γ-methyl allyl chloride of -14.8 ml/mole at the same temperature. Accordingly, the temperature difference between the data reported in Table II tends to obscure the differences in the ΔV^* values rather than accentuate them. Whether or not the ΔV^* values for allyl and β-methyl allyl chlorides reflect a true S_N2 type mechanism cannot be established conclusively. However, le Noble (11) has reviewed the volumes of activation of a number of bimolecular reactions for which other evidence suggests a simultaneous bond-making and bond-breaking reaction mechanism and has suggested that for such limiting S_N2 reaction types, a ΔV^* value between -5 and -10 ml/mole is to be expected. The ΔV^* values reported here suggest that allyl and β-methyl allyl chloride hydrolyze by a mechanism that might be termed non-limiting S_N2. In reactions for which the rate is controlled by an S_N1 type ionization process, the ΔV^* is expected to be of the order of -15 ml/mole (14). Hence the -14.8 ml/mole value of ΔV^* for the hydrolysis of *trans*-γ-methyl allyl chloride suggests an S_N1 type mechanism.

By far the most instructive presentation of the available data on the allyl chloride system is that presented in Table IV. Here are presented in summary form all of the activation parameters for allyl, β-methyl, and *trans*-γ-methyl allyl chlorides. It was on the basis of ΔC_P^* values shown, that Robertson and co-workers (7) classified the allyl and β-methyl allyl chlorides as S_N2 like and α-methyl and *trans*-γ-methyl allyl chlorides as

S_N1. While a classification of this type could be based on ΔH^* values, the relative differences in these parameters was not great. The more sensitive of the two temperature-derived activation parameters was the second differential ΔC_P^*. While it is unfortunate that rate/pressure data for α-methyl allyl chloride proved to be unobtainable in this work, the remaining three allyl chloride substrates provide sufficient data to compare ΔV^* and $d\Delta V^*/dP$ with ΔH^* and ΔC_P^* values. A very similar picture emerges. As discussed above, a classification into S_N1 and S_N2 type mechanisms is possible on the basis of ΔV^* alone, but a much clearer separation of types becomes apparent when the second derivative $d\Delta V^*/dP$ values are examined. It is, therefore, clear from Table IV that first derivatives of the rate with respect to pressure (ΔV^*) and temperature (ΔH^*) are considerably inferior to second derivatives, $d\Delta V^*/dP$ and ΔC_P^*, as activation parameters for use as mechanistic probes.

The main reason for examining the temperature dependence of activation volume in the case of the allyl chloride was to permit appropriate compensation to be made for the considerable temperature difference between the pressure studies of the three allyl systems. However, the observed small value for $d\Delta V^*/dT$ is, in itself, an interesting observation. Walling and Schugar (15) have previously commented on the apparent lack of temperature sensitivity of ΔV^* although Laidler and Chen (16) reported that ΔV^* for the hydrolysis of ethyl acetate changed from -9.9 ml/mole at 25 °C to -4.8 ml/mole at 2.4 °C. Even in the latter case, however, $d\Delta V^*/dT$ is less than 0.25 ml/mole deg compared with a value of less than 0.1 ml/mole deg in the case of allyl chloride hydrolysis. It is worth noting that in the ethyl acetate case, although the reaction mechanism differs from solvolysis, the temperature range involved includes the temperature of maximum density of water and, if ΔV^* in any way reflects solvent reorganization, it might be expected to show its maximum temperature dependence passing through the Td(max) of water. Whatever the explanation of the lack of temperature sensitivity of ΔV^* may be, it can at least be said, that since ΔV^* is the difference in volume between the initial and the transition states, the volumes of both of these states respond in a remarkably similar manner to temperature change. This observation is noteworthy since if the solvent is deemed to be more highly electrostricted around the more polar transition state, it might be reasoned that the volume of the transition state entity would be significantly less sensitive to temperature than the more "loosely solvated" initial state. The apparent lack of sensitivity of ΔV^* to temperature might, therefore, be interpreted as suggesting that the solvent cage around the initial state is a good deal more rigid and temperature stable than has heretofore been believed.

Conclusions

The heat capacity and pressure dependence of volume of activation appear to be more sensitive to variations in the reaction mechanism for the allyl chloride solvolyses studied than are the first derivative parameters, enthalpy and volume of activation. The temperature dependence of the enthalpy and volume of activation makes it advisable to determine these parameters at comparable temperatures before using their relative values as indicators of likely mechanistic types.

An electron spin resonance study of ultraviolet photolyzed methanol adsorbed on porous high-silica glass[1]

MICHIE SHIMIZU AND H. D. GESSER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

AND

M. FUJIMOTO[2]
Department of Physics, University of Manitoba, Winnipeg, Manitoba

Received September 13, 1968

The electron spin resonance (e.s.r.) spectra of $\cdot CH_3$, $\cdot CHO$, H and/or D, and possibly $\cdot CH_2OH$ or $\cdot CH_2OD$ were found by the ultraviolet (u.v.) photolysis of methanol —OH or —OD on porous high-silica glass at 77 °K. These e.s.r. spectra resemble the results of the u.v. photolysis of X-irradiated methanol indicating that some perturbation and/or sensitization occurred in the molecules by the glass surface. The absence of e.s.r. spectra from the same systems on the acid-leached glass, on the totally fluorinated glass, or on the totally —OH covered glass suggests that (*i*) the co-existence of surface contaminants, such as Al and Zr and not B, and some of surface —OH could be responsible for producing these free radicals, and (*ii*) the methanols adsorbed on these glass surfaces are stabilized against u.v. photolysis.

Canadian Journal of Chemistry, 47, 1375 (1969)

Introduction

In previous work (1, 2), we reported that porous high-silica glass was a good host for methyl radicals which had been formed from CH_3I by u.v. photolysis. On the other hand, these porous glasses have been well studied as catalysts for alcohol dehydration and some hydrocarbon crackings (3–6).

Sullivan and Koski (7) found (by e.s.r. measurements) free radicals identified as $\cdot CH_3$, $\cdot CH_2OH$, and $\cdot CHO$ trapped in a frozen methanol matrix during u.v. irradiation at 77 °K, and Yang *et al.* (8) found (by vapor pressure chromatography (v.p.c.)) that H_2, CO, CH_4, HCHO, $(CH_2OH)_2$, and glycerine were produced by u.v. photolysis of liquid methanol. As a result of these findings we undertook to examine the trapping of these radicals on the surface of porous glass by the method previously described (9), and to explore the general usefulness of porous glass as a free radical host and/or the relationship between the nature as catalyst and free radical host.

Experimental

Adsorbents

The adsorbents, rods of 2 mm diameter × 20 mm length Corning Code #7930 porous Vycor® glass, were treated in the same manner as in our previous work (9), except, in the present study, some of them were "not acid-leached"[3] with hot 18*N* HNO_3. After washing, some of the glasses were thermo-leached in air at 500 °C for 5–16 h until they had no infrared (i.r.) spectra in the C—H bonding region from 3100 to 2500 cm^{-1}, and they were then degassed or fluorinated (10, 11). The adsorbents were denoted as V, VFp, or VF for the original, partially, or totally fluorinated glasses, respectively, and are further characterized by informations in brackets. For example, VFp (700 °C, 5 h, OH = $\frac{1}{2}$) means a partially fluorinated glass degassed at 700 °C for 5 h and which retained about $\frac{1}{2}$ of the OH of the original glass. The original glass was degassed at 800 °C for 5 h. In this example, therefore, the glass was a half-fluorinated.

The surface areas of these glasses, determined by the B.E.T.-method (12) using the effective cross-sectional area of methanol molecule of 17.8 $Å^2$ at 0 °C, were approximately 120 m^2/g for V(700 °C); 110 m^2/g for V(800 °C); 100 m^2/g for VFp(700 °C); 48 m^2/g for VFp(800 °C); and VF(800 °C). In this report, the amounts adsorbed were represented by the surface coverage $\%\theta$ related to each B.E.T.-monolayer of methanol for convenience.

Ultraviolet photolysis of all these adsorbents produced no e.s.r. signals.

Adsorbates

Methanol-OH, spectroscopic grade of Fischer Scientific Co., was distilled over Drierite at 68 °C in dried air. It was further purified by bulb-to-bulb distillation in vacuo with the middle one-third portion retained. The methanol-OD obtained from Merck and Co., Inc. was redistilled in vacuo. The i.r. spectra of the methanols in gas phases from 4000 to 400 cm^{-1} showed that the CH_3—OH had no absorption due to water and B—O bondings, while the CH_3—OD had some absorption at 3683, 1495, and

TABLE I

Appearances of e.s.r. spectra of free-radicals from water and methanol adsorbed on porous high-silica glass produced by u.v. irradiation at 77 °K

		Systems	
e.s.r.-Signals	Group*	Adsorbates	Adsorbents
None	A-*a*	None	All glasses† (450 °C, 16 h)
	b	Water	
	c	Methanols‡	
	d	None	V(800 °C, 5h, OH = 1)**
	e	None	VFp(700 °C, 5 or 16 h, OH = ½)§
	f	None	VFp(800 °C, 1, 3, or 5 h, OH < 1/20)‖
	g	None	VF(800 °C, 1.5 h, OH = 0)¶
	h	Methanols	VF(800 °C, 1.5 h, OH = 0)
	j	Water	All glasses(800 °C, 5h)
	k	Methanols	All glasses(800 °C), stored at room temperature over 2 weeks
Poor	B-*p*	Methanols	V(800 °C, 5h) acid-leached
	q	Methanols	VFp(700 °C, 5h) acid-leached
	r	Methanols	VFp(800 °C, 5h) acid-leached
Good	C-*x*	Methanols	V(800 °C, 5h) nonacid-leached
	y	Methanols	VFp(700 °C, 5h) nonacid-leached
	z	Methanols	VFp(800 °C, 5h) nonacid-leached

*The Groups are explained by the following example: Group A-*a* denotes the system of none adsorbate – all glasses (450 °C, 16h).
†"All glasses" means "V, VFp, or VF with acid-leaching or nonacid-leaching".
‡"Methanols" means "CH_3—OH and —OD".
§Prepared by dipping glass in 12.5% of NH_4F aqueous solution for 0.5h. The samples were then dried at 110 °C for 20 min and then degassed.
‖Prepared by dipping glass in 30% slightly basic solution for 1 h. The samples were then dried at 110 °C for 20 min and then degassed.
¶Prepared by dipping glass in 30% neutral solution for 1.5 h. The samples were then dried at 110 °C for 20 min and then degassed.
**As reference standard for OH retained.

1365 cm^{-1} indicating the presence of a small amount (less than 1%)[4] of CH_3—OH and trimethylborate (9). These impurities in CH_3—OD could not be removed by repeating the distillation. However, these i.r. spectra did not change notably during the course of this work. Ultraviolet photolysis of these methanols, CH_3—OH or —OD, generated very small e.s.r. signals with full strength of arc[5] for 1 h, indicating that the effects seen are due to the photolysis of the methanols which are adsorbed on the glasses and are not due to the bulk materials.

Methods

The experimental methods were similar to those used in our previous work (9), that is, the sample cells, which were made of "Infrasil" quartz tubing, were connected to a standard vacuum line to prepare the surface, to add adsorbate, or to degas.

The e.s.r. signals were observed with a Varian E-3 e.s.r. spectrometer at 77 °K at surface coverages of less than 1% and about 5%, 30%, and 80%. Before and after the e.s.r. measurements, the i.r. spectra of the sample were taken at room temperature with a Perkin–Elmer Model-337 spectrometer using an external recorder. The full beam of a 100 W medium pressure mercury arc, Hanovia S-100 Alpine Burner, was focused on the sample, which was kept in fresh liquid nitrogen in a quartz Dewar. The detailed experimental techniques have been described elsewhere (1, 2, 6, 9).

Results

Electron Spin Resonance

The e.s.r. results could be divided into three groups as listed in Table I. Group A gave no e.s.r. signals with u.v. irradiation for 1 h in the e.s.r. cavity[6]. Group B gave poor e.s.r. signals with u.v. photolysis out of the cavity[6] for 1 h or more. Group C showed good e.s.r. spectra, as shown in Figs. 1 and 2 with u.v. irradiation in the cavity almost immediately (within a few min).

The major experimental features are as follows:

(*a*)[7] All u.v. photolysis with a Pyrex filter gave no e.s.r. signals. The difference between direct photolysis and that with a Vycor filter was only a small time delay in signal development and implied a small change in effective intensity.

(*b*) The adsorption systems belonging to Group C were common to those of Group B. The

[4]Estimated by infrared spectra.
[5]These results agreed with those of Yang *et al.* (8) and Milliken and Johnsen (13).
[6]The intensity of u.v. irradiation out of the cavity was almost twice that in the cavity.
[7]These paragraphs will be referred to in the discussion.

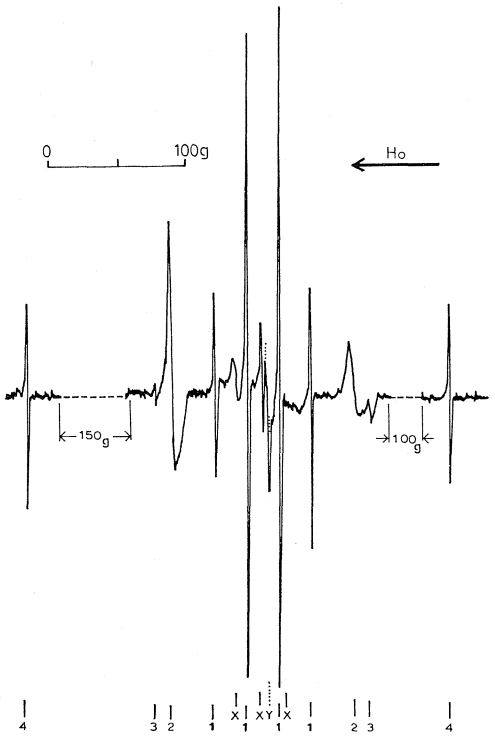

FIG. 1. Electron spin resonance spectra of VFp(800 °C)—CH_3OD system (about 80% θ); u.v.-photolyzed for 10 min at 77 °K. *1* denotes $\cdot CH_3$; *2*, $\cdot CHO$; *3*, D; *4*, H; ×, an unknown substance ($\cdot CH_2OH$ and/or $\cdot CH_2OD$?); Y (dotted line), Dewar and empty cell.

only difference between them was the leaching methods of the glasses. All glasses in Group B were acid-leached, whereas in Group C, the glasses were only thermo-leached.

(*c*) The e.s.r. spectra in Group C were similar in appearance, despite the different surface coverages, the different adsorbents of V or VFp, and even the different adsorbates of CH_3—OH or —OD, except for the spectra of D.

(*d*) In Group B, the e.s.r. spectra were similar in appearance to those in Group C, but were about 100 times less intense.

(*e*) The assignments in Figs. 1 and 2 for $\cdot CH_3$, $\cdot CHO$, H, D, and an unknown substance X have been made from the e.s.r. spectra results of Sullivan and Koski (7) and many workers (14). The spectra of D appeared only in the CH_3—OD systems. The unknown X may be $\cdot CH_2OH$ and/or $\cdot CH_2OD$, although this is not definite because of the weakness of the signals. An interesting phenomenon is the resemblance of these spectra to those from u.v. photolysis of X-irradiated methanol in bulk, determined by Milliken and Johnsen (13).

(*f*) The e.s.r. spectra grew very slowly indicating that the major reactions had ended within a few min with u.v. irradiation. It was, therefore, not possible to get enough data to clarify the mechanism of free radical formation.

Infrared Spectra

The i.r. spectra of methanol adsorbed on glasses

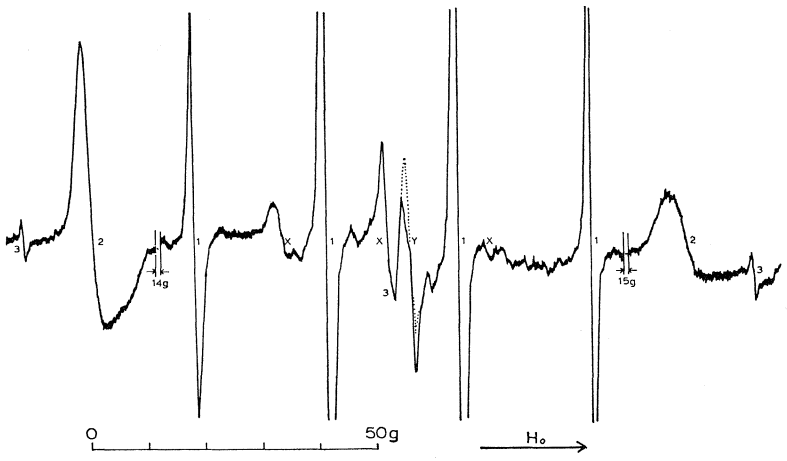

FIG. 2. Electron spin resonance spectra of VFp(800 °C)—CH_3OD system (about 80% θ); u.v.-photolyzed for 1 h at 77 °K (expanded). The notions are the same as those used in Fig. 1.

acid-leached or nonacid-leached, and before and after e.s.r. measurements, were all similar to each other. The detailed results of i.r. spectra of these systems will be reported in another paper (6).

Discussion

On the basis of the experimental results mentioned above, (i.e., methanols adsorbed on the porous glass showed no photo-inhibition effect with a Vycor filter, although Yang *et al.* (8) have shown that photolysis of liquid methanol was completely inhibited when a Vycor filter removed the 1847 Å-line and restricted photolysis to 2537 Å. See also section (*e*) of the results and Group A-*d* to -*f* in Table I) it is clear that some perturbation and/or sensitization occurred in the methanol molecules by some parts of the glass surfaces. The recent paper by Pariiskii *et al.* (15), where silica sensitized the photodecomposition of H_2, seems to support this.

It is well established that the adsorbent porous high-silica glass surfaces have hydroxyl $\equiv$Si—OH, siloxane bridge $\equiv$Si—O—Si$\equiv$, and analogous groups of B, Al, etc. (3–6, 9, 16). Of these functional groups, the surface hydroxyls are not u.v. photolyzed as shown in Group A-*a*, -*b*, and -*j*, and seem to inhibit the u.v. photolysis of adsorbed methanol of Group A-*c* when present in large surface concentration, and according to Low and Ramasubramanian (16) may extend over the monolayer. However, VF(800 °C, 1.5 h) of Group A-*h*, which has no OH according to the i.r. spectra (6, 11), has lost the activity for u.v. photosensitization while V(800 °C) and VFp(700 or 800 °C) of Group C seem to retain the activity. This implies that the co-existence of some surface —OH is required for such a sensitized reaction to occur on the surface.

It is reasonable to conclude that the surface siloxanes and fluorines both have little or no roles to play in the u.v. production of free radicals which bring about e.s.r. signals. This conclusion can be drawn because the acid-leached glasses (800 °C) of Groups A and B gave very poor e.s.r. signals, despite the existences of $\equiv$Si—O—Si$\equiv$ and $\equiv$Si—F on their surfaces which were confirmed by our i.r. studies (6, 9).

Considering the results of our works (6, 9) (i.e., the surface methoxides on the glass were very stable against u.v. photolysis at 77 °K, and the reaction of methanol molecules with the surface —OH of glasses to form the methoxides was slow), it might be suggested that the surface methoxides are stabilized during the storage of samples of Group A-*k* and destroy the u.v. photosensitization.

The effect of acid-leaching on such glass was reported by Little *et al.* (17). They showed that there was (*i*) no loss of boron, and (*ii*) a loss of Al and Zr from the surface which was estimated at about 0.4%. This was responsible for the isomerization and polymerization of adsorbed butene.

From our results, it might also be suggested that the similarity of i.r. spectra between the samples Groups B and C indicated no loss of boron, and, therefore, the surface boron has no effect on the photosensitization of methanol under these conditions, even though $=$B—OCH_3 is considered as a starter for methanol cracking during thermotreatment by Low and Harano (5). The results also suggest that siloxane-like bridges of the surface impurities, (Al and Zr, but not B) with the co-existence of some surface —OH (as mentioned above) could be responsible for this photosensitization of CH_3—OH or —OD molecules. Because of their low concentration, these could be independent of the surface coverages. The trace quantities of these surface impurities remaining on the glass surfaces after acid-leaching could account for the poor e.s.r. signals of Group B.

Despite the loss of Al and Zr, the absence of a notable change in i.r. spectra between these sample groups may be explained as follows: (*i*) the quantities of surface contaminants, mainly Al and Zr, on the glass were too small to identify any differences, and/or (*ii*) based on the results of Greenler (18), the surface $=$Al—OCH_3 may have so similar a structure to surface $\equiv$Si—OCH_3 and/or $=$B—OCH_3, that it could not be distinguished from them.

The stabilization tendency must also be accounted for. From the remarkable decrease and loss of photosensitization during the storage of all samples in Group A-*k*, it may be speculated that there were some less stable states of methanol at the early stage of adsorption, e.g., on siloxane-like surface bridges of Al and Zr which should be photosensitive. For example, H in CH_3 might be caught on metal-sites directly, and then transfered to a more stable form with aging. There is also a possibility that distillation of stop-cock

grease to the surface might mask and poison the active sites (19). This should be examined in an ultra-high vacuum grease free system.

The absence of a notable change of i.r. spectra before and after u.v. irradiation can be explained as follows: (*i*) the change in quantity was too small to be detectable with i.r. spectra, and/or (*ii*) most of the reactions would be reversible on the surface under these conditions.

Greenler (18) has suggested that the reaction of methanol on alumina occurs as follows:

$$CH_3—OH + —Al—O—Al—O— \rightarrow —\underset{\displaystyle OCH_3}{\underset{|}{Al}}—O—Al— + H$$

with H presumably forming =Al—O..H. However, this reaction cannot be considered to be the entire source of H or D in view of the relatively weak D-signals.

Reactions of alcohols adsorbed on MgO. Part I. Heterogeneous reactions with hydrogen atoms and trapped electrons at room temperature: a new technique in surface chemistry

D. R. SMITH[1] AND A. J. TENCH
Chemistry Division, Atomic Energy Research Establishment, Harwell, Berkshire, England

Received October 23, 1968

A series of alcohols, adsorbed on MgO powder, have been bombarded by a stream of hydrogen atoms at room temperature and the radicals thus formed are detected by electron spin resonance. Methanol, ethanol, *n*-propanol, iso-propanol, *n*-butanol, *sec*-butanol, and allyl alcohol have been studied. The radical species produced have been identified and radical lifetimes varying from minutes to hours at 300 °K have been observed. For methanol, the first monolayer appears to be chemisorbed as methoxy groups whereas the ethanol data indicate that some of the molecules in the first monolayer are physically adsorbed. The higher alcohols form secondary radicals via hydrogen elimination from the primary radical; the isopropyl alcohol radical appears to isomerize before losing hydrogen. Allyl alcohol undergoes hydrogen atom abstraction in preference to addition to the double bond and yields the α-hydroxy-allyl radical. Methanol and ethanol have also been reacted with electrons trapped on a MgO surface to form stable alkoxide ion radicals trapped at oxygen ion vacancies on the surface of the lattice.

Introduction

In recent years there has been an increasing amount of evidence that free radicals can be stabilized on the surface of insulators. The observation of such intermediate species is of considerable relevance to problems in catalysis. However, in many cases where high energy radiation has been used to form the radicals, the situation is complicated by the number of paramagnetic fragments formed in the solid and by poorly understood energy-transfer processes that take place from the solid. These difficulties can be overcome, if the radicals are produced by a chemical reaction from the gas phase. In this present study our objective was to investigate the radicals formed when molecules adsorbed on a surface are bombarded with H-atoms.

There have been various studies of heterogeneous reactions of atoms or hydroxyl radicals with organic compounds. Solids investigated at room temperature are polymer "fluffs" (1, 2), suspensions on quartz wool (3), or pure finely divided powders (4–7); some compounds which are liquid at room temperature have been bombarded with atoms in the frozen state (8–10). Heterogeneous reactions with adsorbed molecules have been very few. Kokes (11) mentions the reaction of hydrogen atoms with oxygen adsorbed on ZnO, but the interpretation of the results is difficult; oxygen atoms have been reacted with NO_2 adsorbed on 13X molecular sieve to give what is thought to be NO_3 (12).

The formation of radicals stabilized on surfaces using atom bombardment has several advantages over conventional methods. Firstly, compounds that are volatile liquids may be adsorbed at room temperature and may form radicals which are stabilized on the surface even at room temperature. Secondly, usually only one kind of radical species is formed, thus simplifying the spectra. Thirdly, the radicals are formed in an exposed position and are readily available for further reactions; this is in contrast to studies in crystals and glasses where the radicals are buried in the matrix.

Tench and Smith (13) have shown that the heterogeneous reaction of hydrogen atoms with MgO leads to the formation of reactive surface centers. In this present work, a series of alcohols was adsorbed to form approximately a monolayer on the surface which was then reacted with H-atoms at room temperature. Alcohols were chosen because they are strongly adsorbed, and because important catalytic reactions involving dehydrogenation and dehydration are known to occur over oxide catalysts (14–17). The radicals formed are detected and identified by electron spin resonance (e.s.r.) techniques and their reactions studied.

This work is closely related to the field of heterogeneous radiation chemistry and in a later paper (Part II), results for the irradiated systems will be reported for comparison.

Experimental

In an initial experiment a conventional hydrogen gas flow system through the TE_{102} e.s.r. cavity was constructed. Hydrogen atoms formed by a 2450 MHz microwave discharge were monitored by their e.s.r. signal. This was used to determine the optimum experimental conditions for obtaining the maximum concentration of hydrogen atoms, free from contamination by other atoms. Oxygen impurity was converted to water in a "Deoxo" unit. When this water was not removed, the hydrogen atom concentration increased by a factor of 20; however, there was then a significant concentration of oxygen atoms. Typical conditions in a pure dry H_2 flow were: 8 Torr pressure, 300 cm s^{-1} linear flow rate, and 60 W microwave discharge. Ample hydrogen atoms were obtained without having to poison the walls of the apparatus.

The apparatus for sample bombardment was made of Pyrex except for silica tubing in the discharge zone and where specified in Fig. 1. Preparation of MgO and adsorption of alcohols is performed in a silica side-tube. This sample is kept "safe" in this side-tube at 77 °K while the rest of the apparatus is "cleaned" by a stream of hydrogen atoms for 10 min. Then, after warming the sample to room temperature, the apparatus is rotated 180° about a greased joint, allowing the sample to fall into a 350 ml Kjeldahl flask. The hydrogen atom stream flows through a focussing nozzle inside the flask and reacts with the sample as it falls into the flask and while lying on the bottom.

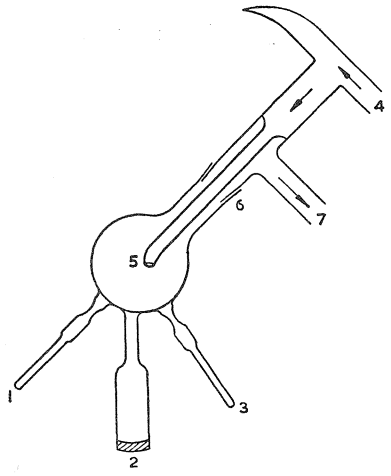

FIG. 1. (1) and (3), silica e.s.r. sample tubes; (2), silica sample preparation tube containing a 2 mm layer of powder; (4), hydrogen atom flow from the microwave discharge zone; (5), 0.5 cm nozzle to focus the hydrogen atom stream; (6), B 29/32 greased joint to permit rotation of the flask; (7), to the pumps and to the adsorbate inlet port.

After 5 or 10 s of atom bombardment, the flask is rotated further so that the powder falls into a silica e.s.r. sample tube. This tube is promptly immersed in liquid nitrogen to preserve any unstable radicals. The sample tube is then sealed off at a constriction. Prior to starting the flow of hydrogen atoms, "blank" samples were poured into a second silica e.s.r. sample tube on each run and sealed off.

When necessary, this apparatus permits atom bombardments at 77 °K by cooling the bottom of the flask and the e.s.r. sample tube in a polystyrene liquid nitrogen Dewar. This Dewar is "keyhole" shaped and deep enough to permit rotation of the apparatus in the Dewar. Such techniques have been found useful in some atom bombardments of pure oxides reported elsewhere. The technique is felt to be simpler than that described by Herak (18).

MgO was made by decomposing the carbonate in air at 900 °C. About 0.6 g of the oxide was placed in the sample preparation side tube and was gradually heated in vacuum to 800 °C in 2 h. This oxide has been previously found to have a surface area of about 25 m^2g^{-1} by B.E.T. adsorption methods. After the powder had cooled to room temperature, 3×10^{-3} ml (except when specified otherwise) of deaerated alcohol was admitted. The adsorption, monitored by a silicone oil manometer, was complete in 30 s. Half the sample was then taken off for comparison as a "blank" and the other half treated as described above. Samples were stored under liquid nitrogen (usually for no more than 10 min) until e.s.r. measurements could be made.

The alcohols were used as received from the supplier. They were deaerated by conventional freeze, pump, and thaw techniques, no effort being made to remove dissolved CO_2. The alcohols used were: methanol (B.D.H. Aristar), ethanol (B.D.H. Analar), *n*-propanol (B.D.H. Reagent), *i*-propanol (B.D.H. Analar), and B.D.H. Reagent grade *n*- and *sec*-butanol, and allyl alcohol. The MgO purity, determined by spectrographic analysis was, in p.p.m. (wt./wt.): Mn (< 2), Fe (< 20), Cr (< 5), Al (20), Si (< 30).

The e.s.r. spectra were obtained at $\sim$9.2 GHz using 100 kHz field modulation. In the diagrams the spectra are displayed as a first derivative and the field increases from left to right. Various field modulation amplitudes were used during this work and the splitting constants quoted, unless otherwise indicated, are those measured directly from the spectra and can be compared with spectra obtained in glasses or polycrystalline materials; the quoted values for the splitting constant are measured to $\sim \pm 0.5$ G.

Results

1. Reaction with Hydrogen Atoms

The first derivative spectra of the radicals are shown in Figs. 2–5, the magnetic field increasing from left to right. A field modulation of approximately 3 G at 100 kHz was used in each figure. In general, the spectra were obtained at 77 °K but room temperature spectra are shown if there is a significant difference. The narrow line on the

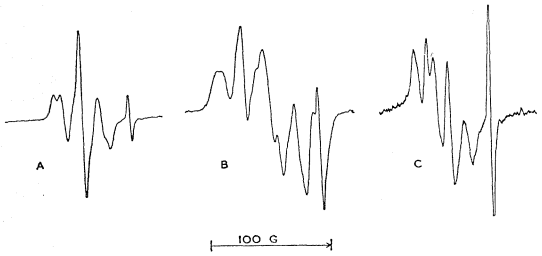

FIG. 2. A, methanol at 77 °K; B, ethanol at 77 °K; C, ethanol at 77 °K after 2 min at room temperature.

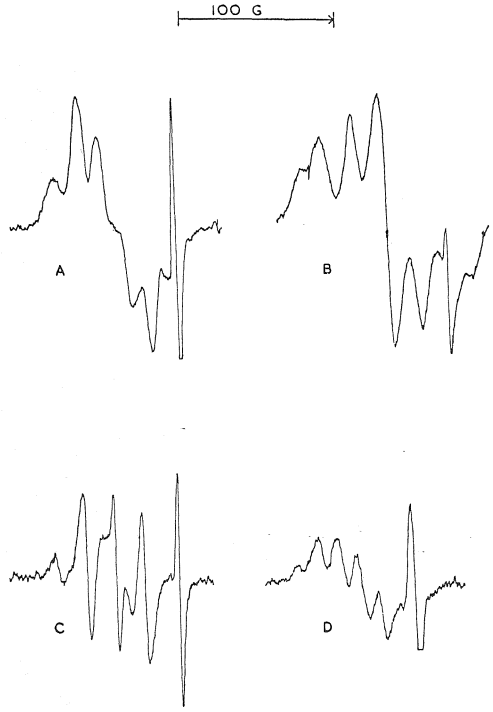

FIG. 3. A, *n*-propanol at 77 °K; B, isopropanol at 77 °K; C, isopropanol at room temperature, 2.5 min after warming up from 77 °K; D, isopropanol at room temperature 19 min after warm-up.

high field side of each spectrum is due to < 5 p.p.m. Cr^{3+} impurity with $g = 1.9796$; at high gain, 4 hyperfine lines are apparent from ^{53}Cr ($I = \frac{3}{2}$) natural abundance 9.54%. The e.s.r. spectrum obtained from each blank is shown in Fig. 4D; the low field lines are due to Fe^{3+} impurity ions (< 20 p.p.m.) and make a negligible contribution to the spectra at the normal amplifier gains used, except for the spectrum in Fig. 3D.

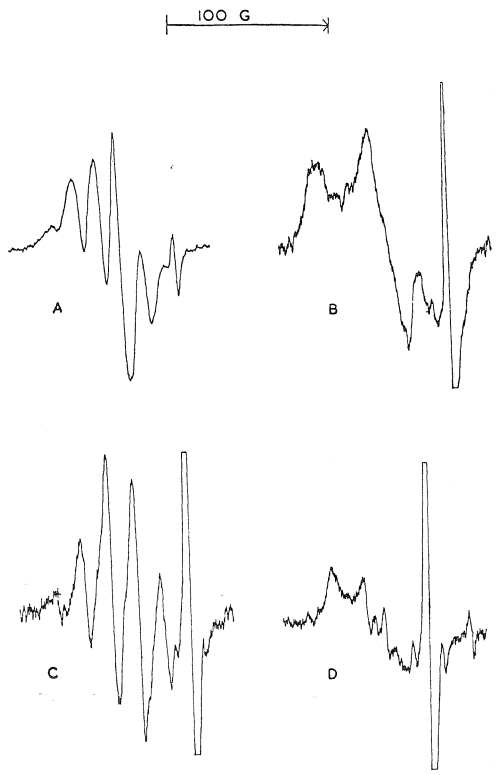

FIG. 4. A, *n*-butanol at 77 °K; B, *sec*-butanol at 77 °K; C, *sec*-butanol at room temperature; D, a typical "blank".

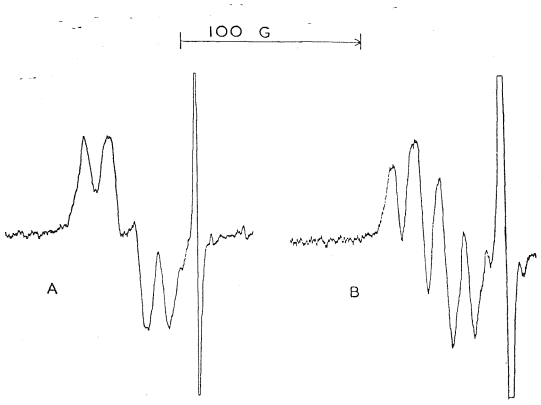

FIG. 5. A, allyl alcohol at 77 °K; B, allyl alcohol at room temperature.

Within experimental error, all the radicals observed below have $g = 2.0030 \pm 0.0005$.

Methanol

At 77 °K the triplet e.s.r. spectrum in Fig. 2A was obtained from methanol. A similar, though

For personal use only.

less intense spectrum was observed at room temperature, though no line narrowing or reduction of anisotropy in the two outer lines occurred. This triplet is assigned to a $\cdot CH_2X$ radical where the identity of X will be discussed later. The asymmetry of the two outer lines can be interpreted in terms of an axially symmetric hyperfine interaction (19) and analysis of the spectrum gives $A_{\parallel} = 24.0$ and $A_{\perp} = 13.7$ G ($A_{\text{average}} = 17.1$ G). At room temperature this radical decayed bimolecularly with an initial second order half life of 3 min.

Two experiments were carried out to study the effect of surface coverage. In the first, the usual quantity (3×10^{-3} ml CH_3OH on 0.6 g MgO) of methanol was adsorbed, followed by 30 min of pumping at room temperature. Hydrogen atom bombardment gave an identical e.s.r. spectrum, with intensity similar to that obtained when no pumping was performed after adsorption. Furthermore, the radicals decayed at the same rate with second order kinetics. The second experiment involved the same procedure but this time only one-half as much methanol was adsorbed initially. The yield of radicals was about the same but the decay kinetics were different. The decay of radicals now followed first order kinetics and the half life had increased to 11 or 12 min.

When CH_3OD (1.5×10^{-3} ml on 0.6 g MgO) was treated similarly, the central line of the e.s.r. triplet had a width between derivative maxima of 3.3 G compared to 4.2 G when CH_3OH was used.

When hydrogen atoms were reacted with magnesium methoxide powder, the resultant e.s.r. spectrum was similar to Fig. 2A, though only one-third as intense. The spectrum can be interpreted as arising from $(\dot{C}H_2O)^-Mg^{2+}$ radicals and gives $A_{\parallel} = 25.1$, $A_{\perp} = 12.6$, and $A_{\text{average}} = 16.8$ G. The width between derivative maxima of the central line was 4.0 G. The room temperature decay of these radicals was second order with an initial half life of about 8 min. Allowing for the lower concentration, this decay rate is the same as for $\cdot CH_2X$ radicals formed after absorption of 3×10^{-3} ml CH_3OH on 0.6 g of MgO.

Ethanol

This initially gave the e.s.r. spectrum in Fig. 2B. It is basically a quintet with an average proton hyperfine coupling $A_H = 21.3$ G. After 2 min at room temperature the radical giving this spectrum had decayed. There remained a second spectrum, Fig. 2C, predominantly a 1:3:3:1 quartet with an average $A_H = 13.9$ G. This spectrum remained after several days at room temperature. Poorly resolved peaks in the initial spectrum suggest that the 1:3:3:1 radical was also present, and remained after the main radical decayed away. In experiments where 3×10^{-3} and 1.5×10^{-3} ml of C_2H_5OH were adsorbed, followed by pumping for 30 min at room temperature, the initial yield of radicals was reduced to about a quarter of the number obtained without subsequent evacuation. Only the 21.3 G quintet was formed and when this disappeared by thermal decay, the 13.9 G quartet was not observed. The decay curves were not sufficiently precise to establish the kinetic order but the half lives increased to about 2 and 5 min respectively, with decreasing coverage. Such short half lives cause difficulty with measurement of the decay curve for these powders, because of an unknown time lag in the warm-up time of the sample.

Higher Alcohols

Normal propanol gave a poorly resolved sextet, Fig. 3A, with $A_H = 13.9$ G; the spectrum was only slightly better resolved at room temperature. This decayed in about 20 min. iso-Propanol gave a septet with $A_H = 19.3$ G at 77 °K, Fig. 3B. At room temperature, 2.5 min after removing the sample from the liquid nitrogen Dewar, the unusual spectrum in Fig. 3C was obtained. It seems to consist mainly of a quintet with $A_H = 19.3$ G and the three central lines have equal intensity. After 19 min at room temperature, a poorly resolved sextet, Fig. 3D, with $A_H \simeq 13.6$ G remained. This decayed by only 10% in the following 30 min. The spectrum looks like a septet because of an underlying absorption due to iron impurity.

At 77 °K, *n*-butanol gave a 13.7 G sextet with an underlying singlet, Fig. 4A. At room temperature the singlet disappeared and the symmetrical sextet remained, with only slightly improved resolution. The width between derivative maxima for the 2 most intense lines was about 7.5 G. This radical decayed slowly with an initial half life of 2.5 h. *sec*-Butanol gave a poorly resolved triplet at 77 °K, Fig. 4B, with $A_H = 34$ G. At room temperature this had changed irreversibly to a sextet, Fig. 4C, with $A_H = 17$ G. On

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

recooling to 77 °K the sextet remained, though less well resolved. At room temperature the sextet decayed bimolecularly with an initial half life of 10 min.

Allyl alcohol gave the poorly resolved quartet in Fig. 5A at 77 °K while at room temperature the resolution improved, Fig. 5B; in each case the hyperfine coupling A_H was 13.7 G. At room temperature the radical decayed bimolecularly with an initial half life of 13 min.

It is of interest to know the fraction of the absorbed molecules converted to radicals and the concentration of the radicals (N_R). These data are summarized in Table I for those experiments where 3×10^{-3} ml of an alcohol was absorbed on 0.6 g MgO, without subsequent pumping.

TABLE I

Radicals formed from ROH adsorbed on MgO

ROH	N_R (spins/g $\times 10^{-16}$)	N_R/N_{ROH} ($\times 10^3$)	Initial $t_{\frac{1}{2}}$ (min)
MeOH	4.4	0.6	3
EtOH	19.6	3.9	<1
n-PrOH	5.2	1.3	—
i-PrOH	14.0	3.6	—
n-BuOH	7.0	2.1	150
sec-BuOH	5.2	1.6	10
Allyl OH	3.7	0.9	13

2. Reaction with Electrons

It has been established in separate experiments (13) that hydrogen atoms will react directly with MgO to form electrons trapped at an anion vacancy:

[1] $$H + O^{2-} \rightarrow e^- + OH^-$$

This was carried out, forming the blue colored powder characteristic of the trapped electrons on the surface. In separate experiments, the usual quantity of MeOH or EtOH was then admitted to the powder; in each case, the blue color disappeared instantly. The e.s.r. spectrum due to the trapped electrons was replaced by that of alcohol radicals. The intensity in each case was low because of the low starting concentration of electrons. Methanol and ethanol formed the same e.s.r. spectra as in Fig. 2A and 2B. The hyperfine couplings from the methanol radical were slightly lower, however, $A_{\parallel} = 23.4$, $A_{\perp} = 12.4$, and $A_{average} = 16$ G. The methanol radical was more stable than before but this may be due in part to its low concentration. Half of the ethanol radicals decayed in 5 min, leaving a radical which was completely stable at room temperature. The spectrum of this radical at room temperature contained much narrower lines (~ 3 G) and it was resolved into two quartets. The quartet splitting was 20.6 G and the splitting between quartets was 13.5 G. This spectrum is shown in a later paper on the radiolysis of these systems. The other alcohols also decolorized the blue powder but the e.s.r. signals were too weak for useful examination, probably because of the large line width.

Discussion

1. Radical Identification

Many of the spectra mentioned in the results are characterized by e.s.r. hyperfine couplings in the range 13.5–14.0 G compared to the normal range for β-protons of 20–22 G found for alcohol radicals in solution (20). Such low hyperfine constants must be associated with a considerable delocalization of the unpaired electron density from a single carbon 3p orbital. The proton hyperfine coupling in alcohol radicals is already considerably lower than that observed for alkyl radicals (21), and this further decrease could arise from (*1*) some delocalization of the electron into the surface or (*2*) the formation of unsaturated alkene species. The first of these seems unlikely because the *g* value would be expected to have a positive shift, and no change is observed. The second possibility appears most likely since the formation of unsaturated compounds from alcohols on some oxides at high temperatures is a well known process (14–17) and it is likely that the alcohol radicals might undergo a similar loss of hydrogen. The discussion in the subsequent pages follows this hypothesis except for the initial radicals from methanol, ethanol, and isopropanol.

Methanol and Ethanol

The triplet e.s.r. structure and hyperfine coupling for the methanol radical indicate that it is either the radical $\dot{C}H_2OH$ formed by hydrogen abstraction from physisorbed CH_3OH, or the radical $(\dot{C}H_2O)^-Mg^{2+}$ formed from methanol chemisorbed as a methoxy compound. We favor the latter because the hyperfine coupling agrees with that obtained by reaction with magnesium methoxide, and because the yield is not decreased

by pumping at room temperature. One would expect $(CH_3O)^-$ to be tightly held, but physisorbed CH_3OH should be pumped off and the yield of radical decreased, contrary to the results. In support, adsorption of less than a monolayer of methanol on MgO results in infrared (i.r.) absorption features, attributed to $(CH_3O)^-$, which are not diminished by pumping (22). Similar results have been obtained on Al_2O_3(23). The hydroxyl proton must be nearby and chemisorption probably occurs according to the schematic reaction [2]. Presumably, most of the first monolayer becomes chemisorbed.

[2] $$\begin{matrix} CH_3OH & & CH_3^- \\ \downarrow & \rightarrow & O \quad H^- \\ \ldots Mg^{2+}O^{2-}\ldots & & \ldots Mg^{2+}O\ldots \end{matrix}$$

The e.s.r. parameters for the initial radical (Fig. 2B) from ethanol, and the decrease in yield caused by pumping, indicate that this is the $CH_3\dot{C}HOH$ radical formed by hydrogen abstraction from physisorbed alcohol molecules. After pumping for 30 min, only a quarter as many radicals were formed. A small fraction of the first monolayer of ethanol must be very strongly physisorbed or has become bonded to the surface by a reaction analogous to [2]. The stable radical (Fig. 2C) was eliminated by pumping. This indicates that the radical was formed by reaction with a weakly adsorbed molecule, rather than by decomposition of $CH_3\dot{C}HOH$. It is difficult to assign the 13.9 G quartet to other than the acetyl $(CH_3\dot{C}O)$ radical even though the hyperfine coupling is slightly less than the 16.7 ± 1.8 G given by Morton and Falconer (24). Our g value of 2.003 is also in disagreement with their value of 2.0055 ± 0.0008 but their spectrum is poorly resolved from that of $\dot{C}H_3$ radicals. When ethanol is adsorbed on Al_2O_3 and heated at 170 °C, the acetate ion is formed according to the i.r. measurements of Greenler (21) and it seems likely that a similar reaction occurs on MgO at room temperature (22). It is possible that a small proportion of acetaldehyde can also be formed on the surface and when the hydrogen atom stream flows over the sample, reaction [3] would lead to the formation of acetyl radicals (25).

[3] $$CH_3CHO + H\cdot \rightarrow CH_3\dot{C}O + H_2$$

The acetaldehyde would not be strongly adsorbed and thus, on pumping, it would desorb and the radical could not be formed.

Propanols

The radical giving a 13.9 G sextet (Fig. 3A) from *n*-propanol is difficult to identify positively. We speculate that hydrogen abstraction forms the $CH_3CH_2\dot{C}HOH$ radical and that this promptly eliminates H_2 to give $CH_3\dot{C}HCHO$ or $CH_2 \cdots CH \cdots CH(OH)$. The α-hydroxy-allyl radical gives a 13.7 G hyperfine splitting, but the spectrum consists of 4 lines (see below). It is certainly similar to the central 4 lines in Fig. 3A (cf. Fig. 5A). On the other hand, the spectrum of $CH_3\dot{C}HCHO$ would normally be a quintet with 4 equivalent protons, the aldehydic proton having a very small coupling (26), and this does not fit the data. The identification is not certain but it seems likely that the observed spectrum arises from a mixture of radicals, probably involving the formation of the α-hydroxy-allyl radical.

The initial radical from isopropanol (Fig. 3B) gives a 19.3 G e.s.r. septet. This is undoubtedly the $(CH_3)_2\dot{C}(OH)$ radical. At room temperature, another radical exists for a few minutes, giving a 19.3 G quintet with three equal intensity lines in the middle, Fig. 3C. Probably the isopropyl alcohol radical has isomerized to give the $CH_3CH_2\dot{C}HOH$ radical. In the solid phase this has been known to give a 1:2:2:2:1 spectrum (27). Differing line widths cause the intensity ratio to appear greater than 2:1 in our spectrum. Finally, the 13.6 G sextet is left. This is believed to be the same radical as was obtained from propanol, formed by elimination of H_2 from $CH_3CH_2\dot{C}HOH$, since it seems to be a descendant of $CH_3CH_2\dot{C}HOH$ and has similar hyperfine coupling, structure, and lifetime to the radical from *n*-propanol.

Butanols

The *n*-butanol result (Fig. 4A) may be similarly explained. A hydrogen atom abstracts from the parent molecule to form $CH_3(CH_2)_2\dot{C}HOH$; this splits off H_2 to give $CH_3CH \cdots CH \cdots CHOH$ or $CH_3CH_2\dot{C}HCHO$; in this case, only the allylic radical could possibly give a 13.7 G sextet with line intensities such as those observed. It would give a 1:5:10:10:5:1 sextet and the hyperfine coupling would be close to that observed. The α-hydroxy-allyl radical $CH_2 \cdots CH \cdots CHOH$, discussed below has $A_H = 13.7$ G for comparison. Dehydration of the radical does not occur since this would lead to a spectrum consisting of a septet and not the sextet observed.

At 77 °K, *sec*-butanol gives three very wide

For personal use only.

lines separated by 34 G (Fig. 4B) and at room temperature gives a 17 G sextet of well resolved lines. One would expect that the primary radical formed would be $CH_3\dot{C}(OH)CH_2CH_3$. However, this radical would neither give the structure nor the hyperfine splitting observed in the e.s.r. spectrum. We believe that, like most of the cases discussed above, this radical has eliminated H_2 to form a secondary radical. This reaction could form either the substituted allylic radical $CH_3C(OH) \cdots CH \cdots CH_2$ or one of the ketone radicals $CH_3CO\dot{C}HCH_3$ and $CH_3COCH_2\dot{C}H_2$. The allylic radical would give a sextet with $A_H \simeq 13.5$–14 G and $CH_3CO\dot{C}HCH_3$ would give a quintet, so these two may be ruled out. However, $CH_3COCH_2\dot{C}H_2$ fits all the observations and we assign both the 77 °K and the room temperature e.s.r. spectra to this radical. These spectra may be interpreted in terms of previous observations on the *n*-propyl radical $CH_3CH_2\dot{C}H_2$ (19, 25). Cochran *et al.* (19) have given a theoretical discussion of the case which fits the 77 °K spectrum. The 34 G triplet is due to a 34 G interaction from the two β-protons with the lines corresponding to $I = \pm 1$ for the two α-protons being so broadened by hyperfine anisotropy that they are not resolved and cause considerable broadening of the lines in the 34 G triplet. Cochran *et al.* obtained $A_H = 35$ G for the two β-protons in the *n*-propyl radical, in support of our assignment. The room temperature 17 G sextet can arise from the same radical, if one of the β-protons has $A_H = 34$ G and the other plus the two α-protons have $A_H = 17$ G. This was observed for the *n*-propyl radical by Ayscough and Thomson (28). Thus two cases exist in the literature in which the same radical gives different β-proton couplings when trapped in two different environments. This suggests that the $CH_3COCH_2\dot{C}H_2$ radical on an MgO surface can be trapped in different environments.

Allyl Alcohol

The 13.7 G quartet from allyl alcohol has been observed by others, for example Chachaty and Schmidt (8) and Maas and Volman (29) in the solid phase and Livingston and Zeldes (20) in the liquid phase. This spectrum is thought to arise from the α-hydroxy-allyl radical $CH_2 \cdots CH \cdots CHOH$. Evidently, abstraction of the α-proton is preferred to addition to the double bond.

2. Electron Reactions

When methanol and ethanol are reacted with electrons trapped on the surface of MgO, the situation is entirely different compared to the case where they are first adsorbed and then reacted with hydrogen atoms. This is discussed below in the section on surface effects since we prefer to limit this section to radical identification. The stable radical formed by reaction of ethanol with an electron seems to be the ethoxide ion radical $(CH_3\dot{C}HO)^-$ with the α-proton giving $A_\alpha = 13.5$ G and the methyl protons giving $A_{CH_3} = 20.6$ G. We base this assignment on spectroscopic and mechanistic arguments. Bennett (30) has observed the e.s.r. spectrum of $(CH_3\dot{C}HO)^-$ in sodium and potassium ethoxide. He found $A_\alpha = 13$ and $A_{CH_3} = 19.2$ G. Our parameters are close to those of Bennett and less than the corresponding values of 15.4 and 22.2 G for the isotropic couplings of $CH_3\dot{C}HOH$ in solution (20). In addition, one would expect reactions [4]–[6] to occur.

$$[4] \quad e^- + CH_3CH_2OH \rightarrow CH_3CH_2O^- + H$$

$$[5] \quad H + CH_3CH_2OH \rightarrow CH_3\dot{C}HOH + H_2$$

$$[6] \quad e^- + CH_3CH_2OH \rightarrow CH_3CHO^- + H_2$$

Reactions [4] and [5] would explain the formation of relatively unstable $CH_3\dot{C}HOH$ radicals and reaction [6] would account for the formation of $(CH_3\dot{C}HO)^-$. A concerted reaction has been postulated by Bennett *et al.* (31) to explain the formation of alcohol radicals during thermal and photolytic bleaching of electrons trapped in various alcohol matrices at low temperature. Our spectrum obtained from the reaction of electrons with methanol gave $A_{average} = 16$ G, which is midway between Bennett's value of 15 G for $(\dot{C}H_2O)^-$ in sodium and potassium methoxide (30) and our value of 16.8 G for $(\dot{C}H_2O)^-Mg^{2+}$ in $Mg(OCH_3)_2$. This, coupled with reactions analogous to [4]–[6], leads us to suppose that a mixture of $(\dot{C}H_2O)^-Mg^{2+}$ and $(\dot{C}H_2O)^-$ is present, the latter being trapped at an oxygen ion vacancy.

3. Effect of Surface

Radicals trapped on a surface may have properties which differ from those of similar radicals trapped, say, in a matrix of the parent compound. Bond and molecular rotations may be slowed down or oriented with respect to the surface and bond symmetries may be altered. Electron spin density might be decreased due to delocalization into the matrix (32). The possibility of different trapping sites, restricted

For personal use only.

movement, and differing radical–molecule, radical–radical distances on a two-dimensional surface can alter the radical stability and the rate and mechanism of decay. A new phenomenon, which seems to have been observed for the first time in this work, is the formation of secondary radicals via elimination of a hydrogen molecule from the parent radical, evidently catalyzed by the surface or an impurity ion on the surface.

Electron spin delocalization into the MgO matrix would be indicated by lower than normal proton hyperfine couplings, positive g shifts if the delocalization is onto a matrix oxygen nucleus, or the observation of a hyperfine interaction with the 10% abundant $I = 5/2$ Mg^{25} nuclei. The latter is not observed but would not be expected due to the low abundance and high nuclear spin of Mg^{25} coupled with the low signal to noise ratio and relatively high line width in most of the e.s.r. spectra observed. All the radicals had a g value close to 2.003, which is normal for the saturated alcohol radicals and the allylic radicals (20). There is a discrepancy in our value of $g = 2.003$ for $CH_3\dot{C}O$ compared to 2.006 (24) but in view of the uncertainty of identification, no significance can be attached to this. To the best of our knowledge, the proton hyperfine couplings are also normal, though even a 5% decrease might not be detected, due to the line widths of our spectra. The $(\dot{C}H_2O)^-Mg^{2+}$ radical on MgO gives $A_{average} = 17.1$ compared to 16.8 G for $(\dot{C}H_2O)^-Mg^{2+}$ in $Mg(OCH_3)_2$. $CH_3\dot{C}HOH$, $CH_3\dot{C}(OH)CH$, and $CH_2 \cdots CH \cdots CHOH$ give A_H values of 21.3, 19.3, and 13.7 G compared to average values of 20.5, 19.7, and 13.7 G for the same radicals in solution (20). This is good agreement considering the line widths involved.

Some evidence of rotational freedom and orientation on the surface can be obtained from the axially symmetric hyperfine anisotropy shown by the two outer lines in the e.s.r. spectrum of the $(\dot{C}H_2O)^-$ radical. The hyperfine tensor for α-protons has three different principal values, and the line shape corresponding to an axial symmetry could be observed only if the radical was rotating. It seems likely that the radical is rotating about the C—O bond giving rise to ⊥ and ∥ components of the hyperfine tensor. Such a rotation would be considerably hindered if the radical were lying flat on the surface and the C—O bond of the radical probably lies in a plane perpendicular to the surface. This is in agreement with the orientation of the methoxy groups inferred from i.r. data (22).

Different trap environments have shown three effects. At 77 °K the two β-protons in the radical $CH_3COCH_2\dot{C}H_2$ (formed from *sec*-butanol) both gave $A_H = 34$ G. At room temperature, this radical has presumably reoriented or moved to a different type of trapping site, since now one β-proton gives $A_H = 34$ and the other 17 G. These numbers indicate different relative orientations of the β-carbon hydrogen bonds with respect to the p orbital containing the unpaired electron (see, for example, ref. 28). The second effect is most dramatically shown by the $(CH_3\dot{C}HO)^-$ ion radical, formed by reaction of ethanol with an electron. Since this electron was trapped at a surface oxygen ion vacancy (33) it is reasonable to presume that the ethoxide ion radical is also trapped there, with the oxygen fixed at this site and the rest of the radical pointing outwards. This ion radical is completely stable at room temperature so it must be fixed in position. This trapping site will be somewhat "buried" in the lattice and is evidently protected against even a chain transfer radical migration mechanism. The third phenomenon due to trap environment involves surface concentration, and hence spatial separation of radicals and parent molecules. This is reflected in the kinetics and rate of radical decay. When $(\dot{C}H_2O)^-Mg^{2+}$ radicals are formed in the presence of a monolayer of $(CH_3O)^-$ on the surface of MgO, the $(\dot{C}H_2O)^-Mg^{2+}$ radicals decay bimolecularly, with a half life of 3 min. In this case, we suggest that the migration required to achieve combination is via a series of atom transfer reactions

[7]
$$\begin{array}{ccccccccccc} \dot{C}H_2 & CH_3 & CH_3 & & CH_3 & \dot{C}H_2 & CH_3 & & CH_3 & CH_3 & \dot{C}H_2 & \\ O & HO & HO & \rightarrow & O & HO & HO & \rightarrow & O & HO & HO & \rightarrow \text{ etc.} \\ Mg & O\,Mg & O\,Mg & & Mg & O\,Mg & O\,Mg & & Mg & O\,Mg & O\,Mg & \end{array}$$

However, when the same number of $(\dot{C}H_2O)^-Mg^{2+}$ radicals is formed, with the rest of the surface having approximately half a monolayer of $(CH_3O)^-Mg^{2+}$, this mechanism cannot occur. The radicals then decay more slowly in a unimolecular reaction, with a half

life of 10 min. The nature of this unimolecular decay is not known.

Conclusion

A new method has been developed for forming and studying free radicals on surfaces. It has the merit that the radicals are formed without perturbing the matrix, unlike heterogeneous radiation chemistry. Identification of the radicals formed, sheds light on the nature of the adsorption of the parent compound in some cases, and in other cases indicates the occurrence of secondary reactions on the surface. A major observation is that, for *n*-propanol, iso-propanol, *n*-butanol, and *sec*-butanol, once the initial radical is formed by hydrogen atom abstraction from the carbon adjacent to the hydroxyl group, it eliminates H_2 to form a secondary radical. This type of reaction presumably is able to occur on the surface because combination and disproportionation reactions have been slowed down. In solution, the latter reactions are rapid and H_2 elimination is not observed. However, when another hydroxyl group or a halogen is present on the β-carbon atom, the situation is reversed and elimination of H_2O or HX occurs (26) under suitable conditions. Effects of trapping site and surface coverage on stability and mode of free radical disappearance have also been demonstrated.

Free radicals by mass spectrometry. XL. Primary processes and transient intermediates in the mercury ($^3P_1$) photosensitization of hydrazine[1]

A. JONES[2] AND F. P. LOSSING

Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received November 25, 1968

The low pressure mercury ($^3P_1$) photosensitized decomposition of hydrazine has been studied at 55 °C in a fast flow reactor coupled to a mass spectrometer. Direct evidence was obtained for the participation of N_2H_2, N_2H_3, NH_2, and NH in the decomposition, and two primary decomposition modes were established

$$Hg(^3P_1) + N_2H_4 \rightarrow NH_2 + NH_2 + Hg(^1S_0) \quad \text{and} \quad Hg(^3P_1) + N_2H_4 \rightarrow N_2H_3 + H + Hg(^1S_0)$$

Introduction

Although the direct photolysis of N_2H_4 has been studied, there appear to have been no investigations of the mercury photosensitized decomposition. The earlier direct photochemical work was summarized in 1963 by Husain and Norrish (1) who discussed the photodecomposition in terms of the two primary processes

[1] $$N_2H_4 \rightarrow NH_2 + NH_2$$

[2] $$N_2H_4 \rightarrow N_2H_3 + H$$

In later work (2–5) on the vacuum ultraviolet photolysis, other primary processes have been postulated including

[3] $$N_2H_4 \rightarrow NH + NH_3$$

[4] $$N_2H_4 \rightarrow N_2H_2 + H_2$$

$Hg(^3P_1)$ has an excitation energy of 112.2 kcal mole^{-1} and reactions [1]–[4] above have enthalpy changes ΔH^0 of 56 ± 2, 78 ± 3, 57.3 ± 3, and 26.0 ± 5 kcal mole^{-1}, respectively. Thus all these reactions are thermochemically possible in the reaction of hydrazine with $Hg(^3P_1)$. Interest in an investigation of the mercury ($^3P_1$) photosensitized decomposition of hydrazine, therefore, centers on determining which of these possible primary decomposition modes occur.

Experimental

The apparatus and experimental procedure have been described previously (6). Briefly, the mercury photosensitized reactions were investigated using a fast flow system coupled to a mass spectrometer. The reactant and mercury vapor at partial pressures of a few microns are carried in a stream of helium at 8 mm pressure through a tubular reactor (maintained at 55 °C) which is illuminated by a low-pressure mercury lamp of high intensity. The residence time in the illuminated zone is about 1×10^{-3} s. Following the illuminated zone, the reaction stream passes over a small orifice through which a representative sample flows directly into the ionization chamber of a mass spectrometer. Observation of free radical products as well as stable products can be made. The length of the reaction zone can be varied by insertion of a metal sleeve to shield a part of the reactor from the incident light.

Results and Discussion

Initial experiments showed that under the conditions employed it was possible to decompose up to 80% of the hydrazine in the reactor. This would indicate a very large quenching cross section for N_2H_4 towards triplet mercury atoms. Addition of carbon monoxide to the reaction stream caused an increase in the rate of decomposition suggesting (7, 8) that the reaction proceeds, at least in part, by the formation of an electronically excited state of N_2H_4.

When a few microns of hydrazine vapor were added to the reaction stream with the lamp off, the mass spectrometer recorded the mass spectrum of the pure hydrazine. On illumination of the reactor, a composite mass spectrum was obtained consisting of the mass spectrum of the undecomposed hydrazine plus the spectra of the reaction products. Subtraction of the hydrazine spectrum then gave the mass spectrum of the reaction products. The product mass spectrum at 50 eV obtained in this way was consistent with the formation of nitrogen, hydrogen, and ammonia together with a compound having peaks at $m/e = 29$ and 30. This has been identified as diimide, N_2H_2, (see below). No products of mass greater than 32 were detected.

A quantitative estimation of the products formed under these conditions could not be made owing to the fact that the mass spectral sensitivity of N_2H_2 could not be measured, since this compound is unstable under ordinary conditions, nor could any allowance be made for its fragment peaks at m/e 28 and 2 since its mass spectrum at 50 eV is not known.

Formation of Transient Intermediates

Although the formation of diimide is often invoked as a reaction intermediate (9), direct observations in the gas phase are few. It was first observed, mass spectrometrically, by Foner and Hudson (10) in the reactions occurring when HN_3 or N_2H_4 is subjected to an electrodeless discharge in a fast flow system. A study of the thermal decomposition of anthracene-9,10-diimine (11) in a mass spectrometer established N_2H_2 as a reaction product. More recently, Willhoft and Robertson (12) have observed its formation in the catalytic decomposition of hydrazine at low pressure on platinum. The latter authors report a ratio of 1.32 for the mass spectrometric peaks 29/30 (parent − 1)/(parent) using 70 eV electrons. The value found in this work, 29/30 = 1.30 (at 50 eV electron energy) is in excellent agreement with this value. The evidence for the formation of diimide in our system thus appears conclusive.

It was thought possible, in view of the results obtained in the direct photolysis, that the free radicals N_2H_3, NH_2, and NH may play a part in the decomposition. A search for these was made by adding to the reaction stream a small partial pressure of mercury dimethyl which is photodecomposed in the reactor to form methyl radicals. In this way, methyl addition products of free radicals present can be detected by the mass spectrometer. Although no dimethylamine $(CH_3)_2NH$ (which could have been formed by the successive additions of CH_3 to NH) was detected, the presence of N_2H_3 and NH_2 radicals was established by the detection of monomethylhydrazine, CH_3NHNH_2, and methylamine CH_3NH_2.

Using low energy electrons for direct detection of radicals, a large increase at $m/e = 16$ (NH_2^+) was observed, supporting the detection as above by methyl addition. Under the same conditions an increase at $m/e = 15$ (NH^+) was also observed. It was first thought that this might be a fragment ion of some other species present. However, an examination of the energetics of possible ionization fragmentation processes leading to the formation of NH^+ gave the following calculated minimum appearance potentials (see below for thermochemical values used)

NH^+ from N_2H_3 (16.7 eV), N_2H_2 (18.9 eV), NH_3 (17.5 eV), NH_2 (17.6 eV).

Since the electron energy (about 15 eV) used in this experiment was lower than any of these thresholds, the observed increase at $m/e = 15$ appears to be attributable to the free radical NH. The ionization potential (13) of NH, 13.1 eV, is consistent with this observation.

Primary Decomposition Reactions

On addition of successively increasing amounts of mercury dimethyl to the reaction stream, a plateau is reached in the "titration" curve when the radical being titrated is formed in a primary decomposition step. Results for the titrations of N_2H_3 and NH_2 radicals are shown in Fig. 1 and are consistent with the occurrence of the two primary decomposition reactions

[5] $Hg(^3P_1) + N_2H_4 \rightarrow N_2H_3 + H + Hg(^1S_0)$
$\Delta H^0 = -34 \pm 3$ kcal mole^{-1}

[6] $Hg(^3P_1) + N_2H_4 \rightarrow NH_2 + NH_2 + Hg(^1S_0)$
$\Delta H^0 = -56 \pm 2$ kcal mole^{-1}

From the measured sensitivities of CH_3NH_2 and CH_3NHNH_2, the limiting yields showed that for every molecule of CH_3NHNH_2, ca. 4.6 molecules of CH_3NH_2 are formed. This would suggest that reaction [6] is some 2.3 times faster

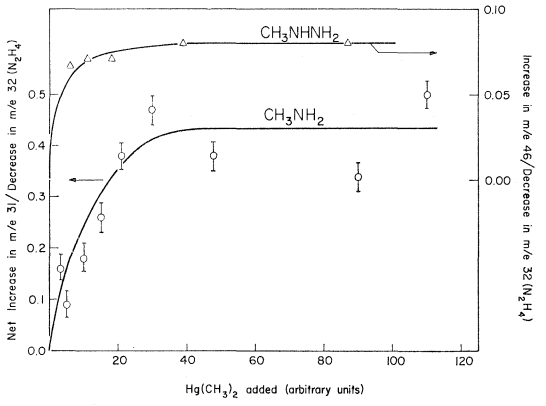

FIG. 1. Formation of CH_3NHNH_2 and CH_3NH_2 by titration of N_2H_3 and NH_2 radicals with added CH_3 radicals.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

than reaction [5]. However, encounters between methyl radicals and NH_2 and N_2H_3 can also lead to disproportionation products by the reactions

[7] $$CH_3 + N_2H_3 \rightarrow CH_4 + N_2H_2$$
$$\Delta H^0 = -52 \pm 6 \text{ kcal mole}^{-1}$$

[8] $$CH_3 + NH_2 \rightarrow CH_4 + NH$$
$$\Delta H^0 = 0 \pm 3 \text{ kcal mole}^{-1}$$

If, as is likely, reaction [7] is faster than reaction [8] (it is some 50 kcal more exothermic), the factor of 2.3 can be regarded as an upper limit for k_6/k_5. An attempt was made to measure the sensitivity of N_2H_4 and so determine what fraction of the decomposition could be attributed to reactions [5] and [6]. It was found, however, that hydrazine undergoes a rapid surface decomposition at low pressures in the sample line, and no reliable measurement of the mass spectral sensitivity could be made.

In view of the products obtained, two other primary decomposition steps (both thermochemically feasible) are possible

[9] $$Hg(^3P_1) + N_2H_4 \rightarrow N_2H_2 + H_2 + Hg(^1S_0)$$
$$\Delta H^0 = -86 \pm 5 \text{ kcal mole}^{-1}$$

[10] $$Hg(^3P_1) + N_2H_4 \rightarrow NH_3 + NH + Hg(^1S_0)$$
$$\Delta H^0 = -55 \pm 3 \text{ kcal mole}^{-1}$$

Attempts to detect diimide and hydrogen in the presence of a large excess of methyl radicals, which would indicate the occurrence of reaction [9], resulted in inconclusive results due to interference from the mass spectra of other species present. Although no dimethylamine was found on addition of methyl radicals, some support for reaction [10] comes from experiments in which the peak at $m/e = 17$ (NH_3) was monitored during a methyl radical titration. These experiments showed that this peak decreased by only about 50% in the presence of an excess of CH_3, indicating that at least part of the ammonia is formed directly and not via free radical intermediates.

It is of interest to contrast the mercury photosensitized decomposition of hydrazine with that of the isoelectronic molecule ethane in which no C—C bond rupture occurs, and only the C—H bond is split. This difference may be understood in terms of formation of an electronically excited N_2H_4 molecule leading to fragmentation by two, or possibly more, modes of reaction, while ethane decomposes by a direct attack of $Hg(^3P_1)$ on a C—H bond. In ethane no appropriate excited state appears to be available.

Thermochemical values (kcal mole^{-1}) employed are as follows: $\Delta H_f^0(N_2H_4) = 22.7$ (14), $\Delta H_f^0(N_2H_2) = 48.7 \pm 5$ (10), $\Delta H_f^0(NH_3) = -11.0$, $\Delta H_f^0(CH_4) = -17.9$ (15), $\Delta H_f^0(CH_3) = 34.0 \pm 1$, $\Delta H_f^0(H) = 52.1$, $\Delta H_f^0(N) = 113.0$, $D(NH_2—NH_2) = 56 \pm 2$ (16), $D(N_2H_3—H) = 78 \pm 3$ (17, 10), and $D(N—H) = 74 \pm 3$ (18).

Tensorial properties of an electronic Raman effect of the thulium ion[1]

J. A. KONINGSTEIN AND TOA-NING NG
E. W. R. Steacie Building, Department of Chemistry, Carleton University, Ottawa, Canada

Received November 5, 1968

The low temperature laser excited Raman spectrum of the compound thulium gallium garnet reveals the presence of an electronic transition of the thulium ion. The tensor associated with this transition can contain some asymmetry. Polarization measurements show, however, that the amount of asymmetry is too small to be detectable.

Introduction

Recently the phonon spectrum of a single crystal of thulium gallium garnet ($Tm_3Ga_5O_{12}$) was investigated by means of laser Raman spectroscopy (1). The scattering tensors for the phonon modes are relatively simple because the garnet crystals belong (2) to the cubic space group O_h^{10} (*Ia3d*). Although there are as many as 80 atoms in the primitive cell, the factor group analysis suggests that a maximum number of 21 Raman lines can be expected (3). The Raman lines are of symmetry A_{1g}, E_g, T_{2g}, or of combinations of these species because the non-vanishing components of the scattering tensor for the vibrational Raman effect are divided over these three representations of the factor group O_h. For TmGaG a satisfactory assignment of the phonon spectrum could be made from polarized Raman spectra of an oriented crystal.

An interesting property of the Tm^{3+} ion is that its electronic ground state is one of the crystal field components of the $^3H_6$ manifold. The $2J + 1$-fold degeneracy of this manifold is completely removed for the thulium ion in the garnet crystal because the symmetry at the site of the rare earth ions belongs to the group D_2. The labelling of the crystal field levels can thus be such that the lowest lying level does not belong to the totally symmetric representation of the group D_2. This of course is nearly always the case in the vibrational Raman effect. Attention should thus be given to the integral

$$\int \psi_n^* \alpha_{\rho\sigma} \psi_m \, d\tau$$

which reflects the selection rules for the electronic transitions. ψ_n and ψ_m represent the wave functions of the initial and terminal states and $\alpha_{\rho\sigma}$ is an element of the scattering tensor. This integral is not equal to zero if the product of the irreducible representations $\Gamma_m \times \Gamma_\alpha \times \Gamma_m$ contains the totally symmetric representation of the group D_2. Γ_α can thus belong to all species occuring in the product $\Gamma_n \times \Gamma_m$. Another complication is that the scattering tensor for the electronic transition can be asymmetric (4). For the vibrational Raman effect it is not necessary to consider the transformation properties of the antisymmetric combination $\alpha_{\rho\sigma} - \alpha_{\sigma\rho}$ (where ρ and σ stand for x, y, and z). It was recently demonstrated that antisymmetry for rare earth transitions is quite important and results in profound changes in the polarization properties of Raman lines (5–7). Finally, interactions of rare earth ions in the unit cell are very small and although the symmetry of the crystal has to be adopted for the selection rules, this does not result in extra splitting effects. Of the 12 possible electronic Raman transitions of TmGaG, only one could be detected. Its intensity is, however, strong enough to measure the various elements of the scattering tensor. The tensor is symmetric and the components of this tensor are in agreement with the symmetry of the crystal field.

Theory

The trivalent thulium has the electronic configuration $Xe(4f)^{12}(5s)^2(5p)^6$. This configuration gives rise to a large number of Russell–Saunders terms. The lowest lying multiplet is ^3H and the ground manifold is $^3H_6$. This state is for the free ion 13-fold degenerate; however, for TmGaG this degeneracy is completely removed because the symmetry of the crystal field is orthorhombic. The thulium ion is surrounded by 8 oxygen ions located on the corners of a distorted cube (2) and the actual site symmetry is that given by the group D_2. The garnet crystals are, however, cubic and the space group is O_h^{10} (*Ia3d*).

Rare earth ions in garnet crystal experience a rather strong crystal field and the ground manifold can have an overall splitting of as much as 500 cm^{-1}. Raman scattering to the electronic levels thus occurs at low shifts and coincidences with the phonons are apt to occur. There are 80 atoms in the primitive cell giving rise to 21 Raman lines and all of them occur (3) with shifts $< 800\ cm^{-1}$.

The electronic Raman lines are allowed because the $^3H_6$ manifold levels have the same parity. A priori calculation of the absolute intensities revealed (8) that the transitions are weak and may well be obscured by the phonon spectrum.

For detailed study of the polarization properties, it is necessary to consider the symmetry labelling of the crystal field levels in terms of the species A, B_1, B_2, and B_3 of the group D_2. It follows that the non-vanishing elements of the scattering tensor between any of these levels belong to the same species. The product of the totally symmetric species with the other species equals the representation of these species and the product of $B_1 \times B_2 = B_3$ etc. The transformation properties of the antisymmetric combinations $\alpha_{xy} - \alpha_{yx}$, $\alpha_{xz} - \alpha_{zx}$, and $\alpha_{yz} - \alpha_{zy}$ are identical to the species B_1, B_2, and B_3, respectively. To these species belong also the symmetric combinations $\alpha_{xy} + \alpha_{yx}$, $\alpha_{xz} + \alpha_{zx}$, and $\alpha_{yz} + \alpha_{zy}$. Exact calculation of the antisymmetric combination can only be made if the wave functions of the states are known in great detail (5). The wave functions can only be calculated if the strength and symmetry of the crystal field is known and for TmGaG a reliable crystal field analysis has not been made.

The experimental data are obtained from measurements on the cubic garnet crystals and only combined effects are seen, not site group spectra. In fact, there are in the unit cell 12 sites of symmetry D_2 but the interactions of the rare earth ions in the unit cell are known to be extremely small and in employing correlation tables, the correct labelling of the levels and the transformation properties of the scattering tensor in the group O_h are directly obtained. The symmetry of the levels and the possible tensors are given in Tables I and II. One notes that in some cases more than one combination transforms according to the same species, and in such instances it is convenient to define a scattering matrix. The elements of this matrix are computed by taking the sum of the squares of identical elements of the individual contributing tensors (4). Intensities of the polarized Raman spectra can now be related to the elements of the matrix if the direction of propagation of the incident excitation radiation is along the cubic a axis and the direction of observation along the cubic b or c axis.

TABLE I

Transformation properties of crystal field levels of the thulium ion in site and space group

Symmetry properties of crystal field levels	
Site group (D_2)	Space group (O_h)
A	A_{1g}
B_1	T_{1g}
B_2	$T_{1g}+T_{2g}$
B_3	$T_{1g}+T_{2g}$

TABLE II

Scattering tensors for various representations of the group O_h

Representation	Elements of the tensor
A_{1g}	$\alpha_{xx}+\alpha_{yy}+\alpha_{zz}$
E_g	$\alpha_{xx}-\alpha_{yy}$; $2\alpha_{zz}-\alpha_{xx}-\alpha_{yy}$
T_{2g}	$\alpha_{xz}+\alpha_{zx}$; $\alpha_{xy}+\alpha_{yx}$; $\alpha_{yz}+\alpha_{zy}$
T_{1g}	$\alpha_{xz}-\alpha_{zx}$; $\alpha_{xy}-\alpha_{yx}$; $\alpha_{yz}-\alpha_{zy}$

Unfortunately this condition could not be met in our experiments on TmGaG. The incident laser beam was in fact parallel to the [111] direction and the direction of the scattered light perpendicular to the (101) plane. Under these experimental conditions, the observed intensities are not directly related to the elements of the scattering matrices. However, if the individual contributing tensors mentioned above are subjected to specific rotations, then new matrices are obtained whose elements are related to the observed intensities. The specific rotations are rather simple. First a rotation is carried out over an angle of 45° around one of the cubic axes (say y-axis) of the crystal and second, the same operation is performed again but now with the newly created x'-axis as axis of rotation (1). The new axes are now parallel to the experimental X, Y, and Z axes. The radiation of a He–Ne laser was parallel to the experimental Z-axis and the direction of observation of the scattered light was along the X-axis. By a suitable choice of polarization of the incident laser beam and, by employing an analyzer

in front of the slit of the monochromator, the following elements of the scattering matrix can be measured: YY, YZ, XY, and XZ. The computation of the scattering matrices for the experimental axis is a relatively straightforward matter and the result of the calculation is given in Table III.

Results and Discussion

The phonon spectrum of TmGaG has been discussed in a recent publication and of importance here is the Raman spectrum with shifts around 180 cm^{-1}. Polarized low temperature Raman spectra of the crystal in that spectral region are shown in Figs. 1 and 2. Absorption and fluorescence measurements revealed that a crystal field level of the $^3H_6$ manifold of TmGaG is situated at 187 cm^{-1} above the ground state (9). In the Raman spectrum of this compound a band is observed at the same frequency and a comparison of the Raman spectrum of TmGaG with the spectrum of a single crystal of YbGaG or YGaG shows that the line at 187 cm^{-1} is unique. In accordance with the findings of the absorption and fluorescence spectra, we assign this weak transition to an electronic effect of the Tm^{3+} ion. According to theory one expects a maximum number of 12 electronic transitions but a search for the other transitions was negative. The absolute values of electronic Raman intensities can be

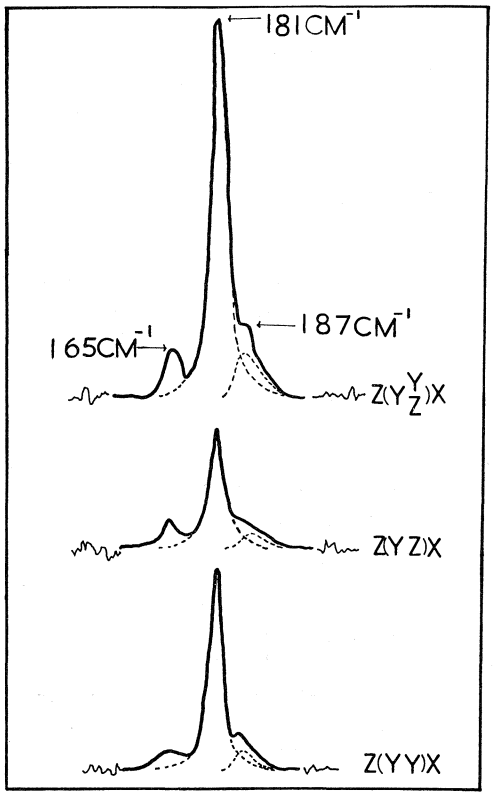

FIG. 2. The polarized Raman spectrum of the single crystal but now showing the components $YY + YZ$, YY, and YZ. The power of the laser beam was 50 mW and the spectra were photoelectrically recorded. The lines on 165 and 181 cm^{-1} are phonon modes and the line on 187 cm^{-1} is the electronic Raman line.

calculated and this calculation for the Tm ion suggests (8) that the cross sections can be as low as 10^{-34} cm^2. From Fig. 1 it is concluded that the intensity of the electronic transition is an order of magnitude smaller than the intensities associated with the phonon modes. A comparison with the intensity of the line of benzene at 992 cm^{-1} shows that the intensity of the phonon lines is approximately two orders of magnitude smaller than the intensity of the benzene line. The experimentally (10) determined cross section of this line is $\sim 10^{-29}$ cm^2. Consequently the estimated cross section of the electronic line is $\sim 10^{-32}$ cm^2. It is thus not surprising that some of the other electronic transitions are not observed.

Also, the antisymmetry of the scattering tensor of this ion has been computed (5). Theory predicts that the amount of asymmetry should be small. From Tables I and II it is seen that the tensors of the electronic transitions are those belonging to the species A_{1g}, T_{1g} or the combination of $T_{1g} + T_{2g}$. Transitions associated with a tensor belonging to the species T_{1g} are thus extremely weak because the amount of asymmetry is small. Also, all other transitions are related to a tensor which is nearly completely symmetric. Values of integrated intensities of some phonon modes of symmetry E_g and T_{2g} are given in Table IV. Also the intensity pattern is compared with appropriate elements of the scattering matrices in Table IV. Reasonable agreement exists between the two sets of values. Integrated intensities of the electronic line are given in Table V. Here again a comparison is made with the intensity matrices and the conclusion is reached that within experimental error the line of Tm^{3+} ion in TmGaG is of symmetry T_{2g}. For this transition, the antisymmetric tensor could contribute

TABLE IV

Relative intensities of some polarization measurements of phonon modes of TmGaG

Frequency phonon mode (cm^{-1})	Symmetry	Relative intensity I_{YY}	I_{YZ}	I_{XY}	I_{XZ}

		5	2	1.5	2	(found)

and the experimental data are thus in agreement with the theory which predicts that the amount of asymmetry should be small.

The energy level diagram of the thulium ion in the host lattice yttrium aluminium garnet has been studied (11) up to energies of 37 000 cm^{-1}. At low temperature, absorptions do not take place at the wavelengths of the principal lines of the argon ion laser. For TmGaG a similar situation can be expected and one might think that more information can be obtained in employing the argon ion laser. Nevertheless, the procedures presented here are valid for all rare earth ions in the garnet host lattices and in future work, use will be made of this type of calculation to relate the crystal field to the polarization properties of electronic Raman transitions.

Concluding Remarks

There is no difference in the electric dipole matrix element $\langle\psi_m|e\rho|\psi_n\rangle$ (where ρ is x, y, or z) for rare earth ion transitions if these ions are imbedded in cubic crystals. The symmetry characterization of the crystal field components of the split LSJ manifolds—in terms of the irreducible representations of the group which describes the appropriate symmetry at the site of the lanthanide ion—cannot directly be made from the fluorescence or absorption spectra. Such assignments can be made from polarization measurements of electronic Raman transitions. For TmGaG one transition has been observed employing the He–Ne laser as an exciting source. The Raman band is of symmetry T_{2g}. This suggests that the transition occurs between the levels of symmetry A and B_2, A and B_3, or B_1 and B_2, B_1 and B_3. The exact labelling of the level of the ground state can thus in principle be found by a process of elimination if the electronic transitions to other levels could be observed. This unfortunately is not the case for TmGaG, but for TbAlG, at least

10 electronic transitions have been observed between the crystal field levels of the $^4F_6$ manifold (12).

Many electronic Raman transitions of rare earth ions have been observed, and presently it can be said that the absolute intensity of these transitions depends strongly on the electronic configuration of the rare earth ions. Fortunately, excitation radiation at different wavelengths is now available for Raman spectroscopy and it thus seems possible to relate crystal field calculations with polarized electronic Raman spectra of rare earth ions.

Acknowledgment

The authors are thankful to Dr. B. A. Buchanan for supplying the single crystal of thulium gallium garnet.

Solvation thermodynamics of ions: free energies in water, ammonia, and fused LiCl–KCl eutectic

JAMES A. PLAMBECK
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received August 21, 1968

Conventional free energies of solvation of ions are calculated from appropriate thermodynamic data in water, liquid ammonia, and fused LiCl–KCl eutectic. These are fitted to a modified Born-charging equation, whose origin and significance are discussed. Statistical tests are applied to certain aspects of the form of the equation. Parameters obtained from the equation can be used to calculate the free energies of solvation of single ions.

Introduction

In the simplest approach (1), the free energy of charging a sphere of radius r to charge ze in vacuum is given by

$$\Delta G_{\mathrm{BC\ g}} = z^2e^2/2r$$

while in a solvent of dielectric constant ε the corresponding free energy is

$$\Delta G_{\mathrm{BC\ s}} = z^2e^2/2r\varepsilon$$

so that the free energy of transfer of a spherical ion from vacuum to such a medium is

$$[1] \quad \Delta G_{\mathrm{BC}} = \Delta G_{\mathrm{BC\ s}} - \Delta G_{\mathrm{BC\ g}} = \frac{-z^2e^2}{2r}(1 - 1/\varepsilon)$$

This will be referred to as the Born-charging free energy of solvation.

It is well known (2) that free energies calculated from the above equation are generally much greater than those calculated from experimental thermodynamic data. The reconciliation of theory and experiment has been approached in two ways. The first, exemplified by the work of Latimer, Pitzer, and Slansky (3), argues that the ionic radii used in eq. [1] should not be crystallographic radii but larger values, which would give a better fit to the data. These larger radii are justified as being more characteristic of a noncrystalline environment, and various empirical radii and correction factors for crystal radii have been employed in this approach. This approach has been criticized by Laidler and Pegis (4). The second approach, exemplified by the work of Noyes (5, 6) is to assume that the ionic sizes are known and constant (crystallographic radii) but that, in view of the large electrostatic potential gradient near the surface of an ion, the solvent in its vicinity is highly polarized. Under these circumstances the bulk dielectric constant of the solvent can no longer be assumed to be correct in the immediate neighborhood of ions, and agreement between theory and experiment is achieved by using an "effective dielectric constant" or dielectric saturation parameters.

The approach of the present paper to the reconciliation is almost identical in mathematical form, but not in physical interpretation, to the second approach mentioned above.

Theory

An appropriate formulation of the problem for aqueous solutions is that given by Noyes (5). Generalizing this formulation we obtain, for any solvent,

$$[2] \quad \Delta G_{\mathrm{SOLV}}{}^0 = \Delta G_{\mathrm{CON}}{}^0 + z\Delta G_{\mathrm{R}}{}^0$$

where z is the ionic charge and $\Delta G_{\mathrm{SOLV}}{}^0$ (Noyes: $\Delta F_{\mathrm{HYD}}{}^0$) is the free energy of solvation of the ion in question, $\Delta G_{\mathrm{CON}}{}^0$ (Noyes: $\Delta F_{\mathrm{CON}}{}^0 - \Delta F_{\mathrm{NEUT}}{}^0$) is the conventional free energy of solvation of the ion, and $\Delta G_{\mathrm{R}}{}^0$ (Noyes: $\Delta F_{\mathrm{H}}{}^0$) is a reference free energy of solvation. The value of the *conventional* free energy of solvation of any ion in any solvent is calculable unambiguously if sufficient thermodynamic data are available. These data must include at least ionization potentials, dissociation energies, sublimation energies, and electromotive force (e.m.f.) values. Such calculations are available in the literature (5, 7).

The solvation energy, $\Delta G_{\mathrm{SOLV}}{}^0$, can be considered as being strictly electrostatic, $\Delta G_{\mathrm{EL}}{}^0$, if the solvation process is considered as the sum of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

three steps: discharging the gaseous ion, solvating the then-neutral species, and recharging the solvated neutral species. Noyes (5) has discussed the approaches to the second of these steps and we accept his conclusion that there is zero free energy of hydration for neutral species. There is still a free energy term for this step, arising wholly from the change from gaseous (1 atm) to liquid (1 molar) standard states (Noyes: $\Delta F_{NEUT}{}^0$) which is incorporated in the $\Delta G_{CON}{}^0$ values given here. We can, therefore, write

$$[3] \qquad -\Delta G_{CON}{}^0 = z\Delta G_R{}^0 - \Delta G_{EL}{}^0$$

where the terms on the right-hand side of the equation are unknown but $\Delta G_{CON}{}^0$ is known. The Born-charging equation unquestionably gives $\Delta G_{EL}{}^0$ correctly for any sphere of macroscopic dimensions, and for such spheres the macroscopic dielectric properties of the solvent are applicable. Thus, in the limit as the ionic radius r approaches infinity, $\Delta G_{EL}{}^0$ approaches $\Delta G_{BC}{}^0$.

For ions of real size in real solvents, however, the Born-charging equation cannot hold, because real solvent molecules are about the same size as real ions. To entities of ionic size, water or any other solvent will appear not as a continuum but as a collection of discrete molecular entities. It is only as the size of an ion approaches infinity on a molecular scale that the Born-charging equation should hold. It will hold in the limit of large ions, however, regardless of the actual sizes of ions or of the dielectric saturation effects, if any, in their vicinity because such effects become negligible at large radius. Thus, in the limit of $1/r \rightarrow 0$,

$$\Delta G_{EL}{}^0 = z^2K/r$$

where $K = \frac{1}{2}e^2(1 - 1/\varepsilon)$ and it is reasonable to represent the actual electrostatic charging energy as a power series expansion in reciprocal radius

$$[4] \quad \Delta G_{EL}{}^0 = -z^2K/r - z^2A/r^2 - z^2B/r^3 - z^2C/r^4 - \ldots$$

since the limit of such a series at infinite radius will be the same as that of the first term. The constants $A, B, C, \ldots$ are empirical and may have either positive or negative values.

From the above argument we now obtain

$$[5] \quad -\Delta G_{CON}{}^0/z = \Delta G_R{}^0 + zK/r + zA/r^2 + zB/r^3 + \ldots$$

in which $-\Delta G_{CON}{}^0/z$ is known and $\Delta G_R{}^0$, A, $B, \ldots$ are unknown. This equation should apply to all ions in any solvent if the appropriate value of K for that solvent is used.

The empirical constants $A, B, C, \ldots$ need have no specific physical significance as apparently assumed by Noyes (5, 6) and de Ligny and Alfenaar (8). They are deviations from the continuous dielectric medium model inherent in the Born equation which can be interpreted as arising from specific ion–solvent interaction, dielectric saturation, ion–quadrupole interactions, or simply the fact that ions see solvent molecules as discrete entities. What is significant is that in the limit of infinite ionic size these deviations all go to zero, and by this method a value of $\Delta G_R{}^0$ for a solvent can be obtained.

The calculation of $\Delta G_R{}^0$ requires values for the empirical constants $A, B, C, \ldots$; these and $\Delta G_R{}^0$ itself can be calculated by the method of least squares in any solvent for which sufficient experimental data are available. In this calculation, it cannot *a priori* be assumed that the deviations from the Born model, and hence the empirical constants, will be the same for anions and cations or that any particular number of empirical constants will be necessary; statistical tests must be applied to determine these aspects of the form of the equation. The results of this paper differ from previous calculations (5, 6, 8, 10) primarily in the use of data for ions of *all* charges (but only of inert-gas electronic structure, for reasons given below), thus giving a more soundly based value.

The value of $\Delta G_R{}^0$ obtained by this procedure can be used to calculate the free energies of solvation of single ions, as will be shown below, but is not itself the free energy of solvation of any ion. The value of $\Delta G_R{}^0$ is in principle neither measurable nor calculable by strictly thermodynamic procedures. This is because measurement of the potential of a single electrode is not possible.

The potential of the reference electrode system in any solvent is therefore arbitrarily assigned the value zero and all other potentials measured with respect to it (e.g., the aqueous hydrogen electrode). This is equivalent to defining the conventional free energy of solvation of the reference ion (ion of the reference electrode couple; hydrogen ion in aqueous solutions) as a fixed quantity whose numerical value is completely determined by the choice of standard states for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the system but cannot be calculated by strictly thermodynamic procedures. Thus, the values of $-\Delta G_{CON}^0/z$ given in Table I for hydrogen ion in water and liquid ammonia, and for Pt(II) in fused LiCl–KCl eutectic, incorporate this assumption explicitly while the values for all other ions do so implicitly. The assumption is removed on the subtraction of ΔG_R^0 from the values of $-\Delta G_{CON}^0/z$ given in Table I, and the absolute free energy of solvation (or free energy of transfer from vacuum to solvent) of any ion in kcal/mole is obtained by multiplying that sum by $-z$.

The exact physical meaning of ΔG_R^0 is not at present clear, and probably depends on the nature of the solvation mechanism assumed although the numerical value of ΔG_R^0 does not. Thus ΔG_R^0 includes any deviation from the zero energy assumption such as that suggested by Noyes (6), using the three-step approach; if the solvation occurs in a one-step procedure as the ion moves across the phase boundary as suggested by Stokes (9), an interpretation on the basis of interfacial potentials would appear preferable.

One of the advantages of the present method is that it is applicable to any solvent and that the value of ΔG_R^0 for that solvent is determined from data taken only in that solvent. Values of ΔG_R^0 can be compared between any pair of solvents for which reasonably extensive electromotive force series exist, without the necessity of assumptions regarding the free energy of transfer of any specific ions from one solvent to another. In this context, it should be pointed out that the most common such assumption (11) is that the free energy of transfer for a large ion of low charge, such as rubidium ion, between two solvents is zero, and hence the conventional free energy of transfer is to be wholly ascribed to the difference between the reference free energies of solvation of the two solvents. In the light of the present approach, this assumption appears reasonable because for such ions the deviation from the Born equation is minimal. Moreover, the Born-charging free energy of solvation for the ion in the two solvents will be nearly the same if their dielectric constants are similar.

Data and Calculations

Free Energies

Values of conventional free energies of solvation have been calculated previously (2, 5, 7). In the light of more recent data and the necessity of using as many experimental values as possible, a recalculation was considered necessary for this work. Aqueous data were taken from circular 500 (12) except for the halogens. The conventions used were those of Noyes (5, 6, 13). Values of ΔG_f^0 for monatomic gas elements were taken from Stull and Sinke (14) and free energies of formation of ions were calculated from the recent ionization potential data of Moore (15) or, in the case of the halogens, from Wagman *et al.* (16).

Minor entropic contributions to the free energies were calculated from the data of Moore (15) or Kelley and King (17); such contributions are of the order of a few kcal/mole and in no case seriously affect the arguments of this work. Data were lacking for the Pt(II) and Rh(III) ionic energy levels (15) and entropic contributions for these species were assumed zero. Liquid ammonia data were taken from compilations of Jolly (18). For aqueous ions, the values of ΔG_{CON}^0 given in Table I correspond closely to those calculated previously (5, 7). The calculation of ΔG_{CON}^0 values in fused LiCl–KCl eutectic at 450 °C was more complex. The values of ΔG_f^0 for the fused salt-solvated ions were calculated from the e.m.f. data tabulated by Plambeck (19, 20). It must be noted that the reference ion in this solvent is not solvated H^+ but solvated Pt(II). Additional corrections for changes in standard states were necessary for lithium and chloride ions, which are solvent constituents, and were made on the assumption of Henrian behavior. The data and conventional free energies of solvation calculated from them are given in Table I for all three solvents.

All free energy calculations were carried out to the nearest cal/mole. This was done to avoid introducing rounding errors into the computer calculation procedure and is not meant to imply that all such figures are significant. The usual significant figures convention is *not* used in this paper and should not be applied to any tabulated data given here; some of the problems in its use have been discussed (21). For most ions, the accuracy of the free energies is probably a few kcal/mole, probably arising primarily in the ionization potentials; a more elaborate discussion is considered to be beyond the scope of this paper. Estimates of error in data compilations are conspicuous by their absence, and the errors involved are more likely to be systematic than random.

*Units of ΔG_R^0 and standard error are kcal/mole; the constants give kcal/mole when multiplied by r to appropriate power.

†Addition of constants does not improve fit beyond this point; see text.

Other Data

The crystallographic radii given are those of Pauling (22). The radius of Cu^{2+} was assumed equal to that of Zn^{2+} on the basis of their Goldschmidt radii since no Pauling radius was available. Values of dielectric constants of water were taken from Owen *et al.* (23) and of liquid ammonia from Grubb, Chittum, and Hunt (24). No measured value for the dielectric constant of fused LiCl–KCl eutectic is available; the value of 3.0 used was suggested by Van Artsdalen and Jaffe (25). These dielectric constants give the following values of K: H_2O, 25°, 163.908; NH_3, 25°, 156.202; LiCl–KCl, 450°, 110.684 kcal Å/mole.

Calculations

The conventional free energies of solvation and radii for the ions of inert gas electronic structure given in Table I were fitted to eq. [5] by a double-precision least-squares multiparameter computer program (26) used on the University of Alberta IBM 360 computer. The results of these fits are given in Table II. The standard error cited is the square root of the sum of the squares of the deviations of the experimental values of $\Delta G_{CON}^0/z$ divided by the number of degrees of freedom (number of experimental points less number of adjustable parameters). The "best" form of eq. [5], denoted by asterisks in Table II, is shown with the data for each solvent in Figs. 1–3. The "best" equation form was that giving the least

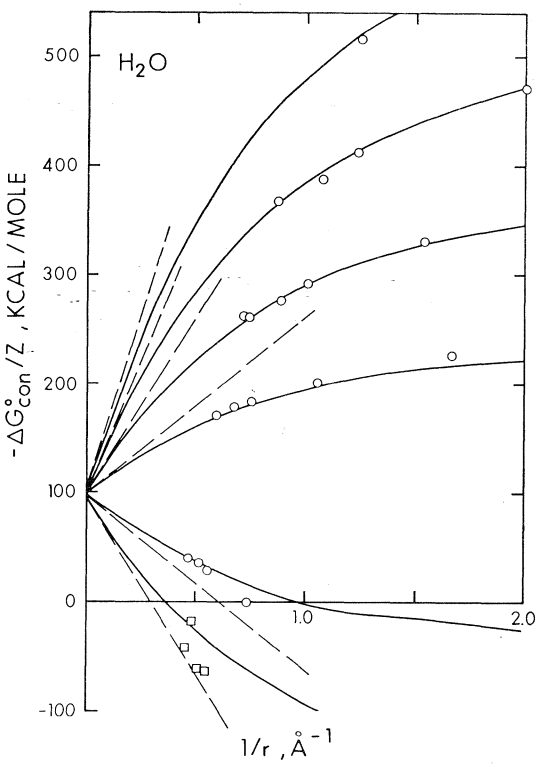

FIG. 1. Plot of $-\Delta G_{CON}^0/z$ against reciprocal radius for water at 25 °C. Dashed lines are those given by the Born equation, solid lines those given by the best form of eq. [5]. Circles, points used in least square fit; squares, other points. Beryllium point omitted for greater horizontal expansion.

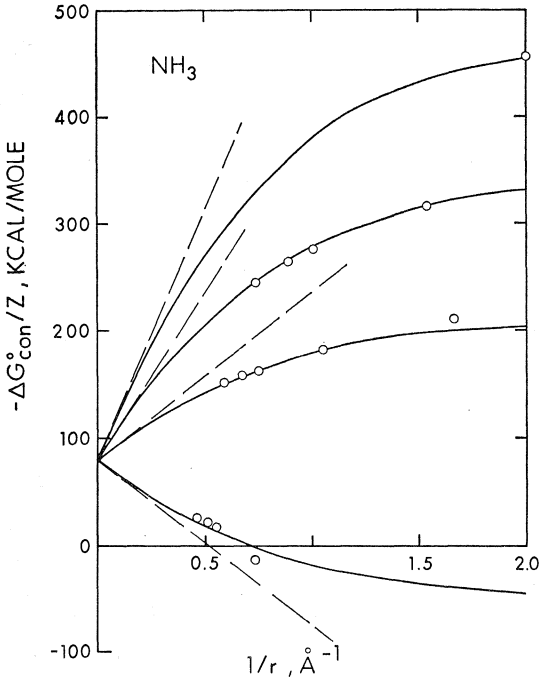

FIG. 2. Plot of $-\Delta G_{CON}{}^{0}/z$ against reciprocal radius for liquid ammonia at 25 °C; as Fig. 1.

standard error in fitting to the inert-gas ion data in that solvent, *provided* that the successively higher terms were actually required as shown by partial F test (27). This was necessary to avoid confusion of the decrease in standard error due to the decrease in degrees of freedom of the system with an actual improvement in fit.

Several alternative forms of eq. [5] have been suggested in the literature, and it appeared desirable to examine them. The present form, in which the free energy of solvation varies with the square of the ionic charge z, is to be preferred to a form in which the free energy of solvation varies directly with ionic charge, because with the present form the empirical constants calculated using only data for ions of unit charge also fitted the data for ions of greater charge, while if a direct dependence on charge were assumed, the data for ions of greater charge could not be fitted using such constants. This is in agreement with the conclusion reached by Laidler (28) that the entropy of solvated ions varies with the square of the ionic charge; the limit approach of the present paper leads to an equation for ionic entropy of solvation of the same form as that for free energy.

In view of the previous use of separate empirical constants for anions and cations (5), it was felt desirable to examine this alternative form of equation. The use of separate anion and cation constants produced less improvement in fit than the introduction of additional terms; e.g., the improvement in fit on the addition of the same term in $1/r^3$ for both was much greater than that produced by using separate anion and cation terms in $1/r^2$. The same result was obtained upon weighting the values for the three largest anions so as to compensate for the disparity in numbers of anion and cation points. If *no* deviation terms were applied to the anions, i.e. the free energies of solvation of anions were calculated using only the Born term and the empirical value of $\Delta G_R{}^0$, a slight improvement in fit appeared for water. However, when the assumption of different anionic and cationic behavior was treated as a decrease of one in the degrees of freedom of the system, a partial F test showed that the improvement is not significant at the 95% confidence level.

Use of different forms of eq. [5] for anions and cations appears to be unjustified.

A final possibility is that an equation which is a series in charge/radius ratio might fit the data better than one in radius alone. Attempts were therefore made to fit the data to the equation

$$[6] \quad -\Delta G_{CON}^{0}/z = \Delta G_R^{0} + zK/r \pm z^2A/r^2 \pm z^3B/r^3 \pm \cdots$$

in the same manner as to eq. [5]. The fit was in all cases much worse than that of eq. [5] with the same number of parameters. It is, therefore, concluded that the deviations from the Born term can best be expressed as a series in radius alone. A similar conclusion, expressed in different terms, was reached by Noyes (5). This implies, but does not prove, that the deviation of experimental data from the Born equation can be ascribed solely to the breakdown of the continuum aspect of the model inherent in that equation.

It was also considered desirable to compare the fit of the present model to that obtained from the additive-radius approach of Latimer, Pitzer, and Slansky (3). In the notation of the present paper, such a model is expressed in the equation

$$[7] \quad -\Delta G_{CON}^{0}/z = \Delta G_R^{0} + zK(r + A)$$

where A was considered an empirical constant. The same sets of data used for the fits in Table II were fitted to this equation with the following results. H_2O: ΔG_R^{0}, 100.000 kcal/mole, A, 0.78 Å, (standard error (s.e.), 9.0 kcal/mole). NH_3: ΔG_R^{0}, 82.842 kcal/mole, A, 0.72 Å, (s.e., 10.1 kcal/mole). LiCl–KCl: ΔG_R^{0}, 118.711 kcal/mole, A, 0.40 Å, (s.e., 26.3 kcal/mole). The values of ΔG_R^{0} obtained by this approach are in agreement with those in Table II, but the fit is in all cases poorer than that obtained using the best form of eq. [5]. Use of separate constants for anion and cation radii did not improve the fit beyond the improvement expected for a decrease of one degree of freedom in any of the three solvents. It is, therefore, concluded that attempts to reconcile theory and experiment by adding empirical constants to ionic radii will produce a worse fit than the use of a reciprocal-radius series in the form of eq. [5] and should be avoided.

Discussion

General

As shown in Figs. 1–3, eq. [5] fits the values of conventional free energies of solvation well for each of the three solvent systems investigated. Since these solvents are of widely divergent character it is probable that this approach is applicable to any solvent. In all three solvents the value of ΔG_R^{0} given by the "best" form of the equation is well within one standard error of the value given by the equation with one additional term. Except in the case of liquid ammonia where the "best" equation contains only two empirical power terms, the same is true of the value given by the equation with one fewer term, indicating the relative insensitivity of the calculated ΔG_R^{0} to the number of empirical terms.

Although the ionic radii used throughout this work were Pauling radii, several other sets of ionic radii have been advocated. Identical calculations were therefore made using the Goldschmidt radii, van der Waals radii (9), and an extended set of the Gourary and Adrian radii (29) whose use in ionic solvation has been advocated by Blandamer and Symons (30). In most cases the values of ΔG_R^{0} calculated using any of these sets of radii were well within one standard error of that calculated using the Pauling radii; the values calculated using Gourary and Adrian radii were usually slightly more than one standard error greater than those calculated using any other set. No set of radii consistently gave lower standard errors in all three solvents. On the basis of this work there appears to be no specific set of ionic radii which is particularly applicable to solution thermodynamics of ions.

The points used to establish the empirical constants for each solvent were those for all ions of inert gas structure for which reliable data were available. The electron affinities of the chalcogens are not accurately known (31, 32) and hence these ions were not used in the calculation; nevertheless, they fit the calculated curves quite well, as appears in Figs. 1 and 3. Considerable efforts were made to obtain additional points for ions in the LiCl–KCl system. Unfortunately, Na–Cs, Ca–Ra, and F_2 react with this solvent. The Ti(IV) point shown in Fig. 3 is estimated using the e.m.f. data of Flengas (33) taken in NaCl–KCl at 700 °C, but reported formation of K_2TiCl_6 makes the estimation unreliable. The point for S^{2-} is calculated from e.m.f. data recently obtained in this laboratory, but was not used to establish the parameters due to the inaccurate electron affinity

mentioned above; e.m.f. data for O^{2-}, Se^{2-}, and Te^{2-} are not available.

Reference Free Energy of Solvation

For fused LiCl–KCl, the reference ion is Pt(II), and for liquid ammonia and water the reference ion is the hydrogen ion, solvated as they are in infinitely dilute solutions. Although the hydrogen–hydrogen ion standard potential has been measured in the fused salt system (34), the standard state of the ion in this medium is quite different from that in liquid ammonia and water and hence cannot be directly compared among the three media. The standard states for hydrogen ion in water and liquid ammonia are the same, however, and a direct comparison is possible. The difference between the values of the reference free energy of solvation, ΔG_R^0, in water and liquid ammonia is 18.6 kcal/mole from the data of Table II, that in liquid ammonia being less. This is in good agreement with the difference of 22.8 kcal/mole calculable from the e.m.f. series tabulated by Strehlow (11), and in even better agreement with the value of 19.6 kcal/mole calculable from the data in Table I; these are obtained on the basis of his assumption that the free energies of solvation of the rubidium ion are the same in both media. This agreement, well within the error of the present approach, is good but not surprising, since the free energy of solvation for larger ions should approach the reference free energy of solvation in any solvent. The assumption of Strehlow is thus seen to be an approximation to the limit approach of the present paper.

The value of ΔG_R^0 for water can be combined with that given in Table I for the aqueous hydrogen ion to give the free energy of solvation of the hydrogen ion as -264.4 ± 6.1 kcal/mole; the corresponding value for liquid ammonia is -283.0 ± 4.9 kcal/mole. No value for liquid ammonia is available for comparison with this calculation, but the value for the free energy of solvation of hydrogen ion in water of -260.5 ± 0.5 kcal/mole obtained by Randles (35) is in good agreement with the value obtained here.

Ions of Transition Metals

Ions of inert-gas electronic structure can all be considered, to a first approximation, as charged spheres. Their interaction with solvents should then differ only as their charges and/or radii. This cannot *a priori* be assumed for ions whose electronic structure is not that of an inert gas, however, and an examination of such ions is therefore desirable. Sufficient data (Table I) appear to be available to permit a systematic investigation only of the first-row transition elements in water and fused LiCl–KCl eutectic, although the fragmentary available data indicate similar behavior for the second-row transition elements and in liquid ammonia. The difference between the conventional (Table I) free energies of solvation of these ions and those predicted by the "best" least-squares equation for inert-gas ions of the same radii were calculated; in all cases the true free energy of solvation is greater than that predicted by the inert-gas equation, as shown in Figs. 4 and 5. These differences are clearly related to the d electron structure of the ion rather than to the radius, since the double-peaked curve is also obtained for a similar plot obtained on the assumption of constant radius. It must therefore be concluded that the greater energy of solvation of transition metal ions arises from interaction between their d orbitals and the surrounding

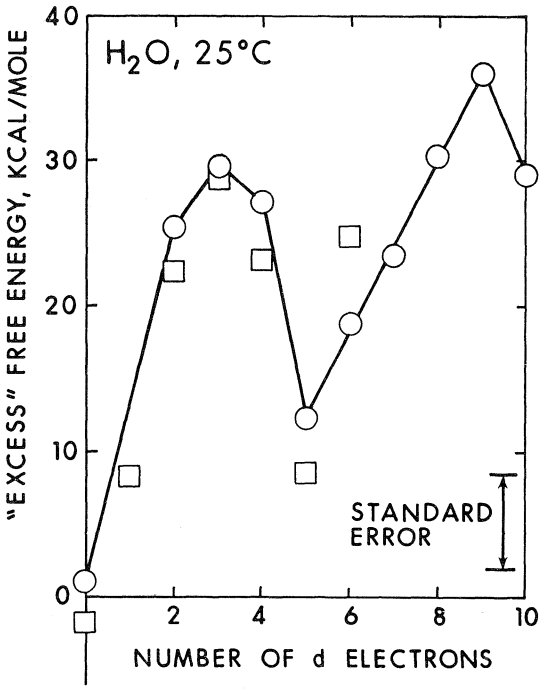

FIG. 4. Plot of "excess" free energy of solvation for first-row transition metal ions in water at 25 °C (see text) against d electronic structure. Circles, dipositive ions; squares, tripositive ions. Ions of d^0 structure used with other inert-gas ions to determine deviation parameters.

ERRATUM

The points for these ions in Fig. 5 should be raised by the difference between th values just given and those in Table I. The pap is not otherwise affected.

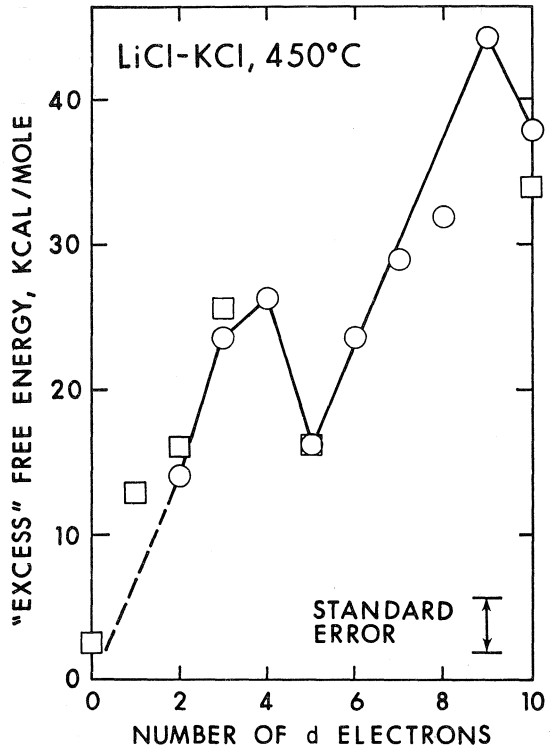

FIG. 5. Plot similar to Fig. 4 except in fused LiCl–KCl eutectic at 450 °C.

solvent molecules. The relation between thermodynamic properties of these ions and their d orbitals has been extensively reviewed (36).

Conclusion

It is concluded that the method of extrapolation to infinite ionic size, previously used in aqueous solution for ions of unit charge, is applicable to two quite different solvents and to polyvalent ions as well. The single-ion free energies of solvation obtained are in good agreement with literature values. Alternative forms of the equation, and the approach of empirically increasing the ionic radius, are examined and shown to be less desirable. Empirical constants included in the equation are interpreted simply as breakdown of the continuum solvent model inherent in the Born equation rather than as having specific physical significance.

Study of isotopic effects and determination of the quadrupole coupling constant from the nuclear magnetic resonance spectra of monodeuterobenzene in a nematic phase

P. DIEHL AND C. L. KHETRAPAL[1]
Department of Physics, University of Basel, Switzerland

Received October 21, 1968

The proton and the deuteron magnetic resonance spectra of monodeuterobenzene have been studied in the nematic phase of a mixture of 50% 4-methoxybenzylidene-4-amino-α-methyl cinnamic acid-*n*-propyl ester and 50% anisole – azophenyl-*n*-capronate at room temperature.

The proton spectrum is studied as a superposition of three 5-spin sub-spectra due to coupling with one deuteron (spin $I = 1$) and analyzed iteratively as a 7-spin system, treating the deuteron as two spin $\frac{1}{2}$ particles.

The values of the dipole–dipole couplings show minor but significant deviations due to isotopic substitution, from those expected for the regular hexagonal geometry. Two parameters are necessary to define molecular orientation. The ratio of the two orientation parameters is reported.

The ratios $(r_{HD}/r_{HH})_{ortho}$ and $(r_{CH} - r_{CD})/(r_{HH})_{ortho}$ are obtained. They indicate a reduction in the time average value of the C—D bond length compared to the C—H one.

It is suggested that the orientation parameters from the proton spectrum of the molecule are used in order to determine the deuteron quadrupole coupling constant from deuteron magnetic resonance (d.m.r.) spectra of partially deuterated molecules dissolved in the nematic phase. The method is applied to the present case. Its limitations and the sources of errors are discussed.

Canadian Journal of Chemistry, **47**, 1411 (1969)

Introduction

The analysis of the proton magnetic resonance spectra of partially oriented molecules in the nematic phases usually provides information about the molecular geometry. Such studies have attracted the attention of several workers. No work, however, seems to have been reported on the influence of isotopic substitution on such spectra and hence on the molecular geometry. Also, the literature on the d.m.r. spectra of molecules dissolved in the nematic phase is limited (1). On the other hand, since the interaction of the deuteron quadrupole moment with the electric field gradients of the bond through which the deuteron is attached to the molecule, are manifested in the d.m.r. spectra in the nematic phases, such studies are extremely informative. The spectrum of a deuteron in a C—D bond is a doublet, the spacing (Δ) of which is given by

$$[1] \qquad \Delta = \frac{3}{2}\left(\frac{e^2qQ}{\mu_D}\right) \cdot |S_{C-D}|$$

where q is the electric field gradient experienced by the deuteron quadrupole moment Q and S_{C-D} is the degree of orientation of the C—D bond axis. The degree of orientation S_{ij} along the axis joining the two nuclei i, and j is given as follows

$$[2] \qquad D_{ij} = -\frac{h\gamma_i\gamma_j}{4\pi^2 r_{ij}^3} \cdot S_{ij}$$

where D_{ij} is the direct coupling between the two nuclei separated by a distance r_{ij}, and γ is the magnetogyric ratio.

If S is determined from the proton spectrum of the molecule, one can determine the deuteron quadrupole coupling constant $(e^2qQ)/\mu_D$ from the spacing of the d.m.r. spectrum in the nematic phase.

The present paper describes the proton and the deuteron magnetic resonance spectra of monodeuterobenzene oriented in the nematic phase of a mixture of 50% 4-methoxy benzylidene-4-amino-α-methyl cinnamic acid-*n*-propyl ester (**1**) and 50% anisole-azophenyl-*n*-capronate (**2**) at room temperature. The study has been made with a view to understand the effect of one deuterium substitution on the proton spectrum and hence on the molecular geometry, as well as to determine the deuteron quadrupole coupling constant.

Experimental

A 24 mole % solution of monodeuterobenzene obtained from Stohler isotope chemicals was studied in the nematic phase of (**1**) + (**2**) at 27 °C.

$D_{26} = D_{46}$	-11.6 ± 0.3	$(r_{CH} - r_{CD})/r_{12}$	0.008 ± 0.008
$D_{14} = D_{25}$	-50.3 ± 0.5	(e^2qQ/μ_D)	196.5 ± 1.3 kHz
D_{24}	-75.5 ± 0.5		
D_{15}	-76.3 ± 2.1		
D_{36}	-6.9 ± 0.3		

*The errors of the parameters given are larger than the most probable values. They are defined under section Analysis of the proton spectrum.

The proton spectrum was recorded on a Varian spectrometer HA60 operating in the field sweep mode without lock. The statistical error in the measurement of line positions (side band technique) was ± 1.5 Hz. The average line width was 8 Hz.

The d.m.r. spectrum was studied in the same sample and at the same temperature at 7.65 MHz in the absorption mode with 40 Hz modulation.

Results and Discussion

Analysis of the Proton Spectrum

The proton spectrum is shown in Fig. 1.

The spectrum is a superposition of three 5-spin sub-spectra due to coupling with one deuteron ($I = 1$) with equal coupling constants but different effective Larmor frequencies. The various effective Larmor frequencies are $(2D_{HD} + J_{HD})$, 0, and $-(2D_{HD} + J_{HD})$ corresponding to the states with $m(D) = +1$, 0, and -1 of the deuteron, on the assumption that a deuterium substitution does not produce a detectable chemical shift between the ortho, meta, and para protons. The various sub-spectra were first computed on the basis of a 6-fold symmetry in the molecule, i.e. with only one S-value. It was then possible to identify lines corresponding to each sub-spectrum. An iterative analysis of the whole spectrum was then carried out as a 7-spin system treating the deuteron as two spin $\frac{1}{2}$ particles. The known J-values (2) ($J_{HD} = (\gamma_D/\gamma_H)J_{HH}$) and the LAOCOONOR program (3) on a UNIVAC 1107 computer were used for the analysis. The intensity of each line of the zero spin state sub-spectrum had to be halved in order to obtain the real spectrum. The root-mean-square error between the observed and the calculated line positions was 1.5 Hz. The calculated spectrum is shown (E) in Fig. 1*b* and the values of the parameters are given in Table I. Using these parameters the sub-spectra were calculated and are reproduced in B, C, and D of Fig. 1.

The signs of the direct and the indirect couplings are found to be opposite to each other. Since the indirect couplings in benzene are known to be positive, the sign of the direct ones must be negative. This corresponds to the fact that the molecule orients preferentially with its plane along the direction of the magnetic field.

The errors of the various parameters, reported in Table I, are not the most probable ones given by the computer program, but are larger. They were estimated by changing all the observed line positions by ± 1.5 Hz, the accuracy of the measurement, in such a way that the position of each line deviated from the calculated by the maximum possible amount. Using these values, the spectrum was again iteratively calculated. The difference between the values of the parameters thus obtained and those obtained before was taken as the error.

Influence of Deuterium Substitution

Table I indicates that the value of D_{12} is not equal to that of D_{23}, and both of these are smaller than $D_{16} \cdot (\gamma_H/\gamma_D)$ $(-400.6 \pm 4.5$ Hz) where $\gamma_H/\gamma_D = 6.5144$. This corresponds to deviations from a regular hexagonal geometry of the molecule. As a consequence of the effective C_{2v} symmetry, two orientation parameters S_{11} and S_{22} (Fig. 1) are necessary to specify the molecular orientation. They are related to D_{12}, D_{23}, and the ortho proton–proton distance in benzene by eqs. [3] and [4]

$$[3] \qquad D_{12} = -\frac{h\gamma_H^2}{4\pi^2 r_{12}^3} S_{22}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$[4] \quad (D_{23} - \tfrac{1}{4}D_{12}) = -\frac{3}{4}\frac{h\gamma_H{}^2}{4\pi^2 r_{12}{}^3} S_{11}$$

$$[5] \quad (S_{22}/S_{11}) = \frac{3}{4}\frac{D_{12}}{(D_{23} - \tfrac{1}{4}D_{12})}$$

S_{11} and S_{22} can be determined individually but with relatively low precision from the known $[(r_{HH})_{ortho}]$ in benzene (2.481 ± 0.005 Å) (4). However, S_{22}/S_{11} is independent of $(r_{HH})_{ortho}$ (eq. [5]) and can, therefore, be determined quite precisely. The value is included in Table I. S_{22}/S_{11} is significantly different from unity (1%). The results indicate that the deuterium substitution reduces the orientation.

If it is assumed that a deuterium substitution does not change the carbon ring geometry and the geometry of the remaining 5 protons in deuterobenzene, the relations between the ratios of the various H—D distances to r_{12} and the direct couplings are given by eqs. [6] and [7].

$$[6] \quad (\gamma_H/\gamma_D)D_{i6}(r_{i6}/r_{12})^5 = \left\{\left(\frac{r_{i6}}{r_{12}}\right)^2 - 0.75\right\} \times D_{12} + (D_{23} - \tfrac{1}{4}D_{12})$$

where $i = 1$ or 2

$$[7] \quad (\gamma_H/\gamma_D)D_{36}(r_{36}/r_{12})^3 = D_{12}$$

Equation [8] allows one to obtain $(r_{CH} - r_{CD})/r_{12}$ as a function of H—D and H—H distances

$$[8] \quad \frac{(r_{CH} - r_{CD})}{r_{12}} = \left\{0.5 - \left[\left(\frac{r_{16}}{r_{12}}\right)^2 - 0.75\right]^{\frac{1}{2}}\right\}$$

The derivation of eqs. [6]–[8] is straightforward from eqs. [4] and [5] and the angles θ and φ (defined in Fig. 1). These angles, in turn, can be expressed in terms of r_{12} and r_{i6}.

Equations [6] and [7] do not provide the values of r_{26}/r_{12} and r_{36}/r_{12}, respectively, with any reasonable precision because of the larger uncertainties of D_{26} and D_{36}. However, eqs. [6] and [8] give (r_{16}/r_{12}) and $(r_{CH} - r_{CD})/r_{12}$ values with reasonable accuracy (Table I). The results indicate a slight reduction of the time average value of the C—D bond length compared to C—H. This is in agreement with results obtained from different spectroscopies (4–6).

Deuteron magnetic resonance spectrum

The spectrum is shown in Fig. 2. It is essentially a doublet caused by the quadrupole interaction (Δ = 14 750 ± 50 Hz). Each component of the doublet is broadened due to the unresolved H—D couplings and is actually an envelope of several lines. Using eq. [1] and the S_{22} value calculated on the basis of $r_{12} = 2.481 \pm 0.005$ Å (4), a value of the quadrupole coupling constant equal to 196.5 ± 1.3 KHz is obtained. The value is more accurate than the one determined from spin–lattice relaxation studies and from d.m.r. of polycrystalline benzene-d_6 (7, 8). The above uncertainty of 1.3 KHz arises mainly from the uncertainty of r_{12}. If r_{12} can be measured more precisely, the accuracy of the quadrupole coupling constant measurement can be increased.

An obvious limitation of the present method of determination of the quadrupole coupling constant is the condition that the molecule must contain a sufficient number of protons so that the orientation parameters can be determined. The limitation can be overcome at the cost of precision. The present example demonstrates that the isotopic substitution reduces the orientation by about 1% only. One can, therefore, use a mixture of fully deuterated and undeuterated molecules for such a study. The proton spectrum in the mixture will provide the orientation parameters which can be used for the calculation of the quadrupole coupling constants from the d.m.r. spectra. If, in future, more is known about the isotopic effects on the molecular orientation, it may be possible to improve the accuracy of the measurements by taking into account these effects.

Proton magnetic resonance investigation of the system zinc perchlorate – methanol: evidence for the association of zinc and perchlorate ions

S. A. AL-BALDAWI AND T. E. GOUGH[1]
Department of Chemistry, University of Waterloo, Waterloo, Ontario
Received May 22, 1968

The proton magnetic resonance spectrum of the system zinc perchlorate – methanol is reported for a range of sample concentrations and temperatures. The results are interpreted in terms of association between the zinc and perchlorate ions, and the various features of the spectrum discussed in terms of this interaction. From the temperature-dependence of line-widths, $E_a = 14 \pm 2$ kcal mole^{-1} and $\log_{10} A = 16 \pm 3$ are estimated for the molecular exchange of methanol from the solvation shell of zinc into the bulk solvent.

Introduction

Nuclear magnetic resonance (n.m.r.) has been used by many workers in the study of electrolyte solutions, and recent reviews (1, 2) may be used as a key to the existing literature. Of particular interest is the fact that, under suitable conditions, it is possible to observe a separate resonance for solvent molecules bound into the primary solvation shell of various cations, and hence to determine the primary solvation number of these cations. With one exception (3) the reported primary solvation numbers are close to 6 (4–9); a value of 5 has been reported for the magnesium ion in liquid ammonia (3), but the authors discount ionic association as the factor responsible for this result. We report here the results of such studies performed on solutions of zinc perchlorate in methanol.

The stereochemistry of zinc is complicated; coordination numbers of 4 (10–12), 5 (13, 14), and 6 (10, 11, 15) have been reported. However, it appears that the aquo-zinc ion is octahedral both in the solid state (16) and in solution (17); accordingly, it is reasonable to expect a primary solvation number of 6 for the zinc ion in methanol.

Raman spectra of aqueous solutions of several perchlorates give no indication of perchlorate complexes (18), while the Raman spectra of aqueous solutions of zinc nitrate show that contact ion-pair formation does not occur unless the molar ratio of water to zinc is less than 6:1 (19). However, conductivity vs. concentration plots for zinc perchlorate in 50–50 methanol–acetone are non-linear and at reduced temperatures exhibit a maximum (20), suggesting that zinc perchlorate ion-pairs may be detectable in anhydrous media.

Experimental

Preparation of Solutions

Anhydrous methanol was prepared by the method of Grunwald, Jumper, and Meiboom (21); anhydrous zinc perchlorate was prepared by heating zinc perchlorate hexadioxanate (22) *in vacuo* at 120 °C for a few hours. Solutions of zinc perchlorate in methanol were prepared on the vacuum line and a portion sealed into an n.m.r. tube; the remainder of the sample was quantitatively analyzed for zinc using EDTA and Eriochrome Black indicator (23).

As a check on the anhydrous nature of the zinc perchlorate hexadioxanate, n.m.r. spectra of a 0.6 *M* solution of this compound in acetone were recorded. The addition of the salt caused no detectable increase in the intensity of the resonance attributed to residual water in the acetone; however, the addition did cause a marked downfield shift of this resonance confirming its assignment as being due to residual water. We estimate an upper limit of 0.1 molecule of water per zinc to be present in the zinc perchlorate hexadioxanate.

Recording of n.m.r. Spectra

Nuclear magnetic resonance spectra were recorded on a J.E.O.L. C-60 spectrometer and were individually calibrated using audio-frequency side-bands generated by a JNM-SD-20B spin decoupler. The resonance of the methyl protons was used as an internal reference. The temperature of the sample was controlled by a JES VT2 unit modified by the inclusion of a Thermovolt relay operated by a thermocouple placed adjacent to the sample. Sample temperatures were determined by measuring the chemical shift between the methyl and hydroxyl protons of a sample of pure methanol, prepared as above. This shift, δ c.p.s., was converted to temperature, T °C, by means of the equation $T = 1.95\ (106 - \delta)$.

Results

Proton magnetic resonance spectra of solutions of zinc perchlorate in methanol were recorded for

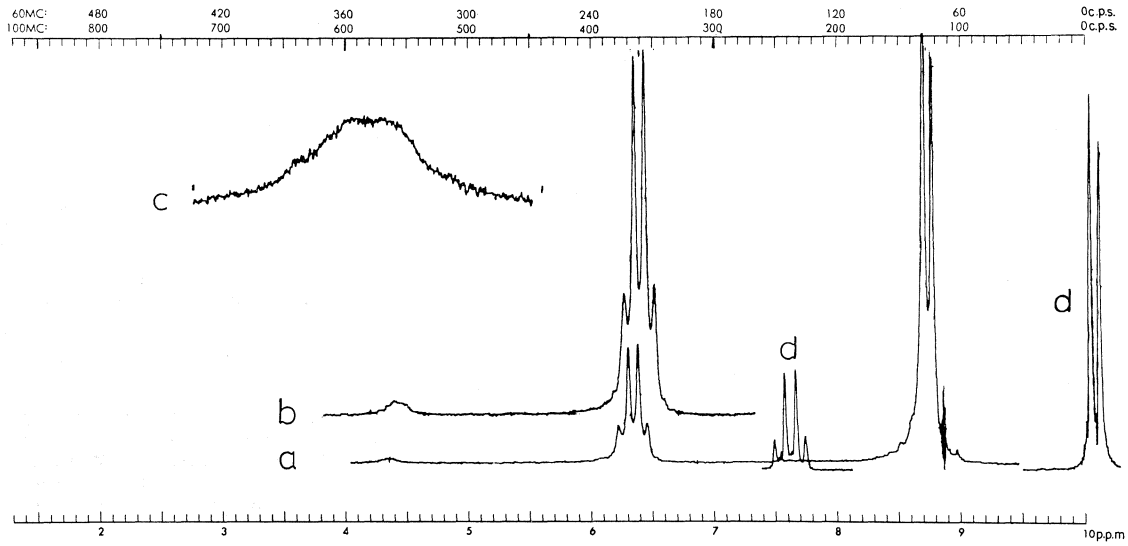

FIG. 1. (*a*) Proton magnetic resonance spectrum at 60 Mc/s of a 0.25 *M* solution of zinc perchlorate in methanol at −83 °C; (*b*) magnified spectrum of the hydroxyl region; (*c*) expanded (×5) spectrum of the bound hydroxyl resonance; (*d*) reference spectrum of pure methanol.

15 solute concentrations, up to 1.8 *M*, at sample temperatures from −90 to +30 °C.

At the highest sample temperature studied, both the methyl and hydroxyl proton resonances were singlets. Decreasing the sample temperature to −50 °C sufficiently slowed down proton exchange reactions for spin–spin splitting between the methyl and hydroxyl protons to be observed, although the high viscosity of the more concentrated samples precluded the resolution of these splittings. Further decrease in temperature caused the hydroxyl proton resonance to broaden asymmetrically to low fields and finally to split into two discrete absorptions; for the most dilute sample, spin–spin splitting with the methyl protons could be seen for both hydroxyl proton resonances (see Fig. 1).

The relative area of the lower field hydroxyl proton resonance increased with increase in the concentration of zinc perchlorate, and we therefore attribute this resonance to methanol molecules participating in the solvation shell of the zinc ion. For convenience, we refer to these solvating methanol molecules as "bound". From measurements of the relative areas of the two hydroxyl proton resonances and of the concentration of zinc perchlorate, estimates were made of the average number of methanol molecules bound to each zinc ion. In Fig. 2, this solvation

number is plotted against the concentration of zinc perchlorate. In Fig. 3, the chemical shift of the bound hydroxyl protons is also plotted as a function of the concentration of zinc perchlorate, the sample temperature (−82 °C) being the same as that for the results in Fig. 2. Both this chemical shift and the solvation number were found to show considerable, and similar dependence upon the concentration of zinc perchlorate. In Fig. 4, once again for the same sample temperature of

−82 °C, the chemical shift of the remaining hydroxyl protons is plotted as a function of the concentration of zinc perchlorate.

In Fig. 5, the average chemical shift of the hydroxylic protons is plotted as a function of the concentration of zinc perchlorate for a range of sample temperatures. For the plot at −82 °C the results were obtained by calculating the weighted average of the two observed hydroxyl resonances; at the remaining temperatures exchange reactions performed this averaging and only one hydroxyl resonance was observed. At high temperatures,

the addition of zinc perchlorate to methanol shifts the hydroxyl resonance to low fields. However, at higher concentrations and lower temperatures the addition of zinc perchlorate causes a high field shift of this resonance.

Correlation times for the exchange of methanol from the solvation shell of zinc into the bulk solvent were obtained by comparing the line shapes of the experimental spectra with the spectra computed using the expression of Gutowsky and Saika (24). In computing these spectra it was assumed that each methanol exchanged molecularly (5) with no change in its nuclear spin quantum numbers. Hence, each hydroxyl resonance was simulated as a quartet even though this structure was not always resolvable. It was further assumed that the transverse relaxation times of the methyl and of both kinds of hydroxyl protons were all equal; for each set of experimental conditions the value of this parameter was then evaluated by comparison of the observed line shape of the methyl protons with those calculated for a doublet of Lorentzian lines using several trial values of the transverse relaxation time. The reciprocals of the exchange correlation times obtained at several temperatures were fitted to the Arrhenius equation, and hence values of the energy of activation and the frequency factor for the removal of a methanol molecule from the solvation shell of zinc were obtained (Table I). The average values obtained were $E_a = 14 \pm 2$ kcal/

0.78	13.3	15.4
1.10	15.7	19.0

mole, $\log_{10} A = 16 \pm 3$; the large scatter in $\log_{10} A$ is caused by the small range of temperatures over which significant line-width effects were observable, coupled with the long extrapolation required to evaluate this parameter.

Discussion

From Fig. 2 it can be seen that as the concentration of zinc perchlorate is increased, the primary solvation number of zinc decreases, approximately from 6 to 4. The concentration of zinc perchlorate in these samples is too low for this decrease to be interpreted in terms of competition between zinc ions for the available methanol molecules; therefore, the decrease is attributed to the progressive displacement of methanol, by perchlorate from the solvation shell of zinc. This modification of the environment of the zinc ion is also reflected in the dependence of the chemical shift of the bound hydroxylic protons upon concentration (Fig. 3). If the zinc ion were not to experience any interaction with the perchlorate ion, then the chemical shift of hydroxyl groups bound to the zinc ion should be independent of the concentration of zinc perchlorate; such is not the case. As the concentration of zinc perchlorate is increased, the resonance of the bound hydroxylic protons shifts to higher fields. This shift is compatible with a decrease in the cationic character of the zinc ion brought about by association between it and perchlorate ions. The resonance of the non-bound hydroxylic protons also shifts to higher fields as the concentration of zinc perchlorate is increased (Fig. 4).

The plots in Fig. 5 show the concentration dependence of the average value of the chemical shift of all the hydroxylic protons in the sample, and are thus equivalent to previous studies performed on aqueous solutions of electrolytes (25–27). The curvature of these plots also indicates the presence of associated zinc species in methanol, and the concentration at which the plots begin to break may be taken as the concentration at which association becomes appreciable. As might be expected, a decrease in temperature decreases the concentration at which significant association occurs.

Values obtained for E_a of the removal of methanol from the solvation shell of zinc were not sufficiently precise for the evaluation of any trend in this parameter with changes in concentration. Hence, we are unable to determine the effect on E_a of the introduction of a perchlorate ion into the solvation shell of zinc. The value of 14 ± 2 kcal/mole is similar to the 16.7 kcal/mole previously observed for the removal of methanol from the solvation shell of magnesium (5). This similarity may be taken as supporting evidence for the applicability of the postulated exchange model and the associated Bloch equations.

The value obtained for $\log_{10} A$, 16 ± 3, is extremely high and would seem to rule out a bimolecular rate determining step in the mechanism whereby methanol is exchanged between the bulk and bound regions. Thus the mechanism of this exchange, like that of the magnesium perchlorate – methanol system (5), must involve a unimolecular, rather than a pseudo-unimolecular, rate-determining step. Similar unimolecular mechanisms have been postulated to interpret the kinetics of solvent and ligand exchange reactions studied in aqueous solution by relaxation techniques (28).

To interpret our experimental data, we are led to postulate the existence, in solutions of zinc perchlorate in anhydrous methanol, of the species $[Zn(MeOH)_6]^{2+}$ and $[Zn(MeOH)_4(ClO_4)_2]$; in addition, the presence of $[Zn(MeOH)_5(ClO_4)]^{+}$ would seem reasonable, though this species is not essential to our interpretation.

Received September 12, 1968

Organoantimony compounds of the type R_3SbX and $(R_3Sb)_2OX$, where R is methyl or phenyl, and X is a bivalent anionic group such as SeO_4, CrO_4, or C_2O_4, have been prepared. Structural characteristics of these compounds have been determined by studying their infrared spectra in the solid state between 4000 and 250 cm^{-1}. The spectral results indicate that in both types of compounds the anion X is co-ordinated to the R_3Sb or (R_3Sb—O—SbR_3) group resulting in non-ionic, five coordinate, polymeric structures.

Introduction

Structural aspects of trialkyl- and triphenyl-antimony(V) derivatives, R_3SbY_2, such as halides, nitrates, and carboxylates have been investigated by several workers (1–8). These compounds are covalently constituted, with trigonal bipyramidal structures in which the organic groups occupy equatorial positions. They are monomeric when dissolved in non-polar organic solvents. A few trimethylantimony derivatives of the type R_3SbX, where X is a bivalent anion, have also been studied by Clark and one of the present authors (1). Unlike the corresponding dihalides, dinitrates, or dicarboxylates, these compounds do not dissolve in non-polar solvents. However, infrared (i.r.) spectral studies (1) indicate that these compounds also have non-ionic five coordinate structures possibly involving bridging anion groups and planar trimethylantimony groups. Similar conclusions have been drawn by Doak *et al.* (4) for triphenylantimony sulfate and oxybis(triphenylantimony)sulfate. In continuation of our studies on organoantimony compounds we have prepared several new derivatives of the type R_3SbX and $(R_3Sb)_2OX$ and have examined their structural aspects by i.r. spectroscopy in the 4000 to 250 cm^{-1} region.

[1]Presented in part at 51st Annual Conference of Chemical Institute of Canada, Vancouver, June 5, 1968.

[4]Summer Research Assistant, University of Guelph, 1968.

Experimental

Compounds of the type R_3SbX were prepared by reacting trimethyl- or triphenyl-antimony dichloride or dibromide with the appropriate silver salt in the solvent indicated in Table I. $(R_3Sb)_2OX$ derivatives were prepared in a similar manner by the reaction of oxybis(trimethyl- or triphenyl-antimony)dichloride or dibromide and the silver salt. The solvent was removed under vacuum except where preparations were performed in aqueous solutions. In each case the final product was dried under vacuum. Trimethyl- or triphenyl-antimony dichloride or dibromide and corresponding oxybis dihalides were prepared according to methods described in the literature (1, 2, 4). Elemental analyses were performed by Dr. A. B. Gygli, Microanalytical Laboratory, Toronto, or by the Schwarzkopf Microanalytical Laboratory, New York. Analytical data are recorded in Table I.

Infrared spectra were recorded on a Perkin–Elmer model 521 spectrophotometer. Samples were prepared as mulls in Nujol, hexachlorobutadiene, or halocarbon oil, and then placed between plates of cesium iodide or cesium bromide. Several spectra of each compound were recorded at different concentrations. Melting points were measured on a Gallenkamp melting point apparatus in glass tubes with one end open.

Results and Discussion

R_3SbX compounds studied in this investigation include trimethyl- and triphenyl-antimony selenates, and triphenylantimony chromate and oxalate. The latter two compounds were sought to provide a comparison between analogous trimethyl- and triphenyl-antimony(V) compounds. Oxybis(trimethyl- or triphenyl-antimony) derivatives, $(R_3Sb)_2OX$, studied include the selenates, chromates, oxalates, and oxybis-(trimethylantimony)sulfate.

R_3SbX Derivatives

The observed i.r. absorption frequencies due to the anion groups in the R_3SbX compounds are given in Table II. The results show that in each case the spectrum of the anion part, X, differs significantly from that of the free anion. In any of these compounds the symmetry of the anion group does not appear to be higher than C_{2v}. Moreover, the symmetric stretching frequencies which are forbidden in the i.r. spectrum of the free anion are observed as strong bands. Marked shifts are also observed in some of the vibrational frequencies. The spectroscopic observations can best be explained in terms of coordination of the X group to the R_3Sb group. In the solid state the symmetry of an anion of high symmetry can also be reduced due to the lower site symmetry of the ion in the crystal lattice. However, in view of previous spectroscopic studies of Clark and Goel on a variety of organotin (9, 10) and organoantimony (1) acid derivatives, we do not consider that the spectroscopic observations can be attributed entirely to the solid state effects. In fact, the i.r. spectra due to the anion groups in some of the R_3SbX compounds can be compared with the spectra of related covalent species. An examination of the i.r. spectra (11) of numerous coordination compounds of oxyanions, and the results of the vibrational analysis of some oxyanion–metal complexes (12), show that when the anion is involved in coordination, the intensity of the symmetric stretching vibrations is greatly increased as compared with the effects caused by low site symmetry of the anion. Similarly, the splitting of the degenerate modes and the frequency shifts are also related to the degree of covalency of the metal–oxygen bond.

The SeO_4^{2-} ion belongs to the point group T_d and has four fundamental vibrational frequencies arising from symmetric and asymmetric stretching and bending modes. Only the asymmetric modes are i.r. active. The symmetric and asymmetric stretching frequencies for the free SeO_4^{2-} have been reported (11) at 833 and 875 cm^{-1}, respectively, and the corresponding bending frequencies are 335 and 432 cm^{-1} (11), respectively. In the i.r. spectra of trimethyl- and triphenylantimony selenates there are four strong well resolved bands near 950, 900, 800, and 750 cm^{-1} which can be attributed to the selenate absorption. In the low frequency region the selenate absorption bands occur near 475–485, 438–445, 388, and 350–355 cm^{-1}. Although i.r. spectral data on coordinated selenates are not available, the observed frequencies of the selenate group in both the compounds indicate that the selenate group is involved in coordination through two of its oxygen atoms.

The chromate absorption frequencies in triphenylantimony chromate are more or less similar to those observed in trimethylantimony chromate (1), and dimethyltin chromate (9).

The absorption frequencies of the oxalate group in triphenylantimony oxalate agree very well with those of trimethylantimony oxalate (1), and metal–oxalato complexes (11). The oxalate absorption bands at 1740, 1655, 1360, and 1200 cm^{-1} in triphenylantimony oxalate correspond to the C—O stretching frequencies reported for *cis*-dimethyl oxalate (13).

With respect to the absorption bands due to the trimethyl- or triphenyl-antimony group, the spectra of R_3SbX compounds do not show any significant change when compared to the spectra of trimethyl- or triphenyl-antimony dihalides (5, 4). In the case of trimethylantimony selenate, weak absorption bands are observed in the C—H symmetric and asymmetric stretching (3000–2900 cm^{-1}), and C—H symmetric and asymmetric bending (1400–1200 cm^{-1}), and CH_3 rocking (862 cm^{-1}) regions. Only the asymmetric Sb—C stretching frequency is observed at 590 cm^{-1}. The presence of only one Sb—C stretching vibration indicates that the trimethylantimony group is planar. All the triphenylantimony compounds studied show absorption bands associated with monosubstituted phenyl groups. In the low frequency region, absorption bands due to the triphenylantimony group occur near 450 and 290 cm^{-1}. Metal–carbon stretching frequencies in heavy metal–phenyl compounds have not been established unequivocally. In the case of triphenylantimony dinitrate and oxybis(triphenylantimony)dinitrate, Doak *et al.* (4) consider the absorption at 450 cm^{-1} to be due to the Sb—C asymmetric stretch, while Tranter *et al.* (14) assign the band near 290 cm^{-1} to the Sb—C asymmetric stretch. Both bands occur in all the triphenylantimony(V) compounds including the dichloride (which is trigonal bipyramidal) and triphenylantimony (which would probably be pyramidal). No conclusions can therefore be reached concerning the geometry of the triphenylantimony group on the basis of its i.r. spectrum. However, in view of the almost identical spectra of the X groups in trimethyl- and triphenyl-antimony derivatives, we suggest that the analogous trimethyl- and triphenylantimony compounds have similar structures.

$(R_3Sb)_2OX$ Derivatives

Investigations on a few oxybis(trimethyl- and triphenyl-antimony) derivatives such as halides, nitrates, and perchlorates (2, 4, 5, 14, 15) have been reported. From i.r. studies, Doak *et al.* (4) consider that oxybis(trimethylantimony)diperchlorate and dichloride are ionic and contain the ion $[(CH_3)_3Sb]O_2^{2+}$. On the other hand, oxybis(triphenylantimony)dichloride (15) and dinitrate (14) are reported to be non-ionic, on the basis of electrical conductance and i.r. spectral data. Among the oxybis derivatives of dibasic acids only oxybis(triphenylantimony)sulfate has been studied (4), and it was reported to be non-ionic. In this investigation we have prepared several oxybis(trimethyl- and triphenyl-antimony) derivatives of dibasic acids and examined their i.r. spectra.

The significant difference between the i.r. spectrum of the oxybis(trimethylantimony) group and that of the trimethylantimony group is the occurrence of a very strong band near 775 cm^{-1} (due to the Sb—O—Sb group) and a weak band near 530 cm^{-1} (possibly due to Sb—C symmetric stretch), in the former case. In the phenyl series the Sb—O—Sb group gives rise to a strong band near 750 cm^{-1}. However, in most of the compounds we have examined, the Sb—O—Sb absorption is masked by strong bands due to the anionic groups. The observed i.r. absorption frequencies

which can be attributed to the anion groups in oxybis(trimethyl- and triphenyl-antimony)selenates, chromates, and oxalates, and oxybis(trimethylantimony)sulfate are listed in Table III. Considering the spectral features of the anion group, none of the above compounds can be described as ionic, in the solid state. In $[(CH_3)_3Sb—O—Sb(CH_3)_3]^{2+}$ cation, each of the antimony atoms would be bonded by four covalent bonds and both the symmetric and asymmetric Sb—C stretching vibrations would be expected to give rise to i.r. absorption bands of medium intensity. Infrared spectra of all the oxybis(trimethylantimony) derivatives studied show a band of medium intensity (580 cm^{-1}) due to Sb—C asymmetric stretch, but only a weak band (near 530 cm^{-1}) in the region of Sb—C symmetric stretch (16). Since the i.r. spectra of the anion groups in analogous R_3SbX and $(R_3Sb)_2OX$ compounds show similar features, a similar structural function for the anion group is indicated in both types of compounds.

Infrared spectra of oxybis(trimethylantimony)-selenate and sulfate also show two additional bands of medium intensity near 3350 and 1050 cm^{-1}. These bands could not be removed even after prolonged pumping and drying of the samples. The samples were also washed with acetone to remove trimethylantimony hydroxide which might be formed. Since no absorption is observed between 1700–1500 cm^{-1}, the above mentioned bands cannot be due to the presence of either free or coordinated water. The formulation of the products as hydrogen selenate or hydrogen sulfate can be ruled out from the analytical data. The two bands may be associated with the Sb—OH bond. In hydroxo complexes of ruthenium (17) O—H stretching and Ru—OH bending frequencies are observed at 3500–3200 and 1000–970 cm^{-1}, respectively. Although there are conflicting reports (4) about the existence of compounds of the type $R_3Sb(OH)Y$ or $[R_3Sb(OH)_2]X$, we consider that the products most likely contain trimethylantimonyhydroxy sulfate or selenate, $[(CH_3)_3SbOH]_2SeO_4$ or $[(CH_3)_3SbOH]_2SO_4$. However, the formulation of the hydroxy species as adducts of the type $[(CH_3)_3SbO]_2H_2SO_4$ or $[(CH_3)_3SbO]_2H_2SeO_4$ cannot be ruled out.

Summarizing, the results of this investigation further support the conclusions derived earlier by Clark and Goel (1), from the i.r. studies of trimethylantimony(V) compounds. Compounds of the type R_3SbX are indicated to be non-ionic solids possessing five coordinate structures, most likely involving bridging X (through two of its oxygen atoms) and R_3Sb groups. The interaction between R_3Sb and X is not significantly affected by changing R from methyl to phenyl, suggesting structural similarities between analogous methyl and phenyl derivatives. The $(R_3Sb)_2OX$ compounds also appear to have the above structural features.

Acknowledgments

Some new diphosphine-bridged nickel carbonyl and cyclopentadienyl compounds

A. J. CARTY, A. EFRATY, AND T. W. NG
Chemistry Department, University of Waterloo, Waterloo, Ontario

Received October 25, 1968

The binuclear diphosphine bridged monocarbonyl compound $[Ni(CO)]_2(DPPA)_3$ has been obtained by reaction of $Ni(CO)_4$ with bis(diphenylphosphino)acetylene (DPPA) under mild conditions and by displacement of π-cyclopentadienyl groups from $[\pi\text{-}C_5H_5Ni(CO)]_2$ at room temperature. The latter reaction suggests a possible route to other monocarbonyl nickel phosphine compounds not available by direct reaction of $Ni(CO)_4$ with phosphines. The preparation and characterization of the binuclear compounds $[Ni(CO)_2]_2(DPPA)_2$, $[Ni(CO)_3]_2(DPPA)$, and $(\pi\text{-}C_5H_5NiI)_2(DPPA)$ are also described.

Canadian Journal of Chemistry, 47, 1429 (1969)

Introduction

Although tertiary phosphines readily displace one or two carbonyl groups from $Ni(CO)_4$ to give substitution products of the types $Ni(CO)_3(PR_3)$ and $Ni(CO)_2(PR_3)_2$, compounds containing only one residual carbonyl group are rare and difficult to obtain (1). Trialkyl and Triarylphosphites (2) as well as certain triphosphines (3) will, however, give monocarbonyl products under appropriate conditions. In several recent publications (4) we have described the preparation and characterization of a series of binuclear complexes of the ligand bis(diphenylphosphino)acetylene **1**. We now find that this ligand reacts with $Ni(CO)_4$ and

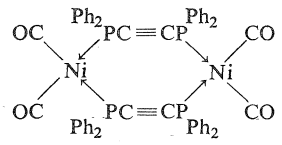
$$Ph_2PC{\equiv}CPPh_2$$

1

$[\pi\text{-}C_5H_5Ni(CO)]_2$ under very mild conditions to give a diphosphine bridged product $[Ni(CO)]_2(DPPA)_3$, DPPA = bis(diphenylphosphino)acetylene, having only one terminal carbonyl group per nickel atom. These and related reactions are the subject of this note.

Results and Discussion

The ligand **1** readily displaces two carbonyl groups from $Ni(CO)_4$ in diethyl ether to give a binuclear compound analyzing as $Ni_2(CO)_4(DPPA)_2$. The infrared spectrum in the region 1600–650 cm^{-1} closely resembles that of the free ligand except for certain changes in frequency and intensity similar to those noted previously (4*c*). A carbon tetrachloride solution spectrum in the ν(CO) region shows two peaks at 2005, 1944 cm^{-1} consistent with the two modes ($a_1 + e$) expected for the C_{2v} local symmetry of a disubstituted $Ni(CO)_2L_2$ species. ν(C≡C) of the coordinated ligand appears in the Raman[1] at 2117 cm^{-1}, 20 cm^{-1} higher than in the free ligand, confirming unambiguously that the triple bond is uncoordinated (4). Since the linear P—C—C—P skeleton of **1** prevents chelation the most likely



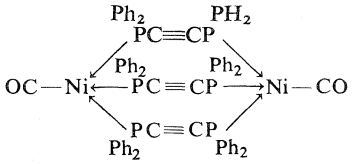
2

structure is **2** having two bridging bis(diphenylphosphino)acetylene groups. The only other example of a stable diphosphine-bridged carbonyl compound of this type is $[Ni(CO)_2]_2(DEPE)_2$, DEPE = 1,2-bis(diethylphosphino)ethane, isolated as a by-product in the preparation of $Ni(CO)_2(DEPE)$ by Chatt and Hart (3), although Meriwether and Leto (6) have found nuclear magnetic resonance (n.m.r.) evidence for $[Ni(CO)_2]_2(DPPE)_2$, DPPE = 1,2-bis(diphenylphosphino)ethane, in solution, and other workers (7, 9, 10) have prepared monobridged compounds of the type $[Ni(CO)_3]_2(P_2R_4)$ (R = Ph, Me, CF_3).

Compound **2** reacts smoothly with **1** in ethanol affording a yellow, air-stable compound. Microanalysis and molecular weight data are consistent with a binuclear species $[Ni(CO)]_2(DPPA)_3$. A

[1]Raman measurements were made on the solid compounds using helium–neon laser excitation.

single ν(CO) band (a_1) at 1938 cm^{-1} in carbon tetrachloride solution suggests a C_{3v} environment of one carbonyl group and three phosphorus atoms per nickel atom and the appearance of ν(C≡C) at 2120 cm^{-1} in the Raman confirms structure **3** for this compound. The compound is, therefore,



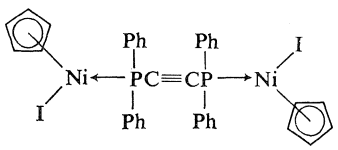
3

structurally analogous to $(CuCl)_2(DPPA)_3$ and $(AuI)_2(DPPA)_3$ (4). A further point of interest is the unexpected appearance of two ν(CO) bands at 1940, 1925 cm^{-1} in a mull spectrum of $[Ni(CO)]_2(DPPA)_3$. This feature has been noted previously for monocarbonyl compounds (3) and may in this case be due to interaction between carbonyl groups on different nickel atoms. Direct reaction of $Ni(CO)_4$ and **1** in ethanol also gives **3** in good yields. This represents the first preparation of a monocarbonyl nickel phosphine complex by direct reaction under mild conditions, and implies that **1** is at least as effective as phosphites in labilizing the CO groups of $Ni(CO)_4$.

In pentane at −10°, $Ni(CO)_4$ reacts with **1** to yield a product having ν(CO) at 2078, 2004 cm^{-1}. This is the spectrum expected for a monobridged tricarbonyl species but the material is impure and difficult to separate from the dicarbonyl.

Few substitution reactions of $[(\pi\text{-}C_5H_5)Ni(CO)]_2$ with phosphines have been reported (1). Tetraalkyldiphosphines replace both carbonyl groups and are cleaved in the process giving the dimeric phosphido bridged species $[(\pi\text{-}C_5H_5)Ni]_2(PR_2)_2$ (8). By contrast $[(\pi\text{-}C_5H_5)Ni(CO)]_2$ reacts with **1** at 25 °C in benzene to give a 20% yield of a product having no $\pi\text{-}C_5H_5$ groups and identical with **3** obtained from $Ni(CO)_4$ and **1**. This is an unusual reaction since carbonyl groups are preferentially removed in substitution reactions of $[(\pi\text{-}C_5H_5)Ni(CO)]_2$ and other π-cyclopentadienyl carbonyls (1), although recent work (11) has shown that π-cyclopentadienyl groups can be removed from $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ by phosphines under extreme conditions. Apparently the reduction Ni(I) → Ni(0) occurs in order to retain the inert gas configuration for nickel, since the bridging properties of **1** and the long P—P distance clearly prevent retention of the metal–metal bond present in $[(\pi\text{-}C_5H_5)Ni(CO)]_2$.

However, reaction of iodine with a solution of $[(\pi\text{-}C_5H_5)Ni(CO)]_2$ and **1** in benzene gives dark red, diamagnetic $[(\pi\text{-}C_5H_5)NiI]_2$(DPPA) having no carbonyl groups but showing a sharp single cyclopentadienyl resonance at δ = 5.27 in the n.m.r. Molecular weight data and the absence of ν(C≡C) in the infrared again confirm the presence of a bridging diphosphine. If the π-cyclopentadienyl group is considered as a tridentate ligand, this compound has structure **4** containing a single diphosphine bridge.



4

X-Ray structural determinations of compounds **2** and **3** are now in progress and we are currently exploring the reaction of $[(\pi\text{-}C_5H_5)Ni(CO)]_2$ with other phosphines as a possible route to other monocarbonyl substitution products.

Experimental

Microanalyses and molecular weight determinations were by Alfred Bernhard, Mulheim, Germany and A.B. Gygli, Toronto. Melting points were determined in evacuated capillaries and were uncorrected. Infrared spectra were obtained using Beckmann IR-9 and -10 spectrometers. Proton magnetic resonance spectra were measured with Varian A60 and HA-100 spectrometers using tetramethylsilane as an internal reference. For all the cyclopentadienyl compounds described, sharp n.m.r. spectra were obtained and the compounds were thus presumed to be diamagnetic.

All reactions were carried out under a blanket of nitrogen.

Bis(diphenylphosphino)acetylene was prepared as previously described (4*c*). Cyclopentadienylnickel carbonyl dimer was prepared by a reported method (12).

[Di-μ-bis(diphenylphosphino)acetylene]-tetracarbonyldinickel

A solution of $Ni(CO)_4$ (1.7 g, 10.0 mmoles) in ether (50 ml) was added dropwise to **1** (4.0 g, 10.0 mmoles) in ether (100 ml). The reaction mixture was refluxed for 1 h. On cooling to room temperature white crystals of the product were formed. Recrystallization from dichloromethane/ethanol gave the pure material, m.p. 180–200°, decomp.

Anal. Calcd. for $Ni_2(CO)_4(DPPA)_2$, mol. wt. 1018: C, 66.1; H, 4.0. Found: mol. wt. 995; C, 66.0; H, 3.91.

[Tri-μ-bis(diphenylphosphino)acetylene]-dicarbonyldinickel

$[CpNi(CO)]_2$ (1.0 g, 3.3 mmoles) and **1** (3.3 g, 8.4 mmoles) were refluxed in benzene (60 ml) for 2 h. The hot reaction mixture was filtered and ethanol added to give a pale yellow crystalline product which was recrystallized from dichloromethane–ethanol. The same product can be obtained at room temperature with longer reaction times, m.p. 264–265°, decomp.

Anal. Calcd. for $Ni_2(CO)_2(DPPA)_3$, mol. wt. 1357: C, 70.8; H, 4.5. Found: mol. wt. 1304; C, 70.4; H, 4.4.

Direct reaction of $Ni(CO)_4$ with **1** in refluxing ethanol gave $Ni_2(CO)_2(DPPA)_3$ in 75% yield. $Ni_2(CO)_4(DPPA)_2$ also reacted with **1** in boiling ethanol to give the same product.

Diiodo-μ-bis(diphenylphosphino)acetylene-di-π-cyclopentadienyldinickel

$[CpNi(CO)]_2$ (1.5 g, 4.9 mmoles), **1** (2.0 g, 5.0 mmoles), and iodine (1.5 g, 5.9 mmoles) were stirred at room temperature in benzene (60 ml) for 10 h. The reaction mixture was filtered, and ethanol added to the filtrate. On reducing the volume of the solution, red crystals of the product were obtained. Recrystallization was from dichloromethane/ethanol, m.p. 172–173°.

Dehydrochlorination of chlorodihydridocarbonylbis(triphenylphosphine)Ir(III) in the presence of strong bases

J. F. Harrod, D. F. R. Gilson, and R. Charles
Chemistry Department, McGill University, Montreal, Quebec
Received October 21, 1968

The dehydrochlorination of dihydridochlorocarbonylbis(triphenylphosphine)iridium(III) by organic and inorganic bases is described. The manner in which this reaction provides a formal link between the homolytic activation of hydrogen at a single metal center and the heterolytic activation of hydrogen is discussed.

Canadian Journal of Chemistry, 47, 1431 (1969)

In the course of attempts to synthesize hydridocarbonylbis(triphenylphosphine)iridium(I) (compound **1**), we have investigated the reaction of chlorodihydridocarbonylbis(triphenylphosphine)iridium(III) (**2**) with a variety of bases. The rationale for such a synthesis, depicted in eq. [1], derives from the relationship between the activation of molecular hydrogen through homolytic oxidative addition, and the heterolytic activation path frequently observed in aqueous solution (1). The two types of activation process may be schematically represented as in eqs. [2] and [3].

[1] 
2 **1**

L = base, P = $(C_6H_5)_3P$

[2] $M + H_2 \rightarrow MH^- + H^+$

[3] $M + H_2 \rightarrow H—M—H$

The essential difference between these two processes is that, axiomatically, in eq. [2] there is some other species in the system which is a stronger base than MH^-, whereas in eq. [3] there is not.

[Tri-μ-bis(diphenylphosphino)acetylene]-dicarbonyldinickel

$[CpNi(CO)]_2$ (1.0 g, 3.3 mmoles) and **1** (3.3 g, 8.4 mmoles) were refluxed in benzene (60 ml) for 2 h. The hot reaction mixture was filtered and ethanol added to give a pale yellow crystalline product which was recrystallized from dichloromethane–ethanol. The same product can be obtained at room temperature with longer reaction times, m.p. 264–265°, decomp.

Anal. Calcd. for $Ni_2(CO)_2(DPPA)_3$, mol. wt. 1357: C, 70.8; H, 4.5. Found: mol. wt. 1304; C, 70.4; H, 4.4.

Direct reaction of $Ni(CO)_4$ with **1** in refluxing ethanol gave $Ni_2(CO)_2(DPPA)_3$ in 75% yield. $Ni_2(CO)_4(DPPA)_2$ also reacted with **1** in boiling ethanol to give the same product.

Diiodo-μ-bis(diphenylphosphino)acetylene-di-π-cyclopentadienyldinickel

$[CpNi(CO)]_2$ (1.5 g, 4.9 mmoles), **1** (2.0 g, 5.0 mmoles), and iodine (1.5 g, 5.9 mmoles) were stirred at room temperature in benzene (60 ml) for 10 h. The reaction mixture was filtered, and ethanol added to the filtrate. On reducing the volume of the solution, red crystals of the product were obtained. Recrystallization was from dichloromethane/ethanol, m.p. 172–173°.

Dehydrochlorination of chlorodihydridocarbonylbis(triphenylphosphine)Ir(III) in the presence of strong bases

J. F. Harrod, D. F. R. Gilson, and R. Charles
Chemistry Department, McGill University, Montreal, Quebec
Received October 21, 1968

The dehydrochlorination of dihydridochlorocarbonylbis(triphenylphosphine)iridium(III) by organic and inorganic bases is described. The manner in which this reaction provides a formal link between the homolytic activation of hydrogen at a single metal center and the heterolytic activation of hydrogen is discussed.

Canadian Journal of Chemistry, 47, 1431 (1969)

In the course of attempts to synthesize hydridocarbonylbis(triphenylphosphine)iridium(I) (compound **1**), we have investigated the reaction of chlorodihydridocarbonylbis(triphenylphosphine)iridium(III) (**2**) with a variety of bases. The rationale for such a synthesis, depicted in eq. [1], derives from the relationship between the activation of molecular hydrogen through homolytic oxidative addition, and the heterolytic activation path frequently observed in aqueous solution (1). The two types of activation process may be schematically represented as in eqs. [2] and [3].

[1] 
2 **1**

L = base, P = $(C_6H_5)_3P$

[2] $M + H_2 \rightarrow MH^- + H^+$

[3] $M + H_2 \rightarrow H—M—H$

The essential difference between these two processes is that, axiomatically, in eq. [2] there is some other species in the system which is a stronger base than MH^-, whereas in eq. [3] there is not.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The first known example of eq. [3] was the reaction of hydrogen with chlorocarbonylbis-(triphenylphosphine)iridium(I) (**3**) to produce **2** (2). This synthesis is normally effected at room temperature in organic solvents of low basicity, e.g. benzene, methylene chloride, a condition which would favor oxidative addition rather than heterolytic splitting. We have treated **2** under a variety of basic conditions using both organic bases, e.g. tetramethylethylenediamine, pyridine, and inorganic bases, e.g. Na_2CO_3, KOH, in both benzene and ethanol. In all cases dehydrochlorination occurred, but not according to the stoichiometry of eq. [1]. The product of the reaction consisted of ca. 50% hydridocarbonyltris(triphenylphosphine)iridium(I) (**4**) and an uncharacterized mixture of carbonyl–phosphine-iridium complexes. The presence of **4** as a major component of the mixture was confirmed by observation of a 1:3:3:1 quartet (τ = 20.9; J(P—H) = 24 Hz in CH_2Cl_2) in the proton magnetic resonance and by infrared absorptions at 2070 cm^{-1} (ν_{Ir-H}) and 1925 cm^{-1} (ν_{CO}). The CO band of the other fraction was at 1985 cm^{-1} (strong).

Dehydrochlorination of **2** by KOH in ethanol, in the presence of excess triphenylphosphine, led to the exclusive formation of **4**, in high yield. The stoichiometry of this reaction is thus

[4] 
4

That reaction [4] goes via dehydrochlorination rather than some other route involving hydride abstraction from solvent was proven unequivocally by dedeuteriochlorination of the dideuterido analogue of **2** under the same conditions. The reaction product gave two intense carbonyl bands at 1945 cm^{-1} (CO *trans* to deuterium (3)) and 1920 cm^{-1} (CO *trans* to protium), the former being about three times the intensity of the latter. Assuming the extinction coefficients for the two complexes to be identical, at least 75% of the product was produced directly by dedeuteriochlorination, in spite of the fact that the reaction occurred in a vast excess of normal ethanol.

The possibility that thermal dissociation of **2**, with loss of H_2, occurs during this reaction is discounted on the evidence that only infrared bands of **2** and **4** were observed during the reaction. In addition, loss of hydrogen would be irreversible under the conditions of reflux under N_2 and the effectively quantitative yields of **4** would not be achievable.

Several syntheses of **1** have been reported by Malatesta (4). We have repeated one of these, namely carbonylation of iridium(IV) iodide, followed by reflux with triphenylphosphine in ethanolic KOH. This reaction yielded a product indistinguishable from the product of our dehydrochlorination reaction, consisting of a mixture of **4** and other unidentified carbonyl containing species. The infrared spectrum of this mixture was the same as that reported by Malatesta for compound **1** (4). It is our opinion that **1** is not stable under the conditions of the reactions described above and apparently it disproportionates readily to **4**, and other species containing carbonyl groups and only a single phosphine ligand. This would also provide an explanation for the anomalous observation of two carbonyl bands in the infrared spectrum of **1** reported by Malatesta (4). No other complex of the type $P_2(CO)IrX$ has been shown to exhibit more than a single carbonyl stretch.

Although the above dehydrochlorination reaction appears to represent the first example of a *heterolytic* splitting of H_2 *via* a stable dihydrido intermediate, the use of dehydrohalogenation of monohydridoiridium(III) complexes as a general synthetic route to iridium(I) complexes has recently been reported by Shaw (5). A similar principle may be operative in the base promotion of reaction [5], described by Wilkinson (6), although the existence of a stable seven-coordinate dihydride of Ru(IV) seems most unlikely[1] (8).

[5] $P_3RuCl_2 + H_2 \rightarrow P_3RuClH + HCl$

[1]A ruthenium(IV) dihydride does not seem so unlikely in view of the recent synthesis of P_3RuH_4.

Experimental

Chlorocarbonylbis(triphenylphosphine)iridium(I) was prepared by the method of Collman and Kang (7). The hydrogen and deuterium adducts were prepared as described by Vaska and DiLuzio (2).

Preparation of Hydridocarbonyltris(triphenylphosphine)-iridium(I) by Dehydrochlorination of the Dihydride **2**

The following is the preferred synthesis of the complex **4** in our laboratory. It allows preparation of **4** in high overall yield, proceeding in simple steps from iridium trichloride trihydrate.

A suspension of the dihydride **2** (3 g), triphenyl phosphine (3 g), and ethanolic KOH (4 ml; 0.9 *M*) in ethanol (30 ml) was boiled for 2 h under nitrogen. After the mixture had cooled to room temperature, the yellow solid was filtered and washed with ethanol. The precipitate was triturated with benzene and the residue of potassium chloride filtered off. The benzene solution was evaporated to dryness *in vacuo* and the solid residue recrystallized from benzene/hexane. Yield after recrystallization: 3.3 g (86%). The reaction with the dideuteride was carried out under conditions identical with those described above.

The above reaction was carried out in the absence of added triphenylphosphine under N_2, H_2, or CO. Under N_2 or H_2 it was necessary to avoid exposure of the yellow solid to air before the removal of KCl was completed. The products under N_2 and H_2 were the same. Under CO the initial product obtained was different, giving two strong, almost coincident, broad CO bands at 1930 and 1955 cm^{-1} in the infrared. Over a period of about an hour in methylene chloride at room temperature this product reverted to the same mixture of compounds obtained under N_2, or H_2. This change was manifest by the gradual appearance of the characteristic quartet due to **4** in the nuclear magnetic resonance spectrum and the appearance of infrared bands identical with those of the products obtained under N_2 or H_2.

Spectroscopic Measurements

Nuclear magnetic resonance spectra were measured with a Varian A60 spectrometer using a C-1024 CAT attachment. The samples were saturated solutions in methylene chloride.

Infrared spectra were measured in methylene chloride and in benzene. The latter solvent obscures the carbonyl absorption of **4**, which probably accounts for the fact that Malatesta reported two carbonyl absorptions for **1** in methylene chloride, but only one in benzene (4). Spectra were also recorded of thin films spread from solution by evaporation. These spectra were identical with those obtained with methylene chloride within the resolution of the instrument used (Perkin–Elmer 257).

Polarographic reduction of D-mannurono-γ-lactone

J. R. Johnston and R. J. Thibert
Department of Chemistry, University of Windsor, Windsor, Ontario

Received December 2, 1968

The polarographic reduction of D-mannuronolactone is a diffusion controlled process, and is analytically applicable over the concentration range 20–100 μg lactone per ml. The addition of KH_2PO_4 gives similar results to those obtained with D-glucuronolactone, but the results suggest that the D-mannuronolactone ring is less reactive.

Canadian Journal of Chemistry, **47**, 1433 (1969)

Introduction

In conjunction with a detailed study of the polarography of D-glucuronolactone (1), a preliminary investigation was conducted with D-mannurono-γ-lactone. Because of the structural similarities of D-glucurono-γ-lactone and D-mannurono-γ-lactone, it was assumed that their polarographic behavior would be much the same. Since it had been found that D-glucuronolactone could not be reduced at the dropping mercury electrode in buffered solutions, but was reducible in unbuffered solutions (2), D-mannuronolactone was also studied in unbuffered solutions.

For personal use only.

This paper reports the results of this preliminary investigation and compares them to the corresponding results found for D-glucuronolactone (1).

Experimental

Materials

Gelatin (purified, calfskin) was obtained from Eastman Organic Chemicals; D-mannuronolactone from General Biochemicals, Inc.; mercury (triply distilled) from Engelhard Industries of Canada, Ltd.; and KCl and KH_2PO_4 from Fisher Scientific Co., Ltd. (Fisher certified reagents). Deionized water, obtained by passing distilled water through a column containing Rexyn I-300 Research Grade resin (a mixed bed resin), was used throughout.

Methods

The calibration procedure was exactly the same as that reported for D-glucuronolactone over the range 0–100 μg per ml (1). Polarograms were run over the voltage range −1.0 to −2.0 V with the appropriate sensitivity setting, using the Sargent (E. H. Sargent and Co.) model XXI polarograph. The polarographic cell was an H-cell with a saturated calomel electrode (s.c.e.) as the reference electrode. All $E_{1/2}$ values are reported with respect to the s.c.e. The capillary characteristics were: $m = 1.101$ mg s^{-1}, $t = 4.87$ s, $m^{2/3}t^{1/6} = 1.388$ $mg^{2/3}s^{-1/2}$. All polarograms were run at 25 °C with a mercury column height of 50 cm. No damping was used.

pH measurements were made with a Radiometer type TTTlc titrator (used as a pH meter), and a Radiometer model PHA630T scale expander. The meter was standardized with buffers of pH 4.01 (potassium acid phthalate) and pH 6.48 (Radiometer buffer solution S1001).

Phosphate was added by pipetting the desired amount of KH_2PO_4 from a stock solution of 1 mg PO_4^{3-} (as KH_2PO_4) per ml.

Results and Discussion

Over the concentration range 50–100 μg D-mannuronolactone per ml, there is a linear relationship between i_D and the concentration of the lactone, as is shown in Table I. The value of i_D at a lactone concentration of 20 μg per ml does not fall on this line, but is reproducible. The half-wave potential for the reduction was found to be −1.49 V.

As can be seen from Table I, there is only a slight change in pH with increasing D-mannuronolactone concentration. This behavior is similar to that noted with D-glucuronolactone solutions.

A plot of diffusion (i_D) vs. the square root of the height of the mercury column (the height of the mercury column was varied from 30–50 cm) showed that the reduction process is diffusion controlled. This is in marked contrast to the results obtained in this concentration range for D-glucuronolactone (1), where the reduction process was found to be kinetic or catalytic in nature.

TABLE I

Variation of the diffusion current of D-mannuronolactone*

μg Lactone per ml	i_D (μA)†	μg PO_4^{3-} per ml‡	pH
0	0	0	5.10
20	0.150	0	5.07
50	1.14	0	5.07
80	1.99	0	5.05
100	2.51	0	5.05
100	2.37	10	5.04
100	0	30	5.03

*All solutions are 0.2 *M* KCl and 0.005% with respect to gelatin.
†When no phosphate was present, these i_D values are the average of triplicate values.
‡Phosphate added as KH_2PO_4.

Upon the addition of KH_2PO_4, solutions containing 100 μg D-mannuronolactone per ml behaved in a similar manner to D-glucuronolactone solutions of this concentration. There was very little change in the pH, and increasing the phosphate concentration caused the polarographic wave height to be depressed until the wave was obliterated.

The reduction of D-glucuronolactone is a kinetic or catalytic process, indicating that the lactone undergoes a reaction prior to its reduction at the dropping mercury electrode. The fact that the reduction of D-mannuronolactone is a diffusion controlled process indicates that either D-mannuronolactone reacts very quickly on being dissolved, or does not react to any appreciable extent prior to its reduction. In the aqueous gelatin – KCl medium, the most probable reaction would be hydrolysis of the lactone to the acid. Should this reaction occur rapidly, the D-mannuronic acid ($pK_a = 3.38$) produced would completely overwhelm the buffer capacity of the gelatin – KCl solution, and the pH should decrease markedly on increasing the lactone concentration. The pH data in Table I show that D-mannuronolactone does not undergo such a reaction immediately on dissolution. Therefore, it would appear that D-mannuronolactone does not undergo a reaction prior to its reduction, while D-glucuronolactone does. This difference indicates that the D-mannuronolactone ring is less reactive than the D-glucuronolactone ring.

When KH_2PO_4 was added, 10 μg PO_4^{3-} per

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ml caused a perceptible decrease in the diffusion current of D-mannuronolactone (100 μg per ml), and 30 μg PO_4^{3-} per ml eliminated the wave entirely. This is considerably more $H_2PO_4^-$ than was the case with D-glucuronolactone where 7.5 μg PO_4^{3-} per ml sufficed to depress the wave to the residual current (1). This is taken as further evidence that the D-mannuronolactone ring is less reactive than the D-glucuronolactone ring.

Thermal reaction of the U(VI) and Th(IV) 8-hydroxyquinoline adducts

A. CORSINI AND J. ABRAHAM[1]

Department of Chemistry, McMaster University, Hamilton, Ontario

Received September 18, 1968

The use of [^{14}C]-8-hydroxyquinoline has shown that when the 8-hydroxyquinoline adducts, $UO_2(C_9H_6NO)_2 \cdot C_9H_7NO$ and $Th(C_9H_6NO)_4 \cdot C_9H_7NO$, are thermally converted to the normal compounds, $UO_2(C_9H_6NO)_2$ and $Th(C_9H_6NO)_4$, intermolecular ligand exchange in the solid phase occurs. The extent to which the exchange equilibrium proceeds suggests that the thermal energy absorbed is sufficient to promote considerable metal–ligand bond rupture.

Canadian Journal of Chemistry, **47**, 1435 (1969)

The 8-hydroxyquinoline "addition" compounds (adducts), $UO_2(C_9H_6NO)_2 \cdot C_9H_7NO$ and $Th(C_9H_6NO)_4 \cdot C_9H_7NO$, are structurally interesting compounds (1–3) that have been exploited for analytical purposes for many years (4). A significant analytical reaction is the thermal conversion of the adducts to 8-hydroxyquinoline and the normal complexes, $UO_2(C_9H_6NO)_2$ and $Th(C_9H_6NO)_4$ (4–10).

The complete mechanism of each thermal reaction has not been unambiguously determined, although proposals concerning mechanism have been made (5, 10–12).

In the present study, the use of [^{14}C]-8-hydroxyquinoline has provided evidence that during the thermal reaction, extensive bond rupture between the central metal [U(VI) or Th(IV)] and the ligand occurs, resulting in an appreciable amount of solid-phase intermolecular ligand exchange.

Experimental

The uranyl and thorium nitrate hexahydrates (ANALAR, British Drug Houses) were used without further purification. Unlabelled 8-hydroxyquinoline (certified grade, Fisher Scientific Co.) was purified by sublimation.

[1]Present address: Department of Chemistry, Dalhousie University, Halifax, Nova Scotia.

The [^{14}C]-8-hydroxyquinoline was prepared by diluting about 50 mg of [^{14}C]-glycerol (0.5 mC, Volk Radiochemical Co., Chicago) with 28.7 mg of unlabelled glycerol and thereafter following the procedure of Manske *et al.* (13) for the preparation of unlabelled 8-hydroxyquinoline. The crude material (yield 70%) was steam distilled and recrystallized from aqueous ethanol, m.p. 73.5–74.0 °C, specific activity 3.58 ± 0.02 mV/s mg (see below).

The [^{14}C]-8-hydroxyquinoline was used to prepare the U(VI) and Th(IV) adducts. The U(VI) compound was synthesized by Moeller and Wilkins' method (14) for the preparation of the unlabelled compound. The Th(IV) compound was prepared as follows: 25.0 ml of a Th(IV) solution (1.4 mg Th/ml) was diluted to 50 ml with water and heated to about 70 °C. In turn, the following solutions (warmed to 70 °C) were added dropwise with stirring: 8.0 ml of a 1.8% solution of [^{14}C]-8-hydroxyquinoline (1.8 g dissolved in 6 ml of glacial acetic acid and diluted to 100 ml with water), and 15 ml of an aqueous solution containing 2 g of ammonium acetate. The pH was adjusted to 6.5–7.0 with 1.0 *M* aqueous ammonia, the volume adjusted to about 90 ml with water, and the mixture digested for 1 h at 70 °C. The orange precipitate was filtered by suction, washed with 100 ml of hot water, adjusted to pH 7.5 ± 0.5 with dilute ammonia, and dried for 3 h by suction and about 15 h over P_2O_5. The compound is deficient in 8-hydroxyquinoline, having a composition close to $Th(C_9H_6NO)_4 \cdot 0.9C_9H_7NO$ (unpublished results).

The normal bis and tetrakis compounds were prepared thermally from the respective *unlabelled* adducts. The apparatus and the preparation of $UO_2(C_9H_6NO)_2$ were as described previously (12). $Th(C_9H_6NO)_4$ was prepared

ml caused a perceptible decrease in the diffusion current of D-mannuronolactone (100 μg per ml), and 30 μg PO_4^{3-} per ml eliminated the wave entirely. This is considerably more $H_2PO_4^-$ than was the case with D-glucuronolactone where 7.5 μg PO_4^{3-} per ml sufficed to depress the wave to the residual current (1). This is taken as further evidence that the D-mannuronolactone ring is less reactive than the D-glucuronolactone ring.

The [^{14}C]-8-hydroxyquinoline was used to prepare the U(VI) and Th(IV) adducts. The U(VI) compound was synthesized by Moeller and Wilkins' method (14) for the preparation of the unlabelled compound. The Th(IV) compound was prepared as follows: 25.0 ml of a Th(IV) solution (1.4 mg Th/ml) was diluted to 50 ml with water and heated to about 70 °C. In turn, the following solutions (warmed to 70 °C) were added dropwise with stirring: 8.0 ml of a 1.8% solution of [^{14}C]-8-hydroxyquinoline (1.8 g dissolved in 6 ml of glacial acetic acid and diluted to 100 ml with water), and 15 ml of an aqueous solution containing 2 g of ammonium acetate. The pH was adjusted to 6.5–7.0 with 1.0 *M* aqueous ammonia, the volume adjusted to about 90 ml with water, and the mixture digested for 1 h at 70 °C. The orange precipitate was filtered by suction, washed with 100 ml of hot water, adjusted to pH 7.5 ± 0.5 with dilute ammonia, and dried for 3 h by suction and about 15 h over P_2O_5. The compound is deficient in 8-hydroxyquinoline, having a composition close to $Th(C_9H_6NO)_4 \cdot 0.9C_9H_7NO$ (unpublished results).

The normal bis and tetrakis compounds were prepared thermally from the respective *unlabelled* adducts. The apparatus and the preparation of $UO_2(C_9H_6NO)_2$ were as described previously (12). $Th(C_9H_6NO)_4$ was prepared

by heating the adduct (150–200 mg) in vacuo (0.1 mm Hg) at 165–170 °C for 1½ h.

The apparatus for the wet-oxidation of [^{14}C]-containing compounds and the collection of radioactive carbon dioxide has been described elsewhere (15). Measurements of [^{14}C]-radioactivity were made by the "rate-of-drift" method (16), which yields units of mV/s mg. It was not necessary in this work to convert to the more customary units of disintegrations/s mg.

Thermal Ligand Exchange

Known amounts of the [^{14}C]-adduct and of the unlabelled normal complex were ground and mixed thoroughly by mortar and pestle and carried through the thermal-conversion procedure. The specific activity of the residual normal complex and of the sublimed 8-hydroxyquinoline was determined and used to estimate the extent of intermolecular ligand exchange during the thermal reaction (Tables I and II).

TABLE I

Intermolecular ligand exchange in thermal reaction of $UO_2(C_9H_6NO)_2 \cdot C_9H_7NO$*

Specific activity (mV/s mg)			Exchange equilibrium (%)
Measured	Complete exchange†	No exchange†	
	Sublimed 8-hydroxyquinoline		
3.16	2.03	3.58	27
	Residual bis compound		
1.79	2.03	1.67	33
		Average	30 ± 3

*Unlabelled bis compound taken: 58.7 mg. Labelled addition compound taken (initial specific activity of C_9H_7NO, 3.58 mV/s mg): 64.6 mg.

†Calculated from the initial specific activity of C_9H_7NO and the amounts of the species taken.

TABLE II

Intermolecular ligand exchange in thermal reaction of $Th(C_9H_6NO)_4 \cdot C_9H_7NO$*

Specific activity (mV/s mg)			Exchange equilibrium (%)
Measured	Complete exchange†	No exchange†	
	Sublimed 8-hydroxyquinoline		
2.74	1.96	3.58	52
	Residual tetrakis compound		
1.90	1.96	1.78	67
		Average	60 ± 8

*Unlabelled tetrakis compound taken: 110 mg; labelled addition compound taken (initial specific activity of C_9H_7NO, 3.58 mV/mg s): 126.5 mg.

†Calculated from the initial specific activity of C_9H_7NO and the amounts of the species taken, using the formula $Th(C_9H_6NO)_4 \cdot 0.9\text{-}C_9H_7NO$.

Results and Discussion

Since the specific activity of the 8-hydroxyquinoline used to synthesize the adduct compounds was 3.58 mV/s mg, the specific activity of the 8-hydroxyquinoline sublimed in the thermal reactions should, in the absence of intermolecular exchange, have the same value. The data of Tables I and II show that the value in each case is significantly lower. The difference between 3.58 and the measured value is well beyond the precision error of ±0.06[2]. Similarly, in the absence of intermolecular exchange, the specific activity of the residual bis and tetrakis compounds should have the calculated values listed in the tables. The measured values, however, are higher[3].

These results could be obtained only if the labelled adduct and the unlabelled normal compound were involved in an intermolecular exchange of ligands during the thermal reaction. The large precision error in the extent of exchange, for the Th(IV) adduct particularly, arises because the difference between the specific activity for complete and no exchange for the residual normal compounds is small and subject to a considerable error (20–30%) in measurement. Therefore, the extent of exchange equilibrium based on the data for the sublimed 8-hydroxyquinoline is more reliable.

The larger extent of exchange for the Th(IV) adduct compared to that for the U(VI) compound reflects the greater overall lability of the Th(IV) adduct, which, for example, requires a lower temperature for the thermal reaction and is more extensively dissociated in organic solvents.

The energy of the thermal reaction is sufficient to cause appreciable bond rupture and intermolecular ligand transfer in the solid phase. The transfer involves the mono- *and* bi-dentate ligands, both of which have been shown (1–3) to be present in the U(VI) and Th(IV) adducts. The exchange mechanism could involve the transfer of the monodentate ligand in the labelled adduct to the normal compound to produce a labelled intermediate adduct (reaction [1] below), followed by intramolecular ligand exchange in this intermediate (reaction [2]) which involves, basi-

[2]The standard deviation for the combustion and counting method is ±0.04, as determined on 16 samples. The precision error for the difference between two such measurements is thus ±0.06.

[3]It can readily be shown for both the U(VI) and Th(IV) compounds that within experimental error, a radiobalance exists between the decrease in specific activity of the sublimed 8-hydroxyquinoline and the increase in specific activity of the residual bis and tetrakis compounds.

cally, only a proton transfer. These reactions would account for the distribution of [^{14}C]-activity found experimentally[4].

[1] $MQ^*_n \cdot H^*Q + MQ_n \rightleftharpoons MQ^*_n + MQ_n \cdot H^*Q$

where H*Q = [^{14}C]-8-hydroxyquinoline.

[2] $MQ_n \cdot H^*Q \rightleftharpoons MQ_{n-1}Q^* \cdot HQ$

The occurrence of reactions [1] and [2] would make possible reactions [3] and [4]. Reaction [3] would not alter the effect of reaction [2] on the

[3] $MQ_{n-1}Q^* \cdot HQ + MQ^*_n \rightleftharpoons MQ_{n-1}Q^* + MQ^*_n \cdot HQ$

[4] $MQ^*_n \cdot HQ \rightleftharpoons MQ^*_{n-1}Q \cdot H^*Q$

specific activity of the sublimed 8-hydroxyquinoline and the residual normal compound, although reaction [4] would somewhat offset this effect.

No direct evidence for intramolecular ligand exchange was obtained in the experiments but it must be presumed that this exchange occurs, since it would operate through transfer of the proton on the monodentate ligand: a low energy process compared to intermolecular ligand exchange.

Finally, we could not prepare the adduct in which only the monodentate ligand is labelled[5]. The occurrence of exchange could be detected using such a compound, although it would not be possible to distinguish intermolecular from intramolecular exchange.

[4]Complete equilibration of the activity is not obtained since the monodentate ligand is eliminated before such equilibration can occur.

[5]The addition of a solution of H*Q to MQ_n yielded $MQ^*_n \cdot H^*Q$, even for short reaction times.

Anilinium chloride as a model for the transition state for benzyl chloride solvolysis

Ikchoon Lee and J. B. Hyne

Department of Chemistry, The University of Calgary, Calgary, Alberta

Received August 10, 1967

The solvent composition dependence of the partial molal volume of the transition state of benzyl chloride solvolysing in water–ethanol mixtures is compared with that of anilinium chloride and a number of quaternary alkyl ammonium chlorides. It is concluded that anilinium chloride is not a good electrostatic model for the benzyl chloride transition state even though it may be a fair structural model. The partial molal volume of tetraethylammonium chloride is very similar to that of the transition state suggesting that charge development in the activation process is far from being fully ionic.

Canadian Journal of Chemistry, **47**, 1437 (1969)

We have recently reported the dependence of the partial molal volume, $\bar{V}_t$, of the transition state for benzyl chloride solvolysis on the composition of the ethanol–water solvolysing medium (1) and also the behavior of the partial molal volumes of a series of tetraalkylammonium salts,

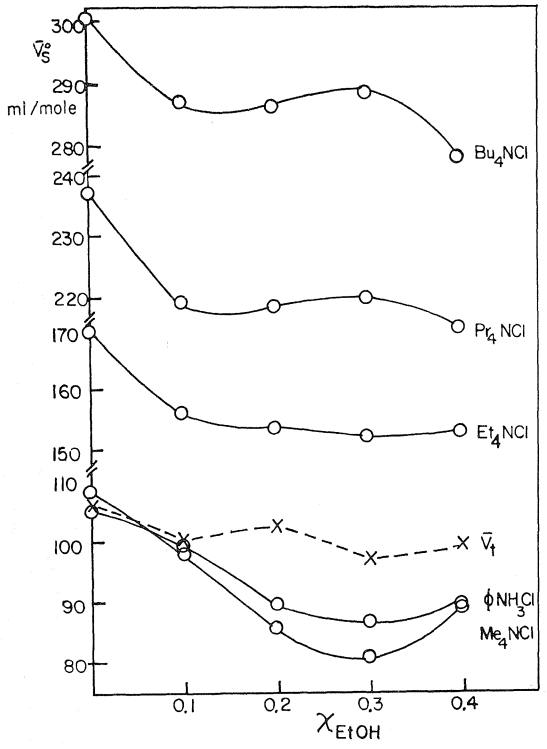

FIG. 1. Dependence of partial molal volumes of tetraalkylammonium chlorides, anilinium chloride, and benzyl chloride transition state on mole fraction ethanol.

$\bar{V}_s^0$, in the same solvents (2) (see Fig. 1). The general similarity in behavior between the transition state and the salts prompted us to use the partial molal volume behavior as an experimental probe to determine whether anilinium chloride was a reasonable model for the transition state of benzyl chloride solvolysing in ethanol–water solvent mixtures. Anilinium chloride is a reasonable structural model for the transition state of benzyl chloride but the question remains as to whether it represents a reasonable charge distribution model.

That there is charge development in the C—Cl bond of benzyl chloride during the activation process has never been denied; the as yet unanswered question is whether this charge development more nearly approximates the classical S_N1 type of transition state, which implies incipient ion formation along the reaction path towards an intermediate benzyl carbonium and chloride ion, or the less charge developed S_N2 transition state. Since partial molal volumes of solute species are strongly dependent on electrostriction phenonema and these in turn reflect charge density on the solute species, it is not unreasonable to expect that a comparison of partial molal volume behavior of the transition state with model compounds of known charge type might yield information on the charge type of the transition state.

Experimental Results

The partial molal volume data for the series of quaternary alkylammonium salts used in Fig. 1 have been reported previously (2). The method previously described was used without modification to obtain the results shown below for anilinium chloride.

Eastman reagent grade aniline hydrochloride was twice recrystallized from acetone and dried *in vacuo* at 80° for at least 24 h before use. Magnesium dried ethanol and double distilled water mixtures were prepared by weight.

Procedure and accuracy of density measurements were the same as described previously (2). Apparent molal volumes ϕ were calculated using the equation

$$\phi = \frac{M_2}{d_0} - \frac{1000}{d_0}\frac{(d - d_0)}{C}$$

where M_2 is the molecular weight of aniline hydrochloride, C is the concentration in moles per liter, and d and d_0 are the density of solution and solvent respectively. Values of ϕ and densities are summarized in Table I. Partial molal volumes $\bar{V}^0$ were then obtained from ϕ and its concentration dependence using the relation

$$\phi = \bar{V}^0 + SC^{1/2}$$

where S is the limiting slope. The values of $\bar{V}^0$ and S for each solvent composition are

water ; $\phi = 105.1 + 2.4\,C^{1/2}$

0.10 mole fraction ethanol ; $\phi = 99.5 + 16.7\,C^{1/2}$

0.20 " " " ; $\phi = 89.7 + 49.5\,C^{1/2}$

0.30 " " " ; $\phi = 86.7 + 54.5\,C^{1/2}$

0.40 " " " ; $\phi = 89.0 + 41.0\,C^{1/2}$

Discussion

The data presented in Fig. 1 show that the behavior of $\bar{V}_t$ for benzyl chloride from pure

water up to 0.1 mole fraction ethanol is remarkably similar to the behavior of the volumes of both $Me_4N^+Cl^-$ and $C_6H_5NH_3{}^+Cl^-$. Beyond this point, however, there is marked divergence and the shape of the $\overline{V}_t$ curve is much more similar to that for the partial molal volume of $Et_4N^+Cl^-$. The marked reduction in volume for anilinium chloride up to 0.3 mole fraction is not observed for $\overline{V}_t$. This can only mean that the charge density and hence the electrostriction caused by the transition state of benzyl chloride is considerably less than in anilinium chloride, but it is still somewhat greater than the surface charge associated with $Et_4N^+Cl^-$.

We can conclude, therefore, that while anilinium chloride is a fair structural model for the solvolysis transition state of benzyl chloride there is less charge development in the transition state than is represented by anilinium chloride. The surface charge density on the transition state, however, is not by any means small, since the volume behavior establishes that it is at least as great as that characteristic of $Et_4N^+Cl^-$. It must be remembered, however, that what is being observed in these studies is the *sum* of the electrostriction effects of both the anion and the cation.

The similarity in behavior of the transition state and $Et_4N^+Cl^-$, therefore, merely implies that the sum of the electrostriction effects at 0.3 mole fraction are comparable. Nothing is implied about the relative charge densities on the individual ions; for example, the degree of charge development in the transition state may well be much less than the full ionic character of $Et_4N^+Cl^-$, but the charge that has developed in the transition state may be much more accessible to the solvent than is the case in the bulkier tetraethylammonium cation.

There is obviously a temptation to use the evidence presented here to comment on the question as to whether benzyl chloride solvolysis is S_N1 or S_N2! This temptation will be resisted if for no other reason than the fact that we have already described the transition state, through comparison with models, in much greater detail than the S_N1–S_N2 categorization is capable of doing. Charge is developed in passing from the initial to the transition state and the accessibility of solvent to that charge is intermediate between that for anilinium chloride and tetraethylammonium chloride. Whether solvent interaction with the transition state is describable as "covalent interaction" or "ion–dipole electrostriction" is not a resolvable question at present.

Distortions in tetrahedral copper(I)–phosphine complexes : bis(triphenylphosphine)copper(I) nitrate

G. G. MESSMER AND GUS J. PALENIK
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received October 30, 1968

The crystal structure of bis(triphenylphosphine)copper(I) nitrate has been determined by a three-dimensional X-ray diffraction study. The copper(I) atom is bonded to the two phosphines and two oxygen atoms of the nitrate group. However, the molecule is distorted from that of an ideal tetrahedron, with the P—Cu—P angle being 131.1°.

Canadian Journal of Chemistry, **47**, 1440 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The molecular structure of bis(triphenylphosphine)copper(I) nitrate has been in question since the compound was first prepared by Cotton and Goodgame (1). The various structures suggested include a tricoordinate monomer (1), a nitrate bridged dimer (1), and a monomer involving a bidentate nitrate group (2). We undertook an X-ray crystal structure determination to resolve these conflicts. The results of our study have raised a number of questions regarding the nature of the copper–phosphorus bond and dπ–dπ bonding.

Bis(triphenylphosphine)copper(I) nitrate was prepared following the method reported by Cotton and Goodgame (1). Long acicular crystals were grown by slowly cooling a hot saturated ethanol solution. The crystals are monoclinic with $a = 22.254$, $b = 9.197$, $c = 15.440$ Å, $\beta = 101.56°$, and 4 molecules per unit cell, with the space group $I2/a$ or Ia. The intensities were measured using a General Electric Diffractometer, automated by the Datex Corporation. A total of 4197 measurements were made employing molybdenum radiation ($K\alpha_1 = 0.70926$ Å) and the stationary crystal – stationary counter technique. After averaging the equivalent reflections and correcting for the background, a total of 1343 reflections were considered as observed and used in the analysis.

The three dimensional Patterson yielded trial coordinates for both the copper and phosphorus. The symmetry appeared to be $I2/a$ which is in agreement with the statistical distribution of intensities. The positions for the light atoms were determined from electron density calculations. The trial structure was refined by full-matrix least-squares methods, first with isotropic thermal parameters, then with anisotropic thermal parameters to an R of 0.074.

The molecular structure of bis(triphenylphosphine)copper(I) nitrate is that of a bidentate nitrate monomer. However, the angular distortions are among the largest observed for the nominally tetrahedral copper(I) atom. The P—Cu—P angle is 131.1°, which is larger than the P—Cu—P angle of 123.3° reported by Lippard and Melmed (3) in borohydridobis(triphenylphosphine)copper(I), or the angle of 123.8° reported by Corfield and Shearer (4) in phenylethynyl(trimethylphosphine)copper(I). The large P—Cu—P bond angles in the three complexes cannot be rationalized on the basis of steric repulsions since the trimethylphosphine ligand is smaller than the triphenylphosphine ligand. Furthermore, the P–metal–P angles in four other coordinate complexes involving triphenylphosphine as a ligand are smaller than in the present case. For example, the P—Ni—P angle in $Br_2Ni[(C_6H_5)_3P]_2$ (5) is 110.4°, where Ni—P is 2.333 Å, and the P—Pt—P angle is 98.2° in $[(C_6H_5)_3P]_2PtCO_3$ (6), where the P—Pt distance is 2.24 Å. The metal–P distances in the Ni and Pt complexes are reasonably close to the Cu—P distances (2.222 to 2.276 Å) found in the three Cu(I)–phosphine complexes. The larger angle found in the nitrate complex relative to that in the borohydride case may indicate increased dπ–dπ bonding in the latter structure. Further structural studies are in progress on other phosphine copper(I) complexes to aid in understanding the distortions in these compounds.

The nitrate group is bidentate with N—O distances of 1.24 Å for N—O (bridging) and 1.16 Å for N—O (terminal). The shorter N—O

distance is uncorrected for thermal motion, which would increase the N—O length by 0.03 to 0.06 Å. The analysis of the thermal parameters will be carried out after our refinement is concluded.

The transmission of a species of mass m over a one-dimensional barrier can be estimated from the Wigner (1) current formula

$$[1]\quad \text{Current} = e^{-\beta V_0}\left(\frac{1}{\beta} - \frac{\hbar^2\beta}{24m}V_2 - \frac{\hbar^2}{96m}\frac{V_4}{V_2}\right)$$

where $\hbar$ = Planck's Constant/2π, and $\beta = 1/kT$, with k = the Boltzmann constant and T = the absolute temperature.

Usually the first term in $\hbar^2$ is considered as providing an adequate measure of tunneling so that

$$[2]\quad \text{Tunneling} = T_1 = -e^{-\beta V_0}\left(\frac{\hbar^2\beta}{24m}V_2\right)$$

$V_2/2$ can be taken as the coefficient of the quadratic term in a parabolic representation of the potential for small x as

$$[3]\quad V(x) = V_0 + x^2\frac{V_2}{2}$$

If V_0 is fixed as the height of the barrier, V_2 can be found by a least squares fit to either a discrete set of $V(x)$ and x, or the $V(x)$ generated by an appropriate analytical form. The value obtained for V_2 and the accuracy of the representation of the potential by eq. [3] will, of course, depend on the potential and how closely it is approximated by the parabola [3]. The values of V_2 obtained, when some of the more common types of potential are represented by eq. [3], are given in the second column of Table I. The ratio of the current for a parabola with a given height and width to the current for a different type of potential with the same height and width is given in the last column as the "shape factor". This clearly shows that different barrier types, having the same height-to-width characteristics, yield currents differing by as much as a factor of 2 from one another. Obviously care should be exercised in assessing barrier characteristics, e.g. width, from a knowledge of tunneling current only. Conversely any calculated tunneling contribution will depend on the shape assumed for the potential.

The equation for T_1 may be converted to an expression in terms of height and width. This is done quite simply by first defining that width = $W = 2|x_n|$ where x_n is the value of the argument when the potential $V(x_n) = V_0/n$. Here n is an

TABLE I

Tunneling as a function of barrier shape*

Barrier type	V_2	Second Wigner term $e^{+\beta V_0} \times T_1 \times 10^{16}$	T_1(parabola)/T_1(curve) = shape factor
Parabola	-1.042×10^5	14.57	1.0
Gaussian	-1.676×10^5	23.44	0.62
Eckart	-1.837×10^5	25.69	0.57
exp $(-a\|x\|)$	-2.392×10^5	33.45	0.45

*Barrier height = $V_0 = 1.7368 \times 10^{-12}$ ergs/molecule (25 kcal/mole), temperature = 300 °K, particle mass = $m = 8 \times 10^{-23}$ g, barrier width at 1/4 height = $W = 1$ Å.

integer, for example, $n = 2$ for a width defined as "width at half-height". Solving eq. [3] for x_n gives

$$x_n = \pm \left[\frac{-2V_0}{V_2} \left(\frac{n-1}{n} \right) \right]^{1/2}$$

But

$$W = 2|x_n| = 2 \left[\frac{-2V_0}{V_2} \left(\frac{n-1}{n} \right) \right]^{1/2}$$

and since V_0 = height = H this gives

$$V_2 = -8 \frac{H}{W^2} \left(\frac{n-1}{n} \right)$$

Hence, the tunneling current can be expressed in terms of more familiar height and width parameters as

$$T_1 = \left(\frac{\hbar^2 \beta}{3m} \right) \frac{H}{W^2} \left(\frac{n-1}{n} \right) e^{-\beta H}$$

so that

[4] Current =

$$e^{-\beta H} \left[\frac{1}{\beta} + \frac{\hbar^2 \beta}{3m} (H/W^2) \left(\frac{n-1}{n} \right) \right]$$

Equation (4) is the same numerically as T_1 in the first row of Table I and, as indicated in Table I, is different, by a factor, from T_1 obtained for the other types of potentials. When the height and width are evaluated for the different potential types given in Table I, the value of T_1 obtained by eq. [4] is very nearly the same as the value given by the product of the shape factor and T_1, as obtained by the more tedious curve fitting method, i.e., T_1(by curve fitting)·(shape factor) = T_1 (by simple height-to-width formula, eq. [4]). Consequently, if the shape factor appropriate to the potential of interest is read from Table I, then eq. [4] can be used to quickly obtain the tunneling current for a large variety of values of H and W for various potential types.

In all of the foregoing, only the first two terms of eq. [1], resulting from the parabolic potential [3], were used in obtaining the current. Certainly potentials which differ markedly in shape from that of a parabola would be better represented by

$$[5] \qquad V(x) = V_0 + \frac{V_2}{2!} x^2 + \frac{V_4}{4!} x^4$$

and consequently both the second and third terms of eq. [1] would be used to generate the quantum mechanical tunneling current.

$$[6] \quad T = -e^{-\beta V_0} \frac{\hbar^2 \beta}{24m} V_2 - e^{-\beta V_0} \frac{\hbar^2}{96m} \frac{V_4}{V_2}$$

$$= T_1 + T_2$$

Again V_2 and V_4 can be obtained by a least squares fit to a set of $V(x)$ and x and will differ somewhat depending on the shape of the potential. However, this variation will be less since the fourth order term allows better accommodation of the variations in shape. What appears to be more important is the range of x over which the fitting is carried out. In Wigner's derivation, the potential in [5] was assumed to be valid over the "transition region", i.e., the region in which the distribution function was significantly different than that obtained classically. Specifically, since tran-

sition over the barrier was considered, the "transition region" of interest was for small values of x. Consequently eq. [5] must be made to fit the potential only over the appropriate small range of x encompassing the "transition region". Table II indicates the ratio T_2 to T_1 for different transition regions. The third term, T_2, is very dependent on the magnitude of the transition region. Consequently any estimation of the significance of the third term in the calculation of the tunneling current can lead to serious errors unless care is taken in estimating the dimensions of the "transition region".

Stereochemistry of bimolecular nucleophilic opening of a dioxolenium ring fused to an anchored cyclohexane system[1]

J. F. KING[2] AND A. D. ALLBUTT

Department of Chemistry, University of Western Ontario, London, Ontario

Received November 18, 1968

This paper describes the characterization of certain dioxolenium salts in which the heterocyclic ring is fused (via positions-4 and -5) to an anchored cyclohexane ring, and the steric course of their bimolecular cleavage with nucleophilic reagents. It was found that diaxial opening is normally favored strongly over diequatorial; this is accounted for in terms of differences in angle strain in the transition states. The presence of an axial (angular) methyl group gave a preference for diequatorial opening; on the other hand an analogous investigation of the diaxial : diequatorial opening ratio with epoxides showed the stereochemistry of the reaction to be virtually insensitive to an angular methyl group. These observations are interpreted in terms of the different non-bonded interactions arising from the different geometrical arrangements of epoxides and dioxolenium ions. The variation in the diaxial : diequatorial opening ratio is shown to be of significance in the interpretation of rates of diaxial → diequatorial rearrangement.

Canadian Journal of Chemistry, 47, 1445 (1969)

Introduction

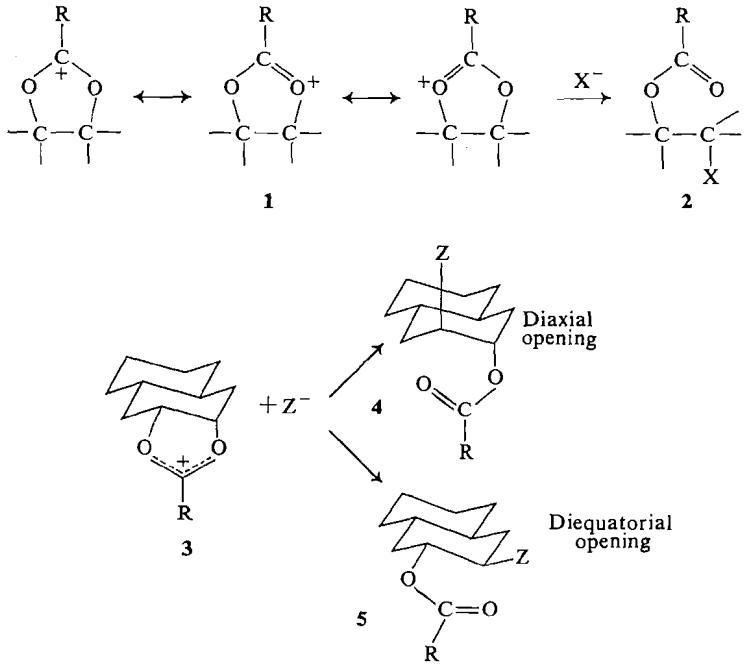
Dioxolenium or acyloxonium ions (**1**) have comparatively recently achieved the status of species whose existence, both as transitory intermediates and isolable products, has been rigorously proved (1). Amongst the characteristic reactions of such species is nucleophilic displacement at one of the uncharged carbon atoms, e.g. **1** → **2**, a reaction known to take place with inversion of configuration. When a dioxolenium ring is fused to an anchored six-membered ring[3] as in **3**, the two oxygen atoms differ in their stereochemistry and attack of **3** by an unspecified nucleophile Z^- could lead in principle to either the diaxial product **4**, or its diequatorial isomer **5**. For reasons connected with our study of the diaxial → diequatorial rearrangement (2) and which are dealt with more fully elsewhere in this paper, we wished to know the ratio of the amount (or rate) of diaxial opening to that for diequatorial; throughout this paper this is referred to as the diaxial:diequatorial opening ratio. Contemplation of the question led to the realization that it was part of the larger problem of the stereochemical course of S_N2 reactions in six-membered ring systems and warranted study in its own right.

An attempt to predict the diaxial:diequatorial opening ratio of dioxolenium ions was unsuccessful because it revealed the existence of opposing influences of uncertain magnitude (cf. ref (2)). From the work of Eliel and co-workers on S_N2 reactions of 4-*t*-butylcyclohexyl derivatives (3), one might expect that displacement of the axial oxygen (diequatorial opening) might be the easier reaction. But bimolecular nucleophilic attack on *three-membered* rings fused to six-membered systems almost invariably takes place with displacement of the quasi-equatorial function — i.e. diaxial opening; included within the scope of this "diaxial opening rule" at present are epoxides (4), three-membered ring halonium ions (5),

[1]Part of the work described in this paper has been published in preliminary form: J. F. King and A. D. Allbutt. Chem. Commun. 14 (1966).

[2]Fellow of the Alfred P. Sloan Foundation, 1966–1968.

[3]We use the term *anchored* in this paper to denote a six-membered ring in the chair conformation which is sterically constrained so that conformational inversion to the other chair form is either impossible or of such high energy as to be of no importance. Such a system is not truly rigid (though we have used this description previously), since it may flip into boat forms (either twist or symmetrical).



ethylenimmonium ions (6), and episulfonium ions (7). Because of the ring strain introduced by the presence of the three-membered ring in these systems, it is evident that any extensions to predict the behavior of five-membered ring systems would have to be made with caution, but examination of molecular models suggested (2) that the opening of dioxolenium ions may also show signs of ring strain in the diequatorial opening not present in the diaxial cleavage. It was evident that at the outset of this study there was not sufficient basis for making any sort of a quantitative prediction of the diaxial:diequatorial opening ratio and we thereupon set out to investigate the question experimentally.

Results and Discussion

Synthesis and Proof of Structure of the Dioxolenium Ions

Winstein and Buckles (8) first provided evidence that treatment of vicinal halohydrin esters with silver salts gave the dioxolenium ion as a transitory intermediate, and Meerwein *et al.* (9) showed that if the anion were sufficiently inert the dioxolenium salt could be isolated. Accordingly we treated 2β-bromo-5α-cholestan-3α-yl anisate (**6**) with silver hexafluoroantimonate and obtained the dioxolenium hexafluoroantimonate (**7**) as white crystals melting at 196–198°.

The infrared spectrum of **7** shows no absorption from 1610 to 2000 cm^{-1}, but the 1400–1600 cm^{-1} region displays four prominent bands, at 1600(m), 1540(m), 1465(s), and 1435(m), respectively. These four bands are found with the other two anisoxonium hexafluoroantimonates **3***a* and **10***a*, whereas the benzoxonium species **3***b* and **10***b* show bands at 1600(m), 1520(s), and 1460(s) cm^{-1}. Magnuson, *et al.* (10) reported that 2,4,4,-5,5-pentamethyldioxolenium perchlorate absorbs strongly at 1536 and 1511 cm^{-1}. As a consistent interpretation we suggest that the stretching modes of the O—C—O system in the dioxolenium ions are 1520 and 1460 cm^{-1} for the 2-phenyl substituted (benzoxonium) compounds, and 1460 and 1435 cm^{-1} for the *p*-methoxyphenyl (anisoxonium) species. The lower frequency of the *p*-methoxyphenyl- vs. phenyl-, as well as phenyl- vs. methyl-substituted compounds, is ascribable to conjugation. The bands at 1600 cm^{-1} and 1540 cm^{-1}, are probably due to the aromatic system. All of the hexafluoroantimonates showed strong absorption at 660 cm^{-1} characteristic of the SbF_6^- anion.

The nuclear magnetic resonance (n.m.r.) spectrum of **7** was also consonant with the dioxol-

6 7

enium ion structure, with a singlet at 4.0 p.p.m. due to the methoxyl group, a broad multiplet around 5.8 p.p.m. arising from the hydrogens on C-2 and C-3. The aromatic absorption might be described either as a widely spaced quartet or a slightly perturbed pair of doublets at respectively 8.26 and 7.17 p.p.m., (J = 9 c.p.s.). These bands are in excellent agreement with the presence of a strongly electron-withdrawing group para to the methoxyl function. The other hydrogens of the steroidal skeleton absorbed between 0.5 and 2.0 p.p.m., the C-19 hydrogens evidently appearing at 0.83 p.p.m. (for further information see the more detailed account elsewhere (11)).

Carbon and hydrogen analyses were in good agreement with the oxonium ion structure **7**, which was further supported by the chemical reactions of the material. Treatment with tetraethylammonium bromide gave the expected mixture of the diaxial and diequatorial bromohydrin anisates; the relative amounts of the two isomers is, of course, the subject of prime interest of this account and is discussed more fully below. Reaction of **7** with dilute acetic acid, which was virtually instantaneous, gave a half ester which on alkaline hydrolysis gave the known glycol 5α-cholestan-2α,3α-diol (12). Of the two possible half esters, that in which the anisoxyl group is axial was formed in much greater amount, this remarkable stereoselectivity has already been reported in a brief communication (13), and will be discussed more fully in a subsequent publication.

It is clear that the physical and chemical data unambiguously establish **7** as the structure of the product obtained by reaction of **6** with silver hexafluoroantimonate. A number of other dioxolenium hexafluoroantimonates (**3***a*, **3***b*, **10***a*, and **10***b*) were obtained similarly. In all instances the spectroscopic and chemical properties were analogous to those already described for **7** and were clearly compatible only with the dioxolenium ion formulations, though in certain instances the carbon analysis was somewhat low, perhaps because the samples may have taken up water prior to analysis.

Bimolecular Nucleophilic Cleavage of the Dioxolenium Ions

Each of the dioxolenium salts was treated in solution with tetraethylammonium bromide. The reaction was practically instantaneous and gave a good yield of the mixed halohydrin esters. The total yields of the ester mixtures and the relative amounts of diaxial and diequatorial products in each mixture are listed in Table I. No particular attempt was made to optimize the reaction conditions, as the diaxial:diequatorial opening ratio appeared completely insensitive to the total yield. Methylene chloride was used as the reaction solvent in comparing the different substrates. Reaction of **7** in nitromethane and acetonitrile solutions gave little or no change from methylene chloride.

It is evident that the salt derived from decalin (**3**) most closely approximates the simple cyclohexane system, whereas the steroidal derivatives because of the presence of angular methyls and other perturbing groups might be expected to deviate to a greater or lesser degree from the norm. The "norm" as manifest by the reaction of **3**, is that diaxial opening is favored to the extent of about 20:1. The β-oxonium salts **10***a* and **10***b* behave very similarly, an observation which is not surprising since the stereochemical changes on proceeding from the initial to the transition state would be expected to be much the same as in the decalin derivative. Similarly, variation of the nature of the attacking nucleophile did not affect the reaction very much, chloride ion giving

almost exactly the same diaxial:diequatorial opening ratio. That found with the benzoate anion is somewhat lower, though still strongly favoring the diaxial product. This is similar to an observation made by Meakins and co-workers (14) who found a diaxial:diequatorial opening ratio of 9 under the conditions of the Prevost reaction in benzene at room temperature.

Reaction of the α-oxonium salt **7**, however, might be expected (cf. ref. (2)) to be different, because in the transition state for diaxial opening the attacking nucleophile must certainly be close enough to the angular methyl group (C-19) to experience strong repulsion that is without counterpart in the diequatorial cleavage. The experimental results are clearly in accord with these considerations, the major product being the *diequatorial* isomer, though only by a factor of two.

This observation is to be contrasted with that made with the corresponding epoxide, 5α-cholestan-2α,3α-epoxide (**11**). This compound like its β-isomer (**14**), when cleaved with hydrobromic acid has been reported to give the diaxial isomer as the only isolated product (15). After some reflection it seemed to us that there could be two distinct situations which could lead to the difference in sensitivity to introduction of the angular methyl group shown by 2α,3α-dioxolenium species and the 2α,3α-epoxide. On the one hand it is possible that the methyl group increases the activation energy for diaxial opening by the same amount in both the dioxolenium and epoxide reactions, and that there is simply a much

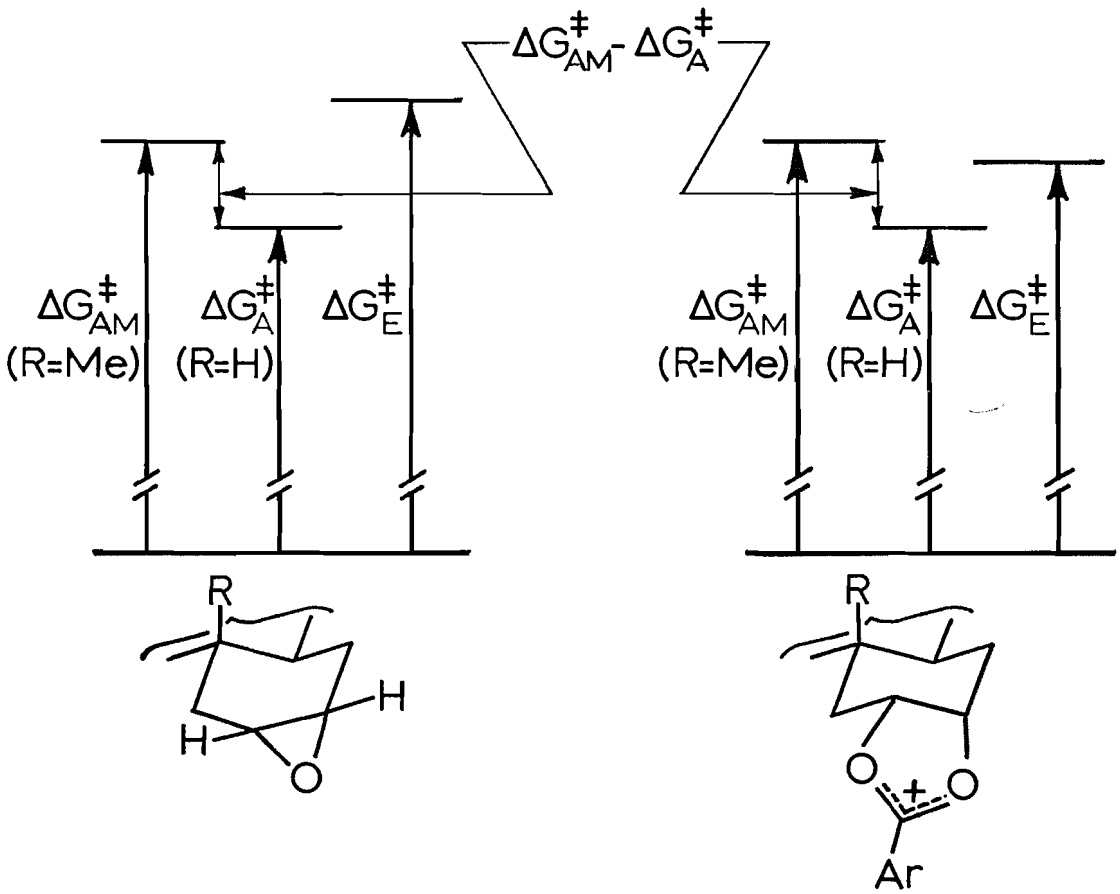

FIG. 1. Schematic energy diagram for the effect of angular methyl groups on the cleavage of epoxide and dioxolenium systems in which $(\Delta G^{\ddagger}_{E} - \Delta G^{\ddagger}_{A})_{epoxide} > (\Delta G^{\ddagger}_{AM} - \Delta G^{\ddagger}_{A})_{epoxide} = (\Delta G^{\ddagger}_{AM} - \Delta G^{\ddagger}_{A})_{dioxolenium\ ion} > (\Delta G^{\ddagger}_{E} - \Delta G^{\ddagger}_{A})_{dioxolenium\ ion}$.

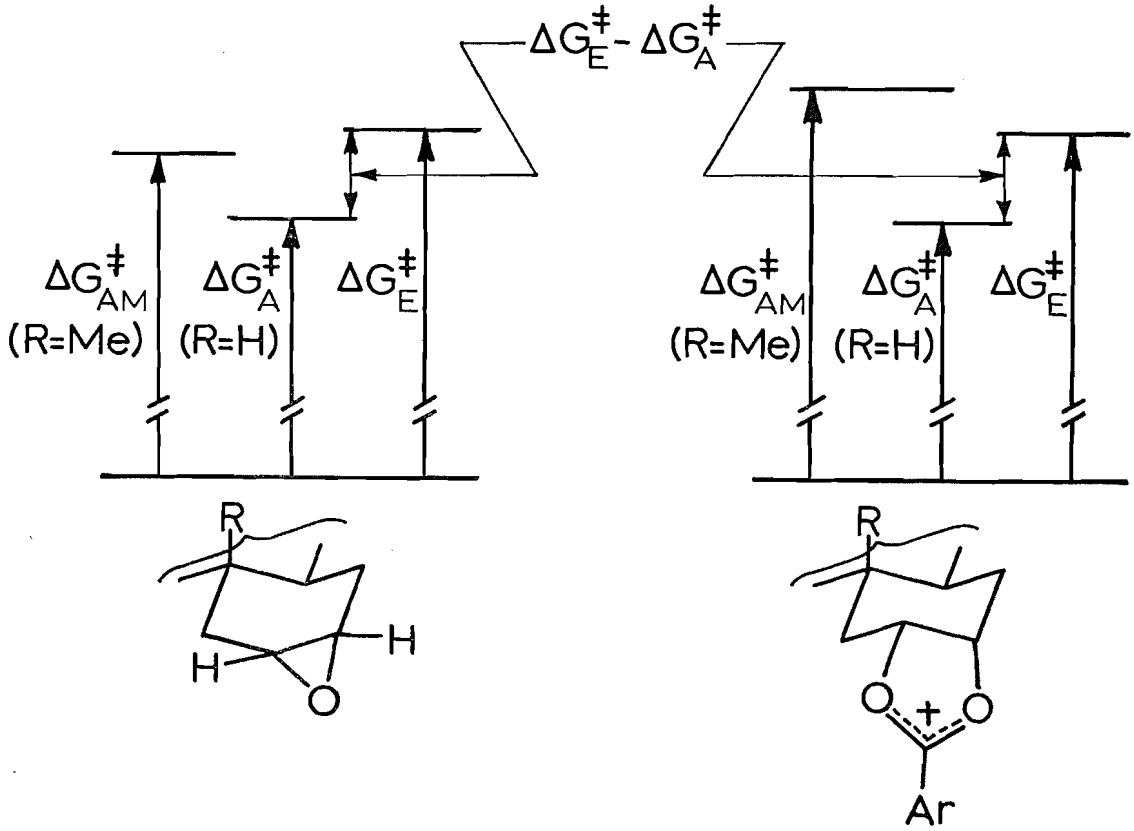

FIG. 2. Schematic energy diagram for the effect of angular methyl groups on the cleavage of epoxide and dioxolenium systems in which $(\Delta G_{EM}^{\ddagger} - \Delta G_A^{\ddagger})_{\text{dioxolenium ion}} > (\Delta G_E^{\ddagger} - \Delta G_A^{\ddagger})_{\text{dioxolenium ion}} = (\Delta G_E^{\ddagger} - \Delta G_A^{\ddagger})_{\text{epoxide}} > (\Delta G_{AM}^{\ddagger} - \Delta G_A^{\ddagger})_{\text{epoxide}}$.

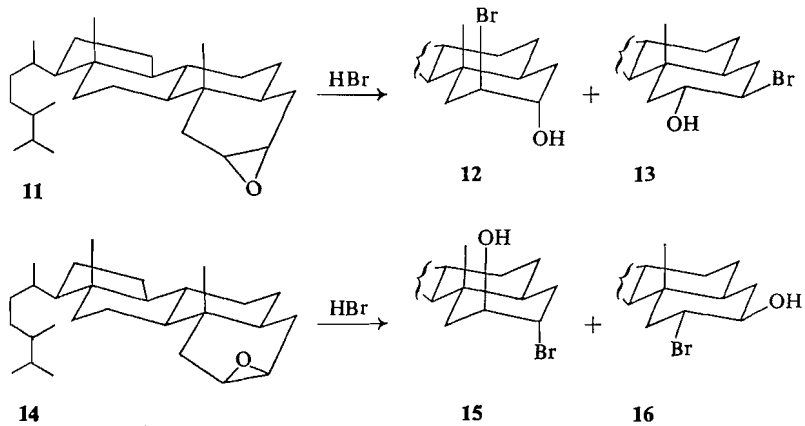
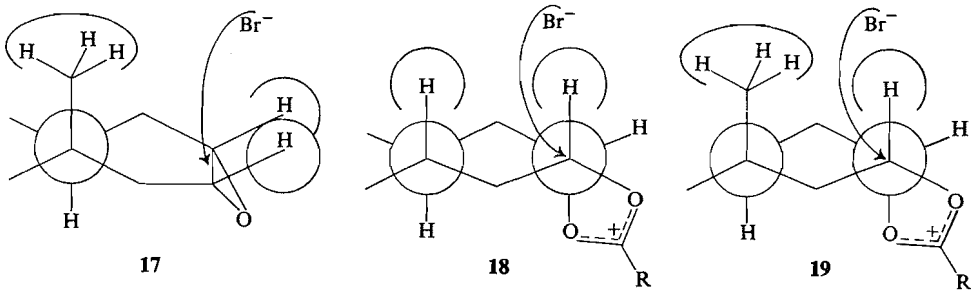


greater tendency for the epoxide to open diaxially. The energy relationships for such a situation are summarized schematically in Fig. 1. The effect of introducing the angular methyl group leads to an activation energy increase of $\Delta G_{AM}^{\ddagger} - \Delta G_A^{\ddagger}$ which is the same for both the epoxide and dioxolenium ion cleavages, but which is less than $\Delta G_E^{\ddagger} - \Delta G_A^{\ddagger}$ in the epoxide case (and hence



diaxial opening predominates) and greater than $\Delta G_E^{\ddagger} - \Delta G_A^{\ddagger}$ in the dioxolenium ion opening. The latter circumstance leads to the major reaction being diequatorial opening. On the other hand the same experimental consequence would result from the circumstances summarized in Fig. 2. In this case the unperturbed epoxide and dioxolenium ion have the same diaxial:diequatorial opening ratio and the effect of the methyl group is greater with the dioxolenium ion opening — sufficiently so as to make diequatorial opening preferred. It is evident that each of these two possible situations is, in fact, an extreme case in which the observed result derives entirely from one cause; it is, of course, entirely possible that the actual circumstance has its origins partly from one effect partly from the other.

To obtain a semi-quantitative estimate of the relative importance of these factors it is merely necessary to acquire data for the opening of the corresponding epoxides analogous to those listed in Table I for the dioxolenium ion reactions. Estimation of the composition of the product of the reaction of *trans*-decalin-2,3-epoxide with hydrobromic acid proved impracticable by the thin-layer chromatographic procedures that had been of such value in obtaining the data in Table I, though the presence of the diaxial bromohydrin as the major product and the diequatorial bromohydrin in small amount was indicated. With the steroidal epoxides **11** and **14**, however, the diaxial:diequatorial opening ratios were found to be 97:3 and 95:5 for the β-epoxide **14** and α-epoxide **11**, respectively. These correspond to $\Delta G_E^{\ddagger} - \Delta G_A^{\ddagger}$ values at room temperature of 2.1 and 1.7 kcal/mole, and are very close to the value of 2.3 kcal/mole found for the opening of the β-anisoxonium salt **9***a* (and also to the 1.7 kcal/mole found with the decalin dioxolenium salt **3**). Introduction of the angular methyl group in the epoxide case thus has little if any effect, whereas in the dioxolenium ion reaction it makes diaxial opening more difficult by roughly 2 kcal/mole. These results indicate that the reality corresponds remarkably closely to the situation depicted in Fig. 2.

The probable origin of this circumstance is perhaps most simply explained with reference to structures **17–19**. It is apparent that because of the relative openness of the epoxide system, attack on C-2 as indicated by the arrow in **17** ought to be comparatively facile. With the dioxolenium ion, the introduction of the angular methyl group places a large obstacle directly in what would be the path of any group about to initiate diaxial opening of the dioxolenium ring, and the reaction path indicated by the arrow in **19** will have severe non-bonded interactions in the transition state not present in the process shown in **18**.

Origin of the Normal Preference for Diaxial S_N2 Opening of Dioxolenium Ions

As a preliminary to understanding how the normal preference for diaxial opening of dioxolenium ions by bimolecular nucleophilic attack arises, it is instructive to examine the geometry of the transition state of the S_N2 reaction of a simple cyclohexane derivative. Structures **20–23** illustrate, albeit in somewhat oversimplified form, the change in geometry between the starting material and the transition state for displacement by a nucleophile N^- of a substituent X which is respectively equatorial and axial. The simplest case, in which the substituents on both carbons α to the reacting center are hydrogen atoms, has been the subject of a penetrating analysis by Eliel (3, 16). When N^- is larger than X^- it is found that the axial isomer reacts faster than the equatorial; for $N^- = PhS^-$ and X = tosylate, in 87% ethanol at 25°, $\Delta G_{Eq}^{\ddagger} - \Delta G_{Ax}^{\ddagger} = 2.1$ kcal/mole. Part of the difference in activation energy is ascribed to the difference in free energy of the

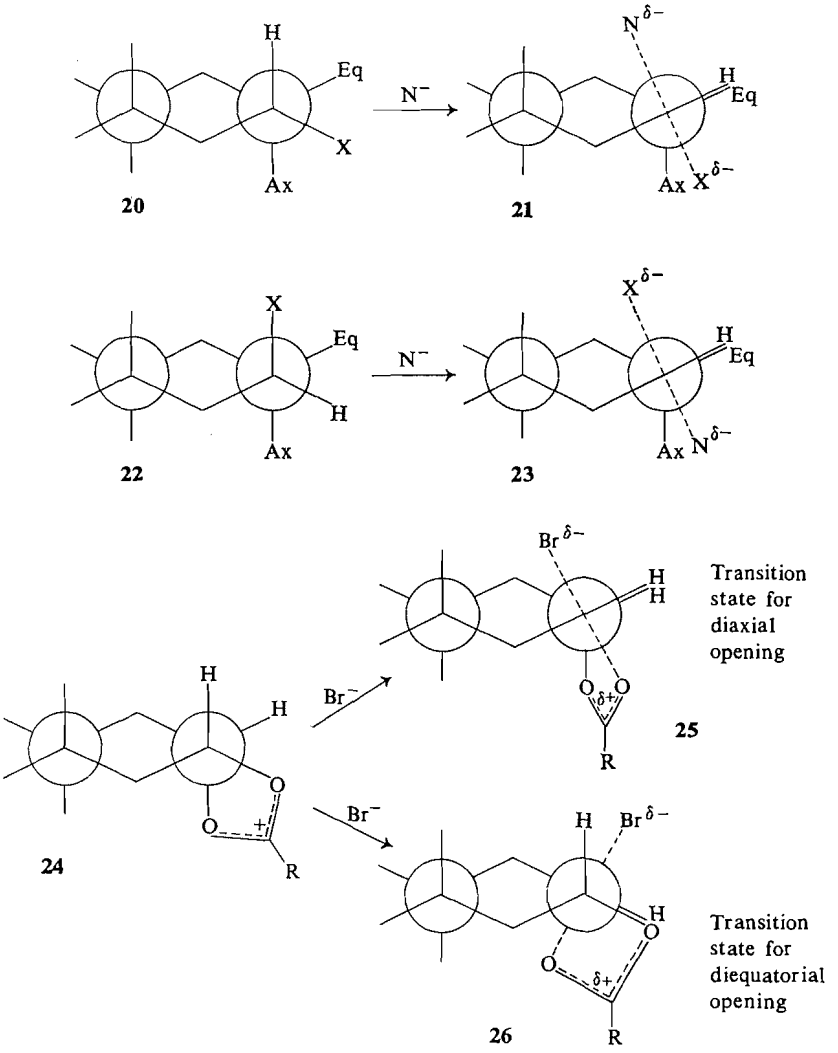
For personal use only.



starting materials, $-\Delta G^{\circ}_{OTs}$ (the "*A* value") being about 0.7 kcal/mole. The remainder (1.4 kcal/mole) is believed to be largely due to the non-bonding interactions of the quasi-axial group in the transition state; i.e. when N is larger than X, these interactions are greater in **21** than in **23**.

If one of the α-carbon atoms bears a substituent then other factors must be added to those already considered by Eliel. Relevant to the present discussion are the circumstances which arise when this substituent is *cis* to the leaving group. When the leaving group is equatorial the α-*cis* substituent is axial, and in the transition state (**21**) the dihedral angle between the α-*cis* substituent (Ax) and the leaving group (X) is 30°. On the other hand when the leaving group is axial, the α-*cis* substituent is equatorial; in the transition state the dihedral angle is 90°, and the hydrogen attached to the carbon undergoing exchange of substituents and the α-*cis* function become eclipsed.

In the event that the α-*cis* group and the leaving group form a ring, as in the dioxolenium ion system described in this paper, the effect of this alteration in the dihedral angle is to flatten the substituent ring when the leaving group is equatorial and to pucker the same ring when the leaving group is axial. Structures **24–26** display in somewhat idealized fashion this effect for the dioxolenium ion system. It would seem very

For personal use only.

likely that the preferred conformation of a free dioxolenium ion is a flat or very nearly flat ring, but fusion with a cyclohexane ring probably requires the dioxolenium ring to be somewhat puckered as indicated in **24**, and (though not shown in **24**) the cylohexane ring probably to be somewhat flattened. Displacement of the axial oxygen (diequatorial opening), which would be preferred in the simpler system described by Eliel, would lead to greater puckering of the heterocyclic system (as in **26**), that is to say, to a considerable increase in the angle strain. Diaxial opening, on the other hand, results in a diminishment of the puckering in the ring (as in **25**) and hence to a lessening of the angle strain. It would appear that this effect of angle strain, perhaps with an eclipsing interaction between oxygen and hydrogen added, is sufficient to completely overshadow the non-bonding interaction effects which presumably control the stereochemistry in the absence of α-substituents.

It is perhaps illuminating to compare this rationale with the currently accepted interpretation of the diaxial preference in the opening of epoxides and other three-membered ring species. Inspection of molecular models readily leads to the expectation that diaxial opening of an epoxide would be expected to be facile, but the corresponding direct diequatorial opening is difficult to visualize. It is probably easier to consider the reverse process, i.e. the formation of an epoxide, for example, by internal displacement. The formation of the epoxide from the diaxial starting material **27** is sterically favorable, but from the diequatorial anion **28** the formation of the ring would require a remarkable distortion of the normal bond angles in order to follow the arrows. For comparison, the formation of a dioxolenium ion is illustrated analogously by **29** and **30**. Again with the diaxial substrate **29** the reaction is straightforward, but with **30** the angular distortions are not so great that one can dismiss the possibility out of hand. For the diequatorial opening (or formation from diequatorial starting materials) of epoxides and other three-membered ring species, it has been postulated that the reaction proceeds via a diaxial boat or flexible conformation which then flips into (or has previously flipped from) the diequatorial chair form (17, 18). It is possible that the diequatorial opening of the dioxolenium species is also taking place through a boat conformation. In our view neither examination of molecular models nor the experimental evidence available at present demands such an interpretation. The above discussion of diequatorial opening (and closing) may be summarized in the following way. With epoxides direct diequatorial opening is sterically absurd and any diequatorial product arises from the boat-diaxial compound followed by conformational inversion. With dioxolenium ions direct diequatorial opening must at the very least be considered as a possible route. There is good reason to believe that such opening would produce increased angle strain, but whether or not this is sufficient to make the activation energy for this process greater than that through the diaxial boat is unknown.

33 34 35

Returning to structures **20**–**23**, it is of interest to speculate on the possible influence of an α-substituent that is not part of a ring with the leaving group (e.g. a methyl group). If such an α-methyl group were equatorial as in **20** (or **22**), and the gauche Me:X interaction significant, then in the transition state **21** (or **23**) the Me:X interaction would be smaller than in the starting material. It is at least conceivable that this lowering of the non-bonded interaction energy would be sufficient to outweigh the eclipsing Me:H interaction and any non-bonded repulsion between the attacking nucleophile N and the equatorial methyl group. Under such circumstances the effect of introducing an equatorial α-methyl group would be to *accelerate* the S_N2 displacement with respect to the unsubstituted compound. An axial α-methyl substituent, on the other hand, would be expected to slow the reaction owing to a 30° interaction in the transition state (**21** or **23**) between the methyl group and N or X.

The Diaxial:Diequatorial Opening Ratio and the Diaxial → Diequatorial Rearrangement

As mentioned in the Introduction, the present research was instigated by questions arising from our study of the diaxial → diequatorial rearrangement (2), a reaction which may be illustrated in a general way by **31** ⇄ **32**. It has become evident that in the more polar media, at least, the diaxial → diequatorial rearrangement is in all likelihood taking place by internal return from intermediate ion pairs, e.g. **33** ⇄ **34** ⇄ **35**. It is further evident that any detailed investigation of the mechanism using the kinetic method will at some stage require some knowledge of the relative rates of the individual steps. In more specific terms, if one uses the steady state assumption (and if k_{-2} is very small), then k_a the measured rate constant for the overall reaction **33** → **35** is given by $k_a = k_1/(1+k_{-1}/k_2)$. That is, a change in k_a accompanying a change in structure (e.g. a change in X or Y), could be due to a change in either k_1 or the diaxial:diequatorial opening ratio, k_{-1}/k_2.

In investigating the diaxial → diequatorial rearrangement of **6** and **9** (in nitromethane at 99°), we found (2) that k_a for **6** was 6 times greater than that for **9**. We were reluctant to attempt any interpretation of this difference at that stage because it seemed that k_{-1}/k_2 might well be different for the two isomers, but, as mentioned at the beginning of this paper, by a magnitude which we could not predict. If one takes as a rough first approximation of k_{-1}/k_2 in nitromethane at 99°, the values of the diaxial:diequatorial opening ratio listed in Table I, then one finds that k_1 for **9** is about 5 times faster than k_1 for **6**. In other words, because of a more than 70-fold difference in k_{-1}/k_2 the relative values of k_a and k_1 for **6** and **9** are inverted. This would seem to be an instructive illustration of how the overall rate of a multistep reaction is not always an accurate indicator of the rate of the slow step.

In the context of this paper it is attractive to assign the origin of the smaller value of k_1 for **6** vs. **9**, in part at least, to non-bonding interactions in the transition state for the ionization step, and which are illustrated for the reverse process by structure **19**.

Experimental

Vacuum capillary melting points were determined with a Gallenkamp melting point apparatus, other melting points on a Köfler hot stage; they are uncorrected. Infrared spectra were obtained with Beckman IR-5 or IR-10 instruments using sodium chloride cells, except for those run in the region 600–750 cm^{-1} to analyze mixtures of bromohydrin esters, which were run on a Beckman IR-5A instrument equipped with CsBr optics and using KBr cells. Infrared spectra and rotations were run in chloroform (Fisher Spectranalyzed grade, containing 0.75% ethanol) except where another solvent is specified. Nuclear magnetic resonance (n.m.r.) spectra were run on a Varian A-60 spectrometer in $CDCl_3$, unless otherwise specified. Thin-layer chromatography (t.l.c.) was carried out using Camag silica gel DF 5, if not otherwise indicated.

Petroleum ether refers to the fraction of boiling range 30–60°. Drying of organic extracts was carried out with anhydrous magnesium sulfate. Tetraethylammonium bromide and chloride (Eastman) were recrystallized from methylene chloride – petroleum ether and dried under vacuum prior to use.

Preparation of Acyloxonium Hexafluoroantimonates

The general procedure used was similar to that des-

cribed by C.B. Anderson (19): A known amount of diaxial bromoester in nitromethane was treated with an equimolar quantity of silver hexafluoroantimonate (Alfa Inorganics Inc., Beverly, Massachussetts). After standing overnight at room temperature the reaction mixture was filtered and the filtrate evaporated under reduced pressure at room temperature. The residue was dissolved in a minimum quantity of methylene chloride and crystallization effected by the addition of anhydrous ether. The product was collected by filtration and dried under high vacuum. All of the above steps were carried out in a dry box containing phosphorus pentoxide and filled with nitrogen; in all the experiments involving these acyloxonium salts all weighings and transfers were carried out in a dry box. With the steroid bromoesters, because of their low solubility, it was found necessary to heat the reaction mixture at 50°.

5α-Cholestan-2α,3α-p-anisoxonium Hexafluoroantimonate (7)

2β-Bromo-5α-cholestan-3α-yl-*p*-anisate (**6**, 1.0 g) was treated overnight with silver hexafluoroantimonate (0.57 g) in nitromethane (10 ml) at 50°. The product was isolated as described above. Crystallization from methylene chloride : ether gave 5α-cholestan-2α,3α-*p*-anisoxonium hexafluoroantimonate (0.7 g), m.p. 196–198° (sealed capillary tube), $[\alpha]_D$ +21° (CH_2Cl_2). The n.m.r. spectrum showed signals at 0.83 (singlet), 4.0 (singlet), a broad multiplet centered at 5.77, and a signal interpreted as an AB quartet, δ_A 7.17, δ_B 8.26 p.p.m., J_{AB} 9 c.p.s. These peaks were assigned to the C-19 methyl group,[4] the methoxyl group, the C-2 and C-3 hydrogens (axial and equatorial) and to the phenyl hydrogens respectively.

Anal. Calcd. for $C_{35}H_{53}O_3SbF_6$: C, 55.40; H, 7.0. Found: C, 55.42; H, 7.0.

5α-Cholestan-2β,3β-p-anisoxonium Hexafluoroantimonate (10a)

3α-Bromo-5α-cholestan-2β-yl *p*-anisate (**9***a*, 1.82 g) was treated with silver hexafluoroantimonate (1.07 g) in nitromethane (10 ml) as described above. Crystallization from methylene chloride : ether gave 5α-cholestan-2β,3β-*p*-anisoxonium hexafluoroantimonate (**10***a*, 1.31 g), m.p. 188–189° (sealed capillary tube), $[\alpha]_D$ −74° (CH_2Cl_2). The n.m.r. spectrum showed peaks at 0.87 (singlet) and 4.03 (singlet), a broad unresolved multiplet centered at 5.82 and a quartet at 7.20 and 8.30 p.p.m., J_{AB} 9 c.p.s. These bands were assigned to the C-19 methyl group, the methoxyl group, the C-2 and C-3 hydrogens (equatorial and axial) and to the phenyl hydrogens respectively.

Anal. Calcd. for $C_{35}H_{53}O_3SbF_6$: C, 55.40; H, 7.0. Found: C, 54.95; H, 6.87.

5α-Cholestan-2β,3β-benzoyloxonium Hexafluoroantimonate (10b)

A solution of 3α-bromo-5α-cholestan-2β-yl benzoate (**9***b*, 1.07 g) in nitromethane (15 ml) was treated with silver hexafluoroantimonate (0.57 g) for 12 h at 50°. Crystallization from methylene chloride : ether gave 5α-cholestan-2β,3β-benzoyloxonium hexafluoroantimonate (**10***b*, 0.85 g), m.p. 140–141°, $[\alpha]_D$ −28° (CH_2Cl_2).

Anal. Calcd. for $C_{34}H_{51}O_2SbF_6$: C, 56.12; H, 7.07. Found: C, 55.45; H, 6.68.

9β,10α-Decalin-2β,3β-p-anisoxonium Hexafluoroantimonate (3a)

2β-Bromo-9β,10α-decalin-3β-yl *p*-anisate (**8***a*, 1.93 g) was treated with silver hexafluoroantimonate (1.8 g) in nitromethane (10 ml) as above. Crystallization from methylene chloride : ether gave 9β,10α-decalin-2β,3β-*p*-anisoxonium hexafluoroantimonate (**3***a*, 2.15 g), m.p. 178–179° (sealed capillary tube). The n.m.r. spectrum (CD_2Cl_2) had a peak at 4.02 (singlet), an unresolved multiplet at 5.78 and a quartet at 7.20 and 8.30 p.p.m., J_{AB} 9 c.p.s. These bands were assigned to the methoxyl group, the C-2 and C-3 hydrogens (equatorial and axial) and the phenyl hydrogens respectively.

Anal. Calcd. for $C_{18}H_{23}O_3SbF_6$: C, 41.32; H, 4.43. Found: C, 40.92; H, 4.61.

9β,10α-Decalin-2β,3β-benzoyloxonium Hexafluoroantimonate (3b)

2β-Bromo-9β,10α-decalin-3α-yl benzoate (**8***b*, 1.0 g) was treated with silver hexafluoroantimonate (1.0 g) in nitromethane (10 ml), as described above. Crystallization from methylene chloride : ether gave 9β,10α-decalin-2β,3β-benzoyloxonium hexafluoroantimonate (**3***b*, 1.24 g), m.p. 142–144° (sealed capillary tube). The n.m.r. spectrum (CD_2Cl_2) had an unresolved multiplet centered at 5.89 and a complex multiplet centered at 8.08 p.p.m., assigned to the C-2 and C-3 hydrogens (equatorial and axial) and the phenyl hydrogens respectively.

Anal. Calcd. for $C_{17}H_{21}O_2SbF_6$: C, 41.41; H, 4.30. Found: C, 41.49; H, 4.32.

Reaction of 5α-Cholestan-2α,3α-p-anisoxonium Hexafluoroantimonate (7) with Bromide Ion in Methylene Chloride

A solution of the salt (250 mg) in methylene chloride (10 ml) was treated with tetraethylammonium bromide (670 mg). After standing for 1 h at room temperature the reaction mixture was diluted with ether and washed several times with water, dried, and the solvent removed under reduced pressure. The product (197 mg), $[\alpha]_D$ 0°, was shown by t.l.c. (benzene) to consist of two compounds corresponding to the diaxial (R_f 0.53) and the diequatorial (R_f 0.56) bromoanisates.

The infrared spectrum showed also that a mixture had been obtained. The diaxial bromoester, 2β-bromo-5α-cholestan-3α-yl *p*-anisate (**6**) had absorption at 695 cm^{-1} (m) while the diequatorial bromoester, 3β-bromo-5α-cholestan-2α-yl *p*-anisate, had absorption at 695 (w) and 714 cm^{-1} (m). The product from the reaction above was dissolved in CS_2 to give a suitable concentration and the infrared spectrum taken between 800 and 600 cm^{-1}. Mixtures of the diaxial and diequatorial bromoanisates were prepared and dissolved in CS_2 to give the same concentration as that of the product, and their infrared spectra in the same region were determined. From a comparison of the peak heights at 714 and 695 cm^{-1} it was

[4]The assignment of the C-19 methyl peak position followed from the observation that it was only methyl peak whose position changed in the various ring A derivatives. The other methyl peaks appeared at 38, 48, and 54 c.p.s. downfield from the tetramethylsilane signal, and since these peaks did not change with the ring A substituents, they are not recorded.

concluded that the product contained approximately 68% diequatorial and 32% diaxial bromoanisate.

*Reaction of 5α-Cholestan-2β,3β-p-anisoxonium Hexafluoroantimonate (**10a**) with Bromide Ion in Methylene Chloride*

A solution of the salt (154 mg) in methylene chloride (10 ml) was treated with tetraethylammonium bromide (500 mg) for 30 min as described above. Thin-layer chromatography (benzene) showed the product to be almost entirely bromoanisate with a small amount of material at the origin (most likely hydrolysis product). The product was purified by t.l.c., using benzene as the developing solvent. The product (101 mg), $[\alpha]_D + 34°$, had an infrared spectrum almost identical with that of 3α-bromo-5α-cholestan-2β-yl *p*-anisate (**9***a*). Crystallization from methylene chloride : pentane gave 3α-bromo-5α-cholestan-2β-yl *p*-anisate (**9***a*) identified by m.p., mixture m.p., and infrared spectrum.

The two bromoesters could not be separated very easily by t.l.c. In most solvent compositions used the product showed only one spot, but, multiple elution in benzene (seven times) showed the product to consist of two materials corresponding to the diaxial and diequatorial bromoanisates, with only a trace of the diequatorial compound being present.

In a second experiment the anisoxonium salt (297 mg) gave, on treatment with tetraethylammonium bromide in methylene chloride, 229 mg of product, which was dissolved in CS_2 and its infrared spectrum around 700 cm^{-1} determined. In the infrared spectrum of the diequatorial bromoanisate, 2α-bromo-5α-cholestan-3β-yl *p*-anisate, there was a peak at 716 cm^{-1} (w) which did not appear in the spectrum of the diaxial bromoester, 3α-bromo-5α-cholestan-2β-yl *p*-anisate (**9***a*). Mixtures of the diaxial and diequatorial bromoanisates were prepared and dissolved in CS_2 to give the same concentration as that of the reaction product. From the intensity of the peak at 716 cm^{-1} in the infrared spectra of the mixtures of diaxial and diequatorial bromoanisates and in the spectrum of the product, it was estimated that there was less than 3% of the diequatorial bromoanisate present in the reaction product.

*Reaction of 5α-Cholestan-2α,3α-p-anisoxonium Hexafluoroantimonate (**7**) with Bromide Ion in Acetonitrile*

The anisoxonium salt (7, 225 mg) was treated with tetraethylammonium bromide (630 mg) in acetonitrile (10 ml) for 1 h as described above. The product, $[\alpha]_D$ 0°, had an infrared spectrum (CS_2), in the region 800 to 600 cm^{-1} which corresponded to the same product composition as obtained in methylene chloride, i.e. 68% diequatorial and 32% diaxial bromoanisates.

*Reaction of 5α-Cholestan-2α,3α-p-anisoxonium Hexafluoroantimonate (**7**) with Bromide Ion in Nitromethane*

The salt (0.23 g) was treated with tetraethylammonium bromide (0.59 g) in nitromethane (10 ml) for 23 h at room temperature as previously described, and gave 164 mg of bromoanisate mixture $[\alpha]_D + 5°$. The infrared spectrum (CS_2) corresponded to a product composition of 60% diequatorial and 40% diaxial bromoanisate.

Reaction of 9β,10α-Decalin-2β,3β-p-anisoxonium Hexafluoroantimonate (3a) with Bromide Ion in Methylene Chloride

A solution of the salt (**3***a*, 0.26 g) in methylene chloride (10 ml) was treated with tetraethylammonium bromide (1.05 g) for 1 h at room temperature as described above. The product (0.18 g) had an infrared spectrum almost identical with that of 2β-bromo-9β,10α-decalin-3α-yl *p*-anisate (**8***a*). Thin-layer chromatography [benzene : cyclohexane (1:1)], after two elutions, showed two compounds, corresponding to the diaxial (R_f 0.44) and diequatorial (R_f 0.35) bromoanisates, with only a trace of the diequatorial bromoester being present. Crystallization from petroleum ether gave 2β-bromo-9β,10α-decalin-3α-yl *p*-anisate, identified by m.p., mixture m.p., and infrared spectrum.

The crude product from above was dissolved in chloroform (0.7 ml). Mixtures of the diaxial and diequatorial bromoanisates were prepared and dissolved in chloroform to give the same concentration as that of the product. A standard number of drops of each solution were applied to t.l.c. plates which were then eluted twice with benzene : cyclohexane (1:1). The plates were sprayed with 30% sulfuric acid and charred, and the intensities of the spots compared. By this method it was estimated that the amount of diequatorial bromoanisate was approximately 5%.

Reaction of 9β,10α-Decalin-2β,3β-p-anisoxonium Hexafluoroantimonate (3a) with Chloride Ion in Methylene Chloride

A solution of the salt (**3***a*, 95 mg) in methylene chloride (10 ml) was treated with tetraethylammonium chloride (350 mg) for 30 min at room temperature. Thin-layer chromatography [benzene : cyclohexane (1:1)] after two elutions, showed the product (54 mg) to consist of almost entirely diaxial chloroanisate together with a small amount of the diequatorial compound. Crystallization from methylene chloride: methanol gave 2β-chloro-9β,10α-decalin-3α-yl *p*-anisate (38 mg) identified by m.p., mixture m.p., and infrared spectrum.

The crude product (54 mg) from the above reaction was dissolved in chloroform (0.5 ml). Mixtures of the diaxial and diequatorial chloroanisates were prepared and also dissolved in chloroform to give the same concentration as that of the product. A standard number of drops of each solution (from the same dropping pipette) were applied to t.l.c. plates, which were then eluted with benzene : cyclohexane (1:1) four times. From the intensities of the spots, after charring, it was estimated that the amount of diequatorial chloroanisate was about 6% of the product.

*Reaction of 5α-Cholestan-2β,3β-benzoyloxonium Hexafluoroantimonate (**10b**) with Bromide Ion in Methylene Chloride*

A solution of the benzoyloxonium salt (**10***b*, 250 mg) in methylene chloride (15 ml) was treated with tetraethylammonium bromide (1.0 g) for 1 h at room temperature. The product (182 mg) showed one spot upon thin-layer chromatography (benzene) and had an infrared spectrum almost identical with that of the diaxial bromobenzoate, **9***b*. Crystallization from ether : methanol

gave 3α-bromo-5α-cholestan-2β-yl benzoate (140 mg), m.p. 115–116°, mixture m.p. with authentic sample 114–115°; $[\alpha]_D$ +51°. The infrared spectrum was identical to that of an authentic sample.

Reaction of 9β,10α-Decalin-2β,3β-benzoyloxonium Hexafluoroantimonate (3b) with Benzoic Acid and N,N-Diisopropylethylamine

N,N-Diisopropylethylamine (131 mg) (Fluka AG, Buchs SG, Switzerland) was dissolved in methylene chloride (2.5 ml) and added to a solution of benzoic acid (128 mg) in methylene chloride (2.5 ml). To the resulting mixture was added the decalin benzoyloxonium salt (*3b*, 100 mg) and the solution allowed to stand at room temperature for 24 h. The reaction was washed several times with water, dried, and the solvent evaporated. Thin-layer chromatography (benzene) showed two spots corresponding in R_f values to the diaxial and diequatorial dibenzoates with only a small amount of the diequatorial compound being present. These two materials were separated by t.l.c., eluting with benzene. 9β,10α-Decalin-2α,3β-diyl dibenzoate (7 mg) crystallized from ether : methanol and was identified by m.p., mixture m.p. with authentic sample, and infrared spectrum. 9β,10α-Decalin-2β,3α-diyl dibenzoate (48 mg) crystallized from ether : methanol and was identified by m.p., mixture m.p. with authentic sample, and infrared spectrum.

Reaction of 9β,10α-Decalin-2β,3β-p-anisoxonium Hexafluoroantimonate (3a) with N,N,-Diisopropylethylamine and Trifluoroacetic Acid

N,N-Diisopropylethylamine (125 mg) in methylene chloride (2.5 ml) was added to a solution of trifluoroacetic acid (113 mg) in methylene chloride (2.5 ml). To the resulting solution the decalin anisoxonium salt (*3a*, 100 mg) was added and the reaction allowed to stand at room temperature for 36 h. The solution was washed several times with water, dried and the solvent evaporated. Thin-layer chromatography (benzene) showed the product (49 mg) to consist of almost entirely one compound together with a trace of a second compound, both being visible under ultraviolet light. Crystallization from pentane gave 9β,10α-decalin-2β-yl *p*-anisate-3α-yl trifluoroacetate, m.p. 66–68°; ν_{max} 1780, 1710 cm^{-1}. The n.m.r. spectrum showed peaks at 3.83, 5.25 (2*H*, multiplet, half-width 5 c.p.s.) and a quartet 7.95 and 6.91 p.p.m., J_{AB} 9 c.p.s. These absorptions were assigned to the methoxyl group, C-2 and C-3 hydrogens (both diequatorial) and the phenyl ring hydrogens respectively.

Anal. Calcd. for $C_{20}H_{23}O_5F_3$: C, 59.99; H, 5.79. Found: C, 59.81; H, 5.87.

Reaction of Epoxides with Hydrobromic Acid

(i) 2,3-Epoxy-9β,10α-decalin

A solution of the epoxide (20) (198 mg) in methylene chloride (20 ml) was shaken with 48% aqueous hydrobromic acid (5 ml) for 5 min. The methylene chloride solution was washed with dilute solutions of sodium bisulfite and sodium bicarbonate, water, dried and then evaporated. The residue (279 mg) was dried under vacuum.

On silica gel thin-layer chromatography [benzene : ether (1:1)] it was found that the diaxial and diequatorial bromohydrins had the same R_f value. If the t.l.c. plate was developed with iodine vapor, the diequatorial bromohydrin showed up, but the diaxial did not develop. With the product from the reaction a small amount of the diequatorial material was detected using this method. Thin-layer chromatography using Merck aluminium oxide G and ether : methanol (98:2), separation of the bromohydrins was achieved, with the diequatorial compound moving slower than the diaxial material. In the product from the epoxide opening reaction a small amount of the diequatorial bromohydrin was again detected, but owing to poor development on charring, no estimate of the amount of this compound could be made.

(ii) 5α-Cholestan-2α,3α-epoxide (11)

The epoxide (99 mg) in methylene chloride (30 ml) was treated with aqueous hydrobromic acid as described in (*i*). Thin-layer chromatography [benzene : ether (9:1)] showed the product (115 mg) to consist of a mixture of the corresponding diaxial and diequatorial bromohydrins, (**12**) and (**13**) (R_f 0.38 and 0.55) with only a small amount of the diequatorial material being present.

(iii) 5α-Cholestan-2β,3β-epoxide (14)

The epoxide (104 mg) in methylene chloride was treated as above (*i*). The residue (122 mg) was shown by t.l.c. [benzene : ether (9:1)] to be a mixture of the two possible bromohydrins, again only a small amount of the diequatorial compound being detected. In this case the diequatorial bromohydrin (2α-bromo-5α-cholestan-3β-ol, **16**) ran slower (R_f 0.39) than the diaxial bromohydrin (**15**) (R_f 0.49).

The analyses of the products from (*ii*) and (*iii*) were carried out by quantitative thin-layer chromatography in a similar manner to that described for the analysis of the decalin bromoanisate mixtures. For 5α-cholestan-2α,3α-epoxide the product mixture was estimated to consist of 95% of diaxial and 5% diequatorial bromohydrins. For 5α-cholestan-2β,3β-epoxide the product was estimated to contain 97% diaxial and 3% diequatorial bromohydrins.

Preparation of the Decalin Halohydrins

(i) 2β-Bromo-9β,10α-decalin-3α-ol

Treatment of 2,3-epoxy-9β,10α-decalin (20) with aqueous hydrobromic acid (48%) following the analogous procedure (15) for the steroidal bromohydrins gave 2β-bromo-9β,10α-decalin-3α-ol, which was purified by recrystallization from petroleum ether; m.p. 77–78°; ν_{max} 3600 cm^{-1}. The n.m.r. spectrum showed signals at 2.08 (singlet) and 4.23 (multiplet), assigned to the hydroxyl group and the protons at C-2 and C-3.

Anal. Calcd. for $C_{10}H_{17}OBr$: C, 51.50; H, 7.35; Br, 34.27. Found: C, 51.61; H, 7.32; Br, 34.44.

(ii) 2α-Bromo-9β,10α-decalin-3β-ol

A solution of 2α-bromo-9β,10α-decalin-3β-yl *p*-anisate (180 mg) plus 35% perchloric acid (2 ml) in dioxan (10 ml) was refluxed for 96 h. The reaction was diluted with water and extracted with ether; the ether extracts being then washed with dilute sodium bicarbonate solution and water, dried and evaporated. Thin-layer chromatography [benzene : ether (9:1)] showed the product to consist of two compounds (R_f 0.63 and 0.38). The faster running material had the same R_f value as the starting material and was visible under ultraviolet light. The second compound was not visible under ultraviolet light. These two

For personal use only.

materials were separated by t.l.c., the plates being developed with iodine vapor. The slower moving band gave 70 mg of 2α-bromo-9β,10α-decalin-3β-ol which was recrystallized from ether : pentane; m.p. 86–87°; ν_{max} 3480 cm^{-1}. The n.m.r. spectrum had a band at 2.57 (singlet, OH), and a broad multiplet centered at 3.75 p.p.m. (C-2 and C-3 hydrogens).

Anal. Calcd. for $C_{10}H_{17}OBr$: C, 51.50; H, 7.35; Br, 34.27. Found: C, 51.56; H, 6.93; Br, 34.40.

(iii) 2β-Chloro-9β,10α-decalin-3α-ol

Prepared by treating a solution of 2,3-epoxy-9β,10α-decalin (20) in methylene chloride (20 ml) with hydrogen chloride gas for 5 min. The reaction solution was washed with dilute sodium bicarbonate solution, water, dried, and the solvent evaporated under reduced pressure. The product was crystallized from ether : pentane; m.p. 72–73°; ν_{max} 3600 cm^{-1}. The n.m.r. spectrum had bands at 2.18 (singlet, O—H) and 4.08 p.p.m. (2*H*, half-width 11 c.p.s.).

Anal. Calcd. for $C_{10}H_{17}ClO$: C, 63.63; H, 9.08; Cl, 18.79. Found: C, 63.64; H, 8.98; Cl, 18.75.

General Procedure for the Preparation of the Halohydrin Esters from the Alcohols

About 1 to 2 equivalents of the acid chloride were added to a solution of the alcohol in 5 to 10 times its weight in pyridine. After standing at room temperature overnight, the reaction mixture was poured into ether and washed with dilute hydrochloric acid solution, dilute sodium bicarbonate solution and water, dried and the solvent evaporated. Further purification was effected by column chromatography on silica gel (British Drug Houses chromatographic grade).

(i) 3α-Bromo-5α-cholestan-2β-yl Benzoate (9b)

The alcohol was obtained as previously described (15). The ester was recrystallized from ether : methanol; m.p. 114–115°, $[\alpha]_D$ +50°; ν_{max} 1715 cm^{-1}. The n.m.r. spectrum had absorption at 4.53 (multiplet), 5.48 (multiplet), 7.57 and 8.07 (both multiplets). These bands were assigned to the C-3 hydrogen (equatorial), the C-2 hydrogen (equatorial) and to the phenyl hydrogens respectively.

Anal. Calcd. for $C_{34}H_{51}O_2Br$: C, 71.43; H, 8.99. Found: C, 71.15; H, 9.04.

(ii) 3α-Bromo-5α-cholestan-2β-yl p-anisate (9a) was prepared as described previously (2); m.p. 117–120°, $[\alpha]_D$ +36°. The n.m.r. spectrum showed signals at 1.07 (singlet), 3.88 (singlet), 4.50 (half-width 8 c.p.s.), 5.43 (half-width 8 c.p.s.), and 6.93 and 8.02 p.p.m. J_{AB} 9 c.p.s. assigned to the C-19 methyl group, the methoxyl group, the C-3 hydrogen (equatorial), the C-2 hydrogen (axial) and to the phenyl hydrogens, respectively.

(iii) 2β-Bromo-5α-cholestan-3α-yl p-anisate (6) was prepared as before (21); m.p. 107–109°, $[\alpha]_D$ +82°; reported m.p. 136–138°, $[\alpha]_D$ +83°; m.p. on admixture with an authentic specimen 134–136°. Comparison of infrared spectra and thin-layer chromatographic behavior confirmed the identity. The n.m.r. spectrum showed absorption at 1.17 (singlet), 3.87 (singlet), 4.45 (half-width 7 c.p.s.), 5.40 (half-width 7 c.p.s.), and 6.98 and 8.00 p.p.m., J_{AB} 9 c.p.s., assigned to the C-19 methyl group, the methoxyl group, the C-2 hydrogen (equatorial) the C-3 hydrogen (equatorial) and to the phenyl hydrogens respectively.

(iv) 2α-Bromo-5α-cholestan-3β-yl p-anisate was prepared as before (2); m.p. 173–175°; reported m.p. 174–176°. The n.m.r. spectrum showed bands at 0.90 (singlet), 3.88 (singlet), 4.4 and 5.1 (both broad diffuse bands) and 6.95 and 8.05 p.p.m. (J_{AB} 9 c.p.s.), attributed to C-19, C-2 and C-3 (both axial), and phenyl hydrogens, respectively.

(v) 2β-Bromo-9β,10α-decalin-3α-yl p-anisate (8a) was recrystallized from petroleum ether, m.p. 61–63°; ν_{max} 1705 cm^{-1}. The n.m.r. spectrum had signals at 3.78 (singlet), 4.50 (half-width 6 c.p.s.), 5.38 (narrow multiplet), and 6.96 and 8.00 p.p.m. J_{AB} 9 c.p.s., assigned in the same way as above.

Anal. Calcd. for $C_{18}H_{23}O_3Br$: C, 58.86; H, 6.31; Br, 21.49. Found: C, 58.99; H, 6.46; Br, 21.60.

(vi) 2β-Chloro-9β,10α-decalin-3α-yl p-anisate was recrystallized from methylene chloride : methanol, m.p. 57–59°; ν_{max} 1705 cm^{-1}. Then. m.r. spectrum showed absorption at 3.85 (singlet), 4.35 (half-width 8 c.p.s.), 5.28 (half-width 7 c.p.s.) and 6.97 and 7.99 p.p.m. J_{AB} 9 c.p.s., assigned as above.

Anal. Calcd. for $C_{18}H_{23}O_3Cl$: C, 66.95; H, 7.18; Cl, 10.98. Found: C, 66.73; H, 7.03; Cl, 11.04.

(vii) 2β-Bromo-9β,10α-decalin-3α-yl benzoate (8b) was recrystallized from methylene chloride : petroleum ether, m.p. 110–111°; ν_{max} 1710 cm^{-1}. The n.m.r. spectrum had signals at 4.47 (half-width 7 c.p.s.), 5.37 (narrow multiplet), 7.43 (multiplet) and 8.0 (multiplet), assigned to the C-2 and C-3 hydrogens and the phenyl hydrogens respectively.

Anal. Calcd. for $C_{17}H_{21}BrO_2$: C, 60.53; H, 6.28; Br, 23.69. Found: C, 60.57; H, 6.28; Br, 24.01.

(viii) 9β,10α-Decalin-2α,3β-diyl dibenzoate

The alcohol was obtained by the method of Ali and Owens (22). The ester was purified by t.l.c. (benzene) and then recrystallized from ether : methanol, m.p. 113–115°; ν_{max} 1710 cm^{-1}. The n.m.r. had bands at 5.30 (broad band), 7.33, and 7.70 p.p.m. (both complex multiplets).

Anal. Calcd. for $C_{24}H_{26}O_4$: C, 76.14; H, 6.92. Found: C, 76.24; H, 6.70.

(ix) 9β,10α-Decalin-2β,3α-diyl dibenzoate

9β,10α-Decalin-2β,3α-diol (23) was treated as described above. The product was purified by t.l.c. [ether : benzene (5:95)] and recrystallized from methylene chloride : petroleum ether; m.p. 148–150°; ν_{max} 1710 cm^{-1}. The n.m.r. spectrum had bands at 5.35 (multiplet, half-width 4 c.p.s.), 7.42 and 8.02 p.p.m. (multiplets), assigned to the C-2 and C-3 hydrogens and the phenyl hydrogens respectively.

Anal. Calcd. for $C_{24}H_{26}O_4$: C, 76.14; H, 6.92. Found: C, 75.80; H, 6.62.

3β-Bromo-5α-cholestan-2α-yl p-anisate

This was prepared by the diaxial → diequatorial rearrangement of 2β-bromo-5α-cholestan-3α-yl *p*-anisate as previously described (21); m.p. 112–115°, $[\alpha]_D$ −35°; reported m.p. 114–115°, $[\alpha]_D$ −37°.

2α-Bromo-9β,10α-decalin-3β-yl p-anisate

This was prepared from 2β-bromo-9β,10α-decalin-3α-yl *p*-anisate (**8***a*, 0.4 g) by heating at 130° for 18 h under nitrogen. Thin-layer chromatography, eluting four times with benzene : cyclohexane (1:1), showed two spots, very close together, with R_f values of 0.63 and 0.54 respec-

tively, the faster moving material corresponding to the diaxial bromoanisate (**8***a*). The pyrolysis product was separated by t.l.c. as above; under ultraviolet light a broad band was observed on the t.l.c. plates, with no apparent separation. The lower half of this band was removed from the plates and extracted with chloroform (+1% methanol). After filtration, evaporation of the extract yielded 2α-bromo-9β,10α-decalin-3β-yl *p*-anisate, which was recrystallized from ether : petroleum ether, m.p. 122–124°; ν_{max} 1730 cm^{-1}. The n.m.r. spectrum had bands at 3.80 (singlet), 4.0 (multiplet), 5.08 (broad band) and 6.87 and 7.97 p.p.m. (J_{AB} 9 c.p.s.).

Anal. Calcd. for $C_{18}H_{23}O_3Br$: C, 58.86; H, 6.31; Br, 21.49. Found: C, 58.76; H, 6.20; Br, 21.72.

Rearrangement of 2β-Chloro-9β,10α-decalin-3α-yl p-anisate to 2α-Chloro-9β,10α-decalin-3β-yl p-anisate

The diaxial chloroanisate (500 mg) in a test tube, flushed with nitrogen and stoppered by a plug of cotton wool, was heated at 140° for 96 h. Thin-layer chromatography [benzene : cyclohexane (1:1)] of the product (a dark brown oil) showed two spots running very close together. These two materials were separated by eluting with benzene : cyclohexane (1:1) five times; under ultraviolet light the materials showed up as a wide spread band on the plates. This band was cut in half and each half extracted, the upper half gave 390 mg which was almost entirely diaxial chloroanisate, and the lower half (108 mg) gave the diequatorial chloroanisate, recrystallized from methylene chloride : methanol; m.p. 106–107°, ν_{max} 1705 cm^{-1}. The n.m.r. had absorption at 3.80 (singlet), 4.0 (broad multiplet), 5.0 (broad band) and 6.87 and 7.97 p.p.m. (J_{AB} 9 c.p.s.).

Anal. Calcd. for $C_{18}H_{23}O_3Cl$: C, 66.95; H, 7.18; Cl, 10.98. Found: C, 66.74; H, 7.02; Cl, 10.98.

Structure of the product obtained in the base-catalyzed condensation of acetone and indanedione-1,3

STEPHEN J. KUHN
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario[1]
Received December 27, 1967[2]

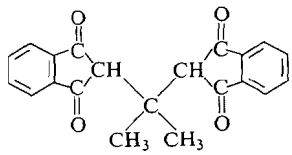
It has been found that acetone and indanedione-1,3 gives 1,1-dimethyl-3-oxo-1,2,3,9*a*-tetrahydro-9-indanedionylene fluorene in the presence of a base, instead of 1,1-dimethyl-3-oxo-1,2,3,4-tetrahydro-9-indanedionylene fluorene or other products claimed in the literature. The nuclear magnetic resonance spectra of the product and some of its derivatives have been recorded.

Canadian Journal of Chemistry, 47, 1461 (1969)

Introduction

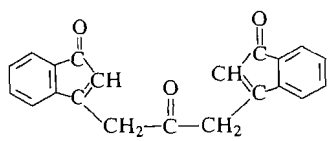
The base-catalyzed condensation of acetone and indanedione-1,3 has been studied by a number of investigators.

Radulescu and Georgescu (1) have suggested that one molecule of acetone condenses with two molecules of indanedione-1,3 through the carbonyl group of the acetone and the methylene group of the indanedione. They postulated structure **1** for their product. Cirulis (2) has suggested



1

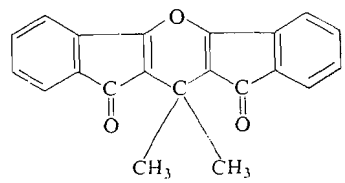
that the condensation takes place between the methyl groups of the acetone and the carbonyl group of the indanedione (**2**). Kalnins (3) assigned



2

a pyrane type of structure **3** for the product, which is formed by the further condensation of **1**.

Geita and Vanags (4) have shown that the product forms by the condensation of 2 moles of acetone with 2 moles of indanedione-1,3 by splitting off 3 moles of water. They postulated the product as 1,1-dimethyl-3-oxo-1,2,3,4-tetrahydro-9-indanedionylene fluorene (**4**) formed as shown in Scheme 1.



3

They have concluded from the infrared (i.r.) spectrum that the indanedione group is present in the molecule.

For some time we have been interested in the base-catalyzed condensation of ketones and indanedione-1,3 and it occurred to us that the condensation may take a course other than that suggested by Geita and Vanags, leading to a compound isomeric with theirs (Scheme 2).

Experimental

Many of these compounds were prepared by using slightly modified methods of Cirulis (2) and Geita and Vanags (4).

1,1-Dimethyl-3-oxo-1,2,3,9a-tetrahydro-9-indanedionylene Fluorene (5)

A mixture of 140 ml of acetone, 15 g of indanedione-1,3, and 7 g of piperidine was heated under reflux on a water bath for 1 h then allowed to stand at room temperature for 5 h. The dark-blue solution was added in small portions to 1.5 l of well stirred 10% aqueous acetic acid. The brownish-yellow precipitate was collected on a filter, washed with water, and then washed several times with alcohol. After the alcohol treatment, the solid was washed with 10% Na_2CO_3 solution, then with 10% aqueous acetic acid solution. After drying, the yellow

SCHEME 2

product was crystallized from glacial acetic acid, yielding 9.7 g of product, m.p. 198–200 °C.

Anal. Calcd. for $C_{24}H_{18}O_3$ (mol. wt., 354.0): C, 81.35; H, 5.08. Found (mol. wt., 360.0): C, 81.3; H, 5.07.

1,1-Dimethyl-2,9a-dibromo-3-oxo-1,2,3,9a-tetrahydro-9-indanedionylene Fluorene (6)

Compound **5**, (5 g) was dissolved in 50 ml of glacial acetic acid, 1.5 ml of bromine was added and the mixture was heated on a water bath for 4 h. After cooling and standing for 5 h, a brownish-yellow solid precipitated. It was filtered and purified by dissolving it in warm chloroform and reprecipitated by ether. The pure product (6.5 g) was yellow with m.p. 216–217°C.

Anal. Calcd. for $C_{24}H_{16}Br_2O_3$: C, 56.24; H, 3.12; Br, 31.25. Found: C, 56.4; H, 3.12; Br, 30.95.

1,1-Dimethyl-3-oxo-9a-methyl-1,2,3,9a-tetrahydro-9-indanedionylene Fluorene (7)

Compound **5**, (5 g) was dissolved in 50 ml 1% solution of $NaOCH_3$ in dry methanol, then 10 g of methyl iodide was added to the reaction mixture. The reaction mixture was refluxed for 5 h. Upon cooling a brownish-yellow solid precipitated (5.1 g). The solid product was crystallized from glacial acetic acid, m.p. 251 °C. The product was a mixture of **5** (30%) and 7 (70%). A small amount of pure 7 was isolated from the mixture (5g) by washing it on a glass filter 10 times with 100 ml hot, aqueous 10% K_3PO_4 solution. It was then crystallized from hot acetic acid, dimethyl sulfoxide, *N,N*-dimethyl formamide, hexamethyl phosphoramide, and finally from acetic acid. The product was obtained with m.p. 265 °C, yield 0.3 g.

Anal. Calcd. for $C_{25}H_{20}O_3$: C, 84.2; H, 5.4. Found: C, 84.1; H, 5.3.

3-Oxime of 1,1-Dimethyl-3,9-dioxo-1,2,3,9a-tetrahydrofluorene (10)

Compound **5**, (12 g) and 16 g hydroxylamine hydrochloride were added to 200 ml of ethyl alcohol and the mixture was heated to the boiling point, then 10 g sodium bicarbonate was added in small portions. After the addition of the bicarbonate the reaction mixture was refluxed for 1 h, then filtered hot. Upon cooling more indanedione dioxime precipitated. This was filtered off and the mother liquor was diluted with 1 l of cold water. The solid which precipitated upon dilution of the mother liquor was filtered, then mixed with 1 l of water, boiled for 10 min and filtered hot, then crystallized from a small amount of ethyl alcohol. Yellow crystals 5 g were obtained, m.p. 199–201 °C.

1,1-Dimethyl-3,9-dioxo-1,2,3,9a-tetrahydrofluorene (11)

Compound **10**, (3 g) was dissolved in 80 ml of 18% HCl, 8 ml of glacial acetic acid was added, and the mixture was refluxed for 3 h. The hot solution was filtered and the mother liquor was diluted with a little cold water. Upon standing yellow crystals (1 g) separated from the

mother liquor. The product was crystallized from ethyl alcohol, m.p. 146–148 °C.

Anal. Calcd. for $C_{15}H_{14}O_2$: C, 79.66; H, 6.19. Found: C, 79.7; H, 6.16.

1,1-Dimethyl-3,9-dioxo-9a-deuterio-1,2,3,9a-tetrahydrofluorene (13)

Potassium phosphate (4.24 g, 0.02 mole) was dissolved in 30 ml of heavy water and 2.26 g (0.01 mole) of **11** were added to the solution. Upon shaking the mixture a homogeneous dark blue solution was obtained, which was acidified with CH_3—COOD. The yellow precipitate was filtered, washed with water, dried, and crystallized from ethyl alcohol (2.1 g), m.p. 146–147 °C.

Anal. Calcd. for $C_{15}H_{13}DO_2$: C, 79.3; D + H, 6.6. Found: C, 79.21; D + H, 6.5.

Nuclear Magnetic Resonance

The nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer operating at room temperature. The chemical shifts were measured relative to internal tetramethylsilane.

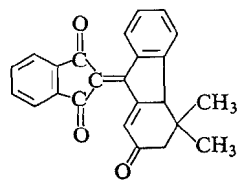
Results and Discussion

Molecular weight measurement and analytical results agree equally with formula **4** or **5**.

The nuclear magnetic resonance (n.m.r.) spectrum of the product **5** in $CDCl_3$ (Fig. 1) shows peaks in the methyl, methylene, aromatic, aliphatic single proton, and olefinic proton regions. The signals have been tentatively assigned as follows: the peaks at 0.78 and 1.61 p.p.m. (internal TMS) to different sets of methyl protons; the two doublets centered at 2.59 and 4.06 p.p.m. respectively to two different methylene protons on the same carbon with a coupling constant of 19 c.p.s.; the doublet centered at 3.13 p.p.m. to an aliphatic proton and another doublet centered at 8.78 p.p.m. to an olefinic proton, these two protons having a coupling constant of 2 c.p.s., and the pattern centered around 7.78 p.p.m. to the aromatic protons. Integration of the peaks shows there are six methyl protons, two single protons, two methylene protons, and eight aromatic protons in the molecule. These results indicate that **5** is the right structure for the product. The proton at position-4 resonates at unusually low field.[3] However, Hayashi (5) has reported that the vinyl protons in substituted α-cyanocinnamic esters can resonate as low as 8.75 p.p.m. Double irradiation experiments have shown that proton-9*a* and proton-4 are coupled (Fig. 2). When proton-9*a* was replaced by deuterium (**5***a*) the signal for proton-4 coalesced to a broad singlet. Using the double resonance technique the methylene protons were also decoupled.

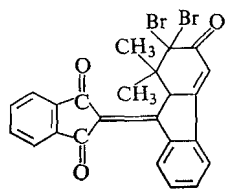
The doublet centered at 2.59 p.p.m. assigned to one of the methylene protons appears to have some fine structure. A careful inspection of the spectrum reveals that there is a small coupling between this proton and the olefinic proton at position-4 ($J \approx 0.5$ c.p.s.).

Structures **5***a* and **5** would give similar n.m.r. spectra; however, it is unlikely that the condensation would follow the path involving reaction of an indanedione carbonyl with an acetone carbonyl producing **5***a*.

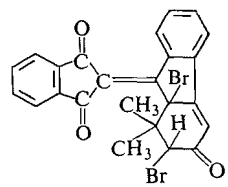


5*a*

Bromination of **5** in hot acetic acid gave a dibromo product **6**. The n.m.r. spectrum of **6** (in $SOCl_2$, internal TMS) shows peaks at 1.08 p.p.m. (3 Me protons), at 1.95 p.p.m. (3 Me protons), at 6.5 p.p.m. (aliphatic single proton), and at 8.78 p.p.m. (olefinic proton). The eight aromatic protons center at 7.63 p.p.m. The olefinic proton and the other single proton are coupled (0.7 c.p.s.). Based on this spectrum the following structure has been assigned to **6**.[4]



6



6*a*

To obtain more information on the structure

[3]One of the referees has suggested that this unique proton in **5** is that in the aromatic nucleus in proximity to the carbonyl group and that Fig. 1 is equally difficult to reconcile with **4** unless it is a mixture of isomers.

[4]One of the referees has suggested that allylic bromination rather than *gem*-dibromination appears more probable.

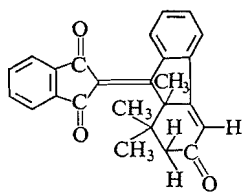
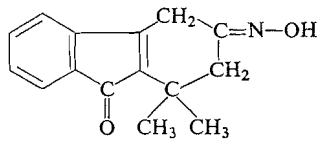
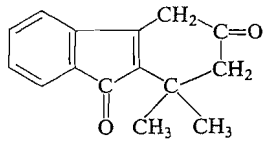
of the dibromo product, **5** was deuterated at position-9*a*, by dissolving it in a hexadeuterated dimethyl sulfoxide solution of K_3PO_4 followed by acidification with CH_3—COOD and brominated in hot acetic acid. If *gem*-dibromination takes place, both of the doublets assigned to the methylene protons should disappear from the spectrum of the compound. If the bromination takes place at positions-2 and -9*a*, a signal for proton-2 should be present in the spectrum. The signal for proton-2 is still present in the spectrum of the dibromo product indicating that **6***a* best represents the structure for the dibromo compound. Protons-2 and -4 are still coupled (0.7 c.p.s.) and this unusual coupling was misinterpreted in the original manuscript for coupling between the -4 and -9*a* protons. Cirulis (2) methylated the condensation product by treating it with $NaOCH_3$ and refluxing the Na salt with excess methyl iodide. He isolated a product which he claimed was a dimethylated derivative. Upon repeating his experiment and investigating the n.m.r. spectrum of the product (in $CDCl_3$) it was found that it consisted of approximately 30% of unchanged **5** and 70% of a new monomethylated product. While the monomethylated product (**7**) has a similar spectrum to **5**, all the peaks have shifted, the signal assigned to the 9*a*-proton has disappeared, the olefinic proton gives only a single peak, and in the methyl proton region a new signal has appeared. Integration of the peaks shows that there are nine methyl protons, two methylene protons, one olefinic proton, and eight aromatic protons in the compound. The peaks were assigned as follows: peaks at 0.63 and 1.51 p.p.m. to the methyl protons attached to C-1; the peak at 1.30 p.p.m. to the new methyl group at the 9*a*-position; the two doublets centered at 2.74 and 3.75 p.p.m. respectively (J_{AB} 20.5 c.p.s.), to the methylene protons; single peak at 8.73 p.p.m. to the olefinic proton; and the pattern centered around 7.76 p.p.m. to the aromatic protons. Based on the n.m.r. spectrum the following structure has been assigned to **7**. Pure **7** can be isolated



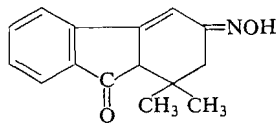
7



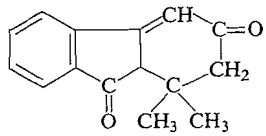
8



9



10



11

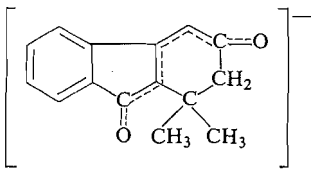
by base extraction and repeated crystallization of the mixture.

To obtain more experimental proof for the structure of **5** it was treated with hydroxylamine. Geita and Vanags (4) have claimed that **5** and hydroxylamine gave the dioxime of indanedione-1,3 and **8**. Upon hydrolysis **8** should give **9**. The n.m.r. spectrum of this product has shown, as it was expected, that **11** represents the correct structure for the compound (Fig. 3), and **10** is its precursor.

The spectrum still shows the presence of two different methyl proton peaks (at 0.88 and 1.56 p.p.m. respectively). The methylene protons are centered at 3.26 p.p.m. and appear as a pair of doublets in which the chemical shift difference of AB (10.5 c.p.s.) is smaller than J_{AB} (17 c.p.s.). The olefinic proton and the aliphatic single proton are coupled (2 c.p.s.) and centered at 6.53 and 3.31 p.p.m. respectively. The aromatic protons are centered at 7.75 p.p.m. The large upfield shift

of proton-4 in **11** compared to proton-4 in **5** is striking and may be due to change in the extent of conjugation of the molecule.

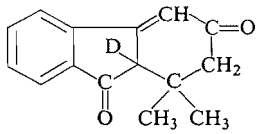
Compound **11** dissolves in aqueous NaOH or aqueous K_3PO_4 (but not in Na_2CO_3 solution) forming a dark-blue solution, indicating the formation of a carbanion **12**.



12

The n.m.r. spectrum of this solution shows only one signal for the methyl protons and one signal for the methylene protons, indicating that the cyclohexene ring is either coplanar, or that there is a rapid inversion of configuration at position-9*a*. The signal for proton-9*a* has disappeared from the spectrum and the proton in the 4-position gives only a single peak.

When **11** was treated with K_3PO_4 in D_2O solution followed by acidification with CH_3—COOD, the 9*a*-deuterated compound was obtained (**13**). The n.m.r. spectrum of **13** in $CDCl_3$



13

is similar to the spectrum of **11**. However, there is no signal for proton-9*a* and the proton in position-4 gives only a broad single peak.

The mass spectrum and infrared (i.r.) spectrum of **5** have also been recorded. The molecule–ion (M^+) was observed and the fragmentation pattern is consistent with structure **5**. The i.r. spectrum shows two carbonyl stretching bands at 1682 and 1720 cm^{-1} which can be assigned to the carbonyls of the indanedionyl part of the molecule. Another carbonyl band at 1675 cm^{-1} may be due to C=O stretching of the cyclohexenone part of the molecule. Both aromatic and aliphatic hydrogens were observed. The i.r. spectrum is in general consistent with structure **5**.

One can conclude from these results that **5** represents the structure of the product formed in the base-catalyzed condensation of acetone and indanedione-1,3. Radulescu and Georgescu (1) and Kalnins (3), however, may have isolated an intermediate in the condensation reaction or were dealing with the impure **5**. Cirulis (2), Kalnins (3), and Geita and Vanags (4), have isolated **5**, but have assigned the wrong structure to it. These results do not prove, however, the mechanism of the condensation. Compound **5** may form as we suggest in Scheme 2 or it is possible that **4** forms first according to the scheme of Geita and Vanags (4), (Scheme 1) and then is isomerized to **5** during the reaction. It is interesting to note, that mesityloxide and indanedione-1,3 did not give **5** in a similar condensation. The condensation of bindone (bisindanedione) and acetone also gave a different product.

Attempts have also been made to carry out similar condensations between indanedione-1,3 and 3-pentanone or 1,3-diphenylacetone respectively; however, no product similar to **5** could be isolated from these reactions.

Acknowledgments

The writer is grateful to C. G. Carlson and J. S. McIntyre for the helpful discussion and suggestions, and to H. D. Mak and J. P. Heeschen for recording the nuclear magnetic resonance spectra, and to S. T. King and J. C. Tou for the mass and infrared spectra. The author is also thankful to the referees for many valuable suggestions and comments. The microanalyses and molecular weight determinations were carried out in the Microanalyses Laboratory, Toronto.

1,3-Dipolar cycloaddition of nitrile oxides. II. Reactions with *o*-quinoid structures

WILLIAM IBRAHIM AWAD AND MICHEAL SOBHY
Chemistry Department, Faculty of Science, Ain Shams University, Abbassia, Cairo, United Arab Republic

Received May 24, 1968

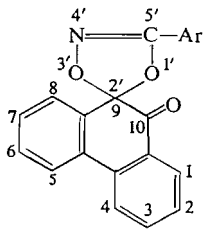
o-Chloro-, 2-chloro-4-methoxy-, and 5-chloro-3,4-methylenedioxy-benzonitrile oxides react with phenanthrenequinone, chrysenequinone, phenanthrenequinonimine, chrysenequinonimine, and phenanthrenequinone monoxime to give a 1:1 adduct. Tetrabromo-*o*-quinone gives an adduct with benzonitrile *N*-oxide in ratio of 1:2.

When benzoyl chloride or benzyl chloride was allowed to react with benzonitrile oxide, dibenzohydroxamic acid, *o*-benzohydroxamic benzyl ether were obtained respectively.

The constitution of the products is discussed.

Canadian Journal of Chemistry, 47, 1473 (1969)

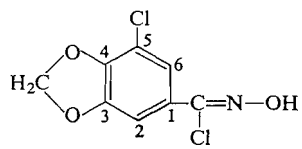
In continuation of our previous work (1, 2), *o*-chloro-benzonitrile oxide, 2-chloro-4-methoxybenzonitrile oxide, and 5-chloro-3,4-methylenedioxybenzonitrile oxide were reacted with phenanthrenequinone to give 9(10)-phenanthrone-10(9)-spiro-5′-aryl-1′,3′,4′-dioxazoles (**1**).



1

1 *a*, Ar = $C_6H_4Cl(o-)$
b, Ar = $C_6H_3(OCH_3)(Cl)(4\text{–}2)$
c, Ar = $C_6H_2(O_2CH_2)(Cl)(3,4\text{–}5)$

During the preparation of the hydroxamic acid chloride by passing chlorine gas into piperonaldoxime a chlorine atom enters the aromatic ring, as well, to give **2**. A similar reaction was previously observed (2, 3). Oxidation of **2** gave an acid, m.p. 238° which proved to be different from 6-chloro-3,4-methylenedioxybenzoic acid (m.p. 208°) (4), the latter being the only known chloromethylenedioxybenzoic acid. Thus we can conclude that the nuclear chlorine is in the 2- or 5-position. Since the 2-position can be considered as sterically deactivated as compared with the 5-position, the product is most probably chlorinated in the latter position.



2

The dioxazoles **1** are stable to both acids and alkalies and give 2,4-dinitrophenylhydrazone derivatives. Oxidation of these compounds with chromic anhydride gives phenanthrenequinone. The dioxazoles **1** show $\nu_{C=O}$ and ν_{N-O-}, and their ultraviolet spectra show close similarity (cf. Experimental).

Phenanthrenequinonimine gives, with the above mentioned nitrile oxides, 9(10)-phenanthrone-10(9)-spiro-(1′,5′-dihydro-3′-aryl)-1′,2′,4′-oxadiazoles (**3**).

These compounds give 2,4-dinitrophenylhydrazone derivatives which are different from the corresponding phenanthrenequinone ones. This fact led to the conclusion that the addition of the nitrile oxides takes place on $\diagdown C{=}N{-}H$ rather than on $\diagdown C{=}O$ of the monoimine. The infrared spectra of these products showed besides $\nu_{C=O}$, ν_{N-O}, and ν_{N-H}.

4

Benzonitrile *N*-oxide gives with phenanthrenequinone monoxime a product to which structure **4** is assigned.

It is a 1:1 adduct (deduced by analytical data) with $\nu_{C=O}$ at 1690 cm^{-1} and a clear hydrogen bonded ν_{O-H} between 3060–2800 cm^{-1} (broad band). It also gives a dinitrophenylhydrazone derivative.

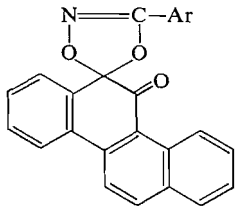
Chrysenequinone reacts similarly with the previously mentioned nitrile oxides to give 1,2-benz-9(10)-phenanthrone-10(9)-spiro-5′-aryl-1′,-3′,4′-dioxazoles (**5**).

Structure **5** is preferred to **6** on steric grounds (5). These compounds are stable to both acids and alkalies and give dinitrophenylhydrazone derivatives and upon oxidation chrysenequinone is obtained. Their infrared spectra showed $\nu_{C=O}$ and ν_{N-O}. Their ultraviolet spectra show clear similarity with those previously described (1).

Chrysenequinonimine behaves similarly to give 1,2-benz-9(10)-phenanthrone-10(9)-spiro-(1′,5′-dihydro-3′-aryl)-1′,2′,4′-oxadiazoles (**7**). For a discussion of chrysenequinonimine structure see ref. (5).

Their 2,4-dinitrophenylhydrazone derivatives are different from those of the corresponding quinone derivatives and their infrared spectra showed ν_{N-H} besides $\nu_{C=O}$ and ν_{N-O-}. The ultraviolet spectra of these compounds are indentical with the corresponding ones previously described (1).

When arylnitrile oxides are allowed to react



5

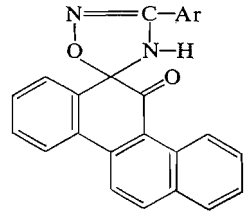
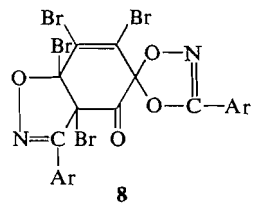
a, Ar = $C_6H_4Cl(o\text{–})$
b, Ar = $C_6H_3(OCH_3)(Cl)(4\text{–}2)$
c, Ar = $C_6H_2(O_2CH_2)(Cl)(3,4\text{–}5)$



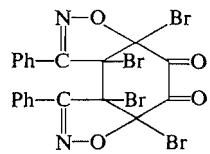
7

a, Ar = $C_6H_4Cl(o\text{–})$
b, Ar = $C_6H_3(OCH_3)(Cl)(4\text{–}2)$
c, Ar = $C_6H_2(O_2CH_2)(Cl)(3,4\text{–}5)$

with *o*-tetrabromobenzoquinone, almost colorless products are obtained. Analytical data show that two molecules of the nitrile oxide add to one molecule of the quinone, a fact which is different from the case of phenanthrenequinone or chrysenequinone derivatives. We believe that one carbonyl and one carbon–carbon double bond are involved in the reaction since the infrared spectra show $\nu_{C=O}$. Structure **8** is assigned.



8



8′

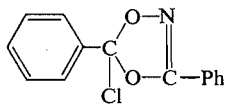
8 *a*, Ar = C_6H_5
b, Ar = $C_6H_4Cl(o\text{–})$
c, Ar = $C_6H_2(O_2CH_2)(Cl)(3,4\text{–}5)$

The addition to activated double bond has been previously observed (6). The availability of the carbon–carbon double bond for this reaction is more obvious in the case of *o*-tetrabromoquinone than in the case of phenanthrenequinone and its derivatives. This may be the reason why the former adds two molecules of arylnitrile oxides while the latter reacts only with one molecule.

Structure **8′**[1] is also compatible with the known data. However, the authors are more inclined to structure **8** since the product does not give the test for 1,2-dioxocompounds (7).

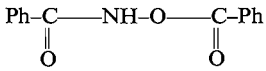
Attempts to extend the possibility of 1,3-dipolar addition to the carbonyl group of acid chlorides did not lead to the expected dioxazole (**9**). However, the infrared spectrum of the product showed two bands for carbonyl stretching frequency, one at 1754 cm^{-1} and the other at 1660 cm^{-1}, together with an ν_{NH} at 3333 cm^{-1}, and the product

[1]This structure was proposed by one of the referees.



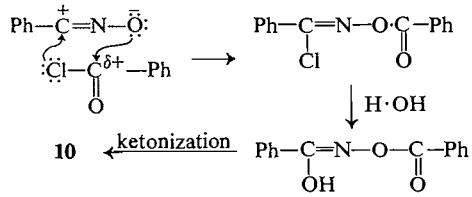
9

was chlorine free. These data are in conformity with dibenzhydroxamic acid (**10**). This was proved

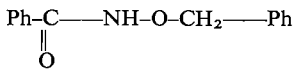


10

by melting and mixture melting point with an authentic sample (8). This product can be formed according to the following scheme.



Moisture is expected to be present in the benzonitrile oxide as it is prepared here. The intermediate chloro-compound, which has been isolated in other cases (9), was not isolated in this case. Benzyl chloride was also allowed to react with benzonitrile oxide and the product proved to be *O*-benzohydroxamic benzyl ether (**11**) by melting and mixture melting point with an authentic specimen (10).



11

Experimental

Melting points are not corrected. Analyses were carried out by Alfred Bernhardt, Max Planck Institute, Mülheim, Ruhr, Germany. Infrared spectra were measured on a Perkin–Elmer Infracord Model 137 spectrophotometer in KBr wafers. Ultraviolet spectra were measured on a Perkin–Elmer spectracord Model 4000A spectrophotometer in ethyl alcohol solutions.

Preparation of 5-Choloro-3,4-methylenedioxybenzohydroxamic Acid Chloride (2)

Piperonaldoxime (10 g) dissolved in chloroform – carbon tetrachloride mixture (1:1) (20 ml) was cooled to about 0° and chlorine gas was passed into the solution slowly. The solution turned green and the chloride separated as fine greenish powder after 90 min. It was filtered off and used without purification in the preparation of 2-chloro-3,4-methylenedioxybenzonitrile oxide.

Oxidation of 5-Chloro-3,4-methylenedioxybenzohydroxamic Acid Chloride

The hydroxamic acid chloride (1 g) (in acetone) was treated dropwise with aqueous potassium permanganate solution (2%) till the color of the permanganate dominates. The excess of the permanganate was destroyed. The precipitate formed was filtered off. The latter was extracted with sodium carbonate solution (20%). The alkaline extract was cooled and acidified with dilute HCl. The acid obtained was crystallized from acetic acid into colorless crystals, m.p. 238° (poor yield).

Anal. Calcd. for $C_8H_5O_4Cl$: C, 47.88; H, 3.49; Cl, 17.70. Found: C, 48.22; H, 3.10; Cl, 17.52.

Action of Benzonitrile N-Oxide and its Derivatives on o-Quinones. General Procedure

An ethereal solution of benzonitrile *N*-oxide or its derivatives (from 10 g of the corresponding benzohydroxamic acid chloride) was refluxed with the quinone (1 g) suspended in dry benzene for 2 h on a water bath. the reaction mixture was kept overnight at room temperature. The reaction product was filtered off, washed with ether, and crystallized from a suitable solvent (cf. Table I).

The 2,4-dinitrophenylhydrazone derivatives were crystallized from a suitable solvent.

Reaction of Benzonitrile N-Oxide with Phenanthraquinone Monoxime

Phenanthraquinone monoxime (1 g) was treated with an ethereal solution of benzonitrile *N*-oxide (from 5 g benzohydroximic acid chloride). The reaction mixture was left at room temperature for 30 min and then refluxed gently for another 30 min. The yellowish oil separated after removing the solvent was solidified by trituration with light petroleum ether (b.p. 40–60°). Crystallization from light petroleum ether (b.p. 60–80°) gave **4** in colorless crystals, m.p. 161–162° (0.5 g, yield 35%).

Anal. Calcd. for $C_{21}H_{14}N_2O_3$: C, 73.38; H, 4.09; N, 8.18. Found: C, 73.68; H, 4.12; N, 8.23.

The 2,4-dinitrophenylhydrazone derivative was prepared as usual and crystallized from benzene, m.p. 190°.

Anal. Calcd. for $C_{27}H_{18}N_5O_6$: C, 63.78; H, 3.56; N. 13.76. Found: C, 64.38; H, 3.78; N, 12.80.

Action of Substituted Benzonitrile N-Oxide on Quinonimines. General Procedure

Quinonimine (1 g) in dry ether or benzene was treated with the ethereal solution of benzonitrile *N*-oxide derivative (from 7 g of the corresponding benzohydroxamic acid chloride). The reaction was completed as mentioned before. The solid product obtained after removal of most of the solvent was filtered off, washed with ether, and crystallized from a suitable solvent (cf. Table II).

The 2,4-dinitrophenylhydrazone derivatives were prepared as usual and crystallized from a suitable solvent (cf. Table II).

Action of Benzonitrile N-Oxide on Benzoyl Chloride

The ethereal solution of benzonitrile *N*-oxide (from 10 g of PhCCl-NOH) was added to benzoyl chloride (1 g) dissolved in ether. The reaction mixture was kept at room temperature for 30 min. On cooling and treating with excess light petroleum ether (b.p. 40–60°) colorless

For personal use only.

crystalline compound separated out. Crystallization from petroleum ether (b.p. 40–60°) gave dibenzhydroxamic acid (**10**), m.p. 162°, undepressed on admixture with an authentic sample (8).

Preparation of O-Benzohydroxamic Benzyl Ether

Benzyl chloride (2 g) was treated with the ethereal solution of benzonitrile *N*-oxide (from 10 g of PhCCl-NOH). The reaction mixture was left at room temperature for a few hours and then boiled gently for 1 h on a water bath. After removal of most of the ether, petroleum ether (b.p. 40–60°) was added and the solution was left at room temperature for two days during which colorless plates separated out, were filtered, washed with petroleum ether, and crystallized from petroleum ether (b.p. 40–60°) to give *O*-benzohydroxamic benzyl ether (**11**), m.p. 105°, undepressed when mixed with an authentic sample (10), (0.6 g, yield 33%).

Synthesis of epimeric 2-acetamido-2-deoxyheptoses from D-mannose, D-galactose, and D-talose[1]

C. F. GIBBS,[2] D. T. WILLIAMS,[2] AND M. B. PERRY
Division of Biochemistry and Molecular Biology, National Research Council of Canada, Ottawa, Canada

Received September 3, 1968

D-Mannose, D-galactose, and D-talose were converted *via* the action of nitromethane to their corresponding 3,4,5,6,7-pentaacetoxy-1-nitro-1-heptene derivatives which on treatment with ammonia afforded the epimeric 2-acetamido-1,2-dideoxy-1-nitroheptitol derivatives. The 2-acetamido-1,2-dideoxy-1-nitroheptitols were converted *via* the Nef reaction to the corresponding 2-acetamido-2-deoxyheptoses. The configuration of the 2-acetamido-2-deoxyheptoses was established by their degradation to known 2-acetamido-2-deoxyhexitol derivatives. The properties of the 2-acetamido-2-deoxyheptoses are described.

Canadian Journal of Chemistry, 47, 1479 (1969)

2-Amino-2-deoxyhexuronic acid derivatives, related to compounds found in microbial products (1–5) were required in order to study their biological and analytical chemistry. An approach to their synthesis was considered in which glycosides of 2-acetamido-2-deoxyheptopyranosides were oxidized by one mole of periodate, in the manner previously described for neutral heptose derivatives (6–8), resulting in almost exclusive scission of the exocyclic C_6–C_7 glycol system to yield C_6-aldehydo derivatives which are oxidized to the corresponding hexuronosides. This paper records the synthesis of six 2-acetamido-2-deoxyheptoses used as precursors for the above work.

D-Mannose, D-galactose, and D-talose were converted to the corresponding 3,4,5,6,7-pentaacetoxy-1-nitro-1-heptenes and after treatment with ammonia, the resulting epimeric 2-acetamido-1,2-dideoxy-1-nitroheptitols were converted to 2-acetamido-2-deoxyheptoses *via* the Nef (9) reaction. The epimeric 2-acetamido-1,2-dideoxy-1-nitroheptitols derived from D-mannose and D-galactose were each obtained in pure form and were used separately for the preparation of the individual 2-acetamido-2-deoxyheptoses, however, the epimeric 2-acetamido-1,2-dideoxy-1-nitroheptitols derived from D-talose could not be resolved and the mixture was therefore converted to the corresponding 2-acetamido-2-deoxyheptoses which were separated by column chromatography.

The identity of the 2-acetamido-2-deoxyheptoses and their 2-acetamido-1,2-dideoxy-1-nitroheptitol precursors was established by degradation of each 2-acetamido-2-deoxyheptose to a 2-acetamido-2-deoxyhexitol. Oxidation of each 2-acetamido-2-deoxyheptose with one mole of periodate resulted in the major glycol scission (ca. 90–98%, measured by H.CHO production) taking place at the C_6–C_7 glycol system and the product, without isolation, was reduced with borohydride to yield a 2-acetamido-2-deoxyhexitol which was identified by gas–liquid chromatographic (g.l.c.) analysis of its penta-*O*-acetyl-2-acetamido-2-deoxyhexitol derivative (10).

Since the completion of the work, Satoh and Kiyomoto (11) have described the synthesis of the epimeric 2-acetamido-1,2-dideoxy-1-nitroheptitols from D-galactose and D-mannose by the direct action of ammonia on the derived 2,3,4,5,6,7-hexa-*O*-acetyl-1-deoxy-1-nitroheptitols and proved the structure of 2-acetamido-2-deoxy-D-*glycero*-D-*talo*-heptitol and 2-acetamido-2-deoxy-D-*glycero*-L-*manno*-heptitol by degradation to D-serine and L-serine respectively. The physical properties of the compounds described by Satoh and Kiyomoto are in reasonable agreement with our results and the assignments of the configurations based on degradation to 2-acetamido-2-deoxyhexitol derivatives are in complete agreement.

The prepared 2-acetamido-2-deoxyheptoses were pure by paper chromatography but all were extremely hygroscopic and gave variable melting points. Gas–liquid chromatographic analysis of the trimethylsilylated powdered 2-acetamido-2-deoxyheptoses (12) gave one major peak, however, the trimethylsilylated heptoses, after equilibration in water, showed several peaks indicating

For personal use only.

the presence of anomeric forms. The gas chromatograms of the powdered heptoses, trimethylsilylated after exposure to the room atmosphere, were almost identical to the water-equilibrated samples indicating that the observed absorption of atmospheric water results in rapid anomerization of the products and thus explains the difficulties experienced in determining satisfactory melting points.

Experimental

Paper chromatography was performed by the descending method (13) on Whatman No. 1 filter paper using pyridine – ethyl acetate – water (2:5:5 v/v, top layer) as the mobile phase. Glycoses were detected with 1% silver nitrate in acetone, followed by 2% sodium hydroxide in ethanol (14) and their rates of movement are quoted relative to D-galactose (R_{gal}).

Gas–liquid chromatography was carried out at 220 °C using a Hewlett–Packard model 402 chromatograph with a hydrogen flame detector and fitted with glass U tubes (4 ft × 6 mm × 3 mm internal diameter) packed with 10% neopentylglycol sebacate polyester on 80–100 mesh acid washed Chromosorb W. Retention times of compounds are quoted relative to 2-acetamido-2-deoxy-1,3,4,5,6-penta-*O*-(trimethylsily)-D-glucitol (T_{GN}) or 1,2,3,4,5,6-hexa-*O*-acetyl-D-glucitol (T_G).

Melting points were determined on a Fisher–Johns apparatus and are corrected. Solutions were concentrated under reduced pressure, below 40 °C. Optical rotations were determined at 20 °C using a Perkin–Elmer 141 polarimeter.

(A) Synthesis of 2-Acetamido-2-deoxy-D-glycero-D-talo-heptose and 2-Acetamido-2-deoxy-D-glycero-D-galacto-heptose

(1) 2-Acetamido-1,2-dideoxy-1-nitro-D-glycero-D-talo-heptitol and 2-Acetamido-1,2-dideoxy-1-nitro-D-glycero-D-galacto-heptitol

3,4,5,6,7-Pentaacetoxy-D-*manno*-1-nitro-1-heptene (25 g) prepared from D-mannose (15), was suspended in methanol (250 ml) at 0 °C and dry ammonia was added to saturation. The mixture was brought to room temperature and after 16 h it was concentrated to a syrup and, following the addition of ethanol (50 ml), crystalline 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*talo*-heptitol was obtained which after recrystallization from an ethanol–methanol mixture (2:1) gave the pure product (8 g, 49%) which had m.p. 184–185 °C and $[\alpha]_D$ +20.4° (*c*, 3.4 in water), (lit. (11) m.p. 180–181 °C and $[\alpha]_D$ + 21.4°).

Anal. Calcd. for $C_9H_{18}N_2O_8$: C, 38.30; H, 6.43; N, 9.92. Found: C, 38.0; H, 6.5; N, 9.8.

The original ethanolic mother liquors were concentrated to a thin syrup which on keeping afforded crystalline 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*galacto*-heptitol which after recrystallization from an ethanol–acetone mixture (1:1) gave the pure product (1.2 g, 7.4%) having m.p. 166–167 °C and $[\alpha]_D$ −28.8° (*c*, 1.3 in water) (lit. (11), m.p. 159–160.5 °C and $[\alpha]_D$ −26.4°).

Anal. Calcd. for $C_9H_{18}N_2O_8$: C, 38.30; H, 6.43; N, 9.92. Found: C, 38.2; H, 6.6; N, 9.8.

(2) 2-Acetamido-2-deoxy-D-glycero-D-talo-heptose

2-Acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*talo*-heptitol (6.7 g), dissolved in 2 *N* sodium hydroxide solution (16 ml), was added dropwise with vigorous stirring to concentrated hydrochloric acid (13 ml) and after boiling the mixture for 5 min it was cooled to 0 °C and saturated with hydrogen chloride gas. The precipitated sodium chloride was removed and after concentration to a syrup it was dried *in vacuo* over potassium hydroxide to yield 2-amino-2-deoxy-D-*glycero*-D-*talo*-heptose hydrochloride (5 g). The product which failed to crystallize was *N*-acetylated by shaking its solution in water (100 ml) containing methanol (15 ml) and acetic anhydride (2 ml) in the presence of Dowex-1 ($CO_3^=$) ion-exchange resin (60 ml) for 30 min at room temperature and, after filtration, the filtrate was passed down a column of mixed Rexyn 101 (H^+) and Rexyn RG6 (OH^-) ion-exchange resins (60 ml). The eluate was concentrated to a syrup (5.3 g) which was fractionated by cellulose column chromatography (16) using butan-1-ol half saturated with water as the mobile phase, to yield pure 2-acetamido-2-deoxy-D-*glycero*-D-*talo*-heptose (2.7 g). The product gave crystals from an ethanol – ethyl acetate mixture which were extremely hygroscopic and did not give a satisfactory melting point, $[\alpha]_D$ −15° (*c*, 1.7 in water). A single spot was obtained on paper chromatography having R_{gal} 1.63.

Anal. Calcd. for $C_9H_{17}NO_7$: C, 43.03; H, 6.82; N, 5.58. Found: C. 42.8; H, 6.8; N, 5.5.

Gas–liquid chromatographic analysis of the trimethylsilylated (12) crystalline 2-acetamido-2-deoxy-D-*glycero*-D-*talo*-heptose gave a major peak (T_{GN} 1.60) and minor peak (T_{GN} 3.36) whereas the trimethylsilylated glycose after equilibration in water showed four peaks having T_{GN} 1.56, 1.60 (major), 2.67, and 3.36.

(3) Degradation of 2-Acetamido-2-deoxy-D-glycero-D-talo-heptose to 2-Acetamido-2-deoxy-D-talitol

2-Acetamido-2-deoxy-D-*glycero*-D-*talo*-heptose (50 mg) in water (5 ml) was oxidized by the addition of sodium metaperiodate (43 mg) in water (2 ml) and after 1 h at room temperature the mixture was passed through mixed Rexyn 101 (H^+) and Duolite A4 (OH^-) ion-exchange resins (15 ml) and the eluate was treated with sodium borohydride (35 mg). After 3 h the mixture was acidified with acetic acid and after passing down a column of Rexyn 101 (H^+) ion-exchange resin (10 ml) the eluate was concentrated to dryness and then further concentrated after the addition of methanol (4 × 20 ml). Paper chromatography of the product showed a major component (R_{gal} 1.26) corresponding to 2-acetamido-2-deoxytalitol and very minor components having R_{gal} 0.98, 1.56, and 1.80. The major component isolated by preparative paper chromatography afforded crystalline 2-acetamido-2-deoxy-D-talitol which had m.p. 146–148° undepressed on admixture with an authentic sample. The fully acetylated glycitol (10) on g.l.c. gave a single peak (T_G 2.69) having the same retention time as penta-*O*-acetyl-2-acetamido-2-deoxy-D-talitol.

(4) 2-Acetamido-2-deoxy-D-glycero-D-galacto-heptose

2-Acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*galacto*-heptitol (3 g) was subjected to the series of reactions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

used for the synthesis of 2-acetamido-2-deoxy-D-*glycero*-D-*talo*-heptose (expt. *A* (*2*)) to give 2-acetamido-2-deoxy-D-*glycero*-D-*galacto*-heptose (1.3 g) which after recrystallization from an ethanol – ethyl acetate mixture had m.p. 164.5–165.5 °C and $[\alpha]_D$ +81.5° → +75.5° (40 min equilib. value; *c*, 1.7 in water).

Anal. Calcd. for $C_9H_{17}NO_7$: C, 43.03; H, 6.82; N, 5.58. Found: C, 42.8; H, 6.6; N, 5.5.

Paper chromatographic analysis of the 2-acetamido-2-deoxy-D-*glycero*-D-*galacto*-heptose showed a single spot having R_{gal} 1.05. Gas–liquid chromatography of the trimethylsilylated crystalline heptose showed peaks having T_{GN} 3.39 (major) and 6.32 and the trimethylsilylated heptose after equlibration in water showed peaks having T_{GN} 2.30, 2.42, 3.39, and 6.32.

*(5) Degradation of 2-Acetamido-2-deoxy-*D*-glycero-*D*-galacto-heptose to 2-Acetamido-2-deoxy-*D*-galactitol*

2-Acetamido-2-deoxy-D-*glycero*-D-*galacto*-heptose (50 mg) was oxidized with periodate as described above (expt. *A*(*3*)) to yield 2-acetamido-2-deoxy-D-galactitol (43 mg) which after recrystallization from aqueous acetone had m.p. and mixture m.p. 174–175 °C. Gas–liquid chromatography of the fully acetylated derived 2-acetamido-2-deoxy-D-galactitol gave a single peak (T_G 3.32) corresponding to authentic 1,3,4,5,6-penta-*O*-acetyl-2-acetamido-2-deoxy-D-galactitol.

*(B) Synthesis of 2-Acetamido-2-deoxy-*D*-glycero-*L*-manno-heptose and 2-Acetamido-2-deoxy-*D*-glycero-*L*-gluco-heptose*

*(1) 2-Acetamido-1,2-dideoxy-1-nitro-*D*-glycero-*L*-manno-heptitol and 2-Acetamido-1,2-dideoxy-1-nitro-*D*-glycero-*L*-gluco-heptitol*

3,4,5,6,7-Pentaacetoxy-D-*galacto*-1-nitro-1-heptene (42 g) prepared from D-galactose (17) was treated in the way described for 3,4,5,6,7-pentaacetoxy-D-*manno*-1-nitro-1-heptene (expt. *A* (*1*)). The concentrated product, dissolved in ethanol, on cooling gave 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-L-*manno*-heptitol (22 g, 80%), m.p. 191 °C which after recrystallization from ethanol had m.p. 197 °C and $[\alpha]_D$ +13° (*c*, 0.8 in water) (lit. (11), m.p. 189–190 °C and $[\alpha]_D$ +12.9°).

Anal. Calcd. for $C_9H_{18}N_2O_8$: C, 38.30; H, 6.43; N, 9.92. Found: C, 38.5; H, 6.6; N, 9.9.

The concentrated ethanolic mother liquors were extracted with chloroform to remove acetamide and the residue, moistened with ethanol, gave 2-acetamido-1,2-dideoxy-D-*glycero*-L-*gluco*-heptitol (2.2 g, 8%), m.p. 140–146 °C which after recrystallization from ethanol gave the pure product which had m.p. 149–150 °C and $[\alpha]_D$ +9° (*c*, 1.6 in water) (lit. (11), 144.5–145.5 °C and $[\alpha]_D$ +10.7°).

Anal. Calcd. for $C_9H_{18}N_2O_8$: C, 38.30; H, 6.43; N, 9.92. Found: C, 38.7; H, 6.7; N, 9.8.

*(2) 2-Acetamido-2-deoxy-*D*-glycero-*L*-manno-heptose*

(*a*) 2-Acetamido-1,2-dideoxy-1-nitro-D-*glycero*-L-*manno*-heptitol (3 g) was converted to 2-acetamido-2-deoxy-D-*glycero*-L-*manno*-heptose (0.8 g) (m.p. 180–183 °C) using the previously described experimental procedure (expt. *A* (2)).

(*b*) An improved yield of 2-acetamido-2-deoxy-D-*glycero*-L-*manno*-heptose was obtained as follows (18). 2-Acetamido-1,2-dideoxy-1-nitro-D-*glycero*-L-*manno*-heptitol (12.5 g) was dissolved in a solution of $Ba(OH)_2 \cdot 8H_2O$ (13.8 g) in water (220 ml) and the mixture was (added dropwise with stirring to a solution of sulfuric acid (23 g) in water (96 ml). After 30 min at room temperature the reaction mixture was neutralized ($BaCO_3$), filtered, and the filtrate after concentration was fractionated by cellulose column chromatography using butan-1-ol half saturated with water as the mobile phase to yield pure 2-acetamido-2-deoxy-D-*glycero*-L-*manno*-heptose (5.5 g, 50%) obtained from ethanol solution as an amorphous powder which had m.p. 174–185 °C and $[\alpha]_D$ −33° → −17° (equilib. value; *c*, 1.4 in water).

Anal. Calcd. for $C_9H_{17}NO_7$: C, 43.03; H, 6.82; N, 5.58. Found: C, 43.2; H, 7.0; N, 5.5.

Paper chromatographic analysis of the 2-acetamido-2-deoxy-D-*glycero*-L-*manno*-heptose showed a single spot having R_{gal} 1.34 and the trimethylsilylated product on g.l.c. showed a major peak (T_{GN} 1.48, ca. 98%) and a minor peak (T_{GN} 2.06) whereas the trimethylsilylated heptose after equlibration in water showed peaks having T_{GN} 1.48, 2.06, 2.62, and 3.4.

*(3) Degradation of 2-Acetamido-2-deoxy-*D*-glycero-*L*-manno-heptose to 2-Acetamido-2-deoxy-*L*-mannitol*

2-Acetamido-2-deoxy-D-*glycero*-L-*manno*-heptose (142 mg) was degraded with periodate under the previously described conditions (expt. *A* (*3*)) to yield crystalline 2-acetamido-2-deoxy-L-mannitol (82 mg) which had m.p. and mixed m.p. 140 °C and $[\alpha]_D$ +7.7° (*c*, 1 in water).

Anal. Calcd. for $C_8H_{17}NO_6$: C, 43.05; H, 7.68; N, 6.27. Found: C, 43.1; H, 7.4; N, 6.2.

The derived 2-acetamido-2-deoxy-L-mannitol (60 mg) was acetylated (10) to yield 1,3,4,5,6-penta-*O*-acetyl-2-acetamido-2-deoxy-L-mannitol which after recrystallization from methanol had m.p. and mixture m.p. 189 °C and $[\alpha]_D$ −12.4° (*c*, 0.8 in chloroform), and gave a single peak on g.l.c. (T_G 3.54) having the same retention time as an authentic sample.

Anal. Calcd. for $C_{18}H_{27}NO_{11}$: C, 49.88; H, 6.28; N, 3.23. Found: C, 49.7; H, 6.2; N, 3.3.

*(4) 2-Acetamido-2-deoxy-*D*-glycero-*L*-gluco-heptose*

2-Acetamido-1,2-dideoxy-1-nitro-D-*glycero*-L-*gluco*-heptitol (0.8 g) treated by the modified (18) Nef reaction described above (expt. *B* (*2b*)) afforded 2-acetamido-2-deoxy-D-*glycero*-L-*gluco*-heptose as an amorphous powder (187 mg) which had m.p. 152–156 °C and $[\alpha]_D$ −56° → −41° (24 h equilib. value; *c*, 0.8 in water).

Anal. Calcd. for $C_9H_{17}NO_7$: C, 43.03; H, 6.82; N, 5.58. Found: C, 43.0; H, 6.7; N, 5.5.

The heptose gave a single spot on paper chromatography (R_{gal} 1.05) and the trimethylsilylated powder, and product of equilibration in water, on g.l.c. gave two peaks having T_{GN} 3.8 and 5.2.

*(5) Degradation of 2-Acetamido-2-deoxy-*D*-glycero-*L*-gluco-heptose to 2-Acetamido-2-deoxy-*L*-glucitol*

2-Acetamido-2-deoxy-D-*glycero*-L-*gluco*-heptose (10 mg) was degraded by one mole of periodate (expt. *A* (*3*)) and, following reduction and acetylation of the product, g.l.c. analysis revealed a major peak (90%) having T_G 2.87 corresponding in retention time with 1,3,4,5,6-penta-*O*-acetyl-2-acetamido-2-deoxyglucitol.

*(C) Synthesis of 2-Acetamido-2-deoxy-*D*-glycero-*L*-allo-heptose and 2-Acetamido-2-deoxy-*D*-glycero-*L*-altro-heptose*

*(1) 3,4,5,6,7-Pentaacetoxy-*D*-talo-1-nitro-1-heptene*

To a vigorously stirred solution of D-talose (6 g) in methanol (75 ml) and nitromethane (75 ml) was added a solution of sodium (2.7 g) in methanol (60 ml) and after 8 h at room temperature the mixture was kept at 0 °C for 12 h. The precipitated product was collected and its solution in water (60 ml) was passed down a column of Rexyn 101 (H^+) ion-exchange resin (100 ml). The eluate and washings were concentrated to a syrup which was dissolved in acetic anhydride (70 ml) and, following the addition of sulfuric acid (0.1 ml), the mixture was heated on a boiling water bath for 30 min. The cooled reaction mixture was poured onto crushed ice (11) and the product, after extraction with chloroform in the usual way, was concentrated to a syrup (12.5 g) containing the acetate derivatives of the epimeric 1-deoxy-1-nitroheptitols (19).

The above syrup (12 g) in ethyl benzene (150 ml) was boiled for 1 h in the presence of sodium bicarbonate (25 g) and the filtered solution after concentration was fractionated on a column of silica gel using a benzene–acetone (4:1) mixture to yield pure 3,4,5,6,7-pentaacetoxy-D-*talo*-1-nitro-1-heptene (3 g, 21%) which had m.p. 88–89 °C and $[\alpha]_D$ +24° (*c*, 0.4 in chloroform).

Anal. Calcd. for $C_{17}H_{23}NO_{12}$: C, 47.12; H, 5.35; N, 3.23. Found: C, 47.1; H, 5.2; N, 3.1.

*(2) Reaction of 3,4,5,6,7-Pentaacetoxy-*D*-talo-1-nitro-1-heptene with Ammonia*

3,4,5,6,7-Pentaacetoxy-D-*talo*-1-nitro-1-heptene (3 g) was treated with ammonia as previously described (expt. *A* (*1*)) to yield a mixture of 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-L-*allo*-heptitol and 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-L-*altro*-heptitol (2.8 g) (ca. 1:1 by silica gel thin-layer chromatography using pyridine – ethyl acetate – water (2:5:5)) which could not be resolved by fractional crystallization or chromatography.

The mixed 2-acetamido-1,2-dideoxy-1-nitroheptitols (2.6 g) were converted to the corresponding 2-acetamido-2-deoxyheptoses by the modified Nef reaction (expt. *B* (*2b*)) and following their fractionation by cellulose column chromatography (160 × 3 cm), using butan-1-ol half saturated with water as the mobile phase, pure 2-acetamido-2-deoxy-D-*glycero*-L-*altro*-heptose (103 mg) and 2-acetamido-2-deoxy-D-*glycero*-L-*allo*-heptose (172 mg) were, in order of elution, obtained.

*(3) 2-Acetamido-2-deoxy-*D*-glycero-*L*-altro-heptose*

The heptose was obtained from ethanol as a hygroscopic amorphous powder having m.p. 78–82 °C and $[\alpha]_D$ −11° → −8.5° (24 h equilib. value; *c*, 1 in water).

Anal. Calcd. for $C_9H_{17}NO_7$: C, 43.03; H, 6.82; Found: C, 42.1; H, 7.2.

The heptose gave a single spot on paper chromatograms (R_{gal} 1.66) and the trimethylsilylated glycose on g.l.c. gave four peaks having T_{GN} 1.14, 1.97, 2.10, and 2.66.

The heptose on degradation (expt. *A* (*3*)) gave 2-acetamido-2-deoxy-L-altritol and the derived 1,3,4,5,6-penta-*O*-acetyl-2-acetamido-2-deoxy-L-altritol on g.l.c. gave a single peak (T_G 2.60) having the same retention time as an authentic derivative.

*(4) 2-Acetamido-2-deoxy-*D*-glycero-*L*-allo-heptose*

The heptose had m.p. 70–90 °C and $[\alpha]_D$ +19° → +25° (24 h equilib. value; *c*, 1 in water).

Anal. Calcd. for $C_9H_{17}NO_7$: C, 43.03; H, 6.82; N, 5.58. Found: C, 42.9; H, 6.6; N, 5.5.

On paper chromatography the heptose gave a single spot (R_{gal} 1.23) and the trimethylsilylated glycose on g.l.c. gave peaks having T_{GN} 1.12, 1.44, 2.08, 2.35, and 2.54.

The heptose on degradation (expt. *A* (*3*)) gave 2-acetamido-2-deoxy-L-allitol and the acetate derivative on g.l.c. gave a single peak (T_G 2.26) having the same retention time as 1,3,4,5,6-penta-*O*-acetyl-2-acetamido-2-deoxy-L-allitol.

Further studies on the Stobbé condensation with 2-methyl cyclohexanone

A. M. El-Abbady, M. El-Ashry, and S. H. Doss
Department of Chemistry, University College for Girls, Ain Shams University, Cairo, United Arab Republic
Received April 22, 1968

2-Methyl cyclohexanone is condensed with dimethyl succinate in the presence of potassium tertiary butoxide giving a solid mixture of isomers of the corresponding alkylidene and alkenyl half-esters. On alkaline hydrolysis this gives β-carboxy-β-(2-methyl cyclohex-1-enyl)propionic acid. The keto-ester obtained by cyclization of the half-ester yielded the corresponding unsaturated ketone after acid hydrolysis and decarboxylation. Reduction of the keto-ester affords the corresponding α,β-unsaturated ester. Both the unsaturated ketone and ester are easily hydrogenated in the presence of platinum oxide to the corresponding saturated ketone and ester.

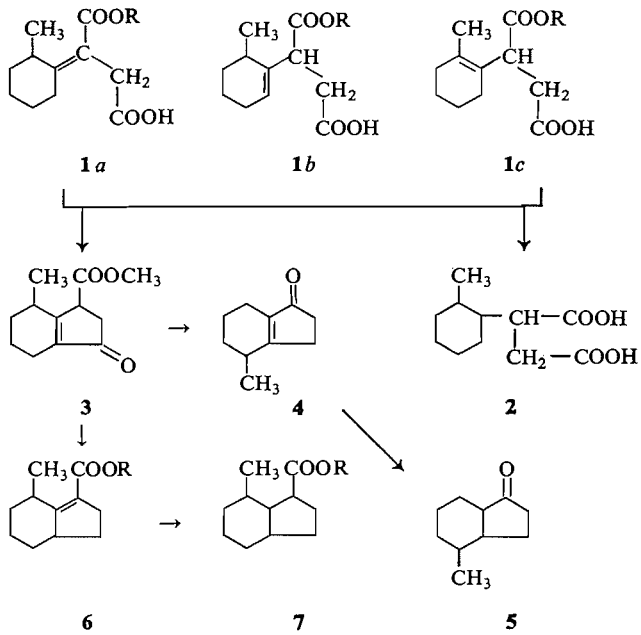
Cook and Phillip (1), and Chatterjee and Bhattacharyya (2) reported the Stobbé condensation of 2-methyl cyclohexanone with diethyl and dimethyl succinate respectively in the presence of potassium *t*-butoxide. They obtained the half-ester, β-carbethoxy-β-(2-methyl cyclohex-1-enyl)propionic acid (**1***c*; R = C_2H_5) as a solid, and β-carbmethoxy-β-(2-methyl cyclohex-1-enyl)propionic acid (**1***c*; R = CH_3) as an oil.

In the present investigation the above reaction was repeated for further study and for the preparation of a methyl perhydroindane nucleus which can be regarded as an intermediate for the synthesis of steroid-like compounds.

2-Methyl cyclohexanone was condensed with dimethyl succinate in the presence of potassium *t*-butoxide (3) to yield the corresponding half-ester as an oil. The yield was found to be greatly increased (from 71% (2) to 90%) by increasing the molality of potassium *t*-butoxide. This oil solidified and was found to be a mixture of isomers (**1***a*, **1***b*, and **1***c*; R = CH_3). The ultraviolet (u.v.) absorption spectrum showed one strong band at 225 mμ (ε 10 000), characteristic of α,β-unsaturated esters (see ref. 4, p. 32). This indicated the presence of the half-ester (**1***a*; R = CH_3) as one isomer of the mixture. It seems that this isomer is present in a small amount as indicated by the low value of the molecular extinction coefficient. Moreover, no 2-methyl cyclohexanone could be isolated from a mild oxidation of the half-ester mixture using alkaline permanganate at room temperature, but instead a neutral carbonyl compound was obtained which gave a 2,4-dinitrophenyl hydrazone. This substance is still under investigation. Repeating the oxidation at 0° failed to give any neutral carbonyl substance. The infrared (i.r.) spectrum of the half-ester showed bands at 2800–2500 (w), 1750 (s), 935 (v), and 810 (s) cm^{-1}, characteristic of the stretching frequencies of hydroxyl and carbonyl groups of saturated acids and esters, the hydroxyl deformation (out of plane) of acids, and the CH (out of plane) deformation vibrations of trisubstituted alkenes respectively (5). These vibrations strongly suggest the presence of the isomer (**1***b*; R = CH_3). Finally the nuclear magnetic resonance (n.m.r.) spectrum showed signals at 1.6 and 5.1 p.p.m. (δ), characteristic of a methyl group attached to an unconjugated double bond and a vinyl proton respectively (see ref. 4, p. 175). This indicated the presence of the two isomers (**1***b* and **1***c*; R = CH_3).

The half-ester mixture on alkaline hydrolysis gave one homogeneous crystalline dibasic acid, m.p. 157°, which probably has the structure of one of the three possible isomers (**1***a*, **1***b*, and **1***c*; R = H). This acid showed no u.v. absorption in the characteristic region of the α,β-unsaturated acids (220–260 mμ), thus excluding structure (**1***a*; R = H). Its i.r. spectrum showed bands at 2800–2500 (w), 1740 (s), and 930 (v) cm^{-1}, characteristic of the stretching frequencies of hydroxyl and carbonyl groups of saturated acids and the hydroxyl deformation (out of plane) of acids respectively (5). The disappearance of the strong band at 810 cm^{-1} characteristic of γ CH of trisubstituted alkenes (shown by the half-ester) excluded structure (**1***b*; R = H) and confirmed structure (**1***c*; R = H) for this unsaturated dibasic acid. The presence of the olefinic linkage was chemically proved by



catalytic hydrogenation giving the known 2-methyl cyclohexyl succinic acid (**2**), m.p. 163–164° (lit. 2, m.p. 155–156°).

The crude half-ester was converted into its acid chloride (6) which was then cyclized (7). The neutral oily product thus obtained was found to be the keto-ester (**3**). It gave a 2,4-dinitrophenyl hydrazone and a semicarbazone.

Acid hydrolysis and decarboxylation of the keto-ester was effected by refluxing with a mixture of glacial acetic acid, constant boiling hydrobromic acid, and water to give the corresponding unsaturated ketone (**4**) in a good yield. It gave a 2,4-dinitrophenyl hydrazone in addition to the known semicarbazone (1).

The u.v. spectra of the keto-ester and the unsaturated ketone in ethanol had maxima at 237 mμ (ε 6162) and 236 mμ (ε 11 000) respectively. These values confirm the presence of α,β-unsaturated ketone grouping (see ref. 4, p. 139).

The unsaturated ketone (**4**) was then hydrogenated at a platinum oxide catalyst, absorbing one mole of hydrogen to give 4-methyl-*cis*-perhydro-indan-1-one (**5**) as a colorless oil. The n.m.r. spectrum showed mainly signals at 0.9 and 1.05 p.p.m. (δ), characteristic of a methyl group attached to a secondary carbon atom. This oil gave a 2,4-dinitrophenyl hydrazone and the known semicarbazone (1).

Clemmensen's reduction of the keto-ester (**3**) afforded mainly a neutral oil, which is probably the α,β-unsaturated ester (**6**; R = CH_3) since its observed absorption band λ_{max}(ethanol) 230 mμ (ε 6021) agrees with those reported for α,β-unsaturated esters in alcoholic solution (8, and ref. 4, p. 143). Alkaline hydrolysis of the unsaturated ester gave the corresponding α,β-unsaturated acid (**6**; R = H) as a colorless oil.

The unsaturated ester was then hydrogenated in the presence of platinum oxide to yield the corresponding saturated ester (**7**; R = CH_3) as a colorless oil. The n.m.r. spectrum showed mainly signals at 0.9, 1.05, and 3.6 p.p.m. (δ) corresponding to a methyl group attached to a secondary carbon atom and to a methyl ester group. Alkaline hydrolysis of this oil gave 7-methyl perhydroindan-1-carboxylic acid (**7**; R = H) as a colorless solid.

Experimental

Infrared spectra were recorded on a Beckmann IR4 double beam spectrometer using a sodium chloride cell. The ultraviolet absorption spectra were determined with a Unicam 700 spectrophotometer.

Strobbé Condensation

A solution of 2-methyl cyclohexanone (22.4 g, 0.2 mole) and dimethyl succinate (44 g, 0.3 mole) in *t*-butanol (40 ml) was added with stirring to a hot solution of potassium *t*-butoxide (from potassium metal, 11.7 g, 0.3 mole, in dry *t*-butanol 200 ml). The experiment was

For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

continued as usual (3) and the resulting viscous oil (about 41 g, 90%) solidified on keeping and cooling as glittering colorless crystals (a mixture of isomers **1**; R = CH_3), m.p. 126–129° (from aqueous methanol).

Anal. Calcd. for $C_{12}H_{18}O_4$: C, 63.71; H, 7.96. Found: C, 63.92; H, 7.73.

Oxidation of the Half-ester

The half-ester (1 g) was dissolved in a 20% sodium carbonate solution (10 ml). Aqueous potassium permanganate solution (10%) was added dropwise with stirring till the color of permanganate became permanent. The solution was kept at room temperature for 2 h then extracted with ether. The ethereal layer afforded a brown oil. This gave a 2,4-dinitrophenyl hydrazone as glittering yellow crystals, m.p. 161–162° (from ethanol).

Anal. Found: C, 43.39; H, 3.72; N, 24.57.

β-*Carboxy-*β-*(2-methyl cyclohex-1-enyl)propionic Acid (1c; R = H)*

The half-ester (2 g) was refluxed in 10% sodium hydroxide solution (20 ml) for 3 h. On acidification this precipitated the unsaturated dibasic acid (**1***c*; R = H), 1.7 g, m.p. 157° (from benzene).

Anal. Calcd. for $C_{11}H_{16}O_4$: C, 62.26; H, 7.54. Found: C, 62.07; H, 7.78.

2-Methyl Cyclohexyl Succinic Acid (2)

The unsaturated dibasic acid (1 g), dissolved in glacial acetic acid (15 ml), was shaken with hydrogen in the presence of platinum oxide (0.1 g) until uptake of hydrogen (one mole) was complete (3½ h). This afforded the known saturated diacid (**2**), m.p. 163–164° (from water) (lit. 2, m.p. 155–156° from ether – petroleum ether).

Anal. Calcd. for $C_{11}H_{18}O_4$: C, 61.68; H, 8.41. Found: C, 61.90; H, 8.29.

Cyclization of the Half-ester

The half-ester (5 g) in dry benzene (50 ml) was treated with pyridine (2.3 ml) and redistilled thionyl chloride (2 ml) at 0° for ½ h. The benzene solution of the acid chloride was decanted from the solid cake, which was then pulverized and washed by decantation with dry benzene. The acid chloride solution and washings were treated with stannic chloride (2 ml) for 15 h at 0°; the benzene solution was then poured on ice and concentrated hydrochloric acid (15 ml) and shaken. This was worked up as usual (7) giving 3-carbmethoxy-4-methyl-4,5,6,7-tetrahydroindan-1-one (**3**) as a pale-yellow liquid, b.p. 110° at 0.6 mm.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.23; H, 7.69. Found: C, 69.98; H, 7.65.

Recrystallization from ethanol yielded a semicarbazone as pale-yellow crystals, m.p. 227–228° (decomp.).

Anal. Calcd. for $C_{13}H_{19}O_3N_3$: C, 58.86; H, 7.17; N, 15.84. Found: C, 58.70; H, 7.12; N, 15.73.

Its 2,4-dinitrophenyl hydrazone melted at 201–202° (decomp., from ethanol).

Anal. Calcd. for $C_{18}H_{20}O_6N_4$: C, 55.67; H, 5.15; N, 15.6. Found: C, 55.45; H, 5.12; N, 15.33.

4-Methyl-4,5,6,7-tetrahydroindan-1-one (4)

The keto-ester (3.4 g) was refluxed with glacial acetic acid (45 ml), constant-boiling hydrobromic acid (26 ml), and water (13 ml) for 1 h. The mixture was poured carefully on crystalline sodium carbonate (125 g) in sufficient water to form a slurry. The product was extracted with ether and dried (Na_2SO_4). This yielded 4-methyl-4,5,6,7-tetrahydroindan-1-one as a pale-yellow liquid (2 g), b.p. 84° at 0.4 mm.

Anal. Calcd. for $C_{10}H_{14}O$: C, 79.95; H, 9.39. Found: C, 79.72; H, 9.12.

It gave a semicarbazone, m.p. 240° (decomp.) from ethanol (1).

Anal. Calcd. for $C_{11}H_{17}ON_3$: C, 63.74; H, 8.27; N, 20.27. Found: C, 63.46; H, 8.25; N, 19.27.

Its 2,4-dinitrophenyl hydrazone melted at 208° (from acetic acid).

Anal. Calcd. for $C_{16}H_{18}O_4N_4$: C, 58.17; H, 5.49; N, 16.96. Found: C, 58.07; H, 5.56; H, 16.96.

4-Methyl-cis-perhydroindan-1-one (5)

A solution of the unsaturated ketone (1.2 g) in glacial acetic acid (10 ml) was shaken with hydrogen in the presence of Adams platinum oxide (0.15 g) until the absorption of hydrogen was ceased. After filtration, the acetic acid was neutralized with sodium carbonate solution. This yielded the saturated ketone as a colorless liquid (0.8 g), b.p. 65–67° at 0.5 mm.

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.95; H, 10.59. Found: C, 78.70; H, 10.42.

It gave a semicarbazone as colorless crystals, m.p. 210–212° (decomp.) from ethanol (1).

Anal. Calcd. for $C_{11}H_{19}ON_3$: C, 63.20; H, 9.10; N, 20.10. Found: C, 63.41; H, 8.92; N, 19.88.

Its 2,4-dinitrophenyl hydrazone recrystallized as orange crystals from methanol, and melted at 205–206°.

Anal. Calcd. for $C_{16}H_{20}O_4N_4$: C, 57.83; H, 6.02; N, 17.39. Found: C, 57.97; H, 5.93; N, 17.18.

7-Methyl-$^1\Delta^{(8)}$*-hexahydroindan-1-carboxylic Acid (6; R = H) and its Methyl Ester (6; R = CH_3)*

To amalgamated zinc wool (20 g) in water (20 ml) and concentrated hydrochloric acid (40 ml) was added the keto-ester (5 g) in toluene (35 ml). The mixture was refluxed for 30 h with addition of concentrated hydrochloric acid (10 ml) every 6 h. The toluene layer was separated and the aqueous layer extracted with ether. The combined toluene and ether extracts, after washing with sodium bicarbonate solution, water, and drying (Na_2SO_4), afforded mainly the unsaturated ester (**6**; R = CH_3) as a pale-yellow oil (3.1 g), b.p. 85° at 0.04 mm.

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.23; H, 9.28. Found: C, 74.43; H, 9.54.

A mixture of this oil (1 g) and 5% sodium hydroxide solution (20 ml) was refluxed for 3 h. The alkaline solution, after washing with ether, was cooled in ice and acidified to give the unsaturated acid (**6**, R = H) as a colorless oil, b.p. 92° at 0.05 mm.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.33; H, 8.90. Found: C, 72.97; H, 9.35.

7-Methyl Perhydroindan-1-carboxylic Acid (7; R = H) and its Methyl Ester (7; R = CH_3)

A solution of the unsaturated ester (**7**; R = CH_3) (2 g) in absolute ethanol (30 ml) was shaken with hydrogen in the presence of Adams platinum oxide (0.2 g), until the absorption of hydrogen ceased. Filtration and removal of the solvent afforded the saturated ester (**7**; R = CH_3) as a colorless oil, b.p. 142° at 0.05 mm (1.8 g).

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.47; H, 10.20. Found: C, 73.22; H, 10.09.

The saturated ester (1 g) was refluxed for 6 h with 10% sodium hydroxide solution (10 ml) and ethanol (10 ml). Removal of the alcohol, washing the aqueous residue with ether, then acidification gave the saturated acid (**7**; R = H) as a colorless oil (0.8 g), b.p. 88–90° at 0.03 mm, which solidified on keeping, m.p. 157–158° (from benzene).

A mechanistic study of the base-catalyzed methanolysis and hydrolysis of the hydrogen phthalate ester of 4-bromo-4′-nitrobenzhydrol

K. G. RUTHERFORD, O. A. MAMER,[1] AND B. K. TANG
Department of Chemistry, University of Windsor, Windsor, Ontario

Received October 8, 1968

The hydrogen phthalate ester of 4-bromo-4′-nitrobenzhydrol has been subjected to base-catalyzed methanolysis and hydrolysis. In both cases the $B_{AC}2$ mechanism has been observed. There is no evidence of ortho-carboxylate anion participation ($B_{AC}1$ mechanism). The results have been substantiated by kinetics, stereochemistry, and ^{18}O isotope studies.

Canadian Journal of Chemistry, 47, 1487 (1969)

The base-catalyzed solvolysis of hydrogen phthalate esters is especially interesting because of the following mechanistic possibilities for such systems: (*1*) alkyl–oxygen fission involving: (*a*) prior ionization ($B_{AL}1$); (*b*) nucleophilic displacement ($B_{AL}2$); (*2*) acyl–oxygen fission involving: (*a*) ortho-carboxylate anion participation ($B_{AC}1$); (*b*) normal ester solvolysis ($B_{AC}2$).

Paths *1a* and *2a* should exhibit first order kinetics (in ester only) while paths *1b* and *2b* should be characterized by second order kinetics (first order in both ester and base). In the case of the alkaline hydrolysis of these esters, ^{18}O isotopically enriched hydroxide ion will appear ultimately in the alcohol fragment through an alkyl–oxygen fission mechanism, and in the phthalic acid if an acyl–oxygen mechanism prevails. From the stereochemical standpoint, path *1a* should lead to racemization of an optically active center, *1b* should result in an inversion of configuration, and both *2a* and *2b* should lead to the retention of configuration. Thus, by observing the kinetics, the ^{18}O isotopic distribution among the reaction products and the stereochemistry of a given solvolysis, one should be able to deduce which path is operative.

In the benzhydryl hydrogen phthalate series, path *1a* has been observed to be quite general when the 4-position of one of the benzene rings is substituted by electron releasing groups. Thus, Davies (1) showed that when optically active 4-methylbenzhydryl hydrogen phthalate was treated for 24 h with boiling methanol, a 20% yield of racemic 4-methylbenzhydryl methyl ether was obtained along with 74% of the original ester. Similarly, 4-alkylthio- (2) and 4-dialkylamino- (3) substituted benzhydryl esters lead to racemized products on solvolysis. Path *1b* to our knowledge has not been observed in hydrogen phthalate ester solvolysis and is indeed extremely rare in the case of base solvolysis of other carboxylic esters.

Path *2a* was first observed by Bender (4) who showed that the ortho-carboxylate anion has an intramolecular catalytic effect on the hydrolysis of methyl hydrogen phthalate. More recently, Thanassi and Bruice (5) have shown ortho-carboxylate anion participation in the hydrolysis of phenyl- and 2′,2′,2′,-trifluoroethyl hydrogen phthalate. Such was not the case with poorer leaving groups, however, and the authors concluded that hydrogen phthalate esters with good leaving groups hydrolyze with catalysis of the ortho-carboxylate anion, while those with poor leaving groups (methoxy and 2′-chloroethoxy) hydrolyze with catalysis of the neutral carboxylic acid function.

Puckowski and Ross (6) reported that optically active 2-, 3-, and 4-nitro, 3,5-dinitro-, and 3-bromobenzhydryl hydrogen phthalate esters yielded optically active benzhydrols on treatment with 0.2 *N* aqueous sodium hydroxide or with 10% aqueous sodium carbonate (presumably by either path *2a* or *2b*). In view of the work of Thanassi and Bruice, one might expect that the nitro-substituted benzhydryl hydrogen phthalates would undergo acyl–oxygen fission according to path *2a* since nitro-substituted benzhydroxy moieties would be classified as good leaving groups.

In a recent study in our laboratory on the sodium methoxide catalyzed methanolysis of a series of benzhydryl hydrogen phthalate esters, results similar to those of Puckowski and Ross were obtained for those esters which were

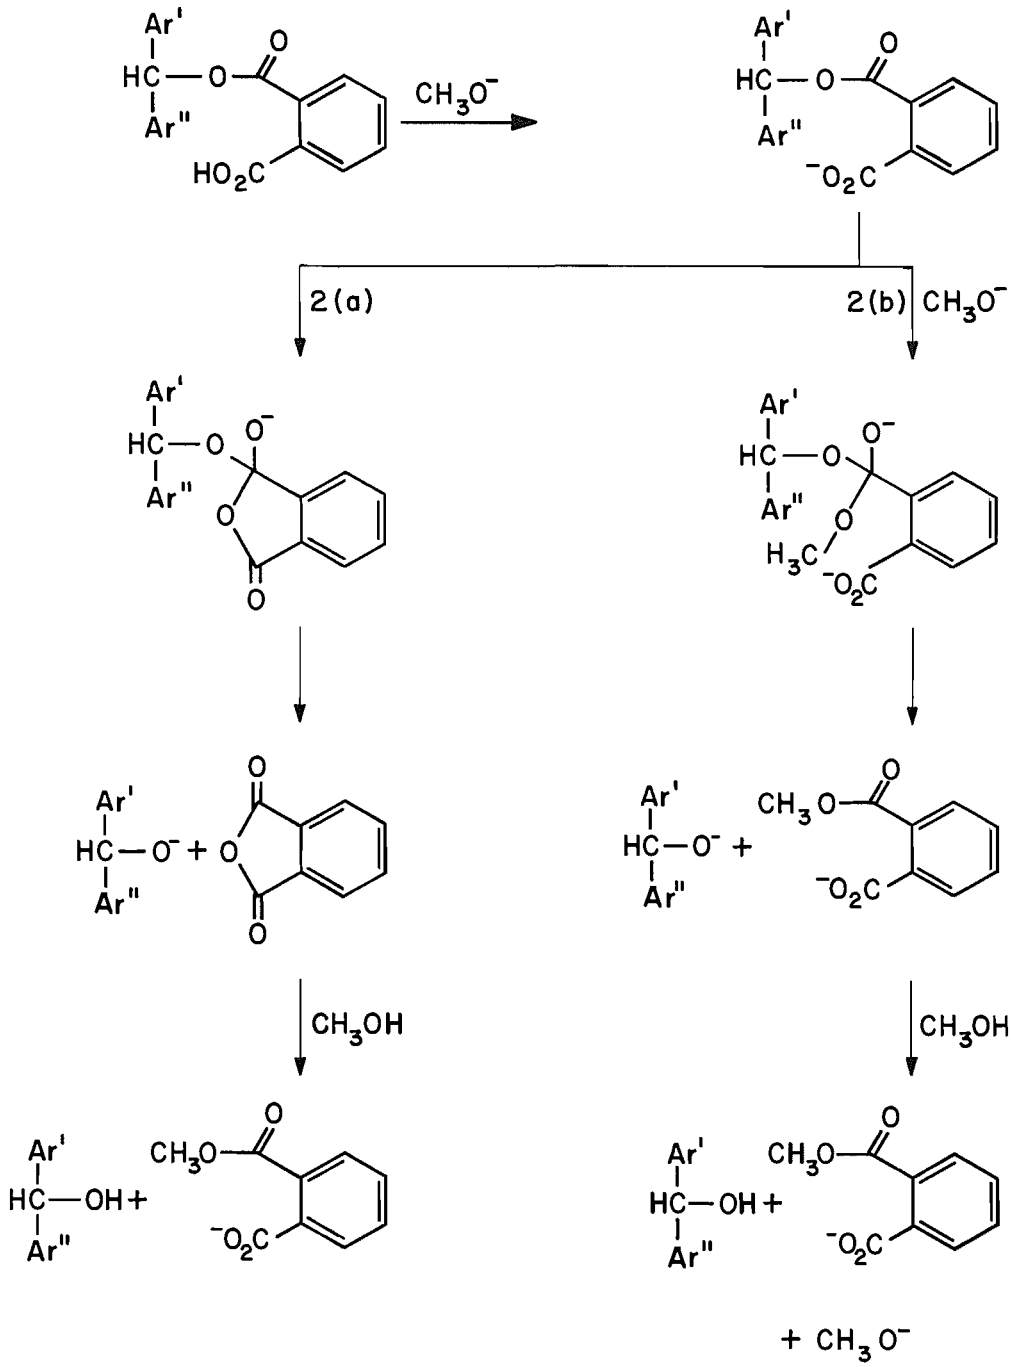

FIG. 1. Reaction paths leading to acyl–oxygen fission in the methoxide ion catalyzed methanolysis of 4-bromo-4′-nitrobenzhydryl hydrogen phthalate.

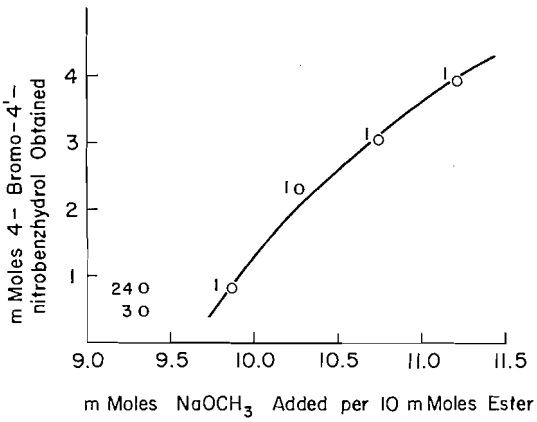

FIG. 2. Methoxide ion catalyzed methanolysis of 4-bromo-4′-nitrobenzhydryl hydrogen phthalate in moles hydrol obtained vs. mmoles methoxide added to 10 mmoles ester. Numbers accompanying datum points indicate reaction time in h.

substituted in one of the benzene rings by even the weaker electron-seeking atoms (4-Cl, $\sigma = +0.227$). We chose to study in more detail the base-catalyzed methanolysis and hydrolysis of 4-bromo-4′-nitrobenzhydryl hydrogen phthalate. The presence of the nitro group and bromine atom should make the benzhydroxy group an excellent leaving group and thus path *2a* should be observed to some extent. Figure 1 shows the two accepted mechanisms for these solvolyses involving acyl–oxygen fission (*2a* and *2b*).

Results and Discussion

Methoxide Ion Catalyzed Methanolysis Studies

Figure 2 shows the effect of adding increasing amounts of sodium methoxide to a solution of 4-bromo-4′-nitrobenzhydryl hydrogen phthalate. It can be seen that as the methoxide is added progressively to the ester solution, no appreciable methanolysis occurs even after the lapse of 24 h at 25° until the equivalent point is reached. Further addition of methoxide (i.e. in excess of equivalency) results in a progressive increase in the amount of 4-bromo-4′-nitrobenzhydrol produced after 1 h of reaction time. Thus when 11.2 mmoles of methoxide are added to 10 mmoles of the ester, approximately 40% methanolysis is realized at the end of 1 h. It is to be noted at the lower left portion of the graph that when 9.34 mmoles of methoxide are added to 10 moles of ester, no significant difference in yields of the benzhydrol is observed at the end of 3 and 24 h. The solvolysis obtained before equivalency probably arose from local high base concentrations existing briefly during the initial mixing. It would appear from the above that the intramolecular catalyzed methanolysis of this ester by the ortho-carboxylate anion is relatively insignificant, and that mechanism *2a* can be essentially discounted as a reaction path.

It was decided to substantiate this indirect stoichiometric evidence with a kinetic study of the reaction. If the reaction proceeds via path *2b*, the addition of base in excess of equivalency should cause a rate enhancement paralleling that observed in normal ester solvolysis. Such kinetic studies for methoxide catalyzed methanolysis present a problem. Since the concentration of methoxide does not change after equivalency regardless of the mechanistic path, the normal acid–base titrimetric methods usually followed in normal ester hydrolysis cannot be employed. It was decided then to follow the rate of reaction using gravimetric means. The ester was dissolved in tetrahydrofuran (THF) and a standard sodium methoxide solution was added. Aliquots of the reaction mixture were removed at intervals and rapidly acidified with hydrochloric acid. The methyl hydrogen phthalate formed from the reaction was found to be soluble under the conditions used. Thus only 4-bromo-4′-nitrobenzhydrol and unchanged hydrogen phthalic ester were precipitated after rapid acidification. From the weights (w) of the precipitates obtained, the concentration of the unchanged ester was calculated from the following relationship.

By mass balance

$$N_A + N_B = N_A \quad [1]$$

and

$$N_A M_A + N_B M_B = W \quad [2]$$

where N_A and N_B are the number of moles of the ester and benzhydrol respectively in the precipitate, and M_A and M_B are the corresponding molecular weights. N_{Ao} is the number of moles of ester expected to be in the aliquot taken at time zero and is calculated as

$$N_{Ao} = V_{aliq.} \times [\text{ester}]_{t=0} \quad [3]$$

The aliquot volume is 50 ml, and the reaction solution is made up to 0.020 moles ester per 275 ml reaction volume.

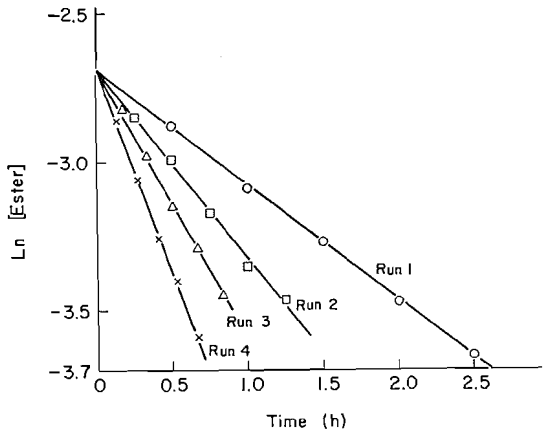

FIG. 3. Methoxide ion catalyzed methanolysis of 4-bromo-4′-nitrobenzhydryl hydrogen phthalate. Rate first-order in ester concentration. Excess methoxide ion concentration: run 1, 1.0; run 2, 2.0; run 3, 3.0; run 4, 4.0 mmoles methoxide ion per 20 mmoles ester in 275 ml reaction volume.

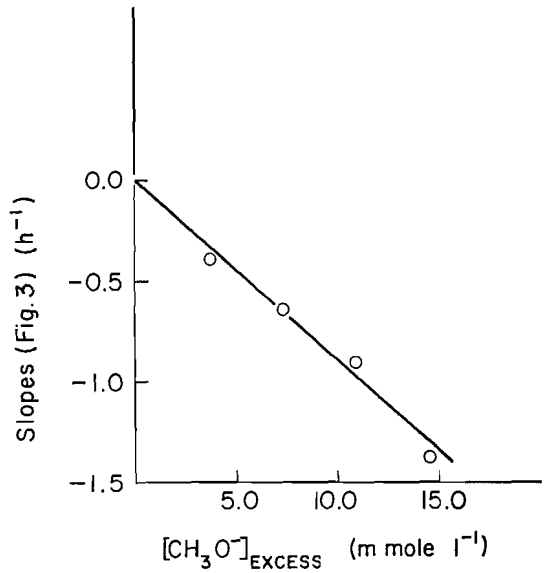

FIG. 4. Slopes from Fig. 3 vs. concentration of excess methoxide ion showing first-order dependency of rate on methoxide ion concentration in excess of equivalency.

Therefore

$$[4] \qquad N_{Ao} = 0.050 \times \frac{0.020}{0.275} = 0.00364 \text{ moles}$$

By arranging [1] and substituting in [2] we have for a 50 ml aliquot:

$$[5] \qquad N_A = \frac{W - N_{Ao}M_B}{M_A - M_B} = \frac{W - 1.121}{148}$$

Therefore

$$[6] \qquad [\text{ester}] = \frac{N_A}{0.050\,1} = \frac{W - 1.121}{7.40}$$

Thus expression [6] provides for the convenient determination of the concentration of the unreacted ester (in mole l^{-1}) in the solvolyzing solutions from the weight of the precipitate (in g) obtained from each aliquot.

Figure 3 shows the first-order dependency of the reaction rate on the ester anion concentration. Each line represents an experiment different from the others only in the concentration of methoxide ion existing in excess of equivalency. A linear relationship (Fig. 4) is shown to exist between the slopes of the first-order plots of Fig. 3 and the concentration of methoxide ion remaining in excess of equivalency. This indicates that the solvolytic rate is proportional to that quantity of methoxide ion that is in excess of equivalency and not consumed by the reaction (Fig. 1). This observed proportionality dismisses path *2a* as being of importance as this path suggests that the rate should be independent of the concentration of excess methoxide ion. On the other hand, path *2b* predicts the experimentally observed first-order dependency in both ester anion and methoxide ion concentrations.

Thus the second-order rate law for the reaction is then:

$$[7] \qquad \frac{d[\text{ester}]}{dt} = -k_2[\text{ester}][CH_3O^-]_{\text{excess}}$$

where k_2 (l mole^{-1} h^{-1}) is the slope of the line in Fig. 4.

Therefore

$$[8] \qquad k_2 = 89.0$$

Hydroxide Ion Catalyzed Hydrolysis Studies

The hydroxide ion catalyzed hydrolysis of the same hydrogen phthalate ester was found to follow a kinetic scheme similar to that for the methoxide ion study. Figures 5 and 6 show the dependency of the hydrolytic rate on the concentration of both the ester and the excess hydroxide ion. A similar mathematical treatment based on aliquot precipitate weights was employed to calculate the concentrations of unreacted ester remaining in each aliquot.

In order to effect a reaction on a convenient time scale, the concentrations of the basic ion were increased approximately ten-fold over those

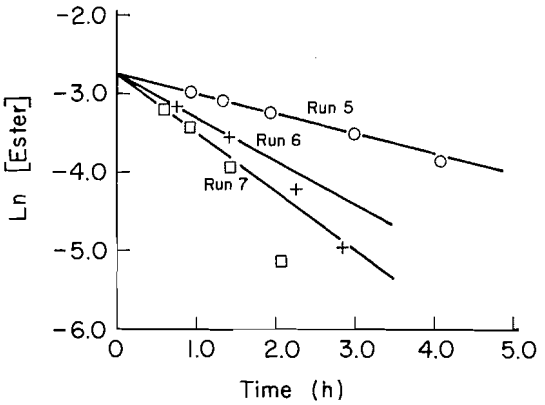

FIG. 5. Hydroxide ion catalyzed hydrolysis of 4-bromo-4′-nitrobenzhydryl hydrogen phthalate. First-order in ester concentration. Excess hydroxide ion concentration: run 5, 13.4; run 6, 25.2; run 7, 36.8 mmoles hydroxide ion per 10 mmoles ester in 137.5 ml reaction volume.

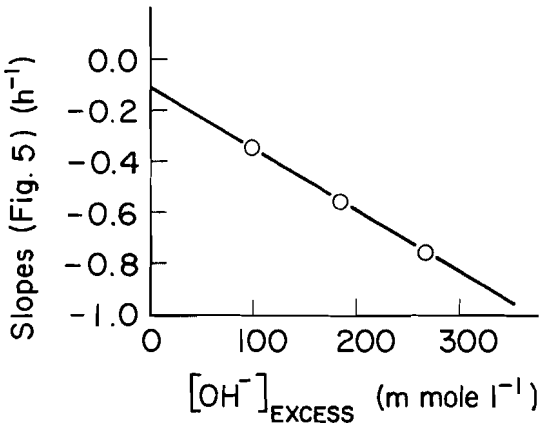

FIG. 6. Slopes from Fig. 5 vs. concentration of excess hydroxide ion. First-order rate dependency on excess hydroxide ion concentration.

used in the methanolysis study. The lines in Fig. 6 are straight at least in the range of conversions found in the methanolysis study. The apparent increase in the hydrolytic rate with increasing conversion is probably not a kinetic effect but only a mechanical handling error caused by incomplete precipitation of the reaction products or incomplete transfer of the products to the weighing crucibles. This gravimetric method becomes increasingly sensitive to errors arising from incomplete collection of the products as the hydrolysis nears completion. A loss or gain of 3 mg of precipitate for example at 92% completion (last datum point in run 7, Fig. 5) causes an uncertainty of 0.4 logarithm units at that point.

Another method of analysis was used in the first few samples as a check on the gravimetric procedure. This was a titrimetric method involving the measurement of an apparent neutralization equivalent of a quenched aliquot, from which the concentration of the unsolvolyzed ester in the reaction mixture was calculated (7). It was found early in the experiments that the two methods gave results agreeing to within 7% of each other, with the conversions determined through the titrimetric method being consistently lower. From the point of view of convenience, the titrimetric method was abandoned and the kinetics studied by only the gravimetric method.

The initial slopes (Fig. 5) are directly proportional to the concentration of hydroxide ion in excess of equivalency (Fig. 6). Thus for the hydrolysis

$$[9] \qquad \frac{d[\text{ester}]}{dt} = -k_2[\text{ester}][OH^-]_{\text{excess}}$$

where k_2 (l mole^{-1} h^{-1}) is the slope of the line in Fig. 6.
Therefore

$$[10] \qquad k_2 = 2.40$$

It is to be noted from Fig. 6 that at equivalency (i.e. $[OH^-]_{\text{excess}} = 0$) there appears to be a slight hydrolytic rate. It is not clear whether this is due to hydrolysis occurring via path *2a* or an overall displacement of the line downwards, caused by localized and transient high base concentrations generated on mixing.

The second-order nature of the alkaline hydrolysis of this ester indicates that the ester anion and the hydroxide ion are both involved in the rate-determining step. In the interpretation of these kinetic results, a problem arises here which did not arise in the methanolysis studies. Thus the absence of 4-bromo-4′-nitrobenzhydryl methyl ether in the methanolysis of the benzhydryl ester discounts any argument that the kinetics could be explained by path *1b*. Although intuitively one might not expect any variation in mechanism, it is necessary to eliminate *1b* as a reaction path.

The same conclusion can be drawn from a stereochemical study of this same ester. The methoxide ion catalyzed methanolysis of optically active 4-bromo-4′-nitrobenzhydryl hydrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

phthalate ($[\alpha]_D^{25}$ +0.87°) yielded optically active 4-bromo-4′-nitrobenzhydrol ($[\alpha]_D^{25}$ +0.23°). Since the methanolysis reaction was shown to result in acyl–oxygen cleavage, the configuration of the hydroxyl group was then established. When the same optically active ester was subjected to hydroxide ion catalyzed hydrolysis, similar optical activity for the "hydrol" ($[\alpha]_D^{25}$ +0.50°) was noted. It must be concluded then that hydrolysis as well as methanolysis by the benzhydryl ester in this study proceeds by the attack of the base at the ester carbonyl (path *2b*).

It is difficult to rationalize the failure of the ortho-carboxylate anion to participate in the removal of the 4-bromo-4′-nitrobenzhydroxy group without resorting to an argument based on a steric effect preventing the formation of the five-membered ring intermediate. Certainly, any electrical influences affecting the ester carbonyl would be the same whether or not this group was attacked by carboxylate, methoxide, or hydroxide.

Since the ring substituents are in the 4-position of the benzhydryl portion, only electrical effects can be realized from these sources. It might be deduced then that benzhydryl hydrogen phthalate esters, in which the overall effect of substituent groups is to withdraw electrons from the carbinyl carbon atom, undergo base-catalyzed solvolysis according to the $B_{AC}2$ mechanism.

Experimental

4-Bromo-4′-nitrobenzhydryl Hydrogen Phthalate

A solution of 4-bromo-4′-nitrobenzhydrol (8)[2] (31 g, 0.10 mole) phthalic anhydride (16.3 g, 0.11 mole), and pyridine (100 ml) was added to a 300 ml conical flask. Sodium hydride (5.28 g, 0.11 mole, of a 50% dispersion in mineral oil) was added with stirring at a rate adjusted to keep the temperature of the solution below 35°. When the addition was completed, the flask was loosely stoppered and the mixture was magnetically stirred for a period of 6 h. The mixture was then poured slowly into 1 l of 2 *N* hydrochloric acid. The organic material was extracted twice with two 100 ml portions of chloroform which was then washed three times with 0.1 *N* hydrochloric acid, dried over anhydrous sodium sulfate, and the solvent removed *in vacuo*. The remaining gum was dissolved in 0.2 *N* sodium hydroxide (750 ml) and the resultant solution filtered through a fine sintered glass plate. The solution was slowly acidified with dilute hydrochloric acid thus yielding the crude ester (42 g, 92%) m.p. 171–180°. Recrystallization from a chloroform – petroleum ether (b.p. 30–60°) solvent pair produced the pure ester (38 g) m.p. 184–185°. The infrared spectrum of the compound showed the following bands: a broad OH band beginning at 3500 cm^{-1} and merging with CH stretching at 3000 cm^{-1} (characteristic of carbonyl OH stretching), an ester carbonyl stretching at 1736 cm^{-1}, and an acid carbonyl stretching at 1702 cm^{-1}, aromatic skeletal vibrations at 1602 and 1490 cm^{-1}, and nitro group stretching at 1524 and 1350 cm^{-1}.

Anal. Calcd. for $C_{21}H_{14}BrNO_6$ (neutralization equivalent, 456.24): C, 55.30; H, 3.60. Found (neutralization equivalent, 455.7): C, 55.70; H, 3.23.

(+)-Bromo-4′-Nitrobenzhydryl Hydrogen Phthalate

A solution of the racemic ester (20 g, 0.044 mole), brucine (16 g, 0.041 mole), and acetone (250 ml) was heated at reflux for 10 min. Removal of the solvent at reduced pressure yielded the brucine salt as a bright-yellow spongy glass. Three successive recrystallizations of the salt from 2:1 toluene–methylcyclohexane yielded the salt as a brilliant yellow powder (10.5 g), m.p. 138–140°. The salt was too highly colored to allow determination of its specific rotation. The melting point range could not be improved by further recrystallization. A solution of the salt in acetone (200 ml) was poured into ice-cold 0.2 *N* hydrochloric acid (400 ml) which yielded the ester. The resolved ester was obtained as a white crystalline material (5.1 g, 23% on resolution) m.p. 180–181°, $[\alpha]_D^{25}$ + 0.87° (l, 2; *c*, 4.0 in acetone) after one recrystallization from chloroform – petroleum ether.

Solvolytic Reactions of 4-Bromo-4′-Nitrobenzhydryl Hydrogen Phthalate

(a) With Sodium Methoxide

The ester (4.5 g, 0.01 mole) was dissolved in anhydrous THF (30 ml), and to this was added a methanol solution of sodium methoxide (1.0 g, 0.044 mole sodium; 30 ml anhydrous methanol). The solution was stirred for 5 min and then poured over a slurry of ice (20 g) and concentrated hydrochloric acid (5 ml), yielding 4-bromo-4′-nitrobenzhydrol (3.0 g, 97%), m.p. 150–154°. Saturation of the cold mother liquor with potassium chloride and extraction with ether yielded methyl hydrogen phthalate (0.2 g, 12%) m.p. 82–83°. When this procedure was repeated with the optically active ester (4.0 g, 0.0088 mole), (+)-4-bromo-4′-nitrobenzhydrol (2.15 g, 80%), m.p. 157–159°, was obtained having $[\alpha]_D^{25}$ +0.23° (l, 2; *c*, 2.15 in acetone).

(b) With Methanol

The racemic ester was recovered unchanged (92%) after heating at reflux in methanol for 24 h.

(c) With Aqueous Sodium Hydroxide

A solution of (+)-4-bromo-4′-nitrobenzhydryl hydrogen phthalate (2.25 g, 0.0049 mole) in THF (25 ml) was mixed with 2 *N* sodium hydroxide (400 ml). After standing for 30 min, the mixture was rendered neutral with dilute hydrochloric acid. The 4-bromo-4′-nitrobenzhydrol (1.2 g, 80%) so obtained had m.p. 156–158°, $[\alpha]_D^{25}$ +0.50° (l, 2; *c*, 6 in acetone).

A sample of the racemic ester (1.0 g, 0.0022 moles) was similarly treated with ^{18}O labeled aqueous sodium hydroxide (0.2 g, 0.0050 moles NaOH; 1 ml 20% ^{18}O enriched H_2O; 1 ml THF). The benzhydrol obtained

[2]For preparation and characterization of this alcohol, see reference 8.

from this reaction was found by mass spectrometry[3] not to be enriched in ^{18}O over natural abundance. On the other hand, the phthalic acid contained 4.58% ^{18}O enrichment (99.8% of the theoretically required amount).

Kinetic Study of the Solvolysis of 4-Bromo-4'-Nitrobenzhydryl Hydrogen Phthalate

(a) With Methoxide

Stoichiometric study—Known amounts of the ester (4.56 g, 0.010 mole) were dissolved in anhydrous THF (40 ml volumes). To each ester solution was added a carefully pipetted quantity of a standard methanolic sodium hydroxide solution (0.934 *N*) prepared from anhydrous methanol (500 ml) and freshly cut sodium (11.5 g, 0.5 mole). The resulting solutions were tightly stoppered and kept in a constant temperature bath at 25 °C for varying lengths of time. The samples were then poured quantitatively into ice-cold water (300 ml) and the resulting solutions were rapidly made acidic (pH 2) with 2 *N* hydrochloric acid. The precipitates were allowed to remain in contact with the mother liquor for ½ h to ensure high yields of the insoluble material. The crystalline precipitates were collected in preweighed sintered glass crucibles (medium porosity), washed with distilled water, air dried for 6 h, and finally dried *in vacuo* for 12 h. The weights of the precipitates were then noted, and the extents of conversion were calculated for each sample (Fig. 2).

Kinetic study—A different method of conducting the kinetic study of the solvolysis with sodium methoxide was used in determining the reactant orders. The ester samples (9.12 g, 0.020 moles) were dissolved in volumes of THF (150 ml). Varying amounts (22.5–25.7 ml) of the methanolic sodium methoxide stock solution (0.934 *N*) were pipetted into volumes of anhydrous methanol (100 ml). The methanol solutions were then poured rapidly and quantitatively into the rapidly stirred ester solutions to start the experiment. Immediately the reaction solutions were diluted to exactly 275 ml with anhydrous methanol (less than 5 ml being sufficient), and tightly stoppered. The solutions were kept in a constant temperature bath (25°). At intervals during the length of the reaction period, aliquots (50 ml) were removed from the reaction flasks and were quenched and weighed exactly as described above. The concentrations of unreacted ester were then calculated as described previously.

(b) With Hydroxide

The kinetics of the alkaline hydrolysis of 4-bromo-4'-nitrobenzhydryl hydrogen phthalate were followed by gravimetric technique similar to that described above. In all the kinetic experiments with aqueous hydroxide, the following method was used. Samples of the ester (4.56 g, 0.010 mole) were dissolved in volumes of anhydrous THF (30 ml) and these solutions were quantitatively added to volumes of aqueous potassium hydroxide solution (100 ml) of different concentrations. The solutions were immediately diluted to 137.5 ml (less than 10 ml being sufficient). The solutions were kept in a constant temperature bath (25° ± 0.5°). At intervals during the length of the reaction period, aliquots (25 ml) were withdrawn from the reaction flasks and were quenched and the precipitates weighed in exactly the manner described previously.

[3]Limiting sensitivity $^{18}O/(^{18}O + ^{16}O) < 0.05\%$. Analysis was performed by Morgan and Schaffer Corp., Montreal, Quebec.

Stereochemistry of hydrogenation of 19-substituted 5α-cholestan-3-ones[1]

Y. WATANABE AND Y. MIZUHARA[2]
Chemical Laboratory, School of Medicine, Keio University, Hiyoshi, Yokohama, Japan

AND

M. SHIOTA
Chemical Laboratory, Ochanomizu University, Otsuka, Tokyo, Japan

Received September 27, 1968

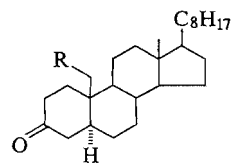
The effect of 19-substituents on the stereochemistry of hydrogenation of 19-substituted 5α-cholestan-3-ones was examined. It has been shown that hydroxyl, acetoxyl, and methoxyl groups have some effect in increasing 3α-alcohols on hydrogenation over platinum in ethanol compared with the case of the unsubstituted ones.

Canadian Journal of Chemistry, 47, 1495 (1969)

The stereochemistry of the alcohols resulting from the catalytic hydrogenation of steroidal ketones has been known to be very sensitive to the reaction medium (1–3), and the reason for this is a debated point (3, 4). On the other hand, the substituent effect on the stereochemistry of hydrogenation of ketones has not yet been well examined, and an investigation of the effect of some substituents in a rather rigid steroidal system seems to be of interest. Previously, we reported on the catalytic hydrogenation of 3β-acetoxy-19-hydroxy- and 3α,19-dihydroxycholest-5-enes and showed that the 19-hydroxyl group in the above compounds is effective in increasing the proportion of 5β-dihydro compounds (5, 6). It appeared that the lone paired electrons of the oxygen atom of the 19-hydroxyl group made it easier for the catalyst to approach the β-side of the molecule. As part of the investigation of the effect of 19-substituents on stereochemistry of hydrogenation we examined the influence of 19-substituents on the proportion of 3α- and 3β-alcohols obtained in the catalytic hydrogenation of 19-substituted 5α-cholestan-3-ones.

The proportion of the 3α-alcohol obtained in hydrogenation of 5α-cholestan-3-one over platinum has been reported to vary with acidity of the solvent used (1, 2), and the 3α-alcohol became the main product of hydrogenation by adding small amounts of hydrochloric acid to the solvent (3). As the stereochemistry of the hydrogenation of steroidal 3-ketones appears very susceptible to the influence of the condition of the reaction, for instance, the catalyst used, solvent, temperature and other factors, the proportion of 3α-alcohols obtained in hydrogenation of several ketones under the same condition was compared with that of 5α-cholestan-3-one in the present experiments.

We synthesized the 19-substituted 5α-cholestan-3-one derivatives listed below.



1*a* R = H
1*b* R = OH
1*c* R = OAc
1*d* R = OCH_3
1*e* R = Cl

TABLE I

Optical rotatory dispersion molecular amplitude (in dioxane)

Compound	Molecular amplitude
1*a*	+49
1*b*	+14
1*c*	+37
1*d*	+31
1*e*	+27
2	+114

positive Cotton effect curves such as that of 5α-cholestan-3-one, but some differences in amplitude were observed. Especially in 19-hydroxy-3-one (**1***b*) a considerable decrease of the positive amplitude was seen, and this phenomenon has been interpreted by Crabbé (7, 8) to be due to the possibility that the compound exists as the free and intramolecular hemiketal form. It has also been shown that the introduction of 6β,19-epoxide causes the considerable increase in molecular amplitude compared with that of 5α-cholestan-3-one.

The above ketones were hydrogenated over platinum in acetic acid and in ethanol solution, and the proportion of 3α- and 3β-alcohols was determined by gas–liquid chromatography. The results are reported in Table II. The experimental results of the reduction of the compound **1**, **2**, and **3** with sodium borohydride in methanol are also mentioned for comparison. The configurations of the epimeric alcohols obtained in the hydrogenation of **1***a*, **1***b*, **1***c*, **1***e*, **2**, and **3** have already been established (5, 6). The configurations of the products from the 19-methoxy derivative (**1***d*) have been assigned on the basis of nuclear magnetic resonance (n.m.r.) spectra. The differences in the chemical shift and in the half-widths of the peaks of the epimeric C-3 protons were used (3), namely, the 3α-alcohol had a C-3 proton peak centered at 5.05 p.p.m. (half-width 8 c.p.s.), while in the 3β-one it was centered at 4.7 p.p.m. (23 c.p.s.), as the 3-acetoxy derivative.

When reduced with sodium borohydride, all hydrogenated compounds gave about 10% of 3α-alcohols as in the case of 5α-cholestan-3-one and it was shown that 19-substituents have little effect on the steric course of the reaction. The catalytic hydrogenation in ethanol gave proportions of 3α-alcohols varying with the change of 19-substituent and it was observed that the presence of the 19-substituents such as hydroxyl, acetoxyl, and methoxyl groups caused the increase of the proportions of 3α-alcohols by 10–20% in ethanol. In acetic acid, the proportion of 3α-alcohol was shown to decrease a little in all 19-substituted derivatives compared with that in the unsubstituted one.

TABLE II

The proportions of 3α- and 3β-alcohols obtained in reduction*

Compound (19-substituent)	$NaBH_4$		H_2/Pt–EtOH		H_2/Pt–AcOH	
	3α-	3β-	3α-	3β-	3α-	3β-

2	12	88	17	83	2	98
3	9	91	6	94	1	99

*Proportions expressed as percentages.

From the above experimental results, the effect of 19-substituents on hydrogenation in ethanol appears to be due to electronic interaction between substituents and catalyst rather than steric effect. In acetic acid, this interaction appears to be weakened by protonation, and the steric course of the hydrogenation seems to be more controlled by steric factors. On the hydrogenation of the 5,6-double bond, the effect of the 19-hydroxyl group in increasing the 5β-dihydro compound was shown to be weakened in acetic acid, but 3β-acetoxy-19-hydroxycholest-5-ene gave 36.5% of the 5β-dihydro compound even when it was hydrogenated over platinum in acetic acid, while 3β-acetoxycholest-5-ene afforded only 10% of the 5β-dihydro compound under the same conditions. On the other hand the effect of the 19-hydroxyl group completely disappeared in acetic acid on the reduction of the 3-keto group. On the basis of these results, it was supposed that the hydrogen bonding between the 19-hydroxyl group and the π-electrons of the 5,6-double bond contributed to the determination of the steric course of hydrogenation together with the lone paired-electrons of the oxygen atom. Not only hydroxyl but also acetoxyl and methoxyl groups appear to have some effect on the stereochemistry of hydrogenation of the 3-keto group in ethanol. Though the effect of acetoxyl and methoxyl groups as above has scarcely been reported, it

has been suggested that the lone paired-electrons of the oxygen atoms in these groups may play some role to promote the β-side hydrogenation. On the hydrogenation of the 5,6-double bond the 19-acetoxyl group has no effect in increasing the 5β-dihydro compound both in ethanol and in acetic acid. But in the case of the reduction of the 3-keto group an acetylation of the 19-hydroxyl group did not cause a large change in the proportion of the 3α-alcohol. This difference in the effect of the 19-acetoxyl group and the 3-keto group on the reduction of the 5,6-double bond seems to be related to the difference in the distance between the 19-substituent and the unsaturated bond to be hydrogenated, or may be due to a steric effect.

Numerous intramolecular reactions of A/B-*trans*- and Δ^5-steroids possessing functional groups at C-3 and C-19 have been reported (9–13). As the flexibility of ring A allows the interaction of the functional groups at C-3 and C-19, it is not clear that the larger effect of 19-hydroxyl group than that of others is partially attributed to the formation of the intramolecular hemi-ketal. From a consideration of the o.r.d. and n.m.r. results, it is suggested that the steric course of hydrogenation depends much more from the nature of the substituent at C-19 than from the possible changes of conformation occurring in ring A.

Experimental

All melting points are uncorrected. Nuclear magnetic resonance spectra were obtained at 60 Mc.p.s. on $CDCl_3$ solution containing TMS as an internal standard; the chemical shifts are expressed in p.p.m.; s = singlet, q = quartet.

3β-Acetoxy-19-benzoyloxy-5α-cholestane (4a)

Benzoylation of 3β-acetoxy-19-hydroxy-5α-cholestane (5) with pyridine and benzoyl chloride at room temperature gave **4a**, which was recrystallized from methanol, m.p. 125–126°; $[\alpha]_D^{26}$ +30.6° ($CHCl_3$, *c*, 1.625); ν_{max} (KBr) 1733, 1720, 1603, 1585, 1273, 1247, 1117, 1028, and 720 cm^{-1}; λ_{max} (EtOH) 231 mμ (ε 13 900), 274 mμ (ε 1 100).

Anal. Calcd. for $C_{36}H_{54}O_4$: C, 78.50; H, 9.88. Found: C, 78.62; H, 9.72.

3β-Hydroxy-19-benzoyloxy-5α-cholestane (4b)

Hydrolysis of **4a** with 0.5% KOH–ethanol gave **4b**, which was recrystallized from acetone–methanol, m.p. 154.5–155.2°; $[\alpha]_D^{26}$ +41.7° ($CHCl_3$, *c*, 1.440); ν_{max} (KBr) 3420, 1717, 1603, 1585, 1270, 1118, 1033, 1029, and 715 cm^{-1}; λ_{max} (EtOH) 231 mμ (ε 13 100), 274 mμ (ε 950).

Anal. Calcd. for $C_{34}H_{52}O_3$: C, 80.26; H, 10.30. Found: C, 79.96; H, 10.53.

19-Benzoyloxy-5α-cholestan-3-one (1f)

A solution of 300 mg of 3β-hydroxy compound (**4b**) in 30 ml of acetone was oxidized with 0.7 ml of 8 *N* chromic–sulfuric acid solution at 0° for 30 min. The crude product (270 mg) was recrystallized from acetone–methanol; yield, 230 mg, m.p. 152–152.5°; ν_{max} (KBr) 1718, 1603, 1585, 1273, 1115, 1030, and 719 cm^{-1}; λ_{max} (EtOH) 231 mμ (ε 13 600), 274 mμ (ε 910); n.m.r. (δ): 4.72 (s, 19-CH_2), 7.4–8.15 (aromatic H); o.r.d. (*c*, 0.0057, dioxane, 20°): $[\phi]_{450}$ +360°, $[\phi]_{315}$ +2430°, $[\phi]_{288}$ 0°, $[\phi]_{283}$ −320°.

Anal. Calcd. for $C_{34}H_{50}O_3$: C, 80.58; H, 9.95. Found: C, 80.78; H, 10.19.

19-Hydroxy-5α-cholestan-3-one (1b)

19-Benzoyloxy compound (**1f**) was hydrolyzed with 5% KOH–ethanol solution at room temperature. The crude product was recrystallized from methanol, m.p. 143.5–144.5°; ν_{max} (KBr) 3420, 1720 (weak), and 1045 cm^{-1}; n.m.r. (δ): 4.18 and 4.00 (AB type q, J = 10.5 c.p.s., 19-CH_2); o.r.d. (*c*, 0.0071, dioxane, 20°): $[\phi]_{450}$ +380°, $[\phi]_{313}$ +1730°, $[\phi]_{275}$ +330°, $[\phi]_{260}$ +590°.

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 80.54; H, 11.52. Found: C, 80.67; H, 11.52.

19-Acetoxy-5α-cholestan-3-one (1c)

Acetylation of **1b** with pyridine and acetic anhydride overnight at room temperature gave the acetate (**1c**). Recrystallization of the crude product from methanol gave a pure product, m.p. 99.5–100.5°; ν_{max} (KBr) 1735, 1710, 1249, 1240, and 1050 cm^{-1}; n.m.r. (δ): 4.49 (s, 19-CH_2), 2.10 ($OCOCH_3$); o.r.d. (*c*, 0.006, dioxane, 20°): $[\phi]_{450}$ +270°, $[\phi]_{315}$ +2180°, $[\phi]_{293}$ 0°, $[\phi]_{274}$ −1560°, $[\phi]_{260}$ −1250°.

Anal. Calcd. for $C_{29}H_{48}O_3$: C, 78.32; H, 10.88. Found: C, 78.49; H, 10.96.

3-Ethylenedioxy-19-benzoyloxy-5α-cholestane (5a)

19-Benzoyloxy-3-ketone (**1f**) was converted into the ethylenedioxy derivative by exchange dioxolonation (14). The mixture of 250 mg of 3-ketone (**1f**) and 7 mg of *p*-toluenesulfonic acid in 4 ml of 2-methyl-2-ethyl-1,3-dioxolane was refluxed for 6 h. After cooling, the reaction mixture was diluted with benzene and the resulting solution was washed with sodium bicarbonate solution and with water, and dried over sodium sulfate. Evaporation of the solvent *in vacuo* gave the crude product, which was recrystallized from acetone–methanol; yield, 200 mg, m.p. 138.5–139.5°; $[\alpha]_D^{26}$ +42.9° ($CHCl_3$, *c*, 1.625); ν_{max} (KBr) 1715, 1274, 1115, 1104, 1073, 1028, 946, and 710 cm^{-1}; λ_{max} (EtOH) 231 mμ (ε 13 600), 274 mμ (ε 910); n.m.r. (δ): 3.95 (s, 3-ethylenedioxy), 4.52 (s, 19-CH_2), 7.4–8.15 (aromatic H).

Anal. Calcd. for $C_{36}H_{54}O_4$: C, 78.50; H, 9.88. Found: C, 78.37; H, 9.79.

3-Ethylenedioxy-19-hydroxy-5α-cholestane (5b)

19-Benzoyloxy compound (**5a**) was hydrolyzed with 5% KOH–ethanol under reflux for 45 min. The crude product was recrystallized from *n*-hexane, m.p. 146.1–146.7°; $[\alpha]_D^{26}$ +48.1° ($CHCl_3$, *c*, 2.075); ν_{max} (KBr) 3530, 1112, 1103, 1097, 1040, and 946 cm^{-1}; n.m.r. (δ):

3.95 (s, 3-ethylenedioxy), 3.75, and 4.00 (AB type q, J = 12 c.p.s., 19-CH_2).

Anal. Calcd. for $C_{29}H_{50}O_3$: C, 77.97; H, 11.28. Found: C, 77.74; H, 11.16.

3-Ethylenedioxy-19-methoxy-5α-cholestane (5c)

Potassium metal (55 mg) was added to a solution of 100 mg of 19-hydroxy compound (**5b**) in 5 ml of dry benzene, and the mixture was refluxed for 2 h with vigorous stirring. Then methyl iodide (2 ml) was added and the refluxing was continued for 3 h (15). After cooling, methanol was added, the reaction mixture was diluted with ether, and the solution was washed with water and dried over sodium sulfate. Evaporation of the solvent gave the crude product (92 mg), which was purified by chromatography on alumina eluting with *n*-hexane–chloroform (10:1). Recrystallization of the product purified by chromatography gave 70 mg of the pure methoxy compound (**5c**), m.p. 128–129°; $[\alpha]_D^{26}$ +30.0° ($CHCl_3$, *c*, 1.340); ν_{max} (KBr) 1110, 1096, 1070, 978, and 810 cm^{-1}; n.m.r. (δ): 3.32 (s, OCH_3), 3.51 (s, 19-CH_2), 3.97 (s, 3-ethylenedioxy).

Anal. Calcd. for $C_{30}H_{52}O_3$: C, 78.20; H, 11.38. Found: C, 78.38; H, 11.52.

19-Methoxy-5α-cholestan-3-one (1d)

A solution of 140 mg of **5c** and 14 mg of *p*-toluenesulfonic acid in 20 ml of anhydrous acetone was refluxed for 15 h. After cooling, the solution was diluted with ether and washed with sodium bicarbonate solution and water, and dried over sodium sulfate. The crude product obtained was recrystallized from acetone–methanol; yield, 90 mg, m.p. 104–105°; ν_{max} (KBr) 1723, 1110, and 960 cm^{-1}; n.m.r. (δ): 3.33 (s, OCH_3), 3.62 (s, 19-CH_2); o.r.d. (*c*, 0.0059, dioxane, 20°): $[\phi]_{450}$ +170°, $[\phi]_{315}$ +1970°, $[\phi]_{291}$ 0°, $[\phi]_{273}$ −1100°, $[\phi]_{260}$ −850°.

Anal. Calcd. for $C_{28}H_{48}O_2$: C, 80.71; H, 11.61. Found: C, 80.62; H, 11.92.

19-Chloro-5α-cholestan-3-one (1e)

Oxidation of 3β-hydroxy-19-chloro-5α-cholestane with 8 *N* chromic–sulfuric acid solution at 0–5° for 30 min gave **1e**, which was recrystallized from methanol, m.p. 107.2–108°; ν_{max} (KBr) 1717, 778, and 730 cm^{-1}; n.m.r. (δ): 3.86 and 4.02 (AB type q, J = 13 c.p.s., 19-CH_2); o.r.d. (*c*, 0.0053, dioxane, 20°): $[\phi]_{450}$ +240°, $[\phi]_{315}$ +1810°, $[\phi]_{291}$ 0°, $[\phi]_{273}$ −930°, $[\phi]_{260}$ −710°.

Anal. Calcd. for $C_{27}H_{45}OCl$: C, 77.01; H, 10.77. Found: C, 76.98; H, 11.05.

6β,19-Epoxy-5α-cholestan-3-one (2)

The epoxy compound (**2**) was synthesized by usual oxidative cyclization of 3β-acetoxy-6β-hydroxy-5α-cholestane with lead tetraacetate – iodine (16, 17) followed by hydrolysis and oxidation. Recrystallization of the crude product from methanol gave a pure product, m.p. 131–132.5°; ν_{max} (KBr) 1725, 1490, 1034, 1022, and 960 cm^{-1}; n.m.r. (δ): 3.95 (s, 19-CH_2); o.r.d. (*c*, 0.0019, dioxane, 20°): $[\phi]_{450}$ +760°, $[\phi]_{315}$ +6290°, $[\phi]_{307}$ +5650° (shoulder), $[\phi]_{292}$ 0°, $[\phi]_{270}$ −5140°, $[\phi]_{260}$ −4700°.

Anal. Calcd. for $C_{27}H_{44}O_2$: C, 80.94; H, 11.07. Found: C, 81.11; H, 11.13.

Reduction of 5α-Cholestan-3-one Derivatives with Sodium Borohydride

A solution of 20 mg of 5α-cholestan-3-one in 2 ml of methanol was treated with 20 mg of sodium borohydride at room temperature for 30 min. After addition of a small amount of acetic acid, the reaction mixture was treated with water and ether, and the ethereal extract was washed with water to neutrality. The reduction product was analyzed by gas–liquid chromatography (g.l.c.) as the trimethylsilyl ether.

Catalytic Hydrogenation of 5α-Cholestan-3-one Derivatives over Platinum Catalyst

(*A*) A solution of 10 mg of **1a** in 1 ml of acetic acid was hydrogenated in the presence of 3 mg of pre-reduced platinum oxide under atmospheric pressure at room temperature for 2 h. After the catalyst was removed by decantation, ether and water were added. The ethereal solution was washed with sodium bicarbonate solution and with water, dried, and evaporated. The residue was analyzed by g.l.c. as above.

(*B*) A solution of 10 mg of **1a** in 1 ml of ethanol was hydrogenated with 5 mg of pre-reduced platinum oxide for 2 h. After addition of ether, the catalyst was removed by filtration. Evaporation of the solvent *in vacuo* gave a product, which was analyzed by g.l.c. as above.

Acknowledgments

The authors wish to express their appreciation to Teikoku Hormone Manufacturing Company, Ltd., for the elemental analyses. Part of the expenses have been covered by the Grant in Aid for Fundamental Scientific Research of the Ministry of Education.

Structures of yeast mannans containing both α- and β-linked D-mannopyranose units[1]

P. A. J. GORIN, J. F. T. SPENCER, AND S. S. BHATTACHARJEE[2]
Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received December 18, 1968

Several mannans from yeasts give proton magnetic resonance spectra with distinctive H-1 signals at higher field than τ 4.55. A number of these mannans were investigated polarimetrically and each has a specific rotation corresponding to a mixture of α- and β-D-linkages. Four were partially hydrolyzed and shown to have most of the α-linkages in the main chains and the β-linkages in the side chains. Detailed structural investigations showed that the *Pichia pastoris* mannan probably has an α-(1→6)-D-mannopyranosyl main-chain substituted in the 2-positions with a substantial proportion of *O*-α-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-*O*-α-mannopyranosyl side-chains (**1**). The related mannan from *Citeromyces matritensis* has a similar main-chain, which is substituted in the 2-positions by α-D-mannopyranosyl units and β-(1→2)-pyranose-linked D-mannotriosyl and perhaps mannobiosyl side-chains (**2**).

Canadian Journal of Chemistry, 47, 1499 (1969)

The proton magnetic resonance (p.m.r.) spectra of yeast mannans and galactomannans in D_2O at 70° have been studied and used in structural and taxonomic studies (1–4). The spectra obtained from 28 out of the 189 species examined contained a substantial proportion of H-1 signals at higher field than τ 4.55 (Table I[3]), in contrast with the majority of yeast mannan and galactomannan spectra which have H-1 signals at τ 4.0–4.55. The high field signals were of interest to us since they suggested β-D-pyranoside units on consideration of the relative chemical shifts of H-1 signals of the α- and β-anomers of the methyl D-mannosides. Methyl β-D-mannopyranoside H-1 has τ 4.92 compared with the H-1 signals of its α-anomer (τ 4.71), methyl α-D-mannofuranoside (τ 4.50) and its β-anomer (τ 4.58). To check our conclusion, the specific rotations of a few of the yeast mannans giving high field signals were measured (Table II) and found to be intermediate between those of mannans containing α-D-linkages (baker's yeast mannan, +88° (5)) and β-D-linkages (*Rhodotorula glutinis* mannan, −78° (6)). Since each of the examined mannans (Table II) gave only one peak on ultracentrifugation, it appeared likely that each molecular species contained both α- and β-D-linkages;[3] a hitherto unreported structural feature in yeast mannans. A number of mannans

TABLE II

Specific rotations of yeast mannans with H-1 signals at relatively high field, and the mannans formed on partial hydrolysis

Source of mannan	High field signals, τ	Specific rotation	Specific rotation of acid-degraded mannan with yield
Brettanomyces anomalus	4.60, 4.67	+1°	+55°, 31%
Citeromyces matritensis	4.55, 4.61	−12°	+44°, 11.5%
Pichia pastoris	4.56, 4.60	+12°	+50°, 22%
Saccharomyces lodderi	4.68	−34°	—
Saccharomyces rosei	4.60	−16°	+20°, 27%

were therefore selected for further structural examination.

The mannans of *Pichia pastoris*, *Citeromyces matritensis* (the perfect form of *Torulopsis globosa* (7)), *Bretannomyces anomalus*, and *Saccharomyces rosei* were subjected to a preliminary structural investigation. The β-linkages appeared to be mainly in the side chains since partial acid hydrolysis with 0.33 *N* H_2SO_4 at 100° (8) provided polymers with higher specific rotations than the parent mannans (Table II). The p.m.r. spectra of each of the degraded mannans contained a strong signal at about τ 4.57, which corresponds to the chemical shift of H-1 of a linear mannan containing α-(1→6)-D-mannopyranosyl units (Fig. 1). Such a polymer has been obtained by partial acid hydrolysis of the galactomannan from *Schizosaccharomyces octosporus* and identified by its periodate oxidation characteristics. The H-1 signal patterns in the spectra of the degraded mannans have a strong resemblance to that of degraded baker's yeast mannan, obtained under comparable acid hydrolysis conditions (Fig. 1). The material contains an α-(1→6)-linked D-mannopyranosyl main-chain with some of the units substituted in the 2-positions by α-D-mannopyranosyl units (2, 8).

The structures of the side chains in the mannans of *Pichia pastoris* and *Citeromyces matritensis* were investigated in more detail. The results obtained from the *Pichia* mannan are presented first since they have a bearing on the *Citeromyces* mannan.

Side-chain fragments containing (1→2)-linkages were obtained from *Pichia pastoris* mannan by partial acetolysis which cleaves α-(1→6)-linkages in preference to (1→2)- and (1→3)-D-mannopyranose linkages (9, 10). The product was deacetylated and resolved into di-, tri-, tetra-, and penta-saccharides by cellulose column chromatography. Proton magnetic resonance spectroscopy of each fraction (H-1 region) indicated that only the disaccharide (16% yield) and pentasaccharide (26% yield) were homogeneous. The former has a spectrum and specific rotation corresponding to 2-*O*-α-D-mannopyranosyl-D-mannose, but the latter required further investigation to elucidate its structure. The penta-

saccharide is linear and contains (1→2)-linked mannopyranosyl units, since methylation–fragmentation gave 2,3,4,6-tetra-*O*-methylmannose (1 part) and 3,4,6-tri-*O*-methylmannose (3.8 parts), identified and estimated by gas–liquid chromatography (g.l.c.) of the methyl glycosides and the trimethylsilyl ethers of the methyl glycosides (10, 11). The presence of both α- and β-linkages was indicated by a specific rotation of −3°. The sequence of the linkages was determined as follows. Fragments were obtained from the pentasaccharide by a Smith degradation (12) involving oxidation by lead tetraacetate in acetic acid, followed by sodium borohydride reduction and partial hydrolysis (pH 2, 100°) of the resulting alditols. Following use of 3 moles/mole of oxidant for 3 h, mannotetraosyl mannitol, mannotriosyl mannitol, and mannobiosyl mannitol were formed and isolated. With a higher proportion of oxidant over a longer period of time, 2-*O*-α-D-mannopyranosyl-D-mannitol was obtained and tentatively identified by the chemical shift of the H-1 proton and its mobility on a paper chromatogram. The degradation occurs according to the scheme shown in Fig. 2 and assignments of configuration were made by comparing the specific rotations of consecutively related pairs of compounds that were formed during the degradation. For example, the reduced trisaccharide must contain a β-linkage since it has a lower specific rotation (−14°) than 2-*O*-α-D-mannopyranosyl-D-mannitol (+40°). By consideration of the consecutive increases or decreases in specific rotation on going from reduced trisaccharide to reduced tetrasaccharide to reduced pentasaccharide, the latter compound must be *O*-α-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-*O*-α-D-mannopyranosyl-(1→2)-D-mannitol.

Since insufficient 2-*O*-α-D-mannopyranosyl-D-mannitol was obtained for a measurement of specific rotation, another approach was used to prove the configuration of the α-linkage adjacent to the reducing end-unit of the pentasaccharide. The reducing end-unit of the pentasaccharide was removed by the following method (13). Bromine oxidation, followed by saponification gave the sodium salt of the aldonic acid, which was oxidized with lead tetraacetate to the mannotetraosyl tartronic acid semialdehyde derivative, and partial hydrolysis gave *O*-α-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-D-mannose which was purified by cellulose column chromatography. The alditol obtained by sodium borohydride reduction was homogeneous since it gave 3 H-1 signals of equal magnitude. Its specific rotation, −27°, is lower than that of the alditol (−5°) obtained by reduction of the pentasaccharide, indicating that the glycosidic linkage attached to the reducing end-unit of the pentasaccharide has an α-configuration.

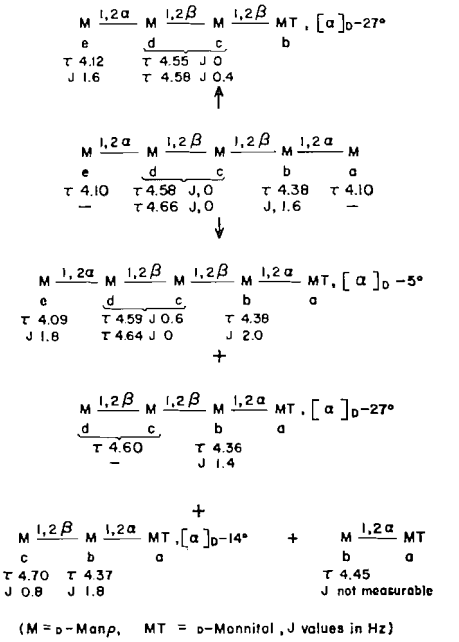

FIG. 2. Specific rotations, τ and *J* values of H-1 signals of fragments obtained from the *Pichia pastoris* pentasaccharide.

The mannan of *P. pastoris* was analyzed by the methylation–fragmentation technique, and the resulting partly methylated mannoses were characterized by g.l.c. of the methyl glycosides and the trimethylsilyl derivatives of the methyl glycosides. These fragments were 2,3,4,6-tetra-*O*-methylmannose, 3,4,6-tri-*O*-methylmannose, and 3,4-di-*O*-methylmannose, in accord with the probable structure of **1** containing an α-(1→6)-linked D-mannopyranosyl main-chain substituted in the 2-positions with a substantial proportion of (1→2)-linked D-mannopyranosyl side-chains. An average side-chain length of 3 is indicated by the formation of 0.25 mole of formic acid per mole of anhydromannose unit on periodate oxidation.

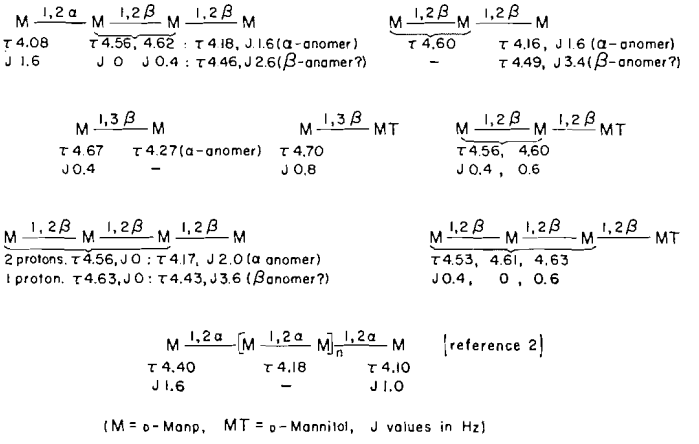

FIG. 3. τ and *J* values of H-1 signals of mannose oligosaccharides.

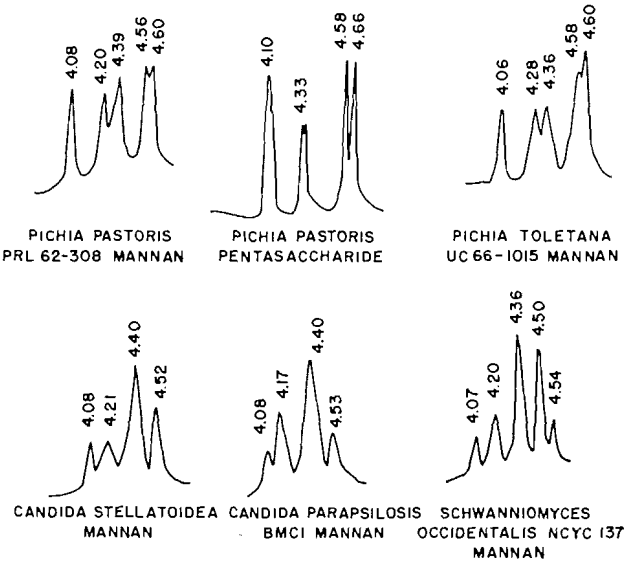

FIG. 4. Proton magnetic resonance spectra containing a signal at ca. τ 4.08.

The low field H-1 p.m.r. signal of the pentasaccharide at τ 4.10 corresponds to 2 protons and is of interest because signals of this chemical shift occur in spectra of a number of yeast mannans. The signal arises partly from the reducing end *a* (Fig. 2) by analogy with the reducing end-unit signal of α-(1→2)-linked D-mannopyranosyl oligosaccharides at τ 4.10 (2). In the case of mannose oligosaccharides containing a β-(1→2)-linkage in this position, signals of higher chemical shift are observed (Fig. 3). The other proton contributing to the signal at τ 4.10 is that of the non-reducing end-unit *e* since a low field signal is absent from mannotriosyl mannitol derived by the Smith degradation. Of 88 types of spectra from yeast mannans and galactomannans examined, 16 contain a signal close to τ 4.08, which may be due to (1→2)-linked side-chains with the terminal unit α-linked to the adjacent unit which is then followed by consecutive β-linkages. This signal is strongest in the spectra of *Pichia pastoris*, *Pichia toletana*, and *Candida* sp. CBS 5389 mannans. Weaker signals at τ 4.08 are present in spectra of mannans from *Candida parapsilosis*

For personal use only.

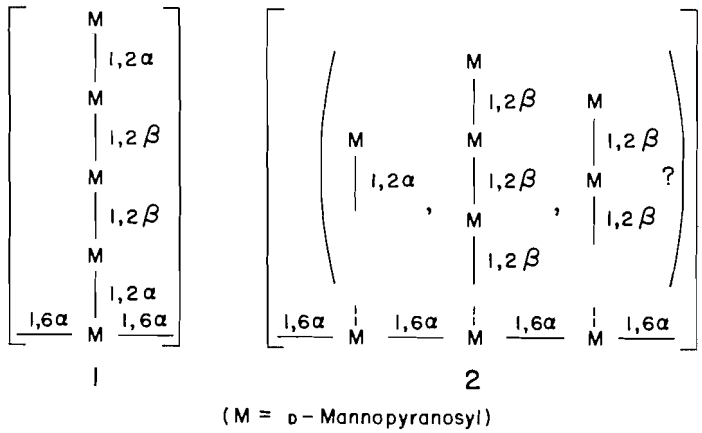

FIG. 5. Structures of mannans of *Pichia pastoris* (1) and *Citeromyces matritensis* (2).

(BMC 1), *Candida stellatoidea*, *Hansenula fabianii*, *Torulopsis halophila*, *Torulopsis famata*, *Torulopsis* sp. 62-304, *Schwanniomyces occidentalis* (Fig. 4). Low field signals are prominent in the p.m.r. spectra of galactomannans from *Candida lipolytica*, *Dipodascus albidus*, *Nadsonia fulvescens*, and *Trichosporon fermentans*, but these appear to arise from structures associated with D-galactopyranosyl units (1).

The nature of the side chains in *Citeromyces matritensis* mannan was determined by partial acetolysis over a shorter period of time than that described for the *P. pastoris* mannan. 2-*O*-α-D-Mannopyranosyl-D-mannose (10% yield), a trisaccharide (4% yield), and a tetrasaccharide fraction (5% yield) were isolated. The trisaccharide fraction contained only (1→2)-linkages, as shown by the methylation–fragmentation technique, but its homogeneity could not be determined from the H-1 region of its p.m.r. spectrum. This was complex and it appeared that an appreciable proportion of β-anomer existed in addition to the α-anomer. However, reduction with sodium borohydride gave an alditol with 2 equal H-1 signals, as would be expected from a single compound. In addition, its specific rotation of −36° indicates the presence of 2 β-D-linkages since *O*-β-D-mannopyranosyl-(1→2)-*O*-α-D-mannopyranosyl-(1→2)-D-mannitol obtained on Smith degradation of the *Pichia pastoris* pentasaccharide, has a higher rotation of −10°. The tetrasaccharide fraction was characterized as containing β-(1→2)-linked D-mannopyranose units by similar considerations of its methylation–fragmentation products and specific rotation. The derived alditol gave 3 equal H-1 signals and its specific rotation of −58° is lower than the −25° of *O*-β-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-*O*-α-D-mannopyranosyl-(1→2)-D-mannitol, obtained by the Smith degradation of the *P. pastoris* pentasaccharide. *O*-α-D-Mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-D-mannitol, described earlier in this section, has a similar specific rotation of −27°.

Methylation–fragmentation of *Citeromyces matritensis* mannan gave 2,3,4,6-tetra-*O*-methylmannose, 3,4,6-tri-*O*-methylmannose, and 3,4-di-*O*-methylmannose. The mannan probably contains an α-(1→6)-D-mannopyranose main-chain, substituted in the 2-positions by side chains. The side chains consist of single mannopyranosyl units attached α-D-(1→2)- to the main chain, and β-D-(1→2)-pyranosidically-linked mannotriosyl units attached by β-linkages to the main chain (**2**). 2-*O*-β-D-Mannopyranosyl-D-mannosyl side-chains are not necessarily present since the β-D-(1→2)-linked trisaccharide obtained in the acetolysis experiment could have arisen by partial degradation of the homologous tetrasaccharide. The formation of 0.40 mole of formic acid per mole of anhydromannose unit on periodate oxidation shows that the average side-chain length is 1.5 units, shorter than that of the *Pichia pastoris* mannan.

The chemical shifts of the H-1's of the mannose-containing oligosaccharides obtained during the course of this investigation are recorded in Figs.

2 and 3. It can be seen that the H-1's of mannopyranosyl units with β-linkages are at higher field than those of corresponding α-linked analogues, and with the exception of reducing end-units the J values of the β-linked units are smaller. It can also be observed that oligosaccharides with a β-linkage attached to the 2-position of the reducing end give complex p.m.r. spectra since, in contrast to oligosaccharides with an α-linkage in this position, both the α- and β-forms of the reducing sugar can be detected.

Experimental

The cultural methods used in production of yeast cells and the method of isolation of mannans from the cells are summarized in a previous publication (1). The yields of mannans based on dry cell-weight are recorded in Table I. The mannans were tested for homogeneity by sedimentation at 59 000 r.p.m. as 0.15, 0.30, and 0.60% solutions in 0.5% aqueous sodium chloride. The p.m.r. spectra of the mannans were obtained using a 100 Mc.p.s. Varian spectrometer from 20% solutions in D_2O at 70° with tetramethylsilane as the external standard. The p.m.r. spectra of oligosaccharides were obtained under identical conditions, except for the use of lower sugar concentrations. The mannans from *P. pastoris* and *C. matritensis* were hydrolyzed to D-mannose which was crystallized and identified. Paper chromatography was used to identify mannose from the other mannans. Paper chromatography of oligosaccharides was carried out using *n*-butanol – ethanol – water (2:1:1 v/v/v) as solvent and ammoniacal silver nitrate as spray reagent.

Methylation–Fragmentation of Mannans and Mannose-Containing Oligosaccharides

The mannans and mannose-containing oligosaccharides were methylated by the Haworth procedure (14) and the partially methylated products were further methylated by the Kuhn method (15) for a week. The fully methylated materials did not show hydroxyl absorption in the infrared (i.r.) at 3600 cm^{-1} on examination of 0.8% chloroform solutions in a cell with a path length of 5 mm.

The methylated mannans were partially methanolyzed in refluxing 3% methanolic hydrogen chloride overnight and the product hydrolyzed in N H_2SO_4 at 100° overnight. The partially methylated mannose derivatives were fractionated into di-*O*-, tri-*O*-, and tetra-*O*-methyl fractions on cellulose columns by the previously described method (2) from both mannans. These components were shown to be 3,4-di-*O*-, 3,4,6-tri-*O*-, and 2,3,4,6-tetra-*O*-methylmannose by a g.l.c. method (10, 11).

Periodate Oxidation Characteristics of Mannans from P. pastoris and C. matritensis

After 1, 2, and 3 days the *P. pastoris* mannan consumed 1.13, 1.20, and 1.21 moles/mole of anhydromannose unit with formation of 0.20, 0.24, and 0.25 mole/mole of acid, respectively. For the *C. matritensis* mannan the respective consumption figures were 1.20, 1.25, and 1.34, and acid production of 0.35, 0.40, and 0.41 mole/mole. Each of the polyalcohols obtained on sodium borohydride reduction of the polyaldehydes gave glycerol (paper chromatogram) on hydrolysis.

Partial Hydrolysis of Mannans

The mannans were partially hydrolyzed as 10% solutions in 0.33 N H_2SO_4 at 100° (2, 8). After 20 h samples were abstracted and residual polysaccharide precipitated by addition of 10 volumes of ethanol. The products were isolated by centrifugation followed by filtration. The specific rotations and yield of degraded mannans are recorded in Table II and their p.m.r. spectra in Fig. 1.

Partial Acetolysis of the P. pastoris Mannan

The mannan (2.0 g) was shaken for 5 days in acetic anhydride (12 ml) – acetic acid (12 ml) containing H_2SO_4 (1.2 ml) at 25°. The reaction mixture was added to excess ice-cold aqueous sodium bicarbonate and after 3 h the acetates were extracted with chloroform, which was evaporated to dryness. The acetates were deacetylated in chloroform–methanol (25:25 ml) containing 0.1 N methanolic sodium methoxide (30 ml). Examination on a paper chromatogram showed mannose-containing disaccharide and oligosaccharides running at 1.4 and 0.31, 0.46, 0.60 and 0.83 the rate of lactose (R_{lact}). The sugars were fractionated on a cellulose column (40 cm × 4.5 cm diameter) using the following acetone–water (v/v) mixture. Four liters of a 6:1 v/v mixture eluted mannose (0.15 g) and a disaccharide fraction (0.34 g) with $[\alpha]_D$ +35° (*c*, 0.9 H_2O) and R_{lact} 1.4, equal H-1 signals at τ 4.12 and 4.42. It consisted predominantly of 2-*O*-α-D-mannopyranosyl-D-mannose although a much smaller signal at τ 4.70 could arise from the non-reducing end H-1 of 2-*O*-β-D-mannopyranosyl-D-mannose. A 4:1 v/v mixture (3 l) eluted trisaccharides (190 mg, R_{lact} 0.83) which gave a complex p.m.r. spectrum indicating a mixture. Similarly the tetrasaccharide fraction (160 mg, R_{lact} 0.72 and a trace at 0.46) eluted with a 7:2 v/v ratio (3 l) was a mixture. Finally a 3:1 v/v mixture (2 l) was used to obtain a pentasaccharide (0.53 g, R_{lact} 0.31), which had H-1 signals at τ 4.10 (2 protons) and 1 proton signals at τ 4.33, 4.58, and 4.66, and $[\alpha]_D$ −3° (*c*, 0.9 H_2O). It was shown to contain only (1→2)-linkages by the methylation–fragmentation technique.

Smith Degradation of the Pichia pastoris Pentasaccharide to Oligosaccharide Alditols

The pentasaccharide (150 mg) was dissolved in water (1 ml) and acetic acid (50 ml) added. Lead tetraacetate (3 moles/mole of pentasaccharide) was dissolved by shaking, and after 3 h excess reagent was destroyed by addition of ethylene glycol (0.5 ml) and oxalic acid (2.9 moles/mole) in acetic acid. Water (200 ml) was added, the solution filtered, and the filtrate evaporated to dryness. Salts were removed by an aqueous suspension of mixed-bed resins followed by filtration. Sodium borohydride (0.2 g) was added to the filtrate and after 1 h Amberlite IR120 (H^+ form) was added, the solution filtered off, and evaporated to a residue which was freed from boric acid by repeatedly dissolving in methanol and evaporating the solution. The products were partially hydrolyzed at 100° for 1 h in an aqueous solution (10 ml) adjusted to pH 2 with H_2SO_4. The solution was neutralized, filtered, and evaporated and on paper chromatography the product gave spots with R_{lact} 0.45, 0.75, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

1.07 corresponding to mannotetraosyl mannitol, mannotriosyl mannitol, and mannobiosyl mannitol, respectively. The mixture was fractionated on a cellulose column and acetone–water (4:1 v/v) eluted the trisaccharide alditol (18 mg) with R_{lact} 1.07, $[\alpha]_D$ −14° (*c*, 0.6 H_2O) and equal H-1 signals at τ 4.70 and 4.37. A 3:1 v/v mixture eluted the tetrasaccharide alditol (31 mg) with R_{lact} 0.75, $[\alpha]_D$ −27° (*c*, 1.0 H_2O) and H-1 signals at τ 4.60 (2 protons) and 4.36 (1 proton) and a 2:1 v/v mixture eluted the pentasaccharide alditol (23 mg) with R_{lact} 0.45, $[\alpha]_D$ −5° (*c*, 0.8 H_2O) and equal H-1 signals at τ 4.09, 4.38, 4.59, and 4.64. The signal at τ 4.09 was moved downfield on addition of sodium tetraborate and thus arises from an α-linked non-reducing end-unit (2).

An experiment similar to above, but using 6 moles of lead tetraacetate per mole of pentasaccharide over 9 h, was carried out. From the pentasaccharide (200 mg) a product (5 mg) was formed and isolated and corresponded to 2-*O*-α-D-mannopyranosyl-D-mannitol on a paper chromatogram. It had an H-1 signal at τ 4.45.

Conversion of the Pichia pastoris Pentasaccharide to a Reduced Mannotetraose

The pentasaccharide (200 mg) was dissolved in water (20 ml) containing bromine (1 ml). After 6 days excess bromine was removed by evaporation, the solution neutralized (Ag_2CO_3), filtered, treated with Amberlite IR120 (H^+ form), and evaporated to a small volume. The sodium salt of the aldonic acid was obtained by addition of sodium hydroxide and heating at 100°. The solution was evaporated to approximately 3 ml and acetic acid (100 ml) added, followed by lead tetraacetate (4 moles/mole of aldonate). After 2 h the excess oxidant was destroyed and removed by the procedure described above. The mannotetraosyl tartronic acid semialdehyde derivative, thus formed, was converted to a mannotetraose by hydrolysis in 50% aqueous acetic acid (20 ml) at 100° for 1 h. Fractionation of the product on a cellulose column using acetone–water (3:1 v/v) as eluant gave the mannotetraose (71 mg) with $[\alpha]_D$ −23° (*c*, 0.9 H_2O) and single proton H-1 signals at τ 4.08, 4.56, 4.62, and others at τ 4.18 (0.6 proton) and τ 4.46 (0.5 proton). The alditol derived by sodium borohydride reduction had $[\alpha]_D$ −27° (*c*, 0.7 H_2O) and equal H-1 signals at τ 4.12, 4.55, and 4.58.

Partial Acetolysis of the C. Matritensis Mannan

The mannan was acetolyzed for 3 days using the same reagents and quantities as in the acetolysis of the *P. pastoris* mannan. The acetates were converted to the free sugars which were fractionated on a cellulose column using the eluants described previously. Mannose (1.1 g), 2-*O*-α-D-mannopyranosyl-D-mannose (194 mg), with $[\alpha]_D$ +37° (*c*, 0.7 H_2O) and equal H-1 signals at τ 4.12 and 4.42, *O*-β-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-D-mannose (92 mg) with R_{lact} 0.97, $[\alpha]_D$ −31° (*c*, 0.6 H_2O) and H-1 signals at τ 4.60 (2 protons), 4.49 (0.2 proton), and 4.16 (0.7 proton), and *O*-β-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-*O*-β-D-mannopyranosyl-(1→2)-D-mannose (103 mg) with R_{lact} 0.85, $[\alpha]_D$ −49° (*c*, 0.4 H_2O) and H-1 signals at τ 4.56 (2 protons), 4.63 (1 proton), 4.43 (0.3 proton), and 4.17 (0.7 proton) were obtained. The tri- and tetrasaccharide were shown to contain only (1→2)-linked D-mannopyranosyl linkages by the methylation–fragmentation g.l.c. technique. The respective alditols derived by sodium borohydride reduction of the tri- and tetrasaccharide had $[\alpha]_D$ −36° (*c*, 0.7 H_2O) with equal H-1 signals at τ 4.60 and 4.56 and $[\alpha]_D$ −58° (*c*, 0.3 H_2O) with equal H-1 signals at τ 4.53, 4.61, and 4.63.

Acknowledgments

Signs of proton–proton and proton–fluorine spin–spin coupling constants in 2-fluoro-3-methylpyridine. Sigma and pi contributions to coupling in a nitrogen heterocycle[1]

T. SCHAEFER,[2,4] S. S. DANYLUK, AND C. L. BELL[2,3]

Division of Biological and Medical Research, Argonne National Laboratory, Argonne, Illinois 60439

Received November 13, 1968

The signs of all proton–proton and proton–fluorine spin–spin coupling constants in 2-fluoro-3-methylpyridine have been determined by double and triple resonance experiments. The signs of the long-range coupling constants, J^{H,CH_3} and J^{F,CH_3} are the same as in fluorotoluene derivatives. Their magnitudes are consistent with the assumption that the nitrogen atom primarily polarizes the σ bonds in the molecule, leaving the π contribution to the long-range coupling relatively unaffected.

Canadian Journal of Chemistry, 47, 1507 (1969)

Introduction

Hoffman's (1, 2) methyl group replacement technique (=C—H → =C—CH_3) has been used to measure π electron contributions, $J(\pi)$, to ring proton – ring proton coupling constants, J^{HH}, in toluene derivatives (3–5), as well as to ring proton – ring fluorine couplings, J^{HF}, in fluorotoluene derivatives (6). Since $J_{o,p}^{H,CH_3} < 0 < J_{o,p}^{F,CH_3}$ it follows (2) that $J_o^{HF}(\pi) < 0$ while $J_{o,p}^{H,H}(\pi) > 0$. These results are in agreement with theory and experiment (7–14), which give the hyperfine interaction constants Q_{CH}, Q_{CCH}, and Q_{CF} as negative, positive, and positive, respectively.

In general, the π contributions to J_o^{HH} and J_o^{HF} in benzene derivatives are much smaller than σ contributions (7) and, therefore, substituent effects upon these couplings can be rationalized most easily in terms of an inductive, alternating model (14, 15) primarily involving the polarization of σ bonds by the substituent. These effects are expected to decrease rapidly with an increase in the number of intervening bonds between the substituent and the carbon atoms to which H or F are attached. In pyridine derivatives the electronegative nitrogen atom is directly bonded to the carbon atoms in question. Consequently, the changes in magnitude of J^{HH} and J^{HF} are strikingly greater than in benzene derivatives (15–17), reflecting the relatively large polarization of the σ core by the nitrogen atom. The polarization of the σ core is also apparent in the chemical shifts of ^{13}C and ^{1}H in pyridine (18, 19).

The question therefore arises of how strongly the polarized σ core influences the π electrons. A strong influence should result in changes in J^{H,CH_3} and J^{F,CH_3} since they are presumably dominated by a π electron mechanism. In this paper we determine the signs and magnitudes of $J_{o,m,p}^{H,CH_3}$ and of J_o^{F,CH_3} in 2-fluoro-3-methylpyridine and compare them to those found in benzene derivatives.

Experimental

2-Fluoro-3-methylpyridine from Peninsular Chem-Research, Inc. was examined as dilute solutions in tetramethylsilane (TMS) and benzene-d_6. The resonance from proton-6 (H_6) consisted of a broad (10 c.p.s.) peak. Addition of sufficient trifluoroacetic acid (TFA) to the TMS solution to serve as an alternate locking signal also relaxed the ^{14}N spin states (20). The effect of the ^{14}N–H_6 coupling was still observable as a slight broadening of the H_6 resonance peaks but did not now obscure the splittings due to the coupling between H_6 and the other nuclei in the molecule. Decomposition of 2-fluoro-3-methylpyridine was noted in concentrated hydrochloric acid and in TFA solutions with the most likely products being pyridones (21).

Solutions were degassed by the freeze–pump–thaw technique. Proton magnetic resonance spectra were recorded on a DA-60-I spectrometer in the frequency sweep mode. Double and triple resonance experiments were performed in the usual manner (22–25). When decoupling the methyl protons it was necessary to lock to the TFA signal. Double resonance experiments were also carried out in benzene-d_6 solutions in order to check that the presence of small amounts of TFA in the TMS solution had not noticeably affected the magnitudes or signs of the coupling constants.

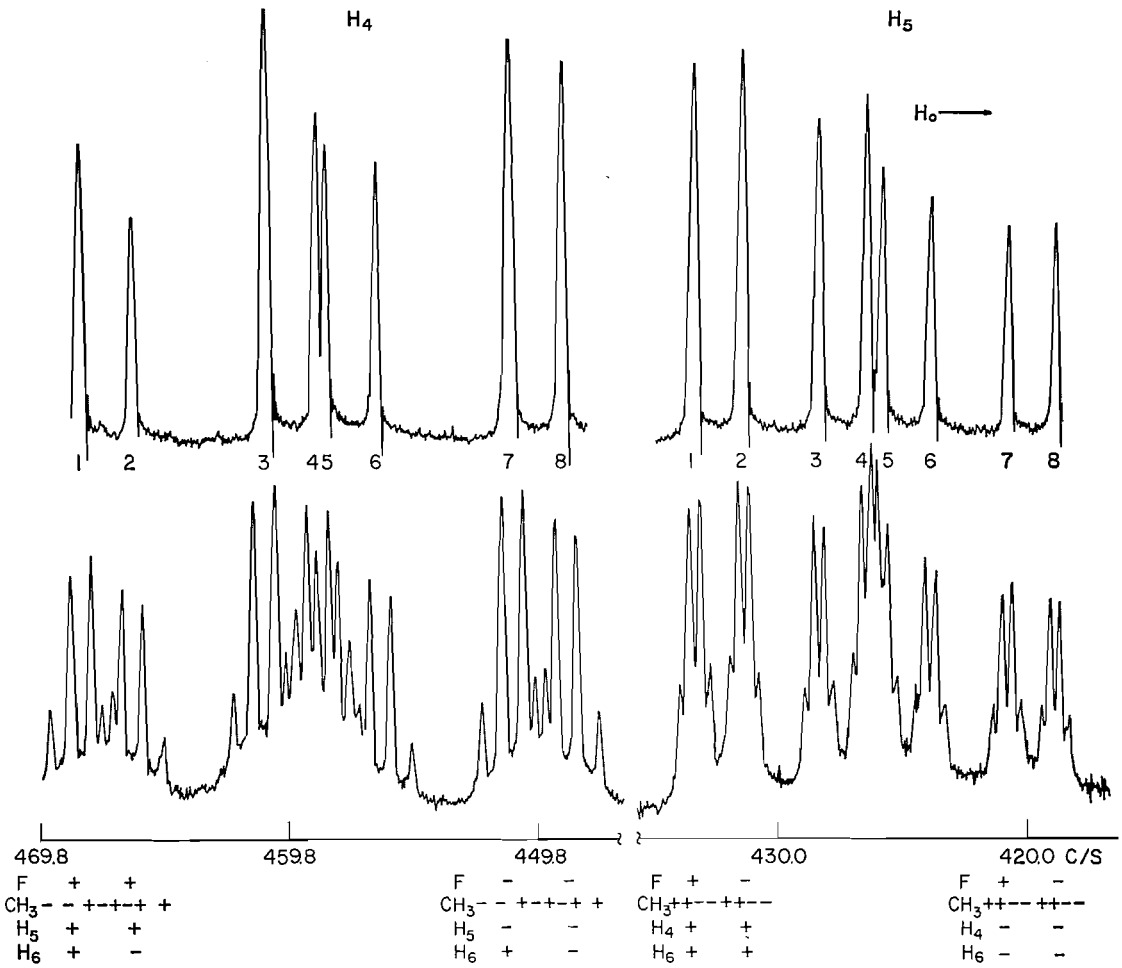

FIG. 1. The lower part shows the proton resonance spectrum of H_4 and H_5 in 2-fluoro-3-methylpyridine (**1**) in TMS at 60 Mc.p.s. As in all figures the scale is to low field of internal TMS. The spin states of coupled nuclei are given with the convention that the plus sign under the low-field resonance peak of a proton refers to a positive coupling between it and the coupled nucleus. The upper part shows the eight resonance peaks of each of H_4 and H_5 when the methyl protons are decoupled. These peaks, each of which refers to a quartet in the single resonance spectrum, are numbered from low to high field and are referred to in later figures.

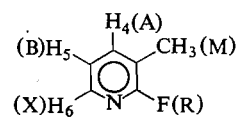
Results

1. Relative Signs of Coupling Constants

The proton resonance spectrum of H_4 and H_5 of **1** is presented in the lower part of Fig. 1. As in all the figures, the external magnetic field increases from left to right. The upper part of Fig. 1 shows the eight resonance peaks of each proton when the methyl protons are decoupled. The spin states of the coupled nuclei are labeled at the bottom of Fig. 1 with the convention that the plus sign under the low-field resonance peak of a proton refers to a positive coupling between that proton and the labeled nucleus. This convention is followed throughout the paper.



1

In Fig. 2*c*, the resonance of H_6 indicates the presence of residual broadening caused by incomplete relaxation of the coupling to ^{14}N. In Fig. 2*b*, the methyl protons have been decoupled, while in Fig. 2*a* an additional weak irradiation of peak

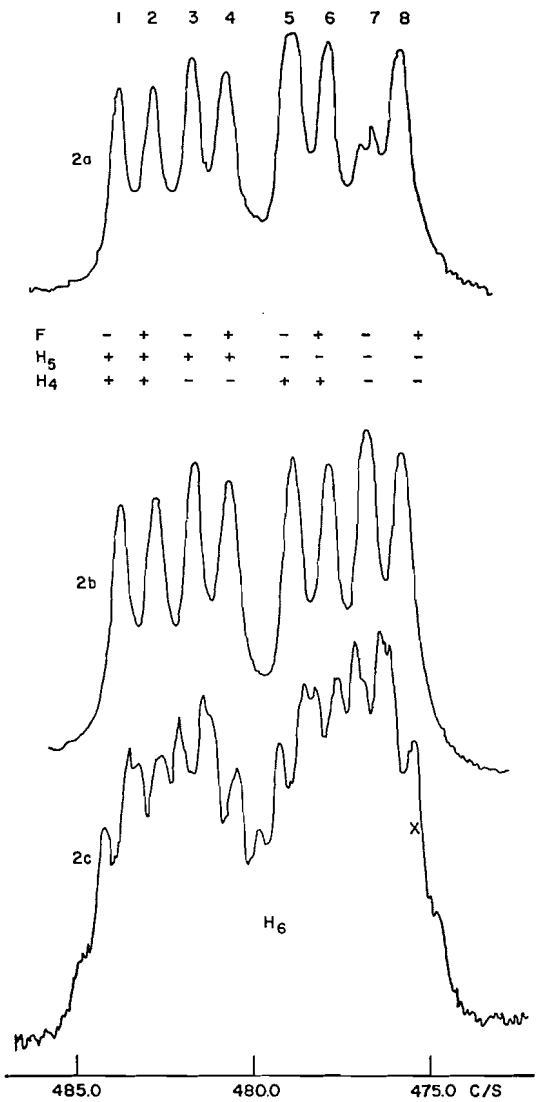

FIG. 2. The proton resonance spectrum of H_6 in **1**. In (*c*) the single resonance spectrum can be compared with the relatively well resolved eight peak pattern obtained in (*b*) by decoupling the methyl protons. In (*a*) peak 7 is affected by weak irradiation of peak 8 of H_4. The peak marked X in (*c*) is referred to in Fig. 3.

8 of H_4 (see Fig. 1) affects peak 7 of H_6. It follows that $J_m^{F,H_4}/J_m^{F,H_6} < 0$ and that $J_o^{H_4,H_5}/J_o^{H_5,H_6} > 0$.

In Fig. 3*a*, the peak marked X in the resonance of H_6 in Fig. 2*c* is being weakly irradiated by a second radio frequency field. The zero beat between the first and second radio frequency fields at the position of X is clearly noticeable. Peak X corresponds to the more intense, high-field peak of the quartet into which peak 8 (Fig. 2*b*) is split by the methyl protons. Observation of the quartets, numbered 7 and 8, of H_5 clearly shows that a low-field transition in quartet 7 is affected (Fig. 3*a*). Consequently, $J_m^{H,CH_3}/J_p^{H,CH_3} < 0$, $J_m^{F,H_6}/J_p^{F,H_5} < 0$, and $J_o^{H_4,H_5}/J_m^{H_4,H_6} > 0$.

In Fig. 3*b*, the more intense, low-field peak of the quartet corresponding to peak 1 of H_5 (Fig. 1) is weakly irradiated while observing the low-field quartets (1 and 2) of H_4. The more intense, high-field peak of the low-field quartet (peak 1) is affected. Hence, $J_o^{H,CH_3}/J_m^{H,CH_3} < 0$, $J_o^{H_5,H_6}/J_m^{H_4,H_6} > 0$, and $J_p^{F,H_5}/J_m^{F,H_4} > 0$.

In Fig. 4*a*, the 16 peaks of the methyl proton resonance are displayed. Below it in Fig. 4*d* the H_6 protons are decoupled, resulting in what is very nearly a first-order octet due to coupling with H_4, H_5, and F. Other experiments in which H_5 was decoupled, together with the observation of the single resonance spectra of the ring protons, allowed the spin labeling of the methyl peaks in Fig. 4*a* as shown.

In Fig. 4*b*, the methyl proton single resonance spectrum is shown under somewhat lower resolution (the smaller splittings amount to less than 0.20 c.p.s. and cannot always be resolved as well as in Fig. 4*a*). In Fig. 3*c* the high-field quartet (peak 8 in Fig. 1) of H_5 is being decoupled. Peaks 7 and 9 of the methyl proton resonance collapse and coincide with peak 8. In Fig. 4*e* the methyl single resonance spectrum is again given and can be compared with Fig. 4*f*, where peaks 1 and 2 collapse when the quartet 7 of H_5 is decoupled. Therefore $J_o^{H,CH_3}/J_o^{H_4,H_5} < 0$, $J_p^{H,CH_3}/J_o^{H_5,H_6} < 0$, and $J_o^{F,CH_3}/J_p^{H,F} > 0$. All of the sign determinations were supported by many additional experiments not described here.

2. *Spectral Analysis*

The ring proton resonance, with the methyl protons decoupled, was analyzed as the ABX part of an ABXR spectrum (see **1**). The analysis is valid because $J_{AX}/\nu_A - \nu_X$ and $J_{BX}/\nu_B - \nu_X$ are both less than 0.1. The ring proton shifts were corrected for effects analogous to Bloch–Siegert shifts (26, 27). The final shift parameters should not be treated as standard values because of the relatively high concentration (ca. 30%) of the solute and because of the presence of some trifluoroacetic acid.

The small couplings from the ring protons to the methyl protons were obtained from the

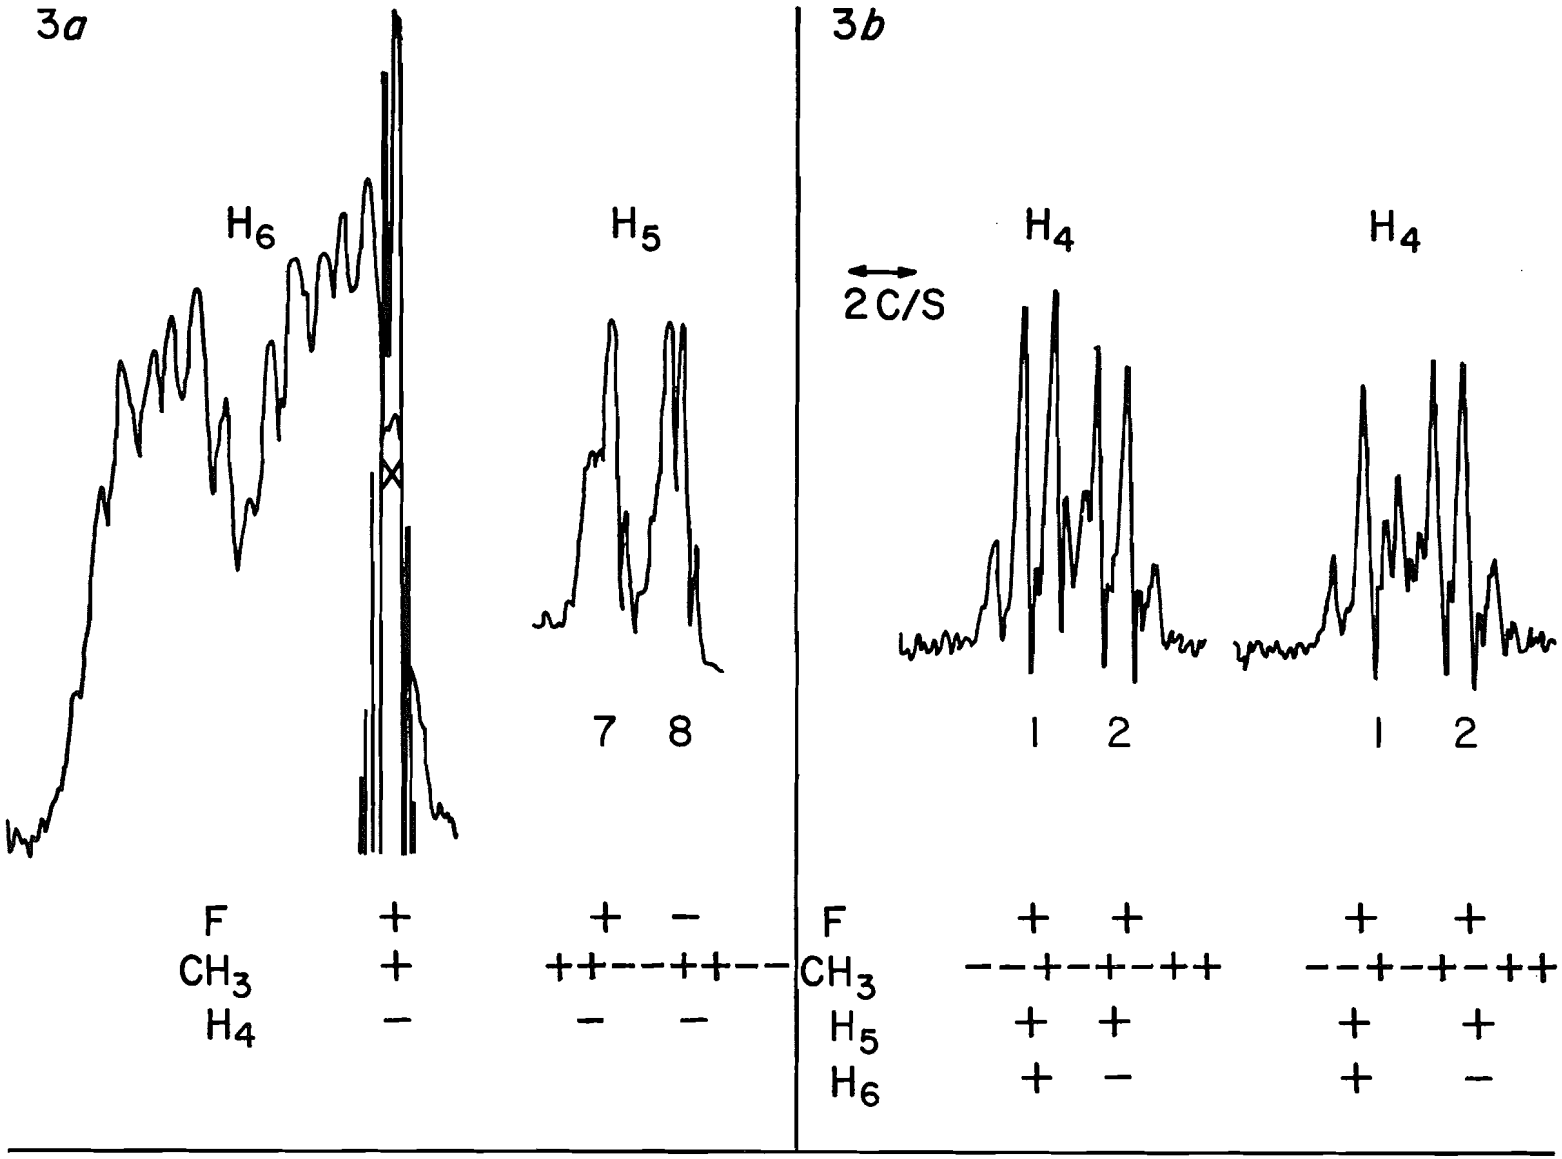

FIG. 3. In (*a*) the peak marked X in the resonance of H_6 is weakly irradiated while observing the pair of high-field quartets in the resonance of H_5. Note the zero beat pattern between the observing r.f. field and the irradiating field. The frequency scale of 2 c.p s./cm in this figure is twice as large as in the other figures.

For personal use only.

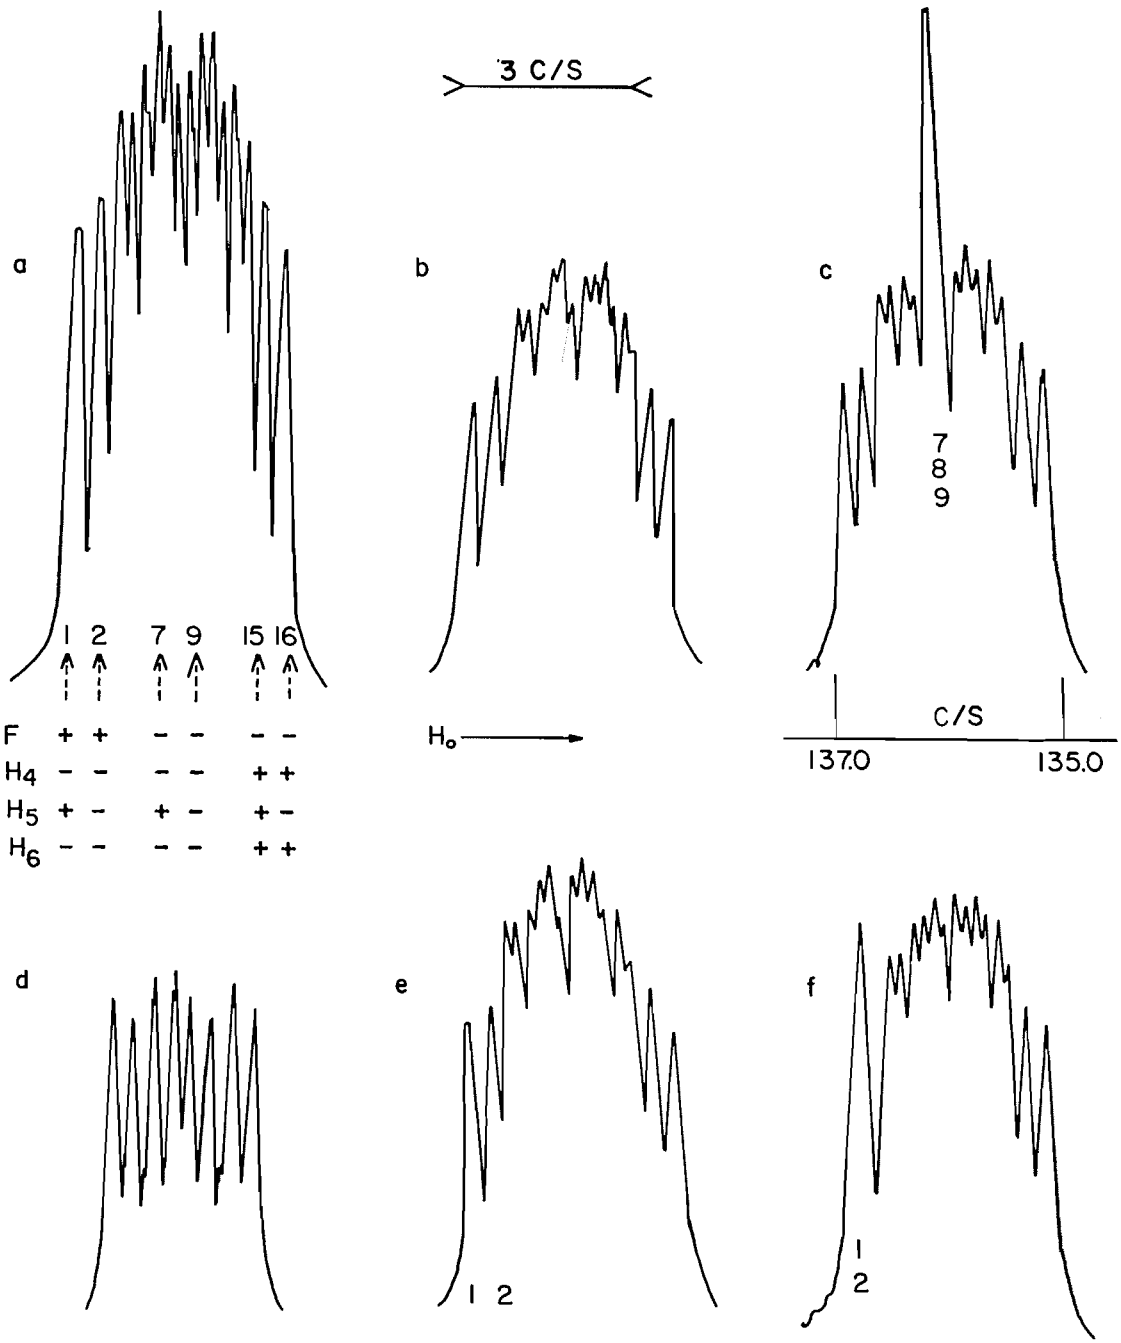

FIG. 4. In (*a*) the 16 peaks of the single resonance of the methyl protons in **1** are displayed. In (*b*) a lower resolution single resonance spectrum is compared with (*c*) in which the high-field quartet of H_5 (peak 8) is being decoupled. In (*e*) the single resonance spectrum is juxtaposed to the pattern obtained in (*f*) where quartet 7 of H_5 is weakly irradiated. In (*d*) is shown the approximately first-order octet obtained while decoupling H_6.

observed splittings in the ring proton resonance. Decoupling of H_5 resulted in an AXM_3R proton spectrum from which J_o^{F,CH_3} could be determined.

Deck (16) has shown that $J_m^{F,H_4}/J_o^{HH} > 0$ in 2-fluoropyridine derivatives. Since J_o^{HH} is positive (28) and since J_m^{F,H_4} in 2-fluoro-3-methylpyridine is undoubtedly of the same sign as in 2-fluoro-3-bromopyridine (16), it can be concluded that J_m^{F,H_4} in the former compound is also positive. A summary of the constants, in c.p.s., and the chemical shifts v, in p.p.m. relative to internal TMS, is given below

$$\nu_{CH_3} = -2.212 \pm 0.002$$
$$\nu_{H_4} = -7.643 \pm 0.005$$
$$\nu_{H_5} = -7.102 \pm 0.005$$
$$\nu_{H_6} = -7.997 \pm 0.005$$
$$J_m^{F,H_4} = 9.93 \pm 0.06$$
$$J_m^{F,H_6} = -1.02 \pm 0.05$$
$$J_p^{F,H_5} = 1.83 \pm 0.04$$
$$J_o^{H_4,H_5} = 7.50 \pm 0.08$$
$$J_o^{H_5,H_6} = 5.01 \pm 0.07$$
$$J_m^{H_4,H_6} = 1.98 \pm 0.06$$
$$J_o^{H,CH_3} = -0.85 \pm 0.05$$
$$J_m^{H,CH_3} = 0.40 \pm 0.03$$
$$J_p^{H,CH_3} = -0.7 \pm 0.1$$
$$J_o^{F,CH_3} = 1.45 \pm 0.06$$

Discussion

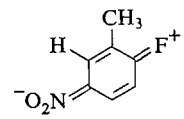
1. *The Methyl Proton – Ring Proton Coupling Constants*

The signs of J^{H,CH_3} in **1** are the same as those found in toluene derivatives (3). Molecular orbital theory predicts, that for alternant hydrocarbons and freely rotating methyl groups,

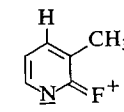
$$[1] \qquad J^{H,CH_3} \propto Q_{CH}\, Q_{CCH}\, P^2/\Delta E$$

where Q_{CH} and Q_{CCH} have values near -23 and $+25$ G, respectively; ΔE is a mean excitation energy to triplet states; and P is the mobile bond order between the carbon atoms to which the proton and methyl group are attached. In a recent study of radical anions of methylpyridines, Talcott and Myers (29) give Q values very near those found in anions of toluene derivatives. The signs of $J_{o,p}^{H,CH_3}$ are thus in agreement with the electron spin resonance data.

The magnitude of J_p^{H,CH_3} could only be determined to within 0.1 c.p.s. but the magnitude of J_o^{H,CH_3} (0.85 c.p.s.) is nearly 0.2 c.p.s. greater than that found in many toluene derivatives (5, 3031); however, $J_o^{H,CH_3} = -0.87$ c.p.s. in 2-fluoro-4-chloro-5-nitrotoluene (6). The resonance structures **2** and **3** suggest an increase in P^2 in eq. [1]



2

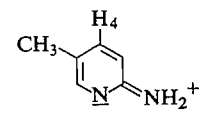


3

and therefore cause an increase in the magnitude of J_o^{H,CH_3}. It is interesting to note that fluorine is one of the stronger resonance electron donors while the nitro group is a strong electron acceptor by resonance (32).

Evidence for the importance of structure **3** is available from ^{14}N pure quadrupole resonance spectra of pyridine derivatives (33, 34). Methyl substituents in the *meta* position affect neither the σ nor the π populations on nitrogen. *Ortho* or *para* chlorine substituents substantially increase the π population on nitrogen (33). Because fluorine is a considerably better π donor than chlorine (32) the large magnitude of J_o^{H,CH_3} in 2-fluoro-3-methylpyridine can best be explained in terms of an increase of P^2.

A final piece of evidence in favor of this interpretation is the magnitude of J_o^{H,CH_3} (0.65 c.p.s.) in 2-amino-5-methylpyridine (35). Resonance structure **4** does not increase P^2 between C_4 and



4

C_5, resulting in a "normal" value of J_o^{H,CH_3}.

The magnitude of J_m^{H,CH_3} in **1** is within the range observed in toluene derivatives (6, 30). Simple molecular orbital theory (7) predicts $J_m^{H,CH_3} = 0$, but a valence bond calculation (36) suggests that $J_m^{H,CH_3} > 0$. The stereospecificity of $J_m^{H,CHCl_2}$ in $\alpha,\alpha,2,6$-tetrachlorotoluene (37) further indicates the existence of σ contributions (38)

to J_m^{H,CH_3}. We find $|J_m^{CH_3,CH_3}| = 0.25 \pm 0.02$ c.p.s. in 2,4,6-trimethylbenzaldehyde, 0.1 to 0.2 c.p.s. less than the observed range of J_m^{H,CH_3} (30). On the basis of the methyl group replacement technique (1), σ contributions to J_m^{H,CH_3} are therefore about 0.15 c.p.s., amounting to approximately one-third of its magnitude. Consequently, J_m^{H,CH_3} cannot be discussed exclusively in terms of eq. [1].

2. The Methyl Proton – Fluorine Coupling

The sign of J_o^{F,CH_3} is the same as in fluorotoluene derivatives (6). Its magnitude is about 0.5 c.p.s. smaller than in *o*-fluorotoluene (39) or in 2-fluoro-4-chloro-5-nitrotoluene (6). On the assumption that π contributions dominate J_o^{F,CH_3}, the positive sign implies a positive Q_{CF}. The latter is a composite term, consisting of positive and negative contributions from diagonal and off-diagonal terms in the π electron spin density matrix (9). It is not obvious how the nitrogen atom in **1** will affect these terms. A decrease in the positive contributions to Q_{CF}, an increase in the negative contributions, or both, could cause the observed decrease in J_o^{F,CH_3}. The present results strongly suggest that the π contribution dominates J_o^{F,CH_3} even in the presence of a directly bonded heteroatom.

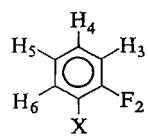
It would be expected therefore that 3-fluoro and 4-fluoromethylpyridines will also display positive $J_{o,p}^{F,CH_3}$ values. On the other hand, J_m^{F,CH_3} is small (6, 39) and its sign needs to be determined in a series of fluoromethylpyridines.

3. Ring Proton and Ring Proton – Fluorine Couplings

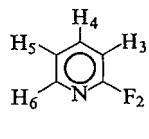
The substituent dependence of the coupling constants between ring protons and between ring protons and fluorine nuclei can be rationalized on the basis of the inductive, alternating model (15) as follows. Consider molecules **5** and **6**. Experimentally (15, 16, 40, and 41) the relevant changes, ΔJ, induced by a substituent of electronegativity $E_X > E_H$, are summarized in the columns below.

J	ΔJ_X	ΔJ_N	J	ΔJ_X	ΔJ_N
F_2,H_3	±	−	F_2,H_6	+	−
F_2,H_4	−	+	H_5,H_6	+	−
F_2,H_5	−	+	H_3,H_4	v. small	v. small

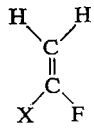
If ΔJ is caused by an alternation of charge (42) along the σ bonds then $|\Delta J_N| > |\Delta J_X|$ and ΔJ_X is of opposite sign to ΔJ_N. The experimental results for derivatives of **5** and **6** agree, in the main, with these predictions. However, several points can be noted; the experimental ΔJ_o^{HF} values are accurately known mainly for X = halogen (40). There is also the probability of strong van der Waals interactions between X and F (43). Furthermore, substituents *ortho* to F in **5** may cause changes in π contributions to J_o^{HF} which are comparable in magnitude to changes induced through the σ system (6). For purposes of discussing ΔJ_o^{HF} it is probably better to compare **6** and **7**.



5



6



7

In **7**, J^{HF}_{cis} decreases from 20.1 c.p.s. in vinyl fluoride (44) to 7.7 c.p.s. when X = Cl (45) and to 0.6 c.p.s. when X = F (46). Comparison of ΔJ^{HF}_{cis} with ΔJ^{HH}_{cis} in vinyl derivatives (47) emphasizes that $\Delta J^{HF} \gg \Delta J^{HH}$. In view of these results, the change in J_o^{HF} from 8.90 c.p.s. in fluorobenzene (48) to −2.8 c.p.s. in 2-fluoropyridine (16, 17) is not entirely unexpected. In fact, in 2-fluoropyrazine, $J_o^{HF} = -8.17$ c.p.s. (49). In contrast, no negative J_o^{HH} values are found even in pyrazines (49).

The positive J_o^{F,CH_3} in 2-fluoro-3-methylpyridine therefore implies that to a good approximation the π contribution to J_o^{HF} is relatively unaffected even though the total J_o^{HF} changes in sign. In this sense it is reasonable to distinguish between σ and π contributions to J_o^{HF} in heterocyclic molecules.

J_p^{HF} is positive in 2-fluoropyridine but is negative in substituted fluorobenzenes (6, 40). On the reasonable assumption that the unknown J^{F,CH_3} in 2-fluoro-5-methylpyridine is positive, comparable σ and π contributions to J_p^{HF} may be inferred. Further measurements are needed to confirm this point.

J_m^{F,H_6} in **1** is negative, as it also is in 2-fluoropyrazine (16, 49). The small, negative $J_m^{H_2,H_6}$ in pyridine (50) is consistent with these data and with the inductive, alternating model. It would be of interest to measure the sign of J_m^{F,CH_3} in 2-fluoro-6-methylpyridine. $J_m^{F,H_4} = 9.9$ c.p.s. in **1** is the largest known *meta* proton–fluorine coupling. It is larger than most *ortho* proton–fluorine

couplings in fluorobenzene derivatives and approaches the largest known value of J_o^{HF} = 10.4 c.p.s. in 1,2-difluorobenzene (51).

$J_{o,m}^{HH}$ values in 2-fluoro-3-methylpyridine lie within 0.15 c.p.s. of those in pyridine (50, 52), as expected on the basis of the inductive, alternating model of substituent effects.

Conclusions

The π contributions to $J_{o,p}^{H,CH_3}$ and to J_o^{F,CH_3} in 2-fluoro-3-methylpyridine have the same signs and comparable magnitudes as in benzene derivatives. This is so even though J_o^{HF} in 2-fluoropyridines is negative, in contrast to its large positive value in fluorotoluene derivatives. These results are consistent with a model of substituent effects on J^{HH} and J^{HF} in which the substituent acts primarily through the σ framework in benzene and pyridine derivatives. Further measurements on a series of fluoromethylpyridines are indicated.

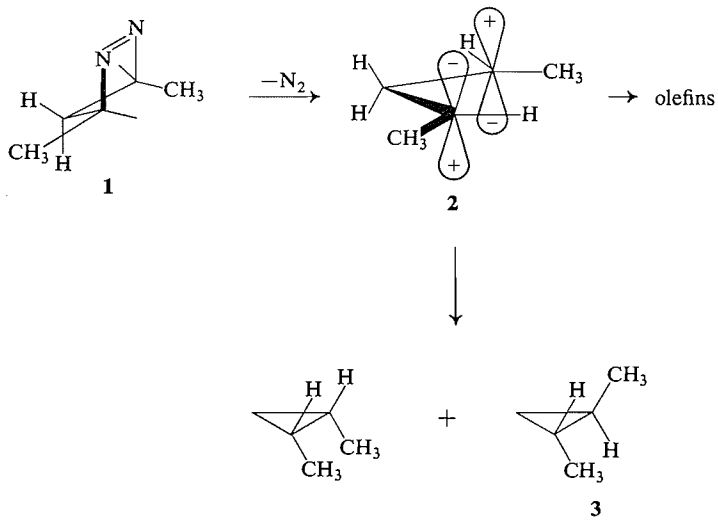
Preparation, absolute configuration, and thermolysis of (*3R*:*5R*)-(+)-*trans*-3,5-dimethyl-1-pyrazoline

ANUPAMA MISHRA AND ROBERT J. CRAWFORD
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received September 30, 1968

Thermolysis of (*3R*:*5R*)-(+)-*trans*-3,5-dimethyl-1-pyrazoline produces 25.6% of *trans*-1,2-dimethylcyclopropane of 23% optical purity having the *S*:*S* configuration. Thermolysis mechanisms which explain the racemization and the double inversion process are discussed. The absolute configuration of *active*-2,4-pentanediol and 2,4-dibromopentane is correlated with that of 4-hydroxy-1-pentene.

Canadian Journal of Chemistry, 47, 1515 (1969)

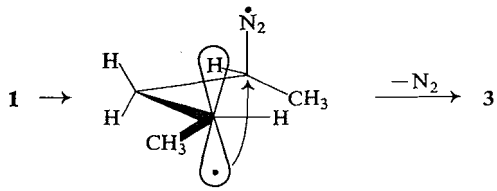


SCHEME 1

Introduction

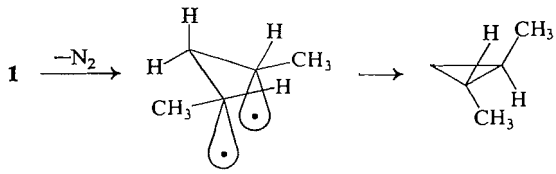
The gas-phase thermolysis of 1-pyrazoline has been shown to proceed by cleavage of both carbon–nitrogen bonds (1) to produce a hydrocarbon intermediate which in turn produces propylene and cyclopropane (2). The intermediate suggested for the thermolysis is such that the two hydrogen atoms attached to each end of the trimethylene species are in the plane defined by the three trimethylene carbon atoms. This has been referred to as the O,O-trimethylene configuration and extended Hückel molecular orbital calculations support the suggestion that it represents an energy minimum (3).

The thermolysis of *trans*-3,5-dimethyl-1-pyrazoline (**1**) produces 73% *cis*-1,2-dimethylcyclopropane, 25% of the *trans* isomer (**3**), and 1% each of *cis*- and *trans*-2-pentene. These products were rationalized as in Scheme 1 (2). The stereochemistry of the intermediate (**2**) is such that optically active **1** on thermolysis should generate racemic **3** if **2** is an intermediate. Recently alternative mechanisms have been proposed which may account for the minor product. Roth and Martin (4) have observed what is essentially inversion at both carbons (to which the azo nitrogens are attached) in the thermolysis of *exo*,*exo*-5,6-dideuterio-2,3-diazabicyclo[2·2·1]hept-2-ene, and by analogy the **3** produced upon thermolysis of active **1** should be optically active and involve inversion at each of its asymmetric centers (Scheme 2). Allred and Smith (5) using a similar bicyclic system have proposed a recoil mechanism by which **1** would be expected to produce a pyramidal diradical intermediate (**4**) which could close to produce **3**.



SCHEME 2

Again optically active **1** would be expected to produce **3** by inversion at both asymmetric centers (Scheme 3).



SCHEME 3

Correlations of Configurations

Chart 1 shows the method of synthesis, rotations, and absolute configurations of each of the compounds used in the sequence from (*R*)-(−)-4-hydroxy-1-pentene (6) to (*3R*:*5R*)-(+)-*trans*-3,5-dimethyl-1-pyrazoline. The 4-hydroxy-1-pentene was resolved via the brucine salt of the phthalate half ester (6*b*). Oxymercuration (7) of the hydroxy-1-pentene followed by borohydride reduction gave an 80% yield of 2,4-pentanediol consisting of a 30:70 mixture of *meso* and *active* forms. This mixture was not separated but converted directly to the dibromide using the procedure of Pritchard and Vollmer (8). The ratio of *active* to *meso* remained essentially that of the reactant, suggesting that the dibromide was produced by inversion of both centers in a clean manner (8, 9). The dibromide was then converted to the pyrazolidine and oxidized to the pyrazoline without characterization of rotation at the pyrazolidine stage (the latter is air sensitive and generally contains some of the 1-pyrazoline). The magnitude of rotation of each of these compounds was put on a firm basis by the resolution of *rac-trans*-3,5-dimethylpyrazolidine using (+)-10-camphorsulfonic acid, the pyrazolidine thus resolved was oxidized to give **1** with $[\alpha]_D^{25}$ +605°.

Thermolysis of 1

The resolved pyrazoline **1** on thermolysis produced *cis*- and *trans*-2-butene (1% each), *cis*-1,2-dimethylcyclopropane (73%) and *trans*-1,2-dimethylcyclopropane (25%); only the latter product has an asymmetric center and thus, to minimize losses, the hydrocarbon products were isolated and the total hydrocarbon fraction examined. The proportion of *cis* and *trans* isomers was then determined by gas–liquid chromatography (g.l.c.) and upon correction for the percentage of *cis*-3,5-dimethyl-1-pyrazoline in the starting material the optical activity of the **3** produced from *active*-**1** was calculated. Table I gives the results of several runs carried out in this manner. The percentage of *cis*-3,5-dimethyl-1-pyrazoline in the initial mixture was determined by 100 MHz nuclear magnetic resonance (n.m.r.) spectroscopy. This ratio was verified by the g.l.c. analysis of the cyclopropane

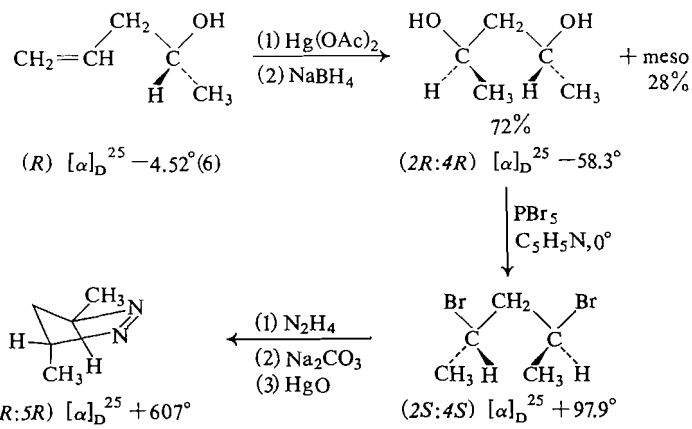


CHART 1: Preparation of (*3R*,*5R*)-(+)-*trans*-3,5-dimethyl-1-pyrazoline with maximum observed rotations.

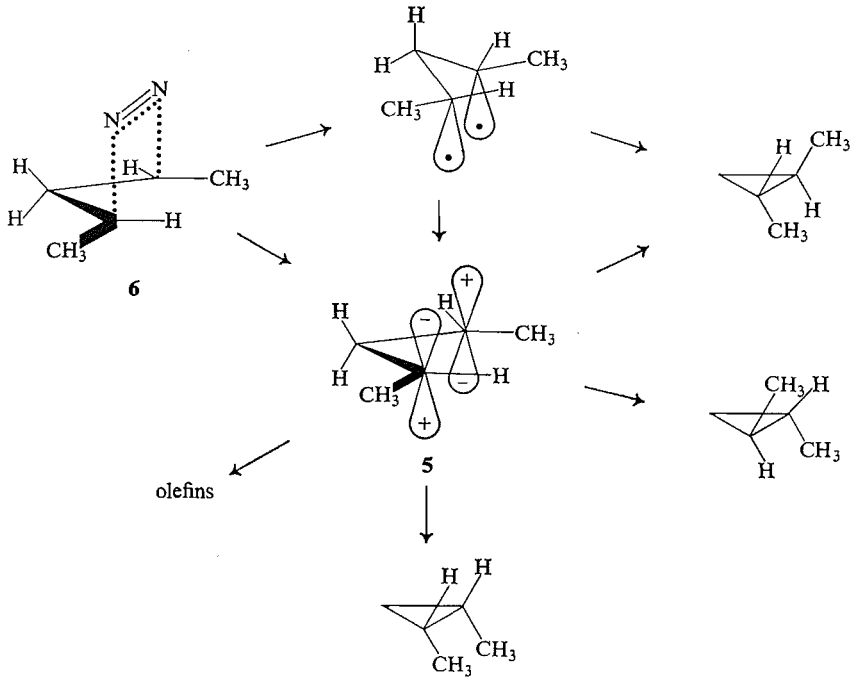

SCHEME 4

and olefin products obtained upon thermolysis, and agreement to within 1% was obtained for the amount of *cis*- and *trans*-3,5-dimethyl-1-pyrazoline. Because the rotation of the hydrocarbon product was the same in sign as that of the reactant, and because of the magnitude of the rotation of **1** relative to that of **3**, it was necessary to be sure that unreacted **1**, or its tautomer, was not a contaminant. This was achieved by passing the whole product mixture through a 20 ft Carbowax 20M column and by collection of only the hydrocarbon fraction.

The results from Table I indicate an excess of double inversion to retention of absolute configuration of 23.6 ± 1.7% for the *trans*-1,2-dimethylcyclopropane (10) produced from *active*-**1**. The most concise scheme that fits the kinetic and stereochemical data is that shown as Scheme 4. This incorporates the pyramidal diradical suggested by Allred and Smith (5) to account for the optically active portion of the **3** produced, which is 6% of the total product. The racemic **3**, *cis*-1,2-dimethylcyclopropane and olefins are believed to arise from the trimethylene intermediate **5**. The present data cannot distinguish between **5** being formed directly from **1** via the transition state **6**, and a small fraction going via the pyramidal diradical or whether all of the material goes via the pyramidal diradical, 94% of which in turn produces **5**. Similarly the possibility exists that the 6% optically active *trans*-1,2-dimethylcyclopropane is produced via a mechanism similar to that suggested by Roth and Martin (4).

Experimental

The nuclear magnetic resonance spectra were obtained using a Varian A-60 and a Varian HA 100 spectrometer. Optical rotations were measured using a 1.00 dm cell in a Perkin–Elmer Model 141 spectropolarimeter and a Jasco ORD-UV5 spectrophotometer. A Wilkens Aerograph Autoprep was used for the preparative g.l.c. and a Gow-Mac Model TR-11-B,w thermal conductivity cell with a Gow-Mac Model 40-05C power supply was used on a vacuum line for analytical g.l.c. and the trapping of hydrocarbon samples (11).

Resolution of trans-3,5-Dimethylpyrazolidine and its Conversion to trans-3,5-Dimethyl-1-pyrazoline (1)

trans-3,5-Dimethylpyrazolidine was originally resolved through its *N,N'*-bishydroxymethylene-(+)-camphor derivative (2). However, regeneration of the pyrazolidine from this derivative proved to give too low a yield to be useful in this work. Among the different acids employed for an attempted salt formation, (+)-10-camphorsulfonic acid was found to be the most suitable.

‡Calculated using $[\alpha]_D^{25}$ for 3 of 46°, if all 3 from optically pure 1 was active (see Experimental).
§Rotation taken in methanol; value 46° from diglyme assumed.
‖Diluted with racemic material.
¶Diglyme used as solvent.

Crude *trans*-3,5-dimethylpyrazolidine (6 g, 0.06 mole) was dissolved in ether (50 ml) and then added to a solution of (+)-10-camphorsulfonic acid (25 g, 0.11 mole) in ether (1500 ml). The reaction mixture containing the salt was stirred at room temperature for 2 h and the solids were separated by filtration (about 20 g). The salt was dissolved in methanol (300 ml) and ether (1500 ml) was added to precipitate an impurity having a wide melting point range, from 195–210°. The bulky filtrate was evaporated to dryness on a rotary evaporator and the residue was dissolved in a minimum volume of methanol, and ether (400 ml) was added to precipitate the salt (6 g, m.p. 120–125°). Dissolution of this substance in methanol (10 ml) and reprecipitation by ether gave 3.5 g of the salt m.p. 128–132°. Recrystallizations were repeated until the m.p. was found to be constant at 135–137°. The n.m.r. spectrum of the salt in deuteriochloroform indicated that the pyrazolidine and the sulfonic acid were present in the ratio 1:2 respectively.

The salt was decomposed with aqueous potassium carbonate solution until the solution became basic and it was then extracted three times with ether. The ether extracts were combined and dried over anhydrous sodium sulfate. The product was oxidized by mercuric oxide to the 1-pyrazoline, which was separated by g.l.c. on a 20 ft column of 10% Uconinsoluble on Fluoropak; $[\alpha]_D^{25}$ +605° (CH_3OH, *c*, 7.5 × 10^{-3} g/ml).

Larger quantities of **1** were prepared from the active glycol as described below.

R(−)-4-Hydroxy-1-pentene and S(+)-4-Hydroxy-1-pentene

4-Hydroxy-1-pentene was prepared by the method of Whitmore (12) from allyl bromide and acetaldehyde. This compound was converted to its acid phthalate ester and resolved through its brucine salt according to the procedure of Levene (6*c*).

The acid phthalate ester (crude, 130 g) was dissolved in warm acetone (50 ml) and then added to a suspension of brucine (200 g) in warm acetone (700 ml). The solution thus obtained was filtered and slow crystallization was allowed to occur at room temperature after it was seeded with the proper diastereomeric crystal. The crystals thus obtained had a m.p. of 144–146°; yield 140 g. Three more recrystallizations in progressively larger volumes of acetone gave a product having m.p. 148–149°, yield 125 g. The alcohol was recovered from the salt in about 90% yield.

The *S*(+)-alcohol corresponded to an optical purity of 93.4% (6). The *R*(−)-alcohol obtained from the mother liquor had an optical purity of 50.6%.

2,4-Pentanediol

This compound was prepared from 4-hydroxy-1-pentene, following the method of Brown and Geoghegan (7).

Starting with 4-hydroxy-1-pentene (17.2 g, 200 mmole) and mercuric acetate (64 g, 200 mmole) dissolved in a mixture of water (200 ml) and tetrahydrofuran (THF) (200 ml), the oxymercuration was conducted for 12 min at room temperature. A sodium hydroxide solution (200 ml, 3 *M*) was added, followed by a sodium borohydride solution (200 ml of 0.5 *M* $NaBH_4$ in 3 *M* sodium hydroxide). The reaction mixture was saturated with sodium chloride and the THF layer separated. The aqueous layer was extracted three times with THF (100 ml) and the combined THF solutions were dried over anhydrous potassium carbonate. Removal of the solvent and distillation gave the glycol (16 g, 80%), b.p. 70–74°/3mm. Analysis of the diol by g.l.c. on a polyethyleneimine column gave the ratio of the *active* to *meso* isomers.

R(−)-4-hydroxy-1-pentene of 50.6% optical purity gave the diol mixture of α_D^{25} −21.1° (methanol; *c*, 4.43 × 10^{-2} g/ml). Since the percentage of the *active* form was 71.6 ± 0.2%, the minimum rotation of (*2R*:*4R*)-(−)-2,4-pentanediol is $[\alpha]_D^{25}$ −58.3°.

S(+)-4-hydroxy-1-pentene of 93.4% optical purity gave the diol mixture of $[\alpha]_D^{25}$ +35.8° (methanol; *c*, 2.5 × 10^{-2} g/ml). Since the *active* form in the mixture was 64.8 ± 0.3%, the minimum rotation of (*2S*:*4S*)-(+)-2,4-pentanediol is +59.1°.

2,4-Dibromopentane

This compound was prepared by the method of Pritchard and Vollmer (6) by the action of phosphorus pentabromide on 2,4-pentanediol. A sample of *(2S:4S)*-(+)-2,4-pentanediol of 93.4% optical purity gave the 2,4-dibromopentane $[\alpha]_D^{25}$ +65.1° (CCl_4; *c*, 1.5×10^{-2} g/ml).

Analysis of the dibromide by g.l.c. using a Carbowax 20M column indicated the *active* form to be 71.2 ± 0.5%, thus *(2R:4R)*-(+)-2,4-dibromopentane has $[\alpha]_D^{25}$ +97.9°.

3,5-Dimethyl-1-pyrazoline (1)

This compound was prepared as previously described (2). The ratio of the *trans* to *cis* isomers was determined by measuring the absorptions due to the methyne protons at C-3 and C-5 in the 100 MHz n.m.r. spectrum of the sample.

This ratio was verified by the analysis of cyclopropane and olefin products obtained by the thermal decomposition of the mixture. Since the product ratios from each of pure *cis*- and *trans*-3,5-dimethyl-1-pyrazolines are known, the ratio actually obtained can be used to solve the percentage of individual components present in the mixture. The values from n.m.r. and g.l.c. agreed within 1%. The value from n.m.r. was used to calculate the stereospecifity of the thermal decomposition and optical rotation. The *active* dihalide reacts more readily than the *meso* compound and thus there is a slight enrichment in the percent *trans*.

(*a*) The dihalide sample derived from *(S)*-(+)-4-hydroxy-1-pentene of 93.4% optical purity produced a sample of 3,5-dimethyl-1-pyrazoline (84.3 ± 0.5% *trans* by n.m.r.; 84.8 ± 1.0% by g.l.c.) α_D^{25} −0.851° (CH_3OH; *c*, 1.83×10^{-3} g/ml); $[\alpha]_D^{25}$ −588°.

(*b*) The dihalide sample derived from *(R)*-(−)-4-hydroxy-1-pentene of 50.6% optical purity produced a sample of 3,5-dimethyl-1-pyrazoline (88.4 ± 0.8% *trans* by n.m.r.; 88.3 ± 0.3% by g.l.c.) α_D^{25} +0.623° (CH_3OH; *c*, 1.83×10^{-3} g/ml); $[\alpha]_D^{25}$ +630°.

(*c*) The dihalide sample derived from *(R)*-(−)-4-hydroxy-1-pentene of 31% optical purity produced a sample of 3,5-dimethyl-1-pyrazoline (85% *trans* by n.m.r.) $\alpha_D^{25°}$ +0.366° (CH_3OH; *c*, 2.21×10^{-3} g/ml); $[\alpha]_D^{25}$ +603°.

The average value of 607 ± 21° agrees with the value of 605° obtained by direct resolution from the pyrazolidine.

Thermal Decomposition of Optically Active trans-3,5-Dimethyl-1-pyrazoline

Decomposition of the optically active compound was affected by transferring it to a glass bulb with a break-seal and then degassing the system thoroughly before sealing. The pressure at the temperature of decomposition varied from 1–2 atm. After the decomposition was over, the container was connected to a vacuum line and the seal broken. Nitrogen was pumped off and the other products trapped by liquid nitrogen. This was later transferred to a system suitable for g.l.c. analysis. The whole mixture was passed through a 20 ft column of Carbowax 20M to ensure that only the hydrocarbon products were collected. Hydrocarbon products collected were later weighed and transferred into 1 ml of diglyme and their optical rotation measured.

The column marked calculated maximum for the hydrocarbon product in Table I was calculated using $[\alpha]_D^{25}$ +46° for *trans*-1,2-dimethylcyclopropane (10). The theoretical maximum of *active-trans*-1,2-dimethylcyclopropane present was calculated from the known amount of optically pure **1** that was present in the sample on the basis that all of the 25.6% of **3** produced would be optically active.

Controls

A sample of *(3S:5S)*-(−)-3,5-dimethyl-1-pyrazoline, containing 15.6% of the *cis* isomer, was heated to 205° for 10 min (63% reaction for the *trans* isomer and 48.4% reaction for the *cis* isomer (2)) then quenched. The n.m.r. spectrum of the unreacted material indicated 81 ± 1% *trans* and 19 ± 1% *cis*. The values calculated from the rate data are 80% *cis* and 20% *trans*. The original sample had a rotation of $[\alpha]_D^{25}$ −588°, the recovered sample had a rotation of $[\alpha]_D^{25}$ −592°. Thus the reactants do not isomerize under the reaction conditions. *Active-trans*-1,2-dimethylcyclopropane was similarly recovered unchanged.

Reduction of trichloromethylcarbinols.[1] Hydrogenolysis of phenyl(trichloromethyl)carbinol and 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone on metal surfaces

EBERHARD KIEHLMANN, ROBERT J. BIANCHI, AND WILKINS REEVE
Departments of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

AND

University of Maryland, College Park, Maryland

Received September 13, 1968

Reduction with zinc in neutral or acidic medium or catalytic hydrogenation of phenyl(trichloromethyl)-carbinol (**1**) gives β,β-dichlorostyrene (**2**), β-chlorostyrene (**3**), and phenyl(dichloromethyl)carbinol (**4**). β,β-Dichlorostyrene is the sole product of reduction of phenyl(trichloromethyl)carbinyl methyl ether with zinc and acetic acid. Lithium in liquid ammonia reduces the trichloromethyl group of **1** to give α-phenethyl alcohol (**5**) in low yield; acetophenone and β-phenethyl alcohol have been identified as by-products of this reaction.

Clemmensen reduction of 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**6**) does not yield the expected 1,1,1-trichloro-6-methyl-2-heptanol; instead, 1,1-dichloro-6-methyl-1-hepten-4-one (**7**) and 1,1-dichloro-6-methyl-1-heptene (**8**) are formed as the main reaction products. Long reflux time, efficient stirring, and the employment of a large excess of amalgamated zinc and concentrated hydrochloric acid favor the formation of **8** while **7** is obtained in high yield when sulfuric acid is used instead of hydrochloric acid.

A mechanism for the reduction of trichloromethylcarbinols (**1** and **6**) with zinc has been proposed, **7** being postulated as an intermediate in the formation of **8**.

Canadian Journal of Chemistry, 47, 1521 (1969)

Introduction

In the course of investigations on the mechanism of nucleophilic displacement reactions of phenyl(trichloromethyl)carbinol (**1**) and on synthetic methods for the preparation of aliphatic trichloromethylcarbinols, it became desirable to reduce the trichloromethyl group of **1** to a methyl group without changing the structure and configuration of the adjacent asymmetric carbon, and to reduce selectively the carbonyl function of 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**6**) to a methylene group without causing structural changes in the terminal trichloromethylcarbinol residue (—CHOH—CCl_3). Since it was observed that in most reactions of **1** and **6** several functional groups undergo structural changes simultaneously, we decided to investigate the mechanism of interaction between a trichloromethyl group and an adjacent hydroxyl group when these compounds are treated with metallic reducing agents.

Although the literature contains several reports on the hydrogenolysis of haloalkanes containing isolated trihalomethyl groups, little is known about the reduction of trihalomethylcarbinols. Nagao and Sato (1) have described an electrolytic method for the conversion of a CCl_3 group to a $CHCl_2$ or CH_2Cl group; Dinesman (2) observed the formation of β,β-dichlorostyrene from phenyl(trichloromethyl)carbinol and zinc in acetic acid; and Kaspar and Wiechert (3) have reported the complete reduction of a tribromomethyl group by catalytic hydrogenolysis over Raney nickel. Studies on the reduction of haloalkanes and -alkenes over palladium (4) have shown that hydrogen chloride inhibits the hydrogenolysis of ethyl chloride at 120° in proportion to its concentration, and that $CF_2{=}CCl_2$ suffers hydrogenolysis more readily than hydrogenation yielding $CF_2{=}CHCl$ (82%) and $CF_2{=}CH_2$ (18%) but not $CHF_2{-}CH_3$ when treated with an insufficient amount of hydrogen (5). On the basis of this information we selected palladium, platinum oxide, Raney nickel, zinc, lithium, and sodium as catalysts and reducing agents for our investigations.

Experimental

All melting points are corrected. Analyses were performed by Dr. Franz Kasler. The infrared (i.r.)

[1]Taken in part from the Ph.D. theses of Eberhard Kiehlmann and Robert J. Bianchi, University of Maryland, 1964 and 1967.

spectra were recorded on a Beckman IR-5 spectrometer using a thin film of neat liquid between sodium chloride plates. Nuclear magnetic resonance (n.m.r.) spectra were run on a Varian A-56/60 spectrometer using TMS as internal standard and $CDCl_3$ as solvent (unless specified otherwise). Chemical shifts are reported in τ units (10.00 p.p.m. downfield from TMS). Vapor-phase chromatographic (v.p.c.) analyses were performed on a Varian Aerograph model 1200-1 HY-FI III gas chromatograph using a 5 ft × $\frac{1}{8}$ in. column packed with 5% Carbowax 20M on Aeropak 30.

All quantitative estimates of the composition of product mixtures by gas–liquid chromatographic (g.l.c.) and n.m.r. spectroscopic analysis are based on comparison of integrated peak areas obtained for the various components of a reaction mixture with those obtained for standard mixtures prepared from the pure components. The v.p.c. peak areas were measured planimetrically. For the purpose of analysis and identification, small samples of all the components of a product mixture were isolated in >95% purity by fractional distillation or preparative gas chromatography. Preparative separations were performed on a Varian Aerograph A-90-P3 using a 30% QF-1 column 20 ft × $\frac{3}{8}$ in.

Phenyl(trichloromethyl)carbinol (*1*)

Compound **1** was prepared from benzaldehyde, chloroform, and powdered potassium hydroxide as described in the literature (6). The desired product was obtained in 31% yield, b.p. 141–143°/15 mm.

Reduction of 1 with Zinc and Acetic Acid

A solution of 45.1 g (0.20 mole) of **1** in 300 ml of glacial acetic acid was cooled to 0°. After the addition of 50 g (0.765 g-atoms) of zinc dust, the mixture was stirred for 1 h at ice-bath temperature. There was no visible evidence of reaction. Excess zinc was filtered off and water was added. Extraction with ether, washing with water and aqueous sodium carbonate solution, and distillation gave 33 g of crude product, b.p. 91–102°/12 mm. The product mixture was shown by g.l.c. and n.m.r. spectroscopic analysis to consist of 66% β,β-dichlorostyrene (**2**), b.p. 98–101°/15 mm, 10% *cis*-β-chlorostyrene (**3***a*), 8% *trans*-β-chlorostyrene (**3***b*), b.p. 91–93°/15 mm, and 12% starting material (**1**).

Nuclear magnetic resonance absorption peaks:
2, ν_{max} ($CDCl_3$) τ 3.28 singlet (1 proton, —CH=CCl_2), 2.75 multiplet (5 protons, C_6H_5—);

Reduction of 1 with Zinc Amalgam under Standard Clemmensen Reduction Conditions (7)

A mixture of 100 g (1.53 g-atoms) of mossy zinc, 7.5 g of mercuric chloride, 5 ml of concentrated hydrochloric acid, and 125 ml of water was shaken for 5 min in a stoppered 1-l flask. The aqueous solution was decanted and 54.0 g (0.24 mole) of phenyl(trichloromethyl)-carbinol, 75 ml of water, and 175 ml of concentrated hydrochloric acid were added to the amalgamated zinc The reaction mixture was vigorously refluxed for 11 h during which period three 50-ml portions of concentrated hydrochloric acid were added at 3-h intervals. Dilution with water, extraction with ether, drying ($MgSO_4$), and evaporation of the solvent gave 27.0 g of crude product, b.p. 106–109°/21 mm, which was found by v.p.c. and n.m.r. spectroscopic analysis to have the following composition: 55% **2**, 16% **3***a*, 12% **3***b*, and 17% unidentified by-products.

1,1,1-Trichloro-2-hydroxy-6-methyl-4-heptanone (6)

This compound was prepared from methyl isobutyl ketone and chloral as described in the literature (8); **6** was obtained in 58% yield, m.p. 86–87° (lit. (8) 86–87°).

Reduction of 6 with Zinc Amalgam (Standard Conditions)

Following the procedure outlined for the reduction of **1** with zinc amalgam, 64.4 g (0.26 mole) of **6** gave 40.4 g of crude product. Vacuum distillation through a modified Widmer column at 12 mm pressure gave the following three fractions: forerun, 1.3 g, b.p. 40–77°; 1,1-dichloro-6-methyl-heptene (**8**), 16.5 g, b.p. 80–83°; 1,1-dichloro-6-methyl-1-hepten-4-one (**7**), 20.3 g, b.p. 105–110°.

Anal. Calcd. for $C_8H_{14}Cl_2$ (**8**): C, 53.05; H, 7.79; Cl, 39.15. Found: C, 53.02; H, 8.00; Cl, 38.90.

Anal. Calcd. for $C_8H_{12}Cl_2O$ (**7**): C, 49.25; H, 6.20; Cl, 36.34. Found: C, 49.71; H, 6.35; Cl, 35.98.

The yields obtained were 35% (**8**) and 40% (**7**), respectively. Spectroscopic analysis:

8; i.r.: ν_{max} (neat) 1615 cm^{-1} (C=C), no absorption at the frequencies characteristic for OH and C=O; n.m.r.: ν_{max} (CCl_4) τ 4.30 triplet (1 proton, —CH=CCl_2), 7.97 multiplet (2 protons, —CH_2—CH=CCl_2), τ 8.5 to 8.8 multiplet (5 protons, $\rangle$CH—CH_2—CH_2—), 9.15 doublet (6 protons, $(CH_3)_2C$).

7; i.r.: ν_{max} (neat) 1630 cm^{-1} (C=C), and 1720 cm^{-1} (C=O), no OH absorption; n.m.r.: ν_{max} (CCl_4) τ 3.74 triplet (1 proton, —CH=CCl_2), 6.61 doublet (2 protons, —CO—CH_2—CH=CCl_2), 7.66 multiplet (3 protons, $\rangle$CH—CH_2—CO—), and 9.10 doublet (6 protons, $(CH_3)_2C$).

The structure assignments were further verified by qualitative functional group tests ($KMnO_4$, Br_2/CCl_4, 2,4-DNPh, and Na fusion).

1,1-Dichloro-6-methyl-1-hepten-4-one (7)

1,1,1-Trichloro-2-hydroxy-6-methyl-4-heptanone (**6**) (64.4 g, 0.26 mole) was reduced with zinc amalgam and sulfuric acid by the procedure outlined for the reduction of **1** (for details, see Table II, No. 2). The usual work-up procedure gave 46.5 g of crude product which was fractionated at 17 mm pressure to give 32.5 g (64% yield) of 1,1-dichloro-6-methyl-1-hepten-4-one (**7**), b.p. 110–120°/17 mm.

Anal. Calcd. for $C_8H_{12}Cl_2O$: C, 49.25; H, 6.20; Cl, 36.34. Found: C, 49.31; H, 6.48; Cl, 36.10.

In addition to this main product, 2.8 g (6% yield) of 1,1-dichloro-6-methyl-1-heptene (**8**), b.p. 80–104°/17 mm,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and 7.0 g (11% recovery) of unreacted 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone, b.p. 144–164°/17 mm, were isolated by fractional distillation.

1,1-Dichloro-6-methyl-1-heptene (8)

Following the procedure outlined for the reduction of **1**, 64.4 g (0.26 mole) of **6** was reduced with zinc amalgam and hydrochloric acid (for details, see Table II, No. 4). The crude reaction product (35 g) was distilled through a modified Widmer column to give 28 g (60% yield) of 1,1-dichloro-6-methyl-1-heptene (**8**), b.p. 75–82°/14 mm. No 1,1-dichloro-6-methyl-1-hepten-4-one was found in the v.p.c. (decyl phthalate column at 170°) of the crude product.

Reduction of 1,1-Dichloro-6-methyl-1-hepten-4-one (7)

Reduction of 76.7 g (0.394 mole) of **7** with 250 g of amalgamated zinc in hydrochloric acid (27 h reflux time, other procedural details as described before) and fractional distillation of the crude product obtained after extraction with methylene chloride, drying ($MgSO_4$), and evaporation of the solvent gave 12.3 g (17% yield) of 1,1-dichloro-6-methyl-1-heptene (**8**), b.p. 83–88°/15 mm, and 28.0 g (37% recovery) of unreacted 1,1-dichloro-6-methyl-1-hepten-4-one (**7**), b.p. 113–120°/15 mm.

Reduction of 1,1,1-Trichloro-2-hydroxy-6-methyl-4-heptanone (6) with Zinc and Acetic Acid

Following the procedure outlined for the reduction of **1** with zinc and acetic acid, 49.6 g (0.20 mole) of **6** gave 38.6 g of crude product which was found by v.p.c. and n.m.r. spectroscopic analysis to have the following composition: 65% 1,1-dichloro-6-methyl-1-hepten-4-one (**7**), b.p. 104–105°/15 mm, 24% 1-chloro-6-methyl-1-hepten-4-one, b.p. 85–90°/15 mm, and 3% unidentified, low-boiling products. Spectroscopic identification of 1-chloro-6-methyl-1-hepten-4-one: i.r.: ν_{max} (neat) 1635 cm^{-1} (C=C), 1715 cm^{-1} (C=O); n.m.r.: ν_{max} ($CDCl_3$) τ 9.07 doublet (6 protons, $(CH_3)_2C$), 7.68 multiplet (3 protons, $\rangle CH—CH_2—$), 6.67 doublet (2 protons, $—CH_2—CH=C$), 3.93 multiplet (2 protons, —CH=CH—Cl).

Catalytic Hydrogenation of Phenyl(trichloromethyl)-carbinol (1)

A solution of 5.0 g (0.022 mole) of **1** in 95% ethanol was hydrogenated over 20% palladium/carbon catalyst at room temperature and 40 p.s.i. of hydrogen pressure. Filtration of the reaction mixture and evaporation of the solvent gave 1.3 g of crude product which was shown by v.p.c. and spectroscopic analysis to consist of 25% starting material and 75% phenyl(dichloromethyl)-carbinol (**4**). A sample of pure **4**, m.p. 54–55° (lit. (9) 56°) was isolated from this mixture by preparative g.l.c. and identified by n.m.r. spectroscopy. The rest of the products are believed to be lower-boiling components which evaporated with the solvent. There were indications of ethylbenzene having formed during the reaction.

Reduction of (+)Phenyl(trichloromethyl)carbinol (1) with Lithium in Liquid Ammonia

To a stirred solution of 5.0 g (0.022 mole) of **1** in 1 l of liquid ammonia (taken from an ammonia cylinder without further purification) was added 1.0 g (0.14 mole) of lithium metal (small pieces). At the appearance of the blue color, after approximately 90 s, a solution of 24 g (0.30 mole) of ammonium nitrate in 200 ml of liquid ammonia was added to destroy lithium amide and unreacted lithium metal. Evaporation of the solvent, addition of 200 ml of 2 *N* hydrochloric acid, extraction with ether, drying ($MgSO_4$), and distillation gave 0.25 g of crude product, b.p. 84–85°/8 mm. The product mixture was shown by n.m.r. spectroscopy to consist of 85% α-phenethyl alcohol, 11% β-phenethyl alcohol, and 4% acetophenone. The specific rotation of this mixture was measured using a polarimeter (Franz Schmidt and Haensch, Berlin S.) with sodium lamp as light source and a two-decimeter tube. The measured value of $[\alpha]_D^{25}$ +18.6° (*c*, 5.0 g of solute per 100 ml of toluene solution) corresponded to 37% optical purity (lit.(10)$[\alpha]_D^{25}$ +50.6° for optically pure L-α-phenethyl alcohol).

Results

As shown in Table I, β,β-dichlorostyrene (**2**) has been found as the major product of reduction of phenyl(trichloromethyl)carbinol (**1**) with zinc, zinc–copper couple or zinc amalgam in neutral or acidic solution. In all but one of these reactions β-chlorostyrene (**3**) was formed as minor product. The reductions with zinc–copper in ethanol and with amalgamated zinc in hydrochloric acid were accompanied by the formation of small amounts of phenyl(dichloromethyl)carbinol (**4**) and β-phenethyl chloride, respectively. Reduction with Raney nickel or hydrogenation over 5% palladium/carbon results in the replacement of only one chlorine atom of **1** by hydrogen while simultaneous hydrogenolysis of one carbon–chlorine bond and ring hydrogenation was observed with platinum oxide as catalyst.

No α-phenethyl alcohol (**5**) was detected in any of these experiments, and no olefinic products were formed when the reduction of **1** was carried out in neutral alcoholic solution with catalysts and reducing agents other than zinc.

The reaction of 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**6**) with zinc in acetic acid or aqueous mineral acid leads to the same structural changes as the corresponding reactions of **1** except that under the standard conditions of the Clemmensen reduction, i.e. reflux with amalgamated zinc in strong hydrochloric acid, the carbonyl group of **6** is also reduced. The data summarized in Table II show that the formation of **8** is facilitated by long reflux time and high concentration of hydrochloric acid, and that **7** becomes the major product when the reduction is carried out in sulfuric acid. The

§$(CH_3)_2CH$—CH_2—CO—CH_2—CH=CH—Cl.

intermediacy of **7** in the formation of **8** has been demonstrated by Clemmensen reduction of pure **7**. In glacial acetic acid as solvent, zinc dust reduces phenyl(trichloromethyl)carbinyl methyl ether ($C_6H_5CHOCH_3$—CCl_3) to β,β-dichlorostyrene (**2**), and **6** to 1,1-dichloro-6-methyl-1-hepten-4-one (**7**) and 1-chloro-6-methyl-1-hepten-4-one.

Alkali metals in liquid ammonia were found to convert phenyl(trichloromethyl)carbinol (**1**) to α-phenethyl alcohol (**5**) in low yield with partial racemization at the CHOH carbon and formation of acetophenone and β-phenethyl alcohol as by-products. When sodium or potassium was used as reducing agent instead of lithium, the reduction proceeded more rapidly and the yield of acetophenone increased at the expense of α-phenethyl alcohol. This indicates that hydrogenolysis of the CCl_3 group occurs at the metal surface and is not accomplished by the solvated electrons. Confirming this conclusion, acetophenone was formed as the main product

when sodium was first dissolved in liquid ammonia to produce solvated electrons (blue) and **1** was subsequently added to the stirred solution.

Discussion

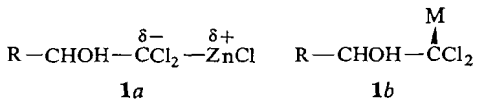
Reductions with Zinc and Catalytic Hydrogenolyses

On the basis of the experimental results summarized in Table I and of our present knowledge on electrochemical reduction processes and on the mechanism of the Clemmensen reduction (7, 11), it is proposed that the reduction of trichloromethylcarbinols with zinc in neutral or acidic solution is due to a heterogeneous reaction on the metal surface. It is the polar character of the carbonyl group, i.e., the high electrophilicity of the carbonyl carbon, which makes the Clemmensen reduction possible for aldehydes and ketones but not for carboxylic acids or esters, since the partial positive charge on the carbonyl carbon of the latter compounds is reduced by resonance interaction with the second oxygen atom. Due to the inductive effect of three chlorine atoms, the trichloromethyl carbon of **1** is sufficiently electrophilic to undergo adsorption and reduction on the zinc surface, but the cationic character of the mono- or dichloromethyl carbon is not sufficient to allow for replacement of all three chlorine atoms of **1** by hydrogen. In addition, the presence of a good leaving group (OH) in α-position to the trichloromethyl group, the acidity of the reaction medium, and the magnitude of the overvoltage of hydrogen on the metal surface have a marked effect on the course of the reaction and the structure of the products.

In the first step, the organic molecule diffuses to the metal surface where it is chemisorbed forming a carbon–metal bond. Since the metal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

acts as an electron source pumping electrons into the molecule, the intermediate organometallic complex may be represented by structure **1***a* (in analogy to Grignard reagents) or more generally by **1***b* where M represents the metal surface (the latter presentation is used throughout this paper):

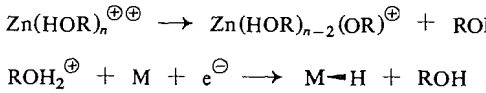


1*a* **1***b*

A wedge-shaped bond is used between carbon and metal to indicate the electron density distribution. This chemisorbed species (**1***b*) may undergo further reaction to form the observed products (see Table I) by any one of the three routes (*a*, *b*, and *c*) shown in Reaction Scheme 1.

Which of these routes is followed depends on the free energies of activation and on the nature of the transition states involved in the various reaction steps under different experimental conditions. Route *a*, stabilization of the chemisorbed molecule by formation of a double bond and elimination of water, apparently requires the lowest activation energy and is particularly favored in strongly acidic solution after preliminary protonation of the OH group. Thus, the presence of a good leaving group in the α-position accounts for the formation of β,β-dichlorostyrene (**2**) as the major product of reduction of **1** with zinc (Table I, Nos. 1–4). The same elimination of electronegative α-substituents due to the "pressure" of the electron gas of the metal on adjacent bonds has been observed for the Clemmensen reduction of various α-hydroxy ketones (12, 13). Desorption and combination of **1** with a proton (route *c*) is unfavorable because this process requires a relatively high activation energy due to the overvoltage of hydrogen on the zinc surface. Thus, phenyl(dichloromethyl)carbinol (**4**) is formed only in low yield when a zinc–copper couple is used as reducing agent.

In close similarity to the final steps of the Clemmensen reduction (11), the formation of β-chlorostyrene (**3**) may be explained by the "push" of the electron gas of the metal. Elimination of a chloride ion from the carbon bonded to the metal surface generates an electron-deficient carbon, and stabilization takes place by migration of a neighboring hydride ion (surface hydride), elimination of water, and desorption of the organic molecule from the metal surface (route *b*). The metal hydride is believed to be formed by discharge and dehydration of protonated solvent molecules on the metal surface and chemisorption of the resulting hydrogen atoms:



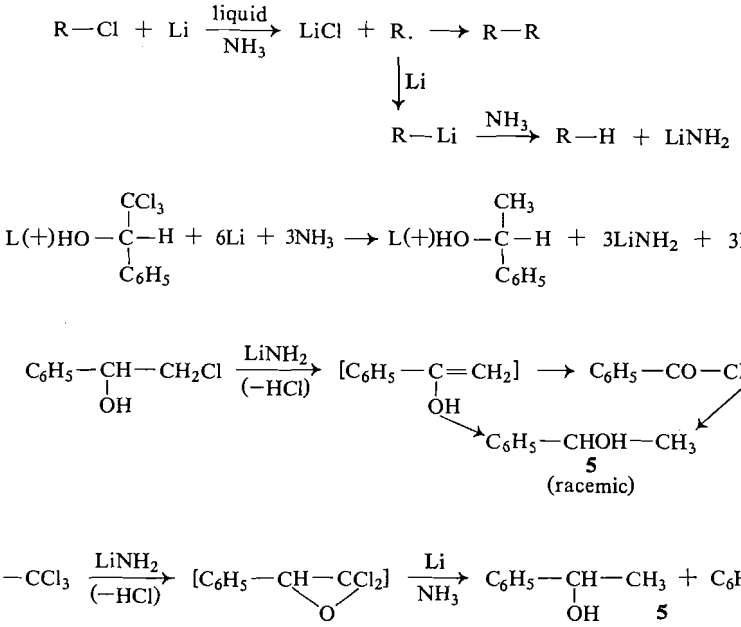
It is again the overvoltage of hydrogen on the metal surface which inhibits rapid combination of the hydride ion or the new organometallic intermediate (**1***c*) with protons to form H_2 or β-hydroxy-β-phenethyl chloride, respectively.

The mechanism of catalytic hydrogenolysis of **1** over Raney nickel, palladium, or platinum oxide is not well understood. In analogy to the preceding discussion and to the heterogeneous reaction of hydrogen with alkenes on catalytic surfaces, it may be assumed that on these metals "bonding" by chemisorption is partially replaced by weaker adsorption forces, and that the CCl_3 carbon of **1** but not the $CHCl_2$ carbon of **4** is sufficiently electrophilic for adsorption (or chemisorption) and hydrogenolysis to occur (via route *c*, Reaction Scheme 1). Thus phenyl-(dichloromethyl)carbinol (**4**) is rapidly desorbed from the catalyst surface before the reduction can proceed any further.

The reduction of 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**6**) by zinc amalgam has been shown to be a two-step process. First, the trichloromethylcarbinol (—CHOH—CCl_3) is converted to a dichlorovinyl compound (—CH=CCl_2) by the mechanism outlined for route *a* (Reaction Scheme 1, R = *i*-Bu$COCH_2$). This step requires a lower activation energy than the regular Clemmensen reduction thus accounting for the absence of 1,1,1-trichloro-2-hydroxy-6-methylheptane in the product mixture. The second, slow step is the Clemmensen reduction of the carbonyl group (11). Route *b* (Reaction Scheme 1, R = *i*-Bu$COCH_2$) accounts for the formation of 1-chloro-6-methyl-1-hepten-4-one when **6** is reduced with zinc in glacial acetic acid.

It should be pointed out that the steric requirements for chemisorption of chlorinated carbon on metal surfaces are largely unknown; further studies will be needed on the factors

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



determining the strengths of the carbon–metal bonds of the various chemisorbed complexes postulated in Scheme 1 (and thus determining the activation energies required for desorption and stabilization of the desorbed molecules).

Reduction with Lithium

The mechanism of the reaction of phenyl-(trichloromethyl)carbinol (**1**) with lithium in liquid ammonia is probably closely related to the formation of organometallic derivatives (or dimeric products) when alkyl halides are allowed to react with alkali metals (14).

Three consecutive reaction steps of this kind would convert a trichloromethyl group to a methyl group with retention of configuration at the adjacent —CHOH— carbon.

The formation of acetophenone may be explained by dehydrohalogenation of the intermediate β-hydroxy-β-phenethyl chloride, and the racemic α-phenethyl alcohol may be due to subsequent reduction of acetophenone by excess lithium.

Both β-phenethyl alcohol and α-phenethyl alcohol may also be formed via a *gem*-dichloroepoxide intermediate (6).

Acylation and alkylation of 1,3-dimethoxybenzene in polyphosphoric acid

T. R. KASTURI AND K. M. DAMODARAN
Department of Organic Chemistry, Indian Institute of Science, Bangalore-12, India

Received August 20, 1968

Products of the reaction of 3-halo- and 3-ethoxypropionic acids with 1,3-dimethoxybenzene (**4**) in polyphosphoric acid have been shown to be 2′,4′-dimethoxy-3-(2,4-dimethoxyphenyl)-propiophenone (**6**) and 1,5-bis[3-(2,4-dimethoxyphenyl)-3-keto-propyl]-2,4-dimethoxybenzene (**15**) and these have been prepared by unambiguous syntheses. 2′,4′-Dimethoxy-3-ethoxypropiophenone (**3***a*) and 2′,3,4′-trimethoxypropiophenone (**3***d*) have been synthesized by the reaction of 3-chloro-2′,4′-dimethoxypropiophenone (**3***c*) with ethanol and methanol respectively.

Canadian Journal of Chemistry, **47**, 1529 (1969)

Friedel–Crafts acylation of aromatic compounds with bifunctional reagents (1) like halo- or alkoxypropionic acids in polyphosphoric acid (PPA) is rather difficult (2). Musgrave and coworkers (3) have reported unsuccessful attempts at acylations of 3,4-dimethoxyphenyl-, as well as 3,5-dimethoxyphenylacetic esters with substituted octanoic acids (**1***a*,*b*,*c*). One example wherein acylation employing 3-chloropropionic acid in PPA is successful, is that of Davis and Watkins (4) who have prepared the 3-chloropropionyl ketone **2***a* by the reaction of 3-chloropropionic acid with the ester **2***b*.

In connection with a synthetic project on hand, we needed 2′,4′-dimethoxy-3-ethoxypropiophenone (**3***a*) as a starting material. We thought of preparing compound **3***a* by acylation of 1,3-dimethoxybenzene (**4**) with 3-ethoxypropionic acid using PPA. First, PPA was chosen as the reagent as, unlike aluminium chloride, it is known to effect Friedel–Crafts acylations without causing aryl–alkyl ether cleavage (2, 5–8). We also anticipated that at lower reaction temperatures, the alkyl–alkyl ether linkage will remain unaffected.

Adopting Dev's general procedure (8) for PPA acylations with minor modifications, we treated 1,3-dimethoxybenzene with 3-ethoxypropionic acid in the presence of PPA at 40° for about 3–5 min.[1] The neutral product of the reaction was chromatographed on alumina to give two[2] ketonic substances, designated **A** and **B**, in 1:4 ratio. The occurrence of the M^+ peak at *m/e* 330 in the mass spectrum[3] of ketone **A** substantiated the molecular formula $C_{19}H_{22}O_5$. This ketone showed λ_{max} at 226, 269, and 300 mμ (ε 22 000, 14 500, and 8600) indicating the presence of a 2,4-dimethoxybenzoyl chromophore (10) in the molecule. The presence of a benzoyl group was indicated by peaks at 1661 (C=O of conjugated carbonyl), 1605, and 1575 cm^{-1} (aromatic C=C) in the infrared (i.r.) spectrum. Further, it gave the following signals in the nuclear magnetic resonance (n.m.r.) spectrum: 3.10 (m, 8 H), 3.81 (s, 6 H, two aromatic methoxyls), 3.87 (s, 6 H, two aromatic methoxyls), 6.33–6.70 (m, 4 H), 7.09 (d, 1 H, J = 9.5 Hz), and 7.83 δ (d, 1 H, J = 9.5 Hz).

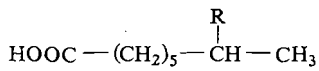
Sodium borohydride reduction of ketone **A** gave a carbonyl-free hydroxylic substance, while its hydrogenolysis with diborane (11) gave the desoxo compound **5***a*. On the basis of the above data, ketone **A** was assigned the structure, 2′,4′-dimethoxy-3-(2,4-dimethoxyphenyl)-propiophenone (**6**). The mass spectral fragments *m/e* 165 (strong, **7**), 151 (strong, **8**), and 138 (weak, **9**) further substantiated this structure, which was proved by its unambiguous synthesis (*vide infra*).

Ketone **B**, which had an M^+ peak at *m/e* 522 in its mass spectrum showed λ_{max} at 227, 268, and 304 mμ (ε 40 800, 27 600, and 17 900), characteristic of a 2,4-dimethoxybenzoyl chromophore (10). The presence of carbonyl group and aromatic ring was indicated by peaks at 1661 (C=O of conjugated carbonyl), 1605, and 1575 cm^{-1} (aromatic C=C) in the i.r. spectrum. The

[1]In acylations employing PPA, reaction temperature and time are found to be critical factors (9).

[2]Thin-layer chromatography showed the presence of small amounts of other substances, which are under investigation.

[3]We are thankful to Dr. J. S. Shannon, Division of Entomology, C.S.I.R.O., Chatswood, New South Wales, Australia, for his help in obtaining the mass spectra reported herein and their interpretation.



1 *a*, R = OAc

f, R_1=R_2=CH_2CH_2COOH

complex n.m.r. spectrum showed peaks at 2.75–3.37 (m, 8 H), 3.81, 3.83, and 3.85 (18 H, probably six aromatic methoxyls), 6.37–6.60 (m, 5 H), 6.93 (s, 1 H), and 7.83 δ (d, 2 H, J = 9.5 Hz). Sodium borohydride reduction of ketone **B** gave a carbonyl-free hydroxylic substance, while diborane reduction gave a carbonyl-free desoxo compound **5***b*, indicating its benzylic nature.

The molecular weight as well as the presence of the fragments *m/e* 357 (weak, **10**), 343 (strong, **11**), 177 (weak, **12**), 165 (strong, **7**), and 151 (weak, **13**) in its mass spectrum led us to consider structures **14** or **15** for this ketone. The mass spectrum clearly ruled out the third alternative structure **5***c*, as it is not possible to derive the ion at *m/e* 343 from it. Further, structure **5***c* could be precluded on mechanistic grounds also (12).

In order to differentiate between structures **14** and **15**, these compounds were prepared by unambiguous methods as follows:

[1] **4** + **5***d* → **6** + **14**

[2] **4** + **5***f* → **15**

Preparation of the acid **5***d* has already been reported (13, 14). However, we tried alternative methods for preparing this acid. For example, treatment of 7-methoxydihydrocoumarin, obtained by high pressure hydrogenation (15) of 7-methoxycoumarin over Raney nickel catalyst, with cold alkali, followed by methylation with dimethyl sulfate in the presence of potassium carbonate in refluxing acetone, and saponification gave the acid **5***d* in good yields. The best and easiest method for the preparation of **5***d* was by the addition of methyl acrylate to 1,3-dimethoxybenzene in pyrophosphoric acid,[4] followed by saponification.

Reaction of the acid **5***d* with a fourfold excess of 1,3-dimethoxybenzene in PPA gave in good yield, according to eq. [1], the monoketone **6** and the unsymmetrical diketone **14** in 2:1 ratio. Compound **6** was identical with the aforementioned ketone **A**. The n.m.r. spectrum of the unsymmetrical diketone **14** was significantly

different from that of ketone **B** in the aromatic region (see Experimental).

Acylation of 1,3-dimethoxybenzene with the diacid **5***f* (16) in PPA according to eq. [2] led to the exclusive formation of the symmetrical diketone **15**, which was identical with the previously mentioned ketone **B**.

Having failed to obtain the required propiophenone **3***a* by the reaction of 1,3-dimethoxybenzene with 3-ethoxypropionic acid, we carried out the acylation of 1,3-dimethoxybenzene with 3-bromopropionic acid in PPA with a view to getting the bromoketone **3***b* which could easily be converted to the ethoxyketone **3***a* by known procedures. Chromatography of the neutral product from this reaction gave only the aforementioned ketones **6** and **15** in 3:1 ratio.

Acylation of 1,3-dimethoxybenzene with either 3-ethoxypropionyl chloride (cf. ref. 17) in the presence of aluminium chloride (7, 18) in carbon disulfide medium or with 3-chloropropionic acid in PPA, resulted only in the formation of the ketones **6** and **15**.

In the present work, the formation of monoketone **6** can be visualized by initial acylation (7) of 1,3-dimethoxybenzene with one molecule of 3-halo- or alkoxy-propionic acid, and subsequent electrophilic attack on a second molecule of the highly reactive aromatic ether **4** (7). The alkylation reaction might proceed by either of the following mechanisms:

(*a*) Elimination of 3-halo or alkoxy group to give the corresponding α,β-unsaturated carbonyl derivative followed by alkylation (7), or

(*b*) Formation of the intermediate complexes such as **16**, or **17** (1, 19, 20), which *in situ* might attack the aromatic ether **4**.

In order to get a clear picture of this mechanism, we carried out the reaction of the chloroketone **3***c* (*vide infra*) with 1,3-dimethoxybenzene in PPA. Thin-layer chromatography (t.l.c.) of the neutral product showed the presence of the starting chloroketone[5] as well as ketones **6** and **15**. In the light of this result and that of Davis and Watkins (4), mechanism (*a*) could be ruled out.

Since acylation of 1,3-dimethoxybenzene as the first step might result in the exclusive formation of the intermediate complex **16** or **17**, there is no possibility for the formation of the unsymmetrical ketone **14** in these reactions by further acylation of the monoketone **6**. However, the symmetrical ketone **15** may be formed by further alkylation of the ketone **6** or by simultaneous dialkylation of 1,3-dimethoxybenzene by the intermediate complex **16** or **17**. This is evident from the aforementioned alkylation reaction of 1,3-dimethoxybenzene with the chloroketone **3***c*. This is further substantiated by the reaction of either of the alkoxy ketones **3***a* or **3***d*[6] with 1,3-dimethoxybenzene in PPA, when the same ketones **6** and **15** were formed.

Finally, the required ethoxypropiophenone **3***a* was prepared by acylation of 1,3-dimethoxybenzene with 3-chloropropionyl chloride in the presence of aluminium chloride in carbon disulfide medium (cf. ref. 18), followed by heating the resulting chloroketone **3***c* with either ethanolic potassium hydroxide (17, 21) or sodium iodide in ethanol (17). Similarly, the corresponding methoxypropiophenone **3***d* was also synthesized. The structures of ketones **3***a* and **3***d* were confirmed by their ultraviolet (u.v.), i.r., and n.m.r. spectra.

Experimental

Melting points (hot stage) and boiling points reported herein are uncorrected. Ultraviolet (ethanol solution) and infrared (i.r.) spectra were recorded on a Beckmann DU and a Perkin–Elmer model 137B Infracord spectrophotometers respectively. Nuclear magnetic resonance spectra were taken in $CDCl_3$ or CCl_4 solution on a Varian A-60 spectrometer using tetramethylsilane as internal standard. All organic extracts were dried over anhydrous sodium sulfate. Neutral alumina and silica gel were used for column chromatography and thin-layer chromatography (t.l.c.) respectively. Light petrol refers to fraction boiling 45–65°. Microanalyses were carried out by Messrs. B. R. Seetharamia and H. S. Thyagarajan of this department.

Reaction of 1,3-Dimethoxybenzene

(a) With 3-Ethoxypropionic Acid

A mixture of 1,3-dimethoxybenzene (6.9 g, 0.05 mole) and 3-ethoxypropionic acid (5.9 g, 0.05 mole) was added in one lot to PPA (phosphorus pentoxide (35 g) and *ortho*-phosphoric acid (15 ml)) at 40° and stirred vigorously for 3–5 min. The pale-red viscous reaction mixture was decomposed with ice-cold water and the resulting oily organic material was extracted with benzene. The benzene extract was washed successively with water, saturated aqueous sodium bicarbonate, and water. The solvent was distilled off and the residue (8 g) was chromatographed. The benzene – light petrol fraction (1 g) gave, on crystallization from ethanol, ketone **6**, m.p. 88–89°.

[5]However, the chloroketone could not be isolated after chromatography over neutral alumina, as it probably underwent decomposition.

[6]These experiments were suggested by one of the referees.

(b) With 3-Bromopropionic Acid

A mixture of 1,3-dimethoxybenzene (3.5 g, 0.025 mole) and 3-bromopropionic acid (3.9 g, 0.025 mole) was poured in one lot into PPA (phosphorus pentoxide (16.25 g) and *ortho*-phosphoric acid (9.8 ml)) kept at 0°. The mixture was stirred vigorously and the temperature gradually raised to 20° during 15 min. Stirring was continued for a further 30 min at 40° during which time evolution of hydrogen bromide was observed. The reaction mixture was worked up as before to yield an oily residue (4.5 g) which, on chromatography, gave two fractions; the benzene fraction (2.9 g), on crystallization from ethanol, afforded ketone **6**, m.p. 88–89°, while recrystallization of the ether fraction (0.9 g) from ethanol furnished diketone **15**, m.p. 125–127°.

(c) With 3-Ethoxypropionyl Chloride

Powdered aluminium chloride (16 g) was added during 1 h to a stirred mixture of 1,3-dimethoxybenzene (16 g) and 3-ethoxypropionyl chloride (15 g) in carbon disulfide (32 ml) at 0°. The mixture was stirred at room temperature and let stand overnight. The supernatant liquid was decanted and the dark-red complex decomposed with crushed ice. The organic material was extracted with ether; the extract was washed successively with water, 5% aqueous sodium hydroxide, and water. The residue (20 g), obtained after evaporation of the solvent, was chromatographed; the light petrol – benzene fraction (2 g), on crystallization from ethanol, gave ketone **6**, m.p. 88–89°; the benzene–ether fraction (14 g), on crystallization from ethanol, yielded diketone **15**, m.p. 125–127°.

(d) With 3-Chloropropionic Acid

A mixture of 1,3-dimethoxybenzene (3.45 g) and 3-chloropropionic acid (2.71 g) was added in one lot to PPA (phosphorus pentoxide (17.5 g) and *ortho*-phosphoric acid (7.5 ml)) at 35° and stirred for 30 min. After work-up, the residue (4 g), on chromatography followed by crystallization from ethanol, gave ketone **6** (1.5 g), m.p. 88–89°, and diketone **15** (0.5 g), m.p. 125–127°.

(e) With 3-Chloro-2',4'-dimethoxypropiophenone (3c)

The chloroketone **3***c* (5.7 g, 0.025 mole) was added in one lot to a mixture of 1,3-dimethoxybenzene (3.45 g, 0.025 mole) and PPA (phosphorus pentoxide (17.5 g) and *ortho*-phosphoric acid (7.5 ml)) at 45° and stirred vigorously for 30 min. After work-up, the residue was chromatographed to give two fractions; the benzene fraction (3.8 g), on crystallization from ethanol, afforded ketone **6**, m.p. 88–89°, and the chloroform fraction (2 g) yielded diketone **15**, m.p. 125–127°.

(f) With 2',3,4'-Trimethoxypropiophenone (3d)

The methoxypropiophenone **3***d* (1.12 g) was added to a mixture of 1,3-dimethoxybenzene (0.69 g) and PPA (phosphorus pentoxide (3.5 g) and *ortho*-phosphoric acid (1.5 ml)) at 45° and stirred vigorously for 10 min. After work-up, the residue was chromatographed into two fractions; crystallization from ethanol gave monoketone **6** (0.4 g), m.p. 88–89°, and the diketone **15** (0.2 g), m.p. 125–127°.

(g) With 2',4'-Dimethoxy-3-ethoxypropiophenone (3a)

The ethoxypropiophenone **3***a* (0.6 g) was added to a mixture of 1,3-dimethoxybenzene (0.35 g) and PPA (phosphorus pentoxide (1.75 g) and *ortho*-phosphoric acid (0.75 ml)) at 45° and stirred vigorously for 10 min. After work-up, the residue was chromatographed to give two fractions; the benzene fraction (0.22 g), on crystallization from ethanol, afforded ketone **6**, m.p. 88–89°, and the chloroform fraction (0.15 g) yielded diketone **15**, m.p. 125–127°.

*Hydrogenolyses of Ketones **6** and **15** with Diborane*

(*i*) A solution of borontrifluoride–etherate (5 ml) and diglyme (13 ml) was added to ketone **6** (0.30 g) and sodium borohydride (0.95 g). After 3 h at room temperature, the reaction mixture was heated at 40–50° for 2 h, and cooled. Methanol was added to destroy the excess of diborane, the mixture diluted with ice-cold water, and extracted with benzene. The extract was washed with water. Removal of benzene followed by purification gave 2',4'-dimethoxy-3-(2,4-dimethoxyphenyl)propylbenzene (**5***a*) as an oil (0.29 g), b.p. 120°/1–2 mm (bath temperature); ν_{max} (neat): 1613 and 1587 cm^{-1}; λ_{max}: 226 and 279 mμ (ε 17 250 and 6300).

Anal. Calcd. for $C_{19}H_{24}O_4$: C, 72.15; H, 7.59. Found: C, 72.28; H, 7.18.

(*ii*) Similarly, hydrogenolysis of diketone **15** afforded 1,5-bis[3-(2,4-dimethoxyphenyl)propyl]-2,4-dimethoxybenzene (**5***b*) as an oil, b.p. 175–180°/1–2 mm (bath temperature); ν_{max} (neat): 1613 and 1587 cm^{-1}; λ_{max}: 227 and 280 mμ (ε 30 000 and 11 500).

Anal. Calcd. for $C_{30}H_{38}O_6$: C, 72.85; H, 7.74. Found: C, 72.81; H, 7.71.

7-Methoxydihydrocoumarin and its Conversion into 2,4-Dimethoxyphenylpropionic Acid (5d)

A solution of 7-methoxycoumarin (22) (10 g) in ethanol (80 ml) was hydrogenated over Raney nickel catalyst (3 g) at 90–100° at 200 atm of hydrogen for 45 min. After cooling the solution, the catalyst was filtered off, and the ethanol evaporated. The residue (10.5 g) yielded, on distillation, 7-methoxydihydrocoumarin (13) as an oil, b.p. 158–160°/0.5–1 mm; ν_{max} ($CHCl_3$): 1770, 1631, and 1590 cm^{-1}. Treatment of 7-methoxydihydrocoumarin with 5% aqueous sodium hydroxide followed by acidification afforded 2-hydroxy-4-methoxyphenylpropionic acid, m.p. 138–139°; (lit. (13), m.p. 138–139.5°).

A solution of 2-hydroxy-4-methoxyphenylpropionic acid (0.10 g) and dimethyl sulfate (0.1 ml) in acetone (10 ml) was refluxed in the presence of anhydrous potassium carbonate (0.30 g) for 20 h. The mixture was cooled, filtered, and the solvent removed *in vacuo* in the cold. The residue was treated with water, extracted with ether, and the solvent distilled off. A benzene solution of the residue was filtered through alumina (3 g) and distilled to give **5***e* (0.10 g), b.p. 135–140°/1–2 mm (bath temperature); (lit. (14), b.p. 160°/10 mm); $n_D^{25.7}$ 1.5170; ν_{max} (neat): 1757, 1610, and 1585 cm^{-1}.

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19. Found: C, 64.32; H, 7.04.

Saponification (16) of the ester **5***e* gave the acid **5***d*, m.p. 103–104°; (lit. (13, 14), m.p. 102.5–103.5°).

Methyl 2,4-Dimethoxyphenylpropionate (5e)

Methyl acrylate (18.8 g) was added during 20 min to a

stirred mixture of pyrophosphoric acid (150 g) and 1,3-dimethoxybenzene (90 g), maintained at 65°. Stirring was continued for an additional 30 min. The reaction mixture was poured onto crushed ice and water (400 ml), and let stand for a while. The resulting oily product was extracted with ether, and the extract washed successively with water, saturated aqueous sodium bicarbonate, and water. Removal of ether and distillation of the residue yielded the ester **5***e* (30 g), b.p. 154–155°/1–2 mm.

*2′,4′-Dimethoxy-3-(2,4-dimethoxyphenyl)-propiophenone (**6**) and 2,4-Dimethoxy-1-[1-keto-3-(2,4-dimethoxyphenyl)-propyl]-5-[3-keto-3-(2,4-dimethoxyphenyl)-propyl]-benzene (**14**)*

A mixture of 1,3-dimethoxybenzene (13.80 g) and the acid **5***d* (5.25 g) was poured in one lot into PPA (phosphorus pentoxide (35 g) and *ortho*-phosphoric acid (15 ml)) maintained at 50–53° and stirred vigorously for 15 min. The residue was chromatographed; the benzene fraction (5 g), on crystallization from ethanol, afforded ketone **6**, m.p. 88–89°; crystallization of the benzene–chloroform fraction (2.5 g) from ethanol furnished the diketone **14**, m.p. 143–144°; λ_{max}: 227, 267, and 304 mμ (ε 39 100, 26 000, and 16 800); ν_{max} (Nujol): 1661, 1597, and 1575 cm^{-1}; n.m.r.: 2.71–3.41 (m, 8 H), 3.80, 3.89 (s, 18 H, six aromatic methoxyls), 6.41–6.59 (m, 5 H, aromatic protons), 7.08 (d, 1 H, J = 9.5 Hz, proton H_c), 7.67 (s, 1 H, proton H_b), and 7.81 δ (d, 1 H, J = 9.5 Hz, proton H_a).

*1,5-bis[3-Keto-3-(2,4-dimethoxyphenyl)-propyl]-2,4-dimethoxybenzene (**15**)*

A mixture of the diacid **5***f* (4.2 g) and 1,3-dimethoxybenzene (15 g) was added in one lot into PPA (phosphorus pentoxide (35 g) and *ortho*-phosphoric acid (15 ml)) kept at 50–52° and stirred vigorously for 10 min. The dark-red reaction mixture after work-up gave a viscous oil (8 g) which, on trituration with light petrol followed by recrystallization from ethanol, afforded diketone **15**, m.p. 126–128°.

*3-Chloro-2′,4′-dimethoxypropiophenone (**3***c*)*

A solution of 1,3-dimethoxybenzene (7.2 g) in carbon disulfide (10 ml) was added during 30 min to a stirred mixture of 3-chloropropionyl chloride (5.9 g) and powdered aluminium chloride (6.9 g) in carbon disulfide (10 ml) at 0–5°. Stirring was continued at room temperature for further 8 h and the reaction mixture was allowed to stand overnight. After work-up, a crystalline solid (10.5 g) was obtained, which, on recrystallization from methanol, yielded white needles of chloroketone **3***c* (8 g), m.p. 101–102°; ν_{max} (Nujol): 1658, 1603, and 1572 cm^{-1}; λ_{max}: 229, 268, and 305 mμ (ε 13 400, 12 100, and 8 500).

*2′,4′-Dimethoxy-3-ethoxypropiophenone (**3***a*)*

(*i*) A solution of the chloroketone **3***c* (1 g) in ethanolic potassium hydroxide (2 g in 60 ml) was stirred at room temperature for 5 min followed by heating on a steam bath for 5 min. The reaction mixture, after cooling, was neutralized with 4 *N* acetic acid, ethanol was removed *in vacuo* in the cold, and the residual oil was extracted with benzene. The extract was washed successively with water, saturated aqueous sodium bicarbonate, and water. Removal of benzene gave a crystalline solid (1 g) which, on recrystallization from light petrol, afforded white plates of ketone **3***a*, m.p. 42–43°; ν_{max} (Nujol): 1658, 1605, and 1572 cm^{-1}; λ_{max}: 228, 267, and 302 mμ (ε 14 000, 12 400, and 8 150); n.m.r.: 1.12 (t, 3 H), 2.87–3.70 (m, 6 H), 3.78 (s, 3 H), 3.85 (s, 3 H), 6.31–6.50 (m, 2 H), and 7.60 δ (d, J = 9.5 Hz, 1 H).

Anal. Calcd. for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61. Found: C, 65.38; H, 7.58.

(*ii*) A mixture of the chloroketone **3***c* (1.5 g) and anhydrous sodium iodide (10 g) in dry ethanol (50 ml) was refluxed on a steam bath for 36 h. About half of the solvent was removed *in vacuo*, and ether (200 ml) was added to the mixture. The ether solution was washed with 5% aqueous sodium thiosulfate and water. Ether was distilled off and the residue (1.5 g) crystallized from light petrol to give ketone **3***a* (1.2 g), m.p. 42–43°.

*2′,3,4′-Trimethoxypropiophenone (**3***d*)*

A solution of the chloroketone **3***c* (1 g) in methanolic potassium hydroxide (2 g in 60 ml) was stirred for 5 min at room temperature followed by heating on a steam bath for 5 min. The cooled reaction mixture was neutralized with 4 *N* acetic acid. Methanol was removed *in vacuo* in the cold, and the crystalline residue was filtered off, washed with water, and dried. Recrystallization from light petrol yielded white needles of the ketone **3***d* (0.8 g), m.p. 56–57°; ν_{max} (Nujol): 1658, 1605, and 1572 cm^{-1}; λ_{max}: 228, 267, and 303 mμ (ε 14 000, 12 400, and 8 200); n.m.r.: 2.84–3.70 (m, 4 H), 3.21 (s, 3 H), 3.73 (s, 3 H), 3.81 (s, 3 H), 6.17–6.42 (m, 2 H), and 7.51 δ (d, J = 9.5 Hz, 1 H).

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19. Found: C, 64.18; H, 7.04.

Acknowledgments

We are thankful to Professor D. K. Banerjee for his keen interest in this work, to Professor George R. Pettit, Arizona State University, Tempe, Arizona, U.S.A., for kindly furnishing the n.m.r. spectra, and to Dr. G. Subrahmanyam for useful discussions. Thanks are also due to the authorities of the Indian Institute of Science and the Council of Scientific and Industrial Research, New Delhi, for the award of research fellowships to one of us (K.M.D.).

Secondary kinetic isotope effects in bimolecular nucleophilic substitutions. III. Deuterium effects in the Bunte salt reaction of methyl halides and sulfonates

G. E. JACKSON AND K. T. LEFFEK
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received December 16, 1968

Secondary kinetic deuterium isotope effects have been measured for the reaction between thiosulfate ion and methyl-d_3 halides and sulfonates in 50% v/v ethanol–water. The results are used to extend the correlation of Seltzer of k_H/k_D with the difference between the polarizabilities of the attacking nucleophile and the leaving group.

Dissociation constants for the $[NaS_2O_3]^-$ ion have been determined by conductivity measurements for the reaction conditions and used to calculate the concentration of free thiosulfate ions present in the reaction mixture. The activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, based on second order rate constants calculated with respect to the concentration of thiosulfate ion, are reported.

Canadian Journal of Chemistry, 47, 1537 (1969)

Introduction

Secondary deuterium isotope effects in non-solvolytic S_N2 reactions, although generally smaller than analogous effects in S_N1 or solvolytic S_N2 reactions, are, nevertheless, large enough to warrant systematic study. An earlier paper (1) in this series showed that for the Bunte salt reaction

$$S_2O_3^{2-} + RBr \rightarrow RS_2O_3^- + Br^-$$

of certain alkyl bromides in 50% v/v ethanol–water, α-deuterium isotope effects were normal ($k_H/k_D > 1$) and could be as large as 7%. The direction of this effect was opposite to that expected from the solvolytic studies of Hartman and Robertson (2) and the magnitude was, at that time, greater than any previous measurements (3, 4). Since then several reports have confirmed the frequent occurrence of normal secondary deuterium isotope effects in S_N2 reactions; e.g., Wu and Robertson (5) found normal effects for the attack of phenoxide and ethoxide ion on deuterated trimethylsulfonium ion, Östman (6) obtained ratios (k_H/k_D) between 1.05 and 1.09 for the chloride-36 exchange of α-deuterated benzyl chloride and both 2-thenyl and 3-thenyl chloride. Recently, Seltzer and Zavitsas (7) have measured the iodide-131 exchange of methyl-d_3 iodide ($k_H/k_D = 1.05$ in methanol and 1.10 in water) and also proposed a correlation of isotope effects with the polarizabilities of the attacking nucleophile and leaving group. For a given alkyl group the rate ratio was correlated with the difference between the Edwards E-value (8–10) for the entering and leaving groups ($E_n - E_1$).

This paper further explores the deuterium isotope effect in Bunte salt reactions and, in particular, tests Seltzer's correlation for this system in which the value of ($E_n - E_1$) is large and positive, outside of the range of ($E_n - E_1$) previously available.

Results and Discussion

Solutions of sodium thiosulfate in 50% v/v ethanol–water are not fully ionized (11) and it has been shown for the case of magnesium thiosulfate and *n*-propylbromide that the reaction takes place entirely via the thiosulfate ion (12). Thus the second order rate constant calculated with respect to the concentration of thiosulfate ion does not vary with the ionic concentration, whereas that calculated with respect to the stoichiometric sodium thiosulfate concentration does vary with the stoichiometric concentration. However, the latter rate constants may be used in isotopic studies since

$$k_{2(\text{ionic})} = \frac{k_{2(\text{stoich.})}}{\alpha}$$

where α is the fraction of thiosulfate present as $S_2O_3^{2-}$ ions. All values of k quoted in this paper are second order rate constants calculated with respect to the stoichiometric sodium thiosulfate concentration.

Isotope Effects

Since extensive selective solvation takes place

when sodium thiosulfate is dissolved in alcohol–water mixtures, it is necessary to be sure that no significant changes in isotopic rate ratio can be produced by variation of the solvent medium. Table I contains results obtained for several solvent mixtures and concentrations of sodium thiosulfate. Ethyl-1,1,d_2 bromide was used as the substrate as this compound was known to give an isotope effect of about 7% (1).

The experimental requirements preclude large variations in the medium, but it can be seen that no distinct changes in rate ratio occur, and that none is likely to occur from accidental variations in the medium or reagent concentration which is large compared to the experimental error.

The correlation of Seltzer and Zavitsas of k_H/k_D with $(E_n - E_1)$ (7), although strictly valid only for solvent water, works well with the Bunte salt isotope effects previously reported (1).

Since $E = 2.52$ for thiosulfate, a large normal isotope effect would be expected for the Bunte salt reactions of alkyl sulfonates. Some results for a series of methyl compounds are shown in Table II.

Qualitatively, the sulfonate rate ratios are as predicted by the correlation. The plot k_H/k_D versus $(E_n - E_1)$, including the results presented in Table II, is given in Fig. 1. Drawing a line with a slightly steeper gradient than that used by Seltzer gives a reasonably good correlation of the effect, except for a few points already discussed by Seltzer and Zavitsas (7).[1]

In the above correlation the fact that the rate measurements were made at temperatures varying between 25° and 100 °C has been ignored. The justification for this is that a number of secondary deuterium isotope effects have been found to be independent of temperature (13, 14).[2]

However, none of the rate ratios included in the above plot has been tested experimentally because of the difficulty of determining the temperature dependence of a small effect over the experimentally accessible range of tempera-

[1]Another anomalous result has been found for the attack of cyanide ion on methyl-d_3 iodide in aqueous solution by A. Willi (private communication). For this reaction $k_H/k_D = 0.926$.

ture, although a closely related reaction to No. 8 of Fig. 1 has been investigated (14). As the 12% effect found with methyl-d_3 *p*-toluensulfonate is the largest of this type observed to date, an attempt to determine its temperature dependence was made. The results are given in Table III. Although the rate ratios are not precise enough to separate the isotope effect into its enthalpic and entropic contributions, it is clear that the rate ratio is not markedly dependent on temperature so that no serious error in the correlation plot is likely to arise from this source. Robertson *et al.* (15) have suggested that the relation between these secondary isotope effects and temperature may be a further means of distinguishing between S_N1 and S_N2 mechanisms. Arguing from the theoretical treatment of Wolfsberg and Stern (16), they suggested that temperature-independent isotope effects are more likely to occur in an S_N2 reaction than in an S_N1 reaction. As far as the results in Table III show no clear change with temperature, they agree with Robertson's proposal.

Activation Parameters

Calculation of activation parameters from the rate constants would yield values which were correct only for one particular sodium thiosulfate concentration. To obtain true parameters, it is necessary to use k_2/α. Conductivity measurements were carried out using the procedure

described by Bevan and Monk (11) to determine the fraction of sodium thiosulfate, α, which was present in the 50% ethanol–water solution as free thiosulfate ion at temperatures between 20° and 40 °C.

For the system

$$[NaS_2O_3]^- \rightleftarrows Na^+ + [S_2O_3]^{2-}$$

the dissociation constant K_{diss} is related to α by the expression

$$K_{diss} = \frac{\alpha^2 C \cdot f_{S_2O_3}{}^{2-}}{(1 - \alpha)}$$

where C is the stoichiometric sodium thiosulfate concentration and $f_{[S_2O_3]}{}^{2-}$ is the activity coefficient of the thiosulfate ion. Table IV shows the average values of K_{diss} obtained at the various temperatures using solutions of concentration less than 10^{-3} M, together with those of α calculated for the actual reaction conditions of the rates quoted in Table III. Bevan and Monk (11) measured K_{diss} for sodium thiosulfate at 25 °C and obtained a value of 1.45×10^{-2}, about 10% lower than our result.

When the apparent rate constants are divided by α, the true second order rate constants, i.e.,

those which do not change with change of the sodium thiosulfate concentration, are obtained. Figure 2 shows plots of k_H/α and k_D/α vs. $10^3/T$, for methyl and methyl-d_3 *p*-toluenesulfonate: from which the following true activation parameters were obtained by least squares computations:

$$CH_3OTs\ \Delta H_H^{\ddagger} = 12.6_5 \pm 0.07\ \text{kcal}\cdot\text{mole}^{-1}$$
$$\Delta S_H^{\ddagger} = -22.7_6 \pm 0.25\ \text{cal}\cdot\text{mole}^{-1}\cdot\text{deg}^{-1}$$
$$CD_3OTs\ \Delta H_D^{\ddagger} = 12.6_4 \pm 0.13\ \text{kcal}\cdot\text{mole}^{-1}$$
$$\Delta S_D^{\ddagger} = -23.02 \pm 0.4_4\ \text{cal}\cdot\text{mole}^{-1}\cdot\text{deg}^{-1}$$

Hammett *et al.* (17, 18) determined apparent activation parameters for several Bunte salt reactions, one of which was re-determined by Bevan and Monk (11) with magnesium thiosulfate as reagent, from which true activation parameters were calculated using k_2/α values. It is now possible to recalculate Hammett's results (17, 18) with k_2/α values using our conductivity measurements to calculate the values of α for the reaction conditions used by Hammett. These revised activation parameters, recorded in Table V, were obtained graphically since rate constants are available at only three temperatures in most cases. The temperature range 12.5° to 37.5° was used, except for methyl bromide for which two, at 10° and 20° were used.

The changes in enthalpy and entropy of activation with change in alkyl group remain almost the same as those originally reported by Hammett *et al.* (17, 18), but the absolute values are markedly different (compare with the figures quoted by Streitwieser (19)). These reactions are now seen to be characterized by low enthalpies of activation which are balanced by large negative entropies of activation. The recalculated values are qualitatively very similar to those for Menschutkin reactions in nitro-

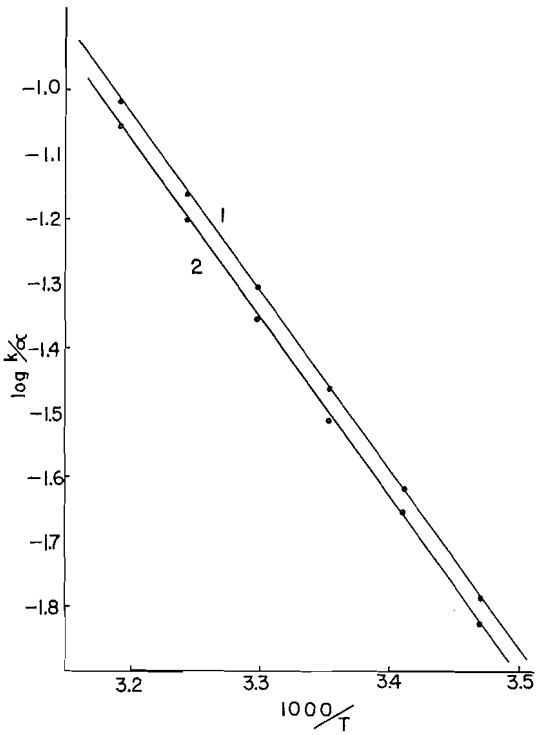

FIG. 2. Temperature dependence of the corrected rate constants for the reactions between methyl *p*-toluenesulfonate (1) and methyl-d_3 *p*-toluenesulfonate (2) and thiosulfate ions in 50% v/v ethanol–water solvent.

TABLE V

Activation parameters for the attack of thiosulfate ion on alkyl esters in 50% v/v ethanol–water solvent*

Compound	$\Delta H^{\ddagger}$ (kcal·mole^{-1})	$\Delta S^{\ddagger}$ (cal·mole^{-1}·deg^{-1})

‡This work.

benzene and benzene solvent (19). The low enthalpies of activation are to be expected from a large polarizable nucleophile such as the thiosulfate ion, since the energy required to place the electrons into a bond forming position would be small. Negative entropies of activation are characteristic of S_N2 reactions where two entities in the initial stage are merging into one in the transition state. However, the size of the parameters in these Bunte salt reactions requires further discussion. The doubly charged thiosulfate ion is strongly and preferentially solvated by water molecules when dissolved in 50% aqueous ethanol. Concentrated solutions separate into two immiscible layers. On the other hand alkyl compounds will not be expected to be nearly as efficient in solvent sorting until the bromine takes on a fractional negative charge in the transition state. This fractional negative charge has been transferred from the thiosulfate ion which still carries more than one unit of negative charge. Thus, the amount of solvent sorting may well be increased in the transition state relative to the initial state, which would introduce another negative contribution to the entropy of activation.

Experimental

Materials

Ethyl-1,1,d_2 bromide (99.5% isotopic purity) was supplied by Merck, Sharp and Dohme Ltd., and methyl-d_3 iodide (99.5%) by Stohler Isotope Chemicals. The normal compounds were reagent grade chemicals which were dried and fractionally distilled before use.

Methyl-d_3 methanesulfonate was prepared by reaction of silver methanesulfonate (1 g) in pure acetonitrile (40 ml) with methyl-d_3 iodide (0.31 ml) at 50° for 8 h. The suspension was filtered to remove silver iodide and the solvent was removed under vacuum. Recovery of the silver iodide showed that the reaction had gone to completion. The product, after purification by distillation under reduced pressure, was obtained in about 75% yield.

Methyl-d_3 *p*-toluenesulfonate was prepared by a similar procedure. The protium analogues were purchased from Eastman Organic Chemicals.

The solvent was prepared and analyzed as described previously (1).

Kinetic Methods

The method used was that described in Part I of this series (1). The initial concentration of the ethyl bromides was 0.020–0.025 *M*. For the ethyl compounds the thiosulfate concentration was initially about 0.05 *M* (except for the runs quoted in Table I) and for the methyl compounds about 0.02 *M*.

Conductance Measurements

The conductance measurements were made with a Wayne Kerr Universal Bridge B221 and stirred cells, which were the cells used by Robertson *et al.* (15) for ethanol–water mixtures. The dissociation constants of the ion pair (K) and the degrees of dissociation (α) were calculated by the method described by Bevan and Monk (11, 12).

Acknowledgments

The authors are grateful for financial support of this work by the National Research Council of Canada and, in particular, thank Dr. R. E. Robertson (National Research Council) for the loan of conductivity cells.

Ortho lithiation of *N,N*-dimethylbenzenesulfonamide by *n*-butyllithium. Condensation with electrophilic compounds[1]

HAMAO WATANABE, RICHARD A. SCHWARZ, AND CHARLES R. HAUSER
Department of Chemistry, Duke University, Durham, North Carolina

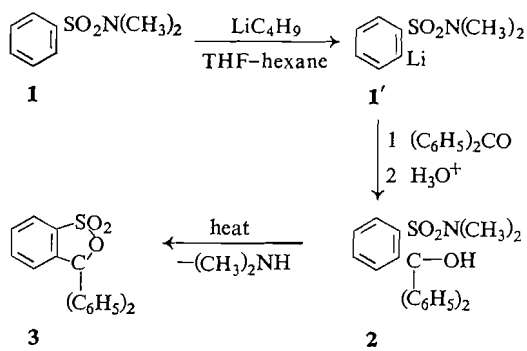
AND

J. LEWIS AND D. W. SLOCUM
Department of Chemistry, Southern Illinois University, Carbondale, Illinois

Received October 30, 1968

N,N-Dimethylbenzenesulfonamide was converted by *n*-butyllithium to the *ortho*-lithiosulfonamide, which was condensed with benzophenone, benzonitrile, phenylisocyanate, and carbon dioxide to form a carbinol, an imine, an amide, and an acid, respectively. The carbinol was cyclized thermally to give a sultone. The imine was converted to the corresponding ketone, oxime, and phenylhydrazone. The oxime underwent a Beckmann rearrangement to afford the same amide that was obtained in the reaction of the *ortho*-lithiosulfonamide with phenylisocyanate.

Canadian Journal of Chemistry, 47, 1543 (1969)



SCHEME 1

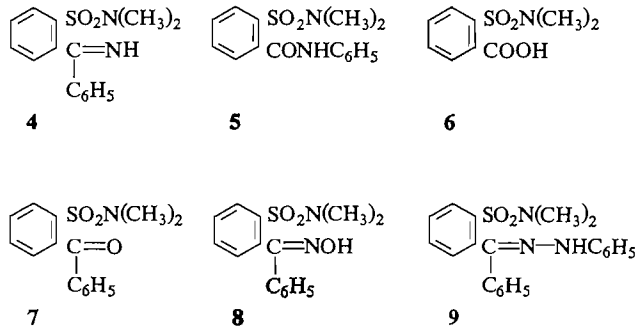
Although the carbonyl group of *N,N*-dimethylbenzamide is attacked by *n*-butyllithium leading to formation of valerophenone (1), the sulfonyl group of *N,N*-dimethylbenzenesulfonamide (**1**) should be less susceptible to attack by this reagent so that ring lithiation of **1** to form *ortho*-lithiosulfonamide **1′** appeared feasible. This was verified in the present investigation by condensation with electrophilic compounds in tetrahydrofuran (THF)–hexane to give *ortho* derivatives. Thus, **1′** underwent an addition reaction with benzophenone to afford carbinol-sulfonamide **2**, which underwent thermal cyclodeamination to produce sultone **3** (Scheme 1).

Similarly, lithiosulfonamide **1′** underwent addition reactions with benzonitrile, phenyl isocyanate, and carbon dioxide to form imine-sulfonamide **4**, carboxamide-sulfonamide **5**, and acid-sulfonamide **6**, respectively. The imine **4** was hydrolyzed to form ketone **7**, and condensed with hydroxylamine and phenylhydrazine to give oxime **8** and phenylhydrazone **9**, respectively; incidentally, the ketone **7** failed to afford oxime **8** or phenylhydrazone **9** under similar conditions.

The yields of these products were good to excellent (57–93%), except that for sultone **3**. Their structures were supported by analyses and/or absorption spectra (see Experimental).

Although the yield of sultone **3** was only 30%, this is better than that (18%) obtained previously by the action of hot sulfuric acid on carbinol-sulfonamide **11** (R = C_6H_5), which was prepared by condensation of dilithiosulfonamide **10** with benzophenone (2). The more characteristic reaction of carbinol-sulfonamides of type **11** involves

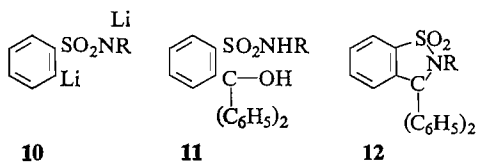
[1]Supported by the Army Research Office (Durham, North Carolina).



4 5 6

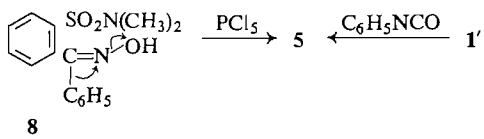
7 8 9

cyclodehydration to form sultams of type **12** (2); this reaction has generally been effected by treatment of **11** with cold sulfuric acid, followed by water (2). Similar treatment of carbinol-sulfonamide **2** has now resulted only in recovery of **2**.



10 11 12

Oxime-sulfonamide **8** underwent a Beckmann rearrangement with phosphorus pentachloride to form amide-sulfonamide **5**, which was shown to be identical with that obtained from lithiosulfonamide **1′** and phenylisocyanate, (Scheme 2).



8

SCHEME 2

Although this result would ordinarily be considered to establish the indicated configuration of the oxime in which phenyl and hydroxyl are *trans* (see Scheme 2), there appears to be a possibility that the other isomer of the oxime might have given the same result by isomerization prior to rearrangement. This might have occurred because of the expected reluctance of the aryl group in oxime **8**, which has the strongly electron attracting sulfonyl substituent, to undergo migration. An attempt to test this possibility by isolation and rearrangement of the other isomer of the oxime, however, was unsuccessful.

An attempt to extend the present method of lithiation and condensation to *N,N*-diphenylbenzenesulfonamide was unsuccessful. Incidently, this sulfonamide was obtained in excellent yield (92%) when benzenesulfonyl chloride and diphenylamine were treated with pyridine (3), but not when this chloride and amine were treated with aqueous alkali or with excess amine in ether according to other earlier methods (4).

Experimental[2]

Ortho-Lithiation of N,N-Dimethylbenzenesulfonamide (1)

A solution of 0.025 mole of *N,N*-dimethylbenzenesulfonamide (**1**, m.p. 47–48°; lit (4, 5) 47–48°) in 50 ml of tetrahydrofuran (THF)[3] in a dry flask under nitrogen was cooled to 0°, and 20 ml (0.030 mole) of a solution of 1.59 *M* *n*-butyllithium in hexane[4] was added during 5–6 min. After stirring for 30 min at 0°, the brown suspension was considered to contain 0.025 mole of monolithiosulfonamide **1′**. The suspension was employed at 0° as described below.

Condensation of Lithiosulfonamide 1′ with Benzophenone to Form Carbinol-sulfonamide 2

To a stirred, cold suspension of 0.025 mole of lithiosulfonamide **1′** was added under nitrogen, during 4 min, a solution of 5.47 g (0.030 mole) of benzophenone in 30 ml of THF,[3] and the stirring was continued for 30 min at 0°. To the resulting clear, dark-brown solution (cooled in an ice bath) was added, with stirring, 20 ml of water followed by 30 ml of 5% hydrochloric acid. The two layers were separated. After saturation with sodium chloride, the

[2]Melting points are uncorrected. Elemental analyses were performed by Janssen Pharmaceutica, Beerse, Belgium, and by M-H-W Laboratories, Garden City, Michigan, and by Alfred Bernhardt, West Germany. Infrared spectra (KBr method) were produced on Perkin–Elmer Infracord Model 137 and 237 spectrophotometers. Nuclear magnetic resonance spectra were obtained with a Varian A-60 spectrometer and signals are reported in p.p.m. downfield from an internal tetramethylsilane standard.

[3]Freshly distilled from lithium aluminium hydride.

aqueous layer was extracted three times with ether, and the extracts were combined with the organic layer. After washing twice with a saturated solution (30 ml) of sodium chloride and drying ($MgSO_4$), the solvent was removed under reduced pressure on the steam bath. The crystalline residue was stirred with a little methanol, and the mixture was filtered. The solid was washed with a little methanol, and dried in air to give 7.46 g (82%) of α,α-diphenyl-*o*-(*N*,*N*-dimethylsulfamyl) benzyl alcohol (**2**), m.p. 162–164° and 164–165° (fine crystals) after recrystallization from acetone–methanol; i.r. 3380 (OH), 1303 and 1140 cm^{-1} (SO_2); n.m.r. ($CDCl_3$) 8.15–6.78 (m, 14.1, aromatic), 6.78 (s, 1.0, OH), and 2.57 p.p.m. (s, 6.0, N-CH_3).

Anal. Calcd. for $C_{21}H_{21}NSO_3$: C, 68.64; H, 5.76; N, 3.81; S, 8.73. Found: C, 68.29; H, 5.76; N, 3.88; S, 8.62.

Cyclization of Carbinol-sulfonamide **2**

Cyclization of 1.0 g of **2** was effected by heating it under a slow stream of nitrogen in a Wood's metal bath at 185–195° for 6 h. After cooling, the molten mass was dissolved in a little hot methanol, and the solution was allowed to stand overnight. The resulting crystals were collected, and recrystallized from methanol to afford 0.26 g (30%) of 3,3-diphenyl-2,1-benzoxathiole-1,1-dioxide (**3**) (fine leaflets), m.p. 162–164°, undepressed on admixture with an authentic sample (2) of **3** (m.m.p. 163–165°); the i.r. spectra of the two samples were identical.

When the cyclization of **2** was effected at 205–215° in the presence of 20 mg of benzoyl peroxide, sultone **3**, m.p. 162–164°, was obtained in 10% yield.

Condensation of Lithiosulfonamide **1′** *with Benzonitrile to Form Imine-sulfonamide* **4**

This reaction was effected as described above for benzophenone to give a brown-red suspension which was cooled in an ice bath and stirred with 20 ml of water followed by 30 ml of 10% hydrochloric acid. The resulting two layers were separated. The acidic, aqueous layer, which was combined with acidic extracts of the organic layer, was made basic with potassium carbonate powder. After standing in a current of air under a hood for several hours, the crystalline solid was collected, washed with water, and dried in air to give 5.69 g (79%) of *o*-(*N*,*N*-dimethylsulfamyl)benzophenone imine (**4**), m.p. 153–156° and 155.5–156.5° (as prismatic crystals) after recrystallization from methanol; i.r. 3255 (NH), 1600 (C=N), 1345 and/or 1335 (SO_2), and 1155 cm^{-1} (SO_2); n.m.r. ($CDCl_3$) 8.22–7.17 (m, 9.1, aromatic and NH), and 2.57 p.p.m. (s, 6.0, N—CH_3).

Anal. Calcd. for $C_{15}H_{16}N_2SO_2$: C, 62.47; H, 5.60; N, 9.72. Found: C, 62.69; H, 5.20; N, 9.47.

Hydrolysis of imine-sulfonamide **4** (1.0 g) was effected by refluxing it with 40 ml of 5% sulfuric acid for 1 h. After cooling, the mixture was filtered. The solid was washed with water, and dried to give 0.85 g (85%) of *o*-(*N*,*N*-dimethylsulfamyl)benzophenone (**7**), m.p. 146–147.5°. Recrystallization from methanol afforded 0.76 g (76%) of **7** (fine crystals), m.p. 147–148°; i.r. 1660 (CO), 1330 and 1155 cm^{-1} (SO_2); n.m.r. ($CDCl_3$) 8.08–7.22 (m, 9.1, aromatic), and 2.72 p.p.m. (s, 6.0, N-CH_3).

Anal. Calcd. for $C_{15}H_{15}NSO_3$: C, 62.26; H, 5.23; N, 4.84. Found: C, 62.11; H, 5.19; N, 4.74.

Oximation of imine-sulfonamide **4** (2.50 g) was effected by refluxing it with 1.21 g of hydroxylamine hydrochloride and 3.54 g of sodium acetate (hydrate) in 80 ml of 70% (by weight) aqueous ethanol for 24 h. After cooling, the solution was allowed to stand overnight in a current of air under a hood. The resulting prismatic crystals were collected and recrystallized from methanol to give 2.55 g (97%) of *o*-(*N*,*N*-dimethylsulfamyl)benzophenone oxime (**8**) (large prismatic cluster), m.p. 156–158°. Another recrystallization from methanol gave 2.25 g (85%) of **8**, m.p. 158–160° and 156.5–158.5° i.r. 3420 (broad) and 3250 (broad, OH), 1630 (very weak, C=N), 1320 and 1150 cm^{-1} (SO_2); n.m.r. (acetone-d_6) 10.38 (s, 0.8, OH), 8.17–6.95 (m, 9.4, aromatic), and 2.63 p.p.m. (s, 6.0, N-CH_3).

Anal. Calcd. for $C_{15}H_{16}N_2SO_3$: C, 59.19; H, 5.30; N, 9.20. Found: C, 59.05; H, 5.19; N, 9.14.

Condensation of imine-sulfonamide **4** (2.0 g) with phenylhydrazine (2.25 g) was effected in 100 ml of 50% acetic acid by refluxing the solution for 24 h. After standing overnight at room temperature, the resulting prismatic yellow crystals were collected to give 1.65 g (63%) of *o*-(*N*,*N*-dimethylsulfamyl)benzophenone phenylhydrazone (**9**), m.p. 167–168.5° and 168.5–169° after recrystallization from acetone–methanol; i.r. 3280 (NH), 1580 (C=N), 1315 and 1105 cm^{-1} (SO_2); n.m.r. ($CDCl_3$) 8.45–8.07 (m, 0.9, NH), 7.85–6.60 (m, 14.8, aromatic), and 2.42 p.p.m. (s, 6.0, N-CH_3).

Anal. Calcd. for $C_{21}H_{21}N_3SO_2$: C, 66.46; H, 5.58; N, 11.07. Found: C, 66.54; H, 5.88; N, 10.99.

Condensation of Lithiosulfonamide **1′** *with Phenylisocyanate to Form Sulfobenzanilide* **5**

This reaction was effected as described above for benzophenone to give a dark-brown, clear solution, which was cooled in an ice bath and stirred with 20 ml of water followed by 25 ml of 5% hydrochloric acid. The mixture, which consisted of two layers and suspended solid, was partly evaporated in a current of air under a hood. The mixture was filtered. The solid was washed with water, a little ether, and then dried in air to give 4.35 g (57%) of carboxamide-sulfonamide **5** (fine crystals), m.p. 202–204° and 204.5–205.5° after recrystallization from acetone–methanol; i.r. 3280 and 3258 (NH), 1650 (CO), 1340 and 1160 cm^{-1} (SO_2).

Anal. Calcd. for $C_{15}H_{16}N_2SO_3$: C, 59.19; H, 5.30; N, 9.20. Found: C, 59.49; H, 5.34; N, 9.09.

The two layers of the filtrate (see above) were separated, and the organic layer was worked up to give 1.26 g of fine crystals, m.p. 175–195°, which seemed to consist partly of **5**.

Carbonation of Lithiosulfonamide **1′** *to Form Carboxysulfonamide* **6**

Method A

A solution of **1′** was prepared by slowly adding 47 ml (0.0752 mole) of 1.6 *M* *n*-butyllithium in hexane[4] to a stirred solution of 11.71 g (0.0632 mole) of **1** in 250 ml of dry ether under argon at room temperature. Stirring was continued for 1 h and then carbon dioxide (from a CO_2 generator) was bubbled through the reaction mixture for 30 min. A saturated solution of sodium carbonate was added, the aqueous and ether–hexane layers were separated, and the aqueous layer was made acidic with dilute hydrochloric acid. The cloudy acidic solution was extracted with ether. The ethereal extract was dried ($MgSO_4$)

and the solvent was removed under reduced pressure to give a yellowish oil which crystallized overnight to yield 8.60 g (63%) of *o*-(*N*,*N*-dimethylsulfamyl)benzoic acid (**6**), m.p. 98–102°; i.r. (Nujol mull) 2630 and 2540 (OH) (6), 1710 (C=O), 1370 (SO_2), 1300 (C—O or OH) (6), 1165 and 1155 (SO_2), 735 cm^{-1} (ortho disubstitution); n.m.r. ($CDCl_3$) 11.28 (s, 1.0, CO_2H), 7.70 (m, 4.0, aromatic), and 2.85 p.p.m. (s, 5.8, N-CH_3).

Anal. Calcd. for $C_9H_{11}NSO_4$: C, 47.15; H, 4.83; O, 27.92; N, 6.11; S, 13.99. Found: C, 47.14; H, 4.81; O, 28.05; N, 5.89; S, 13.94.

Method B

A solution of 0.05 mole of **1′** in 200 ml of THF[3] was prepared under nitrogen from 9.16 g (0.05 mole) of **1** and 35 ml (0.055 mole) of 1.59 *M* *n*-butyllithium in hexane.[4] After 1 h, the solution of **1′** was poured onto 500 g of dry ice in a 1 l Erlenmeyer flask which had been swept with dry nitrogen. After the excess dry ice had evaporated, 200 ml of water and 100 ml of ether were added. The layers were separated. The organic phase was extracted twice with saturated sodium bicarbonate solution and the extracts were combined with the aqueous layer. After washing with ether, the aqueous solution was acidified with 3 *N* hydrochloric acid. The resulting acidic solution was extracted with ether and the extracts were combined. After washing with saturated sodium chloride solution, the ethereal solution was dried ($MgSO_4$). The solvent was removed under reduced pressure on the steam bath to yield 8.59 g (75%) of **6** as a pale-yellow oil which crystallized slowly (48 h) to give light-yellow needles, m.p. 96–98° and 97–101° when the sample was placed in the bath at 94° and the temperature then raised.

*Beckmann Rearrangement of Oxime-sulfonamide **8** to Form Sulfobenzanilide **5***

A solution of 1.00 g of oxime **8** in 30 ml of THF[3] and 20 ml of anhydrous ether was cooled to 0° in an ice bath, and 1.00 g of phosphorus pentachloride was added. The mixture was magnetically stirred for 3 h at 0°, and then poured onto 30 g of ice. After making basic with sodium carbonate powder, the mixture was partly evaporated in a current of air under a hood (overnight). The white crystalline solid was collected, washed with water, and dried to give 0.77 g (77%) of carboxamide-sulfonamide **5** (fine bulky crystals), m.p. 203–205°, undepressed on admixture with the authentic sample of **5** prepared as described above (m.m.p. 204–205°), and the i.r. spectra of the two samples were identical.

*Attempt to Prepare Second Isomer of Oxime-sulfonamide **8***

A boiling solution of 0.70 g of oxime **8** in 70 ml of anhydrous ether was saturated with anhydrous hydrogen chloride gas (15 min) to form a white precipitate. After refluxing for 10 min, the mixture was poured onto excess of saturated sodium becarbonate solution in an ice bath. The resulting, basic mixture was partly evaporated in a current of air under a hood (overnight). The solid was collected, washed with water, and dried in air to give 0.67 g of recovered oxime **8**, m.p. and m.m.p. 156–158°; the i.r. spectrum was identical with that of the starting oxime.

Also, a solution of 0.8 g of oxime **8** in 8 ml of concentrated sulfuric acid at 0° was allowed to stand for 1 h, and then poured onto 50 g of ice. The resulting white precipitate was collected, washed with water, and dried in air to give 0.75 g of recovered oxime **8**, m.p. and m.m.p. 157.5–159.5°; the i.r. spectra of the two samples were identical.

Beckmann rearrangement of these samples of oxime **8** (recovered after treatment with the acids) with phosphorus pentachloride in THF–ether under the conditions described above afforded, on work-up, carboxamide-sulfonamide **5** in 73–74% yield.

Alcaloïdes stéroïdiques. LXXXIX.[1] Transposition d'une *N*-chloroazétidine. Synthèse partielle du cyclo-18(*N*) méthoxy-17ξ aza-17*a* D-homo androstane-5α

CLAUDE BENEZRA[2] ET XAVIER LUSINCHI
CNRS, Institut de Chimie des Substances Naturelles, 91-Gif-sur-Yvette, France

Reçu le 12 décembre 1968

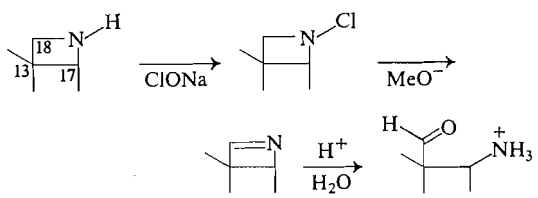
Traité dans les conditions de Ruschig [(*1*) hypochlorite de sodium; (*2*) méthanolate de sodium dans le méthanol], le cyclo-18(*N*) amino-17β androstane-5α, **5**, conduit à un produit transposé le cyclo-18(*N*) méthoxy-17ξ aza-17*a* D-homo androstane-5α, **7**. La structure de ce composé a été prouvée chimiquement: l'hydrogénolyse de **7**, suivie d'une formylation conduit au *N*-formyl aza-17*a* D-homo androstane-5α, **9**, préparé indépendamment à partir de l'androstane-5α ol-17β. Les spectres infrarouges, de résonance magnétique nucléaire et de masse sont interprétés et des transpositions apparentées sont brièvement passées en revue.

Treatment of 18(*N*)-cyclo-17β-amino-5α-androstane, **5** under Ruschig conditions [(*1*) sodium hypochlorite; (*2*) sodium methoxide in methanol] gave the rearranged 18(*N*)-cyclo-17ξ-methoxy-17*a*-aza-D-homo-5α-androstane, **7**. The structure of this compound has been proved chemically: hydrogenolysis of **7**, followed by formylation, gave *N*-formyl-17*a*-aza-D-homo-5α-androstane, **9** prepared independently from 5α-androstan-17β-ol. Infrared, nuclear magnetic resonance, and mass spectra are discussed and related rearrangements are briefly reviewed.

Canadian Journal of Chemistry, 47, 1547 (1969)

Conformément aux résultats établis par Kaminsky et Lamchen (2) pour des oxazirannes pyrrolidiniques simples, la transposition par irradiation ultraviolette (u.v.) de l'oxaziranne stéroïdique **3** (3) conduit avec un rendement de 60% à l'azétidine stéroïdique *N*-acétylée **4**, offrant ainsi une méthode de passage de la série du pregnane à la série de l'androstane. L'oxaziranne **3** étant facilement préparé à partir de la conessine **1** par l'intermédiaire de la pyrrolidine **2** (4), il est donc possible d'envisager l'obtention, par ouverture de l'hétérocycle azétidinique, de dérivés de l'androstane substitués sur les carbones 17 et 18.

La méthode de Ruschig *et al.* (5) peut formellement être envisagée comme un procédé d'ouverture de l'hétérocycle selon le schéma réactionnel suivant:



L'élimination d'acide chlorhydrique, impossible avec l'hydrogène porté par le carbone 17 (règle de Bredt), peut éventuellement s'effectuer avec un des hydrogènes en 18.

Cependant deux facteurs rendaient aléatoire a priori une telle élimination. Celle-ci n'a jamais encore été observée avec les hydrogènes du carbone en 18, même comme réaction secondaire. Généralement, pour des structures convenables, l'élimination s'effectue préférentiellement sur un autre carbone: carbone 20 pour la chloramine dérivée de la *N*-déméthylconanine (4); carbone benzylique pour les dérivés benzylamino-18 (6). Dans certains cas, la chloramine oxyde préférentiellement une fonction voisine. C'est ainsi que, traitée en milieu alcalin, la monochloramine d'un dérivé de l'amino-18 prégnanol-20β se cyclise pour conduire à un dérivé à structure pyrrolidinique analogue à **2** (6). Dans le cas de la chloramine du monométhylamino-18 prégnane, aucun produit défini n'a pu être isolé (7). Si ces exemples n'excluent pas rigoureusement la possibilité d'une élimination avec un des hydrogènes en 18, ils établissent que cette réaction est suffisamment inhibée pour que l'élimination s'effectue de préférence sur un autre point de la molécule ou qu'un autre type de réactivité des chloramines soit révélé. D'autre part, dans l'éventualité d'une élimination sur le carbone 18 celle-ci aboutirait à la formation d'une azétine. Celle-ci reste improbable. Il semble en effet que les azétines ne puissent exister que pour des substitutions très particulières de l'hétérocycle (8*a*, 9). Il n'était

[1]Alcaloïdes stéroïdiques. LXXXVIII, ref. 1.

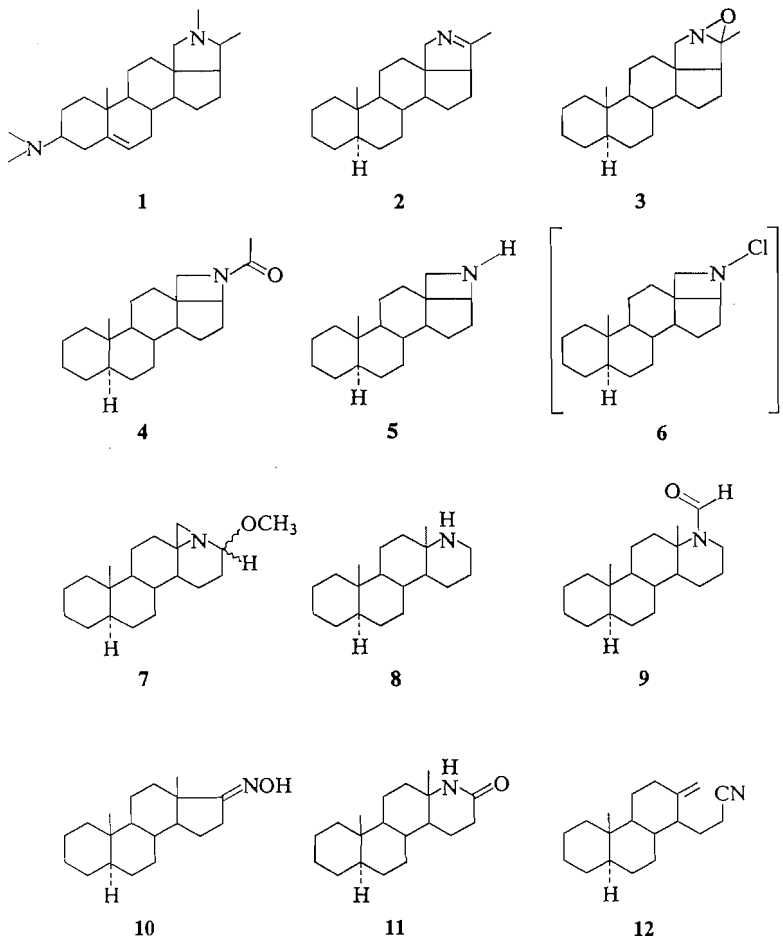
For personal use only.



donc pas sans intérêt d'étudier la réactivité de la chloramine **6**.

L'azétidine libre **5** est préparée à partir du dérivé *N*-acétylé **4** (3) par hydrolyse dans un mélange d'acide chlorhydrique, d'éthanol et d'eau (10). L'ouverture de l'hétérocycle au cours de l'hydrolyse reste possible (8*b*). Une analyse élémentaire satisfaisante du dérivé **5** n'a pu être obtenue. Cependant l'obtention du pic moléculaire convenable en spectrographie de masse, la présence dans le spectre de résonance magnétique nucléaire (r.m.n.) d'un système AB caractéristique du méthylène en 18 et le retour à l'acétylazétidine **4** par acétylation montrent que, dans les conditions de l'hydrolyse, le cycle est conservé.

L'action de l'hypochlorite de sodium sur l'azétidine **5** conduit à la chloramine **6** qui a conservé la structure azétidinique. Le spectre de r.m.n. de cette chloramine présente en effet le système AB caractéristique du méthylène 18.

Si cette chloramine, **6**, est chauffée à reflux pendant $2\frac{1}{2}$ h dans une solution méthanolique de méthanolate de sodium, elle conduit à un mélange de produits dont est isolé par chromatographie, avec un rendement de 56%, un dérivé à structure aziridinique correspondant à la formule **7**, cyclo-18(*N*) méthoxy-17ξ aza-17*a* D-homo androstane-5α.

Le composé **7**, de masse moléculaire 303, absorbe dans l'infrarouge (i.r.) à 3020 cm^{-1}. Le spectre de r.m.n. ($CDCl_3$) correspond apparemment à un produit homogène. Il met en évidence un groupement méthoxy, présente par ailleurs un signal élargi à 1.53 p.p.m., qui persiste après deutériation, et un doublet de doublet à 3.82 p.p.m. dont les intensités des pics sont voisines. Ces données excluent une structure azétine. La

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

masse moléculaire 303 et la présence du groupe méthoxy pouvaient faire penser à un dérivé résultant de l'addition d'une molécule de méthanol sur la fonction imine de l'azétine. Cependant dans cette éventualité le spectre de r.m.n. aurait dû présenter un signal correspondant à un proton mobile et un singulet à champ faible dû à l'hydrogène en 18 qui serait alors sur un carbone portant un groupement méthoxy. En revanche, les données sont en accord avec la structure aziridinique proposée **7**. Le signal à 1.53 p.p.m. correspond dans ce cas aux deux hydrogènes du cycle aziridinique en 18. Ces protons sont signalés à 1.60 p.p.m. pour l'aziridine elle-même (11). Le doublet de doublet à champ faible correspond au proton en 17: partie X d'un système ABX ($J_{AX} \neq J_{BX}$). La bande à 3020 cm^{-1} du spectre i.r. peut être attribuée à la vibration des liaisons C—H du cycle aziridinique (12). Le spectre ne présente pas aux environs des 1220 cm^{-1} de bande particulière. Généralement donnée comme caractéristique d'une aziridine, cette bande n'est cependant pas signalée par tous les auteurs (12*e*). Il est à noter que sur le spectre de r.m.n. effectué dans le benzène le signal à 1.53 p.p.m. est remplacé par deux pics fins à 1.41 et 1.58 p.p.m. Les deux protons du cycle aziridinique ne couplent donc pas entre eux, résultat en accord avec les couplages géminaux généralement très faibles observés pour ce type de protons (13).

La structure **7** a été d'autre part vérifiée par une corrélation chimique. Cette corrélation a été effectuée au niveau du D-homo azastéroïde **8** facilement accessible à partir de l'androstanone-17. On pouvait en effet espérer obtenir ce composé en une seule étape par simple hydrogénolyse en présence de platine du dérivé **7**, avec élimination de la fonction éther (14) et ouverture simultanée du cycle aziridine sur la liaison *N*, C-18, conduisant ainsi à une pipéridine. Les hydrogénolyses d'aziridines cycliques décrites par Nagata *et al.* (12*a*) montrent en effet que l'ouverture de l'aziridine s'effectue très sélectivement sur la liaison C—N qui conduit à la formation d'hétérocycles azotés à 6 atomes. Traité par l'hydrogène en présence de platine Adams, le dérivé **7** conduit effectivement au D-homo aza-17*a* androstane **8** (42%) qui, difficilement cristallisable, a été formylé, **9**. Le spectre de r.m.n. montre la présence d'un méthyle angulaire en plus du méthyle-19. Le composé a été identifié au *N*-formyl aza-17*a* D-homo androstane-5α préparé par synthèse à partir de l'androstanolone.

La fonction cétonique en 3 de l'androstanolone est éliminée par réduction de Wolff–Kishner. L'androstanol-17β obtenu est oxydé dans les conditions de Jones pour conduire à l'androstanone-17. L'oxime de cette dernière, **10**, conduit par transposition de Beckmann à la lactame **11**. Le *N*-formyl aza-17*a* D-homo androstane-5α est obtenu par réduction à l'hydrure d'aluminium-lithium de cette dernière, suivie de formylation. Il est identique au dérivé obtenu par hydrogénolyse suivie de formylation du dérivé **7**.

La transposition de Beckmann de l'oxime d'un céto-17 androstane[3] a été effectuée de nombreuses fois (15). Le réactif généralement utilisé est le chlorure de l'acide *p*-acétamidobenzènesulfonique. L'oxime **10**, traitée dans des conditions analogues par ce réactif ne conduit pas à la lactame **11** qui est par contre obtenue avec un rendement de 40% au moyen de l'oxychlorure de phosphore (16). La réaction est effectuée par action du chlorure d'acide dans la pyridine, suivie de dilution à l'eau puis d'acidification. Nous avons observé qu'avec le chlorure de l'acide *p*-acétamidobenzènesulfonique un précipité se forme après addition d'eau alors que rien ne précipite avec l'oxychlorure de phosphore; ce n'est qu'après acidification du milieu que dans ce dernier cas la lactame précipite, immédiatement. Il a été vérifié, par analyse sur couche mince, que, dans le premier cas, le précipité formé, vraisemblablement l'ester de l'oxime, n'évoluait pratiquement pas au contact de l'acide et que, dans le second cas, la solution aqueuse avant acidification ne renfermait pas la lactame, même après un contact prolongé. La transposition n'a donc lieu qu'après acidification et elle semble alors très rapide. Nous avons accessoirement isolé le nitrile éthylènique **12**, produit de fragmentation qui accompagne généralement la transposition de Beckmann (15 *c,d*).

Les résultats obtenus pour le dérivé **7** ne permettent pas de préciser la stéréochimie autour du carbone 17. Le proton en 17 forme avec les deux protons en 16 un système ABX avec $J_{AX} \neq J_{BX}$. Ceci traduit pour des protons appartenant à un cycle à 6 atomes des positions relatives voisines d'axiales–axiales et axiales–équatoriales. Une des deux conformations possibles de chacun des

[3]La lactame **11** vient d'être décrite, très récemment (25). Les constantes pour ce dérivé sont en bon accord avec les nôtres.

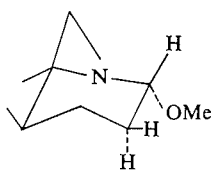
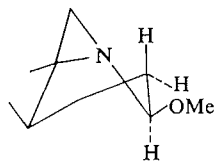
épimères en 17 présente une telle relation. Conformation pseudo-chaise pour le dérivé méthoxy-17β **14**, et forme pseudo-bateau pour le dérivé méthoxy-17α **13**. Cette dernière conformation étant pour cet isomère vraisemblablement plus stable que la conformation pseudo-chaise pour laquelle un certain encombrement apparaît entre le groupe méthoxy et l'hydrogène β du pont méthylènique en 18.



13

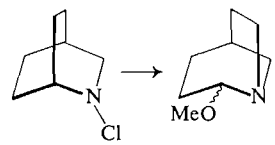


14

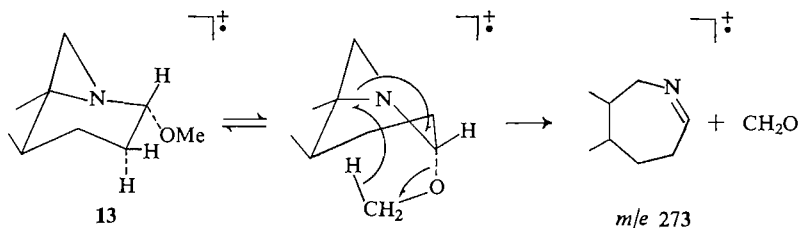
Le pic de base du spectre de masse du dérivé **7** est à $m/e = 273$ ($M^+ - 30$). Ce pic correspond à la perte des éléments du formol CH_2O. La formule proposée permet d'en donner une interprétation hypothétique. Il est à remarquer qu'une telle interprétation peut être formulée à partir de l'une ou de l'autre des configurations épimères en 17.[4]

Le rendement observé en produit de transposition **7** (56% isolé) et l'homogénéité stérique de ce produit montrent que la réaction de *trans*-position est largement prépondérante et qu'elle est vraisemblablement stéréospécifique. Cependant plusieurs produits secondaires résultant de l'action du méthanolate de sodium sur la chloramine **6** n'ont pû être isolés. L'éventualité de la formation de l'autre épimère en 17 n'est donc pas entièrement écartée ni la possibilité d'une réaction secondaire faisant intervenir les hydrogènes en 18.

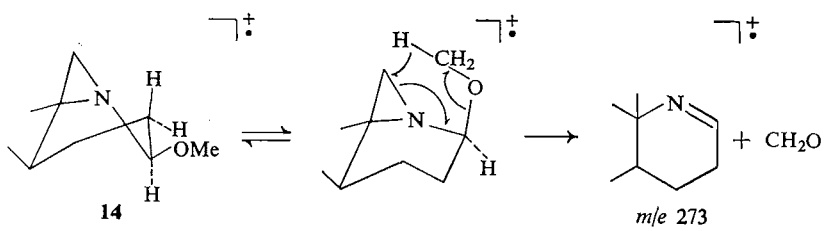
Des exemples de transpositions de chloramines aliphatiques ont été récemment décrits par Gassman et Fox (17), et Gassman et Cryberg (18). Ces transpositions sont observées au cours de l'action d'un sel d'argent sur une solution méthanolique de la chloramine, donc dans des conditions différentes de celles que nous avons décrites: action du méthanolate de sodium dans le méthanol. C'est ainsi que la chloramine dérivée de l'isoquinuclidine se transpose avec intervention du méthanol:



Un seul isomère est obtenu dont la stéréochimie n'a pû être précisée. Cependant, au cours de l'isomérisation dans les mêmes conditions du triméthyl-4,7,7 chloro-2 aza-2 bicyclo[2,2,1]-heptane (18), à côté du dérivé de transposition chloré, prépondérant, un dérivé transposé méthoxylé a été isolé avec un rendement de 8.5%, dont la structure correspond à une inversion de configuration sur le carbone transposé.



13 *m/e* 273

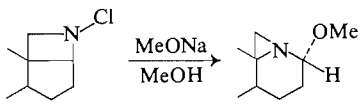


14 *m/e* 273

[4]Cette interprétation nous a été aimablement suggérée par le Dr. P. Longevialle que nous tenons à remercier.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Ces résultats s'interprètent au mieux (17) par l'hypothèse de la formation intermédiaire d'un ion mésomère analogue à celui invoqué dans les transpositions classiques du bicyclo[2,2,1]heptane, qui s'accompagnent également d'inversion de configuration (19). Dans le cas de la transposition que nous avons observée en milieu alcalin, il s'agit vraisemblablement d'un mécanisme concerté avec inversion de configuration sur le carbone 17 et formation de l'isomère méthoxy-17α.[5] La conformation **13** plus stable que **14**, semble en effet le mieux rendre compte du spectre de r.m.n. obtenu.



Il est à noter que des essais de transposition effectués avec la chloramine **6** dans le méthanol en présence de nitrate d'argent ont conduit à des mélanges complexes dont aucun produit défini n'a pû être isolé. Il n'est pas sans intérêt de remarquer que, parallèlement, des réactions de transfert d'hydrure observées pour certaines chloramines en présence de sels d'argent (20) ont été observées, en milieu alcalin, potasse dans le méthanol, par d'autres auteurs (21).

Il a été constaté au cours de cette étude que l'hydrogénolyse du groupe méthoxy du dérivé **7** (22) ne pouvait être effectuée par l'hydrure d'aluminium-lithium, même après action prolongée dans le tétrahydrofuranne à reflux. Cette inertie pourrait être due à l'impossibilité pour ce produit de s'équilibrer avec une forme immonium qui rendrait compte de la réductibilité des éthers de *gem*-aminocarbinols (23). Une telle structure immonium ne peut se former à partir du dérivé **7**, les liaisons autour de l'atome d'azote ne pouvant se mettre dans un même plan.

En conclusion, la réaction de Ruschig ne permet pas l'ouverture de l'hétérocycle de l'azétidine stéroïdique **5**, qui conduit dans ces conditions à un produit transposé. L'étude des dérivés obtenus par quaternarisation de l'azote du cycle azétidinique devrait vraisemblablement permettre d'obtenir cette ouverture.

[5]L'un des rapporteurs nous fait remarquer à juste titre que le passage du système aza-7 bicyclo[3,2,0]heptane **5** rattaché au squelette perhydrophénanthrénique au système aza-1 bicyclo[4,1,0]heptane **7** conduit certainement à une diminution de la contrainte stérique, ce qui permet une interprétation supplémentaire du comportement inhabituel de la chloramine **6** par rapport à celui de chloramines moins tendues.

Partie expérimentale

Les points de fusion sont pris en tube capillaire et corrigés. Les pouvoirs rotatoires sont déterminés dans le chloroforme (RP contenant 0.5% d'éthanol) avec le Quick-polarimètre électronique Jouan–Roussel. Les spectres de r.m.n. sont effectués en solution dans le deutérochloroforme sur un spectromètre Varian A-60. Les déplacements chimiques sont mesurés en δ par rapport au tétraméthylsilane (δ = 0). Les spectres de masse sont déterminés sur le spectrographe de masse MS-9. Les chromatographies sur couche mince (c.c.m.) sont faites sur des plaques neutres préparées à partir du silicagel G (Merck) et révélées soit par pulvérisations successives de réactif de Draggendorf puis d'acide sulfurique à 60%, soit par pulvérisation d'une solution éthérée d'acide sulfurique suivie de calcination.

Cyclo-18(N) amino-17β androstane-5α, 5

Une solution dans 125 ml d'éthanol absolu de 1.27 g de *N*-acétyl cyclo-18(*N*) amino-17β androstane-5α, **4** (3) est additionnée d'un mélange de 75 ml d'eau et 130 ml d'acide chlorhydrique concentré. Après un reflux de 16 h, la solution est concentrée sous vide jusqu'à 100 ml environ. Le précipité formé, essoré, lavé à l'eau et séché sous vide sur anhydride phosphorique correspond à 1.05 g de chlorhydrate de cyclo-18(*N*) amino-17β androstane-5α, 84%, homogène en c.c.m.

Un échantillon de ce précipité (92 mg) est agité avec une solution de soude dans l'eau (10%). L'extraction à l'éther fournit 75 mg de cyclo-18(*N*) amino-17β androstane-5α, **5**, p.f. 90–92°; $[\alpha]_D^{20}$ +12° (*c*, 0.25), après sublimation sous vide poussé.

Une analyse centésimale convenable n'a pû être obtenue pour $C_{19}H_{31}N$ = 273.45. Spectre de masse: pic moléculaire à *m/e* 273. Spectre de r.m.n.: à 0.69 p.p.m. un singulet (CH_3-19); à 3.12 p.p.m. un singulet correspondant à 1 proton, disparaissant par deutériation (N—H); centré à 3.30 p.p.m., un système AB, J = 9 c.p.s., $\delta_A - \delta_B$ = 0.35 p.p.m. (CH_2-18); à 3.76 p.p.m. un multiplet correspondant à 1 proton (H-17).

Une solution de 21 mg du dérivé **5** dissous dans 0.5 ml de pyridine est additionnée de 0.5 ml d'anhydride acétique et laissée une nuit à la température ambiante. Après dilution à l'eau, le milieu est extrait à l'éther. L'extrait éthéré, après lavage avec une solution d'acide chlorhydrique 2 *N*, puis avec une solution de bicarbonate de sodium puis à l'eau, est séché sur sulfate de sodium puis évaporé à sec. Le produit obtenu (22 mg) est identique au *N*-acétyl cyclo-18(*N*) amino-17β androstane-5α, **4**, (3).

Cyclo-18(N) méthoxy-17ξ aza-17a D-*homo androstane-5α, 7*

Une solution de 1.035 g du chlorhydrate de cyclo-18*(N)* amino-17β androstane-5α, **5**, dans 42 ml de chlorure de méthylène est agitée pendant 2 h en présence de 42 ml d'une solution d'hypochlorite de sodium (0.45 mole/l). La phase organique lavée à l'eau jusqu'à neutralité est séchée sur sulfate de sodium puis évaporée sous vide à la température ambiante. La laque obtenue, homogène en c.c.m., correspond à la chloramine **6**. Spectre de r.m.n.: à 0.66 p.p.m. un singulet (CH_3-19); à 3.65 p.p.m. un système AB, J = 10 c.p.s., $\delta_A - \delta_B$ = 0.11 p.p.m.; à 4.0 p.p.m. un multiplet correspondant à un proton (H-17).

La laque obtenue est dissoute dans une solution méthanolique de méthanolate de sodium (1.8 g de sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

dans 120 ml de méthanol). Après 2½ h de reflux, le milieu refroidi est extrait avec un mélange d'éther et de chlorure de méthylène. Le résidu d'extraction, 0.95 g, est chromatographié sur 30 g d'alumine Merck standard diluée avec 3% d'eau. Après élution à l'hexane de 10 mg de produit de tête non identifié sont élués successivement à l'hexane, à l'hexane–benzène puis au benzène pur 573 mg (56%) de cyclo-18(*N*) méthoxy-17ξ aza-17*a* D-homo androstane-5α, **7**, homogène à la c.c.m. et dont le spectre de r.m.n. est pratiquement identique à celui de l'échantillon analytique. Celui-ci est obtenu par sublimation sous vide poussé, p.f. 91–92°, $[\alpha]_D^{20}$ +61° (*c*, 0.95).

Anal. Calc. pour $C_{20}H_{33}NO$: C, 79.15; H, 10.96; N, 4.62. Trouvé: C, 78.90; H, 10.99; N, 4.70.

Spectre de masse: pic moléculaire à *m/e* 303; pics à *m/e* 273 ($M^+ - 30$ pic de base) et à *m/e* 272 ($M^+ - 31$), perte de CH_3O. Spectre i.r. (Nujol): bande à 3020 cm^{-1}, faible (CH_2 aziridinique); entre 1050 et 1150 cm^{-1} bandes fines caractéristiques de la vibration C—O. Spectre de r.m.n.: ($CDCl_3$); à 0.75 p.p.m. un singulet (CH_3-19); à 1.53 p.p.m. un signal élargi (CH_2-18); à 3.47 p.p.m. un singulet correspondant à 3 protons (OCH_3); à 3.82 p.p.m. un quadruplet correspondant à un proton (—C*H*(OMe)—CH_2), (C_6H_6); à 0.70 p.p.m. un singulet (CH_3-19); à 1.40 et 1.58 p.p.m. deux singulets (CH_2-18), à 3.59 p.p.m. un singulet correspondant à 3 protons (OCH_3), à 3.78 p.p.m. un doublet de doublet correspondant à un proton (—C*H*(OMe)—CH_2).

La chromatographie poursuivie avec des mélanges de benzène–éther puis à l'éther et à l'éther–méthanol (9/1) fournit des mélanges de produits renfermant le dérivé **7**. L'élution au méthanol fournit 57 mg de matière de départ **5** (6%).

N-Formyl aza-17a D-*homo androstane-5α*, ***9***

(1) A Partir du N-Cyclo-18(N) méthoxy-17ξ aza-17a D-*homo androstane-5α*, ***7***

Une solution de 300 mg de **7** dans un mélange de 300 ml d'éthanol à 95° et 100 ml d'acide acétique, est hydrogénée à pression atmosphérique et température ambiante en présence de 250 mg de platine Adams, pendant 22 h. Après élimination du catalyseur par filtration, le milieu est évaporé à sec. Le résidu repris à l'eau, alcalinisé à l'ammoniaque et extrait à l'éther, fournit 275 mg d'un produit pulvérulent blanchâtre qui est chromatographié sur 9 g d'alumine standard. Sont isolés, par élution au benzène et au mélange benzène–éther (4/1, puis 1/1) 67 mg de produits non identifiés, puis à l'éther pur et à l'éther–méthanol (9/1, puis 8/2) 114 mg d'un produit pulvérulent pratiquement unitache à la c.c.m., correspondant à l'aza-17*a* D-homo androstane-5α, **8**.

Ce composé (30 mg) est traité pendant 45 min par un mélange acide formique (0.06 ml) – anhydride acétique (0.16 ml) à 80°. Après refroidissement et addition d'eau, le précipité gommeux qui se forme peut être cristallisé dans l'acétone fournissant 3 mg de *N*-formyl aza-17*a* D-homo androstane-5α, **9**. 15 mg de ce composé sont obtenus à partir du résidu d'évaporation des eaux-mères, par chromatographie sur couche épaisse. Plaque 20 × 20 cm préparée à partir de 5.5 g de silice G (Merck); élution par un mélange méthanol – chlorure de méthylène (3/97); pulvérisation par le réactif de Morin et examen en u.v. Elution de la bande révélée par un mélange méthanol – chlorure de méthylène (3/97). Le produit obtenu p.f. 182–183°; $[\alpha]_D^{20}$ −5° (*c*, 0.7) est identique au *N*-formyl aza-17*a* D-homo androstane-5α préparé à partir de l'androstane-5α oxime-17, **10** (p.f., p.f. mélange, $[\alpha]_D$, i.r., r.m.n. et c.c.m.).

(2) A Partir de l'Aza-17a D-*homo androstane-5α one-17*, ***11***

Une suspension de 710 mg de **11** dans 200 ml d'éther anhydre est additionnée de 730 mg d'hydrure d'aluminium-lithium et chauffée à reflux pendant 4 h. Après une nouvelle addition de 300 mg d'hydrure d'aluminium-lithium le reflux est poursuivi pendant 3 h. L'excès d'hydrure est détruit par addition d'éther humide puis d'eau. L'alumine formée est essorée et lavée à l'éther. Les filtrats éthérés, lavés à l'eau, séchés sur sulfate de sodium et évaporés à sec laissent 610 mg d'un résidu pulvérulent blanc dont l'analyse par c.c.m. révèle qu'il contient une certaine quantité du produit de départ. Une solution de ce résidu dans l'éther contenant quelques gouttes de méthanol est extraite à l'aide d'une solution aqueuse d'acide chlorhydrique 2*N*. La phase éthérée lavée à l'eau, séchée et évaporée à sec fournit 69 mg de matière de départ **11**. La phase chlorhydrique alcalinisée par de la lessive de soude est extraite à l'éther, puis avec un mélange éther – chlorure de méthylène. Les phases organiques réunies, lavées à l'eau, séchées et évaporées à sec laissent 444 mg de résidu correspondant à l'aza-17*a* D-homo androstane-5α, **8**, homogène à la c.c.m. (66% par rapport à la lactame transformée).

Les 444 mg de dérivé amine sont chauffés à 80° pendant 45 min dans un mélange de 2.25 ml d'acide formique et de 6.75 ml d'anhydride acétique. Après refroidissement et addition d'eau, le précipité gélatineux qui se forme est essoré et cristallisé dans l'acétone fournissant 250 mg de *N*-formyl aza-17*a* D-homo androstane-5α **9**, p.f. 180°. Un échantillon analytique est obtenu par cristallisation dans l'acétone; p.f. 183°; $[\alpha]_D^{20}$ −6° (*c*, 0.99).

Anal. Calc. pour $C_{20}H_{30}NO$: C, 79.15; H, 10.96; N, 4.62. Trouvé: C, 79.04; H, 10.98; N, 4.55.

Spectre i.r. (Nujol) : bande à 1660 cm^{-1} (O=C—N). Spectre de r.m.n.: à 0.765 p.p.m. un singulet (CH_3-19); à 1.23 p.p.m. un singulet (CH_3-18); à 4.45 p.p.m. un multiplet (CH_2-17); à 8.40 p.p.m. un singulet correspondant à 1 proton (H—C=O).

Androstanol-17β

Une solution de 3.5 g d'androstanol-17β one-3 dans 120 ml d'une solution résultant de l'action de 6.8 g de sodium sur 120 ml de glycol est additionnée de 16.8 ml d'hydrate d'hydrazine et chauffée à reflux pendant 5 h. Après refroidissement le milieu est versé dans un mélange eau-glace. L'extraction à l'éther fournit 3.2 g d'androstanol-17β (96%), p.f. 167°, litt. 164–166° (24).

Androstanone-17

3.2 g d'androstanol-17β oxydés dans les conditions de Jones fournissent 3.2 g d'androstanone-17, p.f. 120°, litt. 122° (24). Spectre i.r. (Nujol): bande à 1750 cm^{-1} (C=O).

Oxime de l'Androstanone-17

Une solution de 2.8 g d'androstanone-17 dans 450 ml d'éthanol à 95° est additionnée de 2.8 g de chlorhydrate d'hydroxylamine et 2.8 g d'acétate de sodium. Après 2 h de reflux et addition d'eau (500 ml), le précipité formé est

essoré et cristallisé dans le méthanol fournissant 2.24 g d'oxime de l'androstanone-17 (81%), homogène en c.c.m., p.f. 175°, $[\alpha]_D^{20}$ +19° (*c*, 1.1).

Anal. Calc. pour $C_{19}H_{31}NO$: C, 78.84; H, 10.80; N, 4.84. Trouvé: C, 78.84; H, 11.08; N, 4.81.

Aza-17a D-*homo androstane-5α one-17*, **11**. *Seco-13,17 androstane-5α ène-13,18 nitrile-17*, **12**

Une solution dans 250 ml de pyridine anhydre de 3 g de l'oxime de l'androstanone-17 est additionnée, goutte à goutte, a 0°, de 7 ml d'oxychlorure de phosphore. Après une nuit d'agitation à la température ambiante, 500 ml d'eau sont ajoutés puis de l'acide chlorhydrique 2 *N* jusqu'à pH 2–3. Le précipité qui se forme est essoré (1.73 g). Le filtrat est extrait au chlorure de méthylène. La solution organique est lavée à l'eau, séchée sur sulfate de sodium et évaporée à sec.

Le précipité, cristallisé dans le méthanol, fournit 0.73 g d'aza-17*a* D-homo androstane-5α one-17, **11**, homogène à la c.c.m. L'échantillon analytique est obtenu par recristallisation dans le méthanol. p.f. 298–303°, $[\alpha]_D^{20}$ +14° (*c*, 1.07).

Anal. Calc. pour $C_{19}H_{31}NO$: C, 78.84; H, 10.80; N, 4.84. Trouvé: C, 78.54; H, 10.66; N, 4.54.

Spectre i.r. (Nujol): bandes à 3160 et 3040 cm^{-1} (N—H); à 1668 et 1605 cm^{-1} (O=C—NH).

Les eaux-mères de cristallisation évaporées à sec sont réunies au résidu de l'extraction au chlorure de méthylène (1.04 g). Un échantillon de 120 mg est chromatographié sur couche épaisse: plaque 20 × 20, préparée avec 20 g de silicagel G (Merck); élution avec un mélange chlorure de méthylène–méthanol (96/4); pulvérisation au réactif de Morin et repérage des bandes par u.v.; extraction au chloroforme. Sont isolés de cette façon: 30 mg de la lactame **11** (rendement global en lactame 42%) et 63 mg (19%) de seco-13,17 androstane-5α ène-13,18 nitrile-17, **12**. Un échantillon pour analyse de ce dérivé est obtenu par sublimation sous vide poussé, p.f. 58–60°, $[\alpha]_D^{20}$ 21° (*c*, 0.37).

Anal. Calc. pour $C_{19}H_{29}N$: C, 84.07; H, 10.77; N, 5.16. Trouvé: C, 84.02; H, 10.71; N, 5.27.

Spectre i.r. (Nujol): bandes à 3080, 1643, 902 cm^{-1} (C=CH_2) et 2250 cm^{-1} (—CN). Spectre de r.m.n.: à 0.70 p.p.m. un singulet (CH_3-19) a 4.49 et 4.79 p.p.m., deux singulets correspondant chacun à un proton (C=CH_2).

Remerciements

Nous remercions le Professeur Janot et le Docteur Goutarel pour tout l'intérêt qu'ils ont porté à ce travail, le Docteur O. E. Edwards pour une lecture critique du manuscrit et la communication de ses résultats sur les *N*-chloramines avant publication ainsi que le Docteur R.R. Fraser pour d'utiles discussions. Les spectres de masse ont été effectués par le Docteur Longevialle, les spectres de r.m.n. par Madame Allais et les microanalyses dans le laboratoire de Microanalyse du CNRS à Gif-sur-Yvette.

Kinetic isotope effect for the thermally-induced migration of hydrogen in cyclopentadienes

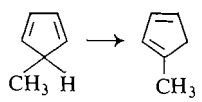
STEWART MCLEAN, C. J. WEBSTER, AND R. J. D. RUTHERFORD
Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received November 28, 1968

The Arrhenius parameters have been obtained for the rearrangement of 5-methylcyclopentadiene by a 1,2-hydrogen migration and for the corresponding rearrangement of 5-methylpentadeuteriocyclopentadiene. The results, taken in conjunction with those reported previously, allow the effect of the methyl group on the rate of hydrogen migration to be assessed. The kinetic isotope effect is of particular interest because the hydrogen transfer takes place through a transition state that is unequivocally non-linear.

Canadian Journal of Chemistry, 47, 1555 (1969)

We have previously studied the migration of the C-5 hydrogen in certain appropriately substituted cyclopentadienes and we have shown that a pathway exists by which a thermally-induced, intramolecular 1,2-hydrogen shift can take place; a study of the kinetics of the rearrangement (e.g. **1** → **2**) showed that it had true first order characteristics, and the Arrhenius parameters for the migration process were determined in certain cases (1). Related studies have been made by others (2, 3), and the significance of these results as examples of 1,5-sigmatropic processes was pointed out by Woodward and Hoffmann (4).



1 **2**

A determination of the kinetic isotope effect for the hydrogen migration process would be of considerable value for several reasons. We would like to determine the effect of various substituents on the rate of the migration process, and a knowledge of the rate of hydrogen migration in cyclopentadiene itself would be valuable in establishing a basis of comparison; the degenerate rearrangement in cyclopentadiene itself is, of course, unobservable by the techniques we have used, and it has not been experimentally possible to obtain dependable kinetic results for the derivative involving the smallest possible change, 5-deuteriocyclopentadiene[1] (1). However, Roth (3) has been able to study the rate of *deuterium* migration in 5-*H*-pentadeuteriocyclopentadiene, and a knowledge of the kinetic isotope effect for the process would allow his results and ours to be interrelated.

The kinetic isotope effect is also of theoretical interest because the intramolecularity of the hydrogen transfer process unambiguously places certain severe restrictions on the transition state for the reaction. The vast majority of kinetic isotope effects for hydrogen transfer reactions that have been investigated have involved linear transition states with respect to the bond making–bond breaking processes; the predominant contribution to the activation energy has then come from the C—H stretching components that are undergoing change, and although attempts have been made to incorporate bending force constants into calculations (5*a*) for linear transition states, non-linear transition states with a significant C—H bending component appear to have been considered in only a few special cases (5*b*). In contrast, the hydrogen migration in cyclopentadienes requires unequivocally a non-linear transition state in which the C—H bending component is important, and, in fact, the rearrangement can be viewed as the result of an exaggerated C—H bending vibration. For the rearrangement of cyclopentadiene itself, provided that no metastable intermediate is implicated, the transition state must be symmetrical, with the hydrogen equally bonded to the migration origin and the migration terminus. Furthermore, it appeared reasonable to assume at the start that the distortion of this symmetry in the 5-methylcyclopentadiene case, would have a minimal effect on the characteristics of the transition state.

[1]We are very grateful to Professor A. G. Harrison and Mr. D. Priddle for carrying out these measurements for us.

Unfortunately, one further modification had to be introduced into the system in order to make the study of the kinetic isotope effect for the 5-methylcyclopentadiene case experimentally feasible. It was not possible to develop a synthesis of 5-methyl-5-deuteriocyclopentadiene and we had to be content to use 5-methylpentadeuteriocyclopentadiene (**1**-D), which is readily available from cyclopentadiene-d_6. The second order effects of the 4 extra deuterium atoms could not be determined and the assumption was made that their combined effect would be small relative to the primary effect associated with the migrating atom.

In our first experiments we simply used the technique we have previously described (1) to monitor the decay of the methyl signal of 5-methylcyclopentadiene (**1**-H) and its deuterio derivative (**1**-D) while each was maintained at a fixed temperature in the probe of the nuclear magnetic resonance (n.m.r.) spectrometer. The k_H/k_D values obtained varied over a range that was greater than that of the expected experimental error and we decided that it would be necessary to have more precise temperature control and calibration than the variable temperature probe affords. We then used a technique in which the reaction was carried out in a thermostatted bath and then quenched by rapid cooling; the progress of the reaction was then determined from the area of the 5-methyl signal measured in an n.m.r. spectrometer with the probe temperature set low enough that no appreciable further rearrangement of the sample could take place. In this way we were able to study the rearrangement over the temperature range most suitable for each (5–25° for **1**-H and 20–40° for **1**-D). Table I shows the values obtained for k_H(migration), the average value for the (statistically-corrected) rate constant for the hydrogen migration process itself, and the rate constant, k_H(decay), for the process actually measured, the decay of the 5-methyl signal in **1**-H. The corresponding values for **1**-D are shown in Table II, and in Table III these values are corrected for the presence in **1**-D of incompletely deuteriated material. The correction was based on the isotopic dilution of the C_5D_6 precursor, determined mass spectrometrically, and assumed that the methyl group entered the molecule in a random fashion; the value obtained in this way for the isotopic dilution of 5-*D*-5-methyl species is probably an upper limit.

Comparison of the results recorded in Table I with those we obtained previously (1) reveals a significant difference between the two sets of figures for the values of k_H(migration) at each temperature. This difference, which has caused us some concern, probably arises from a systematic error in one of the sets of figures; in our earlier work (1) we depended on the calibration of the variable temperature probe, while in the present investigation our technique has allowed a much higher degree of precision in the determination of the reaction temperature, and consequently we believe that our present results are the more dependable and the temperatures recorded previously were 4–5° too low. In agreement with this, the Arrhenius plot of our present results gave a good straight line, the slope of which was the same, within the expected limits of accuracy, as that obtained in the earlier study. Our present results correspond to:

$$k_H(\text{migration}) = (7.49 \times 10^{10}) \exp(-19\,930/RT)\ s^{-1}$$

$$E_a = 19.9 \text{ kcal/mole (standard deviation 0.3)}$$

$$\Delta S^{\ddagger}\ (300\ °K) = -10.8 \text{ e.u. (standard deviation 1.0)}$$

Comparison of the results in Tables II and III shows that slightly better first order kinetic plots were obtained when the correction for isotope dilution was applied. The differences between the two sets of figures are, in fact, within the expected limits of error for this technique, and this serves to confirm our supposition that our material was of sufficient isotopic purity. When each set of kinetic data was plotted separately, there was very little difference in the Arrhenius parameters obtained, but the standard deviations of slope and intercept were very slightly lower in the corrected case. We choose, therefore, to report the results obtained from Table III which are:

$$k_D(\text{migration}) = (7.58 \times 10^{11}) \exp(-22\,350/RT)\ s^{-1}$$

$$E_a = 22.35 \text{ kcal/mole (standard deviation 0.1)}$$

$$\Delta S^{\ddagger}\ (300\ °K) = -6.2 \text{ e.u. (standard deviation 0.3)}$$

It can be seen that the Arrhenius activation energy for deuterium migration is greater than that for hydrogen migration, but the entropy of activation is less negative for deuterium; from these results it follows that the free energy of activation for deuterium migration is higher by about 1.1 kcal mole^{-1} in the temperature range studied. The values for k_H/k_D, calculated from the Arrhenius plot, show a substantial temperature dependence, being 7.67 at 7 °C, 5.75 at 27 °C, and 4.45 at 47 °C; the isokinetic temperature is 253 °C, calculated by extrapolation and with the assumption that the Arrhenius plots are linear through the whole range.

It is clear from a comparison of our present results with those of Roth (3) that, as we had previously suggested (1), the 5-methyl group appreciably lowers the activation energy for the migration of the hydrogen from C-5, leading to an increase in the rate of rearrangement. The 1-methyl isomer (with methyl at sp^2 carbon) is appreciably more stable than the 5-methyl isomer (with methyl at sp^3 carbon) (1); it is probable that the methyl group in the first isomer has a stabilizing effect relative to the unsubstituted case and it is possible that the methyl group has the opposite effect in the second case. The lowering of the activation energy for the rearrangement of 5-methylcyclopentadiene may reflect both influences, one raising the ground state and the other lowering the transition state energy. It seems probable in any case that the transition state is appreciably affected by the stabilizing influence of the methyl group at the incipient sp^2 carbon center, and to this extent the approximation made earlier that the distortion of the symmetry of the transition state by the methyl substituent could be neglected is inaccurate, but it is difficult to place this on a quantitative basis with any confidence. The stabilization of the 1-methyl isomer with respect to the 5-methyl isomer (from equilibrium studies (1)) and the lowering by the methyl group of the activation energy for hydrogen migration (from the kinetic comparison of substituted and unsubstituted cyclopentadienes) are both about 2 kcal/mole, indicative that the major part of the effect that the methyl group has in the product is already felt in the transition state. However, the equilibrium values are recognized to be only very approximate and the activation energy figures are based on the difference between our results and those of Roth (3), both of which have probable error limits that are appreciable relative to the difference.

Because measurements were made on **1**-H and **1**-D under conditions that were as nearly identical as possible, the phenomenological aspects of the study of the kinetic isotope effects can, we feel, be accepted with some confidence. The range of k_H/k_D values is not unusual and the rate differences can be traced to both enthalpy and entropy factors. However, because we have not been able to separate primary and secondary isotope effects and because of the difficulties already outlined regarding the nature of the transition state, we do not feel that it is appropriate at this time to do more than comment briefly on the theoretical significance of the results. The important feature of this rearrangement is the non-linearity of the transition state; the difference in activation energy between the hydrogen and the deuterium cases could be attributed to the complete loss in the transition state of one bending mode (near 1360 cm^{-1} for C—H) and smaller contributions from other modes, but we have not followed this approach any further than the observation than any meaningful calculation will require consideration of a more extensive portion of the molecule and its associated vibrational modes. The extent of tunneling is another question of considerable interest here (and it may be noted that proton tunneling in "Woodward–Hoffmann forbidden" cases is a question of further interest); the ratio of pre-exponential factors we have determined ($A_H/A_D \sim 0.1$) has a value that has been considered evidence for an appreciable degree of tunneling (5*c*), but we recognize that our data have been obtained over a restricted temperature range only and the evidence is therefore suggestive rather than definitive.

Experimental

A Varian A-60 nuclear magnetic resonance (n.m.r.) spectrometer equipped with a variable-temperature probe was used. Analyses of isotopic composition were carried out directly by mass spectrometry using an AEI MS902.[1]

Cyclopentadiene-d_6

A solution of NaOD in D_2O, prepared by the reaction of Na_2O_2 (5.0 g) with D_2O (33.0 g), was vigorously stirred for 1 h at 0° in an atmosphere of nitrogen with cyclopentadiene (12.0 g) and 25 ml dimethyl sulfoxide. When the mixture was allowed to settle, three layers separated. The upper layer was partly deuteriated cyclopentadiene (62 atom % D) and the lower layers were dimethyl sulfoxide and partly exchanged D_2O (which could be recovered by distillation and used again in a preliminary treatment of another sample of cyclopentadiene). When the partly deuteriated cyclopentadiene was taken through another two cycles of this process, the composition of the product typically obtained was: C_5D_6, 82.3; C_5D_5H, 15.3; $C_5D_4H_2$, 1.9; less highly deuteriated species 0.5 (95.6 atom % D).[2] Material of at least this isotopic purity was converted to 5-methylpentadeuteriocyclopentadiene by the method described previously for cyclopentadiene itself (6).

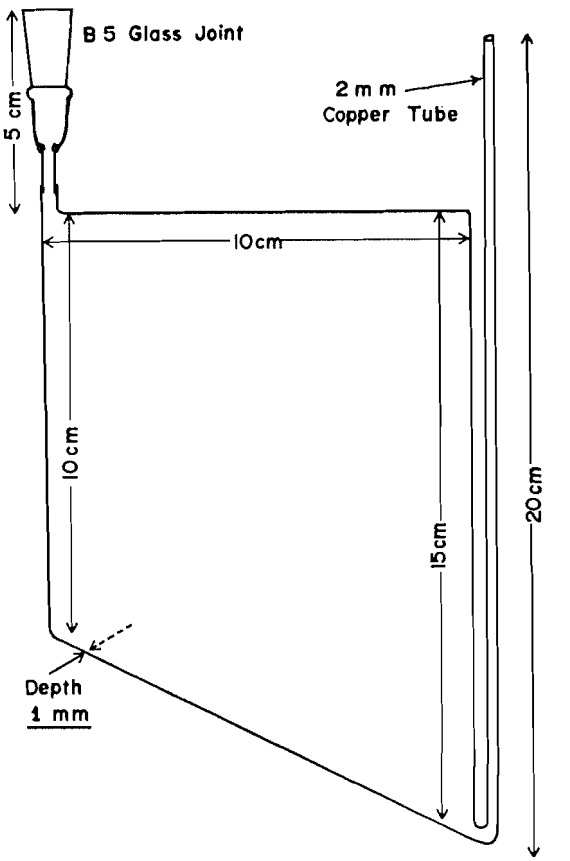

FIG. 1. The reaction vessel.

Kinetic Measurements

The reaction vessel shown in Fig. 1 was constructed from thin copper sheet. Reactants were introduced from a syringe which was adapted to fit the glass joint, and, when a sample was required, a measured volume could be forced through the copper tube, to which was connected

[2]This method was developed in this laboratory by Mr. T. F. W. McKillop and we are very appreciative of the experimental skill that he demonstrated in doing so. Under the conditions used here virtually no deuteriation of the DMSO takes place (on the basis of the mass spectrum of recovered DMSO); the rate of base-catalyzed hydrogen exchange in DMSO is known to be strongly dependent on the composition and nature of the reaction medium and it is interesting to note that, under prescribed conditions, the DMSO – D_2O – NaOD system can be used to prepare DMSO-d_6 rapidly and efficiently (7).

a piece of flexible Teflon tubing, by a pumping action of the syringe.

The reaction vessel containing 8 ml of a 4% solution of hexamethyldisiloxane in carbon tetrachloride was placed in a thermostatted bath (±0.02°) and, when thermal equilibrium was established, the substituted cyclopentadiene (2 ml) was added and thoroughly mixed with the solvent by agitation of the reaction vessel. Aliquots were withdrawn at measured intervals and collected in chilled n.m.r. sample tubes, which were then immediately placed in a mixture of dry ice and acetone and stored there until they could be examined in an n.m.r. spectrometer with a probe temperature of −20°. Peak areas were then measured by electronic integration after optimum instrumental conditions had been established. The area of the 5-methyl peak was measured relative to that of (*a*) the hexamethyldisiloxane signal and (*b*) the total methyl signal of all methylcyclopentadienes.

The data obtained were analyzed by a standard least squares routine using an IBM 7094 computer to obtain first order rate constants. The values obtained from areas as a fraction of the total methyl signal gave more consistent results and these are reported in Tables I and II. Arrhenius parameters were obtained by the corresponding least squares analysis. Corrections for the effects of isotope dilution were made on the assumption that the methylation reaction replaced hydrogen or deuterium in the precursor cyclopentadiene in a random manner; thus 5-methyl-5-H species would be formed from 1/6 of the C_5D_5H molecules, 1/3 of the $C_5D_4H_2$ molecules, and so on. The typical deuteriated cyclopentadiene described above would then lead to 3.5% 5-methyl-5-H species in the product. The actual concentration of 5-methyl-5-D species at time t, $D(t)$, was calculated from the apparent concentration $S(t)$ based on the 5-methyl n.m.r. signal and the concentration of 5-methyl-5-H species, $H(t)$, which in turn was calculated from the above fractions and the value of k_H(decay) obtained from the Arrhenius plot.

$$D(t) = S(t) - H(t) = S(t) - H(0) \exp(-k_H t)$$

Rate constants calculated from these corrected values are reported in Table III.

Received January 9, 1969

Floccosic acid, floccosin, its magnesium complex, and a green iron-containing pigment, floccoviridin, were isolated from *E. floccosum*. Structure **7** is proposed for floccosic acid, and degradative work defining some of the functions in floccosin as depicted in partial formula **C** is described.

Canadian Journal of Chemistry, 47, 1561 (1969)

Isolation

The chloroform and acetone extracts of dry, powdered mycelium of *Epidermophyton floccosum*, previously extracted with petroleum ether and diethyl ether, yielded the metabolites floccosin and floccosic acid. Floccosin was obtained in a yield of approximately 1% of the dry mycelium,[6] and floccosic acid in 0.02% yield on one occasion.[6] It could not be isolated from subsequent batches of mycelium. When the chloroform extract was worked up by preparative thin-layer chromatography (t.l.c.), a yellow major compound containing magnesium with the virtual exclusion of all other metals was obtained in 0.5% yield. Nuclear magnetic resonance (n.m.r.) and infrared (i.r.) spectra, in conjunction with analytical data, indicated that it consisted of floccosin complexed with magnesium. All attempts to remove the metal resulted in extensive decomposition, with recovery of approximately 5% of floccosin. When the neutral fraction of the chloroform extract of the mycelium was chromatographed on silica gel thin layers using chloroform – acetic acid (9:1) as eluent, a green band appeared immediately behind the solvent front. From this band, floccoviridin, a green iron-containing complex, was eluted. The iron content of this compound was found to be about 1.0%.[7] Since very little of this material was obtained (200 mg from 2 kg of mycelium), no work has been done on it.

Floccosin

Floccosin, a yellow crystalline magnesium-free pigment, had the molecular formula $C_{30}H_{26}O_{14}$. This formula was based on elemental analysis, n.m.r. proton count[8] (see Table II) and osmometric weight determination of the parent compound and some of its derivatives. The total proton count in the n.m.r. spectrum of floccosin was 13. Floccosin therefore possessed a molecular structure consisting of two identical halves, joined by an odd number of bonds. The dimeric nature of floccosin was confirmed by the mass spectrum of floccosin tetra-trimethylsilyl ether, which showed a peak at 811 (calculated molecular ion: 898). Floccosin formed a tetramethyl ether and two isomeric tetraacetates **A** and **B**. The spectral data of floccosin and its derivatives are summarized in Tables I–IV. No interpretable

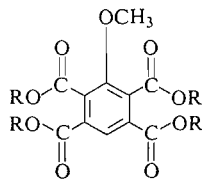
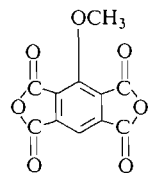
mass spectrum of floccosin or the above derivatives could be obtained.

Oxidation of tetramethylfloccosin with alkaline permanganate yielded anisole-2,3,5,6-tetracarboxylic acid **1***a* (1), which was identified by mixed m. p. and comparison of the i.r. spectrum with that of a synthetic sample.



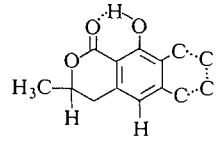
1*a*, R = H
1*b*, R = CH_3



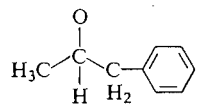
2

Methylation of **1***a* with diazomethane yielded the tetramethyl ester **1***b*, (2), which was also identified by mixed m. p. and comparison of the i.r. spectrum[9] with that of a synthetic sample. Nuclear magnetic resonance and mass spectrometry (M^+ = 340) also confirmed its structure. The anisole tetracarboxylic acid, **1***a*, was also converted to its dianhydride **2**, m.p. 215–217°, by sublimation.

From the n.m.r. spectrum of floccosin and its derivatives, and spin decoupling experiments on floccosin,[10] the following structural unit **A** could be derived. Taken in conjunction with the results of the oxidation of tetramethylfloccosin, partial structure **B** may be written for floccosin. The lactone function of floccosin absorbed in the i.r. at 1670 cm^{-1}. Upon acetylation or methylation



A



B

of floccosin, this carbonyl function reverted to its normal position at 1730–1735 cm^{-1}, proving that the lactone function in floccosin was strongly hydrogen-bonded.

Acetylation of floccosin with pyridine – acetic anhydride containing triethylamine for a short period of time gave floccosin tetraacetate **A**, ν 1785 and 1770 cm^{-1}, δ 2.33 p.p.m. (6H), $[\alpha]_D$ −126.9°. Recrystallization from methanol converted tetraacetate **A** to a mixture of tetraacetates **A** and **B**, a mixture also obtained by acetylation of floccosin with pyridine – acetic anhydride. Prolonged heating in methanol gave floccosin tetraacetate **B**, ν 1785 and 1735 cm^{-1}, δ 2.08 (3H), 2.18 (3H), p.p.m., $[\alpha]_D$ +62.4°. The conversion of tetraacetate **A** to tetraacetate **B** must have involved transformation of an acetate (ν 1770 cm^{-1}) to an aliphatic acetate (ν 1735 cm^{-1}), the absorption of which overlapped with the absorption due to the lactone function.

In an attempt to prove the nature of the oxygen functionality absorbing at 1700–1715 cm^{-1} (see Table I), floccosin tetraacetate **A** was treated with hydroxylamine hydrochloride and sodium acetate in aqueous methanol at room temperature. A crystalline product, floccosin diacetate, was obtained. Reacetylation gave floccosin tetraacetate **B**. The main spectral differences between tetraacetate **B**, ν 1785 and 1735 cm^{-1}, and the diacetate, ν 3400, 1735, and 1675 cm^{-1}, were consistent with the hydrolysis of the acetate group, which, as a hydroxy group, was hydrogen-bonded to the lactone function. Floccosin diacetate was further characterized by conversion to dimethylfloccosin diacetate.

When tetramethylfloccosin was heated under reflux with acetic anhydride and zinc dust for a few minutes, a naphthalene derivative **3***a*, $C_{14}H_8O_2(OCH_3)_2(OAc)_2$, was obtained in 43% yield. Using the same method, dimethylfloccosin diacetate was also transformed to **3***a*. The oxygen function lost during the zinc – acetic anhydride reduction was present in tetramethylfloccosin as a methoxy group and in dimethylfloccosin diacetate as an acetate group, and must therefore

[9]The infrared spectrum was kindly supplied by Dr. J. S. E. Holker, Department of Organic Chemistry, University of Liverpool, England.

[10]We wish to thank Miss M. Feser, Department of Chemistry, University of Alberta, Edmonton, Alberta, who performed this experiment.

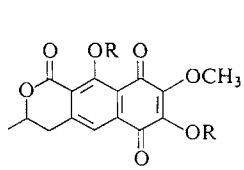
have been attached to ring **C** of floccosin as a hydroxy group.

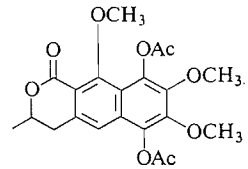
Hydrolysis of **3a** in a nitrogen atmosphere gave diol **3b**, which could be reacetylated to **3a**. Both **3a** and **3b** showed the appropriate n.m.r. signals and i.r. absorption bands. Oxidation of **3a** with alkaline hydrogen peroxide gave 3-methoxy-5(2'-hydroxypropyl)trimellitic acid δ-lactone (**4**), the structure of which was derived from its origin and spectral data.[6] Oxidation of **3a** with alkaline hydrogen permanganate gave anisole tetracarboxylic acid **1a**.

Diol **3b** was readily oxidized by air to a dark, unidentified crystalline product. Reductive acetylation of this material did not regenerate **3a**, implying that the two hydroxy groups in **3b** did not bear an *ortho* or *para* relationship. No identifiable quinone could be obtained by oxidation of **3b** with silver oxide. Comparison of the ultraviolet (u.v.) spectrum of **3b** with those of catechol, resorcinol, and hydroquinone, made a *meta*-relation of the two hydroxy groups in **3b** very likely. Compound **3b** gave a positive Gibbs test (3), showing that the position *para* to a phenolic group was unsubstituted.

Compounds **3'a** and **3'b** are alternative formulations for **3a** and **3b**, and cannot be ruled out at the present time. However, the low value (1695 cm^{-1}) for the lactone absorption in **3b** suggested that a hydroxyl group may be present in a position permitting conjugation, thus favoring **3b** over **3'b**. When floccosin was heated under reflux in glacial acetic acid with potassium iodide for a short time, a naphthoquinone **5a**, $C_{15}H_{12}O_7$, ν 3300, 1690 cm^{-1} (hydrogen-bonded lactone) and 1660 cm^{-1} (quinone), λ_{max} 218 (ε 14 850), 230 (shoulder 12.650), 272 (9640), and 385 mμ (3990) was obtained in 48% yield. The n.m.r. spectrum in deuterated pyridine showed peaks which were consistent with structure **5a**: a singlet at 10.90 p.p.m. (2 protons, —OH); a peak at 6.85 p.p.m.



5a, R = H
5b, R = Ac
5c, R = CH_3



6

(1 proton, aromatic); a singlet at 3.44 p.p.m. (3 protons, —OCH_3); and the acyloxypropyl grouping, [0.65 p.p.m. (3 protons, doublet); 2.16 p.p.m. (2 protons of ABX system); and 3.90 p.p.m. (1 proton of ABX system, multiplet)] which is present in floccosin and its derivatives. The solvent peaks obscured the aromatic proton at 6.85 p.p.m. However, integration and comparison with pure solvent accounted for this proton. The low field signal (10.90 p.p.m.) disappeared on shaking with deuterium oxide. Neither a Rast nor an osmometric molecular weight determination could be obtained due to insolubility of **5a**.

Acetylation of compound **5a** with pyridine – acetic anhydride gave a diacetate **5b**, ν 1785 cm^{-1} (phenolic acetate) and 1735 cm^{-1} (lactone), λ_{max} 212 mμ (ε 14 000); 260 mμ (ε 12 800); inflexion at 284 mμ (ε 5430); and 344 mμ (ε 2130). The n.m.r. spectrum showed the same general features as in **5a** except that the hydroxyl peaks were replaced by two acetate peaks at 2.48 and 2.55 p.p.m. The above spectral data were consistent with the acetylation of two hydroxyl groups, one of which was hydrogen bonded to the lactone. Osmometric molecular weight determination indicated the monomeric nature of the diacetate **5b**. Treatment of compound **5a** with methyl iodide and silver oxide in chloroform gave the dimethyl ether **5c**, ν 1735 cm^{-1}, λ_{max} 214 mμ (ε 23 900); 267 mμ (ε 16 600); and 354 mμ (ε 4150). The n.m.r. spectrum indicated replacement of two hydroxyl groups in **5a** by methoxyl groups at 4.20 and 4.25 p.p.m.

Reductive acetylation of the dimethyl ether **5c** with zinc dust and acetic anhydride yielded a

For personal use only.

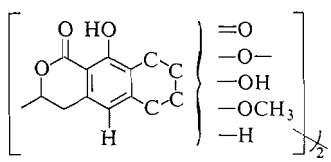
napthalenic compound **6**, $C_{14}H_7O_2(OCH_3)_2(O_2CCH_3)_3$. The i.r. spectrum now showed no quinone bands but peaks at 1770 and 1740 cm^{-1}, attributable to phenolic acetate and lactone absorptions respectively. The u.v. spectrum showed maxima at 254 mμ (ε 35 300); 300 mμ (ε 3670); and 350 mμ (ε 2100). The spectrum, as expected, was similar to that of 1,7-dimethoxy-6,8-diacetoxy-3(2′-hydroxypropyl)-2-naphthoic acid δ-lactone (**3***a*). The n.m.r. spectrum showed methoxyl peaks at 3.95 p.p.m. (6 protons) and 3.85 p.p.m. (3 protons), and acetate peaks at 2.45 p.p.m. (3 protons) and 2.40 p.p.m. (3 protons). The change brought about by the reductive acetylation was then the conversion of the two quinone oxygens to two acetate groups.

In the naphthoquinone **5***c*, the three rings are arranged in a linear fashion, since oxidation gave anisole-2,3,5,6-tetracarboxylic acid, which was identified as its methyl ester. The structure of the quinone must therefore be represented as in **5***a*, with the methoxy and hydroxy groups on the quinone ring perhaps exchanged, if **3′** rather than **3** proves to be the correct formula of the naphthalene compound obtained from the zinc – acetic anhydride reduction of tetramethylfloccosin.

Catalytic reduction of tetramethylfloccosin with platinum oxide in ethyl acetate – acetic acid gave as one of many products **3***b*, identified by its i.r. and u.v. spectrum and mixed m.p. determination. All other experiments tried on floccosin did not lead to characterizable products.

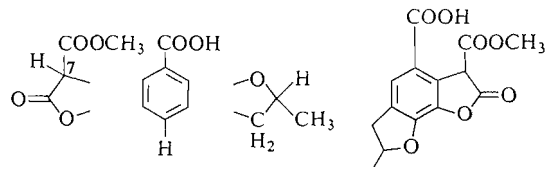
Based on the data presented, the following partial structure **C** can be written for floccosin.



C

Floccosic Acid

Floccosic acid $C_{14}H_{12}O_7$, ν 3500–2500 and 1675 cm^{-1}, δ 11.66 p.p.m., formed a methyl ester, ν 1720 cm^{-1}, δ 4.04 p.p.m. Both floccosic acid and its methyl ester absorbed at 1795 (5-membered lactone) and 1755 cm^{-1} (aliphatic methyl ester). The n.m.r. spectrum of floccosic acid showed the appropriate signals for a $CH_3CH(O)CH_2Ph$ group (1.6 p.p.m., 3H, doublet, 3.15, 2H, ABX-system, 4.86, 1H, multiplet) similar to those observed for floccosin, xanthomegnin (4), vioxanthin, and viopurpurin (5), a methoxy group (3.86 p.p.m.) most likely associated with the ester function absorbing at 1755 cm^{-1}, an aromatic proton (7.36 p.p.m.), and a singlet at 5.97 p.p.m. (C-7 in **7**). The u.v. spectrum of floccosic acid and its methyl ester resembled that of benzoic acid derivatives. These spectral features suggested partial structure **D** for floccosic acid. Comparison of the u.v., i.r., and mass spectra of floccosic acid



D **7**

and its methyl ester with those of appropriate model compounds suggested structure **7** for floccosic acid, without excluding any of the other possible isomeric structures, in which rings **A** and **C** are attached to the central ring in a different manner.[11] Floccosic acid melted over a 20° range. Since it appeared homogeneous by t.l.c. and n.m.r., it was very likely that the lack of sharpness of the m.p. was due to epimerization at the C-7 position.

Experimental

The i.r. spectra were recorded on a Perkin–Elmer model 337 spectrophotometer. The n.m.r. spectra were recorded on a Varian A-60 spectrometer. The u.v. spectra were measured in ethanol, on a Perkin–Elmer model 350, and a Beckman recording model DK spectrophotometer. The optical rotations were measured on a Carl Zeiss 367732 polarimeter, using chloroform as solvent. The mass spectra were recorded by the Morgan and Schaffer Corporation, 5110 Courtrai, Montreal, Quebec. The elemental analyses, and osmometric molecular weight determinations were performed by the Mikroanalytisches Laboratorium Beller, 34 Gottingen, Theaterstrasse 23, Germany. The melting points were determined on a Kofler hot stage.

Preparation of Mycelium

The fungus was grown in 500 ml Erlenmeyer flasks containing 200 ml medium at room temperature in the dark for 3 weeks. The medium consisted of 4% crude glucose (cerelose), 2% neopeptone Difco, 0.05% yeast extract Difco, 0.005% inositol, 0.001% thiamine, and 1.5% agar. The cultures were autoclaved, and the harvested mycelium washed free from adhering medium by

[11]For detailed discussion, see Ph.D. thesis of J. L. Tudor, McGill University, Montreal, Quebec.

TABLE V

Solvent	Time (days)	Code	Yield* (g)	Average yield (%) of dry mycelium
Hexane	7	H	13.36 (12.60)	3.37
Diethyl ether	7	E	5.63 (5.96)	1.5
Chloroform	7	C-1, C-1⁻†	14.38 (15.40)	3.87
Chloroform	7	C-2	2.50 (2.70)	0.67
Chloroform	7	C-3	1.00 (2.10)	0.40
Acetone	7	A-1	4.40 (4.40)	1.14
Acetone	7	A-2	2.60	0.68

*Bracketed values refer to the second run.
†C-1⁻ refers to the second run.

boiling three times in water. After pressing, the mycelium was freeze-dried, and milled in a ball-mill.

Isolation of Metabolites

Powdered mycelium of *Epidermophyton floccosum* (384 g, first run; 386 g, second run) was stirred twice with 4 l of various solvents at room temperature for one week each. The extraction results are summarized in Table V.

Floccosin

Fraction C-1 was dissolved in 2 l of methylene chloride and washed successively with (*a*) aqueous methanol (2:1, 3 × 1.5 l), (*b*) 1.6% hydrochloric acid in aqueous methanol (4:1, 3 × 1.25 l), (*c*) aqueous methanol (4:1, 3 × 1.25 l), (*d*) 1% sodium carbonate in aqueous methanol (1:1, 3 × 2 l), (*e*) aqueous methanol (1:1, 1 × 2 l), (*f*) 0.5% sodium hydroxide in aqueous methanol (1:1, 3 × 2 l), and (*g*) aqueous methanol (1:1, 1 × 2 l), yielding fractions C-1*a*, C-1*b*, etc. respectively. All washings were re-extracted with 2 × 2 l portions of methylene chloride.

Fraction C-1*e* was acidified with 60 ml of concentrated hydrochloric acid, and re-extracted with three 2 l portions of chloroform. After washing with water, the chloroform was evaporated to dryness. A pale-yellow powder (1.305 g) was obtained. The i.r. spectrum of this material indicated that it consisted of a fairly pure sample of floccosin. This material was introduced onto a column consisting of an inert support, (sand and cellulose), and washed with hexane, ether, methanol, and chloroform successively. The chloroform wash was crystallized, after evaporation from chloroform–methanol; floccosin (0.919 g), m.p. 261–263°, was obtained. Similarly, fraction C-1*g* gave floccosin (1.75 g), m.p. 263–265°. From the second run (C-1⁻), fraction C-1⁻ *g* gave floccosin (2.2 g), m.p. 263–264°, by the same procedure.

The washed, neutral powdery chloroform extract (5 g) was introduced onto a similar column, and washed with hexane, ether, methanol, chloroform, and chloroform – acetic acid (9:1). The combined chloroform and chloroform – acetic acid washings yielded floccosin (0.77 g), m.p. 256–259°, after removing acetic acid by repeated washing with water.

The neutral chloroform extract did not yield reproducible amounts of floccosin in subsequent runs. The acetone extracts were treated in the same fashion and also yielded floccosin, although in lesser amounts.

Floccosin was recrystallized from chloroform–methanol, m.p. 263–264° with decomposition. The average yield of floccosin was approximately 1% of dry mycelium.

Anal. Calcd. for $C_{30}H_{26}O_{14}$: C, 59.02; H, 4.29; O, 36.69. Found (osmometric mol. wt., 646): C, 59.00, 59.22; H, 4.08, 4.47; O, 36.98, 36.66.

Floccosic Acid

Dried mycelium of *Epidermophyton floccosum* (1 kg) was extracted with various solvents as described above. The combined chloroform and acetone extracts (C-1, C-2, C-3, A-1, and A-2 of two other runs), were submitted to a washing procedure similar to that described for floccosin. The sodium carbonate wash C-1*d* was acidified and re-extracted with chloroform. The chloroform extract was evaporated to dryness. The brown residue was introduced onto a column consisting of an inert support and washed with hexane, ether, methanol, and chloroform. The ether wash was evaporated to dryness and partially dissolved in benzene. The benzene soluble portion was chromatographed on silica gel (100 g). Elution was effected with benzene and benzene–ether mixtures. Benzene–ether (8:2) gave approximately 200 mg of crystalline floccosic acid, which was recrystallized from methanol, m.p. 156.5–178.5°, yield: 0.02% of dry mycelium.

Anal. Calcd. for $C_{14}H_{12}O_7$: C, 57.54; H, 4.14; O, 38.32. Found: C, 57.50; H, 3.89.

Yellow Magnesium–Floccosin Complex

Dry powdered mycelium (930 g) was extracted in a Soxhlet extractor successively with 4 l petroleum ether (b.p. 40–60°), 4 l diethyl ether, and 4 l chloroform for 7 days each. The chloroform extract upon evaporation to dryness yielded a dark-brown material (30 g), which was dissolved in 2 l chloroform, and washed extensively with water, 5% hydrochloric acid, 5% sodium bicarbonate, and 3% sodium hydroxide. The remaining neutral chloroform solution was evaporated to dryness, giving solid material (25 g). This material was placed in a Soxhlet extractor and extracted with solvents (600 ml) in the following sequence for 24 h each: hexane, diethyl ether, methanol, benzene, and methylene chloride. The benzene extract yielded solid material (9.2 g) upon evaporation to dryness. Part of this material (4.6 g) was dissolved in methylene chloride and chromatographed on silica gel thin layer plates using methylene chloride – methanol (9:1 v/v) as eluent. The developed chromatogram showed two main bands: a reddish brown band just above the start, and a yellow band which moved with the solvent front. The yellow band was cut out and eluted with a mixture of methanol and methylene chloride. Upon

For personal use only.

evaporation of the solvent a yellow material (magnesium–floccosin complex) was obtained, yield: 0.5% of dry mycelium. The magnesium complex did not melt. Found: C, 56.02; H, 3.89; O, 32.95; ash, 0.351 mg in 4.141 mg.

Isolation of Floccoviridin

Dry powdered mycelium (463.6 g) was extracted in a Soxhlet extractor as described in the isolation of the yellow magnesium complex. The chloroform extract was evaporated to dryness, yielding 16.0 g of dark brown material, which was washed extensively with water, 5% hydrochloric acid, 5% aqueous sodium bicarbonate, and 3% sodium hydroxide solution.

The remaining neutral chloroform phase was evaporated to dryness, and the dry material was washed with 3 × 900 ml hexane and 2 × 600 ml diethyl ether. The neutral solid material (5 g) remaining was dissolved in chloroform and chromatographed on silica gel thin layers (½ mm thick) with methylene chloride – acetic acid (9:1 v/v) as eluent. A series of bands, brown, yellow, orange, and green (increasing R_f values), developed. The green band was removed and eluted with a methylene chloride – acetic acid mixture (approx. 9:1). The solvent was evaporated and traces of acetic acid were removed by azeotroping with benzene. The green pigment was further purified by rechromatography on silica gel thin layers, using methylene chloride – pyridine (9:1 v/v) as eluent. The green pigment (120 mg) was recovered by elution from the silica gel and evaporation to dryness, (yield 0.03% of dry mycelium). Found: C, 60.20; H, 4.90; ash: 0.397 mg brown residue in 4.293 mg. X-ray fluorescence analysis indicated that the sample contained 1% of iron. Optical spectroscopy indicated that together the metals copper, tin, calcium, silicon, and aluminium were present to the extent of less than 0.1%. No other metals were detected.

Floccosin Tetraacetate 'A'

Floccosin (100 mg) was dissolved in pyridine (3.0 ml). Triethylamine (0.25 ml) and acetic anhydride (1.5 ml) were added. The mixture was shaken and allowed to stand for 15 min at room temperature in the dark. The solution was poured onto crushed ice, and set aside until the ice melted. The white flocculent solid was filtered off and washed with water. A quantitative yield of floccosin tetraacetate '**A**' was obtained, m.p. 216–227°.

Anal. Calcd. for $C_{38}H_{34}O_{18}$: C, 58.61; H, 4.37; O, 37.02. Found: C, 58.90; H, 4.23; O, 36.92.

*Floccosin Tetraacetate '**B**'*

Floccosin tetraacetate '**A**' was refluxed in methanol for 4 days, and then crystallized from methanol, m.p. 246–248°.

Anal. Calcd. for $C_{38}H_{34}O_{18}$: C, 58.61; H, 4.37; O, 37.02. Found: C, 58.85; H, 4.26; O, 36.85.

Floccosin Diacetate

Floccosin tetraacetate '**A**' (100 mg) was dissolved in methanol (10 ml). Hydroxylamine hydrochloride (100 mg) and sodium acetate (180 mg) were dissolved in a minimum of water and methanol (10 ml) and this solution was added to that of the tetraacetate. After standing for about 18 h at room temperature, yellow needle-like crystals of the diacetate (45 mg) separated out, while the solution turned brown. The crystals were filtered off and recrystallized from methanol, m.p. 259–261°.

Anal. Calcd. for $C_{34}H_{30}O_{16}$: C, 58.79; O, 36.89; H, 4.32. Found (osmometric mol. wt., 675): C, 58.96, 59.10; O, 36.51, 37.08; H, 4.43, 3.94.

Tetramethylfloccosin

Floccosin (108 mg) was dissolved in dioxane (10 ml). Methyl iodide (10 ml) and silver oxide (375 mg) were added, and the mixture was stirred at room temperature for 48 h. The supernatant was filtered off and evaporated to dryness. Crude tetramethylfloccosin (127 mg) was recovered and crystallized several times from a methylene chloride – methanol mixture, m.p. 258–261° (with decomp.).

Anal. Calcd. for $C_{34}H_{34}O_{14}$: C, 61.26; H, 5.14; O, 33.60. Found (osmometric mol. wt., 650): C, 60.86; H, 4.84; O, 34.17.

Dimethylfloccosin Diacetate

Floccosin diacetate (83 mg) was dissolved in methyl iodide (6 ml). Silver oxide (200 mg) was added, and the mixture was stirred for 24 h at room temperature. The solution was filtered off and evaporated to dryness. Dimethylfloccosin diacetate was recovered as a white amorphous solid in quantitative yield, m.p. 180–184°.

Anal. Calcd. for $C_{36}H_{34}O_{16}$: C, 59.84; H, 4.74; O, 35.42. Found: C, 60.13; H, 4.40; O, 35.45.

*Anisole-2,3,5,6-tetracarboxylic Acid (**1a**) from Tetramethylfloccosin*

Aqueous potassium permanganate (120 ml, 5%) was added, in small portions over a period of 48 h, to a suspension of tetramethylfloccosin (100 mg) in 2 *N* sodium hydroxide solution (35 ml) under reflux. The manganese dioxide formed was filtered off and washed. The entire filtrate was acidified with concentrated hydrochloric acid, heated nearly to boiling, and again treated with 5% potassium permanganate until the oxidant was in slight excess. After 10 min, the excess reagent was reduced with sulfur dioxide. Crude anisole-2,3,5,6-tetracarboxylic acid (79 mg) was isolated from the resulting solution by continuous liquid–liquid extraction with ether, m.p. 248–250°; ν KBr 1730, 1705 cm^{-1}. The i.r. spectrum was identical with that of a synthetic sample.

*Anisole-2,3,5,6-tetracarboxylic Acid Tetramethyl Ester (**1b**)*

Anisole-2,3,5,6-tetracarboxylic acid (40 mg) was treated with diazomethane in an ether solution. The solvent was evaporated to dryness, and the resulting product was sublimed at 70° and 10^{-2} Torr yielding the pure ester (42 mg), m.p. 104–105°; ν KBr 1740, 1725 cm^{-1}. The i.r. spectrum was identical with that of a synthetic sample.

*Anisole-2,3,5,6-tetracarboxylic Acid Anhydride (**2**)*

Anisole-2,3,5,6-tetracarboxylic acid (6.5 mg) was heated at 165° for 4 h under atmospheric pressure in a narrow tube, and for 12 h at 165° and 10^{-2} Torr. The sublimate consisted of pale-yellow prisms, m.p. 215–217°; ν KBr 1845, 1825, 1780, and 1765 cm^{-1}.

*1,7-Dimethoxy-6,8-diacetoxy-3(2'-hydroxypropyl)-2-naphthoic Acid δ-Lactone (**3a**)*

Tetramethylfloccosin (410 mg) and sodium acetate (200 mg) were added to acetic anhydride (20 ml). The mixture was heated to boiling under reflux, and zinc

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

powder (1.8 g) was added. Boiling was continued for 7 min. The reaction mixture was immediately cooled and filtered. The zinc residue was washed with chloroform. The entire filtrate was reduced in volume, under low pressure, until all of the chloroform had been removed. Crushed ice was then added to the acetic anhydride solution, and the mixture was stirred until all of the anhydride was hydrolyzed. The yellowish white precipitate formed was extracted with three portions of chloroform, each of which was washed three times with water. The entire chloroform extract was evaporated to dryness. The solid residue was crystallized from methanol yielding 221 mg of white needle-like crystals, which were recrystallized several times from methanol, m.p. 169–170°, ν KBr 1770, 1720, 1630, 1610, and 1570 cm^{-1}, λ_{max} 350 mμ (ε 2190), 295 mμ (ε 6570), 252 mμ (ε 52 600), and 224 mμ (ε 20 450); δ ($CDCl_3$) 1.47 p.p.m., (3H, doublet); 2.38 and 2.48, (3H each, singlets); 3.06 (2H of *ABX* system); 3.94 and 4.10 (3H each, singlets); 4.62 (1H of AB*X* system); 7.32 (1H, doublet); and 7.96 (1H, singlet).

Anal. Calcd. for $C_{20}H_{20}O_8$: C, 61.85; H, 5.19; O, 32.96. Found (osmometric mol. wt., 386): C, 62.08, 61.76; H, 4.83, 5.06; O, 33.00, 33.20.

1,7-Dimethoxy-6,8-dihydroxy-3-(2'-hydroxypropyl)-2-napthoic Acid δ-Lactone (3b)

1,7-Dimethoxy-6,8-diacetoxy-3-(2-hydroxypropyl)-2-naphthoic acid δ-lactone (**3***a*) (200 mg) was dissolved in methanol (20 ml). Concentrated hydrochloric acid (5 ml) and water (5 ml) were added, and the mixture was stirred under nitrogen at room temperature for 3 days. The yellow solution was extracted with chloroform. The chloroform solution was evaporated to dryness and the yellow solid residue was crystallized from chloroform under nitrogen to yield yellow crystals of **3***b* quantitatively, m.p. 227–230° (with decomp.); ν KBr 3430, 3420, 1695, 1630, 1615, 1580, and 1530 cm^{-1}; λ_{max} 365 mμ (ε 1870), 298 (4800), 263 (31 770), 225 (15 970), δ (pyridine-d_5) 0.58 p.p.m. (3H, doublet); 2.16 (2H of *ABX* system); 3.32 and 3.38 (3H, each singlets); 3.78 (1H of AB*X* system), 6.98 and 7.38 (1H each, singlets); signals due to the hydroxyl protons were not seen because of the presence of water in the solvent.

Anal. Calcd. for $C_{16}H_{16}O_6$: C, 63.15; H, 5.30; O, 31.55. Found (osmometric mol. wt., 307)[14]: C, 62.25; H, 4.70; O, 31.55.

3-Methoxy-5-(2-hydroxypropyl) Trimellitic Acid δ-Lactone (4)

1,7-Dimethoxy-6,8-diacetoxy-3-(2-hydroxypropyl)-2-naphthoic acid δ-lactone (330 mg) was dissolved in methanol (40 ml). Sodium hydroxide (4 g) in water (20 ml) was added. Hydrogen peroxide (10 ml, 30%) was then added slowly, while the solution was stirred at room temperature for 0.5 h. An additional portion of hydrogen peroxide (10 ml) was added and stirring was continued for a total of 5 h. The light amber solution was acidified with concentrated hydrochloric acid and extracted in a continuous liquid–liquid extractor with ether. The ether solution was evaporated to dryness, and the white solid residue was crystallized from ether–hexane to yield crystalline 3-methoxy-5-(2-hydroxypropyl) trimellitic acid δ-lactone (150 mg), m.p. 193–194°.

Anal. Calcd. for $C_{13}H_{12}O_7$: C, 55.72; H, 4.32; O, 39.97. Found: C, 55.12, 56.13; H, 4.90, 3.62; O, 39.91, 40.22.[15]

3-Methoxy-5(2'-hydroxypropyl) Trimellitic Anhydride δ-Lactone (5)

3-Methoxy-5-(2-hydroxypropyl) trimellitic acid δ-lactone was heated at 150° in a tube (12 in. long, ¼ in. diameter), sealed at one end, under vacuum for 24 h. A yellow melt solidified on the cool portion of the tube; ν KBr 1860, 1770, 1730, and 1620 cm^{-1}.

Oxidation of 1,7-Dimethoxy-6,8-diacetoxy-3-(2-hydroxypropyl)-2-naphthoic Acid δ-Lactone (3a)

Compound **3***a* (20 mg) was dissolved in 2 *N* sodium hydroxide (15 ml) and oxidized with 5% aqueous potassium permanganate (15 ml) using the method described above for the oxidation of tetramethylfloccosin. Liquid–liquid extraction with diethyl ether for 24 h gave a crystalline material whose i.r. spectrum and t.l.c. behavior were identical to **1***a*. Methylation with diazomethane in ether gave an ester which had the same retention time (7 min, 5% DC-710 on chromosorb W, acid washed, 45/60, 240 °C) as **1***b*.

Silylation of Floccosin (8)

To a solution of floccosin (10 mg) in anhydrous pyridine (0.2 ml) was added hexamethyldisilazane (0.2 ml) and bis(trimethylsilyl)acetamide (0.1 ml). The mixture was shaken for 30 s and allowed to stand at room temperature for overnight.

The mixture was then separated by t.l.c. (silica gel G)[16] using anhydrous ether as the developing solvent. The u.v. active band (R_f 0.9) was scraped off and dissolved with anhydrous ether. After stripping the solvent with a stream of nitrogen, a creamish crystalline material was obtained. Recrystallization from anhydrous ether gave colorless needles, m.p. 130–133° (decomp.), ν (KBr) 1250, 850, 755 [$Si(CH_3)_3$], and 1040 cm^{-1} (Si—O—C).

1,6-Dihydroxy-5,8-diketo-7-methoxy-3(2'-hydroxypropyl)-2-naphthoic Acid δ-Lactone (5a)

A mixture of floccosin (256 mg), potassium iodide (724 mg), and glacial acetic acid (25 ml) was refluxed for 10 min. After cooling, the mixture was diluted to 250 ml with water. The red precipitate (180 mg) was filtered and collected. The filtrate was titrated against sodium thiosulfate. Calcd. (for one active oxygen): 13.56 ml of 0.01 *N* $Na_2S_2O_3$. Found: 11.40 ml.[17]

The aqueous solution was then extracted with methylene chloride, washed with water, dried over anhydrous sodium sulfate, and the solvent evaporated to yield 68 mg of a red crystalline material. This was combined with the

[14]This compound could not be completely purified, because of the ease with which it is oxidized by air, when in solution.

[15]The inexact analysis is probably due to the fact that thorough drying could not be achieved, without the formation of the anhydride.

[16]The plates, after standing at room temperature for 2 days, were heated at 120° for ½ h immediately before use.

[17]The low value is probably due to the difficulty in determining the end point since the solution was orange in color.

red precipitate above and crystallized from methylene chloride to give 123 mg (48%) of red needle-like crystals, m.p. 262° (with decomp.); $[\alpha]_D^{25}$ −42° (*c*, 0.1, chloroform).

Anal. Calcd. for $C_{15}H_{12}O_7$: C, 59.21; H, 3.98; O, 36.81. Found: C, 58.90; H, 4.20; O, 37.10.

1,6-Diacetoxy-5,8-diketo-7-methoxy-3-(2′-hydroxypropyl)-2-naphthoic Acid δ-Lactone (5b)

Compound **5***a* (50 mg) was dissolved in pyridine (1 ml) and acetic anhydride (6 ml) added. The mixture was stirred overnight at room temperature and then poured on ice chips to destroy excess acetic anhydride. The yellow precipitate (45 mg) was filtered and crystallized from a methylene chloride – methanol mixture to give yellow needles, m.p. 169–170°; $[\alpha]_D^{25}$ −256° (*c*, 0.1, chloroform).

Anal. Calcd. for $C_{19}H_{16}O_9$: C, 58.76; H, 4.15; O, 37.08. Found (osmometric mol. wt., 395): C, 58.97; H, 4.35; O, 36.90.

1,6,7-Trimethoxy-5,8-diketo-3-(2′-hydroxypropyl)-2-naphthoic Acid δ-Lactone (5c)

A mixture of compound **5***a* (56 mg), methyl iodide (10 ml), silver oxide (531 mg), and chloroform (20 ml) was refluxed for 30 min. After cooling, the silver oxide was filtered and the filtrate taken to dryness to give a quantitative yield of the dimethyl ether. Crystallization from a chloroform–methanol mixture afforded yellow needles, m.p. 166–168°; $[\alpha]_D^{25}$ −362° (*c*, 0.1, chloroform).

Anal. Calcd. for $C_{17}H_{16}O_7$: C, 61.44; H, 4.85; O, 33.70. Found (osmometric mol. wt., 340): C, 61.32; H, 4.86; O, 33.75.

1,6,7-Trimethoxy-5,8-diacetoxy-3-(2′-hydroxypropyl)-2-naphthoic Acid δ-Lactone (6)

A mixture of the dimethyl ether (**5***c*) (12.5 mg), acetic anhydride (4.5 ml), pyridine (0.5 ml), and zinc dust (236 mg) was stirred at room temperature for 5 h. The solution was filtered and the precipitate washed with methylene chloride. The filtrate and washings were combined and after removing the methylene chloride *in vacuo*, ice chips were added. When the ice had melted the resulting aqueous solution was extracted with methylene chloride. The organic phase was washed with 5% aqueous hydrochloric acid and water. After the solvent was evaporated the crude extract was separated by t.l.c. on silica gel G, (benzene–acetone, 4:1). The major band (R_f 0.50) was eluted with chloroform and crystallized from an ether–chloroform mixture, m.p. 168–170° (decomp.); $[\alpha]_D^{25}$ −198° (*c*, 0.1, chloroform).

Anal. Calcd. for $C_{21}H_{22}O_9$: C, 60.28; H, 5.30. Found: C, 60.32; H, 5.48.

Oxidation of 1,6,7-Trimethoxy-5,8-diketo-3-(2′-hydroxypropyl)-2-naphthoic Acid δ-Lactone (5c)

The dimethyl ether **5***c* (20 mg) was oxidized with potassium permanganate using the method described for the oxidation of **3***a*. After the usual work-up, methylation of the crude extract with diazomethane gave anisole-2,3,5,6-tetra-carboxylic acid tetramethyl ester which was identified by comparison of its g.l.c. and t.l.c. behavior with an authentic sample.

Methyl Ester of Floccosic Acid

Floccosic acid (100 mg) was dissolved in methanol (10 ml), and a slight excess of diazomethane in ether was added. The mixture was allowed to stand for 10 min and was then evaporated to dryness. The methyl ester was obtained in quantitative yield; it was crystallized from methanol, m.p. variable, 160–180°.

Anal. Calcd. for $C_{15}H_{14}O_7$: C, 58.82; H, 4.58; O, 36.30. Found: C, 58.72; H, 4.80.

Distribution of substituent groups in *O*-(2-aminoethyl)cellulose

E. J. ROBERTS AND S. P. ROWLAND

Southern Regional Research Laboratory, Southern Utilization Research and Development Division, Agricultural Research Service, United States Department of Agriculture, New Orleans, Louisiana

Received June 17, 1968

O-(2-Aminoethyl)cellulose (degree of substitution 0.14), prepared by reaction of sodium 2-aminoethyl sulfate with cotton fabric, was hydrolyzed to glucose and mono-*O*-(2-aminoethyl)-D-glucopyranoses which were identified by gas–liquid chromatography (g.l.c.). Complications arise from reactions between the functional group at C-1 of the glucose unit and the amine function of a substituent. The distribution of 2-aminoethyl substituents in the 3-*O*- and 6-*O*-positions of the D-glucopyranosyl units of cotton cellulose was estimated to be 0.20:1.00 from direct analysis of the hydrolyzate of *O*-(2-aminoethyl)cellulose, but the total substitution in the 2-*O*-position could not be estimated in this manner. The ratio of substituents in the 2-*O*-, 3-*O*-, and 6-*O*-positions was found to be 0.64:0.14:1.00 when the amino groups were converted to hydroxyl groups by diazotization, and the distribution was estimated in terms of the 2-hydroxyethyl substituents. It has been observed that a substantial fraction (57.5%) of the 2-*O*-(2-hydroxyethyl)-D-glucose from the chemically modified cellulose exists in the form of the inner glucosides. Several new monosubstituted glucoses have been prepared and characterized by g.l.c. for this purpose.

Canadian Journal of Chemistry, 47, 1571 (1969)

Introduction

Development of an understanding of the chemistry of the hydroxyl groups of the D-glucopyranosyl units of cotton cellulose is dependent upon a knowledge of the relative reactivities of these hydroxyl groups toward a variety of reagents. In this regard, but also in connection with the characterization of the products from reaction of cellulose with *tris*-(1-aziridinyl)phosphine oxide, we have been interested in the reaction of cellulose with sodium 2-aminoethyl sulfate and the distribution of the resulting substituents at the 2-*O*-, 3-*O*-, and 6-*O*-positions of the D-glucopyranosyl units.

In previous publications, we have delineated the distribution of *O*-[2-(diethylamino)ethyl] substituents in the D-glucopyranosyl residues of chemically modified cellulose (1, 2) and starch (2). This paper describes the relative distribution of substituent groups resulting from the related rate-controlled reaction of sodium 2-aminoethyl sulfate with cotton cellulose. The unambiguous approach to the identification of the hydrolysis products of the modified cotton by chromatographic comparison with authentic glucose derivatives has been employed.

Experimental

Gas–Liquid Chromatography

The gas–liquid chromatograms (g.l.c.) were obtained with an Aerograph model 1520 instrument equipped with a hydrogen flame ionization detector. The column was based on a solid phase of acid-washed, dimethyldichlorosilane-treated Chromosorb W of 60–80 mesh obtained from Johns-Manville Corporation. The liquid phase consisted of SE-30 from Wilkins Instrument and Research Incorporated. The column was prepared in a $\frac{1}{8}$ in. outer diameter tube, 5 ft in length; it carried a 5% liquid phase and was operated isothermally at 185 and 190° with a carrier gas flow of 20 ml/min and an inlet pressure of 65 p.s.i. Similar columns with liquid phases of QF-1 and XE-60 were investigated but these did not give as good separations of *O*-(2-aminoethyl)-D-glucopyranoses and the *O*-(2-hydroxyethyl)-D-glucopyranoses as the SE-30 column. All samples to be analyzed were equilibrated overnight in dry pyridine before conversion to the trimethylsilyl ethers (3).

Preparation of O-(2-Aminoethyl)cellulose

Scoured and bleached 48 × 48 cotton sheeting was padded with a solution prepared by dissolving 20 parts by weight of 2-aminoethylsulfuric acid in 80 parts of a 37.5% solution of sodium hydroxide. The wet pick-up was adjusted to 159%. The fabric was heated at 130° for 15 min on steam-heated rotating cans. The treated fabric was washed with cold water and then with hot (85°) water; this was followed by rinsing with dilute acetic acid, dilute ammonium hydroxide, and finally with water. The fabric was dried on a tenter frame; it contained 0.64% nitrogen corresponding to a degree of substitution of 0.075, at this stage. The fabric was subjected to a second treatment in exactly the same manner; the finished product contained 1.20% nitrogen, corresponding to a degree of substitution of 0.14.

Diazotization of O-(2-Aminoethyl)cellulose

Ten grams of *O*-(2-aminoethyl)cellulose ground in the Wiley Mill to pass a 20-mesh screen was suspended in 150 ml of a 20% solution of sodium hydroxide and stirred for 30 min. The swollen chemically modified cellulose was removed by filtration and was washed several times with water to remove the sodium hydroxide. It was then suspended in 300 ml of 20% acetic acid; 10 g of sodium nitrite were added slowly and stirring was maintained for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1.5 h. The diazotized modified cellulose was isolated by filtration and was washed free of acidity with water prior to air drying. The sample of diazotized cellulose contained 0.34% nitrogen.

Hydrolysis of O-(2-Aminoethyl)cellulose or Diazotized O-(2-Aminoethyl)cellulose

Five grams of the chemically modified cellulose were hydrolyzed with sulfuric acid by the three-step process of Hägglund (4) as modified by Zollinger (5). The sulfuric acid was removed with barium hydroxide and the solution was concentrated and freeze-dried. The nitrogen content of the hydrolyzate was 1.10%; the yield was 4.9 g. The nitrogen content of the hydrolyzate from diazotized *O*-(2-aminoethyl)cellulose was 0.2%; the yield was 4.8 g.

Synthesis of 2-O- , 3-O- , and 6-O-(2-Aminoethyl)-D-glucopyranoses, 3-O-[N-(2-Aminoethyl)-2-aminoethyl]-D-glucopyranose, and 2-O- , 3-O- , and 6-O-(2-Hydroxyethyl)-D-glucopyranoses

The glucose derivatives were prepared by the conventional method of blocking all hydroxyl groups except that for the desired substituent. Since the *O*-aminoethyl substituents were introduced under alkaline conditions, the blocking groups had to be stable to alkali and to be easily removable after introduction of the substituent groups.

The sulfuric acid used in the hydrolysis of the blocking groups was removed by adding barium hydroxide to pH 10–11 to insure the presence of free basic amine groups in the *O*-(2-aminoethyl)-D-glucopyranoses. The excess barium ions were precipitated by carbon dioxide and the solutions were decolorized with Darco carbon G-60. The filtrates were concentrated under reduced pressure and the products were freeze-dried.

All of the *O*-(2-aminoethyl)-D-glucopyranoses and some of the intermediate compounds were amorphous solids that did not crystallize. The intermediates were therefore purified by crystallization at the last possible step in the synthesis before removal of the blocking groups. Some of the derivatives contain impurities due to small amounts of side reaction or slightly incomplete reaction in the last stage of the syntheses. However, the compounds are considered to be authentic derivatives since they were prepared by unambiguous methods.

Methyl 3-O-Benzyl-4,6-O-benzylidene-2-O-carbethoxymethyl-α-D-glucopyranoside

To 25 g (0.067 mole) of chromatographically pure methyl 3-*O*-benzyl-4,6-*O*-benzylidene-α-D-glucopyranoside (1) in 500 ml of dry dioxane were added 2.4 g (0.1 mole) of sodium hydride. After a 16-h period at room temperature (with stirring), 13 g (0.067 mole) of ethyl bromoacetate were added. An additional 13 g (0.067 mole) of ethyl bromoacetate was added after 4 h of stirring. Gas–liquid chromatographic analysis of the reaction mixture after 16 h at room temperature showed that the reaction was complete. The solid was removed by filtration and was washed with dioxane. The combined filtrate and washings were evaporated to a syrup. The syrup was dissolved in 200 ml of ether and washed twice with water. The ether solution was dried with sodium sulfate and evaporated, yielding 27 g (87% of theory) of white needles. After three crystallizations from methanol, 22.5 g of the pure product, m.p. 99–101°, were obtained. The product showed a single peak in g.l.c. with the SE-30 column operated isothermally at 250°.

Anal. Calcd. for $C_{25}H_{30}O_8$: C, 65.48; H, 6.58. Found: C, 65.39; H, 6.47.

Methyl 3-O-Benzyl-4,6-O-benzylidene-2-O-carbamoylmethyl-α-D-glucopyranoside

Methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-*O*-carbethoxymethyl-α-D-glucopyranoside, 20 g (0.044 mole) were dissolved in 800 ml of absolute ethanol which was saturated with ammonia. The solution was stirred at room temperature for 4 h and the alcohol was evaporated under reduced pressure, yielding 18 g (98% of theory) of white microscopic needles melting at 176–180°. After two crystallizations from methanol the m.p. was 180–183°. Neither the amide nor its trimethylsilyl derivative could be eluted from the SE-30 column at 250°.

Anal. Calcd. for $C_{23}H_{26}O_7N$: C, 64.33; H, 6.29; N, 3.26. Found: C, 64.10; H, 6.27; N, 3.21.

Methyl 2-O-(2-Aminoethyl)-3-O-benzyl-4,6-O-benzylidene-α-D-glucopyranoside

To a solution of 15 g (0.036 mole) of methyl 3-*O*-benzyl-4,6-benzylidene-2-*O*-carbamoylmethyl-α-D-glucopyranoside in 300 ml of dry tetrahydrofuran were slowly added 2.8 g (0.072 mole) of lithium aluminium hydride. After stirring overnight at room temperature, the excess lithium aluminium hydride was destroyed by cautious addition of wet tetrahydrofuran. The solid was removed by filtration and was washed with tetrahydrofuran. The combined filtrate and washings were evaporated, yielding 14 g (95% of theory) of a white waxlike solid.

2-O-(2-Aminoethyl)-D-glucopyranose

Methyl 2-*O*-(2-aminoethyl)-3-*O*-benzyl-4,6-*O*-benzylidene-α-D-glucopyranoside, 14 g (0.034 mole), was dissolved in 200 ml of ethanol and 1.5 g of 10% palladium/carbon, together with 25 ml of 2 *N* sulfuric acid (essential for hydrogenolysis), were added. The solution was shaken under a slight positive hydrogen pressure at room temperature until the theoretical amount of hydrogen (3 moles) was absorbed (about 4 h). This removed the benzyl and benzylidene groups. The catalyst was removed by filtration and the solution was evaporated under reduced pressure to a residual volume of 30 ml. Sulfuric acid (75 ml, 2 *N*) was added and the solution was refluxed for 16 h. The sulfuric acid was removed with barium hydroxide; the solution was decolorized with Darco G-60 carbon and was evaporated to a volume of about 25 ml. This solution was freeze-dried, yielding 6.4 g (85% of theory) of tan, highly viscous syrup. Gas–liquid chromatography of the trimethylsilylated product on the SE-30 column operated isothermally at 185° showed two peaks (designated 2 in Fig. 1) as expected for the two anomers of 2-*O*-(2-aminoethyl)-D-glucopyranose. Three additional peaks, one designated 2″ and two designated 2′, were also present. These are considered to be the inner *N*-glucosyl derivative of the 2-*O*-(2-aminoethyl)-α-D-glucofuranose and the two anomeric forms of the inner *N*-glucosyl derivative of 2-*O*-(2-aminoethyl)-D-glucopyranose by analogy to the results obtained for 2-*O*-(2-hydroxyethyl)-D-glucose (6, 7).

3-O-(2-Aminoethyl)-D-glucopyranose

3-*O*-(2-Aminoethyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose, 2 g (0.0066 mole), prepared by the pro-

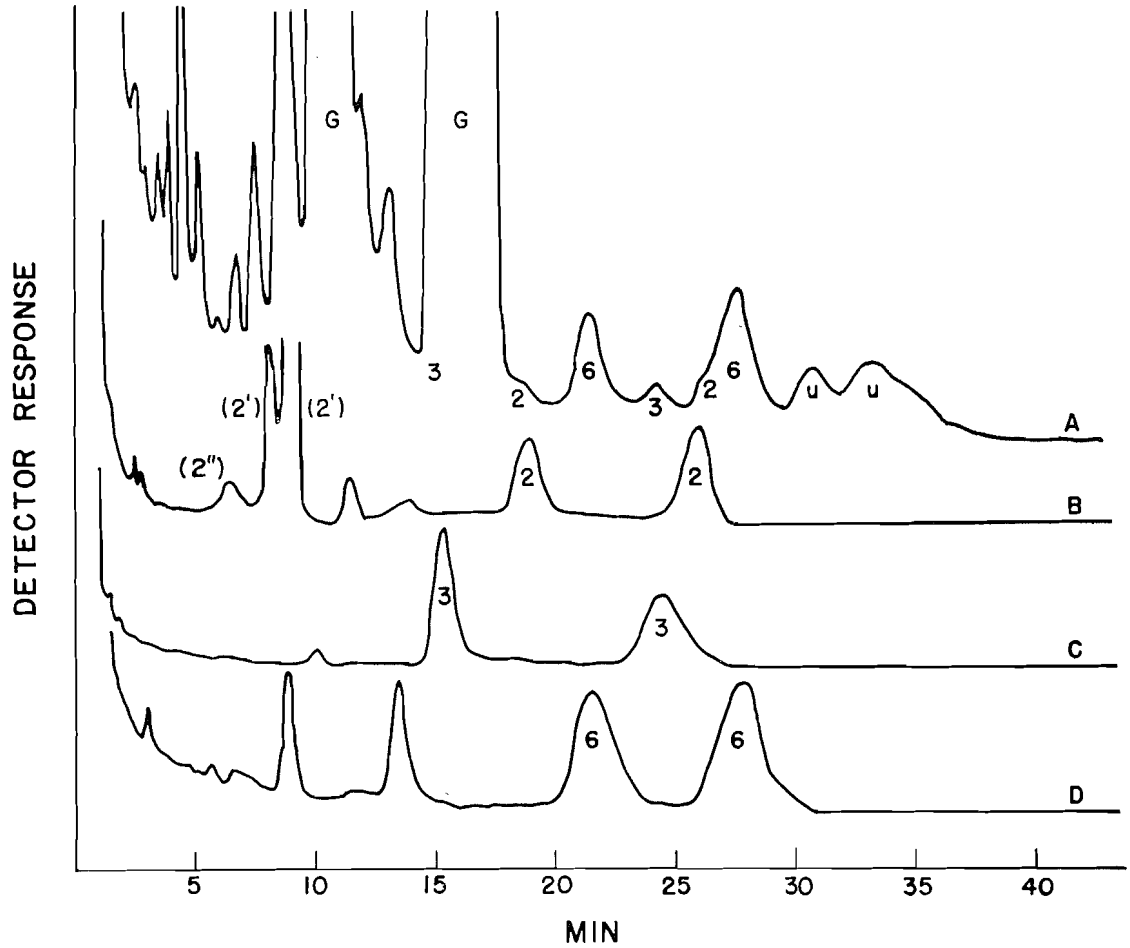

FIG. 1. Chromatograms of trimethylsilyl derivatives on an SE-30 column operated isothermally at 185°. Curve A is the hydrolyzate of *O*-(2-aminoethyl)cellulose; Curve B is 2-*O*-(2-aminoethyl)-D-glucopyranose; Curve C is 3-*O*-(2-aminoethyl)-D-glucopyranose; and Curve D is 6-*O*-(2-aminoethyl)-D-glucopyranose. Peaks labeled G are the anomers of glucose. The peaks designated 2″ and 2′ are believed to be the inner *N*-glucosyl forms of the 2-*O*-(2-aminoethyl)-D-glucose. Peaks designated U are unknowns.

cedure described by Corbett (8) was refluxed in 50 ml of 1 *N* sulfuric acid for 16 h. The sulfuric acid was removed with barium hydroxide and the solution was concentrated and freeze-dried, yielding 1.4 g (70% of theory) of tan, hygroscopic, amorphous solid. Gas–liquid chromatography of the trimethylsilylated derivative on the SE-30 column operated isothermally at 185° showed only the anomeric peaks for the 3-*O*-(2-aminoethyl)-D-glucopyranose (Fig. 1).

6-O-Carbamoylmethyl-1,2;3,5-di-O-methylene-α-D-glucofuranose

6-*O*-Carbomethoxymethyl-1,2;3,5-di-*O*-methylene-α-D-glucofuranose, 15 g (0.061 mole), (chromatographically pure) prepared by the procedure of Shyluk and Timell (9) was suspended in 400 ml of concentrated ammonium hydroxide and was stirred for 4 h at room temperature. The solution was then evaporated under reduced pressure; the product crystallized, yielding 12.8 g (88% of theory) of white needles melting at 127–130°. After recrystallization from methanol, the m.p. was 130–132°. Neither the amide nor its trimethylsilyl derivative could be eluted from the SE-30 column operated isothermally at 185°.

Anal. Calcd. for $C_{10}H_{15}O_7N$: C, 45.97; H, 5.74; N, 5.36. Found: C, 45.90; H, 5.77; N, 5.29.

6-O-(2-Aminoethyl)-1,2;3,5-di-O-methylene-α-D-glucofuranose

6-*O*-Carbamoylmethyl-1,2;3,5-di-*O*-methylene-α-D-glucofuranose, 10 g (0.033 mole), was dissolved in 300 ml of dry tetrahydrofuran and 2.5 g (0.066 mole) of lithium aluminium hydride was added slowly. The mixture was stirred at room temperature for 16 h. The excess lithium aluminium hydride was destroyed by the cautious addition of a 10% solution of water in tetrahydrofuran. The

For personal use only.

solid was removed by filtration and washed with tetrahydrofuran. The combined filtrate and washings were evaporated, yielding 8.4 g (91% of theory) of colorless syrup which did not crystallize.

6-O-(2-Aminoethyl)-D-*glucopyranose*

6-*O*-(2-Aminoethyl)-1,2;3,5-di-*O*-methylene-α-D-glucofuranose, 8.4 g (0.033 mole), were refluxed for 16 h in 100 ml of 1 *N* sulfuric acid. The acid was removed with barium hydroxide. The solution was concentrated and freeze-dried yielding 4.8 g (74% of theory) of tan, amorphous solid. Gas–liquid chromatography of the trimethylsilylated derivative on the SE-30 column operated isothermally at 185°, showed two expected anomeric peaks for the 6-*O*-(2-aminoethyl)-D-glucose (Fig. 1). Two small peaks were also present. These peaks did not correspond to glucose in retention time and were not identified.

*3-O-[N-(2-Aminoethyl)carbamoylmethyl]-1,2;5,6-di-O-isopropylidene-α-*D-*glucofuranose*

3-*O*-Carbomethoxymethyl-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose, 5 g (0.015 mole) (chromatographically pure) prepared by the method of Shyluk and Timell (9), were dissolved in 5 g (0.083 mole) of freshly distilled ethylenediamine. The solution was allowed to stand at room temperature and after 4 h, g.l.c. showed that the reaction was complete as indicated by the disappearance of the starting compound. The solution was heated at 135° and 50 μ pressure to remove the unreacted ethylenediamine. The product, 5.2 g (94% of theory), was a clear amorphous solid.

*3-O-[N-(2-Aminoethyl)-2-aminoethyl]-1,2;5,6-di-O-isopropylidene-α-*D-*glucofuranose*

To 5.2 g (0.014 mole) of 3-*O*-[*N*-(2-aminoethyl)carbamoylmethyl]-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose in 200 ml of dry ether was added 1.0 g (0.028 mole) of lithium aluminium hydride. After a 16-h period at room temperature with stirring, the excess lithium aluminium hydride was destroyed by the cautious addition of wet ether. The solid was removed by filtration and was washed with ether. The combined filtrate and washings were evaporated yielding 4.5 g (90% of theory) of slightly yellow, clear amorphous solid.

3-O-[N-(2-Aminoethyl)-2-aminoethyl]-D-*glucopyranose*

3-*O*-[*N*-(2-Aminoethyl)-2-aminoethyl]-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose, 4.2 g (0.012 mole), was refluxed for 16 h in 100 ml of 1 *N* sulfuric acid. The sulfuric acid was removed with barium hydroxide. The solution was concentrated to a volume of 20 ml and freeze-dried, yielding 2.2 g (70% of theory) of tan, amorphous solid. Gas–liquid chromatography of the trimethylsilylated derivative, on the SE-30 column operated isothermally at 185°, showed only the two expected anomeric peaks for the glucose derivative.

*Methyl 3-O-Benzyl-4,6-O-benzylidene-2-O-(2-hydroxyethyl)-α-*D-*glucopyranoside*

Methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-*O*-carbethoxymethyl-α-D-glucopyranoside, 2.5 g (0.0055 mole), described above and chromatographically pure, were dissolved in 200 ml of dry ether; 0.4 g (0.011 mole) of lithium aluminium hydride was added and the mixture was stirred for 5 h. The excess lithium aluminium hydride was destroyed by the cautious addition of wet ether. The solid was removed by filtration and was washed with ether. The combined filtrate and washings were evaporated yielding 2.2 g (96% of theory) of white needles. After crystallization from methanol the m.p. was 108–110°.

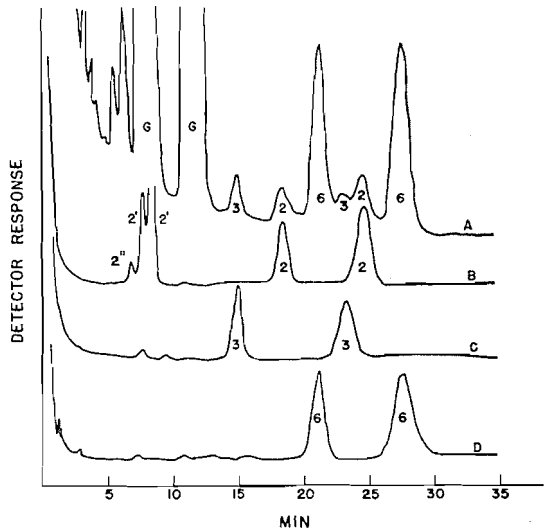

FIG. 2. Chromatograms of trimethylsilyl derivatives on an SE-30 column operated isothermally at 190°. Curve A is the hydrolyzate of diazotized *O*-(2-aminoethyl)cellulose; Curve B is 2-*O*-(2-hydroxyethyl)-D-glucopyranose; Curve C is 3-*O*-(2-hydroxyethyl)-D-glucopyranose; and Curve D is 6-*O*-(2-hydroxyethyl)-D-glucopyranose. Peaks labeled G are the anomers of glucose, and the peaks labeled 2″ and 2′ represent the inner glucosides of 2-*O*-(2-hydroxyethyl)-D-glucose.

2-O-(2-Hydroxyethyl)-D-*glucopyranose*

Methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-*O*-(2-hydroxyethyl)-α-D-glucopyranoside, 2.0 g, was dissolved in 150 ml of ethanol; 1 g of 10% palladium/carbon and 50 ml of 2 *N* sulfuric acid (necessary for hydrogenolysis) were added. The solution was shaken under a slight positive hydrogen pressure until the amount of hydrogen (3 moles) required to remove the benzyl and benzylidene groups was absorbed. The catalyst was removed by filtration and the alcohol was evaporated to a volume of 50 ml. The solution was refluxed for 16 h to hydrolyze the glucoside. The sulfuric acid was removed with barium hydroxide and the solution was concentrated and freeze-dried, yielding 1.0 g (85% of theory) of white amorphous solid. Gas–liquid chromatography of the trimethylsilylated derivative on the SE-30 column operated isothermally at 190° showed two anomeric peaks for the 2-*O*-(2-hydroxyethyl)-D-glucopyranose (designated 2 in Fig. 2). Three additional peaks, one designated 2″ and two designated 2′, with shorter retention times than the anomers of 2-*O*-(2-hydroxyethyl)-D-glucopyranose were also present. The peak designated 2″ was shown to be 1,2-*O*-ethylene-α-D-glucofuranose, the first peak labelled 2′ was shown to be 1,2-*O*-ethylene-β-D-glucopyranose, and the second peak labelled 2′ was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

shown to be 1,2-*O*-ethylene-α-D-glucopyranose (6). Hook and Lindberg (7) showed that the anomeric 2-*O*-(2-hydroxyethyl)-D-glucopyranoses are converted to the three inner glucosides noted above by heating in dilute acid solution.

3-O-(2-Hydroxyethyl)-D-glucopyranose

This derivative was prepared by lithium aluminium hydride reduction of 4.0 g of chromatographically pure 3-*O*-carbomethoxymethyl-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose by the procedure of Shyluk and Timell (9). The isopropylidene groups were removed by hydrolysis. Gas–liquid chromatography of the trimethylsilyl derivatives of the freeze-dried sample on the SE-30 column operated isothermally at 190° showed only the anomeric peaks for 3-*O*-(2-hydroxyethyl)-D-glucopyranose (Fig. 2).

6-O-(2-Hydroxyethyl)-D-glucopyranose

This derivative was prepared by reduction of 4 g of chromatographically pure 6-*O*-carbomethoxymethyl-1,2;3,5-di-*O*-methylene-α-D-glucofuranose with lithium aluminium hydride by the method of Shyluk and Timell (9). The methylene groups were removed by hydrolysis and the product was freeze-dried. Gas–liquid chromatography of the trimethylsilylated derivative on the SE-30 column operated isothermally at 190° showed only the two anomeric peaks of 6-*O*-(2-hydroxyethyl)-D-glucopyranose (Fig. 2).

Conversion of 6-O-(2-Aminoethyl)-D-glucopyranose to 6-O-(2-Hydroxyethyl)-D-glucopyranose by Diazotization

6-*O*-(2-Aminoethyl)-D-glucopyranose, 1.0 g (0.0045 mole) was dissolved in 100 ml of 20% acetic acid; 5.0 g (0.072 mole) of sodium nitrite was added slowly and stirring was maintained for 1.5 h. The solution was then concentrated below 50° and was freeze-dried. Silylation and g.l.c. of the freeze-dried product showed only a trace of the peaks corresponding to the original 6-*O*-(2-aminoethyl)-D-glucopyranose and showed pronounced peaks corresponding to 6-*O*-(2-hydroxyethyl)-D-glucopyranose. The new peaks represented a 79.5% conversion of the starting material to product, assuming the detector response of the two compounds to be equal. No additional peaks resulting from the diazotization were detected.

Removal of Glucose from Hydrolyzed O-(2-Hydroxyethyl)cellulose by Fermentation

One gram of the hydrolyzate of diazotized *O*-(2-aminoethyl)cellulose was dissolved in 25 ml of water. The pH was adjusted to 4.5 with acetic acid and 0.5 g of brewers yeast was added. After 24 h, the glucose had been consumed. The yeast was removed by filtration. The filtrate was concentrated below 50°. Silylation and g.l.c. of a sample of the freeze-dried product showed three peaks (one designated 2″ and two designated 2′ in Fig. 2) corresponding to the inner glucosides of 2-*O*-(2-hydroxyethyl)-α-D-glucofuranose and 2-*O*-(2-hydroxyethyl)-D-glucopyranose (α+β) in addition to peaks for 2-*O*-, 3-*O*-, and 6-*O*-(2-hydroxyethyl)-D-glucopyranoses. The three peaks representing the inner glucosides amounted to 57.5% of the total 2-*O*-(2-hydroxyethyl)-D-glucoses. The peaks for the inner glucosides are hidden under the first glucose peak in the original hydrolyzate (i.e., prior to removal of the glucose).

Results

Syntheses of 2-O-, 3-O-, and 6-O-Substituted-D-glucopyranoses

The identification of the various components in the hydrolyzates from *O*-(2-aminoethyl)cellulose necessitated the preparation of three types of monosubstituted-glucopyranoses: (*a*) 2-*O*-, 3-*O*-, and 6-*O*-(2-aminoethyl)-D-glucopyranoses, (*b*) 3-*O*-[*N*-(2-aminoethyl)-2-aminoethyl]-D-glucopyranose, and (*c*) 2-*O*-, 3-*O*-, and 6-*O*-(2-hydroxyethyl)-D-glucopyranoses. Three of these compounds, 2-*O*-(2-aminoethyl)-D-glucopyranose, 6-*O*-(2-aminoethyl)-D-glucopyranose, and 3-*O*-[*N*-(2-aminoethyl)-2-aminoethyl]-D-glucopyranose, were prepared for the first time but the routes and the reactions are conventional. The preparation of the known derivatives is illustrated in the case of the 3-*O*-substituted-D-glucopyranoses in Fig. 3. With few exceptions, the intermediates as well as the final products were hygroscopic and amorphous. Recoveries of crude products from each step were above 70%; in spite of our inability to purify the intermediates at each step in the synthesis, the final products have generally been remarkably free of impurities as measured by g.l.c.

Chromatograms of the trimethylsilyl derivatives of the mono-*O*-(2-aminoethyl)-D-glucopyranoses are shown in Fig. 1, and the curves for the trimethylsilyl derivatives of mono-*O*-(2-hydroxyethyl)-D-glucopyranoses are shown in Fig. 2. Both of the 2-*O*-substituted-D-glucopyranoses contained extra components. These components of the 2-*O*-(2-aminoethyl)-D-glucopyranose, by analogy to the results from the corresponding 2-hydroxyethyl compound (6, 7), are considered to be the inner *N*-glucosyl amines resulting from the reactions of the functional groups at C-1 with the amine group of the 2-aminoethyl substituent at C-2.

The relative retention values for the mono-*O*-substituted-D-glucopyranoses in g.l.c. are summarized in Table I. The ratios of anomers of the individual glucose derivatives (in the form of the trimethylsilyl ethers) are summarized in Table II. For a specific substitution isomer of glucose, these ratios are essentially constant for these substituted glucoses and for the *O*-[2-(diethyl-

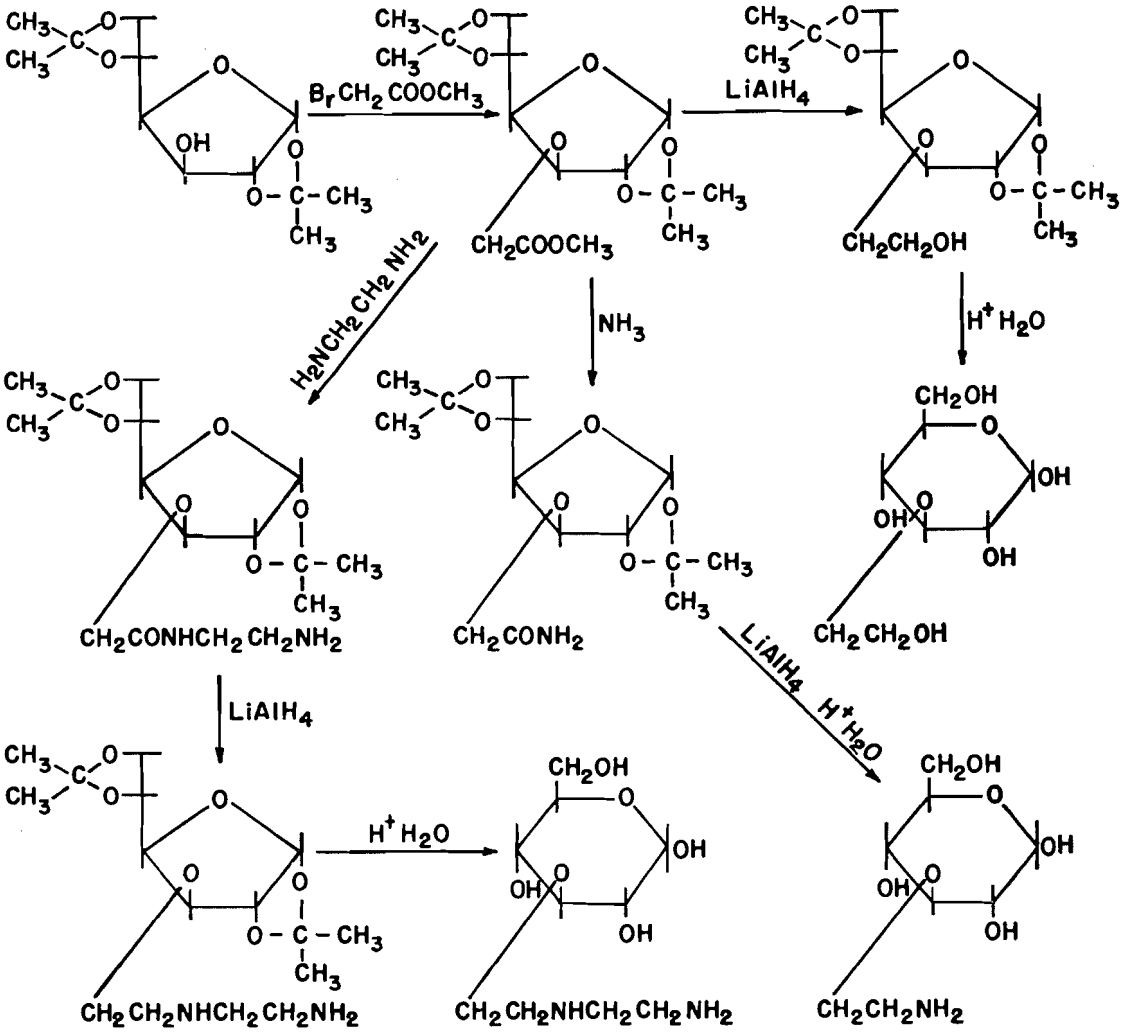

FIG. 3. Schematic illustration of the preparation of the three types of substituted glucoses using the 3-*O*-derivatives as an example.

amino)ethyl]-D-glucopyranoses[1] (1) and are quite similar to those of the *O*-(methylsulfonylethyl)-D-glucopyranoses (10) which have been reported earlier.

Determination of Aminoethyl Substituents in O-(2-Aminoethyl)cellulose

O-(2-Aminoethyl)cellulose, which was prepared by double treatment of cotton fabric with sodium 2-aminoethyl sulfate in the presence of excess base at 130°, was hydrolyzed with sulfuric acid to a mixture of glucose and *O*-(2-aminoethyl)-D-glucopyranoses. This hydrolyzate was converted to the corresponding trimethylsilyl ethers and was analyzed by g.l.c. which showed the presence of the 2-*O*- , 3-*O*- , and 6-*O*-(2-aminoethyl)-D-glucopyranoses (see Fig. 1). These were identified by comparison of retention times and by peak enhancement with the corresponding known derivatives. The first anomers of the 2-*O*- and 3-*O*-isomers were hidden beneath the second peak of glucose; the second peak of the 2-*O*-isomer was not well separated from the second peak of the 6-*O*-isomer. Several columns were investi-

gated; the SE-30 column gave the most satisfactory separations.

Two peaks, designated U in Curve A of Fig. 1, with greater retention times than the second peak of the 6-*O*-isomer were present in the hydrolyzate. The possibility that these peaks represented *O*-[*N*-(2-aminoethyl)-2-aminoethyl]-D-glucopyranoses was examined by comparison of the mobility of 3-*O*-[*N*-(2-aminoethyl)-2-aminoethyl]-D-glucopyranose with that of the components of hydrolyzed *O*-(2-aminoethyl)cellulose on paper electrophoresis in 0.75 *M* formic acid (2). Individual position isomers are not separated by electrophoresis under these conditions. No evidence was found for the presence of *O*-[*N*-(2-aminoethyl)-2-aminoethyl]-D-glucopyranoses in the hydrolyzate. The nonidentity was further verified by g.l.c.

Paper electrophoresis of the hydrolyzate showed the presence of a component which exhibited characteristics of a reducing sugar and an amine and which had a lower mobility than *O*-(2-aminoethyl)-D-glucopyranose. This suggests that we are dealing with a molecule which is larger than *O*-(2-aminoethyl)-D-glucopyranose but which contains no more amino groups. It is believed that this component corresponds to the peaks designated U in Curve A of Fig. 1 and that it represents a mixture of *N*-glucosyl-(2-aminoethyl)-D-glucopyranoses. Compounds of this type arise from facile reaction of sugars with amines (11, 12).

Three difficulties were encountered in attempts to determine the ratio of 2-aminoethyl substituents in the 2-*O*-, 3-*O*-, and 6-*O*-positions of the D-glucopyranosyl units. The first difficulty, already noted above, was the inability to realize better separation in g.l.c. than those illustrated in Fig. 1. Removal of the preponderance of free glucose, the second difficulty, could not be achieved by fermentation without simultaneous destruction of the substituted glucoses; however, *O*-[2-(diethylamino)ethyl]-D-glucopyranoses were not attacked by fermentation. The third difficulty concerned reproducibility of results from one to another hydrolyzate of the *O*-(2-aminoethyl)cellulose. The question of stability of the ether linkage between the aminoethyl substituent and the glucose unit was settled by showing in electrophoresis (0.75 *M* formic acid) that 3-*O*-(2-aminoethyl)-D-glucopyranose was recovered and that no trace of glucose or ethanolamine was formed when the substituted glucose was subjected to the same conditions employed for hydrolysis of the *O*-(2-aminoethyl)cellulose. A significant change did occur, however, as a result of the strenuous conditions of hydrolysis applied to 3-*O*-(2-aminoethyl)-D-glucopyranose. There

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was formed a component whose mobility in electrophoresis was greater than that of the substituted glucose and which was not eluted in g.l.c. These data are consistent with the formation of material of higher molecular weight, i.e., reaction of the functional group at C-1 of an *O*-(2-aminoethyl)-D-glucopyranose with the amino function of another unit. Reactions of this type are known (11, 12) and occur to extents which are dependent upon the specific conditions of reaction and concentrations of the media (13). In connection with this third difficulty, it is concluded that the inconsistencies in the results obtained with different hydrolyzates resulted from varying degrees of reaction of glucose with the amino functions of substituent groups.

One of the more satisfactory chromatograms of a hydrolyzate of an *O*-(2-aminoethyl)cellulose (in the form of its trimethylsilyl ether) is reproduced in Fig. 1. By taking full advantage of (*a*) the resolution of a single anomer of each of the 2-*O*- and 3-*O*-substituted glucoses into distinctly separate peaks, (*b*) the established ratio of anomers in the individual substituted glucoses (Table II), and (*c*) a computer-curve analyzer, the ratio of peaks for substitution in the 2-*O*- , and 3-*O*- , and 6-*O*-positions was estimated to be 0.25:0.20:1.00. This ratio takes only the normal form of the 2-*O*-(2-aminoethyl)-D-glucopyranose into consideration, since the peaks which are believed to represent the inner *N*-glucosyl forms are hidden under the glucose peaks. Assuming that the ratio of inner *N*-glucosyl forms to normal form of the 2-*O*-(2-aminoethyl)-D-glucopyranose is the same in the hydrolyzate of *O*-(2-aminoethyl)cellulose as in the synthesized 2-*O*-(2-aminoethyl)-D-glucopyranose, this ratio becomes 0.83:0.20:1.00.

Determination of Hydroxyethyl Substituents in Diazotized O-(2-Aminoethyl)cellulose

It was found that diazotization of the alkali-swollen, Wiley-milled *O*-(2-aminoethyl)cellulose eliminated most of the nitrogen from the chemically modified cellulose and converted the 2-aminoethyl groups to 2-hydroxyethyl groups. Due to the questionable results obtained with hydrolyzed *O*-(2-aminoethyl)cellulose, it was expedient to determine the distribution of 2-aminoethyl groups in terms of 2-hydroxyethyl groups.

Diazotization of a sample of 6-*O*-(2-aminoethyl)-D-glucopyranose under conditions identical to those employed in the diazotization of the *O*-(2-aminoethyl)cellulose showed that the 6-*O*-(2-aminoethyl)-D-glucopyranose was converted to 6-*O*-(2-hydroxyethyl)-D-glucopyranose in 79.5% yield as determined by g.l.c.

The nitrogen content of 1.20% in *O*-(2-aminoethyl)cellulose was reduced to 0.34% by diazotization. Hydrolysis of the diazotized *O*-(2-aminoethyl)cellulose yielded a product containing 0.20% nitrogen. The residual nitrogen remaining after diazotization and hydrolysis is believed to result from the reaction of carbonyl groups (formed during the reaction of the cellulose with the sodium 2-aminoethyl sulfate) with amino groups. The Schiff bases which are formed (14) are not eliminated by diazotization. This will be described in detail in a subsequent paper.

Gas–liquid chromatography of the trimethylsilyl derivatives of the hydrolyzate from diazotized *O*-(2-aminoethyl)cellulose showed the presence of the 2-*O*- , 3-*O*- , and 6-*O*-(2-hydroxyethyl)-D-glucopyranoses. Good separations were realized on the SE-30 column without removal of the large amount of glucose present (Fig. 2). The glucose derivatives in the hydrolyzate were identified by comparison of retention times and peak enhancement with authentic known derivatives. The second peak of the 3-*O*-isomer was not completely separated from the first peak of the 6-*O*-isomer. The ratio of the anomers of the 3-*O*-isomer (see Table II) was utilized to calculate the area of the second peak of this isomer. The ratios of the areas of the peaks of the 2-*O*- , 3-*O*- , and 6-*O*-isomers in the hydrolyzate were calculated by triangulation on three chromatograms and were found to be 0.27, 0.26, 0.28:0.13, 0.13, 0.15:1.00, 1.00, 1.00 for the 2-*O*- , 3-*O*- , and 6-*O*-isomers. Average values are 0.27:0.14:1.00; this ratio takes into consideration only the normal form of the 2-*O*-(2-hydroxyethyl)-D-glucopyranose since the peaks of the inner glucosides are hidden under the peaks of glucose.

It was necessary to remove the glucose from the hydrolyzate (by fermentation) in order to obtain a measure of the inner glucosides of the 2-*O*-substituted glucose. Gas–liquid chromatography of the product (after fermentation, freeze-drying, and silylation) showed that 57.5% of the 2-*O*-(2-hydroxyethyl)-D-glucopyranose was in the form of the inner glucosides. By considering all forms of the 2-*O*-(2-hydroxyethyl)-D-glucose in the hydrolyzate-fermentate, the distribution of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

substituent groups was estimated to be 0.64:0.14:1.00 for the 2-*O*-, 3-*O*-, and 6-*O*-isomers.

Discussion

The etherification of cellulose with sodium 2-aminoethyl sulfate is a rate-controlled (irreversible) reaction. This is one of the few rate-controlled reactions of cellulose in which the substitution predominates at the 6-*O*-position. In this regard, the distribution of 2-aminoethyl substituents lies between those of the allyl group and the 2-hydroxyethyl group.[2] It has been pointed out that the preferential reaction of the hydroxyl group at C-2 decreases as the size of the reagent molecule increases (21, 22). The data of Table III show a progressive decrease in the relative amount of substitution at the 2-*O*-position in proceeding from methyl chloride to ethyl chloride to 2-diethylaminoethyl chloride. Comparison of the results from the reactions of cellulose with methyl chloride and dimethyl sulfate suggests that the distribution is affected by the size of the leaving group of the reagent as well as that of the entering group. These and other considerations of the data in Table III emphasize that steric factors play an important role in these reactions.

TABLE III

Distribution of substituents in cellulose ethers prepared by rate-controlled reactions

Reagent	Ratio of substituents 2-*O*-	3-*O*-	6-*O*-	Reference
Sodium 2-aminoethyl sulfate	0.64	0.14	1.00	—
2-Diethylaminoethyl chloride	1.27	0.35	1.00	1
Methyl chloride	2.50	0.50	1.00	15
Dimethyl sulfate	1.75	0.50	1.00	16
Ethyl chloride	2.25	0.50	1.00	17
Sodium allyl sulfate	0.70	0.20	1.00	18
Sodium chloroacetate	0.80	0.40	1.00	19
Ethylene oxide	0.30	0.10	1.00	20

The aminoethylation of cellulose via sodium 2-aminoethyl sulfate and the methylation of cellulose via sodium methyl sulfate occur with similar sluggishness, both reactions requiring strong base and elevated temperature (23). In contrast, the diethylaminoethylation of cellulose via 2-(diethylamino)ethyl chloride proceeds readily with strong base at room temperature (1). The latter reaction is considered to be facilitated by intermediate formation of the diethylenimmonium ion (1, 24). While ethylenimine is formed under the conditions employed for aminoethylation of cellulose, our attempts and those of others (23, 25, 26) to realize reaction between ethylenimine and cellulose (under conditions comparable to those involving sodium 2-aminoethyl sulfate) in the presence of strong base have been generally unsuccessful. Under pressure at elevated temperature in the presence of cellulose, ethylenimine undergoes a reaction; it has been suggested that polyethylenimine is deposited in the fibers under these conditions (much of the pertinent work has been summarized briefly by Segal and Eggerton (25) and by Einsele (26)). The similarity between reactions of cellulose with sodium 2-aminoethyl sulfate and sodium methyl sulfate is basis for belief that these are bimolecular substitution reactions proceeding by a similar mechanism; i.e., little or no participation of the amino group in the case of the reaction of sodium 2-aminoethyl sulfate.

The foregoing mechanistic consideration is consistent with the substantially different distributions of substituents at the 2-*O*-, 3-*O*-, and 6-*O*-positions which resulted from aminoethylation and diethylaminoethylation. The former reaction would be subject to the greater steric effect and would be expected to show increased preference for substitution at the 6-*O*-position.

[2]It should be noted, however, that the distribution of 2-hydroxyethyl substituents resulting from reaction of cellulose with ethylene oxide may need revision if the inner glucosides were present and were not measured in the analysis of product.

NOTES

Reactions of hydrazines with phosphate esters

JAN H. VIS AND PHYLLIS MEINKE

The Standard Oil Company (Ohio), Research and Development Department, Broadway Laboratory, Cleveland, Ohio

Received July 15, 1968

Phosphate esters with the general formula $(RO)_2P(O)OR'$, with R = methyl or phenyl, and R′ = H, methyl, or phenyl, but with a maximum of two phenyls per molecule, react with hydrazines to form hydrazinium phosphates. Continued substitution of hydrazine protons by methyl groups appears to be a combination of methylation by phosphate esters and proton abstraction by part of the hydrazine present.

Canadian Journal of Chemistry, 47, 1581 (1969)

The reactions of phosphate esters with various types of compounds, including alkyl- and arylhalides, alcohols, and amines have been studied extensively (1–4). However, little attention has been paid to their reactions with hydrazines. Klages *et al.* (5) reported the formation of a quaternary hydrazine salt from the exothermic reaction of *unsym*-dimethylhydrazine and trimethyl phosphate. Similar salts were obtained in low yield by reacting *unsym*-dimethylhydrazine and some organic esters under special temperature and pressure conditions (6). Normally the reaction products from organic esters and hydrazines are acylhydrazines. With phosphate esters, however, hydrazines formed hydrazine salts exclusively, as illustrated by the example we wish to report.

The selection of hydrazines and phosphate esters was based on their availability, and was restricted to compounds containing hydrogen atoms, methyl, and phenyl groups, because of their simple and easily detectable nuclear magnetic resonance (n.m.r.) signals. A schematic representation of the reactions and products is given in Table I.

In order to explain the formation of some unexpected reaction products we investigated the possibilities of exchange reactions between hydrazine salts and hydrazines or phosphate esters. These reactions are schematically represented in Table II.

Experimental

Materials and Apparatus

The selected hydrazines and phosphate esters were: hydrazine, methylhydrazine, *unsym*-dimethylhydrazine, *sym*-dimethylhydrazine, *unsym*-diphenylhydrazine, *sym*-diphenylhydrazine, trimethyl phosphate, dimethyl phenyl phosphate, methyl diphenyl phosphate, triphenyl phosphate, diphenyl phosphate.

Dimethyl phenyl phosphate was prepared from dimethyl phosphite (7). *sym*-Dimethylhydrazine and *unsym*-diphenylhydrazine were prepared from their HCl salts by treatment with NaOH. These salts, dimethyl phosphite, and all other chemicals were commercially available. Elemental analyses were carried out in this laboratory and by Crobaugh Laboratories, Cleveland, Ohio. Infrared (i.r.) spectra were obtained using a Perkin–Elmer 521 instrument. The spectra were taken from both KBr disks and Nujol mulls. Integrated nuclear magnetic resonance spectra were recorded on a Varian DP-60 spectrometer from deuteriodimethylsulfoxide (DMSO-d_6) solutions with TMS as internal standard.

Procedure

All reactions were performed in the following manner:

A slight excess of the hydrazine in ether was slowly added to a solution of the phosphate ester in ether, with stirring and at room temperature. After the addition the mixture was stirred for 1–3 h. During the reaction, oils or solids separated from the solution. These products were separated, washed with ether to remove starting materials, and subsequently recrystallized. When the reactants were mixed without solvent, the reactions were strongly exothermic after a short induction period. The only exceptions were triphenyl phosphate which did not react with *unsym*-dimethylhydrazine, and the diphenylhydrazines which did not react with methyl diphenyl phosphate.

1,1,1-Trimethylhydrazinium[1] *Dimethyl Phosphate (1)*

This was prepared from 6.6 g (0.11 mole) *unsym*-dimethylhydrazine and 14 g (0.1 mole) trimethyl phosphate as white hygroscopic crystals, yield, 16.6 g (83%),

m.p. 88–90° (ethyl acetate (EtOAc)/hexane). The i.r. spectrum showed significant absorption at 3210 and 3103 cm^{-1} (*asym*- and *sym*-NH_2 stretch). The n.m.r. spectrum exhibited singlets at 3.22 τ (NH) and 6.62 τ (NCH_3), and a doublet at 6.64 τ(P-OCH_3, $J_{P\text{-}OCH_3}$ = 10.5 c.p.s.).

Anal. Calcd. for $C_5H_{17}N_2O_4P$: C, 30.00; H, 8.50; N, 14.00. Found: C, 29.10; H, 8.50; N, 13.50.

1,1,1-Trimethylhydrazinium Methyl Phenyl Phosphate (2)

This was prepared from 0.7 g (0.012 mole) *unsym*-dimethylhydrazine and 2.02 g (0.01 mole) dimethyl phenyl phosphate as colorless needles, yield, 1.8 g (70%), m.p. 82° (EtOAc/hexane). The i.r. spectrum showed significant absorption at 3210 and 3106 cm^{-1} (*asym*- and *sym*-NH_2 stretch). The n.m.r. spectrum showed singlets at 3.30 τ (NH) and 6.70 τ (NCH_3), a multiplet at 2.28 (phenyl), and a doublet at 6.57 τ (P-OCH_3, $J_{P\text{-}OCH_3}$ = 11 c.p.s.).

Anal. Calcd. for $C_{10}H_{19}N_2O_4P$: C, 45.80; H, 7.25; N, 10.69. Found: C, 45.50; H, 7.50; N, 10.90.

1,1,1-Trimethylhydrazinium Diphenyl Phosphate (3)

This was prepared from 1.5 g (0.025 mole) *unsym*-dimethylhydrazine and 5.2 g (0.02 mole) methyl diphenyl phosphate as white crystals, yield 4.8 g (72%), m.p. 118° (EtOH/hexane). The i.r. spectrum showed significant absorption at 3243 and 3128 cm^{-1} (*asym*- and *sym*-NH_2 stretch). The n.m.r. spectrum exhibited singlets at 3.60 τ (NH) and 6.77 τ (NCH_3), and a multiplet at 2.82 τ (phenyl) in an area ratio of respectively 1.8:9:10.

Anal. Calcd. for $C_{15}H_{21}N_2O_4P$: C, 55.50; H, 6.48; N, 8.63. Found: C, 55.25; H, 6.42; N, 8.42.

1,2-Dimethylhydrazinium Diphenyl Phosphate (4)

The product was obtained from 0.7 g (0.011 mole) *sym*-dimethylhydrazine and 2.6 g (0.01 mole) methyl diphenyl phosphate as white crystals; yield, 1.1 g. It was to be expected that in analogy with the reaction of methylhydrazine with methyl diphenyl phosphate, a 1,1,1-trimethyl, 2-methyl hydrazinium salt should also have been formed. Such a salt, however, could not be isolated. Compound **4** was also obtained from 0.03 g (0.001 mole) *sym*-dimethylhydrazine and 0.5 g (0.002 mole) diphenyl phosphate, as white crystals, yield, 0.3 g (60%), m.p. 90° (EtOAc/hexane). The composition of the reaction product was independent of the ratio of the starting materials. The i.r. spectrum showed significant absorption at 3242 cm^{-1} (NH stretch), as well as at 2675 and 2510 cm^{-1} (*asym*- and *sym*-NH_2^+ stretch). The n.m.r. spectrum exhibited a broad singlet at 1.50 τ (NH), a singlet at 7.48 τ (NCH_3), and a multiplet at 2.82 τ (phenyl).

Anal. Calcd. for $C_{14}H_{19}N_2O_4P$: C, 54.20; H, 6.12; N, 9.04. Found: C, 53.67; H, 6.13; N, 9.20.

Methylhydrazinium Diphenyl Phosphate (5)

The product was obtained from 1.1 g (0.025 mole) methylhydrazine and 5.2 g (0.02 mole) methyl diphenyl phosphate. Fractionated crystallization from EtOAc/hexane gave 2 g of **3** at room temperature and subsequently 2.5 g of **5** (m.p. 52–54°) by chilling to −20°. The white waxy crystalline product was identical to the product from 0.1 g (0.002 mole) methylhydrazine and 0.5 g (0.002 mole) diphenyl phosphate, yield, 0.4 g (66%). The i.r. spectrum showed significant absorption at 3271 and 3171 cm^{-1} (*asym*- and *sym*-NH_2), and at ±2750 and 2500 cm^{-1} (*asym*- and *sym*-NH_2^+). The n.m.r. spectrum exhibited singlets at 3.30 τ (broad, NH) and 7.44 τ (NCH_3), and a multiplet at 2.80 τ (phenyl). The area ratio (phenyl + NH):NCH_3 = 15.4:3. Purification problems reduced the significance of analysis. However, the structural possibilities of the compound are limited and both n.m.r. and analysis indicate the presence of only one phosphate anion per molecule. (Compare compound **8**.)

1,1-Dimethylhydrazinium Diphenyl Phosphate (6)

The product was obtained from 0.7 g (0.023 mole) hydrazine and 5.2 g (0.02 mole) methyl diphenyl phosphate. The result was a mixture of products from which 0.6 g of **3** could be isolated by fractionated crystallization from EtOAc/ether at −20°. The rest consisted of an oily mixture of three components which could not be separated. The i.r. spectrum of this oil proved to be composed of the spectra of **5**, **6**, and hydrazinium diphenyl phosphate. Pure **6** was prepared from 0.35 g (0.006 mole) *unsym*-dimethylhydrazine and 1 g (0.004 mole) diphenyl phosphate as white crystals; yield, 1.15 g (95%); m.p. 104° (EtOAc/hexane). The i.r. spectrum showed significant absorption between 3200 and 2350 cm^{-1} (NH_3^+ stretch), and at 2147 cm^{-1} (NH_3^+ combination). No absorptions were present which could be assigned to NH_2 or NH_2^+. The n.m.r. spectrum exhibited singlets at 1.90 τ (NH) and 7.40 τ (NCH_3), and a multiplet at 2.80 τ (phenyl) with an area ratio of respectively 3:10:5.9.

Anal. Calcd. for $C_{14}H_{19}N_2O_4P$: C, 54.19; H, 6.13; N, 9.05. Found: C, 54.11; H, 6.08; N, 8.55.

Hydrazinium Diphenyl Phosphate (7)

Like compound **6**, this was one of the products from the reaction between hydrazine and methyl diphenyl phosphate.

Pure **7** was prepared by adding 0.07 g (0.0022 mole) hydrazine in 2 ml EtOH to 0.5 g (0.002 mole) diphenyl phosphate in 15 ml ether. A viscous oil was obtained, yield, 0.3 g. Recrystallization from EtOAc/hexane gave 0.2 g (40%) of flaky, white crystals, m.p. 70°. The composition of the product was independent of the ratio of the starting materials. The i.r. spectrum showed significant absorptions at 3358 and 3297 cm^{-1} (*asym*- and *sym*-NH_2 stretch), 3225–2500 cm^{-1} (broad, NH_3^+ stretch), and 2085 cm^{-1} (NH_3^+ combination). The n.m.r. spectrum exhibited a singlet at 3.50 τ (broad, NH) and a multiplet at 2.80 τ (phenyl) in an area ratio of 1.1:2 respectively.

Anal. Calcd. for $C_{12}H_{15}N_2O_4P$: C, 51.10; H, 5.32; N, 9.93. Found: C, 51.02; H, 5.60; N, 9.81.

Methylhydrazinium bis(Diphenyl Phosphate) (8)

The product was obtained from 0.1 g (0.002 mole) methylhydrazine and 1 g (0.004 mole) diphenyl phosphate as white crystals, yield, 0.8 g (72%), m.p. 88.5° (EtOAc/hexane). The same product was obtained from 0.3 g (0.001 mole) **5** and 0.25 g (0.001 mole) diphenyl phosphate, yield, 0.5 g (81%) **8**. The i.r. spectrum showed significant absorption between 3200 and 1800 cm^{-1} as a broad and rather unresolved band indicating both NH_2^+ and NH_3^+. There was no indication of NH_2. The n.m.r. spectrum exhibited singlets at 3.65 τ (broad, NH) and 7.42 τ (NCH_3), and a multiplet at 2.80 τ (phenyl). Area ratio phenyl:NCH_3 = 23:3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Anal. Calcd. for $C_{25}H_{28}N_2O_8P_2$: C, 54.90; H, 5.13; N, 5.13. Found: C, 54.60; H, 5.07; N, 4.86.

Both n.m.r. and analysis indicated the presence of two phosphate anions per molecule. (Compare compound **5**.)

1,2-Diphenylhydrazinium bis(Diphenyl Phosphate) (9)

The product was obtained from 0.37 g (0.002 mole) *sym*-diphenylhydrazine and 0.5 g (0.002 mole) diphenyl phosphate as white crystals, yield, 0.3 g (48%), m.p. 225° (decomp.) (EtOH). The i.r. spectrum showed significant absorption at 2850 and 2600 cm^{-1} (*asym*- and *sym*-NH_2^+ stretch). There was no evidence of uncharged —NH. The n.m.r. spectrum exhibited a singlet at 1.25 τ (NH) and a multiplet at 2.82 τ (phenyl) in an area ratio of 4.4:30.

Anal. Calcd. for $C_{36}H_{34}N_2O_8P_2$: C, 63.10; H, 4.98; N, 4.09. Found: C, 63.00; H, 5.01; N, 3.94.

1,1-Diphenylhydrazinium Diphenyl Phosphate (10)

A white cotton-like product was obtained from 0.37 g (0.002 mole) *unsym*-diphenylhydrazine and 0.5 g (0.002 mole) diphenyl phosphate, yield, 0.8 g (92%), m.p. 126–129° (EtOAc/hexane). The i.r. spectrum showed a broad band at 3140 to 2300 cm^{-1} (NH_3^+ stretch) and a band at 2170 cm^{-1} (NH_3^+ combination). There was no evidence of NH_2. The n.m.r. spectrum showed a singlet at 0.80 τ (NH) and a multiplet at 2.82 τ (phenyl) in an area ratio of 3.3:20.

Anal. Calcd. for $C_{24}H_{23}N_2O_4P$: C, 66.40; H, 5.30; N, 6.46. Found: C, 66.88; H, 5.42; N, 6.40.

Reaction between Methylhydrazinium Diphenyl Phosphate (5) and Hydrazine

A sample of 0.6 g (0.002 mole) hydrazinium salt was stirred with 0.07 g (0.0021 mole) hydrazine in 10 ml ether and 1 ml EtOH for 1 h. The resulting oil was separated from the mixture and recrystallized from EtOAc/hexane, giving 0.2 g (36%) of **7**.

Reaction between 1,1-Dimethylhydrazinium Phosphate (6) and Hydrazine

A solution of 0.04 g (0.0012 mole) hydrazine in 2 ml ether and 0.5 ml EtOH was added to a slurry of 0.3 g hydrazinium salt in 5 ml ether. Immediately an oil was formed. After stirring for $\frac{1}{2}$ h the oil was separated and recrystallized from EtOAc/hexane giving 0.18 g (64%) **7**.

Reaction between 1,1-Dimethylhydrazinium Phosphate and Methylhydrazine

A solution of 0.5 g (0.0011 mole) methylhydrazine in 2 ml ether was added to a slurry of 0.3 g (0.001 mole) hydrazinium salt in 5 ml ether. After stirring for $\frac{1}{2}$ h, an oil was formed. The oil was worked up to give 0.2 g (70%) (EtOAc/hexane) methylhydrazinium diphenyl phosphate **5**.

Reaction between 1,2-Diphenylhydrazinium bis(Diphenyl Phosphate) (9) and unsym-Dimethylhydrazine

A slurry of 0.34 g (0.0004 mole) hydrazinium salt in 5 ml ether was treated with 0.06 g (0.001 mole) hydrazine in 1 ml ether. After stirring for 3 h, the mixture was filtered and the residue was recrystallized from EtOAc/hexane giving 0.18 g (60%) **6**.

Reaction between 1,2-Diphenylhydrazinium bis(Diphenyl Phosphate) and sym-Diphenylhydrazine

Mixing equimolar amounts of the compounds did not result in a reaction. After stirring for 24 h the hydrazinium salt was recovered quantitatively.

Reaction between 1,1-Dimethylhydrazinium Diphenyl Phosphate and Methyl Diphenyl Phosphate

Stirring a mixture of equimolar amounts of the hydrazinium salt and the phosphate ester in an EtOH/ether solution for 3 h yielded only starting materials.

Discussion

Hydrazinium salts, commonly prepared from hydrazines and alkylhalides, are usually formed in such a way that the most highly substituted nitrogen atom is quaternized (8). It has been suggested that this is caused by a more basic character of that nitrogen atom (9).

Klages *et al.* (5) suggest that the reason for quaternization is a kinetic one: Hydrazines are basically hydrophilic, and methyl halides are lipophilic. The more highly substituted the hydrazine, the more lipophilic it becomes, thus facilitating the approach between the methyl halide and the hydrazine, especially that side of the hydrazine which is most highly substituted. This way asymmetric and complete substitution is promoted.

Hinman (10) suggests that continued substitution on the same nitrogen atom is favored by a better ability of the substituted nitrogen to stabilize the positive charge in the transition state. In our experiments we found that in the reactions between hydrazines and phosphate esters containing at least one methyl group, continued substitution is also favored. Reaction of methyl diphenyl phosphate with hydrazine, methylhydrazine, or *unsym*-dimethylhydrazine resulted each time in the formation of a 1,1,1-trimethylhydrazinium salt. However, in the case of hydrazine and methylhydrazine the formation of 1-methyl-, and 1,1-dimethylhydrazinium salts was also observed.

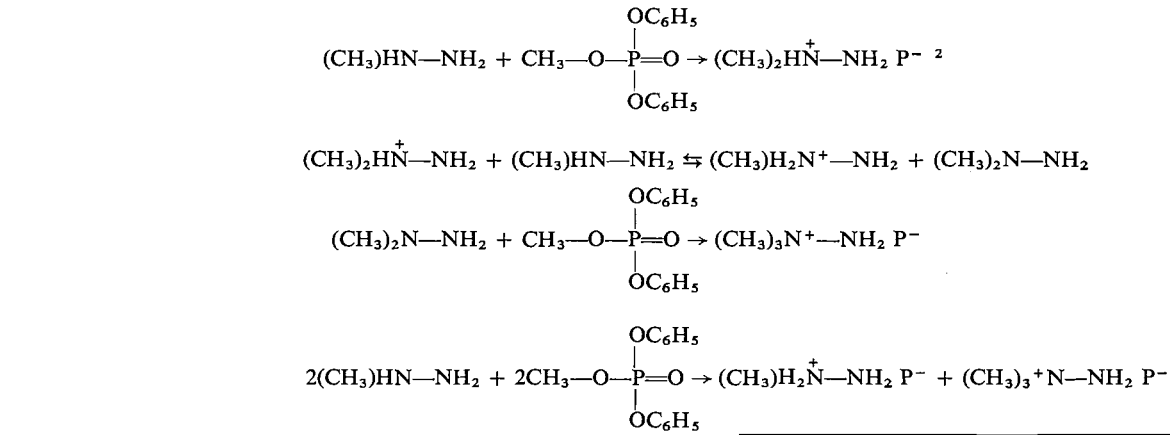
This could not be due to incomplete reaction between the hydrazine and the phosphate ester, because these partly substituted salts did not react with methyl diphenyl phosphate. Partly substituted salts did, however, react with certain hydrazines, as shown in Table II. The data in Table II show that the hydrazines can be placed in the following order of ability to displace other hydrazines from their salts:

$$H_2N—NH_2 > (CH_3)HN—NH_2 > (CH_3)_2N—NH_2 > (C_6H_5)HN—NH(C_6H_5)$$

For hydrazine and the methylhydrazines this

sequence is identical to the one found by Hinman with respect to their base strengths (10).

This suggests that the reaction of methylhydrazine and methyl diphenyl phosphate (See Table I) takes place according to the following scheme:



Methylhydrazine being a stronger base than *unsym*-dimethylhydrazine will liberate it from its salt to form *unsym*-dimethylhydrazine and methylhydrazinium diphenyl phosphate. Similar schemes can be devised for the reactions of diphenyl methyl phosphate with hydrazine and with *sym*-dimethylhydrazine. This suggests that the driving force for continued substitution is not just the ability of the nitrogen atom to accommodate still another methyl group. Continued substitution can only take place when the free hydrazine is basic enough to abstract protons from the intermediate hydrazinium salts.

The methylated hydrazine has to be liberated from its salt before it can be methylated further, as is demonstrated by the fruitless attempt to methylate 1,1-dimethylhydrazinium diphenyl phosphate with methyl diphenyl phosphate.

The i.r. spectra were taken from the crystalline material and showed distinctive differences in NH absorption frequencies for the different salts. The *asym*- and *sym*-NH_2 stretching absorptions displayed in the i.r. spectra of compounds **1**, **2**, **3**, **5**, and **7** in the ranges of 3358–3190 cm^{-1}, and 3297–3080 cm^{-1} respectively are in accord with NH_2 stretching vibrations found in the literature for hydrazinium salts (11–13). These bands are absent in compound **6**, which indicates the structure $(CH_3)_2N—{}^+NH_3$ instead of the expected $(CH_3)_2HN^+—NH_2$. This indication is strengthened by the presence of *asym*- and *sym*-NH_3^+ stretching bands as well as a NH_3^+ combination band, which according to the literature generally range from 3225–2300 cm^{-1} (12) and 2170–2085 cm^{-1} (14) respectively. A similar situation exists in **10**.

Thus we find that methylation of *unsym*-dimethylhydrazine by methyl diphenyl phosphate gives a quaternary nitrogen, whereas reaction with diphenyl phosphate gives a charged non-substituted nitrogen. Similar protonation of the non-substituted nitrogen in 1-methyl,1-phenylhydrazine by picric acid was observed by Aubagnac *et al.* (15).

NH_3^+ stretching and combination bands were also observed in **7**. In **8**, both NH_3^+ and NH_2^+ appear as an extremely broad and unresolved band.

NH_2^+ *asym*- and *sym*-stretch displays itself as two bands in compounds **4**, **5**, and **9**. The wavenumbers are slightly lower than those found for secondary amine salts, which range between 3000 and 2700 cm^{-1} (16).

Acknowledgments

The authors wish to thank Dr. R. J. DeGray for his continuous and stimulating interest. They thank Mr. Frank Knoll and Mr. Herb Grossman for determination of the n.m.r. spectra in this work, and Mr. Richard Wander for his assistance in C, H, and N analyses.

Hydrogen bonding in some *t*-amino-alcohols related to methadone

A. F. CASY AND M. M. A. HASSAN
Faculty of Pharmacy, University of Alberta, Edmonton, Alberta

Received May 7, 1968

Hydroxyl stretching frequency data upon 1-dimethylamino-3,3-diphenylhexan-4-ol and related amino-alcohols are reported which give evidence of unusually strong intramolecular hydrogen bonding between the hydroxy and *t*-amino functions of these compounds. In corresponding salts, concentration independent ν_{OH} bands, typical of hydrogen bonded species, also occur and a bonded system comprising anion, OH, and N^+H functions is proposed together with probable methadol base and salt conformations.

This paper reports some spectroscopic properties of 1-dimethylamino-3,3-diphenylhexan-4-ols related to methadone, work undertaken as part of a conformational study of analgesics (1–3). The main point of infrared (i.r.) interest regarding the conformation of α- and β-methadol (**1***a*), the diastereoisomeric alcohols derived from methadone, lies in the detection of intermolecular and/or intramolecular hydrogen bonding of type **2** for the bases and **3** (or some variant) for

$$Me_2NCHRCH_2CPh_2CH(OH)Et$$

the hydrohalide salts, through a study of ν_{OH} bands.

2 **3** **4**

The non-basic analogue, 4,4-diphenylhexan-3-ol, **4** showed both free and bonded ν_{OH} bands as a film and in solutions above 5% in CCl_4 while more dilute solutions displayed single, free[1] ν_{OH} bands (Table I). In sharp contrast, solutions of the isomeric methadols (α- and β-**1***a*) and normethadol **1***b* showed no distinct ν_{OH} bands; these appeared as broad shoulders superimposed upon the ν_{CH} bands as is clearly apparent on comparing the 3μ region of the α-methadol spectrum with that of the hydrocarbon analogue, 3-dimethylamino-1, 1-diphenylbutane (Table I, nos. 2–3 and Fig. 1). No change in the ν_{OH} band appearance occurred upon dilution of the methadol solution to 0.03% (i.e. to well below the concentration of 0.005 mole/l generally regarded as sufficiently low to exclude intermolecular association (4)), and this result indicates that very strong intramolecular hydrogen

[1] ν_{OH} Bands near 3600 cm^{-1} are regarded as free throughout this paper although most have positions indicative of weak π...HO bonding, intramolecular in character (4).

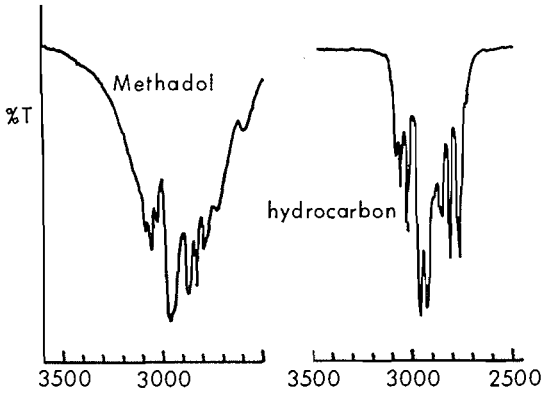

FIG. 1. Infrared spectrum (3 μ region) of α-methadol and its hydrocarbon analogue, 3-dimethylamino-1,1-diphenylbutane (both 10% in CCl_4).

bonding occurs in these compounds.[2] If such be the case, the bonding must be of type **2** because the effect is not seen in the non-basic analogue **4**. There was no significant difference in the ν_{OH} bands of the three amino-alcohols (Table I, nos. 2 and 3) examined at comparable dilutions. The O*H* proton magnetic resonance signals of the α- and β-methadols in $CDCl_3$ had low-field positions (5) anticipated for strongly hydrogen bonded hydroxyls (α, broad band τ 1.43; β, signal fell within aromatic signal τ 2.5–3.1) but these data do not provide evidence of intramolecular effects because they relate to strong solutions.

Intramolecular hydrogen bonding is well documented in non-aromatic amino-alcohols such as β-dimethylaminoethanol and 1-methyl-3-piperidinol (4, 6) which have the correct geometry for an N – HO interaction, but the order of the effects is much less in these two compounds than in the methadols. Thus a weak solution of β-dimethylaminoethanol in CS_2 showed a broad but distinct ν_{OH} (b) band well removed from the ν_{CH} absorption plus a small ν_{OH} (f) band, while a dilute solution of the 3-piperidinol in CCl_4 similarly displayed distinct free and bonded ν_{OH} bands (Table I, nos. 4 and 5). The unusually strong N — HO bonding seen in the methadols appears to be characteristic of phenyl substituted amino-alcohols because simi-

[2]There is a possibility of the bands arising from "abnormal" intermolecular association (mainly dimerization) but this rare phenomenon has not been reported for amino-alcohols (4).

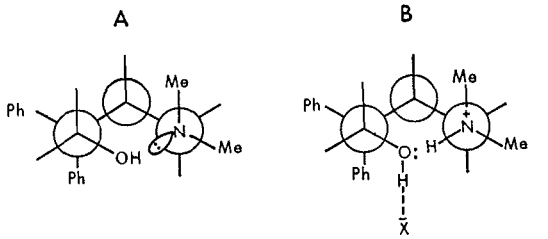

FIG. 2. Representation of probable methadol and normethadol conformations: **A**, base; **B**, protonated base. Some substituents on carbons α- to N and OH have been omitted. In **A** the N-lone-pair orbital is represented.

lar ν_{OH} shoulders were also noted in the related *vic* and *gem* diphenyl *t*-alcohols, **5** and **6** respectively. These alcohols must therefore adopt solute conformations in which the hydroxyl and

$Me_2NCH_2CHMeCPh(OH)CH_2Ph$

5

α β
$MeNCH_2CHMeCPh_2OH$
(and α-Me isomer)

6

amino functions lie close enough together to permit intramolecular hydrogen bonding, as illustrated for the methadols in Fig. 2.

Hydrohalide salts of the two methadols and of normethadol were examined as Nujol mulls and solutions in $CHCl_3$ (the salts were insoluble in CCl_4 and CS_2). This solvent had the disadvantage of (*a*) preventing the use of cells larger than 2 mm because of compensation problems, and (*b*) introducing possible solvent effects. The latter factor is probably only of small significance since the proton donor properties of $CHCl_3$ appear to be small as judged from the near-identical ν_{OH} shoulders obtained for normethadol base as solute in CCl_4 and $CHCl_3$. All spectra of the salts exhibited broad but distinct ν_{OH} bands (Table I, nos. 2 and 3) which were clearly apparent even in solutions more dilute than 0.5% where resolution was not optimum because of cell width restrictions; very weak free ν_{OH} bands near 3580 cm^{-1} appeared in 1% and weaker solutions. The intense broad bands were typical of strongly bonded species and their positions were unaltered on dilution; hence, it is probable that intramolecular effects are again in force. Similarly placed, but sharper bands (also concentration independent) were seen in corresponding methiodides (Table I, no. 3), thus the

interactions responsible for bonded ν_{OH} bands in these compounds do not require an acidic proton on nitrogen as in **3** and involvement of the anion (viz. O—H.....$\bar{X}$) is more probable. In support, ν_{OH} for crystalline choline chloride is reported[3] as 3289 cm^{-1} while tropine hydrochloride, of geometry which precludes an intramolecular $\overset{+}{N}H$/OH association, displays a concentration independent ν_{OH} bonded band near 3350 cm^{-1} plus a weak free band (Table I, no. 6).

In the present series, the influence of the anion upon the O—H stretching frequency is apparent from data upon normethadol salts (Table I, no. 3), ν_{OH} band positions varying from salt to salt. Anions are generally concluded to bond to the acidic proton of amine salts and hence to be responsible for the lower wavenumbers of ν^{+}_{NH} compared with ν_{NH} bands (7, 8). Thus the ν^{+}_{NH} positions of amino-alcohol salts in which OH and $\overset{+}{N}H$ protons compete for the anion, would be expected to fall at higher wavenumbers than those of analogues lacking free OH functions. The dilute solution spectra of most methadol salts, however, displayed broad complex bands between 2200 and 2800 cm^{-1} with maxima near 2300 and/or 2600 cm^{-1}, typical of bonded $R_3\overset{+}{N}H$ protons. Similar bands were seen, for example, in hydrochlorides of α-acetylmethadol **7** and the hydrocarbon analogue **8** in which exclusive $\overset{+}{N}H....\bar{X}$ bonding may occur.

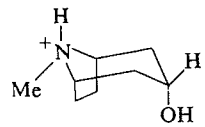
$Me_2NCHMeCH_2CPh_2C(OCOMe)Et$

7

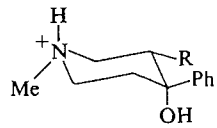
$Me_2NCHMeCH_2CPh_2H$

8

It is therefore concluded that a hydrogen bonded system comprising anion, OH, and $\overset{+}{N}H$ functions obtains in most methadol salts. Bonding of this type could take the form $O—H....\bar{X}....H—\overset{+}{N}$ or $\bar{X}....H—O:....H\overset{+}{N}$ either of which require the two proton groups to be fairly close together. Hence, it is to be expected that salts of amino-alcohols of geometry which precludes proximate OH and $\overset{+}{N}H$ groups will be populated by separate $OH....\bar{X}$ and $\overset{+}{N}—H....\bar{X}$ species. It is significant, in this respect, that spectra of the salts of tropine **9** and the 4-phenylpiperidinols **10** display both bonded and free ν_{OH} bands (Table I, nos. 6–8) while the ν^{+}_{NH} band



9



10 R = H or Me

of tropine hydrochloride has higher wavenumber maxima than those of the methadol salts. The OH and $\overset{+}{N}H$ stretching frequency characteristics of hydrochlorides of the more flexible phenyl substituted amino-alcohols **5** and **6** were similar to those of methadol salts.

The three-component hydrogen bonded system proposed for methadol salts rests upon the assumption of the ν^{+}_{NH} bands, present in their spectra, being due to bonded functions. Evidence for $\overset{+}{N}H....\bar{X}$ bonding, and in particular for assigning bands in the 2200–2800 cm^{-1} region to bonded rather than free $\overset{+}{N}H$ groups, is not extensive and is mostly indirect, e.g. movement of the ν^{+}_{NH} band of certain *t*-amine hydrochlorides to higher wavenumbers when water of crystallization is present, is attributed to a weakening of $\overset{+}{N}H.....\bar{X}$ bonding through formation of water–anion bonds (7), and its further study is desirable. We have noted poorly defined ν^{+}_{NH} bands in the Nujol mull spectra of base salts involving bulky anions, e.g. iodides, iodates, nitrates, and nitrites, the more characteristically placed bands reappearing in dilute solution spectra.[4] It appears, therefore, that $\overset{+}{N}H....\bar{X}$ bonding is weak in the solid state forms of these salts. Normally placed ν^{+}_{NH} bands are also absent in the spectrum (mull) of the perchlorate of 3-dimethylamino-1,1-diphenylbutyl cyanide; instead, a strong band at 3080 cm^{-1} (i.e. close to the secondary amine N—H range) is present (Fig. 3). The normethadol perchlorate spectrum (mull) similarly lacks

[3]M. E. Senko and D. H. Templeton. Private communication (quoted by Pimental and McClellan (8)).

[4]A. F. Casy and M. A. A. Hassan. Unpublished results.

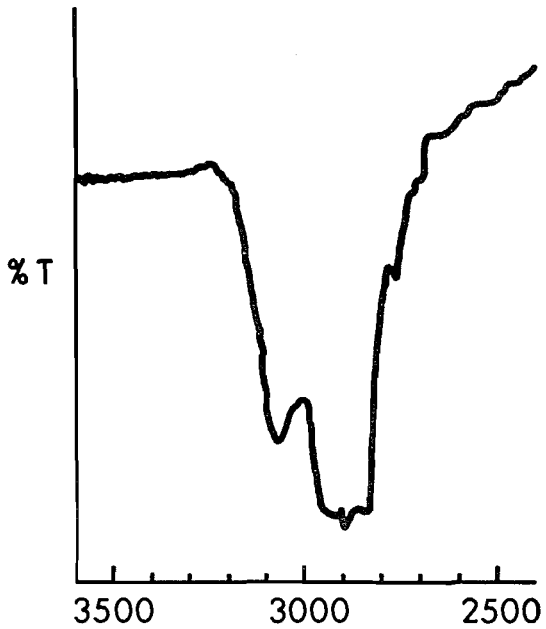


FIG. 3. Infrared spectrum (3 μ region) of the perchlorate of 3-dimethylamino-1,1-diphenylbutyl cyanide (Nujol mull).

the usual ν^{+}_{NH} features and has bands at 3160 and 3570 cm^{-1} tentatively assigned to ν^{+}_{NH} and ν_{OH} (both weakly bonded) respectively, plus a broad bonded absorption near 3350 cm^{-1} due, in part at least, to water of crystallization. Solution data upon this perchlorate, unique amongst normethadol salts examined in showing a pronounced free ν_{OH} band, could not be obtained because the salt was insoluble in $CHCl_3$.

If the operation of intramolecular bonding between chloride ion, OH, and $\overset{+}{N}H$ functions in methadol salts be accepted as a reasonable assumption on the basis of the i.r. evidence presented here, favored salt conformations similar to those of the free bases may be proposed, e.g. Fig. 2B in which anion bonding to OH is represented. Possible pharmacological implications of these conclusions will be discussed elsewhere.

Experimental

Infrared spectra were recorded with a Beckman IR-10 spectrophotometer. Cells of path length 0.05 mm (10–5%), 0.5 mm (5–3%), 2 mm (1.0–0.5%), and 12 mm (<0.5%) were used for solution studies in CCl_4. A 2 mm cell was the largest usable when $CHCl_3$ was solvent. Most of the compounds have been described previously (9–12) or were commercially available. New compounds are described below.

4,4-Diphenylhexan-3-ol

Ethyl bromide (5.45 g) in dry benzene (10 ml) was added to a mixture of diphenylacetonitrile (9.65 g), powdered sodamide (2 g), and benzene (50 ml) which had previously been stirred at 30–40° for 1 h, and the product heated under reflux for 12 h. The benzene solution was then washed with water, dried over anhydrous sodium sulfate, evaporated to dryness, and the oily residue distilled to give 1,1-diphenylpropylcyanide (10 g), b.p. 120°/0.2 mm.

Anal. Calcd. for $C_{16}H_{15}N$: C, 86.8; H, 6.8. Found: C, 86.6; H, 6.7.

This cyanide (6.63 g) in dry toluene (100 ml) was added to ethyl magnesium bromide in ether (40 ml) prepared from ethyl bromide (9.7 g) and magnesium (2.2 g). The ether was removed, the mixture heated under reflux for 3 h, and then added to ice and concentrated hydrochloric acid (40 ml). The basic ketimine (6.5 g), ν_{max} 1709, 1636 cm^{-1} (C=NH) recovered from the aqueous phase, with hydrogen chloride gave 1,1-diphenylpropyl ethyl ketimine hydrochloride, m.p. 203–205° from ethanol ether, ν_{max} 1679 cm^{-1} (C=N).

Anal. Calcd. for $C_{18}H_{22}ClN$ (equiv. wt., 287): C, 75.1; H, 7.7; N, 4.9. Found (equiv. wt., 285): C, 74.4; H, 7.8; N, 4.75.

The ketimine (6 g) was heated under reflux with concentrated hydrochloric acid (25 ml) for 8 h and the oil which separated was isolated by ether extraction and distilled to give 4,4-diphenylhexan-3-one (4.5 g), b.p. 114–118°/0.25 mm.

Anal. Calcd. for $C_{18}H_{20}O$: C, 85.7; H, 8.0. Found: C, 86.3; H, 7.8.

4,4-Diphenylhexan-3-one (5.04 g) in ether (50 ml) was added dropwise to $LiAlH_4$ (0.76 g) in ether (50 ml). After a period of stirring (2 h at R°, 1 h at reflux temperature) the mixture was treated with water (15 ml) and filtered. The residue from the dried filtrate was distilled to give 4,4-diphenylhexan-3-ol, b.p. 134–136°/2–5 mm.

Anal. Calcd. for $C_{18}H_{22}O$: C, 85.0; H, 8.7. Found: C, 84.8; H, 8.5.

Inner glucosides of the anomeric 2-*O*-(2-hydroxyethyl)-D-glucoses

E. J. ROBERTS AND S. P. ROWLAND

Southern Regional Research Laboratory, Southern Utilization Research and Development Division, Agricultural Research Service, United States Department of Agriculture, New Orleans, Louisiana

Received October 16, 1968

It has been found that 2-*O*-(2-hydroxyethyl)-D-glucopyranose is partially converted to 1,2-*O*-ethylene-α-D-glucofuranose, 1,2-*O*-ethylene-α-D-glucopyranose, and 1,2-*O*-ethylene-β-D-glucopyranose when heated in dilute acid solution. The ratio of the furanose derivative to the pyranose derivatives is dependent upon the concentration of the acid (3, 5). The three inner glucosides of 2-*O*-(2-hydroxyethyl)-D-glucose have been characterized by gas–liquid chromatography. The interrelationship of 2-*O*-(2-hydroxyethyl)-D-glucose and its inner glucosides is also reported.

Canadian Journal of Chemistry, 47, 1592 (1969)

Introduction

Studies of the distribution of substituents in *O*-(2-hydroxyethyl)starch (1) and *O*-(2-hydroxyethyl)cellulose (2) have been reported. In recent studies of the distribution of substituents in *O*-(2-hydroxyethyl)starch, Bollenback *et al.* (3) and Srivastava *et al.* (4) reported the presence of a small quantity of 1,2-*O*-ethylene-α-D-glucofuranose resulting from the hydrolysis of *O*-(2-hydroxyethyl)starch with 0.75 *M* sulfuric acid. They concluded that the inner glucoside is formed by the dehydration of 2-*O*-(2-hydroxyethyl)-D-glucopyranose during the acid hydrolysis of the modified starch. No 1,2-*O*-ethylene-β-D-glucofuranose or the corresponding pyranose derivatives were reported.

Hook and Lindberg (5) have shown that 1,2-*O*-ethylene-α-D-glucofuranose and the corresponding α- and β-pyranose derivatives are formed upon heating 2-*O*-(2-hydroxyethyl)-D-glucopyranose in dilute hydrochloric acid.

This note reports the characterization of 2-*O*-(2-hydroxyethyl)-D-glucopyranose, 1,2-*O*-ethylene-α-D-glucofuranose, and the inner glucosides of α- and β-2-*O*-(2-hydroxyethyl)-D-glucopyranose by gas–liquid chromatography (g.l.c.). The interrelationship of 2-*O*-(2-hydroxyethyl)-D-glucopyranose and its inner glucosides is also reported.

Experimental

Gas–Liquid Chromatography

The gas–liquid chromatograms (g.l.c.) were obtained on an Aerograph model 1520 instrument. The samples to be analyzed were silylated, and the SE-30 column was operated isothermally at 190° as described by Roberts and Rowland (6).

1,2-O-Ethylene-α-D-glucofuranose

In an attempt to synthesize 2-*O*-(2-aminoethyl)-D-glucopyranose, methyl 3-*O*-benzyl-2-*O*-carbomethoxymethyl-4,6-*O*-benzylidene-α-D-glucopyranoside was prepared by the procedure described by Roberts and Rowland (6) for the preparation of the corresponding 2-*O*-carbethoxymethyl derivative. The product (10 g) was obtained as a syrup which did not crystallize. The syrupy methyl 3-*O*-benzyl-2-*O*-carbomethoxymethyl-4,6-*O*-benzylidene-α-D-glucopyranoside (10 g, 0.023 mole) was stirred into 400 ml of concentrated ammonium hydroxide in which it was insoluble. The mixture was stirred, and after 6 h the syrup had solidified. The solid was removed by filtration and was crystallized from methanol, yielding 10 g of white crystals melting at 130–135°.

Inner glucosides of the anomeric 2-*O*-(2-hydroxyethyl)-D-glucoses

E. J. ROBERTS AND S. P. ROWLAND

Southern Regional Research Laboratory, Southern Utilization Research and Development Division, Agricultural Research Service, United States Department of Agriculture, New Orleans, Louisiana

Received October 16, 1968

It has been found that 2-*O*-(2-hydroxyethyl)-D-glucopyranose is partially converted to 1,2-*O*-ethylene-α-D-glucofuranose, 1,2-*O*-ethylene-α-D-glucopyranose, and 1,2-*O*-ethylene-β-D-glucopyranose when heated in dilute acid solution. The ratio of the furanose derivative to the pyranose derivatives is dependent upon the concentration of the acid (3, 5). The three inner glucosides of 2-*O*-(2-hydroxyethyl)-D-glucose have been characterized by gas–liquid chromatography. The interrelationship of 2-*O*-(2-hydroxyethyl)-D-glucose and its inner glucosides is also reported.

Canadian Journal of Chemistry, 47, 1592 (1969)

Introduction

Studies of the distribution of substituents in *O*-(2-hydroxyethyl)starch (1) and *O*-(2-hydroxyethyl)cellulose (2) have been reported. In recent studies of the distribution of substituents in *O*-(2-hydroxyethyl)starch, Bollenback *et al.* (3) and Srivastava *et al.* (4) reported the presence of a small quantity of 1,2-*O*-ethylene-α-D-glucofuranose resulting from the hydrolysis of *O*-(2-hydroxyethyl)starch with 0.75 *M* sulfuric acid. They concluded that the inner glucoside is formed by the dehydration of 2-*O*-(2-hydroxyethyl)-D-glucopyranose during the acid hydrolysis of the modified starch. No 1,2-*O*-ethylene-β-D-glucofuranose or the corresponding pyranose derivatives were reported.

Hook and Lindberg (5) have shown that 1,2-*O*-ethylene-α-D-glucofuranose and the corresponding α- and β-pyranose derivatives are formed upon heating 2-*O*-(2-hydroxyethyl)-D-glucopyranose in dilute hydrochloric acid.

This note reports the characterization of 2-*O*-(2-hydroxyethyl)-D-glucopyranose, 1,2-*O*-ethylene-α-D-glucofuranose, and the inner glucosides of α- and β-2-*O*-(2-hydroxyethyl)-D-glucopyranose by gas–liquid chromatography (g.l.c.). The interrelationship of 2-*O*-(2-hydroxyethyl)-D-glucopyranose and its inner glucosides is also reported.

Experimental

Gas–Liquid Chromatography

The gas–liquid chromatograms (g.l.c.) were obtained on an Aerograph model 1520 instrument. The samples to be analyzed were silylated, and the SE-30 column was operated isothermally at 190° as described by Roberts and Rowland (6).

1,2-O-Ethylene-α-D-glucofuranose

In an attempt to synthesize 2-*O*-(2-aminoethyl)-D-glucopyranose, methyl 3-*O*-benzyl-2-*O*-carbomethoxymethyl-4,6-*O*-benzylidene-α-D-glucopyranoside was prepared by the procedure described by Roberts and Rowland (6) for the preparation of the corresponding 2-*O*-carbethoxymethyl derivative. The product (10 g) was obtained as a syrup which did not crystallize. The syrupy methyl 3-*O*-benzyl-2-*O*-carbomethoxymethyl-4,6-*O*-benzylidene-α-D-glucopyranoside (10 g, 0.023 mole) was stirred into 400 ml of concentrated ammonium hydroxide in which it was insoluble. The mixture was stirred, and after 6 h the syrup had solidified. The solid was removed by filtration and was crystallized from methanol, yielding 10 g of white crystals melting at 130–135°.

For personal use only.

Ten grams of this compound was reduced with lithium aluminium hydride (6) yielding 8.5 g of white crystals melting at 125–129°. The benzyl and benzylidene groups were removed by hydrogenolysis (7), and the glucosidic methyl group was removed by refluxing in 100 ml of 1 *N* sulfuric acid for 16 h. The sulfuric acid was removed with barium hydroxide. The barium sulfate was removed by filtration. The filtrate was concentrated to a dark syrup, and upon cooling, 400 mg of crystals separated. After two recrystallizations from methanol, 300 mg of white crystals melting at 221–223° were obtained; $[\alpha]_D^{25} - 57°$(*c*,1,water), lit. (3) m.p. 222–223° and $[\alpha]_D^{25} - 58°$(*c*,1,water) and lit. (5) m.p. 218–220° and $[\alpha]_{578} - 56°$(water).

Anal. Calcd. for $C_8H_{14}O_6$: C, 46.60; H, 6.80. Found: C, 46.54; H, 6.92.

It is therefore apparent that the methyl 3-*O*-benzyl-2-*O*-carbomethoxymethyl-4,6-*O*-benzylidene-α-D-glucopyranoside underwent hydrolysis of the ester in the ammonium hydroxide rather than the expected amide formation. The resulting ammonium salt, upon reduction, was partially converted to the 2-*O*-hydroxyethyl derivative which was cyclized to 1,2-*O*-ethylene-α-D-glucofuranose during the hydrolysis step.

The nuclear magnetic resonance spectrum of this compound showed a doublet at $\tau = 4.55$ p.p.m., (3-(trimethylsilyl)-1-propanesulfonic acid, sodium salt as internal standard) $J_{1,2} = 2.5$ Hz, identical to the spectrum reported by Hook and Lindberg (5).

Hydrolysis of 1,2-O-Ethylene-α-D-glucofuranose

1,2-*O*-Ethylene-α-D-glucofuranose (100 mg, 0.00049 mole) was dissolved in 100 ml of 2 *N* sulfuric acid and was refluxed overnight. The sulfuric acid was removed with barium hydroxide. The barium sulfate was removed by filtration, and the filtrate was concentrated and freeze-dried. Silylation and g.l.c. of the freeze-dried product showed that the 1,2-*O*-ethylene-α-D-glucofuranose was converted to a mixture consisting of 49.4% 1,2-*O*-ethylene-α-D-glucopyranose, 26.5% 1,2-*O*-ethylene-β-D-glucopyranose, 24.1% 2-*O*-(2-hydroxyethyl)-D-glucopyranose, and a trace of the original 1,2-*O*-ethylene-α-D-glucofuranose.

1,2-O-Ethylene-β-D-glucopyranose

This compound was prepared by a procedure similar to that described by Helferich and Werner (8), who dehydrohalogenated the iodo analogue with sodium hydroxide. To 25 g (0.10 mole) of amorphous 2-chloroethyl-β-D-glucopyranoside (9) dissolved in 250 ml of water were added 40 g of barium hydroxide. The solution was stirred under reflux for 16 h. The solution was cooled and the excess barium hydroxide was precipitated with carbon dioxide. The barium carbonate was removed by filtration. The filtrate was evaporated to dryness, and the residue was extracted with methanol. Upon cooling, 10.5 g (81% of theory) of white crystals melting at 215–217° were obtained. After two crystallizations from methanol, the m.p. was unchanged; $[\alpha]_D^{25} + 60.5°$(*c*, 1.7104, water), lit. (8) m.p. 210–211°, $[\alpha]_D^{21} + 56°$(water).

Anal. Calcd. for $C_8H_{14}O_6$: C, 46.60; H, 6.80. Found: C, 46.61; H, 6.89.

Hydrolysis of 1,2-O-Ethylene-β-D-glucopyranose

1,2-*O*-Ethylene-β-D-glucopyranose (1 g, 0.0049 mole) was refluxed for 16 h in 100 ml of 2 *N* sulfuric acid in the same manner as described for the hydrolysis of 1,2-*O*-ethylene-α-D-glucofuranose. The hydrolyzate was freeze-dried yielding 1 g of amorphous solid. Silylation and g.l.c. analysis of a sample of the hydrolyzate showed a mixture of products consisting of 67.4% 1,2-*O*-ethylene-β-D-glucopyranose, 17.4% 1,2-*O*-ethylene-α-D-glucopyranose, 15.2% 2-*O*-(2-hydroxyethyl)-D-glucopyranose, and a trace of 1,2-*O*-ethylene-α-D-glucofuranose.

1,2-O-Ethylene-α-D-glucopyranose

To 500 ml of 2-chloroethanol containing 5% hydrogen chloride were added 36 g (0.20 mole) of α-D-glucose and 200 ml of benzene. The mixture was stirred under reflux with a water trap connected to the apparatus until no further water was liberated (about 3 h). The hydrogen chloride remaining was removed with an excess of lead carbonate. The lead salts were removed by filtration. The filtrate was decolorized with Darco carbon G-60 and concentrated in a rotary evaporator at 90° and 12 mm pressure, yielding 45 g (93% of theory) of a thick syrup which did not crystallize. Silylation and g.l.c. analysis of the product showed that 74% of the 2-chloroethyl-D-glucoside was the α-anomer (first peak) and 26% was the β-anomer. Only a trace of glucose was present.

The syrupy mixture of glucosides (45 g, 0.18 mole) was converted to a mixture of α- and β-1,2-*O*-ethylene-D-glucopyranoses in the same manner as described for the preparation of 1,2-*O*-ethylene-β-D-glucopyranose. The yield was 30.4 g (80% of theory) of a thick syrup. After several unsuccessful attempts to crystallize the product, it was dissolved in water and freeze-dried.

Silylation and g.l.c. of a sample of the freeze-dried mixture showed that the product was 70% 1,2-*O*-ethylene-α-D-glucopyranose (second peak) and 30% β-anomer.

Results and Discussion

During a study of the distribution of 2-aminoethyl groups (after conversion to 2-hydroxyethyl groups) in *O*-(2-aminoethyl)cellulose (6), it was necessary to prepare the 2-*O*-, 3-*O*-, and 6-*O*-(2-hydroxyethyl)-D-glucopyranoses. Gas–liquid chromatography of the silylated 2-*O*-(2-hydroxyethyl)-D-glucopyranose showed three peaks (designated 2″, 2′, and 2′ in curve A, Fig. 1) in addition to those representing the anomeric forms of 2-*O*-(2-hydroxyethyl)-D-glucopyranose (designated 2 and 2 in curve A, Fig. 1).

The retention time of the peak designated 2″ (curve A, Fig. 1) was identical to that of 1,2-*O*-ethylene-α-D-glucofuranose (curve D, Fig. 1). For this reason it was suspected that the two peaks designated 2′ (curve A, Fig. 1) might be the anomeric 1,2-*O*-ethylene-D-glucopyranoses.

Gas–liquid chromatography of the trimethylsilyl ether of 1,2-*O*-ethylene-β-D-glucopyranose showed a retention time (curve B, Fig. 1) identical to that of the first peak designated 2′ (curve A, Fig. 1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

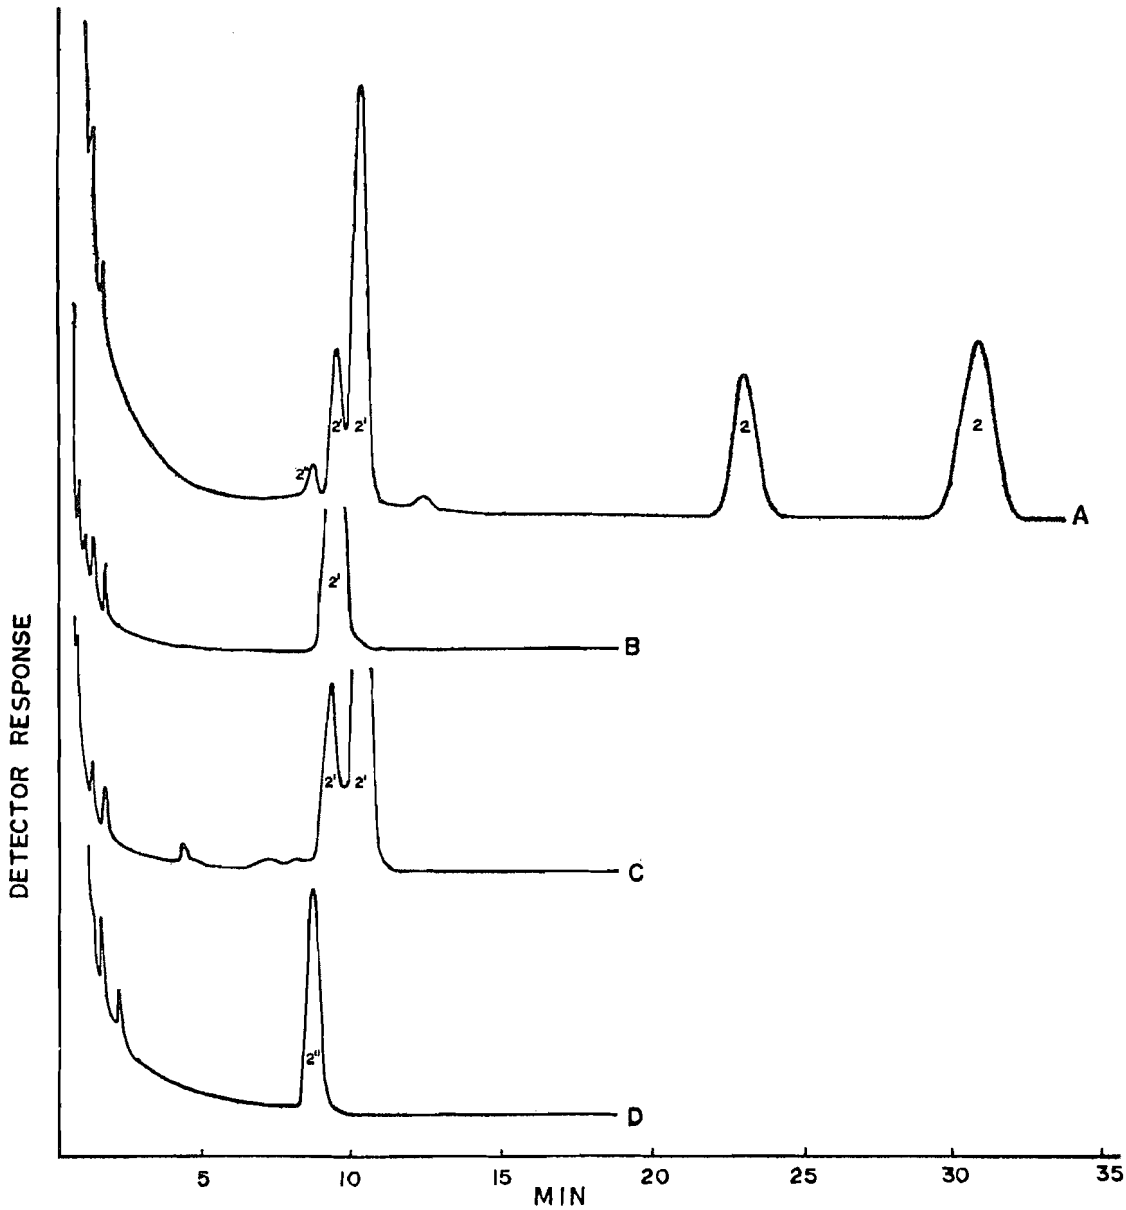

FIG. 1. Chromatograms of trimethylsilyl derivatives on SE-30 column operated isothermally at 190°. Curve A is 2-*O*-(2-hydroxyethyl)-D-glucoses and the inner glucosides. Curve B is 1,2-*O*-ethylene-β-D-glucopyranose (2′). Curve C is a mixture of (predominantly) 1,2-*O*-ethylene-α-D-glucopyranose and 1,2-*O*-ethylene-β-D-glucopyranose (2′ and 2′). Curve D is 1,2-*O*-ethylene-α-D-glucofuranose (2″).

The 1,2-*O*-ethylene-α-D-glucopyranose contained some of the β-anomer. Gas–liquid chromatography of the mixture showed that the second peak, designated 2′ (curve A, Fig. 1), corresponded to that of 1,2-*O*-ethylene-α-D-glucopyranose (second peak designated 2′, curve C, Fig. 1). The 2-*O*-(2-hydroxyethyl)-D-glucopyranose preparation was found to contain 3.0% 1,2-*O*-ethylene-α-D-glucofuranose, 13.0% 1,2-*O*-ethylene-β-D-glucopyranose, 38.4% 1,2-*O*-ethyl-

ene-α-D-glucopyranose, and 45.6% 2-*O*-(2-hydroxyethyl)-D-glucopyranose based on peak areas.

Bollenback *et al.* (3) have pointed out that by inspection of molecular models, *cis* (α)-fused ring formation is favored over the *trans* (β). This conclusion is consistent with the results reported in this paper. However, no strains were observed in the model of the *trans* pyranose configuration.

Bollenback *et al.* (3) did not report the detection of either α- or β-1,2-*O*-ethylene-D-glucopyranose. This suggests that the mild conditions employed in the hydrolysis of starch favor the formation of the furanose form, while the more strenuous conditions necessary for the hydrolysis of cellulose favor the pyranose form. Hook and Lindberg (5) also reported a predominance of the furanose form of 1,2-*O*-ethylene-α-D-glucose resulting from the treatment of 2-*O*-(2-hydroxyethyl)-D-glucopyranose and methyl 2-*O*-(2-hydroxyethyl)-β-D-glucopyranoside with 1 *N* hydrochloric acid.

The inner glucosides are obviously formed by dehydration of 2-*O*-(2-hydroxyethyl)-D-glucopyranose during acid hydrolysis of the blocking groups.

These results suggest that previous reports on the distribution of 2-hydroxyethyl groups in *O*-(2-hydroxyethyl)starch and *O*-(2-hydroxyethyl)cellulose should be reexamined since the inner glucosides must be considered as part of the 2-*O*-(2-hydroxyethyl)-D-glucopyranose.

Fluoranthene studies. IV. Nitration of 2-nitro-, 3-nitro-, and 2-acetamido-fluoranthene

E. H. Charlesworth and Caroline U. Lithown
Department of Chemistry, The University of Manitoba, Winnipeg, Manitoba

Received November 27, 1968

Nitration of 3-nitrofluoranthene yields 3,9-dinitrofluoranthene, and nitration of 2-acetamidofluoranthene yields 2-acetamido-3-nitrofluoranthene. The orientation of both these compounds has been proved. Nitration of 2-nitrofluoranthene has given a dinitro product, but its orientation has not been established. A number of other new fluoranthene derivatives are described.

Canadian Journal of Chemistry, 47, 1595 (1969)

In 1964 Charlesworth and Blackburn (1) showed that 3-amino and 3-acetamidofluoranthene were brominated in pyridine solution in the 2-position. This was in agreement with the postulate of Kloetzel *et al.* (2) that a strongly activating substituent in the A ring would cause further substitution to occur in the same ring. Blackburn (3), in his experimental work and not mentioned in the above paper, describes a bromination of 3-acetamidofluoranthene (**3**) in acetic acid which gave a rather poor yield of a product, m.p. 265–266 °C. This product gave a large depression on mixing with 3-acetamido-2-bromofluoranthene and was not studied further at the time. Blackburn's concluding sentence reads "the possibility exists that this compound

A number of other new fluoranthene derivatives are described.

Canadian Journal of Chemistry, 47, 1595 (1969)

In 1964 Charlesworth and Blackburn (1) showed that 3-amino and 3-acetamidofluoranthene were brominated in pyridine solution in the 2-position. This was in agreement with the postulate of Kloetzel *et al.* (2) that a strongly activating substituent in the A ring would cause further substitution to occur in the same ring. Blackburn (3), in his experimental work and not mentioned in the above paper, describes a bromination of 3-acetamidofluoranthene (**3**) in acetic acid which gave a rather poor yield of a product, m.p. 265–266 °C. This product gave a large depression on mixing with 3-acetamido-2-bromofluoranthene and was not studied further at the time. Blackburn's concluding sentence reads "the possibility exists that this compound

9

is an isomer of 3-acetamido-2-bromofluoranthene".

Kaminska and Mazonski (4) report the preparation of 3-acetamide-8-bromofluoranthene (**4**), m.p. 260–262 °C, by a bromination of the 3-acetamido derivative in a mixture of glacial acetic acid and carbon tetrachloride. We have repeated their bromination and find no melting point depression on mixing with Blackburn's product. Isolation of two different bromination compounds proves that not only directing substituents must be considered, but the solvents and conditions used in the bromination as well.

We have prepared a third bromo isomer, namely 3-acetamido-9-bromofluoranthene (**5**). This has been obtained by the reduction and acetylation of 3-nitro-9-bromofluoranthene prepared by the method of Campbell and Keir (5).

As the bromination of 2-nitro and 2-acetamidofluoranthene had been studied by Charlesworth and Dolenko (6), it now seemed desirable to undertake nitration studies of these two products. An attempt at nitration of 2-nitrofluoranthene was reported by Wilshire (7), but the orientation of the product was not established. Unfortunately we have not been able to obtain sufficient chromatographed product to work extensively with it. Mass spectral studies do not prove the position of the second nitro group, but the 8- or 9-position seems most probable.

Nitration of 2-acetamidofluoranthene (**6**) gave a mononitration product **7** and hydrolysis gave the 2-aminonitro product **8.** Deamination by diazotization and treatment with hypophosphorous acid gave the well-known 3-nitrofluoranthene (**2**), indicating that the nitro group had entered position-3. Oxidation of 2-amino-3-nitrofluoranthene (**8**) gave 1-fluorenone carboxylic acid (**9**), which is further proof that the nitro group had entered the A ring. Catalytic reduction of 2-acetamido-3-nitrofluoranthene (**7**) gave the rather crude 2-acetamido-3-aminofluoranthene (**10**). Acetylation gave 2,3-diacetamidofluoranthene (**11**) identical with that prepared by Kloetzel, King, and Menkes (2) from 3-acetamido-2-nitrofluoranthene (**12**).

Further nitration of 3-nitrofluoranthene (**2**) was attempted by Wilshire (7), but gave only a very crude product of m.p. 180–280° which was not studied further. By nitration at 70–80° in acetic anhydride with fuming nitric acid, we obtained dinitro product (**13**) which after several purifications by thin–layer chromatography (t.l.c.) and finally sublimation *in vacuo*, appeared to be reasonably pure. The corresponding diamine obtained by reduction was isolated in the form of its diacetamido derivative (**14**). No depression in melting point occurred on mixing with an authentic sample of 3,9-diacetamidofluoranthene (**14**), prepared from 3,9-diacetyl-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

fluoranthene (**15**) by a Schmidt reaction with sodium azide, as described by Campbell *et al.* (9). Both samples of diacetamidofluoranthene also gave identical infrared (i.r.) and ultraviolet (u.v.) spectra. This evidence proves the 3,9-orientation of the dinitro compound. This 3,9-dinitrofluoranthene was extremely stable to oxidation and no dinitro fluorenone carboxylic acid was isolated.

Experimental

Melting points are corrected and have been determined on a Fisher–Johns melting point apparatus. The following instruments have been used, a Perkin–Elmer 450 spectrophotometer for u.v., a Perkin–Elmer 137 spectrophotometer for i.r., and a Hitachi Perkin–Elmer RMU 6 D mass spectrometer.

3-Nitrofluoranthene (**2**) was prepared from fluoranthene (**1**) by the method of Garascia *et al.* (8), reduced to 3-aminofluoranthene, and acetylated to the 3-acetamido derivative (**3**) by following the directions of Kloetzel *et al.* (2).

2-Nitrofluoranthene was produced from fluoranthene in seven steps, as also described by Kloetzel *et al.* (2). In three further steps also described by them the 2-nitrofluoranthene was changed to 2-acetamidofluoranthene (**6**).

3-Acetamido-8-bromofluoranthene (4)[1]

Bromine (1.0 ml) in glacial acetic acid (25 ml) was added dropwise over a period of 20 min to a stirred solution of 3-acetamidofluoranthene (2.0 g) in glacial acetic acid (190 ml) at 80 °C. The mixture was stirred at 80 °C for a further 35 min during which time a small amount of precipitate separated. This crude product was filtered and crystallized from chlorobenzene (charcoal). It melted at 249–250 °C. On further crystallization from pyridine it melted at 265–266 °C. There was no depression of melting point on mixing with a sample of 3-acetamido-8-bromofluoranthene, m.p. 260–262 °C, prepared by the bromination directions of Kaminska and Mazonski (4). The i.r. and u.v. spectra of the two samples also confirmed their identity. Infrared peaks (Nujol) are at 3.13, 6.01, 6.52, and 7.84 μ.

There is a large melting point depression on mixing with a sample of 3-acetamido-2-bromofluoranthene, m.p. 266–267 °C as prepared by Charlesworth and Blackburn (1).

3-Acetamido-9-bromofluoranthene (5)

3-Amino-9-bromofluoranthene obtained by Campbell and Keir (5) by reduction of 3-nitro-9-bromofluoranthene with iron powder was prepared by us, by reduction with platinum as described by Charlesworth and Dolenko (6) for the corresponding 2-acetamido-9-bromofluoranthene. Acetylation of Campbell and Keir's amine gave the apparently hitherto unprepared 3-acetamido-9-bromofluoranthene. It was obtained as light-yellow needles, m.p. 280–281 °C from chlorobenzene.

Anal. Calcd. for $C_{18}H_{12}ONBr$: N, 4.1; Br, 23.6. Found: N, 4.0, Br, 23.9.

Infrared peaks for this compound (Nujol mull) are at 3.23, 6.15, 5.60, and 7.90 μ. Admixture with 3-acetamido-8-bromofluoranthene gave a melting point depression of at least 30°.

Nitration of 2-Nitrofluoranthene

Fuming (95%) nitric acid (1 ml) was added dropwise with stirring to a solution of 2-nitrofluoranthene (0.5 g) in freshly distilled acetic anhydride (15 ml). The solution was refluxed for 3 h, cooled to room temperature, and allowed to stand overnight. The solid (0.15 g) which precipitated out of solution was filtered, washed with water, dried, and dissolved in benzene. The benzene solution was chromatographed on a column (12 in. × ½ in.) filled with alumina (Brockman, neutral, activity I) and the dinitrofluoranthene was eluted in the first portion. The pure 2,(?)-dinitrofluoranthene (0.08 g) was isolated from acetone as bright-yellow needles, m.p. 345–347 °C (sublimation).

Anal. Calcd. for $C_{16}H_8O_4N_2$: N, 9.59. Found: N, 9.60.

Infrared peaks (Nujol) are at 6.55 and 7.43 μ. Mass spectra: M^+/e; 292, 276, 262, 246, 234, 216, 202, 200.

2-Acetamido-3-nitrofluoranthene (7)

2-Acetamidofluoranthene (1.3 g) was dissolved at 80–85 °C in glacial acetic acid (130 ml) to which acetic anhydride (10 drops) had been added. Concentrated nitric acid (0.66 ml) was added dropwise and the solution stirred at the aforementioned temperature for 3 h. The reaction mixture was then allowed to stand at room temperature in an open vessel for 2 days. During this time, most of the solvent evaporated and black crystals (0.8 g) of m.p. 150–153 °C were formed. On recrystallization from glacial acetic acid (charcoal) the 2-acetamido-3-nitrofluoranthene separated as golden-yellow micro crystals of m.p. 190–193 °C. It can also be obtained as bright yellow flocculent needles by crystallization from ethanol–water.

Anal. Calcd. for $C_{18}H_{12}O_3N$: N, 9.21. Found: N, 9.17.

Infrared peaks of this compound (Nujol) occur at 3.02, 5.97, 6.22, 6.57, and 7.27 μ.

2-Amino-3-nitrofluoranthene (8)

2-Acetamido-3-nitrofluoranthene (0.6 g) was hydrolyzed by refluxing for 3 h with a mixture of ethanol (33 ml, 95%) and concentrated hydrochloric acid (33 ml). After the reaction mixture had cooled it was neutralized with 10% aqueous sodium hydroxide solution, and the crude amine (0.5 g) collected. It was recrystallized from ethanol–water, dried in a vacuum desiccator, and then in a drying pistol over P_2O_5. It melted at 244–246 °C.

Anal. Calcd. for $C_{16}H_{10}O_2N_2$: N, 10.68. Found: N, 10.97.

Infrared peaks occur at 2.90, 3.02, 6.00, 6.27, 7.34, and 7.95 μ.

Deamination of 2-Amino-3-nitrofluoranthene

Sodium nitrite (0.09 g) was dissolved at room temperature in a solution of concentrated sulfuric acid (3.1 ml) and water (0.2 ml). The solution was cooled to −5 °C and powdered 2-amino-3-nitrofluoranthene (0.25 g) was carefully added at this temperature. The reaction mixture

[1]This was prepared with the assistance of B. J. Blackburn.

For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was stirred at the stated temperature for 30 min. Precooled 50% hypophosphorous acid (6.53 ml) was added over a period of 30 min such that the temperature did not exceed 5 °C. The reaction mixture was allowed to stand for 6 days at 2–3 °C, after which it was diluted with 3 volumes of water. The precipitate formed was filtered, washed with sodium hydroxide solution (10%) and water. After drying, it was recrystallized from glacial acetic acid and gave pure 3-nitrofluoranthene (0.12 g) m.p. 156–158 °C.

Anal. Calcd. for $C_{16}H_9O_2N$: N, 5.76. Found: N, 5.57.

A mixed m.p. with an authentic sample of 3-nitrofluoranthene prepared by direct nitration of fluoranthene gave no depression. Infrared and u.v. spectra of the two specimens also confirmed their identity. Infrared peaks (Nujol) are at 6.24, 6.62, and 7.56 μ.

Oxidation of 2-Amino-3-nitrofluoranthene

A solution of chromic anhydride (1.5 g) in water (2 ml) and glacial acetic acid (2 ml) was added over a period of 10 min to a boiling suspension of 2-amino-3-nitrofluoranthene (0.4 g) in glacial acetic acid (20 ml). The mixture was refluxed for 4 h and then poured into dilute sulfuric acid solution (50 ml, 1:4 v/v) and allowed to stand at room temperature overnight. The separated solid was filtered, washed with dilute acid, then water and allowed to dry. It was purified by dissolving in 5% sodium carbonate solution, filtering out a small amount of insoluble material. The acid was reprecipitated by acidification with 25% sulfuric acid, collected, and dried. On crystallization from acetic acid, fluorenone-1-carboxylic acid (**9**) was obtained as orange needles (0.12 g) which melted at 191–193 °C.

Admixture with an authentic sample of fluorenone-1-carboxylic acid prepared by the oxidation of fluoranthene gave no melting point depression. Infrared spectra of the two specimens were also identical.

*2-Acetamido-3-aminofluoranthene (**10**)*

2-Acetamido-3-nitrofluoranthene (0.5 g) and palladium–charcoal catalyst (0.056 g) were suspended in absolute ethanol (21 ml). The suspension was hydrogenated at a pressure of 21 p.s.i. for 24 h. The product was brought into solution by adding pyridine (25 ml) and heating. The catalyst was filtered and most of the solvent evaporated under vacuum. Crude 2-acetamido-3-aminofluoranthene (0.38 g) precipitated on dilution with water. It was recrystallized from pyridine as a bright yellow solid (0.28 g) which melted at 204–206 °C.

Anal. Calcd. for $C_{18}H_{14}ON_2$: N, 10.21. Found: N, 8.85.

As this analysis indicates a rather crude amine it was purified by t.l.c. on silica gel. The plate was developed five times using (*a*) chloroform – 1%methanol; (*b*) chloroform – 3%methanol, (*c*) chloroform – 5%methanol, (*d*) chloroform – 7%methanol, and (*e*) chloroform – 10% methanol. The lowest band on extraction gave yellow needles, m.p. 235–236 °C.

Anal. Calcd. for $C_{18}H_{14}ON_2$: N, 10.21. Found: N, 10.97.

*2,3-Diacetamidofluoranthene (**11**)*

Impure 2-acetamido-3-aminofluoranthene (0.15 g) was dissolved in pyridine (25 ml) and acetic anhydride (4 drops) was added. The solution was stirred at room temperature for 90 min and allowed to stand for 2 h to allow some of the pyridine to evaporate. A bright yellow solid precipitated and was crystallized from glacial acetic acid as cream colored microcrystals (0.13 g). These melted at 262–263 °C and the m.p. was not depressed by admixture with 2,3-diacetamidofluoranthene of m.p. 267–268 °C prepared as described by Kloetzel, *et al.* (2). Comparison of i.r. and u.v. spectra of the two samples confirmed the identity of the two samples.

*3,9-Dinitrofluoranthene (**13**)*

Fuming (95%) nitric acid (2 ml) was added dropwise, over a period of 10 min, to a mixture of 3-nitrofluoranthene (2.0 g) in acetic anhydride (60 ml) maintained at 65–71 °C. The nitration mixture was stirred at 70–80 °C for 30 min and then allowed to stand at room temperature for a further 90 min. The solid (1.5 g) was filtered and washed with water. After two crystallizations from glacial acetic acid (charcoal) it was obtained as yellow-orange crystals (0.75 g), of m.p. 275–276 °C.

Anal. Calcd. for $C_{10}H_8N_2O_4$: N, 9.60. Found: N, 10.26.

The somewhat high nitrogen suggested the presence of a little trinitrofluoranthene, so the product was developed twice by t.l.c. on silica gel and finally sublimed at 150° *in vacuo*.

Anal. Calcd. for $C_{16}H_8N_2O_4$: C, 65.7; H, 2.76; N, 9.60. Found: C, 64.7; H, 2.73; N, 9.56.

Oxidative treatment of the dinitro compound with chromic anhydride in the conventional manner in an attempt to isolate a substituted fluorenone was unsuccessful. Unchanged starting product only was isolated.

*3,9-Diacetamidofluoranthene (**14**)*

3,9-Dinitrofluoranthene (1.5 g), and palladium–charcoal (0.25 g) were suspended in ethanol (100 ml). The dinitro compound was reduced with hydrogen under pressure (26–23 p.s.i.) for 6 h. The catalyst was filtered off and the solvent evaporated to about 10 ml. The solution of the diamine was unstable and darkened quickly, so it was isolated as its diacetyl derivative, by adding pyridine (25 ml) and acetic anhydride (5 ml). The mixture was stirred at room temperature for 10 h. The excess solvent was evaporated *in vacuo* and the cream colored solid which separated was filtered and crystallized from benzene. The 3,9-diacetamidofluoranthene (0.9 g) was isolated as a light-yellow solid, m.p. ~ 360 °C (lit. ref. 9, 370 °C).

Admixture with an authentic sample of 3,9-diacetamidofluoranthene prepared from 3,9-diacetylfluoranthene by a Schmidt reaction with sodium azide according to the directions of Campbell, *et al.* (9), did not depress the melting point. These workers established the orientation by conversion of the 3,9-diamino dihydrobromide by a Sandmeyer reaction into 3,9-dibromofluoranthene. Our own attempts to pass from the crude 3,9-diamine to the 3,9-dibromo compound were unsuccessful.

Comparison of i.r. and u.v.s pectra of the two samples of the diacetamidofluoranthene confirmed their identity.

Electron impact-induced rearrangements of acetylenic compounds[1]

R. T. APLIN
Dyson Perrins Laboratory, Oxford, England

AND

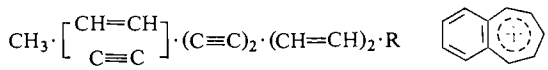
S. SAFE
Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received September 18, 1968

The mass spectra of all-*trans*-hepta-2,4-dien-6-yn-1-ol (**3**) and all-*trans*-hepta-2,4-dien-6-yn-1-al (**6**) are remarkably similar to benzyl alcohol and benzaldehyde respectively. Comparison of α-*d*-all-*trans*-hepta-2,4-dien-6-yn-1-ol (**5**) and α-*d*-benzyl alcohol shows that the deuterium in the $C_7H_7^+$ tropylium ion is randomized in both compounds.

Canadian Journal of Chemistry, 47, 1599 (1969)

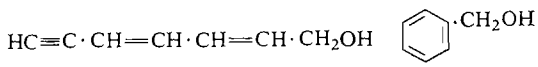
A problem of mass spectrometry concerns the formation of the $C_7H_7^+$ tropylium ion and other stable aromatic species. Acetylenic compounds of the type (**1**) undergo extensive rearrangement to give the $C_{11}H_9^+$ ion (**2**), as a major fragment (1). The C_7 acetylenic alcohol (**3**) possesses the yne-diene chromophore which is often contained in more complex polyacetylenes and upon electron impact affords a spectrum which resembles



1 **2**

R = —CH_2OH, —CH_2OAc, —$CH_2CH_2CH_2OH$, —$(CH_2)_4 \cdot CH{=}CH_2$, —$CH(OH)(CH_2)_3 \cdot CH{=}CH_2$

that of benzyl alcohol (**4**). A comparison of the fragmentation patterns is shown in Fig. 1. In addition it has been previously shown (3, 4) that the mass spectra of toluene and several of



3 **4**

its acyclic C_7H_8 isomers are also similar, each giving a strong $C_7H_7^+$ tropylium ion. The formation of the $C_7H_7^+$ ion from benzyl alcohol (**4**) and several of its deuterated derivatives occurs with complete hydrogen (or deuterium) and carbon scrambling (5–8). Recently, however, Meyerson *et al.* (9) have shown that the statistics for diphenylmethane-α-d_2 fragmentation support tropylium-1,2-d_2 as the precursor for the $C_5H_5^+$ ion. Bohlmann and his co-workers (2) have examined the spectra of several acetylenic compounds in which both the $C_{11}H_9^+$ and $C_7H_7^+$ ions are assigned linear structures in which hydrogen scrambling has not occurred.

We have now determined the mass spectrum of the deuterated alcohol (**5**) and compared it with that of α-*d*-benzyl alcohol. Examination of the $C_5H_5^+$ and $C_5H_4D^+$ ions indicates that for

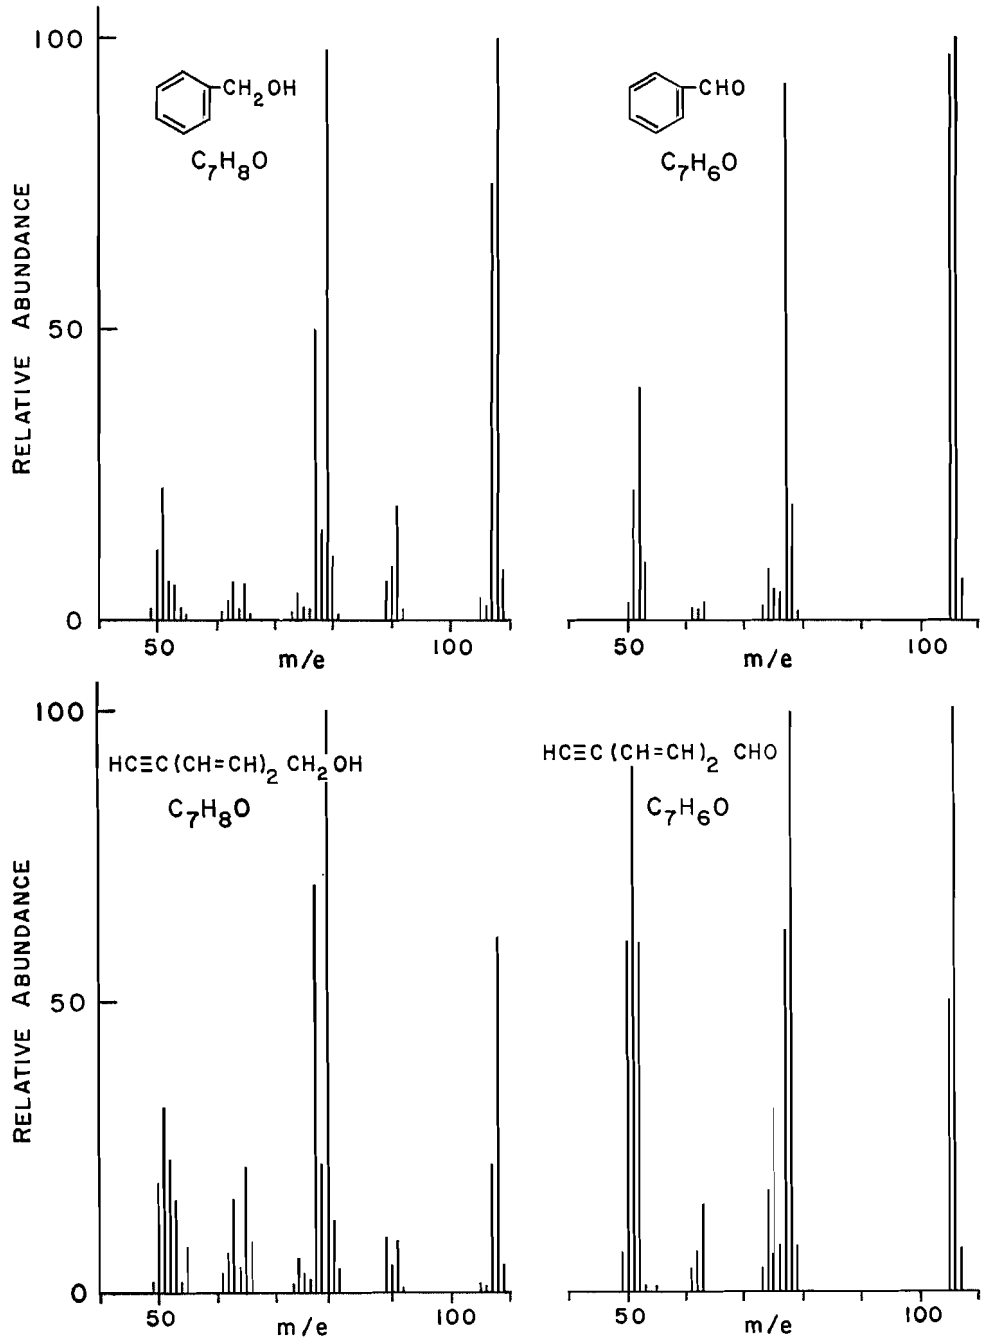

FIG. 1. A comparison of mass spectral fragmentation patterns.

the deuterated acetylenic alcohol (**5**), 74% of the deuterium is retained in the latter ion; the spectrum for α-*d*-benzyl alcohol shows 69% of the label retention (6) in the $C_5H_4D^+$ ion. These data are in agreement with 71% calculated for complete equilibration of the hydrogen atoms in the $C_7H_7^+$ precursor. The results obtained for the deuterated alcohol (**5**) and α-*d*-benzyl alcohol clearly indicate a common ion fragmentation pathway but the nature of the $C_7H_7^+$ ion, commonly designated as the tropylium moiety, is still not certain. The hydrogen atoms in the acetylenic

alcohols (**6**) and (**7**) are also equilibrated (12) in their decomposition to $C_9H_7^+$ (*m/e* 115) represented as the indene ion (1).

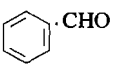
A comparison of the mass spectra of the acyclic C_7 aldehyde (**8**) and benzaldehyde (**9**) is shown in Fig. 1. In both spectra metastable ions at m* 104 (106 $\xrightarrow{-H\cdot}$ 105), m* 76 (78 $\xrightarrow{-H\cdot}$ 77), and m* 56.4 (105 $\xrightarrow{-CO}$ 77) are observed. Since some evidence has been reported that acetylenic compounds give prominent linear ions (2) this result raises some doubt about the cyclic nature

$HC{\equiv}C\cdot CH{=}CH\cdot CH{=}CH\cdot CHO$ **8**



9

of the $C_6H_5^+$ ion (10) which is reported to be a prominent fragment in the mass spectra of benzaldehyde and several other monosubstituted phenyl derivatives.

Experimental

Mass spectra were measured with a Consolidated Electrodynamics Corporation 21-110B instrument using electrical detection. Samples were introduced by effusion of vapor from a glass reservoir at 80 °. Several spectra in sequence showed constancy of the mass spectral patterns and absence of thermal reactions in the inlet system.

All-trans-hepta-2,4-dien-6-yn-1-ol (3)

The alcohol (**3**) was prepared by the method of Bohlmann *et al.* (11) in which Zincke aldehyde (all-*trans*-5-methylanilinopentadienal) is converted into all-*trans*-hepta-2,4-dien-6-yn-1-al (**6**) by the action of lithium acetylide in liquid ammonia; the alcohol is readily obtained by sodium borohydride reduction of the corresponding aldehyde.

All deuterated derivatives were prepared by sodium borodeuteride reduction of the corresponding aldehydes.

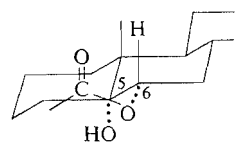
considerable use in determining the conformation of the hydroxyl group concerned in the formation of the acetate (2). The origin of these multiple bands was suggested by these authors, as due to the presence of an equilibrium mixture of labile rotational isomers resulting from hindrance to the rotation about one or both of the C—O bonds of the axial acetate group. No indication was given, however, for the actual conformation of these isomers. It was also implied in these arguments that the strong single band of the equatorial acetate was due to free rotation around the C—O bonds.

Recent optical rotatory dispersion (o.r.d.) studies have, however, shown that both the axial and the equatorial acetates of secondary hydroxyl groups in rigid systems as the steroids, have no free rotation in solution, but assume a preferred conformation (3). Nuclear magnetic resonance (n.m.r.) spectral studies of different esters of steroid hydroxyl groups also lead to the same conclusion and extend it to the esters of tertiary and primary hydroxyl groups (4). We now wish to report that i.r. spectral studies fully support the above conclusions.

The preferred conformation of the esters of steroid C_6 α- and C_6 β-hydroxyl groups can now be represented by **1** and **2** respectively (wherein the carbonyl group nearly eclipses the secondary hydrogen atom concerned), and that of the C_5 α-ester by **3** (wherein the carbonyl group is situated near to, and at an equal distance from, the C_4 α-H and the C_6 α-H) (4). Models would then show that in the steroid 5α,6β-diol monoesters of type **2** or **3** intermolecular hydrogen bonds would be possible between the ester carbonyl of one, and the free hydroxyl group of the other molecule. But intramolecular hydrogen bonds would not be possible as the minimum distance between the two would be over 3.5 Å. In the case of 5α,6α-diol-6-monoacetates of type



1

1 also, no intramolecular hydrogen bond would be possible if the acetate group is in conformation **1**, since the distance between the two is then over 4 Å. Intermolecular hydrogen bonds would also be difficult, because the other steroid molecule has to be near the highly hindered β-face of one molecule. Data collected from 9 steroid esters and given in Table I, fully support the above arguments.

The axial secondary acetate **4** which cannot form any hydrogen bond displays a single carbonyl absorption at about 1733 cm^{-1} in $CHCl_3$ solution, but **5** and **6** which have in addition a 5α-OH show an additional carbonyl band at a lower frequency in all the solvents tried, except dioxan. Similarly in the other esters **7** and **8** formate and benozate, an additional carbonyl band is found at a lower frequency. Compound **9**, which has its acetate at C_4, but with the same conformation as those at C_6, also behaves similarly. Compound **10** also (type **3**), as would be expected, shows an additional absorption at a lower frequency. The fact that the ratio of the intensity of the higher frequency band to that of the lower frequency band (it varies from 1.32 to 5.35 for compound **5**) is dependent on concentration (0.05–0.005 *M* solutions were used), with the corresponding changes in the OH absorption region, and the fact that, in dioxan solution, the lower frequency band completely disappears, clearly shows that the lower frequency band is due to intermolecular hydrogen bonding.

The 5α,6α-diol 6-equatorial monoacetate **12** shows only a single carbonyl absorption at the higher frequency, and that it is due to a non-bonded carbonyl is vouched for by the spectrum of the 6α-acetate, **11**. By rotating the carbonyl group of **1** through 180° along the C_6—O axis (when it would ultimately become 1,3-*cis*-diaxial with the C_5 α-OH), conformations can be obtained in which the carbonyl can readily form intermolecular or intramolecular hydrogen bonds. But the molecule does not appear to do so, in spite of the possible energy release by hydrogen bonding. Also in compounds of type **2**, intermolecular hydrogen bonding would have been difficult if the carbonyl had assumed other conformations in which it goes near the hindered β-face of the molecule. Thus, it would appear that the conformation of the ester carbonyl group of secondary hydroxyl groups are stabilized near the methine hydrogen atoms (and probably those of esters of tertiary and primary alcohol groups near the methine and methylene protons concerned), perhaps due to some intramolecular forces, which are not yet very clear (6). The energy of this stabilization of conformation, or that required to move it from the preferred conformation appears to be more than that gained by hydrogen bonding of the carbonyl with a favorably placed hydroxyl group, since the 6α-acetate carbonyl does not get hydrogen bonded to the 5α-OH.

This preferred conformation of the carbonyl group would at least partly account for the absence of hydrogen bonding noted in the ground state, between the carbonyl and hydroxyl groups, in the i.r. spectra of 1,3-*cis*-diol monoacetates (7).

Experimental

The spectra were determined in the solvents given, on a Perkin–Elmer Model 221 spectrophotometer, using a sodium chloride prism and grating. Concentrations varying from 0.05 to 0.005 *M* solutions were used. The intensities of peaks were measured by the areas enclosed by them.

8,Cholestan-3β,5α,6β-triol-3-methyl Ether-6-benzoate

Benzoyl chloride (2 ml) was added to a solution of cholestan-3β,5α,6β-triol-3-methyl ether (300 mg) in pyridine (2 ml) and left at room temperature overnight. The reaction mixture was then poured into ice cold water, extracted with ether, worked up in the usual way, and crystallized from methanol. Yield, 200 mg, m.p. 154°, $(\alpha)_D$ −26° (*c*, 1.0 in chloroform), ν_{max}, 3400 (hydroxyl) 1718, and 1700 cm^{-1} (ester carbonyl in CCl_4).

Carbonyl ammine complexes of ruthenium(II)

A. D. ALLEN, T. ELIADES, R. O. HARRIS, AND P. REINSALU

Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario

Received September 6, 1968

A series of carbonyl tetrammine and pentammine complexes of ruthenium(II) has been prepared. The compounds have been characterized by analytical techniques and by the reactions they undergo. Some carbonyl triammine and nitrogen tetrammine compounds are also reported.

Canadian Journal of Chemistry, 47, 1605 (1969)

Introduction

There have been several reports of substituted carbonyl complexes of ruthenium(II). These are generally of the type $[RuXYCOA_3]$ (1) and *cis*- and *trans*-$[RuXY(CO)_2A_2]$ (2) where X = Cl^-, Br^-, NCS^-; Y = H^-, Cl^-, Br^-, NCS^-; and A = PR_3, AsR_3 (R = alkyl or aryl), and $[RuS_2CO]$ and $[RuS_2(CO_2)]$ (3) where S = $R_2NCS_2^-$. No simple ammine carbonyls of ruthenium have been reported, but a number of similar complexes such as nitrosyl-pentammines (4) and -tetrammines (5), sulfur dioxide-tetrammines (6) and -pentammines (7), and nitrogen-pentammines (8) are known. We now report the preparation and characterization of some carbonyl–ammine–ruthenium(II) complexes and nitrogenaquotetrammine–ruthenium(II) complexes.

Experimental

The instruments used in this work were a Perkin–Elmer 521 infrared (i.r.) spectrophotometer (Nujol mull between KBr plates), a B and L 505 spectrophotometer (1 cm fused silica cells), and a Varian HA 100 nuclear magnetic resonance (n.m.r.) spectrometer. A Gouy balance was used for the magnetic susceptibilities. Micro-analyses were performed by A. B. Gygli, Toronto (see Table I).

Preparations

1. Chloropentammineruthenium(III) Dichloride, $[Ru(NH_3)_5Cl]Cl_2$

This was prepared by the method of Gleu (10) except that the oxidation of the hexammineruthenium(II) to hexammineruthenium(III) was carried out using bromine vapor instead of concentrated nitric acid (unpublished results). This method of oxidation has the advantage of excluding nitrate from the solution which, if not removed completely, tends to give insoluble brown products.

2. cis-Dichlorotetrammineruthenium(III) Chloride, cis-$[Ru(NH_3)_4Cl_2]Cl$

This was prepared by the method of Gleu and Cuntze (11) through the oxalatotetrammine.

3. trans-Chloro(sulfur dioxide)tetrammineruthenium-(II) Chloride, trans-$[Ru(NH_3)_4SO_2Cl]Cl$

This was prepared by the method of Gleu *et al.* (6).

4. Carbonylpentammineruthenium(II) Dihalide, $[Ru(NH_3)_5CO]X_2$ where X = Cl^-, Br^-, I^-

Chloropentammineruthenium(III) dichloride (1 g, 0.0034 mole) was dissolved in 0.1 *M* sulfuric acid (or 0.1 *M* formic acid). Freshly prepared amalgamated granulated zinc (2 g) was added. Carbon monoxide was passed through the stirred mixture for 2–3 h at room temperature. The appropriate anion was then added to the pale yellow filtrate. The colorless to pale yellow precipitate of $[Ru(NH_3)_5CO]X_2$ that formed on cooling was washed with cold water, alcohol, and ether, and air dried, yield 0.6 g (61.5%) for X = Cl^-. The product can be recrystallized from dilute ammonia.

5. cis-Aquocarbonyltetrammineruthenium(II) Dihalide, cis-$[Ru(NH_3)_4H_2OCO]X_2$ where X = Br^-, I^-

cis-Dichlorotetrammineruthenium(III) dichloride (1 g, 0.0036 mole) was dissolved in water and enough sulfuric acid (or formic acid) was added to bring the pH to 4.5–5.5. Freshly prepared amalgamated zinc (2 g) was added. Carbon monoxide was passed through the stirred solution at room temperature for 5 h while the pH of the solution was kept at about 4.5–5.5 by dropwise addition of dilute acid. Addition of the appropriate anion to the yellow filtrate gave, on cooling, a pale yellow precipitate of *cis*-$[Ru(NH_3)_4H_2OCO]X_2$, which was washed with alcohol and ether and air dried, yield 0.42 g (25%) for

X = I^-. The product can be recrystallized from dilute HX.

6. trans-Aquocarbonyltetramminеruthenium(II) Dihalide, trans-[Ru(NH$_3$)$_4$H$_2$OCO]X$_2$ where X = Cl$^-$, Br$^-$, I$^-$

trans - Chloro (sulfur dioxide) tetramminеruthenium (II) chloride (1 g, 0.0033 mole) was made into a slurry with 20 ml 0.1 *M* formic acid. Carbon monoxide gas was passed through the stirred mixture at 70° for 2–3 h. After about 1 h the starting material had dissolved to give a pale red solution, and as the reaction neared completion, the color slowly changed to yellow. Addition of the appropriate anion to the cooled filtrate gave a colorless to yellow precipitate of *trans*-[Ru(NH$_3$)$_4$H$_2$OCO]X$_2$ which was washed with ice-cold water, alcohol, and ether, and air dried, yield 0.8 g (84%) for X = I^-. The product may be recrystallized from hot dilute HX.

7. trans-Thiocyanatocarbonyltetramminеruthenium(II) Thiocyanate, trans-[Ru(NH$_3$)$_4$NCSCO]NCS

trans-Aquocarbonyltetramminеruthenium(II) dichloride (0.5 g, 0.0017 mole) was dissolved in 10 ml of warm water. To the clear colorless solution 5 ml of a saturated solution of sodium thiocyanate was added and the mixture was kept at 50° for 30 min. Colorless needle-like crystals of *trans*-[Ru(NH$_3$)$_4$NCSCO]NCS which formed on cooling to 0° were recrystallized from hot methanol, washed with ethanol and ether, and air dried, yield 0.4 g (70%).

8. Nitrogenaquotetramminеruthenium(II) Dihalide, [Ru(NH$_3$)$_4$H$_2$ON$_2$]X$_2$ where X = Cl, Br, I

cis-Dichlorotetramminеruthenium(III) chloride[1] (1 g, 0.0036 mole) was dissolved in 20 ml of water and excess sodium azide (2 g) was added to the solution, which was stirred at room temperature for 15 min. The resulting red solution was cooled to 10°. Acidification with methanesulfonic acid to pH 2, gave a vigorous reaction with evolution of gas and loss of color. Addition of the appropriate anion gave a colorless to pale yellow precipitate of [Ru(NH$_3$)$_4$H$_2$ON$_2$]I$_2$ which was recrystallized from dilute HX, washed with alcohol and ether, and air dried, yield 0.68 g (40%) for X = I. Nitrogenoaquotetrammine can also be prepared in poor yield from *cis*-dichlorotetramminеruthenium(III), by treatment with amalgamated zinc under nitrogen. A dimeric ion is first formed which on treatment with ammonia yields nitrogenoaquotetramminеruthenium(II).

Results and Discussion

Typical i.r. spectra are shown in Figs. 1–4 and summarized in Table II. By comparison with similar ruthenium complexes (8, 9), all bands can be assigned to coordinated ammonia vibrations, except for the following. In the carbonyl complexes a strong band in the region 1970–1890 cm^{-1}, is assigned to ν_{C-O} (Table III), and another two bands in the region 500–600 cm^{-1}, δ_{C-O} and ν_{M-C} (12–14). In the nitrogen complexes a strong band in the region 2120–2080 cm^{-1} is assigned to ν_{N-N} and another in the region 450–550 cm^{-1} to ν_{M-N} (8). A high energy shoulder on the ρ_{NH_3} band in the region 850–780 cm^{-1} for all aquotetrammine complexes is assigned to coordinated water (15).

‡Unpublished results.

§The infrared spectrum of this compound was reported by Vogt *et al.* (18), who assigned the bands at 1304 and 1280 cm^{-1} to SO stretching vibrations and the band at 1245 cm^{-1} to the δ_{NH_3} symmetric vibration. We have found that the bands at 1340 and 1280 cm^{-1} shift to 1062 and 998 cm^{-1} on deuteration, the band at 1248 cm^{-1} being unshifted. We have, therefore, assigned the bands at 1304 and 1280 cm^{-1} to δ_{NH_3} symmetric vibrations and the band at 1248 cm^{-1} to SO stretching vibrations. We also found that ν_{NH_3} vibrations (3300, 3170 cm^{-1}) were at lower frequency than reported by Vogt *et al.*

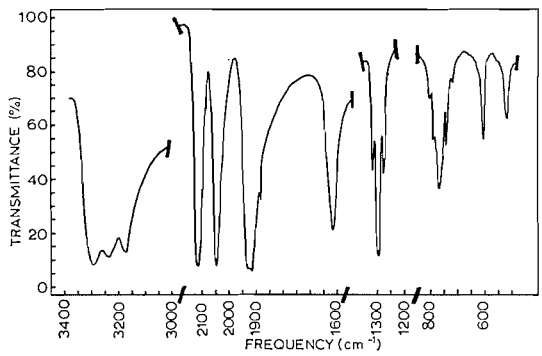

FIG. 4. Infrared spectrum of *trans*-$[Ru(NH_3)_4NCSCO]NCS$.

In the case of the thiocyanato carbonyl complex, two additional bands at 2118 and 2050 cm^{-1} are assigned to coordinated ν_{C-N} and free (ionic) ν_{C-N} respectively, and two bands at 800 and 745 cm^{-1} are assigned to coordinated ν_{C-S} and ionic ν_{C-S}. On the basis of the i.r. spectrum (Fig. 4) it appears that the thiocyanate is coordinated through the nitrogen rather than the sulfur (16). Replacement of ionic thiocyanate by iodide (by ion exchange) removes the two bands assigned to the free thiocyanate (2050, 745 cm^{-1}).

The electronic spectra of these complexes in aqueous solution have been examined in the region 200–600 mμ. Spectra of all the carbonyl complexes are similar, with absorption maxima in the region 275–290 mμ, $\varepsilon_{max} \simeq 200$–300. The nitrogen complex shows a strong absorption at 220 mμ with $\varepsilon_{max} \simeq 13\,000$.

The p.m.r. spectra were taken in D_2O. The *trans*-aquocarbonyl complex (**1**) should show a single band, corresponding to 4 equivalent ammonia ligands. The carbonylpentammine (**2**) should show two bands, in the ratio 1:4, one for the ammonia *trans* to the carbonyl and one for the four ammonias *cis* to the carbonyl. The *cis*-aquocarbonyl isomer (**3**) should exhibit three bands, in the ratio 1:1:2, one from the ammonia *trans* to the carbonyl, one from the ammonia *trans* to the aquo group, and one for the two ammonia ligands *trans* to each other.

plexes and the deuterated solvent reduced the quality of these spectra, and may account for the poor quantitative result, but the presence of the right number of bands supports other strong evidence in favor of the formulations given for these isomers.

Magnetic Measurements

All the complexes are diamagnetic at room temperature, consistent with spin-paired d^6 ruthenium(II).

Conductivity Measurements

Conductivities were measured in dimethyl sulfoxide in the concentration range 10^{-5} to 10^{-4} *M* at 24°. The results obtained (Fig. 6) indicate that all of the complexes are 2:1 electrolytes except the *trans*-$[Ru(NH_3)_4CONCS]NCS$, which is a 1:1 electrolyte. Halide analysis of the iodide salt of the carbonyl thiocyanato complex gave the required one equivalent of iodide.

Mass Spectra

Analysis of the gas obtained by thermal decomposition of $[Ru(NH_3)_4H_2OCO]I_2$ complex in vacuo gave a substantial band at mass 28 indicating CO or N_2 or both. At high resolution the mass 28 band analyzed to give a $CO:N_2$ ratio of 4:1, confirming the liberation of carbon monoxide from the complex. Similar analysis of the $[Ru(NH_3)_4H_2ON_2]I_2$ complex gave a substantial band at mass 28 and 14 confirming the liberation of nitrogen.

Reactions with Ammonia and Acid

Both the *cis*- and the *trans*-aquocarbonyl and the aquonitrogentetramminеruthenium(II) ions react with aqueous ammonia to give an almost quantitative yield of the carbonyl (or nitrogen) pentammine complex. Treatment of the carbonyl pentammine complex with dilute hydrochloric acid gives the *trans*-aquocarbonyltetrammine. This isomer is unaffected by dilute hydrochloric acid, but the *cis*-aquocarbonyl complex loses one ammonia on warming in dilute (3 *N*) acid giving insoluble products which analyze for dihalocarbonyltriammineruthenium(II). The aquonitrogentetrammine complex gives with acid the unidentified blue solutions which are characteristic of ruthenium(II) (17). The reactions are summarized below

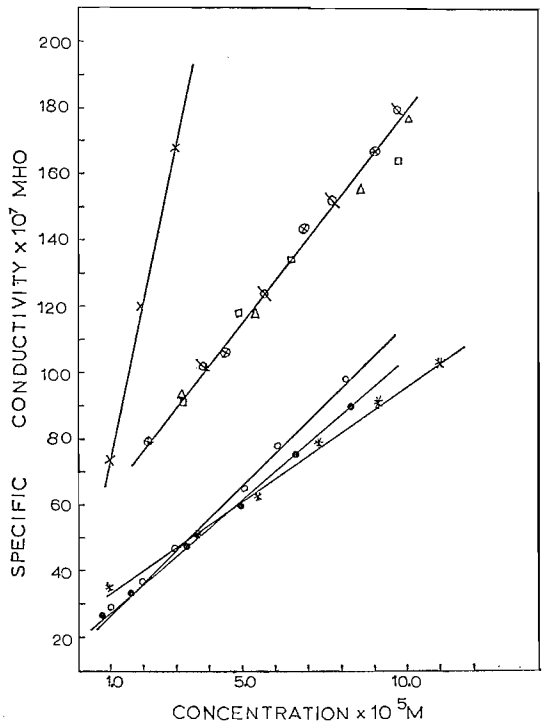

FIG. 6. Conductivity of some complexes of ruthenium in dimethyl sulfoxide at 24°: ×, $[Ru(NH_3)_6]I_3$; *, tertiarybutylammonium iodide; ○, NH_4SCN; ●, *trans*-$[Ru(NH_3)_4CONCS]NCS$; △, *trans*-$[Ru(NH_3)_4H_2OCO]I_2$; ⊕, *cis*-$[Ru(NH_3)_4H_2OCO]I_2$; □, $[Ru(NH_3)_5CO]I_2$; ⊗, $[Ru(NH_3)_4H_2ON_2]I_2$.

The lability of the ammonia *trans* to a carbonyl group is similar to that in nitrosylruthenium(II) complexes, indicating the high *trans* effect of the carbonyl group. These carbonyl complexes are very resistant to oxidation. For example, bromine in hydrobromic acid seems to have no effect at room temperature and on heating, some ammonia is replaced but the carbon monoxide remains attached. The complex products obtained are always diamagnetic, indicating no oxidation. This behavior is similar to that observed with nitrosylruthenium complexes (4) but not with the corresponding nitrogen complexes (8) where oxidation to ruthenium(III) occurs more readily. The carbonyl group can, however, be replaced by nitric oxide by treatment with aqueous nitric acid.

Fragmentation and rearrangement processes in the mass spectra of perhalogenoaromatic compounds. Part II.[1] Pentafluorophenyl derivatives of Group IV[2,3]

J. M. MILLER
Department of Chemistry, Brock University, St. Catharines, Ontario

Received October 8, 1968

The mass spectra of compounds of the type $(C_6F_5)_4M$ (M = Si, Ge, Sn, and Pb) have been studied. Bond forming rearrangements were detected, involving fluorine abstraction by the central atom, forming perfluorophenylene ions and neutral metal fluoride species. The heavier metals give simpler spectra and fragmentation schemes. The bulk of the ion current is carried by fluorocarbon ions for the silicon derivative and by organometallic or metal fluoride ions in the other three cases, SnF^+ and PbF^+ forming the base peaks in their spectra. When M is carbon in the compounds $(C_6F_5)_3COH$ and $(C_6F_5)_2CO$, there is little evidence for rearrangements and transfer of fluorine to the central carbon atom.

Canadian Journal of Chemistry, 47, 1613 (1969)

Introduction

The mass spectra of some pentafluorophenyl derivatives of phosphorus, germanium, silicon, and phosphido-bridged iron carbonyls were shown to exhibit not only normal fragmentation, but also molecular rearrangements involving elimination of central atom-fluoride species formed by fluorine transfer, leaving perfluorophenylene type ions (1). King (2*a*, *b*) and Bruce (2*c*) also have established, by metastable ion analysis, the formation of neutral metal fluorides in mass spectra of a series of aliphatic and aromatic fluorocarbon derivatives of iron and cobalt. Similar results are also reported for manganese derivatives (3). Cavell and Dobbie have reported on fragmentations and rearrangements for a series of trifluoromethyl derivatives of arsenic (4, 7) and phosphorus (5–7).

In this paper the mass spectra of pentafluorophenyl derivatives of Group IV elements are discussed along with postulated mechanisms for the observed rearrangements.

Experimental

Tetrakis(pentafluorophenyl)germane was prepared as described previously (1). Tris(pentafluorophenyl)carbinol was supplied by Filler[4]. The compounds $(C_6F_5)_4M$ (M = Si, Sn, and Pb) were supplied by Tamborski[5]. Decafluorobenzophenone was purchased from Pierce Chemical Company. All samples with the exception of the carbinol and benzophenone were purified by a further sublimation before use.

Mass spectra were recorded on an A.E.I. Model MS9 instrument at 70 eV using the heated inlet system (200°) and on a Hitachi RMU-6E instrument, also at 70 eV but using a direct inlet probe. Spectra obtained on the two instruments were similar. Problems arose with the tin and lead compounds which deposited a conducting metallic film on the insulators in the source, necessitating frequent cleaning. For comparisons, several portions of the spectra were also examined using a Bendix Model 12 time-of-flight mass spectrometer. This instrument, with its lower resolution and difficulty in observing metastable ions, is more suitable for the studies of reaction energetics, rather than for fragmentation and rearrangement pathways.

Results and Discussion

Table I contains a listing of the most important ions in the spectra of the compounds $(C_6F_5)_4M$ (M = Si, Ge, Sn, and Pb)[6]. To facilitate comparisons, since the central atoms are polyisotopic in nature, the ion abundances are taken as a sum of all isotopic contributions and are expressed as a % of the total positive ion current. Part A of Table I shows the metal containing ions while Part B is a list of the major ions containing only carbon and fluorine. Table II summarizes the observed metastable ions.

*For polyisotopic species the metastable ion is calculated for the most abundant isotope. For these very broad peaks it is impossible to accurately determine the *m/e* of the maximum.

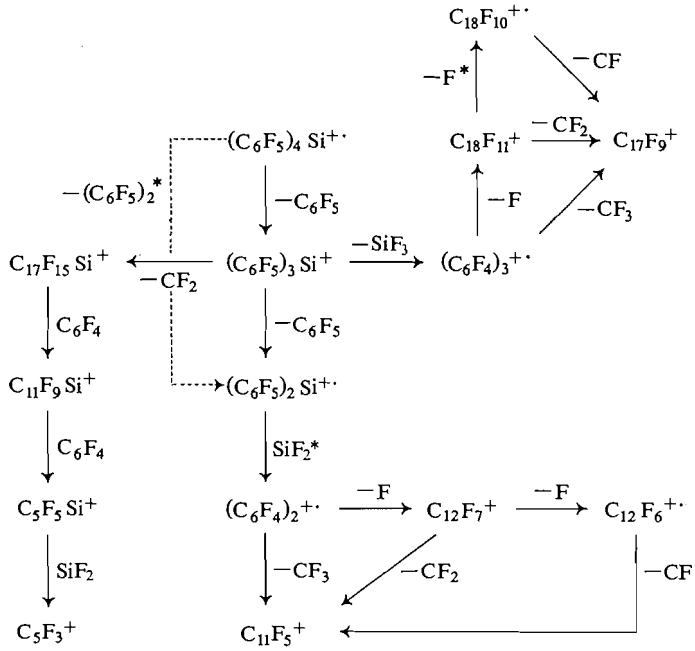

FIG. 1. Breakdown of $(C_6F_5)_4Si$.

Unlike the phosphorus compounds studied previously (1), the Group IV derivatives show few metastable transitions in their mass spectra, making assignment of fragmentation and rearrangement pathways more difficult.

(a) $(C_6F_5)_4Si$

The spectrum of the silane differs from the other three in several respects. There are many more peaks assignable to fluorocarbon fragments and it is the only example in this series, except for the $C_{17}F_{13}Ge^+$ ion, in which the metal atom is found attached to fluorocarbon fragments after the cleavage of an aromatic ring, e.g. $C_{17}F_{13}Si^+$, $C_{11}F_9Si^+$, and $C_5F_5Si^+$. Since Tamborski *et al.* (8) have reported that the thermal stability of the silane is less than that of the germane and stannane, a higher degree of fragmentation might be expected, but this fragmentation is a result of electron bombardment and certainly not due to thermal breakdown in the inlet system. Although the fraction of the total ionization carried by fluorocarbon fragments is highest for the silane, under the conditions of these experiments the yields of $(C_6F_4)_3^{+\cdot}$ and $(C_6F_4)_2^{+\cdot}$ are less than for the germane, contrary to earlier predictions (1).

The fluorocarbon peaks bear strong resemblance to the fragmentation pattern of the three perfluorophenylenes, ($C_{12}F_8$, $C_{18}F_{12}$, and $C_{24}F_{16}$), reported by Cohen and Massey (9). This indicates that many of the fluorocarbon species may have as their precursor ions $C_{12}F_8^{+\cdot}$, $C_{18}F_{12}^{+\cdot}$, and $C_{24}F_{16}^{+\cdot}$. In particular, the former two ions are quite abundant.

These phenylene ions likely are formed by loss of SiF_2, $SiF_3\cdot$, and SiF_4 from $(C_6F_5)_2Si^{+\cdot}$, $(C_6F_5)_3Si^+$, and $(C_6F_5)_4Si^{+\cdot}$, respectively. In contrast to the other three compounds studied in this work, and their hydrogen analogues (10, 11), the ion $(C_6F_5)_3Si^+$ is exceedingly weak. The more complex nature of the mass spectrum of $(C_6F_5)_4Si$ when compared to its Group IV homologues is paralleled by similar behavior for the $(C_6H_5)_4M$ series (M = Group IV elements), for which Enrione and Warren (12) have reported that the spectrum and processes become more complicated as one proceeds to lighter central atoms. The scheme in Fig. 1 illustrates the breakdown of the silane.

(b) $(C_6F_4)_4Ge$

The spectrum of the germane bears some resemblance to that of $(C_6H_5)_4Ge$ (1, 10). The most intense peaks (after taking into account the various isotopes of germanium) are $(C_6F_5)_3Ge^+$

For personal use only.

and $(C_6H_5)_3Ge^+$ respectively. The intensity of these peaks are in marked contrast to the weak R_3M^+ peak of the silane. Characteristic of the germane fragmentation is the rearrangement which leads to the formation of two phenylene radical ions, $(C_6F_4)_3^{+\cdot}$ and $(C_6F_4)_2^{+\cdot}$ in high yield, whereas $(C_6H_4)_2^{+\cdot}$ and $(C_6H_4)_3^{+\cdot}$ were not observed in the spectrum of $(C_6H_5)_4Ge$ (1). Certainly fluorine abstraction by germanium is more prevalent than is hydrogen abstraction from the phenyl analogue, as is indicated by the presence of species such as $(C_6F_5)_2GeF^+$, $G_6F_5GeF_2^+$, GeF^+, and the presence of ions such as the biphenylenes which are undoubtedly formed by fluorine shifts to the central atom. Although metastable ions were not observed for the biphenylene rearrangement in the case of Group IV fluoroaromatics, mechanisms have been clearly established by metastable ions for phosphorus compounds (1). A fragmentation scheme for the germane is shown in Fig. 2. Some of the pathways are by analogy with $(C_6F_5)_4Sn$ for which metastable ions were observed.

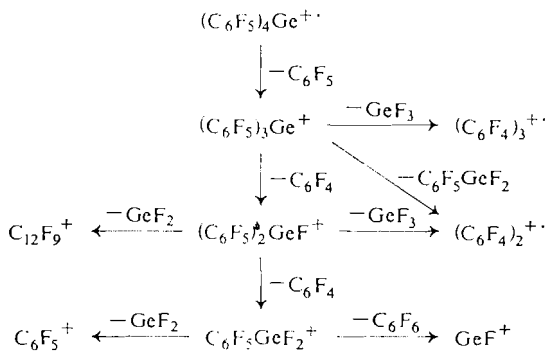

FIG. 2. Breakdown of $(C_6F_5)_4Ge$.

Formation of octafluorobiphenylene ions, $(C_6F_4)_2^{+\cdot}$, appears to result from the elimination of $GeF_3\cdot$ from $(C_6F_5)_2GeF^+$ compared to what appears to be SiF_2 elimination from $(C_6F_5)_2Si^{+\cdot}$, the analogue of this latter ion being absent in the spectrum of the germane. Alternatively, a $C_6F_5GeF_2\cdot$ radical could be eliminated from the abundant ion $(C_6F_5)_3Ge^+$, to produce the biphenylene ion. Dodecafluorotriphenylene ions, $(C_6F_4)_3^{+\cdot}$ could result from $GeF_3\cdot$ elimination from $(C_6F_5)_3Ge^+$. Transfer of three fluorines in a single elimination step has been established previously for Group V derivatives (1, 4, 6).

(c) $(C_6F_5)_4Sn$

The nature of fragmentation and rearrangement processes continues to change on going to heavier central atoms. The spectrum of the stannane shows a much weaker molecular ion than that of the germane, but the R_3M^+ ion retains a prominent place in the spectrum. However, unlike the spectrum of $(C_6H_5)_4Sn$, the $(C_6F_5)_3Sn^+$ ion is not the most intense in the spectrum. The ion SnF^+ is now most intense, indicative perhaps of the gradual weakening of the metal carbon bonds on descending the group. Intensities of the phenylene ions also drop off compared to the germane. For the first time, $C_6F_5M^+$ ions are observed, presumably as one stage leading to the formation of SnF^+ and $Sn^{+\cdot}$ ions. The bare metal ion, not present in the spectrum of the silane and germane is apparent for the stannane.

Apart from these few new ions and changes in intensities, the breakdown scheme (Fig. 3) is similar to that of the germane. Metastable ions were observed, verifying the mode of formation of $(C_6F_5)_2SnF^+$ and $C_6F_5SnF_2^+$ ions through elimination of uncharged C_6F_4 species. In contrast,

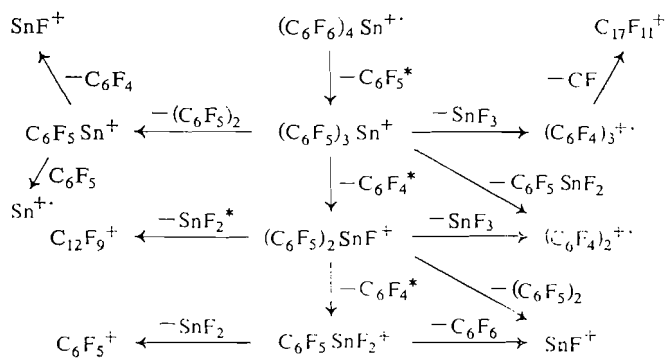

FIG. 3. Breakdown of $(C_6F_5)_4Sn$.

For personal use only.

no major formation of tin–hydrogen bonds was detected in the spectrum of $(C_6H_5)_4Sn$, not surprising since the tin–hydrogen bond is quite weak. Such species are most abundant in the spectra of ethyl–tin derivatives where $Sn–H^+$ abundance parallels the ethyl content of the compound. No evidence is found for any partial fragmentation of the fluoroaromatic rings of any tin containing ions in contrast to the situation observed for phenyl–tin derivatives. This does not rule out such reactions as ring opening and expansion to a seven-membered ring by metal insertion.

(d) $(C_6F_5)_4Pb$

Simplification of the spectra continues to the last member of the series $(C_6F_5)_4Pb$. The parent ion and species such as $C_6F_5PbF_2^+$ are now much weaker, or absent. There are essentially only four strong ions, $(C_6F_5)_3Pb^+$, $C_6F_5Pb^+$, PbF^+, and $Pb^{+\cdot}$ giving a much abbreviated reaction scheme (Fig. 4). Like the tin spectrum the strongest peak is due to MF^+ with the other three major ions being of similar intensity. The increased intensity of $Pb^{+\cdot}$ is not unexpected because of the relatively weak nature of the lead–carbon bond. The observed drastic increase of the RM^+ ion has also been noted for phenyl–lead relative to phenyl–tin compounds (11) although the difference is much smaller than that observed in this case.

Metastable ions clearly show that the route outlined in the scheme (Fig. 4) is a major source of the large PbF^+ peak. For tin the weakness of the precursor ion $C_6F_5Sn^+$ may indicate that SnF^+ is formed via a different pathway, or simply that $C_6F_5Sn^+$ is unstable yielding SnF^+ virtually as soon as it is formed. Going one stage farther back in the sequence, the metastable established loss of $(C_6F_5)_2$ from $(C_6F_5)_3Pb^+$ could not be verifled for tin, but cannot be eliminated until further studies have been carried out. Bi-

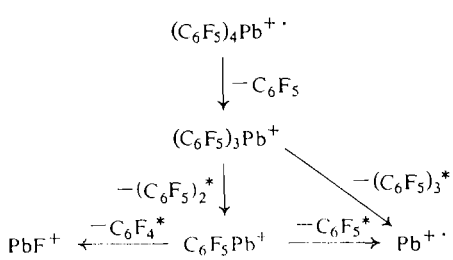

FIG. 4. Breakdown of $(C_6F_5)_4Pb$.

phenyl elimination has been established as a major process for phenyl derivatives of germanium, tin, and lead (11). A weak metastable ion suggests a reaction

$$(C_6F_5)_3Pb^+ \rightarrow Pb^{+\cdot} + C_{18}F_{15}$$

but it is more likely to be a rapid two step elimination of $(C_6F_5)_2$ and $C_6F_5\cdot$ as outlined in (Fig. 4) and suggested by Chambers *et al.* (11) for an analogous loss of $C_{18}H_{15}$ from $(C_6H_5)_3Sn^+$. Species of the type $C_6F_5MF_2^+$ and $(C_6F_5)_2MF^+$, important in the spectra of the germane and stannane, are notably absent for the lead derivative.

*Total metal containing ions.
†Fluorocarbon attached to a metal–fluorine species.

(e) Modes of Fragmentation

Major variations in the mode of breakdown of tetrakis(pentafluorophenyl) derivatives of Group IV under electron bombardment are apparent simply from the nature of the species carrying the ion current (Table III). There is a large change in the % of ion current carried by metal containing species, especially between the silane (27%) and stannane and plumbane (80 and 88%). These latter two are similar to their phenyl analogues in this respect. Metal–fluorocarbon ions carry about half of the current when M = Ge, Sn, or Pb, but only a quarter of the current for the silane. The bulk of this difference arises because of the lack of $(C_6F_5)_3Si^+$ ions (0.4%) compared to the other three compounds for which the analogous ions account for 20–25% of the total ion current. Ions of the R_3M^+ type have been found to be the most abundant ions in the spectra of hydrogen analogues of these compounds (10, 11), but only for the germane is this observed for pentafluorophenyl derivatives. The molecular ions are quite strong for all except the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

lead compound. For both tin and lead the most abundant ion is MF^+, a species which is 4 to 5 times weaker for the germane and virtually nonexistant for the silane. Only for silicon was a MF_3^+ ion observed. Its relative intensity was 4 times that of the SiF^+ peak. $Sn^{+\cdot}$ and $Pb^{+\cdot}$ were the only metal ions observed but these were less abundant than in spectra of $(C_6H_5)_4M$ derivatives for which $Ge^{+\cdot}$ was also observed. This may be indicative of the greater stability of fluoroaromatic derivatives. The weakening of C—M bonds as M becomes heavier can in part explain the increase in metal and metal–fluoride ions. However, there is also the change from general reactions of type [1]

$$[1] \qquad RM^+ \rightarrow R^+ + M$$

which are more common for the lighter metals, to reactions of type [2]

$$[2] \qquad RM^+ \rightarrow M^+ + R$$

which predominates for the heavier metals. This change in charge distribution is also apparent in the change from 73% of the ion current carried by fluorocarbon fragments for the silane to only 12% for the plumbane. Only for the silane does the most abundant ion, $C_{12}F_7^+$, lack a metal atom. The germane, and more particularly the stannane, have a significant % of the ion current (7 and 14%, respectively) carried by species in which fluorine transfer to the metal has occurred while a fluoroaromatic entity remains attached. Ions such as $(C_6F_5)_2MF^+$ and $C_6F_5MF_2^+$ play a significant role in their breakdown mechanism.

Comparisons with mass spectra of the phenyl analogues show as many differences as similarities. No evidence has been reported for the elimination of M—H species leading to phenylene formation. However, loss of $(C_6H_5)_2$ is quite common. The corresponding analogous process with the fluorinated derivative was verified by metastables in evidence for the following cases

$$(C_6F_5)_3Pb^+ \rightarrow C_6F_5Pb^+ + (C_6F_5)_2$$

$$(C_6F_5)_4Si^{+\cdot} \rightarrow (C_6F_5)_2Si^{+\cdot} + (C_6F_5)_2$$

This latter reaction is analogous to similar eliminations from odd electron ions $(C_6H_5)_4M^{+\cdot}$ (M = Ge or Sn). However, when M = Ge or Sn such behavior is not detected for $(C_6F_5)_4M^{+\cdot}$. The lack of any biphenylene ion formation in the spectra of Group IV tetraphenyls is somewhat surprising. In the mass spectra of various phosphines (1, 13) biphenylene ion formation is observed, but arises via a different mechanism than the formation of $(C_6F_4)_2^{+\cdot}$ ions. Biphenylene ions are also found in the spectrum of 2,2′-diiododiphenyl mercury (14), but these are obviously due to the presence of halogen atoms.

The fluoroaromatic derivatives did not show ions corresponding to successive acetylene eliminations found for tetraphenyl derivatives of germanium, tin, and lead (10, 11).

Even electron ions predominate in the spectra of the fluoroaromatics as is the case for their phenyl analogues, and for both series, the molecular ion usually eliminates an odd electron neutral fragment. The abundant R_3M^+ ion eliminates an even electron neutral fragment. Exceptions to this behavior may occur in reactions of the following type

$$(C_6F_5)_3M^+ \rightarrow (C_6F_5)_3^{+\cdot} + MF_3$$

and

$$(C_6F_5)_3M^+ \rightarrow (C_6F_4)_2^{+\cdot} + C_6F_5MF_2$$

although these might possibly be two step eliminations. Apart from the molecular ions, $Sn^{+\cdot}$ and $Pb^{+\cdot}$, the only significant metal containing odd electron ions were $(C_6F_5)_2Si^{+\cdot}$ and $C_6F_5SiF^{+\cdot}$, again illustrating the different behavior of

the silane. The remaining odd electron ions are fluorocarbon species such as the phenylene radical ions.

(f) $(C_6F_5)_3COH$ and $(C_6F_5)_2C{=}O$

Since tetrakis(pentafluorophenyl)methane was not available, the mass spectra of tris(pentafluorophenyl)carbinol and decafluorobenzophenone were obtained in an attempt to compare the behavior of fluoroaromatic derivatives of carbon to fluoroaromatic–organometallics of Group IV. Table IV summarizes the abundances of major peaks in the spectra as a % of the total ion current and Table V summarizes the observed metastable ions. Both spectra have in common the base peak at *m/e* 195 corresponding to $C_6F_5CO^+$, and carrying about one third of the total ion current, but whereas the benzophenone has a strong molecular ion, that for the carbinol is very weak, the first stage of breakdown being loss of $H^\cdot$ and $C_6F_5^\cdot$ forming the $(C_6F_5)_2C{=}O^{+\cdot}$ ion of similar intensity to the molecular ion of the benzophenone. With the exception of peaks attributable to hydrogen transfer from the carbinol, remaining parts of the spectra are very similar. There is evidence, supported by a metastable transition in the bezophenone spectrum, for the elimination of C_3F_6O

$$(C_6F_5)_2CO^{+\cdot} \rightarrow C_{10}F_4^{+\cdot} + C_3F_6O$$

There is essentially no elimination of the central carbon to form phenylenes as only very weak peaks were observed (0.3% of the total ion current in both spectra) for $C_{12}F_8^{+\cdot}$ ions and a trace of $C_{18}F_{12}^{+\cdot}$ was detected in the carbinol spectrum. In both cases 13 and 19 carbon ions were more abundant, and the carbon lost in the weak C-12 and C-18 peaks could also be a result of ring cleavage. Carbon monoxide is not lost from $(C_6F_5)_2CO^{+\cdot}$ ions but metastable ions show that CO is ejected from $C_6F_5CO^+$.

(g) Mechanism of Fragmentation

The absence of fluorine migrations and rearrangements leading to phenylene ions and neutral central atom–fluoride species when the central atom is carbon is consistent with evidence obtained when another first row element, namely nitrogen, was involved. Fluorine atom transfers were not observed in the mass spectra of trifluoromethylamines (15). Cavell and Dobbie (5) have suggested that rearrangement processes in trifluoromethylphosphines arise because of interactions of non-bonding fluorine p orbitals with vacant d orbitals on phosphorus, nitrogen lacking the appropriate orbitals. An explanation involving d orbitals is applicable to the pentafluorophenyl derivatives of silicion, germanium, tin, and lead which possess vacant d orbitals, whereas carbon lacks these orbitals. The involvement of d orbitals can also explain the existance of fluorine transfer to transition metals (1–3). Hawthorne, Mays, and Simpson (3) have suggested that when there are unsaturated σ-bonded organic ligands, the rearrangement ions can be rationalized by assuming that the ligand becomes π-bonded to the metal during fragmentation. Their conclusion is based on fluorine migrations which occur from all three ortho-, meta-, and para-substituted fluorophenyl manganese pentacarbonyls to the metal, although the ortho migration is most favored. However, well established scrambling of substituents or aromatic rings could account for this observation. In the nonaromatic case of chlorohexafluorocyclopentenyl manganese and rhenium pentacarbonyls no evidence was found for fluorine or chlorine migration to the metal (16). For Group IV elements such a σ–π rearrangement could explain reactions of the type

$$(C_6F_5)_3M^+ \rightarrow (C_6F_5)MF^+ + C_6F_4$$

$$(C_6F_5)_2MF^+ \rightarrow C_6F_5MF_2^+ + C_6F_4$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and perhaps formation of the phenylenes, although satisfactory stereochemistry exists for simple σ-bonded intermediates, especially if d orbitals participate in the transition structure. The σ–π scheme is less satisfactory, however, in explaining the loss of neutral metal fluoride species and the formation of charged fluoroaromatic fragments.

The rearrangement reactions and fluorine transfers observed in the mass spectra of the Group IV fluoroaromatic derivatives are certainly not due to thermal decompositions in the inlet system, since the high thermal stability of these compounds has been established by Tamborski *et al.* (8). Biphenylene ions are unlikely to be formed by fragmentation of the previously formed decafluorobiphenyl since the abundance of this species is low and its mass spectrum (17) shows only small yields of $(C_6F_4)_2^{+\cdot}$ ions. It is necessary to conclude that, despite a lack of metastable ion evidence, the phenylene ions are formed by rearrangements including fluorine transfers and elimination of neutral metal–fluoride containing species.

A mass spectral study of the energetics of this type of reaction is now underway along with pyrolysis studies.

Diethyl lead dinitrate

D. POTTS AND A. WALKER
Chemistry Department, Scarborough College, University of Toronto, Toronto 5, Ontario
Received October 25, 1968

The reaction, at 0 °C, between tetra-ethyl lead and dinitrogen tetroxide in both nitromethane and diethyl ether as solvents has been studied. The product in both solvents is always diethyl lead dinitrate, the properties of which have been investigated and compared with both dimethyl tin dinitrate and triethyl lead nitrate. The infrared spectrum is consistent with covalent unidentate nitrate groups, while molecular weight and conductivity measurements indicate that the compound behaves essentially as a 1:2 electrolyte in water and dimethyl sulfoxide. Decomposition of diethyl lead dinitrate in solution and in the solid state is discussed with the aid of ultraviolet spectroscopy and thermogravimetric analysis.

Following the work on $Me_2Sn(NO_3)_2$ (1), it was of interest to us to investigate the organo-nitrate chemistry of lead, where it might be expected that the organic groups would be more easily replaced, possibly giving $Pb(NO_3)_4$ as a final product. The reaction between tetra-ethyl lead and dinitrogen tetroxide though vigorous (and sometimes explosive), always stops at the diethyl lead dinitrate stage. Further replacement of ethyl groups was not possible even when the product was treated with dinitrogen pentoxide.

We have consistently been unable to repeat the work of Hetnarski and Urbański (2), who claim that the product of the reaction when carried out in diethyl ether as solvent at 0 °C is $[(NO)_2PbEt_4]^{2+}(NO_3)_2^-$, with no replacement of the ethyl groups. Under these conditions we find the product to be the same as in nitromethane solution, namely, diethyl lead dinitrate.

Diethyl lead dinitrate has been previously made by Hurd and Austin (3) by the reaction of nitric acid on tetra-ethyl lead in hot chloroform, but they did not investigate its properties in detail. They did note that triethyl lead nitrate and lead(II) nitrate were present in the reaction mixture and our investigation shows that these products are the result of decomposition of diethyl lead dinitrate in solution.

This paper discusses the properties of diethyl lead dinitrate and in particular the decomposition reactions which it undergoes.

Results and Discussion

Diethyl lead dinitrate is a white amorphous solid and is non-deliquescent. On heating in a bunsen flame the compound explodes. The compound is only stable at temperatures below 0 °C. At room temperature significant decomposition occurs within two weeks and the compound turns progressively reddish brown in color, presumably due to lead dioxide, while the infrared (i.r.) spectrum of the solid indicates the formation of ionic nitrate.

Diethyl lead dinitrate is appreciably soluble in cold water and polar organic solvents but is insoluble in non-polar solvents.

Infrared Spectrum

The total i.r. spectrum observed for $Et_2Pb(NO_3)_2$ is, in cm^{-1}, as follows: 1495 s,sp; 1450 vw,sh; 1421 m; 1380 w,sh; 1309 s,sp; 1259 s,sp; 1169 s,sp; 1032 m,sp; 1018 s,sp; 972 w; 809 m,sp; 745 w; 731 s,sp; 714 m,sp; 498 w; and 430 vw (where s = strong, m = medium, w = weak, vw = very weak, sh = shoulder, sp = sharp).

In order to assign bands associated with the ethyl groups, the spectrum of Et_2PbCl_2 was taken, and by direct comparison, the following bands can definitely be assigned to vibrations of the nitrato groups: 1495, 1421, asymmetric NO_2 stretch; 1309, 1259, symmetric NO_2 stretch; 1032, 1018, NO stretch; and 809 cm^{-1}, NO_3 out-of-plane rock.

As was found with the spectrum of $Me_2Sn(NO_3)_2$ (1), the observed splitting of the (NO) and (NO_2) stretching modes is consistent with a tetrahedral structure for $Et_2Pb(NO_3)_2$ containing two unidentate nitrato groups. The smaller value of the splitting between the (NO_2) asymmetric and symmetric stretching frequencies and the higher frequency of the (NO) stretches as compared to $Me_2Sn(NO_3)_2$ is consistent with a less covalent metal–nitrato bond in the lead

TABLE I

Molar conductivities of aqueous solutions of diethyl lead dinitrate

Molar concentration	Molar conductivity (Ω^{-1} cm^2)		
	Fresh solution, 25 °C	Solution, boiled 5 min	Solution, boiled 2 days
0.0010	222	328	218
0.0025	217	324	214
0.0050	209	318	208
0.0075	202	311	201
0.0100	194	305	195

compound. The bands at 498 and 430 cm^{-1} are assigned to the two Pb—C stretching modes and are also in agreement with a tetrahedral model.

Infrared Spectrum of Et_3PbNO_3

A pure sample of Et_3PbNO_3 was prepared by the action of $AgNO_3$ on Et_3PbCl in methyl cyanide, and its i.r. spectrum is as follows: 1455 sh; 1438 m; 1420 m; 1375 m; 1280 s,b; 1225 m,sp; 1158 s,sp; 1039 m,sp; 1030 m,sp; 970 w; 952 w; 815 m,sp; 720 w,sp; 690 s,sp; 475 m; and 445 cm^{-1} vw.

By comparison with the spectrum observed for Et_3PbCl the following bands can be assigned to vibrations of the nitrato group: 1438, asymmetric NO_2 stretch; 1280, symmetric NO_2 stretch; 1039, NO stretch; and 815 cm^{-1}, NO_3 out-of-plane rock. The bands at 475 and 445 cm^{-1} are assigned to Pb—C stretching modes indicating a non-planar structure for the Et_3Pb group. The nitrate bands are consistent with a unidentate nitrato group, and as was the case with Me_3Sn-NO_3 (1), the nitrato group is less covalently bound to the lead atom than in $Et_2Pb(NO_3)_2$.

Molecular Weights

Using Analar lead nitrate as a reference 1:2 electrolyte in water, it was found that over the concentration range 0.01–0.06 *M* at 25 °C, a fresh solution of diethyl lead dinitrate behaves as a 1:2 electrolyte and is consistent with a molecular weight of 389.3.

Conductivities

Molar conductivities for solutions of diethyl lead dinitrate in water and dimethyl sulfoxide are given in Table I and Table II respectively. A fresh aqueous solution has values nearly consistent with a 1:2 electrolyte in water (ca. 240 Ω^{-1} cm^2, at 0.001 *M*), and on boiling under reflux for 5 min these conductivities rise sharply to around 330 Ω^{-1} cm^2; on prolonged boiling under reflux the conductivity drops to the initial value of the fresh cold solution.

TABLE II

Molar conductivities of solutions of diethyl lead dinitrate in dimethyl sulfoxide at 25 °C

Molar concentration	Molar conductivity (Ω^{-1} cm^2)	
	Fresh solution	Solution 24 h old
0.0025	64.3	66.8
0.0050	61.5	61.5
0.0075	58.3	58.3
0.0100	56.5	56.5
0.0125	55.0	55.0

In dimethyl sulfoxide a fresh solution also has values consistent with a 1:2 electrolyte in this

solvent (1) and no change in conductivity was observed even upon standing for 24 h at 25 °C.

Ultraviolet Spectra

The spectrum of a freshly prepared aqueous solution of diethyl lead dinitrate at 25 °C is shown in Fig. 1, curve A.

The observed peak at 300 mμ (ε = 18.76) is consistent with the presence of two nitrate ions per mole. By comparison, the spectrum of lead nitrate in water at 25 °C has a peak at 300 mμ (ε = 16.50).

The solution is virtually unchanged on standing at 25 °C for a period of 12 h (Fig. 1, curve B). On refluxing a fresh solution for only 5 min the spectrum is that of curve C in Fig. 1. The appearance of an intense charge transfer band completely obscures the nitrate ion spectrum.

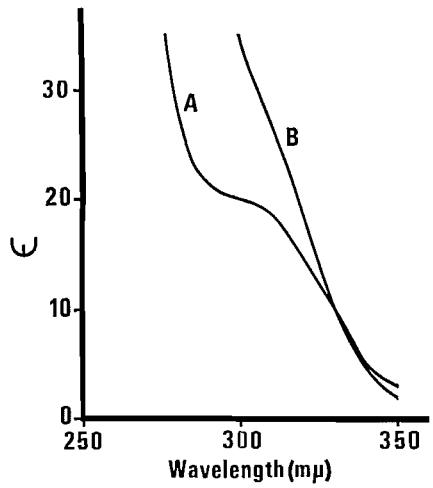

FIG. 2. Ultraviolet spectra of solutions of diethyl lead dinitrate in dimethyl sulfoxide: A, fresh solution at 25 °C; B, solution on standing 12 h at 25 °C.

A freshly prepared solution of diethyl lead dinitrate in dimethyl sulfoxide at 25 °C has the spectrum shown in Fig. 2, curve A. The nitrate ion in this solvent absorbs at 312 mμ (4). Curve A shows only an inflection at this wavelength, and on standing for 12 h at 25 °C the solution has the spectrum shown in Fig. 2, curve B.

Figure 3 shows the spectra obtained for solutions of diethyl lead dinitrate in methyl cyanide. Curve A is a fresh solution at 25 °C and shows a peak at 290 mμ (ε = 22.4); curve B shows the solution on standing for 12 h at 25 °C with a peak at 285 mμ (ε = 29.0), and this solution had

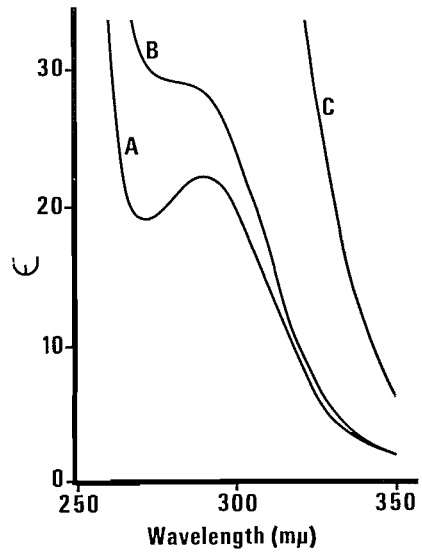

FIG. 3. Ultraviolet spectra of solutions of diethyl lead dinitrate in methyl cyanide: A, fresh solution at 25 °C; B, solution on standing 12 h at 25 °C; C, fresh solution boiled for 5 min.

by then deposited crystals of lead(II) nitrate. Curve C is the fresh solution refluxed for 5 min and this solution immediately deposited a large amount of lead(II) nitrate.

Figure 4 shows similar spectra for solutions in

methyl alcohol. Curve A has a peak at 294 mμ ($\varepsilon = 21.9$), curve B is the spectrum on standing for 12 h, and curve C that of a fresh solution refluxed for 5 min.

While ionization is obviously occurring in fresh cold solutions of diethyl lead dinitrate in methyl alcohol and methyl cyanide, the wavelengths of the peak maxima indicate (1, 4) some degree of covalent metal nitrate interaction though not as much as for many metal nitrates in these solvents. The inflection observed in the fresh cold solution in dimethyl sulfoxide is not, however, consistent with simple dissociation into diethyl lead and nitrate ions, and a charge transfer spectrum is already evident. Discussion of the refluxed solutions and those obtained upon standing at 25 °C for 12 h will be deferred until the next section.

A diffuse reflectance spectrum of solid diethyl lead dinitrate has a peak maximum at 277 mμ which is consistent with covalent metal nitrate interaction.

Reactions in Solution

A fresh aqueous solution at 25 °C is neutral and on treatment with hydrogen sulfide yields a cream precipitate characteristic of the diethyl lead ion (5). On refluxing for 5 min the solution becomes quite acidic (pH = 3.5), thus explaining the high conductivities observed. This acidity probably results from hydrolysis of the diethyl lead ion following initial ionization

$$(C_2H_5)_2Pb(NO_3)_2 + 2H_2O \rightleftharpoons (C_2H_5)_2Pb(H_2O)_n^{2+} + 2NO_3^-$$

$$(C_2H_5)_2Pb(H_2O)_n^{2+} \rightleftharpoons (C_2H_5)_2Pb(H_2O)_{n-1}(OH)^+ + H^+$$

It should be noted that this hydrolysis only occurs on refluxing, as compared to the more acidic $(CH_3)_2Sn^{2+}$ ion which undergoes hydrolysis in cold solution (1).

On treating the refluxed solution with hydrogen sulfide, it became apparent that hydrolysis was not the only process occurring, since a black precipitate of lead(II) sulfide was obtained. On buffering the supernatant liquid (5), a non-characteristic brownish precipitate occurred, which is probably a mixture of organolead and lead(II) sulfides. After refluxing the solution 2 days, it finally became neutral again, and the conductivity dropped to that of the original cold solution. Treatment of this solution with hydrogen sulfide yielded a black precipitate of lead(II) sulfide, and the supernatant liquid upon buffering yielded a pure white precipitate, characteristic of the Et_3Pb^+ ion (5). It is known (5) that aqueous solutions of dialkyl lead salts tend to decompose into trialkyl lead salts and lead(II) salts, particularly upon heating. Such a decomposition can be represented by the equation

$$2Et_2Pb(NO_3)_2 \rightarrow Et_3PbNO_3 + EtNO_3 + Pb(NO_3)_2$$

It is also known (6) that trialkyl lead salts have a charge transfer spectrum which is continuous over the 200–350 mμ region. In keeping with this we found that a solution of triethyl lead nitrate in water had such a spectrum, in contrast to the diethyl lead dinitrate which does not. Thus the charge transfer spectrum observed in curve C of Fig. 1 can be attributed to the presence of some triethyl lead nitrate in solution. Complete decomposition of the diethyl lead species in aqueous solution obviously requires prolonged refluxing for two reasons. Firstly, we found that even a refluxed solution of triethyl lead nitrate, lead(II) nitrate, and ethyl nitrate is not acidic and yet the solution of diethyl lead dinitrate required 2 days refluxing before the acidity due to the hydrolysis products disappeared. Secondly, the conductivity of the diethyl lead dinitrate remained high for the same period before dropping to values consistent with the decomposition products.

The charge transfer spectra observed in curves B and C for both methyl alcohol and methyl cyanide and curves A and B for dimethyl sulfoxide (DMSO) can likewise be assigned to the formation of triethyl lead nitrate in solution. While it is not difficult to understand a rise in temperature effecting some decomposition of the diethyl lead dinitrate in the solvents after only 5 min, the behavior on standing at 25 °C does not follow a regular pattern. The rate of decomposition of fresh solutions at 25 °C as measured by the appearance of charge transfer bands, is in the decreasing order

$$DMSO >> MeOH > MeCN >>> H_2O$$

which follows the order of increasing dielectric constant with the exception of dimethyl sulfoxide in which the rate is by far the fastest. One might expect the mechanism of decomposition to involve the transfer of a charged ethyl species as has been suggested (5), and this process will be slowest in media of high dielectric constant due to extensive non-specific solvation (7). By

contrast dimethyl sulfoxide will enter into strong specific interaction (7) with the diethyl lead ion and presumably will thus facilitate the rupture of a lead–carbon bond.
