Attempts to analyze quantitatively the decomposition products in the refluxed aqueous solution proved difficult due to separation of the products in this medium. However, the results in methyl cyanide proved much more conclusive. A solution of diethyl lead dinitrate in methyl cyanide was refluxed on a water bath for 30 min. During this period crystalline lead(II) nitrate was deposited quantitatively according to the proposed mechanism. The supernatant liquid was removed under vacuum and passed through a gas chromatograph showing only the presence of solvent and ethyl nitrate. The residual yellow solid analyzed as follows:

Anal. Calcd. for Et_3PbNO_3: C, 20.20; NO_3^-, 17.40. Found: C, 19.08; NO_3^-, 18.33.

A solution of this residual solid in water had a charge transfer ultraviolet spectrum and when treated with hydrogen sulfide gave a characteristic white precipitate of the Et_3Pb^+ ion. The i.r. spectrum was also identical with that obtained for Et_3PbNO_3 prepared as mentioned previously.

Pyrolysis

A sample of diethyl lead dinitrate was heated under a vacuum of 10^{-2} mm to 200 °C. During this period the sample remained white and did not melt. The residual solid had an i.r. spectrum identical with that of lead(II) nitrate and a nitrate analysis was as follows:

Anal. Calcd. for $Pb(NO_3)_2$: NO_3^-, 37.5. Found: NO_3^-, 36.8.

An aqueous solution of the residue gave only a black precipitate when treated with hydrogen sulfide. A colorless oil was collected in a liquid nitrogen trap during the period in which the sample was heated, but no oxides of nitrogen were observed. This oil had an i.r. spectrum identical to that of a mixture of tetra-ethyl lead and ethyl nitrate with the latter component predominant.

By comparison, when a sample of triethyl lead nitrate was similarly heated, the original yellow solid melted to a yellow liquid at 100 °C and resolidified to a white solid at 150 °C. During the liquid stage the sample spluttered considerably, leaving a residue of lead(II) nitrate.

The residual solid was identified as lead(II) nitrate and a colorless oil was again collected in the cold trap. This oil was also a mixture of tetra-ethyl lead and ethyl nitrate, as identified by its i.r. spectrum, but now the former component was predominant.

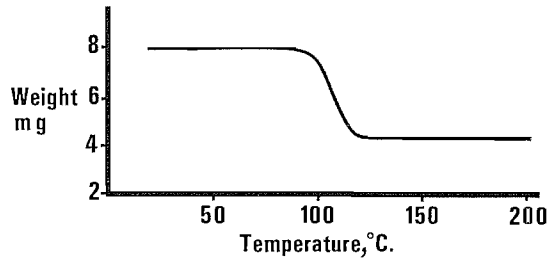

FIG. 5. Thermogravimetric analysis of diethyl lead dinitrate.

The spluttering of the liquid in the triethyl case precluded an investigation by thermogravimetric analysis, but this was done for diethyl lead dinitrate and is shown in Fig. 5. The weight loss observed is consistent with the decomposition

$$3Et_2Pb(NO_3)_2 \rightarrow 2Pb(NO_3)_2 + Et_4Pb + 2EtNO_3$$

and no intermediate stable product is detectable, such as the triethyl lead nitrate which is produced in the solution decompositions observed.

A possible equation for the decomposition of triethyl lead nitrate is

$$3Et_3PbNO_3 \rightarrow Pb(NO_3)_2 + 2Et_4Pb + EtNO_3$$

which results in relative concentrations of tetra-ethyl lead and ethyl nitrate which are the reverse of those obtained from the diethyl lead dinitrate. The observed i.r. spectra of the two oils produced qualitatively confirm this.

Finally, it is interesting to note that we found that triethyl lead chloride sublimes unchanged at 60 °C under vacuum, while diethyl lead dichloride decomposes to triethyl lead chloride and lead(II) chloride.

Experimental

Diethyl Lead Dinitrate

Tetra-ethyl lead (5 ml) was placed in a 250 ml two-necked flask fitted with a P_2O_5 guard tube and a dropping funnel. Dry nitromethane (15 ml) was added to the flask, forming a separate layer above the tetra-ethyl lead. Dinitrogen tetroxide (20 ml) was mixed with 25 ml of dry nitromethane and placed in the dropping funnel. The flask was cooled in an acetone – dry ice bath and the $N_2O_4 - CH_3NO_2$ mixture added a few drops at a time. Between each addition the flask was allowed to warm to about 0 °C. A white solid formed immediately above the tetra-ethyl lead layer, the solution became green, and much

gas was evolved. After the reaction was complete, an excess of dinitrogen tetroxide was added, and the product was filtered and washed with fresh dinitrogen tetroxide. The product was dried under vacuum to remove solvent traces and was isolated as a white amorphous powder, yield 7.33 g.

The reaction using diethyl ether as solvent was carried out following the procedure described (2).

Analyses for nitrate were done with nitron, for carbon by the Van Slyke wet oxidation technique, and for lead by evaporation to dryness with concentrated nitric acid followed by chromate determination.

Anal. Calcd. for $Et_2Pb(NO_3)_2$: C, 12.3; NO_3^-, 31.9; Pb, 53.2. Found: C, 12.3; NO_3^-, 31.5; Pb, 52.6.

Triethyl Lead Nitrate

A 1:1 mole ratio of triethyl lead chloride and silver nitrate was dissolved in dry methyl cyanide. The precipitated silver chloride was removed by filtration and the solvent was removed under vacuum. The product was purified by extraction with chloroform.

Anal. Calcd. for Et_3PbNO_3: C, 20.2; NO_3^-, 17.4. Found: C, 20.6; NO_3^-, 17.2.

All solvents were dried and purified by standard methods and organo-lead halides used were reagent grade chemicals.

Ultraviolet spectra were recorded using a Cary No. 14 spectrophotometer using fused silica cells and dried spectroscopic solvents.

Infrared spectra were recorded using a Beckman IR 12 spectrophotometer, with Nujol and halocarbon mulls between both KRS-5 and high density polyethylene windows.

Molecular weights were determined using a Hewlett–Packard vapor pressure osmometer model 302.

Conductivities were recorded using a Beckman model RC-18 bridge system, and a cell following the design of Greiner (8).

Thermogravimetric analysis was done using an R. L. Stone furnace and a Cahn electrobalance.

Abstraction of hydrogen atoms from bicyclo[2.1.1]hexane by methyl radicals and chlorine atoms: photochlorination of 1-methylbicyclo[2.1.1]hexane

R. SRINIVASAN AND F. I. SONNTAG

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

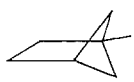
Received November 13, 1968

Photolysis of acetone has been used as a source of methyl radicals to study the abstraction of hydrogen atoms from bicyclo[2.1.1]hexane by methyl radicals. The reaction was found to have an activation energy of 10.3 kcal/mole and a pre-exponential factor that is typical of other abstraction reactions. The absolute rate of abstraction of hydrogen atoms from bicyclo[2.1.1]hexane by chlorine atoms at room temperature was measured to be 8.1×10^{10} l mole^{-1} s^{-1}. The photochlorination of 1-methylbicyclo-[2.1.1]hexane in solution gave both the 1-chloromethyl and 2- or 3-chloro-1-methylbicyclohexanes. The relative rates of attack at the methyl and the 2- or 3-position were determined to be 1:2.1. It is pointed out that the rate parameters for the abstraction of an H atom from bicyclo[2.1.1]hexane by a methyl radical are slower than for cyclopentane, as would be expected for a highly strained hydrocarbon, whereas the abstraction by chlorine is slightly faster than the rate for cyclopentane.

Canadian Journal of Chemistry, 47, 1627 (1969)

Introduction

The study of the chemistry of strained small-ring compounds is of considerable interest in understanding the nature of chemical bonding. Quantitative data, on the basis of which correlations between strain and reactivity may be made, are not extensive. In this work we have obtained quantitative data on the abstraction of a hydrogen atom from bicyclo[2.1.1]hexane (**1**) by a chlorine atom or a methyl radical, and



1

2

competitive rates of chlorination of 1-methylbicyclo[2.1.1]hexane (**2**).

Experimental

Materials

Bicyclo[2.1.1]hexane was prepared by the photoisomerization of 1,5-hexadiene (1). Following distillation, it was partially chlorinated in order to remove all the unsaturated impurities, and finally purified by vapor phase chromatography. Its m.p. was 26.5°. 1-Methylbicyclo-[2.1.1]hexane was prepared by the photoisomerization of 2-methyl-1,5-hexadiene (2). It was purified in the same way as the bicyclo[2.1.1]hexane. Acetone (Mallinckrodt TR grade) was dried over Drierite and distilled *in vacuo* before use. Chlorine gas (Matheson Co.) was used as obtained in the solution phase experiments.

Apparatus

The photolysis of acetone vapor at 3130 Å was used as the source of methyl radicals. The light source was a Hanovia S-100 medium pressure mercury arc which was energized through a Sola constant voltage transformer. The light beam was collimated, filtered with Pyrex glass (2 mm thickness), and admitted to the cylindrical quartz reaction cell of 9.3 cm length and 186.3 cc volume. The cell was placed in a furnace which was heated electrically. The temperature of the furnace was constant to ±1° during a run.

Procedure

Samples of acetone and bicyclo[2.1.1]hexane were measured in a calibrated part of the vacuum line and mixed together by condensation. The two compounds had boiling points which differed by only 15°. After photolysis, the mixture was separated into fractions by distillation. The fraction that was removed at liquid nitrogen temperature was found to consist of methane and CO. It was analyzed quantitatively by mass spectrometry. A second fraction which was removed at −156° was ethane only. The residue was analyzed by vapor phase chromatography. Three product peaks were invariably present in the C_7 region and were identified as C_7H_{12} compounds by mass spectrometry. Attempts to prepare them in substantial quantity for further identification proved fruitless.

Reaction of Cl(3/2) with Bicyclo[2.1.1]hexane

These experiments were carried out by Davis and Braun[1] by the technique which has been described in detail elsewhere[2]. The method involves the direct measurement of the concentration of chlorine atoms in the reaction system made up of chlorine gas and bicyclo-[2.1.1]hexane vapor by the change in the intensity of chlorine resonance fluorescence.

Photochlorination of 1-Methylbicyclo[2.1.1]hexane in Solution

The apparatus and procedure were exactly the same as in the earlier study (1) of the photochlorination of bicyclo[2.1.1]hexane in solution.

Results

1. Reaction of CH_3· with Bicyclo[2.1.1]hexane

The photolysis of acetone in the absence of addend yields methane and ethane by reactions [1] and [2] only. Conditions for which this

[1] $CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_2COCH_3$

[2] $2CH_3 \rightarrow C_2H_6$

mechanism is valid are quite well established (3). The usual treatment (3) applied to data obtained in the interval 150 to 225° led to

$$\log k_1/k_2^{\frac{1}{2}} = (4.2 \pm 0.9) - ((9200 \pm 500)/2.303RT)$$

in units of l mole^{-1} s^{-1}. The Arrhenius parameters agree reasonably well with those recently obtained (4), even though the present data were taken at less than 20 mm pressure of acetone, and thus are near the low end of the "high pressure" region discussed by Shaw and Toby (4). This pressure was chosen to permit the slow abstraction from bicyclo[2.1.1]hexane to compete when the hydrocarbon was present. Under those conditions, methane is also formed in reaction [3]

[3] $CH_3 + C_6H_{10} \rightarrow CH_4 + C_6H_9$

The usual treatment of the data gives $k_3[C_6H_{10}]/k_2^{\frac{1}{2}}$. These values at various temperatures have been plotted in the usual way in Fig. 1. The best line through the points, which was determined by least-squares analysis, corresponded to a value for $E_3 - \frac{1}{2}E_2$ of 10.3 ± 0.5 kcal/mole. Using the expression $k_2 = 2 \times 10^9 T^{\frac{1}{2}}$ l mole^{-1} s^{-1} (4), the value of log A_3 can be calculated to be 8.7 in the same units.

2. Reaction of Cl(3/2) Atoms with Bicyclo-[2.1.1]hexane

This reaction was studied at room temperature at 2 different pressures of bicyclo[2.1.1]hexane. The bimolecular rate constant was 8.13 × 10^{10} l mole^{-1} s^{-1}, with an uncertainty of ±10%.

3. Photochlorination of 1-Methylbicyclo[2.1.1]-hexane in Solution

In preparative experiments, it was found that photochlorination of 1-methylbicyclo[2.1.1]-hexane gave 2 monochloro products in about 20% yield. The products were separated by vapor phase chromatography. The first product, amounted to a third of the total monochloro compounds, was analyzed as follows.

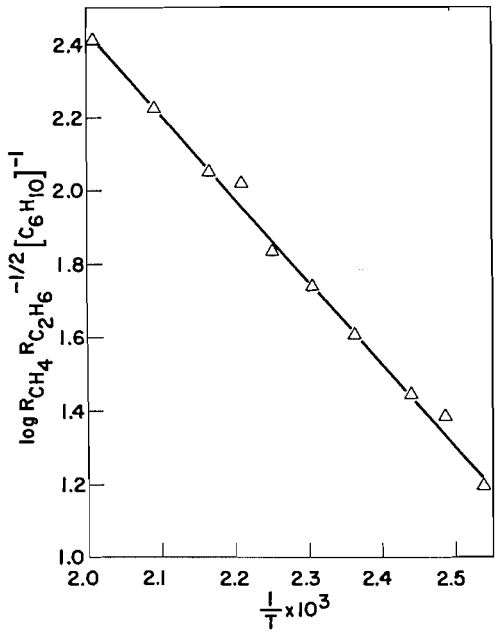

FIG. 1. Arrhenius plot for the abstraction of hydrogen atoms from bicyclo[2.1.1]hexane by methyl radicals. The ordinate should be multiplied by 8.00 × 10^{-5} to convert to units of l$^{\frac{1}{2}}$ mole$^{-\frac{1}{2}}$ s$^{-\frac{1}{2}}$.

Anal. Calcd. for $C_7H_{11}Cl$: C, 64.37; H, 8.49. Found: C, 64.61; H, 8.55.

It had an intense infrared absorption at 724 cm^{-1} (C—Cl) and no strong absorption between 1350 and 1400 cm^{-1}, showing the absence of a CH_3 group. Its nuclear magnetic resonance (n.m.r.) spectrum consisted of a singlet 6.31 τ (2H), a broad absorption at 7.58 τ (1H), and a complex absorption from 8.1 to 9.0 τ which accounted for the remaining protons. The material could be reduced with sodium and ethanol to regenerate 1-methylbicyclo[2.1.1]hexane. This showed that the chloro compound had the same carbon skeleton as 1-methylbicyclo[2.1.1]-hexane. The absence of a methyl absorption in the infrared, coupled with the unsplit absorption at 6.31 τ due to 2 protons, indicates that the chlorine was most probably in a CH_2Cl group adjacent to a carbon with no protons on it. The structure **3** would fit all of these observations. The remainder of the monochlorinated product is believed to be a mixture of possibly 2 com-

pounds, although it could not be resolved into 2 peaks on a gas chromatograph.

Anal. Calcd. for $C_7H_{11}Cl$: C, 64.37; H, 8.49; Cl, 27.14. Found: C, 64.34; H, 8.47; Cl, 27.37.

Its infrared spectrum showed a medium absorption at 1365 cm^{-1} (CH_3—) and an intense one at 710 cm^{-1} (C—Cl). There was no evidence of unsaturation. In the n.m.r. spectrum there was no absorption $> 5.5\ \tau$. There was an absorption at about 5.7 τ which had 1/11 of the total intensity of the spectrum. The remaining absorptions formed a complex pattern from 7.3 to 9.1 τ. In 2-chlorobicyclo[2.1.1]hexane, the proton on the 2-carbon occurs at 5.7 τ as a doublet with a splitting of 7 cycles (1). In the present case, the absorption at 5.7 τ was made up of a pair of doublets 17 cycles apart, each of which had a separation of 7 cycles. This material was most probably a mixture that was made up of nearly equal amounts of **4** and **5**, since extrapolation from earlier results on the photochlorination of bicyclo[2.1.1]hexane indicated that substitution in the ring in **2** would occur almost exclusively in the 2- and/or 3-positions (1).

The results of quantitative studies are given in Table I. The study was complicated by the fact that the $C_6H_{11}Cl$ compounds reacted much more rapidly with chlorine than with hydrocarbon so that the conversion had to be kept low. At the same time, only 16–20% of the hydrocarbon that disappeared was observed to lead to **3**, **4**, and **5**. The ratio of **3** to **4** + **5** (*i*) could be consistently reproduced, (*ii*) held constant over conversions which ranged from 0 to 20%, and (*iii*) was the same at 5 and 32°. Owing to experimental problems in separating 1-methylbicyclo[2.1.1]hexane from cyclohexane in the gas chromatograph, it was not possible to obtain accurate data on the relative rates of monochlorination of these two compounds. The result of only one run is included in Table I.

Discussion

In an earlier investigation on the photochlorination of bicyclo[2.1.1]hexane in solution (1), it was observed that (*i*) the chlorination was highly selective since better than 95% of the attack occurred at only one of 4 possible sites in the molecule, and (*ii*) the rate of monochlorination was comparable to the rate of monochlorination of cyclohexane, which meant that on a per atom basis, the C—H bond in the 2-position in bicyclo[2.1.1]hexane was slightly *more* reactive than a C—H bond in cyclohexane. Both these observations are considered unusual (5), in reference to what is known of the photochlorination of linear, aliphatic compounds. Bicyclo[2.1.1]-hexane should, strictly speaking, be compared to other strained, bicyclic systems. It has already been noted (1) that the data on the photochlorination of bicyclo[2.2.1]heptane (6) also show the trends that are observed in bicyclo-[2.1.1]hexane.

The experiments undertaken in this study were intended to examine if

(*i*) The abstraction of a hydrogen atom from

bicyclo[2.1.1]hexane by a radical other than chlorine (i.e. methyl) shows the trend that has been observed with the same radical and other strained hydrocarbons.

(*ii*) The absolute rate of reaction of chlorine atoms and bicyclo[2.1.1]hexane supports the contention that this rate is greater than that between chlorine atoms and a saturated, unstrained hydrocarbon.

(*iii*) In the photochlorination of 1-methylbicyclo[2.1.1]hexane, the chlorination in the 2- or 3-positions shows an acceleration in comparison to chlorination at the methyl group, which would serve as an internal reference for the reaction.

We shall analyze the present data in terms of these questions.

Accurate rate parameters for a large number of abstraction reactions of methyl radicals are known (7, 8). In a series of saturated hydrocarbons, which serve as the donor molecules, the activation energies increase as the C—H bonds go from tertiary to secondary and primary, while for similarly substituted C—H bonds, the activation energies increase with increasing strain in the molecules. The activation energies for abstraction from cyclopentane, cyclobutane, and cyclopropane (all of which contain only secondary C—H bonds) are 9.1, 10.1, and 12.9 kcal/mole, respectively (8). In bicyclo[2.1.1]hexane, it is reasonable to assume that abstraction of a hydrogen atom will occur only in the 2-position, since even such an unselective agent as a chlorine atom will abstract hydrogen from only that position 95% of the time. Although the 2-position is part of a cyclopentane ring, the fusion of a second ring should increase the strain in the 5-membered ring. One may expect the activation energy for the abstraction of a hydrogen atom to be considerably more than that for a cyclopentane ring (strain energy $\sim$ 6 kcal/mole), and comparable to that for a cyclobutane (strain energy 26.1 kcal/mole) or a cyclopropane (strain energy 27.5 kcal/mole) (9). The experimental value of 10.3 kcal/mole for [3] indicates the considerable influence of strain on the activation energy. The A factor for [3] when reduced to a per "active hydrogen" basis is comparable to those for similar abstractions from cyclopropane, cyclobutane, and cyclopentane (8). These data strongly suggest that the C—H bond in the 2-position in bicyclo[2.1.1]hexane behaves predictably as far as the abstraction reaction by methyl radicals is concerned[3].

The absolute rate of the abstraction reaction [4] in the gas phase when RH is cyclohexane is

$$[4] \qquad Cl + RH \rightarrow HCl + R$$

not known, but the rate with RH = cyclopentane has been found to be 8.35×10^{10} l mole^{-1} s^{-1} at 25 °C (10). The relative rates of abstraction of a hydrogen from cyclopentane and bicyclo[2.1.1]hexane would hence be 1:0.97. On an "active hydrogen" basis, this ratio would be cyclopentane:bicyclo[2.1.1]hexane = 1:2.4. From the rates of photochlorination of cyclopentane and cyclohexane in solution, it is known (11) that[4] abstraction from cyclopentane is 0.85 (relative to cyclohexane as 1.00) per hydrogen at 68° and 0.95 at 0°. If, at 25°, this value is taken to be 0.9, and assumed to be applicable to the gas phase reaction, the ratio cyclohexane:bicyclo[2.1.1]hexane (on a per "active hydrogen" basis) would be 1:2.2. This compares favorably with the value of 2.4 that was found (1) by competitive chlorination of cyclohexane and bicyclo[2.1.1]hexane in solution. There seems to be no doubt that on the basis of per "active hydrogen", bicyclo[2.1.1]hexane is more reactive towards chlorine atoms than cyclohexane.

The photochlorination of 1-methylbicyclo[2.1.1]hexane is obviously not a simple reaction as the yield of monochlorinated products is poor. A check of the consistency of the present values on chlorination, at two competitive sites within the molecule, against the earlier values on competitive attack on bicyclo[2.1.1]hexane and cyclohexane (if methylcyclohexane is used as a reference compound to provide a correlation between the two ring systems), showed that the

---

[3]The trend has been found to persist in the more highly strained bicyclic hydrocarbons. The activation energy for the abstraction of a hydrogen by methyl radicals from bicyclo[1.1.1]pentane has been measured to be 11.2 kcal/mole. It is likely that in the case of bicyclo[1.1.0]butane and bicyclo[2.2.0]hexane, the hydrocarbon may not survive the temperatures at which such competitive abstraction reactions can be studied.

[4]The reactivity of cyclopentane relative to cyclohexane is so nearly the same that there are other studies in the literature (5) that place cyclopentane ahead of cyclohexane on the reactivity scale. However, it seems to be agreed that the difference is no more than $\pm 10\%$, so that this is the correction that has to be applied in this investigation to the bicyclo[2.1.1]hexane value to take it from cyclopentane scale to the cyclohexane scale.

present results were not in quantitative agreement with the earlier work (1).

In conclusion, it is relevent to speculate on the cause of the increased reactivity of the hydrogen in the 2-position in bicyclo[2.1.1]hexane relative to cyclohexane. Since the experiments with methyl radicals show that the activation energy for abstraction does increase as would be expected, the activation energy for the abstraction process [5] may be expected to be about 200 cal/

[5] $Cl\cdot$ +  $\longrightarrow$ HCl + 
mole greater than the value of 600 cal/mole that has been measured for cyclopentane (10). There is a similar increase in going from cyclopentane to cyclobutane. The resultant value of log A_5 = 11.4 would be outside the observed range of 9.7–10.6 for the values of log A for such reactions (10). There is no doubt that more data on reaction [5] over a range of experimental conditions are needed before these unusual effects can be explained.

Vibrational spectra and a force field for H_2S_3 and H_2S_4[1]

H. WIESER AND P. J. KRUEGER
Department of Chemistry, University of Calgary, Calgary, Alberta

AND

E. MULLER AND J. B. HYNE
Fundamental Sulphur Research Group, Alberta Sulphur Research Ltd., Department of Chemistry, University of Calgary, Calgary, Alberta

Received November 8, 1968

The infrared and Raman spectra of H_2S_3 and H_2S_4 in CCl_4 and CS_2 solutions are reported and a complete assignment is presented. On the basis of the spectra and their temperature and concentration dependence, H_2S_3 is considered to be in the GG and H_2S_4 in the GG'G conformation. A valence force field is derived which provides a least-squares fit between observed and calculated frequencies for both molecules simultaneously, with an average error of 1.5 cm^{-1} (or 0.4%) over all frequencies.

Canadian Journal of Chemistry, 47, 1633 (1969)

Introduction

Except for the work of Fehér *et al.* (1) the vibrational spectra of the hydrogen polysulfides have not been studied in any detail. Fehér's Raman spectra were those of the pure liquid, while no infrared (i.r.) spectra have been reported yet. Moreover, the vibrational assignments which have been made are incomplete, and conformational analysis has not been attempted (2).

In this communication the i.r. and Raman spectra of H_2S_3 and H_2S_4 in solution (CS_2 and CCl_4) are reported, together with complete assignments. At the same time an attempt was made to establish whether the two polysulfides exist in one or more conformations, and if so, to identify these alternatives. Assuming that the geometrical parameters of H_2S_2 (3) and S_8 (4) may also apply to the polysulfides (Fig. 1) and allowing only staggered conformations, there are 4 possible rotamers for H_2S_3 and 10 possible rotamers for H_2S_4. Since in H_2S_3 the 3 sulfur atoms lie in a plane, the various conformations differ only in terms of the angles of the S—H bonds with respect to this plane. In H_2S_4, on the other hand, the 4 S atoms need not lie in a single plane. Since polymeric sulfur chains are highly coiled (5), it was assumed in the first instance that the G conformation about the central S—S bond is the most stable. However, a similar decision could not be made with regard to the conformations of the S—H bonds without first considering the spectroscopic results. Figure 1 shows the two conformers which were finally chosen as the most probable ones (see Discussion). In addition, an attempt was made to find a refined force field (modified valence force field) which would provide the best possible fit between the calculated and observed frequencies of both molecules simultaneously (in the harmonic oscillator approximation).

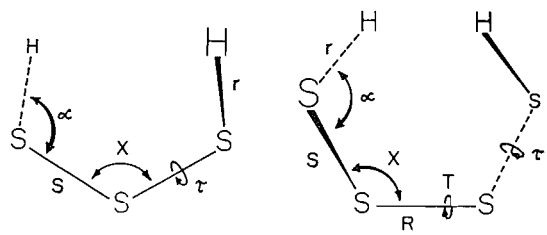

FIG. 1. Internal coordinates for H_2S_3 (GG conformer) and H_2S_4 (GG'G conformer); the geometrical parameters are those for H_2S_2(3) and S_8 (4). r_{S-S} = 2.048 Å, r_{S-H} = 1.352 Å, ∠SSS = 107° 55′, ∠SSH = 91° 57′, dihedral ∠SS–SS = 98° 39′, dihedral ∠SS–SH = 90° 37′.

Experimental

Compounds and Spectra

Solutions of H_2S_3 and H_2S_4 in CCl_4 and CS_2 (2 *M*) were prepared by the reaction of liquid H_2S with SCl_2 and S_2Cl_2 as reported previously (6). The purity of the polysulfides, as established by nuclear magnetic resonance (n.m.r.) (7), was found to be 90 ± 2 mole % for H_2S_3 and 95 ± 2 mole % for H_2S_4, the higher sulfanes being present only in small quantities. The solvents used (CCl_4 and CS_2) were spectrograde quality as supplied by Fisher Scientific Co.

The i.r. spectra were recorded on a Perkin–Elmer 621 spectrophotometer over the range of 4000–400 cm^{-1}

[1]Presented at the 15th Spectroscopy Symposium of Canada, Toronto, October 21–23, 1968.

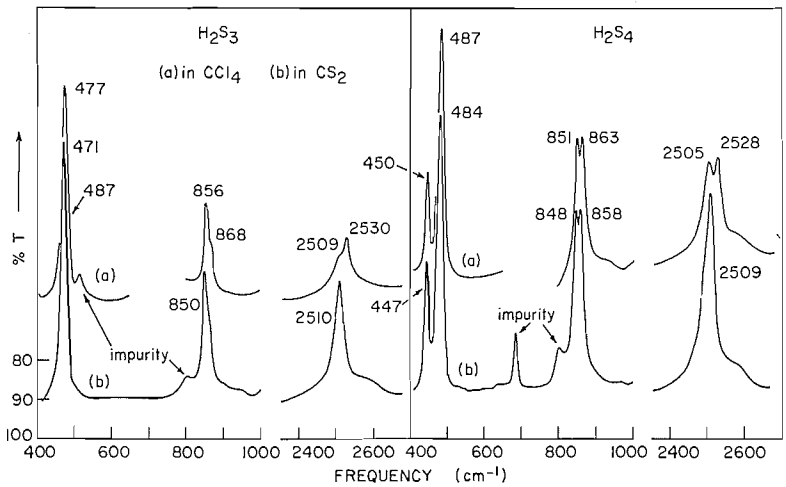

FIG. 2. Infrared spectra of H_2S_3 and H_2S_4 in CCl_4 and CS_2 solutions (2 *M*).

using 0.1 and 1.0 mm KBr or 2.0 cm Infrasil cells depending on the concentrations of the solutions. The Raman spectra were obtained with a Cary 81 spectrophotometer equipped with a He–Ne laser (6328 Å exciting line, 50 mW power output). Since the coaxial excitation mode was found to be the most convenient, the depolarization ratios had to be corrected by comparison with spectra of CCl_4 obtained with the same capillary cells. Accurate depolarization ratios therefore cannot be reported. Except where indicated otherwise, all measurements were made at room temperature.

Both instruments were calibrated in the conventional manner. The frequency values reported constitute averages of several runs. By comparing the spectra of several different preparations of the same polysulfide containing different percentages of the higher sulfanes, the absorptions could be assigned unambiguously and any interference from other sulfanes ruled out. The spectra are reproduced in Figs. 2 and 3.

Force Field Calculations

The force constants were determined by an iterative technique (8) which provided a least-squares fit between the observed and calculated frequencies. Seventeen observed frequencies were entered for GG H_2S_3 and GG'G H_2S_4 and weighted in a reciprocal manner. Convergence led to an average error of 1.5 cm^{-1} (or 0.4%) over the entire frequency range.

The internal coordinates and geometrical parameters are defined in Fig. 1. Table I defines the group and skeletal coordinates, and Table II lists and identifies the refined valence force constants. The initial values for the main constants for the calculations were taken as those for H_2S_2 (9) and S_8 (10) and these are listed in the last column of Table II. The H_2S_2 values were adjusted since our calculations made no provisions for anharmonicity. Initially all interaction force constants were set to zero. The force field as defined in Table II is modified so that interactions which probably would not contribute to the potential energy have been neglected arbitrarily. Transformation of the force field based on internal coordinates to a force field in terms of the symmetry coordinates as required by Wilson's **FG** method (11) shows that 9 of the 16 possible interaction constants have been considered for H_2S_3 and 15 of the 31 possible constants have been considered for H_2S_4. The observed and calculated frequencies for GG H_2S_3 and GG'G H_2S_4 are listed in Table III, together with the potential energy distributions based on the diagonal contributions from the group coordinates defined in Table I.

Discussion

Assignments

According to the n.m.r. proton shifts and the positions and shapes of the S—H stretching bands, H_2S_3 in CCl_4 forms intermolecularly hydrogen bonded polymers in concentrated solutions (2 *M*) and intramolecularly bonded monomers in dilute solution (0.02 *M*). In CS_2 the intramolecular bonds are competing with the intermolecular interaction with the solvent molecules, even at low concentration (7). The question arises whether the H_2S_3 monomer undergoes a conformational change upon forming intermolecular hydrogen bonds. In this work no significant shifts in the position of the absorptions of H_2S_3 upon dilution in CCl_4 have been noted except for the S—H stretching band as reported previously (7). Moreover, the doublet structure of the S—H bending absorption apparent in the i.r. spectrum of the CCl_4 solution persists in the Raman spectrum of the CS_2 solution. There are two ways in which the results may be interpreted; either H_2S_3 remains in the same conformation regardless of the environment, or the vibrations (except S—H stretching) are insensitive to conformational changes.

Our assignments and calculations are based on the GG conformer (Fig. 1), since in this conformation intramolecular hydrogen bonding may be achieved by both hydrogen atoms. This conformer has C_2 symmetry, giving rise to 5 vibrations of symmetry species *A* and 4 of *B*. The

*Frequencies in italics entered into force field refinement. Abbreviations are: s, strong; m, medium; w, weak; vw, very weak; sh, shoulder; bd, broad; p, polarized; d, depolarized.

†Potential energy distributions are given in % contribution of the diagonal force constants for coordinates defined in Table I. Because of some off-diagonal negative contributions, the sum of the diagonal contributions may exceed 100%. Only contributions of 10% or more are listed.

‡Measurements in dilute solution.

vibrations of species *A* should give polarized Raman lines; they have been assigned accordingly. It is interesting to note the intensity reversal of the 477 and 487 cm^{-1} vibrations on going from the i.r. to the Raman spectrum.

H_2S_4 in CCl_4 solution shows the usual concentration dependent self-association, although the monomer does not appear to be as strongly intramolecularly bonded as H_2S_3 (7). In CS_2 solution, association between the sulfane and solvent molecules appears to be preferred even at low concentration (0.02 *M*) (7). As an extension of this work the temperature dependence of the "free" S—H stretching band in very dilute CCl_4 solution (0.02 *M*), and of all absorptions in 2 and 1 *M* CCl_4 solutions, was tested over a temperature range of 40 °C (+20 to −20 °C). No changes in the shapes of any bands as a function of the temperature could be observed, and concentration changes did not result in any significant shifts in the band positions (except for the S—H stretching absorption). Moreover, changing the solvent from CCl_4 to CS_2 (2 *M* solutions) resulted only in a general shift to lower frequencies for all absorptions (about 20 cm^{-1} for the S—H stretching band and about 5 cm^{-1} for all others). It appears therefore that essentially no conformational rearrangement is occurring, unless the band positions are the same for two or more conformers.

Our assignments and calculations have been based on the GG'G conformer (Fig. 1), since again in this conformation both hydrogen atoms are able to form hydrogen bonds. It is of interest to note that the crown form of the S_8 ring has exactly that arrangement of bonds. Due to the C_2 symmetry point group of this conformer, the 12 normal modes can be divided into 7 vibrations of symmetry *A* and 5 of *B*. Only the *A*-type vibrations should give rise to polarized Raman lines

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which have been assigned accordingly. The S^- (*B*-type) and S^+ (*A*-type) vibrations are considered to overlap, with the prominent lines being measured at 487 and 484 cm^{-1} in the i.r. and Raman spectra, respectively.

Valence Force Field

In view of the spectral behavior of the CCl_4 and CS_2 solutions of H_2S_3 and H_2S_4, the choice of the GG and GG'G conformers, respectively, seems the most reasonable. It is in these conformers that the non-bonded interactions required to explain the doublet structure of the S—H stretching and bending and the S—S stretching vibrations, are most plausible. In the valence force field the non-bonded interactions have been taken into consideration by introducing $f_{rr'}$, $f_{SS'}$, and $f_{\alpha\alpha'}$. As shown in Table III, the force field so derived results in an excellent fit between the observed and calculated frequencies, whereas if the non-bonded interaction constants are neglected, a reasonable fit simply cannot be achieved. Using this refined force field, it was found that the frequencies calculated for other conformations were not significantly different. Consequently the calculated force field rests heavily on the validity of the arguments supporting the conformers selected.

Anion–molecule complexes in solution. III.[1] Nuclear magnetic resonance studies of halide ion – alcohol association

R. D. GREEN AND JOHN S. MARTIN

Received September 24, 1968

Certain alkyl-, aryl-, and arene-substituted alcohols form linear, hydrogen bonded complexes with bromide and other halide ions in tetrachloromethane. The hydroxyl proton shifts ca. 4 p.p.m. downfield in the complex, regardless of the degree or type of substitution. The interaction is enhanced by inductive electron withdrawal by substituents on the C—O—H moiety. A comparison of the present results with infrared spectroscopy shows that the absorption at ca. 3300 cm^{-1} is entirely due to 1:1 alcohol–anion complexes. The a coefficient in Buckingham's equation for electrostatic interaction of a molecule with an ion, $\delta\sigma_E = aE_z - bE^2$, is found to be 5.5 for alcohol O—H bonds.

Canadian Journal of Chemistry, 47, 1639 (1969)

Introduction

Nuclear magnetic resonance (n.m.r.) and infrared (i.r.) spectroscopy have been used extensively in the detection and characterization of the hydrogen bonding of alcohols and other hydroxyl bearing compounds to a variety of bases (1–3). Characteristically, hydrogen bond formation results in a decrease in shielding of the hydrogen nucleus. The extent of this deshielding has been regarded as a measure of hydrogen bond strength, in much the same way as have hydrogen bond shifts and intensities in the i.r. (1, 3, 4). Both the i.r. frequency shift and the n.m.r. shielding change have been correlated with the enthalpy of hydrogen bond formation (5).

Pursuant to our studies of specific complexes to anions in weakly interacting solvents, we have observed deshielding of hydroxyl protons in methanol, primary, secondary, and tertiary alcohols, and a phenol, of magnitude up to 4.5 p.p.m., on addition of a tetrabutylammonium salt to a dilute solution of the alcohol in tetrachloromethane. We interpret the monotonic salt concentration dependence of the hydroxyl proton shifts as arising from specific hydrogen bonded interaction of the alcohols with the anions. Conditions have been chosen to favor one to one complex formation; the alcohol concentration was kept as low as possible (0.1 M) to minimize alcohol to alcohol hydrogen bonding, and the proton shielding observed as a function of the halide ion concentration.

[1]For Paper I see ref. 23, and for Paper II see ref. 24.

Experimental

Materials

Methanol

This was Shawinigan reagent grade, and contained less than 0.2% water when received. This material was dried by storing over 4A molecular sieves (m.s.) for several days; the initial vigorous effervescence ceased after about 24 h. The tightly stoppered vial was kept in the dry-box. Samples containing methanol and tetrabutylammonium bromide decomposed slowly, the n.m.r. spectrum showing a change after 1 day, but no observable change within 1 h of sample preparation. All spectra were obtained within 1 h of preparation of the sample.

Ethanol

This was 98%, as received, and showed no benzene in the n.m.r. and, at most, traces of water. This material was distilled, and a center fraction totalling ca. 75% collected on m.s. The fraction collected was refluxed over the m.s. for 1 h. The material was then redistilled with a center fraction totalling ca. 50% being collected on m.s. (boiling range 0.4 °C). The tightly-stoppered flask was immediately transferred to the dry-box, where the ethanol was placed in a storage vial over fresh m.s. A subsequent Karl Fischer titration of a portion of this material showed no detectable water (less than 0.01% by volume) in the ethanol.

2-Propanol

Fisher reagent grade material was dried over m.s. for several days before being used.

2-Methyl-2-propanol

British Drug Houses reagent grade material was received as a colorless liquid. This was dried over m.s., the container being kept warm in a water bath. On cooling, the material crystallized.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Phenylmethanol, 1-Phenylethanol, and 4-Methoxyphenylmethanol

These materials, all Eastman "white label", were dried over m.s. before use.

2-Phenyl-2-propanol

This was kindly supplied by L. B. Green, and was dried over m.s. Its n.m.r. spectrum showed no significant impurities.

4-Nitrophenylmethanol

This was Eastman "white label" grade, and was used as received, since the n.m.r. signal of the OH proton (dissolved in CH_3CN) was a sharp triplet.

Tetra-n-butylammonium Bromide, Tetra-n-butylammonium Iodide

The Eastman "white label" salts were pumped under vacuum in a desiccator (over P_2O_5) for several weeks, then stored in the dry-box.

Tetra-n-butylammonium Chloride

This was from Eastern Chemical Corportion and contained benzene which was not easily removed by pumping. The salt was dissolved in a small volume of CCl_4, then precipitated by adding cyclohexane. The salt so obtained was then dried by pumping as above and found by n.m.r. to be free of benzene. It, too, was stored in the dry-box.

Tetrachloromethane

This was Shawinigan reagent grade, and was passed through a column of alumina (activity grade I); tetramethylsilane was added to serve as an n.m.r. internal reference before storing in the dry-box over m.s.

Tetramethylsilane (TMS)

This was obtained from NMR Specialties and was refrigerated over m.s. before using.

Procedures

All samples were prepared inside a sealed dry-box which was kept under a slight positive pressure of dry nitrogen. Volumetric tubes (2 ml) were weighed before and after solid materials (usually salt) were placed in them. Enough solvent was added to dissolve the solids, then the liquids were added using a 10 or 50 μl syringe. The solutions were made up to the mark with solvent, thoroughly mixed, and ca. 0.5 ml transferred to n.m.r. sample tubes fitted with auxilliary stopcocks to exclude air, connected to a vacuum rack, degassed by freezing and pumping, and sealed.

The concentrations of the solid materials were calculated from their weights and the volumes of the volumetric tubes. Concentrations of liquids were calculated from their volumes and densities.

The n.m.r. spectra were obtained, for the most part on Varian HA-60 and A-60 spectrometers, with a few on a Varian HA-100 fitted with a C-1024 time-averaging computer. The internal reference was always TMS. The line positions were measured from the chart calibrations (1 Hz = 1 mm) in the case of A-60 spectra; HA-60 spectra were measured by setting the sweep oscillator at the resonance, and measuring the difference between its frequency and that of the lock-in oscillator.

The operation of the C-1024 with the HA-100 was modified by installing auxiliary microswitches to limit the travel of the recorder carriage to about one fifth of the full chart width. The modification allowed single peaks in dilute samples to be accumulated efficiently. Accumulated spectra were calibrated by measuring frequency differences at the limit switches and interpolating to find the peak positions.

Results

Analysis of n.m.r. Shielding vs. Concentration

The hydroxyl proton shift dependence on salt concentration was analyzed to yield the limiting shift in the 1:1 complex and the association constant by an iterative Benesi–Hildebrand–Scott (B–H–S) method, described in Paper I of this series (see ref. 23). Uncertainties quoted in derived quantities include contributions from the uncertainties in measurement of shifts and concentrations, and generally are about twice as large as uncertainties based on standard deviation of fit alone.

In this study, the association constant, K, falls in the range 10 to 125 M^{-1}. Consequently, in many cases, at salt concentrations of about 1 M, essentially all of the salt was complexed and the shielding became independent of concentration. This directly-observed complex shift in all cases verified the value derived from the B–H–S analysis.

Tables I and II give the ambient-temperature (ca. 27 °C) equilibrium constants (K), and limiting complex shifts (Δ_c) for a number of alkyl- and arene-substituted carbinols complexed with halide ion in tetrachloromethane.

Complicating the treatment of these systems as involving simple 1:1 complex formation, is the well-known self-association of alcohols (6, 7), even at very low concentrations. Figure 1 shows the concentration dependence of the OH-proton shielding of phenylmethanol from 0.002 to 0.2 M; the three points of the most dilute solutions were obtained from spectra accumulated on the C-1024 computer, using as many as 300 scans per spectrum. The region below about 0.1 M is very nearly linear with the possible exception of a small "dip" near 0.05 M. It is evident that extrapolation to infinite dilution gives a δ_{OH} for "free" phenylmethanol of -1.05 p.p.m., whereas at the 0.1 M concentration used in this study, the δ_{OH} is -1.50_5 p.p.m., that is, 0.45 p.p.m. to low field of the "free" OH resonance.

We have performed a "dummy" calculation on a set of parameters typical of an alcohol in order to arrive at an estimate of the amount of error introduced into our results by the assump-

tion that our measured shifts are not influenced by alcohol self-association.

We take as numbers representative of alcohol–anion complexing $\Delta_c = -4$ p.p.m.; $K_c = 25$. For simplicity we assume that at low concentrations the dimer, in which one of the two OH protons is hydrogen bonded, is the only polymer present (8, 9). Consistent with previous studies (7) we assume a typical dimerization constant, K_D, of 0.75 M^{-1}. We estimate the shielding in the dimer using the slope of the dilution curve at zero concentration, using the relation (10)

$$[1] \qquad \left(\frac{\partial\Delta}{\partial C}\right)_{C\to 0} = 2K_D\Delta_D$$

This yields $\Delta_D = -3.1$ p.p.m.

At each of 4 typical salt concentrations, the concentrations of all species were computed and iterated to self-consistency. Duplicate calculations were performed, with and without self-association. The results of these two sets of computations are given in Table III. It is evident that self-association effects practically no measurable change in the n.m.r. observations.

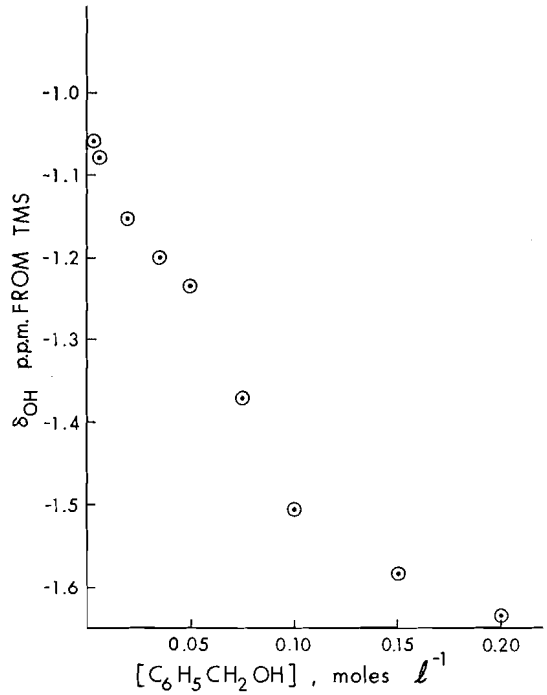

FIG. 1. Dilution curve for O—H shift of phenylmethanol in tetrachloromethane.

TABLE III

Computed shieldings, for typical case, including contribution from alcohol self-association*

[Salt] *M*	Complex shift (p.p.m.)	Dimer shift (p.p.m.)	Total shift (p.p.m.)	
			With dimers	Without dimers
0.1	2.08	0.06	2.14	2.20
0.2	3.00	0.02	3.02	3.00
0.4	3.54	0.01	3.55	3.54
0.6	3.68	0.00	3.68	3.68

*Total alcohol concentration assumed: 0.1 *M*.

Consequently, we consider that our treatment of the data in terms of only the one alcohol–anion complexing process is justified; all the more so in that the points at high concentration, which are least influenced by dimerization, are most heavily weighted in the analysis (see Appendix, Paper I). Hence, in Table I, equilibrium constants are given as obtained directly from the B–H–S analysis. By adding the dilution shift of the alcohol from 0.1 *M* to zero concentration, Δ_{diln}, to the limiting shift obtained from the B–H–S analysis, Δ_c(raw), obtained in the usual way, the resulting Δ_c(corrected) (see Fig. 2) should be quite a precise measure of the difference in shielding of the hydroxyl proton in an isolated alcohol molecule, and in the complex with the anion.

As may be seen in Table I, this correction for

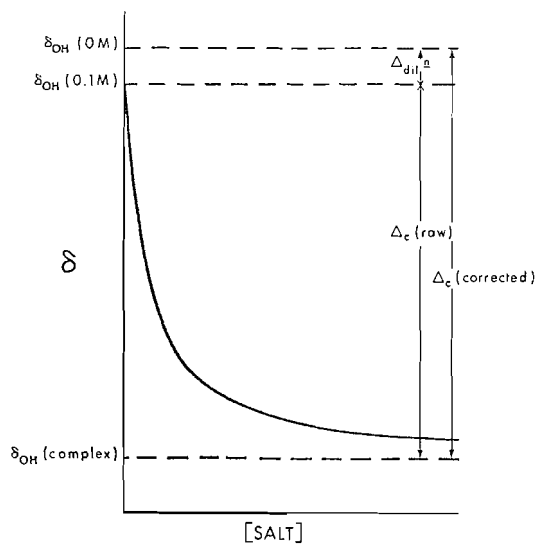

FIG. 2. Derivation of O—H complex shifts.

self-association, Δ_{diln}, is typically only about 2–3 times the experimental uncertainty, the average standard error being 0.11 p.p.m., and the average correction 0.33 p.p.m.

Three-point dilution curves (0.03, 0.06, 0.10 *M*) were obtained for all the other alcohols; these were all linear and were used to obtain each dilution shift individually, although all were found to fall within quite a narrow range of values.

It is apparent that, within the experimental uncertainty, the complex shifts are the same no matter what the degree of substitution by alkyl (methyl) groups. However, an arene substituent consistently accompanies shifts approximately 0.2 to 0.5 p.p.m. greater.

Infrared vs. Nuclear Magnetic Resonance

Several studies (11, 12) have been made on this type of system using i.r. spectroscopy. These have, of necessity, assumed that the new band at about 3300 cm^{-1} is due to OH hydrogen bonded to the anion; however, it has also been suggested (11) that this band may be due to aggregations of polymeric alcohol, with the anion as a center of nucleation.

Our n.m.r. results are obtained under conditions which tend to favor 1:1 complex formation over larger aggregates. Complexes of the type 1:*n* (more than one ion per alcohol) are unlikely, since the alcohol has only one electrophilic site (this may not be true of some aryl alcohols: *vide infra*). The 1:*n* aggregates also bring ions of like charge together. Some *n*:1 complexes may occur, although the alcohol concentration is kept as low as possible to avoid this. In any case, it is not readily apparent why the presence of one alcohol on an ion should have a large effect on its interaction with a second molecule. The analysis weights most strongly the points at high salt concentration, where *n*:1 complexes are least

*[1-Phenylethanol] = 0.05 M.

likely. In any case, no systematic deviation from the B–H–S straight lines was observed.

We have examined the i.r. spectrum of one of these systems, 1-phenylethanol and tetrabutylammonium bromide, under conditions essentially identical to those of the n.m.r. study. If the band at 3300 cm^{-1} is due entirely to 1:1 ion–molecule complexes, then the i.r. absorption intensity should vary in the same way as the n.m.r. shift, and yield the same equilibrium constant.

In Table IV are given the absorbances of 5 solutions at 3610 and 3300 cm^{-1}, measured by reading the absorbance relative to a baseline defined as a straight line connecting the two minima closest to the band measured.

The spectrum of the sample containing no salt exhibited two absorptions, at ca. 3470 and 3390 cm^{-1}, which have been assigned to associated forms of alcohols (6, 8, 11). These absorptions are either absent or obscured by the band at 3300 cm^{-1} when salt is present (see Fig. 3).

Table IV also contains estimates of K obtained at each salt concentration by two methods: (*1*) taking the decrease in absorbance at 3610 cm^{-1} as a measure of the decrease in free alcohol concentration; (*2*) taking the result for one sample (the third in the table) as exact, and computing the complex concentrations at other concentrations using it as a standard. It matters little which sample is taken as the standard: for example, using the fourth sample, and its value of $K = 30$, instead of the third sample and its $K = 44$, the average value of K derived by method (*2*) becomes 39 instead of 43, an insignificant difference.

The average value of K from Table IV is $49 \pm 20\ M^{-1}$. In view of the crudity of the i.r. measurements, this is in reasonable agreement with the n.m.r. determination, $39 \pm 14\ M^{-1}$.

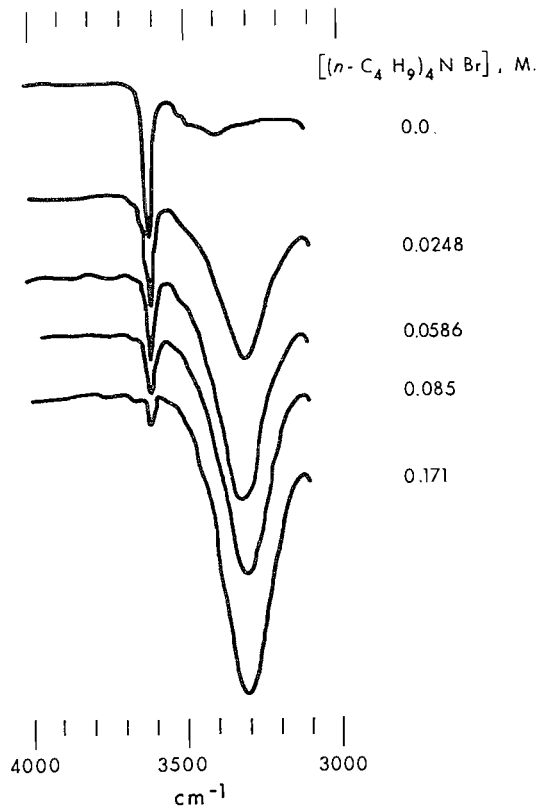

FIG. 3. O—H stretch region of 1-phenylethanol vs. concentration of $(n\text{-}C_4H_9)_4NBr$.

If the i.r. determination with the largest deviation from the mean, 91 M^{-1}, is rejected, the i.r. average is $43 \pm 9\ M^{-1}$. The deviant point may reasonably be disregarded, since it is derived from the smallest difference between two large numbers. We consider this to be reasonable evidence that the absorption band at 3300 cm^{-1}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

is entirely due to 1:1 complexes between the alcohol and the anion.

Discussion

Effect of Alcohol Structure

The equilibrium constants for complexes with bromide ion show marked dependence on the degree of alkyl substitution at the α-carbon atom (Table I). K decreases by 30 to 50% for each additional methyl or benzyl group; on the other hand, it is hardly affected by substitution of a phenyl group for hydrogen (70 vs. 71; 40 vs. 39; 21 vs. 15). These observations correlate with the inductive character of the substituents; alkyl groups are known to be more electron donating than phenyl groups or hydrogen; increasing alkyl substitution leads to an accumulation of negative charge in the hydroxyl group, rendering it less acidic and less attractive to a negative ion.

Subject to the usual reservations concerning linear free energy relationships (13), it is possible to correlate the relative free energies of bromide complex formation (as log K) with the Taft inductive substituent constants, σ* (14). These have been shown to be reasonably additive. By regarding the —COH moiety as the core of all the alcohols, only 4 values of σ* are required, normalized for convenience to H: H, 0.0; CH_3, −0.49; C_6H_5, +0.11; $C_6H_5CH_2$, −0.27.

Figure 4 is a graph of log K as a function of Σσ*, for the complexes in Table I, not including the last 3 entries. The relationship is linear, consistent with our assertion that the variation of K reflects inductive properties of the substituents. The only point falling badly off the line is the one for $C_6H_5C(CH_3)_2OH$, a highly-substituted alcohol; this may reflect an effect of crowding.

Inductive charge withdrawal from the electrophilic site should affect primarily the enthalpy of complex formation. The validity of the foregoing free energy correlation rests, as all such correlations do, on the assumption that the entropy of complex formation either does not change, or varies in the same manner as the enthalpy, in the set of complexes studied.

The most apparent influence on the strength of complex formation of alcohols to bromide ions *via* their hydroxyl groups is thus the inductively determined electrophilicity of the binding site.

Effect of Anion Size

Table II shows the effect of changing the size

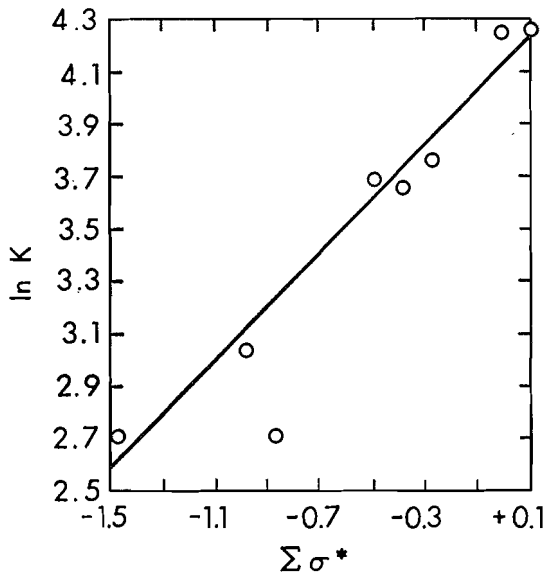

FIG. 4. Dependence on substituent inductive parameters of alcohol – bromide ion equilibrium constant.

of the anion on the complex formation with 1-phenylethanol. Since tetrabutylammonium iodide is insoluble in CCl_4, the tetraheptylammonium salt was used. Consistent with the model of purely electrostatic interactions in hydrogen bonding to anions, as developed in Paper I, the complex shifts are largest for the smallest anion. In addition, the equilibrium constant increases in roughly three-fold steps in the progression $I^- < Br^- < Cl^-$, consistent with a complex energy dominated by electrostatic interaction with the anion field.

Interaction with the Aromatic Ring

It was observed during the course of this investigation that the addition of tetrabutylammonium bromide to a CCl_4 solution of an arene alcohol resulted in a change in the n.m.r. spectrum of the phenyl protons; whereas, in the absence of salt, these were all essentially equivalent and gave rise to a single narrow band, the spectrum broadened into a very complex multiplet having, at the highest salt concentrations, a total width of about 20–25 Hz.

In an endeavor to find out what part or parts of the ring were being affected, and to simplify the spectral analysis involved, the complexing behavior of 4-nitrophenylmethanol and 4-methoxyphenylmethanol with bromide ion was studied.

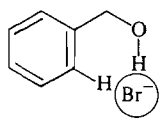
TABLE V

Comparison of hydroxyl- and *ortho*-proton behavior in 4-substituted phenylmethanols on addition of bromide ion

4-Substituent	Δ_c(OH) (p.p.m.)	Δ_c(*ortho*) (p.p.m.)	K(OH) (M^{-1})	K(*ortho*) (M^{-1})
OCH_3*	−3.82	−0.13	49	19
NO_2†	−2.50	−0.16	10	4

*Solvent: CCl_4.
†Solvent: CH_3CN.

It was found that, in both cases, the ring protons *meta* to the CH_2OH group were unaffected by the addition of salt, while those *ortho* to the group shifted downfield monotonically with salt concentration. Both K and Δ_c values were evaluated from the shift of the *ortho* ring protons in the same manner as reported previously for the OH proton shifts. These values are given in Table V and compared with the corresponding values for the OH proton constants. Since, for reasons of solubility, the 4-nitro compound was run in acetonitrile as solvent, the results are not directly comparable to those run in CCl_4. Nonetheless, for both the 4-MeO and 4-NO_2 compounds, the equilibrium constant is found to be a factor of three smaller for "complexing" of the *ortho* protons than for the OH protons. Figure 5, which is a plot of OH shift vs. *ortho*-proton shift for each of the 4-methoxy- and 4-nitrophenylmethanol, shows clearly that there is not a simple proportionality between the salt concentration dependent shift of the *ortho* hydrogens and that of the hydroxyl hydrogen. Thus these two shifts cannot both reflect formation of a single complex, either through inductive transmission of a deshielding effect from the primary binding site to the other hydrogen, or through formation of a chelated complex:



The case where only bromide ion already bound at the hydroxyl could then complex a ring site would also lead to simple proportionality between the two shifts, and thus must be rejected.

On the other hand, the presence of a hydroxyl group near the ring does appear to be necessary for anion–ring interaction. The methyl ether of phenylmethanol exhibits no ring perturbation on addition of bromide ion. The ring protons of 4-methylphenol shift downfield on addition of bromide ion; the ring protons of methoxybenzene are unaffected by the presence of bromide ion.

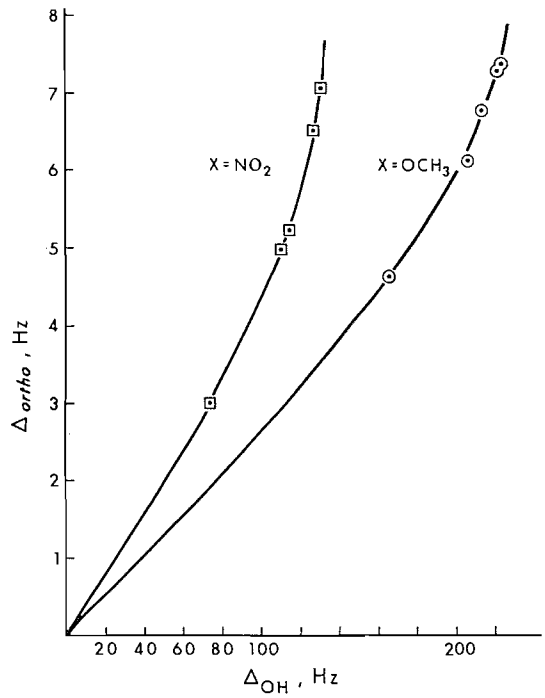


FIG. 5. Comparison of shifts of O—H and *ortho*-phenyl proton signals in 4-substituted phenylmethanols.

Moving the hydroxyl group to a position β- to the ring, as in 2-phenylethanol, results in the ring being unperturbed by formation of bromide complex by the hydroxyl group.

Interaction of bromide ion with aromatic rings has been observed in other cases. The *ortho* hydrogens in the phenoxy substituent of certain β-D-glucopyranosides were observed to shift downfield on formation of halide ion complexes with the pyranose ring (Paper II). The *meta* and

para hydrogens of nitrobenzene are deshielded on addition of bromide ion (15).

It is apparent that a more systematic study of the interactions between aromatic systems and halide ions will be necessary before the mechanism of the interaction can be understood. The results reported here do, however, indicate that both the nature and orientation of the interacting sites are significant.

Chemical Shift in the Complex

The complex shifts in Table I, for bromide complexes to hydroxyl hydrogens in a variety of aliphatic and aromatic structures, are consistently about twice as large as those reported in Paper I for bromide complexes to C—H hydrogens. The total range of complex shifts is about 30% of the average shift. It appears reasonable, therefore, to attempt to account for the hydrogen deshielding, on formation of a complex to the hydroxyl group, as a property of the O—H bond.

An electrostatic field model of the deshielding may be devised, analogous to that used for C—H bonds in Paper I. There is no body of theoretical or experimental results concerning electrostatic deshielding of O—H hydrogens comparable to that for C—H; however, assuming that the interaction with the ion is entirely electrostatic, an equation governing electrostatic perturbation of the O—H bond analogous to the Buckingham equation (16) for C—H may be assumed

$$[2] \quad \delta\sigma_E = a \times 10^{-12} E_z - b \times 10^{-18} E^2$$

The z-axis is directed from O to H. The coefficient of E^2, b, may be assumed to have the hydrogen atom value (17); this results in the contribution from the E^2 term being about 10% of the total observed shift.

We postulate that the electrostatic field may be regarded as originating at the center of the ion. If the distance from the ion center to the hydrogen nucleus is ρ Å, and the angle between the O—H and H—ion vectors is θ, the complex shift, in p.p.m., is predicted to be

$$[3] \quad \Delta_c = -4.803\, a\, (1/\rho^2) \cos\theta - 23.07\, b\, (1/\rho^4)$$

Assuming a collinear complex ($\cos\theta = 1$), the complex shift was a quadratic in $(1/\rho^2)$. The internuclear distance observed in many H bonded complexes is typically 0.3–0.6 Å less than the sum of the appropriate van der Waals radii. We have chosen, as before, to represent ρ as

$$[4] \quad \rho = r_- + r_H - 0.5$$

where r_H is the hydrogen van der Waals radius, 1.2 Å, and r_- is the crystal radius (18) of the ion.

It is now possible to evaluate the a coefficient using experimentally obtained complex shifts, Δ_c. A plot of $(\Delta_c + 23.07\, b/\rho^4)$ vs. $(4.803/\rho^2)$ should yield a straight line through the origin, of slope a. The data for complexes in Tables I and II, excepting the phenol, are plotted in Fig. 6. The experimental uncertainty does not permit evaluation of the straight line postulate. From the slope of the best straight line through the origin, we obtain $a = 5.5 \pm 0.3$ e.s.u.$^{-1}$. The magnitude of this coefficient relative to the value of 3.0 determined in Paper I for C—H is reasonably certain. Its absolute magnitude must be regarded as a lower limit, since counter-ion effects, the actual degree of hydrogen bond shortening, and dielectric polarization effects may contribute (see discussion of these in Paper I).

The systematic trend of the points in Fig. 6, tending towards a negative intercept, is difficult to understand. The van der Waals shifts, which are

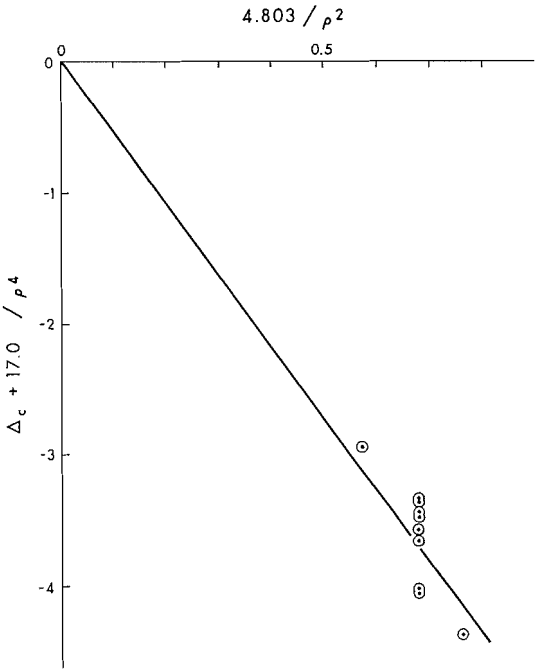

FIG. 6. Buckingham's a — coefficient for alcohols.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

likely to be about the same for the three ions, would tend to produce a positive intercept. One possible explanation might be that there is a variation in the degree of hydrogen bond shortening: greatest for Cl^- and least for the most weakly interacting I^-. If the bond shortenings were taken as Cl^-, 0.6 Å; Br^-, 0.5 Å; I^-, 0.4 Å; instead of 0.5 Å for all ions, then the Cl^- and I^- would be on the line shown. This is not to argue that the bond shortenings have the values postulated, but that reasonable variation of the shortening could account for the observed discrepancy.

In view of the fact that the deviations of the points for Cl^- and I^- from the line are less than the range found for Br^-, concern over these deviations would presently appear unwarranted.

It is apparent that the O—H proton shielding is more sensitive to the electrostatic field than the C—H proton shielding, by a factor of nearly two. Our coefficient of the linear field term a_{OH}, is 5.5; the coefficient a_{CH}, measured in trichloromethane by the same method, was 3.0 (Paper I). This value was in agreement with several other determinations (19).

Buckingham's derivation of the linear field dependence of the shielding (16) treats the covalently bound hydrogen as a hydrogen atom, perturbed by a charge λ at a distance R. The coefficient of the linear term is then,

$$[5] \quad a = (\lambda/R^2) \times 1.5 \times 10^{-18} \text{ e.s.u.}^{-1}$$

Although it is unrealistic to expect that λ or R should represent observable molecular properties, it is evident that a positive charge is analogous to an electronegative atom covalently bonded to hydrogen. The effective λ, and thus a should reasonably increase with increasing electronegativity of the atom to which the hydrogen is bonded. This is consistent with the observation that a_{OH} is larger than a_{CH}.

Evaluation of a_{OH} is of considerable importance, since the electrostatic contribution to the chemical shift is needed in studies of ionic hydration (20). In the past, a_{OH} has been estimated (21) or assumed to be equal to a_{CH}; it appears that this may have led to an underestimate of the polarization contribution to hydration shifts.

Conclusions

Halide ions appear to interact specifically with the hydroxyl proton of an alcohol, in dilute solutions in a relatively inert solvent. This is consistent with the accepted view that the strong solvation of small anions by alcohols is primarily *via* hydrogen bonding (22). In addition, weak interaction occurs with the *ortho* protons of phenyl substituents located α- to, or directly bonded to the hydroxyl group. No significant interaction of the anion with any other site in the alcohols was observed.

The correlation of the association constant with the inductive properties of substituents, and the dependence of both association constant and complex shift on the ionic radius, suggest that the interaction with the hydroxyl group is primarily electrostatic, and is controlled by the electrophilicity of the hydroxyl hydrogen.

The hydroxyl hydrogen complex shifts are substantially independent of the nature of the group to which the hydroxyl group is bonded, and suggest that the susceptibility of a hydrogen to electrostatically induced shielding change is essentially a bond property.

The coefficient, a, of the linear field term in the "Buckingham" equation [2] is significantly larger for O—H than for C—H, in accordance with the bond polarities. Assuming that trihalomethanes and alcohols form halide complexes of similar (presumably linear) structure with respect to the hydrogen, we have determined that $a_{OH}/a_{CH} = 1.8$. A reasonable estimate of a_{OH} is 5.5 e.s.u.$^{-1}$, subject to the same reservations which applied to the previous determination of a_{CH}.

Oxidations involving silver. II. The oxidation of alcohols and aldehydes with silver(II) picolinate

T. G. CLARKE, N. A. HAMPSON, J. B. LEE[1], J. R. MORLEY, AND B. SCANLON
Department of Chemistry, University of Technology, Loughborough, Leicestershire, England

Received March 29, 1968

The oxidation of alcohols by argentic picolinate has been studied and has been shown to give high yields of aldehyde and ketone. Examination of the oxidation of aldehydes shows that smooth conversion to the acid occurs in most cases, but in some cases, an anomalous reaction occurs, which probably involves attack upon the aromatic ring of substituted benzaldehydes. The oxidation of aldehydes occurs much more slowly than alcohol-oxidation under similar conditions.

Canadian Journal of Chemistry, **47**, 1649 (1969)

In connection with the use of solid silver anodes (1) for the oxidation of organic compounds, we examined the effect of some complexing agents upon the course of oxidations at these electrodes. Since oxidation may proceed by formation of some species which diffuse into the mass of the electrolyte (2) before reacting, it was important to know the behavior of these species. One such species in our studies was silver(II) picolinate.

The argentic oxides produced at a silver anode, or in persulfate oxidations of silver salts, are stoichiometrically AgO. Study shows them to be in fact lattice compounds of Ag(I) and Ag(III), (3). In contrast, complexing agents such as picolinic acid permit the isolation of definite Ag(II) compounds (4), thus offering the possibility of studying the oxidizing activity of the Ag(II) state[2] uncomplicated by Ag(III); likewise derivatives of Ag(III) may be obtained and studied (5)[3].

One measure of the relative oxidizing power of these compounds is their relative oxidation potential. We measured the electrode potentials of the systems H^+ $pic^-/Ag(I)$ $pic_{(s)}/Ag$ and H^+ $pic^-/Ag(II)pic_{2(s)}/Ag$ at 25 °C and pH 5, and found them to be respectively 0.694 and 0.720 V. The corresponding (extrapolated) electrode potentials for the $Ag/Ag_2O/OH^-$ and $Ag/AgO/OH^-$ systems are 0.60 and 0.86 V respectively. Although these figures represent free energy changes for reversible equilibria, and most organic oxidations are not reversible processes in this sense, the figures indicate the approximate oxidizing power of the reagents. We have found one immediate difference between the oxide and picolinate, namely that, while the latter usually (but not always) undergoes the equivalent of a one-electron change giving silver(I) picolinate as product, under similar (neutral) conditions AgO usually undergoes a two-electron change, metallic silver being the main inorganic product in most of the cases we have examined. Differences in selectivity of action and products formed might be expected from this, but, while differences have been noted, they are surprisingly few. Thus, for example, both reagents convert benzylic alcohols to aldehydes (some acid also is obtained using AgO), toluene and *p*-cymene to benzaldehyde and *p*-cumaldehyde respectively, and 2-ethylhexanol to 2-ethylhexanal. With each reagent, alcohols are oxidized more slowly than amines, which oxidize more slowly than phosphines and phosphites. (The oxidation of triphenylphosphite by AgO at room temperature, for instance, is almost explosive.)

Our experiments show, in those cases we have examined, that product-wise there is a close parallel with oxidations at the electrode, under similar conditions[4].

We here discuss the oxidizing action of silver(II) picolinate in isolation from the electrode system. The action of AgO will be discussed separately[4].

---

[1]Author to whom all correspondence should be addressed.

[2]Details of the preparation and reactivity of some new Ag(II) complexes will be presented shortly in Part VI (in preparation).

[3]The oxidation of organic compounds by these reagents proceeds in many ways more parallel to the action of Cu(III) derivatives; J. B. Lee, unpublished results.

[4]For a preliminary survey of the oxidizing actions of Ag(II) picolinate and AgO see ref. 18 and Parts III and IV of this series, which are in preparation.

Oxidation of alcohols proceeds rapidly in neutral conditions at moderate temperatures. The overall reaction may be written

$$2Ag(pic)_2 + R_2CHOH \rightarrow 2Ag(pic) + R_2C{=}O + 2\ pic\text{-}H$$

(pic = picolinate)

While the rate of reaction is influenced by the nature of the solvent, (use of dimethyl sulfoxide (DMSO), for example, generally leads to more rapid reaction) we find that reaction proceeds quite satisfactorily in water, despite the heterogeneous nature of the system, and isolation of products is simplified. Volatile products may be swept out in a nitrogen stream; less volatile products are isolated by extraction with a suitable solvent. Reaction is rapid in the 30–70 °C range.

Secondary alcohols are converted in high yield into ketones. More interestingly, high yields of aldehydes are obtained from primary alcohols with negligible over-oxidation to acids. Table I lists some products and yields obtained. No attempt has been made to maximize these yields. The identity of the products has been confirmed in each case by physical properties, chromatographic comparison, formation of derivatives, and/or examination of infrared (i.r.) and proton magnetic resonance (p.m.r.) spectra, as appropriate.

TABLE I

Reaction of alcohols with silver(II) picolinate

Alcohol	Product	% Yield*
CH_3	Formaldehyde	80
Ethyl	Acetaldehyde	77
n-Propyl	Propionaldehyde	71
iso-Propyl	Acetone	80
n-Butyl	Butyraldehyde	76
iso-Butyl	iso-Butyraldehyde	57
sec-Butyl	Ethylmethyl ketone	68
n-Amyl	*n*-Valeraldehyde	74
iso-Amyl	iso-Valeraldehyde	61
n-Hexyl	*n*-Hexaldehyde	69
2-Ethylhexyl	2-Ethylhexaldehyde	55
n-Heptyl	*n*-Heptaldehyde	54
n-Decyl	*n*-Decaldehyde	68
DL-Phenylethyl	Acetophenone	73
2-Phenylethyl	Phenylacetaldehyde	61
Bornyl	Camphor	66
Cyclohexyl	Cyclohexanone	70
Benzyl	Benzaldehyde	80
p-Nitrobenzyl	*p*-Nitrobenzaldehyde	83
Anisyl	Anisaldehyde	87
Veratryl	Veratraldehyde	83
Piperonyl	Piperonaldehyde	77
Tetrahydrofurfuryl	Tetrahydrofurfuraldehyde	62
2-Ethoxyethyl	2-Ethoxyacetaldehyde	53

*No attempt was made to maximize yields.

These results indicate the wide applicability of the reagent. Many methods are available for the preparation of aldehydes from primary alcohols, but nearly all suffer from limitations in one or other respect, giving low yields, involving severe conditions, or product-isolation difficulties. Recently Syper (6) has described the use of AgO as an oxidant but the conditions he employed (hot concentrated acids) are rather severe. In our experience AgO is a useful oxidant in neutral or mildly alkaline conditions[4].

Chromic acid oxidations (7) may give good yields, but involve acid conditions, and formation of esters etc. often reduces yields, unless the aldehyde can be removed quickly from the mixture (8). *t*-Butyl chromate and chromium trioxide in pyridine are more successful (9), but may occasionally prove hazardous. Manganese dioxide[5] has been often applied for benzylic and allylic alcohols (10) and may in certain cases oxidize saturated systems if a large excess of oxidant is used (11). The strongly basic conditions of the Oppenauer oxidation are conducive to condensation and polymerization of the aldehyde (12). A variety of other reagents including selenium dioxide (13), nickel peroxide (14, 16), nitrogen tetroxide (15), lead(IV), thallium(III), and mercury(II) complexes (16), and *N*-halo-compounds (17), etc. have been used for these conversions, but often usefully only with benzylic alcohols.

The influence of structure on rate of oxidation is illustrated in Tables II–V. Table II lists the approximate rates of oxidation of some aliphatic alcohols under comparable conditions relative to ethanol, as standard. It can be seen that the rate decreases with increasing chain length for primary and secondary alcohols; primary alcohols are oxidized more rapidly than secondary alcohols. Applications of these differences to selective oxidation of single hydroxyl groups in polyhydroxy compounds and sugars will form the subject of a later publication. Benzyl alcohol is oxidized somewhat more readily than ethanol,

[5]We (J.B.L. and T.G.C.) have used a method for the preparation of highly active MnO_2, sufficiently active to inflame alcohols on contact in some cases, but even in this case a large excess of reagent is required, and losses occur unless excess oxidant is carefully destroyed with SO_2.

TABLE IV

Approximate relative oxidation rates of some β-alkoxy alcohols

Alcohol	Rate*
Ethanol	100
2-Ethoxyethanol	80
2-Butoxyethanol	71
2-Acetoxyethanol	31
Tetrahydropyran-2-carbinol	59
Tetrahydrofuran-2-carbinol	76

*Relative to ethanol as 100.

and Table III illustrates the effect of various substituents upon the rate of oxidation of benzylic alcohols relative to benzyl alcohol itself. It is clear that the reaction is facilitated by electron-releasing groups, retarded by electron-attracting substituents. It is interesting to note that the effect of a β-oxygen function is to markedly increase the rate of oxidation over that which one might expect for a molecule of similar steric size. Table IV lists the approximate oxidation rates of some β-alkoxy alcohols, and one β-acyloxy alcohol, compared with ethanol as standard, and it may be seen that 2-ethoxyethanol, for example, is oxidized considerably more quickly than *n*-amyl alcohol which is approximately equivalent sterically. The influence of substituents in cyclohexanols, on the oxidation rate relative to the rate of oxidation of cyclohexanol itself, is shown in Table V. Since these materials were mixtures of *cis* and *trans* isomers, little more can be concluded beyond noting the obvious reduction in rate with steric crowding of the hydroxyl group.

Although the reagent converts primary alcohols into aldehydes in good yield, the oxidation of aldehydes to acids also proceeds smoothly in most cases. Aliphatic, aromatic, and heterocyclic aldehydes are oxidized rapidly in neutral aqueous solution at 50 °C. Aliphatic aldehydes (e.g. 2-ethylbutanal and 2-ethylhexanal) are oxidized more quickly than for example furfural, which again oxidizes more quickly than benzaldehyde. The rate of oxidation of aromatic aldehydes is increased by electron-releasing substituents, and decreased by electron-attracting substituents, as can be seen by reference to Table VI, which indicates the approximate rates relative to furfuraldehyde (taken as 100).

TABLE V

Approximate relative oxidation rates of some cyclohexanols

Alcohol	Rate*
Cyclohexanol	100
4-Methylcyclohexanol	35
3,5-Dimethylcyclohexanol	33
2,5-Dimethylcyclohexanol	31
2,2-Dimethylbutanol-3†	10

*Relative to cyclohexanol as 100.

For personal use only.

The yields of acid obtained were often less satisfactory (*p*-nitrobenzoic acid, for example was isolated in only 31% yield), and in two cases highly anomalous reactions occurred. Thus with piperonal and veratraldehyde very rapid reduction of the silver(II) picolinate occurred, but in neither case could any trace of the corresponding acids be found. Furthermore, the aldehydes were largely (approx. 80%) recovered unchanged. Although no definite product has been isolated, it would appear that the oxidant is consumed, in these two cases, in attack upon the aromatic ring, with cleavage occurring rapidly to the exclusion of the expected mode of action, and with consumption of several moles of oxidant per mole of aldehyde.

Silver in the Ag(I) state is well known to complex with olefines and aromatic rings, and the oxidation of benzene to benzoquinone by AgO (6) may involve a similar (unstable) coordination compound. Our results with a number of other systems are in agreement with the possible formation of (unstable) Ag(II) olefine- and aryl-complexes. In contrast, the successful oxidation of piperonyl alcohol and veratryl alcohol to the corresponding aldehydes without complication must depend upon the more powerful coordination of the alcoholic oxygen to the silver in these two cases. Since the other aromatic aldehydes examined react more normally, we consider that the electron-releasing effect of the substituent groups is sufficient to favor aryl–silver rather than oxygen–silver coordination for piperonal and veratraldehyde.

The successful oxidation of alcohols to aldehydes depends upon the lower reactivity of the latter. Thus benzyl alcohol is oxidized at approximately 20 times the rate for benzaldehyde under similar conditions; the rates for both benzyl alcohol and paranitrobenzyl alcohol have been included in Table VI for comparison.

The oxidation of hydroquinone was examined. 1,4-Benzoquinone was obtained in 89% yield. The use of the reagent with this type of compound is probably restricted by the great instability of the products.

Silver(II) picolinate is a square planar complex isomorphous with the analogous copper(II) derivative and probably having a *trans* planar structure like the latter.

Oxidation could proceed through an outer-sphere mechanism, with electron-transfer via an OH^- or a water ligand, or the relative rates observed for aliphatic alcohols may represent the steric requirements for formation of an Ag—O linked intermediate, before the actual oxidation process. On this basis the effect of changing substituents on the reactivity of benzyl alcohol would reflect the changing nucleophilicity of the alcohol oxygen atom.

Further experiments, including kinetic and labelling studies, are under way to clarify the mechanism.

Experimental

Infrared spectra were recorded using Perkin–Elmer 237 and 257 spectrophotometers. Nuclear magnetic resonance spectra were measured upon a Perkin–Elmer R 10 (60 megacycle) instrument. Ultraviolet (u.v.) spectra were recorded using a Unicam S.P. 800 instrument. Where available, analytical grade materials were used. Otherwise reagent grade materials were suitably purified. Gas–liquid chromatographic (g.l.c.) examination of materials was carried out using Pye 104 Chromatographs, single and dual columned, isothermal, or temperature programed models, and one or more stationary phases including silicone oil, dinonyl phthalate, tricresyl phosphate, PEGA, carbowax, and apiezon L, usually 5% or 10% upon celite. (Nitrogen gas carrier; flame-ionization detector.)

Picolinic Acid

α-Picoline (50 g, 0.54 mole) and potassium permanganate (90 g, 0.57 mole) in water (2.5 l) were heated on a steam bath until no purple coloration remained. A further 90 g portion of potassium permanganate in water (500 ml) was added and heating was continued until again no purple coloration remained. The mixture was cooled slightly and then filtered at the pump through a thin layer of Kieselguhr. The precipitated manganese dioxide was washed with boiling water (1 l). The combined filtrate and washings were concentrated under reduced pressure to give about 200 ml of solution. The solution was acidified to congo red with concentrated hydrochloric acid. Solvent was removed at the pump and the residue was repeatedly extracted with portions (250 ml) of 95% aqueous ethanol. Evaporation of the extract gave α-picolinic acid (40 g, 60% of theoretical yield) m.p., 128–129 °C, raised to 136–138 °C on recrystallization from ethanol. The p.m.r. spectrum showed a multiplet at 1.0–2.0 τ (in D_2O), with no other signals. The i.r. spectrum (KBr discs) showed bands at 3420 (b, s), 3100 (w), 1720 (w), 1654 (m), 1600 (s), 1563 (w), 1516 (w), 1446 (w), 1378 (s), 1388 (w), 1286 (m), 743 (s), and 672 (s) cm^{-1}.

Argentic Picolinate

The method of Cox *et al.* (4) proved unsatisfactory in our hands, and the following modification was developed. To a solution of picolinic acid (61.5 g, 0.5 mole) in water (2 l) was added a solution of silver nitrate (42.5 g, 0.25 mole). Aqueous potassium persulfate (33.8 g, 0.125 mole) was added to the vigorously stirred suspension. Stirring was continued for 48 h. The red precipitate was separated,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

washed with distilled water, and dried in darkness at room temperature in vacuo to constant weight; yield 75 g. This material was stable on storage in the dark at room temperature over several months.

Silver(II) Oxide (AgO)

A solution of sodium hydroxide (36 g) in water (500 ml) was brought to 80 °C, and maintained at this temperature while potassium persulfate (37.5 g) and silver nitrate (25.5 g) were added successively with stirring, the latter substance being added in small portions. Stirring was continued for 5 min, and the solution was maintained at 80 °C for a further 45 min. The cooled solution was filtered at the pump, and the residue was washed successively with sodium hydroxide (5 g) in water (500 ml), and then distilled water (500 ml). The dark brown argentic oxide was dried in vacuo; yield 18.3 g (almost quantitative).

Oxidations with Argentic Picolinate

The following are typical procedures.

Oxidation of Methanol

Methanol (1 ml) was stirred at 40 °C with argentic picolinate (2.1 g) in DMSO (15 ml) and water (15 ml), while a stream of N_2 swept the surface. The N_2 was passed into aqueous 2,4-dinitrophenylhydrazine (19) and the yellow precipitate was separated, washed, dried, and weighed (0.48 g, 80%); m.p. 165–166 °C, (lit. (19) m.p. 166 °C).

Oxidation of C_2–C_{10} Alcohols

Using a similar technique with N_2 blown *through* the solution, the aldehydes (or ketones) up to C_{10} could be swept from the mixture, although it was necessary to raise the temperature, after reaction was complete, to recover all the highest boiling members.

To confirm that no skeletal rearrangement had occurred, the p.m.r. spectra of the 2,4-dinitrophenylhydrazones were routinely examined. All these showed resonances at 0.88 τ (1 proton, doublet, very slightly split further, $J_{H_3H_5}$ = 2.8 c.p.s.), $H_{(3)}$: 1.65 τ (1 proton double doublet $J_{H_3H_5}$ = 2.8 c.p.s. and $J_{H_5H_6}$ = 9.8 c.p.s.), $H_{(5)}$: 2.05 τ (1 proton doublet $J_{H_6H_5}$ = 9.8 c.p.s.), $H_{(6)}$: 1.0 τ (broad singlet, NH). The signal due to the $H_{(1')}$ proton (i.e. —CH=N—) in aldehyde 2,4-dinitrophenylhydrazones regularly appeared at 2.4 τ (triplet usually, quartet for acetaldehyde) where no β-branching was present. β-Branched compounds gave doublets centered at 2.45 to 2.55 τ. Remaining signals were as expected in the 7.4–9.1 τ region, and no evidence of any skeletal change was observed.

Oxidation of Isoborneol

A mixture of isoborneol (0.01 mole, 1.54 g) and argentic picolinate (0.02 mole, 7.0 g) in DMSO (10 ml, containing a little water) was warmed to 40 °C for 15 min with gentle stirring, by which time the red coloration had disappeared. The mixture was poured into water (250 ml), filtered, and the residue and filtrate extracted with chloroform. The chloroform layers were combined and washed several times with water, dried over magnesium sulfate, filtered, and evaporated. Camphor (66% yield) was obtained, identical in i.r. spectrum with authentic material (m.p. 170–171 °C), on precipitation as 2,4-dinitrophenylhydrazone. It was identical in retention time on g.l.c. with authentic camphor, and had the expected p.m.r. spectrum.

Oxidation of DL-*Phenylethanol*

Phenylethanol (0.01 mole, 1.2 g) and argentic picolinate (0.02 mole, 7.0 g) were warmed together in DMSO (10 ml) for 10 min at 40 °C. The mixture was poured into water (300 ml) and extracted with petroleum–ether (60–80°). The petrol extract was washed, dried, and evaporated to give acetophenone (73%) identical in i.r. spectrum with authentic material m.p., 246–247 °C (lit. 250 °C) (2,4-dinitrophenylhydrazone). It was identical in retention time on g.l.c. with authentic material.

Oxidation of Hydroquinone

A mixture of hydroquinone (0.31 g) and argentic picolinate (2.0 g) in water (10 ml) was heated using a magnetic stirrer at 50 °C until the red coloration was discharged. The mixture was extracted with ether (2 × 50 ml) and the extract filtered and evaporated to give 1,4-benzoquinone (89%) as a yellow powder which gradually darkened on storage. This material was identical in i.r. spectrum, and in retention time on g.l.c. with authentic material.

Oxidation of Anisyl Alcohol

Anisyl alcohol (0.79 g) and argentic picolinate (4.0 g) were heated with stirring in water (50 ml) at 70 °C. After 25 min the mixture was cooled and extracted with ether. The dried ether layer was examined by g.l.c. (S.E. 30 on Celite: 210°), which showed only ether and anisaldehyde to be present. Evaporation of the extract gave anisaldehyde (0.7 g; 87%, identical in i.r. spectrum with authentic material).

Oxidation of Anisaldehyde

Anisaldehyde (0.4 g) and argentic picolinate (2.0 g) were heated with stirring in water (30 ml) at 70 °C. Stirring was continued until the reaction was complete (9.6 h). The mixture was acidified with dilute HCl and extracted with ether and chloroform. Evaporation of the extracts gave anisic acid.

Measurement of Relative Rates of Oxidation

Approximate measurements of relative reaction rates were made by taking appropriate quantities of materials at a selected thermostat temperature and measuring *either* the decrease in absorbance with time at 325 mμ *or* the disappearance of the red coloration against time. Whilst not suitable for accurate determination of absolute rates, the relative order of rates was found to be reasonably reproducible.

Oxidation of p-Nitrobenzaldehyde

A mixture of *p*-nitrobenzaldehyde (0.43 g) and argentic picolinate (2.0 g) was stirred vigorously in water (10 ml) at 70 °C. After 26 h the reaction was complete. The mixture was acidified with slightly more than the calculated amount of dilute hydrochloric acid, extracted, and the solution was examined by thin-layer chromatography (silica, eluted with ether). The major component corresponded in R_f (0.74) to authentic *p*-nitrobenzoic acid. After isolation, the acid was obtained (0.15 g, 31%) identical in physical constants (m.p., 240–241 °C, i.r. spectrum) with authentic material.

Oxidation of Piperonaldehyde

Piperonaldehyde (0.43 g) and argentic picolinate (2.0 g) were stirred in water (10 ml) at 70 °C. After 25 min no

argentic picolinate remained. The mixture was acidified (dilute HCl, calculated quantity) and extracted with ether and chloroform. From the extracts, piperonaldehyde (0.3 g) was recovered but no acid was found. Repetition of the reaction several times led in each case to rapid reduction of argentic picolinate, but in no case was the expected acid found, and in each case a good recovery of aldehyde was obtained.

Electrode Potentials

The electrode potentials of the systems Ag(pic)/Ag and $Ag(pic)_2/Ag$ were measured (at pH 5 and 25 ± 0.1 °C) against a calomel reference electrode (saturated) using a potentiometer (Tinsley Type 4363E). Solution junctions were made at an asbestos wick, the junction potential being eliminated using saturated KCl. Full details of results will be communicated later.

A ^{19}F nuclear magnetic resonance investigation of the formation of $Sb_2F_{11}^-$ and $Sb_nF_{5n+1}^-$ in the CsF–SbF_5, *t*-butyl halide – SbF_5, and tetraalkylammonium hexafluoroantimonate – SbF_5 systems

J. BACON, P. A. W. DEAN, AND R. J. GILLESPIE
Department of Chemistry, McMaster University, Hamilton, Ontario

Received September 23, 1968

Fluorine nuclear magnetic resonance spectra have been obtained for the *t*-butyl fluoride – SbF_5, *t*-butyl chloride – SbF_5, tetraethylammonium hexafluoroantimonate – SbF_5, and cesium fluoride – SbF_5 systems, both with and without SO_2 solvent. In SO_2 solution the anion is $Sb_2F_{11}^-$ for all the systems, any remaining SbF_5 being converted to $SbF_5 \cdot SO_2$. It is concluded that in the systems that do not contain SO_2, higher polymeric anions $Sb_nF_{5n+1}^-$, where $n > 2$, are present. *t*-Butyl chloride and *t*-butyl fluoride give the *t*-butyl carbonium ion, as has been previously reported. Tetrabutylammonium and benzyltrimethylammonium cations appear to decompose to a carbonium ion and an adduct $SbF_5 \cdot NR_3$ in the presence of SbF_5.

Canadian Journal of Chemistry, 47, 1655 (1969)

Introduction

By reacting alkyl fluorides with antimony pentafluoride or antimony pentafluoride dissolved in liquid sulfur dioxide, Olah and coworkers (1) were able to obtain a colored[1] liquid which they formulated as a solution of the alkylcarbonium hexafluoroantimonate in SbF_5 (or SO_2), e.g.

$$(CH_3)_3CF + SbF_5 \rightarrow (CH_3)_3C^+ \cdot SbF_6^-$$

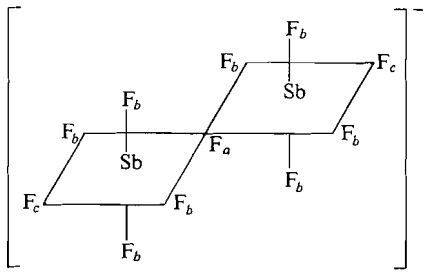
They obtained proton magnetic resonance spectra consistent with the production of the dimethylcarbonium, trimethylcarbonium, and dimethylethylcarbonium ions from solutions of propyl fluorides, butyl fluorides, and amyl fluorides, respectively, the proton–fluorine coupling disappearing and the proton chemical shifts and the proton–proton and carbon–proton coupling constants being in agreement with a planar sp^2-hybridized structure for the carbonium ion. While they reported that the ^{19}F spectra of these complexes showed the absence of covalent C—F bonds, no fluorine spectra were given, nor was the anion identified. The definite identification of the anionic species in these complexes is of considerable interest, particularly as evidence that the complex is ionic and not a rapidly exchanging donor–acceptor complex. We have, therefore, used ^{19}F nuclear magnetic resonance (n.m.r.) spectroscopy to investigate the nature of the anion in various fluoride–SbF_5 systems.

[1]Recent work by Olah *et al.* (2) shows that carbonium ions themselves are colorless, the colored solutions arising from the presence of polymeric impurities.

Results and Discussion

The CsF–SbF_5 System

Neither cesium fluoride nor cesium hexafluoroantimonate is appreciably soluble in liquid sulfur dioxide. However, an exothermic reaction occurs between SbF_5 and CsF in the presence of this solvent. When $SbF_5/CsF = 2.0$, the product of the reaction is quite soluble and the ^{19}F n.m.r. spectrum of the solution at $-60°$ is that of the $Sb_2F_{11}^-$ anion, previously reported by Gillespie and Moss (3) for solutions of SbF_5 in HF. The spectrum is shown in Fig. 1. It consists of a multiplet at 89.4, a doublet of doublets at 109.1, and a quintet at 131.2 p.p.m. from external $CFCl_3$. This is essentially the same spectrum as was observed previously for a 20.9% solution of SbF_5 in hydrogen fluoride (3) and attributed to the $Sb_2F_{11}^-$ ion, **1**.



1

The low field multiplet is assigned to the bridging fluorine F_a, the doublet of doublets to the eight equivalent fluorines F_b, and the quintet to the two equivalent fluorines F_c. A weak doublet is present at 100.1 p.p.m., and may be attributed to

TABLE I

^{19}F chemical shifts* for various complexes in liquid SO_2

Complex	Chemical shift				
	F_a	F_b	$F_c + F_e$	F_d	F_f
$CsSb_2F_{11}$	89.4	109.1	131.2	100.1	—
$SbF_5 \cdot SO_2$	—	—	133.7	100.9	—

*In p.p.m. relative to $CFCl_3$. Complexes externally referenced by sample interchange: F_a, $Sb_2F_{11}^-$ bridging fluorine (9-line multiplet); F_b, $Sb_2F_{11}^-$, F_b (doublet of doublets); F_c, SbF_{11}^-, F_c (quintet); F_d, $SbF_5 \cdot SO_2$ doublet; F_e, $SbF_5 \cdot SO_2$ (quintet); F_f, unassigned peak (see text).

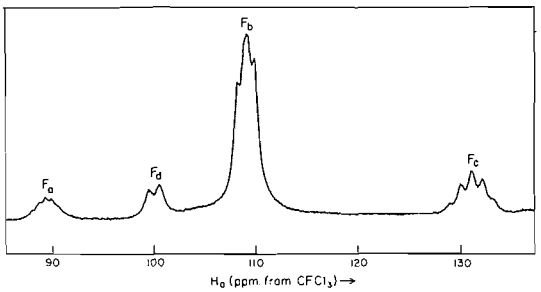

FIG. 1. ^{19}F (94.077 MHz) spectrum of $CsSb_2F_{11}$ in SO_2 at −60 °C.

the presence of a small amount of $SbF_5 \cdot SO_2$; this compound in liquid SO_2 at low temperatures gives rise to a doublet at 100.9 and a quintet at 133.7 p.p.m. (Table I). (Moore *et al.* (4) have previously reported 105 and 137 p.p.m. for these values.) The $SbF_5 \cdot SO_2$ quintet is not seen in the present case; it probably lies under the right hand side of the $Sb_2F_{11}^-$ quintet at 131.2 p.p.m. Sulfur dioxide can be recovered quantitatively from this solution leaving a white solid of composition $CsF \cdot 2SbF_5$ which may be recrystallized from sulfur dioxide. In a solution having $SbF_5/CsF > 2.0$ the $Sb_2F_{11}^-$ spectrum remains essentially unchanged while the peaks attributed to $SbF_5 \cdot SO_2$ increase in intensity. There is no indication of the formation of $Sb_3F_{16}^-$ or higher polyanions. Even for the composition $SbF_5/CsF = 1.0$, the solution appears to contain only the $Sb_2F_{11}^-$ anion and not the SbF_6^- anion as might have been expected. It appears that although $CsSbF_6$ is rather insoluble in SO_2, $CsSb_2F_{11}$ is relatively soluble. If higher polymeric anions exist they clearly undergo complete solvolysis (to $Sb_2F_{11}^-$) in solution in sulfur dioxide.

t-Butyl Halide/SbF_5 Solutions in SO_2

We prepared the "trimethylcarbonium hexafluoroantimonate" compound reported by Olah *et al.* (1) by allowing *t*-butyl fluoride vapor to react with antimony pentafluoride on a vacuum line until the product had the composition *t*-BuF/SbF_5 = 1/3.8. Under our experimental conditions this is the smallest amount of SbF_5 required for complete reaction with the *t*-butyl fluoride. Slightly larger amounts of SbF_5 can be used, but when *t*-BuF/SbF_5 = 1/5, an almost colorless layer separates out, as previously reported (1). This colorless layer appears to be almost entirely SbF_5; the ^{19}F resonance at low temperatures shows only the SbF_5 spectrum (5), while the room temperature ^1H spectrum shows a very weak single line resonance in the $(CH_3)_3C^+$ region. Hence *t*-butyl fluoride and SbF_5 are miscible in the range $3.8 \leqslant SbF_5/t\text{-BuF} < 5$ only, and any further addition of SbF_5 causes an SbF_5 layer containing a very small amount of alkylcarbonium ion to separate out. The SbF_5 layer is slightly less viscous than purified SbF_5 while the colored layer is much less viscous. The colored layer, neat or dissolved in liquid SO_2, gives the same room temperature proton spectrum as that reported by Olah *et al.* (1), namely the strong single resonance assigned to $(CH_3)_3C^+$.

When the *t*-BuF/3.8SbF_5 mixture was dissolved in SO_2, the ^{19}F n.m.r. spectrum shown in Fig. 2 was obtained at −80°. Clearly both the $Sb_2F_{11}^-$ (F_a, F_b, F_c) anion and $SbF_5 \cdot SO_2$ (F_d, F_e) are present, the quintet resonances of both species overlapping. The stoichiometry implies $Sb_2F_{11}^-/SbF_5 \cdot SO_2$ = 1/1.8 assuming these are the only two species present. Spectral areas are in the ratios $F_a/F_b/(F_c+F_e)/F_d$ = 1.4/8.0/3.7/5.7, which are close to the values of 1/8/3.4/5.6 expected for $Sb_2F_{11}^-/SbF_5 \cdot SO_2$ = 1/1.4; a small amount of $SbF_5 \cdot SO_2$ appears to separate out of the solution. We have not definitely assigned the remaining

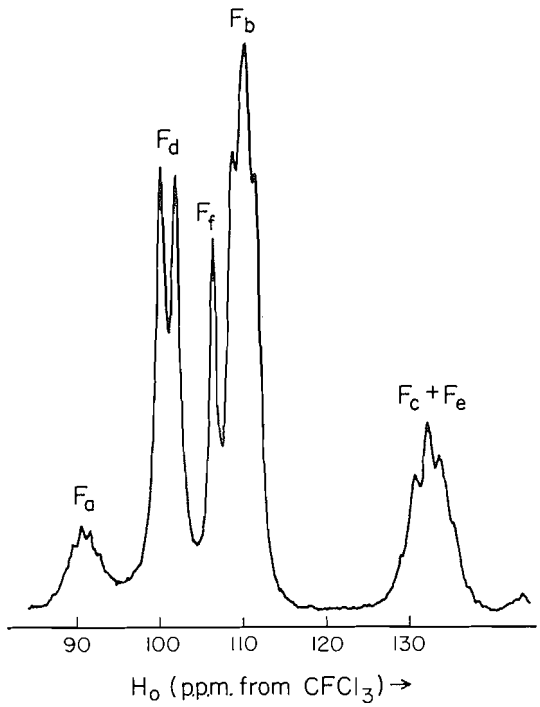

FIG. 2. ^{19}F (56.445 MHz) spectrum of *t*-BuF/3.8-SbF_5 in SO_2 at −80 °C.

resonance, the single peak at 106.6 p.p.m., F_f. It can possibly be attributed to some fluorine-containing species of antimony(III) such as SbF_3 complexed with SbF_5. We noted a slight charring of these solutions with time, hence some of the carbonium ion may be oxidized by SbF_5, accounting for the presence of antimony(III).

Alkyl chlorides also give rise to alkylcarbonium ions on reaction with SbF_5 (1). From the low temperature ^{19}F spectrum of *t*-BuCl/5.5SbF_5 in SO_2 solution (Table I), it appears quite definitely that the anion is again $Sb_2F_{11}^-$ and not the previously suggested SbF_5Cl^-.

We conclude, therefore, that the anion of both the "alkylcarbonium hexafluoroantimonate" and "alkylcarbonium chloropentafluoroantimonate" complexes in SO_2 solution is actually $Sb_2F_{11}^-$. In the latter case the chlorine is presumably present in some neutral species such as $SbF_4Cl \cdot SO_2$ which precipitates from solution.

The $Et_4NSbF_6/SbF_5/SO_2$ System

Et_4NSbF_6 is very soluble in liquid SO_2. The low temperature ^{19}F n.m.r. spectra of mixtures of this salt and SbF_5 in SO_2 (Table I) indicate that for $SbF_5/SbF_6^- \leqslant 1$, the $Sb_2F_{11}^-$ ion is formed quantitatively from SbF_5 within the limits of observation. When $SbF_5/SbF_6^- > 1$ the ^{19}F n.m.r. shows the $Sb_2F_{11}^-$ spectrum and the spectrum of $SbF_5 \cdot SO_2$. When tetrabutylammonium or benzyltrimethylammonium hexafluoroantimonate are dissolved in SO_2 together with SbF_5, the solutions are colored and some solid separates out in each case. It seems likely that carbonium ions are produced from the NR_4^+ cation and that the solid is an adduct of the form $SbF_5 \cdot NR_3$. This explanation is in accord with the absence of a corresponding reaction with the Et_4N^+ cation which would not be expected to give a stable carbonium ion.

We note from Table I the close similarity of the ^{19}F chemical shifts of $Sb_2F_{11}^-$ in SO_2 solutions of $CsSb_2F_{11}$, alkyl halide/SbF_5 mixtures, and Et_4NSbF_6/SbF_5 mixtures. Since interactions between Cs^+ or NR_4^+ and the $Sb_2F_{11}^-$ anion are almost certainly quite small, we can conclude that there is also no strong interaction between the carbonium ion and the $Sb_2F_{11}^-$ anion.

The t-Butyl Fluoride–SbF_5 and Et_4NSbF_6–SbF_5 Systems

We have obtained the ^{19}F spectra of both the *t*-butyl fluoride and Et_4NSbF_6 mixtures with SbF_5 in the absence of SO_2 solvent as a function of temperature.

The low temperature spectrum of the neat *t*-BuF/3.8SbF_5 mixture shown in Fig. 3 consists of a very broad line (δ = 110 p.p.m. relative to external $CFCl_3$) which has superimposed on it the spectrum of SbF_5 (5). As the temperature is lowered, the broad peak increases in width ($\approx$ 2000 Hz at −40 °C) and the area of the SbF_5 peaks increases but at no time exceeds 10% of the main spectrum. This SbF_5 appears to be present as a suspension in the *t*-BuF/SbF_5 (see below).

Et_4NSbF_6 is soluble in SbF_5 in the absence of any other solvent in the approximate range $5 \leqslant SbF_5/SbF_6^- \leqslant 11$ at room temperature. The ^{19}F spectrum of these solutions is a single

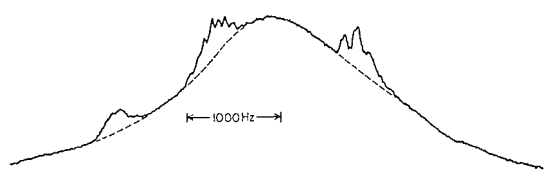

FIG. 3. ^{19}F (56.445 MHz) spectrum of *t*-BuF/3.8-SbF_5 at −40 °C.

broad line ($\approx$ 800 Hz half width at 0 °C; δ = 113.2 relative to external $CFCl_3$) at all temperatures. A solution having $SbF_5/SbF_6^- = 11.6$ was homogenous at room temperature, but on lowering the temperature it became turbid. The spectrum of this solution below room temperature showed a broad line with the spectrum of SbF_5 superimposed upon it. This and the observed turbidity suggests that some of the SbF_5 now exists as a suspension in Et_4NSbF_6/SbF_5. As the temperature was lowered, the area of the SbF_5 spectrum increased relative to that of the broad line, reaching 36% of the total area at −40 °C. These changes in area were reversible. With $SbF_5/SbF_6^- > 12$, homogenous solutions could not be prepared even at room temperature; two layers were formed. The lower layer gave the SbF_5 spectrum while the spectrum of the upper layer showed only the broad line observed for the homogenous solutions.

If the homogeneous liquids were in fact solutions of $(CH_3)_3C^+Sb_2F_{11}^-$ and $Et_4N^+Sb_2F_{11}^-$ in SbF_5 it seems quite unlikely that SbF_5 should separate out under certain conditions of temperature and concentration as we have observed.

The above results are consistent with all the SbF_5 in the homogeneous systems being incorporated into a polynuclear anion which disproportionates with increasing length or decreasing temperature into a smaller anion and polymeric SbF_5. (In this interpretation *t*-BuF/3.8-SbF_5 would be regarded as a mixture of $(CH_3)_3C^+Sb_3F_{16}^-$, $(CH_3)_3C^+Sb_4F_{21}^-$, and possibly $(CH_3)_3C^+Sb_5F_{26}^-$.) The proposed long, unstable anion might be expected to break up and reform readily, giving the broad temperature dependent line observed and the decomposition of such an anion by the SO_2 solvent is not surprising. The liquids may, therefore, be regarded as room temperature fused salts.

Conclusions

Polynuclear anions $Sb_nF_{5n+1}^-$ have previously been postulated by Aubrey and Van Wazer (6) who studied solutions of $SbCl_5$ in SbF_5 using ^{19}F n.m.r., conductivity, and viscosity measurements. They suggested the reaction

$$4SbCl_5 + (5n + 1)SbF_5 \rightleftarrows 5SbCl_4^+ + 5Sb_nF_{5n+1}^-$$

but were unable to identify the anion with any certainty. Gillespie and Moss (3) found that at high concentrations of SbF_5 in HF ($\geqslant$ 30 mole % SbF_5), changes occurred in the n.m.r. spectrum which could be attributed to some formation of higher polyanions such as $Sb_3F_{16}^-$, but these could not be definitely identified. Ruff (7) has prepared the crystalline complex $N_2F_4 \cdot 3SbF_5$, m.p. 74–78°, which may contain the $Sb_3F_{16}^-$ anion, since the complex $N_2F_4 \cdot 2SbF_5$, m.p. 116–119°, dissolved in SO_2 as $N_2F_3^+$ and $Sb_2F_{11}^-$ (7).

In addition to $N_2F_4 \cdot 2SbF_5$, a number of 1:2 SbF_5 complexes also exist: $BrF_5 \cdot 2SbF_5$, m.p. $\approx$ 60° (8); $XeF_2 \cdot 2SbF_5$, m.p. 63° (9); $KrF_2 \cdot 2SbF_5$, m.p. $\approx$ 50° (10); and $XeF_6 \cdot 2SbF_5$, m.p. 108° (11). Some or all of these complexes may contain the $Sb_2F_{11}^-$ anion[2].

The present work shows that the $Sb_2F_{11}^-$ ion is stable as the simple cesium salt and that it is stable in sulfur dioxide solution. Attempts to make sulfur dioxide solutions of the higher polyanions in sulfur dioxide were not successful as the complex $SbF_5 \cdot SO_2$ is formed preferentially. In other words the higher polyanions, if they are formed, undergo essentially complete solvolysis in sulfur dioxide whereas the $Sb_2F_{11}^-$ anion is reasonably stable and undergoes only a limited amount of solvolysis to SbF_6^- and $SbF_5 \cdot SO_2$. It appears that higher polyanions are formed in the absence of sulfur dioxide, for example, in mixtures of alkyl fluorides or tetraalkylammonium fluorides with SbF_5. Indeed over the range where single phase homogenous systems are formed, they appear to be room temperature fused salts with the formulae $R^+Sb_nF_{5n+1}^-$ or $R_4N^+Sb_nF_{5n+1}^-$. We note that the 1:2 complexes cited above are all relatively low melting (50° $\leqslant$ m.p. $\leqslant$ 116°) and that $N_2F_4 \cdot 3SbF_5$, has a m.p. 42° below that of the 1:2 complex with N_2F_4. It seems reasonable, therefore, that a salt containing $Sb_nF_{5n+1}^-$, where $n \geqslant 4$, would be liquid at room temperature.

Experimental

Fluorine n.m.r. spectra were obtained using either a Varian DA-60 spectrometer operating in the HR centerband mode or a Varian HA-100 spectrometer. Low temperature spectra were obtained using a Varian V4540 temperature controller and a variable temperature analytical probe.

[2]Professor Peacock informs us in a private communication that an X-ray diffraction study of $XeF_2 \cdot 2SbF_5$ shows this to be the case for this compound.

Antimony pentafluoride was obtained from Ozark Mahoning Company and distilled twice in glass apparatus immediately before use. *t*-Butyl fluoride was prepared by the reaction (12) of *t*-butyl alcohol and 48% hydrofluoric acid at 60–70 °C in plastic apparatus. *t*-Butyl chloride was obtained commercially. Isobutylene impurities were removed from both halides by treatment with bromine and distillation.

Benzyltrimethylammonium hexafluoroantimonate was from Alfa Inorganics Inc., and was used without purification.

Tetraethylammonium hexafluoroantimonate was prepared by mixing solutions of SbF_5 and Et_4NOH in excess 48% hydrofluoric acid; the precipitate was washed with anhydrous ether and dried in vacuo. The product was purified by precipitation from dichloromethane solution using carbon tetrachloride. The tetrabutylammonium salt was prepared similarly; the starting material was tetrabutylammonium chloride.

Cesium hexafluoroantimonate was prepared by the method of Kolditz and Rehak (13).

All mixtures were made up under moisture free conditions in a dry box. The R_4NSbF_6/SbF_5 and CsF/SbF_5 mixtures were made up by weighing the salt into an n.m.r. tube followed by addition of a weighed amount of antimony pentafluoride from a glass hypodermic syringe. The tubes were closed with detachable taps and attached to a vacuum line where the sulfur dioxide (which had been dried by standing the gas over P_2O_5) was condensed in. The tubes were sealed and weighed. For the alkyl halides a small amount (about 0.03 mole) of SbF_5 was placed in a 100 ml round bottomed flask equipped with a detachable tap. The flask was then attached to the vacuum line and evacuated; the *t*-butyl halide was allowed to evaporate very slowly into the SbF_5 flask and react over the period of 1 h. Nuclear magnetic resonance samples were made up by transferring small amounts from the reaction flask to n.m.r. tubes equipped with detachable taps in the dry box. The n.m.r. tubes, with taps, were then attached to the vacuum line, any SO_2 required distilled in, and sealed.

Cesium μ-Fluoro-bis(pentafluoroantimonate)

Cesium fluoride (1 mole) and antimony pentafluoride (2 moles) were weighed into a glass reaction vessel having a side arm and a receiver. Sulfur dioxide (about 5 moles) was condensed onto the solids at liquid nitrogen temperature and the vessel sealed. As the reaction mixture warmed up, a vigorous exothermic reaction began, with local boiling of the solvent; cooling was necessary and when boiling ceased, the temperature was kept at 50° for 12 h to ensure completion of the reaction. The sulfur dioxide was condensed into the receiver and the side arm sealed off. The portion having the solid was opened in the dry box and the solid recrystallized from sulfur dioxide.

The method of Johnson and Newman (14) was used to determine antimony; a slight excess of boric acid was added to complex the fluoride just before the titration with iodine. Fluoride was determined by potentiometric titration with La(III) using an Orion specific ion electrode. Cesium was determined as the tetraphenylborate (15).

Potentiostatic study of ferrous–ferric kinetics at bright gold and platinum electrodes

SIDNEY BARNARTT

Edgar C. Bain Laboratory For Fundamental Research, United States Steel Corporation, Monroeville, Pennsylvania

Received August 15, 1968

Ferrous–ferric reaction kinetics on gold in chloride and sulfate solutions, and on platinum in a sulfate solution, were studied potentiostatically. The data illustrate the importance of precise potential control and of automatic ohmic compensation. The standard exchange current density is $0.38/f$ A cm^{-2} (where f is the mean ionic activity coefficient) on platinum; it is an order of magnitude larger on gold.

Canadian Journal of Chemistry, 47, 1661 (1969)

In potentiostatic investigations of electrode kinetic mechanisms, the electrode potential is usually maintained constant within ± 1 to 5 mV. This is adequate for a slow electrode reaction, characterized by standard exchange current density $i_{0,s} < 10$ mA cm^{-2}, which can be studied at high overpotentials (in the Tafel region). More rapid reactions must be studied at low overpotentials (1–4), where closer potential control is required. This is particularly true if it is desirable to work within the linear current-potential region (4, 5). Also, rapid reactions at constant potential are associated with large currents which decrease with time (6, 7), because mass-transfer polarization builds up quickly. Therefore the ohmic drop in the electrolyte between the test electrode and reference probe causes the applied potential step to vary, unless accurate compensation is provided (8–12). Compensated potential control to ± 0.1 mV was the goal of the present work. Some of the problems involved were examined in a study of the ferrous–ferric reaction at gold and platinum electrodes. The standard exchange current density is found to be much higher on gold than on platinum. The data on gold emphasize that large errors can be incurred unless almost full ohmic compensation is continuously applied.

Experimental

Potentiostat

The essential features of the potentiostatic circuit employed are indicated schematically in Fig. 1. The circuit is shown in the mode required for a cathodic reaction at the test electrode; on–off and cathodic–anodic switches are omitted for simplicity. The circuit was designed around two units previously described (8), a transistorized voltage controller (v.c.) and a transistorized ohmic compensator (o.c.). It was necessary to change these units from a.c. to d.c. operation in order to reduce a.c. components of the control voltage to < 0.1 mV peak to peak.

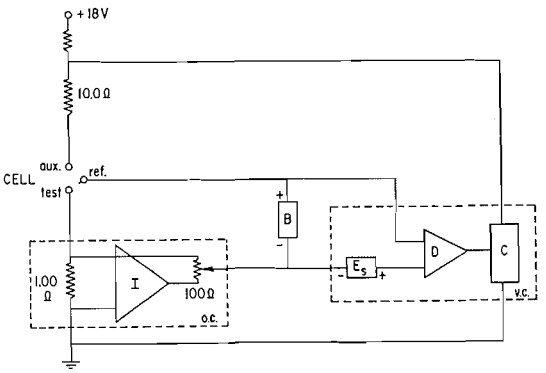

FIG. 1. Schematic diagram of potentiostatic circuit.

Current from the 18 V power supply had two parallel paths to ground, one through the cell and the other through the current regulator C of the voltage controller. The controller, containing also difference amplifier D and Zener reference potential E_s, exhibited stability within ± 0.1 mV but did not have very high internal impedance. At a given potential setting it drew a fixed current from the reference electrode, e.g. 10^{-6} A at $E_s = 5$ mV. A bias current supply B (battery operated, 0–10 μA) was inserted to supply most of this current and it was thus possible to eliminate errors from the reference-electrode current, as shown later. The ohmic compensator contained an inverter amplifier I (amplification $= -1$) which reproduced accurately the voltage drop across the 1.00 Ω resistor, changed its sign, and applied it across a ten-turn potentiometer. Setting the potentiometer to yield a fraction u of this voltage drop, where u is the known uncompensated resistance between the reference and the test electrodes (u varied from 0.13 to 0.21 Ω in this work), compensated for the ohmic voltage iu at any cell current i. In each experiment the test electrode was initially at its reversible potential before the potential step was applied. Current–time ($i-t$) curves, for times up to 50 ms after application of the potential step, were photographed on a storage oscilloscope (Tektronix type 564, with 3A3 and 3B3 plug-in units).

Cell

The simple cell used, Fig. 2, was designed to provide

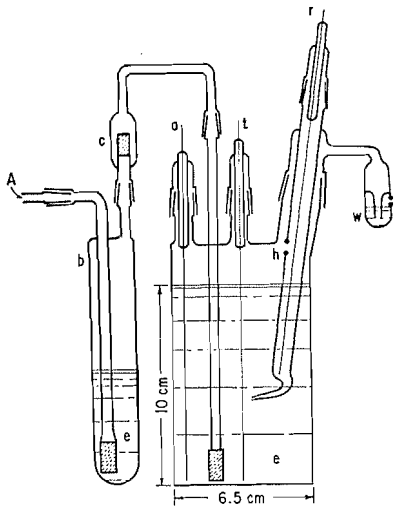

FIG. 2. Cylindrical cell.

essentially undistorted cylindrical symmetry. The central wire test electrode (t), of diameter 1.00 mm, was separated by a distance of 3 cm from the similar auxiliary electrode (a). Because of this large separation, the auxiliary electrode (which ideally should have been a coaxial cylinder) was expected to induce insignificant non-uniformity in the current density over the test electrode.

The reference-electrode (r) compartment terminated in a short capillary of tip diameter d (0.6–1 mm), the tip being placed a distance $2d$ from the test electrode to avoid shielding errors (13). The internal IR drop in the electrolyte between the capillary tip and a cylindrical test electrode of radius r_0 and length L is given by (14)

$$[1] \qquad V_{IR} = i\rho r_0 \ln \frac{r_0 + 2d - d/3}{r_0}$$

where i is the current density and ρ the electrolyte resistivity. The corresponding electrolyte resistance is therefore

$$[2] \qquad R_e = \frac{\rho}{2\pi L} \ln \frac{r_0 + 2d - d/3}{r_0}$$

Electrodes were positioned in the cell with standard-taper joints sealed with Teflon sleeves. An argon atmosphere was maintained by passing cylinder argon (99.995%) through metal and Teflon tubing into bubbler (b) containing some of the test electrolyte (e), then through a fritted-glass droplet trap (c) into the cell, and out of the cell through water trap (w); air initially trapped above the reference electrode diffused out through hole (h). Argon flow was turned off during electrochemical measurements.

The electrodes were made from 1 mm diameter platinum wires sealed into Pyrex tubes by a transition seal to Corning No. 3321 glass on the wire. The platinum test electrode (3.14 cm^2 geometrical working area) was polished to a bright finish, ending with abrasive of diameter 0.3 μm. The gold test electrode was made from a similar platinum electrode which was plated with gold to a thickness of 15 μm from the cyanide bath; $KAu(CN)_2$, 0.08 M; KCN, 0.03 M; K_2CO_3, 0.1 M; 60 °C; 3 mA cm^{-2}. The surface was repolished after plating. The platinum reference and auxiliary electrodes were polished and then platinized (15). Just before use all electrodes were cleaned in CrO_3–H_2SO_4 cleaning solution and in 11 M HCl, with prolonged rinsing in distilled water after each step. The test electrodes were given an additional cleaning step, being made cathode for 30 s in 1 M H_2SO_4 at 0.02 A cm^{-2}, using a new portion of the acid each time in order to minimize possible metal transfer from the platinum anode. This acid was purified by treatment with activated charcoal (see below).

Electrolytes

The ferrous–ferric reaction was studied at 25 °C in the following aqueous solutions:

I. 0.100 m $FeCl_2$, 0.100 m $FeCl_3$, 1.00 m NaCl, 0.10 m HCl; pH = 0.87; ρ = 7.8 Ω cm; ε_r = 0.464 V.

II. 0.020 m $FeCl_2$, 0.020 m $FeCl_3$, 1.00 m NaCl, 0.10 m HCl; pH = 0.92; ρ = 8.6 Ω cm; ε_r = 0.465 V.

III. 0.101 m $FeSO_4$, 0.050_5 m $Fe_2(SO_4)_3$, 0.91 m $NaHSO_4$; pH = 0.56; ρ = 6.6 Ω cm; ε_r = 0.423 V.

Here m is molality and ε_r is the reversible potential of the gold electrode at 25 °C with respect to saturated calomel (including any liquid junction potential). In each solution, bright gold, bright platinum, and platinized platinum electrodes exhibited the same potential within $\pm 10^{-5}$ V.

The solutions were prepared from reagent grade salt, redistilled hydrochloric acid, and water redistilled from alkaline permanganate. The chloride solutions were filtered by suction through a "Fine" porosity Pyrex fritted disk; without further treatment these yielded reproducible potentiostatic current–time curves for a period of several hours after immersion of the gold electrode.

The sulfate solution, unpurified, caused a pronounced deactivation of the gold surface with time (described later). This solution was purified by percolating it slowly through a bed of acid-washed activated charcoal, as recommended by James (16). A column of charcoal, volume 25 cm^3 and height 10 cm, supported by a 2 cm "Medium" Pyrex fritted disk, was set up using Pittsburgh Activated Carbon Co. type CPG acid-washed charcoal (14 × 40 mesh, B.E.T. surface area > 1000 m^2g^{-1}). The column was first acid-extracted with hot 6 N HCl (10 batches), then hot doubly-distilled water (10 batches) and hot 6 N H_2SO_4 (5 batches), each batch consisting of 50 cm^3 of liquid at 80–90 °C when poured into the column. Each liquid was drawn through the column initially at a rate of 1 cm/min, slowing gradually to 0.4 cm/min by the final batch. Next a 50 cm^3 batch of 1 N H_2SO_4, followed by a 50 cm^3 batch of the test solution, were drawn through the column and discarded. Finally 1 l of the test solution was passed through the column at 0.2 cm/min; it was collected in two 0.5 l portions, the second portion being used for kinetic studies. Some oxidation occurred during this treatment; to obtain a Fe^{2+}:Fe^{3+} concentration ratio of unity in the purified solution it was necessary to start with a ratio of 1.10.

Results and Discussion

Accuracy of Potential Control

An initial study of the problems involved in

obtaining a constant electrode potential was carried out with the gold electrode in solution I.

(a) Potential Stability

In the study of moderately fast reactions where mass-transfer polarization builds up rapidly, the preselected potential must be achieved very quickly. The mass-transfer effect causes the reaction rate to decrease, and the rate of decrease is greatest at time $t \rightarrow 0$ (6, 7, 17). Thus a relatively fast-rise potential step may be required. With the present cell-circuit combination at a setting of 95% ohmic compensation, potential steps of 4–20 mV were established to ± 0.1 mV in about 1 ms after switching in the cell. The rise time was measured by displaying the upper section of the potential rise on an oscilloscope at 1 mV/cm sensitivity; a mercury-wetted-contact relay (type HG-3A-1008, C.P. Clare Co.) was used in the switching. The rise time was found to decrease as the percentage of ohmic compensation was reduced, becoming 0.1 ms at zero compensation[1]. For reactions having large exchange currents, such slow response can prevent accurate determination of the charge-transfer current from a given $i-t$ curve, as illustrated later. With respect to long-term potential stability, the potentiostat setting drifted < 0.1 mV/h.

(b) Reference-electrode Current

In circuits of very high impedance reference-electrode current can be neglected, but in the present circuit it was not normally negligible and led to two possible sources of error: reference-potential drift, and an ohmic drop within the reference electrode (internal resistance < 1 kΩ). By means of the bias current supply, however, reference-electrode current was reduced to 10^{-7} A or less, and each of these errors remained less than 0.1 mV. Reference-potential drift was monitored by replacing the reference compartment with one containing two identical platinized platinum electrodes, one working and the other detached; potential drift ≪ 0.1 mV/h was observed.

(c) Uncompensated Resistance

If no correction is provided for the uncompensated resistance R_u which comprises electrolyte resistance (calculated from eq. [2]) plus the measured associated lead and contact resistances (0.02–0.03 Ω), then a change ΔV applied by the voltage controller will change the potential of the test electrode by $\Delta V \pm R_u I(t)$, where $I(t)$ is the time-dependent current produced. Here the positive sign applies to cathodic reactions (ΔV negative) and the negative sign to anodic (ΔV positive). Thus the test electrode experiences a potential change smaller than the desired potential step, giving rise to a negative error in the current. If we set the IR compensator to compensate a fraction ϕ of R_u, the electrode potential at time t is given by

$$[3] \qquad \varepsilon(t) - \varepsilon_r = \Delta V \pm (1 - \phi) R_u I(t)$$

Only for full IR compensation ($\phi = 1$) will a current- and time-independent potential be strictly attained. But when the compensator is set at $\phi \simeq 1$, oscillations may be induced (8, 9, 12) causing large fluctuations in cell current and in control voltage. In the present system, over the range $\phi = 0$ to 0.98, the control voltage exhibited no change in d.c. level (> 0.1 mV) and no a.c. components (> 0.1 mV peak to peak). Current oscillations were obtained, however, at ϕ just greater than unity.

Figure 3 presents typical $i-t$ curves for gold in chloride solution I. It illustrates that uncompensated-resistance effects can be very large. The plotted points represent the mean curve from seven oscilloscope traces; the maximum deviation from the mean currents was 3% and the curve was independent of time for a period of several

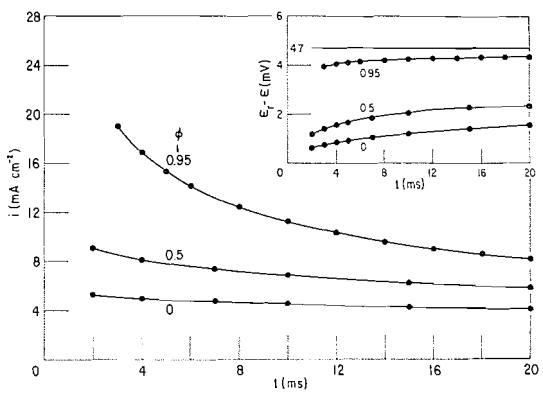

FIG. 3. Ferric ion reduction on gold in solution I, $\Delta V = -4.7$ mV.

[1]The operational characteristics of the present potentiostat have not been determined in sufficient detail for fundamental comparison with circuits recently described. Reference may be made particularly to improved circuits based on operational amplifiers, which are designed for fast response and high stability at 100% ohmic compensation (11, 12).

hours after the test electrode was placed in the cell. Uncertainty in the measurement of the distance of the capillary tip from the gold electrode led to a probable error of 3% in the degree of ohmic compensation. The current–time curves in Fig. 3 demonstrate that large inaccuracies can result from uncompensated resistance, both in the reaction rates (currents) and in the shape of the current–time curve. The uncompensated-resistance effect is illustrated also by the time variation of the electrode potential, shown inset in Fig. 3. These curves were obtained from the measured currents by use of eq. [3], with $R_u = 0.21_3$ Ω. When no ohmic compensation is applied, the electrode potential remains far from the desired value throughout the 0.02 s reaction time; hence the remarkably low currents. Even with 95% compensation, the potential still remains somewhat lower than the desired value.

Effect of Impurities in Sulfate Solutions

In the sulfate solution before activated-charcoal purification, a relatively rapid deactivation of the gold electrode occurred, as shown in Fig. 4. This pronounced deactivation was reduced by the activated-charcoal treatment to less than a $3\%\,h^{-1}$ current decrease; after prolonged use of the gold electrode, the latter could be cleaned again and replaced in the solution to regenerate the original current–time curve. The current levels of the initial (3 min) curve obtained in the unpurified solution were only 5% below the corresponding levels for the purified solution. Platinum test electrodes also exhibited this impurity effect in the sulfate solution.

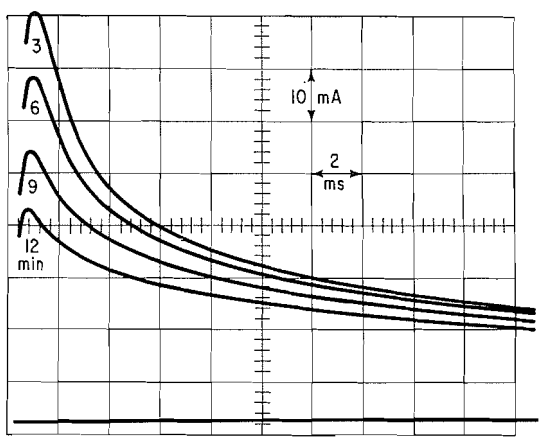

FIG. 4. Ferric ion reduction on gold in unpurified solution III, $\Delta V = -4.8$ mV. Time after electrode inserted into cell is shown.

Evaluation of Exchange Current Densities

The method of analysis used to obtain the charge-transfer current from a given $i - t$ curve is based upon the theoretical relation for planar electrodes

$$[4] \qquad i/i_{t=0} = \exp(\lambda^2 t)\,\mathrm{erfc}\,(\lambda\sqrt{t})$$

Here[2] i is the current density at time t and $i_{t=0}$ its initial value (the desired charge-transfer current density); λ is a constant directly proportional to the exchange current density i_0 and inversely proportional to the concentration (6). The planar-electrode relation is applicable to cylindrical electrodes if λ is sufficiently large (7); this condition is satisfied here as shown later. Because eq. [4] is valid, the "ratio method" of analysis previously described (7, 18) was utilized to evaluate the charge-transfer current. In this method the measured ratio of the current at time t to that at $4t$ gives the value of $\lambda\sqrt{t}$ corresponding to the selected time through the relation (18)

$$[5] \qquad \lambda\sqrt{t} = \frac{a_0(\mathscr{R} - 1) + a_1(\mathscr{R} - 1)^2}{1 + a_2(\mathscr{R} - 1)}$$

$$\mathscr{R} = i(t)/i(4t)$$

$$a_0 = 0.8827$$

$$a_1 = -0.4539$$

$$a_2 = -0.9071$$

Knowing λ, eq. [4] yields $i_{t=0}$, from which i_0 is obtained by the well-known relation for small overpotential (η)

$$[6] \qquad (i_{t=0}/i_0)_{\eta\to 0} = nF|\eta|/RT$$

where F is the Faraday, R the gas constant, T the temperature, and n is unity, the number of electrons involved in the ferrous–ferric reaction.

Considering first the ferrous–ferric reaction on bright gold, we applied this method of analysis to the 95% compensated current–time curve in Fig. 3, and to other such curves determined in solutions I – III over reaction times from 3 to 50 ms. In all cases the experimental ratio $i(t)/i(4t)$ consistently exceeded 1.80 at $t \Rightarrow 3$ ms and increased

[2] $\mathrm{erfc}\,(x) = 1 - \mathrm{erf}\,(x) = 1 - (2/\sqrt{\pi})\int_0^x e^{-z^2}\,dz$

*Anodic reaction at 4.8_5 mV gave same current–time curve.

smoothly with increasing t towards 2 (the theoretical maximum). Taking the ratio 1.80 as being a minimum value for $t = 3$ ms, whence $\lambda\sqrt{t} > 1.51$ and $\lambda > 27$ s$^{-1/2}$, we may compute lower limits to the values of $i_{t=0}$ and i_0. These are listed in Table I. It is true that $i_{t=0}$ cannot be derived with precision from a current ratio corresponding to such a large value of $\lambda\sqrt{t}$ (preferably $\lambda\sqrt{t} <$ unity (6, 19)), because at such long times the reaction rate is controlled mostly by diffusion and only in small part by the charge-transfer process; nevertheless it is felt from the consistency of the current–time curves examined that the exchange current densities listed in Table I all underestimate the true values. Note that incomplete ohmic compensation tends to make $i_{t=0}$ low, since the actual electrode potential deviates more from the nominal value at time t than at $4t$. Our use of eq. [4] is justified only if $\lambda \gg D^{\frac{1}{2}}/r_0$, where D is the average diffusivity of the ferrous and ferric ions (7); D may be given the rough value 10^{-5} cm^2 s^{-1} to obtain $D^{\frac{1}{2}}/r_0 \simeq 0.063$ s$^{-1/2}$, indeed much smaller than λ.

The quantity in the last column of Table I is an estimate of the standard exchange current density $i_{0,s}$. For the first-order (defined at constant potential) ferrous–ferric reaction, we may write (20)

$$[7] \quad i_0/i_{0,s} = [a_{Fe^{3+}}/(a_{Fe^{3+}})_s]^{1-\beta}[a_{Fe^{2+}}/(a_{Fe^{2+}})_s]^{\beta}$$

where a is activity and β the transfer coefficient. Subscript s refers to the electrode in the defined standard state where $(a_{Fe^{3+}})_s = (a_{Fe^{2+}})_s = 1$ mole/1000 cm^3. Equation [7] shows that $i_{0,s}$ is indeed a real current density, measurable in principle and with units of A cm^{-2}, although the same quantity is also a standard rate constant when expressed as $(i_{0,s}/nF)$ in the units cm s^{-1} (with concentration in mole cm^{-3}). When the two ions have the same concentration c, eq. [7] yields $i_0/c = i_{0,s}f$, where f is the mean activity coefficient .Assuming $f < 1$, we obtain the high value of $i_{0,s} > 3$ A cm^{-2} for the ferrous–ferric reaction on gold in the chloride and sulfate solutions.

A more favorable case for quantitative analysis of the potentiostatic $i - t$ curve was obtained with the ferrous–ferric reaction on bright platinum in solution III; $i_{0,s}$ is an order of magnitude smaller for platinum than it is for gold in this solution. Because of the smaller currents involved, ε_{Pt} remained closer to the nominal value as compared with ε_{Au} in Fig. 3 (95% compensation). Also, accurate analysis of the $i - t$ curve by the ratio method was possible because the observed values of $\mathscr{R}$ were sufficiently small (i.e., below 1.6). Typical analytical data are presented in Table II for cathodic Fe^{3+} reduction on platinum at −4.8 mV. The fact that constant values of λ and $i_{t=0}$ are established at $t \geqslant 5$ ms confirms that the $i - t$ curve obeys eq. [4] and that the ratio method of analysis is valid. It was assumed that distortion by the slow electronic transient persisted to 4 ms, hence the first two values in the table were omitted in determining the mean.

The standard exchange current density found here is about 1.5 times the value ($i_{0,s}f = 0.26$ A cm^{-2}) calculated from Anson's galvanostatic data (21) for the ferrous–ferric reaction on bright platinum in similar $NaHSO_4$ solutions. Since differences in surface activity and roughness can result from the particular electrode precleaning procedures used, the agreement may be considered satisfactory.

The result that the classically simple (22) ferrous–ferric reaction is at least an order of magnitude slower on platinum than on gold, two "inert" metals, is surprising. Such dependence on the metal can arise, however, in several different ways; one way is through specific anion adsorption on the platinum. We conclude that new diagnostic experiments on the ferrous–ferric electrode reaction are needed.

In summary, the Fe^{2+},Fe^{3+}(Au) system has been shown to have a high standard exchange current density ($i_{0,s} > 3$ A cm^{-2}), and therefore is an ideal one for illustrating quantitatively the effect of uncompensated (or partly compensated) resistance on potentiostatic kinetics. The effect is to prevent the attainment of a constant potential step, and to yield reaction rates which are too small and which have distorted time dependence. In the case of the Fe^{2+},Fe^{3+}(Pt) system, where $i_{0,s}$ is much smaller, the rather slow potentiostat used in this work was adequate for obtaining precise current–time curves. These curves were analyzed by the ratio method which was shown to yield the charge-transfer current with good precision.

Isomer ratios for the $^{44}Ca(p,n)^{44}Sc^{m,g}$ and $^{85}Rb(p,n)^{85}Sr^{m,g}$ reactions[1]

D. R. SACHDEV AND L. YAFFE

Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Quebec

Received December 19, 1968

Isomeric cross-section ratios for the $^{44}Ca(p,n)^{44}Sc^{m,g}$ and $^{85}Rb(p,n)^{85}Sr^{m,g}$ reactions have been measured over a proton energy range of 6–85 and 6–27 MeV, respectively. Experimental results are compared with calculations based on the Vandenbosch–Huizenga formalism (1, 2), while spin-cutoff parameter values were obtained from various models. For the isomeric pair of $^{44}Sc^{m,g}$, the parameters required to obtain a good fit with the experimental results are in agreement with those of Keedy *et al.* (6). On the other hand, the experimental results for the $^{85}Sr^{m,g}$ isomeric pair are unusually high compared with the calculated isomer ratios. Half-lives of $^{44}Sc^{g}$ and $^{85}Sr^{m}$ were redetermined to be 4.05 ± 0.03 h and 68.0 ± 0.2 min, respectively.

Canadian Journal of Chemistry, 47, 1667 (1969)

The formalism suggested by Vandenbosch and Huizenga (1, 2) for indirectly testing the spin dependence of nuclear level densities by determining isomer ratios has become a very useful method. The formalism is valid only in the low-energy region where the formation of a compound nucleus can, with some justification, be assumed. In order that the calculated and the experimental isomer ratios agree, effective moments of inertia much less than rigid body values, have invariably been required. This, along with some other factors, (like odd–even effects, etc.) strongly suggests that other interactions, particularly the pairing interaction, should be introduced into the calculation. More recent calculations (3–7) have introduced such refinements into the calculation.

In a recent communication (5), the isomer ratios obtained at various proton bombarding energies for the $^{88}Sr(p,2n)^{87}Y^{m,g}$ reaction were reported. The parameters required to fit the calculated values to those observed experimentally were compared with parameters obtained for the isomer ratios from the $^{85}Rb(\alpha,2n)^{87}Y^{m,g}$ and $^{87}Sr(d,2n)^{87}Y^{m,g}$ reactions (4). In all the foregoing cases the reaction proceeded via the same compound nucleus. With the same approach in mind, the isomer ratios for the $^{44}Ca(p,n)^{44}Sc^{m,g}$ reaction were measured and compared with the parameters obtained from isomer ratios found (6, 8–10) for the reaction $^{41}K(\alpha,n)^{44}Sc^{m,g}$. Our measurements have been carried out in the proton bombardment energy region of 6–85 MeV. Since in this energy region it is generally believed that the compound nucleus mechanism slowly changes to the direct interaction mechanism, it should be of interest to see how the isomer ratios are affected.

Isomer ratios have also been measured for the $^{85}Rb(p,n)^{85}Sr^{m,g}$ reaction in the proton bombardment energy region of 6–27 MeV. The results obtained are also compared with theoretical predictions.

Experimental

(a) Target and Irradiations

The target materials were calcium carbonate, enriched to 94.0% in ^{44}Ca and rubidium chloride, enriched to 99.54% in ^{85}Rb[2].

About 1–3 mg of the sample were loaded into a thin aluminium tube which was pinched shut at both ends, rolled flat, and irradiated in the internal circulating beam of the McGill Synchrocyclotron. Corrections for the energy degradation of the beam (though within the energy spread of ± 2 MeV) were made from Sternheimer's (11) range–energy relation. Duration of the bombardments was of the order of 10–15 min.

(b) Chemical Separation

The irradiated aluminium tubes were dissolved in a small amount of dilute hydrochloric acid and a drop of hydrogen peroxide. The procedure for the chemical separation of strontium has been described previously (12). Scandium was purified by tributyl phosphate extraction, essentially similar to the method used by Matsuo and Sugihara (9).

(c) Activity Measurements

$^{44}Sc^{m}$ decays essentially (98.6%) (13) by an isomeric transition to the ground state. The activities of both of these species were determined by following the decay of the 1.156 MeV γ-ray associated with $^{44}Sc^{g}$, by means of a 3 in. × 3 in. NaI (Tl) Harshaw Integral Assembly (resolution 7.5% for the 0.662 MeV γ-ray) coupled to a

For personal use only.

400-channel pulse-height analyzer. At bombardment energies up to 12 MeV, since $^{44}Sc^{g}$ decays predominantly by positron emission, the associated annihilation radiation was also measured by two 1.5 in. × 1.5 in. NaI (Tl) Harshaw Integral Assemblies, gated to accept 0.511 MeV pulses in coincidence (12). At higher bombardment energies the latter technique was not used, since the production of ^{43}Sc (with very similar half-life) by the (p,2n) reaction made the results difficult to interpret.

Isomeric species of ^{85}Sr was also measured by two methods. The first consisted in measuring the γ-rays associated with each of the species. The metastable state was measured by following the decay of the 0.225 MeV γ-ray. To the normal abundance of 85%, one must add 1.3% (4) arising from the decay of the 0.2325 MeV γ-ray, also associated with the isomeric transition. The ground state was measured by its 0.514 MeV γ-ray. A branching ratio of 100% and a conversion coefficient of 0.007 were used (14). Experimental detection efficiencies for the counting assembly were determined by using standard sources.

The other procedure avoided the use of efficiency curves. $^{85}Sr^{m}$ decays by electron capture (13.7%) to an excited state of ^{85}Rb, while $^{85}Sr^{g}$ decays by electron capture (100%) to another excited state of the same residual nucleus. The K X-rays associated with ^{85}Rb were measured with a thin (2 mm) NaI (Tl) Harshaw Integral Assembly coupled to a multi-channel analyzer. Internal conversion coefficients (14) of $\alpha_k = 0.04$ for 0.150 MeV, $\alpha_k = 0.02$ for 0.225 MeV, and $\alpha_k = 0.007$ for the 0.514 MeV γ-rays were used, and an apparent branching ratio of 15.7%, instead of 13.7%, for the metastable state was obtained in this way. (The disadvantage of this method is that a small error in the branching ratio of internal conversion coefficients will greatly influence the measurement.)

The decay curves were all analyzed by the CLSQ decay curve analysis program (15) and this, as well as all the other calculations, was done on the McGill IBM 7044 Computer.

Results

(a) Half-lives

The half-life of $^{44}Sc^{m}$ was determined by following the decay of the 0.270 MeV γ-ray over a period of more than 6 half-lives. It was found to be 2.44 days, identical with the accepted value (14). The half-life of $^{44}Sc^{g}$, followed over a similar period of time, was found to be 4.05 ± 0.03 h, agreeing very well with that found by Tatarczuk and Medicus (16), 4.00 ± 0.02 h. The half-life was determined both by positron as well as γ-ray (1.156 MeV) measurement. The activity was produced by the $^{44}Ca(p,n)^{44}Sc$ reaction at proton bombardment energies of 6–9 MeV.

Similarly the half-life of $^{85}Sr^{m}$ was determined by following the decay of the 0.225 MeV γ-ray over a period of more than 6 half-lives. The activity was produced by the $^{85}Rb(p,n)^{85}Sr$ reaction from a sample of rubidium virtually monoisotopic in ^{85}Rb. The half-life of the ground state is very long (65 days), compared with the metastable state, and any expected interference from the Compton background from the 0.514 MeV γ-ray will be negligible. The same will apply to possible interference from the 0.388 MeV γ-ray from ^{87}Sr (half-life 2.83 h), since the abundance of ^{87}Rb in the enriched target was only 0.46%.

The half-life for $^{85}Sr^{m}$ was found to be 68.0 ± 0.2 min, to be compared with 70 ± 2 min as previously reported (14).

No attempt was made to re-determine the half-life of $^{85}Sr^{g}$. The data were in good agreement with the accepted value of 65.0 days.

(b) Isomer Ratios

The ratio of the formation cross sections of the high-spin species to that of the low-spin species is defined as the isomer ratio throughout this paper, i.e. $\sigma_{^{85}Sr^{g}}/\sigma_{^{85}Sr^{m}}$ and $\sigma_{^{44}Sc^{m}}/\sigma_{^{44}Sc^{g}}$. The experimental results of these ratios are given in Table I. The values obtained for ^{44}Sc by γ-ray and positron measurements are identical within experimental error. The values of the isomer ratios for ^{85}Sr obtained by γ-ray and X-ray measurements are shown separately. The former involves detection efficiencies which are prone to error, while the latter process, as indicated earlier, involves decay scheme data which may lend systematic errors to the results. Unless errors introduced into both methods lie in the same direction, and are of the same general magnitude, it would seem that they are within the errors quoted, which as shown, include only uncertainties in decay curve analysis, photopeak area measurements, and detection efficiencies. The isomer ratios are shown graphically in Figs. 1 and 2.

Calculations and Discussion

(a) Qualitative Considerations

The isomer ratio of ^{44}Sc (Fig. 1) increases rapidly with increasing energy to a proton bombardment energy of about 20 MeV, at which point it begins to decrease until a flat portion is reached at about 40 MeV. At still higher energies the data show a very slight increase with energy, although they are also, within experimental error, consistent with no variation with energy.

The isomer ratio of ^{85}Sr shows a similar behavior, although in this case the peak is reached at

about 17 MeV. The difference in the peak positions of the two curves can be attributed to the threshold of the next reaction, (p,2n), i.e., 14.5 and 10.5 MeV respectively for the $^{44}Ca(p,2n)^{43}Sc$ and $^{85}Rb(p,2n)^{84}Sr$ reactions, as calculated from the tables of Mattauch *et al.* (17).

It is also evident that the isomer ratios continue to increase with bombarding energy, beyond the peaks of the excitation function curves which would be close to the thresholds for the (p,2n) species. This rise beyond the peaks of the excitation function curves lends weight to the hypothesis (5) that competition between neutron and γ-ray emission favors the high-spin species in the present case.

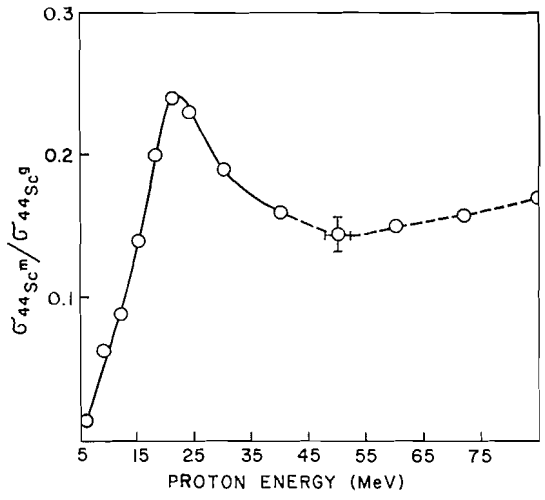

FIG. 1. Experimental isomer ratio ($\sigma_{44Sc^m}/\sigma_{44Sc^g}$) produced in the reaction $^{44}Ca(p,n)^{44}Sc^{m,g}$.

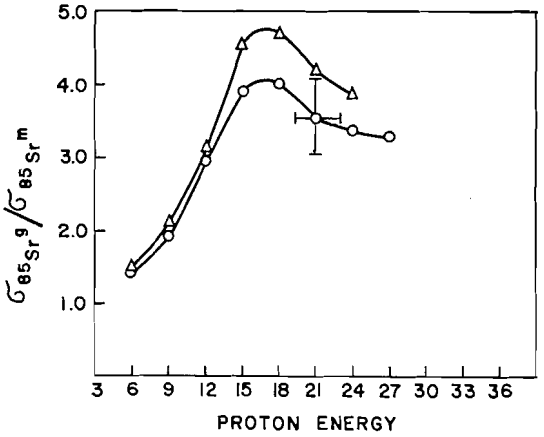

FIG. 2. Experimental isomer ratio ($\sigma_{85Sr^g}/\sigma_{85Sr^m}$) produced in the reaction $^{85}Rb(p,n)^{85}Sr^{m,g}$; ○, γ-ray measurements; Δ, X-ray measurements.

The isomer ratios for ^{85}Sr are much larger than those for ^{44}Sc. The following reasons can be advanced to explain this. The spin in the ground state of ^{85}Rb is 5/2. The spins of the metastable and ground states of ^{85}Sr are 1/2 and 9/2 respectively, with an intermediate state of 7/2. At the end of the de-excitation stage, the last γ-ray from states with spins of 5/2 or greater will populate the ground state (high-spin species), while those states with spins of 3/2 or less will contribute to

For personal use only.

the low-spin state. On the other hand the spin of ^{44}Ca in the ground state is zero, while the spins of the metastable and ground states of ^{44}Sc are 6 and 2 respectively. The last γ-ray from states with spins of 5 or more will cause the metastable state to be populated, while those arising from states with spins of 3 or less will populate the ground state. States with intermediate spin of 4 will populate both states equally.

In Fig. 3 the experimental isomer ratio is plotted as a function of excitation energy of the compound nucleus ^{45}Sc, for the reaction ^{44}K(α,n)^{44}Sc^{m,g} from the data of Matsuo *et al.* (10), Riley *et al.* (8), and Keedy *et al.* (6). The data were compared with those obtained in the present work and show the effect (on isomer ratios) of greater amount of angular momentum associated with incoming α-particles as compared with protons. The excitation energy, E_c, was calculated from the equation $E_c = E_{cm} + Q$, where E_{cm} is the projectile energy in the center-of-mass system and Q is the energy liberated in the reaction to form the compound nucleus, as calculated from the mass tables of Mattauch *et al.* (17).

(b) Calculations

These were performed with the original program of Hafner *et al.* (18). Keedy *et al.* (6) have shown that proton emission would not significantly affect isomer ratios, but implied that in the system studied by them, ^{41}K(α,n)^{44}Sc^{m,g}, α-particle emission might play a role. As before, we have not included competition due to protons or α-particles in our calculation. Details of the calculations have been described previously (5) and only a brief recapitulation is given here.

Three models were used for obtaining the excitation energy, U, and energy-dependent spin-cutoff parameter, σ, needed for the basic equation giving the spin-dependent level density, $\rho(U,J)$

$$\rho(U,J) = \rho(U,0)(2J + 1) \exp\left\{-\frac{J(J+1)}{2\sigma^2}\right\}$$

(*i*) Shifted Fermi Gas Model. With this model the excitation energy is measured from the mass surface of an odd–odd nuclide (19). Since ^{44}Sc is itself an odd–odd nuclide, no pairing correction is required. For ^{85}Sr the pairing energy Δ = 1.4 MeV (20) was subtracted from E to get the value of U. The variation of σ with energy was obtained from the relations

$$U = at^2 - t$$

and

$$\sigma^2 = \frac{It}{\hbar^2}$$

where t is the thermodynamic temperature, a is the usual level-density parameter, and I is the rigid body moment of inertia.

(*ii*) Independent Pairing Model. According to this model (21, 22) the excitation energy is measured from a fictitious mass surface, lying below even that of an even–even nuclide. The correction for the odd–even ^{85}Sr was made by adding Δ = 1.4 MeV, and that for ^{44}Sc by adding 2Δ = 4.0 MeV (20) to the normal excitation energy. All the other equations, including those linking the excitation energy with the spin-cutoff parameter have been given previously (5).

(*iii*) Superconductor Model. An attempt is made by use of this model to compare the nucleus to the superconducting state of a metal. Following Lang (22), Vonach *et al.* (3) used this model to interpret isomer ratios. According to this model, there is a critical energy above which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the superconductor behaves like a normal Fermi gas, except that its ground state is shifted by an amount equal to the condensation energy. Above this critical energy the moment of inertia values correspond to rigid body values, while below this energy the moment of inertia decreases strongly (3) with decrease in excitation energy.

In the present calculations with all these models the value of σ, as previously (5), was not allowed to decrease below certain limiting values. Also neutron emission was restricted to neutrons with kinetic energy of $2T$, where T is the nuclear temperature. Optical model transmission coefficients were used, with parameters due to Perey (23) for protons and those of Campbell *et al.* (24) for neutrons. Only dipole transitions were assumed for the γ-ray cascade. Calculations for the average γ-ray energy were made with the empirical formula given by Vonach *et al.* (3) and described previously (5). The prescription of Vonach *et al.* was also used to determine the isomer-deciding transition. When the excitation energy of the residual nucleus was greater than 2 MeV, the next γ-ray was not an "isomer-deciding" transition. When the excitation energy of the residual nucleus was between 1 and 2 MeV, the probability for the emission of an isomer-deciding transition was taken to be $(2 - E)$, and for not being the case as $(E - 1)$. For excitation energies less than 1 MeV the last γ-ray was assumed to be emitted.

(c) *Comparison of Experimental Results with Calculations*

Figures 4, 5, and 6 show the experimental results for $^{44}Sc^{m,g}$ compared with the calculations based on the three models described. Figure 4 shows the results obtained by using spin-cutoff parameters obtained from the shifted Fermi Gas model calculations. A level-density parameter value of $a = 8$ or $A/5.5$ agrees with the results. It should be noted that, in the data of Keedy *et al.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(Curve A, Fig. 1 of ref. (6)), when the value of a is taken as 5 and the neutron emission energy is limited to $2T$, the ratio of the calculated to experimental isomer ratios is the same as in the present work. This argues in favor of the same parameters applying to the two different systems proceeding via the same compound nucleus.

The Independent Pairing Model calculations shown in Fig. 5 suggest that $a = 6$ or $A/7.5$ agrees best with the experimental results, while the Superconductor Model (Fig. 6) gives values of $a = 6.5$ or $A/7$. For the latter case, Keedy *et al.* (6) found a level-density parameter value of $a = 5$, but their calculations took into account the effect due to competition of protons as well as α-particles, and the slightly higher value obtained by us is probably due to the neglect of these factors. The agreement obtained between the two systems proceeding via the same compound nucleus is gratifying.

In Figs. 7 and 8 the experimental isomer ratios for ^{85}Sr are compared with the calculations from the Shifted Fermi Gas and Superconductor Models, respectively. The calculated results are extremely low compared with the experimental values, and could not be matched, even for extremely low values of the level-density parameters. This is very difficult to explain and does not agree with the results obtained by other workers and us in this mass region. For example, calculations for $^{87}Y^{m,g}$ (5) required the extremely high value of $a = 21$ to match the experimental results for the Shifted Fermi Gas calculations. If one uses a value of $a = 21$ for $^{85}Sr^{m,g}$, the experimental results are a factor of at least 3 higher than the calculated values.

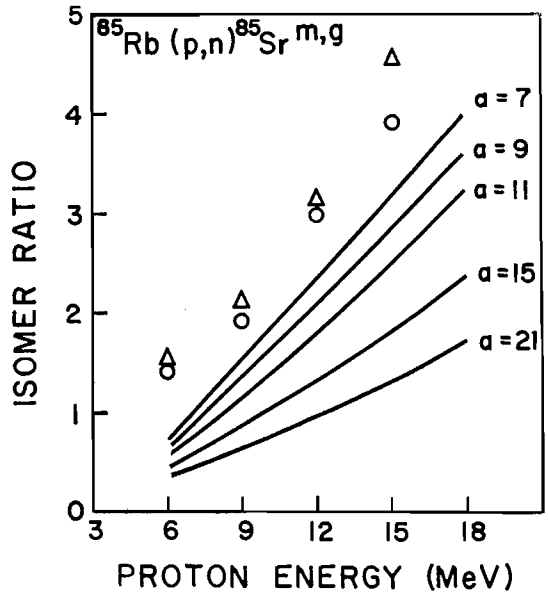

FIG. 7. Comparison of experimental isomer ratios ($\sigma_{^{85}Sr^g}/\sigma_{^{85}Sr^m}$) with calculations based on the Shifted Fermi Gas Model and various values of the level-density parameter; ○, experimental; —, calculated.

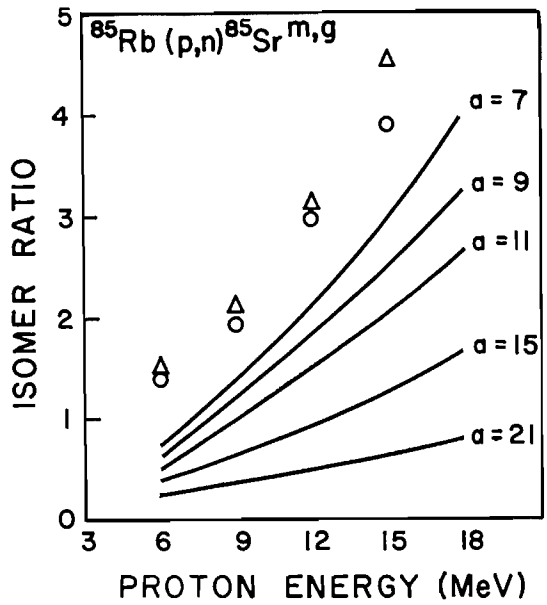

FIG. 8. Comparison of experimental isomer ratios ($\sigma_{^{85}Sr^g}/\sigma_{^{85}Sr^m}$) with calculations based on the Superconductor Model and various values of the level-density parameter; ○, experimental; —, calculated.

In the case of odd–odd nuclides where great discrepancies have also been found, Keedy *et al.* (6) suggested that the spin-cutoff parameter is sensitive to the type of single particle orbitals which are close to the Fermi surface, and as a result one should expect the spin-cutoff parameters to fluctuate from nucleus to nucleus. A more probable explanation in this case may well be the perturbation caused by the existence of an unknown state or states of intermediate spin, perhaps lying close to, but above the metastable state and decaying to the ground state by a crossover transition.

Acknowledgments

We would like to express our appreciation to Dr. R. E. Bell, Director of the Foster Radiation

Laboratory for ready permission to use the McGill Synchrocyclotron and to Mr. R. H. Mills who, as always, cheerfully performed the irradiations.

Liquid hydrogen chloride solvent system. XII. Reactions of some sulfur, selenium, and tellurium compounds[1]

M. E. PEACH
Department of Chemistry, Acadia University, Wolfville, Nova Scotia

Received October 10, 1968

The ions Me_2SCl^+ and $MeSCl_2^+$ have been prepared in hydrogen chloride solution from the oxidation of dimethyl sulfide and methanesulfenyl chloride with chlorine, or from methyl sulfur trichloride ($MeSCl_2^+$), and characterized as their tetrachloroborates and hexafluorophosphates. $Et_2SCl^+BCl_4^-$ and $EtSCl_2^+BCl_4^-$ have been prepared analogously. Dimethyl selenium and dimethyl tellurium solutions were oxidized with chlorine to dimethyl selenium dichloride and dimethyl tellurium dichloride.

Methanesulfenyl chloride solution was ionized due to the protonation of sulfur, and not to the loss of a chloride ion. Methylchlorosulfonium hexafluorophosphate has been characterized. Methane- and ethane-sulfenyl chloride solutions reacted with boron trichloride giving $(RSCl)_2BCl_3$.

Sulfur tetrachloride, selenium tetrachloride, and tellurium tetrachloride were sparingly soluble and showed no acidic or basic properties in the solvent. Sulfur monochloride, sulfur dichloride, selenium monochloride, and tellurium dichloride were non-basic in solution.

The new compounds, $Me_2S_2.BCl_3$ and $Me_2Te.BCl_3$, have been prepared and characterized.

Canadian Journal of Chemistry, 47, 1675 (1969)

Introduction

The reactions of some sulfur compounds in solvent liquid hydrogen chloride have been described previously. Thiols and sulfides act as solvobases of varying strengths, and when treated with the solvoacid boron trichloride, form boron trichloride adducts in solution (1)

$$Me_2S + 2HCl \rightarrow Me_2SH^+ + HCl_2^-$$

$$Me_2SH^+ + BCl_3 \rightarrow Me_2S.BCl_3 + H^+$$

The properties of compounds containing a double sulfur oxygen bond, R_2SO, R_2SO_2, RSO_2Cl, SO_2Cl_2, $SOCl_2$, SO_2, H_2SO_4, $MeSO_3H$, CF_3SO_3H, and $ClSO_3H$ have been studied as potential acids and bases (2). This paper extends the previous work on divalent sulfur compounds by considering the oxidation of certain compounds in solution with chlorine and stabilization of the products as tetrachloroborates or hexafluorophosphates. Analogous reactions have been studied with some selenium and tellurium compounds. The properties of the sulfur, selenium, and tellurium chlorides in solution have also been examined.

Results and Discussion

The dialkylsulfonium ion, R_2SH^+, can only be isolated from hydrogen chloride solution as an unstable hexafluorophosphate (3). The S—H bond formed in solution by protonation of dialkyl sulfides and alkanesulfenyl chlorides has been oxidized with chlorine to form the dialkylchlorosulfonium and alkyldichlorosulfonium ions in solution.

$$R_2SH^+ + Cl_2 \rightarrow R_2SCl^+ + HCl$$

The use of the halogens as oxidizing agents in solvent liquid hydrogen chloride has been studied (4). Dialkyl sulfur dichlorides could not be isolated as stable materials from the oxidation of the sulfide solutions, but the reaction of a solution of the dialkylchlorosulfonium ion with boron trichloride or phosphorus pentafluoride resulted in the formation of dimethyl- and diethylchlorosulfonium tetrachloroborates and dimethylchlorosulfonium hexafluorophosphate. Phosphorus pentafluoride acts as a solvoacid and reacts with solvobases, such as tetramethylammonium hydrogendichloride, according to the equation

$$2Me_4N^+HCl^- + 3PF_5 \rightarrow 2Me_4N^+PF_6^- + PF_3Cl_2 + 2HCl$$

Methyl sulfur trichloride was formed in the chlorine oxidation of methanesulfenyl chloride. Methyl and ethyl sulfur trichlorides and trimethylsulfonium iodide acted as solvobases, forming stable tetrachloroborates, $RSCl_2^+BCl_4^-$ and $Me_3S^+BCl_4^-$, with boron trichloride and an unstable methyldichlorosulfonium hexafluorophosphate with phosphorus pentafluoride. Tri-*n*-butylsulfonium tetrachloroborate has been prepared from tri-*n*-butyl sulfur chloride and boron trichloride, and its properties investigated (5).

[1]For Part XI, see ref. 21.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The methods described here represent a good method of preparing the previously unknown ions R_2SCl^+ and $RSCl_2^+$.

Chlorine oxidation of solutions of alkanethiols or dialkyl disulfides caused a fracture of the S—S bond (formed initially in the alkanethiol reaction) and the formation of the alkanesulfenyl chloride in solution. Methane- and ethane-sulfenyl chlorides both act as solvobases, forming good conducting solutions. These compounds may ionize in either of two ways

[1] $$RSCl + 2HCl \rightarrow [R{-}\underset{\displaystyle H}{\underset{|}{S}}{-}Cl]^+ + HCl_2^-$$

[2] $$RSCl + HCl \rightarrow RS^+ + HCl_2^-$$

The scant evidence for the existence of the sulfenium ion, RS^+, in other media (6) and the observation that sulfenyl chlorides are protonated in strong sulfuric acid (7) both suggest that the ionization may be due to protonation, as in reaction [1]. The reactions of methanesulfenyl chloride in solution with phosphorus pentafluoride, which gave methylchlorosulfonium hexafluorophosphate and not methanesulfenyl hexafluorophosphate, and its oxidation with chlorine to methyl sulfur trichloride, are further evidence in favor of ionization caused by protonation.

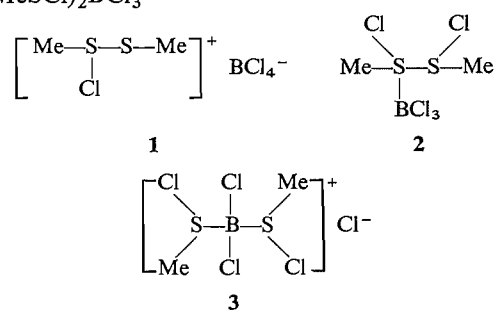
Dimethyl selenium and dimethyl tellurium were found to be strong solvobases which were oxidized with chlorine in solution to dimethyl selenium dichloride and dimethyl tellurium dichloride. Dimethyl selenium dichloride reacted with boron trichloride in solution giving dimethylchloroselonium tetrachloroborate, previously prepared from dimethyl selenium dichloride and boron trichloride at $-25°$ in methylene dichloride (8). A solution of dimethyl tellurium dichloride reacted with boron trichloride to give a dimethyl tellurium dichloride boron trichloride adduct of unknown structure, which lost boron trichloride very readily on pumping at room temperature. Diphenyl selenium dichloride reacted with boron trichloride to form diphenylchloroselonium tetrachloroborate in solution, but this decomposed on warming to room temperature.

The reactions of solutions of diethyl sulfide, dimethyl selenium, and dimethyl tellurium with boron trichloride yielded the corresponding adducts at room temperature,

$$Me_2Se + 2HCl \rightarrow Me_2SeH^+ + HCl_2^-$$

$$Me_2SeH^+ + BCl_3 \rightarrow Me_2SeBCl_3 + H^+$$

although dimethyl telluronium tetrachloroborate was formed in solution. The diethyl sulfide – boron trichloride adduct has been prepared by the reaction of boron trichloride with diethyl sulfide in ligroin (9) and the dimethyl selenium – boron trichloride adduct prepared by the direct interaction of dimethyl selenium and boron trichloride (8). Dimethyl and diethyl disulfides reacted in solution with boron trichloride to form the somewhat unstable boron trichloride adducts, $R_2S_2 . BCl_3$. Methane- and ethane-sulfenyl chlorides reacted with boron trichloride to form an ionic compound in solution of stoichiometry $(RSCl)_2BCl_3$; the methanesulfenyl chloride compound has been characterized (10). Various structures have been suggested for the compound $(MeSCl)_2BCl_3$



1 2

3

of which **3** is favored (10).

The potentially amphoteric chlorides $SeCl_4$ and $TeCl_4$, and SCl_4 were examined; ions of the type MCl_3^+ (11) and $SeCl_6^{2-}$ and $TeCl_6^{2-}$ (12) are all well known. It has very recently been shown that $SeCl_4$ and $TeCl_4$ both dissolve in chlorosulfuric acid to form the ions $SeCl_3^+$ and $TeCl_3^+$ (13). Sulfur, selenium, and tellurium tetrachlorides were all sparingly soluble and did not show any basic properties in solution, failing to react with boron trichloride, although sulfur tetrachloride is known to form an unstable adduct with boron trichloride in the absence of a solvent; this adduct decomposes at $-20°$ (14). Selenium and tellurium tetrachlorides did not react with boron trichloride in the absence of a solvent. The acidic properties, if any, of selenium and tellurium tetrachlorides, dimethyl and diphenyl selenium dichlorides, and dimethyl tellurium dichloride were investigated by mixing them with stoichiometric amounts of tetramethylammonium chloride in the solvent. From the increase in weight observed and the infrared (i.r.) spectrum of the product, it was inferred that tetramethylammonium hydrogen dichloride had

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

been formed, and that none of these chlorides had any acidic properties in liquid hydrogen chloride solution. Sulfur dichloride, sulfur monochloride, selenium monochloride, and tellurium dichloride did not react with boron trichloride in liquid hydrogen chloride or without a solvent.

Comparison of the conductivities of dimethyl sulfide, dimethyl selenium, and dimethyl tellurium shows that for solutions of approximately the same concentration, the basicities are of the same order of magnitude and that changing the Group VI element has little effect on the ease of protonation of Me_2M to form Me_2MH^+. A much greater change in conductivities is observed in changing the methyl group for chlorine; in the series $Me_xSCl_{3-x}^+$ it is observed that the basic strengths are

$$Me_3S^+ > Me_2SCl^+ > MeSCl_2^+$$

The derivatives of tetravalent sulfur, R_2SCl_2 and $RSCl_3$, are considerably less stable than R_2SeCl_2 and R_2TeCl_2 and are comparable to the relative stabilities of sulfur, selenium, and tellurium tetrachlorides. The ions $MeSCl_2^+$, Me_2SCl^+, and Me_2SeCl^+ could be stabilized as tetrachloroborates, but the ion Me_2TeCl^+ could not be stabilized analogously, suggesting that Me_2TeCl_2 may react with boron trichloride to form a non-ionized adduct $Me_2Cl_2Te.BCl_3$ containing a Te—B bond.

Experimental

The apparatus and techniques have been described previously (15). Volatile reactants were distilled into the conductivity cell from a calibrated volume at a known pressure and temperature; by the use of liquid nitrogen, quantitative transfer was possible. Measured volumes of liquids were obtained using a syringe and solids were weighed directly into the cell. The products were very hydrolytically sensitive and were therefore handled in a dry box. Chloride was analyzed gravimetrically and boron acidimetrically as the mannitol–borate complex. Infrared spectra were recorded on a Perkin–Elmer 457 spectrophotometer.

All the reagents were available commercially, unless their preparation is described.

The conductivities of the materials studied are shown in Table I.

Reactions with Chlorine (and Boron Trichloride)

Dimethyl and diethyl sulfide solutions were both separately titrated against chlorine, the titration showing a break when the mole ratio of R_2S:Cl_2 was 1.0:1.0, see Fig. 1. No stable products were isolated at room temperature, both products decomposing with partial chlorination of the alkyl groups. Titration of a solution of a mixture of 1 mole of dimethyl or diethyl sulfide and 1 mole of chlorine against boron trichloride showed end points when the mole ratios R_2SCl_2:BCl_3 were 1.0:1.05 (Me_2SCl_2) and 1.0:1.10 (Et_2SCl_2), see Fig. 1. The high conductivity at the end points in all these titrations indicates the formation of the ions R_2SCl^+ in solution.

White solids dimethylchlorosulfonium tetrachloroborate, m.p. 172–173° and diethylchlorosulfonium tetrachloroborate, m.p. 35–36° were isolated.

Anal. Calcd. for $C_2H_6BCl_5S$: B, 4.32; Cl, 70.8. Found: B, 4.24: Cl, 70.3.

Anal. Calcd. for $C_4H_{10}BCl_5S$: B, 3.94; Cl, 64.6. Found: B, 3.92; Cl, 64.4.

The i.r. spectra of the products showed frequencies characteristic of the RS group, the BCl_4^- ion (16), and S—Cl frequencies at 521(m) cm^{-1} ($Me_2SCl.BCl_4$) and at 536(m) and 516(m) cm^{-1} ($Et_2SCl.BCl_4$).

A solution of methanesulfenyl chloride was oxidized with chlorine to methyl sulfur trichloride; on treatment with boron trichloride, methyldichlorosulfonium tetrachloroborate was formed, which was isolated and characterized by its m.p. and i.r. spectrum.

The reactions of solutions of dimethyl disulfide and ethanethiol with chlorine gave ill-defined products both of which were shown by their i.r. spectra to contain C—Cl and S—Cl bonds. The reaction of 1 mole of dimethyl disulfide solution, after equilibration at −95° and treatment with 1 mole of chlorine and then 1 mole of boron trichloride yielded the same product as the reaction of MeSCl and BCl_3.

Sulfur dichloride was not oxidized in solution with chlorine to sulfur tetrachloride.

Dimethyl selenide formed a colorless solution; titration with chlorine caused precipitation and the end point was not sharp. Dimethyl selenium dichloride was isolated, m.p. 60–62° (lit. 61° (8)). A suspension of dimethyl selenium dichloride was prepared in situ and treated with boron trichloride, to form dimethylchloroselenonium tetrachloroborate, m.p. 81–82° (lit. 58° decomp. (8)).

Anal. Calcd. $C_2H_6BCl_5Se$: B, 3.64; Cl, 59.7. Found: B, 3.56; Cl, 59.6, 58.6.

The i.r. spectrum differs from that reported previously in that distinct tetrachloroborate ion peaks are found at 695, 671, and 663 cm^{-1} (10).

Dimethyl tellurium formed a colorless solution which when titrated with chlorine showed a break at a mole ratio 1.0:1.0 and the very low conductivity indicated the formation of a non-conducting species. White dimethyl tellurium dichloride, m.p. 94–95°, was isolated.

Anal. Calcd. for $C_2H_6Cl_2Te$: Cl, 30.9. Found: Cl, 31.0.

Reaction of a suspension of dimethyl tellurium dichloride, prepared in situ, with boron trichloride, gave an adduct $Me_2TeCl_2.BCl_3$ which decomposed on warming from −80° to room temperature with the quantitative evolution of boron trichloride, leaving solid dimethyl tellurium dichloride.

Reactions of Sulfur Compounds with Boron Trichloride

Methane- and ethane-sulfenyl chlorides, prepared in situ by allowing 1 mole of dialkyl disulfide and 1 mole of chlorine to equilibrate at −20° for ½ h (17), when titrated against boron trichloride, showed sharp breaks at mole ratio RSCl:BCl_3 of 2.3:1.0 (MeSCl) and 2.0:1.0 (EtSCl), see Fig. 2, indicating the formation of an ionic species $(RSCl)_2BCl_3$. A white solid $(MeSCl)_2BCl_3$, m.p. 159° decomp., and a yellow liquid $(EtSCl)_2BCl_3$ were isolated at room temperature.

Anal. Calcd. for $C_2H_6BCl_5S_2$: B, 3.84; Cl, 62.8. Found: B, 3.81; Cl, 62.5.

Anal. Calcd. for $C_4H_{10}BCl_5S_2$: B, 3.48; Cl, 57.1. Found: B, 3.49; Cl, 57.0.

Both products decomposed on standing. In the i.r. spectra RS peaks, B—Cl peaks at 682(s), 655(s) cm^{-1} ($(MeSCl)_2BCl_3$); 656(s), 688(s) cm^{-1} ($(EtSCl)_2BCl_3$); and

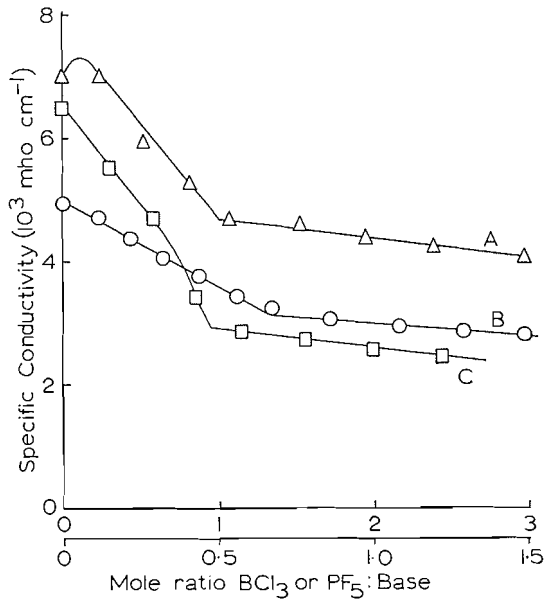

FIG. 2. Conductimetric titrations in liquid hydrogen chloride. A, 0.59 *M* EtSCl and BCl_3 (0–1.5 scale); B, 0.56 *M* MeSCl and PF_5 (0–3 scale); C, 0.51 *M* MeSCl and BCl_3 (0–1.5 scale).

S—Cl peaks at 494(m), 470(m), 460(m) cm^{-1} ($(MeSCl)_2$-BCl_3); and 509(m), 466(m), 452(sh) cm^{-1} ($(EtSCl)_2BCl_3$) were observed.

Methyl and ethyl sulfur trichlorides, prepared in situ from 1 mole of the dialkyl disulfide and 3 moles of chlorine at −20° (18), both reacted with boron trichloride to form the corresponding alkyldichlorosulfonium tetrachloroborate. White methyldichlorosulfonium tetrachloroborate, m.p. 155–156°, precipitated from solution.

Anal. Calcd. for CH_3BCl_6S: B, 3.99; Cl, 78.6. Found: B, 3.91; Cl, 79.6.

The conductiometric titration of ethyl sulfur trichloride against boron trichloride showed a break at mole ratio 1.0:1.0, $EtSCl_3$:BCl_3, see Fig. 3, indicating the formation of the ionic species $EtSCl_2^+BCl_4^-$ in solution, which was isolated as a white solid, m.p. 101–104°.

Anal. Calcd. for $C_2H_6BCl_6S$: B, 4.57; Cl, 69.6. Found: B, 4.17; Cl, 69.9.

The i.r. spectra showed peaks characteristic of the RS group, the BCl_4^- ion (10), and S—Cl frequencies at 522(m) and 496(m) cm^{-1} ($MeSCl_2^+$) and 541(m) and 508(m) cm^{-1} ($EtSCl_2^+$).

Solutions of dimethyl and diethyl disulfide reacted with boron trichloride to form the boron trichloride adducts; no sharp break was observed in the conductiometric titration, both products being colorless liquids which fumed readily in moist air. The diethyl disulfide boron trichloride adduct was also formed by mixing diethyl disulfide with an excess of boron trichloride in a sealed tube, which was opened after standing for 4 days at room temperature. From the amount of boron trichloride recovered it was deduced that an adduct of composition $Et_2S_2.BCl_3$ had been formed, but the colorless fuming

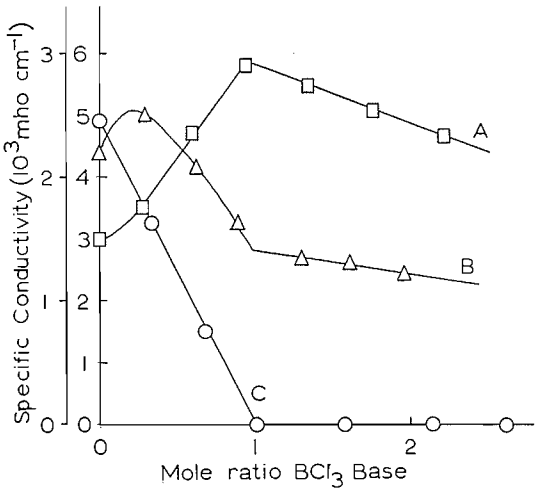

FIG. 3. Conductimetric titrations in liquid hydrogen chloride. A, 0.26 *M* Ph_2SeCl_2 and BCl_3 (0–3 scale); B, 0.40 *M* $EtSCl_3$ and BCl_3 (0–6 scale); C, 0.34 *M* Me_2Se and BCl_3 (0–6 scale).

liquid readily decomposed in a glove box to a brown liquid, and could not be analyzed satisfactorily.

Anal. Calcd. for $C_2H_6BCl_3S_2$: B, 5.11; Cl, 50.3. Found: B, 5.26; Cl, 50.6.

The i.r. spectra showed peaks characteristic of the RS group B—Cl frequencies at 760(vs), 751(vs), 691(m), and 584(s) cm^{-1} ($Me_2S_2.BCl_3$); 759(vs), 750(vs), 696(m), and 582(s) cm^{-1} ($Et_2S_2.BCl_3$); and B—S peaks at 960(m) cm^{-1} ($Me_2S_2.BCl_3$); 1054(m) cm^{-1} ($Et_2S_2.BCl_3$).

Titration of diethyl sulfide solution against boron trichloride showed a sharp break at mole ratio 1.0:1.0 (Et_2S:BCl_3), see Fig. 1, the low conductivity at the end point indicating the formation of the undissociated adduct in solution. Colorless liquid diethyl sulfide – boron trichloride adduct was isolated.

Anal. Calcd. for $C_2H_{10}BCl_3S$: B, 5.55; Cl, 51.7. Found: B, 5.29; Cl, 51.2.

The i.r. spectrum showed peaks characteristic of the EtS group, B—Cl peaks at 743(vs) and 616(s) cm^{-1}, and a possible B—S frequency at 1054(m) cm^{-1}.

Trimethylsulfonium iodide formed a highly conducting solution; titration with boron trichloride showed an end point at mole ratio Me_3SI:BCl_3 of 1.0:1.2. A white solid, trimethylsulfonium tetrachloroborate, decomp. 300°, was isolated.

Anal. Calcd. for $C_3H_9BCl_4S$: B, 4.70; Cl, 61.7. Found: B, 4.60; Cl, 60.4.

This formula was confirmed by the i.r. spectrum which contained only Me_3S^+ ion and BCl_4^- ion frequencies (19, 10).

The compounds sulfur monochloride, sulfur dichloride, sulfur tetrachloride (prepared by allowing 1 mole of sulfur dichloride and 1 mole of chlorine to equilibrate at −60°), and bis(pentafluorophenyl)sulfide formed very poorly conducting solutions and did not react with boron trichloride.

Reactions of Selenium Compounds with Boron Trichloride

Dimethyl selenium solution showed a break at mole ratio 1.0:1.0, Me_2Se:BCl_3, when titrated against boron trichloride, see Fig. 3, the low conductivity at the equivalence point indicating the formation of the undissociated dimethyl selenium – boron trichloride adduct in solution, which was isolated as a white solid, 93–95° (lit. 101–102° (5)).

Anal. Calcd. for $C_2H_6BCl_3Se$: B, 4.78; Cl, 47.0. Found: B, 4.79; Cl, 47.4.

The i.r. spectrum agrees with that reported previously (5).

Diphenyl selenium dichloride when titrated against boron trichloride gave an equivalence point when the ratio Ph_2SeCl_2:BCl_3 was 1.0:1.0, see Fig. 3, the high conductivity indicating the formation of an ionic species, probably $Ph_2SeCl^+BCl_4^-$. After removal of the solvent, the white solid product decomposed on warming to room temperature.

Selenium monochloride and selenium tetrachloride both formed poorly conducting solutions which did not react with boron trichloride.

Reactions of Tellurium Compounds with Boron Trichloride

The reaction of boron trichloride with a solution of dimethyl tellurium produced a white precipitate. After removal of the solvent and pumping at −80° for 2 h, 0.98 mole of hydrogen chloride per mole of dimethyl tellurium was evolved and the white dimethyl tellurium boron trichloride adduct, m.p. 231–233°, remained.

Anal. Calcd. for $C_2H_6BCl_3Te$: B, 3.93; Cl, 38.7. Found: B, 3.81; Cl, 38.6.

The almost quantitative evolution of hydrogen chloride suggests that dimethyl telluronium tetrachloroborate, $Me_2TeH^+BCl_4^-$, had precipitated from solution and decomposed on warming to room temperature, forming the dimethyl tellurium boron trichloride adduct. The dimethyl tellurium boron trichloride adduct decomposed to a black material, probably tellurium, in a dry box within a day. The i.r. spectrum showed frequencies characteristic of the MeTe group and B—Cl frequencies at 750(sh), 712(vs), and 662(s) cm^{-1}.

Tellurium dichloride and tellurium tetrachloride were both sparingly soluble and did not react with boron trichloride.

Reactions with Phosphorus Pentafluoride

A solution of dimethylchlorosulfonium chloride reacted with phosphorus pentafluoride and white dimethylchlorosulfonium hexafluorophosphate, m.p. 182–184°, was isolated.

Anal. Calcd. for $C_2H_6ClF_6PS$: Cl, 14.6. Found: Cl, 14.6.

The i.r. spectrum is consistent with its structure as $Me_2SCl^+PF_6^-$, showing only peaks characteristic of the Me_2SCl^+ and PF_6^- ions (3).

Methanesulfenyl chloride solution was titrated against phosphorus pentafluoride, see Fig. 2; the equivalence point was found at mole ratio 1.3:1.0, PF_5:MeSCl, indicating that the reaction,

$$2\left[\begin{array}{c}\mathrm{MeSCl}\\ |\\ \mathrm{H}\end{array}\right]^+ HCl_2^- + 3PF_5 \rightarrow 2\left[\begin{array}{c}\mathrm{MeSCl}\\ |\\ \mathrm{H}\end{array}\right]^+ PF_6^- + PF_3Cl_2 + 2HCl$$

probably had occurred. White methylchlorosulfonium hexafluorophosphate, m.p. 132–133° decomp., was isolated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Anal. Calcd. for CH_4ClF_6PS: Cl, 15.5. Found: Cl, 15.5.

In the i.r. spectrum PF_6^- ion peaks (3), MeS group peaks and possible S—Cl frequencies at 496(m) and 479(m) cm^{-1} were observed. The S—H frequency would be expected to be very weak and no peak can be assigned with certainty, although there may be one at 2270(vw) cm^{-1}.

An unstable white methyldichlorosulfonium hexafluorophosphate could be isolated from the reaction of a solution of methyl sulfur trichloride and phosphorus pentafluoride. The solid decomposed with loss of PF_5; its i.r. spectrum showed the presence of the ions $MeSCl_2^+$ and PF_6^- (3).

Potential Acids

Solutions were prepared of approximately 2 moles of Me_4NCl and 1 mole of $SeCl_4$, Me_2SeCl_2, Ph_2SeCl_2, $TeCl_4$, and Me_2TeCl_2. After removal of the solvent the increase in weight showed that Me_4NCl had formed Me_4NHCl_2 and not $(Me_4N)_2MCl_6$. The i.r. spectra of the products of the reactions with Me_2SeCl_2, Ph_2SeCl_2, and Me_2TeCl_2 showed the presence of the HCl_2^- ion (20). When 2 moles of Me_4NHCl_2 and 1 mole of $SeCl_4$ or $TeCl_4$ were ground up in Nujol, the i.r. peaks corresponding to the HCl_2^- ion had disappeared, indicating that in the grinding process the HCl_2^- ion had decomposed and the hexachloroselenate and hexachlorotellurate ions had probably been formed. The HCl_2^- ion would not be expected in the i.r. spectra of the Me_4NCl and $SeCl_4$ or $TeCl_4$ reaction products. It can be concluded that none of these chlorides exhibit acidic properties in liquid hydrogen chloride solution.

Reactions with Boron Trichloride without a Solvent

Sulfur monochloride, sulfur dichloride, sulfur tetrachloride, selenium monochloride, selenium tetrachloride, tellurium dichloride, and tellurium tetrachloride were each sealed in a tube under vacuum with an excess of boron trichloride and shaken at room temperature for a week. In all cases, except for sulfur tetrachloride, no reaction occurred and the reactants were recovered. A white solid formed in the sulfur tetrachloride reaction, but after removal of the excess boron trichloride at $-60°$, it started to decompose at about $-20°$ and decomposed too rapidly at room temperature to be analyzed.

Complexes of Co(II), Ni(II), and Zn(II) with pyrazolone ligands[1]

R. A. BAILEY
Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York 12181

AND

T. R. PETERSON
Imperial Color and Chemical Department, Hercules Incorporated, Glens Falls, New York 12801

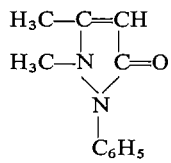
Received November 12, 1968

Complexes of Co(II), Ni(II), and Zn(II) with 4-aminoantipyrine and 4-dimethylaminoantipyrine have been prepared and characterized. These contain chloride, bromide, thiocyanate, nitrate, and perchlorate anions. Magnetic, conductivity, and electronic spectral data show that all of the Ni(II) and Co(II) complexes have high spin configurations and octahedral geometries, with coordinated halide, thiocyanate, and probably nitrate anions in the respective examples. Infrared analysis indicates that all of the complexes containing Cl^-, NCS^-, and NO_3^- anions involve chelated 4-aminoantipyrine, whereas the bromide complexes are only bonded to the organic ligands through nitrogen.

Canadian Journal of Chemistry, 47, 1681 (1969)

Introduction

Complexes of 1-phenyl-2,3-dimethyl-5-pyrazolone (antipyrine) shown below and its 4-amino and 4-dimethylamino derivatives have been of considerable interest.



Antipyrine is expected to be unidentate, bonding through oxygen (other behavior, such as use of the ring nitrogens, is conceivable but unlikely). A large number of compounds of this ligand have been shown to be unidentate and oxygen coordinated from infrared (i.r.) spectral studies (1–5); a variety of coordination geometries are encountered.

A number of 4-aminoantipyrine and 4-dimethylaminoantipyrine compounds with Mn(II), Co(II), Ni(II), Cu(II), Zn(II), and Cd(II) ions were prepared but not characterized structurally by Souchay (6). Three modes of coordination must be considered for these; unidentate behavior with bonding through either the oxygen or the amino nitrogen, or chelation utilizing both these atoms. Infrared studies by Zaitsev *et al.* (7) on compounds of the type M(4-dimethylaminoantipyrine)$_2$(NCS)$_2$, (M = Zn(II), Co(II), and others) indicated chelation. This was confirmed by Dick *et al.* (8) who also showed that the thiocyanate groups in the above compounds were coordinated rather than free as supposed by Zaitsev *et al.* (7). Guru and Rao (9, 10), considering only the carbonyl region of the i.r. spectra, postulated that in Zn(4-aminoantipyrine)$_4$(ClO_4)$_2$ and in Zn(4-aminoantipyrine)$_2X_2$ (X = Cl^-, Br^-, I^-, NCS^-, NO_3^-), tetrahedral geometries are present with unidentate oxygen-bonded organic ligands. None of these i.r. interpretations is particularly convincing, as rigorous assignments of bands in the organic ligands have not been made. Knowledge of the coordination geometry is generally very uncertain.

In this report we have examined the structures of a variety of compounds containing 4-aminoantipyrine and 4-dimethylaminoantipyrine ligands with Co(II) and Ni(II), and have reconsidered some of the conclusions regarding the Zn(II) compounds.

Experimental Section

Materials

$NiBr_2$ (anhydrous), $CoBr_2$ (anhydrous), 4-aminoantipyrine, and 4-dimethylaminoantipyrine were obtained from K and K Laboratories, Inc., and were used without further purification. All other chemicals used were of reagent grade quality.

Syntheses

The nickel and cobalt complexes were prepared using anhydrous ethanol as solvent, following essentially the same procedures reported by Souchay (6). The analytical results are given in Table I. Although the earlier report

[1]Based on part of a thesis submitted by T. R. Peterson to the Graduate School of Rensselaer Polytechnic Institute in partial fulfillment of the requirements for the degree of Doctor of Philosophy, February, 1969.

TABLE I

*Results expressed as %.
†AM = 4-aminoantipyrine; DAM = 4-dimethylaminoantipyrine.

(6) cited the preparation of anhydrous Co(4-dimethylaminoantipyrine)$_2(NO_3)_2$ and Ni(4-dimethylaminoantipyrine)$_2(NO_3)_2$, we were only successful in obtaining the corresponding dihydrate compounds. The zinc compounds were prepared by the method of Guru and Rao (9, 10).

Spectroscopic Measurements

Solid state electronic spectra were obtained by the reflectance technique from finely ground samples, using $MgCO_3$ as standard in a Beckman DU spectrophotometer. Infrared spectra in the region 4000–300 cm^{-1} were obtained by the KBr pellet technique using a Perkin–Elmer Model 621 spectrophotometer.

Magnetic Measurements

Magnetic data were obtained at room temperature by the Gouy technique using $Hg[Co(NCS)_4]$ as calibrant, and results were corrected for diamagnetism and temperature independent paramagnetism in the usual manner (11). The diamagnetism of the organic ligands was determined experimentally and found to be close to the values obtained using Pascal's constants (11). Measurements at a number of field strengths (4–10 000 G) all gave essentially identical results.

Conductivity Measurements

Conductivities were measured in ethanol using an Industrial Instruments Model RC-16 conductivity bridge and a cell having a cell constant of 0.1 cm^{-1}. Allowance was made for the conductivity of the solvent in the calculations.

Analytical Procedures

Analyses for C, H, and N were performed by Schwarzkopf Microanalytical Laboratory, Woodside, New York. Nickel, cobalt, and zinc were determined by EDTA titration (12). Sulfur was determined as $BaSO_4$ using Eschkas mixture to effect decomposition, nitrogen by the Kjeldahl technique, chloride by $AgNO_3$ titration, and perchlorate as the tetraphenylarsonium salt.

Results and Discussion

Conductivity Studies

The equivalent conductances, Λ, of some of the Ni(II) and Co(II) complexes in ethanol are shown in Fig. 1. The values obtained at a concentration of 10^{-3} *N* of ca. 25–40 cm^2 equivalents^{-1} Ω^{-1} are in all cases lower than the value of ca. 55 cm^2 equivalents^{-1} Ω^{-1} found under similar condi-

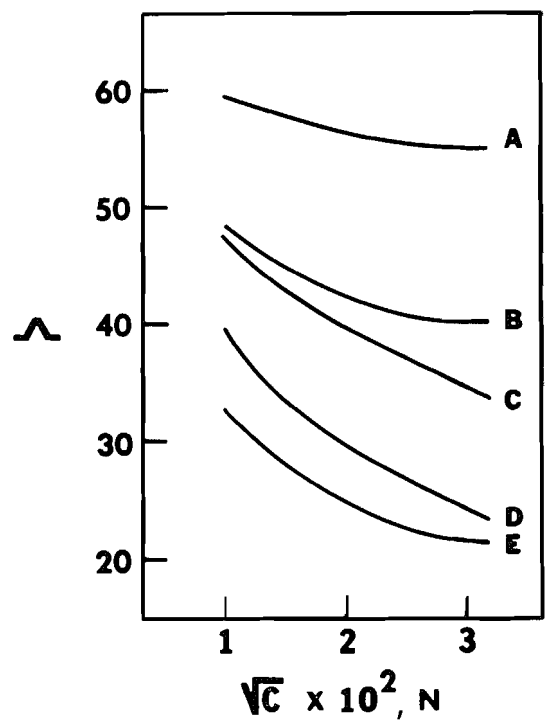

FIG. 1. Conductivity data in ethanol, 25 °C (Λ, equivalent conductivity, cm^2 equivalents^{-1} Ω^{-1}): A, tetraethylammonium bromide; B, Co(4-dimethylaminoantipyrine)$_2(NO_3)_2(H_2O)_2$; C, Co(4-aminoantipyrine)$_4Br_2$; D, Ni(4-aminoantipyrine)$_4Br_2$; E, Ni(4-dimethylaminoantipyrine)$_2(NO_3)_2(H_2O)_2$.

*AM = 4-aminoantipyrine; DAM = 4-dimethylaminoantipyrine.
†Uncorrected molar susceptibility.

tions for tetraethylammonium bromide, a 1:1 electrolyte. The concentration dependence of Λ is typical of weak electrolytes. These results may be interpreted on the basis of partial dissociation of coordinated anions.

Magnetic Susceptibility Studies

The room temperature magnetic moments of all the paramagnetic complexes are given in Table II. The Ni(II) complexes exhibit moments of ca. 3.05–3.23 B.M., while the Co(II) compounds have moments of ca. 4.88–5.0 B.M. These are within the range normally found for both of these ions in octahedral fields (13), and may be compared to the room temperature values of 3.19 B.M. found previously for hexaantipyrine Ni(II) perchlorate and 4.99 B.M. for hexaantipyrine Co(II) perchlorate (4).

Electronic Spectral Studies

The solid state reflectance spectra of the Ni(II) and Co(II) compounds given in Table III and Figs. 2 and 3 are typical of these ions in O_h symmetry, confirming the magnetic susceptibility results. Assignments of the observed bands (Table III) were made on the basis of octahedral geometries using the energy level diagram of Liehr and Ballhausen (14) for the Ni(II) complexes and that of Tanabe and Sugano (15) for the Co(II) complexes. For the Ni(II) complexes the $^3A_{2g} \rightarrow {}^3T_{2g}(F)$ transition (Table III) gives the values of $10\,Dq_{oct}$ directly (15); these are observed to be on the order of ca. 8900–9500 cm^{-1}. The Racah parameter B for the Ni(II) complexes may be evaluated from the relation $B = (\nu_2 + \nu_3 - 3\nu_1)/15$, giving values for the Ni(II) complexes of ca. 875–975 cm^{-1}. These

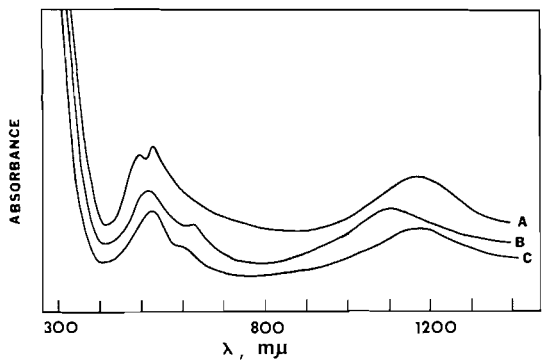

FIG. 2. Reflectance spectra of Co(II) pyrazolone complexes: A, $Co(4\text{-dimethylaminoantipyrine})_2(NO_3)_2(H_2O)_2$; B, $Co(4\text{-aminoantipyrine})_4Br_2$; C, $Co(4\text{-aminoantipyrine})_2(NCS)_2$.

represent reasonable reduction from the free ion value for Ni(II) of 1030 cm^{-1} (15). For the analogous Co(II) complexes, the best fit of the spectra with the energy level diagram could be obtained with values of $10Dq$ of ca. 8900–9400 cm^{-1} and with values of B of the order of 810 cm^{-1}, which may be compared to the free ion value of 971 cm^{-1} (15). As seen in Table III, and Fig. 2, the weak ν_2 band in the Co(II) complexes has been assigned to the spin-allowed transition, $^4T_{1g} \rightarrow {}^4A_{2g}(F)$. This transition, which involves two electrons, would be expected to be of very low intensity (16). It is not observed in Co(4-dimethylaminopyrine)$_2$(NO$_3$)$_2$(H$_2$O)$_2$ here, and is frequently missing in Co(II) spectra. It is to be noted, however, that the spin-forbidden transitions, $^4T_{1g}(F) \rightarrow {}^2T_{2g}(G)$ and $^4T_{1g}(F) \rightarrow {}^2T_{1g}(G)$, are in this region also. In some cases, splitting of the $^4T_{1g} \rightarrow {}^4T_{1g}(P)$ band (ν_3) is seen. This has

*AM = 4-aminoantipyrine; DAM = 4-dimethylaminoantipyrine.

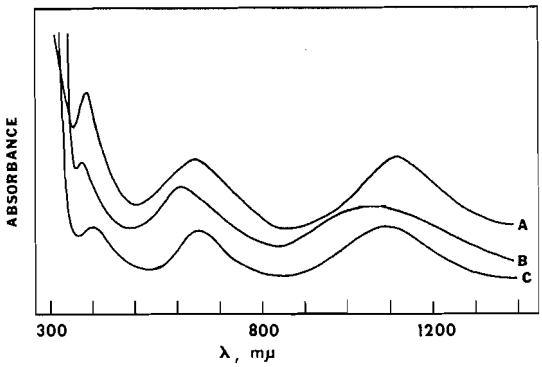

FIG. 3. Reflectance spectra of Ni(II) pyrazolone complexes: A, Ni(4-dimethylaminoantipyrine)$_2$(NO$_3$)$_2$(H$_2$O)$_2$; B, Ni(4-aminoantipyrine)$_2$Br$_2$; C, Ni(4-aminoantipyrine)$_2$(NCS)$_2$.

been explained as spin–orbit splitting of the $^4T_{1g}$(P) state (16).

For the case of Ni(4-aminoantipyrine)$_4$Br$_2$, with the reasonable assumption of unidentate organic ligands and coordinated bromide ions as indicated from the conductance data, application of the rule of average environments using the known value of 10 Dq_{oct} for Br^- (7600 cm^{-1}) (17) yields a value of 10 Dq_{oct} for unidentate 4-aminoantipyrine of 10 450 cm^{-1}. This value is clearly much higher than that observed for Ni–O$_6$ chromophores such as Ni(H$_2$O)$_6^{2+}$ (8900 cm^{-1}) (18), Ni(substituted urea)$_6^{2+}$ (8000–8500 cm^{-1}) (19), and hexaantipyrine Ni(II) perchlorate (7630 cm^{-1}) (4). The observed value is more nearly in the range observed for Ni–N$_6$ chromophores such as in Ni(NH$_3$)$_6^{2+}$ (10 800 cm^{-1}) (18), Ni(pyridine)$_6^{2+}$ (10 100 cm^{-1}) (20), and Ni(methylamine)$_6^{2+}$ (9930 cm^{-1}) (21). It appears that in Ni(4-aminoantipyrine)$_4$Br$_2$, the Ni(II) ion is bonded to the nitrogen atom of the organic ligand.

For Ni(L)$_2$(NCS)$_2$, where L = 4-aminoantipyrine or 4-dimethylaminoantipyrine, similar calculations using the average environment rule in conjunction with the known value of 10 Dq_{oct} for N-bonded thiocyanate groups of 9600 cm^{-1} (22), yield values of 10 Dq_{oct} for the organic ligands of ca. 8550–8850 cm^{-1}. These values are clearly too low for unidentate N-bonded groups as found for dibromotetrakis(4-aminoantipyrine)Ni(II), (10 450 cm^{-1}) and too high for unidentate O-bonded groups as are found in hexaantipyrine Ni(II) perchlorate, (7630 cm^{-1}) previously reported (4), but do agree with the value of ca. 9000 cm^{-1} calculated for this ligand as a chelate assuming the average of 10 Dq values from N- and O-bonded cases. Since the i.r. data (see below) show the thiocyanate ions to be coordinated and terminally bonded to the metal ion and the geometry has been established to be octahedral, bidentate behavior of this organic ligand is expected.

It is not possible to draw conclusions about the structures of either Ni(4-dimethylaminoantipyrine)$_2$(NO$_3$)$_2$(H$_2$O)$_2$ or Co(4-dimethylaminoantipyrine)$_2$(NO$_3$)$_2$(H$_2$O)$_2$ from similar arguments since the various possibilities give similar values of 10 Dq.

The results obtained from the spectra of Co(4-aminoantipyrine)$_4$Br$_2$, Co(4-aminoantipyrine)$_2$(NCS)$_2$, and Co(4-dimethylaminoantipyrine)$_2$(NCS)$_2$, see Table III and Fig. 2, are also straightforward, yielding values of 10 Dq_{oct} for unidentate N-bonded 4-aminoantipyrine in the bromo compound of ca. 10 800 cm^{-1}. This value is in line with 10 Dq_{oct} values found in N-bonded Co(II) complexes such as Co(NH$_3$)$_6^{2+}$ (10 100 cm^{-1}) (18). The 10 Dq value for oxygen bonded antipyrine is much lower, < 7000 cm^{-1} (23). For the thiocyanate complexes the observed value of 10 Dq_{oct} for the organic ligands of ca. 8300 cm^{-1} also indicates that chelation is present as in the corresponding Ni(II) complexes. For these calculations it was assumed that 10 Dq_{oct} was 9/4 the value of 10 Dq_{tet} (1, 23).

Infrared Spectra

The i.r. spectra of all the thiocyanate complexes prepared in this study are in excellent agreement with the earlier report of Dick *et al.* (8). The positions of the ν_{CN} frequency at ca. 2085–2104 cm^{-1}, ν_{CS} at ca. 792–786 cm^{-1}, and δ_{NCS} at ca. 462–480 cm^{-1} in these complexes clearly indicate the presence of only terminal N-bonded thiocyanate groups (24).

The i.r. spectra of the organic ligands are quite complex. In antipyrine and its 4-amino-derivatives, a strong band in the 1650 cm^{-1} region has been attributed to the C=O stretching frequency. This decreases on coordination in antipyrine, and its similar decrease in the amino compounds has been used as evidence for oxygen coordination. In 4-aminoantipyrine, evidence for coordination through nitrogen can be obtained from the N—H stretching frequencies, which should decrease. Chelation should lead to a decrease in both the

C=O stretching frequency and N—H stretching frequencies. As is illustrated in Fig. 4, the bands in the N—H stretching region decrease in all compounds (the $M(L)_2(NO_3)_2(H_2O)_2$ species show O—H bands in this region, so that the N—H bands are rather obscured). Interpretation of the behavior of bands in the 1600 cm^{-1} region is not straightforward, since besides the C=O stretching frequency, the C=C stretching and the H—N—H bending modes occur here. The first of these is usually below the C=O frequency while the second may be expected below 1600 cm^{-1}. Dick *et al.* (8) have suggested that on chelation the C=O band (assigned at 1645–1665 cm^{-1}) disappears and a new band appears at 1610–1635 cm^{-1} which is caused by the stretching mode of the C=N bond which can be written for one of the resonance structures. Assignment of this band to a shifted C=O frequency is probably more reasonable. Sauro and Moeller (25) have shown that this band shifts to about 1600 cm^{-1} in some chelated rare earth pyrazalone complexes.

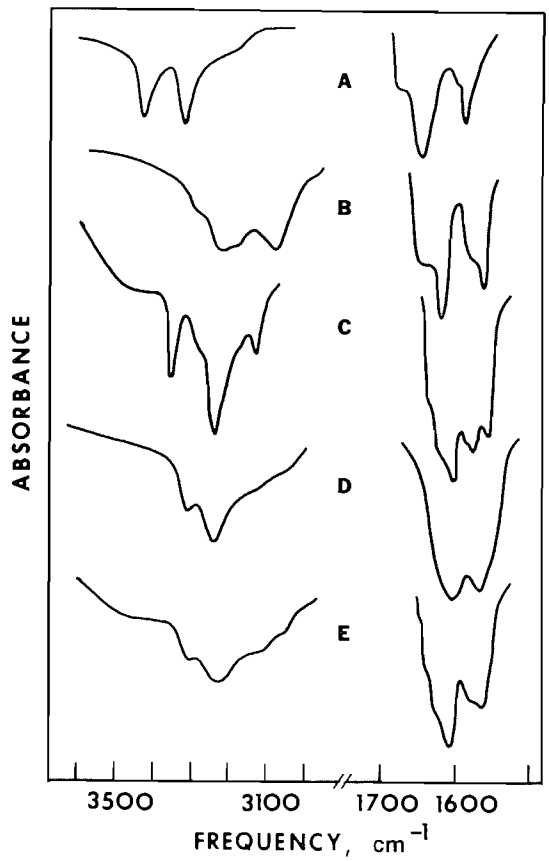

FIG. 4. Infrared spectra of metal 4-aminoantipyrine complexes in the N—H stretching and C=O stretching regions: A, 4-aminoantipyrine; B, Ni(4-aminoantipyrine)$_4Br_2$; C, Zn(4-aminoantipyrine)$_4(ClO_4)_2$; D, Ni(4-aminoantipyrine)$_2(NCS)_2$; E, Zn(4-aminoantipyrine)$_2$-$(NCS)_2$.

The spectra shown for the corresponding nickel and cobalt compounds (Fig. 4) are almost identical and fall into two types; those for the $M(L)_4Br_2$ compounds, which we have considered to be nitrogen bonded on the basis of ligand field data, and those for the nitrates and thiocyanates, where the latter was considered chelated on the above evidence. The bromide spectra show considerable decrease in the positions of the N—H stretching bands, but the bands in the carbonyl region, although somewhat shifted (to about 1620 cm^{-1}), have the same general character as in the free ligand. While the decreases in the 1600 cm^{-1} region are unexplained, they may arise from the fact that these bands are composites of several modes. The chelated thiocyanate spectra, on the other hand, show much more extensive shifts here, as would be expected for coordination through the carbonyl oxygen (to near 1600 cm^{-1}), as well as decreases in the N—H region. The 1600 cm^{-1} region profile is now greatly changed.

The spectrum of Zn(4-aminoantipyrine)$_2$-$(NCS)_2$ and Zn(4-aminoantipyrine)$_2Cl_2$ described by Guru and Rao (9, 10) are nearly identical in the N—H and C=O regions (Fig. 4) and are quite similar to the nickel and cobalt thiocyanate compounds in these ranges. From these data, it appears that the organic ligands are chelated rather than unidentate, and that the compounds are octahedral rather than tetrahedral as the anions are coordinated.

Zn(4-aminoantipyrine)$_4(ClO_4)_2$ is quite different, with a spectrum which is more similar to that of the cobalt and nickel bromides. The N—H stretching frequencies are decreased less, and the 1600 cm^{-1} bands more, than in the former compounds. We hesitate to draw any conclusions as to the mode of bonding in this compound from the i.r. spectrum. Certainly the previous suggestion of unidentate oxygen coordination is questionable, and it is apparent that great care must be taken in interpreting shifts in the spectrum of this ligand, particularly in the 1600 cm^{-1} region.

The i.r. spectra of Co(4-dimethylaminoantipyrine)$_2(NO_3)_2(H_2O)_2$ and Ni(4-dimethylaminoantipyrine)$_2(NO_3)_2(H_2O)_2$ are essentially the

same in the carbonyl stretching region as those of the Ni(II) and Co(II) thiocyanate complexes which appear to be chelated. The presence of either coordinated water or nitrate groups could not be established from their i.r. spectra due to interference from organic ligand bands, but conductance data on both these compounds in ethanol clearly suggest the presence of coordinated nitrate groups. A chelated octahedral structure with non-coordinated water molecules but coordinated anions appears most reasonable.

It is interesting that 4-aminoantipyrine may be either bidentate, or unidentate with bonding through the nitrogen. In the compounds studied here, the latter behavior is found only when Br^- is also coordinated to the metal. Chelation would appear to be expected on entropy grounds. While there is hardly sufficient data on which to draw conclusions, one may speculate that the major difference of Br^- is its greater ability to accept electrons from the metal (via back π-bonding, say), thereby reducing the electron density on the latter. This effect could better be counteracted by donation from nitrogen than from oxygen.

Co(II) complexes with 2-pyrrolidinone

O. BOHUNOVSKY[1], S. C. JAIN, AND R. RIVEST
Department of Chemistry, University of Montreal, Montreal, Quebec

Received October 4, 1968

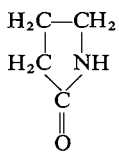
For the known complexes CoL_3X_2 (X = Cl, Br, and L = 2-pyrrolidinone) a more detailed infrared study was made. Together with the electronic spectra this study indicates dissociation of CoL_2X_3 into CoL_2X_2 + L in chloroform and acetone solution. The conductivity measurements and the molecular weight determinations also support dissociation. The probable structure in the solid state is $[CoL_3X]X$. The new 1:1 compound of 2-pyrrolidinone with boron trichloride was prepared to confirm the conclusions made from the infrared spectra of the cobalt complexes.

Les complexes connus CoL_3X_2 (X = Cl, Br, et L = 2-pyrrolidinone) ont été préparés. Une étude plus détaillée des spectres infrarouges et les données des spectres électroniques indiquent la dissociation en CoL_2X_2 + L en solution de chloroform et d'acétone. La structure en phase solide semble être $[CoL_3X]X$. La nouveau composé 1:1 de 2-pyrrolidinone avec le trichlorure de bore a été préparé pour vérifier les conclusions des spectres infrarouges des complexes de cobalt.

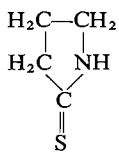
Canadian Journal of Chemistry, **47**, 1689 (1969)

Introduction

Madan and Sturr (1) recently reported complexes of Co(II) halides with 2-pyrrolidinone (**1**) (γ-butyrolactam) (L), CoL_3X_2 and concluded, that the structure is $[CoL_6][CoX_4]$ and that $[CoL_6]^{2+}$ and $[CoX_4]^{2-}$ are present in solution. Here we report the same complexes for X = Cl, Br, or I and a complex of the ligand with BCl_3. From the infrared (i.r.) and electronic spectra in chloroform solution and from the electronic spectral data reported by Madan we propose a different structure.



1



2

In an earlier article (2) the site of coordination of 2-thiazolidinethione (**2**) towards Co(II) was reported to be nitrogen. This conclusion was based besides other arguments, upon the shift of ν(N—H). On the other hand, 2-pyrrolidinone is coordinated through oxygen, but the ν(NH) is also shifted. This shift of ν(NH) in both cases is discussed.

[1]Present address: Research and Development Division, Sherritt Gordon Mines Limited, Fort Saskatchewan, Alberta.

Experimental

All manipulations were performed in a dry-box flushed with nitrogen. Cobalt halides were obtained from Alfa Inorganics and used without further purification; 2-pyrrolidinone was obtained from J. T. Baker Organic Chemicals and recrystallized twice from hexane. Analyses were carried out by Organic Microanalysis, Montreal.

$C_4H_7NO.BCl_3$

Into a solution of 2-pyrrolidinone in dry and alcohol-free chloroform, BCl_3 was bubbled at 0 °C, and a colorless precipitate was formed. To remove excess BCl_3, the mixture was boiled for a short period. The precipitate was then filtered off, washed with chloroform, and dried in vacuo. The compound so obtained was found to be insoluble in CH_2Cl_2 and CCl_4 but was soluble in acetone, m.p. 125°.

$[CoX_2(C_4H_7NO)_3]$

The dichloro- and dibromo-tris-(2-pyrrolidinone)cobalt(II)[2] were prepared by the method of Madan and Sturr (1). *Diido-tris-(2-pyrrolidinone)cobalt(II)* was prepared by refluxing 2.58 g CoI_2 and 2.37 g of 2-pyrrolidinone for 14 h in $CHCl_3$. A dark green solution formed, from which green prismatic crystals formed after a few days standing. These were filtered off and washed with ether. The analytical results are given in Table I.

Spectra

Vibration spectra were recorded on a Perkin-Elmer

[2]The preparation of a complex CoL_3Br_2 was already reported in a patent (3) in 1958. It was described as a red-violet compound with m.p. 125 °C. We observed that this red-violet compound contained more than three ligands per cobalt, but on continued washing with ether, the blue compound, described by Madan, was obtained.

TABLE I
Analytical results

Compound	Carbon (%)		Hydrogen (%)		Nitrogen (%)		Halogen (%)	
	Calcd.	Found	Calcd.	Found	Calcd.	Found	Calcd.	Found
$CoCl_2.3L$	37.45	37.30	5.51	5.54	10.90	10.91	18.44	18.71
$CoBr_2.3L$	30.39	29.55	4.47	4.59	8.86	8.65	33.66	32.68
$CoI_2.3L$	25.34	23.87	3.73	3.61	7.40	6.40	44.70	44.36
$BCl_3.L$	23.75	21.77	3.49	4.8*	6.91	6.18	52.58	51.9*

*The analysis of this very hygroscopic compound, for which the weighing was performed in the open air, differed remarkably from the theoretical value, especially for hydrogen and halogen. The halogen analysis was repeated with exclusion of humidity. This result is given here. Precaution was taken to prevent the loss of HCl during hydrolysis in water.

‡ε_{max} values were calculated by Madan and Sturr (1) based on the assumption of $[CoL_6][CoX_4]$. Half of the values are applicable, if all the Co(II) is tetrahedrally coordinated.
§Because the bands are given in this order by Madan and Sturr (1), it might be that this was a typing mistake and should read 15 600 instead of 16 600.

621 spectrophotometer using cesium iodide optics. Sodium chloride cells were used for the region from 4000–600 cm^{-1} and polyethylene cells, for the region from 600–200 cm^{-1} for solutions. Electronic spectra were obtained on a Cary Model 14 spectrophotometer. Samples were in approximately 10^{-3} M solutions or in Nujol mulls and the technique described by Cotton *et al.* (4) was used.

Molecular Weight and Conductivity

The molecular weight determinations were carried out in nitrobenzene solution by a cryoscopic method. The conductivity was measured with a conductoscope type E 365B (Metrohm Ltd.) using EA 608 immersion cell with cell constant 0.84 cm^{-1}. Molecular weight and molar conductance results are reported in Table IV.

Results and Discussion

The i.r. spectra for CoL_3X_2 in chloroform solution indicate dissociation, showing bands for the uncoordinated as well as for the coordinated ligand (Table III). The visible spectra of these solutions are very similar to the spectra for $[CoX_2(DMA)_2]$ (DMA = N,N-dimethylacetamide) in N,N-dimethylacetamide solution (5). This indicates, that in solution, the species $[CoL_2X_2]$ and L are present, according to

[1] $CoL_3X_2(solid) \rightarrow CoL_2X_2 + L(solution)$

Madan and Sturr (1) concluded from the electronic spectra that the structure of the complexes is $[CoL_6][CoX_4]$. We obtained identical spectra in Nujol mulls and the spectra in chloroform solution were very similar to those obtained by Madan and Sturr in acetone solution with 100-fold excess of the ligand (Table II). Two facts, however, suggest that it is not correct to propose the structure $[CoL_6][CoX_4]$ for these complexes, from the data obtained in solution:

(*1*) The conductivity found by Madan and Sturr is too low to support complete ionization.

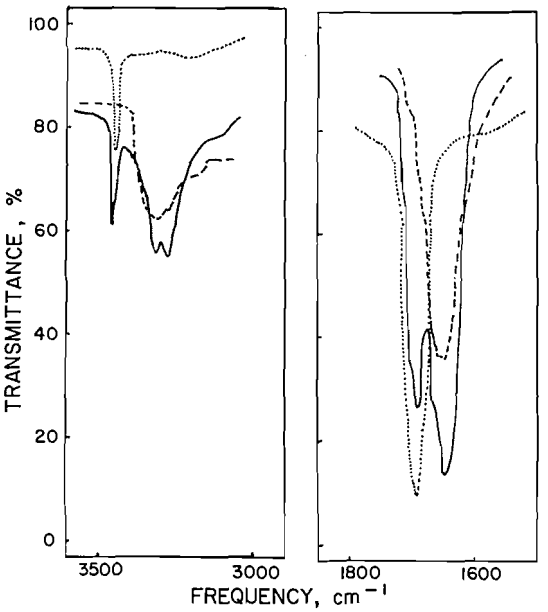

FIG. 1. Infrared spectra of $CoCl_2.3L$ compound in ν(N—H) and ν(C=O) regions; ---, in Nujol mull; ——, in $CHCl_3$ solution; ....., the ligand in $CHCl_3$ solution.

(*2*) Fine (6) reported the spectra of $[CoX_4]^{2-}$ in acetone solution. The spectra found by Madan and Sturr are different from these. The frequencies for the strongest bands for CoL_3X_2 are 800, 1100, and 3700 cm^{-1} higher than the strongest bands for $[CoCl_4]^{2-}$, $[CoBr_4]^{2-}$, and $[CoI_4]^{2-}$, respectively. The high excess of the ligand cannot be responsible for this shift, as Gutmann and Bohunovsky (5) found that spectra of $[CoX_4]^{2-}$ have a negligible variation in solvents of different donor strength. Furthermore, the extinction coefficient for the strongest band, found by Madan and Sturr for "$[CoL_6]$-$[CoX_4]$" is 50% higher than for $[CoCl_4]^{2-}$, which indicates that more than half of the Co(II) ions are tetrahedrally coordinated.

The arguments of Madan and Sturr seem to be valid only inasmuch as some sort of tetrahedrally coordinated Co(II) must be present. Equilibrium [1] explains the visible spectra and accounts for the presence of an uncoordinated ligand indicated by i.r. spectroscopy. Figure 1 is in accordance with the conductivity and does not conflict with the magnetic evidence provided by Madan and Sturr. The following equilibria should, however, be considered to some extent too

[2] $$[CoL_2X_2] + L \rightleftharpoons [CoL_3X]^+ + X^-$$

[3] $$2[CoL_2X_2] + 2L \rightleftharpoons [CoL_5X]^+ + [CoLX_3]^-$$

In acetone it is probably not possible to confirm the dissociation in the i.r. spectra, as the region for the ν(CO) is masked and the ν(NH) is influenced by hydrogen bonding to the solvent in the case of the coordinated and uncoordinated ligand.

The bands for octahedral species reported by Madan and Sturr for CoL_3X_2 at higher concentrations, could be easily explained by a small fraction of $[CoL_5X]^+$, according to equilibrium [3], which should have a band at the same position, but with higher extinction than $[CoL_6]^{2+}$ (10). For the spectra of the solid CoL_3X_2 in Nujol, it does not seem to be correct to suppose the presence of $[CoX_4]^{2-}$ ions. Cotton *et al.* (7) reported the spectra of $[CoX_4]^{2-}$ in different compounds in different mulls. The highest shift of any ν_3 band of $[CoX_4]^{2-}$ due to different environment is 450 cm^{-1}; normally they vary in a range of 300 cm^{-1} only. All the ν_3 bands of CoL_3X_2 in Nujol are about 600 cm^{-1} higher in frequency than the bands for the respective $[CoX_4]^{2-}$ in mulls. This again suggests that fewer than four halogens are coordinated to cobalt.

Molecular Weight and Conductivity

To further confirm whether the structure of $CoCl_2.3L$ is $[CoL_6]^{2+}[CoCl_4]^{2-}$ or CoL_2Cl_2 + L, molecular weight and conductivity measurements were carried out at different concentrations (Table IV). In the case of $[CoL_6][CoCl_4]$, a degree of association of 1 would be expected. We found a degree of association of 0.5 at 0.012 mole concentration which, together with the molar conductance values at various temperatures and concentrations, corresponds to the structure CoL_2Cl + L in solution. Moreover, if an ion $[CoX_4]^{2-}$ was present in solution, it could be precipitated by tetraphenylarsonium chloride. We found that no precipitate was obtained on mixing the two in acetone solutions.

The i.r. spectra (Table III) show, that the ν(NH) as well as the ν(CO) are lowered on complex formation. The shift in ν(CO) indicated coordination through oxygen (1). In our previous article (2) it was concluded from the shift of ν(NH) in the i.r. spectra of complexes of cobalt(II) halides with 2-thiazolidinethione, that the site of coordination was nitrogen. ν(NH) was lowered by 265, 225, and 175 cm^{-1} for the $CoCl_2$, $CoBr_2$, and CoI_2 complex of this ligand

respectively. We found shifts of 126, 138, and 116 cm^{-1} for the ν(NH) of the 2-pyrrolidinone complexes of $CoCl_2$, $CoBr_2$, and CoI_2. In order to obtain a complex of 2-pyrrolidinone, where the site of coordination is expected to be oxygen (11), we prepared the complex to the ligand with BCl_3. It was found to be a 1:1 compound and showed a lowering of ν(CO) of 45 cm^{-1} and a lowering of ν(NH) of 89 cm^{-1}.

The earlier conclusion, that coordination through nitrogen of cyclic thioamides is accompanied by a lowering of the ν(NH) of about 200 cm^{-1} does not, therefore, conflict with the present findings of a lowering of the ν(NH) of about 100 cm^{-1} in the case of coordination through oxygen.

As the i.r. spectra in Nujol, unlike those in solution, indicate that all ligand molecules are coordinated, and from the conclusion drawn from the electronic spectra, it seems reasonable to assume a structure $[CoL_3X]X$ for the complexes in the solid phase.

The assignments of other i.r. bands are given in Table III.

Ferric benzoylacetanilides

A. Syamal

Department of Chemistry, Emory University, Atlanta, Georgia, U.S.A.

Received September 10, 1968

Ferric chelates with benzoylacetanilide and benzoyl-metanitroacetanilide have been prepared and characterized. The complexes are dark red in color and are paramagnetic (μ_{eff} = 5.8 B.M.). Electrolytic conductance, electronic spectra, and infrared spectra of the complexes are reported. Absorption spectra point to weak donor ability of the ligands in comparison to acetylacetone. The complexes are octahedral.

Canadian Journal of Chemistry, 47, 1693 (1969)

There has been appreciable interest in the ferric β-diketone complexes from the standpoint of syntheses, spectra, and structure (1–5). Though ferric complexes with β-diketones are well established, nothing has appeared so far in the literature concerning the ferric complexes of benzoylacetanilides, which are capable of keto–enol tautomerism shown by β-diketones. Little work has been

reported concerning the complexing ability of benzoylacetanilides. Syntheses of oxo-vanadium(IV), dioxo-molybdenum(VI), dioxo-uranium(VI), Ti(IV),Cu(II) (6, 7), and reports concerning the estimation of titanium, vanadium, and mercury (8) are all that have appeared so far. This report describes the syntheses and characterization of ferric chelates with benzoylacetanilide and benzoylmetanitroacetanilide.

Experimental

Ferric sulfate hexahydrate was a product of E. Merck (Germany). Benzoylacetanilide and benzoyl-metanitroacetanilide were prepared according to the published procedures (6, 9).

General Method of Syntheses of the Complexes

Ferric sulfate hexahydrate (1.0 g, 2 mmoles) was dissolved in 30 ml of hot water and a few drops of concentrated H_2SO_4. The appropriate amount of the ligand used was weighed out for a 1:3, Fe^{3+}:ligand complex. This was dissolved in a minimum amount of hot ethanol and this solution was added to the Fe^{3+} solution. To the resulting violet solution, dilute sodium acetate was added dropwise with stirring. The separated dark red oily layer was taken up with ethanol. Water was added dropwise to the ethanol solution resulting in the formation of dark red crystals. These crystals were suction filtered and washed with hot water followed by a warm 50% water–ethanol solution. The product was dried in a desiccator over $CaCl_2$ and P_4O_{10}.

Methods

The electrolytic conductance was measured with the help of a conductivity bridge (fitted with magic eye) and a dip type cell. Room temperature magnetic susceptibility measurements were taken in a Gouy Balance using A.R. $CuSO_4\cdot 5H_2O$ as the calibrant. Electronic absorption spectra in the region of 12.5–50 kK were recorded in methanol solution (concentration varying from 0.5×10^{-3} to 1.0×10^{-3} M) with the help of a Perkin–Elmer spectrophotometer. Infrared (i.r.) spectra were measured in Nujol mulls on a Perkin–Elmer recording spectrophotometer, model 21.

The analyses, molar conductance, and magnetic moment of the compounds are recorded in Table I. The electronic spectral characteristics of the complexes are presented in Table II.

Results and Discussion

When alcoholic solution of benzoylacetanilides is added to an aqueous solution of Fe^{3+}, a fine purple color is formed. Formation of this purple color is characteristic of benzoylacetanilides and no other metals interfere in this color reaction. The analytical data show that the Fe^{3+}: ligand ratio in the complexes is 1:3. The complexes are in general insoluble in water and soluble in methanol, ethanol, chloroform, and carbontetrachloride. The electrical conductance measurements of the complexes in methanol ($\Lambda_M \sim 1$ Ω^{-1} at 25 °C) indicate nonelectrolytic nature of the complexes. The complexes are all paramagnetic and record a magnetic moment ($\mu_{eff} \sim 5.8$ B.M.) close to the spin-only value. This value is in close agreement with the high-spin octahedral structure with 5 unpaired electrons in $3d^5$ system and having Fe^{3+} in the ^6S ground state level (10). The u.v. and visible spectra of the complexes exhibit 2 intense bands around 20.6 and 27.5 kK. These two bands are electron transfer bands corresponding to the transitions $\pi \rightarrow \nu_5$ and $\nu_3 \rightarrow \pi^*$, respectively (4). The high molar absorptivity of these bands is indicative of electron transfer bands rather than the weak, spin-forbidden bands (3, 4). The latter are the only type of d $\leftrightarrow$ d transitions expected in an O_h symmetry Fe^{3+} environment. Probably the characteristic spin-forbidden bands are obscured by the low energy tails of the electron transfer bands and this observation is in line with other octahedral spin-free iron(III) complexes (10). The corresponding

Benzoyl-metanitro-acetanilide	22	20.6(3.20)	40	—	46	—	28	27.2(3.50)
Acetylacetone‡	23	23.2(3.47)	41	—	45	—	27	28.5(3.55)

†$V_1 = 30$ kK, $V_2 = 18$ kK, $\Delta = 18$ kK, $D = 4.5$ kK, $E - A = 4$ kK (1 kK = 1000 cm^{-1}).
‡Taken from ref. 4 for comparison. Figures in the parentheses indicate log ε.

electron transfer bands in *tris*(acetylacetonato) iron(III) occur at 23.2 kK (log ε = 3.47) and 28.5 kK (log ε = 3.55) (3). The band positions suggest that the ligand field of *tris*(acetylacetonato) iron(III) is stronger than those of *tris*(benzoylacetanilido) iron(III) and *tris*(benzoyl-metanitroacetanilido) iron(III). In the uranyl complexes (6) of the present ligands, the OUO stretch frequency was also observed at lower energy than those of the OUO stretch frequency of *bis*(acetylacetonato) UO_2(VI). Thus the electronic absorption spectra undoubtedly identify the ligands benzoylacetanilides as weak donors in comparison to acetylacetone.

Generally 4 electron transfer transitions from or to the π levels of the ligand are expected for octahedral high-spin complexes of the type $Fe(acac)_3$ or $Fe(benzoylacetanilide)_3$. These 4 different electron transfer spectra are (4) I, $\pi \rightarrow \nu_5$; II, $\pi \rightarrow \nu_3$; III, $\nu_5 \rightarrow \pi^*$; and IV, $\nu_3 \rightarrow \pi^*$. For a high spin d^5 configuration the dependence on the parameters V_1, V_2, $E - A$, and D of the transitions I, II, III, and IV is given as $V_1 - 5(E - A) + 8/3\ D$, $V_1 + \Delta - 5(E - A) + 8/3\ D$, $V_2 + 4(E - A) + 8/3\ D$, and $V_2 - \Delta + 4(E - A) + 8/3\ D$, respectively, where V_1 and V_2 are related by the equation: $V_2 + V_1 - (E - A) = 44$ kK (4). D is roughly $7B$ for d electrons, and is known from internal transitions in the d shell of similar complexes to be approximately 4.5 kK. From the experimental results the value of V_1 is derived, noting that the strong band of $Fe(benzoylacetanilide)_3$ or $Fe(benzoyl\text{-}metanitroacetanilide)_3$ at 20.6 kK must belong to the category I. Δ, the ligand field splitting parameter, is assumed to be of the same value (18 kK) as in $Fe(acac)_3$ due to the very close positions of these two types of ligands in the spectrochemical series, and it allows the calculation to be made without prior knowledge of the spectrum. Thus good agreement between the calculated and observed energies of the electron transfer transitions was obtained by choice of suitable parameters (cf. Table II). The electron transfer bands II and III were not observed in these complexes as these bands were obscured by the intense charge-transfer spectra at the calculated frequencies. In the corresponding acetylacetonato complex also, these bands were not observed due to the same reason.

The i.r. spectra of the complexes were characterized by the presence of chelated carbonyl absorptions. In both the complexes the normal carbonyl vibration of the ligand is replaced by metal coordinated carbonyl absorptions at much lower frequencies. The carbonyl spectrum of the chelating ligands benzoylacetanilide and benzoyl-metanitroacetanilide occur at 1700 and 1670 cm^{-1}, respectively. *Tris*(benzoylacetanilido) iron(III) and *tris*(benzoyl-metanitroacetanilido) iron(III) exhibit chelated carbonyl absorptions at 1.66 and 1.625 kK, respectively. The frequency of the carbonyl band of the ligands is therefore shifted to lower frequency (∼ 0.04 kK) by coordination with ferric ion.

Reaction of atomic hydrogen with tetrafluoroethene[1]

LEI TENG AND W. E. JONES
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received August 20, 1968

Hydrogen atoms, generated in a Wood's electric discharge tube, were allowed to react with tetrafluoroethene. The products of the reaction were found to be HF, C_2F_3H, C_2H_2, $C_2F_2H_2$, $C_2F_4H_2$, C_2FH_3, C_2H_4, and CHF_3. The formation of the products with the exception of HF was studied quantitatively from 30–330 °C.

Canadian Journal of Chemistry, 47, 1696 (1969)

Introduction

The reactions of atomic hydrogen with fluorocarbons have received only summary attention in the past. Chadwell and Titani (1), using the discharge tube method at room temperature, found no reaction of hydrogen atoms with methyl fluoride. Later, Dacey and Hodgins (2) investigated the mercury photosensitized reactions of the mixture of tetrafluoromethane and hydrogen molecules but again no evidence was found for the occurrence of a reaction. Clark and Tedder (3–5) studied a series of free radical substitutions in aliphatic compounds. They found that the first step in the reactions of hydrogen atoms with bromotrichloromethane and fluorotrichloromethane was the abstraction of a halogen atom. The resulting trihalomethyl radical added H to form a vibrationally excited molecule, which either stabilized or decomposed by elimination of HX. If fluorocarbons were the reactant species, the elimination of HF always occurred in preference to stabilization.

The kinetics of the reaction of hydrogen atoms with tetrafluoroethene were investigated by Allen, Melville, and Robb (6). They did not study the products of the reaction and it thus seemed worthwhile to study the products of this reaction in an attempt to get an insight into the reaction mechanism.

[1]Presented at the 51st Conference of the Chemical Institute of Canada, Vancouver, June 1968.

Experimental

Hydrogen was supplied by Canadian Liquid Air Ltd. Ethane, ethene, hexafluoroethane, acetylene, and 1,1-difluoroethene were obtained from Matheson Company of Canada Ltd.; trifluoromethane and tetrafluoroethene were obtained from Pierce Chemical Company. Each of these gases was frozen in a liquid nitrogen trap and traces of non-condensable gases were pumped off.

The flow system for this work was a typical Wood–Bonhoffer system similar to those described by many workers. Dry hydrogen flowed into each end of the V-shaped discharge tube. The power from a 3000 V Hammond transformer was rectified and supplied to the discharge tube through a 5000 Ω resistor. With 80 V across the primary of the transformer, and a hydrogen pressure of 4.60 mm Hg, a stable discharge and a stable production of atomic hydrogen were obtained. A molecular hydrogen flow rate of 182×10^{-6} moles/s produced the above pressure when a Cenco HyperVac No. 23 was used as the vacuum pump. The hydrogen atom flow rate was estimated at 0.8×10^{-6} moles/s by reaction with 2-dimethylethylenimine (7).

The mixture of atomic and molecular hydrogen passed from the discharge tube into a cylindrical reaction vessel made from 25 mm o.d. Pyrex tubing. Tetrafluoroethene was admitted to the hydrogen stream through a jet centered in the reaction vessel. The wall of the reaction vessel was thoroughly poisoned with phosphoric acid.

Qualitative and quantitative analysis of the reactant and products was made by gas–liquid chromatography (g.l.c.) on a column of $\frac{1}{4}$ in. copper tubing packed with silica gel which had been coated with 3% squalane (8). Identification was made by comparison of retention times, and where necessary, from mass and infrared (i.r.)

spectra. Quantitative analysis was made by comparison of peak heights with peak height calibration curves prepared by using pure samples of each gas.

Results and Discussion

The products of the reaction of atomic hydrogen with tetrafluoroethene were identified as hydrogen fluoride, 1,1,2-trifluoroethene, acetylene, 1,1-difluoroethene, 1,1,1,2-tetrafluoroethane, vinyl fluoride, ethene, and fluoroform. The production of these products was studied quantitatively[2] for the three temperatures 30, 230, and 330 °C. The compounds C_2FH_3, C_2H_4, and CF_3H have not been included in the quantitative results since the amounts formed were barely detectable and not sufficient to measure quantitatively.

Figure 1 illustrates the flow rate of reacted C_2F_4 and product flow rates at 30 °C. At this temperature, the flow rate of C_2F_4 reacted appears to reach a limiting or plateau value of 4.4 μmoles/s. The major product at 30 °C is C_2F_3H, followed by lesser amounts of C_2H_2, $C_2F_2H_2$, and $C_2F_4H_2$.

At 230 °C similar curves are found, as shown in Fig. 2. At this temperature, the plateau value for the flow rate of C_2F_4 reacted is slightly less than at 30 °C, having a value of 3.9 μmoles/s. The major product now becomes C_2H_2, the flow rate of which has approximately doubled over that formed at 30 °C. It would appear that C_2H_2 has formed at the expense of C_2F_3H, since the flow rate of this product has decreased to approximately half its value at 30 °C. The flow rate

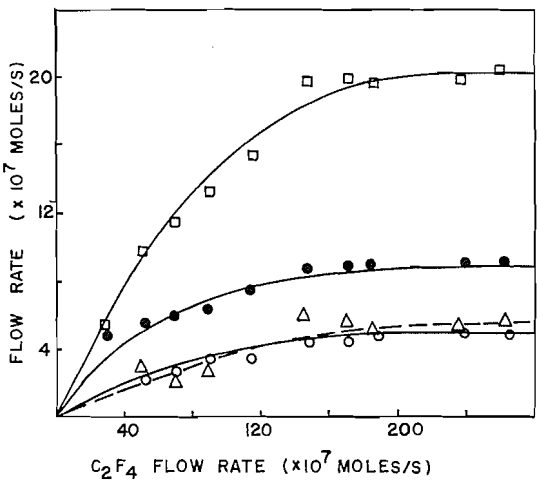

FIG. 3. Flow rates of major products at 330 °C. □, C_2F_4 reacted; product flow rates: ○, C_2F_3H; ●, $C_2F_2H_2$; △, C_2H_2.

of the product $C_2F_2H_2$ has increased slightly while that of $C_2F_4H_2$ has decreased to become almost negligible.

At 330 °C the maximum flow rate of C_2F_4 reacted has fallen to 2.0 μmoles/s as shown in Fig. 3. The major product is now $C_2F_2H_2$ while the production of C_2H_2 and C_2F_3H has dropped markedly and the flow rate of $C_2F_4H_2$ has become negligible.

The original purpose of this study, namely, the determination of the reaction mechanism, has now become extremely complicated by the large number and type of products formed. In order to assist in the formulation and substantiation of the mechanism for this reaction, the reactions of several related compounds are presently under study. These results and the mechanism will be presented in the near future.

Detection of the triple ion (durosemiquinone-Na_2)$^+$ by electron spin resonance spectroscopy

T. E. GOUGH AND P. R. HINDLE
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received November 25, 1968

Reduction of duroquinone by sodium in tetrahydrofuran and in 2-methyltetrahydrofuran in the presence of sodium tetraphenylboride yields the triple ion (durosemiquinone-Na_2)$^+$ which shows hyperfine interaction with twelve equivalent hydrogen and two equivalent sodium nuclei. When the reduction is performed in 1,2-dimethoxyethane, the triple ion is not formed, and the electron spin resonance spectra indicate the presence of an intermolecular cation exchange process.

Canadian Journal of Chemistry, 47, 1698 (1969)

The presence of triple ions in solution has been postulated in the interpretation of conductivity data (1–3); however, there appears to be no well authenticated case of their detection by electron spin resonance (e.s.r.) spectroscopy, in spite of the large number of investigations of ionic association using this technique (4). Triple ions of the formula M_2A^+, where A^- is a radical anion, should be characterized by the interaction of the unpaired electron with the nuclei of two counterions; care should be taken to ensure that the observed species is not an ionic quadrupole, because

the ionic quadrupoles formed by aliphatic (5) and aromatic (6) ketyls also show hyperfine splitting from two alkali metal nuclei. If the electron spin dipolar interaction between the two A^- systems of the quadrupole is strong, then the quadrupole may be recognized by its characteristic solid state e.s.r. spectrum (7). However, if the dipolar interaction is weak, it becomes difficult to distinguish between a triple ion and an ionic quadrupole; for these reasons no firm assignment has been made for the species obtained when naphthalene was reduced for long periods of time by sodium in tetramethylethylenediamine (6).

Reduction of quinones by alkali metals in ethereal solution forms mixtures of free and associated semiquinones (8, 9). Reduction of duroquinone by sodium in tetrahydrofuran was difficult because the sodium rapidly became coated with a coherent greenish film, presumably of the reduction product. An e.s.r. spectrum of the solution recorded at a sample temperature of $-20°$ is given in Fig. 1*a*; it may be analyzed in terms of six equivalent protons with a hyperfine splitting constant of 2.66 G, six equivalent protons with a splitting of 1.20 G, and one sodium with a splitting of 0.25 G. These values are in good agreement with those of a previous report (10). When a 1:1 molar mixture of duroquinone and sodium tetraphenylboride was similarly reduced, the reaction proceeded instantaneously, no protective film was formed on the sodium, and at a sample temperature of $-20°$ the e.s.r. spectrum given in Fig. 1*b* was obtained; this spectrum was analyzed in terms of twelve equivalent protons with a hyperfine splitting constant of 1.94 G, and two equivalent sodium nuclei with a splitting of 0.17 G. No signal was obtained when the reduction of duroquinone by sodium in 2-methyltetrahydrofuran was attempted; the addition of sodium tetraphenylboride allowed rapid reduction to a solution having an intense e.s.r. spectrum analogous to that of Fig. 1*b*. In Fig. 2 the measured sodium hyperfine splitting constants of the three systems are plotted as a function of temperature. For spectra such as that in Fig. 1*b*, the measured proton hyperfine splitting constant was always equal, within experimental error, to the accepted value for durosemiquinone (11) and to the value for the dihydroxydurene cation (12). The e.s.r. spectrum of frozen solutions of the species responsible for Fig. 1*b* was a single line, 12 G wide, at $g = 2$; no half-field resonance was detected.

We attribute the spectrum in Fig. 1*b* to a triple

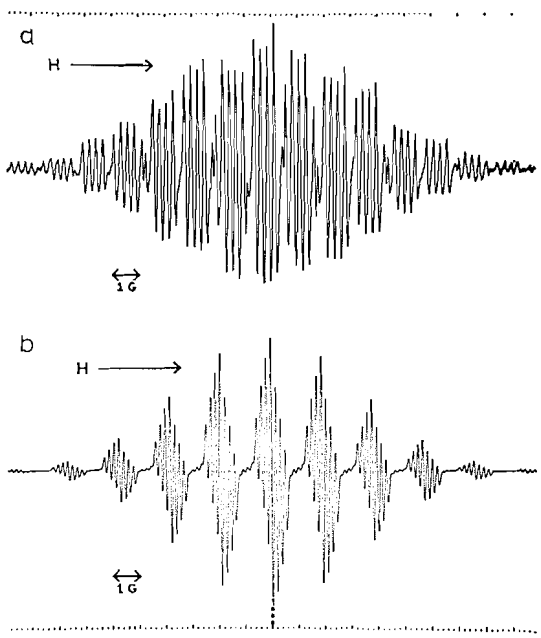

FIG. 1. (*a*) Electron spin resonance spectrum of the solution obtained after the reduction of duroquinone by sodium in tetrahydrofuran; sample temperature -20 °C. (*b*) Electron spin resonance spectrum of the solution obtained after a similar reduction in the presence of sodium tetraphenyl boride; sample temperature -20 °C; the low intensity lines between the main groups are caused by a C^{13} splitting of 1.42 G from the methyl groups.

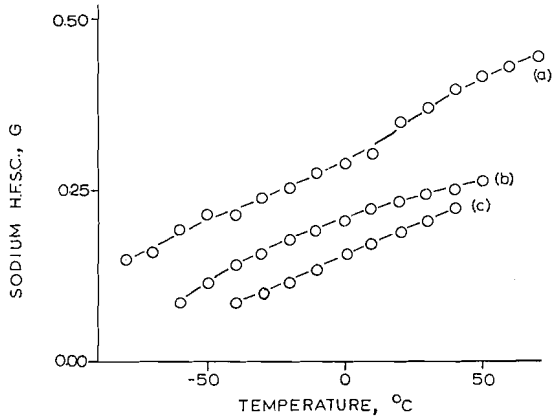

FIG. 2. The dependence upon temperature of the sodium hyperfine splitting constants of the ion-pair (durosemiquinone–Na) in tetrahydrofuran, plot (*a*); and of the triple ion (durosemiquinone-Na_2)$^+$ in tetrahydrofuran, plot (*b*); and in 2-methyltetrahydrofuran, plot (*c*).

ion rather than an ionic quadrupole, because the addition of sodium ions in excess of those introduced by the reduction process is necessary for the formation of this species. Of a substantial number of investigations of the reduction of quinones in ethereal solution (8–10, 13–16), none has given any indication of hyperfine splitting from more than one alkali metal nucleus. Furthermore, the marked increase in solubility (a factor of at least 10^3) of the semiquinone in the presence of added sodium tetraphenylboride indicates that an interaction takes place between the existing ion-pairs and the added salt. Structurally, the triple ion may be thought of as a durosemiquinone anion ionically associated with a sodium cation at each oxygen, a configuration which makes all four methyl groups equivalent. Since each cation of the triple ion will be attracted to a lesser extent than the cation of the ion-pair, the smaller sodium splitting observed when two cations interact supports the hypothesis that a triple ion is formed. Dimerization of the ion-pairs to form ionic quadrupoles should not affect the magnitude of the sodium hyperfine splitting constant.

The addition of a sodium salt does not necessarily bring about the formation of triple ions. Thus, when 1,2-dimethoxyethane was used as the solvent, complex spectra indicating the presence of intermolecular cation exchange processes analogous to those discussed for the *m*-dinitrobenzene anion (17) were obtained; similarly, triple ion formation was not observed (18) when sodium iodide was added to ion-pairs of sodium-9,10-anthrasemiquinone dissolved in 1,2-dimethoxyethane, or to ion-pairs of sodium-2,5-di-*t*-butyl parabenzosemiquinone dissolved in tetrahydrofuran. Semiquinone ion-pairs may also be generated in alcoholic solution in the presence of excess alkoxide (19, 20), but once again, the presence of excess cations does not lead to the formation of triple ions. We are at present conducting a systematic study of the factors which control the formation of triple ions.

Hot molecules in radical combination

T. N. Bell and U. F. Zucker
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received February 25, 1969

1:1 Difluoroethylene is formed when CF_3 radicals react with alkyl silanes. We propose that the olefin results from the rearrangement and decomposition of a hot molecule arising from radical recombination

$$CF_3 + CH_2SiX_3 \rightarrow CF_3CH_2SiX_3^* \xrightarrow{M} CF_3CH_2SiX_3$$
$$\searrow CF_2CH_2 + FSiX_3$$

Canadian Journal of Chemistry, 47, 1701 (1969)

In the presence of the alkylsilanes $(CH_3)_4Si$, $(CH_3)_2SiF_2$, and CH_3SiF_3, the photolysis of hexafluoroacetone (HFA) leads to the expected radical products CF_3H and C_2F_6, but in addition, some CF_2CH_2 is formed. We suggest that this does not arise from a reaction involving excited HFA* with the silanes, from the following evidence: (*a*) The emission spectrum of HFA is not quenched but slightly enhanced by the silanes, in a manner similar to third bodies such as CO_2 (1). (*b*) Addition of sufficient oxygen to quench ^{3}HFA (2) does not suppress the CF_2CH_2 to zero, some 16 mm O_2 being required to eliminate this product. While this does not eliminate ^{1}HFA*, it does suggest that oxygen is acting as a radical scavenger. (*c*) CF_2CH_2 is still formed when the pyrolysis and photolysis of hexafluoroazomethane is used as a radical source.

The CF_2CH_2 is therefore considered to arise from some reaction involving CF_3 radicals. Hydrogen abstraction will lead to CH_2SiX_3 radicals, and the following recombination is possible.

[1] $$CF_3 + CH_2SiX_3 \rightarrow CF_3CH_2SiX_3$$
(X = Me and/or F)

F atoms in a position β to silicon are known to be labile (3*a*, *b*), leading to the thermal unimolecular elimination [2].

[2] $$CF_3CH_2SiX_3 \xrightarrow{\text{Heat}} CF_2CH_2 + FSiX_3$$

In Fig. 1 is plotted the amount of CF_2CH_2 formed when HFA, 60.5 mm, and CH_3SiF_3, 210 mm, were photolyzed for 1 min at 204°, and the reaction mixture then allowed to stand at 204° in the dark for varying periods. It is clear that $R_{CF_2CH_2}$ during photolysis is considerably greater than that formed in the dark reaction. The amount of CO, CF_3H, and C_2F_6 showed no change during this thermal reaction. SiF_4 was also found (infrared and mass spectra). No reaction products were formed on heating the reaction mixture without a period of photolysis.

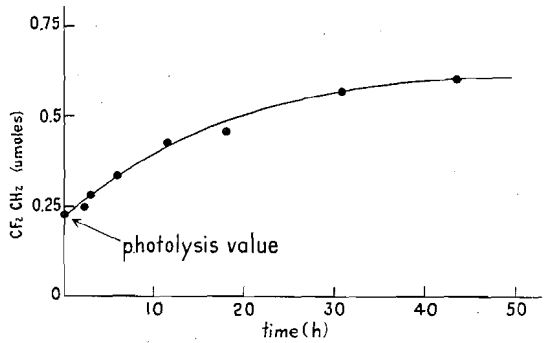

FIG. 1. Amount of CF_2CH_2 formed against time for a photolysis time of 60 s (P_{HFA} 60.5 mm; $P_{CH_3SiF_3}$, 210 mm; temperature, 204°).

In order to explain these results we suggest the formation of a hot molecule in the recombination reaction [3], which leads to the CF_2CH_2 formed during photolysis, reaction [4*b*].

[3] $$CF_3 + CH_2SiF_3 \rightarrow CF_3CH_2SiF_3^*$$

This may be stabilized or decomposed according to reactions [4*a*] and [4*b*],

[4*a*] $$CF_3CH_2SiF_3^* \xrightarrow{M} CF_3CH_2SiF_3$$
[4*b*] $$\searrow CF_2CH_2 + SiF_4$$

The dark reaction leading to the much slower $R_{CF_2CH_2}$ is ascribed to the thermolysis [5].

[5] $$CF_3CH_2SiF_3 \rightarrow CF_2CH_2 + SiF_4$$

The absence of products expected from methyl radicals, allows us to ignore elimination from CF_3CH_3* as a source of CF_2CH_2 (4*a*, *b*).

If the other reactions of CF_3 radicals are hydrogen abstraction, and recombination [6] and [7]

[6] $$CF_3 + CH_3SiF_3 \rightarrow CF_3H + CH_2SiF_3$$

[7] $$CF_3 + CF_3 \rightarrow C_2F_6$$

then, provided reaction [5] goes to completion, $CO = C_2F_6 + \frac{1}{2}CF_3H + \frac{1}{2}CF_2CH_2$. After 43.5 h, we have, as shown in Fig. 1

$$3.75_{(CO)} = 2.95_{(C_2F_6)} + 0.45_{(\frac{1}{2}C_2F_6)} + 0.30_{(\frac{1}{2}CF_2CH_2)} \quad \text{(amounts in μmole)}$$

The CF_3 discrepancy immediately after photolysis is thus recovered during the dark reaction.

A first order Guggenheim plot of the pyrolysis results in Fig 1 gives a good straight line from which $k_5 = 1.6 \times 10^{-5}\ s^{-1}$.

Assuming $A_5 \sim 10^{12}$ yields $E_5 \sim 37$ kcal in agreement with Arrhenius parameters for similar decompositions (3*b*). The hot molecule formed in reaction [3] thus has a large enough excess energy to decompose, assuming the new C—C bond to have a strength ~ 85 kcal.

From reactions [4*a*] and [4*b*], we obtain

[8] $$R_{4a}/R_{4b} = k_{4a}[M]/k_{4b}$$

$R_{4a}/R_{4b} \simeq CF_2CH_2$ (total from pyrolysis)/CF_2CH_2 (photolysis)

The pressure dependence of this ratio is shown below for experiments with photolysis times of 2 min at 200°. The dark decomposition was carried out at higher temperatures. The linear relationship predicted by eq. [8] is not observed. Using the arguments of Pritchard (5*a*, *b*) this could be ascribed to different collisional efficiencies of the two molecules, and multistep deactivation in reaction [4*a*].

TABLE I

Pressure dependence of R_{4a}/R_{4b}

Pressure of M (mm)		
HFA	CH_3SiF_3	R_{4a}/R_{4b}
60.5	210	1.74
116	69	0.76
49.5	70.5	0.67
38.2	48.7	0.30
30.0	30.0	0.15
10.0	20.0	0.06
4.9	10.6	0.09

Elimination reactions from hot molecules formed from radical recombination have been shown to be important (4*a*, *b*; 5*a*, *b*). In our case both rearrangement, presumably through the silicon d orbitals, and elimination occur, and exemplify a new type of process.

It is intended to make a full study of this reaction, and extend the work to systems containing boron, germanium, and tin.

Atmospheric electron–ion and ion–ion recombination processes[1]

MANFRED A. BIONDI
Physics Department, University of Pittsburgh, Pittsburgh, Pennsylvania 15213

Received December 17, 1968

The electron–ion and ion–ion recombination processes of importance in the upper atmosphere are considered, and available laboratory experimental and theoretical information concerning the relevant processes is discussed. For atomic ions the principal electron–ion recombination process is radiative, with theory indicating that the two-body coefficient at ~200 °K is $\sim 10^{-11}$ cm³/s and decreases with increasing electron temperature. Microwave afterglow/mass spectrometer studies of diatomic ionospheric ions (e.g. NO^+, O_2^+, and N_2^+) show a loss by dissociative recombination with a coefficient substantially in excess of 10^{-7} cm³/s at 250 °K and decreasing with increasing electron and ion temperature. There is some evidence from flame studies that H_3O^+ ions exhibit a very large coefficient (10^{-6}–10^{-5} cm³/s) at 300 °K. Ion–ion recombination evidently proceeds by mutual neutralization, with laboratory studies of ions such as NO^+ and NO_2^- indicating a two-body coefficient of the order of 10^{-7} cm³/s at 300 °K. In the lower D region, three-body Thomson recombination may be important, since laboratory studies of "air" ions indicate a three-body coefficient of $\sim 2 \times 10^{-25}$ cm⁶/s at 300 °K.

Canadian Journal of Chemistry, 47, 1711 (1969)

Introduction

The purpose of the present paper is to single out those processes of electron–ion and ion–ion recombination which are of importance in the upper atmosphere, and to discuss the available information from laboratory experiments and theoretical calculations concerning these processes. In order to make clear some of the limitations of current theoretical treatments, results of certain experiments involving non-atmospheric ions will also be discussed. The present paper, in part, brings up to date the reviews presented at the I.A.G.A. Aeronomy Symposium of 1963 (1) and at the COSPAR meeting in Vienna in 1966 (2).

Although conditions encountered in the upper atmosphere are somewhat variable and there is by no means complete agreement concerning the constituents, we have adopted the model given in Table I in order to make clear the regions of operation of the various recombination processes. Several features are apparent from the Table; atomic positive ions predominate in certain regions and molecular ions in others, the neutral density is sufficiently large to affect recombination rates only in the D region, and the electron temperature appreciably exceeds the ion temperature in certain regions (in addition, although not given in the Table, the charged particle densities are rather modest, $< 10^6$ cm^{-3}). The significance of these features will be made clear in the next section.

[1]Some of the research described in this paper has been supported by the Army Research Office (Durham) DA-ARO-D-124-G965, by the Defense Atomic Support Agency, and by the Advanced Research Projects Agency, DA-31-124-ARO-D-440.

Electron–Ion Recombination

The significant electron–ion recombination processes occurring in the ionosphere are dissociative and radiative recombination. These processes involve the capture of the electron by the positive ion without the assistance of a third body in the reaction. We rule out as unimportant three-body processes involving electrons or neutral molecules acting as the third bodies, since the electron-stabilized case theory (3) indicates that the three-body coefficient decreases rapidly with increasing electron temperature from a value of $< 10^{-18}$ cm⁶/s at 250 °K, leading to a maximum effective two-body coefficient, "α", of $< 10^{-13}$ cm³/s which occurs at E-layer altitudes. The available experimental information (see, for example, ref. 4) supports the results of the calculations.

In the neutral stabilized cases, calculations (5) of the three-body coefficient ($\lesssim 10^{-26}$ cm⁶/s for a monatomic third body and $\lesssim 10^{-25}$ cm⁶/s for diatomic third body at 250 °K) suggest that the maximum rate, which would occur in the E region, is equivalent to a two-body coefficient of "α" $< 10^{-12}$ cm³/s. As we shall see, dissociative recombination outweighs this process by a factor of $> 10^5$ and at higher altitudes, where the neutral concentration is lower, even radiative recombination is of greater importance.

A. Radiative Recombination

In the case of atomic positive ions in the

‡H^+ is the principal ion at solar minimum, while He^+ is believed to be the principal ion at solar maximum.

ionosphere, electron capture proceeds via two-body radiative recombination in which an electron makes a radiative transition from a free (continuum) state to a bound state of the resulting atom, i.e.

$$[1] \qquad X^+ + e \rightarrow X^* + h\nu$$

where X^+ and X^* denote ionized and excited states of the atom X. Probably the best information concerning the rates of radiative recombination comes from theoretical calculations (6, 7). It is found that the recombination coefficient is not particularly sensitive to the identity of the positive ion, varying by less than a factor of two in going from H^+ to K^+. The partial recombination coefficient for electron capture into the lower states of the excited atom varies as $T_e^{-0.5}$ (T_e is the electron temperature), while for capture into the highly excited states lying within $\sim kT_e$ of the continuum, it varies approximately as $T_e^{-1.5}$. The total recombination coefficient varies approximately as $T_e^{-0.7}$, starting from a value of $\sim 5 \times 10^{-12}$ cm^3/s at 250 °K. Few experimental studies of recombination have been carried out under conditions where radiative recombination is the predominant process; those that have (see, for example, ref. 8) yield α values in reasonable agreement with theory.

As we shall see shortly, dissociative electron–ion recombination exhibits α values $\gtrsim 10^{-7}$ cm^3/s at electron temperatures $\lesssim 1000$ °K; therefore radiative recombination will be the predominant electron loss process only in regions where the concentration ratio of atomic to molecular ions is $\gtrsim 10^4$. The required atomic ion excess is found in the magnetosphere and the protonosphere and possibly in the sporadic-E layer, and in the latter case the small rate of radiative recombination may account for the layer's persistence.

B. Dissociative Recombination

In those regions of the ionosphere containing molecular ions, electrons are removed by the highly efficient dissociative recombination process. The direct process may be represented in reaction form by

$$[2] \qquad XY^+ + e \rightleftharpoons (XY^*)_{unstable} \rightleftharpoons X + Y + \text{kinetic energy}$$

Here the large recombination coefficient ($\alpha_{diss} \geqslant 10^{-7}$ cm^3/s) results from the radiationless initial capture step (which involves no energy change) which forms the unstable excited molecule, followed by a high probability of dissociation before auto-ionization (first portion of reaction [2] going to the left).

At present the most detailed information concerning the recombination coefficients of molecular ionospheric ions has been obtained from a rather wide variety of experimental studies. We shall discuss these first, emphasizing those experiments in which the ion identity is clearly established, and then shall review recent progress in theoretical calculations of dissociative recombination. As will be seen from Table I, the ions involved are NO^+, O_2^+, N_2^+, H_3O^+, and its hydrated forms. In order to be of use in ionospheric calculations, it is important that the laboratory measurement establish clearly the identity of the ion undergoing recombination and specify as well as possible the electronic and vibrational state of the ion.

Studies of the recombination of electrons with NO^+ ions have been carried out over the temperature range 200–450 °K by Weller and Biondi (9)

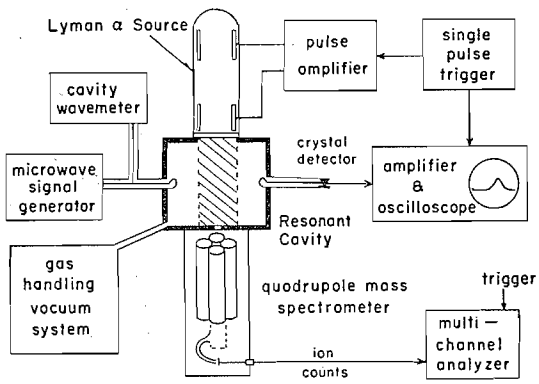

FIG. 1. Schematic diagram of a typical microwave afterglow apparatus employing mass analysis of the ions undergoing electron–ion recombination. In this case a photoionizing source is used to ionize the gas.

using the microwave afterglow apparatus shown in Fig. 1. The NO^+ ions are created in their ground electronic state and in the first few vibrational levels by a pulse of Lyman α radiation (a "single pulse-afterglow" technique is used to avoid negative ion accumulation effects). The recombination coefficient is determined by measuring the rate of decay of average electron density during the afterglow following the pulse (using microwave resonant cavity frequency shift techniques), and the ions undergoing recombination are identified by a mass spectrometer which simultaneously measures the ion currents diffusing to the cavity wall and effusing through a small hole. (Only those data in which the NO^+ ion wall current satisfactorily follows the volume decay of electron density are considered trustworthy.)

In order to obtain accurate recombination coefficients from the average electron density data, computer solutions (10) of the electron continuity equation

$$[3] \qquad \partial n_e/\partial t = -\alpha n_e^2 + D_a \nabla^2 n_e$$

where n_e is the electron concentration and D_a is the ambipolar diffusion coefficient, are used to account for the effect of diffusion on the electrons' spatial distribution within the cavity. By using very low partial pressures of NO($\sim 10^{-2}$ Torr) in neon buffer gas ($\sim$ 5 Torr), complex ion formation is avoided and diffusion loss sufficiently inhibited to provide recombination control of the afterglow. The results of the measurements yield values of $\alpha(NO^+)$ of $(7.4 \pm 0.7), (4.1 + 0.3 - 0.2)$, and $(3.1 \pm 0.2) \times 10^{-7}$ cm^3/s at T = 200, 300, and 450 °K, respectively. (Afterglow conditions are such that $T_e = T_i = T_n = T$.) These values are in good agreement with the results at $T \geqslant 300$ °K of Gunton and Shaw (11), who employed a similar type of apparatus but could not operate their mass spectrometer at the high buffer gas pressures required in their recombination studies. They obtained values $\alpha = (10+2, -4), (4.6+0.5, -1.3)$, and $(3.5+0.2, -0.5) \times 10^{-7}$ cm^3/s at T = 196, 298, and 358 °K, respectively. Weller and Biondi found that, at low temperatures ($\sim$ 200 °K), appreciable concentrations of the dimer ion $(NO)_2^+$ are very difficult to avoid. This ion exhibits a very large recombination coefficient; a value $\alpha[(NO)_2^+] = (1.7 \pm 0.4) \times 10^{-6}$ cm^3/s was obtained (9) at 300 °K. Thus, Gunton and Shaw's large and highly uncertain α value at 196 °K probably resulted from an appreciable concentration of $(NO)_2^+$ ions, illustrating the value of simultaneous mass analysis of the ionic species undergoing recombination.

An interesting study of the recombination of NO^+ ions produced by *chemi*-ionization in mixtures of N, O, and N_2 has been carried out by Young and St. John (12). Currents arriving at pulsed collector electrodes (no mass analysis was employed) were used to measure the rate of growth and the equilibrium value of the charge density produced by the chemi-ionization, leading to a value $\alpha(NO^+) = (4 \pm 1) \times 10^{-7}$ cm^3/s at 300 °K.

Measurements of the recombination of electrons and NO^+ ions at very high temperatures ($\sim$ 3000–5000 °K) are much less certain. Stein *et al.* (13) used microwave techniques to measure the electron density decay in shock-heated air at $\sim$ 2900 °K in which the principal ion is thought to be NO^+, obtaining a value, $\alpha \approx 4 \times 10^{-8}$ cm^3/s. Also, Lin *et al.* (14), from a complicated analysis of ionization behind shock waves in air, concluded that a value, $\alpha \approx 2 \times 10^{-8}$ cm^3/s at 5000 °K, is consistent with their electron density measurements. The measured values of $\alpha(NO^+)$ over the range 200–5000 °K are shown in Fig. 2. It will be seen that the temperature variation can be approximately represented by $\alpha \approx T^{-1}$ ($T_e = T_i = T_n = T$), although at low temperatures the data are sufficiently accurate to indicate noticeable deviations from this simple law.

Systematic studies of the recombination of

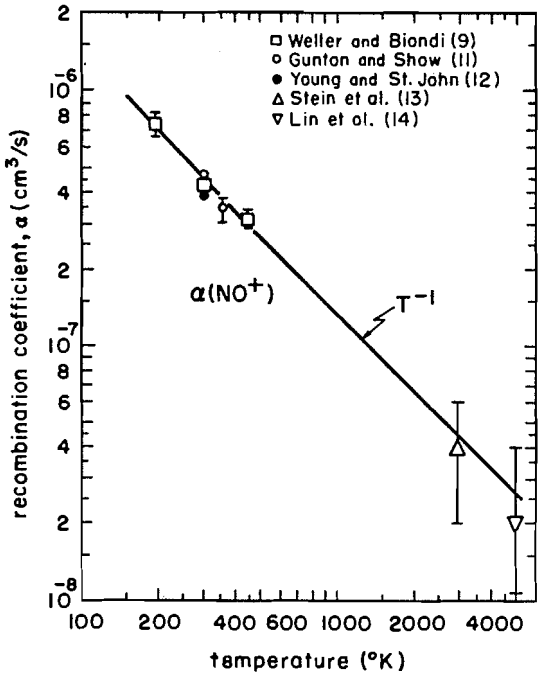

FIG. 2. Temperature dependence of the dissociative recombination coefficient $\alpha(NO^+)$ under conditions where $T_e = T_i = T_n = T$.

electrons with mass-identified O_2^+ ions have been carried out over the temperature range 200–700 °K by Kasner and Biondi (15). A microwave afterglow/mass spectrometer apparatus similar to that shown in Fig. 1 was used, except that a "single pulse" microwave discharge was used to produce O_2^+ ions in their ground electronic and a low vibrational state by a combination of Penning ionization and charge transfer reactions. Triple mixtures of O_2(~ 10^{-2} Torr), Kr(~ 1 Torr), and Ne(~ 20 Torr) were used, and the sequence of neon metastables ionizing krypton which then charge transferred with O_2 was used to prevent formation of O_2^+ ions in electronically excited states. An alternate sequence of neon metastables directly ionizing oxygen molecules can leave the O_2^+ ions in a highly excited vibrational state of the ground electronic state ($X^2\Pi_g$) or even in the metastable excited electronic state ($a^4\Pi_u$).

The recombination coefficient $\alpha(O_2^+)$ was determined from measurements of the decay of average electron density in recombination controlled afterglows. The measured decay curves were either compared with computer solutions (10) of eq. [3] or were corrected for diffusion effects using correction factors given by Gray and Kerr (16). As in the case of NO^+, at low temperatures difficulty with the measurements was encountered as a result of the appearance of significant concentrations of the dimer ion, O_4^+, under certain conditions. Kasner and Biondi obtained a value for the dimer ion recombination coefficient, $\alpha(O_4^+) \approx 2.3 \times 10^{-6}$ cm^3/s at 205 °K.

The values of $\alpha(O_2^+)$ obtained under conditions where the O_2^+ (the only significant ion) wall current satisfactorily follows the electron density decay are (3.0 ± 0.3), (2.2 ± 0.2), (1.7 ± 0.2), (1.37 ± 0.15), (1.25 ± 0.2), and $(1.0 \pm 0.2) \times 10^{-7}$ cm^3/s at 205, 300, 385, 488, 560, and 690 °K, respectively. These values are shown in Fig. 3.

Also shown in Fig. 3 are data obtained by Mentzoni (17) from microwave afterglow studies at high oxygen pressures (~ 2 Torr) which did not employ mass analysis. In view of the inability to identify the ion or its state in Mentzoni's studies, in Fig. 3 we have drawn the curve indicating the temperature dependence through the data of Kasner and Biondi. It will be seen that a single power law temperature dependence, of the form T^{-1}, is followed over the measured range.

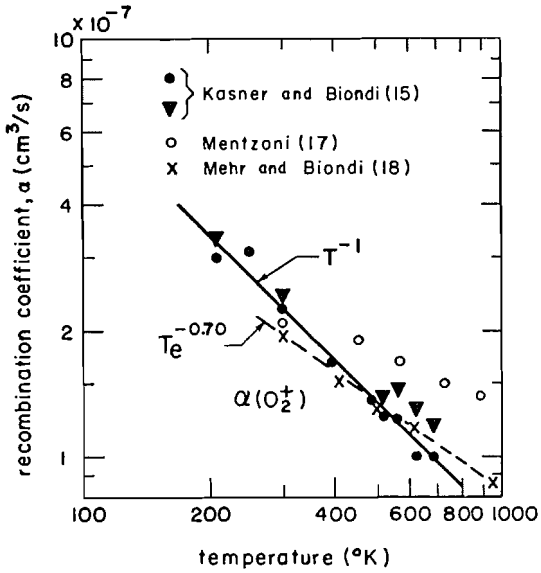

FIG. 3. Temperature dependence of the dissociative recombination coefficient $\alpha(O_2^+)$ under conditions where $T_e = T_i = T_n = T$ (solid line) and under conditions where $T_i = T_n = 300$ °K and T_e is varied (dashed line). The ● symbols indicate triple mixture (O_2, Kr, Ne) studies, while the ▼ and × symbols indicate the binary mixture (O_2, Ne) studies (see text for details).

Very recently, Mehr and Biondi (18) have used a microwave afterglow/mass spectrometer apparatus with microwave electron heating to study $\alpha(O_2^+)$ under conditions such that $T_e \geqslant T_i = 300\ °K$. For O_2^+ ions it is found that $\alpha = 1.95 \times 10^{-7}\ cm^3/s$ at $T_e = 300\ °K$ and decreases as $T_e^{-0.70}$ up to $T_e = 1200\ °K$ and then decreases as $T_e^{-0.56}$ up to $T_e = 5000\ °K$. In these studies excited electronic states of O_2^+ may be present (O_2–Ne mixtures were used); thus the data should be compared with the inverted triangles shown in Fig. 3. Within the combined experimental uncertainties, the variations of $\alpha(O_2)$ are the same when T_e alone is varied and when T_e, T_i, and T_n are all covaried.

Before leaving the subject of dissociative recombination of O_2^+ ions, it should be noted that recently Zipf (19) has used absolute intensity and microwave electron density determinations in oxygen afterglows at 300 °K to determine the partial dissociative recombination coefficients leading to formation of oxygen atoms in the ^1S and ^1D states. He finds that $\alpha'(^1S) \simeq 0.4 \times 10^{-7}\ cm^3/s$ and $\alpha'(^1D) \simeq 1.5 \times 10^{-7}\ cm^3/s$, indicating that a substantial number of the recombination events lead to formation of one of the oxygen atoms in an electronically excited state.

Detailed studies of the recombination of N_2^+ ions and electrons have been carried out by Kasner and Biondi (20) and by Kasner (21) using essentially the same apparatus as in the O_2^+ studies, except that a repetitive pulse-afterglow cycle was used because there was no problem of negative ion accumulation from pulse to pulse. The N_2^+ ions were produced in mixtures of nitrogen ($\lesssim 10^{-2}$ Torr) and neon (~ 20 Torr) by Penning ionization of N_2 by $Ne(^3P_2)$ metastable atoms, assuring that the ions were in their ground electronic and a low ($v \leqslant 4$) vibrational state.

At $T = 300\ °K$, Kasner and Biondi obtained a value $\alpha(N_2^+) = (2.9 \pm 0.3) \times 10^{-7}\ cm^3/s$. From studies at higher partial pressures of nitrogen, they were able to evaluate the dimer ion's recombination coefficient, $\alpha(N_4^+) \sim 2 \times 10^{-6}\ cm^3/s$, although the presence of some N_3^+ ions (which apparently have a rather smaller coefficient) makes this result somewhat uncertain. Kasner (21) extended the studies over the temperature range 200–480 °K and found very little dependence of $\alpha(N_2^+)$ on temperature, a variation as $T^{-0.02}$ providing the best fit to the data (see Fig. 4). Very recent results (10, 18) of microwave

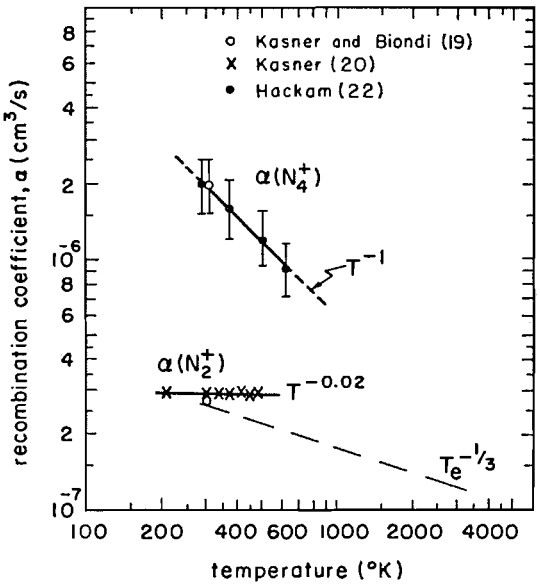

FIG. 4. Temperature dependence of the dissociative recombination coefficient $\alpha(N_2^+)$. The × symbols indicate conditions where $T_e = T_i = T_n = T$, while the dashed line indicates preliminary results obtained when T_e is varied while $T_i = T_n$ is held at 300 °K. The upper curve apparently applies to the variation of $\alpha(N_4^+)$ under conditions where $T_e = T_i = T_n = T$.

electron heating experiments indicate that when $T_+ = T_n = 300\ °K$ and T_e is independently varied, $\alpha(N_2^+)$ varies approximately as $T_e^{-1/3}$ over the range $300\ °K \leqslant T_e \leqslant 3000\ °K$. As we shall see shortly, the dissociative recombination process admits quite different "temperature dependences" when T_e and T_i are varied first together and then independently.

In the data shown in Fig. 4, we have included results of microwave studies of Hackam (22) at higher nitrogen pressures (2–6 Torr) which did not make use of mass analysis. In as much as his value for α at 300 °K agrees with the results of Kasner and Biondi for $\alpha(N_4^+)$, we tentatively conclude that his measured variation as $\sim T^{-1}$ over the range $300\ °K \leqslant T \leqslant 700\ °K$ applies to the N_4^+ ion.

There is little information concerning the magnitudes of the recombination coefficients of the recently discovered D-layer ions, H_3O^+ and its hydrated forms (masses 19, 37, 55). Hydrogen–oxygen–acetylene flame studies at $\sim 2100\ °K$ were carried out by Green and Sugden (23*a*), who used a mass spectrometer to monitor the decay of H_3O^+ ions (the only significant ion).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

They found a value $\alpha(H_3O^+) \simeq 2 \times 10^{-7}$ cm^3/s. Wilson and Evans (23*b*) used microwave techniques to measure the decay of electron density behind shock fronts in argon containing small amounts of oxygen and hydrocarbon (e.g. acetylene). From recombination controlled decays, they found that α varies roughly as T^{-2} over the range 2400 °K $< T <$ 5600 °K, with a value $\alpha \approx 1.5 \times 10^{-7}$ cm^3/s at 3000 °K. Presumably these values refer to H_3O^+ ions. If an inverse temperature dependence of this order is maintained down to much lower temperatures, the coefficient at $\sim$ 300 °K may be in excess of 10^{-6} cm^3/s, perhaps even as large as 10^{-5} cm^3/s. (It has been suggested by Donahue that such a large recombination coefficient is required to offset the enhanced ionization rate implied by the larger D region NO concentrations recently measured in rocket sounding experiments.) Measurements of the recombination coefficients of the ions $H_3O^+ \cdot (H_2O)_n$ at low temperatures ($\sim$ 300 °K) are thus of considerable interest.

Finally, we include determinations of $\alpha(CO_2^+)$ in our discussion of experimental measurements of ionospheric ion recombination coefficients, since it is thought that the ionospheres of Mars and of Venus contain CO_2^+ ions. Using a modification of the microwave afterglow/mass spectrometer apparatus shown in Fig. 1, Weller and Biondi (24) obtained a value $\alpha = (3.8 \pm 0.5) \times 10^{-7}$ cm^3/s at 300 °K and a value $\sim 4 \times 10^{-7}$ at 210 °K for mass-identified CO_2^+ ions.

Recently, several theoretical calculations (25–27) of dissociative recombination coefficients have appeared. None can be said to represent true ab initio calculations, in which the wave functions for the various ion and excited molecule states of reaction [2] are computed and used to obtain the molecular potential curves, the resonance capture cross section, and the probability of auto-ionization as a function of the internuclear separation of the atoms. At present, the calculations employ simplifications and/or use of experimental information concerning the potential curves of the ionospheric ions in order to obtain values of the dissociative recombination coefficients.

It has been shown (27) that, in dissociative recombination, not only the direct process indicated by eq. [2] but also an *indirect* process may contribute significantly to the total recombination coefficient. The indirect process proceeds via resonance electron capture to form a vibrationally excited, stable Rydberg state of the excited molecule which predissociates as a result of a pseudo-crossing with the unstable molecule state indicated in eq. [2]. In addition, the energy dependences of the direct and indirect processes appear to be quite different (27).

Bardsley (27) has calculated the *direct* dissociative recombination coefficient $\alpha_d(NO^+)$ at 300 °K using spectroscopic data to obtain the shape of the ground electronic state of NO^+ and to estimate the resonance capture formation rate and the auto-ionization rate. His value $\alpha_d(NO^+) = 2.6 \times 10^{-7}$ cm^3/s is about 60% of the experimental value, and he argues that the indirect process (for which he is unable to obtain a quantitative estimate) may provide the remainder.

Warke (26) has used a semiclassical formalism to calculate the coefficient of the direct process for the ions O_2^+ and N_2^+ at 300 °K and obtains values $\alpha_d(O_2^+) = 1.1 \times 10^{-7}$ cm^3/s and $\alpha_d(N_2^+) = 2.0 \times 10^{-7}$ cm^3/s at 300 °K, both of which are smaller than the corresponding experimental values. In all three cases, for NO^+, O_2^+, and N_2^+, the theory applies to ions in the $v = 0$ vibration state, while in the experimental measurements the ions may be in a low vibration state as they undergo recombination.

The final point to consider is the energy dependence of the dissociative recombination process. Highly simplified theories (7, 28) of the direct process (reaction [2]) indicate that for a favorable potential curve crossing between the molecular ion and the unstable excited molecule, α varies as $T_e^{-1/2}$ if the initial resonance capture step (left hand portion of reaction [2]) is rate limiting. It is estimated (27) that the indirect process may vary as rapidly as $T_e^{-1.5}$.

Since in some regions of the ionosphere the electron and ion temperatures are equal, while in others they are not (refer to Table I), it is interesting to compare the observed temperature dependences under these differing conditions. Unfortunately, the useful data are comparatively limited. In addition to the recent O_2^+ and N_2^+ results mentioned above, the two cases (10, 29–31) most accurately studied to date are the temperature dependences of $\alpha(Ne_2^+)$ and of $\alpha(Ar_2^+)$ under conditions where on the one hand $T_e = T_i = T_n$ and on the other $T_i = T_n$ and T_e is independently varied.

We noted earlier that $\alpha(N_2^+)$ varies little (21) under conditions where T_e, T_i, and T_n are simultaneously varied over the range 200–480 °K,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

while there is some evidence (18) that $\alpha(N_2^+)$ varies rather *strongly* (approximately as $T_e^{-1/3}$) when T_e alone is varied (see Fig. 4). By way of contrast, Kasner (29) finds that $\alpha(Ne_2^+)$ varies as $T^{-0.42}$ ($T_e = T_i = T_n = T$) over the range 300–500 °K, while Frommhold *et al.* (10) find an essentially identical power law variation with *electron* temperature ($\alpha \sim T_e^{-0.43}$) over the range 300 °K $\leqslant T_e \leqslant$ 11 000 °K with $T_i = T_n =$ 300 °K. Finally, Fox and Hobson (30) carried out shock tube studies of the variation of $\alpha(Ar_2^+)$ under conditions such that $T_e = T_i = T_n$ over the range 1000–3000 °K and obtained a variation as $T^{-1.3}$. In this case, corresponding electron temperature variation studies of $\alpha(Ar_2^+)$ by Mehr and Biondi (31) revealed a weaker temperature dependence (as $T_e^{-0.67}$) over the range 300 °K $\leqslant T_e \leqslant$ 10 000 °K with $T_i = T_n = 300$ °K.

It is possible to account qualitatively for these strikingly different behaviors in terms of the details of the potential curve crossings between the molecular ion and the unstable molecule states and in terms of the changing vibrational state populations of the molecular ion with changing T_i (31). We point out the problem to demonstrate that present theoretical treatments of the dissociative recombination process are essentially in their infancy and to stress the critical importance of being able to specify the ions' electronic and vibrational states in laboratory measurements before the results can be applied with confidence to ionospheric calculations.

Ion–Ion Recombination

As in the case of electron–ion recombination, ion–ion recombination in the ionosphere is evidently controlled predominantly by two-body rather than three-body processes, with the possible exception of the lower end of the D region. At present there is somewhat more theoretical and experimental information available concerning the three-body, neutral stabilized, recombination process than two-body ion–ion recombination processes. This situation is changing rapidly, with a number of experimental and theoretical investigations of two-body processes involving ionospheric ions in progress.

A. Neutral Stabilized (Thomson) Recombination

Many years ago Thomson (32) proposed a simple theory of recombination between positive and negative ions which involved either ion's suffering a collision with a neutral molecule while within a certain "trapping distance" of the other. In reaction form the process may be represented by

$$[4] \qquad X^+ + Y^- + M \rightarrow X + Y + M$$

where X^+, Y^-, and M represent atomic *or* molecular positive ions, negative ions, and neutrals, respectively. Recently, there have been several theoretical treatments of this process (33–37) which either introduced refinements of Thomson's original method of calculation or used novel techniques (e.g. Monte Carlo calculations to follow the histories of the ion pairs).

Thomson (32), Natason (33), and Bates and Moffett (36) predict a variation of the three-body recombination coefficient as $T_i^{-2.5}$, and for the ions of the masses expected in the D region (e.g. NO^+, NO_2^-) a value $K_{\text{Thomson}} \sim 10^{-25}$ cm^6/s is estimated at $T_i = 350$ °K. The available experimental information (38–41) concerning the three-body coefficient largely supports the predicted magnitude. In particular, older studies by Gardner (38) in oxygen and by Sayers (39) in air verify the three-body character of the process and yield a value $K \sim 3 \times 10^{-25}$ cm^6/s at 300 °K.

Mahan and Person (40) used pulsed charge collection in a parallel plate ionization chamber apparatus (without mass identification) to determine the three-body coefficients for a whole series of ions. Of particular interest is their study of what they believe to be the reaction

$$[5] \qquad NO^+ + NO_2^- + N_2 \rightarrow \text{neutrals}$$

for which they obtain a value $K \simeq 2 \times 10^{-25}$ cm^6/s at 300 °K, in satisfactory agreement with the older results. Unfortunately, none of the experimental studies has established the temperature dependence of the recombination process.

From these results, it will be seen that, at the nominal lower D region neutral density of $\sim 10^{15}$ cm^{-3}, the Thomson recombination process presents an *effective* two-body coefficient, "α" $\equiv K[M] \sim 2 \times 10^{-10}$ cm^3/s. As we shall see in the next subsection, true two-body processes such as mutual neutralization apparently provide a much greater ion–ion recombination rate.

B. Two-Body (Mutual Neutralization) Recombination

Probably the simplest and most efficient of the two-body ion–ion recombination processes is that of mutual neutralization, in which the electron is captured from the negative ion by the

TABLE II

Two-body ion–ion recombination coefficients at 300 °K

Investigators	α (cm^3/s)	Ions	Remarks	Reference
Hirsch *et al.*	$(4.4 \pm 1) \times 10^{-8}$	NO^+, NO_2^-, NO_3^-	Mass-identified ions	45
Mahan and Person	$(2.0 \pm 0.5) \times 10^{-7}$	NO^+(?), NO_2^-(?)	No mass analysis	40
Greaves	1×10^{-7}	I_2^+, I^- Br_2^+, Br^-	Mass analysis; variation as $T_i^{-1.5}$ over range 300–340 °K	43, 44
Baulknight and Bortner	5×10^{-8}	O^+, O^- N^+, O^-	Theoretical estimate; variation as $T_i^{-0.5}$ predicted	42

positive ion in a reaction of the form

[6] $$X^+ + Y^- \rightarrow X^* + Y$$

where, once again, the symbols X and Y may refer either to atomic or molecular species. The energetics of the reaction (i.e., the ionization potential of the positive ion and the electron affinity of the negative ion) are such that in many cases, one or both of the neutrals produced may be in excited states.

Theoretical calculations by Baulknight and Bortner (42) for atomic species, i.e. $O^+ + O^-$ and $N^+ + O^-$, suggest that at 300 °K a mutual neutralization coefficient, $\alpha_{mn} \sim 5 \times 10^{-8}$ cm^3/s is to be expected. Further, a variation as $T_i^{-0.5}$ is predicted. There are few experimental studies of mass-identified ionospheric ions with which to compare these predictions; therefore we shall also discuss information obtained for non-ionospheric species.

Greaves (43, 44) employed an afterglow technique making use of radio frequency ($\sim$ 10 MHz) determinations of the dielectric coefficient of the ions to determine the decay of ion concentration during the afterglow. Ion identification was supplied by a small, differentially pumped mass spectrometer appended to the experimental tube. Halogen ions were studied, and for the systems $I_2^+ + I^-$ and $Br_2^+ + Br^-$, a coefficient $\alpha_{mn} \approx 1 \times 10^{-7}$ cm^3/s was obtained from decay curves which clearly exhibited recombination control of the afterglow. Over the temperature range 300–340 °K a decrease of α_{mn} from 1.2×10^{-7} to 1.0×10^{-7} cm^3/s was noted in the case of iodine, suggesting an approximate variation as $T_i^{-1.5}$ over this *very* limited range.

Mahan and Person (40), using the technique described earlier (no mass analysis), have studied ionic recombination in photoionized NO – NO_2 – noble gas mixtures and have argued that the ions under study are probably NO^+ and NO_2^-. From recombination controlled afterglow decays they obtained a value $\alpha_{mn} = (2.0 \pm 0.5) \times 10^{-7}$ cm^3/s, at 300 °K. (The rather large error limit arises chiefly from uncertainties concerning the spatial distribution of the ions in the measuring chamber; refer to the discussion in Section B under heading Electron–Ion Recombination concerning eq. [3] for the corresponding electron–ion case.)

Very recently, Hirsch *et al.* (45) have carried out afterglow studies of ion–ion recombination using an r-f impedance probe to determine the decay of ion concentration in air-like, N_2–O_2 mixtures following ionization by a pulse of MeV electrons. A differentially pumped mass-spectrometer sampled the ions diffusing to the walls of the experimental chamber. For the case in which NO^+, NO_2^-, and NO_3^- were the principal ions in the afterglow they obtained a value $\alpha_{mn} = (4.4 \pm 1) \times 10^{-8}$ cm^3/s at 300 °K.

Thus, it appears that the various studies indicate that the two-body ion–ion recombination coefficient is of the order of 10^{-7} cm^3/s at 300 °K; however, much work is needed to establish more definitely the identities of the ions undergoing recombination and then to specify the particular electronic and vibrational states of the ions. The results of the various investigations are summarized in Table II.

We have omitted from our discussion other two-body ion–ion recombination processes which involve rearrangement of the atoms in the molecules during the reaction, in as much as estimates (46) of the rates of such processes suggest that they are orders of magnitude smaller than the simple mutual neutralization process. Thus, such processes would not be expected to play a

significant role in charge removal from the ionosphere.

Acknowledgments

Comments, Replies, and Summary

COMMENTS BY F. E. NILES

In view of the recent D region mass spectrometric measurements of Narcisi and others, the identity of the principal positive ion at 60 km as NO^+ as given in Table I is highly questionable. The measurements reveal that an ion with mass 37, probably $H_5O_2^+$, is the dominant positive ion for most of the D region. Other water-clustered ions were also detected.

Comments, Replies, and Summary

COMMENTS BY F. E. NILES

In view of the recent D region mass spectrometric measurements of Narcisi and others, the identity of the principal positive ion at 60 km as NO^+ as given in Table I is highly questionable. The measurements reveal that an ion with mass 37, probably $H_5O_2^+$, is the dominant positive ion for most of the D region. Other water-clustered ions were also detected.

REPLY BY M. A. BIONDI

The point is well taken, and Table I and the text have been modified to consider these ions.

COMMENTS BY J. N. BARDSLEY

The well-established theory of dissociative recombination suggests that for a fixed ion temperature the recombination coefficient should vary with the electron temperature, T_e, approximately as $T_e^{-0.5}$. Several experimental investigations have shown variations significantly different from the predicted behavior. I have recently suggested an alternative mechanism for dissociative recombination which could lead to a different temperature dependence. However, this mechanism seems to be possible only at low temperatures, say below 1000 °K, and probably cannot account for deviations from a $T_e^{-0.5}$ law at higher temperatures.

A more likely explanation, as described by Dr. Biondi, is that the deviations are due to the presence of excited vibrational levels of the ion. Experiments carried out on the rare gases have revealed very different temperature variations, depending upon whether the whole gas is heated or the electrons alone. It would be interesting theoretically to check the consistency of these results, but this is not possible due to the paucity of information about the potential curves of rare gas ions. It would, therefore, be useful if the consequences of the two methods of heating could be measured in each of the atmospheric gases.

COMMENTS BY L. M. BRANSCOMB

Since the lifetime of a negative ion in the mesosphere against ion–ion recombination is $\tau = (\gamma N^+)^{-1}$ and even in disturbed (e.g. Polar Cap Absorption) atmospheres the ion density is only $\lesssim 10^5$ while $\gamma \sim 10^{-7}$–10^{-8} cm^3/s, τ is quite long, perhaps 50–100 s or longer, if the ions are "terminal ions" in the sense that they are not subject to photodetachment or associative detachment. Niles commented that in the mesosphere (when H_2O exceeds N^+ by 10^6 or so) hydration of the ions, both positive and negative, will proceed substantially more quickly.

What evidence, experimental or theoretical, is there concerning the effect on the two-body ion recombination rate of clustering? Has a process such as $X^+ + Y^- \cdot (H_2O) \rightarrow X + Y + H_2O$ been examined as a possible efficient stabilization mechanism for the recombination increasing its rate?

REPLY BY M. A. BIONDI

I am not aware of any experimental or theoretical evidence concerning ion–ion recombination rates where one or both of the partners are in a hydrated form.

COMMENTS BY MICHAEL B. McELROY

In reply to a question from the chair (Donahue) concerning recombination processes of interest in other planetary atmospheres, I mentioned the known importance of CO_2^+ on Venus and Mars and the probable importance of HCO_2^+ formed either by $H_2^+ + CO_2 \rightarrow HCO_2^+$ or $CO_2^+ + H_2$. In the outer planets H_3^+ recombination is of interest.

COMMENTS[1] BY WILLIAM ABERTH[2] AND JAMES R. PETERSON[2]

Ion–ion neutralization cross sections have been obtained for the reactants $N^+ + O^-$ (1), $O_2^+ + O_2^-$, and $N_2^+ + O_2^-$. The range of barycentric kinetic energies covered is between 0.1 and 98 eV for $N^+ + O^-$ and $N_2^+ + O_2^-$, and between 0.1 and 50 eV for $O_2^+ + O_2^-$ with about 0.1 eV resolution. The products of the neutralization cross section, Q, times the relative velocity, v, of the $N^+ + O^-$ and the $N_2^+ + O_2^-$ systems, are nearly independent of energy, with values close to 10^{-7} cm^3/s, except below 0.5 eV where a rapid increase of Qv with decreasing energy is observed. The $O_2^+ + O_2^-$ data can be described by the equation $Qv = -3.1 \times 10^{-14}v + 5.7 \times 10^{-8}$ cm^3/s. No rapid increase of Qv with decreasing v below 0.5 eV is observed. However, this system exhibits a greater degree of scatter in the data and such structure may consequently be unobservable.

The merging beams technique (2) involves superimposing particle beams of different speeds and observing their interactions over a known

path length. In the present apparatus the positive and negative ion beams are deflected by a common magnetic field. Both beams have keV energies in the laboratory coordinate system but can have relative energies as low as 0.1 eV while merged. After traveling together about 33 cm, the beams are separated by electrostatic deflection and collected in two Faraday cups. The neutral particles formed by ion–ion neutralization (as well as a much larger "background" of neutrals formed by electron stripping and capture reactions of the beam ions with the ambient gas) continue along the superimposed beam direction. The neutrals are detected indirectly by the secondary electron emission produced when they collide with a stainless steel surface. The component of this current due to ion–ion neutralization is separated from the large background by a beam-chopping technique. The neutralization products are not identified.

2. S. M. TRUJILLO, R. H. NEYNABER, and E. W. ROTHE. Rev. Sci. Instr. **37**, 1655 (1966).

COMMENTS BY FRANKLIN E. NILES

The merging beams experiment has revealed and will reveal interesting results; however, as presently constructed the experiment is deficient in that the products of the reaction are not identified. Unless the products of a reaction can be identified, it is better to ascribe a cross section or a rate constant to a reaction without writing down the products, e.g., $O_2^+ + O_2^- \rightarrow$ products and not $O_2^+ + O_2 \rightarrow 2O_2$. Whenever many reactions are occurring together, the products of the reactions are important. In particular, mutual neutralization with dissociation may be an important source of atomic nitrogen and atomic oxygen in the upper atmosphere. Consequently, rate constants for reactions such as $O_2^+ + O_2^- \rightarrow O + O + O_2$ and $NO^+ + O_2^- \rightarrow N + O + O_2$ need to be determined.

REPLY BY J. R. PETERSON

Dr. Niles' comment is certainly valid. The fact that molecular reaction products were printed on the slides was actually accidental rather than intentional. I would guess that a substantial number, say 25%, of the product molecules are in unbound final states in the $O_2^+ + O_2^-$ reaction, but it is virtually impossible to determine which of the many possible states are involved, at least in our experiment. In principle, it is possible to determine the excited final states in some atomic cases by observing the allowed radiation. We have considered trying to do this for $H^+ + H^-$, where presumably only the $n = 2$ and $n = 3$ states are excited to any extent. I suspect that the most promising method of determining the distribution of final states (including repulsive molecular states) may be through theory, and hopefully we can aid the development of a reliable theory by making good total cross section measurements, as a function of energy, for a number of species.

SUMMARY (1) BY CHAIRMAN, T. M. DONAHUE[3]

With one major exception, the state of agreement between ionospheric requirements and laboratory measurements for dissociative recombination coefficients is now excellent. The temperature dependences for $\alpha(NO^+)$ and $\alpha(O_2^+)$ reported here are very close to those required by the terrestrial ionosphere, nighttime and daytime from the E region to the F_2 peak.

The troubles lie in the D region below 80 km. Here recent measurements of nitric oxide densities by Pearce (1) give values so large that Lyman α ionization and charge transfer from O_2^+ produce NO^+ ten times as fast as dissociative recombination can remove it. This is supposing that

$$n_e = n(NO^+)$$

and

$$\alpha(NO^+) = 8 \times 10^{-7}\ \text{cm}^3\ \text{s}^{-1}$$

In this region, however, such ions as $(H_3O^+)\cdot(H_2O)_n$ are dominant. There is at least a chance that these ions are formed from NO^+ (Ferguson and Fehsenfeld, private communication). There is also a good possibility that negative ion to positive ion density ratios are large at 70 km. (L. Hale, private communication.) Still the problem remains that the source is so strong that recombination coefficients, whether dissociative or neutralization, must be very large for the ions present in the steady state. If, for

[3]Address: Physics Department, University of Pittsburgh, Pittsburgh, Pennsylvania 15213.

example, at 70 km

$$n(NO^+) = 3 \times 10^2 \text{ cm}^{-3}$$
$$n[H_3O^+ \cdot (H_2O)_n] = 1.5 \times 10^3 \text{ cm}^{-3}$$
$$n_e = 3 \times 10^2 \text{ cm}^{-3}$$
$$n^- = 1.5 \times 10^3 \text{ cm}^{-3}$$

the steady state requires that

$$(\alpha + 5\alpha_i)H_3O^+ \cdot (H_2O)_n + \alpha_i(NO^+) = 10^{-4} \text{ cm}^3 \text{ s}^{-1}$$

Hence it appears that recombination rates for hydrated hydronium ions below 200 °K ought to be measured.

The problem of the metal ion removal in sporadic E layers and near 95 km requires eventually that we know α's for species such as MgO^+ or $MgO_2{}^+$, although the ion chemistry of these species is completely mysterious.

Finally, as McElroy mentions, the other planets involve other ions. There is a possibility that $HCO_2{}^+$ is formed at high rates on Venus. The outer planets have atmospheres containing copious quantities of H_2. In their ionospheres $H_3{}^+$ should appear prominently, and at temperatures perhaps as low as 100 °K. Recombination rates for such ions are of current interest.

Inelastic collisions at low energies

A. DALGARNO
Harvard College Observatory and Smithsonian Astrophysical Observatory, Cambridge, Massachusetts
Received December 12, 1968

A summary is presented of the processes by which low energy electrons lose energy in moving through the atmosphere and estimates are given of the cross sections and energy loss rates. The mechanisms by which thermal electrons cool are described and the cooling efficiencies are listed.

Canadian Journal of Chemistry, 47, 1723 (1969)

Introduction

Low energy electrons, moving in the upper atmospheres of the planets, produce luminosity by electronic excitation of the atmospheric constituents and they modify the chemistry of the upper atmospheres through the production of metastable and vibrationally excited species. The low energy electrons also selectively heat the ambient electron and ion gases so that their temperatures tend to rise above that of the neutral atmosphere. A detailed description of the possible modes of energy loss is a fundamental part of the physics and chemistry of planetary atmospheres.

Elastic Collisions

An important energy loss mechanism for low energy electrons in the ionosphere is provided by the transfer of momentum in elastic collisions of the low energy electrons with the thermal electrons of the ionospheric plasma, the high efficiency arising from the equal masses and the long range of the Coulomb repulsion. According to Butler and Buckingham (1), the mean rate of energy loss due to elastic collisions of electrons of velocity v with charged particles of mass M, velocity V, and density n_e is given by

$$[1] \qquad \frac{1}{n_e}\frac{dE}{dx} = \frac{-8\pi^{\frac{1}{2}}}{M}\frac{e^4}{vV}F(v/V)\ln\Lambda$$

where Λ is a parameter characterizing the plasma and

$$[2] \quad F(x) = \frac{1}{x}\int_0^x \exp(-x^2)dx - \left(1+\frac{m}{M}\right)\exp(-x^2)$$

Values of [1] for collisions with electrons have been tabulated by Dalgarno, McElroy, and Moffett (2). Provided that the electron energy exceeds 3 eV, [1] simplifies in the case of collisions with electrons to

$$[3] \quad \frac{dE}{dx} = -n_e\frac{1.3\times10^{-13}}{E}\ln\Lambda \quad \text{eV cm}^{-1}$$

where E is the electron energy measured in eV. Values of $\ln\Lambda$ have been tabulated by Henry and McElroy (3). For plasmas typical of planetary ionospheres, $\ln\Lambda$ is of the order of 15 and [3] is approximately

$$[4] \quad \frac{dE}{dx} = -n_e\times\frac{2\times10^{-12}}{E} \quad \text{eV cm}^{-1}$$

Because of the mass M in the denominator of [1], energy loss through elastic collisions with positive ions is negligible in comparison to collisions with electrons.

Because of the greater neutral particle density, elastic collisions with neutral particles might be an important process of energy loss. For an electron energy substantially in excess of the mean thermal energy of the neutral particles, the mean rate of energy loss may be expressed as

$$[5] \qquad \frac{dE}{dx} = -n(\mathrm{A})\frac{2m}{M}E\,\sigma_m(E)$$

where $n(\mathrm{A})$ is the number density of neutral particles A of mass M and $\sigma_m(E)$ is the momentum transfer cross section, defined in terms of the differential cross section $I(\theta|E)$ for scattering through an angle θ by

$$[6] \quad \sigma_m(E) = 2\pi\int_{-1}^{+1} I(\theta|E)(1-\cos(\theta))\times d(\cos\theta)$$

Since σ_m is of the order of 10^{-15} cm^2, it is clear that the energy loss by momentum transfer in collisions with neutral particles is negligible

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

compared to [1] for the ambient electron and neutral particle densities occuring in planetary ionospheres.

Rotational Excitation

Slow electrons can lose energy by the excitation of the rotational levels of the molecular atmospheric constituents. If it is assumed that rotational excitation is caused largely by the long range interaction of the electron with the quadrupole moment q of the molecule, the Born approximation yields the simple formula for the cross section for excitation from rotational level j to rotational level $j+2$

$$[7] \quad \sigma(j,j+2|E) = 4.7 \times q^2 \frac{(j+1)(j+2)}{(2j+1)(2j+3)} \times 10^{-17} \quad \text{cm}^2$$

(4) where q is measured in atomic units. For N_2, $q = -1.1$ (5). More refined theoretical studies (6) have shown that long range polarization interactions, short range interactions, and distortion are significant effects. However, the low energy experiment data of Engelhardt, Phelps, and Risk (7) can be satisfactorily reproduced by postulating cross sections of the form [7]. In calculating the associated rate of energy loss, it is necessary to take account of rotational de-excitation processes also. Approximate values of the rate of energy loss have been computed by Takayanagi and Takahashi (8). For energies of about 0.5 eV

$$\frac{dE}{dx} = -n(N_2) \times 5 \times 10^{-19} \quad \text{eV cm}^{-1}$$

Molecular oxygen has a small quadrupole moment $q = -0.3$ (5) and the rotational excitation of oxygen may be strongly modified by short range interactions (9). Experimental studies by Mentzoni and Rao (10) showed that the earlier calculations (10, 11) underestimated the energy loss rate. No satisfactory theoretical description of the rotational excitation of oxygen has yet been presented and the most precise information is that derived from swarm data by Hake and Phelps (12). It appears from the analysis that a gross representation of the rotational cross sections for oxygen is provided by [7] with an empirical value of 1.8 for $|q|$. For energies of about 0.5 eV, the associated energy loss rate is approximately

$$\frac{dE}{dx} = -n(O_2) \times 10^{-18} \quad \text{eV cm}^{-1}$$

Rotational excitation of carbon dioxide may be important in the atmospheres of Mars and Venus. Hake and Phelps (12) were unable to derive rotational cross sections from swarm data. The quadrupole moment of carbon dioxide is large and [7] may prove a satisfactory description. Using $q = -3.2$, the energy loss rate is comparable to that for molecular nitrogen.

Fine Structure Transitions

In the upper atmosphere of the planet Earth, energy loss can occur through the excitation of the fine structure levels of atomic oxygen

$$[10] \quad e + O(^3P_J) \rightarrow e + O(^3P_{J'})$$

the cross sections for which have been calculated by Breig and Lin (13). For electrons of energy 0.5 eV, the energy loss rate is approximately

$$[11] \quad \frac{dE}{dx} = -n(O) \times 2 \times 10^{-18} \quad \text{eV cm}^{-1}$$

Vibrational Excitation

It is clear from a comparison of [8], [9], and [11] with [14] that except in regions of very low electron density, neither rotational excitation nor fine-structure excitation compares in efficiency with energy loss through elastic collisions with the ambient electron gas. With increasing energy, vibrational excitation becomes possible and it does provide a mode of energy loss which is competitive with elastic collisions (2).

The vibrational excitation of molecular nitrogen

$$[12] \quad e + N_2(v=0) \rightarrow > e + N_2(v')$$

has been studied experimentally by Haas (14), Schulz (15), Schulz and Koon (16), Boness and Hasted (17), Andrick and Ehrhardt (18), and Ehrhardt and Willmann (19), and theoretical interpretations of the process in terms of a resonating $^2\pi_g$ state of N_2^- have been developed by Schulz (15), Herzenberg and Mandl (20), Chen (21), Gilmore (22), and Bardsley, Mandl, and Wood (23). The associated energy loss rates have been calculated by Dalgarno, McElroy, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Moffett (2) and Takayanagi and Takahashi (8). They pass through a maximum value, given by

$$[13] \quad \frac{dE}{dx} = -n(N_2) \times 3 \times 10^{-16} \quad \text{eVcm}^{-1}$$

at an energy E of 2.5 eV. The efficiency decreases rapidly both at low and at high energies. Vibrational excitation of molecular nitrogen is the dominant mode of energy loss for electrons with energies in the range from 6.5 to about 1 eV throughout most of the F region of the ionosphere.

Vibrational excitation cross sections for molecular oxygen have been derived by Hake and Phelps (12) from swarm data and from cross section measurements by Schulz and Dowell (24) and Boness and Hasted (17). The associated energy loss rates have been calculated by Henry and McElroy (3). They have a flat maximum for energies between 1 and 1.8 eV, given by

$$[14] \quad \frac{dE}{dx} = -n(O_2) \times 8 \times 10^{-18} \quad \text{eV cm}^{-1}$$

and the process is important in and below the ionospheric E region.

Henry and McElroy (3) have also used cross sections derived by Hake and Phelps (12) to calculate the energy loss rates associated with the vibrational excitation of carbon dioxide. The efficiency passes through a maximum given by

$$[15] \quad \frac{dE}{dx} = -n(CO_2) \times 1.5 \times 10^{-16} \quad \text{eV cm}^{-1}$$

at an energy near 0.7 eV and a second maximum, given by

$$[16] \quad \frac{dE}{dx} = -n(CO_2) \times 3.1 \times 10^{-16} \quad \text{eV cm}^{-1}$$

at an energy near 4 eV. Between 1.5 and 3.5 eV, the energy loss rate is given by

$$[17] \quad \frac{dE}{dx} = -n(CO_2) \times 2.5 \times 10^{-17} \quad \text{eV cm}^{-1}$$

Vibrational excitation of carbon dioxide is an important energy loss mechanism in the atmospheres of Mars and Venus. Vibrational excitation is important not only as a mechanism for extracting energy from the energetic electrons but also because the presence of vibrationally excited species can influence the chemistry of the atmospheres. Thus Schmeltekopf, Fehsenfeld, Gilman, and Ferguson (25) have found that the rate of the ion–molecule reaction

$$[18] \quad O^+ + N_2 \rightarrow NO^+ + O$$

increases rapidly with increasing vibrational temperature above 1500 °K (though the effect of the increased ion removal rate of [18] will be balanced in part by an increase in the ion production rate), and Walker (26) has suggested that vibrationally excited nitrogen may heat the electron gas in the E region through super-elastic collisions

$$[19] \quad N_2(v) + e \rightarrow N_2(v') + e$$

Rate coefficients for [19] may be derived from the model calculations of Chen (21).

Electron impact is not the only source of vibrational excitation. The deactivation process

$$[20] \quad O(^1D) + N_2 \rightarrow O(^3P) + N_2^*$$

may be a more abundant source (26, 27) as may be fluorescence processes such as

$$[21] \quad \begin{aligned} &O_2(X^3\Sigma_g^-, v = 0) + h\nu \rightarrow O_2(B^3\Sigma_u^-, v) \\ &O_2(B^3\Sigma_u^-, v) \rightarrow O_2(X^3\Sigma_g^-, v') + h\nu \end{aligned}$$

Electronic Excitation

Molecular oxygen has a number of low-lying metastable levels. The $a^1\Delta_g$ level has a threshold of 0.98 eV and the $b^1\Sigma_g^+$ level has a threshold of 1.63 eV. The cross sections for exciting the $a^1\Delta_g$ and $b^1\Sigma_g^+$ levels are not known with any certainty and their influence on the energy loss rates has been included approximately in the energy loss rates of the section associated with vibrational excitation.

The threshold of the $A^3\Sigma_u^+$ level of molecular oxygen occurs at 4.5 eV. Hake and Phelps (12) suggest that the cross section attains a maximum value of 2×10^{-17} cm^2 at an energy near 7 eV corresponding to an energy loss rate at 7 eV, given approximately by

$$[22] \quad \frac{dE}{dx} = -n(O_2) \times 10^{-16} \quad \text{eV cm}^{-1}$$

At 9.7 eV, the data of Schulz and Dowell (24) indicate another threshold. At this energy there exists a number of exit channels and indeed considerable structure occurs in the experimental

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

data above 8.5 eV. The associated energy loss rate is comparable to [22].

The lowest lying electronically excited state of N_2 is the $A^3\sum_u^+$ state with a threshold at 6.5 eV. It appears from the analysis of Engelhardt, Phelps, and Risk (7) that the associated energy loss rate for electrons of about 8 eV energy is given by

$$[23] \quad \frac{dE}{dx} = -n(N_2) \times 2 \times 10^{-16} \quad \text{eV cm}^{-1}$$

A comparable energy loss rate occurs for excitation to the $B^3\pi_g$ state which has a threshold near 7.4 eV. Above 8.4 eV, further excitation channels open and the energy loss rate increases.

Atomic oxygen has two low-lying metastable levels, the $O(^1D)$ level at 1.96 eV and the $O(^1S)$ level at 4.17 eV. The ^1D level is the upper level of the oxygen red lines at 6300 and 6364 Å and the ^1S level is the upper level of the oxygen green line at 5577 Å.

The cross sections have been computed by Smith, Henry, and Burke (28). At 5 eV, the energy loss rate associated with excitation to the ^1D level is given by

$$[24] \quad \frac{dE}{dx} = -n(O) \times 7 \times 10^{-17} \quad \text{eV cm}^{-1}$$

and the energy loss rate associated with excitation to the ^1S level is given by

$$[25] \quad \frac{dE}{dx} = -n(O) \times 4 \times 10^{-17} \quad \text{eV cm}^{-1}$$

Electron impact is a major source of excitation of the red and green lines in the day airglow.

It appears that excitation of electronic levels of positive ions is not a significant energy loss mechanism for low energy electrons. The cross sections for

$$[26] \quad e + O^+(^4S) \rightarrow e + O^+(^2D)$$

and

$$[27] \quad e + O^+(^4S) \rightarrow e + O^+(^2P)$$

have been calculated by Seaton and Osterbrock (29). Unlike the case of neutral species, the cross sections are finite at threshold. Above 3.3 eV, the energy loss rate is

$$[28] \quad \frac{dE}{dx} = -n(O^+) \times \frac{1.3 \times 10^{-15}}{E} \quad \text{eV cm}^{-1}$$

and above 5.0 eV, the energy loss rate is

$$[29] \quad \frac{dE}{dx} = -n(O^+) \times 2.2 \times 10^{-15} \quad \text{eV cm}^{-1}$$

These rates are negligible compared to [3].

Deactivation of the metastable states of O^+ by thermal electrons is an important process. Its influence on the day glow and twilight glow emission of the O^+ lines has been discussed by Dalgarno and McElroy (30).

Dissociative Attachment

Cross sections for the dissociative attachment processes

$$[30] \quad e + O_2 \rightarrow O + O^-$$

$$[31] \quad e + CO_2 \rightarrow CO + O^-$$

have been measured in several experiments (31). The cross section for O_2 has a maximum value of 1.4×10^{-18} cm^2 at an electron energy of 6.5 eV. The structure of the cross section for CO_2 is more complex. It has a maximum of 1.5×10^{-19} cm^2 at 4.3 eV and a second maximum of 4.3×10^{-19} at 8.1 eV. The processes are of minor importance in aeronomy.

Cooling Mechanisms

The electron gas which is selectively heated by the low energy electrons cools by various mechanisms. A precise evaluation of the cooling rates is valuable since measurements of the ambient electron temperatures can then be analyzed to yield the magnitude of the heat source responsible for the lack of kinetic thermal equilibrium.

Elastic Collisions

At high altitudes where the fractional ionization is large, the major cooling mechanisms are thermal conduction in the electron gas and elastic collisions with the positive ions. Averaging [1] over the Maxwellian velocity distributions of the electron and ion gases, characterized by temperatures T_e and T_i, respectively, the cooling rate corresponding to elastic collisions of electrons with positive ions X^+ is

$$[32] \quad \frac{dU_e}{dt} = \frac{-n_e n(X^+) \times 5 \times 10^{-7} \times (T_e - T_i)}{M(X^+) T_e^{3/2}} \times \ln \Lambda \quad \text{eV cm}^{-3}\,\text{s}^{-1}$$

where $M(X^+)$ is the mass of X^+, measured in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

units of the proton mass (32). Typically $\ln \Lambda \sim 15$ so that for O^+ ions

$$[33]\quad \frac{dU_e}{dt} = -n_e n(O^+) \times 5 \times 10^{-7}(T_e - T_i) \times T_e^{-3/2} \quad \text{eV.cm}^{-3}\ \text{s}^{-1}$$

The electron–ion cooling rate passes through a maximum at $T_e = 3T_i$ so that for $T_e > 3T_i$ it may be necessary to include electron–neutral cooling even in strongly ionized regions.

The cooling due to elastic collisions may be evaluated from [5]. For molecular nitrogen, the momentum transfer cross sections have been derived from swarm data (7) and they lead to a cooling rate (33)

$$[34]\quad \frac{dU_e}{dt} = -n_e n(N_2) \times 1.8 \times 10^{-19} \times T_e(T_e - T_n)(1 - 1.21 \times 10^{-4} T_e) \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

where T_n is the neutral particle temperature. For molecular oxygen, momentum transfer cross sections have been derived also from swarm data (12) and they yield a cooling rate (33)

$$[35]\quad \frac{dU_e}{dt} = -n_e n(O_2) \times 1.2 \times 10^{-18} T_c^{1/2} \times (T_e - T_n)(1 + 3.6 \times 10^{-2} T_e^{1/2}) \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

There are no reliable experimental values at thermal velocities for atomic oxygen, but the most recent theoretical values (34) are consistent at higher velocities with most of the measurements. They give a cooling rate (3)

$$[36]\quad \frac{dU_e}{dt} = -n_e n(O) \times 5.3 \times 10^{-19} T_e^{1/2} \times (T_e - T_n)(1 + 5.7 \times 10^{-4} T_e) \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

Momentum transfer cross sections have been derived for carbon dioxide (12) and they yield (3)

$$[37]\quad \frac{dU_e}{dt} = -n_e n(CO_2) \times 3.0 \times 10^{-16}(T_e - T_n) \times (1 - 5 \times 10^{-5} T_e^{1/2}) \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

Cooling rates for elastic collisions with atomic hydrogen and helium have been computed by Banks (33).

Rotational Excitation

Elastic scattering by neutral atoms is rarely of significance in the evaluation of the cooling efficiency in the atmosphere. In regions where molecular species exist, cooling through rotational excitation is more rapid. Approximate formulae can be derived by adopting [7] for the variation of the cross section with velocity. It may be shown (35) from [7] that

$$[38]\quad \frac{dU_e}{dt} = -n_e n(M) \times 1.17 \times 10^{-10} B q^2 \times \frac{(T_e - T_n)}{T_e^{1/2}} \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

where B is the rotational constant measured in eV.

For N_2, $B = 2.49 \times 10^{-4}$ and $q = -1.0$ and [38] becomes

$$[39]\quad \frac{dU_e}{dt} = -n_e n(N_2) \times 2.9 \times 10^{-14} \times \frac{(T_e - T_n)}{T_e^{1/2}} \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

For O_2, $B = 1.81 \times 10^{-4}$, Hake and Phelps (12) recommend an effective $|q| = 1.8$, and we obtain accordingly

$$[40]\quad \frac{dU_e}{dt} = -n_e n(O_2) \times 6.9 \times 10^{-14} \times \frac{(T_e - T_n)}{T_e^{1/2}} \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

For CO_2, $B = 4.85 \times 10^{-5}$ and $q = -3.2$ so that

$$[41]\quad \frac{dU_e}{dt} = -n_e n(CO_2) \times 5.8 \times 10^{-14} \times \frac{(T_e - T_n)}{T_e^{1/2}} \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

Fine Structure Transitions

It has been pointed out recently (36) that energy loss caused by excitation of the fine structure transitions of atomic oxygen [10] is the dominant cooling mechanism in the F region of the ionosphere. Detailed estimates have been presented by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Dalgarno and Degges (36). A gross representation of their results is provided by the formula

$$[42]\quad \frac{dU_e}{dt} = -n_e n(O) \times \frac{3.4 \times 10^{-12}}{T_n} \times (T_e - T_n) \times (1 - 7 \times 10^{-5} T_e) \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

Vibrational Excitation

With increasing electron temperature, vibrational excitation becomes more efficient than rotational excitation. For molecular nitrogen, vibrational excitation is more efficient for temperatures above 1500 °K (37). Some of the nitrogen vibrational cooling rates, computed by Rees, Walker, and Dalgarno (38), are reproduced in Table I.

TABLE I
Cooling rates*

	Cooling rates at T_n (°K)			
$T_e - T_n$ (°K)	500	700	900	1500
500	2.5	4.8	7.0	10.7
700	5.5	8.7	11.5	25.3
1000	11.9	16.1	19.5	82.0
1500	25.8	49.0	93.1	332.4

*Cooling rates in units of 10^{-13} eV cm^{-3} s^{-1} for unit electron and nitrogen densities corresponding to vibrational excitation of molecular nitrogen.

The calculation assumes that the vibrational distribution of the ambient nitrogen is governed by the neutral particle kinetic temperature. Should this prove not to be the case (cf. Walker (26)), further calculations will be necessary.

Cooling rates through vibrational excitation of molecular oxygen have been calculated by Lane (private communication) from the cross section data of Hake and Phelps (12). If the high electron temperatures derived for the E region by probe measurements (39) are correct, oxygen vibrational cooling will be an important heat sink. Again the position is complicated by the possible departure of the oxygen vibrational distribution from thermal equilibrium.

Cooling by vibrational excitation of carbon dioxide is a very efficient process. Henry and McElroy (3) have computed cooling rates from the cross section data of Hake and Phelps (12). Their results can be represented approximately by the formula

$$[43]\quad \frac{dU_e}{dt} = -n_e n(CO_2) \times 8 \times 10^{-14} \times (T_e - T_n)\{1 + 2.5 \times 10^{-3} \times (T_e - T_n)\} \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

Electronic Excitation

The cooling efficiency resulting from electron impact excitation of the ^{1}D level of atomic oxygen can be derived immediately from the calculated cross sections (28). According to Rees, Walker, and Dalgarno (38)

$$[44]\quad \frac{dU_e}{dt} = -n_e n(O) \times 1.1 \times 10^{-10} T_e^{1/2} \exp(-2.27 \times 10^4/T_e)\{0.406 + 0.357 \times 10^{-4} T_e - (0.333 + 0.183 \times 10^{-4} T_e) \exp(-1.37 \times 10^4/T_e) - (0.456 + 0.174 \times 10^{-4} T_e) \times \exp(-2.97 \times 10^4/T_e)\} \quad \text{eV cm}^{-3}\ \text{s}^{-1}$$

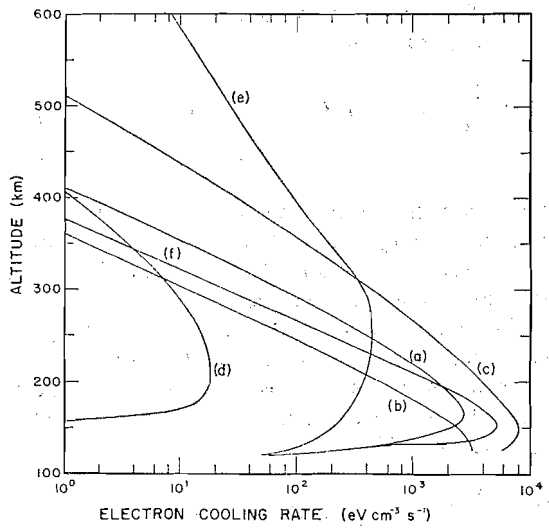

FIG. 1. The electron cooling rates appropriate to the atmosphere and ionosphere at noon, July, 1963. The curves show cooling resulting from excitation of (*a*) vibrational levels of molecular nitrogen, (*b*) rotational levels of molecular nitrogen, (*c*) fine structure levels of atomic oxygen, (*d*) metastable levels of atomic oxygen, (*e*) elastic collisions with positive ions, and (*f*) vibrational levels of molecular oxygen. The rates from elastic collisions with neutral particles and from rotational excitation of molecular oxygen are negligibly small.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Energy transfer from the thermal electrons to excitation energy of the ^1S level of atomic oxygen is unimportant. Energy transfer to excitation of the $a^1\Delta_g$ and $b^1\sum_g{}^+$ levels of molecular oxygen may be significant but the cross sections are largely unknown. Excitation to the higher electronic levels of atomic and molecular oxygen and molecular nitrogen can be neglected for the range of electron temperatures occuring in the ionosphere, as can excitation of the metastable levels of the positive ion of atomic oxygen.

A comparison of the efficiencies of the various cooling processes in the upper atmosphere of the Earth for noon in July 1963 has been given by Dalgarno, McElroy, Rees, and Walker (40). The comparison, supplemented by the addition of the cooling resulting from vibrational excitation of molecular oxygen, is reproduced in Fig. 1.

Comments and Summary

COMMENTS BY A. V. PHELPS

In connection with eqs. [9] and [40] it should be kept in mind that the effective quadrupole moment for rotational excitation of O_2 derived by Hake and Phelps from swarm experiments applies only for electron energies in the range from about 0.1 to 0.3 eV.

It should also be pointed out that the details of the energy dependence of the vibrational excitation cross sections in CO_2 for levels with thresholds above 0.08 eV as given in ref. 12 are based on tentative electron beam data. These cross sections are being reexamined by Schulz and coworkers. Only the behavior of the 0.08 eV cross section near threshold is given by analysis of swarm experiment data. At higher energies the swarm experiments should be regarded primarily as a measure of the sum of the vibrational excitation cross sections, weighted with the energy loss and averaged over an electron energy distribution with a rather large fractional energy width. Thus, the cross sections given in ref. 12 should be useful for energy loss calculations but are of uncertain accuracy for the individual vibrational states.

COMMENTS BY N. P. CARLETON

The electron energy distribution in the E region is well described by a Maxwellian distribution at low energy, with a sharp break to a more or less flat, long tail extending to high energies, thus justifying the classification of electrons as "thermal" and "photo" electrons. This inference comes from a numerical solution of a detailed Boltzmann–Fokker–Planck equation.

If one arbitrarily assigns an N_2 vibrational temperature higher than the gas temperature in the above equation, then the dip in the energy distribution occurring around 2 eV is somewhat filled in and the thermal distribution does not fall so far before breaking off into the high-energy tail.

COMMENTS BY A. V. PHELPS

In the calculation of energy losses in N_2 (or other gases) at high vibrational temperatures of the gas, account must be taken of the excitation of the vibrationally excited molecules and of the corresponding de-excitation processes. At present the only information regarding these cross sections is the theoretical calculation of refs. (1) and (2). As an example of the net effect of the excitation of vibrational excited N_2, the rate of cooling of electrons with energies near 2 eV will be relatively independent of vibrational temperature, for vibrational temperatures well below 2 eV. It is probable that the excitation cross sections for vibrational excitation of vibrationally excited states near threshold are considerably larger than for the $N_2(v = 0)$ level so that the cooling rates for low energy electrons may be significantly modified.

SUMMARY BY CHAIRMAN, L. BRANSCOMB

Since the upper atmosphere of the earth selectively absorbs the non-thermal component of the solar radiation in the hard ultraviolet region, the photoelectrons created in this manner have energies far above the energies of most of the "thermal" particles. As first studies by Dalgarno, McElroy, and Moffett showed, the photoelectrons exchange energy with other electrons, with ions, and with the kinetic and internal energy states of the neutrals. In the first approximation, the kinetic energy distributions of these three species can be taken as Maxwellian, with the coupling between species sufficiently weaker than the energy exchange between particles of similar type that the kinetic energy distributions of each, electrons, ions, and neutrals, can be described by a different temperature parameter. In this approximation the internal energy distributions of the neutrals, while not necessarily characterized by thermodynamic equilibrium at the local temperature of the neutrals, can nonetheless be taken as determined by factors other than energy exchange with the electrons.

Dalgarno's review provides a very convenient and comprehensive summation of present knowledge of all of the processes through which electrons cool by interaction with the atmosphere between their birth as photoelectrons and their final disappearance by recombination (or attachment). To provide estimates of these cooling

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

rates, Dalgarno appeals both to theoretical and experimental sources. Most of the latter data are provided by A.V. Phelps and his colleagues. The two comments by Phelps emphasize the caution with which the experimental data must be used.

The next level of sophistication in the treatment of this problem must involve examination of the actual steady state electron velocity distribution. It must also include examination of non-linear interactions between the electron cooling processes and the internal energy distributions of the neutral molecules. Much of the discussion is centered on the importance of electron cooling through the excitation of nitrogen vibration, followed by exchange of this vibrational energy with other molecules. The inefficiency with which vibration is deactivated from homonuclear molecules raises the possibility of non-thermal populations of molecular nitrogen vibrational states. Carleton pointed out that the resulting effect on the electron velocity distribution may be significant.

In addition, the energy loss processes for electrons in collision with excited vibrational states of nitrogen must be considered.

Finally, the discussion turned to a question that remained unresolved. To what extent does vibrational energy transfer from N_2 to CO_2, followed by infrared radiation, provide an energy drain from the N_2 vibrational "sink"? This mechanism, familiar in laboratory studies of the CO_2 infrared laser, has been considered by Gilmore (unpublished). The current state of knowledge about the rates involved has been reviewed by Taylor and Bitterman (Rev. Mod. Phys. In press). To the extent that this mechanism does remove an appreciable amount of electron energy in the E region, the net effect is the transformation of vacuum ultraviolet solar photons into infrared quanta.

Inelastic scattering of high energy electrons by atmospheric gases[1]

EDWIN N. LASSETTRE

Mellon Institute and the Department of Chemistry, Carnegie-Mellon University, 4400 Fifth Avenue, Pittsburgh, Pennsylvania 15213

Received December 4, 1968

Inelastic scattering of electrons by nitrogen, oxygen, carbon monoxide, carbon dioxide, water, argon, and helium is reviewed. Electron impact spectra at both high (less than 40 keV) and low (greater than 15 eV) kinetic energies are presented and discussed. Collision cross sections and generalized oscillator strengths are described, when data are available, and the connection with optical oscillator strengths is discussed. The limiting selection rules which hold in the excitation of atoms and molecules by electron impact are discussed and typical examples of forbidden transitions are described.

Canadian Journal of Chemistry, 47, 1733 (1969)

Introduction

Scope of Review

In preparing a review of the scattering of high energy electrons by atmospheric gases it seems essential to limit it in some fashion which will permit fairly complete but not merely superficial coverage. By confining it to the discussion of electron impact spectroscopy of atmospheric gases, including measurements of differential collision cross sections, we can hope to approach this objective. In order to get oriented on the orders of magnitude of the energies involved, it is useful to consider the results of some calculations of electronic excitation in gas mixtures.

Energy Degradation in the Excitation of Gases

The calculation (or measurement) of energy degradation in the excitation of gases by fast charged particles is important in many fields, especially radiological physics, radiation chemistry, and atmospheric physics. Some recent calculations by Green illustrate the magnitude of the energies and the problems involved. As a first step in Green's investigation, empirical formulas were developed for fitting differential collision cross sections (1). These were selected partly for convenience in the calculation of total cross sections and general simplification of the numerical calculations. The problem of obtaining a system of cross sections for helium was considered next (2). Empirical cross section equations were then formulated for many transitions in molecular nitrogen (3) and molecular oxygen (4). Cross sections for atomic oxygen were also estimated, mostly from theoretical calculations. These cross sections have been applied to the calculation of auroral intensities (5) and the treatment of the day-glow (6). Obviously many of the finer details of excitation cross sections were omitted in these calculations and extensive use was made of the Born approximation to extend measurements made at one kinetic energy to higher and lower kinetic energies. These surveys do, however, reveal quite clearly how sparse are the data from which meaningful calculations of energy degradation can be made. Moreover, the partition of energy among molecular and ionic species and the energies of secondary electrons are of substantial qualitative interest. Two tables from ref. 5 are of particular interest. Table I shows the percentage of the primary energy which goes into each species when the bombarded atmosphere is 45% N_2, 45% O, and 10% O_2, corresponding roughly to the atmosphere at great altitudes. The percentages change but little for E = 30, 10, 1 keV but excitation (in contrast to ionization) becomes relatively more important at 0.1 keV. The column labeled "remainder" is the percentage of the energy which is lost in the interval from zero to about 1 eV through the processes of rotation, vibration, and elastic scattering. Table II from ref. 5 shows the breakdown into secondary, tertiary, and quaternary spectra and also the average energies. Note in Table I that roughly equal proportions of energy go into excitation and ionization at primary energies of 30, 10, and 1 keV but the proportion producing excitation is considerably larger at a primary energy of 0.1 keV. Note also the low mean energy of secondaries in Table II. Because of this low energy the next collision of a secondary is more likely to excite than to ionize and hence the abrupt drop in the tertiary

[1]Some of the research described in this review was supported in part by the United States Air Force Office of Scientific Research under Grant No. AFOSR-68-1495.

TABLE I

Energy into species

population compared to the secondary. It is not the purpose of this review to critically appraise the theory of Green and collaborators. However, in those calculations liberal use was made of the cross sections measured by the author and his collaborators and hence this affords a good opportunity to consider the current status of these cross sections. It should be noted that the development of electron impact spectroscopy is important to chemistry in ways not directly related to atmospheric phenomena and comments on points relevant to these objectives will be made occasionally. Before discussing electron impact spectra, some definitions and elementary theoretical results must be summarized. This is done in the following section.

The Born Approximation: Generalized Oscillator Strengths

In the discussion of transitions it is useful to employ generalized oscillator strengths which we designate by f. This quantity is defined (in atomic units) as

$$[1] \qquad f = (W/2)\,(k_1/k_2)K^2\sigma$$

where W is the excitation energy, σ is the differential collision cross section, k_1, k_2 are the magnitudes of the wave vectors of the incident and scattered electrons, and K is the magnitude of the change in wave vector of the incident electron on collision. ($(h/2\pi)K$ is the magnitude of the momentum change vector and $h/2\pi = 1$ in atomic units.) When the Born approximation holds we can substitute Bethe's modification of the Born formula into eq. [1] and obtain

$$[2] \qquad f = 2W\,\varepsilon\varepsilon^*/K^2$$

where ε is a matrix element

$$[3] \qquad \varepsilon = \langle\psi_1\,|\,\textstyle\sum_j N_j e^{iKz_j} - \sum_s e^{iKz_s}\,|\psi_2\rangle$$

Here ψ_1, ψ_2 are the eigenfunctions of the scatterer in the initial and final states, N_j is the atomic number of the jth nucleus, and z_j, z_s are the z coordinates of the jth nucleus and the sth electron of the scatterer. It is useful to expand eq. [3] in a power series in K

$$[4] \qquad \varepsilon = \textstyle\sum_{n=1}^{\infty}(iK)^n\varepsilon_n$$

where

$$[5] \qquad \varepsilon_n = (1/n!)\,\langle\psi_1\,|\,\textstyle\sum_j N_j z_j^n - \sum_s z_s^n\,|\psi_2\rangle$$

Then ε_1 is the matrix element of electric dipole moment. If a transition is allowed and K is very small then

$$[6] \qquad f = 2W\,|\varepsilon_1\,|^2$$

If $\varepsilon_1 = 0$ and $\varepsilon_2 \neq 0$, then at small values of K (neglecting higher order powers of K)

$$[7] \qquad f = 2W\,|\varepsilon_2\,|^2K^2$$

Since $z^2 = r^2/3 + (z^2 - r^2/3)$ the quantity ε_2 is expressible in the form

$$[8] \quad \varepsilon_2 = 1/3\langle\psi_1 | \sum_j N_j r_j^2 - \sum_s r_s^2 | \psi_2\rangle + \langle\psi_1 | \sum_j N_j (z_j^2 - r_j^2/3) - \sum_s (z_s^2 - r_s^2/3) | \psi_2\rangle$$

For the lack of a better word we have referred to ε_2 as the matrix element of electric quadrupole moment and any transition for which $\varepsilon_1 = 0$ and $\varepsilon_2 \neq 0$ has been referred to as an electric quadrupole transition. This is not the same as the terminology employed in spectroscopy. In optical spectra only the second term on the right of eq. [8] arises in considering the intensities of electric quadrupole transitions. There is no analogue of the first term on the right. The $1^1S \rightarrow 2^1S$ transition in helium is an example of a transition in which the second term on the right of eq. [8] vanishes but the first does not, while the Lyman–Birge–Hopfield bands of N_2 provide an example in which the first term vanishes and the second does not (7, 8). Garstang (9) has shown that when eq. [8] is substituted into eq. [7] the cross products vanish in summation over magnetic quantum numbers and he has obtained a formula in which Einstein's A replaces the term containing the square of the second matrix element in eq. [8]. The formula, which we omit, is developed in a sufficiently general fashion to include both atoms and diatomic molecules. An application of Garstang's formula will be discussed later.

For convenience in subsequent discussion we note how the cross sections depend on momentum change at small values of K. For transitions in which $\varepsilon_1 \neq 0$ we may assume that $f = 2W\varepsilon_1^2$ at small K and hence, designating the cross section by σ_d

$$[9] \quad \sigma_d \simeq (4\varepsilon_1^2)/K^2$$

We have assumed that $k_2/k_1 \simeq 1$. At zero scattering angle and high kinetic energy $\bar{E}$, $K^2 = W^2/2\bar{E}$ where $\bar{E} = E - W/2$. This relation holds accurately when $W/\bar{E} < 0.1$. Hence

$$[10] \quad \sigma_d \simeq (8\varepsilon_1^2\bar{E})/W^2$$

For quadrupole transitions $\varepsilon_1 = 0$, $\varepsilon_2 \neq 0$, we designate the cross section by σ_Q and find using eq. [7] when K is small

$$[11] \quad \sigma_Q \simeq 4\varepsilon_2^2$$

This is independent of kinetic energy. Hence the ration of σ_d to σ_Q is

$$[12] \quad \sigma_d/\sigma_Q = 2\bar{E}\,\varepsilon_1^2/(W^2\varepsilon_2^2)$$

Electron Impact Spectra: Relative Intensities

Apparatus

High resolution electron impact spectroscopy requires velocity selection before scattering. The first successful monochromatic electron source, based on the 127° analyzer, was developed by Marmet and Kerwin (10). The "electron" velvet used by them was replaced by platinum black by Schulz (11, 12) in his study of very low energy resonances. Ehrhardt (13), McGowan (14), and Brion (15) have also used this source, the latter without coatings (except for gold plate). Of these investigators only Schulz and Ehrhardt did velocity analysis on the scattered electrons (McGowan and Brion used the sources in mass spectrometers). Since the low kinetic energy range (used by Schulz and Ehrhardt) is being covered by another reviewer, we pass on to the consideration of spectrometers which have been used at higher kinetic energy.

Electron sources based on the spherical condenser (hemispheres) have been developed by Skerbele and Lassettre (16) and Simpson (17). High resolution electron spectrometers have been considerably refined and developed by Lassettre and collaborators (18–20) and by Simpson and Kuyatt (21, 22). These are based on hemispheres which are used both for velocity selection before scattering and for velocity analysis afterwards. Both apparatuses permit variation in scattering angle (from -16 to $+16°$ in the instrument of ref. 20 and from -20 to 90° in that of ref. 22). The apparatuses differ in size, in the manner of correction for chromatic aberration, and in the measurement of scattered current (a reed amplifier in refs. 21, 22 and an electron counter in refs. 18–20.) Boersch and collaborators (23–25) (especially Geiger) have achieved the highest resolution in electron impact spectroscopy at very high kinetic energies (most frequently at 25 keV). In their instrument the scattering angle cannot be varied. Crossed electric and magnetic fields (Wien filter) are used in the monochromator.

From an instrumental viewpoint the velocity analyzers used by Turner (26) (in the determination of photoelectron energy distributions) are of interest. In the case of oxygen, the broadening of

bands (presumably thermal) has been observed in comparison to atomic line widths. In these experiments the instrumental line width is reduced by 40% since only one analyzer is employed. The electrostatic analyzers employed in Turner's experiments are based on the 127° analyzer but with intermediate elements to correct for aberration at high entrance angles.

Electron Impact Spectra

Relative Intensities

Since high resolution is now obtainable in electron impact spectroscopy it is useful to exhibit electron impact spectra of the principal atmospheric gases. Spectra at both high and low kinetic energies are included where available and spectra under additional conditions are also given when especially significant points are involved. Since the experimental technique is developing rapidly (a large percentage of all research in electron impact spectroscopy is still in the process of publication) the spectra obtained by investigators other than the present author may not be the best available. An attempt has been made to include at least a portion of each spectrum of the highest resolution in all cases where this is known.

Nitrogen

Electron impact spectra of nitrogen are shown in Fig. 1. The spectra labeled A, B, and C were obtained by Lassettre, Skerbele, Dillon, and Ross (20). The inset at the upper right is a portion of a nitrogen spectrum covering the same range as C, obtained by Geiger and Schröder (27). The complete spectrum is being published elsewhere (28) together with an extended discussion of its interpretation. Spectra A and B are on the same scale but spectrum C cannot be quantitatively compared in intensity with A and B. The resolution obtained by Geiger and Schröder is higher than that of spectrum C but not by a sufficient margin to conceal the striking similarity between the two, despite the fact that the kinetic energy in one case is 25 keV and in the other 33 eV. The most conspicuous exception is the j state at 12.5 eV. The relative intensity of this state is higher at 33 eV than at 25 keV.

At excitation energies less than 12.5 eV Geiger (29) finds no peak at 25 keV. Obviously, however, several such transitions appear in spectra A and B of Fig. 1. These are (electric dipole) forbidden transitions. Mulliken (30) has suggested term symbols and excitation energies for many states of nitrogen. Using his tables we note 24 transitions from the ground state to electronic states which have energies below that of the j state. We deduce from Mulliken's term symbols that only one of these is allowed and this seems not to have been observed in either absorption or emission. Of the remaining 23 transitions, however, a considerable number have been found in the ultraviolet absorption spectrum of nitrogen and several are shown in spectra A and B of Fig. 1. In particular, transition to the E state ($^3\Sigma_g^+$) at 11.87 eV is clearly visible. This transition was observed by Heideman, Kuyatt, and Chamberlain (31) in spectra obtained at 35 and 15.7 eV incident kinetic energy and independently by Meyer and Lassettre (32) in spectra obtained at 400 eV kinetic energy. We thought at first (32) that the E state could not be a triplet when the transition is obtained at such high kinetic energies and spin–orbit coupling cannot mix the proper configurations to make the transition electric dipole allowed. However, it was later recognized (19) that second order terms (see eq. [8]) in the cross section (or generalized oscillator strength) are sufficient to account for the transition. The electron impact spectra of Heideman, Kuyatt, and Chamberlain (31) at 33 and 15.7 eV are shown in Fig. 2. Note the rapid decrease in relative intensity of the 12.93 eV transition as the kinetic energy is reduced.

An array of forbidden transitions, more complete than that of Fig. 1, is shown in Fig. 3. The excitation to $C^3\Pi_u$ is observed (33) over the angle range 3 to 16° although it does not appear in the upper spectrum of Fig. 2 and it was not observed in an earlier investigation (19) at kinetic energies between 30 and 100 eV, presumably due to lower resolution and higher background. Forbidden transitions in N_2 will be discussed further after the introduction of one additional spectrum.

The electron impact spectra shown thus far contain transitions corresponding to the vacuum ultraviolet in a radiation absorption spectrum. In Fig. 4 the spectrum of nitrogen (34) is shown in the vicinity of the elastic peak. A carbon monoxide spectrum is included for comparison. The fundamental vibration is obviously excited together with one overtone. The ratio of the intensity, I, to that I_0, for the elastic peak is $I/I_0 = (4.3 \pm 0.3) \times 10^{-4}$. Between 2 and 15° this ratio is constant. Schulz (11) has observed vibrational excitation in N_2 at very low kinetic energies (2–3 eV) where excitation is attributable to negative

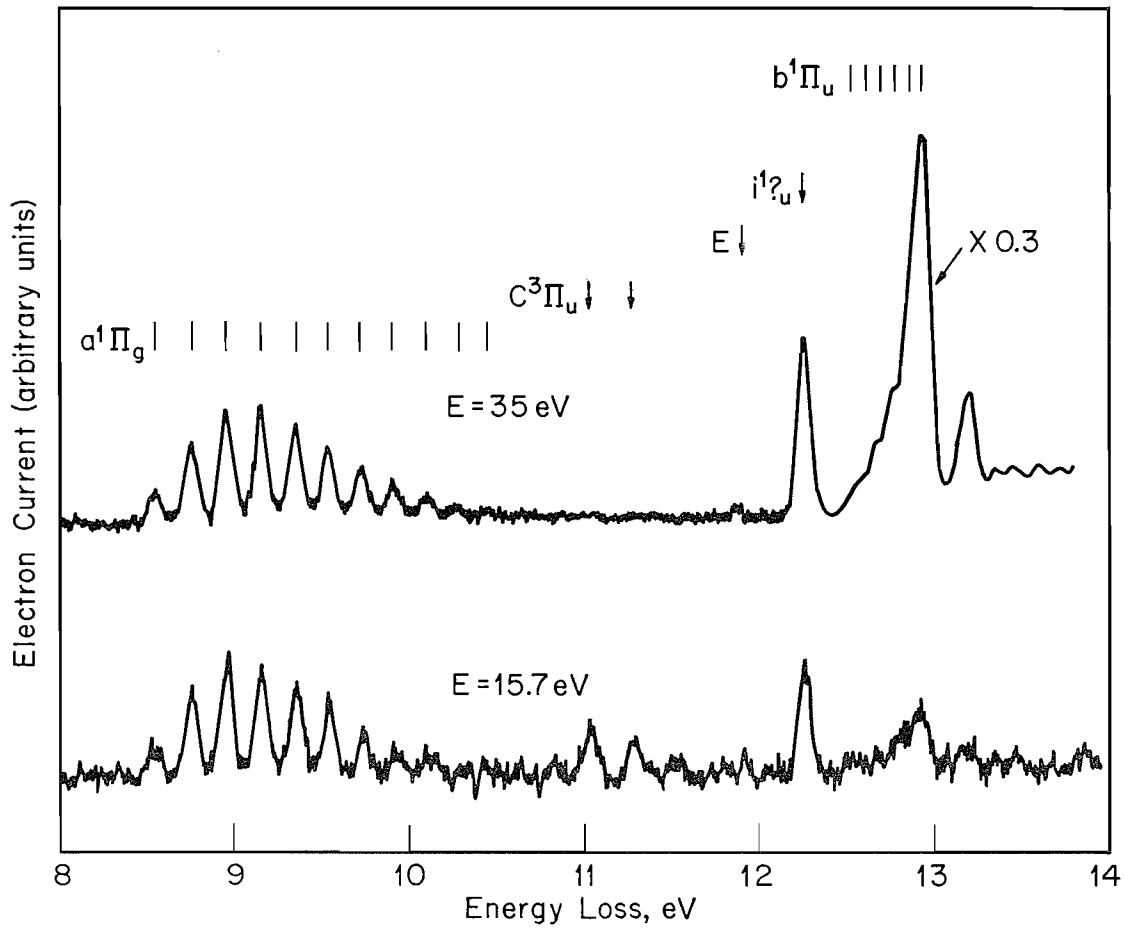

FIG. 2. Electron impact spectra of N_2 at 35 and 15.7 eV electron kinetic energies by Heideman, Kuyatt, and Chamberlain (31). $\theta = 0°$. Note decrease in intensity of 12.93 eV transition.

ion resonances. Figure 4 shows that vibrational excitations in homonuclear molecules are also detectable at much higher kinetic energy. The transitions are, of course, forbidden and are very weak.

Referring back to Fig. 1 the vibrational progression with peak at 9.16 eV is the analogue of the Lyman–Birge–Hopfield band system observed in in the vacuum ultraviolet. Until 1946 it was thought to be an electric dipole allowed system but very weak. In 1946, Herzberg (35) gave strong reasons for believing that the transition is forbidden (upper state $a^1\Pi_g$) and that it appears in the ultraviolet absorption spectrum due to a non-vanishing matrix element of magnetic dipole moment. Wilkinson and Mulliken (36) resolved the rotation lines in the band system well enough to detect not only the system of lines obeying the magnetic dipole selection rules but another system of weaker lines which obey the electric quadrupole selection rules. This observation definitely establishes $^1\Pi_g$ as the upper state term symbol and proves that two different processes are contributing to the band system. Moreover, by determining the relative intensities of the two different types of rotation lines, the proportion of the band intensity due to magnetic dipole and electric quadrupole transitions can be determined. The most recent studies by Vanderslice, Tilford, and Wilkinson (37) give 75% magnetic dipole and 25% electric quadrupole.

The cross section formulas of the previous section are not only based on the Born approximation but assume in addition that the interac-

tion of the incoming electron with the scatterer is the coulomb (electrostatic) term in the Hamiltonian. Since magnetic interactions are neglected entirely, no magnetic dipole excitation mechanism can arise in that theory. Since the Lyman–Birge–Hopfield bands are a prominent part of the electron impact spectrum, it is possible to determine collision cross sections (and hence generalized oscillator strengths) and to determine independently whether the system is forbidden. This has been done by Lassettre and Krasnow (38) and the results are given in Fig. 5. The vibrational levels were not resolved in these experiments but this should not affect the intensity integrated over the band. In Fig. 5 we have used the momentum change ΔP rather than the wave vector K ($h/2\pi(K) = \Delta P$), but the two are numerically equal in atomic units. There is an obvious trend towards zero as the momentum change decreases in accord with the hypothesis that the transition is forbidden. Garstang (9) has analyzed these data further in the following fashion. Since the term symbol for the excited state differs from that for the ground state, the first term on the right of eq. [8] vanishes. Since the second term on the right involves the same matrix element as that appearing in intensity formulas for the absorption of radiation in electric quadrupole transitions, it should

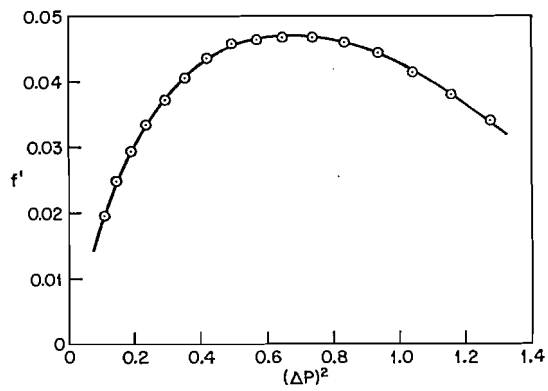

FIG. 5. Generalized oscillator strength vs. square of momentum change (atomic units) for the transition $a^1\Pi_g \leftarrow X^1\Sigma_g^+$ of N_2 (Lyman–Birge–Hopfield bands) by Lassettre and Krasnow (38). Kinetic energy ~ 500 eV.

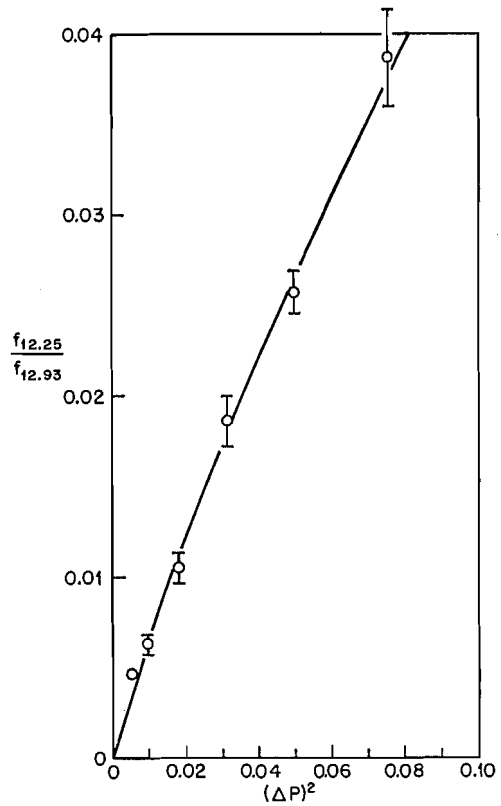

FIG. 6. Ratio of generalized oscillator strength of 12.26 to 12.93 eV transitions of N_2 vs. square of momentum change (atomic units) by Lassettre, Skerbele, and Meyer (19). Kinetic energy 500 eV.

be possible to recast this expression in terms of Einstein's A for the transition. This has been done by Garstang (9). The value of A calculated from the data of Fig. 5 is 2000 s^{-1}. Lichten (39) also measured the lifetime of the state by a molecular beam technique and obtained for A the value 5900 $\pm$ 1000 s^{-1}. This value involves transitions by both magnetic dipole and electric quadrupole mechanisms, hence only 25% of this value, 1500 $\pm$ 250 s^{-1}, is due to electric quadrupole transitions. As Garstang (9) pointed out, this agrees about as well with the value obtained from analysis of the electron impact data as could be expected.

The Lyman–Birge–Hopfield bands are an example of a forbidden system for which the second term on the right of eq. [8] is non-vanishing. We now discuss a transition for which the first term proves to be non-vanishing. The transition referred to is that at 12.26 eV. A transition at approximately this excitation potential was reported by Heideman, Kuyatt, and Chamberlain (31) working at incident kinetic energies of 33 and 15.7 eV and (independently) by Meyer and Lassettre (40) working at 400 eV. Both sets of investigators also reported an excitation potential at 11.87 eV. The first excitation potential (12.26 eV) seemed to agree with Worley's (41) *i* state and the second (11.87 eV) to involve excitation to the *E* state ($^3\Sigma_g^+$). To determine whether the 12.26 eV transition is (electric dipole) allowed, the ratio of the oscillator strengths of the 12.26 and 12.93 eV transitions has been determined (19) and is shown as a function of momentum change for the 12.26 eV transition in Fig. 6. Since the peak at 12.93 eV is the highest in the entire spectrum it is certainly electric dipole allowed, and hence the ratio $f_{12.26}/f_{12.93}$ will approach zero if the 12.26 eV transition is forbidden. From Fig. 6 it is obvious that the transition is forbidden and, moreover, the first non-vanishing power of the momentum change (in a Taylor series expansion) is the second, i.e. $f \propto (\Delta P)^2$ at small momentum changes. Since the ground state term symbol for N_2 is $^1\Sigma_g^+$ it follows from an elementary application of group theory that the term symbols for the excited state must be one of the following $^1\Sigma_g^+$, $^1\Pi_g$, $^1\Delta_g$. After consulting Mulliken's list of term symbols, only one, $^1\Sigma_g^+$, seemed probable and this was proposed in ref. (19). For a transition between two $^1\Sigma_g^+$ states the first term on the right of eq. [8] does not vanish, while the second term vanishes. This is in contrast to the Lyman–Birge–Hopfield bands.

The 12.26 eV transition is strongly forbidden in radiation absorption but Lutz and Dressler (42) have found it at high pressures due to a collision induced dipole moment. They also showed that the 12.26 eV transition is not the same as Worley's *i* state. The latter, although close in excitation energy, actually arises from a radiation absorption process in which the initial state is the excited vibrational level $v'' = 1$ of the ground electronic state.

It was also shown in ref. 19 that the 11.86 eV transition is electric quadrupole (i.e. $\varepsilon_1 = 0, \varepsilon_2 \neq 0$. See section on Born approximation). This was shown by determining the intensity ratio $I_{11.87}/I_{12.26}$ at several kinetic energies and zero scattering angle. The ratio is nearly independent of kinetic energy as it must be if the 11.87 and 12.26 eV transitions are both electric quadrupole in type. This is compatible with the term symbol $^3\Sigma_g^+$ assigned by Mulliken (30) provided that spin–orbit coupling has mixed additional (singlet) configurations such that the transition from the ground state acquires a small electric quadrupole component. It could also be that some different state with term symbol $^1\Sigma_g^+$ is being excited as suggested by Cermak (43) on the basis of the study of Penning ionization.

A third type of transition which can occur in electron impact experiments as well as radiation absorption is one which involves a change in multiplicity. Singlet–triplet transitions are a frequently encountered example. Singlet–triplet transitions in optical spectra are usually encountered under conditions where spin–orbit coupling is significant. If the actual molecular (or atomic) eigenfunction is expressed as a linear combination of eigenfunctions of a Hamiltonian without magnetic terms, then both singlet and triplet terms contribute to the sum when magnetic contributions are taken into account (44). These added terms may make the transition electric dipole allowed (but weak) and hence such transitions will be observed in radiation absorption. They should also be encountered in electron impact spectra. An especially interesting example is provided by the transition to the $C^3\Pi_u$ state of N_2. This transition is the most intense singlet–triplet transition in the ultraviolet absorption spectrum of N_2. It was mentioned earlier that the excitation to $C^3\Pi_u$ was difficult to detect in the kinetic energy range 30 to 100 eV. However, as the resolution was improved and background

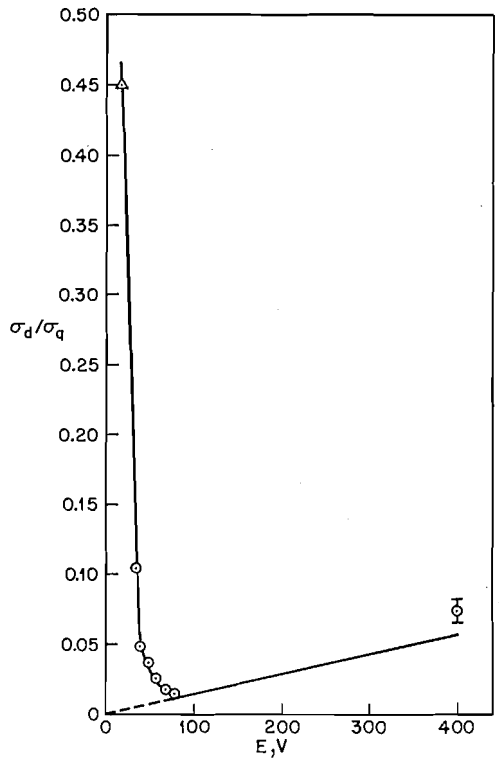

FIG. 7. Ratio of cross section for transition ($v' = 0$) $C^3\Pi_u \leftarrow X^1\Sigma_g^+$ to that for the transition ($v' = 3$) $a^1\Pi_g \leftarrow X^1\Sigma_g^+$ vs. kinetic energy. $\theta = 0°$. ⊙ from ref. 33, △ from ref. 31, Φ from ref. 19. Straight line calculated from ultraviolet absorption coefficients.

decreased, the transition could be detected (see e.g. Fig. 3). It is convenient to deal with the ratio of the intensity of the singlet–triplet transition to the Lyman–Birge–Hopfield (L.B.H.) bands at zero scattering angle. This is given by eq. [12]. Since the second term on the right of eq. [8] is non-vanishing for the L.B.H. bands, we can use Garstang's formula (9) to relate ε_2^2 to Einstein's *A* and hence the absorption coefficient and ε_1^2 can also be related to the absorption coefficient for the singlet–triplet transition. Hence the cross section ratio σ_d/σ_Q can be calculated from the ratio of absorption coefficients in the ultraviolet spectrum after a correction has been made which removes the magnetic dipole contribution to the absorption coefficient. This calculation has been made (32) and the calculated and observed cross section ratios compared (32, 33). The curve obtained in a recent research (33) is shown in Fig. 7. The solid line is calculated using the absorption

coefficients. Only one point has been found at high kinetic energies (19) from spectra of considerably poorer quality than those of Fig. 3. The data apply to forward scattering and show that the region 30–100 eV is not a favorable one for the study of singlet–triplet transitions because they tend to be obscured, not only by other more intense allowed transitions, but by electric quadrupole transitions as well.

An intensity anomaly (45) was encountered in the region between 12.5 and 12.93 eV. The first indication of its existence was the disagreement between the excitation potential for the most intense transition in the electron impact spectrum of N_2 (12.93 eV) and that found by others in the ultraviolet absorption spectrum (12.76 eV). The vibrational levels in the electron impact spectrum were not resolved and the discrepancy was initially attributed to a failure of the Born approximation (45). However, with improved spectrometer design, the spectrum was more completely resolved (at 200 eV kinetic energy) and the observed relative intensities (46) of the vibrational levels agreed well with the Franck–Condon factors calculated by Nicholls (47), provided that the vibrational quantum numbers are re-assigned as recommended by Ogawa, Tanaka, and Jursa (48). Geiger and Stickel (49) have independently studied the nitrogen spectrum at 25 keV kinetic energy and obtained intensity ratios in agreement with those of Meyer, Skerbele, and Lassettre (46). It is obvious, therefore, that no failure of the Born approximation is involved. Meyer, Skerbele, and Lassettre (46) suggested that line saturation in the absorption spectrum could account for the discrepancy between ultraviolet and electron impact spectra. Lawrence, Mickey, and Dressler (50) have re-investigated the absorption coefficients in the ultraviolet and have shown that the relative intensities at high resolution and very low pressures (where line saturation is unimportant) are in agreement with electron impact spectra. Relative intensities obtained in electron impact and in the ultraviolet are collected in Table III. The relative Franck–Condon factors are also included. The agreement is good. Lawrence, Mickey, and Dressler (50) have referred to a new analysis of the N_2 spectrum, involving especially the $b^1\Pi_u$ state, which takes into account the strong perturbations which affect the state. The Franck–Condon factors of Nicholls (47) were calculated from a Morse potential function and perturbations were not explicitly taken into account. A more refined theory which considers this point is obviously needed. Oscillator strengths are also reported in ref. (50). These will be discussed later.

At low kinetic energies (48 eV) the relative intensities of the vibrational levels of the $b^1\Pi_u$ state have been studied as a function of angle (20). The results are collected in Table IV. These data are to be compared with Table III. The agreement is obviously excellent except for the 12.93 eV transition. In the first place we note that the relative intensities do not change with angle except for

the 12.93 eV transition. This peak belongs to a different electronic state ($p'^1\Sigma_u^+$) from the remaining peaks ($b^1\Pi_u$), and hence a change in relative intensity with angle is not surprising. In the section entitled Energy Degradation in the Excitation of Gases, the energy degradation calculations of Green *et al.* were mentioned. These were based on cross sections for the entire electronic transitions and the question arises as to whether the vibrational components change in relative intensity with angle. From Table IV it is obvious that the relative intensities for different vibrational levels of the $^1\Pi_u$ state are not changing with angle even though the state is strongly perturbed by adjacent states. Constant relative intensities (as scattering angle is varied) should greatly simplify calculations of energy degradation and others of a similar nature. The Franck–Condon principle suggests that relative intensities should change but little with angle, but a direct experimental confirmation is well worthwhile. In contrast, there are pairs of *electronic* transitions in N_2 whose relative intensities change by a factor of 10 within the same range of angle.

The relative intensities in the vibrational progression of the transition $a^1\Pi_g \leftarrow X^1\Sigma_g^+$ have also been studied as a function of angle at 48 eV kinetic energy. The results are shown in Table V for 15 members of the progression and for several other electronic transitions by way of contrast. There is some trend for the first two members ($v' = 0, 1$) but the trend is small in comparison to changes in intensity ratios of different electronic transitions. The average relative intensities agree well with the Franck–Condon factors of Benesch *et al.* (51) except at very high vibrational quantum

numbers. It is again obvious that calculations like those of the above mentioned section are greatly simplified because relative intensities in a vibrational progression change but little with angle.

Three members of the vibrational progression associated with the transition $C^3\Pi_u \leftarrow X^1\Sigma_g^+$ have been resolved (20). Relative intensities as a function of angle are given in Table VI. There is no significant change with angle but the average does not agree well with calculated Franck–Con-

1	11.281	0.68	0.70	0.74	0.65	0.77	0.71	0.56
2	11.522	0.45	0.37	0.26	0.35	0.40	0.37	0.19

don factors. The transition is so weak that the intensity measurements are subject to large random errors and an accurate background correction is difficult to make. It is probable, however, that the difference between theory and experiment is real.

Referring back to Table I we see that for a 30 keV incident electron, 32.8% of the energy contributes to excitation of N_2 and 27.1% produces ionization. We now inquire into the state of the ions produced. Much attention has been devoted to the determination of energy levels of positive ions. Limited information is obtained by extending electron impact spectra into the ionized continuum. When this is done auto-ionized transitions are encountered. The theory of line shapes of such transitions has been developed by Fano (52) and has been extensively tested by experiments on atoms, especially helium. This situation will be further discussed in the section on helium. Nitrogen has been studied at high resolution by Geiger and Stickel (49) and by Lassettre, Skerbele, and Meyer (19). Electron impact spectra have been extended into the ionized continuum and three spectra are shown in Fig. 7*a*. The bottom spectrum is that of Geiger and Stickel (49) at 25 keV, the middle figure is from ref. 19 at 200 eV, while the upper figure is a previously unpublished spectrum at 70 eV obtained by Lassettre, Skerbele, and Dillon. The auto-ionized transitions at excitation energies above 17 eV are obvious. Since auto-ionization is accompanied by substantial line broadening there is a loss of detail in the ionized continua which cannot be regained by increase in resolution. Nevertheless, this loss in detail is not inevitable because it results in part from the fact that in an ionized continuum, the energy of the ejected electron is not selected or controlled, and hence the collision (above the ionization limit) is not fully defined. This could be remedied, with an additional velocity analyzer, by counting coincident events. Thus far, this has been done only by Erhardt and Linder (53) at low resolution. However, the expected result at high resolution can be forecast in the following way. At small scattering angles the collision cross section is proportional to the oscillator strength (eq. [1]) and hence the energy spectrum of electrons ejected in a glancing collision should be the same as the energy spectrum of electrons ejected in the absorption of a photon whose energy is that transferred to the molecule in the electron collision. Turner and May have studied the kinetic energy distribution of electrons ejected from N_2 by absorption of helium resonance radiation (54) ($h\nu = 21.21$ eV). The spectrum of ejected electrons observed by Turner and May is shown in Fig. 8. A magnetic velocity analyzer was used. Since the ejected electrons have been completely separated from the ion (whose recoil energy is negligible) the spectrum, in an energetic sense, is that of the positive ion. The relative intensities

within a vibrational progression are given by the Franck–Condon factors with good accuracy. The relative intensities of different electronic states of the ion are determined by the probabilities of simultaneous two electron jumps (one electron excited, the other ejected). A theory of this process must take account of electron correlation. Approximations of the Hartree–Fock type are not adequate. Since the energies of electronic states of positive ions are of great chemical interest, this method has been widely developed and applied by Turner and collaborators under the designation "photoelectron spectroscopy". It would be of considerable interest to develop apparatus for the study of ejected electron spectra when the gas is ionized by electron impact with the transfer of a pre-selected amount of energy

to the scatterer. Spectra similar to Fig. 8 are expected, but it would be of interest to test this point by experiment. However, there are formidable difficulties involved in such experiments.

Mass spectrometric methods for the study of excited ionic states are also well developed and are being reviewed by a different author.

Electron impact spectra of N_2 at low kinetic energy and large scattering angles have been obtained by Doering and Williams (55). Singlet–triplet transitions are prominent under these conditions.

Oxygen

Electron impact spectra of oxygen at 48 eV kinetic energy (20) are shown in Fig. 9. The scattering angle in the upper spectrum is 14° and in the lower, 4°. The broad peak (7–9 eV) corresponding to the dissociation continuum of the Schumann–Runge bands dominates the spectrum. Changes in relative intensity with change in angle are obvious. Geiger and Schröder (56) have also studied the oxygen spectrum at a scattering angle of 0° and kinetic energy of 25 keV. The results are shown in Figs. 10 and 11. Figure 10 is very similar to the small angle spectrum of Fig. 9. The differences are attributable to the different angles and resolving powers. On the other hand there are distinct differences in relative intensity between Figs. 11 and 9. This is especially noticeable in the excitation energy range 10.5 to 12.0 eV and is not attributable either to differences in scattering angle or resolution. The transitions shown in Figs. 10 and 11 are all electric dipole allowed and in Fig. 9 no peak is definitely associated with a forbidden transition. However, the kinetic energy at which the spectra of Fig. 9 were obtained is low enough so that forbidden transitions should be excited. It seems very probable that the differences in relative intensity are due to optically forbidden transitions which are not resolved from the allowed transitions in Fig. 9. In less crowded regions of the spectrum, forbidden transitions are observed. In Fig. 12 the portion of the energy loss spectrum of oxygen from 0 to 2 eV is shown. Aside from the elastic peak (at energy loss 0) all of the remaining peaks arise from forbidden transitions. The fundamental vibration (at 0.196 eV) and one overtone, together with the peak corresponding to $a^1\Delta_g \leftarrow X^3\Sigma_g^-$, are obvious. An overtone of the latter transition is also observed although many spectra were needed to distinguish it from the background. The transition $b^1\Sigma_g^+ \leftarrow X^3\Sigma_g^-$ should be observed at 1.6 eV and there is a suggestion of a peak in Fig. 12. Additional spectra obtained at 60 eV suggest that the transition does occur but it exceeds the background by so little that its intensity cannot be reliably estimated. None of the excited states is new. All are known from previous research. The ratio of the intensity of the $a^1\Delta_g \leftarrow X^3\Sigma_g^-$ to the elastic peak has been determined over the angle range 2 to 15° at kinetic energy 45 eV and found to be constant and equal to $(1.3 \pm 0.2) \times 10^{-4}$.

It is convenient at this point to digress briefly

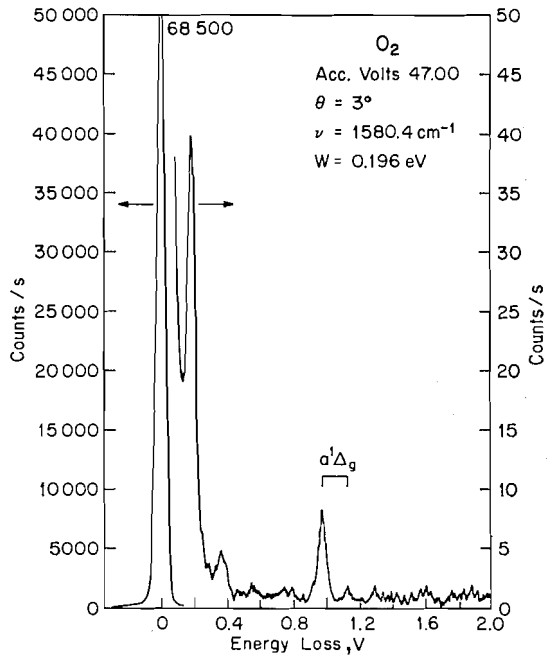

FIG. 12. Electron impact spectrum of O_2 by Skerbele, Dillon, and Lassettre (34).

for some comments on the resolution of velocity analyzers. To complete the basis for this discussion we show one additional electron impact spectrum of oxygen in Fig. 13. In this spectrum the electrons were scattered at a kinetic energy of 70 eV and then retarded to 20 eV, this being the kinetic energy at which electrons traverse the velocity analyzer. When this spectrum was taken, slits of width W equals 0.01 in. were installed in the focal plane and the orbit diameter in the analyzer is D, equals 10 in. Hence the resolving power, R, equals D/W, is 1000. If electrons of a given energy are incident on a velocity analyzer then the fraction transmitted at different energy settings is a triangular curve with half width $\Delta E = E/R$. Since both monochromator and analyzer are involved, a convolution will give the overall fraction transmitted. If electrons pass through both monochromator and analyzer at the same energy then the resultant transfer function is a bell shaped curve with half width $1.4\Delta E = 1.4E/R$. As used in Fig. 13 the half width is 0.028 eV. Turner (26) has analyzed the performance of velocity analyzers in photoelectron spectroscopy and pointed out that the breadth of molecular bands due to unresolved rotational structure is of the order of kT

$\sim$ 0.028 eV, this quantity being largely independent of the structure of the molecule. In Fig. 13 we have a spectrum in which the instrumental band width is equal to the thermal, rotational spread, while in Fig. 11 there is given a spectrum in which the band width is considerably smaller ($\sim$ 0.01 eV). Obviously in Fig. 11 more detail is resolved but the half width of the narrowest peaks is comparable with the 0.028 eV expected for the thermal width. The band width used in Fig. 13 is not the smallest employed in our research. In Fig. 1, spectrum C at 33 eV was obtained with a band width of approximately 0.014 eV. The path length through our scattering cell is 5 cm and the pressures employed range from 0.2 to 1.0 μ. Hence pressure times path length is between 10^{-3} and 5×10^{-3} Torr cm. At these small values (and high angular resolution) the scattered currents become too small for reliable measurement when the band width is less than 0.014 eV. This, however, may be only a temporary block.

Turner (26) has shown that in photoelectron spectroscopy the widths of peaks of molecular ions are distinctly larger than atomic ions. This is illustrated in Fig. 14 which shows the peak widths of lines from an atomic ion (Xe^+) in the right hand part and that due to O_2^+ in the left hand part. Note the peak due to Xe^+ in the left hand spectrum. The peak widths of the atomic lines are 0.015 eV. The O_2^+ peaks are broadened more than the doublet splitting, 0.024 eV. In these experiments electron kinetic energies were only a few volts. More complete O_2^+ spectra have also been obtained by Turner and May (54). A spectrum is shown in Fig. 15. This figure provides the states of the ion and can be considered as an electron ejection spectrum brought about by a

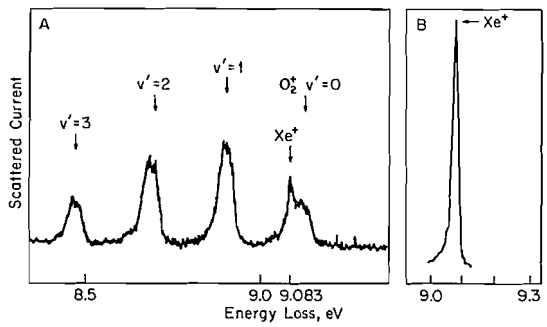

FIG. 14. Energy distribution of electrons ejected from O_2 (left) and Xe (right) on illumination with helium resonance radiation ($h\nu = 21.21$) by Turner (26). The left hand spectrum is due to the excited state $^2\Pi_g$ of the O_2^+ ion while the right hand peak is due to $^2P_{3/2}$ state of Xe^+. Xe mixed with O_2 in left hand spectrum. Note difference in peak widths.

glancing collision in which the incident electron transfers 21.21 eV to the O_2 molecule. A precisely similar case is discussed for N_2.

Water Vapor

An electron impact spectrum of H_2O at low resolution was reported by Lassettre and Francis (57). At higher resolution a spectrum was obtained by Skerbele and Lassettre (58) and at still higher resolution by Skerbele, Meyer, and Lassettre (59). The intensity was studied as a function of angle by Skerbele and Lassettre (60). A spectrum obtained recently (20) at 100 eV is shown in Fig. 16. Term symbols, taken from the compilation of Herzberg (61), are shown on the figure for several transitions.

Very recently, background has been reduced in the vicinity of the elastic peak to such a degree that vibrational transitions can be found. Examples have already been given for N_2 and O_2. In Fig.

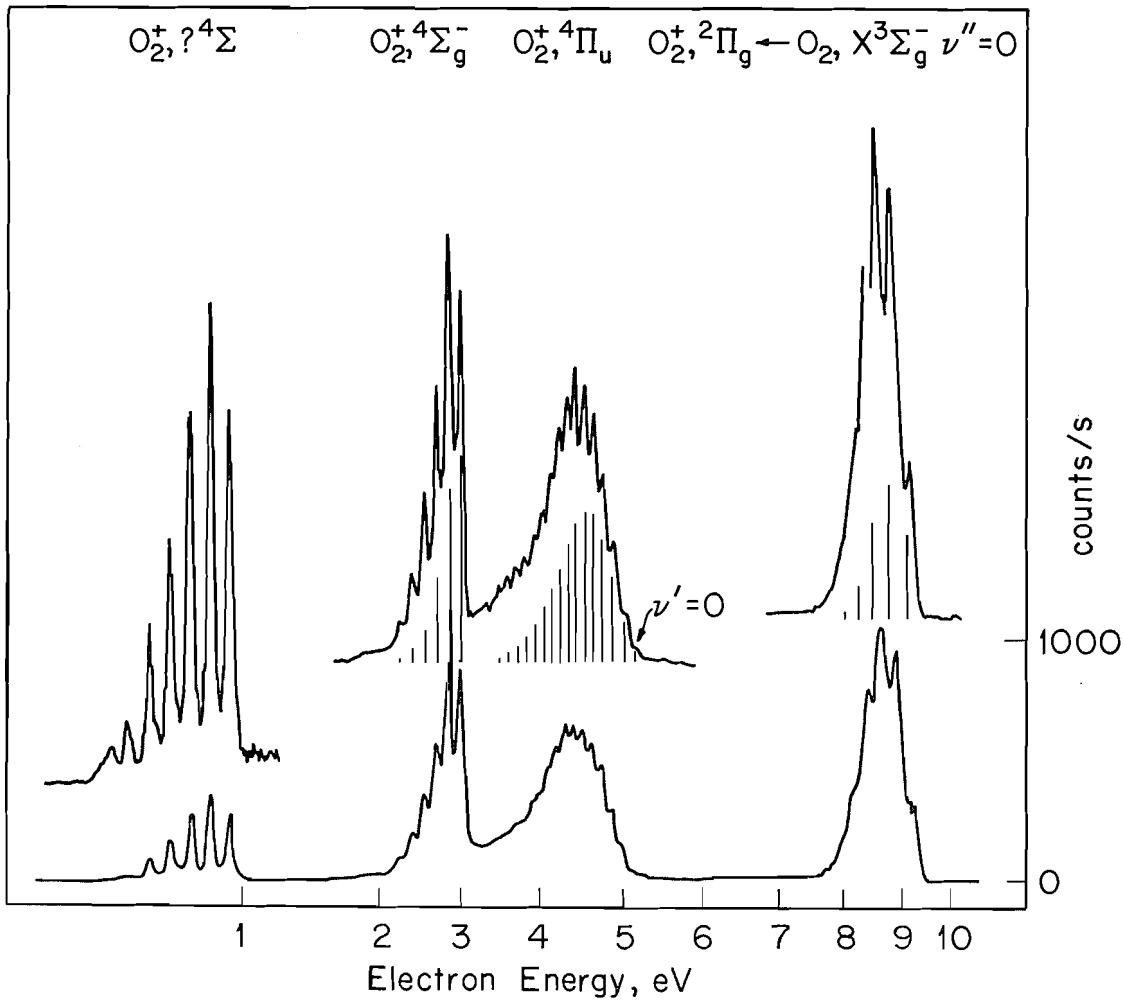

FIG. 15. Energy distribution of electrons ejected by absorption of helium resonance radiation ($h\nu$ = 21.21 eV) by Turner and May (54). Top spectrum at higher sensitivity. Vertical lines are Franck–Condon factors. Magnetic analyzer was used.

17 is shown a rather complete spectrum (62) of water vapor at 55 eV and a scattering angle of 5°. The fundamental vibrations and several overtones are apparent. A portion of the spectrum at a smaller angle (and hence higher scattered current) is shown in the inset. Additional overtones are found. Table VII identifies the frequencies, and gives the observed relative intensities from electron impact spectra and also from the infrared absorption coefficients of others. Note also the weak scattering beginning at 4.5 eV and extending to 6.5 eV. Schulz (63) found such scattering at very low kinetic energies (threshold) and the observation was confirmed by Compton *et al.* (64). In Fig. 17 the excitation is detected at much higher energies. See ref. 65 for positive ion spectra.

Figure 17 is of special interest because of the wide spectral range (infrared to vacuum ultraviolet) covered in a single spectrum. Elastic cross sections are being determined by Bromberg at Mellon Institute. Once these are available, collision cross sections can be determined over the complete spectral range of Fig. 17 with comparative ease.

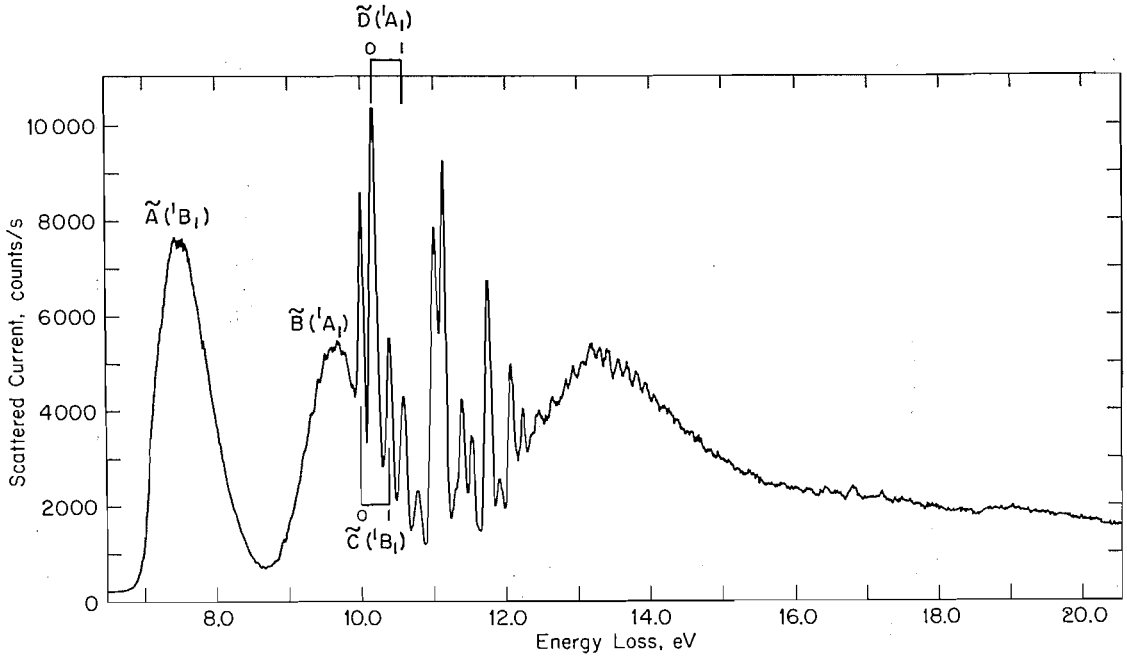

FIG. 16. Electron impact spectrum of H_2O at 100 eV and zero scattering angle by Lassettre, Skerbele, Dillon, and Ross (20).

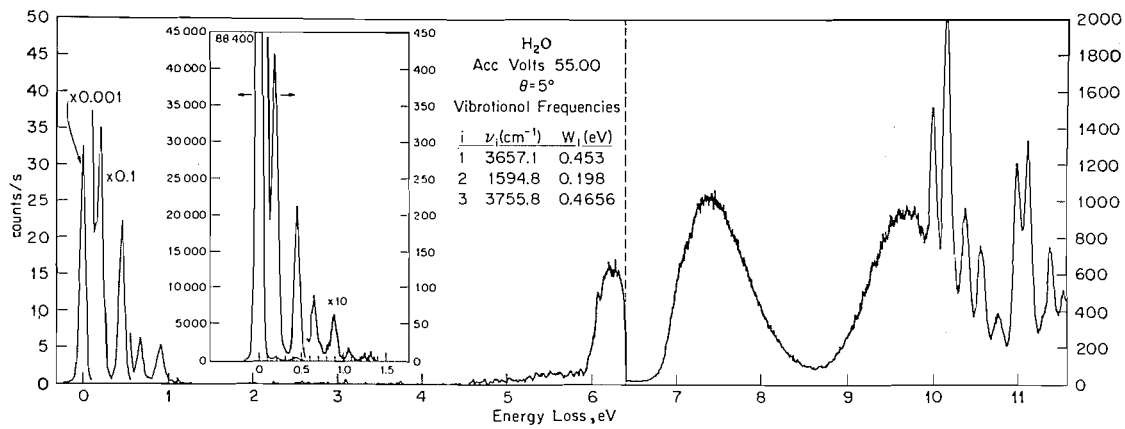

FIG. 17. Electron impact spectrum of H_2O by Skerbele, Dillon, and Lassettre (62). Note vibrational excitations near elastic peak in main spectrum (θ = 5°) and in the inset (θ = 4°). Kinetic energy, 53 eV. In optical equivalent, the spectrum covers the full range from infrared to vacuum-ultraviolet. Note weak scattering from 4.5 to 6 eV, and scale change at 6.4 eV.

Carbon Dioxide

Electron impact spectra of carbon dioxide (20) are shown in Fig. 18. The 7–10 eV region is one in which vibronically allowed transitions are occurring. There is a general change in envelope shape as the kinetic energy decreases but no new lines (attributable to forbidden, perhaps electric quadrupole, transitions) are found. At kinetic energies up to 200 eV, there is very little change in the spectrum outside the 7–10 eV region and no major change in that range.

Near the elastic peak, vibrational excitations are observed (62), as shown on the right in Fig. 19. Geiger and Wittmaack (66) have also observed

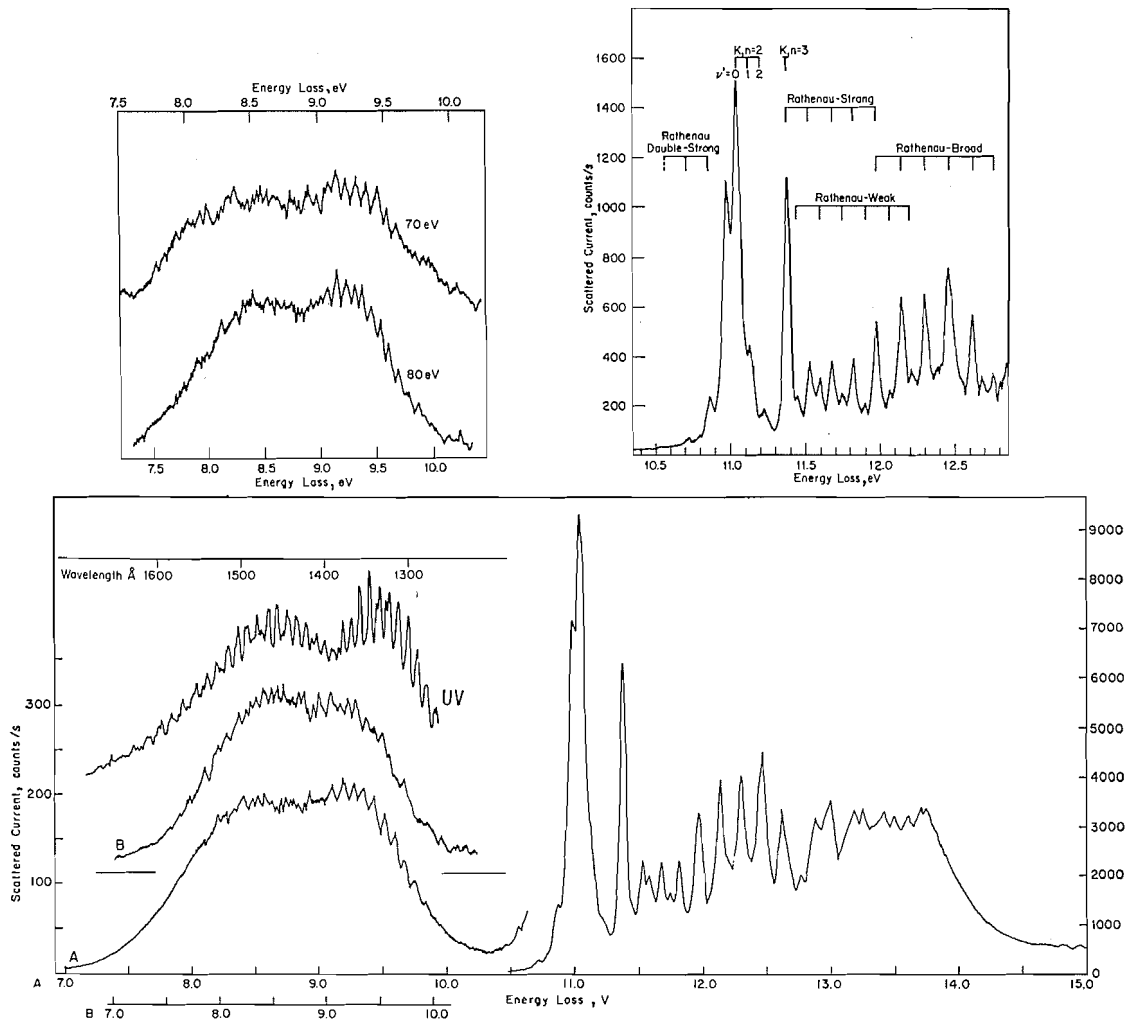

FIG. 18. Electron impact spectra of CO_2 at $\theta = 0°$ and kinetic energies 48 (lower) and 58 eV (upper right) by Lassettre *et al.* (20). Curve A is continuation of 48 eV spectrum while B is a new spectrum at 28 eV kinetic energy. Spectrum labeled UV is ultraviolet spectrum. Note spectra at 70 and 80 eV at upper left.

vibrational transitions at high kinetic energies and their spectra at 25 keV are shown on the left of Fig. 19. The spectra on the right contain the symmetric stretching (forbidden) transition while the spectra on the left do not. This is to be expected in view of the great difference in kinetic energy.

The unsymmetrical stretching vibration is much more intense, relative to elastic scattering, than any of the transitions of N_2 or O_2. The ratio of scattered current at the peak to the elastic peak current is shown in Fig. 20 as a function of scattering angle. For N_2 and O_2 this ratio was essentially constant. Cross section determinations at these kinetic energies would be of considerable interest but have not yet been done.

Argon

Electron impact spectra of argon have been studied at high incident electron energies by Boersch, Geiger, and Hellwig (23) and Boersch (67). An electron impact spectrum (20) is shown in Fig. 21. Chamberlain, Heideman, Simpson, and Kuyatt (68) have studied the spectrum at low kinetic energies. One of their spectra is shown in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

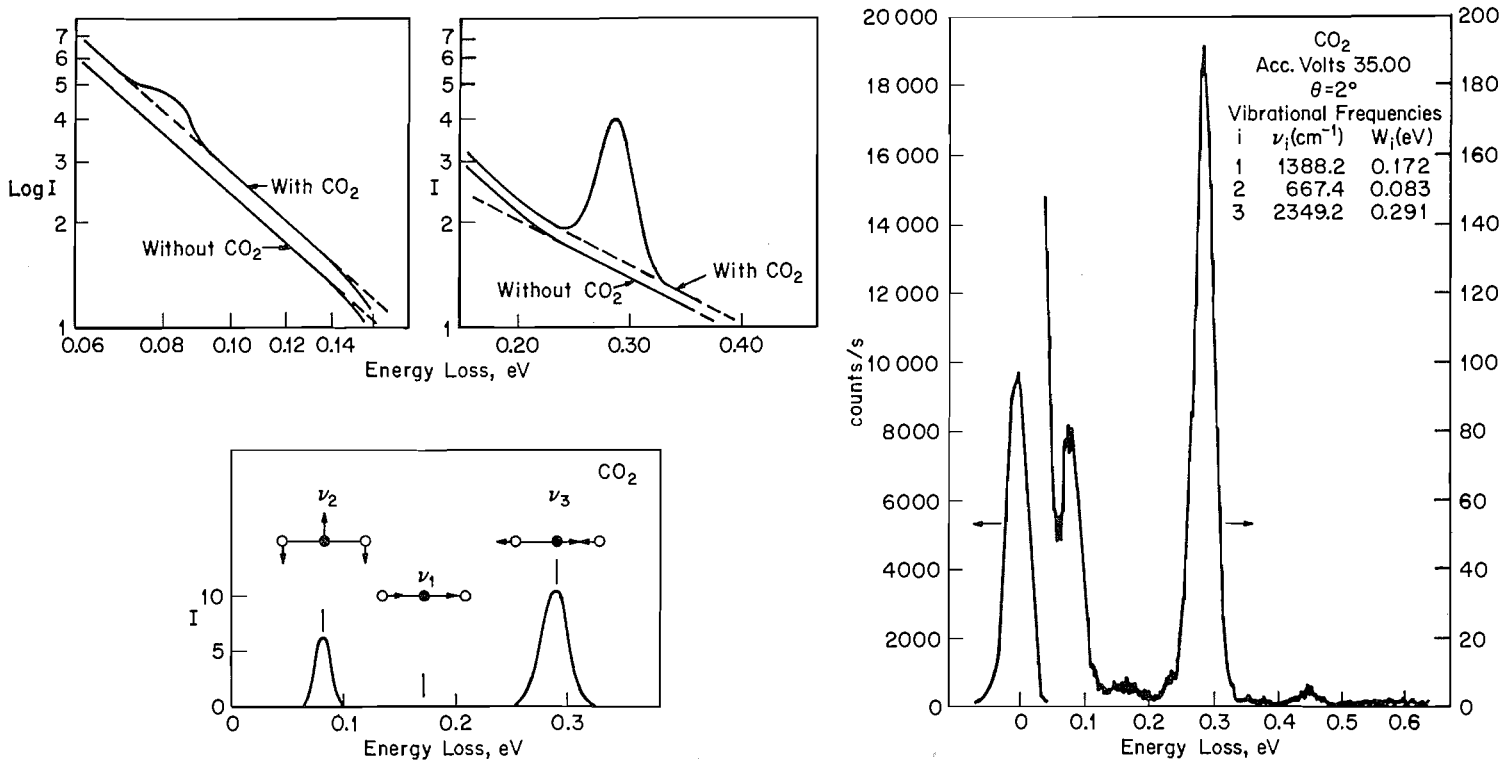

FIG. 19. Electron impact spectrum of CO_2, near elastic peak, containing vibrational transitions. Spectrum at right by Skerbele, Dillon, and Lassettre (62) at 33 eV kinetic energy and that at left by Geiger and Wittmaack (66) at kinetic energy 25 keV. Note forbidden transition at 0.172 eV in spectrum at right. This is missin~ in spectrum at left.

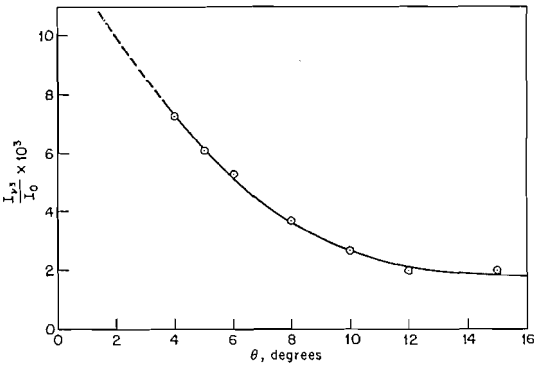

FIG. 20. Ratio of scattered current due to excitation of ν_3 vibration ($h\nu_3$ = 0.291 eV) to that for elastic scattering (see Fig. 19) of CO_2 as a function of scattering angle by Skerbele, Dillon, and Lassettre (62). Kinetic energy 48 eV.

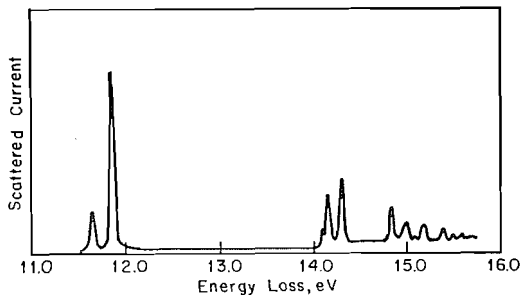

FIG. 21. Electron impact spectrum of argon at kinetic energy 25 keV and zero scattering angle by Boersch (67).

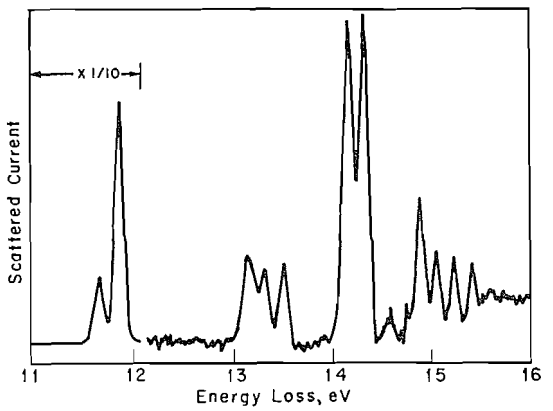

FIG. 22. Electron impact spectrum of argon at kinetic energy 40.7 eV and zero scattering angle by Chamberlain, Heideman, Simpson, and Kuyatt (68). Note forbidden transitions from 13.0 to 13.7 eV.

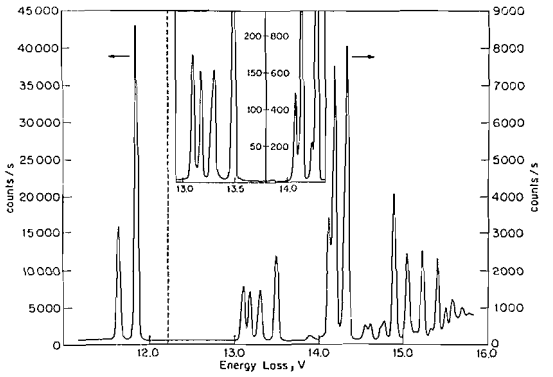

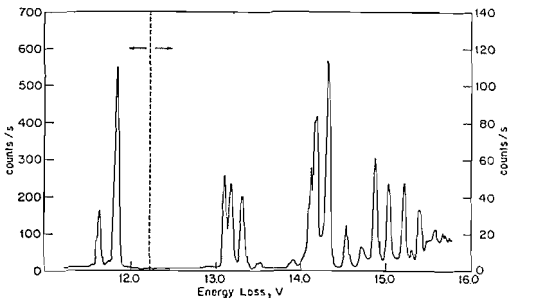

FIG. 23. Argon spectra at an accelerating voltage of 60 for the inset and 50 for the others by Lassettre, Skerbelle, Dillon, and Ross (20). Scattering angle in the top spectrum 0° and at the bottom 15°. Note changes in relative intensity of the four peaks between 13.0 and 13.7 eV.

Fig. 22. More highly resolved spectra at 50 eV have also been obtained (20) and spectra at two angles are shown in Fig. 23. In Figs. 22 and 23 a group of forbidden transitions occurs between 13.0 and 13.7 eV. Note the differences in relative intensities at the two angles of Fig. 23. Theoretical calculations for this group of states would be well worthwhile.

Helium

Helium has been very extensively studied. The substance is widely used as a comparison gas in the determination of collision cross sections (section following) and has considerable theoretical interest as well. Electron impact spectra obtained by four different groups are of interest. High resolution spectra were obtained at zero scattering angle and low kinetic energies by Chamberlain, Heideman, Simpson, and Kuyatt (68). Their spectrum at 30.7 eV is shown in Fig. 24.

An interesting series of electron impact spectra has been obtained by Kupperman and collaborators (69) and the spectra are reproduced in Fig.

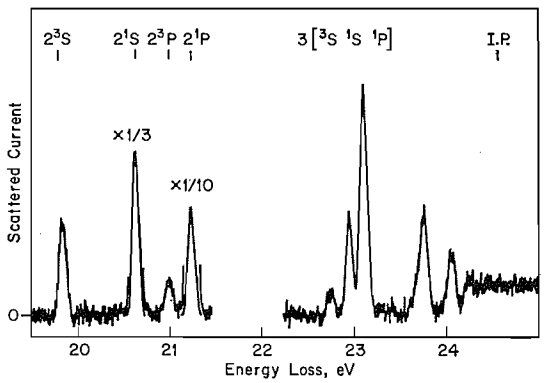

FIG. 24. Helium spectrum at kinetic energy 30.7 eV and zero scattering angle by Chamberlain, Heideman, Simpson, and Kuyatt (68). Note forbidden transitions.

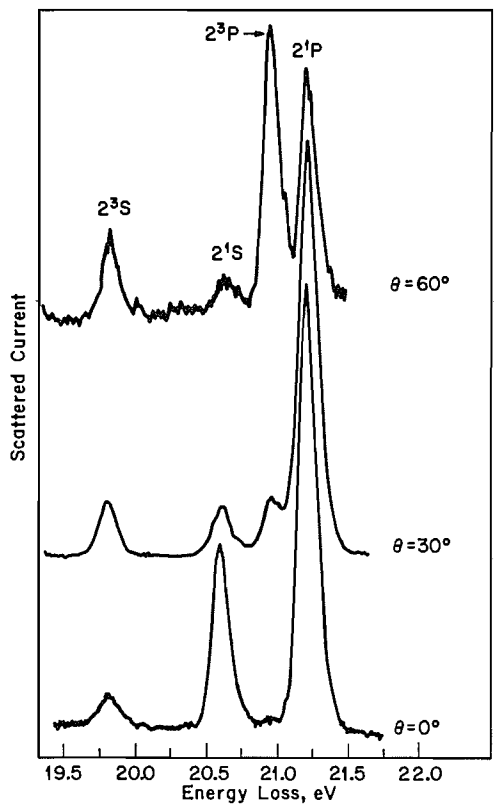

FIG. 25. Helium spectra at different scattering angles by Rice, Kupperman, and Trajmar (69). Kinetic energy 36 eV. Note reversal in relative heights of 2^1P and 2^3P peaks.

25. Note the reversal in relative intensity of the excitations to 2^3P and 2^1P. This (ref. 69) is the first of a series of papers by Kupperman and his coworkers aimed at the development of a new method for the detection and identification of singlet–triplet transitions. It is known from the theory of Ochkur (71) and Bonham (72) that the cross sections of singlet–triplet transitions decrease with increase in momentum change (and hence angle) more slowly than allowed transitions. By studying the relative intensity over an extensive range of angles one can frequently select those transitions which involve changes in multiplicity from the manifold of others which do not involve any such change. The methods seem especially promising for polyatomic molecules.

The spectrum has been studied at 50 eV and small angles by Skerbele and Lassettre (70) (see Fig. 26). The ratios of intensities in Rydberg series exhibit surprising regularities as shown in Table VIII. These observations are of considerable interest in view of the methods used by Green and collaborators in estimating collision cross sections (see section on Energy Degradation in the Excitation of Gases in the Introduction).

Finally Boersch, Geiger, and Schröder (73) have studied the spectrum of helium at 25 keV

kinetic energy and very high resolution. The spectrum is shown in Fig. 27. These experiments were done at high pressures (6–8 Torr) and multiple collisions were encountered in some spectra. Assuming that the scattering cell was the same as that of Geiger and Wittmaack (66) (2.5 cm) we obtain a pressure – path length product between 15 and 20 Torr cm. This is to be compared with pressure – path length products between 0.001 and 0.005 employed by Lassettre and collaborators. Higher pressures can be tolerated at high kinetic energy since electronic free paths are longer.

Collision Cross Sections of Atmospheric Gases

In the discussion of collision cross sections attention will be confined entirely to differential collision cross sections. This excludes the discussion of cross sections determined by the study of emission spectra which is unfortunate but unavoidable.

An extensive discussion of helium is given in the following section. Although helium is not a major atmospheric constituent, the helium cross sections have been extensively used for comparison purposes and have provided a very searching test of the accuracy with which relative cross sections and oscillator strengths can be determined. The comparison of a continuum with an excitation of the discrete spectrum is of special interest and importance. The recent discrepancies with other investigators are also discussed in detail.

In the case of nitrogen and oxygen the discussion is brief. In these sections references to the literature are given with a minimum amount of discussion. The electron impact spectra of both N_2 and O_2 have already been discussed at length in the previous sections and further elaboration seems unnecessary.

Electron impact spectra of carbon monoxide were not described in the above section because collision cross sections and relative intensity distributions in the fourth positive bands have aroused considerable interest and can best be discussed along with electron impact spectra.

Although the collision cross section measurements on CO are less extensive, and less precise, than those on N_2 and O_2, it is necessary to discuss the data at greater length since questions of accuracy in data analysis have arisen. It is convenient to illustrate these points (which arise in other investigations as well) with the fourth positive bands of carbon monoxide. This is done in the section entitled Carbon Monoxide.

References to other cross section determinations are given in the section entitled Other Substances of Atmospheric Interest, and a comparison of optical and electron impact oscillator strengths is given in the following section.

Helium

Collision cross sections for helium have been studied by several groups. The most thoroughly investigated transition is $1^1S \rightarrow 2^1P$. Since this transition has also been used for comparison purposes a special section is directed to it.

$1^1S \rightarrow 2^1P$ Transition

The pioneering theoretical calculation of the collision cross section is due to Massey and Mohr (74) who used the Born approximation and approximate eigenfunctions for the ground and excited states of helium. Early experimental and theoretical investigations have been reviewed by Massey (75). Scattering of electrons as a function of angle was studied by Lassettre, Krasnow, and Silverman (76). Their relative intensity measurements were normalized to the cross section calculated by Lassettre and Jones (77). The measurements were extended by Silverman and Lassettre (78). Since relative cross sections (and generalized oscillator strengths) are obtained, the experiment provides a test of the *shape* of the calculated curve of oscillator strength vs. momentum change. The agreement is good but not perfect (see ref. 78). Small systematic differences between theory and experiment are found especially at intermediate values of the momentum change.

In a recent publication, Vriens, Simpson, and Mielczarek (79) (V.S.M.) have studied the $1^1S \rightarrow 2^1P$ transition in helium. The data were fitted with a semi-theoretical formula and normalized by requiring that the limit of the generalized oscillator strength (at zero momentum change) be equal to the optical oscillator strength calculated by Schiff and Pekeris (80). Several kinetic energies were employed in the range (100–400 eV) and curves of oscillator strength vs. square of momentum change were coincident at kinetic energies of 200 eV and higher. Hence it was concluded that the Born approximation holds but at the same time there is a systematic disagreement (which becomes larger at higher momentum changes) with the results of Lassettre and collaborators (76, 78). Since this work was published, Kim and Inokuti at Argonne National Laboratory (81) have completed a calculation of generalized oscillator strengths using the Born approximation but with accurate approximations to the ground and excited state eigenfunctions. (Hylleraas type combinations containing more than 50 terms for both ground and excited states.) Aside from the use of the Born approximation, the generalized oscillator strength should be accurate to at least 1%. The calculated oscillator strengths agree better with the results of Lassettre and collaborators (76, 78) than with those of Vriens, Simpson, and Mielczarek (79). This is illustrated by Tables IX and X where f's calculated by Kim and Inokuti (column 3) are compared with values reported in refs. 76 (Table I, column 2) and 78 (Table IX, column 2). The % difference is given in column 4. The values calculated from the empirical formula of Vriens, Simpson, and Mielczarek are shown in column 5 and the deviations from column 3 are given in column 6. If we omit the values at the largest momentum changes (where the backgrounds are high) the mean difference between the data of ref. 78 and the calculations of Kim and Inokuti is 2.2%. The average deviation in Table X (again omitting the values at highest momentum change) is 2.8% and the grand average is 2.5% (4.2% if nothing is omitted). Note that the values in column 2 have not been re-normalized. This was not necessary since the normalizations were done in the region $0.3 \leq (\Delta P)^2 \leq 1.0$, and within this range the results of Kim and Inokuti (81) differ but little from those of Lassettre and Jones (77). In Table X the first experimental value of f (0.186) differs considerably from the calculated value. This is undoubtedly due to an error in the experimental f. The average of 6 determinations (calculated from data used in an apparatus calibration (82)) gives the value 0.195 which agrees better with the calculated value (0.202) but which is still too low. In a recent study (83) using the apparatus of ref. 20, we have determined relative oscillator

strengths at 500 eV and scattering angles from 2.5 to 6.0°. The data were fitted using the formula of V.S.M.

$$[13] \quad f = (b/(1 + x)^6)(1 + cx/(1 + x))$$

where $x = (\Delta P)^2/\alpha^2$, and $\alpha^2 = 3.391$. Normalizing the data so that $b = 0.2762$ (as V.S.M. did) we find from a least squares analysis that $c = 0.87$. When V.S.M. fitted this equation to the data in column 2 of Tables IX and X they obtained $c = 0.86$, in excellent agreement with our more recent determination. This suggests that the low values in Table X are in error. Vriens, Simpson, and Mielczarek suggested low angular resolution as the source of error but this gives an error in the wrong direction. The reason for the discrepancy is not definitely known. Incidentally, when V.S.M. fitted their own data the value 0.1 was obtained for c. (When V.S.M. fitted the data of refs. 76 and 78 in the range $0.3 \leq (\Delta P)^2 \leq 1.0$, they obtained $c = 0.2$, in contrast to 0.86 when all data were used.) The limiting oscillator strength at zero momentum change has been studied theoretically by Lassettre, Skerbele, and Dillon. They showed that the limit is equal to the optical oscillator strength whether the Born approximation is satisfied or not. A paper describing these results has been submitted for publication in J. Chem. Phys.

Chamberlain, Simpson, Mielczarek, and Kuyatt (84) have studied the apparent cross section as a function of the pressure and pointed out the importance of multiple collisions. Vriens, Simpson, and Mielczarek (79) suggested that the data of Lassettre and co-workers (76, 78) are in error due to multiple scattering in which an elastic collision is responsible for the main change in direction, while an inelastic collision causes the incident electron to lose energy with little change in direction. Lassettre and John (85) have estimated the proportion of such collisions and concluded that at 500 eV and scattering angle 13° (covering the range of Tables IX and X), multiple collisions contribute less than 1% to the scattered current for the $1^1S \rightarrow 2^1P$ transition. At smaller angles the proportion is less. This study also shows that the percentage error is strongly dependent on apparatus design. Two different apparatuses for which the pressure – path length products are the same (path length being the total distance from source to analyzer entrance aperture) are not necessarily affected to the same extent by multiple scattering. That portion of the path which follows the elastic collision is much less important than that which precedes it, because the target areas for the two collisions are much smaller when the elastic collision occurs first. In view of these results, and the good agreement between experiment and theory at large values of $(\Delta P)^2$ (Tables IX and X), it is believed that multiple scattering is negligible in the experiments of refs. 76 and 78. If the data of V.S.M. are renormalized to the Kim and Inokuti curve, the agreement is fairly good, although there are small systematic deviations. As far as the data of

Lassettre and collaborators are concerned, it agrees in shape with the theoretical f curve of Kim and Inokuti to within an average of 2.5%. In the region $0.3 < (\Delta P)^2 \leq 0.7$ there are small systematic deviations. On the whole, the data agree with the Born approximation although small differences cannot be excluded[2].

Other Discrete Excitations

The $1^1S \rightarrow 2^1S$ transition has been previously studied (76, 78, 86) and the cross section for the transition was also studied by V.S.M. (79). In refs. 76 and 78 the $1^1S \rightarrow 2^1S$ transition was not fully resolved from $1^1S \rightarrow 2^1P$ and the data tend to be scattered since it is difficult to completely subtract out the latter transition. Oscillator strengths obtained in refs. 76 and 78 were fitted with a semi-theoretical formula obtained in a previous research (87). The relation is

$$[14] \quad f = [bx/(1 + x)^6][1 + cx/(1 + x)]$$

where b and c are constants and $x = (\Delta P)^2/\alpha^2$, where $\alpha^2 = 3.551$. The data of refs. 76 and 78 at 500 eV are fitted adequately with $c = 0$ and $b = 0.329$; V.S.M. found $b = 0.271$ and $c = 0$ at 400 eV. The data of Lassettre *et al.* are higher by about 20%. This is due largely to the difference in f for the $1^1S \rightarrow 2^1P$ transition (see preceding section). The data of refs. 76 and 78 are in better agreement with the calculations of Kim and Inokuti. Additional cross sections at kinetic energies to 100 eV have been determined (79). Different values of b and c are needed at each kinetic energy, an indication of failure of the Born approximation, since that theory shows that f should depend only on $(\Delta P)^2$ and not on incident energy. Differential cross sections for excitation to 2^3S were also determined by V.S.M. (79). Although the above cross sections might be re-normalized using the $1^1S \rightarrow 2^1P$ cross section calculated by Kim and Inokuti, this seems premature until the absolute cross section determinations are complete.

Fragmentary values of the cross section for

[2]Absolute cross section determinations (private communication from Chamberlain) are in progress at the National Bureau of Standards and results to date point (tentatively) to a small departure from the Born approximation (measured values ~ 10% less than theoretical with a 5% error). At Mellon Institute an absolute determination is also in progress (by Bromberg) via the determination of absolute elastic cross sections. Two unsuspected errors (one pointed out by Kuyatt) have recently been recognized and additional experiments will be necessary before the results are final. Re-normalization of our relative data by as much as 10% would be difficult to reconcile with a deviation from the Born approximation, since a roughly constant difference between theory and experiment would be involved. The theory of limiting oscillator strengths is being studied.

excitation to the 3^1P state are reported in refs. 76 and 78. These are in error due to contamination by 3^1S (3^1P and 3^1S were not resolved). The cross sections calculated by Kim and Inokuti are certainly more accurate than the experimental values. The total cross sections for excitation to 3^1P calculated by Silverman and Lassettre (88) are also adversely affected by the unresolved (and unrecognized) 3^1S transition.

Helium Continuum

Generalized oscillator strengths in the helium continuum have been reported by Lassettre, Krasnow, and Silverman (76) and by Silverman and Lassettre (78). The limiting oscillator strengths, obtained by extrapolating to zero momentum change, have been reviewed by Silverman and Lassettre (89) as a means of estimating error in *relative* oscillator strength measurements. The results for both discrete and continuum states are given in Table XI (see ref. 89). The oscillator strengths, f_0, for the transitions $1^1S \rightarrow n^1P$ are compared with the values calculated from experimental data by Dalgarno and Stewart (90). The values obtained by Boersch *et al.* are also included, together with values calculated by Miller in a manner similar to that used by Dalgarno and Stewart. The continuum oscillator strengths, f'_0 (in electrons per volt), are given in Table XI*b*. They are compared with the experimental determinations of Baker *et al.* (91) (column 3) and those of Sampson (91) (column 4) and with the theoretical calculations

of Stewart and Webb (92). In Table XI*b*, column 6 gives the percentage differences between columns 3 and 5. The deviations in Table XI*a* are between columns 3 and 5 where values are available, otherwise between columns 2 and 5. The weighted deviation (1/4 for discrete states, 3/4 for continuum) is 6%. There is an auto-ionized transition at 60.1 ± 0.1 eV whose line shape has been treated by Fano (52) who also deduced the auto-ionization probability from the electron impact spectrum. The value found, 6×10^{13} s^{-1} has been checked by Madden and Codling (93) who found (in a spectroscopic study) 5.8×10^{13} s^{-1}. Since the auto-ionized transitions attracted widespread attention and have been the subject of several reviews, we shall not further consider these transitions. The data on helium, summarized in Table XI, are important because they provide a test of the experimental technique. It is obviously important that the collision cross sections in continuous spectra should be *experimentally comparable* with the collision cross sections for excitation to discrete states. Since every transition in Table XI (including continuum states) was investigated by comparing the scattering with that due to $1^1S \rightarrow 2^1P$ excitation in helium, the accuracy of the continuum oscillator strengths is a direct test of the precision with which this comparison can be made. The outcome is obviously favorable. The instrument of ref. 82 has been used in all cases.

Nitrogen

The trend of oscillator strength with momentum change for the Lyman–Birge–Hopfield bands has been discussed in the section entitled Electron Impact Spectra, the determinations being those of Lassettre and Krasnow (38). The remainder of the spectrum has also been studied at low resolution (89). The experimental technique is explained in detail in this reference. Oscillator strengths as functions of momentum change are shown in Fig. 28. The spectra are unresolved. Figure 28*a* refers to the peaks and Fig. 28*b* to the continua or, more accurately, the unresolved sections of the spectra without peaks. Extrapolated generalized oscillator strengths, together with those of O_2 and H_2O, will be further discussed in a subsequent section, Other Substances of Atmospheric Interest. They are also given in Table XII.

Oxygen

Oscillator strengths for the dissociation continuum of the Schumann–Runge bands have been determined (94) and oscillator strengths through the remainder of the spectrum have also been studied in a later research (95). Extrapolated oscillator strengths are given in Table XII. The trend in oscillator strength with momentum change is qualitatively similar to those found for N_2. Figures are shown in ref. 96. Total cross sections were calculated through the spectrum and the fraction of inelastic collisions which excite the Schumann–Runge bands and dissociation continuum was calculated and found to be one tenth. This is a very large fraction and emphasizes again that the transition dominates the spectrum. (See also Fig. 13.) These data are further

[a]Oscillator strengths above the horizontal lines refer to peaks in the spectra and have been integrated over the corresponding peaks. Below the horizontal lines there are no peaks and no integration over the spectrum has been performed, i.e. these are differential oscillator strengths. $f'_0 = (df_0)/(dU)$ expressed in electrons V^{-1}.

discussed in the section entitled Comparison of Electron Impact and Optical Oscillator Strengths.

Carbon Monoxide

Carbon monoxide has been less extensively studied than either N_2 or O_2. One transition ($A^1\Pi \leftarrow X^1\Sigma^+$), the fourth positive bands of optical spectra, is of considerable interest since very large discrepancies have been found between the extrapolated oscillator strength obtained by electron impact and that calculated from lifetime measurements. Because of these discrepancies the substance is discussed in considerable detail. The intensity distribution in the vibrational progression is also of interest.

Oscillator Strengths

Collision cross sections for carbon monoxide were studied by Lassettre and Silverman (96) at low resolution (no velocity selection before scattering). The oscillator strength, integrated over the band system, was studied at three kinetic energies. The extrapolated oscillator strength is 0.24. The generalized oscillator strengths vs. $(\Delta P)^2$ are shown in Fig. 29. The data are probably less precise for this transition than those mentioned in preceding sections for N_2 and O_2 because comparison of helium and CO scattering was not made immediately before and after each run on carbon monoxide (see ref. 82, p. 1239 for a discussion). Cross section determinations for nitrogen were made at the same time and a later, more thorough, investigation gave cross sections for N_2 which are lower by the factor

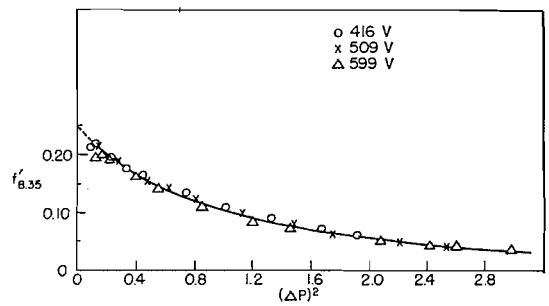

FIG. 29. Generalized oscillator strength of 8.35 eV transition of carbon monoxide vs. square of momentum change (atomic units) at three kinetic energies, by Lassettre and Silverman (96).

0.887 (see ref. 38, p. 1249). Unpublished research by Meyer and Lassettre suggests that the limiting cross section for CO (0.24) and the data of Fig. 29 should also be multiplied by this factor. The data have not been corrected, however, because an absolute determination is in progress at Mellon Institute and a final appraisal must await the completion of these experiments. In the meantime, it is of interest to consider the relative intensities in the fourth positive bands. Oscillator strengths are compared with optical and other determinations in the section entitled Comparison of Electron Impact and Optical Oscillator Strengths.

Born Approximation

Lassettre and Silverman (96) noted that the shape of the peak (consisting of unresolved vibrational levels) corresponding to the fourth

positive bands did not change with angle. Silverman and Lassettre (97) showed that the envelope shape is satisfactorily accounted for by Franck–Condon factors calculated by Jarmain *et al.* (98). As soon as an electron spectrometer was developed which could resolve the fourth positive bands, the system was re-investigated and relative intensities determined (18). The relative intensities seemed to change with angle, although the uncertainties were large. The data were analyzed using the formula of Craggs and Massey (99) in which the dependence of cross section on internuclear distance is neglected. The dependence on angle is accounted for in this way but when a quantity proportional to the Franck–Condon factor is deduced from the data, it is not in fact equal to the Franck–Condon factor calculated by Jarmain *et al.* The disagreement might be due either (*a*) to approximations in the Craggs and Massey formula, e.g. neglecting the dependence of cross section on internuclear distance, or (*b*) error in the Franck–Condon factors due to the assumption of a Morse potential function. The latter possibility was eliminated by Wentink *et al.* (100) who calculated the Franck–Condon factors using the Rydberg–Klein–Rees method (and computer programs developed by Spindler). These more accurate Franck–Condon factors are in even worse agreement with those deduced from the data than the factors calculated by Jarmain *et al.* Obviously, a more accurate theory is needed and one possibility is to take into account the dependence of collision cross sections (for vertical excitations) on internuclear distance. Wentink *et al.* (100) suggested this interpretation and it is indeed possible to account for the deviations in the extrapolated oscillator strength by using the approximation proposed by Nicholls (101) which relates the electronic transition moment to the r centroid, defined as

$$[15] \qquad \bar{r} = \int_0^\infty R_{v'} r R_{v''} \mathrm{d}r$$

where r is the internuclear distance and $R_{v'}$, $R_{v''}$ are vibrational eigenfunctions for the excited and ground electronic states. Nicholls (101) has also given a very convenient approximate formula for the collision cross section which can be put into the following form

$$[16] \qquad \sigma = \sigma_0(\bar{r})\left(\int_0^\infty R_{v'} R_{v''}\right)^2 = \sigma_0(\bar{r}) q_{v'v''}$$

Here $\sigma_0(\bar{r})$ is the collision cross section calculated for a vertical excitation at an internuclear distance equal to $\bar{r}$ and the second factor $q_{v'v''}$ is the Franck–Condon factor. In addition to $\bar{r}$, σ_0 also depends on scattering angle or, more accurately, on the momentum change appropriate to the excitation energy and the scattering angle. Since $\bar{r}$ varies from one vibrational state to another, the same will generally be true of σ_0. If eq. [16] is accurate, then it is apparent that dividing $q_{v'v''}$ into the experimentally observed cross section will give σ_0. This analysis of the data is only applicable at high kinetic energy where the Born approximation holds, but recent studies at lower kinetic energies have revealed a close relation between relative intensities and Franck–Condon factors, and it would be desirable to analyze the data in a different way which does not depend on the Born approximation. Before considering this point further, it will be useful to describe the intensity distributions observed for the fourth positive bands at different kinetic energies.

Relative Intensities

An electron impact spectrum of carbon monoxide is shown in Fig. 30. (Note the weak singlet–triplet transitions.) The fourth positive bands extend from 8 to 10 eV. Relative intensities as functions of angle at 48 eV are shown in Table XIII and at 98 eV in Table XIV. The trends with angle are so small that relative intensities have been averaged over all angles. The averages are compared with Franck–Condon factors calculated by Jarmain *et al.* (98) and Wentink *et al.* (100) in Table XV which also includes previous determinations (103) at 400 eV. Determinations (18) at 200 eV are included although the data are less accurate and are being redetermined. Data at 400 eV have been checked (in an unpublished investigation) and agreement is good except for $v' = 9$ where 0.021 is obtained instead of 0.026. Note that relative intensities at 48 eV and especially at 98 eV are in better agreement with Franck–Condon factors than at 400 eV. This has been confirmed in repeated experiments which show, however, that even at 400 eV agreement gets better at higher vibrational quantum numbers ($v' > 8$). Note that, unlike ref. 18, the relative intensities change but little with angle.

We cannot assume that the Born approximation holds at kinetic energies as low as 48 eV and hence eq. [16] cannot be used to discuss the data.

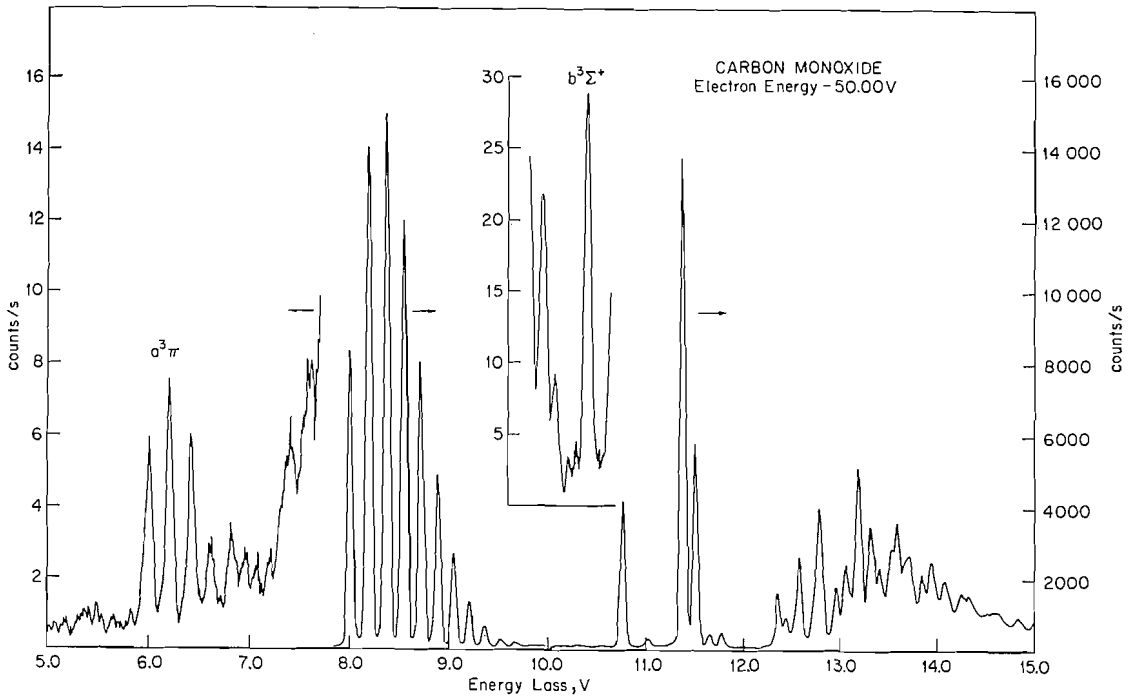

FIG. 30. Carbon monoxide spectrum at zero scattering angle and 48 eV kinetic energy by Skerbele, Dillon, and Lassettre (102). Note singlet–triplet transitions. Fourth positive bands extend from 8–10 eV.

Therefore the problem has been considered from a different viewpoint (see ref. 20) which does not depend on the Born approximation. These results are briefly described in the next section.

Excitation Probabilities

If we consider the excitation of a molecule as a time dependent process, we can then visualize the electronic excitation as occurring in a very short time to produce an excited state in which the state function (not an eigenfunction) describing the nuclear motion is ϕ. If we expand ϕ in a series of vibrational eigenfunctions of the excited state ψ_v, then the square of the v expansion coefficient gives the probability P_{Ev} that the system ends in a vibrational state with quantum number v when we know in advance that an electronic state E has been excited, i.e.

$$[17] \qquad P_{Ev} = |\int \phi \psi_v^* d\tau|^2$$

The quantity P_{Ev} is a conditional probability. Let P_E be the probability per unit time that the electronic state E is excited regardless of v. Then the probability per unit time that the molecule is excited to electronic state E and vibrational level v is

$$[18] \qquad P_E P_{Ev}$$

If the collision lifetime is small in comparison to a nuclear vibration period ($\sim 10^{-13}$ s) the nuclei have no time to redistribute and it is plausible that ϕ is approximately equal to the ground state vibrational function ψ and eq. [17] is the Franck–Condon factor. An exception to this may arise if the incident electron energy is such that resonance occurs to give a temporary negative ion. In that case lifetimes comparable with or greater than 10^{-13} s may be encountered. Under these conditions the nuclei can redistribute within the collision lifetime and ϕ may differ drastically from the ground state vibration function. A resonance can be tested for by determining scattered current as a function of kinetic energy. The data of Tables XIII and XIV were collected under non-resonant conditions.

The above argument is obviously *not* a rigorous demonstration that the relative intensity is independent of angle. We must regard this as a

hypothesis which deserves an experimental test. The data of Tables XIII and XIV provide a beginning of such a test. Note in Table XIII that the relative intensities at $v' = 0$ and 1 exhibit a small but noticeable (and reproducible) change with angle. We have ignored this trend and averaged the relative intensities at all angles in comparing with Franck–Condon factors. A more comprehensive investigation at other kinetic energies and scattering angles is in progress.

Other Substances of Atmospheric Interest

Collision cross section determinations on H_2O similar to those on N_2 and O_2 have been done by Lassettre and White but are not yet published (104). Less complete determinations are also available on CO_2 (105) (see next section for discussion). Geiger (106) and Geiger and Topchowsky (107) have studied oscillator strengths for several transitions in H_2, and obtained results which agree well with theory and with the recent spectroscopic investigation of Hesser, Brooks, and Lawrence (108). The research on hydrogen has not been discussed in detail because it seemed doubtful that this substance qualifies as being of direct aeronomic interest. These researches are, however, quite significant contributions to molecular physics and astrophysics. Extrapolated oscillator strengths for H_2O are given in Table XII.

Comparison of Electron Impact and Optical Oscillator Strengths

Oscillator strengths obtained by Lassettre and collaborators are compared with optical determinations in the section following. In the section entitled Experiments of Geiger, two transitions (in helium and hydrogen, respectively) studied by Geiger and collaborators are compared with experiment or theory.

Experiments of Lassettre and Collaborators

Initially we consider two regions of continuous spectrum, one in N_2 and the other in O_2. In the spectral range 580 to 660 Å the absorption coefficients of nitrogen are essentially constant and the spectrum seems to be continuous (109). Inspection of the spectrum given by Huffman, Tanaka, and Larrabee shows that the average absorption coefficient over this range is 950 cm^{-1} which corresponds to an oscillator strength $f' = (df)/(dW)$ of 0.32 electrons V^{-1}. By interpolating in the electron impact spectrum Silverman and Lassettre found a limiting oscillator strength which was very nearly constant and equal to 0.315 electrons V^{-1} This agrees extremely well with the measurements of Huffman, Tanaka, and Larrabee. Later, Cook and Metzger re-investigated the spectrum and reviewed the determinations made at 584 Å. The results for 6 determinations are shown in Table XVI, the second value being that of Cook and Metzger (110) and the first being that of Huffman, Tanaka, and Larrabee (109). These two values are most likely to be accurate but they differ by 20%. This cannot be attributed to line saturation since a continuum is involved. Huffman, Tanaka, and Larrabee corrected their measurements for fluorescence of the N_2^+ ion. Fluorescence was observed by Cook and Metzger but no correction was needed since their detector was not affected by the fluorescent radiation. In an accompanying review, Huffman has accepted the value 620 cm^{-1} as the probable value of the absorption coefficient at 584 Å. This gives an oscillator strength of 0.210 electrons V^{-1}. Obviously the uncertainty is substantial.

TABLE XVI

980	109
800	110
700	111
620	Huffman[a]
400	112
480	113
351 (at 580 Å)	114

[a]See Table I in accompanying review by R. E. Huffman.

The second continuum, which has been much studied, is the dissociation continuum of the Schumann–Runge bands. A series of determinations covering the period since 1932 is summarized in Table XVII. The electron impact value is 0.230. The accepted optical value (see Huffman's review) is the first entry, 0.161, which is 30% less than the electron impact value.

The relation between refractive index and oscillator strength for a gaseous substance is well known and can be put into the following form

$$n - 1 = 0.01858 \sum (f_i)/(W_i^2 - (h\nu)^2)$$

where f_i is the oscillator strength, n is the refrac-

TABLE XVII

tive index, W_i is the excitation potential, and ν is the frequency. The numerical constant has been calculated in such a way that W_i and $h\nu$ are in eV. Using the data of Table XII the value of $n - 1$ for N_2 at zero frequency has been calculated and found to be 394×10^{-6} while that measured (see ref. 90 for references to literature) at microwave frequencies is 294.1×10^{-6}. The experimental value is 25% less than that calculated from the oscillator strengths. For O_2 the value of $n - 1$ calculated from the oscillator strengths of Table XII at $\lambda = 2479$ Å is 392×10^{-6} while that interpolated from the measurements of Ladenburg and Wolfsohn (119) is 305×10^{-6}. The experimental value is 22% less than the calculated value. For H_2O the value of $n - 1$ calculated at $\lambda = 5460.7$ Å using the oscillator strengths of Table XII is 329×10^{-6} compared with the experimental value (122) of 253×10^{-6}. The experimental value is 23% less than the calculated. In all cases the oscillator strengths of Table XII have been linearly extrapolated to zero in the continuum and the extrapolated values obtained have been used in calculating the refractive indices. These contributions cannot explain the discrepancies between theory and experiment. Since refractive indices can be determined with high accuracy, these discrepancies must be taken seriously, especially since the percentages are all nearly the same for three different substances. Moreover, in the calculation of refractive indices it is not important to have high resolution since a summation over the spectrum is involved.

The cross section determinations on nitrogen (89), oxygen (96), and water (104) were done by comparing the scattering with that due to the $1^1S \rightarrow 2^1P$ transition in helium. An apparatus constant, K, was determined by scattering runs on helium, both before and after investigating the gas (N_2, O_2, or H_2O). This value of K was then used in calculating cross sections for the gas under investigation. An attempt was made, in the paper on nitrogen (89), to place an error bound on the cross section determinations. Assuming that errors from all known sources combine unfavorably, an error of 13% could be accounted for. This includes an estimate of possible error in comparing a sharp peak ($1^1S \rightarrow 2^1P$ in helium) with an unresolved or continuous spectrum. The estimate does not include an estimated extrapolation error. Some additional comments on the pressure measurements are pertinent at this point. Pressure measurements were made with a Knudsen gauge which had been calibrated against a McLeod gauge. The determinations were made before the discovery by Ishii and Nakayama of the streaming error in the McLeod gauge (123). By the time this error was announced, the present author had moved from Ohio State University to Mellon Institute and the gauge could not be re-calibrated. On the basis of the diameters of glass lines connecting the McLeod gauge to its cold trap, a streaming correction was estimated and the earlier conclusion that the Knudsen gauge was independent of gas seemed to be valid (124). Subsequent experience with McLeod gauges by Bromberg and Meyer at Mellon Institute are in approximate accord with this. Such ad hoc estimates are never completely satisfactory but nothing better is available at present. Absolute elastic collision cross sections are being determined at Mellon Institute by Bromberg. Once these measurements are complete an entirely independent check will be possible by comparing the areas of inelastic and elastic peaks using the high resolution spectrometer. Since these measurements are nearing completion it does not seem worthwhile to speculate further except for one point. In ref. 89 the discrepancy was attributed to a failure of the Born approximation. At the time, the intensity anomaly in the nitrogen spectrum seemed to point in this direction (45). However, when the vibration spectrum was resolved (46) it immediately became clear that no failure of the Born approximation was involved and this was confirmed by the work of Geiger and Stickel (49) as discussed in the section entitled Electron Impact Spectra, under the subheading Nitrogen. If we could be certain that the

[a]Obtained from column four on multiplication by 0.887. This factor is indicated by cross section determinations on nitrogen and by the unpublished research of Meyer and Lassettre. See section under Oscillator strength.

Born approximation was satisfied by both helium and nitrogen and the extrapolations were correct, then we would multiply our previous cross sections by 0.75. This factor would also bring our oscillator strengths into line with the probable optical values for the Schumann–Runge continuum of O_2 and the 584 Å region of the N_2 spectrum. In 1959 these cross section measurements were reviewed (125) (before publication) and this discrepancy was pointed out. It was unresolved then and remains so at present.

One of the biggest discrepancies between oscillator strengths obtained by electron impact and other methods is that for the fourth positive bands in carbon monoxide. Hesser and Dressler (126) investigated the life-times of excited states of CO and found that the calculated oscillator strengths are smaller by a factor of 2.6 than those obtained by Meyer, Skerbele, and Lassettre (18), using the value of f_0 for the whole band (0.24) obtained by Lassettre and Silverman (96). This is a much larger factor than anything suggested by comparison with refractive indices. A little improvement is introduced by correcting the electron impact results for a new determination of apparatus constant, K. The value 7.56×10^{10} was used in the original determination (ref. 82, p. 1239) but the value 6.71×10^{10} was found in a later determination on N_2 under conditions which strongly suggest that the earlier value was in error (ref. 38, p. 1249). Generalized oscillator strengths are given in Table XVIII. Column 4 contains the values found in ref. 18 and column 5 contains values corrected to take account of the revised apparatus constant. Column 2 contains values found by Hesser (127) in a recent investigation. The large discrepancies are obvious. Two values obtained by Rich (128) are given in column 3. Rich (128) states that his values agree with the determinations of Hesser and Dressler and when all values for transitions between states are considered this is probably true, but for the only two values which can be compared with our determinations, this is not true. The values are half-way between those of columns 2 and 5. At $v' = 0$ the value obtained by Rich (0.033 ± 0.006) does not differ from that of column 5 (0.0451) by more than the factor 0.75 indicated by refractive indices and the Schumann–Runge bands. The values obtained by Hesser, however, do differ by considerably more than this factor. In the experiments of both Rich and Hesser the transitions studied were from excited to ground state (radiation emitted) while ours are in the opposite direction. A dependence of transition moment on internuclear distance could be found which accounts for the difference, but Rich found no dependence and we cannot be certain that this is the true reason. Thus far the differences are unexplained.

Lawrence, Mickey, and Dressler (50) have determined (by absorption coefficient measurements) the oscillator strength of the band at 965 Å in N_2 and obtained the value 0.055 ± 0.011. From Geiger's N_2 spectrum they obtained 0.14 as the fractional intensity contributed by the

For personal use only.

12.84 eV peak (λ = 965 Å) to the entire region from 11.4 to 13.6 eV of the nitrogen spectrum. Hence 0.055/0.14 = 0.40 is the estimated oscillator strength for this interval compared to 0.872 obtained by Silverman and Lassettre (89). (See Table XII.) Again a much larger factor than 0.75 is obtained. The origin of the fraction 0.14 is not completely clear. Geiger's spectrum gives scattered current. To obtain the oscillator strength each intensity must be multiplied by the cube of the excitation energy and corrected for angular resolution. It is not clear whether this was done.

Experiments of Geiger

Geiger and collaborators have studied oscillator strengths by electron impact at very high kinetic energies by determining the ratio of inelastic to elastic scattering and using the calculated elastic cross section to obtain oscillator strengths for the transition to the state excited in the inelastic scattering process. The helium transition $1^1S \rightarrow 2^1P$ has been studied in this way (129). The experimental value obtained in this way at 25 keV is 0.312 $\pm$ 0.040. This is to be compared to the theoretical value 0.2762 which is known to be accurate (80). An experimental value (131) of 0.27 $\pm$ 0.02 has recently been determined. Kim and Inokuti (130) have also calculated elastic cross sections for helium and have indicated the need to use relativistic kinematics and to make other relativistic corrections. These will no doubt be small (a few %).

Geiger and Topchowsky (107) have determined oscillator strengths for three electronic bands in hydrogen by a method similar to that for helium. The ratio of inelastic to elastic scattering was determined and the oscillator strength for the inelastic excitation determined using the calculated (Born approximation) elastic cross section obtained from an approximate eigenfunction for the H_2 ground state. The oscillator strength agreed well with theoretical values calculated in various ways. Hesser, Brooks, and Lawrence (108) have measured the oscillator strengths of the Lyman bands by resolving the rotation spectrum and measuring line intensities. The measured value for the whole band is 0.29 while Geiger and Topchowsky find a value of 0.30. Relativistic corrections were not made.

It is apparent that comparison of elastic and inelastic scattering within the same spectrum can be successfully used to determine oscillator strengths if reliable elastic cross sections are available. However, Geiger's method cannot be used at low kinetic energies because elastic cross sections calculated using the Born approximation are seriously in error. For example, Bromberg finds that at 500 eV the measured elastic cross section for He at 2° scattering angle exceeds the value calculated from the Born approximation by a factor of 2. Once measured elastic cross sections are available, however, the method should be very useful since it is much simpler to compare two peaks (elastic and inelastic) in the same spectrum than to compare the peaks in different gases.

The good agreement obtained for helium and hydrogen provide no clue to the large discrepancies obtained in N_2, O_2, H_2O, and CO. The data obtained by Lassettre *et al.* on helium are also self consistent (see section entitled Helium Continuum). Moreover, Lassettre and Jones (132) measured oscillator strengths through the hydrogen spectrum. The spectrum was unresolved and the precision was not high but the calculated refractive index agrees with the measured value and the oscillator sum rule is satisfied to within 5%. Hence no discrepancies like those on N_2, O_2, H_2O, and CO arise.

Additional Research of Aeronomic Interest

A program of research on electron impact spectra (and generalized oscillator strengths) of metal vapors is in progress under the direction of Ross. An initial paper on potassium has been published (133). Additional experiments on other alkali atoms are in progress and other metal vapors will be studied.

Collision cross sections for CO_2 at very low kinetic energies (at resonances) have recently been reported by Boness and Schulz (134). Although these energies are below the range covered by this review we note that the measurements have been done. It is interesting to compare their results with those of Fig. 19.

Turner (135) has published a detailed description of his photoelectron spectrometer and a more complete spectrum of O_2^+ at higher resolution than that of Fig. 15 but comparable with that of Fig. 14.

Kim, Inokuti, Chamberlain, and Mielczarek (136) have reported that collision cross sections for atomic substances can be zero at certain momentum changes. A case is encountered in the xenon spectrum where the observed cross section has a pronounced minimum which is nearly zero.

Semi-empirical electron impact cross sections for atmospheric gases[1]

L. R. PETERSON, S. S. PRASAD, AND A. E. S. GREEN
Department of Physics and Astronomy, University of Florida, Gainesville

Received December 8, 1968

The present paper summarizes conveniently the electron-impact cross sections for N_2, O_2, and O used in recent aurora and dayglow studies at the University of Florida. The cross section parameters in their present form are a natural outgrowth of (*a*) the availability of an increasing number of cross section measurements in the laboratory as well as field observations of spectral intensities, and (*b*) more realistic calculations.

The values presented should serve as a useful interim reference list pending the full analyses of current extensive data. Their usefulness for practical applications to problems in aeronomy is enhanced by their integrable functional forms.

Canadian Journal of Chemistry, 47, 1774 (1969)

Introduction

The studies of semi-empirical cross sections for He, N_2, and O_2 (1–4) were attempts to use fragmentary experimental data in conjunction with simple rules derived from both theory and phenomenology to infer complete sets of approximate cross sections. The semi-empirical cross sections developed in these papers for electron impact are based on the Born approximation, which permits one to normalize the high energy limit by the use of optical oscillator strengths, and also are based on a semi-empirical modification to encompass low energy data. The resulting cross sections are then fitted with simple forms of the type given in the present paper for greater convenience in applications. Such complete sets are needed to provide some basis on which to study phenomena of aeronomical interest such as aurora and dayglow (5, 6).

This program, because of new information sources, can now be extensively refined for He, N_2, and O_2, as well as for several other species. First, there is a wealth of new data coming from laboratory measurements, which enable one to be much more realistic than previously. Improvements in resolution, extensions of the energies at which data are available, and additional theoretical sophistications enable one now to better identify states, to profitably consider individual Franck–Condon factors, and to get at the low energy aspects of the cross sections where the Born approximation must be appropriately modified. Second, there are now available increasing numbers of field measurements on spectral intensities which, when compared with realistic calculations, suggest how to modify the cross sections themselves. This is especially true for certain types of cross sections which are very difficult to measure in a laboratory and others which are clearly responsible for spectral lines without interference from chemical, radiative transfer, or similar effects.

The present paper is intended to list in an analytic form the cross sections for N_2, O_2, and O used in our most recent studies (7, 8). These cross sections are basically those of the original studies with some modifications as discussed later. They are meant as a convenient summary to clear the table for the next generation of cross section work, much more ambitious in nature, now in progress at the University of Florida.

All excitation cross sections have been expressed in the form

$$[1] \qquad \sigma_j(E) = \frac{q_0 f_0 c_0}{W_j^2}\left(\frac{W_j}{E}\right)^{\Omega}\sum_s a_s\left(\frac{W_j}{E}\right)^{\Gamma_s}$$

with the restrictions $(a_1,\Gamma_1) = (1,0)$ and $\sum_s a_s = 0$.

The semi-empirical cross sections developed in these papers for electron impact are based on the Born approximation, which permits one to normalize the high energy limit by the use of optical oscillator strengths, and also are based on a semi-empirical modification to encompass low energy data. The resulting cross sections are then fitted with simple forms of the type given in the present paper for greater convenience in applications. Such complete sets are needed to provide some basis on which to study phenomena of aeronomical interest such as aurora and dayglow (5, 6).

This program, because of new information sources, can now be extensively refined for He, N_2, and O_2, as well as for several other species. First, there is a wealth of new data coming from laboratory measurements, which enable one to be much more realistic than previously. Improvements in resolution, extensions of the energies at which data are available, and additional theoretical sophistications enable one now to better identify states, to profitably consider individual Franck–Condon factors, and to get at the low energy aspects of the cross sections where the Born approximation must be appropriately modified. Second, there are now available increasing numbers of field measurements on spectral intensities which, when compared with realistic calculations, suggest how to modify the cross sections themselves. This is especially true for certain types of cross sections which are very difficult to measure in a laboratory and others which are clearly responsible for spectral lines without interference from chemical, radiative transfer, or similar effects.

The present paper is intended to list in an analytic form the cross sections for N_2, O_2, and O used in our most recent studies (7, 8). These cross sections are basically those of the original studies with some modifications as discussed later. They are meant as a convenient summary to clear the table for the next generation of cross section work, much more ambitious in nature, now in progress at the University of Florida.

All excitation cross sections have been expressed in the form

$$[1] \qquad \sigma_j(E) = \frac{q_0 f_0 c_0}{W_j^2}\left(\frac{W_j}{E}\right)^{\Omega}\sum_s a_s\left(\frac{W_j}{E}\right)^{\Gamma_s}$$

with the restrictions $(a_1,\Gamma_1) = (1,0)$ and $\sum_s a_s = 0$.

The constant q_0 is 6.514×10^{-14} eV^2 cm^2, f_0 and c_0 are constants giving the strength, W_j is the excitation threshold, Ω is the cross section fall-off parameter, and a_s, Γ_s determine the overall shape. This equation is used to describe Rydberg states by replacing f_0 with $f^*/(n-\delta)^3$, where n is the principal quantum number and δ is the quantum defect. We note in this regard that it is often convenient for $n > 4$ to sum the Rydberg states using $\sum_{n>n'} 1/(n-\delta)^3 \simeq 1/2(n'-\delta+0.5)^2$. All ionization cross sections are expressed similarly to eq. [1] as

$$[2] \qquad \frac{d\sigma_i(E)}{dW} = \frac{q_0 A_0}{W^2}\left(\frac{I_i}{W}\right)^p \left(\frac{W}{E}\right)^\Omega \sum_s a_s \left(\frac{W}{E}\right)^{\Gamma_s}$$

$$[3] \qquad \sigma_i(E) = \int_{I_i}^{(E+I_i)/2} \frac{d\sigma_i}{dW}\, dW$$

where now W is of course continuous and I_i is the ionization threshold. The parameter p controls the energy-loss behavior of the differential cross section. These forms are convenient in that in applications, where they are usually integrated, the calculations are analytic.

Changes in Ionization Cross Sections and Related Rydberg Series

From the work of Peterson and Green (7) ionization cross sections for N_2 and O_2 are now assumed to have values $p = 1.2$ and 1.1, respectively. In this regard it has been found by further study that the shape parameters (a_s, Γ_s) for O_2 can be made the same as for N_2 and in fact fit the data somewhat better at low energies. For atomic oxygen we have set $p = 1.2$. An additional feature not included by Stolarski *et al.* (3) and Watson *et al.* (4) was dissociative ionization. We have included fits to the dissociative ionization cross sections of N_2 and O_2 assuming that they behave similarly to simple ionization cross sections in the way they produce secondary electrons.

When the ionization cross sections are modified, one must also modify their attached Rydberg series, which means changing the auto-ionization contributions as well. For this purpose we compare the new to the old ionization cross sections at an energy of a few hundred volts and modify the strength of the Rydberg states accordingly.

The situation in N_2 appears on the whole to be reasonable. Guided by the results of McConkey and Latimer (9), Zapesochnyi and Skubenich (10), McConkey *et al.* (11), Stair and Gauvin (12), Srivastava and Mirza (13), and Holland (14), as well as by continuing auroral and dayglow studies by this group (8), we have readjusted the ionization cross sections of Stolarski *et al.* (3) after subtracting the dissociative ionization contribution (15) from the total. The new estimated cross sections are parameterized in Table I.

TABLE I

Parameters for transitions to the various ionization states

Species	State[1]	I_i (eV)	A_0	Ω
	(1,0) $(-1,1)^2$			
N_2	$A^2\Pi_u$	16.73	0.160	0.83
	(1,0) $(-2,1)$ (1,2)			
	$X^2\Sigma_g^+$	15.58	0.370	0.80
	$B^2\Sigma_u^+$	18.75	0.073	0.83
	$D^2\Pi_g$	22.0	0.056	0.83
	$C^2\Sigma_u^+$	23.6	0.060	0.83
	d.i.	25.0	0.380	0.95
O_2	$X^2\Pi_g$	12.1	0.058	0.80
	$a^4\Pi_u$	16.1	0.150	0.80
	$A^2\Pi_u$	16.9	0.150	0.80
	$b^4\Sigma_g^-$	18.2	0.130	0.80
	B	23.0	0.064	0.80
	(1,0) $(-3,1)$ (3,2) $(-1,3)$			
	d.i.($O^+{}^4S$)	18.0	0.400	0.93
	d.i.($O^+{}^2D$)	22.0	0.250	0.93
	(1,0) $(-1,0.3)$			
O	^4S	13.6	0.290	0.85
	^2D	16.9	0.360	0.85
	^2P	18.5	0.190	0.85

[1]The states labeled d.i. represent dissociative ionization.
[2](a_1, Γ_1) $(a_2, \Gamma_2) \ldots (a_s, \Gamma_s) \ldots$

The $B^2\Sigma_u^+$ state has been raised by a factor of about 1.5; the $A^2\Pi_u$ has been changed such that, although the high energy part of the cross section is relatively unchanged, the region below 100 eV is higher by a factor of about 2; and finally, the $X^2\Sigma_g^+$ state is lowered by a factor of about 0.65 overall to be consistent with the total ionization cross section. The strengths of the Rydberg states were changed to reflect these adjustments. The allowed electronic transitions to $b^1\Pi_u$ and $h^1\Sigma_u^+$, however, were left unchanged.

It is of interest to point out that these changes appear to be in the right direction based on other experimental evidence. For example, the work of Geiger and Stickel (16) suggests that about 40% of the 12.85 peak is associated with the $b^1\Pi_u$ state. Lowering R_X (3), which contributes to the 12.85 peak, raises the relative importance of $b^1\Pi_u$ to a value approaching 40%.

TABLE II

Parameters for transitions involving electronic states

Species	State	W_j (eV)	f_0c_0	Ω	(a_s,Γ_s)
N_2	$A^3\Sigma_u^+$	6.14	1.0	4.0	(1,0) (−2,1) (1,2)
	$B^3\Pi_g$	7.30	1.8	4.0	
	$a^1\Pi_g$	9.10	0.14	1.0	
	$C^3\Pi_u$	11.03	0.97	3.0	
	$b^1\Pi_u$	12.85	0.44	0.75	(1,0) (−3,1) (3,2) (−1,3)
	$h^1\Sigma_u^+$	14.00	0.39	0.75	
O_2	9.9 peak	9.9	0.080	0.85	
	$a^1\Delta_g$	0.98	0.000033	0.9	(1,0) (−1,1)
	$b^1\Sigma_g^+$	1.64	0.000037	0.9	
	$A^3\Sigma_u^+$	4.50	0.021	0.9	
	$B^3\Sigma_u^-$	8.4	0.23	0.75	(1,0) (−2,1) (1,2)
O	^1D	1.9	0.013	1.00	
	^1S	4.17	0.0061	1.00	(1,0) (−1,0.5)

The forbidden states of N_2 are still rather uncertain and we have chosen for the time being to retain the old cross sections because of the lack of enough evidence to the contrary. It is worth pointing out, however, that new measurements are available (14, 17, 10, 18) which suggest changes in the next generation work. The forbidden triplet states of N_2 are responsible for the first and second positive as well as the Vegard–Kaplan emissions in the aurora and airglow. These states then are of special interest in that the auroral and dayglow calculation can help us to fix limits on the cross sections. Tables II and III summarize the cross sections and their parameters.

The situation for O_2 is somewhat weaker than for N_2 because of the lack of data at the time of the original work of Watson *et al.* (4). For simplicity, then, with the realization that future work should be especially fruitful for O_2, we have kept the old relative values but have reduced the ionization and Rydberg cross section strengths to accommodate dissociative ionization. In addition the 8.4 eV Schumann–Runge peak is reinterpreted by assuming it to be composed of $R_X(3)$ and $B^3\Sigma_u^-$ with the latter carrying most of the strength rather than the former. Tables I, II, and III give the cross section parameters.

Finally we wish to present a tentative set of cross sections for atomic oxygen. The parameters for the ^1D and ^1S states are estimated from the recent calculations of Smith *et al.* (19) and appear in Table II. However, in an almost complete absence of further data, we have adopted the approach of assigning a shape function to each cross section according to its spin and orbital angular momentum quantum numbers. The assumed shapes are similar to those for helium given by Jusick *et al.* (2) except that we have made the forbidden transitions more sharply peaked. The general approach in estimating cross sections is to first obtain the optical oscillator strengths for the allowed transitions (type 1 in Table IV) leading to a particular ionization continuum. The cross sections for these transitions are then obtained from eq. [1] using $c_0 = 1.5$, and using $f^*/(n-\delta)^3$ to account for the n dependence in the higher members. The value of f^* found for an allowed transition, along with the c_0's given in Table IV, and proper values for δ, are then used for the other transition types leading to the same ionization continua. The comparison of realistic calculations of the resulting spectral lines with field observations indicates

TABLE III

Parameters for Rydberg states leading to the various ionization continua[1]

Species	Rydberg limit	δ	c_0f^*	W_j ($n=3$)
N_2	$X^2\Sigma_g^+$	0.7	6.6	13.0
	$A^2\Pi_u$	1.04	2.2	13.17
	$B^2\Sigma_u^+$	0.87	1.0	15.75
	$D^2\Pi_g$	1.53	0.7	15.7
	$C^2\Sigma_u^+$	0.8	0.7	14.0
O_2	$X^2\Pi_g$	1.08	1.2	8.4
	$a^4\Pi_u$	1.0	2.5	12.7
	$A^2\Pi_u$	1.07	2.1	13.2
	$b^4\Sigma_g^-$	0.69	1.8	15.7
	B	1.0	0.7	19.6

[1]In each case the shape parameters are the same with $\Omega = 0.75$ and with the set of (a_s, Γ_s) being (1,0) (−3,1) (3,2) (−1,3).

TABLE IV

General parameters for estimating cross sections in atomic oxygen

Type	$\|\Delta l\|$	$\|\Delta s\|$	Ω	c_0	Set of (a_s,Γ_s)
1	1	0	0.75	1.5	(1,0) (−3,1) (3,2) (−1,3)
2	0	0	0.75	0.06	(1,0) (−1,2)
3	1	1	3.0	1.4	(1,0) (−2,1) (1,2)
4	0	1	3.0	0.4	(1,0) (−1,1)

that these cross sections are not unreasonable on average.

For the ionization cross sections in O, we use the same estimates as Stolarski and Green (5) with ^4S and ^2D each contributing 40% and ^2P contributing 20% at 100 eV. Some contributions will also come from auto-ionization, but we have not included them. The total ionization cross section is about one half that of O_2 at 10 keV and fits the results of Fite and Brackmann (20) and Rothe *et al.* (21) below 1 keV.

Conclusions

It is hoped that the cross sections presented here will be of assistance to workers in aeronomy by providing a rather complete set. It is comforting that the use of these cross sections leads to good correlation with auroral and dayglow observations, to consistent loss functions in the keV range, and to reasonable values of ionization yield. However, in the face of rather large uncertainties in much of the data, it must be emphasized that continued recycling of these constants will be necessary until atomic cross section experiments or theory become an exact science.

the 6.4 eV region. I should like to direct attention to this in the hope of stimulating some experimental attempts.

REPLY BY E. N. LASSETTRE

The spectral region near 6.4 eV has been studied at an incident kinetic energy of 50 eV but scattering in excess of the background could not be found. It would be of interest to re-investigate this spectral region at higher kinetic energies and reduced resolution. However, this has not yet been done.

QUESTION BY F. A. WOLF[1]

How do you distinguish between exchange and direct excitation processes, i.e., those which result in a change in multiplicity and those which do not?

How much reliability can one ascribe to the threshold behavior of these cross sections?

REPLY BY L. R. PETERSON

Cross sections for exchange and direct excitation processes have a very different form from one another in that exchange cross sections, in contrast to direct cross sections, rise quickly from threshold to peak and then fall off again very rapidly. This behavior can be well represented by our fits by choosing the parameters appropriately.

When speaking of threshold behavior, one must define whether we are talking about how the cross section fit varies with E at very small increments above threshold or how well the peak is represented by the fit when the peak occurs close to threshold. While our fits tend to reproduce the latter definition quite well, we do not worry at all about the former.

COMMENTS BY A. I. STEWART[2]

It is important to realize that in the dayglow, and to a somewhat lesser extent in the aurorae, it is the behavior of the cross section close to threshold which determines the rate of excitation of radiating states by electron impact. Cross sections deduced solely from high-energy scattering data are unlikely to be accurate in this most important region. Attempts to find curve fits to excitation cross sections should, therefore, use parameters which may be adjusted to give agreement at and near threshold with such experimental evidence as is available.

REPLY BY L. R. PETERSON

Consistent with the meaning of threshold behavior as we use it, we feel that the cross section near the peak or perhaps the integrated cross section, as approximated by the peak and width at half maximum, is the dominant feature in the majority of cases.

With respect to the second part of the question, we do agree that the cross sections deduced solely from high energy data are unlikely to be accurate in the region of importance, namely, the peak. For that reason in fitting our cross sections we make use of the many phenomenologically derived subsidiary conditions regarding the shape and magnitude scaling factors.

COMMENTS BY R. W. NICHOLLS[3]

I should like to compliment Dr. Peterson on the work which he, Professor Green, and associates are doing in Florida in an attempt to deal quantitatively with the gross phenomenology associated with the energy degradation of particles and photons which enter the earth's atmosphere. My question relates to the rationale for and the physical meaning of the terms in the empirical expressions they use for cross sections. Some years ago (1–3) when considering the excitation kinetics of N_2 in discharges, I had an occasion to seek plausible empirical expressions for excitation cross sections of the various electronic states of N_2, and found that expressions of the form

$$S(E) = CE^{\frac{1}{2}} \exp(-LE)$$

where C is a constant, fitted the sparse experimental data then available fairly well. I wonder if the Florida group experimented with similar empirical expressions?

REPLY BY A. E. S. GREEN

First, let us return the compliment by remarking that Professor Nicholls was far ahead of his time in using a phenomenological approach to the low energy degradation problem. The function mentioned, however, would fall off too sharply at the high energies involved in auroral and some dayglow applications. Our own functional forms for cross sections have been chosen with these applications in mind, and in view of the analytic forms which are suitable for loss functions.

COMMENTS BY F. R. GILMORE

In interpreting energy-loss measurements in nitrogen, it is important to keep in mind that N_2 has many electronic states which may be excited by electron impact. For example, within 3 eV of the $A^3\Sigma_u^+$ state there are four similar states: $W^3\Delta_u$, $B'^3\Sigma_u^-$, $a'^1\Sigma_u^-$, and $w^1\Delta_u$ (4–6). In the molecular-orbital approximation (1) these states have the same electronic configuration as the A state, so that their formation cross sections are probably comparable (except for varying statistical weight factors). Of course, since their vibrational levels overlap with each other and with other states (especially the strongly-excited $a^1\Pi_g$ state), competition will decrease the contribution of any one state.

Optical emission measurements can help greatly in determining the cross sections for production of specific excited states. However, such measurements are more difficult in N_2 because many of the stronger bands are in the infrared, while their interpretation is also more difficult because of the many possibilities for cascading. In addition to the usual type of cascade, such as $C \rightarrow B \rightarrow A$ (second positive and first positive bands) and $w \rightarrow a \rightarrow a'$, a type involving several vibrational levels of two neighboring electronic states may occur. An important example of the latter should occur when the A state is produced by electron impact. According to Franck–Condon factors (7), a considerable fraction of the A state will be formed in vibrational levels around $v = 10$. These can make radiative transitions to the lowest levels of B state, which then drop back to the A state with emission of first-positive bands. The "reversed" first-positive transitions A (high v) $\rightarrow$ B (low v) might be denoted "last positive" bands[4], since they have not yet been observed experimentally, but should be observable in the positive column of a nitrogen discharge at long wavelengths. The relevant Franck–Condon factors (4) indicate that the strongest bands should lie in the middle infrared.

Preliminary calculations by the writer of relative N_2 and N_2^+ band intensities in the aurora show that the "last positive" bands should be among the strongest emissions in the middle and far infrared regions. They also show that the $A \rightarrow B \rightarrow A$ cascade redistributes the vibrational population of the A state to give reasonable agreement with auroral measurements (8) on the Vegard–Kaplan system ($A \rightarrow X$), so that direct production of the C and B states, followed by cascading to the A state (5), no longer needs to be invoked.

COMMENTS BY J. W. McGOWAN

Another possible excitation mechanism for the Vegard–Kaplan bands is the charge transfer reaction

$$N_2^+(X^2\Sigma_g^+) + NO(X^2\Pi, v = 0) \rightarrow N_2(A^3\Sigma_u^+, v = 1) + NO^+(X^1\Sigma^+)$$
$$\Delta E \approx 0$$

That this mechanism might be of importance comes from the fact that the rate of reaction of N_2^+ with NO is fast, $\sim 5 \times 10^{-10}$ cm^3/s, which usually implies a near energy-resonant process like the one above. Moreover, the measured rotational temperature associated with the Vegard–Kaplan bands tends to be higher than that of the ambient atmosphere. A high rotational temperature is often associated with charge transfer. Finally, the density of NO in the D region is found to be higher than originally thought.

[4] A modification of R. W. Nicholls' impromptu suggestion, "last negative bands".

SUMMARY BY CHAIRMAN, F. R. GILMORE[5]

A large fraction of all published measurements of energy loss in fast electron collisions have been made by Professor E. N. Lassettre and his co-workers, so it was very appropriate that Professor Lassettre began the session by reviewing this field. His comprehensive review showed how greatly our knowledge has increased in the last three or four years. In the incident energy range from tens of eV to tens of keV, energy-loss measurements are now available for most of the atmospheric gases with sufficient resolution to show the vibrational structure, and thus clearly identify the final states produced. For each electronic state, it is usually found that the relative intensities of the different vibrational levels agree with the theoretical Franck–Condon factors, even at incident energies so low that the Born approximation does not hold.

For a number of electronic transitions, data are available on the absolute cross section and its variation with scattering angle. When these are extrapolated to zero momentum loss (corresponding to high incident energies and small scattering angles), the Born approximation predicts a simple relation to the optical f number. Experimentally, good agreement with this relation is found in several cases, but unexplained differences of up to a factor of 3 are found in other cases.

Following Lassettre's review, a paper by Peterson, Prasad, and Green was presented which conveniently summarized in analytic form the cross sections for electronic excitation, dissociation, and ionization of N_2, O_2, and O. This paper nicely complemented the preceding review because it emphasized overall cross sections without regard for vibrational or angular distribution, and it referenced the recent work using optical detection of excited products, which was not covered by Lassettre.

The discussion which followed this paper served to emphasize that the applications of electron-impact data to aeronomic problems attempted so far are quite preliminary and approximate, and much more work will be needed before definitive results are obtained.

Laboratory studies of electron attachment and detachment processes of aeronomic interest

A. V. PHELPS
Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

Received December 18, 1968

Techniques for the study of electron attachment and detachment are reviewed. The rate coefficients for the various processes of aeronomic interest are then discussed. The rates of three-body and dissociative attachment by thermal electrons have been successfully determined by swarm techniques and by high frequency studies of electrons produced by high energy particles and by photoionization. Collisional and associative detachment rates for thermal energy negative ions have been measured using the swarm and flowing afterglow techniques. Radiative attachment rates for some atmospheric negative ions have been calculated from measurements of photodetachment cross sections using crossed photon and ion beam techniques. Electron beam studies and measurements of ion kinetic energy have provided much useful information regarding the dissociative attachment process and the structure of molecular negative ions. Rate coefficients for low energy processes such as the three-body attachment to O_2, the radiative attachment to O, and the associative detachment of O^- in collisions with various atmospheric gases are reasonably well known. Other possibly important low energy processes, such as dissociative attachment to O_3, radiative attachment to O_2, and the associative detachment of O_2^- are less well known.

Canadian Journal of Chemistry, 47, 1783 (1969)

Introduction

Laboratory measurements of the rates of loss of free electrons by collisional attachment to molecular oxygen and radiative attachment to atomic oxygen under conditions of electron energy and gas temperature appropriate to the earth's atmosphere were first reported about 10 years ago. Measurements of photodetachment rates for O^- and O_2^- were made at about the same time. Information concerning such processes as of 1963 were reviewed by Branscomb (1). Although progress has been made in refining and understanding these processes, it was not until 1966 that really significant new laboratory data in the area of electron attachment and detachment processes became available in the form of associative detachment coefficients for O^- and O_2^- in collisions with atomic oxygen (2). These results, along with the accompanying studies of negative ion – molecule reaction rates (2–4) have made possible much more realistic models of the electron – negative ion balance at altitudes where atomic oxygen is present (3–5). In keeping with the purposes of this Symposium we will limit our discussion to some of the laboratory techniques and results which form a basis for atmospheric models.

Electron attachment and detachment processes which are considered to be of aeronomic interest are: three-body attachment, with a ground state molecule or an electron as the third body, and its inverse, collisional detachment; dissociative attachment and its inverse, associative detachment; and radiative attachment and its inverse, photodetachment. The photodetachment process is being reviewed by Schoen (6) and will not be considered here. Similarly, the negative ion – molecule reactions which largely determine the negative ion species which are present in the atmosphere and undergo detachment are being reviewed by Ferguson (7).

The experimental techniques used to study electron attachment and detachment processes are reviewed in Section II. The primary purpose of this review is to provide a basis for a critical discussion of the laboratory data. The results of the laboratory experiments for gases and ions of aeronomic interest are discussed and tabulated in Section III. Section IV contains a discussion of some of the outstanding problems which should be examined in the laboratory.

Laboratory Techniques

Laboratory techniques used for the study of attachment and detachment processes include (*a*) swarm techniques, (*b*) high frequency studies of electrons produced by high energy particles and by photoionization, (*c*) low energy electron beam techniques, (*d*) flowing afterglow techniques, and (*e*) ion beam techniques.

(a) Swarm Techniques

The name swarm techniques is used to designate those experiments in which very low densities

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of electrons (less than about 10^3 electrons/cc) are introduced into a gas where they drift and diffuse through the gas under the action of a weak electric field. As the electrons drift through an attaching gas they form negative ions which in turn may undergo ion–molecule reactions, such as collisional detachment. The electron source may be a photocathode, an α particle source, or a shielded, low temperature filament. The partial pressure of the attaching gas is usually chosen such that a significant fraction of the electrons attach before they reach the most positive electrode of the drift region.

Reviews of electron attachment measurements using the swarm technique are given by Loeb (8), Prasad and Craggs (9), and McDaniel (10). Recent studies have determined the attachment coefficient for low energy electrons from the time variation of the ion current waveform (11, 12), the variation in the magnitude of electron current pulse reaching the anode with the concentration of the attaching gas (13), or the variation in the diffusive spread of negative charge (electrons and ions) with distance along the electric field (14, 15). Drift tubes have been coupled with mass spectrometers in order to identify the negative ions produced by attachment (16, 17).

The processes of collisional and associative detachment of electrons from negative ions can also be studied by the swarm technique. This is accomplished by using an electron filter (8) to separate the electron and ion components of the current. The detached electrons are distinguishable from the electrons which cross the drift tube without attaching because of the differences in time of arrival at the collector electrodes (18, 19).

Advantages of the swarm technique are that (*a*) because of the very low degree of ionization there should be negligible production of excited and dissociated molecules which could cause electron detachment or interfering ionization, (*b*) the temporal behavior of both the electrons and ions can be studied, and (*c*) the loss of electrons and ions due to recombination can be neglected. A disadvantage of the swarm technique is that the electric field used to produce the drift of the electrons and ions also raises the electron energy above the thermal values of principal aeronomic interest. Thermal attachment coefficients can be obtained by extrapolation from higher energies (12) and the energy over which extrapolation is necessary can be made small by the use of thermalizing gases such as CO_2 (18). An important source of error in all experimental studies of attachment using gas mixtures is the possible adsorption of the minority component on the walls with the resultant errors in partial pressures.

(b) High Frequency Studies

The term high frequency studies is used to designate those experiments in which the gas is ionized sufficiently to produce a measurable change in the dielectric properties of the gas. The measurements may be made (*a*) during the decay of electron density following a period of irradiation by a pulsed source (20–27), (*b*) during irradiation of the gas by a steady state source (20, 28, 39), or (*c*) during the decay of density following a pulsed discharge (30–38). A variant of these studies is to use Langmuir probes to measure the time variation of the electron density (21). The radiation used to produce the ionization has been high energy electrons (20, 33, 25, 26, 29), X-rays (28), or Lyman-α photons which ionize NO molecules (21, 23, 24, 27). The transient measurements, (*a*) and (*c*), are relatively easy to interpret when the electron and positive ion densities are so low that recombination can be neglected and the gas pressures are so high that diffusion effects are unimportant (39), i.e. the decay of electron density is exponential with a decay constant equal to the reciprocal of the lifetime of the electron against attachment. The response time of the electronic circuits and of the high frequency system set an upper limit to the decay constant (and gas pressure) which can be studied with the transient decay technique (20, 26). This limit is not present in the steady state measurements provided one corrects the measured change in the dielectric constant for the effects of electron collisions with the gas and the effect of negative ions, if significant (20, 29). The steady state experiments require a knowledge of the rate of electron production by irradiation, since the electron lifetime is equal to the measured electron density divided by the production rate at high pressures.

The advantages of the high frequency techniques are that (a) under conditions where attachment is the dominant electron loss mechanism and the pressure is not too high (less than atmospheric in pure O_2), the electrons are expected to thermalize before they attach (40–42)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and (b) measurements can be made at much higher attaching gas densities than in the swarm technique. A source of error in these experiments is the presence of excited species which may cause detachment and a reduction in the apparent attachment rate (12, 43, 44). This problem is most serious when the electrons are produced by an electrical discharge (30–38), i.e., when the fraction of the electrons with sufficient energy to ionize the gas is small compared to the fraction which can produce excited and dissociated molecules (8, 10). Until the effects of excited species, etc. are understood and measured, high frequency attachment and detachment studies using pulsed discharge produced ionization should be regarded as unreliable sources of data to be applied to aeronomic problems. Although some difficulties have been encountered in irradiation experiments using high energy electrons (20, 29), the high ionization efficiency of high energy particles results in a much lower degree of excitation and dissociation than in a discharge. Properly filtered Lyman-α radiation should produce little excitation and dissociation, although some changes in the electron transient due to frequent and intense irradiation have been reported (23, 24).

(c) Low Energy Electron Beam Techniques

Low energy electron beam techniques for the study of electron attachment employ a beam of nearly monoenergetic electrons which pass through the gas at low densities under conditions which allow collection of the negative ions and/or mass analysis of the ions (9, 10). Because of the difficulties in the control of low energy electrons, only a few electron beam studies have been carried out at low enough energies to yield cross sections of direct applicability to aeronomic problems (45, 46). However, studies of the details of the dissociative attachment process, e.g. temperature dependence of the attachment cross section (47, 48) and kinetic energy of the product ions (49), are possible only with electron beam techniques and have led to a much better understanding of molecular negative ion structure and of the associative detachment process. The associative detachment process is the inverse of the dissociative attachment process and is of considerable aeronomic interest (1–5).

(d) Flowing Afterglow Technique

The flowing afterglow technique is being discussed by Ferguson (7) at this Symposium in connection with ion–molecule reactions. We will simply point out that this technique was used in the first laboratory observation of associative detachment (2) and that the technique is particularly useful when the neutral partner in the associative detachment reaction is a free radical, such as O, or a relatively unstable species, such as O_3 (3). Although the technique has been applied to studies of electron loss by recombination with positive ions (50, 51), an attempt (3) to apply the technique to measurements of electron attachment to O_3 has yielded coefficients which appear to be too large (4, 52). Apparent observations of attachment–detachment effects in a nitrogen flowing afterglow seeded with various attaching gases have been reinterpreted in terms of attachment and recombination (53). The technique has been used to observe the effects of very high temperatures on attachment (53).

(e) Ion Beam Techniques

Negative ion beam techniques have been used to study photodetachment (1, 54, 55), electron induced collisional detachment (56, 57), and neutral particle induced collisional detachment (58). Since the photodetachment experiments and results are being reviewed by Schoen (6) at this Symposium, we will limit our discussion to pointing out that the use of measured photodetachment cross sections and detailed balancing arguments (1, 54) is the only method used thus far for determining radiative attachment cross sections from laboratory data for systems of aeronomic interest. Unfortunately, these techniques cannot be used to obtain accurate cross sections for the radiative attachment of low energy electrons to molecules such as O_2 and OH, because of the uncertainties in the threshold behavior of the photodetachment cross section (54, 55).

Laboratory studies of electron induced collisional detachment have been carried out by crossing a negative ion beam with an electron beam and measuring the rate of production of neutral atoms (56, 57). These experiments are very difficult because of the possibility of space charge interaction of the ion and electron beams, the presence of sources of extraneous signals, and the high ion – neutral atom energies required for efficient neutral atom detection. Thus far, the minimum incident electron energy for which measurements have been reported is about 10 eV.

TABLE I

Recommended rate coefficients

(*a*) Three-body attachment with neutral third body

Reaction	k_1(cm^6/s)	Reference
$e + O_2 + O_2 \rightarrow O_2^- + O_2$	$(1.4\pm0.2) \times 10^{-29}(300/T)e^{-600/T}$ $(195<T<600\ °K)$	(18)
$e + O_2 + N_2 \rightarrow O_2^- + N_2$	$(1\pm0.5) \times 10^{-31}$ $(300<T<500\ °K)$	(12, 30, 39)
$e + O_2 + H_2O \rightarrow O_2^- + H_2O$*	$(1.4\pm0.2) \times 10^{-29}$ $(300<T<400\ °K)$	(70)
$e + O_2 + CO_2 \rightarrow O_2^- + CO_2$	$(3.3\pm0.7) \times 10^{-30}$ $(300<T<525\ °K)$	(70)
$e + NO + NO \rightarrow NO^- + NO$*	$(1.3\pm0.2) \times 10^{-31}$ (300 °K)	(24)
$e + 2N_2O \rightarrow N_2O^- + N_2O$*	$(6\pm1) \times 10^{-23}$ (300 °K)	(67, 68)
$e + NO_2 + N_2 \rightarrow NO_2^- + N_2$	4×10^{-11} cm^3/s† (300 °K)	(27)

(*b*) Collisional detachment with neutrals

Reaction	k_2(cm^3/s)	Reference
$O_2^- + O_2 \rightarrow 2O_2 + e$	$(2.7\pm0.3) \times 10^{-10}(T/300)^{1/2}e^{-(5590/T)}$ $(375<T<600\ °K)$	(18)
$O_2^- + N_2 \rightarrow O_2 + N_2 + e$	$(1.9+0.4) \times 10^{-12}(T/300)^{3/2}e^{(-4990/T)}$	(18)
$O^- + O_2 \rightarrow O + O_2 + e$	$2.3 \times 10^{-9}e^{(-26000/T_i)}$‡ $(4000<\text{“}T_i\text{”}<20\,000\ °K)$	(78)
$O^- + N_2 \rightarrow O + N_2 + e$	Same as $O^- + O_2$	(78)
$O_2^- + O_2(^1\Delta_g) \rightarrow O_2 + O_2 + e$	2×10^{-10} (300 °K)	(77)

(*c*) Dissociative attachment at 300 °K

Reaction	k_3(cm^3/s)	Reference
$e + O_3 \rightarrow O^- + O_2$	$(1-10) \times 10^{-12}$	(52)

(*d*) Associative detachment at 300 °K

Reaction	k_4(cm^3/s)	Reference
$O^- + O \rightarrow O_2 + e$	1.4×10^{-10}	(4)
$O^- + N \rightarrow NO + e$	1.6×10^{-10}	(4)
$O^- + H_2 \rightarrow H_2O + e$	8.0×10^{-10}	(4, 19)
$O^- + NO \rightarrow NO_2 + e$	3.0×10^{-10}	(4, 19)
$O^- + N_2 \rightarrow N_2O + e$	$\sim1\times10^{-19}$	(19, 67)
$O_2^- + O \rightarrow O_3 + e$	2.5×10^{-10}	(4)
$O_2^- + N \rightarrow NO_2 + e$	3.0×10^{-10}	(4)
$O^- + O_2(^1\Delta_g) \rightarrow O_3 + e$	3×10^{-10}	(77)

(*e*) Radiative attachment

Reaction	k_6(cm^3/s)	Reference
$e + O \rightarrow O^- + h\nu$	$(1.3\pm0.1) \times 10^{-15}$ $(150<T<500\ °K)$	(54, 97)
$e + O_2 \rightarrow O_2^- + h\nu$	$10^{-19\pm1}$ (300 °K)	(54, 98)
$e + OH \rightarrow OH^- + h\nu$	$10^{-15\pm1}$ (300 °K)	(55)

*Product ions not mass spectrometrically identified.
†In units of cm^3/s since it is a saturated three-body process (27).
‡Here the ion "temperature" T_i is a value calculated using the Wannier relation (76).

For personal use only.

Laboratory studies of detachment as the result of collisions between beams of negative ions and neutral gas atoms and molecules prior to 1964 have been reviewed by Hasted (58). These measurements are usually made by collecting the detached electrons with an electric field which is perpendicular to the motion of the incident ions. However, in gases where charge transfer is possible, it is necessary to separate the slow ions produced by charge transfer from the detached electrons (59, 60).

Electron Attachment and Detachment Processes

The results of laboratory studies of electron attachment and detachment are discussed in this section on the basis of the type of attachment or detachment process. The results for various gases of aeronomic interest will be discussed under the appropriate process.

(a) Three-Body Attachment with Neutral Third-Body

The three-body attachment process results from a collision between an electron, an electronegative gas molecule, and a third-body which stabilizes the negative ion and can be represented by the reaction

$$[1] \qquad e + X + M \rightarrow X^- + M$$

This reaction occurs at a rate of $k_1[e][X][M]$, where [e], [X], and [M] are the concentrations of electrons, the electronegative gas, and the stabilizing gas. Recommended values of k_1 for atmospheric gases are given in Table I. This type of reaction is usually considered to be of the pseudo three-body type proposed by Bloch and Bradbury (61) in which the electron and the electronegative gas molecule form an excited negative ion which may be stabilized in a collision with a third body M. The lifetime of the excited negative ion against autodetachment is expected to be short (12, 44, 61, 62). A second possibility is a dissociative attachment process involving an electron and a temporary or weakly bound XM complex. Dissociative attachment from a bound molecular complex would lead to an increasing rate coefficient with decreasing gas temperature at fixed electron energy (12).

The three-body attachment process has been found to be the dominant electron attachment process for low energy electrons in O_2 (12, 13, 15, 18, 20, 22, 25, 26, 29, 36, 45, 63), NO (23, 24, 64, 65, 66), and N_2O (67, 68). In view of the differences between recent results (23, 24) for NO, the apparent rapid variation of k_1 with temperature (23) should be reinvestigated. Data obtained in mixtures of NO_2 and other gases (27, 69) give an apparent two-body behavior, i.e., the lifetime of the excited NO_2^- appears to be long enough so that stabilization always occurred. Unpublished data obtained in pure NO_2 indicate a three-body dependence (20). Attachment is not observed in other atmospheric constituents such as N_2 (8–10), CO_2 (70), and H_2O (70–72). Although, gases such as CO_2 and H_2O have a high efficiency as stabilizing molecules during the three-body attachment to O_2 (63, 70, 72), only the stabilization by N_2 (12, 13, 18, 20, 22, 25, 26, 29, 36) and O_2 is likely to be of aeronomic interest. The results of temperature dependent studies (12, 18, 20) of the three-body attachment coefficient in O_2 are shown in Fig. 1. It is to be noted that the uncertainty in k_1 increases with decreasing temperature. No data are available for air-like mixtures at temperatures below room temperature.

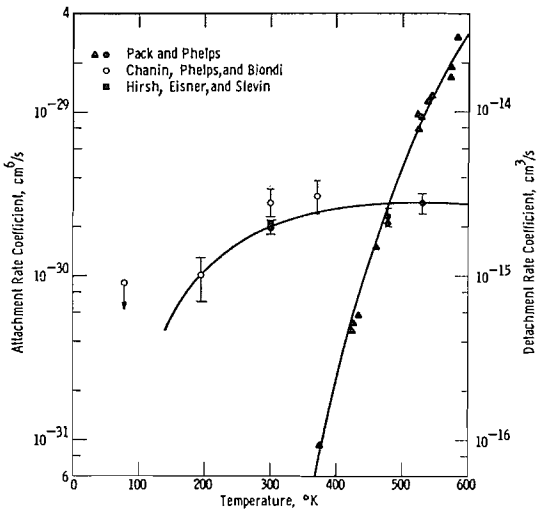

FIG. 1. Electron attachment and detachment in O_2.

On the basis of the numerous laboratory experiments which agree as to the nature and magnitude of the attachment process for thermal electrons in O_2 and O_2–N_2 mixtures at low pressures (< 10 Torr of O_2), experiments that appear to give significantly different attachment

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

coefficients (30–35, 37) must represent experimental situations in which there are interfering processes such as electron detachment. One aspect of the three-body attachment process in O_2 concerning which there is conflicting evidence, is whether or not one has observed effects due to the finite lifetime of the excited O_2^- ion in the Bloch–Bradbury attachment mechanism (61). The results of these experiments are conveniently expressed in terms of the apparent rate coefficient k_a for the formation of the excited O_2^- ion, i.e. the high pressure limit of the measured attachment frequency per unit oxygen density. Values of k_a in cm^3/s of 7×10^{-12} (62), 1.7×10^{-12} (25), and 4×10^{-12} (26) have been reported. The first of these values has been shown (63, 70) to be based on incorrect data, while the last has been found (private communication from the authors) to have been subject to errors because of the finite response time of the microwave cavity when filled with low collision frequency gases (42) at low pressures. Lower limits to k_a of 1.5×10^{-11} (20) and 2.5×10^{-11} (29) have been obtained in pure oxygen using high frequency measurements of the electron density produced by steady state irradiation of O_2 and O_2–N_2 mixtures. These values are somewhat uncertain because of uncertainties (42) as to electron collision frequencies in O_2. Even higher values for the lower limit for k_a have been found when C_2H_4 and CO_2 are used as the stabilizing gases, i.e. 7×10^{-11} cm^3/s from refs. 63 and 70. Although it has been suggested (62) that the Bloch–Bradbury mode for attachment to O_2 may not be applicable in these mixtures, and that negative ion formation occurs via the formation of long lived excited states of CO_4^- and $C_2H_4O_2^-$, the observed pressure dependence of the $[CO_4^-]/[O_2^-]$ ratio (17) is consistent with O_2^- formation followed by conversion to CO_4^- rather than a very efficient stabilization of excited CO_4^- formed in a three-body collision. These arguments are of aeronomic significance because of the differences in the predicted rate of electron attachment in air at pressures approaching atmospheric. Obviously, further work on this point is needed.

At present there are no quantitative theories available regarding the three-body attachment process in molecular gases although theories have been proposed for three-body attachment of electrons in atomic gases (73). In the case of excited negative ions containing large numbers of molecules, such as might be formed in the first step of the Bloch–Bradbury process in polyatomic gases, an attempt has been made to relate the lifetime against autodetachment to the electron affinity (74). In the case of diatomic negative ions, such as O_2^-, the only potentially relevant theoretical calculations are of the equilibrium separation and vibrational constant (75).

(b) Collisional Detachment by Neutrals

The collisional detachment reaction may be written as

$$[2] \qquad X^- + M \rightarrow X + M + e$$

and occurs at a rate of $k_2[M][X^-]$. Recommended values of k_2 are given in Table I. Laboratory measurements of the rate coefficients for the collisional detachment k_2 of electrons from thermal O_2^- ions in collisions with O_2 and N_2 have been made using the swarm technique (18). The measured values of k_2 for O_2^- and O_2 collisions are shown in Fig. 1. Although collisional detachment was not observed at temperatures below 350 °K, it is expected that an extrapolation of these results to lower temperatures should be valid, i.e., that $k_2 \approx 2.2 \times 10^{-18}$ and 1.6×10^{-22} cm^3/s at 300 and 200 °K, respectively. It would appear that other reported measurements of this rate coefficient are too large because of the presence of excited species or dissociated molecules (36) or too small (53) because of the recombination effects. An independent measurement of the adiabatic electron affinity of O_2 would be a valuable test of the consistency of the swarm measurements of the detachment and attachment rate coefficients (18).

The collisional detachment of electrons from O_2^- by O_2 molecules in the $^1\Delta_g$ state has been proposed as an important reaction in the ionosphere (76) and in afterglow studies of electron attachment (43, 44). The rate coefficient for this reaction has recently been measured (77) and is listed in Table I.

Collisional detachment cross sections for O^- and O_2^- ions and N_2 or O_2 molecules have been measured for ion energies as low as 3.6 eV (58–60). Unfortunately, these results are not readily extrapolated to the thermal energies of aeronomic interest. Also, the fixed internal energy of the molecules in these experiments means that the results of the ion beam studies cannot be used to infer temperature dependences of collisional

For personal use only.

detachment rate coefficients. Collisional detachment from non-thermal O^- ions in O_2 and air has been observed using swarm techniques (78) and the measured rate coefficients are consistent with the results of the beam experiments. Evidence for collisional detachment has been observed in NO at elevated temperatures (64). However, the identity of the negative ions is not known (23, 24).

Theories of collisional detachment are available which give cross sections of the correct order of magnitude for collisions between atoms (79, 80) and between H^- and various molecules (81). These theories have not been tested against data obtained with molecular negative ions but are not expected to be applicable in systems where the Bloch–Bradbury model (61) of attachment is appropriate.

(c) Electron Induced Three-Body Attachment and Collisional Detachment

In order to decide whether or not there are aeronomic situations in which the electron density is high enough to result in a significant rate of electron induced three-body attachment or collisional detachment, we will summarize the present state of experiment and theory. Experimental studies of electron induced detachment for H^- (56, 57) agree with the later theories (82, 83) to within experimental uncertainties. However, the O^- results (55) appear to show significantly larger cross sections than predicted for low energy electrons (56, 84). Since the actual rate coefficients are expected to be less than the values given by classical theory, it would appear that electron induced attachment will be negligible compared to neutral particle induced attachment, unless the ratio of the electron to the molecular oxygen concentrations is greater than about one part in 10^5. This condition is not expected to be satisfied under conditions of aeronomic interest for which electron attachment is an important process.

(d) Dissociative Attachment

The dissociative attachment reaction is

$$e + XY \rightarrow X^- + Y \qquad [3]$$

and occurs at a rate of $k_3[XY][e]$, where [XY] is the concentration of the molecule with which the electron interacts. Laboratory studies of the dissociative attachment of electrons to gases of aeronomic interest have been carried out for many years (1, 8–10). In the case of O_2 at room temperature, dissociative attachment occurs only for electron energies above about 4.5 eV (85, 86). As the temperature, i.e. the degree of vibrational excitation, of the O_2 is increased, the threshold for attachment decreases until at 2000 °K the effective threshold is at about 2 eV (47). Although this threshold is still too large for dissociative attachment rate coefficients to be of significance in the earth's atmosphere, the studies of this process in O_2 (47, 49), H_2 (87), and other gases (88), have provided the theoretical background necessary for understanding the associative detachment process discussed in the next section.

Dissociative attachment appears to be the dominant attachment process in O_3 (46, 52) and as such may be a significant aeronomic process (5). Extrapolation of data obtained using swarm techniques (52) to thermal energies (300 °K) yields a rate coefficient for dissociative attachment to O_3 of 10^{-12} to 10^{-11} cm^3/s (see Table I). This value is about an order of magnitude smaller than that obtained from measurements in a flowing afterglow experiment (3) where the electrons may have been non-thermal (4). At present it is not known whether the value of k_3 for O_3 varies significantly with gas temperature at temperatures of aeronomic interest.

Dissociative attachment is an important process in N_2O although there has been considerable disagreement as to the effective threshold for this process (89, 90). It now appears that the early results include effects due to vibrationally excited N_2O (48) and that the rate coefficient for dissociative attachment to N_2O at 300 °K is less than 3×10^{-15} cm^3/s (68). Dissociative attachment in other minor constituents of the earth's atmosphere, e.g., NO, CO_2, and H_2O, occurs with sufficiently high electron energy thresholds and with sufficiently low rate coefficients at aeronomic temperatures so that the reactions can be neglected.

(e) Associative Detachment

Recent laboratory measurements of the rate coefficients for associative detachment reactions of ionospheric negative ions with atomic oxygen (2–4), have shown that these reactions must be included in any accurate ionospheric model (1, 3–5). The associative detachment reaction may be written as

$$X^- + Y \rightarrow XY + e \qquad [4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and occurs at a rate of $k_4[X^-][Y]$. Values of the rate coefficient k_4 measured using the flowing afterglow technique (2, 4) and the swarm technique (17, 19) are listed in Table I. The flowing afterglow technique makes use of measurements of the rate of disappearance of ions while the swarm technique can be used to measure ion destruction (17) or the production of detached electrons (19).

Temperature dependences of the associative detachment rate coefficients have not been measured. Values of k_4 for O^- and H_2 have been found to be independent of ion energy for ion energies below about 0.16 eV, while the values of k_4 for O^- and NO appear to decrease with increasing ion energy (19).

Several theoretical studies have been made of associative detachment (80, 91) but only in the case of $H^- + H$ has theory led to quantitative predictions of rate coefficients (92) for comparison with experiment (93). As suggested by Dalgarno (94), associative detachment rate coefficients may be an appreciable fraction of the rate coefficient k_p for orbiting collisions in the polarization potential of the neutral molecule (10), i.e.

$$[5] \qquad k_p = 2\pi(e^2\alpha/M_r)^{1/2}$$

Here e is the electronic charge, α is the polarizability of the molecule, and M_r is the reduced mass of the colliding particles. In cases where the lifetime of a state of the XY^- complex formed initially in reaction [4] has a short lifetime against autodetachment, e.g. less than 10^{-14} s, a fixed fraction of the collisions will result in the formation of this state and in detachment. The contribution of this state to k_4 will then be a fixed fraction of k_p and, to the accuracy of this model, will be independent of temperature. The reaction of O^- with H_2 appears to be an example of this class (19). When the lifetime of the state is comparable with the duration of a collision ($\sim 10^{-13}$ s), one expects a contribution to k_4 which is smaller than in the case of a short lifetime and which is dependent on the gas temperature. The reaction of O^- with NO appears to be of this class (19). In the case of $O^- + N_2$ (2, 17, 19), associative detachment is not observed even though the reaction is exothermic. It has been pointed out (95) that the low value of k_4 may be due to unfavorable potential energy surfaces due to differences in the stable ground state configurations of the negative ion and the neutral molecule.

(f) Radiative Attachment

The results of determinations of radiative attachment cross sections from laboratory measurements of photodetachment have been reviewed by Branscomb (54). The radiative attachment process can be written as

$$[6] \qquad e + X \rightarrow X^- + h\nu$$

where $h\nu$ is the photon produced by the reaction. The rate of the reaction is $k_6[e][X]$, and the known values of k_6 are given in Table I.

The radiative attachment spectrum for atomic oxygen has been observed (96) and the spectroscopic features of the results are consistent with photodetachment results (54, 97). Direct laboratory measurements of radiative attachment cross sections for low energy electrons in molecular gases are desirable, because of the large uncertainties which result when these cross sections are derived from photodetachment data. These uncertainties may arise because of lack of data near threshold, as in the case of O_2^- (98); because of rotational structure in the photodetachment cross section, as in OH^- (55); or because of differences in equilibrium separation and vibrational level spacing between the neutral and the negative ion, as in O_2^- (44, 75).

(g) Electron Affinities

A knowledge of the electron affinity of a negative ion helps one to predict the behavior of the ion in aeronomic situations by setting limits on the threshold energy for dissociative attachment, collisional detachment, and photodetachment, and on allowed associative detachment and ion–molecule reactions. Table II lists the recommended values or limits on values of the electron

TABLE II

Electron affinity of atmospheric negative ions

Negative ion	Electron affinity* (eV)	Reference
NO^-	<0.43	(2)
O_2^-	0.43 ± 0.02†	(18)
CO_4^-	1.22 ± 0.07	(70)
O^-	1.47 ± 0.01	(49, 96, 97)
OH^-	1.83 ± 0.04	(55)
O_3^-	1.9 ± 0.4	(99)
CO_3^-	Unknown	
NO_3^-	Unknown	
NO_2^-	>3.8	(103)
	<3.8	(2)

*Here the energy quoted is that required to separate the electron from the most stable neutral species, e.g., $e + O_3$ and $e + O_2 + CO_2$.
†The effect of O_4^- formation (102) on the electron – O_2^- equilibrium is less than 20% at 375 °K so that the derived (18) electron affinity of O_2 remains within the error limits quoted.

affinities of negative ions of aeronomic interest. It is to be noted that only for O_2^-, CO_4^-, O^-, and OH^- are laboratory measurements available which give definite values for the electron affinities.

Discussion

The results of laboratory studies discussed in the preceding section show that while considerable progress has been made in determining the important attachment and detachment rate coefficients since the last of the Symposia in 1963, there is still much to be done. For example, while there is good agreement as to the rate coefficient for the attachment of thermal electrons to oxygen in air-like mixtures at room temperature and pressures below about 30 Torr, there is considerable disagreement as to the measured rate coefficient at temperatures near 200 °K and as to the predicted rate coefficients for pressures above 150 Torr. Similarly, while there is good agreement between various experiments as to the rate coefficients for associative detachment of O^- with gases like H_2 and NO, there is only one set of measurements for the important reaction of O^- and O_2^- with O. As yet there is no data regarding the temperature dependence of the associative detachment reactions involving O. At present, the attachment coefficient for thermal electrons to ozone has been obtained only by extrapolation from data obtained at electron energies of 0.1 eV and above, and the temperature dependence of the attachment coefficient has not been investigated.

Laboratory measurements of the rate coefficients for electron detachment as the result of collisions between various negative ions and excited species are necessary in order to allow proper evaluation of such processes in the earth's atmosphere (76) and in laboratory experiments (43, 44). The recent measurements (77) of collisional and associative detachment by $O_2(^1\Delta_g)$ are examples of such a process.

Future laboratory studies of reactions of aeronomic significance should include measurements of the role of water vapor in associative detachment, photodetachment, and negative ion – molecule reactions. Experiments thus far have shown that negative ions readily form complexes or clusters with water vapor (17, 100) and that the clusters are relatively stable (101). Quantitative measurements of the rate coefficients for cluster formation and destruction are required in order to make possible estimates of the importance of the clusters under aeronomic conditions.

Accurate laboratory determinations of the electron affinity of negative ions of aeronomic interest would be very helpful in setting limits on rate coefficients and checking the consistency of laboratory measurements.

Received December 18, 1968

The flowing afterglow technique has been used to study the electron detachment reactions

$$O_2(^1\Delta_g) + O_2^- \rightarrow 2O_2 + e \quad \text{and} \quad O_2(^1\Delta_g) + O^- \rightarrow O_3 + e$$

The rates of these reactions are sufficiently fast to make them important processes in D region ionospheric chemistry.

Canadian Journal of Chemistry, **47**, 1793 (1969)

The dominant negative ion formed in the D region of the earth's ionosphere is O_2^-. The process for this formation is three-body electron attachment (1). Laboratory measurements have already indicated that the associative-detachment reaction between O_2^- and atomic oxygen is important in the determination of the electron density below 100 km (2). Recent rocket-borne photometric measurements have indicated appreciable concentrations of $O_2(^1\Delta_g)$ molecules in the D region (3). It has been suggested that electrons are detached from O_2^- by $O_2(^1\Delta_g)$ (4). Thus, this reaction might play an important role in determining electron densities at altitudes where the $O_2(^1\Delta_g)$ concentration becomes comparable with the atomic oxygen concentration.

The flowing afterglow technique (5) has recently been applied to the measurement of the reaction of O^- and O_2^- with $O_2(^1\Delta_g)$. A simplified schematic diagram of this apparatus is shown in Fig. 1. Both O_2^- and O^- were produced by flowing helium carrier gas containing O_2 past an electron gun. $O_2(^1\Delta_g)$ was added to the gas stream through a downstream port. It was produced by the passage of O_2 through a microwave discharge in a quartz side arm. The rate of production of $O_2(^1\Delta_g)$ was varied by changing the O_2 flow and the discharge power. The discharge products were passed over a glass wool plug containing mercuric oxide in order to remove atomic oxygen (6). This removal was essential since the O atoms associatively detach electrons from both O_2^- and O^- (2). The gas containing molecular oxygen was then passed through a cell 6 cm in diameter and 20 cm in length, located just before the inlet port of the flow tube, where the $O_2(^1\Delta_g)$ content of the gas was determined by measuring

TABLE I

Reaction rate constants* at 300 °K

Reaction	ΔE (eV)	k (cm^3 s^{-1})
$O^-(^2P) + O(^3P) \rightarrow O_2(^3\Sigma_g) + e$	3.6	2×10^{-10}
$O_2^-(^2\Pi_g) + O(^3P) \rightarrow O_3(^1A_1) + e$	0.6	3×10^{-10}
$O^-(^2P) + O_2(^1\Delta_g) \rightarrow O_3(^1A_1) + e$	0.6	$\sim3\times10^{-10}$
$O_2^-(^2\Pi_g) + O_2(^1\Delta_g) \rightarrow 2O_2(^3\Sigma_g) + e$	0.6	$\sim2\times10^{-10}$

*This table shows the measured reaction rates for the reaction of O^- and O_2^- with atomic oxygen and $O_2(^1\Delta_g)$. The approximate exothermicity of each reaction is listed under ΔE.

the intensity of the 1.27 μ emission from $O_2(^1\Delta_g)$. This emission was detected by a PbS photometer. From the measured emission intensity, the geometry of the cell, and the radiative lifetime (7), it was possible to calculate the concentration of $O_2(^1\Delta_g)$ molecules in the cell. This concentration, when combined with the mass flow rate of O_2 and the cell pressure, permits calculation of the flow rate of $O_2(^1\Delta_g)$. Reaction occurs between O^- and O_2^- ions and $O_2(^1\Delta_g)$ neutrals between the flow tube inlet port and the sampling orifice of the quadrupole mass spectrometer. The decrease in negative ion signal as a function of the rate of addition of $O_2(^1\Delta_g)$ provides the raw data from which the rate constants for reactions were determined.

Sample data for reaction of O^- with $O_2(^1\Delta_g)$ are shown in Fig. 2. This is a semilogarithmic plot of detected ion counts per second vs. the addition rate of $O_2(^1\Delta_g)$. This plot is made directly from the computer output of the raw data taken by an on-line data acquisition system; the scale factor for the $O_2(^1\Delta_g)$ flow is listed on the first line below the plot, while the initial O^- signal in counts per second is listed below this. The D's along the ordinate of the plot indicate decades of change in the O^- signal. The experimental points are given by pluses while the computer data fit is indicated by the asterisks.

The measured rate constants for the reactions of O^- and O_2^- with $O_2(^1\Delta_g)$ are shown in Table I. Also shown in this table are the previously measured values (8) for the detachment reactions of O^- and O_2^- with atomic oxygen. The approximate exothermicity of the reactions is also listed. Although the relative values of the $O_2(^1\Delta_g)$ reactions are probably accurate to better than 25%, no greater claim is made than an order of magnitude for the absolute accuracy of the individual values. The chief source of error lies in the uncertainty of the photometer calibration.

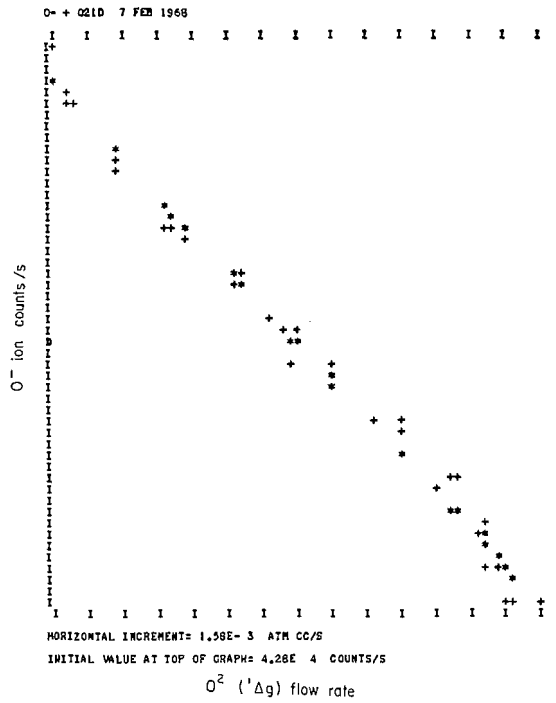

FIG. 2. A reproduction of the reduced data output from the on-line data acquisition system for the reaction of O^- with $O_2(^1\Delta_g)$. This is a semilogarithmic plot with the flow of $O_2(^1\Delta_g)$ in atm cm^3/s plotted along the abscissa and the O^- signal in counts/s plotted along the ordinate (the D's along the ordinate represent decade changes in the O^- signal). The pluses are the experimental points while the asterisks are the computer best fit to this data.

Nevertheless, the work to date has been sufficient to confirm the suspicion that the $O_2(^1\Delta_g)$ reactions play an important role in lower D region ionospheric chemistry.

COMMENTS BY V. A. J. VAN LINT

Our measurements on NO_2 establish a very high rate of electron disappearance. The apparent three-body coefficient near 10^{-27} cm^6/s at 300 °K may be associated with N_2O_4 rather than NO_2. The only escape from this large cross section for NO_2 or N_2O_4 is to assume an even larger cross section for an impurity. The reaction appears to be three-body. There is some evidence that in pure NO_2 the electrons are not completely thermalized before attachment. Therefore, it is possible that the three-body pressure dependence actually reflects a dependence of electron energy on pressure.

Positive ion reactions

WADE L. FITE
Department of Physics, University of Pittsburgh, Pittsburgh, Pennsylvania 15213
Received November 21, 1968

Progress over the past five years in the measurement of rate coefficients and cross sections for interactions between positive ions and neutral molecules of particular interest to aeronomy is reviewed. Emphasis is placed on the methods of experimentation developed for studies in the range of thermal energies and slightly above. Along with discussion of the range of applicability of each of the techniques, illustrated by examples of measurements on processes of aeronomic interest, some evaluation of limitations of applicability and reliability of the measurements is made. A table summarizing results obtained to date on processes pertaining to the atmospheres of the earth and neighboring planets is presented.

Canadian Journal of Chemistry, 47, 1797 (1969)

Introduction

Five years ago at the symposium preceding the present one, two reports summarized experimental work on collisions between ions and neutral atomic systems of interest to aeronomy. Paulson (1) reviewed the situation with regard to experiments at thermal and low energies and the present author summarized experiments where the relative energy was sufficiently high that ion beam methods were employed (2). At that time the higher energy techniques were well established and a number of results had been obtained; however, to apply the results to problems of low energies, extrapolation by rather unreliable means had to be employed. In only a few cases were thermal and low energy data available since the techniques of experimenting at these low energies were in a very early stage of development.

The five years intervening between these symposia has seen the situation reverse itself. The development of low energy experimental methods has been rapid and the amount of low energy data on the principal atmospheric species is now quite large. To an ever-increasing extent, the role of the higher energy experiments is to examine details of reactions in order to better interpret the lower energy results as they apply to the atmosphere and to discover processes deserving of attention in thermal energy experiments.

Accordingly, it is appropriate here to review the principal laboratory methods now in use to obtain thermal energy data on total cross sections and reaction rate coefficients for ion–neutral reactions, to examine briefly the modifications of these methods and alternative methods by which the effects of increased kinetic energy and reactants being in excited states are assessed, and to discuss the ways in which higher energy experiments contribute additional knowledge.

In the interests of brevity the entire field of very high energy (i.e. 1 keV and up) processes will be omitted in this review despite their importance to certain atmospheric phenomena. Only reactions involving positive ions will be considered here, since negative ion reactions are being treated in a separate review by Ferguson (3). Only casual treatment of methods which were described in the reviews (1, 2) of the 1963 symposium will be made here, the reader being referred to these earlier papers; emphasis here will be placed instead on some of the more important newer developments. Lastly, no attempt will be made to present a complete compendium of reaction rate coefficient results; instead a summary of only those reaction rate coefficients most commonly used in chemical aeronomy at low energies is given.

Information Needs and Capabilities

The large bulk of information of present interest to aeronomy is limited to very low kinetic energies, i.e., in the energy range from about 0.015 eV to about 0.15 eV, for this is the range of temperatures in the ambient natural atmospheres of the earth and neighboring planets. While attention has been focussed initially on those atmospheric species which are the major constituents in the atmospheres, i.e., N_2, O_2, and O, it has become increasingly evident that major aeronomic effects involving ions arise through minor atmospheric components such as O_3, NO, OH, CO_2, He, and H. Additionally, mass spectrometric sampling of the D region by

Narcisi and his collaborators (4) has dramatically introduced an interest in reactions involving metals and other materials presumably of meteoritic origin.

While the catalogue of chemical species of interest has increased, the need for detailed information about the role of excited states of reactants has also become apparent. In several instances it has been found in the laboratory that cross sections and rate coefficients depend very strongly on the internal energy of one or both reactants. The importance of excited states in the normal atmosphere has not been well assessed as yet, but in rather special circumstances of a disturbed atmosphere, the effects of internal energy of reactants appear exceedingly important.

In general the information sought for low energy aeronomy is total cross section or reaction rate coefficient data and most experiments are directed at obtaining this type of information. The processes of interest that involve positive ions are (*a*) charge transfer, e.g., $A^+ + BC \rightarrow A + BC^+$, and (*b*) ion–molecule reactions (or ion–atom interchange), e.g., $A^+ + BC \rightarrow AB^+ + C$, the distinction between the two being whether the chemical identity of the reactants is preserved or altered in the collision. While these names are good on laboratory experimental grounds, since the ionic products can be unequivocally determined by using mass spectrometry, the distinction physically is less clear. While charge transfer, for example, can proceed by simple electron transfer as in the case at high energies, low energy charge transfer products can also be formed in one of the decay channels of a transitory complex ion, $(ABC^+)^*$. Since ion–molecule reactions are normally envisaged as proceeding through such a complex ion, some and probably most thermal energy charge transfer reactions are more nearly similar to ion–molecule reactions than to simple electron transfer processes.

In simple electron transfer between systems of the same ionization potential (resonant charge transfer) the energy dependence of the total cross section is given by

$$[1] \qquad Q = (A - B \log E)^2$$

where A and B are constants. When the process is endothermic this dependence is found at high energies, but as the energy is reduced the cross section reaches a maximum at a relative velocity $v_m \cong a|\Delta E|/h$, where ΔE is the energy defect and a is a length of atomic dimensions. At lower energies the cross section diminishes to zero at threshold energy in the center of mass coordinates (see, for example, ref. 5).

For exothermic processes the simple electron transfer cross section is expected to behave similarly to the endothermic case, where ΔE is now the excess energy in the process. However, in cases involving molecules or molecular ions the products can be left in excited states thus leaving ΔE effectively zero. In such cases of "accidental resonance" charge transfer, eq. [1] again describes the dependence of the cross section on energy.

The usual model taken for ion–molecule reaction collisions is that a collision complex is first formed, and redistribution of the atoms within this complex then occurs. In the case of ion–molecule reactions, the mechanism of complex formation is that an incoming ion induces an electric dipole moment in a neutral, and the charge-induced-dipole force attracts the two together. If the initial impact parameter is above a critical amount depending on the relative velocity, the ion will be deflected slightly but probably no reaction will occur; if smaller than this critical amount, the two particles orbit around each other and come closer to where reaction can occur. The cross section for forming an orbiting complex was given by Langevin as

$$[2] \qquad Q(v) = 2e\left(\frac{\alpha}{\mu}\right)^{\frac{1}{2}} \cdot \frac{1}{v}$$

where α is the polarizability of the neutral and μ the reduced mass. Gioumousis and Stevenson (6) and Field, Franklin, and Lampe (7) have established experimentally that for many ion–molecule reactions, eq. [2] does describe the cross sections at energies of a few eV and less. In some cases the inverse velocity dependence is observed but the absolute magnitude of a cross section is less than that predicted. In these cases, one recognizes that a collision complex can decay through various channels leading to new ionic products, to charge transfer and also to no change in products (i.e., scattering), and that the probability of decaying by any one channel will determine the cross section for that one process.

It is of interest to note that for processes described by eq. [2], the rate coefficient,

$$[3] \qquad k = \int Q(v) v f(v) \mathrm{d}v$$

where $f(v)$, the normalized velocity distribution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

function, is independent of any other parameters that might appear in $f(v)$; most notably it is independent of the temperature in the case of a Maxwell–Boltzmann distribution.

The two energy dependences given in eqs. [1] and [2] are often used in extrapolation of high energy data to thermal energies, when it can be established that one or the other is valid at higher energies, and this procedure has usually given fairly good estimates of rate coefficients which have later been determined at very low energies.

In some cases it appears that charge transfer can proceed by both simple electron transfer and by complex formation, as evidenced by velocity dependences given by eq. [1] at higher energies and by eq. [2] at moderate energies. In some cases, most notably the important reaction $O^+ + N_2 \rightarrow NO^+ + N$, neither eq. [1] nor eq. [2] even crudely describes the experimental results.

It has already been pointed out that where a charge transfer process is exothermic, it can still display an energy dependence corresponding to one of resonance charge transfer, i.e., eq. [1]. This is usually taken to imply that the excess energy has been left as internal excitation in the products. Of course the possibility that a product of an ion–molecule reaction is left in an internally excited state is also present. Such products can radiate or dissociate, or, if metastable, remain to participate in future reactions. The last possibility is one of the reasons for studying the role of internal energy in aeronomic reactions even in the ambient atmosphere and the first two possibilities provide additional laboratory methods of studying reactions.

At higher energies, other two-body collisions processes occur. These include direct excitation and/or dissociation of either of the reactants, ionization of the target neutral, and removal of additional electrons from the incident ion, in addition to charge transfer. In general the formation of collision complexes is a low energy phenomenon and eq. [2] fails at ion energies of the order of tens of eV, with the cross section for ion–molecule reactions falling off much more rapidly as the energy is increased.

The principal three-body thermal energy process of interest to aeronomy is clustering, i.e., the addition of neutral molecules to existing ions. The case of clustering of one or more water molecules to ions is particularly noteworthy in the D region.

Laboratory Methods

The laboratory methods in use for the measurement of total cross sections and reaction rates for processes involving positive ions and neutrals can be grouped on the basis of the energy range in which they work. The principal general methods are

1. Thermal energy methods (0.008–0.05 eV):
   (*a*) mass spectrometry of stationary afterglows,
   (*b*) mass spectrometry of flowing afterglows, and
   (*c*) ion cyclotron resonance methods.
2. Thermal to medium energies (0.025–10 eV):
   (*a*) secondary ions in mass spectrometer sources,
   (*b*) pulsed sources on mass spectrometers,
   (*c*) drift tube methods, and
   (*d*) merging beam methods.
3. Medium to high energies:
   (*a*) beams into static gases, double mass spectrometer methods, and
   (*b*) crossed beam methods.

Most of these methods were described in the reviews given at this symposium five years ago (1, 2), and these will not be discussed to any extent in the present summary except to note certain innovations to these older techniques and new results of unusual interest. Three of the methods are new, however, and these will be discussed in some detail. The three new methods are flowing afterglows (1*b*), ion cyclotron resonance (1*c*), and merging beams (2*d*).

1. Thermal Energy Methods

(a) Mass spectrometry of stationary afterglows. Mass spectrometry of stationary afterglows was used several years ago to provide the earliest information on charge transfer and ion–molecule reactions of major importance to aeronomy. In this method a mixture of gases in widely disparate amounts are subjected to a pulse of excitation that produces primary ions from the original gases in amounts roughly proportional to their respective number densities. After cessation of the pulse, these primary ions react with the neutrals and the relative populations of the ions change in time. An aperture is placed in the afterglow chamber and ions emerging from the aperture are analyzed by a mass spectrometer. The assumption is made that the ion currents are proportional to the number densities of the ions in the vicinity of the aperture and the time history of each ion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is taken to represent the time history of the number density of each ion, from which a rate coefficient may be deduced if one also knows the partial pressures of the neutrals in the afterglow chamber. Such experiments were performed by Sayers and his associates (8, 11), Hasted and his collaborators (9), and by Fite *et al.* (10), and are described in ref. 1.

In the past five years, the principal work done with stationary afterglows has been to take advantage of the small volumes involved which makes rather easy the variation of temperature and the study of temperature dependences of ion–neutral reaction processes. Sayers and Smith (11) studied the temperature dependence of $O^+ + O_2 \rightarrow O + O_2^+$, finding a rate that diminished with temperature which has subsequently been determined by Smith and Fouracre (12) to vary as $T^{-0.48(\pm.05)}$ up to about 600 °K, in opposition to temperature independence expected on the basis of Langevin collisions. This result is in good agreement with a stationary afterglow experiment result of Nakshbandi and Hasted (13) and a flowing afterglow experiment of Dunkin *et al.* (14). At temperatures higher than 600 °K, the rate coefficients as determined in a drift tube experiment of Bohme *et al.* (15) and a secondary ion mass spectrometer experiment of Warneck (16) appear to be effectively temperature-independent up to several thousand degrees, i.e., in accord with the orbiting collision model (eqs. [2] and [3]) and then appear to increase with energy (15).

The fact that more has not been done with stationary afterglow mass spectrometry is due to two basic limitations of the general method. First, the gases admitted to the afterglow chamber must be chemically stable and second, all gases are subjected to the excitation pulse. Since the excitation pulse can partially dissociate and excite a neutral gas, one is rarely completely certain that an observed reaction process is occurring with a groundstate molecule of the neutral gas put into the chamber nor certain of the state of the ion. One must work very hard to ensure an unambiguous interpretation of an experimental result.

These two basic problems have been largely alleviated in the flowing afterglow approach.

(b) Mass spectrometry of flowing afterglows. In the flowing afterglow technique which was developed and very successfully used by Ferguson, Fehsenfeld, and Schmeltekopf and their collaborators (17) at the Environmental Sciences Services Administration laboratories in Boulder, Colorado, the variation of ion concentrations with time of the stationary afterglow approach is replaced by variation of ion concentrations with space as an afterglow flows rapidly down a tube. While this in itself offers no advantages, the method does represent a major step forward in that it permits injection of gases into the flow stream without their being subjected to the excitation mechanism making the primary ions and all that this implies.

In a typical experiment a buffer gas (usually helium) is admitted to the entrance end of the flow tube and subjected to electron impact bombardment or microwave power or some other means of producing ions. Slightly downstream, a primary gas is injected into the stream and charge transfer and Penning ionization operate to replace the helium ions by primary ions from the injected gas. Yet further downstream, a secondary gas is injected whose reactions with the primary ions are to be studied. Finally at the end of the flow tube the ions present are sampled by being taken into a differentially pumped mass spectrometer through an aperture normally on the axis of the flow tube. Typical flow speeds are 10^4 cm/s, tube lengths are normally about 1 m, and the gas pressure (being made up almost entirely of buffer gas partial pressure) range is generally between 0.1 and 1 Torr. The quantity of buffer gas handled is quite large and fast Roots pumps are used to maintain the flow and to exhaust the gas after the flow has passed the mass spectrometric sampling device.

As noted above, the advantage of this approach is that secondary gases are injected into the stream below the point where buffer gas ions and primary ions are made, thereby obviating questions of the uncontrolled production of excited states of the neutral reactants, questions which plague stationary afterglow experiments. Additional major advantages are that (*a*) the neutral gases need not be chemically stable but can be either partially dissociated, or put into some excited state, in some specific and separately controlled manner; (*b*) the spatial separations admit optical absorption spectroscopic monitoring of species and states at any point in the flow; (*c*) additional gases can be injected which quench out states and species of primary ions whose presence would confuse interpretation of an experiment, and (*d*) different methods of injection and points of injection can be used to maximize or minimize

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

either wanted or unwanted effects. The excitation means is usually run continuously, but the pulsed mode of excitation can also be employed to advantage. The flexibility afforded by being able separately to control so many of the parameters in flowing afterglow experiments is enormously greater than that available in stationary afterglow experiments, and the flowing afterglow method has now become the standard way of studying thermal ion–neutral reactions.

It would be misleading to suggest that the interpretation of flowing afterglow experiments is not without its problems. Some of these problems originate from the use of a flow system, and it is appropriate to consider the model of what takes place in the flowing afterglow. The flux of primary ions, $\boldsymbol{S}_1$, is presumed to be given by

$$[4] \qquad \boldsymbol{S}_1 = -D_1 N \boldsymbol{\Delta}_1 + N_1 \boldsymbol{v}$$

where N_1 is the primary ion number density, D_1 is the ambipolar diffusion coefficient of the primary ions through the buffer gas, and $\boldsymbol{v}$ is the vector velocity of the stream which is determined by the hydrodynamics of the flow. Applying continuity in the steady state one can write down

$$[5] \quad \nabla \cdot \boldsymbol{S}_1 = -kN_1 n_2 - \sum_{i \neq 2} \beta_i n_i N_1 - \alpha_1 n_e N_1 + \gamma_1 n_1$$

where the first term represents the loss of primary ions due to the reaction of interest with a neutral gas whose number density is n_2, the second term represents loss of primary ions due to other competing processes, the third term is the loss due to electron–ion recombination (and a similar term could be written down for ion–ion mutual neutralization), and the fourth term represents the production of primary ions by Penning ionization by He* and other processes.

Combining these equations

$$[6] \quad (\boldsymbol{v} \cdot \nabla) N_1 = -kn_2 N_1 - \sum \beta_i n_i N_1 - \alpha_1 n_e N_1 + \gamma n_1 + D_1 \nabla^2 N_1$$

The corresponding equation for a secondary ion formed as a product of the reaction between N_1 and n_2 is

$$[7] \quad (\boldsymbol{v} \cdot \nabla) N_2 = +kn_2 N_1 - \sum \delta_j n_j N_2 - \alpha_2 n_e N_2 + \sum \varepsilon_j n_2 N_j + D_2 \nabla^2 N_2 + \gamma_2 n_2$$

where the first term represents the process of interest, the second term losses of secondary ions in tertiary processes, the third term again recombination, the fourth term production of secondary ions in reactions with ions other than the desired primary, the fifth term the ambipolar diffusion losses, and the sixth term production of ions by Penning ionization, etc.

The number densities of the secondary gas(es) are themselves solutions of diffusion equations of the type

$$[8] \qquad (\boldsymbol{v} \cdot \nabla) n_2 = D_n \nabla^2 n_2$$

subject to the boundary conditions and whatever initial conditions are appropriate to the chosen manner of injection.

The complexity of using these three equations and treating them properly is staggering. However, one can manipulate the experimental conditions to simplify the problem somewhat by minimizing the contributions of separate terms. For example, by using sufficiently low plasma densities the recombination terms can be neglected; Penning ionization by He* as an unwanted source of primary or secondary ions can be excluded by admixing a small amount of argon to the helium buffer gas to quench the He*; using clean gases and controlling the means of production of chemically unstable neutral reactant species can minimize competing processes terms, etc. Indeed, much of the success of the ESSA group in using these experiments is due to their ingenuity in finding ways to manipulate gases and experimental parameters in order to display the process of interest.

There are additional problems, however. Questions of mixing of an injected reactant gas with the flow stream enter and are important especially at the high flow velocities used; the form of $\boldsymbol{v}$ is important and although indications are that laminar viscous (Poiseuille) flow is operative over most of the length of most flow tubes, one does not know $\boldsymbol{v}$ in the vicinity of obstructions such as nozzles where the reactant gases are injected. The fact that a pressure gradient along the tube is necessary to maintain the flow further complicates matters.

However, even under "ideal circumstances", i.e., no competing processes and Poiseuille flow, the situation is still not easy. In the cylindrically symmetric case, the equations become

$$[6'] \quad D_1 \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\partial N_1}{\partial r}\right) + D_1 \frac{\partial^2 N_1}{\partial z^2} = v_0 \left(1 - \frac{r^2}{a^2}\right) \frac{\partial N_1}{\partial z} + kn_2 N_1$$

$$[7'] \quad D_2 \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial N_2}{\partial r}\right) + D_2\frac{\partial^2 N_2}{\partial z^2} = v_0\left(1 - \frac{r^2}{a^2}\right)\frac{\partial N_2}{\partial z} - kn_2N_1$$

$$[8'] \quad D_n \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial n_2}{\partial r}\right) + D_n\frac{\partial^2 n_2}{\partial z^2} = v_0\left(1 - \frac{r^2}{a^2}\right)\frac{\partial n_2}{\partial z}$$

where each D is a function of position due to the pressure gradient down the tube.

It is apparent that these three equations cannot be solved by separation of the variables due to the parabolic flow profile, and further approximations must be introduced. One of the simplest approximations assumes that n_2 is constant (i.e., the neutral reactant is distributed uniformly), that N_1 is initially a function of z only and independent of the radius r, and that the flow is "slug flow", i.e., that $v = v_0$ and is independent of r. Under these extreme simplifying assumptions, $N_1(z)$ is given by

$$[9] \quad N_1(z, n_2) = N_1(0)f(r) \times \exp\left[-\left(\frac{D_1}{\Lambda^2} + kn_2\right)\frac{z}{v_0}\right]$$

after sufficient time (distance) has elapsed for the flow to settle into the lowest radial diffusion mode, for which the diffusion length is Λ, and f is a Bessel function. Clearly, by varying n_2 and plotting N_1 on a semi-log plot, the slope gives an indication of the rate coefficient, k. This method of observing primary ion decay, after approximate corrections for parabolic flow, is that normally employed by the ESSA group and has the advantage that by holding the geometry constant, the spatial parameters in eq. [9] are unchanged. This also has the experimental advantage of making unnecessary the moving of sources of either the primary ions or the secondary gases.

It is to be pointed out, however, that if the ambipolar diffusion coefficient is dependent on n_2 this procedure can lead to erroneous results. Since ambipolar diffusion coefficients do change with relative concentrations in an ion mixture and since the ion concentrations are dependent on n_2 through the reaction, it would be expected that the ambipolar diffusion coefficient would be dependent on n_2.

An alternative procedure in data treatment can be used to minimize macroscopic effects of this kind (and also competing process effects). If one defines a ratio, $R = N_2/N_1$, eqs. [6'] and [7'] can be combined to give

$$[10] \quad (\mathbf{v}\cdot\nabla)R = kn_2(1 + R) + R\left\{D_2\frac{\nabla^2 N_2}{N_2} - D_1\frac{\nabla^2 N_1}{N_1}\right\}$$

which in the limit of small R gives

$$[11] \quad v\frac{\partial R}{\partial z} = kn_2(1 + R)$$

and which can be solved along the z-axis to give

$$[12] \quad \log(1 + R) = \frac{k}{v_0}\int n_2(0, E)\mathrm{d}z$$

In this approach, even if n_2 is not uniform, solution of eq. [8] is all that is needed in order to perform the integral.

This "ratio method" which was used by Farragher *et al.* (18) in studying charge transfer between atmospheric ions and sodium atoms, has the disadvantage that one must know the detection efficiency for the primary and secondary ions. If there is mass discrimination in the mass spectrometer or differences in secondary emission coefficient at the electron multiplier detector, these must be corrected for before correct answers can be hoped for.

A third method for analyzing data is to treat the appearance of the secondary ions. Like the decay of the primary ion method, it observes a single ion and therefore is not susceptible to mass discrimination effects. This method handles eq. [7'] in a manner analogous to that used for eq. [6'] in deriving eq. [9]. In an analogous manner, problems of changing diffusion coefficients and other macroscopic effects that depend on n_2 can again lead to erroneous results.

The complexity of properly treating the physics in flowing afterglows is evident from the above discussion. There are, of course, other problems which are shared with stationary afterglow methods which have not received detailed consideration as yet. In particular the processes by which ions emerge through apertures is not at all well understood. The practice of biassing an ion extraction aperture which is often done to improve signal strengths suggests that the ion extraction process is mobility limited. There is some evidence suggesting that the existence of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

negative ions in the plasma affects positive ion extraction (19) and varying an added electronegative reactant gas may lead to spurious results using the primary ion decay method. There is a free jet expansion as the gas leaves the flow tube and enters the mass spectrometer's high vacuum; the extent to which altering gases affects this expansion and in turn the ion extraction has not been investigated.

In general, it seems appropriate to caution any user of rate coefficients obtained from flowing afterglow experiments that errors of a factor of two or three may still be in even the best measurements. The physics of afterglows is quite complex and of flowing afterglows even more so. Factors of two discrepancies are not uncommon with ostensibly identical flow tubes and data handling procedures, even for the simplest processes having the largest rate coefficients. Time and further work on this very fruitful approach will unquestionably clear up some of these remaining problems.

To turn to the positive aspects of flowing afterglow experiments, perhaps the best testament to the fruitfulness of the approach is the list of reactions at the end of this paper whose rate coefficients have been obtained by no other method. Two experiments are appropriate to recount here in the text as well. The first studied reactions of $N_2^+ + O$ (20). In this study nitrogen gas that had been partially dissociated in a separate discharge flowed through a side tube toward the flowing afterglow containing N_2^+ ions. Before admission to the flow, NO was added in the side tube and the titration reaction $NO + N \rightarrow N_2 + O$ produced oxygen atoms at the rate of one O for each NO added. Since the flow rate of NO could be measured, the flow of O into the afterglow was known and the experiment could proceed in a fairly conventional way.

The second particularly interesting experiment involved the reaction $O^+ + N_2 \rightarrow NO^+ + N$, thermal energy values of which had been particularly elusive and irreproducible from one investigator to another using stationary and flowing afterglows. The problem was traced down in the experiment of Schmeltekopf *et al.* (21) who excited the nitrogen in a separate gas discharge before admission to the flow tube. The excited neutral gas was then electron-impact excited to radiating states and from the vibrational temperature of the emitted radiation the vibrational temperature of the original excited N_2 gas was deduced. The remarkable finding was that as the vibrational temperature was increased the rate coefficient was increased enormously. Evidently the scatter in data from other experiments on this reaction arose from different experiments having nitrogen whose vibrational states were populated differently and the lowest value was the best. This $O^+ + N_2$ reaction has the strongest dependence on the internal energy state of the neutral reactant known so far. The fact that the process is also of unusual importance to aeronomy emphasizes the importance of excited states in understanding the upper atmosphere.

(c) Ion cyclotron resonance methods. Many of the uncertainties in the afterglow methods discussed above arise from lack of understanding of how ions emerge through apertures. Clearly these problems could be avoided if the rates of change of ion population could be determined while the ions were in the flow tube. A very attractive method by which this can be done is the use of ion cyclotron resonance.

In this method a magnetic field is put on the afterglow so that each ion follows a circular motion at the ion cyclotron resonance frequency

$$[13] \qquad f_c = \frac{1}{2\pi}\frac{eB}{mc}$$

where B is the magnetic induction, e is the charge, c is the velocity of light, and m is the ion mass. Obviously ions of different e/m will have different cyclotron energies. If a weak radio frequency electric field at the cyclotron frequency is also applied, an ion will pick up energy from the field and this energy absorption can be detected as a load on the rf oscillator. By sweeping either the magnetic field or the oscillator frequency, the appearance of loading on a marginal oscillator evidences the presence of each ion and the strength of the loading gives an indication of the number of ions present. By following the rise and decay rate of various ions one has the information from which reaction rate coefficients can be deduced.

This very attractive approach was first employed to study mobilities and total collision cross sections of ions by Wobschall, Graham, and Malone (22), where the cross section information could be deduced from line widths of the resonance absorption lines. More recently it has been applied to charge transfer and ion–molecule

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

reactions by Baldeschweiler and his associates (23) in nitrogen–hydrocarbon systems, which, unfortunately, are not of very great interest to aeronomy. It will be important to receive data on atmospheric reactions using ion cyclotron resonance in the future, both for what it can add in the way of new information and for what it will contribute to understanding of present afterglow data.

2. Thermal to Medium Energies

(a) Secondary ions in mass spectrometer sources. This method needs little discussion here, having been treated in ref. 1. However, an important new advance has been applied to this approach by the use of photoionization sources for the primary ions. By using light of a given wavelength, the primary ions can be much more selectively produced than on electron impact and production of ions in specific initial states is possible. Warneck (16) has been foremost in applying this important modification of an older method to problems of aeronomical interest.

(b) Pulsed sources on mass spectrometers. See ref. 1.

(c) Drift tube methods. In drift tube methods, primary ions are created at one end of a tube along the length of which a d.c. electric field exists. A primary ion assumes a velocity appropriate to its mobility at the gas pressure in the tube and for the applied electric field. One effectively increases the kinetic temperature of the interactants without appreciably altering the internal energy states populations. A mass spectrometer usually samples the ions emerging from the drift tube which contains a buffer gas and the reactant gas of interest.

Three recent drift tube experiments are noteworthy. In the first, Hasted and his associates (15, 24) changed the primary ion source to one which is mass analyzed and could be made state selective as well. Although the ion enters at relatively high energy (tens to hundreds of eV) it is rapidly moderated down in energy to the steady drift value. By inserting a selected ion into the drift tube, many of the ambiguities of interpretation of results are reduced.

Using groundstate O^+ ions reacting with N_2 to produce NO^+, an energy dependence of the rate coefficient which increased with energy was found, the increase being compatible with the increase in cross section for this reaction as obtained from crossed beam (25) and beam-in-static-gas (26) experiments. The apparent increase in rate coefficient for $O^+ + O_2 \rightarrow O + O_2^+$ at energies greater than 0.5 eV has already been noted earlier in this paper.

A second drift tube experiment of interest was the careful study of Heimerl, Johnsen, and Biondi (27) on reactions between He^+ and both N_2 and O_2, who showed that over the temperature range 300 to 1200 °K the reaction rate coefficients appear to be temperature-independent.

Yet a third drift tube experiment of interest is that of Golden, Sinnott, and Varney (28) who studied the reaction $N_2^+ + O_2 \rightarrow N_2 + O_2^+$ and found that it also appeared to have a temperature-independent rate coefficient in accordance with the Langevin orbiting complex model.

(d) Merging beam techniques. The newest experimental method to arrive on the experimental scene is also one of the most elegant and promises to be extremely useful. This is the technique of merging parallel beams. In this method a fast beam of selected ions of mass m_1 at laboratory energy E_1 is charge transfer neutralized and into this fast beam is merged a beam of ions of mass m_2 travelling at laboratory energy E_2. After the two merged beams have run along together a prescribed distance (i.e., time) the ions are separated out and from the relative signals of the primary and secondary ions the cross section as a function of relative energy, or energy in the center of mass system, may be deduced.

The relative energy is given by

$$[14] \quad E_r = \frac{1}{m_1 + m_2} [\sqrt{(m_2 E_1)} - \sqrt{(m_1 E_2)}]^2$$

It is clear that even though the laboratory energies of the beams are quite high (high enough to produce and handle high current beams), by adjusting E_1 and E_2 the relative energy can be made arbitrarily small. Furthermore the energy spread in the center of mass is scaled down from the laboratory energy spread by a factor comparable to the relative energy divided by the laboratory energy. In this approach it is not necessary to be content to measure only rate coefficients, but instead cross sections as a function of energy as measured on a very fine energy spread scale can be obtained.

This method which was first described by Trujillo, Neynaber, Marino, and Rothe (29)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

has subsequently been applied by those authors to the charge transfer between $Ar^+ + Ar$. Of more interest for aeronomy, and also as an illustration of the unique potentialities of the merging beams technique, we can cite the very recent experiments of Entemann and Rol working in Dr. Neynaber's laboratory (33) who examined collisions between O_2^+ and Na. Analysis of the secondary ions revealed the appearance of NaO^+ which was unequivocally identified, and the cross section for its formation corresponded to a thermal energy rate coefficient of approximately 8×10^{-11} cm^3/s. This product was also sought in the flowing afterglow experiments of Farragher *et al.* (18) but without success due to general noise in the experiment.

While merging beam experiments are difficult to execute because of extremely low signal levels, they are extremely clean experiments and have very few interpretational pitfalls. The beams can be produced cleanly and impurity and competing process effects are automatically excluded; the product ions are unequivocally identified and there is no possibility of confusing different ions of the same e/m (e.g., $H_5O_2^+$ vs. NaN^+, K^+ vs. NaO^+, CO^+ vs. N_2^+, etc.) which can occur in afterglow and drift tube experiments.

The merging beam technique appears to this author to be uniquely able to investigate reactions having small rate coefficients. While flowing afterglows appear suitable for determining large rate coefficients, when small rate coefficients are of interest, one must be extremely cautious in the flowing afterglow because of competing processes, perhaps with unknown impurities, to produce the desired secondary ion, attack of the secondary ion through tertiary processes, etc. Concerns of this kind probably need be worried about only for processes with apparent rate coefficients of 10^{-11} cm^3/s and less.

The one present problem with merging beams for ion–neutral studies of total cross sections is that the neutrals are produced by charge transfer and one is not certain of the internal energy state population of the neutral beam. Unquestionably, techniques will be developed to select states, perhaps such as that described in the following section, and correct this present deficiency.

3. *Medium to High Energies*

At energies of a few eV and higher it is possible to produce ion beams of sufficiently high current to perform either beam-in-static-gas experiments or crossed beam experiments where the ion beam intersects a thermal energy molecular to atomic beam. Such experiments have been discussed in refs. 1 and 2.

Recent work along these lines has continued with a wide variety of processes being examined. The rocket observations of Narcisi (4) have prompted crossed beam experiments on reactions producing and destroying metal ions. Henderson, Mentall, and Fite (30) examined charge transfer between atmospheric ions and sodium, and Turner and Rutherford (34) have made measurements on production of Mg^+, Ca^+, as well as Na^+ in charge transfer reactions between the parent metal atoms and N_2^+, O_2^+, N^+, O^+, NO^+, H_2O^+, and H_3O^+ to supplement a wide variety of measurements on atmospheric reactions between normally gaseous components (31).

Potentially the most important of the recent studies at the higher energies are those of Turner, Rutherford, and Compton (32) on selective absorption of ions in beams passing through gases, for these point the way toward production of high currents of ions in specific states. A problem that has always plagued high energy experiments (and probably low energy experiments as well) is that it is difficult to produce ions in a single state and to know the state population in any ion beam. While one can produce the ions by electron bombardment immediately above threshold and gain reasonable assurance for most ions that only the groundstate ion is being produced, the ion currents so produced are often impossibly low. Turner and his associates took the approach to produce ions in an electron bombardment source at high electron energies where the beam current was high, and then passed the current through an absorbing gas. Those ions in states with high cross sections for charge transfer or ion–molecule reactions will interact with the absorbing gas and be greatly attenuated, while those with low cross sections will be largely transmitted. Experimenting with O^+ and O_2^+ passing through N_2, Ar, and H_2 and looking at the transmitted current as a function of absorbing gas pressure, it was found that two clearly defined straight line sections on a semi-log plot appeared, demonstrating the existence of at least two separate cross sections for reaction for the ions in the beam. By reducing the electron energy to just above threshold, a single straight line appeared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

on the semi-log plot which was associated with the groundstate ion cross section. Comparing the semi-log plots, one can deduce (*a*) the fraction of ions in the beam which are excited when using the high electron energies, (*b*) the cross section for the excited states reacting with the absorbing gas, and (*c*) the cross section for the ground state reaction with the absorber. Among other things, it was learned that electron bombardment at energies typically used in ion sources produce 22 to 33% of the O_2^+ ions in the metastable $^4\Pi_u$ state and 27 to 30% of the O^+ appears to be in the ^2D metastable state.

The cross sections are sufficiently different in these cases that with an absorber gas, the excited states can be virtually completely removed while attenuating the groundstate ion component by a factor of only about 3 to 5. This can give an appreciable improvement in ion currents over sources operating immediately above threshold in order to produce the groundstate ion.

The potentialities of using selective attenuation to produce beams of ions in a given excited state are obvious and further experiments with different absorbing gases along these lines are clearly called for.

Of direct interest to aeronomy is the fact that the cross sections for reaction of the various states of O_2^+ colliding with N_2 at ion energies of about 100 eV differ by factors of 150! Whether many thermal reaction rates also have such spectacular variation with the state of the ionic reactant will be something very important to learn, especially for application to aeronomic situations where ions in excited states can be produced.

It is this author's expectation that a review paper on the subject of reactions between positive ions and neutral molecules given five years hence will have as its central theme the role of excited states.

Si^+ and SiO^+ reactions of atmospheric importance

F. C. FEHSENFELD
Environmental Science Services Administration Research Laboratories, Boulder, Colorado 80302

Received November 21, 1968

Flow system measurements are reported of the approximate rate constants for the gas phase reactions $Si^+ + O_2 \rightarrow SiO^+ + O$, $SiO^+ + N \rightarrow Si^+ + NO$ or $NO^+ + Si$, and $SiO^+ + O \rightarrow Si^+ + O_2$. The constants are, respectively, $< 10^{-11}$, $\sim 1.5 \times 10^{-10}$, $\sim 1.5 \times 10^{-10}$, and 2×10^{-10}, all in $cm^3\ s^{-1}$.

Recently rocket borne mass spectrometers have measured the positive ions present in the earth's lower ionosphere. These measurements indicate that ions of mass 28 and 44 are present in the ionosphere above 85 km. These ions have been tentatively identified as Si^+ and SiO^+. In this presentation I will report some recent laboratory measurements of the reactions of Si^+ with O_2 and SiO^+ with O_2 and atomic oxygen which are relevant to the ionospheric chemistry of Si^+ and SiO^+.

Figure 1 is a simplified schematic drawing of the apparatus used to make these measurements. The system is basically the same flowing afterglow described in the literature. There are, however, two features particular to the present system which will be briefly described. The first of these features is the method used to generate the silicon ions. To do this a few grams of the silicon monoxide is placed in a furnace. The furnace is mounted in a forward section of the flow tube. As the silicon monoxide vapor is evolved it is carried downstream by the buffer gas. In the studies involving SiO^+, argon is used as a buffer. Argon ions and metastables are produced by electron impact and produce SiO^+ from SiO by secondary processes. To produce Si^+ a helium buffer is used. The helium ion and metastables are energetically capable of dissociatively ionizing silicon monoxide. The actual resulting ion composition is roughly 50% Si^+ and 50% SiO^+.

The ions produced in the excitation region are carried down the tube by the flowing gas past a downstream port through which the reactant gas (in this case either O_2 or atomic oxygen) is added. In order to generate atomic oxygen the standard technique is used whereby atomic nitrogen is produced and then reacted with NO. To obtain the atomic nitrogen, N_2 is passed through a microwave discharge where a few tenths of 1% of the N_2 is dissociated. The N_2 containing atomic nitrogen then flows past an inlet where NO is

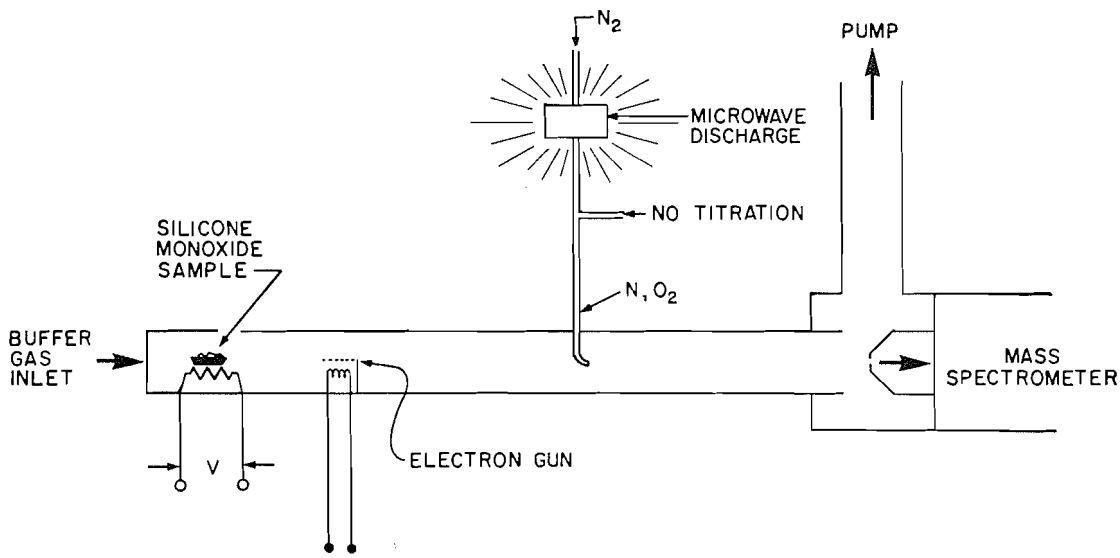

FIG. 1. A simplified schematic representation of the apparatus.

added. The NO rapidly reacts with the atomic nitrogen producing atomic oxygen. The end point of this titration may be detected optically or by the behavior of various ion signals. The measured NO flow at the end point is equal to the total flow of the atomic species. The mixture of N_2 and O then passes into the system. In the region between this inlet and the sampling orifice of the mass spectrometer the reactions between the reactant neutral and the ions take place.

$$Si^+ + O_2 \xrightarrow{k_1} SiO^+ + O$$
$$k_1 < 10^{-11}$$

$$SiO^+ + N \xrightarrow{k_{2a}} Si^+ + NO$$
$$\xrightarrow{k_{2b}} NO^+ + Si$$
$$k_{2a} + k_{2b} \cong 3 \times 10^{-10}\ cm^3/s,\ k_{2a} \cong 2k_{2b}$$

$$SiO^+ + O \xrightarrow{k_3} Si^+ + O_2$$
$$k_3 \cong 2 \times 10^{-10}\ cm^3/s$$

FIG. 2. The measured reaction rates for Si^+ with O_2 and SiO^+ with atomic nitrogen and atomic oxygen.

Figure 2 lists the measured rate constant for the reaction between Si^+ and O_2 and SiO^+ with the atoms of nitrogen and oxygen. The reaction of SiO^+ with atomic nitrogen is fast. The products of this reaction are $Si^+ + NO$ and $NO^+ + Si$. The relative intensity of the product ion signals indicates that about two-thirds of the reaction goes to Si^+ while one-third leads to NO^+. This result is not surprising because these reactions are strongly exothermic. The interesting result concerns the fast reaction of SiO^+ with atomic oxygen. Using the published results for the dissociation energy for SiO^+, this reaction should be about 0.5 eV endothermic. The observation of this reaction either indicates that the published dissociation energy of SiO^+ is high, or the SiO^+ that is present in our experiment is in an excited state. However, the fact that the reaction $Si^+ + O_2$ is slow also argues for the exothermicity of the reverse reaction.

In the atmosphere, SiO^+ is probably produced from SiO or SiO_2. These species probably are deposited in this region by meteor ablation. The reactions which have been reported would suggest that SiO^+ would be rapidly converted to Si^+ by atomic oxygen. The ionospheric measurements indicate that there is a significant concentration of SiO^+ relative to Si^+ in the atmosphere. To maintain such a ratio there is probably a rapid reconversion of Si^+ back to SiO^+.

Aeronomic importance of ion–molecule clustering reactions

D. K. BOHME[1]

Aeronomy Laboratory, Environmental Science Services Administration, Boulder, Colorado 80302

Received November 21, 1968

A literature survey of observations of ion clusters in mass spectrometers indicates that the association rate constant depends on the number of atoms in the cluster. An altitude profile of estimated apparent bimolecular rates of clustering in the atmosphere is made from this empirical correlation. Experimental measurements of the termolecular rate constant for clusters in formation are reported; the temperature dependence of some of these has been measured.

Canadian Journal of Chemistry, 47, 1809 (1969)

The recent mass spectrometric measurements of Narcisi (1) in the D region of the ionosphere have indicated appreciable concentrations of heavy positive ions with masses greater than 45 a.m.u. Some of these heavy ions have been attributed to hydrated cluster ions. The mass 37 ion, presumably the hydrated ion $H_3O^+.H_2O$, was found to be the dominant low-mass positive ion between 60 and 80 km.

Heavy cluster ions have now been identified in many laboratory experiments (2, 3). Recent D region simulation experiments performed in the E.S.S.A. flowing afterglow with air at a temperature of 162 °K and a pressure of 0.1 Torr have yielded evidence for hydrated H_3O^+ ions as

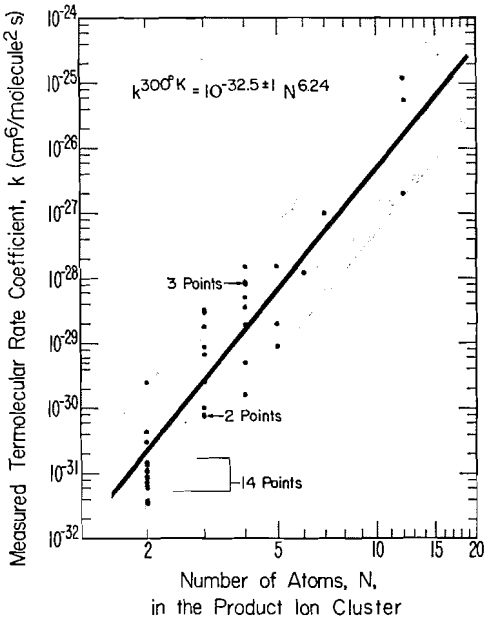

FIG. 1. The measured termolecular rate coefficient plotted as a function of the number of atoms in the product ion cluster.

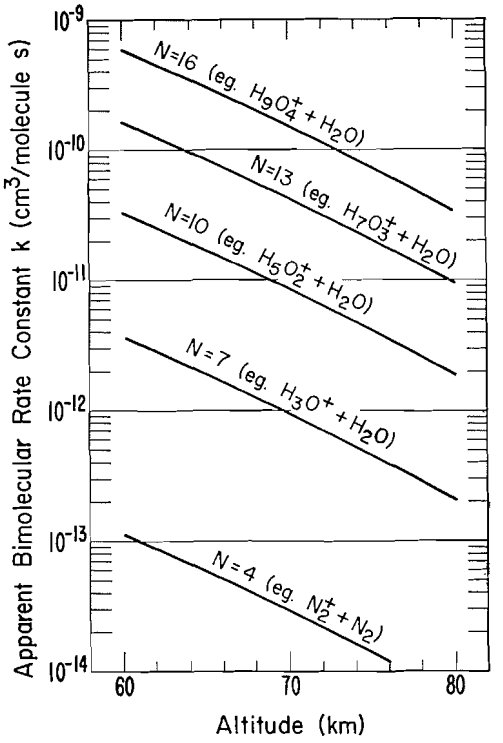

FIG. 2. The estimated apparent rate constant of ion cluster formation at 300 °K plotted as a function of altitude.

large as $H_3O^+.6H_2O$, as well as hydrated O_2^+ and NO^+ ions. The cluster ions N_6^+, N_7^+, N_8^+, N_9^+, as well as He_3^+ and Ar_3^+, were identified mass spectrometrically at 82 °K, apparently for the first time (4). Although observations of heavy cluster ions have been numerous, little is known about the magnitude of specific rates of cluster formation and the dependency of these rates on cluster size, temperature, and pressure.

A consideration of all available laboratory data found in the literature on ion–neutral termolecular association in which a stable cluster is formed indicates a surprisingly systematic variation of the termolecular rate coefficient with the number of atoms N in the product ion cluster. This is illustrated in Fig. 1 for 44 measurements of 27 ion–molecule association reactions. The spread in the data may be attributed, in part, to variations in the stabilization efficiency of the third body and the potential energy configuration of the ion cluster. Nevertheless, the following empirical relation, which allows an order-of-magnitude estimation of the specific termolecular rate k of cluster formation at about 300 °K, may be derived from the plot shown in Fig. 1:

$$[1] \qquad k^{300\,°K} = 10^{-32.5\pm1} N^{6.24}$$

An altitude profile of some estimated apparent bimolecular rates of clustering at 300 °K which can be constructed using eq. [1] is given in Fig. 2. A standard reference atmosphere was used to obtain neutral densities (5). The role of ion cluster formation can be seen to be more important at lower altitudes where the apparent bimolecular specific rates are larger. It is evident from Fig. 2 that the three-body formation of heavy ion clusters involving a large number of atoms ($N \gtrsim 10$) may readily compete with the fairly rapid two-body reactions occurring in the D region of the ionosphere. Atomic and molecular ions with very low specific rates of two-body conversion are likely to be bound to polyatomic molecules such as H_2O by the more rapid three-body formation of ion clusters. This would be the case for the terminal ions in the D region such as NO^+ and NO_3^- as well as atomic ions of low ionization potential such as Na^+, Ca^+, Mg^+, Fe^+, and Si^+.

Recent experiments conducted in the E.S.S.A. flowing afterglow system have indicated several additional empirical relationships. Table I is a list of some positive and negative three-body

TABLE I

Termolecular rate constants measured in the E.S.S.A. flowing afterglow system

Reaction	Temperature (°K)	Rate constant (cm^6/s)
$O_2^+ + O_2 + He$	82	3.1×10^{-29}
$N_2^+ + N_2 + He$	82	1.2×10^{-28}
	280	1.9×10^{-29}
$O^- + CO_2 + He$	280	1.5×10^{-28}
$O^+ + N_2 + He$	82	5.4×10^{-29}
$N^+ + N_2 + He$	82	7.2×10^{-29}
	280	8.6×10^{-30}
$Ar^+ + Ar + He$	82	1.6×10^{-30}
	290	$\sim1.3\times10^{-30}$
$O^- + N_2 + He$	82	1.3×10^{-30}
$Mg^+ + O_2 + Ar$	300	$\sim2.5\times10^{-30}$
$Fe^+ + O_2 + Ar$	300	$\sim1.0\times10^{-30}$
$Ca^+ + O_2 + Ar$	300	$\sim6.6\times10^{-30}$

ion–molecule reactions, the specific rates of which have recently been measured in the E.S.S.A. flowing afterglow at 82 and 280 °K with helium and argon as a third-body over a pressure range 0.1 to 3.0 Torr. At low pressures the kinetics of cluster formation was termolecular at both temperatures, as expected for the ground state ions investigated. The termolecular rate coefficients were found to increase significantly with decreasing temperature. Furthermore, the results indicate that termolecular cluster formation is less strongly dependent upon temperature as the number of atoms N in the product ion cluster increases according to the empirical relation

$$[2] \qquad k_1 = k_0 \left(\frac{T_0}{T_1}\right)^{\frac{N+2}{N}}$$

k_1 and k_0 are the termolecular specific rates at temperatures T_1 and T_0, where $T_0 > T_1$. Equation [2] was derived from the experimental results at the two temperatures 82 and 280 °K for the association of N_2^+ with N_2, N^+ with N_2, and Ar^+ with Ar in helium gas assuming that the termolecular rate coefficient varies as T^{-n}. Therefore, caution must be exercised when invoking eq. [2] to extrapolate the results shown in Figs. 1 and 2 to more realistic D region temperatures.

Finally, the E.S.S.A. flowing afterglow experiments have indicated (6) that the kinetics of the formation of O_4^+ and N_4^+ ion clusters at 82 °K becomes bimolecular above helium pressures of about 1.6 and 0.2 Torr, respectively, as demonstrated in Fig. 3. This result is qualitatively consistent with a clustering process involving a collision sequence of two steps, i.e. initial formation of the intermediate complex followed by stabilization upon collision with a third body. According to such a mechanism, the apparent bimolecular specific rate of ion cluster formation will never exceed the Langevin orbiting rate constant of the initial complex formation, i.e. of two-body ion–molecule reactions. In fact, for the case of O_4^+ and N_4^+ ion cluster formation, the flowing afterglow results at 82 °K indicate an apparent bimolecular specific rate at saturation of only about 7×10^{-12} cm^3/s. It is not yet known whether the apparent bimolecular specific rate of ion cluster formation at saturation is dependent on the gas temperature and on the complexity of the ion cluster.

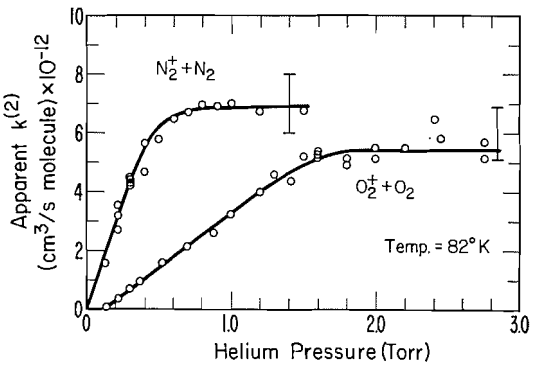

FIG. 3. The experimentally determined bimolecular rate coefficient, $k^{(2)}$, plotted as a function of helium pressure.

A full evaluation of the importance of three-body clustering reactions in the D region of the ionosphere will have to await more laboratory measurements of specific rates at various temperatures and pressures, the complete identification of the large concentrations of heavy positive ions observed in rocket flights, and measurements of neutral concentrations such as principally H_2O and possibly neutral clusters.

Comments, Replies, and Summary

COMMENTS BY M. A. BIONDI

As noted in Dr. Fite's review, drift tube/mass spectrometer measurements of the reaction rate for $N_2^+ + O_2 \rightarrow N_2 + O_2^+$ by Golden, Sinnott, and Varney (1) indicate no dependence on the ion's energy over the range from thermal energy to ~ 1 eV. Dr. Ferguson cited E.S.S.A. flowing afterglow measurements (2) over the temperature range 80–550 °K which revealed a substantial decrease in the reaction rate over this range. Using a drift tube/mass spectrometer to study the same reaction (3), we also find a substantial decrease in the reaction rate with increasing ion energy (see Fig. 1), in disagreement with the result of Golden *et al.* (1) and in agreement with the E.S.S.A. result (2). Also shown in the figure is the reaction $O^+ + CO_2 \rightarrow O_2^+ + CO$, which shows a slight decrease in rate with increasing ion energy, in agreement with the corresponding E.S.S.A. result (2), thus giving us additional confidence in the validity of our energy dependence determinations.

Finally, we include in the figure our results for the energy dependence of the ionospherically interesting charge transfer reaction $O_2^+ + NO \rightarrow O_2 + NO^+$, which has not previously been studied in this energy region.

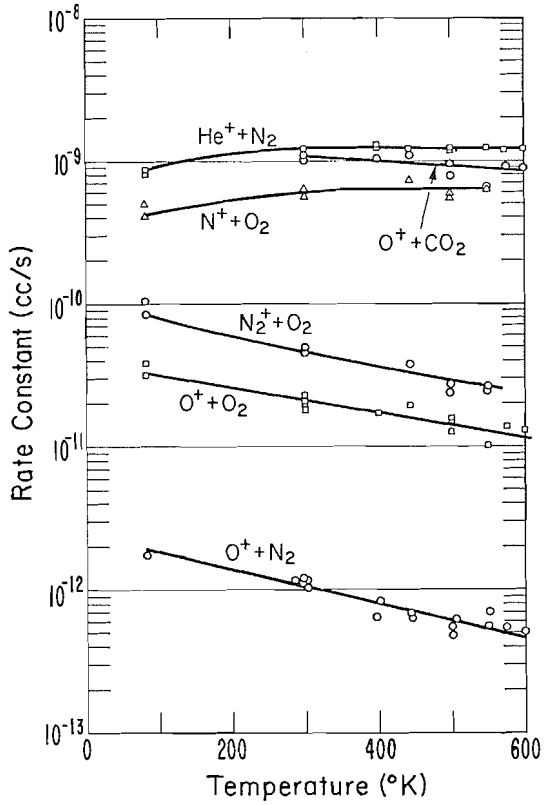

FIG. 2. Rate constants of some positive ion reactions over 80 to 600 °K.

600 °K, in the E.S.S.A. flowing afterglow system (4, 5). These results are shown in Fig. 2. The magnitude and constancy of the rate constant for $He^+ + N_2$ from 300 to 600 °K agrees with results of Heimerl *et al.* (6). The magnitude and temperature dependence of the $O^+ + O_2$ reaction is in excellent agreement with measurements of Smith and Fouracre (7) between 185 and 576 °K. There is a substantial disagreement among various experimenters concerning the $O^+ + N_2$ reaction. The current literature on all these reactions is discussed in ref. 1.

We have proposed a qualitative theory for the decrease in rate constant with increasing temperature for slow reactions in the near-thermal range (5). In brief, it is known from unimolecular decomposition theory and from the temperature dependence of three-body association reaction rate constants (8) that the lifetimes of the intermediate reaction complexes increase with decreasing temperature. It is also known from phase space theory that equilibration of vibrational modes in the complex, prior to breakup, favors the most exothermic breakup channel. The longer the complex lifetime, the nearer the approach to equilibration should be. Therefore, it follows that the reactions of Fig. 1, which are the most exothermic breakup channels, should be favored at low temperatures over thermoneutral elastic breakup (no reaction), as compared to higher temperatures.

COMMENTS BY MARK CHER[2]

I wish to report that we have solved eq. [6′], the continuity equation for Poiseuille flow, by neglecting the term $D_1\partial^2 N_1/\partial z^2$. This approximation is justified because in general, transport along the axial direction by diffusion is small everywhere in the tube (except perhaps very near the walls) compared with transport by convection. The other approximations are the usual ones, namely that D_1, v_0, k, and n_2 (in Fite's notation) are constants independent of position. The solution is

$$N_1(z, r) = N_1(0) \exp\left\{-\left[\frac{D_1\lambda_0^2}{a^2} + (1 + \varepsilon_1)kn_2 - \frac{\varepsilon_2 k^2 a^2 n_2^2}{D_1^2}\right]\frac{z}{v_0}\right\} f(r)$$

where $f(r)$ is the product of an exponential and a confluent hypergeometric function and λ_0, ε_1, and ε_2 are constants equal to 2.710, 0.237, and 0.00115, respectively. These constants were obtained numerically from the boundary condition requiring that N_1 vanish at the walls by setting $f(a) = 0$. Usually the concentration of the added gas n_2 is small, and the third term can be ignored. Note that v_0 in the above equation and in eq. [6′] refers to the *maximum* velocity in a parabolic flow profile, and its value is exactly twice the value of v_0 in eq. [9] for equivalent volumetric flows. Thus, the correction for parabolic flow which has to be applied to the rate

[2]Address: Science Center, North American Rockwell Corp.

constant obtained in the usual way from eq. [9] is the factor 2/1.237 = 1.617. Full details concerning the solution of the above differential equation will appear shortly[3].

REPLY TO MARK CHER

If one is willing to ignore the axial diffusion term in eq. [6′] the equation becomes immediately separable in its variables and can be readily solved as Dr. Cher has done. Other approximate solutions in series form can be obtained even while retaining the axial diffusion term, although the convergence of such series is unfortunately slow and particularly troublesome near walls and in the vicinity of point sources, i.e., exactly where neglect of the axial diffusion term in Cher's approach raises the most concern.

While one can hope that approximate solutions using either approach will not seriously affect the values of rate coefficients obtained in flowing afterglow experiments, I am not aware of any quantitative evaluations of the errors introduced by such approximations.

SUMMARY BY CHAIRMAN, T. M. DONAHUE[4]

As was the case with recombination coefficients, the general state of accord between laboratory measurements and ionospheric requirements is good for ion–molecule reactions. It is gratifying to find that the rate coefficients for removal of O^+ by N_2 and O_2 decrease with temperature as this chairman requested a couple of years ago. It remains to be seen whether the rate constant for $N_2^+ + O \rightarrow NO^+ + N$ will conform also.

On the other hand, it is alarming that the rate constant for $N^+ + O_2$ did not drop. This creates quite a problem because N^+ densities in the F region are much higher than can be reconciled with removal rate constants of order 10^{-9} cm^3 s^{-1} and conventional sources of N^+. Similar difficulties exist in explaining He^+ densities (and H^+ densities also). Except for O^+, in fact, atomic ion densities all seem to present aeronomic problems. Recent measurements in auroras by Narcisi and the Pittsburgh group show that even below 150 km there are three orders of magnitude greater He^+ densities than can be reconciled with a 10^{-9} cm^3 s^{-1} rate constant with N_2. The ratio of H^+ to O^+ at low altitudes suggests that $H^+ + O$ and $O^+ + H$ have different, temperature dependent, cross sections at low energy. The problems of getting rid of Mg^+, Ca^+, Na^+, etc. in "metal" ion layers is now acute in view of Fehsenfeld's report that the oxides of these ions are rapidly reduced by atomic oxygen.

Another problem to be solved is that of forming hydrates of hydronium ions in the D region. The B.R.L. group (9) (Lineberger and Puckett, 1968) has shown that NO^+ can be converted to $NO^+ \cdot H_2O$. Fehsenfeld and Ferguson (10) may have found a chain which converts this ion to $H_3O^+ \cdot (H_2O)_n$. This possibility richly deserves to be followed up.

It also would be interesting to know how the rate constant for $O^+ + N_2(V^*)$ varies with the kinetic energy of the collision partners for various vibrational levels. There is some good indication in auroras that removal of O^+ by N_2 may be slow in spite of high vibrational temperatures.

Problems obviously remain, and the general dependence of rate constants on excitation of ions and neutrals is an outstanding one. However, the situation is gratifyingly better than it was at the Berkeley symposium.

Negative ion – molecule reactions

E. E. FERGUSON
Aeronomy Laboratory, Environmental Sciences Services Administration Research Laboratories, Boulder, Colorado

Laboratory reaction rate constant measurements for negative ion – atom interchange reactions, negative ion charge transfer reactions, and negative ion three-body association reactions of aeronomic interest are reviewed and the available data tabulated. The present experimental techniques in use are briefly summarized. Most of the rate constants have been measured only at 300 °K; in a few cases data is available at energies $\gtrsim$ 1 eV, as well as at 300 °K, so that an indication of the energy dependence of the rate constants is available.

Canadian Journal of Chemistry, 47, 1815 (1969)

Introduction

Almost the entire available knowledge concerning negative ion – molecule reactions of atmospheric interest has been acquired since the I.A.G.A. Aeronomy Symposium held in Berkeley in 1963. The subject of positive and negative ion low energy charge exchange and ion – molecule reactions was reviewed then by Paulson (1), and at the time the only negative ion reaction rate of atmospheric interest known was the reaction

[1] $$O^- + NO_2 \rightarrow NO_2^- + O$$

which had been measured by Henglein and Muccini (2) and found to have a rate constant $\sim 3 \times 10^{-9}$ cm^3/s. (This rate constant has been subsequently measured by three groups and found to be 1.2×10^{-9} cm^3/s at 300 °K.) By way of contrast, a recent review (3) tabulated 15 negative ion neutral reactions of atmospheric interest and fairly detailed negative ion reaction schemes for the atmosphere have now been proposed (4, 5). At least 4 different laboratory groups, utilizing 4 different experimental techniques, have now obtained rate constant data on negative ion – neutral molecule reaction processes.

The negative ion composition of the ionosphere has as yet not been determined experimentally so that even the qualitative predictions based on laboratory measurements have not been subjected to critical test. This is in contrast to the situation for the positive ion chemistry in which direct rocket borne mass spectrometer ion measurements have allowed detailed, quantitative checks of the most important positive ion reaction rate constants, for at least the E and F1 ionospheric layers.

The present review is concerned only with negative ion reactions with neutral molecules, and specifically reactions in which a different heavy negative ion is a product of the reaction. This excludes processes of electron attachment and detachment from neutrals. One of the more important negative ion – neutral molecule reaction processes occurring in the D region is the associative-detachment process in which an electron is released from a negative ion. This process has long been expected theoretically, but was discovered experimentally only in 1966. This class of reactions is included in the electron attachment and detachment processes reviewed by Phelps (6) in the current symposium.

The binary negative ion reactions known which appear likely to be important in the earth's atmosphere are listed in Table I. Brief discussions of some aspects of the role of these reactions in the quiet D region have been given by Fehsenfeld *et al.* (4), Fehsenfeld and Ferguson (7), and Ferguson (3). Recently, LeLevier and Branscomb (5) have presented a discussion of the role of negative ion chemistry in certain disturbed atmospheric conditions. In many respects, more useful observations exist for comparison of the broad atmospheric negative ion behavior with theoretical prediction for disturbed atmospheric conditions. The limited available data for negative ion three-body association reactions are given in Table II.

Discussion of Measurements

Different measuring techniques are often complementary in their capabilities and the energy ranges over which they can be operated. It is very desirable (and of course generally recognized) that the important reactions should be

measured in several different ways when this is possible. A comparison of measurements made by different techniques greatly aids in the evaluation of the precision and reliability of the different methods. It also acts as a safeguard against errors which may arise in experiments due to such factors as lack of knowledge of reactant states, and various subtle experimental problems which may be somewhat hidden in any particular experiment.

A. Mass Spectrometer Experiments

Historically, most positive ion reaction measurements have been carried out in mass spectrometer ion sources. This has not been true, however, of *ionospheric* positive ion reactions and is not true for negative ion reactions in general. The role of mass spectrometer ion source measurements in the elucidation of ionospheric negative ion chemistry is expected to continue to be limited because so many of the most critical re-

*d.t. refers to drift tube, and f.a. refers to flowing afterglow experiments.

actions involve relatively unstable neutral reactants, such as atomic oxygen and ozone, which have not been successfully used in positive or negative ion studies in mass spectrometer ion sources. Also, the most important atmospheric negative ions (e.g. O_2^-, O_3^-, CO_3^-, etc.) are not produced by direct electron impact on a stable gas and accordingly are not suitable for the typical low pressure mass spectrometer ion source studies.

Several mass spectrometer ion source measurements are tabulated in Table I. The early observation by Henglein and Muccini (2) that O^- charge transfers rapidly with NO_2 has subsequently been borne out by more precise measurements. The recent measurement by Paulson (8) of the same reaction has been well supported by the flowing afterglow measurement.

The report by Curran (9) that Cl^- charge transfers rapidly with NO_2 has not been supported, however, by either the thermal energy flowing afterglow results (4) or by a reasonable extrapolation to low energies of the higher energy crossed beam measurements (10).

B. Crossed Beam Measurements

The crossed beam studies carried out by Rutherford and Turner (10) at General Atomic have been valuable in the study of charge transfers of various negative ions to NO_2. The measurements were actually carried out at energies above 2 eV, up to several hundred eV in most cases, and Rutherford and Turner extrapolated their values to thermal (ionospheric) energies. A comparison of their results with thermal energy measurements shows that the charge transfer rate constants do not have a marked energy dependence in the cases studied. The same conclusion was obtained for many positive ion charge transfer reactions studied as a function of energy using the crossed beam technique.

Negative ion – atom interchange reactions have not been studied in crossed beam experiments. Probably these reactions will often not be fast at the several volts and greater energies at which the beam reactions are studied. One complication in the extrapolation of charge transfer rate constants from beam energies to the ionospheric energy range arises if a fast ion – atom interchange process becomes significant at energies below the lowest beam energy studied. One example of such a situation may occur for the reaction

$$[2] \qquad O_3^- + NO_2 \rightarrow NO_2^- + O_3$$

which Rutherford and Turner (10) measured for kinetic energies from 25–400 eV. They extrapolated their data to obtain a 300 °K rate constant of 7×10^{-10} cm^3/s. However, it is not unlikely that at thermal energies, the reaction goes as

$$[3] \qquad O_3^- + NO_2 \rightarrow NO_3^- + O_2$$

rather than by charge transfer! The flowing afterglow results suggested that this might be the case, but were inconclusive and must be repeated with additional measurements (the O_3 concentration) simultaneously carried out in order to resolve this point.

C. Afterglow Measurements

Fite and Rutherford (11) made some interesting qualitative observations on negative ions in air and oxygen afterglows using a stationary afterglow method in which ions were sampled as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

function of time following cessation of a discharge in the gas. They found the ion sampling efficiency to vary with time in the afterglow and this effect precluded any quantitative rate measurements in the stationary afterglows.

The flowing afterglow system developed in the Environmental Sciences Services Administration Laboratory has proved to be very useful for negative ion reaction studies. Most of the reactions tabulated in Table I have been measured by this method. For the ion – atom interchange reactions, few other measurements exist. The flowing afterglow measurements of negative ions have so far been carried out at 300° K. Recently, a new temperature controlled flowing afterglow system has been constructed which operates in the temperature range 82–600 °K. The rate constants of Table I will in time be measured over this temperature range, which includes the temperature range of most concern for atmospheric negative ion reactions.

D. Drift Tube Measurements

So far the application of drift tubes to negative ion studies of atmospheric interest has been concentrated on three-body rate constant measurements. Most of the three-body rate constants of Table II have been measured in drift tubes. The recent upsurge in binary positive ion reaction measurements in drift tubes will perhaps be followed by similar negative ion measurements.

A particular advantage of the drift tube technique is in the capability of varying the reactant ion kinetic energy over a range of values. Variations in ion kinetic energy cannot be assumed in all cases to be equivalent to similar variations in gas temperature in which rotational and vibrational degrees of freedom are equilibrated as well as translational, but will in any case provide very useful data. The temperature or energy variation feature is not so important for ionospheric negative ion charge-transfer and ion – atom interchange reactions as it is in the case of ionospheric positive ion reactions, because the range of temperatures in the D region where negative ions can be important is so much more limited. However, three-body reaction rate constants appear to be much more dependent on temperature than binary reaction rate constants. One difficulty with drift tube measurements, as well as mass spectrometer ion source and crossed beam experiments, will be to achieve ion energies in the sub-300 °K temperature range characteristic of the D region. The afterglow technique, which has been successfully operated at 82 °K with all degrees of freedom equilibrated, has a distinct advantage in this respect.

On the other hand, the drift tube can be used to measure reactions which are endothermic at thermal energy. Slightly endothermic collisional dissociation of negative ion clusters may prove to be important in controlling their concentration in the D region, as one possible application where the drift tube could provide perhaps unique data. Moruzzi and Phelps have successfully determined the stability of the negative ion CO_4^- in drift tube studies, for example (17). The drift tube technique is, of course, quite restricted in the variety of reactants which can be studied.

General Discussion

The Cl^- charge transfer with NO_2 has been included in this review, not because that particular reaction is expected to be of direct ionospheric interest, but because Curran's report that this process was fast has led to the widely accepted conclusion that the process was exothermic, and consequently that the NO_2 electron affinity exceeded that of Cl. Since the recent studies do not find this charge transfer to occur at thermal energies, this conclusion should be reexamined. The value of the NO_2 electron affinity is of some importance in the physics and chemistry of the D region. The observation that F^- does not charge transfer rapidly with NO_2 is also reported in Table I for the same reason, F having about the same electron affinity as Cl. Observation of charge transfer reactions at thermal energy is often a useful way to obtain limits on electron affinities. For example, the observation of fast NO^- charge transfer with O_2 establishes an upper limit of 0.46 eV on the NO electron affinity.

Since there are no serious discrepancies between negative ion rate constants measured by different experimental techniques and since no quantitative atmospheric negative ion chemistry models or direct ionospheric negative ion measurements exist, the question of the precision of measurement is not at this time one of compelling urgency so far as aeronomy is concerned.

In favorable cases, the flowing afterglow and the mass spectrometer ion source techniques are probably reliable to within 30%. This is supported by the intercomparison of the techniques

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

on the $O^- + NO_2$ charge transfer (Table I) and by very much more extensive comparisons for positive ion reactions where the measurement precision considerations are presumably not essentially different. In addition, the flowing afterglow measurements on several negative ion associative-detachment reactions have been compared with drift tube measurements and the agreement has been consistent with such estimated error limits. The uncertainties in reactions involving unstable neutrals such as O, O_3, and even NO_2 are greater than for reactions involving stable neutral reactants such as NO and CO_2, however, due to the greater difficulty of reactant concentration measurements in these cases.

The unknown distribution of vibrational states in the *molecular* negative ion reaction experiments so far carried out adds an element of uncertainty to their measured reaction rate constants. In principle it seems possible to resolve this uncertainty to some extent in flowing afterglow experiments since the lifetime of the negative ion prior to reaction can be varied. Experience would suggest that exothermic charge transfer reactions will not be sensitive to the vibrational state of the molecular ion, since indeed they seem relatively insensitive even to the choice of ion.

Recent refinements in data analysis along with certain improvements in experimental apparatus suggest that flowing afterglow measurements can probably be refined to $\pm 10\%$ type errors in future experiments for favorable cases such as reactions involving stable neutral reactants.

For the near future, aeronomical D region calculations are more likely to be limited by uncertainties in the critical neutral constituent concentrations (e.g. NO, O_3, O, NO_2, and CO_2) than by the uncertainties in reaction rate constants.

Need for Future Work

Of most concern are the possibilities of important reactions not yet considered. To date, no negative ion reactions of the kind considered in this review have been measured involving excited states of the neutral reactants as one example of interest.

A possibility which has been pointed out by Pack and Phelps (12) is that the primary negative ions may rapidly cluster in the lower ionosphere. Ions such as CO_4^-, $O_2^-(H_2O)_n$, $NO_2^-(H_2O)_n$, etc., may be very important. Therefore a number of three-body association reactions of the type

$$X^- + A + M \rightarrow AX^- + M$$

may be of considerable importance. The very limited available data of this type is compiled in Table II, without regard for whether the specific processes tabulated there are likely to occur in the earth's atmosphere or not, since a knowledge of the magnitudes of the few observed rate constants may be helpful in attempting to estimate probable ranges of such three-body coefficients, prior to measurements of the appropriate processes in the laboratory.

A considerable amount of effort will be required in three-body measurements in order to furnish the data which can be expected to be important in the ionosphere. Each cluster ion forming reaction has the new degree of variability associated with different possible third bodies. One would like to know the efficiencies of both O_2 and N_2 in most D region negative ion association reactions. Additionally, the effect of temperature variations on three-body rate constants is generally very much greater than it is for the binary charge transfer and ion – atom interchange reactions.

Finally, one of the more important clustering agents in the D region is likely to be the polar H_2O molecule, which is very difficult to work with quantitatively in the laboratory. Recent developments in the technology of laboratory ion – molecule reaction rate constant measurements certainly will assure a steady increase in the quantitative data required for aeronomical applications.

Comments

COMMENTS BY F. E. NILES

Your statement about the possible importance of clustering agents, particularly H_2O, in the D region for the negative ions is supported by recent laboratory measurements at BRL. Photoionization of a small admixture of NO in a few hundred mTorr of laboratory air resulted in $HN_2O_4^-$ (mass 93) being the dominant negative ion. Other negative ions in decreasing order of the mass spectrometric abundance were $NO_2^- \cdot H_2O$ (mass 64), $NO_2^- \cdot 2H_2O$ (mass 82), NO_2^- (mass 46), and $NO_2^- \cdot 3H_2O$ (mass 100). Other negative ions were also observed.

Absorption cross-sections of atmospheric gases for use in aeronomy

ROBERT E. HUFFMAN[1]
United States Air Force Cambridge Research Laboratory, Bedford, Massachusetts

Received November 21, 1968

The current status of absorption cross-section measurements for aeronomic use is reviewed. Recommended values for the gases O_2, N_2, O, and O_3 are given at wavelengths where there is strong atmospheric absorption in the 3500–10 Å region. A table of absorption and ionization cross-sections at important solar emission lines is given. The problem of insufficient resolution at some wavelengths is discussed, and information on photolysis products is given where available.

Canadian Journal of Chemistry, 47, 1823 (1969)

Introduction

The absorption of solar radiation in the ultraviolet to soft X-ray region is well established as one of the most important mechanisms for creating and maintaining the unique characteristics of the upper atmosphere. As the radiation is absorbed, new constituents such as ions, electrons, and atoms are formed, and the intensity at the absorbed wavelengths is reduced, until at ground level only wavelengths greater than about 2900 Å are observed. The pattern of the absorption is complicated, depending on the variation of absorption with wavelength for each constituent, the atmospheric composition as a function of altitude, and the detailed intensity distribution of the solar spectrum. To understand this absorption profile, it is necessary to have laboratory measurements of the absorption cross-section, or absorption coefficient, which is a measure of the total attenuation of radiation at a given wavelength. This information is useful in aeronomy both to find the altitudes at which solar energy is deposited and to evaluate the flux remaining for further absorption at lower altitudes.

This article reviews the present status of laboratory absorption cross-section measurements and provides recommended values for aeronomical problems. Only wavelength regions and gases particularly important for atmospheric absorption are discussed in detail. The wavelength region considered is from roughly 3500 to 10 Å. The gases discussed at length are molecular oxygen, molecular nitrogen, atomic oxygen, and ozone. These four gases account for most of the solar absorption. There are several older reviews of this general subject (1–3).

[1]1967–68 address: Department of Physics, Imperial College, London, England.

The Absorption Cross-section

The absorption cross-section is defined by the usual absorption law (Beer–Lambert Law)

$$[1] \qquad I(\nu) = I_0(\nu) \exp [-\sigma(\nu)N]$$

In this expression $I(\nu)$ is the transmitted intensity, $I_0(\nu)$ is the intensity incident on the absorbing gas column, $\sigma(\nu)$ is the cross-section, and N is the number of absorbers (molecules or atoms) per cm^2 column in the light path. The cross-section σ is generally given in units of Megabarn (Mb), which is equal to 10^{-18} cm^2. The data may also be presented as the absorption coefficient k, with units of cm^{-1}. It is equal to $\sigma n_0 \cdot 10^{-18}$, where σ is in Mb, and Loschmidt's number n_0, is 2.69×10^{19} cm^{-3}.

The measurement procedure for the absorption cross-section involves finding $I(\nu)$ and $I_0(\nu)$ at known values of ν and N. It is only necessary to measure the ratio $I_0(\nu)/I(\nu)$ and thus the simpler relative calibration of the detector is adequate. For many cases, $\sigma(\nu)$ as calculated from eq. [1] is constant over a range of N values, and this cross-section can then be used to calculate the absorption or the number of absorbing molecules in atmospheric problems. There are, however, important cases discussed in a separate section where the typical laboratory resolution is inadequate and various approximate $\sigma(\nu)$ values must be given.

No review of the experimental details of the light sources, monochromators and spectrographs, and detectors used will be given here. These are covered fully in the references and in reviews (4) and (5).

The absorption cross-section curve itself provides little information about products or excited states formed as a result of the absorption. At most wavelengths considered here, there are a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

number of possibilities including excitation, dissociation, ionization, dissociative ionization, and various other combinations of these processes. The products of dissociation or ionization processes may be left in excited states, and in some cases these states may become deactivated by emission of radiation.

In the observed spectrum or cross-section curve, excitation produces the normal molecular bands and atomic lines generally measured and classified in absorption spectroscopy. Dissociation and ionization processes are indicated by absorption continua. Diffuse bands or lines are an intermediate case and indicate predissociation or autoionization processes. In the wavelength range discussed here, a number of different processes usually occur at the same wavelength.

The absorption cross-section can be considered to represent the sum of partial cross-sections of the various detailed processes. The partial cross-sections give the fractional amounts of the different products resulting from the absorption. For example, the cross-sections for ionized and non-ionized products can be given. For partial cross-sections, a quantitative measurement of the products is required, which generally presents experimental difficulties. Some processes can usually be ruled out by energy considerations. The cross-sections involving photoionization will be dealt with in a separate paper at this symposium.

The photodissociation cross-section and products are of considerable interest, for both the major and minor atmospheric gases, but little detailed information is available. Photochemical investigations may give information on products at some wavelengths. A review is available (6) for many atmospheric gases.

The absorption cross-section is also related to the oscillator strength of the transition (7), and the oscillator strength can be obtained directly from an integration of the observed cross-section curve at sufficiently high resolution. This aspect of the subject is not discussed since oscillator strengths are covered by another paper in this symposium.

Resolution Problems

The resolution of the spectrometer is generally not adequate for atomic lines or sharp molecular bands encountered in the spectrum. Using the normal procedure given above, the cross-section calculated from [1] is not constant but usually decreases with increase in N, and thus more detailed consideration must be given before applying the laboratory measurements to atmospheric problems. The actual cross-section is very large at the line center and rapidly becomes weak away from the center. When a measureable change in transmission is detectable, the narrow, strongly absorbing center of the line is already completely absorbed. The change in absorption with the change in number of absorbers is thus controlled by the weaker absorption in the wings of the line. The cross-section thus appears to become smaller as the amount of gas in the light-path increases.

The problem may be approached by examining the typical spectrometer experiment using continuum background radiation in more detail. The instrument provided a narrow range of frequencies around the nominal value, and an absorption measurement is actually made over this frequency range. If the intensity–frequency relation of the radiation provided at the exit slit at a given nominal spectrometer position ν_0 is $F(\nu)$, then the result of an absorption measurement will be

$$[2] \qquad \frac{I(\nu_0)}{I_0(\nu_0)} = \frac{\int F(\nu) \exp\left[-\sigma(\nu)N\right] d\nu}{\int F(\nu)\, d\nu}$$

The integrations are over the range where $F(\nu)$ has an appreciable value. For a continuum background source, $F(\nu)$ frequently has an almost triangular shape and in this case the integration is effectively between $\pm a$, where a is the half-width. For a light source emitting sharp atomic lines, the frequency range transmitted is generally less than the half-width of $F(\nu)$ and depends on the excitation conditions in the light source. If $\sigma(\nu)$ is constant over the range of frequencies provided by the spectrometer, the exponential may be taken outside the integral in eq. [2], and the usual absorption law eq. [1] results.

For an isolated non-autoionized atomic line, and ignoring pressure-broadening as usually unimportant under atmospheric conditions, the shape of the line is due to a combination of Doppler and natural broadening, which is sometimes called the Voigt profile (7). For oxygen atom at 300 °K and an imaginary line at 1000 Å, the Doppler half-width is 3.1×10^{-3} Å. The natural width for an allowed transition ($\tau = 10^{-8}$ s) at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

1000 Å is 5.3×10^{-6} Å. The typical bandwidth available is from about 0.5 to 0.05 Å. Thus, the absorption line is much narrower than the bandwidth. The values of $I(\nu_0)/I_0(\nu_0)$ obtained depend on the line shape $\sigma(\nu)$ and $F(\nu)$ as shown in eq. [2], and in general $\sigma(\nu)$ cannot be evaluated without some knowledge of the line shape to be expected.

This problem of obtaining useful information under conditions of inadequate resolution is a well-known difficulty in astrophysical and infrared investigations, and several procedures have been developed (7, 8). One technique is to obtain the integral of the absorption curve over a range of N. This is called the equivalent width, or sometimes the total absorption. The equivalent width W is equal to the following

$$[3] \qquad W = \int_0^\infty [1 - \exp(-\sigma(\nu)N)]\, d\nu$$

One can then obtain the "curve of growth" by plotting W against N. This curve would allow an estimate of N to be made if W values were obtained under similar conditions of absorbing gas environment, since W is independent of resolution over fairly wide limits (7, 8). The complete curve of growth for an atomic line is rather complicated even for an isolated line with only natural and Doppler broadening. However, under many conditions the center is completely absorbed and the strong line approximation is applicable, which means that W is proportional to $\sqrt{N}$. This behavior is found when the line has a Lorentz shape, which occurs when the absorption is controlled by the wings of the line. A demonstration of this effect for sharp O_2 bands has been given (9). Although little absorption data on atmospheric gases is now presented in this way, it is suggested that curves of W against N would be of use in some cases. It will be most useful when the solar radiation background is a continuum or when an artificially introduced continuum light source is used. Difficulties include partly overlapped lines, unusual autoionization profiles, and molecular bands.

Continuum background light sources are considered more useful than line sources in general because they give the absorption curve at all wavelengths and lead to a more complete understanding of the absorption processes. However, they give difficulty when a solar line of interest falls at an absorption band or line of the atmospheric gas, since the bandwidth of the continuum usually employed is much larger than the solar line half-width. For these cases, one approach has been to use a light source emitting lines at the solar wavelengths rather than a continuum (10). These lines may be much narrower than the continuum background bandwidths generally available, and thus they more nearly approximate the solar lines in half-width. They are also more intense than usual continuum sources. This is a useful interim procedure, but it is open to criticism for several reasons. First, the lines emitted may be quite different from the solar lines in shape, self-absorption, or relative multiplet intensities, due to differences in excitation conditions in the sun and in laboratory discharges. In fact, the laboratory lines may be as much as 0.1 Å wide (10), which is within the capability of continuum measurements. Furthermore, solar lines from highly ionized atoms are not usually produced in the typical laboratory source, so the continuum background must be used for these cases. Even when using lines, in some cases where $\sigma(\nu)$ varies with N using continuum radiation, a similar variation occurs using line sources. For further progress, more information about the solar line-shapes coupled with high resolution continuum data is needed. Continuum sources offer the advantage of improving the resolution in a straightforward way and of eventually interpreting the data more completely. These improvements in resolution and in knowledge of the solar line shape are not likely to become available soon. Thus, both continuum and line data are valuable to have at the present time, where a large number of measurements have not been made at some wavelengths, and data from both sources is included here.

In conclusion, it is apparent that considerably more attention must be given to cases where resolution is insufficient in order to extract the most information of aeronomic interest from laboratory measurements. In addition, some difficulties in comparing photon absorption and various electron impact experiments might have been avoided by earlier recognition and discussion of these resolution problems (11). Where resolution is not adequate, information about the number of absorbing species must be given. This is now usually given only as a range of values. A plot of transmission or measured apparent absorption cross-section for atmosphere values of N

would be of considerably more value. Throughout this review, regions where the structure has not been adequately resolved will be mentioned.

Cross-section Measurements

General

The following cross-section curves and tables are considered to be the best values available at the present time. In this review, consideration was given to all published values known to the author. The wavelength range covers the upper wavelength where appreciable absorption begins to about 10 Å. These values should be useful at atmospheric densities, except in wavelength regions mentioned where resolution is a problem. The atmospheric temperature may be considerably above or below room temperature, but most cross-sections are measured at room temperature. Where data at other temperatures are available, they are mentioned. The % uncertainties have not been estimated, but they are in the range $\pm 10\%$ except at lines or bands.

In addition to the gases treated in detail, there are a number of minor constituents whose absorption cross-sections are of less importance in aeronomy. The atomic gases in this category include H, N, Ar, He, Na etc., and recent reviews are available (12, 13). Molecular gases include NO, NO_2, N_2O, H_2O, CO_2, CO, H_2, CH_4, etc. Data on these gases have been reviewed (1, 13).

The cross-section in regions where the solar radiation largely consists of strong emission lines is difficult to obtain from published curves. Table I lists the total absorption and total ionization cross-section at these lines from 1215.7 Å (H Ly α) to 304 Å (He Ly α). In order to provide a consistent review within this symposium, Table I was prepared jointly with R. I. Schoen, who discusses ionization cross-sections in detail in another paper.

One problem in the application of laboratory data to atmospheric problems is the unavailability of large-scale cross-section curves. These are frequently not published even when prepared because of space limitations in journals. Such curves are available to aeronomists, by request, from the author. These curves were prepared in connection with previous work from this laboratory. At present, N_2 and O_2 in the 600–1000 Å region at a bandwidth of 0.5 Å are available. It is planned to improve these data in wavelength range and resolution in the near future.

TABLE II

Absorption cross-sections[a] at wavelengths less than 304 Å.

Wavelength[b] (Å)	O_2	N_2	O
247.2	12.3	9.8	6
209.3	9.0	6.5	4
100	1.9	0.84	0.8
68.0	0.9	0.50	0.2
44.6	0.31	0.18	0.1
13.4	0.29	0.089	0.14[c]
9.9	0.14	0.042	0.071[c]

NOTE: Data primarily from refs. 12, 36, and 47. Cross-section in Mb (10^{-18} cm^2).

[a]These cross-sections are assumed to be equal to the ionization cross-section at least to 100 Å, although there are no yield measurements. See also paper by R. I. Schoen in this symposium.

[b]There are a number of solar lines in this region, but there have been few measurements, and also the cross-section curve appears to be relatively smooth. The wavelengths used should allow a reasonable estimate to be made.

[c]This value is one-half the O_2 cross-section.

Molecular Oxygen

Molecular oxygen has important absorption from 2600 Å to lower wavelengths. Cross-section data are given in Figs. 1 to 6. Lower wavelengths are included in the atomic oxygen cross-section curves presented later. Absorption cross-section values at the more intense solar lines are given in Table I, and Table II gives shorter wavelengths. In most cases, at least two measurements are available, and the data are in reasonably good agreement. There are many investigations of the absorption spectrum given in the references.

The weak Herzberg continuum in the 2600–1850 Å region shown in Fig. 1 is usually considered as the primary source of oxygen atoms below 80 km. In this dissociation process, two

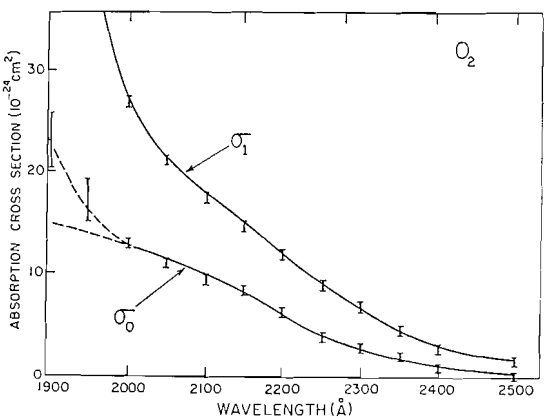

FIG. 1. Molecular oxygen absorption cross-sections; σ_0, value extrapolated to zero pressure; σ_1, 1 atm data, ref. (14).

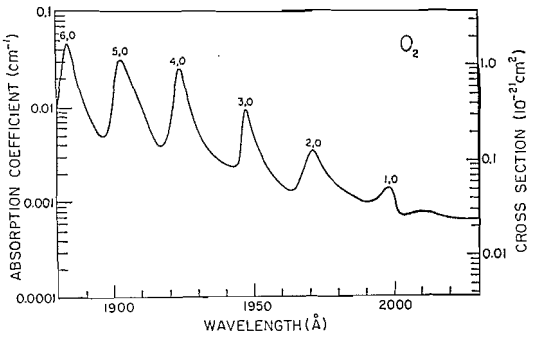

FIG. 2. Molecular oxygen absorption cross-sections, Schumann–Runge bands, ref. (9).

ground state (^3P) oxygen atoms are formed, since there is not sufficient energy to excite the metastable ^1D and ^1S atoms at these wavelengths. There are two measurements in fairly good agreement (14, 9). The cross-sections are very small, and the high pressures necessary result in formation of some O_4 dimer in the cell, so extrapolation to zero pressure is necessary.

The Schumann–Runge bands ($^3\Sigma_u^- \leftarrow {}^3\Sigma_g^+$) between 1750 and 2010 Å require high resolution to obtain accurate cross-sections (1, 9, 15). It is also difficult to separate the Herzberg continuum and the Schumann–Runge bands in the 1900–2030 Å region. Absorption data (9) are given in Figs. 2 and 3, but these are averaged values because of insufficient resolution. It is likely that much experimental work will be done on these bands in the future with high resolution.

The strong Schumann–Runge continuum (1250–1750 Å) is very important, since it is the primary source of oxygen atoms at altitudes greater than 80 km. The cross-section has been

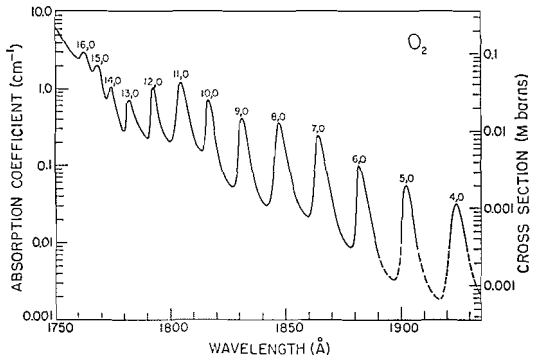

FIG. 3. Molecular oxygen absorption cross-sections, Schumann–Runge bands, ref. (9).

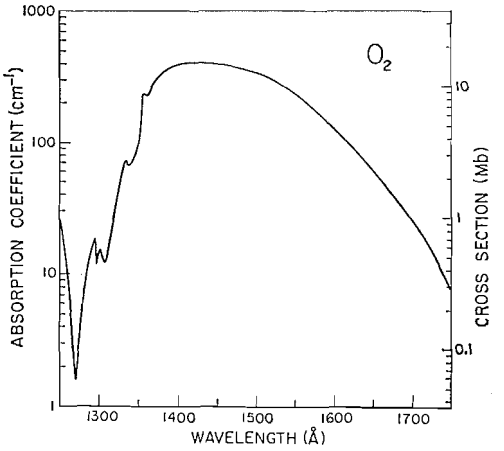

FIG. 4. Molecular oxygen absorption cross-sections, Schumann–Runge continuum, ref. (9).

measured repeatedly with photoelectric techniques with generally good agreement (1, 9, 16–18), and a representative curve (9) is given in Fig. 4. Absorption in the principal continuum is believed to produce one ground state (^3P) and one metastable (^1D) oxygen atom. Evidence from photochemically induced secondary reactions and from emission has been given for $O(^1D)$ production (19, 20), but more direct observation and quantitative cross-sections are also needed. A temperature effect has been discussed (21), and an increase in cross-section with temperature has been found in the 1580–1950 Å region (22).

The spectrum from 1250 Å to the ionization potential at 1027.8 Å is very complex (1, 16). There are several "windows" of low cross-section, one of which corresponds almost exactly to the intense H Ly line. As is well known, this ionizing radiation can penetrate much deeper into the atmosphere than nearby wavelengths.

The region 1070 to 600 Å shown in Figs. 5 and 6 has been studied several times recently with continuum sources (23–25) and a line source (10). The measurements of refs. (25) and (10) are in best agreement and are given more weight in Table I. In this region, ionization and dissociation continua are overlapped by rather diffuse and generally autoionized bands. The dissociation continua in this region have recently been given (25).

Appreciable quantities of the metastable O_2 $a^1\Delta_g$ molecule appear to be present in the upper

For personal use only.

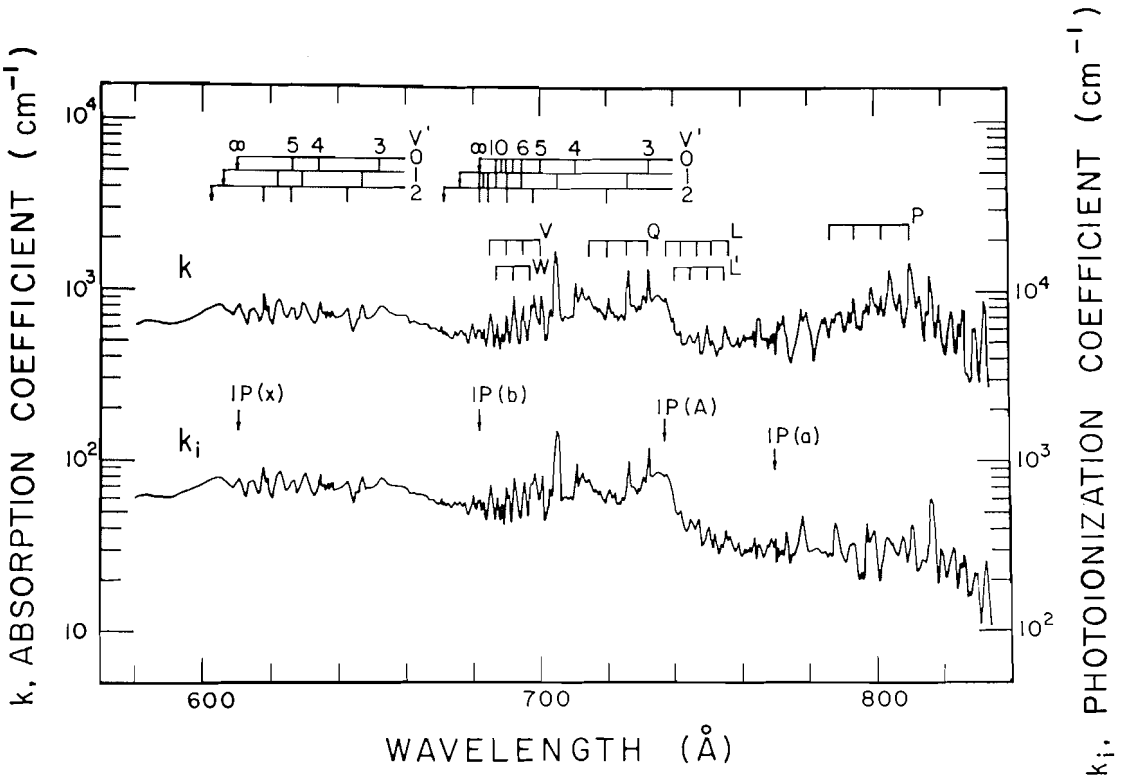

FIG. 5. Molecular oxygen absorption and ionization coefficients, ref. (25).

atmosphere (26, 27). It is conceivable that absorption by this molecule may be more significant than generally realized. Some intense bands attributed to absorption by the $a^1\Delta_g$, or less likely the $b^1\Sigma_g^+$, state have been observed recently in the 830–900 Å region, (28, 29), and recent work has found absorption bands of both the $a^1\Delta_g$ and the $b^1\Sigma_g^+$ states in the 1200–1600 Å region (30).

Molecular Nitrogen

The absorption cross-section of molecular nitrogen at important solar lines is given in Table I, which is based on several recent investigations (10, 31, 24). Table II gives shorter wavelength data. Cross-section curves obtained with continuum background sources in the region 600–1000 Å are given in Figs. 7 and 8. There is an extensive literature on the absorption spectrum which can be traced through the references given. There is one recent paper on absorption at wavelengths less than 600 Å (32).

Molecular nitrogen has a much smaller absorption cross-section than molecular oxygen at wavelengths longer than 1000 Å. The Lyman–Birge–Hopfield bands and several other forbidden transitions are present at wavelengths between 1450 and 1000 Å, but the maximum cross-sections measured are less than 10^{-3} Mb. The resolution is also generally inadequate for precise measurements. There are recent studies on high temperature absorption in this region (33).

There are no strong photodissociation continua for nitrogen, which is different from molecular oxygen. This fact helps to explain why atomic nitrogen is in very small concentration in the atmosphere, while atomic oxygen is a major constituent.

At wavelengths less than 1000 Å, there are a number of strong bands which cannot be measured accurately with the present resolution. The curve of Fig. 7 for the 800–1000 Å region must be regarded as approximate within regions of strong bands (11, 34), but it is useful for illustrating the general absorption in this region. One interesting situation is the coincidence of the strong H Ly γ solar line (972.5 Å) with one of the nitrogen

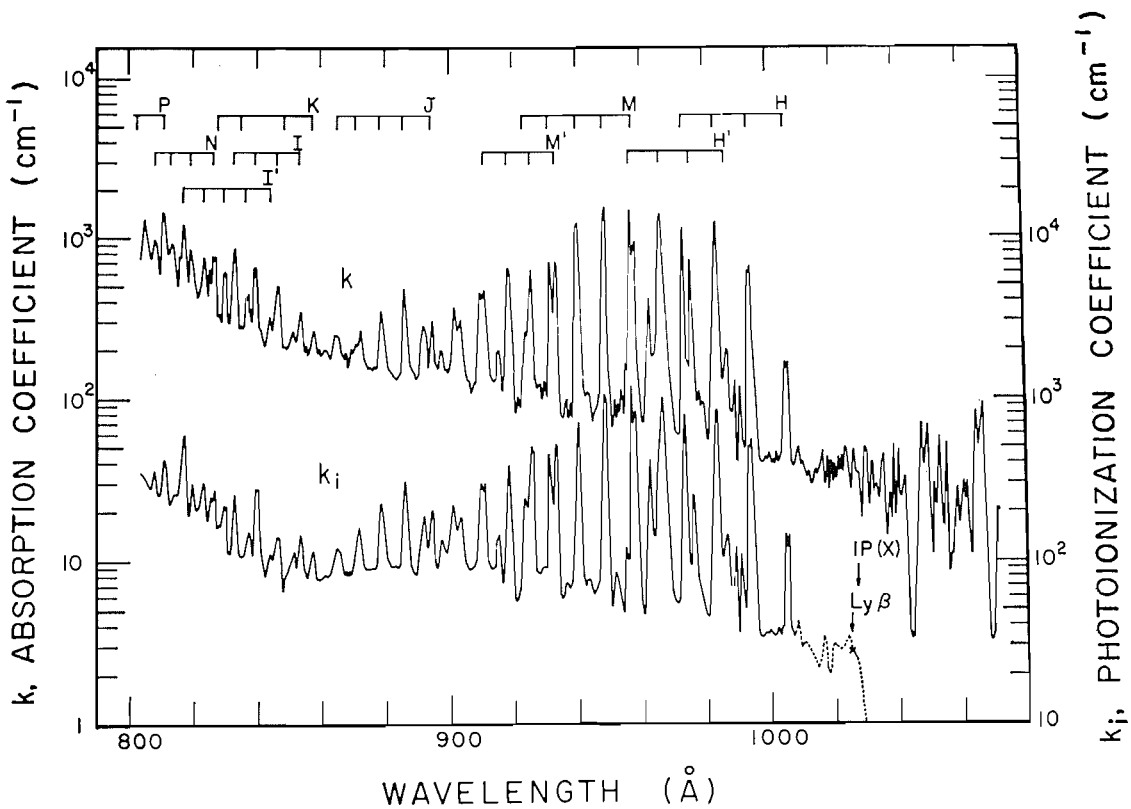

FIG. 6. Molecular oxygen absorption and ionization coefficients, ref. (25).

bands (35). At wavelengths less than the ionization threshold (795.8 Å), most bands become more diffuse because of autoionization, and they are superimposed on the ionization continuum. Thus, the curve of Fig. 8 should be more reliable. Recent unpublished results at Air Force Cambridge Research Laboratories indicate that the step at 661 Å is probably not real. The curve should be rescaled between 600 and 661 Å to form a smooth curve with the longer wavelength values.

Atomic Oxygen

The atomic oxygen spectrum consists of the ionization continuum at wavelengths less than the threshold at 910.4 Å and in addition, line series converging to limits corresponding to the electronic states of the ion. In the continuum region, there is good reason to believe that the absorption and ionization cross-sections are identical, in analogy with the ionization continua of the rare gases (12), except for a few non-autoionizing series lines. Most of the absorption lines at wavelengths less than the ionization threshold are autoionized.

Theoretical (36) and experimental (37, 38) cross-sections are given in Figs. 9 and 10. Table I gives cross-sections at important solar lines. Until quite recently there were no experimental values, but measurements using two independent techniques have now been published. One technique uses discharged oxygen, which requires correction for metastable molecules (37), and the other uses a beam technique requiring calibration against hydrogen atom (38). They are in only fair agreement with each other, but they generally bracket the theoretical curve. Despite these excellent experiments, the need for additional measurements is evident. Tables I and II rely primarily on the theoretical curves. Additional calculations have recently been published (39).

The large number of atomic oxygen absorption lines in the ionization continuum has only been realized recently with the measurement and classification of a number of these series (28). Some of the more intense series members are

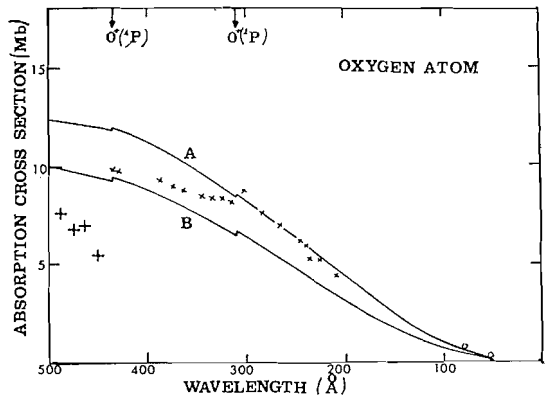

FIG. 10. Atomic oxygen cross-sections. See caption of Fig. 9. Symbol × represents one-half O_2 cross-section, based on ref. (37).

shown in Fig. 9, and it is clear that the lines used in some laboratory measurements were absorbed by oxygen atom lines, leading to high cross-section values (40), compared to nearby lines in the continuum region. If a solar line happens to overlap one of the atomic absorption lines, the absorption cross-section for this solar line will be much larger than the continuum value. The intensity profile with varying altitude will be dependent on the details of the two line shapes involved. Wavelengths where this effect is likely to be important for strong solar lines are given in Table I, and Table III gives the classification and additional wavelengths. The recent measurements also give absorption lines from the meta-stable $O(^1D)$ and $O(^1S)$ states (28), which may be important under special conditions.

TABLE III

Atomic oxygen lines which may absorb solar lines

Solar line (Å)	OI line (Å)	Classification	Remarks
1025.7	1025.76	$^3P_2$–$3d\,^3D^0$	*a*
989.8	990.13	$^3P_1$–$3s'\,^3D^0$	
937.8	937.84	$^3P_2$–$7s'\,^3S^0$	
930.7	930.89	$^3P_1$–$7d\,^3D^0$	
835.3	835.44	$^1D_2$–$10d'\,^1F^0$, $^1D^0$	
834.5	834.34	$^1D_2$–$12s'\,^1D^0$	
832.9	833.10	$^1D_2$–$12d'\,^1F^0$, $^1D^0$	
787.7	788.18	$^1D_2$–$5s''\,^1P^0$	*b*
770.4	770.35	$^3P_1$–$4d'\,^3P_2{}^0$

[a]Solar line known to be broad.
[b]Atomic oxygen line broadened by autoionization.
[c]These lines known to overlap. See refs. 40 and 37.

Ozone

Ozone (O_3) has important atmospheric absorption at wavelengths less than 3500 Å. The cross-section curves are given in Figs. 11 and 12. There have been several measurements in substantial agreement (41, 42). There is less atmospheric absorption at wavelengths less than 2000 Å, because solar radiation of these wavelengths does not penetrate to the altitudes where ozone is present, so this region is not reviewed.

Although the Hartley continuum in the 2000–3000 Å region (Fig. 11) has the larger cross-section, the greater solar intensity at wavelengths greater than 3000 Å makes absorption in the weaker Huggins bands also very important (43). The cross-section data in the region above 3000 Å should be improved in resolution to more

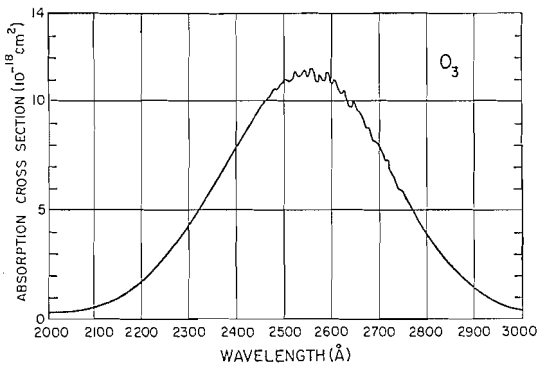

FIG. 11. Ozone absorption cross-sections, ref. (41).

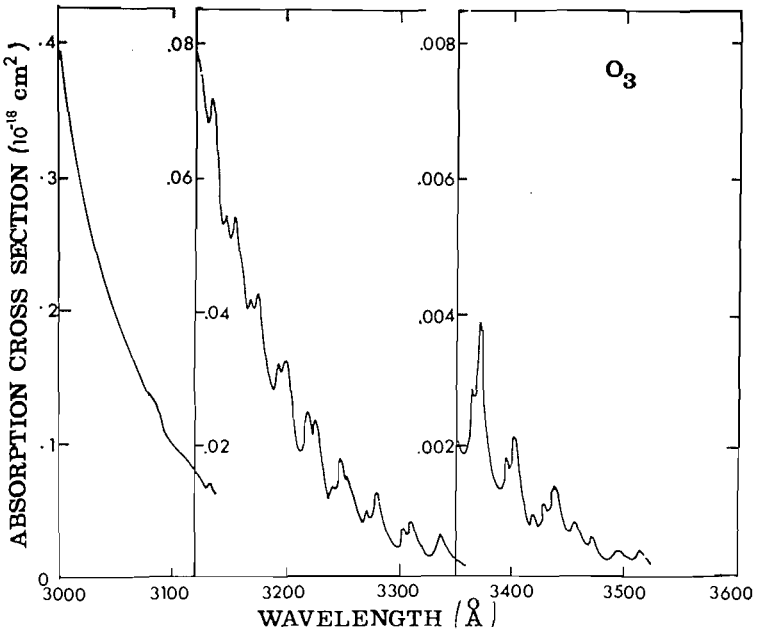

FIG. 12. Ozone absorption cross-sections, ref. (41).

accurately assess its importance. New data in this region have recently been published (44).

The photodissociation products of ozone are of considerable interest, since they appear to be one of the most likely sources of excited oxygen atoms and molecules. At wavelengths less than 3100 Å, it is energetically possible to have O_2 $^1\Delta_g$ and O ^{1}D as products of the ozone photolysis. The threshold for O ^{1}D formation is 4100 Å, but the process would also yield a ground state $X^3\Sigma_g^-$ molecule, which would be a forbidden transition (6). Discussions of the evidence for these products from flash and steady state photolysis have been given (27, 45), and a general conclusion is that O ^{1}D is much better established as a primary product than O_2 $a^1\Delta_g$. However, recent photolysis experiments at 2537 Å have succeeded in observing the O_2 $a^1\Delta_g \rightarrow X^3\Sigma_g^-$ infrared atmospheric bands in emission (49). The intense metastable O_2 absorption bands between 830 and 900 Å previously mentioned (28) have also been observed in the products of ozone photolysis at 2537 Å (50), which supports the presence of metastable O_2 in the products. It can therefore be considered as established that the absorption in this region does yield O_2 $a^1\Delta_g$, but the efficiency is not known.

Conclusions

There is a substantial body of information available on absorption cross-sections which may be used with considerable confidence for aeronomic calculations. Continued work is resulting in a convergence of values from different groups and techniques although this review notes many areas where work is needed. Agreement with the findings of rocket spectrophotometry (46) is also substantial; however, close interaction between laboratory and field studies is necessary to further reduce uncertainties.

Acknowledgments

The author would like to thank Professor W. R. S. Garton, for making facilities available in his group during preparation of this review. Illustrations and/or additional comment were provided by R. B. Cairns, W. Swider, K. Watanabe, and F. Matsunaga. Special thanks are due to Y. Tanaka and J. C. Larrabee for discussions over a period of many years.

Absorption in the spectral range of the Schumann–Runge bands

M. ACKERMAN, F. BIAUME, AND M. NICOLET
Institut D'Aéronomie Spatiale de Belgique 3, Avenue Circulaire, Bruxelles 18, Belgique

Received November 21, 1968

Absorption of silicon lines by O_2 in the Schumann–Runge bands has been measured. The results lead to some conclusions about the nature of the absorption and about the general behavior of the spectrum.

Canadian Journal of Chemistry, 47, 1834 (1969)

Introduction

Early measurements, presented in Fig. 1, of the absorption coefficient of oxygen in the Schumann–Runge bands (1750–2000 Å) and in the Herzberg continuum ($\lambda < 2424$ Å) were mainly performed with light sources providing spectral emission

lines (1–4). Differences between measured values were not clearly understood before analysis of the rotational structure by Curry and Herzberg (5), Knauss and Ballard (6), and Brix and Herzberg (7), all of whom used continuous light sources and high resolution spectrographs.

Absorption measurements by Watanabe, Inn, and Zelikoff (8) using a hydrogen light source showed an apparent pressure effect due to insufficient resolution. They lead to an order of magnitude of absorption intensity useful for semiquantitative applications. Using a slightly higher resolution and assuming the spectral line width, Ditchburn and Heddle (9) have deduced values of the oscillator strengths of the bands. Such results do not agree with those of Bethke (10), deduced from integrated absorption coefficients measured at high pressure, or with those of Hudson (11), obtained recently at different temperatures. This discrepancy has lead to the conclusion that the line half-widths assumed by Ditchburn and Heddle were too small.

The present article reports measurements of the absorption coefficients of O_2 on more than 30 lines of atomic silicon excited in a microwave discharge tube. Such a light source, already described (12), presents various advantages; the spectral lines are narrow and their wavelengths are known with a high accuracy, the uncertainty being less than 0.0015 Å. In addition, such a source produces practically no continuous radiation.

Experimental

The spectral lines have been isolated in our experiments using a 50 cm focal length vacuum monochromator before entering the absorption cell which was a Pyrex tube closed at each end with a quartz lens. Two cell lengths have been used, 217 and 401 cm. The light intensity was monitored by an E.M.I. 6255 Cd photomultiplier. The output was recorded for various O_2 pressures measured by using mercury manometers and MacLeod gauges.

For the data obtained in the region between the 5–0 and the 17–0 band, Beer's law is obeyed and the values range from 1.5×10^{-22} to 1.6×10^{-18} cm^2 and are presented in Table I. In a few cases where the wavenumber of an O_2 rotational line differs only by a fraction of a cm^{-1} from the wavenumber of a silicon line at which the measurement takes place, the absorption cross-section has a negative pressure coefficient. In such cases an inferior limit for the absorption cross-section was obtained by extrapolating to zero pressure. For lower v' values a positive pressure coefficient appears which has already been reported by others (13, 14). We shall not deal here with this part of our data.

Interpretation

The absorption at 56 700.25 cm^{-1} of one of the Si lines corresponds to the maximum of the $3P_1$ line of the 16.0 band and the $11P_2$ line of the 17.0 band of O_2 which are blended at 56 700.37 cm^{-1}. We infer, from the integrated absorption coefficients given by Bethke and from the relative rotational population, that these lines have an equivalent rectangular width of 1 cm^{-1}.

This value is not in disagreement with those given by Wilkinson and Mulliken (15), Heddle (16), and Hudson (11). Assuming that this value is valid for the bands that we consider here, we have calculated the maxima of absorption cross-section at the center of the lines which are close to the silicon lines. We have then plotted the ratios of the measured values σ to the sum of the maximum values σ_i versus the distance $\Delta\nu$ in cm^{-1}, weighted according to the relation

$$\Delta\nu\,(\mathrm{cm}^{-1}) = \frac{\sum \Delta\nu_i \sigma_i}{\sum \sigma_i}$$

The graph of Fig. 2 shows the absorption dependence of the distance from the line even at 30 cm^{-1} from the line center. The error bars indicate only the uncertainty on the measured cross-sections. The scattering of the points can be attributed to the uncertainty of the wavenumbers for the bands having v' values lower than 12, to the assumption of a constant half-width and to the overlapping of the bands which affects Bethke's values.

The solid line represents Rice's formula (17) for the shape of a line broadened by predissociation. To obtain the best fit of this curve with our data the half-width has to be fixed at 1.4 cm^{-1}.

Conclusion

A line half-width of 1.4 cm^{-1}, which must be chosen to obtain the best fit to the data mainly at large values of $\Delta\nu$ where it has the largest influence on the ratio σ/σ_i, indicates that the band oscillator strengths given by Bethke may be too low by as much as a factor of two or three at least for the v' values smaller than 12.

No continuous absorption underlying the bands on which we report in this article can be deduced from our measurements. The data reported here enforce the old idea of Flory (18)

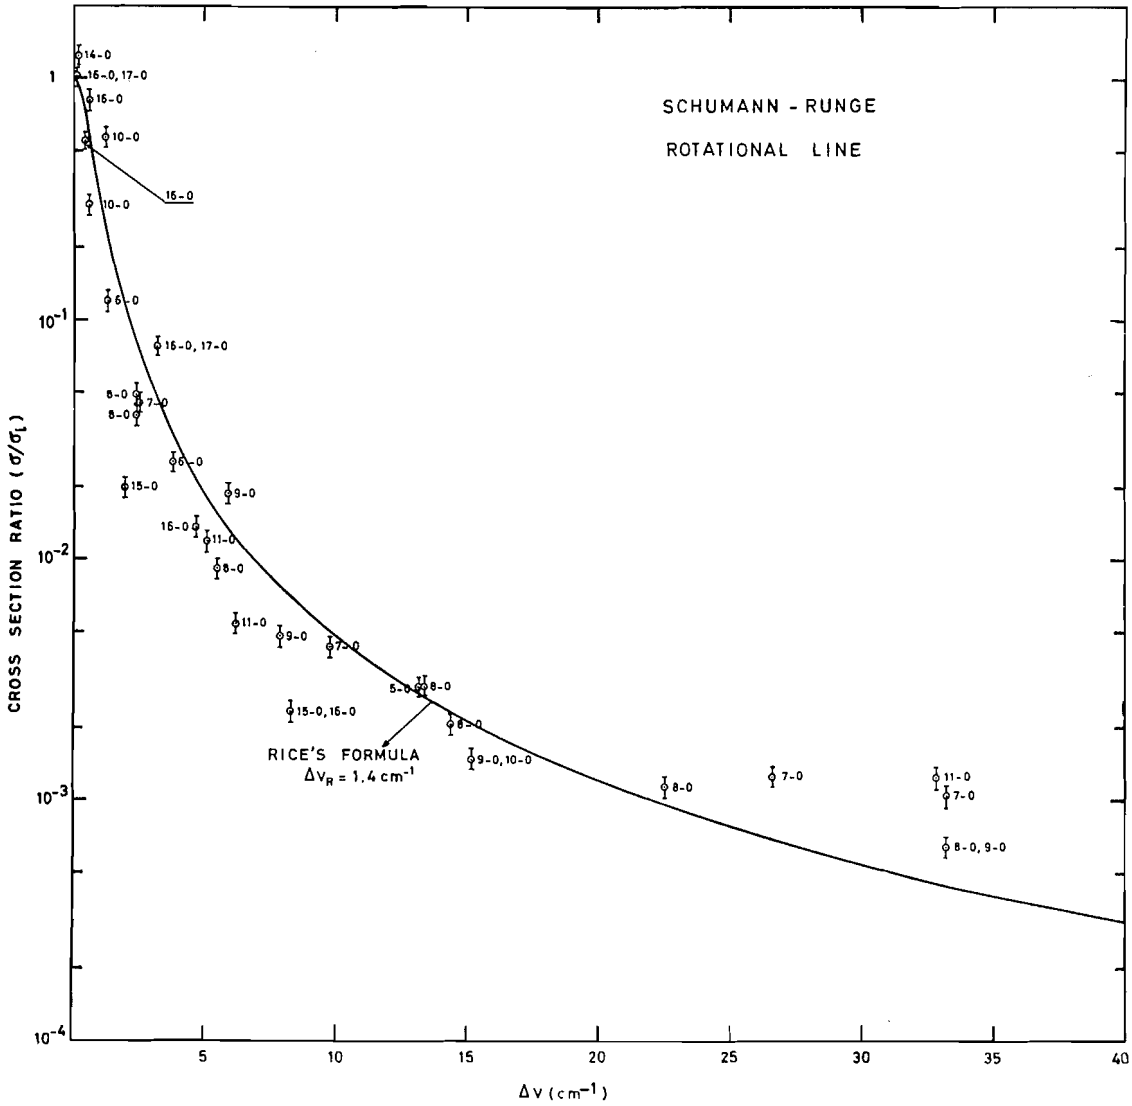

FIG. 2. Ratios σ/σ_l of the measured cross section σ and calculated cross section at the line center σ_l vs. the distance $\Delta\nu$ from the line center.

relating to the predissociation of the oxygen molecule in the Schumann–Runge bands.

A synthetic absorption spectrum can be computed using a line half-width of 1.4 cm^{-1} and Bethke's values for the band oscillator strengths. It exhibits minima and maxima of absorption cross-section which lead to unit optical depth in the atmosphere between altitudes at 25 and 120 km. The deduction of precise values will only become possible when the position of the lines and the strength of the bands has been accurately determined.

Predissociation in N_2 and O_2[1]

ROBERT D. HUDSON[2] AND VIRGINIA L. CARTER
Space Physics Laboratory, Aerospace Corporation, El Segundo, California

Received November 21, 1968

An outline discussion is given of some of the complications in the measurement of absorption cross sections which arise from finite instrumental bandwidths. Application is made to data on O_2 and N_2 from the literature.

Canadian Journal of Chemistry, 47, 1840 (1969)

Introduction

In a recent paper (1) we have shown that published absorption cross sections obtained at maxima or minima could be in error by as much as a factor of two, and that published line and band profiles are probably erroneous because of a failure to take into account the effects of finite instrumental bandwidths. In this paper we should like to present some measurements that we have performed on N_2 (2), and O_2 (3) at high resolution, and to show that another consequence of poor resolution is a loss of information regarding the physical processes that accompany the absorption.

Results

Molecular Oxygen

We would like to discuss the molecular oxygen results first. Our initial aim was to study the effect of temperature on the absorption of oxygen in the Schumann–Runge system, at an instrumental bandwidth of 0.075 Å. The results of our study of the dependence of the continuum on temperature were published some time ago (4). The dependence of the band structure is more complicated as is indicated in Fig. 1, which covers the spectral range from 1878 to 1894 Å. All three absorption traces were obtained with the same concentration of oxygen in the absorption cell, thus the effects that one sees are due entirely to the redistribution in the ground vibrational and rotational levels. The curve at 600 °K is of special interest as the fraction of molecules in the $v'' = 1$ state at that temperature is 0.0234, and yet the 9–1 band obviously gives rise to more absorption than the 6–0 band. This fact reflects the large increase in Franck–Condon factors from the $v'' = 0$ to the $v'' = 1$ levels due in part to the relatively large (0.4 Å) difference between the internuclear separations of the ground $X^3\Sigma_g^-$ and the excited $B^3\Sigma_u^-$ electronic states. One of the most important findings of the analysis was that all of the upper vibrational levels from $v' = 3$ to 17 were subject to predissociation, the individual rotational lines having half-widths varying from 0.5 to 2.3 cm^{-1}. Predissociation in these bands explains the failure, thus far, to observe fluorescence in the Schumann–Runge bands in the upper atmosphere, and provides an additional source of atomic oxygen between 65 and 95 km, both atoms of which will be left in the ^3P state with kinetic energies of up to 1 eV. We have recently measured this photodissociation rate in the laboratory, as a function of column height, at both 200 and 300° K and the resulting atomic oxygen production rate for the CIRA 1965 standard atmosphere (12) is shown in Fig. 2. The curve shown with the Schu-

Received November 21, 1968

An outline discussion is given of some of the complications in the measurement of absorption cross sections which arise from finite instrumental bandwidths. Application is made to data on O_2 and N_2 from the literature.

Canadian Journal of Chemistry, 47, 1840 (1969)

Introduction

In a recent paper (1) we have shown that published absorption cross sections obtained at maxima or minima could be in error by as much as a factor of two, and that published line and band profiles are probably erroneous because of a failure to take into account the effects of finite instrumental bandwidths. In this paper we should like to present some measurements that we have performed on N_2 (2), and O_2 (3) at high resolution, and to show that another consequence of poor resolution is a loss of information regarding the physical processes that accompany the absorption.

Results

Molecular Oxygen

We would like to discuss the molecular oxygen results first. Our initial aim was to study the effect of temperature on the absorption of oxygen in the Schumann–Runge system, at an instrumental bandwidth of 0.075 Å. The results of our study of the dependence of the continuum on temperature were published some time ago (4). The dependence of the band structure is more complicated as is indicated in Fig. 1, which covers the spectral range from 1878 to 1894 Å. All three absorption traces were obtained with the same concentration of oxygen in the absorption cell, thus the effects that one sees are due entirely to the redistribution in the ground vibrational and rotational levels. The curve at 600 °K is of special interest as the fraction of molecules in the $v'' = 1$ state at that temperature is 0.0234, and yet the 9–1 band obviously gives rise to more absorption than the 6–0 band. This fact reflects the large increase in Franck–Condon factors from the $v'' = 0$ to the $v'' = 1$ levels due in part to the relatively large (0.4 Å) difference between the internuclear separations of the ground $X^3\Sigma_g^-$ and the excited $B^3\Sigma_u^-$ electronic states. One of the most important findings of the analysis was that all of the upper vibrational levels from $v' = 3$ to 17 were subject to predissociation, the individual rotational lines having half-widths varying from 0.5 to 2.3 cm^{-1}. Predissociation in these bands explains the failure, thus far, to observe fluorescence in the Schumann–Runge bands in the upper atmosphere, and provides an additional source of atomic oxygen between 65 and 95 km, both atoms of which will be left in the ^3P state with kinetic energies of up to 1 eV. We have recently measured this photodissociation rate in the laboratory, as a function of column height, at both 200 and 300° K and the resulting atomic oxygen production rate for the CIRA 1965 standard atmosphere (12) is shown in Fig. 2. The curve shown with the Schu-

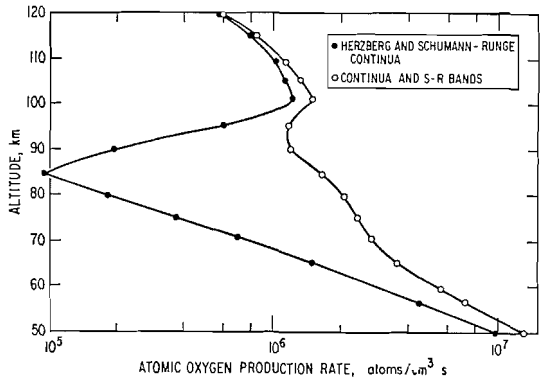

FIG. 2. Comparison of atomic oxygen production rate, between 50 and 120 km, with and without the assumption of predissociation in the Schumann–Runge system.

mann–Runge bands included, is the average of the 200 and 300 °K curves, as, within our experimental error, the results are the same for both temperatures. The additional atoms from predissociation can be seen to fill in the region from 65 to 95 km, giving an overall curve for atomic oxygen production that increases with a decrease in altitude.

Molecular Nitrogen

Figure 3 shows a small portion of the nitrogen absorption spectrum that we have obtained at 0.04 Å bandwidth using photoelectric techniques. We should like to stress that the plot here is of the average cross section over our bandwidth and not the true cross section. For comparison we show some previous experimental results (5, 6). Attempts to fit this curve to theoretical band profiles indicate that the widths of the individual rotational lines are greater than 2 cm^{-1} (compared to Doppler widths of 0.27 cm^{-1}). Line broadening of this magnitude has been reported by Lawrence *et al.* (7) for an absorption band in N_2 at 972 Å. Tilford and Wilkinson (8) have observed intensity anomalies in the emission spectrum of N_2 between 900 and 1130 Å which they ascribe to predissociation, and it seems reasonable to ascribe the broadening seen in absorption to the same phenomenon. We have made a preliminary survey, with 0.038 Å bandwidth, of the absorption bands of N_2 between 800 and 1000 Å, and it appears that most of the bands show widths significantly greater than the corresponding Doppler widths.

We have calculated the production rate of atomic nitrogen in the atmosphere above 150 km assuming (*a*) that all the absorption bands in N_2 between 800 and 1000 Å are indeed predissociated, (*b*) that the room temperature absorption cross sections given by Cook and Metzger (6), Huffman *et al.* (5), Samson and Cairns (9), and Watanabe and Marmo (10) are applicable, (*c*) the solar emission fluxes as given by Hinteregger and Hall (11), and (*d*) the CIRA 1965 standard atmosphere (12) is applicable. The results of this calculation versus altitude are shown in Fig. 4 along with calculated production rates resulting from ion–molecular reactions taken from a recent paper by Ghosh (13). These results indicate that the photoproduction of atomic nitrogen in the upper atmosphere could be a factor of 10^4 greater than has been assumed previously and could contribute significantly to the total production rate of atomic nitrogen in the atmosphere.

The actual photoproduction rate of atomic nitrogen in the upper atmosphere is likely to be different from that shown in Fig. 4, as the use of room temperature absorption cross sections may not be valid at altitudes where the temperature can range from 300 to 1500 °K. The band absorption profiles applicable to the conditions of temperature and pressure in the atmosphere above 120 km, can be calculated from room temperature data, but only when more definitive measurements of the absorption cross sections, band oscillator strengths, and line widths have been made. Account must also be taken of the variation of the Franck–Condon factors with v'' in view of the high probability that, in the upper atmosphere, non-thermal distributions prevail in the ground-state vibrational levels of molecular nitrogen (14).

Conclusion

In conclusion we should like to suggest (*a*) that predissociation in O_2 and N_2 could be of consequence in the chemistry of the upper atmosphere, (*b*) that the calculation of the dissociation rate of N_2 depends on an accurate knowledge of room temperature absorption profiles and Franck–Condon factors, and that the presently published data are insufficient, and (*c*) that physical information of great importance to aeronomic calculations can be lost when insufficient resolution is used in absorption spectroscopy.

Comments, Replies, and Summary

COMMENTS BY G. M. LAWRENCE[1]

The high-resolution absorption measurements of Lawrence, Mickey, and Dressler were made to investigate the relation between electron impact cross-sections and ultraviolet absorption results. They concluded that agreement could be produced by going to low enough pressures and high enough resolution. Thus if one is interested in true absorption coefficients averaged over wavelength one might well consider using electron impact oscillator strengths.

COMMENTS BY J. W. McGOWAN[2]

Preliminary experiments have been carried out in our laboratory on the excitation of N_2 in the vacuum ultraviolet under electron impact. In particular, we have found evidence for the strong dissociative excitation of the first resonance line of atomic nitrogen

$$N_2 + e \rightarrow N(^4P) + N(^4S) + e$$
$$\searrow \rightarrow N(^4S) + h\nu\,(10.3\text{ eV})$$

Measurements were made on N_2 at a pressure near 10^{-6} Torr, using a source of monoenergetic electrons and a photo-multiplier with a LiF window and a KBr photocathode. The spectral sensitivity of our detector is from 1050 to $\sim$ 1450 Å, and therefore responds to radiation from the Lyman–Birge–Hopfield band system and the second negative system as well as the resonance radiation from the lowest ^4P states of the nitrogen atom.

Our preliminary results are shown in the Fig. 1. The approximate value of the cross-section for dissociative excitation is 4×10^{-17} cm^2 for 80 eV

electrons. This has been determined relative to the 2p excitation cross-section of atomic hydrogen.

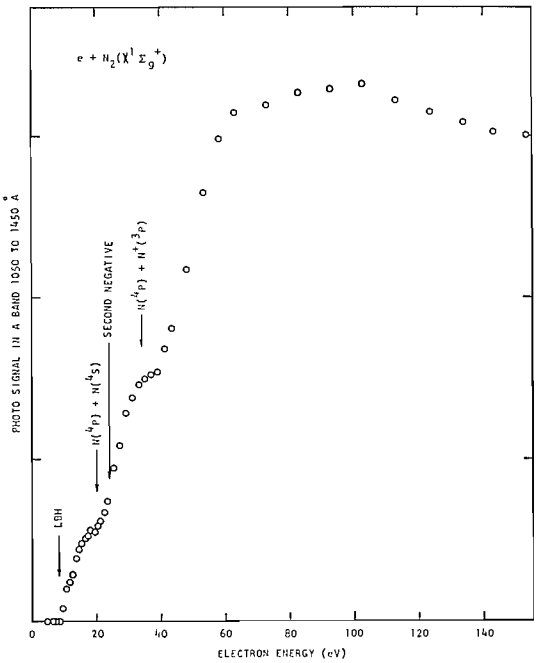

FIG. 1. Plot of photo signal vs. electron energy.

REPLY BY R. E. HUFFMAN

The interesting dissociative excitation process discussed in this comment has not been reported using photon absorption excitation, to the author's knowledge.

SUMMARY BY CHAIRMAN, F. R. GILMORE[3]

Measurements of absorption coefficients for atmospheric gases have been carried out for many years, yet important additions and improvements have just been made recently, and much still remains to be done. These conclusions are evident from R. E. Huffman's authoritative review which began this session. He pointed out that one of the most important problems is getting sufficient spectral resolution for precise measurements in regions where molecular bands or atomic lines are important. This point was reemphasized by the contributed papers of Ackerman, Biaume, and Nicolet, and of Hudson and Carter, which followed. Ackerman presented data on the O_2 Schumann–Runge bands with sufficient resolution to reveal, in considerable detail, the variation of absorption across individual rotational lines. Hudson presented data on N_2 and O_2 with a lesser resolution, but still sufficient to show that many of the line widths are much greater than Doppler widths, due to predissociation. Such predissociated bands may make important contributions to the production rates of atomic nitrogen and oxygen in the upper atmosphere.

As pointed out by both Huffman and Hudson, for atmospheric applications it is often necessary both to obtain good absorption cross sections and to determine the species and excitational states of the photo-absorption products. Much more work is needed in this field. High-resolution spectroscopy frequently provides good clues to the products, but in some cases direct detection schemes seem necessary.

Another area needing more work is the absorption spectroscopy of unstable or excited species, such as atomic oxygen and O_2 $a^1\Delta_g$.

The session concluded with a paper, "The N_2 Vegard–Kaplan System in Absorption", by D. E. Shemansky. This paper has been submitted to the Journal of Chemical Physics, and is not reproduced here. Its results are mentioned briefly in the Summary of the Session on Transition Probabilities and Lifetimes (see below).

Aeronomically important transition probability data

R. W. NICHOLLS
Centre for Research in Experimental Space Science, York University, Toronto, Ontario

Received November 27, 1968

Since the 1963 I.A.G.A. conference at Berkeley our knowledge of radiative transitions which are aeronomically important has been extended particularly into the vacuum ultraviolet region of the spectrum. A brief review is made of the newly established important radiative transitions. Recent experimental and theoretical work on radiative transitions which have aeronomical applications is discussed.

Canadian Journal of Chemistry, 47, 1847 (1969)

Introduction

A review was made (1) at the I.A.G.A. Aeronomy Symposium at the 1963 I.U.G.G. Congress at Berkeley on the state of knowledge of transition probability parameters for radiative transitions in species of aeronomical importance. A wide range of aeronomical phenomena (cold air absorption, hot air absorption, aurora, dayglow, nightglow, twilight glow) were considered there. In this paper, which is not intended to be so extensive, the previous review is supplemented with an account of some of the developments which have occurred in the past few years. The emphasis is more molecular than atomic, and in view of the very large volume of new data treated, reference is made here to papers only.

In the past five years the direction of aeronomical spectroscopy has been by the increased use of rocket, balloon, and satellite techniques to extend the wavelength region of active study into the vacuum ultraviolet region of the spectrum. New firm data in the wavelength region (1000–3500 Å) have been established both in the aurora and in the airglow. Some extensions have also been made in the infrared.

Thus the wavelength region considered in this paper is 1 000 – 10 000 Å. Within this wavelength region height profiles of important species have also been studied, and a continuing debate proceeds on the kinetics of reactions necessary to maintaining the species concentrations. Such work also requires firm knowledge of radiative lifetimes of excited species so that radiative depopulation processes can be accurately compared with collision processes.

For collision processes and reactions, a few hundreds of processes at the most have to be considered and are reviewed in other papers of the symposium. For radiative processes a much greater volume of basic data has to be assessed for all of the thousands of radiative transitions involved. Thus no attempt is made there to present tabular data. There has been a great deal of laboratory and associated theoretical work in the past five years stimulated by the needs of observational aeronomy and astrophysics. Some of this is also reviewed below. Chamberlain's monograph (2) remains an essential reference work to the whole field.

General Concepts

Much of aeronomy consists of diagnostic studies of the upper atmosphere by using the methods of quantitative spectroscopy on auroral and airglow emissions. Clear quantitative discussion of radiative transitions has often been obscured by ambiguous use of the many transition probability parameters which are commonly employed. Tatum (3) has made a very clear exposition of the transition probability aspects of molecular spectra.

The controlling parameters of the $U, v', J' \leftrightarrow L', v'', J''$ radiative molecular transition (symbols conventional (4)) is the transition strength matrix element.

$$[1] \qquad S^{U,v',J'}_{L,v'',J''} = |\int \Psi_{Uv'J'} M \Psi_{Lv''J''} d\tau|^2$$

In most aeronomical situations it is possible to average over the rotational structure of (v',v'') bands. The dominating parameter for such a band is then the band strength

$$[2a] \qquad S_{v'v''} = |\int \psi_{v'} R_e(r) \psi_{v''} dr|^2$$

where the electronic transition moment $R_e(r)$ is defined in eq. [2*b*], and ψ_v are the vibrational wavefunctions.

$$[2b] \qquad R_e(r) = \int \psi_{eu} M \psi_{eL} \, d\tau_e$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

For many band systems it is possible to write eq. [2*a*] in the factored form

$$[2c] \qquad S_{v'v''} = R_e^2(\bar{r}_{v'v''})q_{v'v''}$$

where the *r*-centroid is given by

$$[2d] \qquad \bar{r}_{v'v''} = \int\psi_{v'}\psi_{v''}r\,dr/\int\psi_{v'}\psi_{v''}\,dr$$

and the Franck–Condon factor by

$$[2e] \qquad q_{v'v''} = |\int\psi_{v'}\psi_{v''}\,dr|^2$$

Commonly used transition probability parameters defined in terms of $S_{v'v''}$ are
Einstein *A* coefficient,

$$[3a] \qquad A_{v'v''} \propto \nu^3_{v'v''}S_{v'v''}$$

Einstein *B* coefficient,

$$[3b] \qquad B_{v'v''} \propto S_{v'v''}$$

linear absorption coefficient,

$$[3c] \qquad k_{v'v''} \propto \nu_{v'v''}S_{v'v''}$$

atomic or molecular absorption coefficient or cross section,

$$[3d] \qquad \alpha_{v'v''} \propto \nu_{v'v''}S_{v'v''}$$

intensity or flux,

$$[3e] \qquad I_{v'v''} \propto N_{v'}\nu^4_{v'v''}S_{v'v''}$$

photon mean free path,

$$[3f] \qquad \Lambda_{v'v''} = (k_{v'v''})^{-1} \propto (\nu_{v'v''}S_{v'v''})^{-1}$$

optical depth,

$$[3g] \qquad \tau_{v'v''} = \int k_{v'v''}\,dz \propto \nu_{v'v''}S_{v'v''}$$

oscillator strength,

$$[3h] \qquad f_{v'v''} \propto \nu_{v'v''}S_{v'v''}$$

and radiative lifetime of upper state,

$$[3i] \qquad \tau_{v'} = 1/\sum_{v''}A_{v'v''} = 1/\sum_{v''}\nu^3_{v'v''}S_{v'v''}$$

The band strength dominates all of these, and in that many of them are used diagnostically to determine aeronomic conditions, it is of the greatest importance that firm information be available on band strengths. Thus experimental programs of great variety have been in progress to determine band strengths, and associated theoretical programs have been in progress to study molecular potentials, calculate Franck–Condon factors (which dominate band strengths), and more recently a start has been made to calculate electronic transition moments for simple molecules from an ab initio basis. Until quite recently resort had to be made to experiment for this, as our knowledge of electronic wavefunctions was almost as primitive as the computation power necessary to calculate them to a sufficient degree of accuracy that derived functions of them could be calculated with some confidence. In later sections of this paper we shall very briefly review recent experimental and theoretical work on most aspects of the band strengths for aeronomically important transitions.

The above discussion relates to radiative transitions. Electron collision induced transitions (excitation and/or ionization) may be similarly treated. Cross-sections for excitation and ionization of molecules are controlled by a similar strength factor

$$[4a] \qquad P^{V,v',J'}_{L,v'',J''} = |\int\Psi' V\Psi''\,dr|^2$$

where Ψ's are the respective total wave functions of the system (molecule + electron) before and after collision and V is the potential field in which the electron moves (1, 5, 6). Appeal to the Born–Oppenheimer approximation and to the Born approximation allows eq. [4*a*] to be factored into

$$[4b] \qquad P_{v'v''} = G_e^2(\bar{r}_{v'v''})q_{v'v''}$$

where the perturbation integral $G_e(r)$ involves electronic wave functions of electrons (Ψ_{elec}) and molecule (Ψ_u or Ψ_L)

$$[4c] \qquad G_e(r) = \int\psi'_{elec}\psi_u V\psi''_{elec}\psi_L\,d\tau_e$$

The Franck–Condon factors thus control to a large extent the vibration levels which are excited in electron collisions of molecule, and thus the spectral character of the resulting radiation, provided that the exciting (and/or ionizing) electrons may be represented by plane waves. A classic series of researches by Lassettre and colleagues (see on) in electron energy loss spectroscopy has confirmed how closely the Franck–Condon principle is followed in electron excitation of molecules by relatively energetic electrons, where the Born approximation is applicable.

Aeronomically Important Species and Transitions

With the exception of NO, no great change has occurred during the past five years in the important species and transitions recognized in aero-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

nomical spectra. In contrast, it is apparent from other papers of this symposium that a number of new active species have been proposed to play possible active roles in rate processes. Two atlases of cold air absorption have recently been published (7, 8). Two atlases of airglow spectra have also recently appeared (9, 10). These atlases together with those in Chamberlain's monograph (2) are valuable aids to identification. Krassovsky and Sefov (11) have published a useful review paper on the airglow which lists important emitters. Barth (12, 13) made a most important contribution to the field by firmly establishing NO as an airglow emitter (of the gamma bands). The spectra of N_2, N_2^+, O_2, O_2^+, NO, OH, NI, NII, OI, OII, Na, H, Li, He, and Ca in the airglow and aurora have, in a number of cases reviewed below, been extended into the vacuum ultraviolet and less frequently into the near infrared. A number of the predictions of Swings, Bosman-Crespin, and Arpingny (14) on the nature of the auroral spectrum in the ultraviolet have been borne out. A very useful quantitative review has been made by Marr (15) of the processes which attenuate solar radiation in the atmosphere, particularly in the ultraviolet region of the spectrum. There have been further studies on the emissivity of high temperature air which will not be reviewed here.

The following short list reviews features of atomic and molecular spectra particularly in the vacuum ultraviolet which have been established as important since the last symposium.

Atomic Features

Hydrogen

Lyman alpha at 1216 Å has been recognized as an important feature of the airglow spectrum for some years (16, 17). There is a continuing debate as to whether it is also part of the auroral spectrum (18). Miller, Fastie, and Isler (19) showed that while Lyman alpha, N, O, and N_2 features were detected in the 1050–1550 Å region using rocket techniques, the strength of the Lyman alpha feature seemed to be independent of the orientation of the rocket.

Helium

Krassovsky and Shefov (11) review Soviet interferometric work on the near infrared line at 10 830 Å in the airglow which arises from transition from the metastable 2^3P state at about 21 V to the 2^3S level at about 20 V. The upper state is thought to be excited by energetic photoelectrons produced in photoionizations from solar ultraviolet photons. Tinsley (20) has made similar measurements. Brandt, Broadfoot, and McElroy (21) report observation of the 3889 line of orthohelium in the twilight airglow. This arises from the 3^3P to 2^3S transition.

Oxygen

Vacuum ultraviolet transitions of O and N have been observed in both the aurora and the airglow spectra. For example Fastie, Crosswhite, and Heath (22) reported the strong transition between $^3S_1$ and ^3P ground state of OI. Components of this line lie at 1302, 1304, and 1306 Å. Also observed were the forbidden transition between $^5S_2$ and the ground state at 1355 and 1358 Å. The 1304 feature is one of the strongest in the vacuum ultraviolet spectrum of the aurora.

Nitrogen

Fastie, Crosswhite, and Heath (22) tentatively identified the NI 1200 Å ($2p^3$ 4S–$2p^2$ ^3S) line in the wing of Lyman alpha. The associated 1134 Å NI line was not observed because of decreasing instrumental sensitivity.

Molecular Features

There have been significant extensions to our knowledge of important molecular transitions in the aurora and airglow in recent years, particularly in the ultraviolet. The most important of these is the observation of NO gamma bands by Barth in the airglow and the observation of the Lyman–Birge–Hopfield bands of N_2 in the aurora by Fastie and colleagues. In addition to observational work there has been much activity in developing phenomenological theories of excitation of atmospheric luminosities by electron and photon streams by Barth, Green, and colleagues, in many of which account is taken of numerous molecular band systems.

Nitrogen

The band-system which has received the greatest attention is the $a^1\Pi$–$X^1\Sigma$ Lyman–Birge–Hopfield system of N_2. This has been studied in auroral spectra by Fastie, Crosswhite, and Markham (23), Isler and Fastie (24), Murcray (25), and Fastie, Miller, and Isler (26). There has been speculation that the Birge–Hopfield ($b^1\Pi$–$X^1\Sigma^+$) and the Watson–Koontz ($h^1\Sigma_u^+$–$X^1\Sigma_g^+$) band systems also occur in the auroral spectra. The Lyman–Birge–Hopfield system is the major emitter. Definitive identification or refutation of

For personal use only.

other nitrogen systems may be possible through a photographic study of the vacuum ultraviolet spectrum of the aurora using rocket techniques such as is in progress in the author's laboratory. Recent work suggests that the Lyman–Birge–Hopfield system may well be the only strong emitter. It is surprising, however, that in view of the strength of the N_2^+ ($B^2\Sigma$–$X^2\Sigma$) First Negative spectra in the aurora that the Second Negative bands ($C^2\Sigma$–$X^2\Sigma$) which lie in the same wavelength region as the Lyman–Birge–Hopfield, have not yet been observed. About 23 V is required to excite them directly from the ground state.

In the phenomenological theoretical study of excitation of the ultraviolet spectrum of the aurora by the "stopping" of electron beams, Green and Barth (27) include contributions from the First Negative and Meinel bands of N_2^+, the Vegard–Kaplan, First Positive, Second Positive, Lyman–Birge–Hopfield, Birge–Hopfield, Janin–Watson–Koontz, Herman–Baydon band systems of N_2. This work is part of an extensive program of similar calculations by Green and colleagues. See, for example, Stolarski and Green (28), Green (29), Green and Stolarski (30), and Green and Barth (31). Recent rocket studies by Fastie, Miller, and Isler (26) suggest that some of the estimated contributions from band systems other than the Lyman–Birge–Hopfield may be too large. The Second Negative system of N_2^+ does not seem to have been considered.

Nitric Oxide

One of the most important observations of the past few years is that of Barth (12, 13) of the NO ($A^2\Sigma$–$X^2\Pi$) gamma bands in the spectrum of the airglow. He reports that no beta ($B^2\Pi$–$X^2\Pi$) bands were observed.

Oxygen

Many observations have been made of the O_2 atmospheric ($b^1\Sigma_g^+$–$X^3\Sigma_g^-$) and O_2 infrared atmospheric ($a^1\Delta_g$–$X^3\Sigma_g^-$) emissions from the airglow. No new band systems of O_2 have been observed. Hennes (142) reports extended observations on the O_2($A^3\Sigma$–$X^3\Sigma$) Herzberg I system into the 2300–3800 Å region in a rocket airglow observation. It had previously been observed, for many years, over a small wavelength region from ground-based observations. Barth (32) and Tohmatsu (33) have suggested that there may be a contribution to the dayglow from fluorescently excited O_2 Schumann–Runge ($B^3\Sigma$–$X^3\Sigma$). Although most photon–$O_2(X)$ collisions would dissociate the O_2, some transitions to bound B-levels could re-radiate and redistribute the radiation to longer wavelengths, according to the Franck–Condon principle. The predicted spectrum has been calculated by Barth and Tohmatsu between 1800 and 3000 Å but has not yet been observed.

Continua

The air afterglow continuum from NO + O $\rightarrow$ NO_2^* $\rightarrow$ NO_2 + $h\nu$ (2) which has been one possible contributor to the airglow continuum may be reinforced by the continuum from inverse photodissociation of ozone in the Chapuis region (Gadsen (34)). The process involved is $O_2(a^1\Delta)$ + $O(^3P)$ $\rightarrow$ O_3 + $h\nu$. This additional process may account for the peak in the airglow continuum at 6000 Å.

Experimental and Theoretical Work

Much experimental and theoretical work has been done during the past 5 years to provide reliable and firm data on the transition probability (and related) parameters reviewed in Section II for species of aeronomical importance.

Major trends in experimental work have been

Wavelength Measurements on New Band Systems

See, for example, the work of McFarlane (35) on new infrared band systems of N_2 and of Degen (145) on ultraviolet systems of O_2.

Intensity Measurements in Emission and Absorption

See, for example, the work of Chandriah and Shepherd (36) on band strengths of the N_2 Vegard–Kaplan system, the work of McEwen and Nicholls (37) on band strengths of the Lyman–Birge–Hopfield system of N_2, and the work of Cook and Ogawa (38) on the absorption photoionization spectrum of N_2.

Lifetime Measurements of Excited States

See, for example, the work of Jeunehomme (39, 40) on the radiative lifetimes of the $C^3\Pi$ and $B^3\Pi$ states of N_2 and the $B^2\Sigma$ state of N_2^+ from the decay time of discharges, the work of Fink and Welge (41) and of Hesser and Dressler and colleagues (42, 70) on the radiative life of many molecular states by the phase shift method. Transition oscillator strengths are often calculated from such measurements.

Electron Energy Loss Spectroscopy

Lassettre and colleagues in a distinguished and extensive series of papers in J. Chem. Phys. since

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

1964, have studied the electron energy loss spectra in many gases, including atmospheric gases. They have compared and correlated their cross section measurements with the equivalent optical transition probabilities by appeal to a property of the Bethe generalized oscillator strengths (43). The inelastic cross section is a function of the generalized oscillator strength which, in the limit of zero electron momentum change, becomes the optical transition probability. See ref. (44) for discussion of the relevant theory, and ref. (45) for an application of work to the Lyman–Birge–Hopfield system of N_2. See also Lassettre's review in this symposium.

Similar major trends in theoretical work have been

Ab Initio Quantal Calculations of Molecular Properties

Within the past few years it has become possible, using the capabilities of large electronic computers, to make a start to study from first principles the detailed properties of complex multi-particle systems such as light diatomic molecules, to a sufficient degree of accuracy that comparison with experiment may fairly confidently be made. In early work of this nature the sheer volume of calculation of wave functions precluded the study of them at more than one internuclear separation. The situation is rapidly changing and realistic ab initio calculations of molecular properties are being made in a number of laboratories, notably at the University of Chicago. The topic will not be pursued further here except to mention a recent review of Ohno (46) on calculations on O_2 and N_2.

Molecular Potentials, Molecular Wavefunctions, and Derived Quantities

It is clear from the equations of the section "General Concepts" that the Franck–Condon factors and *r*-centroids are important desiderata for the diagnostic interpretation of aeronomical spectral intensities. These quantities are derived from molecular vibrational (and vibration–rotation) wavefunctions which are themselves solutions of the Schrödinger equation for the one dimensional molecular vibrating rotator appropriate to a specific molecular potential. Thus much effort has been expended in compiling accurate and realistic numerical molecular potentials, using a variety of methods and using experimental measurements of molecular properties as basic data. Gilmore (47, 48) has calculated a definitive set of potentials of N_2, O_2, NO and their ions. Similar work of this nature has been done by Vanderslice (49) and Benesch, Vanderslice, Tilford, and Wilkinson (50). See also the review of Spindler (51) and of Steele, Lippincott, and Vanderslice (144).

There has also been much effort in a number of laboratories to develop efficient and comprehensive computer programs to solve the wave equation numerically appropriate to the numerical potentials and to compute derived quantities of these wavefunctions such as Franck–Condon factors and *r*-centroids. Such work has been done by Jarmain (52–54), Cooley (55, 56), Cashion (57), Zare, Larson, and Berg (58), and by Spindler (51). Work of a similar nature is in progress in the E.S.S.A. laboratories at Boulder (59), at the Air Force Special Weapons Laboratory, Kirtland, New Mexico (60), and in the author's laboratory (61) where a very comprehensive program has been prepared to produce automatically Franck–Condon factor and *r*-centroid arrays (including rotation–vibration interaction) for the variety of realistic potentials. Aeronomic and astrophysical transitions have been emphasized in this work and the results will shortly appear in a number of monographs.

There has also been some activity in the calculation of Franck–Condon factor arrays for a number of transitions appropriate to analytic potentials. A review has been made (62) of nearly 100 transitions studied by the author using the Morse model of potential, and ways by which interpolation among such arrays may be carried out. Not only have radiative transitions between bound states been considered but also excitation and ionization transitions of aeronomical interest with applications to eq. [4*b*] have been published (6, 63). Studies have also been made of Franck–Condon densities of photodissociation continua of O_2 (64, 65). The matrix multiplication property (66) of vibrational overlap integrals of transitions between three cyclically ordered states i, j, k

$$[5] \qquad (i,k) = \sum_j (i,j)(j,k)$$

may provide another rapid way of roughly estimating Franck–Condon factors.

The *r*-centroid concept has been under debate, particularly the circumstances under which it breaks down. A recent detailed study by Drake (67, 68) has shown explicitly the circumstances under which the concept is rigorously valid.

These include the large majority of aeronomic band systems.

Phenomenological Studies of Aeronomical Luminosities

Reference has already been made to the work of Green, Barth, and colleagues (see ref. 69) and relevant references under nitrogen in section above) on the use of phenomenological models for electron stopping power and fluorescence efficiencies to predict spectral energy distributions of aurorae and airglows in planetary atmospheres. This work is briefly discussed in the communication of Peterson at the symposium.

We now make a brief review of specific experimental and theoretical studies of aeronomic species and transitions.

Transitions: A, Molecular Transitions

Nitrogen (N_2)

Lifetime Measurements

Some of the most important experimental work on N_2 during the past five years has been lifetime measurements on electronic states. The triplet states have been the most studied. Jeunehomme (40) has measured the lifetimes of levels of the $B^3\Pi$ state as between 4 and 8 μs, which is equivalent to an oscillator strength f_{00} of the (0,0) band of the First Positive system of 2×10^{-3}. A number of measurements have been made on the lifetimes of levels of the $C^3\Pi$ state which is the upper state of the Second Positive system. Fink and Welge (41) measuring decay of the (0,0) and (0,1) Second Positive bands established a lifetime of 2.7×10^{-8} s for the $v = 0$ level from which an oscillator strength of the (0,0) band of 6.3×10^{-3} was inferred. Jeunehomme (39) measured the lifetime as 47×10^{-9} s, in agreement with the early work of Bennett and Dalby (71). The equivalent oscillator strength of the (0,0) band is 1.89×10^{-2}. He explains the discrepancy with the work of Fink and Welge in terms of recombination–cascade process. The metastable $A^3\Sigma$ state has received attention from a number of workers. Brower and Spieweck (72) measured the decay of the Vegard–Kaplan bands and find the lifetime of the $v = 0$ level to be about 10 s, in contrast with the previous work of Zipf (73), Noxon (74), and Phillips (75) leading to about 1 s and in rough agreement with an early suggestion of Hunten (76) of about 30 s. On the basis of measurements on the absorption coefficients of Vegard–Kaplan bands, Shemansky (77) reports a lifetime of the $A^3\Sigma$ state of 1.27 s (see his communication to the symposium). Brennen (78), on the basis of pressure dependence of N_2 band intensities, has suggested lower limits for the $B(v = 11)$ and $A(v = 0)$ state lifetimes as 2.4 μs and 12 s, respectively. It appears that Dunford's (79) indirect estimate of the A lifetime of 0.08 s is now unacceptable. Peterson (80) reported at the symposium lifetime measurements of the $A^2\Pi$ state of N_2^+ of 12.7 μs from decay of Meinel Band intensities in an N_2^+ molecular beam. Lawrence (81) reported on vacuum ultraviolet intensity measurements on N_2, C, N, O, using the phase shift method.

Intensity Measurements

Intensity measurements have been made in emission and absorption on a number of aeronomically important band systems of N_2.

(i) Vegard–Kaplan System ($A^3\Sigma_u^+$–$X^1\Sigma_g^+$): Chandriah and Shepherd (36) have measured the intensities in emission of 18 bands of the Vegard–Kaplan system, interpreted the results in terms of electronic transition moment variation, and reported an array of relative band strengths. Their measurements are in good accord with those of Carleton and Papaliolios (82) which were used by Nicholls (1) at the last symposium to place band strengths for the system on an absolute basis.

In view of the balance of experimental evidence cited above that the lifetime of $A^3\Sigma_u^+$ levels is about 1 s, it does not appear necessary to radically modify the absolute transition probabilities for Vegard–Kaplan bands presented in ref. 1.

(ii) Lyman–Birge–Hopfield System ($a^1\Pi_g$–$X^1\Sigma_g$): Intensity measurements have been made in emission on this system by McEwen (37, 83) who showed, as had been previously suggested (84), that the electronic transition moment was relatively insensitive to internuclear separation, and thus the band strengths followed Franck–Condon factors. These data may be placed on an absolute basis by use of the oscillator strengths of 10 bands of the $v'' = 0$ progression measured in absorption by Ching, Cook, and Becker (85). The results agree with those of McEwen, and the oscillator strengths of bands lie in the $1–5 \times 10^{-6}$ region. Vanderslice, Wilkinson, and Tilford (86) have confirmed the 1/3 ratio of electric quadrupole to magnetic dipole nature of the transition.

(iii) Other Vacuum Ultraviolet Band Systems: Appleton and Steinberg (87) using absorption through shock-heated N_2 have placed upper

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

limits on the oscillator strengths of the Birge–Hopfield $b^1\Pi$–$X^1\Sigma$ and $b'^1\Sigma$–$X^1\Sigma$ band systems which may have a place in the vacuum ultraviolet auroral spectrum. The absorption coefficient of N_2 between 1000 and 580 Å, which includes a number of potentially important band systems for the auroral spectra, has been measured by Huffman, Tanaka, and Larrabee (88, 89). The absorption and photoionization cross sections of N_2 and O_2 in the wavelength region 303–1037 Å have been measured at strong solar emission line wavelengths by Sampson and Cairns (90). Photoionization and absorption cross sections of N_2 and O_2 in the 600–1000 Å were measured by Cook and Metzger (91) and Cook, Ching, and Becker (92). Photoionization cross section of N_2 in the 734–805 Å region were studied by Cook and Ogawa (38). This work is discussed by Huffman at the symposium (93).

Theoretical Work

Insofar as theoretical work on N_2 is concerned, reference has been made earlier to the work of Gilmore (48) on potential curves. Benesch, Vanderslice, Tilford, and Wilkinson (50) have provided another authoritative set of potential curves for N_2 states below 11 eV derived from a critical assessment of molecular data. They point out inconsistencies in some of the similar curves computed by Zare, Larsen, and Berg (58) which in part invalidate some of the most useful Franck–Condon factor tables published by them for many N_2 transitions appropriate to realistic potentials. In two further papers (94, 95), Vanderslice, Tilford, and Wilkinson present Franck–Condon factor tables for a large number of N_2 transitions computed using realistic potentials. They point out that in a number of cases, earlier calculations using Morse potential are still quite acceptable. Halmann and Laulicht (96–100) published arrays for some N_2 and other band systems using the Morse and realistic potentials for isotopically substituted molecules. Nicholls (63) published Morse arrays for a number of excitation and ionization transitions of N_2.

Ionized Nitrogen (N_2^+)

Lifetime Measurements

Most of the work has been on $v' = 0$ level of the First Negative system for which the following data applies. Hesser and Dressler (42) quote a value of 59×10^{-9} s, Jeunehomme (39) quotes a value of 71.5×10^{-9} s, and Fink and Welge (41) quote a value of 45×10^{-9} s.

Intensity Measurements

Apart from the photoionization absorption work cited above few laboratory intensity measurements have been made recently. Some work on the Meinel and Second Negative systems is in progress in the author's laboratory.

Theoretical Work

A number of the papers cited above contain new data for N_2^+ band systems.

Oxygen (O_2)

Lifetime Measurements

Badger, White and Whitlock (101) in an absorption and curve of growth study of the $a^1\Delta$–$X^3\Sigma$ band at 1.26 μ have found that the lifetime of the isolated $a^1\Delta$ molecule is 45 min, and that this is reduced to 9 min at 1 atm.

Intensity Measurements

Ogryzlo and co-workers (102–104) have studied the intensity of the 6340 Å band of oxygen and shown kinetically that it most likely arises from the radiating collisions complex $(O_2(a^1\Delta))_2$. Intensity measurements have also been made on this feature in atmospheric absorption by Dianov-Klovov (105, 106) who in the last of these papers determines the oscillator strengths of the atmospheric bands ($b^1\Sigma$–$X^3\Sigma$) and the infrared atmospheric bands ($a^1\Delta$–$X^3\Sigma$) as 2.7×10^{-10}, respectively. He measured the lifetime of the $(O_2(^1\Delta))_2$ complex as greater than 0.3×10^{-13} s. Wark and Mercer (107) have measured the Einstein A coefficient of the atmospheric band as 0.145 s^{-1}.

Herzberg I ($A^3\Sigma_u^+$–$X^3\Sigma_g^-$) System: Degen and Nicholls (108) using a newly developed laboratory source of the bands (109) have measured the intensities of 36 bands of the system in the 2590–4880 Å region of the spectrum (110). It was found that the electronic transition moment was relatively independent of internuclear separation and that the relative band strengths follow the Franck–Condon factors quite closely. Some absorption measurements on the same system and its associated photodissociation continuum are in progress in the author's laboratory. Blake, Carver, and Haddad (111) have made some measurements on the continuum.

Schumann–Runge ($B^3\Sigma_g^-$–$X^3\Sigma_g^-$) System: The Schumann–Runge photodissociation continuum transition is one of the strongest sources of free atomic oxygen in the upper atmosphere (15). It has been studied by Metzger and Cook (112), Huffman, Tanaka, and Larabee (89), Goldstein and Mastrup (113), and Evans and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Schexnayder (114). Absorption measurements were made on isotopic bands by Halmann (96).

Vacuum-Ultraviolet Absorptions of O_2: The absorption coefficient of oxygen in the vacuum ultraviolet has been studied by Huffman, Larrabee, and Tanaka (115, 116) and Matsungaga and Watanabe (117).

Theoretical Work: Franck–Condon factors for O_2 transitions have been provided by Nicholls (118) for Morse models of potentials. Hubisz and Nicholls (61) have comparable unpublished data for Klein–Dunham potentials. Isotopic Franck–Condon factors were provided for the Schumann–Runge bands by Hallmann and Laulicht (97–100). Jarmain and Nicholls (64, 65) have made theoretical studies on the Franck–Condon densities of the Herzberg photodissociation continuum.

Ionized Oxygen (O_2^+)

Wavelength Measurements

Linton (119) has reported new bands and new vibrational assignments for bands of the O_2^+ Second Negative ($A^2\Pi_u$–$X^2\Pi_g$) system.

Lifetime Measurements

Jeunehomme (120) reports lifetime measurements and oscillator strengths for the First and Second Negative systems.

Theoretical Work

Nicholls (121) has published Franck–Condon factors for the O_2 First Negative and Second Negative systems.

Hydroxyl (OH)

Few recent laboratory measurements have been made on the vibration rotation spectrum of OH which makes such an important contribution to the airglow. Ferguson and Parkinson (122) present some new calculations on band strengths for this system. The violet electronic system ($A^2\Sigma$–$X^2\Pi$) has been more fully studied; Anketell and Pery-Thorne (123) and Anketell and Learner (124) have measured oscillator strengths of individual lines by the hook method. Bennett and Dalby (125) and Nicholls (141) have published Franck–Condon factors and band strengths.

Nitric Oxide (NO) (Gamma Bands)

The gamma band system of NO has been recently reported in the airglow by Barth. Recent laboratory and theoretical work on this band system is as follows. Jeunehomme (126) reports lifetime measurements and band strengths, as do Callear, Pilling, and Smith (127) and Marr (128). Nicholls (129) reports Franck–Condon factors.

Attention is drawn to the useful and recent privately circulated report by Main (130) on molecular transition probabilities of molecules.

Transitions: B, Atomic Transitions

Oscillator strengths of aeronomically important hydrogen lines (e.g. Lyman alpha) are available from exact theory (131). There have also been a number of recent extensive theoretical studies on atomic oxygen and nitrogen lines (132, 133) particularly those in the ultraviolet. See also the work of Kelly and Armstrong (134). Measurements have been made on OI line oscillator strengths by Parkes, Keyser, and Kaufman (135), McConkey, Burns, Moran, and Emeleus (136), Savage and Lawrence (137), LeBlanc, Oldenberg, and Carleton (138), and Morse and Kaufman (139). The measurements on OI and NI transition oscillator strengths of Prag, Fairchild, and Clark (140) are in good agreement with theory.

Acknowledgments

This work was supported in part by research grants from the National Research Council of Canada and contracts from the Department of Defence Production of Canada. The preparation of this paper would have been impossible without the skillful and effective bibliographic assistance of Mrs. Sandra Innanen.

Vacuum ultraviolet transition probabilities in C, N, O, and N_2

GEORGE M. LAWRENCE
Douglas Advanced Research Laboratories, Huntington Beach, California 92647

Received November 27, 1968

A review is made of the recent works on the transition probabilities for C, N, O, and N_2 in the vacuum ultraviolet.

Canadian Journal of Chemistry, 47, 1856 (1969)

Radiative lifetime measurements can provide accurate transition probabilities by bypassing the difficult task of determining absolute densities. With pulsed excitation, one determines a radiative lifetime by analysis of the observed decay curve. Another method, using radio frequency techniques, is the phase shift method, in which the phase delay between sine wave modulation of

TABLE I

f values, O(I), 1302 Å

Authors	Method, source of absolute scale	*f* value (× 1000)	Time (ns)	Reference	Year of work
Morse and Kaufman	Absorption, gas titration	33 ± 11	2.6	11	1965
Parkes, Keyser, and Kaufman	Absorption, gas titration	21 ± 3	4.0	12	1967
Savage and Lawrence	Phase shift lifetime	35 ± 4	2.4	8	1966
Boldt and Labuhn	Seeded arc, Saha equilibrium	180 ± 45	0.5	4	1967
Hesser and Gaillard	Phase shift lifetime	50 ± 9	1.7	10	1968
Lawrence	Pulse lifetime	46.3 ± 1.2	1.82	6, 7	1968

the excitation and the modulation of the emitted light is measured as a function of frequency. Results using the phase shift method are reported by Lawrence and Savage (1) for "resonance" lines of B, C, N, and their ions. The measurements have estimated error limits on the order of $\pm 15\%$ and can be used to make 20% corrections in some of the arc measurements compiled in the NBS tabulation (2). One important conclusion from the measurements is that central field calculations yield transition probabilities for partially filled p shells which are incorrect by factors of 3 or so. Calculations by Weiss (3) using extensive configuration mixing for C(I) and C(II) yield results within 25% of experiment. The resonance transition probabilities for O(I) at 1302 Å are not as well understood as there is a spread of an order of magnitude in the literature values. Measurements subsequent to those referenced by Professor Nicholls have been made by Boldt and Labuhn (4), Hesser and Gaillard (5), and by Lawrence (6, 7). Table I lists the *f* values. A major source of ambiguity in the lifetime measurements is the cascade correction. For O(I) 1302 Å measured with CO as a sample gas, this correction turned out to be larger than expected (8). The maximum cascading fraction from O(I) 1302 Å is 3.0 for CO, 1.6 for O_2, and 0.95 for H_2O. Such measurements of cascade amounts were made by numerical analysis of pulse-decay curves (9) and can be used to provide vacuum ultraviolet excitation functions by normalization against visible spectra.

Phase shift lifetimes for spectra of H_2, N_2, N_2^+, CO, CO^+, NO, NO^+, BF, CO, BCl, and CO_2^+ are reported by Hesser (10).

Time of flight measurement of N_2 and N_2^+ lifetimes[1]

M. HOLLSTEIN[2], D. C. LORENTS[3], J. R. PETERSON, and J. R. SHERIDAN[4]
Stanford Research Institute, Menlo Park, California 94025

Received November 27, 1968

Lifetime measurements have been carried out on the N_2 first positive and N_2^+ Meinel systems by observing the spatial decay of radiation from fast beams. The neutral beam is excited by near-resonant charge transfer, and the N_2^+ excitation originates in the ion source. The (2,0), (3,0), (3,1), (5,2), (9,5), and (12,8) first positive bands have been measured and the results compare favorably with Jeunehomme's values. The Meinel studies are apparently the first to yield well-defined values for that system. We obtained 12.2 ± 0.2, 11.4 ± 0.2, and 12.2 ± 0.9 μs for the $v' = 3$, 4, and 5 levels, respectively.

Canadian Journal of Chemistry, 47, 1858 (1969)

Introduction

Oscillator strengths and transition probabilities for molecular bands have been determined experimentally by measuring the absorption or emission of radiation by a gas in a state of equilibrium at a known temperature, or by measuring radiative lifetimes. Radiative lifetimes have generally been measured by exciting a gas by a shock wave, discharge, or electron beam and observing the time decay of light in a specified wavelength interval emitted from the excited gas.

We have made direct measurements of lifetimes by using a time of flight method in which the desired species is excited in a monoenergetic beam and the variation in intensity of emitted light with distance along the beam is measured. In the case of neutral species, beam particles are excited in near-resonant charge transfer collisions. The desired species is isolated by mass analysis and ion–neutral separation. The time of flight technique avoids problems of collisional excitation and deactivation, and radiation trapping. The problem of interference from overlapping bands of other emitting systems is eliminated by isolation of the emitting species of interest. Since we excite neutral states of interest in near-resonant electron capture collisions, which preferentially populate the states of interest, problems resulting from cascade contributions to the observed emissions are greatly reduced.

Apparatus and Technique

Ions produced in an electron bombardment ion source (50 eV electrons) are focused, accelerated to energies from 400 to 2500 eV, and mass analyzed before entering an oven where near-resonant electron capture collisions with gases or alkali vapors can take place. After traversing the oven, the remaining ions are deflected from the beam. For lifetime measurements of ion states, the oven is evacuated and the ion beam is allowed to pass directly to the observation region. Figure 1 shows a schematic diagram of the apparatus. Typical operating pressures are 5×10^{-5} Torr in the ion source, about 5×10^{-2} Torr in the oven, 5×10^{-6} Torr in the center chamber, and 4×10^{-7} Torr in the observation chamber.

In the observation chamber, light is alternately sampled from two segments of the beam 2 cm long and 15 cm apart. This is accomplished by using three mirrors, two fixed and one rotatable, as shown in Fig. 2, to direct light alternately from each of the two beam segments through a lens and an interference filter onto the photocathode of a refrigerated EMI type 9558 photomultiplier. The relative intensity for each segment of the beam is determined by counting photoelectron pulses with pulse analyzing and counting circuits having a pulse-pair resolution of 100 mμs. Typical counting rates range from 100 to 10^4/s.

When the lifetimes of neutral species are measured, the background signal, obtained when the ion beam is deflected just before entering the oven, is subtracted from the signal. This background includes dark counts from the photomultiplier and any signal resulting from neutrals present in the beam before it enters the oven. The remaining signal, therefore, consists only of emissions from neutrals produced in the oven. When lifetimes for excited states of ions are measured, the background signal resulting when the ions are deflected from the beam after traversing the oven (which is then empty of vapor) is subtracted from the signal. The latter background includes dark counts and any signal resulting from neutrals present in the beam. For both ion and neutral species, the total measured background signal is, at most, a few % above that resulting from dark counts alone. In the case of neutral species, this reveals the relatively high efficiency of the near-resonant, electron capture collisions in producing the desired excited states.

The total flux of ions and/or neutrals in the beam is monitored with a secondary emission detector with

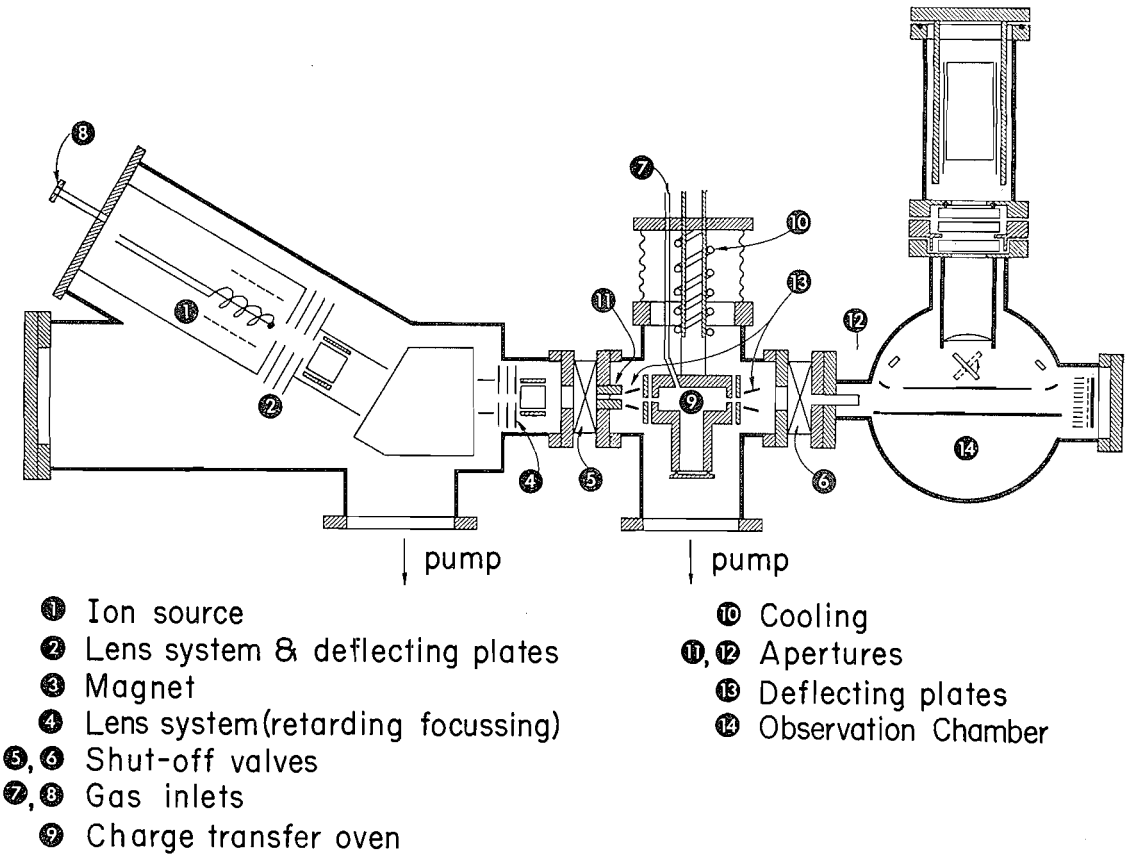

FIG. 1. Schematic diagram of the apparatus.

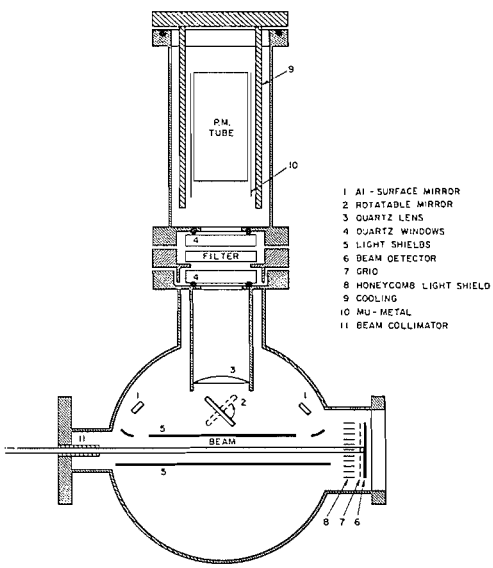

FIG. 2. Observation chamber.

appropriate light baffles to prevent fluorescence at the beam collector surfaces from producing an optical signal.

The optical system is adjusted so that the efficiency is very nearly (within 5%) the same for the detection of light from the two segments of the beam. This relative efficiency is periodically measured by observing light produced under conditions such that the light emitted from the two segments of the beam has the same intensity. As an example, we have used for this purpose the light emitted in the region of 3914 Å, produced in $He^+ + N_2$ collisions at low target gas pressures.

The relative detection efficiencies, $f_1(x)$ and $f_2(x)$, functions of position x along the first and second beam segments, are calculated from the geometry and also experimentally determined by measuring the optical signal from a uniform source as a function of the position along the beam axis. Both methods of determining $f_1(x)$ and $f_2(x)$ agree well.

Lifetimes are measured for a range of velocities from 0.5×10^7 to 1.3×10^7 cm/s. A lack of velocity dependence in the measurements is evidence that the overall relative detection efficiencies for the two beam segments have been properly corrected for, and that no significant

contribution to the signal comes from multiple exponential decays.

Reduction of Data

The variation in the intensity of light from excited beam particles as a function of the distance, x, along the beam is given by

$$[1] \qquad I = I_0 \exp(-x/\tau v)$$

where τ is the lifetime of the excited state and v is the particle velocity.

The optical signals, I_1 and I_2, observed from two beam segments of length a and separated by a distance b are then given by

$$[2] \qquad I_1 = \alpha K \int_0^a f_1(x) \exp(-x/\tau v)\, dx$$

and

$$[3] \qquad I_2 = K \exp(-b/\tau v) \int_0^a f_2(x) \exp(-x/\tau v)\, dx$$

where K is a constant for a given initial flux of excited beam particles and target gas density, α is the ratio of the total detection efficiency for the first beam segment to that for the second beam segment, and $f_1(x)$ and $f_2(x)$ represent the variation in detection efficiency as a function of position along the first and second beam segments, respectively.

The ratio of the measured signals is then

$$[4] \qquad I_1/I_2 = \alpha R(\tau v) \exp(b/\tau v)$$

where

$$R(\tau v) = \int_0^a f_1(x) \exp(-x/\tau v/dx) \int_0^a f_2(x) \exp(-x/\tau v)\, dx$$

The lifetime is then given by

$$[5] \qquad \tau = \left[\frac{v}{b}(\ln I_1/I_2 - \ln \alpha R)\right]^{-1}$$

For the conditions of our experiment, $R(\tau v)$ is always very close to 1 and the lifetime is obtained directly from eq. [5] by letting $R = 1$. However, a computer program has also been used to calculate τ from eq. [5] more exactly by using the known values of $f_1(x)$ and $f_2(x)$ and an iterative procedure.

Results

The first positive system of N_2 was used to determine the lifetime of the $B^3\Pi_g$ state of N_2. This state follows the rapid (0.047 μs) decay of the $C^3\Pi_u$ state which is produced by the electron capture of N_2^+ ions on Rb. The lifetime measurements were made at least 2 μs after the initial excitation, and all cascading from the C state had taken place.

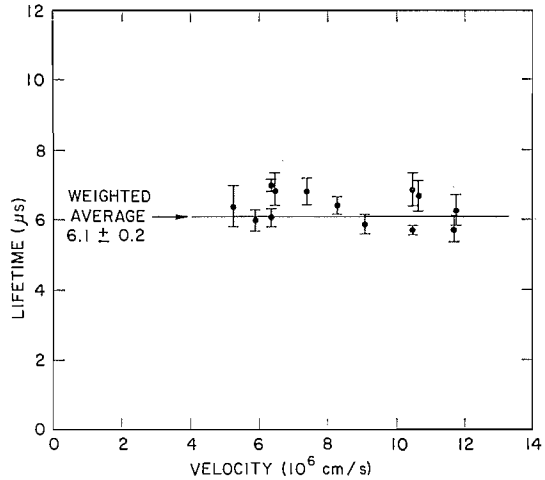

FIG. 3. Lifetime measurements for the $v' = 5$ level of the $B^3\Pi_g$ state of N_2 at various beam particle velocities.

A typical set of data is shown in Fig. 3 for the $v' = 5$ vibrational level of the $B^3\Pi_g$ state of N_2. The lifetime of this level was determined from the spatial decay of the 6705 Å (5,2) band of the first positive system. The errors shown represent the root mean square deviation of the data used for the corresponding points in the figure and arise primarily from the statistics of photon counting and from small beam fluctuations.

Lifetimes for the $v' = 2$, 9, and 11 and 12 (combined) levels of the $B^3\Pi_g$ state of N_2 were determined from the spatial decay of the 7753 (2,0), 5906 (9,5), 5804 (11,7) and 5755 Å (12,8) bands, respectively, of the first positive system of N_2. The lifetime for the $v' = 3$ level was measured by observing the spatial decay of both the 6875 Å (3,0) band and the 7626 Å (3,1) band. Both of the two latter measurements yielded the same lifetime, thus giving further evidence for the validity of the measurements. The results for the first positive system are shown in Table I along with the results of Jeunehomme (1) who measured the temporal decay of light from states excited in a discharge, used a computer program to separate multiple exponential decays, and extrapolated to zero pressure to obtain collision-free values. There is

good agreement between our results and those of Jeunehomme, with a possible discrepancy for $v' = 2$ which is, however, within the combined experimental errors.

We have also determined the lifetimes for the $v' = 3$, 4, and 5 levels of the $A^2\Pi_u$ state of N_2^+ from the spatial decay of the (3,0), (4,1), and (5,1) bands of the Meinel system of N_2^+, respectively. The $N_2^+(A^2\Pi_u)$ state is produced in the ion source, and sufficient quantities to permit measurement are left in the beam when it reaches the observation chamber about one meter from the source. Pressures in the observation chamber are about 4×10^{-7} Torr under these conditions. Increasing this pressure fivefold had no effect on the data.

The results of the Meinel measurements are also given in Table I. The lifetimes are about four times longer than the rough estimate made by Sheridan, Oldenberg, and Carleton (2).

Summary

SUMMARY BY CHAIRMAN,
F. R. GILMORE[1]

Professor R. W. Nicholls opened the session with an able review of the new information on radiative transition probabilities which has been obtained since the last I.A.G.A. Symposium in 1963. Activity in this field has greatly increased, and Nicholls was able to reference nearly a hundred measurements of radiation intensities or lifetimes of atmospheric species, as well as several theoretical calculations. The considerable amount of new information on spectroscopic constants, potential curves, and Franck–Condon factors was also itemized. Reasonably good information on a majority of the transitions that are important to aeronomy is now available, although there are still a number of gaps and a few discrepancies.

After the review paper, G. M. Lawrence discussed the experimental advantages of determining transition probabilities by measuring lifetimes, and listed a number of very recent lifetime measurements on atmospheric species by himself and others. These new data fill in important gaps, especially for atomic oxygen and nitrogen.

The following paper, by Hollstein, Lorents, Peterson, and Sheridan, presented results obtained by a relatively unexploited method: measuring the decay of radiation along a molecular beam. Lifetimes for the N_2 First Positive bands were obtained which agreed with previous work, and the lifetimes of three N_2^+ Meinel bands were found to be about 12 μs.

The session concluded with a paper by D. E. Shemansky and N. P. Carleton, "Lifetime of the N_2 Vegard–Kaplan System" which has been submitted to the J. of Chem. Phys. and is not reproduced here. In this paper they reinterpreted some earlier measurements of Carleton and Oldenberg, and obtained lifetimes for N_2 $A^3\Sigma_u^+$ ($v = 0$) of 1.36 s for the $\Sigma = 0$ substate and 2.7 s for the $\Sigma = \pm 1$ substates. These results are in good agreement with results obtained in absorption by Shemansky, and reported in the session on absorption coefficients.

The collisional deactivation of metastable atoms and molecules in the upper atmosphere

E. C. ZIPF
Department of Physics, University of Pittsburgh, Pittsburgh, Pennsylvania 15213

Received December 13, 1968

It is now possible to produce comparatively large concentrations of highly reactive metastable species in laboratory sources and to study metastable atoms and molecules with very long radiative lifetimes by photoionization mass spectroscopy, by vacuum ultraviolet absorption techniques, or by direct observation of the feeble radiation emitted by these excited species. These methods are being used widely to study the collisional deactivation of aeronomically important metastable species by quenching or by reaction. New information on radiative lifetimes, diffusion coefficients, and reaction rate coefficients is now available. These results are tabulated and reviewed in the light of atmospheric measurements and current theories of the terrestrial airglow and aurora.

Canadian Journal of Chemistry, 47, 1863 (1969)

In recent years ground-based, satellite, and sounding rocket experiments have given us a much clearer picture of the remarkable chemical and physical properties possessed by the metastable species found in our upper atmosphere. During the same period a number of important technical advances in photomultiplier tube design, in digital data processing, in the techniques for further purifying reagent grade gas samples, and in the complementary use of ultra-high vacuum gas-handling systems under stationary or flowing gas conditions, have brought laboratory studies on the excitation and collisional deactivation of metastable species of aeronomic interest to a state of comparable maturity. It is now possible to produce comparatively large concentrations of highly reactive metastable species in laboratory sources and to study metastable atoms and molecules with very long radiative lifetimes (Table I) by photoionization mass spectroscopy, by vacuum ultraviolet absorption techniques, or by direct observation of the feeble radiation emitted by these excited species.

In this paper we are concerned primarily with those collision processes that depopulate a metastable atom or molecule, either by quenching or by reaction. Much of the experimental work in this field is still preliminary and unpublished. In Tables I–IX, presented in the following section, a representative sample of these results has been included. In a number of cases data obtained in sounding rocket studies of the airglow and aurora have guided and corrected the laboratory work and where it seemed appropriate, the atmospheric values have also been included. There is a notable unevenness in the laboratory results reported so far. It is commonplace to find experimenters agreeing on the magnitude of one specific quenching coefficient only to differ by an order of magnitude or more on another, in spite of using the same apparatus and techniques for both measurements. We are fortunate to this extent, however, that for most metastable species there is a consensus of opinion on the identity of the dominant quenching agent in the upper atmosphere and on the magnitude of the quenching coefficient required to account for the observational data. This information is summarized in Table X.

Tables and Notes

Notes on $O_2(a^1\Delta_g)$ Quenching, Table II

Oxygen molecules in the $a^1\Delta_g$ state are remarkably immune to quenching by the major atmospheric gases. Wall collisions are equally ineffective in deactivating this long-lived state. In the typical laboratory source the catalytic efficiency of the walls is generally in the range 10^{-2} to 2×10^{-3} (5, 57) and it is not uncommon to find as much as 10% of the total O_2 concentration in the

§For the process $2[O_2(a^1\Delta_g)] \rightarrow O_2(^3\Sigma_g^-) + O_2(^3\Sigma_g^-) + h\nu(6340\ Å)$.

$a^1\Delta_g$ state. In view of this overall inertness, it may come as something of a surprise to find $O_2(a^1\Delta_g)$ playing a very active role in the physics and chemistry of the D region.

Metastable $O_2(a^1\Delta_g)$ molecules are produced in the upper atmosphere principally by the photolysis of ozone (8),

$$O_3(^1A) + h\nu \rightarrow O_2(a^1\Delta_g) + O(^1D)$$

through the absorption of solar radiation in the Hartley continuum. Other processes that contribute in a minor way include the following

(*i*) Resonance–phosphorescence, (including cascading)

$$O_2(^3\Sigma^-) + h\nu(1.27 \text{ or } 0.76\ \mu) \rightarrow O_2(a^1\Delta_g)(+h\nu\ (1.9\ \mu))$$

(*ii*) Atomic oxygen – ozone reactions,

$$O_3 + O \rightarrow O_2 + O_2(a^1\Delta_g)$$

(*iii*) Chapman 3-body recombination,

$$O + O + M \rightarrow O_2(a^1\Delta_g) + M$$

The slow collisional deactivation of $O_2(a^1\Delta_g)$ coupled with a very long radiative lifetime allow these sources to create an abundant supply of $^1\Delta_g$ molecules above 40 km. Evans *et al.* (8), who measured the altitude profile of the infrared atmospheric system of oxygen $(a^1\Delta_g \rightarrow X^3\Sigma_g^-)$, found that the maximum $O_2(a^1\Delta_g)$ density occurred near 50 km where the concentration of this metastable species was about $3.7\times10^{10}\ cm^{-3}$. The integrated intensity of the infrared atmospheric bands above 30 km was approximately 21 MR, making these bands the brightest feature in the dayglow spectrum.

By analyzing the altitude distribution of $O_2(a^1\Delta_g)$ in the dayglow, Evans *et al.* (8) determined k_d, an overall quenching coefficient that was referred to the total particle concentration $n(M)$

$$O_2(a^1\Delta_g) + M \rightarrow O_2(^3\Sigma_g^-) + M$$

They found that $k_d = 3\times10^{-19}\ cm^3/s$. Although their experiment did not distinguish between O_2 or N_2 as the quenching agent, they concluded, in view of the laboratory work of Arnold and Ogryzlo (5), that N_2 was favored with a quenching coefficient $1.25k_d$. If, however, the quenching is attributed entirely to O_2, the corresponding rate coefficient would have a value of $1.5\times10^{-18}\ cm^3/s$. This is still an order of magnitude smaller than the preliminary value for $^1\Delta_g$ quenching by O_2 ($1\times10^{-17}\ cm^3/s$) obtained recently by Clark and Wayne (61) who detected the metastables by photoionization. If the larger quenching coefficient is accepted, then a much more efficient source of $O_2(a^1\Delta_g)$ molecules will have to be found to explain the comparatively large concentrations observed in the upper atmosphere.

Metastable $O_2(a^1\Delta_g)$ molecules appear to be a major source of O_2^+ ions in the D region. Hunten and McElroy (12) have shown that $O_2(a^1\Delta_g)$ can be ionized by the solar radiation in the wavelength band $\lambda = 1027$–1118 Å which penetrates deeply into the D region

$$O_2(a^1\Delta_g) + h\nu\ [1027\text{–}1118\ Å] \rightarrow O_2^+ + e$$

This mechanism may account for the unusual amount of O_2^+ observed in the D region by Narcisi and Bailey (90, 91).

Equally intriguing is the proposal by Hunten and McElroy (12) that metastable $O_2(a^1\Delta_g)$ may also produce most of the NO found in the D region through the following quenching reaction

$$[1] \qquad N + O_2(a^1\Delta_g) \rightarrow NO + O$$

This process would help account for the large quantities of NO implied by the dayglow observations of Barth (92, 93) provided the reaction coefficient for reaction [1] was about $3\times10^{-13}\ cm^3/s$.

Finally we should note that $O_2(a^1\Delta_g)$ molecules may influence the negative ion equilibrium in the D region through the fast detachment reaction,

$$O_2^- + O_2(a^1\Delta_g) \rightarrow 2[O_2(^3\Sigma_g^-)] + e$$

which proceeds at room temperature with a rate coefficient of $2\times10^{-10}\ cm^3/s$ (62).

Notes on $O_2(b^1\Sigma_g^+)$ Quenching, Table III

There is general agreement that molecular nitrogen is the dominant $O_2(b^1\Sigma_g^+)$ quenching agent in the upper atmosphere,

$$[2] \qquad O_2(b^1\Sigma_g^+) + N_2 \rightarrow O_2 + N_2$$

Laboratory measurements indicate a quenching coefficient $k_2 = (1.5\text{–}2.5)\times10^{-15}\ cm^3/s$ at room temperature. This is in good agreement with the results obtained by Wallace and Hunten (2) who found from sounding rocket studies of the O_2 atmospheric bands $[b^1\Sigma_g^+ \rightarrow X^3\Sigma_g^-]$ that $k_2 = 1.5\times10^{-15}\ cm^3/s$. Molecular oxygen is not an effective $^1\Sigma_g$ quenching agent,

$$[3] \qquad O_2(b^1\Sigma_g^+) + O_2 \rightarrow O_2 + O_2$$

with $k_3 \leqslant 10^{-16}\ cm^3/s$.

The much larger quenching coefficients (e.g., $k_2 = 5\times10^{-13}\ cm^3/s$) reported by Black *et al.* (1) are simply incompatible with the upper atmosphere data. Whether the presence or absence of vibrationally excited O_2

*Metastable species: $O_2(b^1\Sigma_g^+)$, atmospheric bands $[b^1\Sigma_g^+ \rightarrow X^3\Sigma_g^-]$.

molecules in the different laboratory experiments, as proposed by Black *et al.* (94), will explain the discrepancy remains to be seen. The explanation depends in part on the fact that the smaller values for k_2 and k_3 (3, 57, 60) were derived from measurements in which the O_2 pressure was much greater than 1 Torr, whereas in the work of Black and his collaborators, $p(O_2) \ll 1$ Torr. While this may have some bearing on the problem, it should be pointed out that the O_2 pressures in the experiments of Black *et al.* are duplicated in the upper atmosphere at altitudes above 50 km; it is precisely from observational data obtained in this region of the atmosphere that Wallace and Hunten (2) deduced the smaller quenching coefficient $k_2 = 1.5 \times 10^{-15}$ cm^3/s.

The presence of $O_2(b^1\Sigma_g^+)$ molecules in the upper atmosphere is an interesting example of how the collisional deactivation of one metastable species figures prominently in the excitation of still another. Metastable $O_2(b^1\Sigma_g^+)$ molecules are produced efficiently at the expense of metastable $O(^1D)$ atoms

$$[4] \quad O(^1D) + O_2(^3\Sigma_g^-) \rightarrow O_2(b^1\Sigma_g^+) + O(^3P)$$

In the region above 85 km $O(^1D)$ atoms are produced in the daytime by photodissociation of O_2 in the Schumann–Runge continuum [S.R.c.],

$$[5] \quad O_2(^3\Sigma_g^-) + h\nu\ [\text{S.R.c.}] \rightarrow O(^1D) + O$$

and by photodissociation of ozone at lower altitudes

$$[6] \quad O_3(^1A) + h\nu \rightarrow O_2(a^1\Delta_g) + O(^1D)$$

in the Hartley continuum. Although most of the ^1D atoms formed by processes [5] and [6] are quenched by N_2, making reaction [4] a minor ^1D loss process, O_2 quenching of $O(^1D)$ is the dominant source of $O_2(b^1\Sigma_g^+)$ above 100 km and it is still an important source at altitudes as low as 40 km (2).

Based on an analysis of the excitation of the atmospheric bands in auroras, Wallace and Chamberlain (32) concluded that the rate coefficient for reaction [4] was approximately 1×10^{-11} cm^3/s. This conclusion has been supported by the laboratory work of Young and his collaborators (23) and by Noxon (3) who find that an $O_2(b^1\Sigma_g^+)$ molecule is formed nearly every time an $O(^1D)$ atom is quenched by O_2. This is in disagreement with the recent work of Izod and Wayne (57) who report that an $O_2(b^1\Sigma_g^+)$ molecule is formed only once in 500 quenching collisions.

*Metastable species: $N_2(A^3\Sigma_u^+)$, Vegard–Kaplan bands $[A^3\Sigma_u^+ \rightarrow X^1\Sigma_g^+]$.
†For the process: $2N_2(A^3\Sigma_u^+) \rightarrow N_2(C^3\Pi_u) + N_2$.

Notes on $N_2(A^3\Sigma_u^+)$ Quenching, Table IV

The Vegard–Kaplan bands $[A^3\Sigma_u^+ \rightarrow X^1\Sigma_g^+]$ appear prominently in the ultraviolet spectrum of an aurora; they have not been observed in the normal day or night airglow. In auroras, the Vegard–Kaplan system is excited principally by cascade radiation from two other closely related triplet states of nitrogen (40, 76)

$$N_2(X^1\Sigma_g^+) + e \rightarrow N_2(C^3\Pi_u) + e$$
$$N_2(C^3\Pi_u) \rightarrow N_2(B^3\Pi_g) + h\nu \text{ (second positive bands)}$$

$$N_2(X^1\Sigma_g^+) + e \rightarrow N_2(B^3\Pi_u) + e$$
$$N_2(B^3\Pi_g) \rightarrow N_2(A^3\Sigma_u^+) + h\nu \text{ (first positive bands)}$$

Atomic oxygen appears to be the dominant A state quenching agent in the upper atmosphere

$$[7] \quad N_2(A^3\Sigma_u^+) + O(^3P) \rightarrow N_2(X^1\Sigma_g^+) + O^*$$

where the product atom O* may be in the ^1S, ^1D, or ^3P state.

The quenching results based on atmospheric observations were derived by Hunten and McElroy (16) from a consideration of the high rotational temperature (800 °K or more; refs. 38–41) exhibited by the Vegard–Kaplan bands in auroras. When this analysis was undertaken, the accepted value for the radiative lifetime of the $A^3\Sigma_u^+$ ($v' = 0$) state was approximately 10–12 s (77, 78). It was then supposed that there would be sufficient time for $N_2(A)$ molecules formed in an aurora to come into thermal equilibrium with the ambient atmosphere prior

For personal use only.

to radiating. The consistently high rotational temperatures would, therefore, indicate that the height of the emission is around 200 to 220 km and that below 200 km the Vegard–Kaplan system is effectively quenched. In this view the Vegard–Kaplan bands, like the O(I) red line [λ = 6300 Å], are emitted in a diffuse, high altitude glow that pervades the entire sky. If reaction [7] is the dominant quenching process, a quenching coefficient $k = 3 \times 10^{-11}$ cm^3/s would be required to account for the observations.

The agreement between the laboratory value for the quenching coefficient (5×10^{-11} cm^3/s; ref. 17) and the atmospheric estimate is remarkably good. The chief difficulty, however, with this otherwise self-consistent picture is the growing evidence from several recent auroral rocket experiments (ref. 28) that the bulk of the Vegard–Kaplan emission occurs in the vicinity of 120 km and that only very weak emission is observed above 170 km. These results would indicate that the apparent rotational temperature of the Vegard–Kaplan bands is not an accurate measure of the ambient temperature at the altitude of peak emission. The sounding rocket data indicate further that the product of the quenching coefficient and the radiative lifetime must be nearly one order of magnitude smaller than the value adopted by Hunten and McElroy (16). If we accept the laboratory value for the quenching coefficient as being essentially correct, then the radiative lifetime of the $A^3\Sigma_u^+$ state would have to be in the range of 1–2 s in order to be compatible with the observational data. This conclusion agrees well with the new experimental lifetime measurements of Shemansky (67) who finds that $\tau_r = 1.3$ s for the F_2 levels and 2.5 s for the F_1 and F_3 levels.

Notes on O(^{1}S) Quenching, Table V

The processes that create oxygen atoms in the metastable ^{1}S state in the upper atmosphere have been the subject of constant study and speculation since the green line ($^1S \rightarrow {}^1D$; λ = 5577 Å) was first detected in the nightglow by Campbell (79) in 1895. The excitation mechanisms most frequently discussed include the following

(*1*) In auroras (80, 81),

(*i*) Dissociative recombination of O_2^+

$$O_2^+ + e \rightarrow O(^1S, {}^1D, {}^3P) + O$$

(*ii*) Electron impact excitation

$$O(^3P) + e \rightarrow O(^1S) + e$$

(*2*) In the dayglow (37, 82),

(*iii*) Photodissociation of O_2 by solar vacuum ultraviolet (v.u.v.) photons (83)

$$O_2(X^3\Sigma_g^-) + h\nu\,(\text{v.u.v.}) \rightarrow O(^1S) + O$$

in addition to processes (*i*) and (*ii*).

(*3*) In the nightglow (84–86),

(*iv*) The Chapman mechanism

$$O + O + O \rightarrow O(^1S) + O_2$$

which may be an important source of ^{1}S atoms in the low altitude nightglow layer (87, 88), in addition to the dissociative recombination of O_2^+ ions (process (*i*)) which is a significant ^{1}S source in the night-time F region.

TABLE V

Quenching coefficients*

*Metastable species: O(^{1}S), auroral green line [$^1S \rightarrow {}^1D$; λ = 5577 Å].

Ground-based studies of the temporal behavior of the λ = 5577 Å emission in auroras (42–45) and in meteoric wakes (46) show that the ^{1}S state is collisionally deactivated in the upper atmosphere. The early work of Kvifte and Vegard (47) appeared to rule out O_2 as an important ^{1}S quenching agent. More recent laboratory work (21, 4, 52, 53), however, shows that this is not the case. It is now apparent that O_2 quenching competes effectively with radiation in depopulating O(^{1}S) atoms in the nightglow layer at 95 km; it is the dominant loss mechanism in the lower portion of that layer. Molecular nitrogen and atomic oxygen are not effective ^{1}S quenching agents in the upper atmosphere.

Among the minor atmospheric constituents in the D region only water vapor may deactivate O(^{1}S) atoms sufficiently fast to compete with radiation and O_2 quenching

[8] $$H_2O + O(^1S) \rightarrow OH + OH$$

Hesstvedt (89) finds, on the basis of numerical calculations, taking into account the effects of eddy and molecular diffusion fluxes as well as the standard photochemical reactions, that there could be a considerable H_2O density at the altitude of the λ = 5577 Å nightglow. In view of the large rate coefficient (3×10^{-10} cm^3/s) found by Stuhl (52) for process [8], water vapor quenching of O(^{1}S) is a distinct possibility.

Notes on O(^{1}D) Quenching, Tables VI and VII

There is little doubt that molecular nitrogen is the most important O(^{1}D) quenching agent in the upper atmosphere

[9] $$O(^1D) + N_2 \rightarrow O(^3P) + N_2^*$$

*Metastable species: $O(^1D)$, airglow red line [$^1D \rightarrow {}^3P$; $\lambda = 6300$ Å].

In fact, this process competes effectively against radiation up to altitudes of at least 250 km (37). At room temperature reaction [9] has a rate coefficient of approximately $5\text{–}10 \times 10^{-11}$ cm^3/s.

To what extent reaction [9] leads to the production of vibrationally excited nitrogen molecules, N_2^*, has not been determined. In view of the very efficient production of $O(^1D)$ in the daytime by photodissociation of O_2,

$$O_2(^3\Sigma_g^-) + h\nu \text{ [S.R.c.]} \rightarrow O(^1D) + O$$

and by electron impact,

$$O(^3P) + e \rightarrow O(^1D) + e$$

and dissociative recombination in auroras,

$$O_2^+ + e \rightarrow O(^1D) + O$$

this mechanism may indeed be very important in the thermal economy of the daytime E region and at auroral altitudes where it selectively heats the ambient electron gas via super-elastic collisions

[10] $N_2^*(v'' > 0) + e \rightarrow N_2^*(v' < v'') + e + \text{kinetic energy}$

The anomalously high electron temperatures observed in the daytime E region have been attributed by Walker (29) to reactions [9] and [10]. There is certainly ample energy available, but new data on the quenching of N_2^* by CO_2 (Table VIII) suggest that most of this energy is transferred to atmospheric CO_2 molecules where it is ultimately lost by radiation. This process may still be important at somewhat higher altitudes in auroras where very high electron temperatures (2000 °K or more) have been observed in sounding rocket experiments.

Vibrationally excited nitrogen formed by reaction [9] and electron impact may also figure prominently in auroras by enhancing the geophysically important ion–molecule reaction (30)

[11] $$O^+ + N_2^* \rightarrow NO^+ + N$$

At vibrational temperatures less than 1000 °K this reaction proceeds with a rate coefficient of 1×10^{-12} cm^3/s (31). Above 1000 °K the rate coefficient increases rapidly with the vibrational temperature reaching a value of 10^{-11} cm^3/s when $T_v = 2800$ °K. Direct evidence of the importance of this process was obtained by Zipf *et al.* (97) in a pulsating aurora in which the transient response of the ionosphere to incoming pulses of energetic electrons was studied in situ by simultaneous positive ion mass spectroscopy, optical photometry, and measurements of the primary and secondary electron energy spectrum with hemispherical analyzers.

Molecular oxygen also efficiently quenches the ^1D state

[12] $$O(^1D) + O_2(^3\Sigma_g^-) \rightarrow O(^3P) + O_2$$

Recent laboratory measurements (3, 23) indicate a quenching coefficient $k_{11} = 4\text{–}6 \times 10^{-11}$ cm^3/s. The early work of Kvifte and Vegard (47), as re-analyzed by Hunten and McElroy (16), yielded quenching coefficients that are much smaller than the recent laboratory results; presumably this discrepancy is due to the known complexity of an electrical discharge. Although O_2 quenching is not the dominant ^1D loss mechanism in the upper atmosphere, it is, as we have already noted, an important source of excited $O_2(b^1\Sigma_g^+)$ molecules via reaction [4].

*Proposed as a possible energy source for the sodium nightglow.

The apparent disagreement between the dayglow measurements of the ^1D quenching rate above 100 km and Seaton's conclusions (51) based on an analysis of ground-based measurements of the λ5577/λ6300 intensity ratio in auroras has been resolved. Parkinson *et al.* (27) have found in a recent rocket experiment that the O(I) red and green emission lines are emitted from quite different altitude regions in an auroral display. As predicted by Hunten and McElroy (16), the O(I) red line was emitted from a high altitude, diffuse glow that pervaded the entire sky. The rocket experiment showed very clearly the strong deactivation of the ^1D state by N_2 and pointed out the hazards involved in ground-based auroral studies. The rocket data are compatible with an N_2 quenching coefficient of about $5\text{–}10 \times 10^{-11}$ cm^3/s.

The effectiveness of CO_2 as a ^1D quenching agent is the subject of some controversy as Table VII shows. Two groups (Young *et al.* (23), and Preston and Cvetanović (36)) find CO_2 four to five times more efficient than N_2 in depopulating $O(^1D)$ atoms. In neither experiment, however, are $O(^1D)$ atoms directly observed. Noxon (3) disagrees with this result. In an experiment in which he follows the behavior of $O(^1D)$ atoms in a photolysis cell by directly observing the λ = 6300 Å radiation emitted by this species, he concludes that CO_2 is 30 times *less* efficient than N_2. A somewhat similar result has been reported by Clerc and Reiffsteck (100). There is also a difference of opinion concerning the question of quenching versus reaction. Clerc and Reiffsteck have obtained some evidence that the reaction,

$$O(^1D) + CO_2 \rightarrow CO_3$$

is more important than simple quenching,

$$O(^1D) + CO_2 \rightarrow O(^3P) + CO_2$$

This finding disagrees, however, with the photolysis experiments of Slanger (102) which indicate that $O(^3P)$ is definitely one of the products of the ^1D loss mechanism.

Finally, Black *et al.* (98) suggest that the existence of an intermediate CO_3^* complex in equilibrium with the reactants

$$CO_2 + O(^1D) \underset{k_2}{\overset{k_1}{\rightleftarrows}} CO_3^* \xrightarrow{k_3} CO_2 + O(^3P) \text{ or } CO_3$$

may be the key to resolving the CO_2 efficiency problem. They postulate that in their experiment the equilibrium is upset by the presence of the NO used to detect ground-state oxygen atoms, in which case they obtain k_1. Noxon, on the other hand, obtains $k_1 \cdot [k_3/k_2]$ when he observes the $O(^1D)$ decay.

TABLE IX

Metastable diffusion coefficients

Deactivation of $O(^1S)$ and $O_2(b^1\Sigma_g^+)$[1]

F. STUHL AND K. H. WELGE
Centre for Research in Experimental Space Science, York University, Toronto

Received December 13, 1968

Rate constants for the collisional deactivation of $O(^1S)$ and $O_2(b^1\Sigma_g^+)$ are reported. They are obtained by measuring the intensity decay of the $O(^1S \rightarrow {}^1D)$ and $O_2(b^1\Sigma_g^+ \rightarrow X^2\Sigma_g^+)$ emissions after a pulsed production of the excited species.

Canadian Journal of Chemistry, **47**, 1870 (1969)

We wish to report some rate constants for the deactivation of $O(^1S)$ and $O_2(b^1\Sigma_g^+)$ obtained by direct lifetime measurements. $O(^1S)$ and $O_2(b^1\Sigma_g^+)$ were produced in a pulsed mode, and the emissions of $O(^1S \rightarrow {}^1D)$ and $O_2(b^1\Sigma_g^+ \rightarrow X^3\Sigma_g^-)$ were detected photoelectrically. The rate constants were derived from the time-dependence of the excited state density.

The experimental arrangement, which will be described elsewhere in detail, consists in its main part of a repetitively pulsed vacuum-ultraviolet flash light source, a reaction cell, and a detector system at right angles to the exciting light beam. The characteristics of the light source are: flash duration < 2 μs, energy per discharge up to 10 J, repetition frequency up to 20 c.p.s. The low wavelength cut-off was provided by the use of LiF, MgF_2, CaF_2, and BaF_2 windows. The emissions were isolated by tilting narrow band interference filters with peak wavelengths at 5577.5 and 7622.5 Å. The signals were accumulated by signal averaging with a channel width of 10 μs.

[1]This research was supported by grants received from the National Research Council of Canada and the Defence Research Board of Canada.

$O(^1S)$

A suitable source for the formation of $O(^1S)$ was found to be the photodissociation

$$CO_2 + h\nu \rightarrow CO + O(^1S) \quad (\lambda < 1220\ \text{Å})$$

Flashing of CO_2 produced the $O(^1S \rightarrow {}^1D)$ emission when LiF and MgF_2 windows were used. The emission reached its maximum intensity synchronously with the flash. The decay rate was measured first using CO_2 and then later adding other gases. Pressures ranging from about 10^{-2} to a few 100 Torr were used. From the exponential decay, rate constants were obtained in a straightforward manner. The results are given in Table I.

$O_2(b^1\Sigma_g^+)$

For the production of $O_2(b^1\Sigma_g^+)$ the mechanism, as established recently by Noxon (1)

$$[1] \qquad O_2 + h\nu \rightarrow O(^1D) + O(^3P)$$

$$[2] \qquad O(^1D) + O_2 \rightarrow O_2(b^1\Sigma_g^+) + O(^3P)$$

TABLE I

Quenching rate coefficients

Quenching particle	Coefficients (cm^3 $molecule^{-1}$ s^{-1})	
	$O(^1S)$	$O_2(b^1\Sigma_g^+)$
CO_2	4.6×10^{-13}	2.0×10^{-13}
O_2	3.2×10^{-13}	1.1×10^{-16}
CO	9.4×10^{-14}	3.3×10^{-15}
H_2	1.1×10^{-15}	6.4×10^{-13}
N_2	$<5\times10^{-17}$	2.2×0^{-15}
Ar		3.2×10^{-16}
N_2O	1.5×10^{-11}	
H_2O	$\sim4\times10^{-10}$	$\sim2\times10^{-11}$

was used. The rate constant (1) for the energy transfer process is 6×10^{-11} cm^3 s^{-1}. When O_2 was flashed,the emission of $O_2(b^1\Sigma_g^+)$ was found to reach the maximum within less than 10 μs at pressures above a few 10^{-1} Torr. Under the above conditions the rapid rise of the emission intensity may be expected. Pressures of O_2 up to 40 Torr were used. From the decay rates with and without added gases the rate constants given in Table I were derived.

Comments, Replies, and Summary

COMMENTS BY E. A. OGRYZLO[1]

I would like to comment on the collection of quenching constants for $O_2(^1\Sigma_g^+)$ and $O_2(^1\Delta_g)$ which Dr. Zipf presents in Tables I and II. In a paper presented at the Symposium on "The physics and chemistry of the upper atmosphere", Saskatoon, Canada, June 1966, which unfortunately has not yet appeared in the literature, it was pointed out that the results of March *et al.* (9) yield a rate constant for the reaction

$$O_3 + O_2(^1\Sigma_g^+) \rightarrow 2O_2 + O$$

about a factor of 2 larger than the one reported by them, when a correction is made for the continuous formation of $O_2(^1\Sigma_g^+)$ in their system by the process

$$O_2(^1\Delta_g) + O_2(^1\Delta_g) \rightarrow O_2(^1\Sigma_g^+) + O_2(^3\Sigma_g^-)$$

It is probably worth emphasizing that we have not revised our estimation of the rate constant for this latter reaction. We have obtained evidence for a reaction which is second order in $O_2(^1\Delta_g)$ and about 20 times faster. However, we believe this to be the following process which is "spin allowed"

$$O_2(^1\Delta_g) + O_2(^1\Delta_g) \rightarrow O_2(^3\Sigma_g^-) + O_2(^3\Sigma_g^-)$$

The following rate constants (obtained by Arnold, Kubo, and Ogryzlo) for quenching of $O_2(^1\Sigma_g^+)$ which will appear shortly in "Advances in chemistry" may be added to those listed in Table I.

Quenching particles	Rate constants
N_2, Ar, and CO	2.5×10^{-15}
CO_2	5×10^{-14}
H_2O	1×10^{-13}

[1]Address: University of British Columbia, Vancouver, British Columbia.

COMMENTS BY G. BLACK, T. G. SLANGER, AND R. A. YOUNG[2]

We would like to make some comments on the large disparity between the several quenching rates for $O_2(b^1\Sigma_g^+)$ shown in Table I of Dr. Zipf's paper. Our value of 3×10^{-13} cm^3 $molecule^{-1}$ s^{-1} differs by a factor of almost 10^3 from the laboratory measurements of 1×10^{-16} cm^3 $molecule^{-1}$ s^{-1} by Noxon and $\leqslant 1 \times 10^{-16}$ cm^3 $molecule^{-1}$ s^{-1} by Izod and Wayne (not mentioned in the table but to be published in Proc. Roy. Soc.).

It has been suggested that our results pertain to $O(^1D)$ quenching and not $O_2(b^1\Sigma_g^+)$ quenching. Whereas this could be true for some of the N_2 data where a ratio of rate coefficients (nitrogen relative to oxygen) very close to that observed for $O(^1D)$ (Table V) is found, much greater quenching efficiencies were found for CO, N_2O, NO, and CO_2 relative to O_2 than the ratios observed for $O(^1D)$. This rules out the quenching of $O(^1D)$ as the main quenching reaction for these gases.

An explanation of the discrepancy lies, we think, in the different pressure regions of the

[2]Address: Stanford Research Institute, Palo Alto, California.

For personal use only.

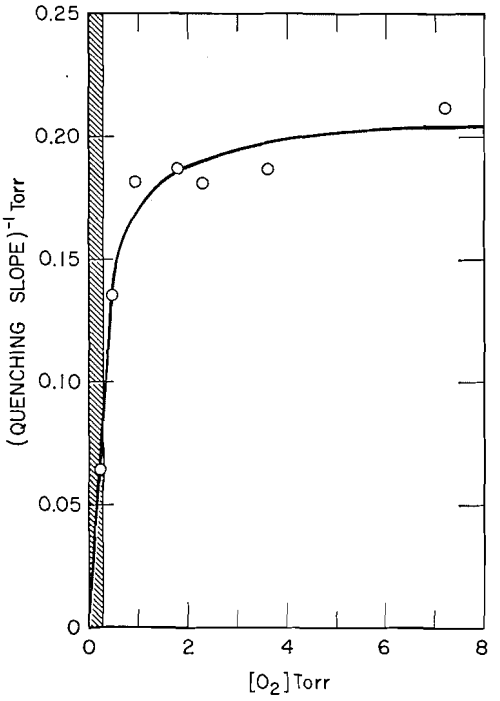

FIG. 1. N_2 quenching data. The reciprocal of the slope of Stern–Volmer graphs vs $[O_2]$; [He] = 10 Torr.

experiments. Our published measurements pertain to an O_2 pressure $\ll 1$ Torr, whereas the other measurements were made at O_2 pressures $\gg 1$ Torr. We took measurements up to O_2 pressures ~ 10 Torr at the same time as our low pressure results but found incompatibility between the low and high pressure data. This is illustrated for our N_2 quenching data in Fig. 1 where the shaded portion indicates the region covered in our previous publication. Similar shaped curves were obtained for CO, N_2O, NO, and CO_2. The ordinate of this graph is $(\tau_0 k_{N_2})^{-1}$ where τ_0 is the lifetime of the quenched species before quenching addition. We interpreted the low O_2 pressure data as pertaining to $O_2(b^1\Sigma_g^+)$ and deduced the value of k_{O_2} shown in Table I from the very strong dependence of τ_0 on O_2 in this pressure region. The high pressure "plateau" region, if interpreted in terms of $O_2(b^1\Sigma_g^+)$ quenching, would give much lower quenching efficiencies, particularly for oxygen, than those deduced in our paper. These are the findings of Noxon and Izod and Wayne. In fact, relative rate coefficients deduced from our "plateau" values for N_2:CO:CO_2 are 1:2:150 in satisfactory agreement with the ratio of 1:2:330 from the absolute values of Noxon using his unpublished value of 5×10^{-13} cm^3 molecule^{-1} s^{-1} for CO_2 quenching of $O_2(b^1\Sigma_g^+)$. Stuhl (unpublished) has recently determined $k_{CO_2} = 2 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1} for this quenching rate. This would bring the ratios into very good agreement.

It is our feeling that the different quenching behavior in the two regions may well reflect quenching of vibrationally excited $O_2(b^1\Sigma_g^+)$ molecules. In unpublished work, $O_2(b^1\Sigma_g^+)$ in the $v' = 2$ has been seen by Noxon and we have seen the $v' = 1$ level (in the (1,1) transition at 7708 Å) with approximately one-tenth the emission intensity of the (0,0) band. The presence of these vibrationally excited molecules should not be surprising in view of the energy resonance with $O_2(b^1\Sigma_g^+)_{v'=2}$ when $O(^1D)$ transfers to O_2.

Definitive experiments to resolve this controversy are presently underway in our laboratory where the decay with time of $O_2(b^1\Sigma_g^+)$ in both ground and excited vibrational states is being determined in a pulsed system.

COMMENTS BY G. BLACK, T. G. SLANGER, G. A. ST. JOHN, AND R. A. YOUNG[2]

We would like to confirm the measurements of Stuhl and Welge on $O(^1S)$ deactivation. We have used a similar technique for obtaining the rate coefficients, that is, measurement of the decay time of the 5577 Å emission as a function of added gas pressure. Our light source was a pulsed 1470 Å Xe lamp, powered by an RF oscillator, while the $O(^1S)$ source was N_2O. The lamp was pulsed at up to 20 c.p.s., with an instrumental decay time of ~ 100 μs. The resulting 5577 Å emission pulse was registered in a signal accumulator and, after a few thousand cycles, an averaged $O(^1S)$ decay curve was displayed on an oscilloscope. The slope of a plot of reciprocal decay time vs. pressure is equal to the quenching rate coefficient of the added gas.

We have so far obtained the following values.

Quenching particle	Rate coefficient, cm molecule^{-1} s^{-1}
C_2H_4	6×10^{-10}
NO	5.5×10^{-10}
N_2O	1.6×10^{-11}
O_2	5×10^{-13}
CO_2	3×10^{-13}
H_2	1×10^{-15}
N_2, Ar, He	$< 3 \times 10^{-15}$

Because of the very rapid rates for the fastest reactants, it must still be confirmed that the values for the slowest reactants are not influenced by contamination.

Previous measurements of $O(^1S)$ deactivation rates (J. Chem. Phys. **44**, 3741 (1966)) gave values considerably lower than those now reported. In these earlier measurements, it was the product of the quenching coefficient and the zero pressure $O(^1S)$ decay time, $k\tau$, that was being measured. It was assumed that τ was the radiative lifetime, 1 s, and thus the quenching coefficients were obtained. The fact that they are too low means that either τ referred to a loss process other than radiation or that the 1 s value, a theoretically calculated number, is too high.

In the present system, the residual $O(^1S)$ lifetime, a value obtained by extrapolating N_2O and buffer gas pressures to zero, is 3 ms. This is certainly too short to be the radiative lifetime, but experiments are continuing to see whether a true value may be obtained.

By comparison of the emission intensity of $O(^1S)$ in N_2O photolysis with the intensity of emission from a reaction with a known quantum yield (for instance, the NO_2* chemiluminescence using O_2 photolysis as an $O(^3P)$ source), one may obtain a value for the $O(^1S)$ quantum yield. Using the new N_2O quenching coefficient of 1.6×10^{-11} cm^3 s^{-1} and a radiative lifetime of 1 s, the quantum yield is 0.5 ± 0.05. The value is proportional to the radiative lifetime, so any decrease in the lifetime will decrease the quantum yield. If the 1 s value is correct, then N_2O photolysis at 1470 Å is an excellent $O(^1S)$ source, and is the obvious system to use for product formation studies.

COMMENTS BY K. WELGE

By using various windows on our photolysis lamps, we find that $O(^1S)$ is not produced from CO_2 at wavelengths longer than about 1220 Å.

COMMENTS BY T. SLANGER

Our experiments confirm Dr. Welge's findings. We have used an absorption cell between a krypton resonance lamp and a photolysis cell. CO_2 was photolyzed, and the resulting 5577 Å emission was monitored. By observation of the change in emission intensity as CO_2 was added to the absorption cell, a value for the CO_2 absorption coefficient at the wavelength that was producing $O(^1S)$ could be measured. This value was found to agree well with the 1165 Å lamp component, and not at all with the one at 1236 Å, even though the 1236 Å intensity is ~ 5 times the 1165 Å intensity. Thus, the continuum in the CO_2 absorption curve that begins at 1190 Å presumably corresponds to the photodissociation

$$CO_2 \xrightarrow{h\nu} CO(X^1\Sigma^+) + O(^1S)$$

This is 0.7 eV more energy than is required on purely thermodynamical grounds.

COMMENTS BY J. NOXON

In connection with the quenching of $O(^1D)$ by CO_2 we have made the following observations.
(*1*) Emission of 6300 Å radiation following CO_2 photolysis indicates production of $O(^1D)$ which appears to be quenched with a rate constant of $k \simeq 3 \times 10^{-12}$.
(*2*) When 1–2% N_2 is added to the system the 6300 Å radiation is quenched.
(*3*) For O_2 photolysis a plot of the intensity of 7600 Å radiation from $O_2(b^1\Sigma_g^+)$ against added CO_2 shows a linear decrease up to ratios of $CO_2/O_3 \geqslant 10$ which indicates that, for the quenching of $O(^1D)$, $k_{CO_2} < 10\, k_{O_2}$ or $k_{CO_2} \simeq 6 \times 10^{-12}$.

COMMENTS BY G. BLACK, T. G. SLANGER, AND R. A. YOUNG

We were very pleased to hear Dr. Ferguson's theory yesterday, explaining the negative temperature coefficient for the reaction

$$N_2 + O^+ \rightarrow NO^+ + N$$

His explanation involved an intermediate, N_2O^{+}*, in equilibrium with the reactants

$$N_2 + O^+ \underset{k_2}{\overset{k_1}{\rightleftarrows}} N_2O^{+*} \xrightarrow{k_3} NO^+ + N$$

where $k_2 = 10^3 k_3$.

This is quite analogous to our scheme explaining the two orders of magnitude difference between our value for the rate coefficient for $O(^1D)$ deactivation by CO_2 and Noxon's. In this case, the intermediate is CO_3* and the proposed reaction is

$$CO_2 + O(^1D) \underset{k_2}{\overset{k_1}{\rightleftarrows}} CO_3^* \xrightarrow{k_3} \begin{matrix} CO_2 + O(^3P) \\ \text{or } CO_3 \end{matrix}$$

where $k_2 = 10^2 k_3$. In our experiments, which are always done in the presence of NO, we

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

suggest that a new loss process for CO_3* becomes available

$$CO_3^* + NO \xrightarrow{k_4} CO_3 + NO$$

where $k_4[NO] \gg k_2$. Thus, the equilibrium is upset, and our method of detection leads to a value for k_1. On the other hand, when $[O(^1D)]$ is measured, as in Noxon's experiments, it is not k_1, but $k_1 \cdot k_3/k_2 = 10^{-2}k_1$, that is obtained.

The obvious way to determine if this idea is tenable is to measure $O(^3P)$ in the absence of NO. If this results in a sharply decreased value for k_1, then the idea would appear to have merit. Such measurements are underway.

Some observations that support the equilibrium concept are available in a comparison of some of our data with Dr. Schiff's. In an article published (Can. J. Chem. **44**, 1981 (1966)), Schiff and Ung showed that the production of O_2 could be completely suppressed in the 1470 Å photolysis of 35 Torr CO_2 by the addition of 0.3 Torr CH_4. Once $O(^3P)$ is produced in the system, it may probably be assumed that it will lead to O_2 formation. Therefore, the data suggest that CH_4 removes $O(^1D)$ more than two orders of magnitude faster than does CO_2.

On the other hand, we find that when photolyzing 3 Torr CO_2 and 0.3 Torr NO, the $O(^3P)$ concentration is halved by the addition of 2 Torr CH_4, indicating that CO_2 and CH_4 remove $O(^1D)$ at comparable rates (the CH_4 needed to halve the $O(^3P)$ concentration is a function of CO_2, so it cannot be argued that NO is the principal deactivator). This observation tends to support the idea that when k_2 is the principal CO_3* loss, then CO_2 will appear to be an inefficient deactivator of $O(^1D)$, but when k_2 is small relative to another CO_3* loss mechanism, CO_2 will appear to be efficient.

COMMENTS BY H. I. SCHIFF

The discrepancy of a factor of 100 in the quenching rates of $O(^1D)$ by CO_2 among investigators is very puzzling. It has been suggested that this discrepancy is due to the difference in detection, whether one follows the disappearance of $O(^1D)$ or the formation of $O(^3P)$. And yet Noxon, who measures ^1D, and Clerc, who essentially measures ^3P, both find low values, while Cvetanović, who follows ^1D, and Black *et al.*, who follow ^3P, both find high values.

The explanation offered by Black *et al.*, referred to in Zipf's review, that it is due to the CO_3* equilibrium, may resolve the difference between them and Noxon, although it is difficult to understand why NO should be so unique in promoting dissociation of the complex to $O(^3P)$. (The stabilization of the CO_3 by NO would not be measured by their method.) It is even more difficult to see how this would help to resolve the difference in the results of Clerc and Cvetanović.

COMMENTS BY M. CLERC

From the measurement of the amount of O_3 produced by the vacuum ultraviolet flash photolysis of O_2–Ar mixtures (1), (O_2 = 1 Torr, Ar = 760 Torr), to which either CO_2 or CO is added, a value of the ratio $k_5/k_3 = 55 \pm 5$ has been determined for the reactions

[3] $$O(^1D) + CO_2 \rightarrow CO_3$$

[5] $$O(^1D) + CO \rightarrow CO_2$$

The results provide indirect evidence for the occurrence of reaction [3] instead of reaction [4]

[4] $$O(^1D) + CO_2 \rightarrow O(^3P) + CO_2$$

Consider the following mechanisms

[1] $$O_2(^3\Sigma_g^-) + h\nu \rightarrow O(^1D) + O(^3P)$$

[2] $$O(^3P) + O_2 + M \rightarrow O_3 + M$$

[6] $$O(^1D) + M \rightarrow O(^3P) + M$$

[7] $$O(^1D) + O_3 \rightarrow 2O_2$$

if the reaction between $O(^1D)$ and CO_2 was a simple collisional deactivation by reaction [4], no variation should be observed in the amount of O_3 formed at the equilibrium after the flash. However, if the $O(^1D)$ reacts with an efficient scavenger, before it can be de-excited by M, the ozone formation should have diminished by one-half. By addition of CO_2 (2 Torr) or CO (0.1 Torr), to the initial (O_2, 1 Torr + Ar, 760 Torr) mixture, the amount of O_3 formed at the equilibrium after the photolytic flash is divided by two. This result shows that by addition of CO_2, the principal reaction is [3], and that by addition of CO, reaction [5] is brought into play.

From the relationship between $[O_3]$ and the added $[CO_2]$ or [CO], the ratio of the rate constants $k_5/k_3 = 55 \pm 5$ is obtained.

Our previous results, (2, 3) have shown that $k_5 = 10^{-11}$ cm^3 molecule^{-1} s^{-1}, from which

one may calculate $k_3 = 2 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1}.

QUESTION BY J. W. McGOWAN

Why don't you consider CO + O_2 as one of the possible competing product channels for the $O(^1D)$ + CO_2 quenching reaction. If these reaction products were formed along with $O(^3P)$ + CO_2, might this not give you a low production rate of $O(^3P)$ and therefore an apparently lower reaction rate?

REPLY BY M. CLERC

We have no direct evidence that CO + O_2 are products of the reaction $O(^1D)$ + CO_2. In any case, if a reaction such as

[1] $$O(^1D) + CO_2 \rightarrow CO + O_2$$

occurred to an important extent, it would lead to a CO quantum yield $1 < \phi_{CO} < 2$ in the photochemistry of CO_2, via the reaction

[2] $$CO_2 + h\nu \rightarrow CO + O(^1D)$$

[2] followed by [1]. A CO quantum yield close to 1 is generally obtained.

Evidently an analysis of the final products would give a definite reply to this question; this we intend to do.

REPLY BY T. SLANGER

At Stanford Research we have measured the $O(^3P)$ quantum yield for CO_2 photolysis at 1470 Å. By making measurements relative to O_2 photolysis, where the $O(^3P)$ quantum yield after $O(^1D)$ deactivation is 2, it is observed that the $O(^3P)$ quantum yield from CO_2 is 1.0. This implies that all of $O(^1D)$ initially produced is ultimately converted to $O(^3P)$. The $O(^3P)$ production rate was measured by chemiluminescence following the addition of NO. It may be argued that NO is then the $O(^1D)$ deactivator and not CO_2, but examination of the results in detail clearly shows that CO_2 is the deactivating species. Thus, the reaction

$$O(^1D) + CO_2 \rightarrow CO + O_2$$

cannot be important.

SUMMARY AND REMARKS BY CHAIRMAN D. M. HUNTEN[3]

This paper shows clearly that the study of metastables is coming of age, in both the laboratory and the upper atmosphere. In the laboratory, there are a variety of detection techniques, those mentioned by Zipf, and also the less direct methods based on differences in chemical reactivity. In the upper atmosphere the subject has been revolutionized by rocket probes of dayglow emissions. In nearly every case an unambiguous identification of the production process and its rate has been possible, and the quenching rate, therefore, follows immediately from the measurements; large systematic errors are nearly impossible. Identification of the quenching partner requires other evidence. Nevertheless, the results from the upper atmosphere can give a valuable check on the laboratory. Zipf has recognized this, but many other laboratory workers seem to ignore it, and some completely unacceptable results have been published.

Several years ago McElroy and I published (4) a predecessor of Zipf's paper; a good indication of the activity of the subject is the degree to which our evaluations must be changed. Among other things, we undertook an analysis of the classical data of Kvifte and Vegard (5) on the red and green lines of oxygen from an electrical discharge. The measurements were made under a wide range of conditions, pressure, tube diameter, and buffer gas, and seemed to give clear indications of the quenching rates for $O(^1S)$ by O_2. The interferences for $O(^1D)$ were less direct, and also were referred to the ^1S result. As Zipf points out (Tables V and VI), the results were low by two and four orders of magnitude. It now seems clear that the discharges were much more complicated than they seemed to be. We did point out that quenching by electrons should be considered, but there may well have been still other factors. In a similar high-power discharge, LeBlanc *et al.* (6) could find no evidence for collisionally-stimulated emission. But a further analysis of the results by Carleton (as yet unpublished) gave much larger quenching coefficients, in the same range as the other values quoted by Zipf. And in this case, laboratory and atmosphere are in excellent agreement.

An unscheduled discussion session was held at the Symposium on the problems connected with the composition of the upper atmospheres of Mars and Venus following the paper by Zipf. This report, written after the meeting, attempts to state the problem and outline some of the current thinking. The atmospheres of these planets are mainly composed of CO_2; the problem is essentially that of understanding the photodissociation of this gas and the subsequent association of the products, CO and O. Superficially, the situation resembles that of O_2 on Earth, which decomposes into O above 90 to 100 km. CO_2, like O_2, has a strong dissociation continuum below about 1800 Å, and the daytime dissociation rate should be about 5×10^{12} cm^{-2} s^{-1} by the reaction

[1] $$CO_2(^1\Sigma) + h\nu \rightarrow CO(^1\Sigma) + O(^1D)$$

The upper atmospheres of Mars and Venus should thus be composed largely of CO and O, with some O_2 from the association of O atoms. A photochemical model of this sort is given by Chamberlain and McElroy (7).

The ionospheric heights and densities measured by Mariner IV on Mars and Mariner V on Venus show with considerable confidence that CO_2 is largely undissociated throughout the upper atmospheres of both planets. Relatively small admixtures of lighter gases would increase the scale heights so much as to make it impossible to fit the observed profiles of electron density. This conclusion is rather general, and independent of detailed ionic reaction mechanisms and rates. With pure CO_2, the Venus ionosphere can be fitted remarkably well; there is still a considerable discrepancy on Mars, but CO_2 is strongly suggested (8–11). A second line of evidence for Venus is the low intensity of the resonance triplet of O at 1304 Å; neither Venera 4 nor Mariner V detected it. Though there are problems of interpretation, these results at least suggest a very small abundance of O at great heights.

Planetary studies thus seem to require that CO and O react much faster than O and O. But the reaction is spin-forbidden (with ground-state O) and thus very slow

[2] $$CO(^1\Sigma) + O(^3P) + M \rightarrow CO_2(^1\Sigma) + M$$

Note that the allowed photodissociation, reaction [1], yields an excited O atom. The inverse of this reaction should be much faster than [2], but presumably a third body is still required. The maximum 3-body coefficient for a simple reaction (10^{-32} cm^6 s^{-1}) is still inadequate by far to maintain an undissociated upper atmosphere.

In the laboratory, it is usual to find that traces of water vapor efficiently catalyze the association by reactions such as

[3] $$CO + OH \rightarrow CO_2 + H$$

[4] $$CO + HO_2 \rightarrow CO_2 + OH$$

but in an upper atmosphere, at total concentrations of 10^{12} cm^{-3} or less, the re-oxidation of the H atoms is very inefficient, and these reactions can readily be ruled out as soon as actual quantities are considered (cf. McElroy (9)).

Laboratory photolysis experiments on CO_2 produce equally mysterious results. Reaction [1], followed by association of O, should produce CO with a quantum efficiency of 1, and O_2 with a quantum efficiency of $\frac{1}{2}$. Mahan (12) found a serious deficiency of O_2; Warneck (13) confirming this result, showed that the missing oxygen was not present as ozone. Taking up a suggestion of Katakis and Taube (14), he postulated a CO_3 molecule, and found indeed that most of the missing oxygen reappeared after a wait of 1 h. Ung and Schiff (15), and Slanger (16) showed that these results depend greatly on the condition of the walls; with certain treatments there is no deficiency of O_2. Young and Ung (17) searched without success for the forbidden 6300 Å emission from $O(^1D)$ and concluded that this metastable atom either reacts with or is quenched by CO_2 with a rate coefficient greater than 10^{-13} cm^2 s^{-1}.

Following the suggestion of Young and Ung, McElroy (8, 9) postulated the following reaction scheme for a planetary atmosphere. The CO_3* molecule is not the same as the CO_3 inferred from the work of Warneck; it is an excited state, best considered as a complex of CO_2 and $O(^1D)$, which can decay or be quenched into the more stable CO_3, or spontaneously dissociate.

[5] $$O(^1D) + CO_2 \rightleftarrows CO_3^*$$

[6] $$CO_3^* + CO \rightarrow 2CO_2$$

Taken together, [5] and [6] constitute a 3-body reaction. But the effective rate coefficient can be much greater than 10^{-32} cm^6 s^{-1}, in the same proportion as the lifetime of CO_3* exceeds

10^{-14} s. (At the Symposium, Phillips independently proposed the same scheme.)

It appears that CO_3 and CO_3* can explain most of the laboratory observations as well. In addition to those mentioned above, from which the suggestions arose, there is the flash photolysis study by Clerc and Barat (18), which showed a decrease of CO in the first 60 μs. Their explanation in terms of reaction with $O(^1D)$ could also be satisfied by CO_3*, which would form on about the same time scale. The latest work finds $k_5 = 2 \times 10^{-13}$ cm^3 s^{-1}. Noxon (19) finds that emission of the 6300 Å line is not strongly quenched by CO_2; the CO_3* would continuously regenerate $O(^1D)$ by the reverse of [5], and the same thing may be happening in the work of Clerc *et al.* But Young and associates (20) find strong quenching in the presence of NO, which presumably swallows up the CO_3* so fast that it cannot regenerate $O(^1D)$ (see their comments).

The explanation is not so clear-cut for the reaction

$$[7] \qquad N_2O + O(^1D) \rightarrow N_2 + O_2$$

Yamazaki and Cvetanović (21), and later Cvetanović (22), studied this reaction in the case where the $O(^1D)$ is produced by photolysis of the N_2O; the reaction is strongly quenched by added CO_2. Warneck (23) observed the reaction [7] to dominate in CO_2 with less than 1% added N_2O. Here, most of the excitation would reside in the form of CO_3*, but a small concentration of $O(^1D)$ would be maintained in equilibrium with it, to react in [7]. We must then postulate that a large excess of N_2O quenches CO_3* to CO_3, or to $CO_2 + O(^3P)$. Under these conditions, CO_2 acts as a quenching agent, or more properly a quenching catalyst.

Direct observations of CO_3 have been made by Moll, Clutter, and Thompson (24), by infrared absorption in a matrix of solid CO_2. The compound was formed in a stream of CO_2 by photolysis or electric discharge. Metastable CO_3* has considerably less status, and for the present its existence must be considered an ad hoc hypothesis. Perhaps its most unlikely property is its postulated formation in the 2-body process (8), though in the laboratory experiments stabilization by a third body is possible. Stabilization for periods as long as us in a planetary atmosphere would seem to require the improbable emission of an infrared photon. Moll *et al.* found that their CO_3 was readily dissociated by visible and near-ultraviolet radiation; its lifetime in sunlight would thus be very short, and that of CO_3* presumably even shorter.

Laboratory measurements of photoionization, photoexcitation, and photodetachment

RICHARD I. SCHOEN
Boeing Scientific Research Laboratories, Seattle, Washington 98124

Received December 18, 1968

This review is devoted to a discussion of laboratory measurements of ionization, fluorescence, and photodetachment. The review is limited to molecules of aeronomic interest but excludes atoms. The section on photodetachment includes only work which has appeared since 1964. Current data are presented on photoionization cross sections, dissociative ionization cross sections, cross sections for the excitation of particular states of ions, relative vibrational excitation probabilities, photodetachment cross sections, angular distributions of electrons from photoionization, and dissociative excitation of neutral molecules. Some suggestions are made for further work.

Canadian Journal of Chemistry, 47, 1879 (1969)

I Introduction

This review deals with those photoabsorption processes which cause the release of charged particles or photons. Laboratory measurements of photoionization cross sections are discussed, and cross sections of excitation into particular ionic states are considered. Some recent work on photodetachment is presented. Experiments in which fluorescence of molecular and atomic species is produced by photoabsorption are examined. The intent is to present values of cross sections and determinations of excitation to particular states which will be of use in aeronomic calculations, to indicate the accuracy of existing data where possible, and to point out areas where more work is needed.

In a preceding review Huffman (1) has discussed photoabsorption cross sections. Within the ionization continuum of any atom, its absorption and ionization cross sections will differ only at rare, non-autoionizing lines. Therefore photoionization cross sections of atoms are not considered here, nor are photoexcitation processes which reveal themselves in the photoabsorption spectrum. Information about states of excitation which is gathered by purely chemical means is also excluded.

Since the aim of this review is to present a critical discussion of current data, some detailed descriptions of experimental pitfalls have been included, and consideration of the pioneering work of purely historical interest has been curtailed. For discussions of the older literature on photoionization, the reader is referred to reviews by Weissler (2) and Watanabe (3). Ditchburn and Öpik (4) give a short discussion of theoretical and experimental aspects of photoionization. Branscomb has presented a comprehensive review of photodetachment (5). More recently Marr (6) has devoted a complete volume to photoionization, and Samson (7) a complete volume to vacuum ultraviolet (u.v.) techniques. The field of vacuum u.v. photochemistry has been reviewed by McNesby and Okabe (8), and the reader should consult their article for information on chemical techniques.

The rest of the paper is divided into topical sections. Section II is devoted to photoionization cross section measurements, section III to dissociative ionization cross sections, and section IV to cross sections for excitation to particular ionic states. In section V fluorescence of excited ions and neutrals is examined, and some recent work on photodetachment is discussed in section VI. Conclusions are presented in section VII.

II Photoionization Cross-section Measurements

The photoionization cross section, $\sigma_i(\lambda)$, is that part of the absorption cross section which represents ionization by absorption of photons of wavelength λ. It is usually assumed that only singly charged ions are produced by photoionization. This assumption is almost certainly correct for the wavelength region $\lambda > 300$ Å and the molecules discussed here. In a typical experiment an ion current, $i(\lambda)$, is produced by monochromatic radiation shining into a chamber like that of Fig. 1. The magnitude of this current is given in eq. [1]

$$[1] \quad i(\lambda) = I_0(\lambda)\{1 - \exp[-nl\sigma_T(\lambda)]\} \times e\sigma_i(\lambda)/\sigma_T(\lambda)$$

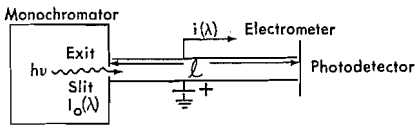

FIG. 1. A schematic diagram of a simple ion chamber. The entrance slit of the chamber is the exit slit of the monochromator.

$I_0(\lambda)$ is the photon flux in photons per second incident on the ion chamber; n is the number of molecules per unit volume; l is the chamber length; e is the electronic charge; and $\sigma_T(\lambda)$ is the cross section for all processes which remove photons from the beam. The ion current, the photon flux, and the cross sections are all functions of the wavelength of incident radiation, λ. The quantity $\sigma_i(\lambda)/\sigma_T(\lambda)$ is called the photoionization efficiency or yield and represents the fraction of absorption which leads to ionization. For our purposes, we assume $\sigma_T(\lambda)$ to be known from other experiments (1).

The "monochromatic" photon flux used in the measurements of photoionization cross sections discussed here comes from a vacuum grating monochromator with an appropriate light source. Neither light sources nor monochromators are discussed here. It should be noted that window materials absorb strongly in the spectral region between 1050 Å and a few hundred angstroms; thus while differential pumping is used to evacuate the monochromators, both light sources and experimental chambers may be gas-filled. If one demands that less than 1% of the light be absorbed in the monochromator, it is necessary that the pressure of absorbing gases in the monochromator be no more than a few times 10^{-5} Torr.

Several options are available to the experimenter who wishes to measure photoionization cross sections. He may choose a comparative method to measure yields, in which case he obtains the ratio of the ion current from the gas of interest to the ion current from a gas of known yield under conditions of incident flux and absorption in the chamber which can be compared quantitatively. He may choose an absolute method, in which case he must make absolute measurements of the incident photon flux, $I_0(\lambda)$, and the ion current, $i(\lambda)$, together with the absorption, $1 - \exp[-nl\sigma_T(\lambda)]$, to obtain the yield, or he must make further absolute measurements of the particle density, n, and the chamber length, l, to obtain the photoionization cross section directly in the small pressure limit. The comparative method is discussed in the next few paragraphs, the absolute method later.

When the comparative method is employed, comparison is usually made with a noble gas (9–12) in which the photoionization efficiency, $\sigma_i(\lambda)/\sigma_T(\lambda)$, is 1 (9, 11, 13). This comparison with a noble gas is limited to wavelengths shorter than 1023 Å (12.127 eV), the ionization threshold of Xe. If measurements in the gas of interest are labeled with subscript M and those in the noble gas with subscript N, we have in the case of identical absorption in the two gases

$$[2] \qquad i_M(\lambda)/i_N(\lambda) = [I_{0M}(\lambda)/I_{0N}(\lambda)][\sigma_{iM}(\lambda)/\sigma_{TM}(\lambda)]$$

or

$$\sigma_{iM}(\lambda) = \sigma_{TM}(\lambda)[i_M(\lambda)/i_N(\lambda)]\,[I_{0N}(\lambda)/I_{0M}(\lambda)]$$

At each wavelength, for each gas, it must be ascertained that a known fraction (generally equal to 1.00) of all the ions is collected, that no electrons are collected on the ion collector, that the photoelectron current from the ion collector is negligible, and that the electrons produced in the photoionization process or from metal surfaces do not produce ions in the gas. The fact that the noble gases all appear to have the same photoionization efficiencies (11, 13, 14) indicates that it is proper to neglect secondary electron emission from the ion collector, as all observers have done. The chief advantage of the comparative method is that absolute measurements of currents and number densities are not required, although number densities must ultimately be measured to obtain $\sigma_{TM}(\lambda)$, the absorption cross section (1).

Relative photon flux measurements are generally made through photoelectric conversion. The measurements may be made directly from the photoelectric emission of a metal plate or indirectly from measurements with a photomultiplier of the visible light output from a material, such as sodium salicylate, which fluoresces under vacuum u.v. radiation. Typically,

For personal use only.

measurements of the incoming photon flux are made without an absorbing gas, to establish a relative value of $I_0(\lambda)$; measurements are then made with the absorbing gas and then measurements without absorbing gas are repeated. The light source is assumed to have an output constant in time, if no significant changes occur between the first and the last measurements (i.e. those measurements without absorbing gas). Cook and Metzger (12) indicate that their helium continuum source is constant to about 2%. Ditchburn (15) has suggested a double beam method to eliminate concern about variations of light source intensity, but his suggestion does not appear to have been used in photoionization measurements. The double ion chamber method (2, 10, 11) is almost equivalent to a double beam technique. Use of this method requires that the familiar single ion chamber be divided into two parts, typically two identical ion chambers. The distance between the front of the first and the front of the second chamber is measured, as is the distance from the photodetector to the chamber entrance slit. The ratio of the currents from the two ion chambers then gives the logarithmic decrement of light intensity in the chamber, and, from this decrement and the measured photodetector current, $I(\lambda)$, the current which the photodetector would give if it were placed at the chamber entrance is calculated. This latter current is the current which would be measured if no gas were in the chamber; thus a measure of $I_0(\lambda)$ can be obtained from $I(\lambda)$. The difficulty is that I_0/I may be a large number. It is doubtful that the accuracy of determining I_0 by this method is better than the 2% claimed above as the accuracy of the assumption that I_0 is a constant. The double ion chamber method does provide a useful check against larger variations in light source intensity.

Changes in the efficiency of a sodium salicylate converter may be misinterpreted as light source intensity changes. Efficiency changes have been noted many times (7), but they can, in most cases, be avoided by making measurements within a few hours of calibration. The cause for changes in the efficiency of the sodium salicylate is unknown. It is known, however, that some reactive gases such as NO_2 decrease the efficiency within minutes. In general, care must be taken that the gas does not affect the photodetector and that the photodetector does not affect the ion current measurements. The latter is especially important when photoemission from a metallic surface is used as a detector (12).

Problems of light scattered from the grating, light reflected from metal surfaces in the ionization chamber, and fluorescent light have been dealt with in some detail by various experimenters (12, 16, 17). These problems are not expected to be important in the work discussed here, nor are problems of wavelength identification.

The problem of resolution, however, is more difficult. When a continuum is used, the instrumental bandpass must be small compared to the width of an absorption feature, in order that measurements of ionization cross sections be reliable. In general, bandpasses which are not small compared with the widths of features produce cross sections which are too low at peaks and too high in valleys. Line sources in which lines are separated at the instrumental bandpass used give cross-section values which may depend upon line profiles in the source. In most cases the source-line widths are 0.1 Å or less (18) and probably are narrow enough. If several lines lie within the bandpass of the instrument used, the cross-section measurement will be accurate only if the cross section is the same for all lines.

The absorption cross section $\sigma_T(\lambda)$ is used directly to calculate the ionization cross section $\sigma_i(\lambda)$ from measured quantities (eq. [2]). Thus the error of measurement of the absorption cross section directly affects the photoionization cross sections measured by the comparative method. Absorption cross sections are discussed by Huffman in a preceding article (1), and a table of absorption and photoionization cross sections of O_2 and N_2 at solar lines is included. In all cases some variation of the comparative method was used in their measurement. Measurements in particular gases are discussed below.

O_2

Preferred values of the photoionization cross section of O_2 at particular solar lines are tabulated in a preceding article by Huffman. In all but a few cases these values are taken from Samson and Cairns (18) but have been rounded off. They are expected to be accurate to 10% except at those wavelengths at which several lines lie within the monochromator bandpass, and sharp variation of the cross section with wavelength is also found in the bandpass. Matsunaga and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Watanabe (19) have used both the helium continuum and the hydrogen many-lined source to obtain data in the 600–1020 Å region with resolution of 0.3 Å with the helium source and 0.2 Å with the hydrogen source. Agreement with the work of Samson and Cairns is within experimental error. The values of Matsunaga and Watanabe are recommended at wavelengths between 600–1020 Å other than those shown in the table. Except where there are strong bands, the values are probably within ±15% between 700–900 Å and somewhat less accurate at longer and shorter wavelengths.

The photoionization efficiencies of Cook and Metzger (12) and of Cook, Ching, and Becker (20), obtained with a continuum source, are lower than those of Samson and Cairns or Matsunaga and Watanabe over much of the spectral range. We think that the results of Cook and associates are less likely to be correct than those of Samson and Cairns or Matsunaga and Watanabe because: *(1)* the latter two groups are in agreement with each other but not with Cook and associates; *(2)* structure which has been found photographically (21, 22) in the absorption spectrum of O_2 in the spectral region 600–650 Å is found in the absorption and ionization cross section curves of Matsunaga and Watanabe but not those of Cook and associates; *(3)* it seems likely that at short wavelengths in regions in which the structure is not strong the photoionization yield should approach 1—Samson and Cairns, and Matsunaga and Watanabe find that it does; Cook and associates find that it does not; and *(4)* the double ion chamber methods used by Samson and Cairns are likely to be the most reliable for measuring the absorption cross section and for eliminating light source variation problems from the yield measurements.

N_2

The photoionization cross sections of Samson and Cairns (18) are preferred for the solar lines shown in the table in Huffman's article (1). The accuracy is again about 10% except in regions of strong band structure. In the spectral region 600–700 Å the results of Samson and Cairns are in good agreement with those of Cook and Metzger (12), who obtained cross sections with the aid of a continuum source and 0.5 Å resolution. The excellence of the agreement, however, is somewhat fortuitous because the absorption cross sections of Cook and Metzger are larger and the photoionization yields smaller than those of Samson and Cairns. In the range 750–800 Å the cross sections of Cook and Metzger and the cross sections of Cook and Ogawa (23), obtained with 0.2 Å resolution, do not agree well with those of Samson and Cairns. The differences are probably in part ascribable to the lack of resolution in a region of band structure. Cook and Ogawa used a technique which required pressure measurements at pressures of a few microns. Pressure measurement errors may have contributed substantially to their total error. The photoionization cross sections of Cook and Ogawa are recommended for those wavelengths between the 700–800 Å not tabulated, and the cross sections of Cook and Metzger are recommended from 600–700 Å. These cross sections are expected to be accurate to ±25%, except where strong band structure is found.

NO

Watanabe *et al.* (24) have worked in the range from 580–1350 Å with the helium continuum (580–950 Å) and the hydrogen many-lined source (860–1350 Å). Their resolution was 0.3 Å in the range 580–950 Å, 0.4 Å in the range 950–1100 Å, and 0.2 Å in the range 1060–1350 Å. These results supersede those of a previous paper (25) and are the preferred measurements. At wavelengths longer than 1020 Å, Watanabe *et al.* used calibration techniques to be described below; otherwise their techniques were the same as those used by Matsunaga and Watanabe (19). We judge that the cross section values given are probably accurate within ±10%, between 700–950 Å, and within ±20% at longer and shorter wavelengths, except in strong bands where the resolution may not be adequate. The photoionization cross section at Lyman-α (1215.7 Å) is 2.0 Mb, and the photoionization efficiency is 0.81.

Photoionization cross sections obtained by Metzger, Cook, and Ogawa (26) with the helium continuum and about 0.5 Å resolution in the spectral range 600–950 Å appear to be uniformly lower than those discussed above. The difference lies largely in the photoionization yields. For instance, Metzger *et al.* found yields to be 78% at 600 Å and less at longer wavelengths, while Watanabe *et al.* found the yields to exceed 90% for wavelengths less than 685 Å.

CO_2

The situation with respect to CO_2 is disturbing. Cairns and Samson (27) have made measurements with a line source and the double ionization chamber technique, while Nakata *et al.* (28) and Cook *et al.* (29) have used the helium continuum and single ion chamber with photomultiplier. In the almost structureless spectral region 600–686 Å, the ionization cross sections of Cairns and Samson are nowhere less than 48% larger than those of Nakata *et al.* and Cook *et al.* The latter two authors agree in this spectral range on the ionization cross sections to within 15%, but the agreement is partly fortuitous since Cook *et al.* find higher absorption cross sections and lower ionization efficiencies than do Nakata *et al.* Most of the difference between the results of Cairns and Samson and the other authors in this spectral region is ascribable to differences in absorption cross section, which are nowhere less than 30% of the values of Cook *et al.* Cook *et al.* and Nakata *et al.* differ by somewhat more than their stated probable errors toward the long wavelength end of the interval.

The helium continuum is weak at wavelengths shorter than 700 Å, and the measurement errors are consequently greater; but it is strong near 800 Å, and the accuracy should be better. At 840 Å the absorption cross section measured by Nakata *et al.* is 25% larger than that measured by Cook *et al.*, and at 880 Å the difference exceeds 40%.

On the basis of the number of electrons available, we would think that the absorption and ionization cross sections of CO_2 would be considerably greater than those of O_2 or CO in the spectral region near 600 Å. They appear to be from the work of Cairns and Samson, not from the work of Nakata *et al.* or Cook *et al.* The question of which values are best remains open, but we suggest those of Cairns and Samson when a choice must be made. It should be noted that the disparity between the results of these experienced and able groups of experimenters casts a shadow over all the cross sections of aeronomic interest mentioned previously.

Other Gases

Watanabe and co-workers (30) have examined the photoionization of NO_2, and Metzger and Cook (31) have measured photoionization cross sections of H_2O.

Absolute Methods and the Extension of the Comparative Method

If the experimenter requires photoionization yields at wavelengths longer than 1022 Å, the long wavelength limit of noble gas photoionization, he has several choices. He may extend the comparative method with transfer standards. To do this, he requires a detector the relative spectral response of which is known, such as a thermopile used with due caution (7). Typically the detector output at a wavelength λ_0 shorter than 1022 Å is measured with no gas in the ion chamber; the ion current from a rare gas is then measured under conditions of total radiation absorption. Measurements of the same quantities are obtained at the wavelength of interest λ_1 with the gas, M, and the yield obtained from the expression

$$\frac{\sigma_{iM}(\lambda_1)}{\sigma_{TM}(\lambda_1)} = \frac{k(\lambda_0)\, i_M(\lambda_1)\, I(\lambda_0)}{k(\lambda_1) i_M(\lambda_0)\, I(\lambda_1)}$$

in which the i_M is the ion chamber current, I is the detector current, and k is the relative sensitivity of the detector as a function of wavelength. For a thermopile, k may be taken as 1. For sodium salicylate, one might used published curves for k (7), which are no more accurate than the thermopile measurements on which they are based, or one might calibrate the sodium salicylate against the thermopile in the above relative sense at a few wavelengths at which large light fluxes are available. Due regard should be paid to the possible ageing of sodium salicylate if it is used (7), as it frequently is because of the much greater sensitivity available from it than from thermopiles.

Another choice is the measurement of absolute photon flux with a thermopile. This involves calibrating the thermopile in air, then recalibrating in vacuum if one wishes to work in a windowless system. After calibration, photon fluxes can be measured absolutely with no gas in the ion chamber, and then the ion chamber can be filled so that ion current can be measured with total absorption of the radiation. The yield is then the ratio of the number of ions detected per second to the number of photons absorbed per second. The absolute method is subject to additional error above that found in the comparative method in each of the extra steps of thermopile calibration and in the measurement of absolute

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

rather than relative ion chamber currents. Hinteregger (32) estimates that absolute calibration of thermoelectric detectors is usually not better than 20%. Watanabe *et al.* (24) have used the absolute method in their work on NO in calibrating their sodium salicylate detector, but they did have an ion chamber comparison with a noble gas to check their calibration at short wavelength.

It should be noted that at no point in measurements of photoionization efficiencies is it necessary to measure the absolute pressure, although it is necessary to measure it when the absorption cross section is measured, and it is necessary that the pressure should be uniform in ion chambers. The uniformity of the pressure has been carefully investigated by those experimenters who have used simple ion chambers (11, 12, 16). The data which have been presented here are thought to be free of errors caused by pressure non-uniformity. As one can see from eq. [1], the absorption cross section can be eliminated from consideration by working under optically thin conditions, i.e., at low pressures. However, one trades measurements of $\sigma_T(\lambda)$ made at relatively high pressures (tens or hundreds of microns) for measurements of $\sigma_i(\lambda)$ made at relatively low pressures (a few microns), with a consequent loss in accuracy in the pressure determination, thus in $\sigma_i(\lambda)$.

The foregoing remarks apply also to absolute measurements of photoionization cross sections in mass spectrometers in which measurements are made under optically thin conditions. In these instruments the ion chamber pressure is likely to be less than a micron, and the flow rates are likely to be high; thus pressure determinations are difficult. Furthermore, the definition of the effective path length of ionization and the collection and detection efficiencies are also difficult. Therefore measurements with mass spectrometers of absolute photoionization cross sections are likely to have much larger systematic errors than do ion chamber measurements.

Comes and Lessman (33) have made absolute photoionization cross section measurements in N_2 with a mass spectrometer. The measurements are in agreement with those of Samson and Cairns (18) below 500 Å but are consistently higher (by more than 50% in places) from 500–700 Å, where band structure should play no important role. Difficulties of absolute measurements of pressure and photon flux can be decreased by the introduction of a noble gas as an internal standard (at least for $\lambda < 1020$ Å).

In a photoionization cross section measurement, instead of allowing the photon beam to traverse an ionization chamber, one may allow it to intersect a molecular beam. In such beam-interaction experiments, which are generally done with mass spectrometers, absolute measurements are afflicted with all of the problems indicated immediately above, plus the problems involved in determining the effective beam–beam interaction region and the molecular density therein.

Very recently Comes and colleagues (34, 35) have measured the photoionization cross sections of atomic oxygen and nitrogen by this technique. The method is a comparative one. First a photodetector is calibrated by comparing its output current to the current from photoionization of a hydrogen atomic beam (36). The photoionization cross section for hydrogen is exactly calculable. Then the current from the photoionization of the atomic species in the atomic beam is measured and compared to the photodetector current to produce a relative atomic photoionization cross section as a function of wavelength. Next, the absolute photoionization cross section of the molecular species (O_2 or N_2, in this case) is measured at one wavelength in a separate ion chamber experiment. Finally, the absolute cross section is obtained by comparison of the photoionization currents from the atomic and molecular constituents of the beam at the wavelength for which the ion chamber experiment was done. It is assumed that the relative concentration of atoms to molecules in the beam can be obtained from the change in the molecular photoionization current produced by the discharge which dissociates some of the molecules to form atoms and a temperature measurement. It is too early for a definitive evaluation of the work; however, the beam method is a very important one for dealing with unstable species and will probably give the best cross sections for their photoionization.

III Dissociative Ionization

We have discussed ion chamber measurements of photoionization cross sections in which no distinction was made between one ion species and another. We now turn to a discussion of measurements of cross sections for the production of specific ion species from dissociative ionization. Such measurements are made by coupling mass spectrometers to monochromators (25, 37–40). Absolute cross sections for dissociative ionization

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

processes can be obtained in two ways. Absolute measurements may be made of the photon flux, neutral number density, the length of photon beam over which ions are collected, the ion current, and detector efficiency as discussed previously. On the other hand, measurements may be made of the relative probability for the production of various ion species, then cross sections for the production of particular species may be calculated by multiplying the relative probability of producing a particular ion type at one wavelength by the total photoionization cross section, which has been obtained at that wavelength in experiments of the kind previously discussed.

Two prominent sources of systematic error exist (38). First, ion fragments with kinetic energy of dissociation tend to be lost from the ion beam in the mass spectrometer because of their motion transverse to the beam direction (41, 42). This effect will always make fragment ions appear to be less numerous than they are. Second, when electron multipliers are used for ion detection (a common practice since photon-produced ion currents are small), ions of different masses and different chemical makeup may be detected with different efficiencies at the electron multiplier. This effect may cause errors in either direction, may depend upon the species being studied, the material of the first dynode of the multiplier, and possibly its surface contamination.

Because of the difficulties outlined above, together with the difficulties of measuring photoionization cross sections, there is relatively little accurate data on dissociative ionization of molecules of aeronomic interest. Selected data are presented below.

N_2

The cross sections for the production of N^+ from N_2, which have been measured by Comes and Lessman (33) with a vacuum monochromator and quadrupole mass spectrometer, are shown in Fig. 2. These recent measurements of Comes and Lessman are preferred to the earlier measurements of Weissler *et al.* (38) who used a vacuum monochromator coupled to a magnetic mass spectrometer. One can compare the "ions-per-photon" curves of Weissler *et al.* obtained by mass spectrometry with ionization cross sections measured with ion chambers. If we use the work of Cairns and Samson (27) for A, Samson and Cairns (18), and Matsunaga and Watanabe (19) for O_2, and Cook and Metzger for N_2 (12), one concludes that the work of Weissler *et al.* deviated by as much as a factor of 3 from accurate ion-chamber measurements.

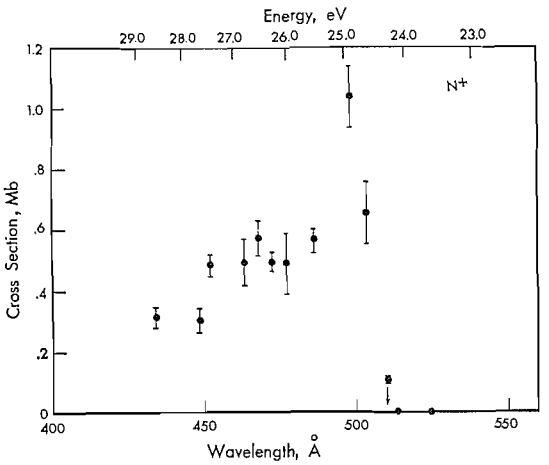

FIG. 2. The dissociative ionization cross section of N_2 as measured by Comes and Lessman (33).

Comparison of the N_2^+ cross sections of Comes and Lessman with photoionization cross sections of Samson and Cairns (18) reveals no systematic error in the wavelength range in which N^+ ions were produced, although there is a systematic error in the N_2^+ cross sections of Comes and Lessman at longer wavelength. It is difficult to estimate the magnitudes of systematic errors in these experiments. Doolittle and Schoen (unpublished) find no energetic ions from N_2 photoionization in this spectral range. Therefore there is probably no discrimination in the collection system between N^+ and N_2^+, but there may be discrimination in the detector, and the relative detection efficiencies for the two ions in this apparatus are not known.

O_2

The dissociative photoionization cross section for the production of O^+ from O_2, shown in Fig. 3, has been measured by Comes *et al.* (34). These measurements were made with a molecular beam. The cross sections were made absolute by comparison with the photoionization cross section leading to O_2^+. During these measurements Comes *et al.* determined the relative detection efficiency of their electron multiplier for O^+ and O_2^+ ions by comparing the pulse height distributions, thereby eliminating one serious measurement problem. It is shown below that dissociative

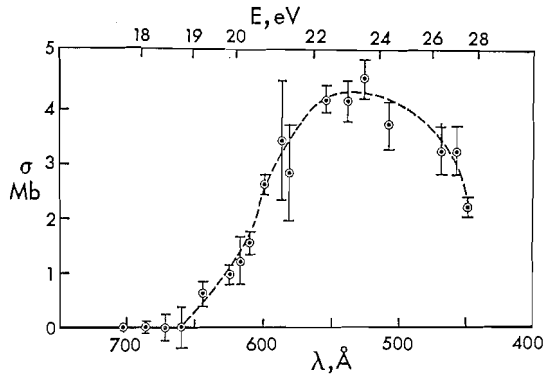

FIG. 3. The dissociative ionization cross section of O_2 as measured by Comes *et al.* (34).

ionization of O_2 produces energetic O^+ ions at wavelengths shorter than 584 Å. How much such energetic ions change the transmission of the time-of-flight mass spectrometer used by Comes and Lessman is not clear, but it is clear that the effect of energetic ions is to make the cross sections appear to be lower than they actually are. Thus the accuracy of the results shown is not known, but they are more likely to be low than high and likely to be more in error at shorter wavelengths than at longer.

Dibeler and Walker (43), without making any claim to measure cross sections, report an O^+ signal 0.03 of their O_2^+ signal at 584 Å. This signal represents a cross section of about 0.7 megabarn (Mb), but the relative transmission and counting efficiencies are unknown. Dibeler and Walker report the formation of O^+ and O^- in the spectral region 718.5–700 Å with a peak intensity of about 0.03 that of the O_2^+ ion at 718.5 Å. Because the correct normalization was very much in doubt, their cross-section curve was not included in Fig. 3. Somewhat earlier, Elder *et al.* (44) had obtained information similar to that of Dibeler and Walker, but at lower resolution.

Other Gases

Although they make no claim to measure photoionization cross sections, Dibeler and coworkers have obtained photoionization mass spectra of CO_2 (43), N_2O and NO_2 (45), and H_2O (46).

IV Excitation of Ions during Photoionization

Electron and Ion Energies

The study of the states of excitation of ions produced by photoionization is generally accomplished by measuring the kinetic energies of the charged particles released or by studying the fluorescence, if any, of the ions. Some of the processes which can take place during photoionization are illustrated in Fig. 4.

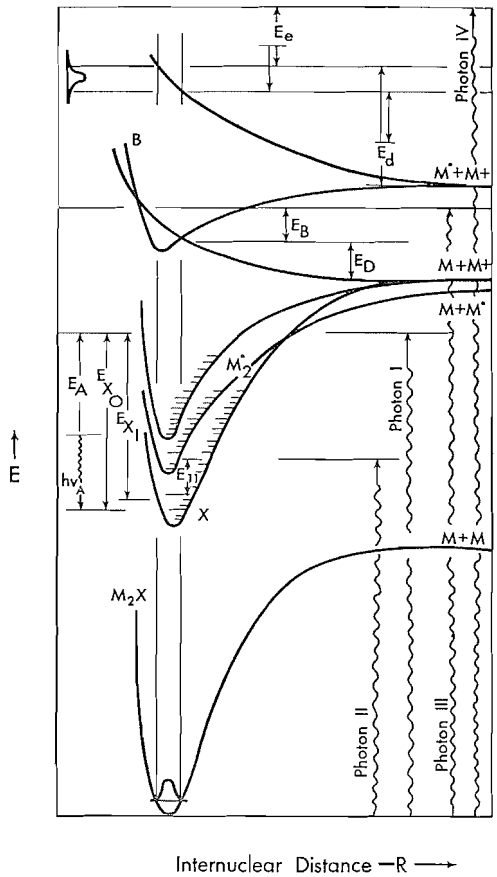

FIG. 4. Ionization processes in a mythical molecule, M_2.

Absorption of photon I may cause a transition to the ground electronic and vibrational state of the molecular ion with the release of an electron of energy E_{X0}, or a transition to the vibrationally excited ground electronic state with the release of an electron of energy E_{X1}, or a transition to the A excited state of the molecular ion with the release of an electron of energy E_A. If selection rules allow, excitation of state A may be followed by the emission of a photon of energy $h\nu_A$. Photon II may be absorbed to produce an excited state of the neutral M_2 which may decay by autoionization to a particular vibrational level of the X state of the molecular ion. The energy of

Spherical analyzer, Frost *et al.* (52). E. Quasi-spherical system with electron multiplier, Samson (53).

the released electron in that case is E_{II}. Absorption of photon III may cause excitation of the B state of the molecular ion, the release of an electron of energy E_B, followed by the predissociation of the molecular ion to release fragments whose total energy is E_D. Photon IV may lead to ionization through a repulsive potential curve with release of an electron which lies in the continuous energy band E_e, and to release of heavy particles the sum of whose energies lies in the corresponding band E_d.

Energies of charged particles have been studied in cylindrical geometries (47–51), spherical (52) and quasi-spherical geometries (53), and with electron focusing systems and plane retarding fields (54–55). Simple retarding potential systems (47–50) and magnetic (51) and electrostatic (56) deflection analyzers have been used in cylindrical geometries as illustrated in Fig. 5A and B, while a lens system is shown in Fig. 5C. The common danger in the use of all cylindrical and focusing systems is that the ion currents measured depend on the angular distributions of the particles which in turn depend on the final states of the ions.

Even if one considers only one ionic final state, it is possible that the angular distribution of the charged particles released upon ionization will depend on the energies of the particles because of centrifugal pseudopotential terms in the Hamiltonian (57) and phases which are a function of energy. All distributions are expected to be in the form $A + B\cos^2\theta$ about the electric vector of polarized light (58–60) in the dipole approximation. A suitable average of this quantity must be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

taken when partially polarized light from a grating, or unpolarized light from a lamp, is used.

True spherical symmetry has not been devised, but approximations thereto have been used by several groups (52, 53), as illustrated in Fig. 5D and E.

If a truly spherical collection system is not available, one might ask what can be used to obviate problems of angular distribution. When one examines the terms in the angular distribution, $A + B\cos^2\theta$, one notices that the average of the second term over a sphere is one-third. Thus, collection at an angle at which $\cos^2\theta$ is one-third will permit one to measure currents which are independent of the angular distribution. Thus, if one makes measurements at an angle of 54° 44′ with respect to the electric vector of polarized light, the measurements will be independent of the angular distribution of the emitted charged particles. Furthermore, one can show that if the light is unpolarized, a measurement at an angle of 54° 44′ with respect to the direction of propagation will be independent of the angular distribution. If one considers three cones of half angle 54° 44′ about three orthogonal axes, one of which is the direction of propagation, one finds that these cones intersect in a line (the 1, 1, 1 direction). Observations made along this line will be independent of angular distribution if the radiation is unpolarized, or if it is polarized, along one of the two axes perpendicular to the direction of propagation. Because of the symmetry of the problem with respect to planes containing any two axes, there are 6 cones and 8 directions of intersection which satisfy the requirement.

Suppose now that the radiation is partially polarized. Consider a plane perpendicular to the direction of propagation and within that plane define an axis parallel to the exit slit of a monochromator. Measure an angle, η, from that axis. Let $f(\eta)$ be the probability that the polarization of a photon lies in the interval $\eta \rightarrow \eta + d\eta$ and expand $f(\eta)$ in a Fourier series. Only terms involving sines and cosines of even multiples of η will occur, because $f(\eta) = f(\eta + \pi)$. By expanding $\cos^2\theta$ one can show that only constant terms and those involving 2η remain. If the distribution is symmetric about the axis chosen and if no term in sin 2η arises, the choice of a direction of observation described above is proper.

Furthermore, it can easily be shown that if no terms in sin 2η arise, the conclusions reached above hold true no matter what solid angle the detector subtends, provided that the detector is circularly symmetric about the line chosen to lie at 54° 44′ with respect to the appropriate axes.

In the systems discussed above, the gas to be ionized is distributed uniformly in vacuum tanks of one kind or another. By using an electrical lens system and the high local densities available from molecular beams, Berkowitz *et al.* (55) were able to make both retarding potential and angular distribution measurements. Vilesov *et al.* (61) have made angular distribution measurements without energy discrimination in a cylindrical tank system.

Two types of experiments may be distinguished: that with a monochromatic radiation source (He 584 Å resonance line) and no monochromator, and that with a monochromator and one of a number of kinds of light sources. In the former case it is expected that the light will be unpolarized; in the latter, partially polarized.

By attributing to each state a fraction of the photoionization cross section proportional to the electron current associated with it, cross sections for various states of excitation can be obtained. Problems which have been discussed previously, such as scattered light, photoelectrons from walls, light-source constancy, etc. are present in electron and ion-energy experiments also. Furthermore, in retarding potential experiments, the efficiency of collection of electrons or ions may depend upon the energy with which they impinge on the collector. Some improvement of collection efficiency can be achieved by coating the collector with carbon black (52), but one runs the risk of introducing inhomogeneities in the potential. Low energy electrons scattered from grids and plates have constituted a significant hindrance to electron energy measurements at low energies. When electron multipliers are used (53–55), care must be taken that the gases introduced do not cause changes in the efficiency or pulse height distribution during the course of the experiment. If electron energies are of interest, the local magnetic field must be reduced to a small fraction of the earth's field in the region of measurement. In all cases gas pressures must be low enough so that gas scattering is not important.

which the ions are left in either the $X^2\Sigma_g^+$ or the $A^2\Pi_u$ state by 584 Å radiation and found them both to be spherically symmetric as illustrated in Fig. 6. If in the ionization to the $B^2\Sigma_u$ state the electron angular distribution is also spherically symmetric, as might be expected from the removal of a σ_u electron to a σ_g (but not a Π_g state) state in the continuum, then all methods of electron energy measurement should give the same results. Table I contains relative excitation cross sections for the three electronic states of N_2^+ which can be excited with 584 Å radiation. It appears that while the relative cross sections for the X and the A states are known to perhaps 20%, that of the B state is known only within about a factor of two. Vibrational distributions have also been investigated at 584 Å and are presented in Table II with some calculated values. Rather large errors are quite possible for small transition probabilities to upper vibrational states in retarding potential measurements. These errors come from two sources: noise proportional to the total current collected and noise from scattered

low energy electrons, both of which are large at low electron energies in electron retarding potential experiments. In Table II agreement is reasonably good, both among experiments and between theory and experiments.

The spectral region around 584 Å does not have strong autoionization bands, but such bands are present at longer wavelengths and may have a large effect on the energy distribution of the outgoing electrons. Figure 7 illustrates the difference in the vibrational distribution in nitrogen in two autoionization bands within a few angstroms of each other. In such regions averages of cross sections for excitation to particular states of the ion over 5 or 10 Å are as likely to be as misleading as the ionization or absorption cross sections so averaged. Therefore investigation with high spectral resolution is required in each autoionization region of interest.

Nonetheless, the only direct information from electron energy experiments concerning the wavelength dependence of the cross sections for excit-

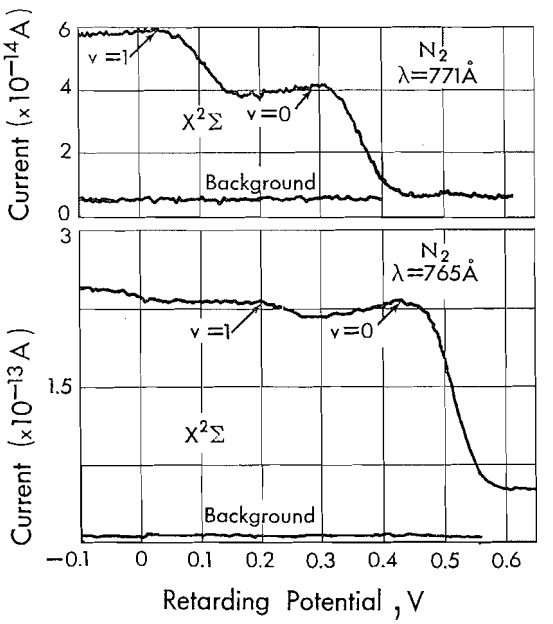

FIG. 7. Electron retarding potential measurements of vibrational excitation in an autoionization region, Schoen and Doolittle (unpublished). Step heights are proportional to excitation probabilities at each wavelength. Step heights at one wavelength should not be compared to step heights at another wavelength.

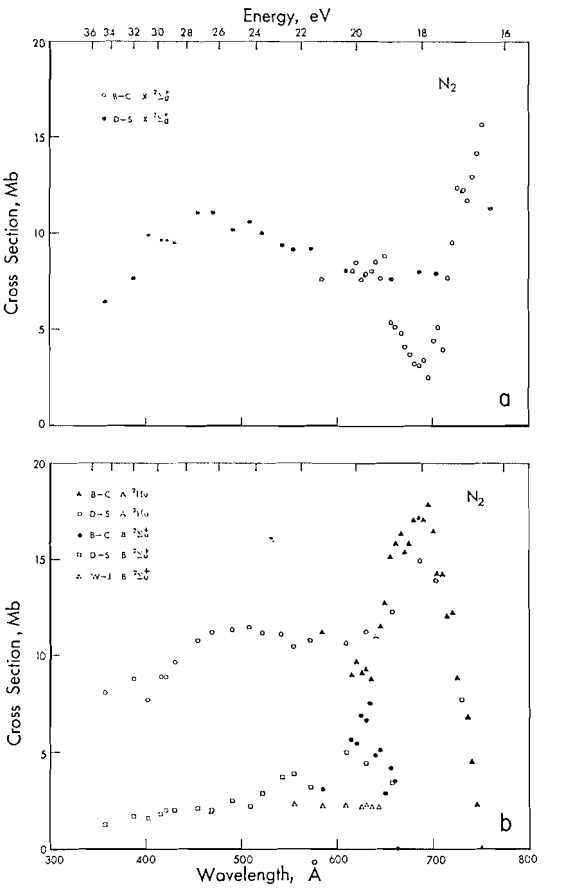

FIG. 8. Photoionization cross sections for the excitation of various states of N_2^+. B–C, Blake and Carver (50). Their results are normalized to the cross sections of Cook and Metzger (12). D–S, Doolittle and Schoen (unpublished). Their results are normalized to the cross sections of Samson and Cairns (18). W–J, Judge and Weissler (66) from fluorescence. Their results are normalized to Frost *et al.* (52) at 584 Å.

ing particular states of the N_2^+ ion has been obtained with relatively large bandwidths and cylindrical analyzers. Blake and Carver (50) have used a continuum source for these measurements (bandwidth $\approx$ 10 Å), and Doolittle and Schoen (unpublished) have used a line source (bandwidth $\approx$ 3 Å). Partial ionization cross sections from these two groups are shown in Fig. 8. There is no information about the angular distribution of the electrons at wavelengths other than 584 Å. To test for discrimination effects which change as the wavelength changes, it is advisable to sum quantities proportional to the cross sections for excitation of the individual states and compare the sum with the total ionization cross section. In a retarding potential experiment, this can be done by dividing the collector current associated with each ionic state by the photon detector current properly normalized to remove any wavelength dependence of photodetector efficiency. The ratio of the measured photoionization cross section to the sum of the quantities calculated above should be a constant independent of wavelength. Doolittle and Schoen (unpublished) have applied such a test to their raw data for N_2 and find that the sum of the partial cross sections appears to be as much as 40% high at long wavelengths and as much as 40% low at short wavelengths. Whether the cause lies in the sodium salicylate converter or in an energy dependence of collection efficiency is not clear. Their data shown in Fig. 8 have been corrected by normalization to the total cross section at each wavelength. Blake and Carver have tested the collection efficiency of their apparatus as a function of electron energy; they find no energy discrimination effects.

O_2

Berkowitz *et al.* (55) have found at 584 Å that the electrons released from O_2 in removal of a π_g electron to produce the $X^2\Pi_g$ state of the O_2^+ ion have a tendency to come out parallel or antiparallel to the direction of the photon beam, as shown in Fig. 9. Removal of other electrons appears to produce only spherically symmetric distributions. Therefore, the apparent cross section for the production of the ground state O_2^+ ion will appear to be too small when measured in cylindrical systems. Some measurements of the relative probabilities of transition to various electronic states with 584 Å radiation incident are given in Table I. No corrections have been made for angular discrimination.

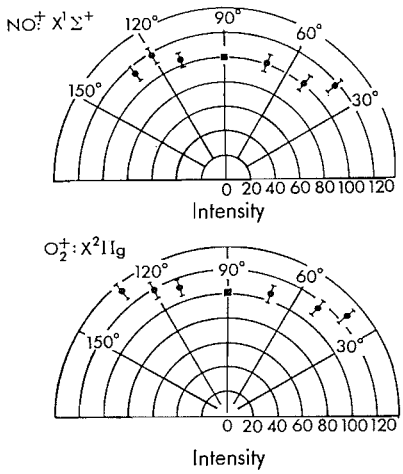

FIG. 9. Angular distribution measurements of electrons released in photoionization. Bottom—excitation of the $X^2\Pi_g$ state of O_2^+. Top—excitation of the $X^2\Pi_g^+$ state of NO^+ from Berkowitz *et al.* (55).

It is interesting that Blake and Carver (50), with a cylindrical apparatus, obtained a larger probability for transition to the $X^2\Pi$ state of O_2^+ than did Vroom (62), who used a spherical retarding potential system. Samson's results (private communication) are from a quasi-spherical geometry (Fig. 5E) and may be affected by polarization of the radiation, but relative transition probabilities certainly agree with Vroom's values to within experimental error. It should be noted that, even with resolution of the order of 20 mV (56), no one has been able to resolve the $A^2\Pi_u$ state from the $a^4\Pi_u$ state. Some relative excitation probabilities of vibrational states in several states, again with 584 Å radiation, are shown in Table II. Deviations from calculated values are significant.

At longer wavelengths, large deviations from the Franck–Condon principle occur in the autoionization region. Blake and Carver (50) ascribe some of the effects seen in this region to the series of events: transition to a super-excited neutral, radiation of a photon in the red or infrared, and finally autoionization. They used a helium continuum with about 10 Å resolution. Doolittle and Schoen (unpublished) have investigated the same spectral region with a line source and somewhat better energy resolution. At some wavelengths they observed strong deviations from the Franck–Condon principle, but no transitions which required the emission of a photon were noted. The difference in results may be ascribable to the differences in wavelengths actually studied and in resolution differences. Figure 10 shows the measured relative transition probabilities to various electronic states as a function of wavelength. In the region between 650 and 800 Å, Doolittle and Schoen made measurements on autoionization lines in a number of cases. Since they worked with a line spectrum and resolution of about 3 Å, it is not likely that in this spectral region their results will be comparable to those of Blake and Carver, who worked with a helium continuum and about 10 Å resolution.

NO

Angular distribution measurements at 584 Å by Berkowitz *et al.* (55) have shown that the removal of the π_g electron, as in the case of O_2, produces an angular distribution peaked along the photon beam (Fig. 9). The most surprising fact to arise from electron energy measurements in NO is that an NO^+ state, $a^3\Sigma$, previously thought to lie 14.22 eV above the ground state of the neutral (67), does not exist there but that there is a state at about 15.5 eV (49, 57) which had not been observed previously. Vroom (62) finds a state at 14.84 eV which he labels $a^3\Sigma$, but this finding is not confirmed by others. Table II gives the relative excitation probabilities of various vibrational states of the ground state of NO^+ with 584 Å incident. Data on the relative transition probabilities to a few, but not all, electronic states are given in Table I. No published data are available for other wavelengths.

CO_2

Measurements by Spohr and Puttkamer (54) on the relative excitation probabilities of various

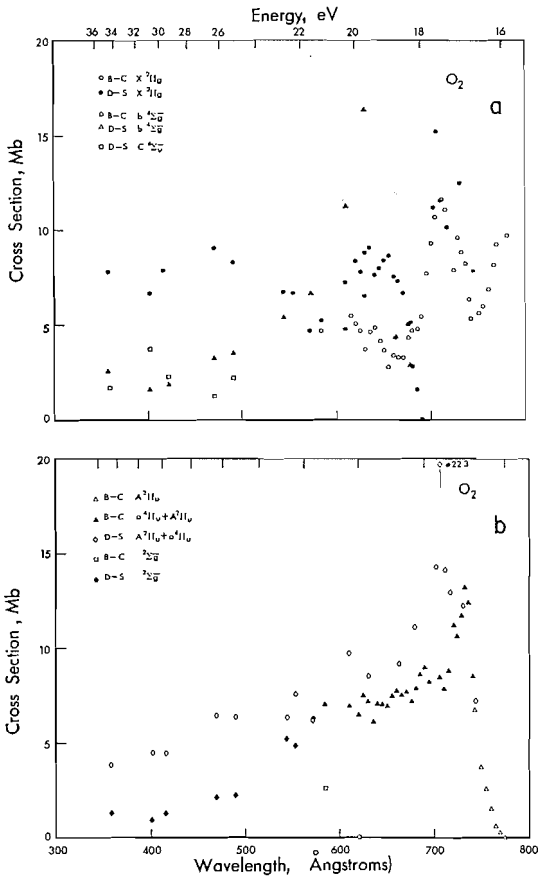

FIG. 10. Photoionization cross sections for the excitation of various states of O_2^+. B–C, Blake and Carver (50); their results normalized to the cross sections of Cook and Metzger (12). D–S, Doolittle and Schoen (unpublished); their results normalized to the cross sections of Samson and Cairns (18) 630 Å $\leqslant \lambda$ and Matsunaga and Watanabe (19) $\lambda \geqslant$ 630 Å.

electronic states excited with 584 Å radiation were obtained with an electron lens and retarding potential system. The results of these measurements are shown in Table I. Vibrational excitation probabilities were also investigated by these authors and by Turner and May (51) who used magnetic analysis.

Other Molecules

Of other molecules of some aeronomic interest, N_2O has been investigated by Turner and May (51), Spohr and Puttkamer (54), and Vroom (62), and NO_2 has been investigated by Spohr and Puttkamer (54) and Vroom (62). Blake and Carver (50) have measured the electron energy spectrum from H_2O with a cylindrical retarding potential analyzer from threshold to 584 Å.

Positive Ions

Positive ions may be studied by any of the various techniques outlined. The energy resolution is not nearly as good as it is for electron experiments because the motion of the neutral parent contributes significantly to the velocity of the ion fragment (68). Vroom (62) has measured the energy distribution of O^+ fragments from the photoionization of O_2 at 584 Å. He used a spherical retarding potential system. Doolittle *et al.* (69) have measured the energy distributions from dissociative photoionization of O_2 and N_2 in a cylindrical system at a number of wavelengths between 584 and 358 Å. No angular distribution measurements have been made.

Ion energy distribution measurements taken at 4 wavelengths in O_2 are shown in Fig. 11. Analysis of these and similar curves taken at other wavelengths and consideration of electron energy data and fluorescence data leads to a number of conclusions. First, the energies of these ions are great enough to cause significant loss from ion beams in some types of mass spectrometers, with consequent underestimation of the probability of formation of O^+ from O_2. Second, the $^2\Sigma^-$ state of O_2 predissociates, and other states of the molecular ion may predissociate. Third, some of the energetic neutrals accompanying the energetic ions are in metastable states.

Doolittle *et al.* (69) have made measurements of the dissociative ionization of O_2 in a mass spectrometer very sensitive to ion energies. They found that perhaps all, but not less than half, of the O^+ ions produced by 584 Å radiation had significantly more than thermal energy. At the same wavelength this group also used a cylindrical retarding potential analyzer to determine that 0.15 of all ions ($O_2^+ + O^+$) collected were energetic. Vroom (62), with a spherical retarding potential analyzer, found 0.075 were energetic. The difference in results might be ascribable to angular distribution effects or discrimination effects in one of the analyzers.

V Excitation of Ions and Neutrals

Fluorescence

While electron and ion energy distribution measurements are very useful in locating ionic

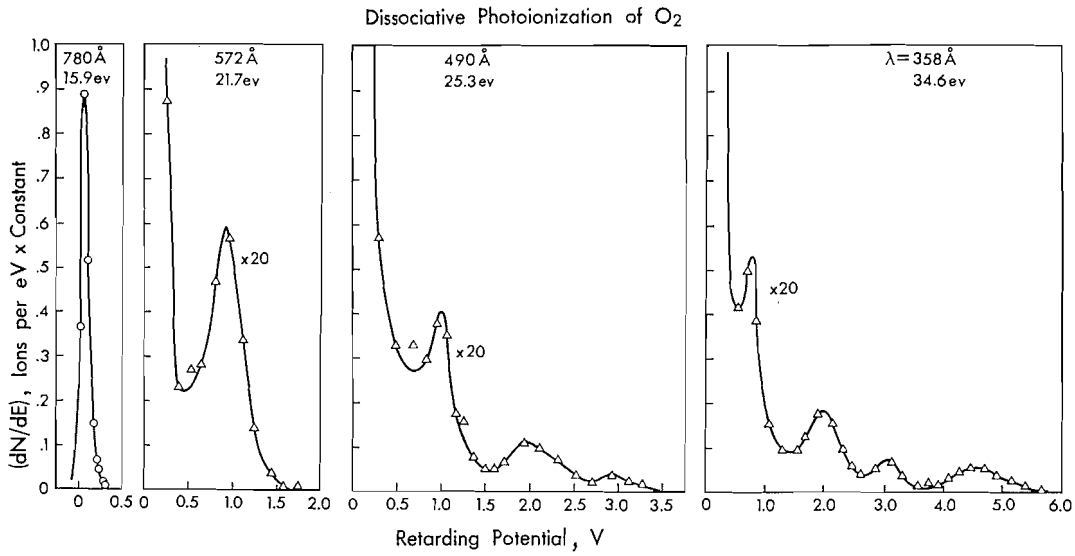

FIG. 11. Ion energy distributions measured at 4 wavelengths, Doolittle *et al.* (69). These curves are derivations of retarding potential curves. The ordinate is multiplied by 20 in the cases of the three shorter wavelengths.

states on energy level diagrams and in determining the relative probabilities of excitation of these states, such measurements give no information about neutrals, no information directly about the classification of electronic states, and occasionally fail to give information about the existence of electronic states, because of overlap of two or more vibrational progressions. Studies of fluorescence may give the missing information and may also give more precise results than electron and ion energy measurements do about the relative probabilities of exciting various electronic or vibrational states. Even failure to detect fluorescence when excitation is known to exist may be useful in determining classification when metastable states are possible.

In a typical fluorescence experiment, radiation of intensity $I_0(\lambda)$ from a monochromator is incident on gas in a cell such as that shown in Fig. 1, and the fluorescent radiation is viewed from the side with a photomultiplier or with a second monochromator and photomultiplier. Fluorescence is detected with an efficiency $F(x, \lambda,\lambda_f, n)$, which is a function of the position, x, of the fluorescing molecules in the chamber, of the incident wavelength, λ, of the fluorescent wavelength, λ_f, and of the molecular number density, n (if gas quenching, diffusion, or absorption of fluorescent radiation are important). If it is supposed that the detection efficiency is non-zero only between the distances L and $L + l$ measured from the chamber entrance, then the observed intensity of the fluorescence is given by

$$[3] \qquad I_f(\lambda,\lambda_f) = I_0(\lambda) \exp[-n\sigma_T(\lambda)L] \int_0^l n\sigma_f(\lambda,\lambda_f) \exp[-n\sigma_T(\lambda)x] F(x,\lambda,\lambda_f,n)\, dx$$

in which σ_f is the cross section for production of the fluorescing state and σ_T is the cross section for all processes which remove photons from the beam. This equation is generally simplified by making, implicitly or explicitly, the assumptions that $n\sigma_T L \ll 1$, $n\sigma_T l \ll 1$, and that the detection efficiency does not depend upon λ, x (between l and $L + l$), or upon n. Under these assumptions, eq. [3] can be simplified to the form

$$[4] \qquad I_f(\lambda,\lambda_f) = I_0(\lambda) nl\sigma_f(\lambda,\lambda_f) F(\lambda_f)$$

or

$$\sigma_f(\lambda,\lambda_f) = I_f(\lambda,\lambda_f)/I_0(\lambda) nlF(\lambda_f)$$

Under the conditions which allow the use of eq. [4], I_f/I_0 is proportional to the cross section for excitation of the fluorescing state. In no experi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ments in which dispersed vacuum ultraviolet radiation stimulated fluorescence has there been a measurement of $F(\lambda_f)$ which allowed a direct determination of $\sigma_f(\lambda,\lambda_f)$; however, the dependence upon incident wavelength of the cross section has been determined in a number of cases. If the value of the cross section is taken from electron energy data at an incident wavelength at which measurement is particularly accurate (584 Å, for instance), then the value is determined at all incident wavelengths from the measured wavelength dependence.

In fluorescence experiments, particular care must be taken not to confuse radiation caused by electrons released from the gas or walls with radiation caused by photon absorption processes. Confusion can also be caused by a change in the polarization of the fluorescent radiation as a function of incident wavelength. Such a change might change the detection efficiency, F, and be confused with a change in the cross section, σ_f. No experimental information about polarization is at hand.

Fluorescence information has been obtained with dispersed, incident radiation only during the past eight years. Some results for specific molecules are given below.

N_2

Cook and Metzger (12) and Huffman *et al.* (17) have determined the threshold for the production of strong visible fluorescence in N_2 to be 661 Å. This is the energy required to excite the $B^2\Sigma_u$ state of N_2^+. Judge and Weissler (66) have dispersed the radiation, identified the expected first negative bands of N_2^+, and determined the variation of the cross section with wavelength. Judge and Weissler chose their cross section value at 584 Å equal to that measured by Frost *et al.* (52) and calculated the cross section at other wavelengths from their measurements of wavelength dependence. Their results are shown in Fig. 8. This wavelength dependence of the cross section for excitation to the $B^2\Sigma_u$ state of N_2^+ is probably more accurate than that obtained from electron energy measurements.

O_2

Beyer and Welge (70) have used magnetic strip multipliers with LiF and CaF_2 windows to detect fluorescence from excited O atoms produced in the dissociation of O_2, Fig. 12. They have observed the direct radiation at 1302, 1304, and

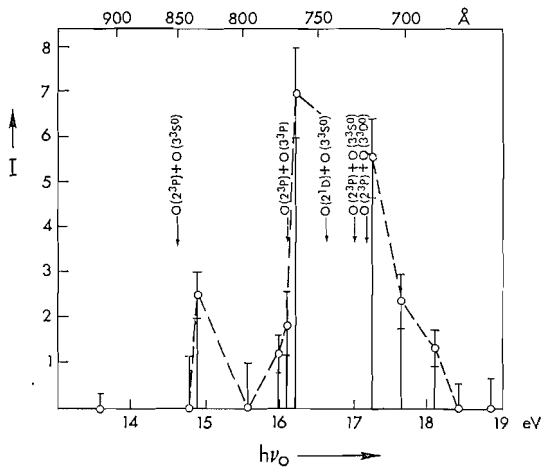

FIG. 12. Fluorescence of O_2 in the spectral range of fluorescent radiation 1250–1500 Å, Beyer and Welge (70). The ordinate is proportional to I_f/I_0. Incident photon energy is marked on the abscissa. These data were taken with a CaF_2 detector window. A LiF window did not change the intensity distribution.

1306 Å from the O(3s ^{3}S) state and the same radiation in cascade from the O(3p ^{3}P) state.

Cook and Metzger (12) and Huffman *et al.* (17) have observed a weak fluorescence in O_2 at thresholds which are identified as 736.5 and 722 ± 5 Å, respectively. The onset of this weak fluorescence is gradual; thus the threshold is difficult to determine. Cook and Metzger, with a photomultiplier which viewed from the side probably had more sensitivity than did Huffman *et al.* who view from the end with a sodium salicylate-coated multiplier. The fluorescence is probably from the $A^2\Pi_u$ state of O_2^+ and represents detection in a case in which electron energy measurements have not indicated a state. Confirmation with dispersed fluorescent radiation is awaited.

Judge and Weissler (unpublished) have detected radiation from the $b^4\Sigma_g^-$ state of O_2^+ and have observed several peculiar shifts of vibrational intensity at wavelengths above 600 Å. These shifts are probably related to autoionization.

NO

In Fig. 13 are shown relative fluorescence yields from NO measured by Beyer and Welge (70). The atomic oxygen lines at 1302, 1304, and 1306 Å that appeared from O_2 in these authors' measurements seem to appear here, also, both by

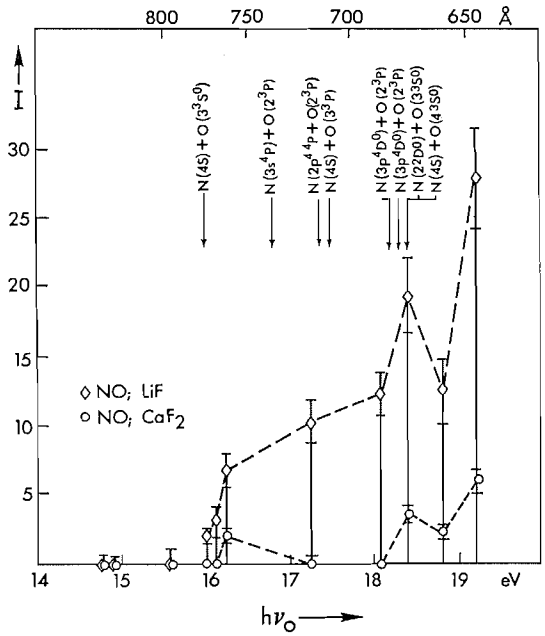

FIG. 13. Fluorescence of NO from Beyer and Welge (70). The ordinate is proportional to I_f/I_0. The incident photon energies are given on the abscissa. The spectral range of the detector was 1100–1500 Å with the LiF detector window and 1250–1500 Å with the CaF_2 window. Two figures in the original are combined here.

direct transition and by cascade. In addition, one or more radiations appear which are not transmitted by CaF_2 but are transmitted by LiF. These are attributed to the atomic nitrogen lines at 1200 and perhaps 1134 Å. In addition, Metzger *et al.* have observed radiation in the vacuum ultraviolet, which they attribute to the $A^1\Pi \rightarrow X^1\Sigma$ transition in NO^+, and have determined the threshold for excitation of this radiation to be 677.4 Å. Metzger *et al.* did not observe the transitions from the neutral atoms. It is not clear why.

VI Photodetachment

Since the whole field of photodetachment has been well reviewed during the last few years (5, 71), only recent work will be discussed here. Of particular interest are several new threshold determinations, cross section measurements, and angular distribution measurements.

The new data of Branscomb *et al.* (72) have been added to that of Smith (73) in Fig. 14 to show the photodetachment thresholds of O^- to form $O(^3P)$ and the $O(^1D)$. The authors point

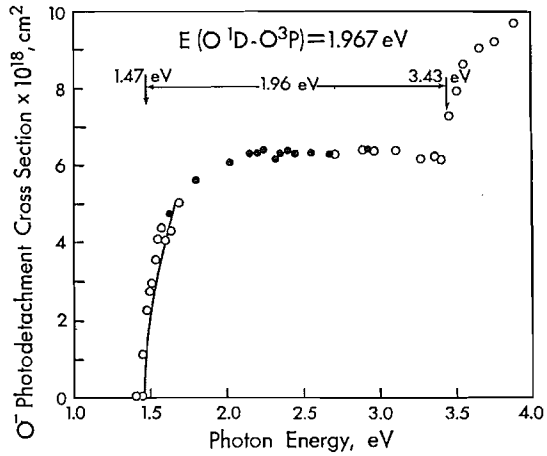

FIG. 14. The photodetachment cross section of O^- as a function of photon energy. The open circles are from Branscomb *et al.* (72); the filled circles are from Smith (73). The data of Branscomb *et al.* were normalized to that of Smith at 1.65 and 2.7 eV.

out that the rate of increase of the cross section above the second threshold is less than calculated, but calibration is very difficult when photon energies exceed 3.7 eV.

Branscomb (74) has measured cross sections for photodetachment of OH^- and OD^-, as shown in Fig. 15. The measurements themselves

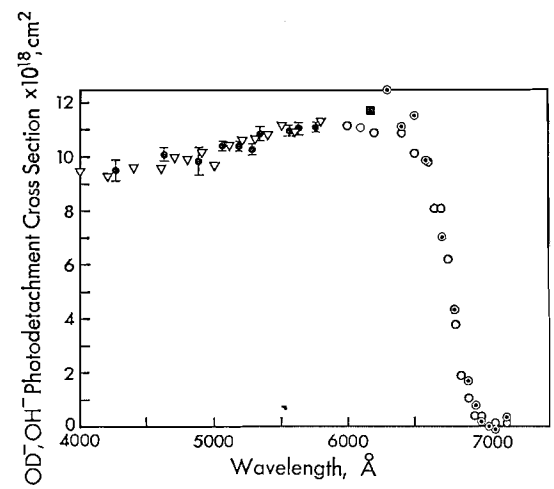

FIG. 15. The cross sections for photodetachment of OH^- and OD^- as a function of wavelength from Branscomb (74). The solid points refer to OH^-; the crosses and circles to OD. The error bars refer to unpublished data of Branscomb and Smith using bandpass filters at about 500 Å resolution. All other data were obtained at a resolution of 100 Å and were placed on an absolute scale by comparison with H^-.

are on a relative basis and were made absolute by comparison to the known H^- cross section photodetachment. We estimate that the cross section of OH^- should be accurate to 20%. Very recent measurements of photodetachment have been made in a drift tube by Woo *et al.* (75). They find the photodetachment rate of O_3^- to be 4.2% that of O^- or $6.0 \times 10^{-2}\ s^{-1}$.

The experimental work of Siegel and Hall (76) on the angular distribution of photodetached electrons from H^- and O^- is compared with the theoretical work of Cooper and Zare (77) in Fig. 16. Several striking facts emerge from the O^- study. First, the agreement of the theory with the measurements is very good. To obtain this agreement the authors had to calculate the mixing ratio of s to d wavefunctions in the outgoing electron wave. Second, the authors found a case in which a cylindrical analyzer might have missed a group of electrons entirely. Third, Cooper and Zare showed that the angular distribution varies with the energy of the incident photons. At threshold the distribution is isotropic. It becomes almost $\sin^2\theta$ (where θ is measured from the electric vector of the incident light) at photon energies roughly 0.8 eV above threshold and then becomes more isotropic with increasing photon energy. Such a change of angular distribution with energy would be interpreted as a change of cross section with energy in many electron energy measurements.

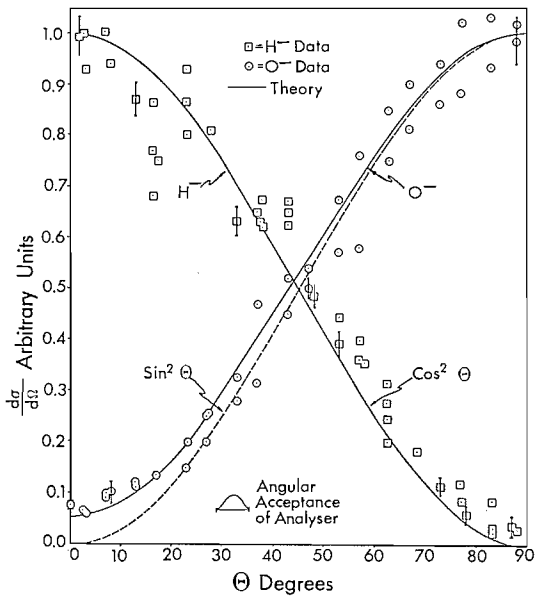

FIG. 16. A comparison of experimental, Siegel and Hall (76), with theoretical, Cooper and Zare (77), values for the angular distributions of electrons from photodetachment of H^- and O^-. The experimental points were obtained at the argon laser wavelength, 4880 Å. The solid curves are the calculated angular distributions.

VII Conclusions

For present purposes of aeronomy, the measurements of photoionization cross sections of O_2 and N_2 have been made with sufficient accuracy at wavelengths longer than 300 Å, except where strong band structure is present. At a few wavelengths where important solar lines lie within strong band structure, measurements with higher resolution may be required. A similar statement may be made about the photoionization cross section of NO at wavelengths longer than 600 Å. There is conflicting data on the photoionization cross section of CO_2 which casts a shadow over other measurements. Further investigation of the photoionization and photoabsorption cross sections of CO_2 are required.

At wavelengths shorter than 300 Å, it is likely that each photon absorbed produces an ion, but this assumption should be tested. There are no measured cross sections of excited species of stable molecules or of free molecular radicals such as OH. Cross sections of such species may be needed, and the beam methods for making the measurements are now being developed.

Much more work is required on the details of ionization processes. The dissociative ionization cross section of O_2 and N_2 should be checked with particular care devoted to the effects of energetic ions and of detector efficiency variation from species to species. The range of measurement should also be extended to wavelengths shorter than 400 Å, the present limit.

Electron and ion energy measurements are in their infancy. There is a need for a set of accurate measurements at wavelengths of solar lines from threshold to 100 Å. These measurements must be made in a system unaffected by the angular distribution of the charged particles. When used to make electron energy measurements, the system must have enough resolution to show vibrational states clearly. More information is needed about angular distributions. The work of Berkowitz *et al.* should be extended to cover other molecules and a wider range in angle and wavelength.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The combination of electron energy measurements, ion energy measurements, and fluorescence measurements presents a powerful array for the analysis of photoionization phenomena. At the present time, it appears that the most accurate cross sections for the excitation of those states which decay by fluorescence can be obtained by combining the best cross sections measured in electron energy experiments at 584 Å with relative fluorescence efficiencies measured over a range of wavelengths of the exciting vacuum u.v. radiation. Dispersion of the fluorescent radiation is highly desirable, but care must be taken to check for polarization effects, which may be a function of the wavelength of the exciting radiation. In many cases fluorescence represents the best method for detecting the existence of excited states. It would seem that much more work is required in the examination of fluorescence caused by vacuum u.v. radiation at all wavelengths of incidence and for most molecules of aeronomic interest.

The picture in photodetachment studies has been changed in the last few years by the increased appreciation of the role of ion–molecule reactions. Fehsenfeld *et al.* (78) have pointed out the importance of NO_2^-, NO_3^-, CO_3^-, and perhaps hydrates of these ions. Photodetachment of these ions will require measurements in the near u.v.

Acknowledgments

During the course of preparation of this paper, the author engaged in discussions and correspondence with a substantial fraction of those whose works are listed in reference and with a number of people working in related fields. To those who generously gave supplementary data, comments, and corrections, the author would like to express his thanks. Comments and Summary

COMMENTS BY J. R. PETERSON[1]

McElroy asked for evidence to support his use of the ratio $N^+/N_2^+ \sim 0.28$ given by Rapp and Englander-Golden (unpublished?) from their electron-impact ionization work. I made measurements (1) on e + N_2 using a crossed beam arrangement and could measure directly the ratio $[N^+(+2N_2^{2+})]/N_2^+$. The absolute values of the cross sections had 20% uncertainties, but the relative values are better. The ratio is about 0.26 at 50 eV, reaches 0.30 at 100 eV, and gradually decreases to 0.25 at 500 eV, substantiating McElroy's choice. The ratio at high energy probably is the same as for photoionization.

For personal use only.

perhaps as much as 10% of the total ion density. In order to account for the observations I argued some time ago (2) that below 400 Å approximately 30% of all photoionization events in N_2 should be dissociative. This number seemed reasonable at the time. It was suggested by laboratory studies of electron impact ionization (3). It is not, however, compatible with the data discussed by Schoen. As he points out, serious experimental difficulties must be overcome before we can attach any confidence to the laboratory data. Until the position improves the aeronomer must grit his teeth and wait. Maybe the present theory of atmospheric N^+ is adequate. On the other hand there may be an important unidentified source of N^+. One possible such source not included in present theories is the reaction

$$O_2^+ + N(^2D) \rightarrow O_2 + N^+$$

Unpublished calculations by the writer suggest that this reaction may be competitive with dissociative ionization at higher altitudes.

The ability to study individual paths for photoionization processes represents an important advance in recent years. The data are invaluable not only for interpretation of dayglow emissions such as the first negative and Meinel bands of N_2^+, but are useful also for in-depth studies of the atmospheric heat budget. These studies are feasible with current data on electron collision processes. The energy of the photoelectron, which carries a major fraction of the incident photon energy, depends of course on the degree of internal excitation of the photoion.

Finally, I should draw attention to the need for data on photoabsorption by metastable species, especially long lived metastables such as $O_2(^1\Delta)$ and $N(^2D)$. Hunten and McElroy (4) have suggested that photoionization of the former molecule is an important source of O_2^+ in the D region. It can be ionized by relatively long wavelength radiation which penetrates deep into the atmosphere at selected frequencies where the O_2 absorption cross-section is small (in the so-called windows).

Neutral reactions involving oxygen and nitrogen

H. I. SCHIFF
Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received December 24, 1968

Methods of production and detection of reactive species of oxygen and nitrogen are discussed briefly. Kinetic data for reactions of these species which have aeronomic interest are reviewed. New data, obtained during the past 4 years are critically compared, and recommendations made for "best" values where possible. An attempt is also made to delineate important areas where additional work is needed to meet the demands of atmospheric modelling.

Canadian Journal of Chemistry, 47, 1903 (1969)

At the Berkeley I.A.G.A. symposium the author was privileged to review (1) the status of the laboratory work on oxygen and nitrogen as of August 1963. It appeared then, that with a few notable exceptions, rate constants for ground state atoms and molecules were known with sufficient accuracy for most aeronomic calculations at 300 °K. Temperature coefficients (or activation energies) were, however, largely lacking. Fortunately, many of the reactions of aeronomic interest have rate constants sufficiently close to collision frequencies that their activation energies could not exceed one kcal mole^{-1}. Two important exceptions were the reactions $O + O_3 \rightarrow 2O_2$ and $N + O_2 \rightarrow NO + O$. Also very little was known at that time about the reaction of metastable atoms, or of molecules which possess appreciable quantities of internal energy. But ground based (2) and rocket borne (2, 3) measurements have shown that considerable concentrations of these excited species are present in the chemosphere. A great deal of laboratory work on both these aspects, temperature dependence, and excited state reactions, has ensued. It is the intention of this paper to review some of the more significant recent developments.

A wide variety of methods has been used, both in the production and in the measurement of reactive species. Electrical discharge sources have enjoyed the widest popularity. Oxygen atoms have been produced directly by discharges through O_2 and indirectly by the now familiar titration reaction

$$N + NO \rightarrow N_2 + O$$

Such discharges also produce an embarassing richness of electronically and vibrationally excited molecules, and it is often difficult to account for their influence on the reaction under study. Discharges through Ar containing only a small amount of O_2 have been used in the hope that virtually complete dissociation will be achieved with no opportunity, therefore, for the formation of excited molecules. This assumption has yet to be unequivocally justified, and the absence of metastable Ar and O atoms demonstrated. Small concentrations of O atoms have been obtained by the total thermal decomposition of O_3 in a furnace (4, 5). Since the temperature used was just sufficient to break the bond, there should be no energy available to excite the products. However, verification should be sought that excited O_2 is not formed by surface-catalyzed recombination on the hot furnace walls. A recent modification of this method (6) consists of the partial decomposition of N_2O on a "Nernst glower" filament. N_2O is relatively inert to O atoms attack, as is the other pyrolysis product, N_2. In addition, any vibrational excitation of either N_2O or N_2 on the filament is known to be rapidly deactivated by the excess N_2O which acts as a carrier.

Photolysis provides a very clean source of excited atoms and molecules, and in many cases the choice of wavelength permits an exact knowledge of their excitation. This method is being exploited successfully to study radiative lifetimes and quenching cross sections. Unfortunately, the concentrations achievable are too low to provide much chemical kinetic data on the reactions. For example, quenching rates of $O(^1D)$ and $O(^1S)$ by N_2, NO, CO_2 etc. can be studied accurately (7, 8) but the nature of the products is not as yet known. Photolysis can be continued for times which are long compared with the half-lives of the reactions concerned in order that sufficient products can be accumulated to permit analysis. Kinetic data must then be inferred from an assumed mechanism which reduces its reliability. One need only

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

quote the example of the controversy which still exists over the photolysis of CO_2 (9).

Shock tube techniques can, in principle, provide kinetic data which, in combination with other methods at lower temperatures, provide more than a sufficient temperature range to span all planetary atmospheric conditions. Unfortunately, the method is largely restricted to studies of the rates of decomposition of diatomic and triatomic molecules which are of no direct interest in aeronomy. What are of interest, of course, are the rates of the reverse processes, viz. the recombination reactions. These are commonly calculated by combination of the dissociation rates with the equilibrium constant for the process. However, it is not clearly established that the use of equilibrium thermodynamics is justified in the time scales involved behind a shock front, particularly whether vibrational equilibrium is established. Recent theoretical work (10) indicated that the rate constant for dissociation could increase by as much as a factor of 3 between 1 and 100% dissociation. Activation energies for dissociation of diatomic molecules are consistently below the bond strengths. Also, temperature dependences of the dissociation are usually expressed in the form

$$k_d = AT^{-n} \exp(-D_0/RT)$$

where D_0 is the dissociation energy, and the equilibrium constant in the form

$$k_d/k_r = B \exp(-D_0/RT)$$

which ignores the change in entropy of the reaction with temperature. Combination of these two expressions gives, of course, an $A'T^{-n}$ dependence for k_r which is, therefore, open to question.

Flames and explosion limits also provide information about atom reactions at relatively high temperatures. Their drawback is that so many coupled reactions occur simultaneously that it is difficult to extract reliable rate constants for individual steps.

Methods for detecting and measuring atom concentrations have become even more diverse than methods of producing them. Titration techniques — NO for N atoms, and NO_2 for H and O atoms — have been widely used. Their validity, formerly challenged, now appears to be verified, the most direct comparison (11) being made with the very simple, but difficult, technique of isolating a known volume of the gas and measuring the pressure drop due to atom recombination. Care must be taken in using titration reactions for low atom concentrations since their rates will then be small even if the rate constant is large. This condition of low atom concentration will, of course, always obtain near the end point. One way to circumvent this difficulty is to add a large excess of the titrant (e.g. NO_2), thereby increasing the rate, and determining the amount consumed, rather than using the chemiluminescent end-point.

The chemiluminescent reactions, NO + O, N + N, N + O, H + NO have been used to follow atom reactions. Although the intensities of the glows resulting from these reactions have been shown to be proportional to atom concentrations, the proportionality factors may depend on the pressure and the nature of the other gases present.

Calorimetric probes covered with catalytic surfaces for atom recombination have been used successfully for following atom reactions when consideration is given to possible perturbations of the gas stream resulting from the removal of the atoms and the heat released. Their main drawback is their low level of specificity, since they may also respond to other energetic species. In fact, if the atom concentration is measured by another method (12), or is known to be zero (13), such probes can be used to study the kinetics of vibrationally (12) or electronically (13) excited molecules.

Absorption spectroscopy has been used in flash photolysis and in flow systems for vibrationally excited molecules (14) and free radicals (15). Resonance absorption by atoms occurs at energies close to the vacuum ultraviolet (u.v.) region and to date has only been used for ground state atoms (16). Emission spectroscopy has been used to study electronically excited molecules, but most of the work has been concerned with the physical processes of quenching and energy exchange rather than with the chemical reactions they undergo. Photoionization has also been used (17) to detect $O_2(^1\Delta_g)$ molecules.

Electron spin resonance (e.s.r.) has been finding increasing use in the study of atom reactions. The main difficulty with this technique appears to be that of calibration. In the most recent work this difficulty appears to be circumvented (18).

Mass spectrometry has the great advantage that reactants and products can, in principle, all

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

be identified. Difficulties are encountered with low sensitivities for free radicals and atoms resulting from deactivation by collisions with the walls of the ion chamber, and specially designed inlet systems and ion sources are required. Another difficulty is the overlapping of fragment ions with the same mass number. This difficulty can be overcome by using doubly charged ions (19) or by combining the mass spectrometer with titration (20) or chemiluminescent (21) techniques. Although in principle it is possible to identify excited molecules by their ionization potentials, in practice this is a difficult procedure.

Following this brief summary of methods of production and detection of reactive species, an attempt will be made to summarize some of the results obtained during the past 4 years. Heats of reaction are shown after each equation in kcal $mole^{-1}$, with the value in eV in brackets. These are calculated from JANAF tables and are at 1 atm and 298.15 °K, since this is the temperature at which the thermochemical data is most reliable, and the one at which many of the reactions discussed have been measured. Rate constants are given in particles cm^{-3} concentration units. Temperature coefficients are given in the Arrhenius form for second order reactions, $k = A \exp(-E/RT)$ where E is in kcal $mole^{-1}$, and either in this form or in the form $k = AT^{-n}$ for third order reactions. Some attempt will be made to suggest a "best" value. This task is often difficult because the rate constants obtained by various authors may differ by several hundred % even though the errors claimed by each are usually much less than 25%. This is largely the result of the time-honored confusion between precision and accuracy. It is relatively easy to evaluate the reproducibility of a set of experiments but much more difficult to assess the absolute errors in atom concentration measurements, flow rates, mixing coefficients, diffusion corrections, wall recombination, etc.

This review of aeronomically interesting reactions is probably not comprehensive. Readers are referred to the tabulation of rate data by Schofield (22), to the monographs by Wright and Winkler (24) for nitrogen reactions, and by Johnson (23) on oxygen reactions.

Reactions

[1] $O + O + M \rightarrow O_2 + M + 119.118(5.1653)$

Recent measurements by Campbell and Thrush (25) agree with earlier ones by Morgan and Schiff (26) at 300 °K for M = N_2 and He but not for M = Ar where they found $k_1(\mathrm{Ar}) = 1.7 \times 10^{-33}$ while the earlier work gave $k_1(\mathrm{Ar}) = 0.9 \times 10^{-33}$. Reeves *et al.* reported (27) a value of 2.8×10^{-33} for this third body but neglected to correct for wall recombination. Morgan and Schiff (26) showed that this would have lowered their value to somewhere between 0.8 and 1.1×10^{-33}. This discrepancy in the case of Ar is unfortunate since it is the only third body used in common in both the low temperature and the shock tube studies.

The most careful and comprehensive shock tube study appears to be that of Wray (28). The rate of O_2 dissociation was investigated from 5 000–18 000 °K and the recombination was studied separately from 1500–3000 °K following complete dissociation of O_3 by the shock. Comparison of these two sets of experiments led to the conclusion that the use of the thermodynamic equilibrium constant was justified in this case. A pre-exponential temperature dependence, T^{-1} was used for the equilibrium constant from 300–3500 °K and a $T^{\frac{1}{2}}$ dependence above 3500 °K. This then gave a $T^{-\frac{3}{2}}$ dependence for the recombination rate at the low temperature range of his measurements which extrapolates to $k = 0.48 \times 10^{-33}$ for M = Ar at 300 °K in satisfactory agreement with Morgan and Schiff (26). However, similar treatment of other shock tube data gives for the exponent, n in the T^{-n} form, 2.5 for O_2 (29) and 3.0 for M = O (30). There is also wide disagreement among shock tube workers regarding relative efficiencies of various third bodies. The temperature dependence should not, however, depend on the nature of the third body if recombination occurs via the very probable mechanism

$$O + O \rightleftarrows O_2^*$$

$$O_2^* + M \rightarrow + M$$

In fact Benson and Fueno (31), in a theoretical treatment of this reaction based on the assumption that M removes vibrational quanta from O_2^* stepwise in amounts $\approx kT$, conclude that the temperature dependence for all M's should be T^{-1}, and claim that all experimental work can be reconciled with this value, although it is difficult to see how Byron's results (29) can be fitted to this conclusion. The most recent shock tube work (32) with M = O_2 shows such a large temperature dependence for the recombination between 3000–3800 °K that it cannot be taken seriously.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

From studies at 190–350 °K, Campbell and Thrush (25) find a T^{-3} dependence for M = N_2, He, and Ar. They conclude that the exponential form $k = 1.5 \times 10^{-34} \exp(1.4 \pm 0.35/RT)$ for M = Ar permits a better fit with shock tube results. Wray (28) also suggested that "n" in the power representation may change with temperature.

Johnson (23) has made a very careful statistical analysis of all available data on the recombination. He concludes that the shock tube data, and the low temperature data can be represented, within the very large scatter of the shock tube results by the expression

$$k_1(\mathrm{Ar}) = 3.6 \times 10^{-31} T^{-1} \exp(-0.34/RT)$$

for M = Ar over the temperature range, 300–15 000 °K. However, for M = O_2, the results of shock tube and low temperature studies cannot be reconciled, so that the corresponding expression

$$k_1(\mathrm{O_2}) = 3.8 \times 10^{-30} T^{-1} \exp(-0.34/RT)$$

was recommended only over the temperature range 1000–1800 °K. It is obvious that more work is required on the effect of temperature on this reaction.

Also in need of clarification is the relative efficiency of O atoms. There is agreement among shock tube workers that it is very high, as much as 50:18:1 for O:O_2:Ar. But Wray points out that this ratio decreases with decreasing temperature, which is also indicated by the failure of room temperature measurements to detect any unusually high efficiencies for O atoms as third bodies. This has some importance at high altitudes where this reaction constitutes a major O atom loss process and where O becomes a major atmospheric constituent.

[2] $O + O_2 + M \rightarrow O_3 + M + 25.45\ (1.103)$

This is the principal reaction responsible for recombination of O atoms below 100 km. When followed by

[3] $$O + O_3 \rightarrow 2O_2$$

the net effect is identical to reaction [1].

Studies of this reaction using discharged O_2 as the atom source have led to rate constants which differ from one another by amounts which are much greater than the uncertainties in the individual measurements. The values were also smaller than those determined indirectly from studies of ozone decomposition. During the past 4 years it has become apparent that these discrepancies were mainly due to two causes:

(*i*) The presence of hydrogenous impurities in the discharged gas which can give rise to H and OH, both of which can catalyze the recombination by the fast reactions

$$H + O_3 \rightarrow OH + O_2$$
$$O + OH \rightarrow O_2 + H$$

The net result of these reactions is kinetically indistinguishable from reaction [3] but occurs with a rate constant some 1000 times larger (33). Moreover the three body reaction (34)

$$H + O_2 + M \rightarrow HO_2 + M$$

is considerably faster than [2] and can feed the chain reactions via the production of OH from

$$HO_2 + O \rightarrow OH + O_2$$

(*ii*) There is now abundant evidence that electrically discharged O_2 contains appreciable quantities of electronically excited O_2 in the $^1\Delta_g$ and $^1\Sigma_g^+$ states which are capable of decomposing O_3.

[5] $$O_2^* + O_3 \rightarrow 2O_2 + O$$

Essentially, reaction [5] reverses the recombination sequence [2] and [3] and results in too low a value for the rate constant of [2]. Mathias and Schiff (35) found that more O_3 could be decomposed than there were O atoms in the discharged O_2, while Kaufman and Kelso (36) found an increase in O atoms when O_3 was added to discharged O_2. These findings not only explain the low values of k_2 found from the earlier discharge studies, but also explain the diversity of results obtained from these studies, since the concentration of electronically excited O_2^* molecules is known to be a sensitive function of gas pressure and purity.

Clyne *et al.* (37) attempted to overcome these problems by discharging argon containing less than 10^{-3} mole % of O_2 although there is some possibility that this method may also produce metastable atoms. They found that the addition of water vapor did not affect the recombination rate which they took as evidence that $O(^1D)$ was not present in their system. This conclusion does not seem to be warranted, however, since it has not been proved that the NO–O glow used to

TABLE I

Relative efficiencies based on Ar = 1

He	N_2	O_2	CO_2	N_2O	CF_4	SF_6	O_3	H_2O	Reference
1.4	1.6	1.7	4.2				4.2		41
1.0	1.4	1.6	3.7	3.7	4.0	8.5	—	15	36
0.68			4.1	3.5					39
		1.1	3.4						5
1.3	1.5	1.7	4.2				4.0		42
1.4	1.6	1.8	3.8				4.0		23

monitor the recombination is applicable to $O(^1D)$ atoms and no account was taken of the possible influence of water vapor on the wall recombination efficiency. They followed [O] by the NO–O glow which was put on an absolute basis by NO_2 titration. The difficulties in the use of this titration for low atom concentrations have been mentioned previously. The value they report for M = Ar is 7.8×10^{-34}.

Kaufman and Kelso (38) decomposed O_3 in a furnace to yield about 0.01% oxygen atoms, which should be free of electronically excited O_2. They followed the recombination by the NO–O glow and obtained at 300 °K, $k_2 = 6.5 \times 10^{-34}$ for M = O_2. Their value for M = Ar of 4×10^{-34} is about half that of the previous workers (37).

Mulcahy and Williams (5) also used thermal decomposition of O_3 as a source of O atoms and the NO–O glow to follow the recombination. Their value of $k_2 = (8.9 \pm 0.9) \times 10^{-34}$ for M = Ar, O_2 is in fair agreement with Kaufman and Kelso and their value of $(7.9 \pm 0.8) \times 10^{-34}$ agrees well with Clyne *et al.* Unfortunately their relative efficiencies for these two third bodies do not agree so well with other workers, as seen in Table I.

Sauer (39, 40) obtained rates for this reaction for pulsed radiolysis studies of CO_2 and N_2O in Ar. They obtained $k_2 = 2.8 \times 10^{-34}$ for M = Ar.

Benson and Axworthy (41) have reviewed the existing data on the thermal decomposition of O_3 and combined it with a new evaluation of the equilibrium constant. Their value for M = O_2 is 3.6×10^{-34}, about half that of Kaufman and Kelso (38). The relative efficiencies shown in Table I are, however, in excellent agreement.

Isotope exchange studies (43, 44) give a rate constant of 1×10^{-12} for exchange and an activation energy (45) of 1.1 ± 0.4.

Klein and Herron (43) ascribe rate constants to the individual steps in the mechanism

$$O + O_2 \underset{B}{\overset{A}{\rightleftarrows}} O_3^* \xrightarrow[(M)]{C} O_3 + M$$

to be $k_A = 1.5 \times 10^{-12}$, $k_B = 1.8 \times 10^{-9}$, $k_C = 7 \times 10^{-13}$. This interpretation has been criticized (41) on the basis that the expected lifetime of O_3^* would more likely correspond to k_B being an order of magnitude larger.

Temperature coefficients obtained by direct studies of this reaction are in good agreement. Clyne *et al.* (37) give an "activation energy" $E_2 = -(1.8 \pm 0.4)$ for M = Ar and $n = (3.4 \pm 0.8)$ in the T^{-n} representation in the range 190–350 °K. Mulcahy and Williams (5) give $E_2 = -(1.7 \pm 0.1)$ and $n = (3.0 \pm 0.2)$ for M = Ar, and $E_2 = -(1.45 \pm 0.14)$ and $n = (2.4 \pm 0.3)$ for M = CO_2 from 213–386 °K. On the other hand, Benson and Axworthy (41) in their review of the indirect value obtained from O_3 decomposition give $E_2 = -0.89$ for M = O_2 near 360 °K. Although the shock tube decomposition study of Jones and Davidson (46) gives $E_2 = -(1.7 \pm 0.3)$, their results are not readily reconciled with the low temperature measurements (37). Johnson has reviewed all existing data on this reaction and recommends

$$k_2 = 1.16 \times 10^{-35} \exp(2.10/RT)$$

for M = Ar with an uncertainty of about 50%.

In summary, it appears that the rate constant at 300 °K is known to within a factor of 2. However, there is a much greater uncertainty in the temperature dependence, or even whether a single analytical form for this dependence can be used over a wide temperature range. Certainly more work should be done between 350 and 1600 °K.

[3] $O + O_3 \rightarrow 2O_2 + 93.7$ (4.06)

There is increasing interest in the height distribution of O_3 in our atmosphere. Meteorologists have long used O_3 as an atmospheric tracer to study circulation patterns and have been concerned with its important contribution to the energy balance in the stratosphere. Aeronomists now realize that it is a major source of OH and O_2-($^1\Delta_g$) airglow emissions. Recently it has been shown (47) to be important in the negative ion chemistry of the D region ionosphere.

It is therefore unfortunate that reaction [3], which plays a dominant role in determining atmospheric O_3 composition, has proved to be so elusive to experimental measurement, particularly measurement of its temperature coefficient. Both direct and indirect methods have been used. The indirect method involves thermal decomposition of O_3, which is now conceded to occur via the mechanism

$$[d, 2] \qquad O_3 + M \rightleftarrows O_2 + O + M$$

$$[3] \qquad O + O_3 \rightarrow 2O_2$$

Only k_d and the ratio of $k_d \cdot k_3/k_2$ can be obtained from such measurements. The activation energy of [*d*] completely dominates the temperature dependence of the rate constant ratios, and has not been determined with sufficient accuracy to provide values for $E_3 - E_2$ which are accurate to better than about 2 kcal mole^{-1}. The uncertainty of E_2, noted in the previous section, makes the indirect method of doubtful value in providing reliable values of E_3. The decomposition of O_3 by visible light gives k_2/k_3 ratios directly (42), but unfortunately has been studied only over a small temperature range.

Direct methods in which O atoms are produced from electrical discharge sources are subject to the difficulties of O_3 decomposition by electronically excited O_2, or by H and OH from hydrogenous impurities, discussed above. Even the N–NO titration method cannot be used reliably since the titration reaction produces vibrationally excited $N_2^{\ddagger}$ which has been shown (48) to decompose O_3.

Mathias and Schiff (35) investigated these effects mass spectrometrically and were able to obtain a value of $k_3/k_2 = 1.2 \times 10^{-19}$ at 300 °K. Combination with Mulcahy and Williams' value (5) for k_2 gives $k_3 = 1.06 \times 10^{-14}$ while combination with Kaufman and Kelso's value (36) gives $k_3 = 0.66 \times 10^{-14}$.

Lundell *et al.* (6) have recently measured k_3 directly in a flow system in which O atoms were generated in the absence of energetic molecules by thermal decomposition of N_2O on a hot filament. They obtained a value of $(1.5 \pm 0.1) \times 10^{-14}$ at 300 °K.

Benson and Axworthy in a recent re-review of thermal O_3 decomposition data suggest

$$k_3 = 5.6 \times 10^{-11} \exp(-5.7/RT)$$

This is based on $E_2 = -0.89$. If, however, a value of $E_2 = -1.7$ is used, E_3 is reduced to 4.9. The shock tube data by Davidson and Jones have been interpreted (46) to give $k_3 = 5.7$ but more recent shock tube work suggests this value is too high (49).

Intezarova and Kondratjev (50) have recently reported a study of the thermal decomposition of O_3 in a flow system at atmospheric pressure from 410–500 °K. The authors claim that their data give them k_3/k_2 ratios directly. They combine this ratio with the value of k_2 derived from the O_3 equilibrium constant, $K = k_d/k_2$ and an average value of k_d from previous thermal decomposition studies. It is not obvious to this author, however, just how this average is obtained, or why they did not derive k_d from their own experiments directly. At any rate, their procedure gave $k_3 = (4.8 \pm 1.5) \times 10^{-12} \exp(3.7 \pm 0.3/RT)$. If their k_3/k_2 ratio is combined with the directly determined value of k_2 from Mulcahy and Williams (5) or Clyne *et al.* (37) the activation energy $E_3 = 3.0 \pm 0.4$ while at 300 °K, combination with Kaufman and Kelso's (38) value of k_2 gives $k_3 = 1.5 \times 10^{-14}$, and with Mulcahy and Williams' k_2, gives $k_3 = 2.1 \times 10^{-14}$.

Castellano and Schumachers' value for k_2/k_3, when combined with the expression by Clyne *et al.* (37) for k_2, gives $k_3 = (1.4 \pm 0.3) \times 10^{-12} \exp(-3.0 \pm 0.4/RT)$.

Lundell *et al.* (51) have recently made a direct measurement of this reaction using decomposition of N_2O on a "Nernst" glower to produce ground state atoms in the absence of O_2. For the temperature range 0–70 °C they obtained $k_3 = 3.2 \times 10^{-11} \exp(-4.5/RT)$.

Johnson (23), reviewed all the existing data on this reaction and recommends $k_3 = 2.00 \times 10^{-11} \exp(-4.79/RT)$.

[4] $O(^1D) + O_3 \rightarrow 2O_2 + 138.8$ (6.02)

The first evidence for this reaction comes from O_3 photolysis. At wavelengths greater than that required to produce $O(^1D)$, the O_3 quantum yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is strictly 2 but at shorter wavelengths quantum yields as high as 16 have been reported. In flash photolysis McGrath and Norrish (52) observed vibrationally excited ground state $O_2^{\ddagger}$ molecules and postulated these and $O(^1D)$ to be the chain carriers

[4a] $O(^1D) + O_3 \rightarrow O_2 + O_2^{\ddagger}\ (v \geqslant 17)$

[4b] $O_2^{\ddagger} + O_3 \rightarrow O_2 + O_2 + O(^1D)$

To make reaction [4b] exoergic requires $O_2^{\ddagger}$ to have $v \geqslant 17$, and the sharp cut-off above the 17th level was taken as evidence for this mechanism. A similar chain could of course, be written for $O(^3P)$ and $O_2^{\ddagger}$ ($v \geqslant 5$) but this apparently does not happen since it is well established that one ^3P atom leads to the consumption of only one O_3 molecule (40, 53).

Bair and his co-workers (54–56), however, found a continuous vibrational distribution of the $O_2^{\ddagger}$ product and observed levels up to $v = 23$ with no sharp discontinuity at $v = 17$. They also found the relaxation of the vibrational distribution to be consistent with a single quantum ladder process and further argued that the population at $v \geqslant 17$ was always too small to account for any appreciable chain decomposition of O_3.

Norrish and Wayne (57) photolyzed O_3 at 2537 Å in the presence of other gases. They found the O_3 quantum yield to increase linearly to 16.7 with O_3 pressure, to decrease to 2 with increased partial pressures of N_2 or CO_2, and to approach zero with increasing O_2 partial pressure. To explain these results they proposed the mechanism

$$O_3 + h\nu \rightarrow O_2^* + O^*$$

$$O_2^* + O_3 \rightarrow 2O_2 + O$$

[4a] $$O^* + O_3 \rightarrow O_2^{**} + O_2$$

[4b] $$O_2^{**} + O_3 \rightarrow 2O_2 + O^*$$

$$O + O_2 + M \rightarrow O_3 + M$$

$$O_2^{**} + \text{wall} \rightarrow O_2$$

where O^* represents $O(^1D)$, O_2^* an excited molecule which can dissociate O_3 but cannot produce an O^*, and O_2^{**} one that can, and is therefore a chain carrier. They still believe, however, that O_2^{**} is a ground state $^3\Sigma_g^-$ molecule with $v \geqslant 17$.

McGrath and McGarvey (58) criticize this conclusion on the basis that it would require an unreasonable amount of energy to be imparted to the O_3^{**} molecule in reaction [4a] while [4b] would require a complex means of spin conversion. They feel it more likely that O_3^{**} is an electronically excited molecule, either in the $^3\Sigma_u^-$ or $^3\Sigma_u^+$ states, and favor the latter because of its greater lifetime.

McKenney and Laidler (59), from theoretical considerations of the potential energy surfaces, prefer the $^3\Sigma_u^-$ state even though reaction [4a] is then endoergic by about 2 kcal mole^{-1}. Molecules in this state should then rapidly radiate in the allowed Schumann–Runge system but the Franck–Condon factors are such that the lower state would be vibrationally excited and could then partake in the Norrish chain. Volman *et al.* (60) originally favored the transition of $^3\Sigma_u^-$ to $^1\Delta_g$ or $^1\Sigma_g^+$ states but chains would then not be possible on energetic grounds. Volman (61) points out that the $^3\Sigma_u^-$ state should also predissociate via the repulsive $^3\Pi$ state to form two $O(^3P)$ atoms. Benson (62) points out that if $^3\Sigma_u^-$ molecules were involved, fluorescence should be observed at about 3400 Å. Since it is not, he favors the $^3\Sigma_u^+$ state.

De More and Raper (63) studied the photolysis in the condensed phase and found that $O(^1D)$ atoms are produced at wavelengths shorter than 3100 Å but in the 3100–3400 Å region both $O(^1D)$ and $O(^3P)$ are formed. They confirm the increased quantum yields at these wavelengths and conclude that $^3\Sigma_u^-$ molecules are the chain carriers since no temperature dependence was observed and the reaction involving $^3\Sigma_u^-$ would require 2 kcal mole^{-1} activation energy.

McNesby and Okabe (64) showed that, at $\lambda \leqslant 2340$ Å, $O(^1S)$ can also be formed and give rise to $^3\Sigma_u^-$ with vibrational excitation.

One might also ask whether $O(^3P)$ atoms could react with O_3 to form $O_2(^1\Sigma_g^+)$ or $O_2(^1\Delta_g)$ which could then be a significant source of airglow emission from these species. However, both these species are known to decompose O_3 and no evidence for chain reactions has been obtained for $O(^3P)$ atoms.

Warneck (65), in a quantum yield study, concluded that $O(^1D)$ reacts with O_3 8 times faster than does $O(^3P)$. However, this conclusion does not appear to be warranted since it is based on the unlikely assumption that the rate of formation of O_3 from $O + O_2 + M$ is the same for both types of atoms. In fact DeMore and Raper (63) showed that O_2 quenched $O(^1D)$ rather than reacted with it.

Snelling and Bair (56) studied the effect of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

added inert gases to the flash photolysis of O_3 and conclude that $k_4 = (3 \pm 1.5) \times 10^{-10}$, i.e. the reaction occurs at virtually every collision. This would be consistent with the finding of DeMore and Raper that the temperature coefficient is low but not with those of Sullivan and Warneck (66) who give $E_4 = 2.4 \pm 1$. However, the latter result must be viewed with suspicion since the ratios of k_4 to k_q, the quenching rate constant of $O(^1D)$ by O_2, obtained in this work, combined with currently acceptable (4) values of k_2 gives $k_4 \geqslant 10^{-8}$!

This discussion has probably emphasized the need for more definitive experiments on the rates and products of this reaction.

[5] $O_2^* + O_3 \rightarrow O_2 + O_2 + O$

In the foregoing sections we have seen that both photolysis and electrical discharge studies indicated the occurrence of this reaction. Wayne (67) pointed out that the occurrence of these reactions would lead to a quantum yield of 4 for O_3 decomposition at zero pressure in agreement with observations. Schiff and Megill (68) pointed out some possible aeronomic implications of these reactions. Although they might affect the rate of energy release and time for attainment of O_3 equilibrium, Hunt (69) has shown that they do not influence the O_3 height profile. Bader and Ogryzlo (13) found that the addition of O_3 decreased the intensity of the $^3\Sigma_g^- \leftarrow {}^3\Sigma_g^+$ emission but had a much smaller effect on the $^3\Sigma_g^- \leftarrow {}^1\Delta$ emission.

March *et al.* (70) studied the rate of the reaction with $O_2(^1\Sigma_g^+)$ and obtained $k_5(^1\Sigma_g^+) = 6 \times 10^{-13}$. They also made a rough estimate of the rate constant with $O_2(^1\Delta_g)$ of about 4×10^{-14}.

McNeal and Cook (17) followed the decrease in $O_2(^1\Delta_g)$ by photoionization as a function of added O_3 and obtained $k_5(^1\Delta_g) = (2.5 \pm 0.5) \times 10^{-15}$. They did not specifically rule out the possibility of photoionization of vibrationally excited O_2 with an equivalent amount of energy, although photolysis studies indicate that either vibrationally excited O_2 does not decompose O_3 or else it is very rapidly relaxed.

[6a] $O_2(^1\Delta_g) + O_2(^1\Delta_g) \rightarrow (O_4)^* \rightarrow 2O_2(^3\Sigma_g^-) + h\nu$ *(6340 and 7640 Å)*

[6b] $O_2(^1\Delta_g) + O_2(^1\Delta_g) \rightarrow O_2(^1\Sigma_g^+) + O_2(^3\Sigma_g^-)$

These very interesting reactions were first reported in the gas phase by Bader and Ogryzlo (13) and have received considerable attention subsequently. The first of these represent a pooling of the energies of the two $(^1\Delta_g)$ molecules to give out a single light quantum. The 6340 Å radiation corresponds to both $O_2(^3\Sigma_g^-)$ molecules being formed in their ground vibrational levels, while the 7640 Å radiation leaves one of the $^3\Sigma_g^-$ molecules in the first vibrational level. The O_4 intermediate has no binding energy and probably has a very transient existence although its radiative lifetime has been estimated (71) to be 3 s. These authors (72) measured the $(^1\Delta_g)$ concentration by means of an isothermal calorimetric probe and found (7) $k_{6a} = 2.5 \times 10^{-22}$. Falik and Mahan (73) measured the $(^1\Delta_g)$ concentration by e.s.r. and obtained $k_{6a} = 5 \pm 1 \times 10^{-23}$ which agrees reasonably well in view of the analytical techniques used.

The second reaction *[6b]* represents an alternative energy pooling process in which one of the O_2 molecules is promoted to the next higher electronic state while the other is deactivated to the ground state. The reaction represents a violation of the spin conservation rule. Young and Black (71) give as the rate constant $k_{6b} = 3 \times 10^{-14 \pm 0.5}$. If it were indeed as high as this it would have considerable aeronomic importance in explaining the persistance of the emission from O_2 $(^1\Sigma_g^+)$ in the airglow, since the radiative lifetime of $^1\Delta_g$ is some 10^3 times longer than that of $^1\Sigma_g^+$. However, Arnold and Ogryzlo (74) have shown fairly convincingly that their rate constant of $k_{6b} = 2.2 \times 10^{-18}$ is more likely to be correct which then renders this reaction too slow to provide a significant source of $O_2(^1\Sigma_g^+)$ molecules in the atmosphere.

[7] $O + N + M \rightarrow NO + M + 151.0$ *(6.55)*

Kretschmer and Petersen (75) followed this reaction in a flow system. They discharged a mixture of 5% O_2 in N_2, determined [O] quantitatively with a Wrede gauge, and followed the reaction by the accompanying NO* emission intensity. Their rate constant $k_7 = 9 \times 10^{-33}$ for $M = N_2$ at 350 °K is considerably higher than previous measurements (76). An interesting sidelight of this work was the evidence presented that at short times after the N_2 discharge, when the N_2 vibrational temperature was high, the dissociation reaction $N_2^{\ddagger} + O_2 \rightarrow N_2 + O + O$ occurred. The same work, however, gave a value

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of $k = 8 \times 10^{-17}$ for the reaction $O + N_2 \rightarrow NO$ which is about 2 orders of magnitude lower than the values reported by other workers.

Campbell and Thrush (77) followed the reaction by simultaneously monitoring the intensities of the Lewis–Raleigh and O–NO afterglows in a system in which N atoms were partially titrated with NO. They obtained $k_7 = 1.1 \times 10^{-32}$, for $M = N_2$ at 300 °K in excellent agreement with the value above. They find only a small temperature dependence corresponding to $E_7 = -(0.3 \pm 0.1)$ or $n = 0.5 \pm 0.2$, the smallest coefficient observed for any three body recombination reaction. The efficiencies for Ar and He relative to N_2 were found to be 0.76 and 0.35 respectively.

[8] $O + NO + M \rightarrow NO_2 + M + 73.23$ (3.175)

Recent measurements using quite different techniques to follow the reaction agree remarkably well. Westenberg and de Haas (18) used e.s.r. to follow [O] and obtained 8.1×10^{-32} for $M = O_2$. Klein and Herron (78) followed the reaction mass spectrometrically and obtained $k_8 = 1.1 \times 10^{-31}$ for $M = N_2$ at 300 °K. They find a temperature dependence over the range 307–505 °K corresponding to $E_8 = -(1.9 \pm 0.1)$ while Clyne and Thrush (79) report $E_8 = -(1.8 \pm 0.4)$ from 212–315 °K. They report relative efficiencies of $N_2:O_2:Ar:He = 1.0:0.87:0.87:0.58$, in agreement with previous measurements. On the basis of these results Kaufman (80) recommended the use of a $T^{-(2.5 \pm 0.3)}$ dependence but the power representation does not fit the different temperature ranges used by these workers as well as does the exponential form.

Klein and Herron (78) also studied the isotopic exchange reaction from which they obtained an exchange rate of 1.8×10^{-12} and deduced the individual rate constants for the elementary processes

$$O + NO \underset{B}{\overset{A}{\rightleftarrows}} NO_2 \xrightarrow[(M)]{C} + M$$

to be $k_A = 3.7 \times 10^{-12}$, $k_B = 7.1 \times 10^{7}$, $k_C = 2 \times 10^{-12}$.

[9] $O + NO_2 \rightarrow NO + O_2 + 45.89$ (1.990)

The only new measurements of this reaction were made by Klein and Herron (78) using a mass spectrometric technique. Some difficulties were encountered with wall contamination of the ion chamber of the mass spectrometer, but studies over the temperature range 278–374 °K yielded the expression

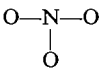
$$k = (3.2 \pm 0.1) \times 10^{-11} \exp(-0.6 \pm 0.2/RT)$$

which gives 5.4×10^{-12} at 300 °K, about twice as large as the value reported earlier (20).

Klein and Herron also used isotopic labelling and report an exchange rate of 7×10^{-12} and rate constants of $k_A = 1.6 \times 10^{-11}$, $k_B = 5 \times 10^{7}$, $k_C = 1.3 \times 10^{-12}$, and $k_D = 2.6 \times 10^{7}$, for the individual steps in the mechanism

$$O + NO_2 \underset{B}{\overset{A}{\rightleftarrows}} NO_3^* \xrightarrow[(M)]{C} NO_3$$
$$\xrightarrow{D} NO + O_2$$

Benson and DeMore (81), however, criticized these values since they are based on the assumption that the same NO_3^* intermediate is involved in reactions C and D. They argue that D must result from an O—N—O—O intermediate while C comes from the symmetric



complex. Klein and Herron (82) reassessed their data accordingly and altered k_A to 1.0×10^{-11} while k_D can no longer be estimated from their data.

[10] $O + H_2 \rightarrow OH + H - 1.87$ (−0.081)

Recent measurements of this reaction are in excellent agreement. Westenberg and de Haas (83) added H_2 to discharged Ar–O_2 in a flow system and followed [O] by e.s.r. For the temperature range 400–950 °K they find $k_{10} = (8 \pm 3) \times 10^{-11} \exp(-10.2 \pm 0.5/RT)$ with a claimed accuracy of 10%. The same authors (84) also investigated the isotope effect when D_2 was substituted for H_2.

Hoyermann *et al.* (85) generated O atoms by N–NO titration and used e.s.r. to follow both O and H atoms over the temperature range 373–478 °K. They find

$$-\frac{d[O]}{dt} = \frac{d[H]}{dt} = 2k_{10}$$
$$= 2.2 \times 10^{-11} \exp(-9.4 \pm 0.15/RT)$$

Wong and Potter (19) used a stirred reactor and a time-of-flight mass spectrometer to follow [O]. They assumed that the secondary reactions were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$O + OH \rightarrow O_2 + H$ and $OH + H_2 \rightarrow H_2O + H$ and used Kaufman's value (15) for their rate constants. For the temperature range 396–597 °K they report

$$k_{10} = 7 \times 10^{-11} \exp(-10.2/RT)$$

The activation energy reported by these three groups is 0.8 kcal mole^{-1} higher than the value of an earlier investigation by Clyne and Thrush (86) using discharge techniques but 1.5 kcal mole^{-1} lower than that of Azatyan *et al.* (87) from flame measurements.

[10a] $O(^1D) + H_2 \rightarrow OH + H + 43.35$ *(1.88)*

De More (88), in a recent study of the photolysis of O_3–H_2 solutions at 87 °K found evidence for this reaction. He concluded that it occurs much more frequently than does straight quenching of the $O(^1D)$ atoms by H_2 and estimated that its rate constant is about $\frac{1}{4}$ that of the $O(^1D)$–O_3 reaction, i.e. about 10^{-11}, and that its activation energy is approximately zero.

[11] $O + CH_4 \rightarrow CH_3 + OH + 0.394$ *(0.0171)*

Avramenko and Kolesnikova (89) report that the reaction proceeds by two parallel primary steps

$$O + CH_4 \rightarrow CH_2O + H_2$$
$$\rightarrow CH_2 + H_2O$$

with an overall rate constant $k_{11} = 3.4 \times 10^{-11} \exp(-7.8/RT)$. Wong and Potter (90), however, did not observe any CH_2O formation mass spectrometrically while Brown and Thrush (91) detected the production of H atoms which can only be reconciled with the primary reaction

$$O + CH_4 \rightarrow CH_3 + OH$$

followed by the subsequent attack of O on OH to form H atoms. They produced O atoms by the N–NO titration technique and follow the reaction by e.s.r. They report, for the temperature range 450–600 °K

$$k_{11} = (1.1 \pm 0.3) \times 10^{-11} \exp(-7.7 \pm 0.3/RT)$$

Cadle and Allan (92) produced O atoms the same way and followed the kinetics by monitoring the O atoms with an isothermal calorimetric probe. Difficulty was encountered because of the complexity of secondary reactions when O_2 was present. On the other hand when O atoms were generated by N–NO titration the rates were so slow that large excesses of CH_4 had to be added. They report, for the range 295–533 °K

$$k_{11} = (1.2 \pm 0.6) \times 10^{-11} \exp(-7.3 \pm 1.5/RT)$$

Azatyan *et al.* (93) obtained a rate constant for this reaction by studying the effect of CH_4 addition to the explosion limit of H_2–O_2 mixtures. They give

$$k_{11} = 0.95 \times 10^{-10} \exp(-8.7/RT)$$

Wong and Potter (90) produced O atoms by the electrical discharge of 1.4% O_2 in Ar and detected them by time-of-flight mass spectrometry. This study gave, from 400–560 °K

$$k_{11} = 1.7 \times 10^{-11} \exp(-10.0/RT)$$

with an estimated accuracy of about ±50%, compared to their earlier study (19) which gave $1.6 \times 10^{-11} \exp(-8.2/RT)$. They attribute the difference in activation energies to the secondary reaction of the excess O_2 which was present in their earlier experiments. However, these earlier results are in better agreement with those of Brown and Thrush (91) who also used an O_2-free system.

Westenberg and de Hass (83) used discharge Ar–O_2 mixtures and e.s.r. detection and obtained, over the range 299–895 °K, with Ar, N_2, and He carriers

$$k_{11} = (2.8 \pm 0.2) \times 10^{-11} \exp(-8.7 \pm 0.7/RT)$$

Since this appears to be the most comprehensive study of this reaction and this rate constant represents a compromise of the other results it is the one recommended.

[11a] $O(^1D) + CH_4 \rightarrow OH + CH_3 + 45.66$ *(1.98)*

De More and Raper (94) photolyzed mixtures of CH_4 and O_3 dissolved in liquid argon. From quantum yield measurements of O_3 consumption they conclude that $O(^1D)$ reacts with CH_4 at a rate 4 times slower than it does with O_3 (i.e. $k_{11a} \approx 10^{-11}$), that about 30% of the collisions result in non-reactive quenching of the (^1D) atoms to $O(^3P)$, and that both processes occur with no activation energy.

[12] $O_2 + 2NO \rightarrow 2NO_2 + 27.34$ *(1.186)*

This reaction is the major oxidation process of NO in the lower atmosphere. Although it has been studied intensively for many years the exact order is still under debate. Tipper and Williams (95) claim that the order depends on pressure and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

amount of inert gas present. Ashmore *et al.* (96) disagree and find that first and second order dependence on O_2 and NO respectively is strictly followed over a wide range of added N_2 pressure. Šolc (97), on the other hand, finds that the respective orders depend on the O_2/NO ratio, and claims that changes in this ratio can affect the rate constant by as much as a factor of 2.

The most recent study of this reaction was reported by Morecroft and Thomas (98) who agree with Ashmore *et al.* (96). The best value for the rate constant for this reaction appears to be $k_{15} = 1 \times 10^{-33}$ at 300° with a small negative activation energy of about 0.5 kcal mole^{-1}.

[13] $O_3 + NO \rightarrow NO_2 + O_2 + 47.8\ (2.07)$

The rate of this reaction was studied by Clyne *et al.* (99) over the temperature range 216–322 °K. The rate expression is given as

$$k_{13} = 0.95 \times 10^{-12} \exp(-2.46 \pm 0.15/RT)$$

which corresponds to 1.5×10^{-14} at 300 °K in satisfactory agreement with earlier determinations (20).

[14] $N + N + M \rightarrow N_2 + M + 226.0\ (9.80)$

Earlier measurements provided a rather wide range of values for the rate constant from 2×10^{-33} to 2×10^{-32} at 300 °K with M = N_2. Several recent measurements indicate that at least part of this spread may have been due to incorrect allowances being made for wall recombinations which seem to be particularly complex in the case of N atoms. Thus it now appears (100–103) that most of the heterogeneous recombination occurs via a process which is second order in [N], in contrast to the usual first order behavior exhibited by other atom wall recombinations. Very dramatic dependence of the wall recombination efficiencies on gas purity, has also been observed, with O_2 showing the greatest effects.

Kretschmer and Petersen (75) give the lowest value of 2.1×10^{-33} which they obtained by following the decay of the Lewis–Raleigh afterglow, both in flowing afterglow and in pulsed afterglow systems, using NO titration and the Wrede gauge for determining absolute concentrations. They attributed higher values obtained by other workers to H_2O impurities which they find can increase the N decay rate, presumably via the fast reaction $N + HO_2 \rightarrow NH + O_2$.

Evanson and Burch (100), however, took even greater precautions to remove water vapor from their flow system and obtained the highest reported value of $2.25 \pm 0.20 \times 10^{-32}$. They find an increase in recombination rate with time after the discharge. Their high value of the rate constant was obtained at times greater than 3 s in a static system using e.s.r. detection. At lower times they postulate the presence of excited N_2* molecules which decompose to N atoms, resulting in a slower apparent recombination rate. They ascribe the lower rate constants reported by other workers to measurements in this short time regime.

Campbell and Thrush (101) followed the "active nitrogen" glow in a flow system over the temperature range 196–327 °K. They report a value of $(3.8 \pm 0.3) \times 10^{-33}$ at 300 °K and a negative "activation energy" of 0.98 ± 0.14. The wall recombination was found to have the opposite temperature coefficient which, they say, explains why Herron *et al.* (102) found only a small temperature dependence. They find Ar to have a similar third body efficiency to N_2 but He, H_2O, and CO_2 to be more efficient by factors of 1.4, 1.6, and 1.9 respectively. They also claim that approximately 50% of the recombination produces N_2 in the $A^3\Sigma_u^+$ state.

Clyne and Stedman (103) report a value of $k_{14} = 7.4 \times 10^{-33}$ at 300 °K for M = N_2. They find they can fit their results over the wide temperature range 90–611 °K to high temperature shock tube values by the expression

$$k_{14} = 1.4 \times 10^{-33} \exp(1.0 \pm 0.3/RT)$$

but not by an AT^{-n} temperature dependence.

There is not, however, a high degree of consistency among shock tube data. Three of the most recent investigations (104–106) give rate constants which agree within the large combined estimated errors in the overlapping temperature range from 8 000–10 000 °K. They differ widely in the relative efficiencies of third bodies especially in the case where M = N. They differ also in the exponent in the temperature dependence T^{-n} Thus Cary (105) finds $n = 1.7$ for N_2 and 1.0 for N, He, and Ar, while Byron (104) finds $n = 0.5$ for N_2 and Ar, and 1.5 for N. Appleton *et al.* (106) find the same coefficient, $n = 1.6$ for Ar, N_2, and N. The very large spread of the rate constants at both high and low temperatures can be fitted equally well to values of n between 1.0 and 1.7. There are a number of theoretical treatments (31, 83, 107) which predict values of n from 0.5 to 1.5.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It is safe to say that the rate constant for this reaction and its temperature dependence still awaits unequivocal determinations. Fortunately this reaction is not a major loss process for atomic nitrogen in the earth's atmosphere.

[15] $O_2 + N \rightarrow NO + O + 31.9$ *(1.38)*

This reaction is believed to provide the major source of NO in the chemosphere. Kaufman (80) has recently reviewed the work on this reaction prior to 1964 and recommended for the rate constant

$$k_{15} = (1.4 \pm 0.2) \times 10^{-11} \exp(-7.1 \pm 0.4/RT)$$

The only recent measurement of this reaction was reported by Vlastaras and Winkler (108) for the temperature range 180–330 °K

$$k_{15} = 6.5 \times 10^{-12} \exp(-7.0/RT)$$

in reasonable agreement with the earlier measurements in spite of the neglect by the authors of atom recombination.

Reactions of N atoms with $O_2(^1\Delta_g)$ have not yet been reported but may be important in atmospheric NO production.

[16] $N + NO \rightarrow N_2 + O + 75.0$ *(3.25)*

This is one of the fastest known bimolecular reactions between neutral species. Its importance in the laboratory for the "titration" of N atoms and for the production of O atoms in the absence of O_2 is well known. Its importance in the atmosphere stems from its ability to convert N and O_2 into O and N_2 by the sequence of reactions [15] followed by [16]. The N_2 formed in this reaction has been shown (48) to be vibrationally excited with enough energy to dissociate O_3. No new measurements of the rate constant for this reaction have been reported so the value (20) of $k_{16} = (2.2 \pm 0.6) \times 10^{-11}$ at 300 °K still stands. Since this value is within a factor of 5 of the gas collision rate, the activation energy cannot exceed 0.5 kcal mole^{-1}.

[17]
$$N + NO_2 \xrightarrow{a} N_2O$$
$$\xrightarrow{b} 2NO$$
$$\xrightarrow{c} N_2 + O_2$$
$$\xrightarrow{d} N_2 + 2O$$

Although this reaction has little aeronomic importance it is interesting because of the variety of reaction channels available, all of which appear to occur. Phillips and Schiff (109) studied this reaction in a flow system using a combination of photometric and mass spectrometric detection. The overall rate constant was found to be $k_{17} = (1.8 \pm 0.2) \times 10^{-11}$ at 300 °K. The percentage reaction into the four channels were (*a*) 4.3 ± 4, (*b*) 33 ± 7, (*c*) 10 ± 12, and (*d*) 13 ± 11. The reaction rate is also so close to gas collision frequency that the activation energy cannot exceed 0.5 kcal mole^{-1}.

Summary

This brief review will at least have shown that neutral reactions involving nitrogen and oxygen have been actively studied during the past 4 years. Progress has been made on the temperature coefficients of a number of aeronomically important rate constants. But, as atmospheric measurements and model calculations improve, so the need for more accurate rate data will increase.

The field of excited atom and molecule reactions has just begun to be cultivated. To date, most of the work on excited species has dealt with quenching rather than with reactive collisions. It is probably safe to predict that two tools which will play major roles in breaking this new ground will be integrating spectroscopic techniques for studying excited reactants and molecular beam techniques for studying excitation of the products.

Comments and Summary

COMMENTS AND SUMMARY BY CHAIRMAN, MICHAEL B. McELROY[1]

The most important problem in this area where laboratory data are inadequate concerns the chemistry of NO. To account for the atmospheric measurements of NO concentrations, (1, 2) one requires an efficient source of this gas in the sub 100 km region of the atmosphere. The temperature is low, less than 200 °K at about 90 km, and previously one could speculate that the reaction

[1] $$N + O_2 \rightarrow NO + O$$

was faster than might be expected from the Arrhenius equation, which employed an activation energy deduced from laboratory studies at relatively high temperatures (> 400 °K). The recent measurements by Vlastaras and Winkler (3), which extend down to 180 °K, would appear to eliminate this particular solution.

The most plausible alternative sources of NO involve metastable species. In particular either

[2] $$N(^2D) + O_2 \rightarrow NO + O$$

or

[3] $$N + O_2(^1\Delta) \rightarrow NO + O$$

could account for the observed NO concentrations if certain conditions are satisfied. It is well known (4) that $N(^2D)$ is quenched in the atmosphere. If reaction [2] is to be important source of NO then the quenching must proceed almost exclusively by this path. The rate coefficient should be of order 10^{-12} cm^3 s^{-1}. Reaction [3] will be important if the relevant rate coefficient is larger than 10^{-13} cm^3 s^{-1}. Laboratory studies of both reactions are urgently required. Until reliable data become available the problem of NO chemistry, a central one for D region ionospheric studies, must remain vexing but unsolved.

The laboratory data for other reactions discussed by Schiff appear adequate for aeronomical applications.

Neutral reactions involving hydrogen and other minor constituents[1]

FREDERICK KAUFMAN
Department of Chemistry, University of Pittsburgh, Pittsburgh, Pennsylvania 15213
Received December 18, 1968

Experimental laboratory work is reviewed for the kinetics of 21 neutral, elementary reactions involving H, OH, HO_2, H_2, CO, N_2O, CH_4, and Na.

Canadian Journal of Chemistry, 47, 1917 (1969)

Introduction

Five years ago, at the Berkeley Symposium, this author presented a review of laboratory studies of relevant neutral reactions involving hydrogen (1). The present paper will attempt to bring that review up to date, and to discuss briefly the reactions of certain other minor constituents, not previously covered, at the suggestion of the organizers of this Symposium. It will not present, specifically, work done at the author's laboratory, and so is likely to be a drab recitation of experimentally measured rate parameters. The seemingly chaotic diversity and corresponding lack of clear trends among such rate parameters is, of course, a consequence of the greater inherent complexity of neutral reactions, whose cross sections are generally smaller, energy barriers larger, interactions weaker, and intermediate states less predictable than those involving electrons or ions. The lively progress of fundamental rate theory (2) during the last few years will, in general, not be reflected in this review. The day when the detailed course of most elementary reactions will be open to investigation by single-collision methods (e.g. crossed molecular beam) in addition to the varied arsenal of bulk methods (with increasing sophistication of specific quantum state analysis) is unfortunately not yet at hand (except for alkali atom reactions), but, hopefully, it is not far off. Until then, we must rely on chemical kinetic information obtained by various methods such as discharge-flow, flash photolysis, steady photolysis, high temperature kinetics and mechanism, flame sampling, shock-tube, and others. For the purpose of this Symposium where the interest centers on reactions of simple atomic species at temperatures from about 200 to 1000 °K, the discharge-flow method has become the most widely used. Its many variants include formation of reactive species in glow discharges, in thermal sources, or by chemical reaction of energetic precursors; reaction with added molecules along a cylindrical flow tube or in stirred-flow reactor; and detection by measurement of a simply related chemiluminescent emission, by wire calorimetry, optical absorption, election spin resonance (e.s.r.) absorption, mass spectrometry, gas titration of the reactive species, or by other methods. As one reviews the published results of such experiments critically, one should keep in mind all inherent limitations or assumptions which will tend to reduce the accuracy of their results. For example, the experimental errors introduced in the measurements of pressure in the 0.1 to 10 Torr range, of all flow rates (properly reduced to $cm^3\ s^{-1}$ at N.T.P. or particles s^{-1}), and of the geometry of the flow tube or reactor, and thereby the elapsed time, are likely to result in a minimum probable error of about 10% in the resultant rate constant. Next, major uncertainties arise from the oversimplification of the gas flow and from uncontrolled side reaction. Thus, for relatively slow reactions, concurrent surface recombination is always a serious problem, and for very fast reactions whose rate often can not be reduced by lowering reactant concentrations because of detector sensitivity, the flow velocity is likely to be high (0.2 to 1×10^4 cm s^{-1}) which complicates the reactant mixing problem, impedes the establishment of Poiseuille flow, and introduces axial pressure gradients. Probable errors of 10% due to these causes would seem to be conservative estimates in most cases. Finally, there are the errors associated with the method of detection. These are particularly serious when the absolute concentration of a reactive species must be

[1]This work was supported by the National Science Foundation under Grant GP-5369 and by the Defense Atomic Support Agency under Grant DA-ARO-D-31-124-G881.

known as in the calculation of bimolecular rate constants for the reaction involving two such molecules. In such cases, uncertainties in the optical or e.s.r. absorption coefficient, discrimination effects in mass spectrometric analysis, unknown detection efficiency and diffusion effects in probe calorimeters, and titration errors (especially overtitration) in chemiluminescent titrations, will add further errors which will usually amount to at least 10 to 20%. It is clear, of course, that in any one series of measurements most of these errors will tend to remain fairly constant, and that, therefore, the average deviation from the mean in such a series is likely to be much smaller than the true probable error. This rather obvious reminder of the difference between precision and accuracy would seem to be out of place in such a review, were it not for the alarming rise in the claimed accuracy of many reported kinetic parameters. Thus, claims of a probable error (single standard deviation) in a rate constant of less than about $\pm 15\%$ should in most cases be disregarded. As an example, one may cite one of the most easily measured rate constants by discharge-flow techniques, the recombination rate constant for

$$O + NO + O_2 \rightarrow NO_2 + O_2$$

which is not a subject of this review, for which six separate investigations have reported values of 5.1, 5.1, 6.0, 6.0, 7.6, and 8.0×10^{-32} cm^6 $molecule^{-2}$ s^{-1}, even though this is a pseudo first order process in which the concentrations of NO and O_2 are easily measured and remain constant and that of O, therefore, need not be known in absolute magnitude.

Review of Recent Rate Data

The writing of this review was much aided by other recent summaries, especially by the excellent evaluation of kinetic rate data of Schofield (3) and by other review articles (4–6). Reactions will be discussed in the approximate order of this author's earlier review (1), beginning with reactions of H, followed by OH, HO_2, H_2, and H_2O, and ending with a few reactions of CO_2, N_2O, CH_4, and of Na. Molecular units (cm^3 $molecule^{-1}$ s^{-1} or cm^6 $molecule^{-2}$ s^{-1}) will be used throughout, and should be assumed to apply when not specified. Specific rate constants are reported, i.e. for the reaction

$$2A \rightarrow B + C$$

$$k \equiv -1/2 \frac{d[A]}{dt} \Big/ [A]^2 = \frac{d[B]}{dt} \Big/ [A]^2$$

or for

$$2A + M \rightarrow A_2 + M$$

$$k \equiv -1/2 \frac{d[A]}{dt} \Big/ [A]^2[M] = \frac{d[A_2]}{dt} \Big/ [A]^2[M]$$

For each reaction, the energy change at absolute zero temperature, ΔE_0^0, will be given in units of kcal $mole^{-1}$, based on the thermochemical data from the JANAF tables (7). Where this author is unaware of new work since his earlier review, that recommended value will be repeated without discussion for increased usefulness. Lastly, apologies are again in order for possible crimes of omission or commission.

A. Reactions of H Atoms

[1] $$H + H + M \rightarrow H_2 + M$$
$$\Delta E_0^0 = -103.26$$

This reaction is of aeronomic interest only for the major planets. It continues to be studied over a wide temperature range, because it is the most important test case of theory and experiment of atom recombination. Larkin and Thrush (8) studied the T dependence (213 to 349 °K) for M = Ar and found $k = 1.2 \times 10^{-32} (273/T)^{0.7}$, in fairly good agreement with the theory of Benson and Fueno (9), although the latter predicts a weaker T dependence ($\sim T^{-0.3}$ for a Lennard–Jones potential for H + H collision complexes).

The extensive work at high T by shock tube techniques can not be reviewed here. Sutton (10) finds a T^{-1} dependence between 2800 and 4500 °K for M = H_2, and his k extrapolates well to discharge-flow data near 300 °K. His k for M = H is about 10 times larger. Hurle (11) is in good agreement with Sutton for M = H_2, but reports a very much larger k for M = H, with a very large negative T dependence, T^{-7}, between 4000 and 6000 °K. Such a value is clearly not extrapolatable to 300 °K, and Hurle is reported to have seen k come to maximum value near 3000 °K and to appear to decrease again at lower T (12). Rosenfeld (12) has suggested an explanation for this interesting observation. More experimental work is needed, especially in an intermediate T range. Although there is qualitative agreement on the relative efficiency of different M, i.e. Ar < N_2 < H_2O < H_2 < H, there remain wide discrepancies in their exact magnitude.

[2] $H + O_2 + M \rightarrow HO_2 + M$
$\Delta E_0^0 = -45.9$

Two studies near 300 °K, one using chemiluminescent (13) and the other probe (14) detection, have shown this to be a "normal" three-body atom–molecule recombination with a k of $(3 \pm 1) \times 10^{-32}$ (M = Ar) and a ratio of about 20 for $k_{H_2O}:k_{Ar}$. From the M-effect on the second explosion limit of H_2–O_2 explosions near 800 °K, similar relative M-efficiencies are obtained which place He and O_2 near Ar, N_2 1.5 to 2 times larger, H_2 3 times larger. Schofield (3) combined most available rate data to obtain $k = 3 \times 10^{-32} (273/T)^{1.3}$ which is likely to be approximately correct although the $T^{-1.3}$ dependence is weaker than that of several similar recombinations.

[3] $H + O_2 \rightarrow OH + O$
$\Delta E_0^0 = 16.63$

The reaction is sufficiently endothermic to be of no direct importance. There is no experimental information on the interesting possibility of a forward reaction with O_2, $X^3\Sigma_g^-$, $v'' \geqslant 4$ or with O_2, $a^1\Delta_g^+$ or $b^1\Sigma_g^+$. From the very large k of the reverse reaction, $(5 \pm 2) \times 10^{-11}$, (1), and the equilibrium constant, 21 exp $(16.8/RT)$, a value of 1×10^{-9} exp $(-16.8/RT)$ is obtained if the reverse reaction k is assumed to be T independent. If the reverse reaction produces substantial vibrational excitation in O_2, the above "thermal" k would be too large. The very large pre-exponential factor indirectly supports such a possibility.

[4] $H + NO + M \rightarrow HNO + M$
$\Delta E_0^0 = -48.6$

Further work on this reaction since the last review included measurement of k at 293 °K for six M as well as measurement of the relative M effect in the concurrent chemiluminescent reaction to form HNO* (15). For M = H_2, k is now found to be 5.7×10^{-32}, compared to 3.8×10^{-32} in the earlier work of the same laboratory (16). The relative efficiencies of M in the recombination, normalized to M = H_2 are: He, 0.47; Ar, 0.54; CO_2, 1.1; N_2O, 1.2; SF_6, 1.9; H_2O, 3.3. The formation of HNO* was found to depend on M in a similar manner. The further bimolecular reaction, $2HNO \rightarrow N_2O + H_2O$, was investigated by Clyne (17) who placed a lower limit of 0.5×10^{-16} on its rate constant, and by Kohout and Lampe (18) who find $k = 6.7 \pm 10^{-16}$ in a photolysis mass spectrometer study.

[5] $H + NO_2 \rightarrow OH + NO$
$\Delta E_0^0 = -29.5$

No new work is available. The direct measurement of Phillips and Schiff (19) at 300 °K gave $(4.8 \pm 0.5) \times 10^{-11}$. Rosser and Wise (20) reported a similar value based on the competition of reaction [5] with the reaction $H + Cl_2 \rightarrow HCl + Cl$. Schofield (3) recalculated k_5 from the data of ref. 20 using more recent kinetic data on $H + Cl_2$, and obtained an excessively large value. This indicates that the temperature dependence of the rate constant ratio is much smaller than reported in (20). Further unpublished work at the author's former laboratory has confirmed the earlier conclusion that there is very little, if any, vibrationally excited OH formed in this reaction.

[6] $H + O_3 \rightarrow OH + O_2$
$\Delta E_0^0 = -77.1$

This reaction was extensively discussed in the earlier review (1). No new data are available on its rate constant, $(2.6 \pm 0.5) \times 10^{-11}$ at 300 °K as reported by Phillips and Schiff (19). Further work in the author's former laboratory has confirmed the formation of highly vibrationally excited OH as a major reaction product and has provided information on its collisional deactivation by various added gases. Anlauf, Macdonald, and Polanyi (21) have recently studied the infrared chemiluminescence of this reaction at pressures down to 10^{-4} Torr under conditions where $OH^\ddagger$ would either react or be deactivated to $v'' = 0$ at the wall of the reactor. The infrared emission indicated a highly non-Boltzmann distribution of $OH^\ddagger$ with increasing populations up to $v'' = 9$, the highest available level, and about 80 to 85% of all molecules in $v'' \geqslant 4$ if the populations in $v'' = 0$ to 2 are estimated by extrapolation. This result is in good agreement with the earlier ultraviolet absorption work (1) in which only molecules with $v'' = 0$ and 1 were observed. The various fates of $OH^\ddagger$ as a result of radiation, physical quenching, or chemical reactions were presented in the earlier review. The detailed course of its reaction with O_3 has been further clarified by DeMore (22) who showed

that the reaction between $OH^{\ddagger}$ and O_3 may produce $H + 2O_2$ via highly excited HO_2 after a single collision rather than only by two successive collisional processes, i.e. $OH^{\ddagger} + O_3 \rightarrow OH + + O_2 + O$, followed by $OH + O \rightarrow O_2 + H$ (1). This helps to explain why the yield of OH, $v'' = 0$, does not increase strongly when very small concentrations of H are reacted with excess O_3.

[7] $$H + OH \rightarrow H_2 + O$$
$$\Delta E_0^0 = -1.9$$

This rate constant is best obtained from its much studied reverse reaction for which three new values have been reported since the last review: $7 \times 10^{-11} \exp(-10.2/RT)$ (23), $2 \times 10^{-11} \exp(-9.2/RT)$ (24), and $8 \times 10^{-11} \exp(-10.2/RT)$ (25). Combined with the equilibrium constant, $k = 0.44 \exp(-1.87/RT)$, and using the larger activation energy, one obtains $3 \times 10^{-11} \exp(8.3/RT)$ which, although differing fairly substantially from the earlier recommended expression (1), does not yield very different rate constants near 300 °K.

[8] $$H + HO_2 \rightarrow 2OH$$
$$\Delta E_0^0 = -38.8$$

[8′] $$H + HO_2 \rightarrow H_2 + O_2$$
$$\Delta E_0^0 = -57.3$$

No new work is available. The earlier rough estimates of $k_8 \geqslant 3 \times 10^{-12}$ stand (1).

B. Reactions of OH

[9] $$2OH \rightarrow H_2O + O$$
$$\Delta E_0^0 = -16.7$$

Since the earlier work (1) which reported $(1.4 \pm 0.3) \times 10^{-12}$ at 300 °K (the quoted 2.8×10^{-12} referred to $-d[OH]/dt = k[OH]^2$, i.e. twice the specific rate constant) several other values have been published. Westenberg and deHaas (26) found $(2 \pm 0.6) \times 10^{-12}$ by a similar method except for e.s.r. detection, and later work in the same laboratory (27) led to $(2.6 \pm 0.25) \times 10^{-12}$ (The stated errors are single standard deviations calculated from the published data.) Wilson and O'Donovan (28) recently re-analyzed Herron's (29) data on the CO + OH reaction and calculated $(1.1 \pm 0.1) \times 10^{-12}$ for the OH + OH reaction. They then performed similar experiments which yielded $(2.1 \pm 0.1) \times 10^{-12}$, but rejected both in favor of their earlier $(2.6 \pm 0.25) \times 10^{-12}$ (28). Several of these authors err in claiming excessive accuracy as discussed in the Introduction, i.e. they simply report the average deviation from the mean of their calculated values, which is sometimes as low as $\pm 3\%$. It is difficult to assess which of the two principal measurements, $(1.4 \pm 0.3) \times 10^{-12}$ by ultraviolet (u.v.) or $(2.6 \pm 0.25) \times 10^{-12}$ by e.s.r. absorption, is more reliable. Experimentally, the u.v. value has a slight edge, because it averages OH over a shorter distance along the flow tube, permits its measurement closer to the mixing point where OH is produced, and uses a better mixing device for the parent $H + NO_2$ reaction. The u.v. method was also used to measure the oscillator strength of the pertinent electronic transition, $^2\Sigma^+ - {}^2\pi$, and a result $f_{0,0} = (7.1 \pm 1.0) \times 10^{-4}$ was obtained (30) in good agreement with the best direct measurement of the radiative lifetime (31) which yields $(8.0 \pm 0.8) \times 10^{-4}$. The effect of adopting the slightly higher f would be a proportional decrease in all OH concentrations and an increase of k from 1.4 to $(1.6 \pm 0.3) \times 10^{-12}$. The higher e.s.r. value, on the other hand, is supported by measurement of the ratio $[O_2]_\infty/[CO_2]_\infty$ at large reaction times when the OH + CO reaction occurs concurrently, even though this support is predicated on the correctness of the OH + CO rate constant. Very likely, the correct k will lie somewhere between 1.4 and 2.6×10^{-11}, but exaggerated claims of high accuracy should be disregarded.

[10] $$OH + O \rightarrow O_2 + H$$
$$\Delta E_0^0 = -16.6$$

No further work is available. The earlier value of $(5 \pm 2) \times 10^{-11}$ at 300 °K stands.

[11] $$OH + O_3 \rightarrow HO_2 + O_2$$
$$\Delta E_0^0 = -38.3$$

DeMore's recent photolysis work (22, 32) supports the earlier conclusion (1) that ground-state OH does not react rapidly with O_3 ($k \leqslant 5 \times 10^{-13}$) whereas excited OH from the $H + O_3$ reaction does so. No direct proof is available for the often invoked chain decomposition of O_3 by this reaction followed by $HO_2 + O_3 \rightarrow OH + 2O_2$, and such a scheme should not be postulated without proof. With highly excited $OH^{\ddagger}$, the reaction proceeds to give $H + 2O_2$ as previously discussed.

[12] $OH + HO_2 \rightarrow H_2O + O_2$
$\Delta E_0^0 = -72.1$

The earlier recommendation of a fast reaction, $k \geqslant 10^{-11}$, on the basis of indirect information on HO_2 production, still stands.

[13] $OH + H_2 \rightarrow H_2O + H$
$\Delta E_0^0 = -14.7$

Two new measurements of this rate constant at 300 °K have been reported, both in good agreement with the earlier value of $(7 \pm 2) \times 10^{-15}$ (1). Dixon-Lewis, Wilson, and Westenberg (27) find $(6.5 \pm 0.5) \times 10^{-15}$ by e.s.r. and Greiner (33), $(6.7 \pm 0.4) \times 10^{-15}$ by flash photolysis and kinetic spectroscopy. Combined with flame and shock tube data, this value has led to several Arrhenius expressions for k such as $6.3 \times 10^{-11} \exp(-5.49/RT)$ (3), $1 \times 10^{-10} \exp(-5.9/RT)$ (1), and $3.8 \times 10^{-11} \exp(-5.2/RT)$ (27) which are also in close agreement over the relevant T range.

C. Reactions of HO_2

No new information is available for the reactions

$$O + HO_2 \rightarrow OH + O_2$$
$$k \geqslant 10^{-11}$$

and

$$2HO_2 \rightarrow H_2O_2 + O_2$$
$$k = 1.5 \times 10^{-12}$$

where k is the specific rate constant.

D. Reactions of H_2

[14] $O + H_2 \rightarrow OH + H$
$\Delta E_0^0 = +1.9$

Several new studies of this important reaction of ground-state oxygen, ^3P, have been reported, as noted above in the discussion of the reverse reaction. The rate expressions are: $7 \times 10^{-11} \exp(-10.2/RT)$ (23), $2 \times 10^{-11} \exp(-9.2RT)$ (24), and $8 \times 10^{-11} \exp(-10.2/RT)$ (25). Combining the first two of these with the earlier 2×10^{-11} $(-9.4/RT)$ (34), Schofield suggested $2.1 \times 10^{-11} \exp(-9.4/RT)$ (3). The most recent of these investigations, by Westenberg and de-Haas (25) who use the discharge-flow method and e.s.r. detection, also indicates deviations from an Arrhenius expression at the low T end of their range (350 °K) which may be due to tunnelling. The higher activation energy of 10.2 kcal seems to be slightly preferable, and an expression $7 \times 10^{-11} \exp(-10.2/RT)$ is recommended.

E. Reactions of CO and CO_2

As additional species are brought in for consideration and review, the number of possible reactions increases exponentially. Only very few of these reactions will be discussed, however, partly because of their low aeronomic interest and partly because of the paucity of laboratory data. Moreover, all reactions of excited states are discussed elsewhere.

[15] $OH + CO \rightarrow H + CO_2$
$\Delta E_0^0 = -24.4$

Three recent measurements near 300 °K have shown that this reaction has a much smaller activation energy than heretofore believed. Thus, Westenberg and Fristrom (35) combined available kinetic data in 1964 to give the rate expression $1.2 \times 10^{-11} \exp(-7.7/RT)$, based in part on incorrect early discharge work (36). Yet since then, all measurements have indicated that $E < 2$ kcal. Herron (30) reported $(8.5 \pm 3) \times 10^{-14}$ at 300 °K and derived $1.5 \times 10^{-12} \exp(-1.7/RT)$ by combination with explosion and flame data; Dixon-Lewis, Wilson, and Westenberg (28) obtained 1.9×10^{-13} at 300 °K and derived $5.0 \times 10^{-13} \exp(-0.6/RT)$; Greiner (34) obtained 1.5×10^{-13} at 300 °K; and Wilson and O'Donavan (29) also obtained 1.5×10^{-13} although they prefer the somewhat higher 1.7×10^{-13} based on the earlier measurement of reaction [9]. A three parameter expression for this rate constant has also been proposed (28) but is surely not warranted in view of the large spread of nearly an order of magnitude in the high T data. A compromise of $9 \times 10^{-13} \exp(-1.0/RT)$ is suggested, albeit without special evidence.

The reverse reaction is endothermic and therefore quite slow. Using the expression $2.3 \times 10^{-3} \exp(+24.7/RT)$ for the equilibrium constant over the range 300 to 1000 °K, the reverse k is $4.0 \times 10^{-10} \exp(-25.7/RT)$. At 1000 °K, the equilibrium constant is 620 which shows that the reverse reaction is not altogether negligible.

[16] $O + CO + M \rightarrow CO_2 + M$
$\Delta E_0^0 = -125.75$

Our understanding of this simple recombination reaction is still in a most unsatisfactory state. There is general agreement that the reaction is at

least two to three orders of magnitude slower than "normal" recombinations such as O + NO + M or H + O_2 + M, and therefore difficult to study in low pressure flow system. But there has been lack of agreement whether the process is of second or third order in the Torr pressure range, and whether it has a positive or negative T dependence. Clyne and Thrush (37) found no measurable reaction at 293 °K at a total pressure of 2 Torr and CO partial pressure up to 0.5 Torr, and placed an upper limit of 8×10^{-35} on the third order k. They also reported a second order chemiluminescent rate constant of $1 \times 10^{-17} \exp(-3.7/RT)$ for M = O_2, indicating a small energy barrier. Mahan and Solo (38) claim the recombination to be second order to pressures as low as 0.2 Torr and report $k = 1.6 \times 10^{-14} \exp(-4.0/RT)$ for the overall reaction and $2 \times 10^{-13} \exp(-9.5/RT)$ for the chemiluminescent reaction. The former value is almost four times as large as the above upper limit at 2 Torr and therefore inconsistent with it. Hartunian, Thompson, and Hewitt (39) studied only the chemiluminescent reaction in a glow-discharge shock tube and reported $1.6 \times 10^{-18} \exp(-2.5/RT)$, in fair agreement with ref. 37 and in good agreement with a value $0.5 \times 10^{-18} \exp(-2.5/RT)$ obtained by Myers and Bartle (40) from shock tube work near 3000 °K. Avramenko and Kolesnikova (41) also reported the overall reaction to be second order with $k = 1.6 \times 10^{-13} \exp(-3.8/RT)$, but this value gives much too high a k at 300 °K and is in strong disagreement with a recent measurement by Mulcahy and Williams (42), whose measured O + CO rate is 100 times slower than the above at 456 °K. In all, it seems likely that the reaction has a small energy barrier and is third order in the few Torr pressure range, but a definitive experimental study has yet to be undertaken.

[17] $$H + N_2O \rightarrow OH + N_2$$
$$\Delta E_0^0 = -62.8$$

The neutral chemistry of N_2O is unlikely to be of much importance in aeronomy because all its reactions involve fairly large energy barriers. This is true of the reaction O + $N_2O \rightarrow$ 2NO whose energy of activation is near 25 kcal and it also applies to this reaction although to a lesser extent. The H + N_2O reaction was investigated indirectly by Fenimore and Jones (43) at 1260 to 1780 °K by flame probe methods. These authors reported $7 \times 10^{-10} \exp(-16.3/RT)$, but this result was based on the high value of the activation energy for reaction [13], and the rate expression should, therefore, now be changed to $1.3 \times 10^{-10} \exp(-11.3/RT)$. This is in fair agreement with more recent measurements by Dixon-Lewis, Sutton, and Williams (44) whose k's indicate a similar activation energy of 10.1 kcal but are smaller in magnitude. Schofield (3) suggests the rate expression $5 \times 10^{-11} \exp(-10.8/RT)$ as a mean of the available data. Because of slowness of this and other N_2O reactions and because of the low concentrations of reactants, it seems clear that its photochemistry will be of much greater importance than the above collisional processes.

[18] $$H + CH_4 \rightarrow CH_3 + H_2$$
$$\Delta E_0^0 = -2.8$$

The above remarks are applicable here. With the exception of the reaction with $O(^1D)$, which is not covered in this review, all other neutral reactions of CH_4 of aeronomic applicability involve energy barriers and are likely to be slow compared with photoexcitation or dissociation. For the present reaction, the ΔE_0^0 of 2.8 kcal calculated from the JANAF tables should probably be replaced by a value of −0.6 kcal based on Golden, Walsh, and Benson's (45) value for the energy of formation of CH_3. Twelve investigations of this reaction are cited in a recent review (4). Reported activation energies range from 4.5 to 15.1 kcal and pre-exponential values from 10^{-14} to 5×10^{-10}, but there is much better agreement on the absolute value of k than is indicated by this large spread. Schofield (3) has combined the data of seven of these studies in an Arrhenius plot and reports $6.7 \times 10^{-11} \exp(-11.6/RT)$ which indicates that the reaction is negligibly slow near 300 °K.

[19] $$OH + CH_4 \rightarrow H_2O + CH_3$$
$$\Delta E_0^0 = -17.6$$

Similar considerations apply here regarding ΔE_0^0 which is more probably −15.4 in view of the recent work on CH_3 (45). This reaction has been studied repeatedly by a variety of experimental methods, with reported activation energies ranging from 5.0 to 9.0 kcal. Schofield's (3) analysis of most available data yields $1.2 \times 10^{-10} \exp(-5.9/RT)$. In view of the very rapid reaction

of OH with O, the steady-state OH concentration is probably very small, and the present reaction is of no importance.

[20] $$CH_4 + O \rightarrow CH_3 + OH$$
$$\Delta E_0^0 = -0.9$$

ΔE_0^0 is more probably +1.3 kcal (45). Several recent studies of this reaction over the T range 300 to 1000 °K are in surprisingly good agreement. Thus, Schofield (3) summarized the available data by the rate expression 5.3×10^{-11} exp $(-7.95/RT)$, where the specific investigations ranged only from 6.9 to 8.7 kcal in their activation energies. Since the time of that summary, two more studies have been published, both using discharge-flow e.s.r. methods: Brown and Thrush (46) obtain 1.2×10^{-11} exp $(-7.7/RT)$ and Westenberg and deHaas (25) report 2.8×10^{-11} exp $(-8.7/RT)$. The latter expression probably represents the most accurate work, and since it also covers a much larger T range than the former, it is to be preferred. It should be remembered that in this rate constant the subsequent reaction of CH_3 with excess O have been taken into account, i.e. the total O-atom decay rate constant is given by $4k$.

[21] $$Na + O_2 + M \rightarrow NaO_2 + M$$

No value of ΔE_0^0 is given for this reaction, because NaO_2 (g) is not listed in the JANAF tables. There exists a recent, indirect measurement of ΔE_0^0 by McEwan and Phillips (47) of -65 ± 3 kcal, based on the approach to equilibrium of the present reaction in O_2-rich H_2–O_2–N_2 flames. Compared with the corresponding values of -45.9 for HO_2, this seems unexpectedly high. These authors also report a value of 2.0×10^{-35} for the rate constant, surprisingly independent of T over the range 1380 to 2030 °K. This is in fairly good agreement with an earlier measurement by Kaskan (48) of 0.8×10^{-33} obtained from flame work at 1 atm pressure in which the reaction order could not be established. Recently, the pressure dependence of this process was investigated by Carabetta and Kaskan (49) over the pressure range from 100 to 1520 Torr, and the third order dependence was verified. A rate constant of 0.83×10^{-33} was reported near 1500 °K. With an assumed T^{-1} to T^{-2} dependence this will lead to a range of 0.5 to 2.5×10^{-32} near 300 °K, 200 to 1000 times smaller than similarly extrapolated results of Bawn and Evans (50) which are probably too large because of the neglect of quenching of $Na(^2P)$, by N_2 as discussed by Blamont and Donahue (51). However, this discrepancy appears too wide to be bridged by correction of the diffusion flame data (50). The flame k's are smaller than one would expect for a fully allowed three-body process involving a large atom and a moderately electronegative molecule, they show no T dependence over a fairly large range, and they lead to an unreasonably large bond energy. Additional work at low T is needed.

To this author's knowledge, no experimental data are available on the kinetics of the reactions $NaO_2 + O \rightarrow NaO + O_2$ and $NaO + O \rightarrow Na + O_2$. If the recent Na—$O_2$ bond strength of 65 kcal is correct and the JANAF value of 71.2 for the Na—O bond strength is accepted, the former process is only about 6 kcal exothermic and the latter 46.8 kcal, only 1.7 kcal less than the excitation energy of $Na(^2P_{1/2})$. The many other exothermic reactions of Na-oxides with H or OH can not be discussed for lack of any laboratory information.

Comments, Replies, and Summary

COMMENTS BY A. FONTIJN[1]

The discrepancy between the determinations of the rate constant of the reaction $Na + O_2 + M \rightarrow NaO_2 + M$, noted in Professor Kaufman's article, may be readily explainable. In the atomic diffusion flame work of ref. 1, a "fog" of sodium oxide particles is present, thus creating a large surface area on which reactions can occur. The rates measured, therefore, may pertain to undefined combinations of homogeneous and heterogeneous reactions and the obtained rate constant may well be orders of magnitude too high, as the comparison to the "hot" flame work seems to suggest.

Steacie (2) has pointed out that reaction products, present in the form of solid particles, may participate in atomic alkali halide reactions. The present observation thus appears to confirm this possibility.

COMMENTS BY L. F. PHILLIPS[2]

Regarding NaO_2, I wish to make the following points:

1. The temperature coefficient (negative) of the reaction $Na + O_2 + M \rightarrow NaO_2 + M$ is obscured in flames by the fact that the nature of M changes with temperature, increasing T being accompanied by increasing partial pressure of H_2O.

2. Carabetta and Kaskan (1) believe that 65 kcal is too low a value for $D^0(Na—O_2)$ because, on the basis of the JANAF value of 90 kcal for D^0(Na—OH), the equilibrium $NaO_2 + H \rightleftharpoons NaOH + O$ would favor NaOH over NaO_2 in flames, contrary to observation. However, in this case

JANAF is wrong, and the value of 77 kcal for D^0(Na—OH) given by Jensen and Padley (2) changes the picture so that the above equilibrium actually favors NaO_2, as observed.

3. Using the listed heat of formation (Gilles and Magrave) of 62 kcal for NaO_2(s) at 298 °K it is possible to deduce a heat of vaporization near 22 kcal for NaO_2(s) at 298 °K. This seems rather low (values for Na metal 26 kcal, NaI 48 kcal, NaOH 47 kcal) but may be reasonable in view of the instability of solid NaO_2 at room temperature. A higher D^0(Na—O_2) value would give a still lower heat of vaporization.

REPLY BY F. KAUFMAN

I can not accept Dr. Phillips' second and third points. Regarding *2*, although the reaction $NaO_2 + H \rightarrow NaOH + O$ becomes slightly endothermic if the value of 77 kcal for D^0(Na − OH) is accepted, the more important process $NaO_2 + OH \rightarrow NaOH + O_2$ is still fairly exothermic. For either reaction (or for $NaO_2 + O \rightarrow NaO + O_2$) one should carry out equilibrium calculations rather than rely on qualitative arguments.

In *3*, it seems strange to rationalize an unusually low heat of vaporization as due to the instability of the solid (presumably with respect to other species in the solid phase). The melting point of NaO_2(c) has been reported to be 825 °K. There seems to be no reason why NaO_2(c) should not readily vaporize to NaO_2(g) if its ΔH_V is only 22 kcal and if the Na—O_2 bond energy is as large as 65 kcal, which makes NaO_2 the most stable gaseous Na-oxide by far, at moderate temperatures. I consider it more likely that the ΔH_V is near 40 kcal, the bond energy also near 40 to 45 kcal, and that the oxide is, therefore, extensively dissociated at elevated temperatures but is formed as an intermediate species which reacts further to produce NaO or NaOH.

SUMMARY AND REMARKS BY CHAIRMAN, D. M. HUNTEN[3]

In the Earth's atmosphere, the reactions of hydrogen and its compounds are of interest in three principal ways:

(*1*) as a possibly significant loss mechanism for ozone, whose concentrations are otherwise predicted to be greater than observed;

(*2*) in connection with the excitation of the Meinel (i.e. vibration–rotation) bands of OH, closely related to (*1*), because the important reaction is $H + O_3 \rightarrow OH + O_2$;

(*3*) as a source of atomic hydrogen, whose behavior is of great interest in the thermosphere and which dominates the exosphere.

An important obstacle to quantitative study has been the lack of certainty about the mixing ratio of H_2O at balloon altitudes. The best aircraft measurements in the lower stratosphere have given low values, but much higher results have frequently been obtained by balloon-borne instruments. There now seems little doubt that most of the difference has been H_2O released from the balloon; the effect is much less important for an aircraft, which does not float along in its own vapor cloud. The most careful work (1) shows consistently a mixing ratio of 3×10^{-6} by volume; the payload must be suspended far below the balloon, and the best measurements are made during descent, initiated by ejection of part of the lifting gas. Optical absorption is also subject to error; Zander (2) has published some direct observations of the vapor cloud, made as the line of observation to the Sun passed near the balloon.

A further uncertainty is the possible role of methane as a source of H atoms. Bates and Nicolet (3) point out that the mixing ratio is 1.5×10^{-6} in the tropopause, and if upward transport is fast enough, an additional 3×10^{-6} of H_2O would be produced. But it may be that the H_2O observations include this contribution.

Calculations of the O–O_3 equilibrium have been made by Hunt (4) with a water–vapor mixing ratio of 5×10^{-6}, close to what is suggested above, and using essentially the rate coefficients recommended by Kaufman. He finds that the inclusion of the hydrogen compounds produces a much better agreement with the observed ozone amounts. The important reactions at high altitudes are Kaufman's reactions [6] and [10], also responsible for the OH nightglow. At lower altitudes reaction [11] is invoked, followed by the reaction of HO_2 with O_3. Kaufman's warnings about this cycle should be kept in mind.

[3]Address: Kitt Peak National Observatory, Tucson, Arizona.

Near 90 km the dominant form of hydrogen becomes H (5), but the details are not well understood, especially the transport processes that must be included. At great enough heights, the H becomes the dominant constituent by gravitational separation, but the treatment is complicated by the upward flux that is required to replace the atoms that escape the Earth's gravitational field altogether.

Other planets show strikingly different problems, which have received less discussion. The atmospheres of the major planets are nearly all H_2, and the temperatures are low. The equilibrium between H_2 and H becomes the analogue of the familiar one between O_2 and O; a preliminary study has been made by Gross and Rasool (6). The minor constituents, CH_4 and NH_3, are subject to photolysis, but no obvious way exists of reforming them, except far down in the dense lower atmosphere (7).

On Mars and Venus there is much CO_2 but little free oxygen. McElroy has suggested that under these conditions much of the upper-atmospheric hydrogen will appear as H_2. Any effect of hydrogen compounds of the CO_2–CO equilibrium is likely to be small, because of the very small concentrations of both hydrogen and oxygen. Atomic hydrogen in the exosphere of Venus has been observed from two planetary probes by the scattered Lyman-α radiation. The radial distribution is anomalous, and one suggestion invoked H_2 in addition to H. The H_2 mechanism has been shown to be self-contradictory (8, 9), and the only remaining possibility seems to be deuterium. If this is so, many interesting problems of atmospheric chemistry and evolution will have to be considered.

Chemiluminescent reactions in the airglow

ROBERT A. YOUNG
Center for Research in Experimental Space Science, York University, Toronto, Ontario

Received December 31, 1968

Laboratory experiments on chemiluminescent reactions involving atomic oxygen of pertinence to the earth's nightglow are reviewed. From simple consideration it is shown that the atomic oxygen concentration in the earth's upper atmosphere must be larger than the presently accepted value of 2×10^{11} atoms/cm^3 at the peak in the atomic oxygen altitude profile. Rocket measurements of the volume emission intensity of 5577 Å radiation and laboratory measurements of the rate of its excitation by three-body atomic oxygen association indicate a peak upper atmospheric atomic oxygen concentration near 10^{12} atoms/cm^3. The excitation of molecular oxygen emission in atomic association is a multistep process involving at least one quenchable precursor. Laboratory results are inadequate to define the excitation mechanism but a strongly temperature-dependent precursor deactivation process is required for laboratory observation to be consistent with the hypothesis that atomic association is the cause of nightglow O_2 emission. Other processes are briefly discussed.

Canadian Journal of Chemistry, 47, 1927 (1969)

Introduction

Planetary atmospheres are inhomogeneous, having a density which decreases approximately exponentially upward from the surface. Photodissociation of this atmosphere by solar radiation produces the reactants which later undergo exothermic reaction. Generally, the effective solar radiation is in the far ultraviolet and is strongly absorbed. Hence photodissociation occurs high in the atmosphere where the atmosphere is tenuous. Since re-association usually requires a three-body process, the fragments diffuse downward where recombination is possible and the resulting molecules diffuse upward. The reactive constituents have a maximum concentration below the height at which maximum photodecomposition occurs and above the height where recombination is more important than diffusion.

This combination of circumstances is usually not suitable for direct laboratory simulation and study, because the total pressure is so low that very large volumes must be employed if surface phenomena are to be sufficiently minimized, and the total rate of product formation is consequently too slow to be detectable. Hence laboratory measurements of possible chemiluminescent processes pertinent to the upper atmosphere are done at considerably higher densities of both the reactive and nonreactive constituents of planetary atmospheres. This increases both the rate of product formation and the rate of secondary collisional phenomena.

Since radiative deactivation of excited species is unimolecular, but collisional deactivation is bimolecular, the overall efficiency of chemiluminescent reactions decreases and emission from other components of the system may increase — because of energy transfer — as the pressure is raised to that necessarily employed in laboratory experiments. Hence collisional deactivation processes must be measured if laboratory results are to be applied in planetary atmospheres.

Since photodecomposition is the result of absorption of ultraviolet solar energy and this energy must drive all atmospheric exothermic processes, it is logical that associative reactions are the major chemical processes occurring in planetary atmospheres. Were this not the case, planetary atmospheres must decompose into simpler constituents. Presumably, this has already occurred if it is possible.

The night airglow is due almost exclusively to chemiluminescent processes utilizing energy stored in photodissociation products created during the day by solar radiation. Since the major effect of the sun on the upper atmosphere of the earth is to dissociate O_2, most nightglow emissions are expected to be produced by processes involving atomic oxygen. Hence it is not surprising to observe emission from O_2 and O. However, it may be surprising that the largest total photon flux is due to OH vibration–rotation bands from the ground electronic state. Table I contains a list of observed nightglow emissions and an estimate of their total intensity.

Overall Consideration of Nightglow Excitation

Before entering into a discussion of specific processes which produce the emissions tabulated

TABLE I*

Intensity of nightglow emissions

Emission	Species	Emission rate in a column of atmosphere (photons/cm² s)	Emission rate (Rayleighs)
5893 Å	Na	1×10^8	100
6300 Å	$O(^1D)$	1×10^8	100
5577 Å	$O(^1S)$	2.5×10^8	250
Continuum (400–10 000 Å)	$NO_2(?)$	1×10^9	10^3
Herzberg bands (3000–4000 Å)	$O_2(A^3\Sigma_u^+)$	1×10^9	10^3
Atmospheric bands (7000–9000 Å)	$O_2(b^1\Sigma_u^+)$	3×10^{10}	3×10^4
Infrared atmospheric (1 μ)	$O_2(a^1\Delta)$	5×10^{10}	5×10^4
Meinel bands (5000 Å – 5 μ)	OH	4.5×10^{12}	4.5×10^6

*This table is derived from Table II.1 in Appendix II of ref. 5 and modified as discussed in Sections 12.3, 13.4, and 13.5.

in Table I, a comparison of the total energy flux released by atomic oxygen association with the energy radiated in the nightglow is instructive. Figure 1 shows the theoretical computation of the altitude profiles of [O], [O_2], and [O_2] + [N_2] = [M] normalized to rocket data for [O] at 120 km. This profile is considered to be the best present knowledge of these constituents. Also shown are the rate of O_2 formation by

[*a*] $$O + O + M \rightarrow O_2 + M$$

and

[*b*] $$O + O_2 + M \rightarrow O_3 + M$$

[*c*] $$O + O_3 \rightarrow 2O_2$$

These production rates were computed using rate coefficients of 3×10^{-33}, 8×10^{-34} cm⁶/s for k_a and k_b (1)[1], and assuming that O_3 is in a steady state. Then the rate of O_2 formed by the series of reactions [*b*] and [*c*] is the rate of O_3 formation by reaction [*b*]. An upper limit to the energy released above 80 km by reaction [*a*] in a cm² column of the atmosphere is 5×10^{10} eV/cm² s and the upper limit by reactions [*b*] and [*c*] is 4×10^{12} eV/cm² s. The energy radiated from O_2 is 1×10^{11} eV/cm² s and that from OH is 5×10^{12} eV/cm² s. It is certain that all the energy which atomic oxygen can liberate by forming O_2, roughly 5 eV/molecule, is not radiated, especially in the atmospheric, infrared atmospheric, and OH Meinel bands.

[1]This reference contains an up-to-date compilation of rate coefficients pertinent to atmospheric phenomena.

These comparisons indicate that unless the atomic oxygen concentration profile (2), as currently accepted, is modified to indicate considerably larger concentration of atomic oxygen, atomic oxygen association by reactions [*a*], [*b*], and [*c*] cannot power the airglow. There is no doubt, in fact, that it does. It will not be surprising, then, if individual processes subsequently discussed are similarly found inadequate to account for specific emission features in the nightglow, if the presently accepted atomic oxygen profile is used.

Chemiluminescent Reactions

All exothermic chemical reactions are potentially chemiluminescent. Unless all the energy released in the chemical reaction is initially converted into kinetic energy, the products must contain excess rotational, vibrational, or electronic energy. In the absence of collision phenomena this energy can only be dissipated by radiation and the chemical reaction would be termed chemiluminescent.

Since the initial reaction involved a collision between reactants, the products must also suffer collisions. Luminescence will then result only when the rate of radiation is larger than the rate of collisional removal of energy. Hence the term "chemiluminescent reactions" is a relative one; an exothermic reaction will generally be luminescent provided radiation rather than collisional processes remove the excess internal energy.

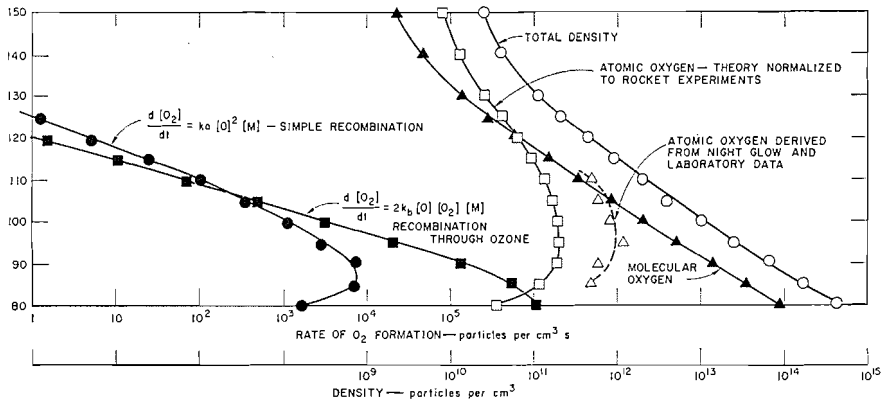

FIG. 1. This figure is a composite of (*a*) the densities of [O], [O_2] and [O_2] + [N_2] derived from calculations in ref. 2, normalized to rocket measurements of atomic oxygen at 120 km, and also adjusted so that [O]/[O_2] = 1 at this altitude in conformance to rocket measurement, (*b*) the rate of O_2 formation using the depicted densities and rate coefficients listed in the text, and (*c*) the atomic oxygen profile deduced from rocket measurement of 5577 Å emission in the nightglow as reported in ref. 8.

Because most exothermic chemical reactions lead to excited products, a study of chemiluminescent reactions is largely a study of the competition between radiation and collisional deactivation of excited atoms and molecules. For a given collision environment, the shorter the radiative lifetime of the excited species the more likely it is to dissipate its excess energy as radiation. Hence emission is more likely from electronically excited species than from vibrationally or rotationally excited species.

Although the energy released in reactions may not be significantly radiated from the initial products because of collisional effects, a large part of this energy may ultimately appear as radiation if deactivation of the products occurs by energy transfer to radiative states. This depends on the radiative lifetime of the acceptor relative to its collisional deactivation lifetime. In short, the appearance of emission during an exothermic chemical reaction depends upon the radiative and collisional characteristics of the entire system in which energy is being released. Because of this, different exothermic reactions may lead to similar emission phenomena provided other constituents are common elements of the two systems. The observed emission may not be unique to a single exothermic reaction.

Since energy radiated out of a reacting system is unavailable for further chemical use, excited products with short radiative lifetimes generally do not play a significant role in the evolution of the reacting system. However, metastable electronically excited species and vibrationally or rotationally excited species may have significant consequences for the evolution of a reaction system. Since the reactive character of a species is determined largely by its outer electronic structure, and electronic excitation changes this structure as significantly as changing its chemical identity, electronically excited species may have an entirely different chemical character from the same species in its unexcited state. Electronic excitation then adds entirely new reactants to a chemical system.

Vibrational and rotational excitation primarily affect the state of motion of the nuclei forming a molecule and have a less direct effect on its chemical behavior. Since the rate coefficients of many reactions depend strongly on temperature over an interval where significant change in the vibrational excitation of the gas does not occur, this dependence must be due either to effects of relative energy of collision or the rotational state of the reactant, or both. Of the two possibilities, the relative energy of the collision is considered more important in determining the rates of chemical processes. Vibrational energy is known to be effective in causing increases in reaction rates, but detailed studies are as yet incomplete.

Laboratory Experiments

Theory

Laboratory experiments generally consist of

measuring the intensity of emission from a particular excited state of a particular chemical species which might be called X_n^*. Then

$$[1] \qquad I(X_n^*) = \frac{[X_n^*]}{\tau(X_n^*)}$$

where $I(X_n^*)$ is the emission in photons/cm^3 s from X_n^* which has a density of $[X_n^*]$ molecules/cm^3 and $\tau(X_n^*)$ is the spontaneous radiative lifetime of X_n^*. If X_n^* is deactivated by species i in a process having coefficient k_i then in a steady state

$$[2] \qquad P(X_n^*) = (1/\tau(X_n^*) + \sum k_i[i])[X_n^*]$$

or

$$[3] \qquad P(X_n^*) = (1 + \tau(X_n^*)\sum k_i[i])I(X_n^*)$$

where $P(X_n^*)$ is the rate of production of X_n^* per cm^3. Since $P(X_n^*)$ is here due to chemical processes, it depends upon the constituents of the system, their densities, and the temperature. The dependence of $P(X_n^*)$ on [i] is the primary data desired from the experiment. From such data the mechanism of excitation and its rate coefficient may be deducible.

It is apparent, however, that steady-state experiments do not give $P(X_n^*)$ unless $\sum k_i[i]$ is known or negligible. Furthermore, unless the processes producing X_n^* are elementary, the functional dependence of $P(X_n^*)$ on [i] will not uniquely determine either the group of processes leading to excitation of X_n^* or the appropriate rate coefficients. This latter difficulty is important, fundamental, and often encountered. It can only be removed by measurement or manipulation of the intermediate compounds involved in the processes forming X_n^*.

Associative reactions are generally three-body processes, since both momentum and energy are unlikely to be conserved in two-body associative processes except through radiation. This is particularly true for atomic association as occurs in the earth's atmosphere. Hence $P(X_n^*)$ in its simplest form is

$$[4] \qquad P(X_n^*) = \sum \bar{k}_i[X][X_{n-1}][i]$$

implying (perhaps)

$$[d] \qquad X + X_{n-1} + i \rightarrow X_n^* + i$$

and then

$$[5] \qquad \sum \bar{k}_i[X][X_{n-1}][i] = (1 - \tau(X_n^*)\sum k_i[i])I(X_n^*)$$

This formulation singles out X and X_{n-1} on the left but not on the right side.

A somewhat more involved process is

$$[e] \qquad X + X_{n-1} + i \rightarrow X_n^* + i$$

$$[f] \qquad X_n^* + i \rightarrow X_n + i$$

$$[g] \qquad X_n^* \rightarrow X_n + h\nu$$

giving

$$[6] \qquad I(X_n^*) = \frac{\sum \bar{k}_i(e)[X][X_{n-1}][i]k_g}{\sum(k_g + \sum k_i(f))[i]}$$

This can be further complicated if an intermediate or precursor excited species is involved.

$$[h] \qquad X + X_{n-1} + i \rightarrow X_n^{**} + i$$

$$[j] \qquad X_n^{**} + i \rightarrow X_n^* + i$$

$$[l] \qquad X_n^{**} + i \rightarrow X_n + i$$

$$[m] \qquad X_n^{**} \rightarrow X_n + h\nu$$

$$[n] \qquad X_n^* + i \rightarrow X_n + i$$

$$[p] \qquad X_n^* \rightarrow X_n + h\nu$$

which leads to the complicated expression

$$[7] \qquad I(X_n^*) = \frac{(\sum \bar{k}_i(h)[X][X_{n-1}][i])(\sum k_i(j)[i])}{\{k_m + \sum(k_i(j) + k_i(l)[i])\}(k_p + \sum k_i(n)[i])}$$

From these formations it can be seen that interpretation of laboratory observation of $I(X_n^*)$ vs. [i] may be difficult.

How Atomic Oxygen Is Made and Measured in the Laboratory

Laboratory experiments on atomic oxygen airglow reactions consists of making, controlling, and measuring atomic oxygen in a largely N_2 atmosphere and measuring the intensity of emission from the appropriate emitting species.

Figure 2 schematically shows a suitable experimental system (3). Nitrogen flows through a microwave discharge at a few Torr pressure where it is partially dissociated, past an inlet for NO which reacts rapidly with N

$$[q] \qquad N + NO \rightarrow N_2 + O$$

to produce O from N, into a large observation bulb, and finally out to a fast mechanical pump.

For personal use only.

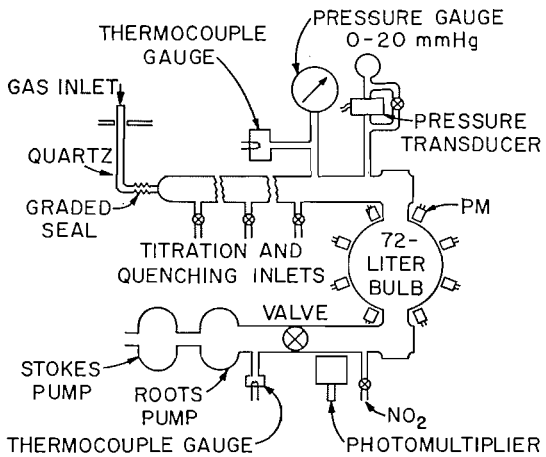

FIG. 2. A schematic diagram of a low pressure flow system suitable for investigating atmospheric chemiluminescent reactions.

The flow velocity in the 4 in. i.d. tubing is 8 m/s and the residence time of the gas in the 72 l bulb is approximately 1 s.

This indirect method of producing atomic oxygen is used to prevent the formation of excited O_2 molecules, except by atom association, and to permit [O] to be controlled by the rate of NO addition to the gas stream. The rate coefficient of reaction [*q*] was first measured using mass spectroscopic techniques (4) and the result has been repeatedly verified (1).

To measure [O], several subsidiary chemiluminescent reactions are utilized (3). The emission of the N_2 first positive bands occurs in the recombination of atomic nitrogen, the NO δ, γ, and β bands are excited in the association of N and O, and NO_2 "continuum" is excited in the association of O and NO. In each instance the intensity of emission is proportional to the simple product of reactant densities

$$[8] \qquad I_{N_2} = K_\alpha[N]^2$$

$$[9] \qquad I_{NO} = K_\beta[N][O]$$

$$[10] \qquad I_{NO_2} = K_\gamma[O][NO]$$

The constants of proportionality may depend upon both gas composition and pressure, but can be empirically obtained by using reaction [*q*]. As NO is added, [N] decreases and [O] increases. When I_{NO} is a maximum, [N] = [O], and [O] can be computed from the rate of [NO] addition and the rate of flow of the gas in the flow system. Knowing [N] and [O] permits K_α and K_β to be computed. As the flow rate of NO into the system is further increased I_{N_2} and I_{NO} decrease to zero when [N] = 0. Further addition of NO causes I_{NO_2} to increase from its previous near zero value. The point of minimum emission is called the null point and corresponds to [N] $\approx$ 0, [NO] $\approx$ 0 and [O] equals the concentration of [NO] that would be present if it did not react. Emission at the null point is, of course, not zero because emission from atomic oxygen association, which is to be studied, is occurring at a maximum rate. However, atomic oxygen association produces much less emission than the other processes.

As [NO] increases beyond the null point I_{NO_2} increases linearly so long as [O] is not appreciably decreased by reations with NO. This is because the series of reactions

$$[r] \qquad O + NO + M \rightarrow NO_2 + M$$

$$[s] \qquad NO_2 + O \rightarrow NO + O_2$$

catalytically recombine O but do not decrease NO. As [NO] increases reactions [*r*] and [*s*] become the dominant ones removing O, and I_{NO_2} decreases. If NO_2 were added to the stream containing only O, I_{NO_2} would increase as reaction [*s*] causes NO to increase, reach a maximum, and then decrease to zero when all O had been consumed. Since a null is more reliably measured, the NO_2 technique is less accurate and more difficult to use in measuring [O] than the NO titration technique.

Emission intensities are generally measured using photomultipliers with interference filters, to restrict their sensitivity to wavelength intervals which isolate the emission feature under study. The intervals to be used are determined from spectroscopic examination of the emission. The filtered photomultipliers are absolutely calibrated using the NO_2 continuum whose spectral distribution and proportionality constant K_γ have been carefully measured.

Excitation of $O(^1S)$

The most conspicuous features on nightglow spectrograms (5) are the 5577 and 6300, 6364 Å lines in the cascade from $O(^1S)$ to $O(^1D)$ to $O^3(P)$. (The third line in the ^1D–^3S transition is so weak as to be unobservable.) These have been studied much more than the other airglow features and their explanation has been sought for over half a century.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Over 30 years ago it was suggested (6) that $O(^1S)$ was excited by

[t] $$O + O + O \rightarrow O_2 + O(^1S)$$

If reaction [t] produces $O(^1S)$ then eq. [3] becomes

[11] $$k_t[O]^3 = (1 + \tau k_i[i])I(^1S)$$

and a plot of

[12] $$[O]^3/I(^1S) \text{ vs. } [O]$$

can be made. Figure 3 shows that this is a single straight line regardless of the other constituents in the system (3). The slope, $\tau k_0/k_t$ and intercept, k_t^{-1} (k_0 equal to the quenching rate coefficient of atomic oxygen) can be used to obtain τk_0 and k_t provided all other k_i are negligible. Since the data in Fig. 3 were taken at several pressures and compositions but fit the same line, this assumption appears to be true.

If other gases are added which do not change [O], then eq. [11] can be divided by a similar equation which now contains two terms in the right-hand side, $k_0[O] + k_Q[Q]$, where Q is the added gas. Rearrangement then gives

[13] $$\frac{I_0(^1S)}{I(^1S)} = 1 + \frac{\tau k_Q[Q]}{1 + \tau k_0[O]}$$

where I_0 referred to the intensity of 5577 Å emission when [Q] = 0. The slope of such a plot

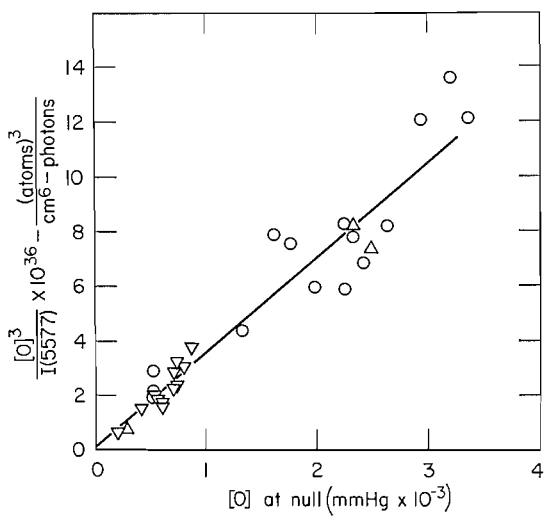

FIG. 3. The dependence of $[O]^3/I_c(5577)$ on [O]. Data are presented for N_2 (○), 1% N_2 in Ar (△), and 1% N_2 in He (▽).

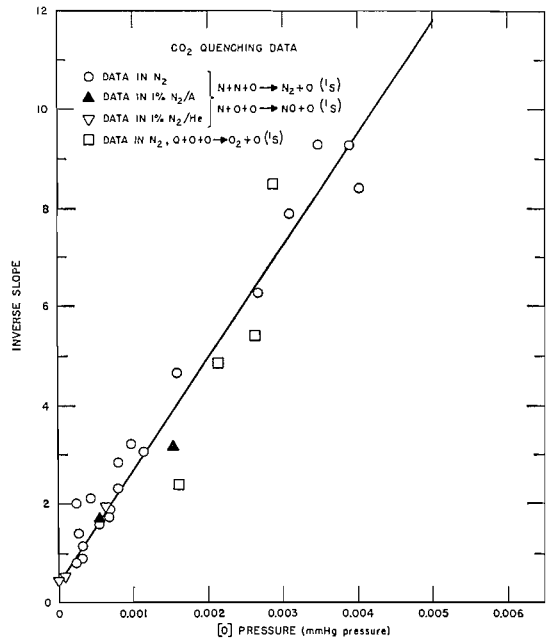

FIG. 4. CO_2 quenching data. The reciprocal of the slope of Stern–Volmer graphs vs. [O]. Data points were taken at total pressures from 0.2 to 11 mm Hg in N_2, 1% N_2 in He, and 1% N_2 in Ar. The $O(^1S)$ was produced by reactions [12], [13], and [14].

is $\tau k_Q/(1 + \tau k_0[O])$ and its inverse should be another straight line if plotted against [O], as Fig. 4 verifies. The intercept of this line is $(\tau k_Q)^{-1}$, its slope is k_0/k_Q, and the ratio is τk_0. Because the intercept in Fig. 3 is so small, it is preferable to use τk_0 obtained from Fig. 4 and the slope of Fig. 3 ($\tau k_0/k_t$) to compute k_t as 1.8×10^{-34} cm^6 molecule. Diffusion has been neglected in this analysis, but since the data of Figs. 3 and 4 are independent of pressure, this approximation is substantiated.

Using the value of τk_0 just obtained in eq. [13], less extensive measurements of I_0/I will give the k_Q/k_0 listed in Table II.

TABLE II*

Rate coefficients for the loss of $O(^1S)$

Rate coefficients	Value
$k_Q(N_2O)$	5.9×10^{-13}
$k_Q(O)$	1.8×10^{-13}
$k_Q(O_2)$	1.0×10^{-13}
$k_Q(CO_2)$	2.5×10^{-14}
$k_Q(H_2)$	3.0×10^{-15}
$k_Q(He,Ar,N_2)$	$< 10^{-17}$

*From ref. 3.

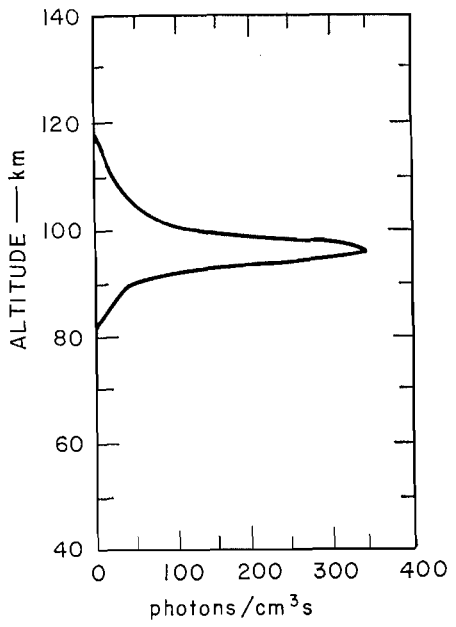

FIG. 5. The emission rate of 5577 Å per cm^3 as a function of altitude as measured by rocket instrumentation (ref. 8).

Using various models (7) of the earth's upper atmosphere, the rate of collisional deactivation of $O(^1S)$ can be computed using the rates listed in Table II — above about 90 km radiation predominates over collisional energy removal. The 5577 Å emission peaks near 100 km are shown (Fig. 5) by rocket probes (8) which penetrate the luminous layer.

From the rocket measurement of $I(^1S)$ as a function of altitude and the assumption that reaction [t] is the excitation process, [O] can be derived. The results of this reduction of rocket nightglow data are shown in Fig. 1, along with mass spectrometer measurement of [O] and theoretical extrapolation into the 100 km region. A very significant discrepancy exists since the atomic oxygen concentration derived from the nightglow observation is approximately 5 times larger than that implied by the theoretical extrapolation of rocket born mass spectrometer measurements. To bring the nightglow results into agreement with the atomic oxygen, it would require k_t to be $\approx 10^{-32}$ cm^6/s.

It has been suggested (9) that $O(^1S)$ is excited in a two step process

[u] $\quad O + O + M \rightarrow O_2^* + M$

[v] $\quad O_2^* + O(^3P) \rightarrow O_2 + O(^1S)$

[w] $\quad O_2^* + M \rightarrow O_2 + M$

[x] $\quad O_2^* \rightarrow O_2 + h\nu$

If reaction [w] dominates over reactions [v] and [x], then

$$[14] \qquad I(^1S) = \frac{k_v k_u}{k_w}[O]^3$$

This requires that $k_w[M] \gg k_v[O]$ or $[O]/[M] \ll k_w/k_v$. Since $k_u \leqslant 3 \times 10^{-33}$ cm^3/s (the measured total rate coefficient for atomic oxygen association), $k_v/k_w > 10^{-2}$ if $k_v k_u/k_w$ is as measured and $[O]/[M] < 10$. In the upper atmosphere near 100 km, $[O]/[M] \approx 10^{-2}$ (for the currently accepted atmosphere) as is also true in the laboratory experiments. Hence in the upper atmosphere eq. [14] is valid and hence the two-step process is also unable to account for the 5577 Å emission.

Only if the conditions under which laboratory experiments are carried out completely supress an excitation mechanism for $O(^1S)$ (which becomes dominant under the true conditions prevalent at 100 km), would it be possible for the presently accepted value of the oxygen concentration at 100 km in the earth's atmosphere to be compatible with the existing laboratory results. Further, if we retain the assumption that the energy eventually appearing as emission at 5577 Å is released in atomic oxygen association, then reaction [w] must so dominate reaction in the laboratory that $k_v k_u/k_w \ll 10^{-34}$ cm^3/s and hence the laboratory observation pertains only to reaction [t] while in the upper atmosphere k_w must decrease by several orders of magnitude. If $k_w = 0$ in the upper atmosphere and all O_2 formed in reaction [u] eventually excites O, $k_u > 10^{-34}$ cm^6/s to account for the observed green line intensity with a peak oxygen concentration $\approx 2 \times 10^{11}$ atoms/cm^3. Hence in the laboratory $k_v/k_w \ll 1$, perhaps 10^{-2}, if the multistep process is to be undetectable in laboratory measurements. Furthermore, this ratio must remain small even when M is Ar or He, since the laboratory results are independent of the gas composition.

The ratio of [O]/[M] in the upper atmosphere and in the laboratory is similar, so the only significant difference apparent between the laboratory environment and the environment near 100 km is the temperature. The temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

dependence of k_u can be neglected. If k_v is constant with temperature, then k_w must have an activation energy of ≈ 0.2 eV. The assumption that $O_2{}^*$ has a radiative lifetime of less than 100 s implies that $k_v > 10^{-14}$ (probably near 10^{-13}) in the upper atmosphere if $O_2{}^*$ is to excite O rather than to radiate. Then k_w at 300 °K must be approximately 10^{-11} or larger. This is a very fast process, particularly for reactants such as He and Ar.

The situation concerning the excitation of the 5577 Å $O(^1S)$ emission in the nightglow is reduced to this: (1) the atomic oxygen concentration near 100 km is about 3 to 5 times larger than current theoretical extrapolations of rocket measurements imply, or (2) errors of a factor of 3 to 5 in atomic oxygen concentration have consistently been made in the laboratory over a period of years using different apparatus, or (3) the deactivation rate coefficient for $O(^1S)$ derived from laboratory experiments is in error, or (4) a two-step process excites $O(^1S)$ in the atmosphere but is subdued in the laboratory by strongly temperature-dependent deactivation processes which have rate coefficients near 10^{-11} cm^3/s even for He and Ar as reactants.

Without new rocket measurements of atomic oxygen by a technique different from mass spectroscopy (resonance absorption is the most promising) it is unlikely that systematic errors, if they exist, will be uncovered. Measurements near 100 km are most desirable because this region is where [O] is largest and where the airglow is strongest. Such measurements would also make comparison with the 5577 Å green line relatively independent of theoretical models of the earth's atmosphere and eddy diffusion coefficients.

It is very unlikely that laboratory measurements of [O] are too low by a factor of 3 to 5 as is required to bring the nightglow-derived atomic oxygen concentration into agreement with the mass-spectrometer-derived atomic oxygen concentrations. Although it is conceivable that more than one N atom is removed per NO molecule injected into the stream, there certainly cannot be more than one oxygen atom liberated per NO molecule added. Hence it is clearly impossible for the NO titration technique to give an underestimate. A laboratory underestimate of atomic oxygen concentration would mean that other rate constants (such as those for excitation of the first positive bands and the NO (β, γ, δ bands) would also be underestimated by a factor of 9 to 25. However, independent measurements do not show this much divergence. In fact, intercomparison of rate coefficients of chemiluminescent reactions made over a period of 5 years in two very different flow systems indicates that any errors in atomic oxygen concentration measurements using the NO-null technique are independent of almost all experimental parameters such as the geometry of the flow tube, the flow speed, the pressure, the residence time, the source of NO, the dissociative discharge conditions, etc.

The deactivation rate of $O(^1S)$ by atomic oxygen was deduced by comparing the rate of its removal by collisions with $O(^3P)$ to its apparent unimolecular rate of decay by radiation. The rate coefficients for $O(^1S)$ removal by several compounds relative to that of $O(^3P)$ were deduced from eq. [13]. There is recent evidence that some of the rates listed in Table II are much too low, perhaps by as much as a factor of 27, while others are approximately correct. Quenching by atomic oxygen has not been independently measured. Since k_t was derived from a measurement of $k_t/\tau k_0$, increasing k_0 by 27 would require that k_t be increased by 27 also, so that this combination of factors remains equal to the experimental results. Such an increase in k_t would decrease the computed atomic oxygen concentration at 100 km by a factor of 3 and reasonable agreement between optical and mass spectrometric measurements would result. This same factor must also be used in computing the rate of

$$[y] \qquad N + N + O \rightarrow N_2 + O(^1S)$$

$$[z] \qquad N + O + O \rightarrow NO + O(^1S)$$

The result of such a correction is that atomic oxygen is then a more efficient third-body for atomic association than are other, less reactive, species.

If the original measurements of $O(^1S)$ deactivation rate coefficients are in error then either the apparent unimolecular decay rate of $O(^1S)$ is faster than 1/s, or the measurements of atomic oxygen are too small. The latter is unlikely.

The same transient studies of $O(^1S)$ emission which implied much larger quenching rate coefficients than those listed in Table II, also implied an apparent unimolecular decay rate greater than 1/s which is associated with radiation. There is circumstantial evidence that this rapid

For personal use only.

decay is due to collision of $O(^1S)$ with H_2O. To simulate, as previously observed the apparent independence of the rate of $O(^1S)$ removal on pressure, gas composition, flow rate, etc. H_2O must be in equilibrium with water sorbed on the walls of the experimental apparatus. If the rate coefficient for deactivation of $O(^1S)$ by H_2O is $\approx 10^{-10}$ cm^3/s then a partial pressure of 10^{-5} Torr would account for the necessary shortened lifetime of $O(^1S)$ during the measurements of k_t and k_0 discussed in this article.

The two-step mechanism is not excluded since it is not inconceivable that He, Ar, and N_2 all deactivate the precursor exciting $O(^3P)$ to $O(^1S)$ in the two-step process with rate coefficients of the order of 10^{-11} cm^3/s, although it seems unlikely. For the rare gases little energy is likely to be removed and the process must be vibration and rotation deactivation or non-radiative collision-induced transition within the precursor molecule. Helium is noted for not inducing electronic transitions, but is an efficient vibration and rotation relaxer. Since rotation relaxation involves too small an energy increment to lead to the large activation energy required to harmonize laboratory results with upper atmosphere observations, the effects of He must be due to vibrational relaxation. This, in turn, means that transfer of energy to $O(^3P)$ occurs only from vibrationally excited states of O_2* which need not be electronically excited. The final evaluation of the significance of vibrational relaxation of O_2*, formed in atomic association, for excitation of $O(^3P)$ to $O(^1S)$ is yet to be made.

In passing, it should be noted that the addition of O_2 to a mixture of O and N_2 indicated simple deactivation of $O(^1S)$ and no change in the excitation mechanism. Hence the presence of O_2 in the real atmosphere cannot account for the difference found between laboratory results and airglow observations.

Excitation of $O(^1D)$

The 6300 and 6364 Å lines from $O(^1D)$ originate mostly from above 200 km (8). This implies that $O(^1D)$ is collisionally deactivated in the 100 km region, since otherwise the 6300 and 6364 Å lines should be as intense as the 5577 Å line. Recent laboratory results (11) indeed verify that both O_2 and N_2 rapidly deactivate $O(^1D)$.

At the great altitudes from which $O(^1D)$ emission occurs, only dissociative recombination of O_2* can produce $O(^1D)$ sufficiently rapidly as has recently been verified by Zipf (10).

Excitation of the O_2 Herzberg Bands

The emission systems of O_2 observed in the O, N_2 afterglow (3) (the Herzberg and atmospheric bands) are also present in the nightglow. There is no doubt that the composite processes occurring in the laboratory cannot account for the airglow emissions. Unfortunately, these processes are not well known for two reasons: (1) the collisional deactivation processes removing the radiative states have not been separately measured, and (2) the excitation processes are complicated.

Figure 5 shows measurements of the intensity of the Herzberg bands of O_2 which occur between 3000 and 4000 Å. A straightforward interpretation of these data is

$$[aa] \qquad O + O + M \rightarrow O_2^* + M$$

$$[bb] \qquad O_2^* + M \rightarrow O_2 + M$$

$$[cc] \qquad O_2^* \rightarrow O_2 + h\nu$$

implying that

$$[15] \qquad I(\text{Herzberg}) = \frac{k_{cc}k_{aa}[O]^2[M]}{k_{cc} + k_{bb}[M]}$$

At low pressure I increases linearly with M giving $k_{aa} = 2.1 \times 10^{-37}$ cm^6/s and at high pressures where $k_{bb}[M] > k_{cc}$, I is constant giving $k_{cc}(k_{aa}/k_{bb}) = 2.3 \times 10^{-21}$ cm^3/s. It can be seen from Fig. 2 that the intensity of this emission would be insignificant. Again, in the nightglow, the conclusion is reached that if atomic association is the source of nightglow energy, there must exist yet unknown dissipative processes operating in the laboratory which do not operate in the upper atmosphere. The simplest reason for this is the difference in temperature between the laboratory and the atmosphere at 100 km. For this to be the case, excitation of $O_2(A^3\Sigma_u^+)$ must be by a multistep process which would replace reaction [*aa*]. Again, the most likely multistep process is vibrational relaxation or non-radiative collision-induced electronic transition.

Excitation of the Atmospheric O_2 Bands

The results of measurements (3) of atomic association to produce $O_2(b^1\Sigma)$ which emit the atmosphere bands are shown in Fig. 6 and again, taken at face value, they indicate that this mechanism is incapable of producing the observed nightglow emission intensities. Because

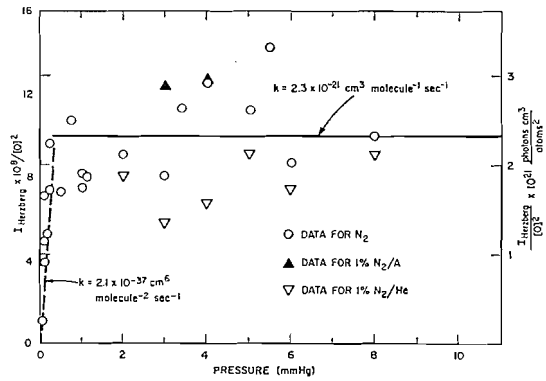

FIG. 6. The intensity of the ultraviolet Herzberg bands of O_2 divided by $[O]^2$ vs. pressure in N_2 (○), 1% N_2 in Ar (△), and 1% N_2 in He (▽).

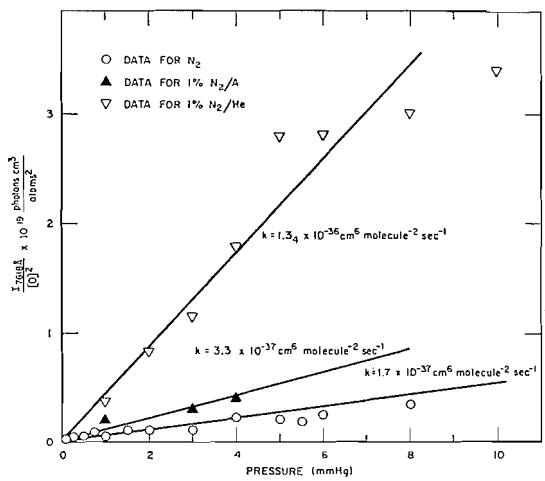

FIG. 7. The intensity of the (0,0) atmospheric band of O_2 at 7618 Å divided by $[O]^2$ vs. pressure in N_2 (○), 1% N_2 in Ar (△), and 1% N_2 in He (▽).

other measurements indicate that some precursor to the emission of both the Herzberg and atmospheric bands is deactivated by N_2, the single-step interpretation is unjustified. It is evident that the processes exciting O_2 are sufficiently complicated that present data in the 1 to 10 Torr range and at 300 °K are insufficient for extrapolating to the condition of 10^{-3} Torr and 200 °K existing in the nightglow region of our atmosphere.

Excitation of the OH Bands

The strong OH emission observed in the nightglow is presumed to arise from

[*dd*] $$H + O_3 \rightarrow OH^* + O_2$$

Such a process has been observed in the laboratory (12) but its rate coefficient has not yet been measured.

Excitation of the NO Bands

Very few nitrogen atoms are expected in the upper atmosphere where emission due to

[*ee*] $$N + O \rightarrow NO^*$$

[*ff*] $$NO^* \rightarrow NO + h\nu$$

will be weak. Reaction [u^{ee}] is a pre-association having a rate coefficient (13) of 1.5×10^{-17} cm^3/s. Emission in these bands occurs near 2000 Å and so would be observable only from above the ozone layer. To date, this emission has not been detected in rocket experiments (14) implying that $[N] < 10^7$ cm^3, using very rough approximations.

Conclusions

It is concluded on general grounds that the peak atomic oxygen concentration is considerably larger than the presently accepted value of 2×10^{11} atoms/cm^3 at 100 km. If the 5577 Å nightglow emission intensity obtained from rocket measurements is excited by reaction [*t*] (i.e., O + O + O → O_2 + $O(^1S)$) with the rate coefficient originally found from laboratory experiments, (1.5×10^{-34} cm^6/molecule s) the peak atomic oxygen concentration is approximately $10^{12}/cm^3$ near 100 km. If the implications of more recent measurements of the deactivation of $O(^1S)$ can be extended to deactivation by $O(^3P)$ then only 3×10^{11} atoms would be necessary to account for the observed nightglow emission of 5577 Å radiation. Although the excitation of molecular oxygen is probably due to three-body atomic oxygen association, this is a multistep process which, so far, has not been completely characterized in laboratory experiments. The excitation of OH has not been quantitatively studied in the laboratory but there is no evidence that reactions of H and O_3 cannot adequately account for nightglow observation.

Chemiluminescent reactions of He(2³S) atoms

MARK CHER AND C. S. HOLLINGSWORTH
Science Center, North American Rockwell Corporation, Thousand Oaks, California 91360

Received December 31, 1968

Rate coefficients for the reactions of He(2³S) atoms with N_2, O_2, CO, and CO_2 were determined by measuring the fractional absorption of 3889 Å light from a helium lamp as a function of the concentration of the neutral gas in a flowing afterglow apparatus. The rate coefficients are in reasonable agreement with those obtained previously from measurements of the emission intensity. It is concluded that the observed chemiluminescence arises from Penning ionization reactions involving the He(2³S) atom.

In previous publications (1, 2) we reported the results of the measurements of the rate coefficients for the chemiluminescent reactions of excited helium with various neutral gases. The technique used was based on the measurement of the spatial variation of the emission intensity in a flowing afterglow apparatus. The emitting species are well-known electronically excited ionic states of the added neutral gases. Although some evidence was presented which strongly suggested that the He(2³S) metastable is the dominant reactive helium species, a more direct identification of the reactant seemed desirable. In this paper we report the results of the measurements of the decay in the concentration of He(2³S) as a function of the concentration of the added gases using a light absorption technique. The purpose of the experiments was to determine rate coefficients for the disappearance of He(2³S) and to compare these with rate coefficients obtained previously from the rate of formation of excited ionized products.

Experimental

Relative concentrations of He(2³S) were obtained as a function of the concentration of the added gas by measuring the fractional absorption of incident 3889 Å light from a low pressure helium discharge lamp. The apparatus and procedure have been described previously (1, 2). Absorption at 3889 Å corresponds to the atomic helium transition $2^3S \rightarrow 3^3P$. The absorption intensity, which was always less than 1%, is consequently proportional to the concentration of He(2³S).

Theory

The two major processes for the disappearance of He(2³S) are diffusion to the walls and chemical reaction with the added neutral gas. The concentration of He(2³S) as a function of position was obtained by solving the continuity equation assuming Poiseuille flow (1) and is shown in eq. [1].

$$[1] \quad \ln [He^*] = \ln [He^*]_0 - \frac{(D_0 p_0)\pi x}{760 \sum FRT} \times \left(\frac{\lambda_0^2}{2}\right) - kx\pi \left(\frac{pr_0}{\sum FRT}\right)^2 \left(\frac{1+\varepsilon}{2}\right) F_N$$

Here [He*] represents the He(2³S) concentration, x is the axial distance from the inlet nozzle of the added gas, $D_0 p_0$ is the diffusion coefficient of He(2³S) at 1 Torr, $\sum F$ is total flow rate in moles/s, R is the gas constant, T is the temperature, p is the pressure, r_0 is the radius of the tube, F_N is the flow rate of the impurity gas, k is the rate coefficient, and λ_0, ε, and π are constants equal to 2.710, 0.237, and 3.14. Since the absorption intensity is proportional to the concentration of He(2³S), a plot of $\ln I_{abs}$ vs. F_N at constant x should produce a straight line with slope S given by

$$[2] \quad S = 1.237 \frac{k\pi x}{2} \left(\frac{pr_0}{\sum FRT}\right)^2$$

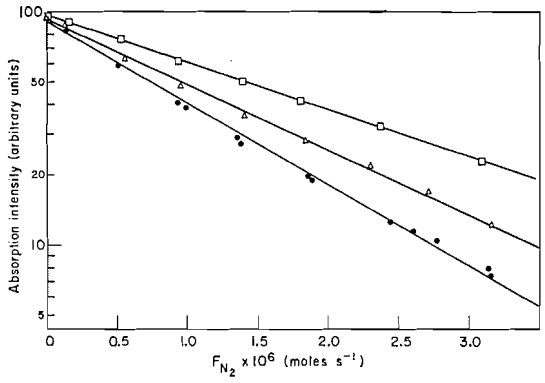

FIG. 1. Absorption at 3889 Å vs. nitrogen flow rate. Flow rate of helium in moles s^{-1}: ●, 2.98×10^{-3}; △, 4.44×10^{-3}; □, 6.51×10^{-3}.

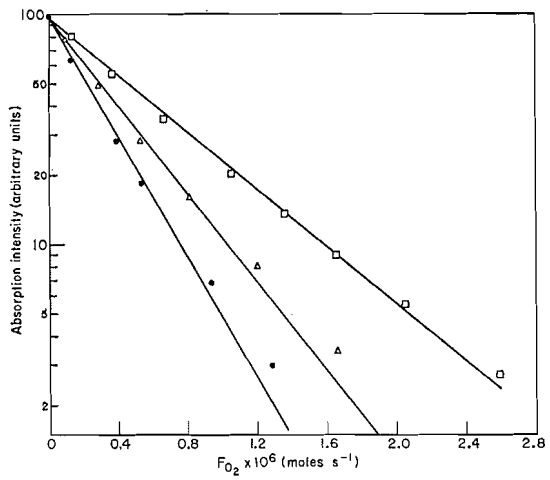

FIG. 2. Absorption at 3889 Å vs. oxygen flow rate. Flow rate of helium in moles s^{-1}: ●, 2.98×10^{-3}; △, 4.44×10^{-3}; □, 6.53×10^{-3}.

Results and Discussion

Measurements of absorption intensity were carried out at several different flow rates of helium in the presence of N_2, O_2, CO, and CO_2. Results are shown in Figs. 1–4. Rate coefficients were determined from the slopes of the graphs according to eq. [2] and are shown in Table I in the column labeled absorption. Because of the small absorption intensities and substantial signal-to-noise problems, these rate coefficients are less precise than those obtained from the emission experiments, and the probable error is estimated at about ±30%. The uncertainty is greater in the measurements with O_2 and CO_2 because of the

shorter flames caused by larger rate coefficients. The value of k is within experimental error independent of pressure or flow rate of helium, as is to be expected.

Table I also shows rate coefficients[1] calculated

[1]It may be recalled that rate coefficients were shown to vary with temperature approximately as $k \sim T$.

at 320 °K from the data based on the emission measurements. In the reactions of O_2 and CO rate coefficients were obtained by monitoring two different emission systems and they are listed separately. Although the rate coefficients from the absorption measurements appear to be consistently higher than the rate coefficients from the emission experiments, the discrepancy is within the rather large expected error, and consequently we consider the two sets of measurements to be in reasonable agreement. We conclude, therefore, that the observed chemiluminescence for all these processes is the result of the Penning ionization reaction

$$He(2^3S) + X \rightarrow He + X^{+*} + e^-$$

where X^{+*} is the upper electronic state of the emitting ion.

Comments and Summary

COMMENTS BY A. O. C. NIER[1]

Dr. Young has suggested that the atomic oxygen concentration on the lower thermosphere may be many times larger than is generally supposed. It is perhaps worth commenting on the situation insofar as direct measurements are concerned. Atomic oxygen determinations have been by optical absorption techniques and by mass spectrometry. In general, but not always, the results lie below the model atmosphere values. These are based mainly on satellite drag measurements.

Von Zahn has suggested that the mass spectrometric atomic oxygen determinations may be too low because of the reaction of atomic oxygen with mass spectrometer ion source surfaces and the formation of compounds such as CO_2 or N_2O (mass 44). While undoubtedly effects such as these exist, it is hard to believe that the atomic oxygen readings could be low by a factor of 5 or more as required by Dr. Young's suggestion. In some of the experiments, such as those of Schaefer of Michigan, the ion sources are relatively open, and in some positions of the rocket there are almost no opportunities for oxygen atoms to collide with surfaces. Yet his values agree well with those of other mass spectrometer

at 320 °K from the data based on the emission measurements. In the reactions of O_2 and CO rate coefficients were obtained by monitoring two different emission systems and they are listed separately. Although the rate coefficients from the absorption measurements appear to be consistently higher than the rate coefficients from the emission experiments, the discrepancy is within the rather large expected error, and consequently we consider the two sets of measurements to be in reasonable agreement. We conclude, therefore, that the observed chemiluminescence for all these processes is the result of the Penning ionization reaction

$$He(2^3S) + X \rightarrow He + X^{+*} + e^-$$

where X^{+*} is the upper electronic state of the emitting ion.

Comments and Summary

COMMENTS BY A. O. C. NIER[1]

Dr. Young has suggested that the atomic oxygen concentration on the lower thermosphere may be many times larger than is generally supposed. It is perhaps worth commenting on the situation insofar as direct measurements are concerned. Atomic oxygen determinations have been by optical absorption techniques and by mass spectrometry. In general, but not always, the results lie below the model atmosphere values. These are based mainly on satellite drag measurements.

Von Zahn has suggested that the mass spectrometric atomic oxygen determinations may be too low because of the reaction of atomic oxygen with mass spectrometer ion source surfaces and the formation of compounds such as CO_2 or N_2O (mass 44). While undoubtedly effects such as these exist, it is hard to believe that the atomic oxygen readings could be low by a factor of 5 or more as required by Dr. Young's suggestion. In some of the experiments, such as those of Schaefer of Michigan, the ion sources are relatively open, and in some positions of the rocket there are almost no opportunities for oxygen atoms to collide with surfaces. Yet his values agree well with those of other mass spectrometer

experiments where the surface conditions are not so favorable. Nevertheless the absolute determination of atomic oxygen remains a serious problem, and the questions raised by Dr. Young should remind us of this fact.

COMMENTS BY K. H. BECKER[2]

1. Recently we have investigated (1) the NO + O air afterglow reaction in the pressure region of 2×10^{-3} to 3×10^{-2} Torr. A pressure dependence of the NO_2* chemiluminescence intensity due to a three-body recombination has been observed in a 200 l glass sphere. The derived quenching constants are in agreement with those of previous fluorescence measurements (2). Similar work on the NO_2* chemiluminescence in a flow-tube experiment (3) agrees with our results. Very recently we found that in a pressure region of about 10^{-4} Torr in a reaction volume as large as 2×10^5 l, no pressure dependence of I_{NO_2*} could be observed. This might indicate that at these low pressures NO_2* is formed by a two-body recombination. A rough comparison of these results with those in the higher pressure region would give an upper limit of 10^{-19} cm^3 (molecule s)$^{-1}$ for the two-body process, but the chemiluminescence spectrum at low pressures has not yet been compared with that at higher pressures.

2. Recently we have found (4) that reaction C_2O + O forms electronically excited CO* in the $A^1\Pi$, $d^3\Delta$, and $e^3\Sigma^-$ states, with an excitation energy up to almost 9 eV. It is known that by the photolysis of CO in the vacuum-ultraviolet C_2O is formed. It might be interesting to analyze the emission from the Martian and Venus atmospheres in search of CO* emission which could give some information about the CO photolysis in these atmospheres.

3. Very little is known about the chemiluminescent reaction O + H. Recently Ticktin, Spindler, and Schiff (5) have studied the OH* chemiluminescence in this system. The formation of OH*($A^2\Sigma^+$) was explained by a two-body recombination, especially indicated by an enhancement at $K' = 13$ ($13Q_2$) for $v' = 0$. A rate constant of 3×10^{-21} cm^3(molecule s)$^{-1}$ for the two-body reaction was derived. Dr. Kley and I have also been working on the O + H reaction recently.

Our findings that (*a*), no perturbation at $K' = 13$ for $v' = 0$ has been seen; (*b*), the OH* emission intensity was found to be linear in (O) but not in (H); (*c*), the rotational population of OH*($A^2\Sigma^+$, $v = 0$) was observed up to $K' = 27$, probably up to $K' = 30$; and (*d*), the reaction C_2H_4 + O showed (6) the same rotational distribution for the (0,0) band as the reaction O + H, both at a total pressure of 2 Torr, led us to the conclusion that the electronically excited OH* is formed neither by a two-body nor by a three-body reaction between O(^{3}P) and H(1^2S). A complex radical mechanism seems to be involved in the formation of the OH* chemiluminescence.

COMMENTS BY H. I. SCHIFF

In connection with Dr. Becker's recent observations, it is difficult to see the connection between the OH emissions arising from the reaction of O atoms with C_2H_4 and with H atoms. Our most recent results indicate that the intensity of the (1,0) emission from the O + H reaction is first order in each of the reactants while the (0,0) intensity is first order in [O] but not in [H]. These results are consistent with the population of the $v' = 0$ level being third order but with H being a particularly effective third body.

REMARKS AND SUMMARY BY CHAIRMAN, MICHAEL B. McELROY[3]

Young's paper is concerned primarily with the mechanism for production of O(^{1}S) in the night-sky. He contends that the abundance of O must be larger than current models of the atmosphere suggest if laboratory and atmosphere are to be

[2]Address: Institut f. Physikalische Chemie, Universität Bonn, Germany.

[3]Address: Kitt Peak National Observatory, Tucson, Arizona.

compatible. Nier's comment suggests that the uncertainties in our present knowledge of the atmosphere are not large enough to bridge the gap from this direction alone. The vacillations of the laboratory chemists on the detailed laboratory mechanism for green line production inspires little confidence on the part of the aeronomer. It is this particular aeronomer's prejudiced view that further laboratory endeavors should justify Chapman's original mechanism

$$O + O + O \rightarrow O_2 + O(^1S)$$

and prove anew that not all that is recent is right and not all that is ancient is wrong.

Received November 5, 1968

The structures of eighteen polychloro-alicyclic ketones prepared by the chlorination of chlorinated phenols, ortho and meta cresols, or the corresponding toluidines were determined by nuclear magnetic resonance, infrared, and ultraviolet spectroscopy. Stereochemistry and the sequence of the formation of these polychloro-alicyclic ketones are described.

Canadian Journal of Chemistry, 47, 1943 (1969)

Introduction

The chlorination of phenols and anilines in acetic acid is an exothermic reaction yielding polychlorocyclohexenones and polychlorocyclohexadienones. Zincke and co-workers (1–3) studied the chlorination products of *p*-cresol and monochloro-*o*-toluidines. von Walther and Zipper (4) prepared polychloro-3-methyl cyclohexenones by the chlorination of *m*-cresol. Muller and Linde (5) reported the preparation of polychlorocyclohexenones from 2,5-dimethylphenol. Denivelle and Fort (6) described the preparations of alkylated polychlorohexadienones. However, the application of current spectroscopic techniques to substantiate the assigned structures of polychloro-alicyclic ketones has been limited to the infrared and ultraviolet spectra of hexachlorocyclohexadienones and octachlorocyclohexenones obtained by Denivelle and Fort (7), and the infrared spectra of tetrachloro-3,5-dimethylcyclohexadien-1-one and hexachloro-3,5-dimethylcyclohexen-1-one reported by Kumamoto and Kato (8). Our recent investigation of these compounds indicates that several of the structures assigned earlier do not satisfy the spectral data. This report discusses the structures of known as well as numerous novel polychloro-alicyclic ketones prepared from chlorinated phenols, *o*- and *m*-cresols or the corresponding toluidines. The sequences of the formation of these compounds are also proposed.

Results and Discussion

Polychloro-acyclic Ketones from Chlorinated Phenols

The work of Denivelle and Fort on cyclohexadienones and cyclohexenones derived from pentachlorophenol has been invaluable as a reference for the structural determination in the present study. The significant infrared (i.r.) and ultraviolet (u.v.) absorptions of these compounds are given in Table I. We have observed that the same u.v. absorption maxima are obtained from these compounds using methanol solutions.

Table I illustrates the dependence of the i.r. absorption band of the carbonyl group on the number of chlorine atoms attached to the adjacent carbons. The effect of the types of conjugation is also evident and only 2,4-cyclohexadien-1-one type conjugation gives two olefinic absorption bands.

To obtain further spectral references for

structural determinations by nuclear magnetic resonance (n.m.r.), hexachlorocyclohexenone (**1**) and heptachlorocyclohexenone (**2**) were prepared from 2,4,6-trichlorophenol and 2,3,4,6-tetrachlorophenol (9), respectively (Tables II and III). The u.v. and i.r. spectra indicate that the double bond present in both ketones is not conjugated to the carbonyl group, namely **1** and **2** are 3-cyclohexenones. Since the n.m.r. spectrum of **1** indicates two non-equivalent protons, the protons originally present at the meta positions are not substituted by the chlorination. Thus, the only structure for **1** that satisfies these conditions is 2,2,4,5,6,6-hexachloro-3-cyclohexen-1-one. The lower field chemical shift of δ 6.51 p.p.m. would then be the olefinic proton and δ 4.99 p.p.m. the other methine proton. The lower i.r. absorption frequency of C=C in **2** compared to **1** suggests that the proton in **2** is not attached to the double bond and the chemical shift of δ 5.18 p.p.m. favors the presence of a non-olefinic proton. Ketone **2** is, therefore, 2,2,3,4,5,6,6-heptachloro-3-cyclohexen-1-one.

Polychloro-3-methylcyclohexenones and Cyclohexadienones

either *m*-cresol, *m*-toluidine, or 2,4,6-trichloro-*m*-cresol is chlorinated in acetic acid. Previously, the structure of 2,4,4,5,6-pentachloro-3-chloromethyl-2,5-cyclohexadien-1-one (4) was assigned to **3**, which was also reported as 2,4,4,5,6,6-hexachloro-3-methyl-2-cyclohexen-1-one (5). However, the i.r. and u.v. spectra of **3** (Table III) are characteristic of a 3-cyclohexenone. Its n.m.r. spectrum indicates the presence of a methyl group (δ CH_3 = 2.30 p.p.m.), a single methine proton (δ CH = 5.06 p.p.m.) but no methylene group. Since the methine proton is originally meta to the methyl group, the small coupling between the methine and methyl protons (J_{H-CH_3} = 0.5 Hz) favors the structure with the methyl group attached to the double bond, which would give the HC—C=C—CH type coupling (10). Moreover, the chemical shift of the methine proton is in the region of the non-olefinic protons of **1** and **2**. The structure 2,2,4,5,6,6-hexachloro-3-methyl-3-cyclohexen-1-one satisfies all these spectral features of **3**.

The spectral data of the ketone (**4**), obtained from the filtrate of the chlorination product of 2,4,6-trichloro-*m*-cresol, indicate it is 2,4,4,6-tetrachloro-3-methyl-2,5-cyclohexadien-1-one as reported previously (6).

Chlorination of tetrachloro-*m*-cresol in acetic acid gives a heptachloro-3-methylcyclohexenone (**5**) and a pentachloro-3-methylcyclohexadienone (**6**). It is evident from the u.v. and i.r. spectra, which are very similar to those of octachloro-3-cyclohexen-1-one in Table I, that **5** is a 3-cyclohexenone. The methyl group is not attached to the double bond, since (*a*) the i.r. absorption frequency for C=C is lower than that of **3** and close to octachloro-3-cyclohexen-1-one, and (*b*) the chemical shift of the methyl protons is up-field relative to that in **3**, which would not be expected if the methine proton of **3** is replaced by a chlorine. The most probable structure of **5** is, therefore, heptachloro-5-methyl-3-cyclohexen-1-one. The spectral data of **6** are in agreement with the structure of 2,4,4,5,6-pentachloro-3-methyl-2,5-cyclohexadien-1-one reported previously (4).

The chlorination of 2,4,6-trichloro-*m*-cresol in carbon tetrachloride in the presence of an equimolar amount of pyridine yielded a mixture (ketone **7**) containing two major components. Both major components contain one methyl group and one olefinic proton. Elemental analysis indicates both are tetrachlorocyclohexadienones. Ultraviolet and i.r. absorption

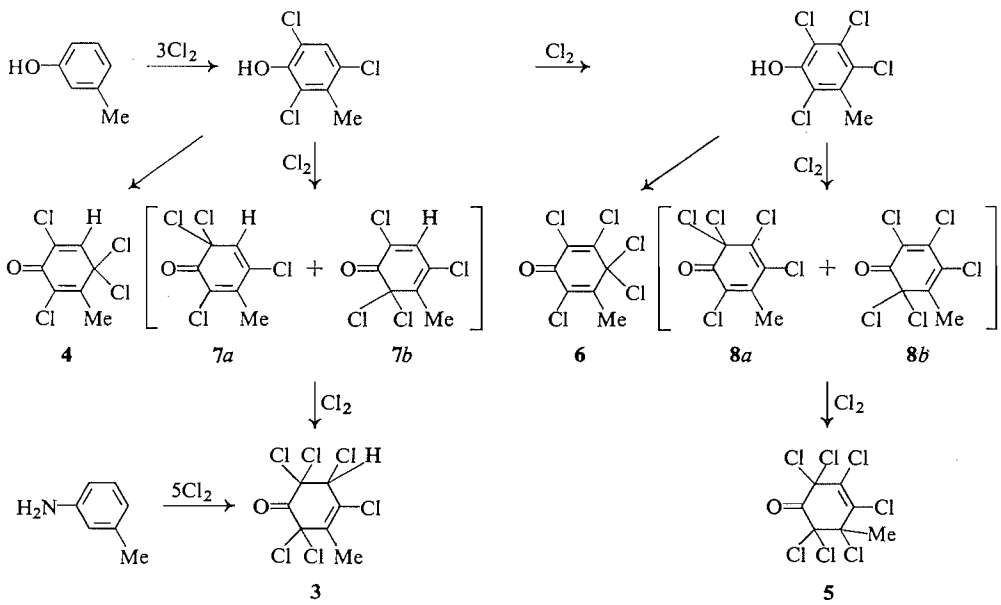
For personal use only.



SCHEME I. Chlorination of *m*-cresols and *m*-toluidine.

peaks observed for the mixture are characteristic of 2,4-cyclohexadienones and show that neither contains the 2,5-dienone structure. The major components must therefore be the two isomeric 2,4-dienones. The chemical shift of the olefinic proton in the n.m.r. spectrum, by comparison to **17**, suggests one component, δ C=CH = 6.79 and δ CH_3 = 2.41 p.p.m. is probably 2,4,6,6-tetrachloro-3-methyl-2,4-cyclohexadien-1-one (*7a*). The other component, δ C=CH = 7.25 and δ CH_3 = 2.33 p.p.m. is then 2,4,6,6-tetrachloro-5-methyl-2,4-cyclohexadiene-1-one (*7b*). The chemical shift of the olefinic proton of the latter component is consistent with that observed for **18**. These compounds are unstable and further chlorination of **7** in acetic acid gives **3** as the major product. The ketone (**8**) obtained from tetrachloro-*m*-cresol by similar chlorination was also a mixture of two isomers in about equal proportions. The structure of these isomers are pentachloro-3-methyl-2,4-cyclohexadien-1-one (*8a*) (δ CH_3 = 2.52 p.p.m.) and pentachloro-5-methyl-2,4-cyclohexadien-1-one (*8b*) (δ CH_3 = 2.45 p.p.m.). It was shown by i.r. data that **8** is formed during the early stage of the chlorination of tetrachloro-*m*-cresol in glacial acetic acid.

Ketones **3**, **4**, **5**, and **6** were identified, by vapor-phase chromatography (v.p.c.) and i.r. spectra in the liquid fraction obtained by chlorination of *m*-cresol in acetic acid. It appears that exhaustive chlorination of *m*-cresol in acetic acid proceeds as shown in Scheme I.

Polychloro-2-methylcyclohexenones and Cyclohexadienones

Four distinct isomers, each with a methyl group and a methine proton with no observable coupling, were identified in the hexachlorocyclohexenones **A**, **B**, and **C** derived from 3-chloro-6-methylaniline, 3-chloro-2-methylaniline, and *o*-cresol, respectively. **A** is a mixture of ketones **9** and **10**; **B** a mixture of **11** and **12**; and **C** a mixture of **9** and **11**. The major component **9** of **C** was isolated by heating **C** with sodium acetate in ethyl alcohol, which decomposed **11**. Ketone **10**, the major component of **A**, was isolated by repeated fractional recrystallization from petroleum ether as the less soluble fraction. Ketones **11** and **12** were separated and isolated by repeated recrystallization of **B** from petroleum ether in which the major component **11** is less soluble. The physical data obtained for these isomers are given in Table IV.

The u.v. and i.r. spectra suggest that the isomers are all 3-cyclohexenones. Based on the n.m.r. spectra and on the position of the chlorine atom in the starting materials used for the preparation

*Anal. Calcd. for $C_7H_4Cl_6O$: C, 26.53; H, 1.27; Cl, 67.14.

of ketones **A** and **B**, **9** and **10** are 2,2,3,4,5,6-hexachloro-6-methyl-3-cyclohexen-1-ones, while **11** and **12** are 2,3,4,5,6,6-hexachloro-2-methyl-3-cyclohexen-1-ones. The identities of these structures are substantiated by the fact that the reduction of **A** and **B** by zinc in methyl alcohol gives 4,5,6-trichloro-*o*-cresol and 3,4,6-trichloro-*o*-cresol, respectively, besides tetrachloro-*o*-cresol. The similarity of the i.r. spectra shown in Fig. 1 suggests that **9** and **10** are stereoisomers as are **11** and **12**.

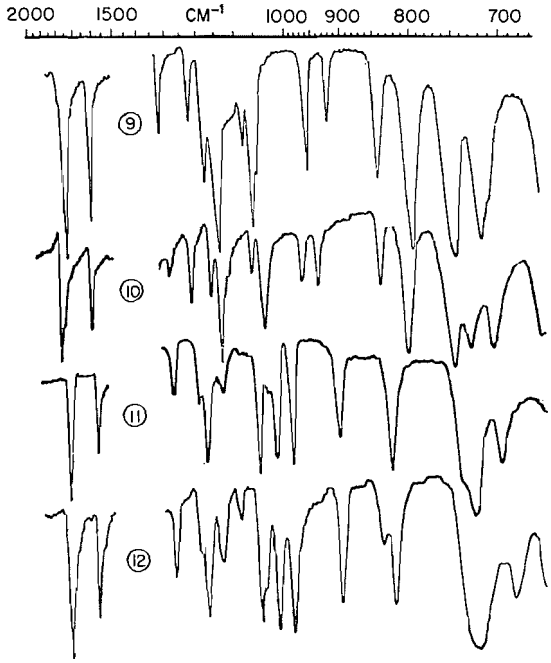

FIG. 1. Infrared spectra of hexachloro-3-cyclohexenones derived from *o*-cresol and *o*-toluidines. These spectra were obtained as Nujol mulls by P and E Model 137B Infracord.

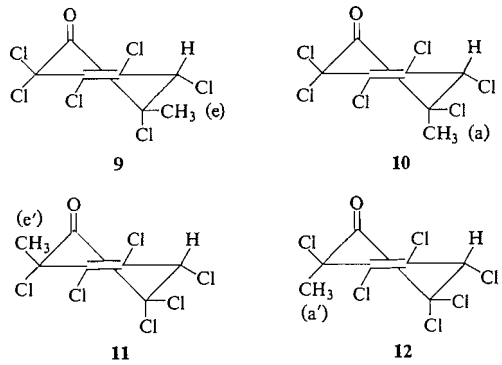
The differences in the chemical shifts of the methyl protons of **9** and **10** (or **11** and **12**) may reflect the differences in the steric configuration of the methyl groups. The chemical shifts of the methine protons of these components are by contrast about equal, suggesting similar steric configurations. It has been shown that for cyclohexanones halogenated on the carbon adjacent to the carbonyl, a chlorine in an equatorial position shifts the i.r. absorption of the carbonyl to a higher frequency than a chlorine in an axial position (11). Also the u.v. absorption maximum of cyclohexanone is shifted to a longer wavelength when substituted by an axial chlorine and to a lower wavelength by an equatorial chlorine (12). Hence, the higher i.r. absorption frequency of the carbonyl in **10** than in **9** signifies that the chlorine in the 6-position is equatorial (e) and the methyl group axial (a) in **10**. Conversely, the methyl group in **9** would be equatorial (e). By analogous interpretation, the methyl group is quasiaxial (a′) in **12** and quasiequatorial (e′) in **11**, since the i.r. absorption frequency of the carbonyl is higher in **12** than **11**. The difference in the u.v. absorption maxima of these ketones is



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

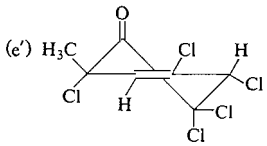
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in agreement with the assigned configurations. The H-5 of the 3-cyclohexenones are probably quasiaxial, since the chemical shifts are up-field relative to H-4 (a′) (δ 5.29 p.p.m.) of 2-methyl naphthalene tetrachloride and the chemical shifts of quasiequatorial H-4 of other naphthalene tetrachlorides are further downfield (13).

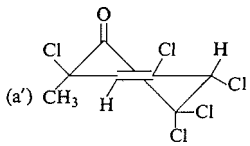
Ketone **13** was previously considered to be either pentachloro-2-methyl-2,4-cyclohexadien-1-one or pentachloro-2-methyl-2,5-cyclohexadien-1-one (2). Its u.v. and i.r. spectra indicate that it is a 2,4-dienone. However, the single high field chemical shift of 2.00 p.p.m. observed for the methyl group means the methyl group is not attached to the conjugated double bond. Hence, **13** is 2,3,4,5,6-pentachloro-6-methyl-2,4-cyclohexadien-1-one.

A heptachloro-2-methylcyclohexenone (**14**) is obtained by further chlorination of **13** in concentrated hydrochloric acid/glacial acetic acid mixture. Compound **14** is also formed, together with **13**, as the major products by direct chlorination of tetrachloro-*o*-cresol in acetic acid. The u.v. and i.r. spectra indicate **14** is also a 3-cyclohexenone. The high i.r. absorption frequency of the carbonyl suggests that there are at least three chlorine atoms on the carbons adjacent to the carbonyl and that the methyl group is in the axial position as in **10** or **12**. Only **12** can give a down-field chemical shift of 2.11 p.p.m. for the methyl protons by a chlorine substitution of the methine proton. The most probable structure of **14**, therefore, appears to be 2,3,4,5,5,6,6-heptachloro-2-methyl-3-cyclohexen-1-one with the methyl group in the quasiaxial position. Similarity of the i.r. absorption bands of **12** and **14** between 850 and 1400 cm^{-1} supports this assigned structure.

Another ketone (**15**) was isolated from the liquid fraction of chlorinated *o*-cresol by v.p.c. This ketone, identified by i.r. spectra, eluted before the hexachloro-2-methylcyclohexenones. It was subsequently identified as the major component of the orange liquid obtained by chlorination of 4,6-dichloro-*o*-cresol or 2-chloro-6-methylaniline in concentrated hydrochloric acid/glacial acetic acid mixture. The chlorine contents of these liquids are close to those of a pentachloro-2-methylcyclohexenone. The common strong i.r. absorption bands at 1760 (C=O) and 1650 cm^{-1} (C=C) and u.v. absorption maximum at 220 mμ shown by these products indicate that **15** is a 3-cyclohexenone. It was found by n.m.r. data that they contain two principal components in common with mixtures of minor components. Each principal component has a methyl group and two non-equivalent methine protons. The two methine protons are coupled (J_{H-H} = 1.50 Hz) and neither is coupled to the methyl protons. The chemical shifts of the major component (**15***a*) are δ CH_3 = 2.07, δ CH = 4.98, δ C=CH = 6.23 p.p.m. and of the minor component (**15***b*) δ CH_3 = 1.89, δ CH = 4.97, δ C=CH = 6.24 p.p.m. Since one of the starting materials 4,6-dichloro-*o*-cresol has protons at only the 3- and 5-positions, it would be expected that the structure of **15** would be similar to **1** except for the presence of a methyl group. Comparison of the methine protons of **1** and **15***a* or **15***b* indicates that the chemical shifts of the non-olefinic protons are essentially equal and that of the olefinic proton of **15***a* or **15***b* is up-field relative to that of **1**. This signifies that the methyl group in both components is on the carbon adjacent to the double bond and that **15***a* and **15***b* are stereoisomers of 2,4,5,6,6-pentachloro-2-methyl-3-cyclohexen-1-one. This structure is supported by the possibility of **11** or **12**, but not **9** or **10**, to give **15** with a methine proton chemical shift of δ CH = 4.97 p.p.m., when the chlorine at the double bond is substituted by a proton. By analogy to **11** and **12**, δ CH_3 = 2.07 p.p.m. of **15***a* being down-field relative to δ CH_3 = 1.89 p.p.m. of **15***b*, the methyl group would be quasiequatorial in **15***a* and quasiaxial in **15***b*. The similar chemical shift differences of the methyl groups of **15***a* and **15***b* and of **11** and **12** support the proposed steric configuration.

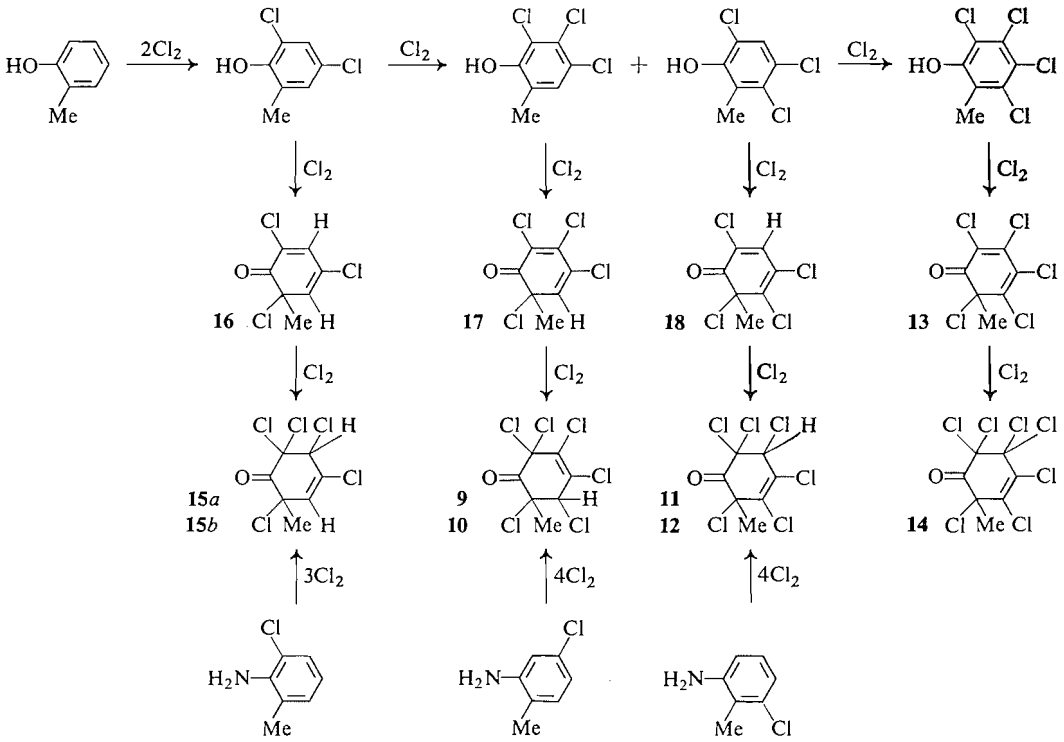


15*a*



15*b*

Infrared and u.v. spectra indicate that chlorination of 4,6-dichloro-, 4,5,6-trichloro-, or 3,4,6-trichloro-*o*-cresol in carbon tetrachloride in the presence of pyridine gives yellow liquids with 2,4-hexadien-1-ones as the major component. The product from 4,6-dichloro-*o*-cresol contains a single 2,4-hexadienone (**16**) and mixtures of minor components. The two non-equivalent protons present in **16** are coupled



SCHEME II. Chlorination of *o*-cresol and *o*-toluidines.

(J_{H-H} = 2.3 Hz) but neither is coupled to the methyl protons. The high-field chemical shift and the lack of coupling of the methyl group indicate that **16** is 2,4,6-trichloro-6-methyl-2,4-cyclohexadien-1-one.

Ketone **D** obtained from a mixture of 4,5,6-trichloro- and tetrachloro-*o*-cresol consists of two principal components. The major component (**17**) (ca. 75%) contains a methyl group and an olefinic proton with no detectable coupling. For the same reason as for **16**, the structure of **17** is 2,3,4,6-tetrachloro-6-methyl-2,4-cyclohexadien-1-one. The other principal component (ca. 25%) is **13**. Ketone **E**, obtained from 3,4,6-trichloro-*o*-cresol, contains one principal component (ca. 85%) and a mixture of minor components. The principal component is probably 2,4,5,6-tetrachloro-6-methyl-2,4-hexadien-1-one (**18**) because of the high-field chemical shift of the methyl group.

The absence of 2-methyl-2,5- and 2-methyl-2,4-cyclohexadien-1-ones may be attributed to the greater ease of chlorination of a methylated carbon than a chlorinated carbon. The n.m.r. spectra indicated several minor compounds in the liquid fractions, but the compounds have not been isolated. In Scheme II is given the probable sequence leading to the major products by the chlorination of *o*-cresols and *o*-toluidines in acetic acid. The relative amounts of these products formed depend on the conditions during chlorination.

Experimental

Analyses

The ultraviolet (u.v.) spectra were obtained as MeOH solutions with a Cary model-11 spectrophotometer. The i.r. spectra of all solid compounds were obtained as Nujol mulls, and those of liquids as films between two NaCl plates using a Perkin–Elmer model-21 spectrophotometer unless specified otherwise. Nuclear magnetic resonance (n.m.r.) spectra were obtained from chloroform-*d* solutions using a Varian Associates A-60 spectrometer. Chemical shifts are reported in p.p.m. with respect to TMS ≡ 0.

Chlorine was determined using an Ag/AgCl half cell, by potentiometric titration of the chloride ion, formed by oxidation of the compounds with sodium peroxide in Parr Bomb.

Preparation of Cyclohexenones and 2,5-Cyclohexenones

The cyclohexenones and the 2,5-cyclohexadienones

were prepared by the chlorination of the appropriate phenols or toluidines in 95% AcOH or in a mixture of glacial AcOH and concentrated HCl (2, 3, 6). Initially, chlorine was passed very rapidly and the temperature was allowed to rise freely but not above 70°. Chlorination was generally continued at a range of 50–60°. The rate of chlorine feed was reduced and slight heating was required as the rate of chlorine uptake decreased. After an excessive amount of chlorine was used, the reaction mixture was allowed to cool to room temperature and solids formed were separated by filtration. The acetic acid solution obtained was concentrated in a rotary evaporator under reduced pressure and poured into a large volume of water. The non-aqueous layer was then dissolved in ethyl ether. The ethereal solution was washed with water, dried (Na_2SO_4), filtered, and the solvent removed *in vacuo*. Liquid products thus obtained were further bubbled with N_2 to remove residual solvents. Solid products were purified by recrystallization. These chlorination products and their analyses are given in Tables II, III, and IV. All 3-cyclohexenones are colorless and 2,5-cyclohexenones are yellowish crystals.

Preparation of 2,4-Cyclohexadienones

Method I (6)

To a stirred solution of cresols in CCl_4 a slight excess of chlorine was passed rapidly and an equimolar amount of pyridine as CCl_4 solution was added, while the temperature was maintained below 45° with cooling. After continued stirring for 45 min the reaction mixture was poured into a large volume of water. The CCl_4 layer was treated similarly to the aforementioned ethereal solution, to obtain the final products.

Method II

A very slight excess of chlorine was passed into a stirred solution of equimolar amounts of cresols and pyridine in CCl_4 with cooling at 20–25°. The subsequent treatment of the CCl_4 solution was the same as above. The data on the 2,4-cyclohexadienones obtained are given in Tables II and III.

Method III

Ketone **13**, m.p. 60–61°, was also prepared by heating ketone **B** in ethanol in the presence of sodium acetate (2). The i.r. spectra of ketone **13** prepared by Method II and III were superimposable.

Reduction of Ketones A and B

To a stirred slurry of **A** (40 g) in MeOH (200 ml) was added zinc powder (28 g) in small portions with stirring and slight heating initially. Vigorous exothermic reaction occurred after a slow start. After refluxing for 4 h, the solution was allowed to cool to room temperature and filtered. The filtrate was poured into 1 l of water slightly acidified with HCl. The solids formed were collected by filtration, washed with water, and air-dried at room temperature; crude yield: 29.1 g. The reduction product, recrystallized from petroleum ether and used to prepare ketone **D**, was a mixture of 3,4,6-trichloro-*o*-cresol [n.m.r.: δ 2.23 (s, CH_3) and 7.18 p.p.m. (s, C=CH)] (ca. 75%) and tetrachloro-*o*-cresol (ca. 25%).

By analogous procedure reduction products (25.6 g) were obtained from **B** (40 g). A mixture of 4,5,6-trichloro-*o*-cresol [n.m.r.: δ 2.33 (s, CH_3) and 7.30 p.p.m. (s, C=CH)] (ca. 95%) and tetrachloro-*o*-cresol (ca. 5%) was used to prepare ketone **E**.

Acknowledgments

We wish to express our thanks to Dr. R. H. Campbell and Mr. C. K. Harmon for the u.v. spectra determinations and to Mr. D. B. Graves for his assistance in the preparation of the compounds.

Some benzophenanthridine alkaloids from *Bocconia arborea*

D. B. MacLean, D. E. F. Gracey, and J. K. Saunders
Department of Chemistry, McMaster University, Hamilton, Ontario

AND

R. Rodrigo and R. H. F. Manske
Department of Chemistry, University of Waterloo, Waterloo, Ontario

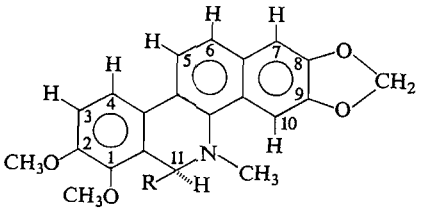
Received December 10, 1968

The minor alkaloids of *B. arborea* have been identified. Three of them have been shown to be dihydrosanguinarine, oxysanguinarine, and 11-*O*-methyldihydrochelerythrine respectively. The structure of the fourth has been established by physical methods and by synthesis as the hitherto unknown 1,3-bis(11-hydrochelerythrinyl)acetone. It does not appear to be an artefact. The high resolution mass spectra of some dihydrochelerythrine derivatives are discussed.

Canadian Journal of Chemistry, 47, 1951 (1969)

One of us had previously reported (1) the isolation of seven alkaloids from this source. We wish now to present evidence for the structures of the four alkaloids then unassigned and designated **A**, **B**, **C**, and **P61** respectively.

Alkaloid **A** (m.p. 304°) and dihydrochelerythrine, **2**, had ultraviolet (u.v.) spectra (in 1,4-dioxan) virtually superimposable on each other and infrared (i.r.) spectra (in $CHCl_3$) that were extremely similar but for the presence of carbonyl stretching absorption in the former at 1710 cm^{-1}. When the mass spectrum of alkaloid **A** was first recorded, the peak of highest mass was found at *m/e* 405 and corresponded in composition to $C_{24}H_{23}NO_5$ (calcd.: 405.1576; observed: 405.1583). The spectrum was similar to that reported (2) for 11-acetonyldihydrochelerythrine, **1** (m.p. 194°) with the base peak appearing at *m/e* 348 corresponding in composition to $C_{21}H_{18}NO_4$ (calcd.: 348.1236; observed: 348.1265). Unfortunately, a good quality proton magnetic resonance (p.m.r.) spectrum of **A** could not be obtained because of its very poor solubility in the common solvents.



1 R = CH_2COCH_3
2 R = H
3 R = OCH_3
4 R = CH_2COCH_2—(2—H)

TABLE I

Nuclear magnetic resonance signals of dihydrochelerythrine and its derivatives

	1	2	3
2-CH_3O	3.89	3.89	3.92
1-CH_3O	3.93	3.93	3.96
O—CH_2—O	6.00	6.04	6.04
>N—CH_3	2.65	2.62	2.77
H_3	6.94	6.94	7.05
H_4	7.52	7.52	7.65
H_5	7.70	7.71	7.80
H_6	7.47	7.49	7.49
H_7	7.09	7.11	7.14
H_{10}	7.50	7.69	7.72
H_{11}	5.03	4.30	5.55
11-OCH_3	—	—	3.46

However, the close similarity of **A** to 11-acetonyldihydrochelerythrine led us to prepare the latter and carefully examine its spectroscopic properties.

The results of our p.m.r. examination are qualitatively similar to those reported by Desai *et al.* (2) but we have been able, with the use of a 100 MHz instrument and with the application of the nuclear Overhauser effect (n.O.e.) (3), to assign all the signals in the spectrum.

The 100 MHz spectrum (Table I, compound **1**) shows singlets of three protons each at δ 2.04 (CH_3—C(=O)—), δ 2.65 (>N—CH_3), δ 3.89 and 3.93 (2×—OCH_3), a two proton singlet at δ 6.00 assigned to the methylenedioxy group, and an ABX system associated with the proton at C_{11}

For personal use only.

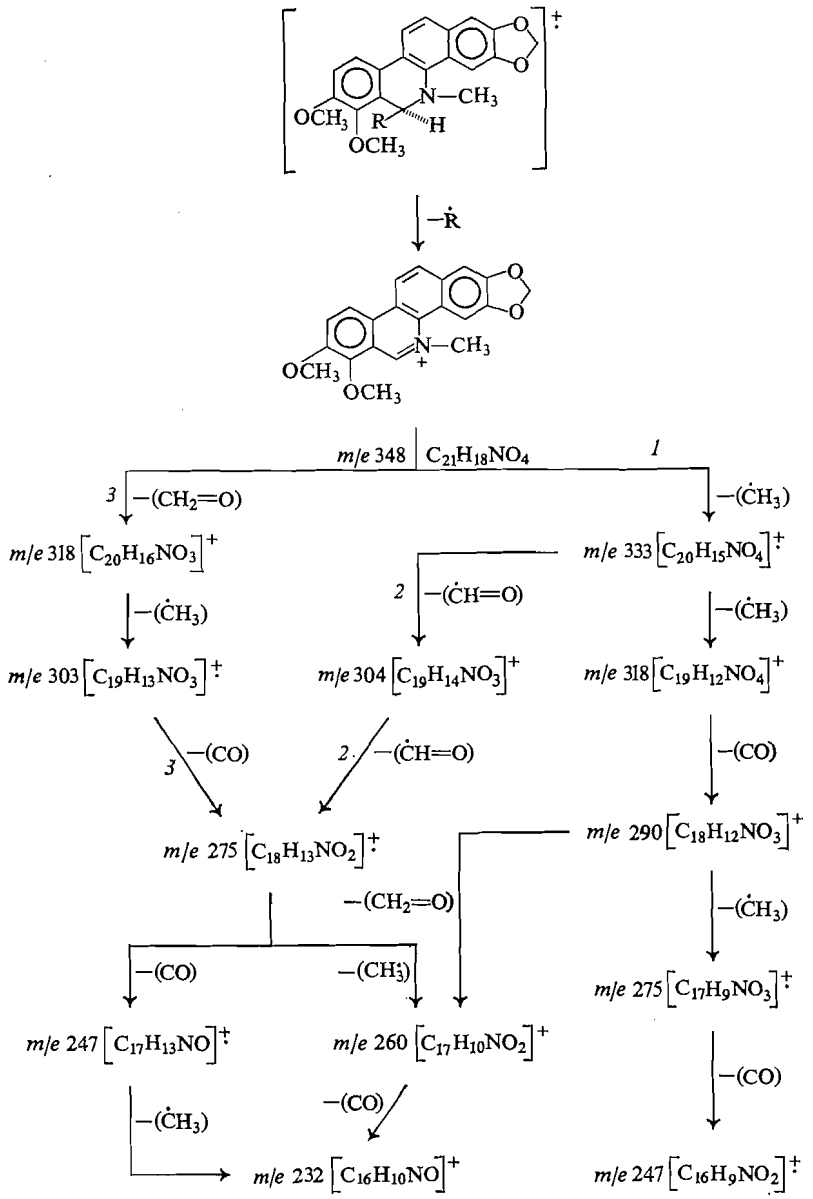
and the two protons at C_{12}. The signals associated with the ABX system are centered at δ 2.23, 2.57, and 5.03, respectively, with coupling constants, $J_{AX} = 4.0$, $J_{BX} = 9.0$, and $J_{AB} = 15.0$ Hz. The aromatic region integrates for six protons comprising two singlets at δ 7.09 (H_7) and 7.50 (H_{10}) and two AB quartets (δ H_3, 6.94; δ H_4, 7.52; $J_{H_3H_4} = 8.3$ Hz and δ H_5, 7.70; δ H_6, 7.47; $J_{H_5H_6} = 8.6$ Hz). The assignment of the signal at δ 7.50 to H_{10} is based on the existence of an n.O.e. between the $\overset{\diagdown}{\underset{\diagup}{N}}—CH_3$ and the signal centered at δ 7.50. Thus, when the sample was irradiated at δ 2.65 (the signal attributed to the $\overset{\diagdown}{\underset{\diagup}{N}}—CH_3$ group) an increase in area of 30% was observed for the signal at δ 7.50. It follows that the signal at δ 7.50 must be assigned to H_{10} while that at δ 7.09 is associated with H_7. Irradiation at δ 2.65 did not affect any other aromatic proton but caused an increase in area of the multiplet centered at δ 5.03 (assigned to H_{11}) by 23%. Similarly an n.O.e. of 24% was observed at the signal δ 6.94 when the methoxyl signals were irradiated. The signal at δ 6.94 must, therefore, be assigned to H_3 from which it follows that the signal at δ 7.52 must be attributed to H_4 since the two are coupled. The remaining AB quartet is assigned to the protons at H_5 and H_6. The lower field proton (δ 7.47) is assigned to H_6 on the basis of n.O.e. measurements. Irradiation at δ 7.09, the signal corresponding to H_7, caused an increase in area of 27% for the signal at δ 7.47. Thus the signal at δ 7.47 must be assigned to H_6 while that at δ 7.70 must be assigned to H_5. These assignments are in agreement with, and confirm, those of Slavik *et al.* (4) who examined other benzophenanthridine alkaloids.

Upon comparison of the spectrum of **1** with the poor quality spectra of alkaloid **A** obtained in DMSO-d_6 and pyridine-d_5, it was apparent that **A** was the bis adduct of chelerythrine and acetone, viz. 1,3-bis(11-hydrochelerythrinyl)-acetone, **4**.

The two compounds had the same ratios of methoxyl to $\overset{\diagdown}{\underset{\diagup}{N}}—CH_3$, to methylenedioxy and to aromatic protons. Moreover, compound **A** also had an ABX system, although not as well resolved as that in the acetone adduct. Compound **A**, however, lacked the singlet (three protons) at δ 2.04 found in the former.

Re-examination of the mass spectrum of **A** revealed an ion of low intensity at *m/e* 752 which had been missed earlier. Accurate mass measurement indicated that this ion had the composition $C_{45}H_{40}N_2O_9$ (calcd.: 752.2734; observed: 752.2759). This is compatible with **4**. Evidently, upon electron impact, hydrogen transfer accompanies the fragmentation process yielding a neutral species of mass 347 and an ion of *m/e* 405. The latter ion fragments as expected with loss of 57 mass units yielded the most intense ion of the spectrum at *m/e* 348. (The mass spectra of compounds **1** and **4** are shown in Fig. 1.) The loss of a substituent at C_{11} is characteristic of benzophenanthridine systems substituted at C_{11} as reported by Slavik *et al.* in their study (4) of the mass spectra of benzophenanthridine alkaloids including various 11-substituted dihydrochelerythrine derivatives. In the case of the latter compounds it was noted that the loss of the R group (Scheme 1) is characteristic of all these compounds and the ion $[M—R]^+$ which they designate '*a*' then undergoes a series of fragmentations via *a*-15, *a*-30, *a*-58, *a*-58-15, *a*-58-30, and *a*-(2 × 58). Slavik *et al.* have not, however, determined the composition of these ions but have drawn some conclusions with respect to their formation. Desai *et al.* (2) have reported that the mass spectrum of 11-acetonyldihydrochelerythrine, **1**, shows a molecular ion peak and an intense peak at *m/e* 348 but they have not commented further on the spectrum. The four compounds (**1**–**4**) which we have examined all show a peak at *m/e* 348 and the other fragment peaks described by Slavik *et al.*

The mass spectra of compounds **1** and **4** are shown in Fig. 1 and a general scheme for the fragmentation of 11-substituted dihydrochelerythrine derivatives in Scheme 1. The compositions given were deduced from the masses measured on a high resolution instrument. In all cases the measured masses agreed with the calculated values within ±3 milli mass units. All measurements were made on compound **1**. There appear to be three independent pathways by which the ion *m/e* 348 fragments further. Pathways *2* and *3* converge at *m/e* 303 or *m/e* 275. Pathway *1* also yields an ion of *m/e* 275 but of different composition. Pathway *1* appears to be dominant



Scheme 1

since the doublets at *m/e* 318, 275, and 247 are enriched in the ions from pathway *1* by factors of 8, 6, and 2 respectively.

None of the pathways demand that CH_3 be lost consecutively from the two methoxyl groups as implied by Slavik *et al.* Instead, a loss of methoxyl methyl may be followed by loss of an N—CH_3 group and this in turn by loss of CO. It is impossible, without labelling studies, to decide the order of sequence of loss of OCH_3 vs. N—CH_3, or to decide whether the loss of CH_2=O and CH=O species arises from the methoxyl or methylenedioxy group. The same pattern of fragmentations is found in the spectra of compounds **2**–**4** and since all spectra contain the common ion of *m/e* 348 one can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

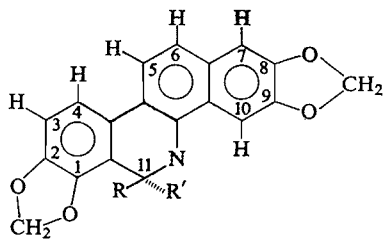
assume that the composition of the fragment ions is the same in the spectra of all four compounds.

The structure of alkaloid **A**, inferred from the spectral data was confirmed by its synthesis by the base-catalyzed condensation of chelerythrine and acetone dicarboxylic acid. It is noteworthy that attempts to synthesize **A** by mild base-catalyzed condensation of chelerythrine with 11-acetonyldihydrochelerythrine were unsuccessful. It is therefore probable that **A** is indeed a naturally occurring alkaloid and not an artefact produced in the isolation process.

Alkaloid **P61** which had been earlier believed (5) to be a pure sample of chelerythrine by reason of its conversion to the pseudocyanide of the latter, is now recognized as 11-*O*-methyldihydrochelerythrine, **3**, on the basis of its p.m.r. spectrum in which every signal could be assigned by analogy with the spectrum of 11-acetonyldihydrochelerythrine (Table I). Furthermore, the mass spectrum of **P61** was in complete accord with the proposed structure and fitted perfectly into the general Scheme 1. **P61** is quite probably an artefact produced in the isolation of the alkaloids from the plant material and it is noteworthy that a similar artefact, the 11-*O*-ethyl derivative, has been isolated (6) from *F. xanthoxyloides.*



5 R = R′ = H
6 R + R′ = O

Alkaloid **B** (m.p. 191°) was recognized as dihydrosanguinarine, **5**, from its 100 MHz p.m.r. spectrum which had singlets at δ 2.58, 4.16, 6.03, and 6.04, corresponding in position and intensity to *N*-methyl, benzylic methylene, and two methylenedioxy groups respectively. The aromatic region of the spectrum integrated for six protons consisting of two singlets at δ 7.06 and δ 7.66 which could be assigned to the C_7 and C_{10} protons, respectively, and two AB quartets (δ H_3, 6.79; δ H_4, 7.24; $J_{H_3H_4}$ = 8.2 Hz and δ H_5, 7.63; δ H_6, 7.43; $J_{H_5H_6}$ = 8.0 Hz). These assignments could be made by comparison with the spectrum of dihydrochelerythrine, **2** (Table I). This structure of alkaloid B was confirmed by oxidation of B in chloroform solution with mercuric acetate to sanguinarine (m.p. 244°).

Alkaloid **C**, after a preliminary purification, crystallized from chloroform–methanol as white leaflets melting at 361° in an evacuated tube. It had a u.v. absorption spectrum typical of a benzophenanthridine alkaloid, and carbonyl stretching absorption at 1655 cm^{-1} in the i.r. spectrum characteristic of a six-membered aromatic lactam. The mass spectrum of **C** showed the molecular ion at *m/e* 347 corresponding to the expected composition $C_{20}H_{13}NO_5$ (calcd.: 347.0794; observed: 347.0796). The p.m.r. spectrum of **C** could not be determined because of its very poor solubility in the common solvents. However, on the basis of the foregoing properties it is clear that **C** is in fact oxysanguarine **6**.

Experimental

Melting points were determined using a Fisher Meltemp apparatus. Mass spectra were recorded on a CEC 21-110B double-focusing mass spectrometer. Samples were introduced through the direct inlet system. Accurate mass measurements (7) were carried out by reference to appropriate peaks in the spectrum of perfluorokerosene (8). Proton magnetic resonance spectra were recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$, unless otherwise specified, using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V4315 frequency counter incorporated in the instrument. Double irradiation was achieved by employing a Hewlett–Packard 201C audiogenerator at the desired frequency. For n.O.e. measurements degassed solutions were used and a procedure similar to that of Anet and Bourn (3) was employed. A Beckmann I.R. 10 spectrometer was used to record i.r. spectra, and a Cary 14 spectrophotometer was used for the u.v. spectra.

11-Acetonyldihydrochelerythrine **1**

Chelerythrine chloride (1 g) was refluxed with acetone (50 ml) and aqueous sodium carbonate (10 ml, 2 g) for 6 h. The excess acetone was removed under reduced pressure and the residue washed thoroughly with water and chromatographed on a short column of silica gel in benzene–acetone (9:1). The product (u.v. blue fluorescent) was collected, the solvent removed, and the residue recrystallized from acetone from which it deposited large colorless plates (0.64 g) melting sharply at 199°, $\nu_{C=O}$(KBr) 1715 cm^{-1}.

1,3-bis(11-Hydrochelerythrinyl)acetone **4**

Chelerythrine (300 mg) was dissolved in pyridine (5 ml), freshly prepared acetone dicarboxylic acid (60 mg) was added, and the solution allowed to stand overnight. The pyridine was removed under reduced

pressure, the residue chromatographed on a column of silica gel in benzene–acetone (9:1), and the u.v. blue fluorescent band collected. This fraction was taken to dryness under reduced pressure and the residue further purified by thin-layer chromatography (t.l.c.) on several plates of silica gel G(20 × 20 × 0.1 cm) in benzene–acetone (9:1). The slower u.v. blue fluorescent major component was eluted and crystallized from chloroform–acetone as colorless plates, m.p. 304° (45 mg).

Alkaloid **A** was similarly freed of a minor impurity by preparative t.l.c. which raised its melting point to 304°.

*Oxidation of Alkaloid **B**, **5**, to Sanguinarine*

Alkaloid **B** (1 g) was refluxed with mercuric acetate (2 g) in chloroform (50 ml) for 12 h. Most of the chloroform was removed under reduced pressure, the solution allowed to cool, and filtered. The filtrate was evaporated to dryness and chromatographed on a short column of silica gel. The column was first eluted with chloroform (100 ml) and the eluate discarded. This was followed by elution with chloroform–acetone (9:1) (100 ml) and the eluate, upon evaporation to dryness and crystallization from chloroform–methanol, yielded colorless needles of sanguinarine, m.p. 244° (740 mg).

*Purification of Alkaloid **C***

Alkaloid C (150 mg) was chromatographed on a column of silica gel (13 × 1.8 cm) and the column was eluted first with hexane–acetone (9:1) (400 ml). The eluate upon crystallization from chloroform–methanol gave colorless crystals, m.p. 275° (62 mg). This compound did not contain nitrogen and was not investigated further. Upon subsequent elution with chloroform–acetone (9:1) (300 ml) the column gave an eluate which could be induced to crystallize from chloroform–methanol as white leaflets (75 mg) melting at 361° in an evacuated tube; u.v.: λ_{max}(dioxan) 284, 293, 334 (shoulder), 344 and 363 (shoulder), and 382 mμ; log ε 4.56, 4.62, 4.15, 4.17, 4.06, and 4.00; i.r.: $\nu_{C=O}$ (KBr) 1655 cm^{-1}.

Optical rotatory dispersion and circular dichroism of diastereoisomers. I. The ephedrines and chloramphenicols

L. A. MITSCHER, F. KAUTZ, AND J. LAPIDUS

Divisions of Medicinal and Natural Products Chemistry, College of Pharmacy, The Ohio State University, Columbus, Ohio 43210

Received July 11, 1968

Optical rotatory dispersion (o.r.d.) and circular dichroism measurements are reported for all four diastereoisomers in both the ephedrine and chloramphenicol series. The Cotton effect associated with the ^1L_b absorption band is a reliable guide to absolute configuration in both series whereas the ^1L_a band is not. Circular dichroism measurements are preferred as the ^1L_a band dominates the o.r.d. curves to such an extent that erroneous assignment is quite possible. An attempt to relate the sign and intensity of the ^1L_b Cotton effect with rotamer population failed due to lack of apparent correlation.

Canadian Journal of Chemistry, 47, 1957 (1969)

The absolute configurations of ephedrine (**1–4**) and chloramphenicol (**5–8**) isomers have been firmly established (1–6). As these two series are closely related to one another in a stereochemical sense and are related to a multitude of biologically important arylamines, we were interested in establishing a rapid, convenient, micromethod for configurational assignment based on optical rotatory dispersion (o.r.d.) and circular dichroism (c.d.) measurements. Insufficient information is presently available in the literature on compounds of this type upon which to make reliable assignments based upon empirical rules much less upon theoretical grounds (7, 8). Therefore, we decided to begin our studies in this area by measuring all of the diastereoisomers of ephedrine and chloramphenicol using modern instrumentation.

Some years ago a pioneering study on the optical rotatory dispersion of a variety of simple aromatic substances included, as one of the examples, (−)-(1R,2S)-ephedrine (9). The best instrumentation available at that time had limited penetrating power and, as will be seen below, the majority of the curve in the most interesting spectral region was unavoidably inaccessible. The results obtained seemed to demonstrate the first extremum of a *negative* Cotton effect. As will be seen from Fig. 1, in fact, when seen *in toto*, a series of low amplitude peaks and troughs are present in the 240–280 mμ region where one would expect the symmetry "forbidden" ^1L_b π–π^* transition to occur (10). These small peaks are superimposed upon large slopes which do not reach maxima above 200 mμ. This is attributed to the very large π–π^* transitions which occur at lower wavelengths in many simple monosubstituted benzenoids. As will be

seen below most clearly in the case of the chloramphenicol isomers, for reasons that are presently obscure, not all of the factors that affect the shape of the spectra are sensitive to stereochemistry so the curves are not exactly enantiomeric. The slope of the curve is such that it is difficult to decide whether the first extremum of the group of peaks at 240–280 mμ is negative as previously assigned in the ephedrine case, or positive. This is a potentially serious problem for the sign of the first extremum at highest wavelength determines the optical family to which a substance is assigned (11).

A clear solution to this problem was found by using circular dichroism (c.d.) measurements. It is well known that whereas short wavelength absorbing functions ordinarily do not seriously interfere with c.d. measurements above 220 mμ, their influence is felt more or less strongly in o.r.d. measurements. This extensive "tailing effect" is not only a function of peak intensity but also of peak separation so that the effect is often minimal at wavelengths far removed from the absorption peak. In the cases at hand, the tailing effect of the short wavelength maxima is so pronounced that it virtually overwhelms the ^1L_b maxima and even dominates the o.r.d. spectrum all the way out to the sodium-D line (589.3 mμ)! The appropriate c.d. spectra of the ephedrines are recorded in Fig. 2 where it will be seen that (−)-(1R,2S)-ephedrine (**1**) and (−)-(1R,2R)-pseudoephedrine (**3**) hydrochlorides actually give a series of *positive* Cotton effects near 260 mμ. It is apparent, then, that the earlier incorrect attribution of a negative sign to this transition is a consequence of the slope of the curve in regions inaccessible at the time. Unfortunately, sensitivity was lost precisely at the wavelength where the low amplitude positive Cotton effects were beginning to appear. An exactly analogous case arising from a similar effect has recently been reported by Craig and his co-workers (12). The absolute configurations of the ephedrines have been firmly established by purely chemical means (1, 2) and so the reversal in designation of sign required by these data does not necessitate a corresponding change in configurational assignment.

So far as data is available to this point (but *vide infra*), the sign of the c.d. maxima of simple aryl chromophores in the 250–270 mμ range has proved to be a reliable guide to absolute con-

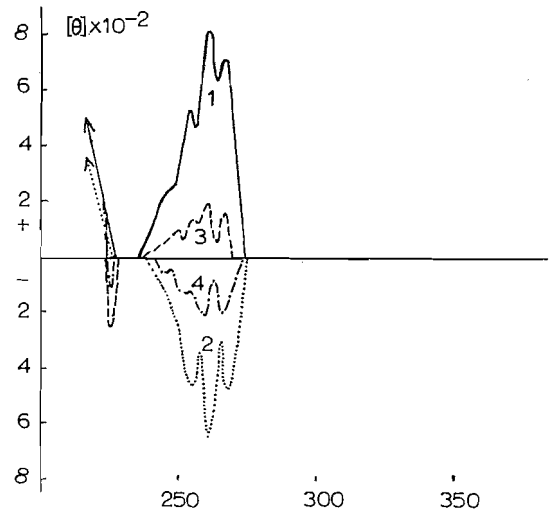

FIG. 2. Circular dichroism curves of the four isomeric ephedrine alkaloids **1–4** in methanol.

figuration, whereas the approach slopes of peaks below 200 mμ have not been directly correlatable with absolute configuration (7, 8, 12–19). Craig has even recorded an example wherein the sign of the latter transition and the corresponding sodium-D line rotation *inverted* when measuring successively the rotations of the free base and then the amine salt (12). The peaks at 250–270 mμ retained their sign although there were intensity differences. We have observed similar changes in intensity in this study but none so strong as to change the sign. In the absence of structural features containing n or p electrons capable of interacting with the benzenoid π cloud (for example, phenylalanine and 1-methylindane) the ^1L_b Cotton effects may be very difficult to detect at all (13, 20). From these findings, it is now clear that o.r.d. measurements of simple aryl chromophores are treacherous guides to absolute configuration whereas c.d. measurements of the ^1L_b band appear to lead to unambiguous answers.

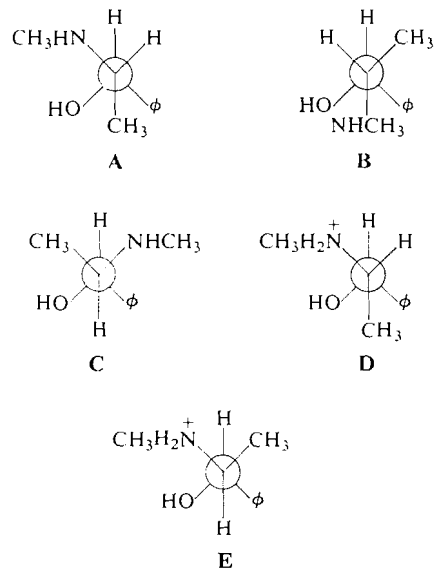
The optical rotations of aryl chromophores of this type reflect the weighted average of the population of the various rotamers through their incremental optical rotatory contributions even though the intimate mechanisms are presently obscure. It seems likely that an explanation of the strong dependence of o.r.d. spectra on experimental conditions could be simply that the peaks below 200 mμ are more sensitive to small changes in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

rotamer ratios than those at 260 mμ because of their much greater magnitude. It is obvious that differentiations between pairs of substances which differ configurationally at centers more distantly removed from the chromophore, such as (−)-ephedrine and (−)-pseudoephedrine, often must be made on the basis of peak amplitude rather than sign. With experimental parameters having a strong influence on amplitude, comparisons must be made between very close models and at as nearly identical conditions as are possible with respect to concentration, solvent and pH. The c.d. peaks at 260 mμ are apparently much less sensitive to the changes at lower wavelength with the exception of modifications in amplitude.

Turning once again to Fig. 2, it is apparent that, using the cautions enumerated above, the ^1L_b c.d. bands are a reliable indicator of the configurations of both asymmetric carbons of the ephedrines when the sign and amplitude are both considered. As expected, the configuration of C-1, which is closest to the aromatic ring, dominates the spectrum and determines the overall sign of the Cotton effect. The configuration of C-2 has an effect on the amplitude. Both (−)-(1R,2S)-ephedrine (**1**) and (−)-(1R,2R)-pseudoephedrine (**3**) hydrochlorides, which have the same configuration at C-1, give positive ^1L_b bands. On the other hand (+)-(1S,2R)-ephedrine (**2**) and (+)-(1S,2S)-pseudoephedrine (**4**) salts give closely enantiomeric c.d. spectra to those of their negative analogues. The *erythro* compounds (ephedrines) give curves with higher amplitudes than the *threo* compounds (pseudoephedrines). Analogous findings have been made with c.d. measurements on the related diastereoisomeric cinchona alkaloids (21). Thus, the diminution of amplitude observed in the *threo* compounds can serve as an indication of the configuration of C-2. The corresponding free bases of **1** and **3** were measured. With natural ephedrine (**1**), this change in conditions results in a considerable diminution of the ^1L_b band and a slight shift in peak positions. With pseudoephedrine (**2**), a slight intensification of the ^1L_b band was noted. Use of dioxane as a solvent in place of methanol (for pseudoephedrine free base) simply reduced the amplitude and brought out some added fine structure.

In cases where steric effects are large, or where overriding effects are present due to strong intramolecular hydrogen bonds, definite preferences will be found for a single rotamer even at ambient temperature. Strong intramolecular hydrogen bonding is indeed found with the ephedrines and has been the subject of a number of investigations (22–25). Most pertinent is a recent study by Portoghese utilizing nuclear magnetic resonance (n.m.r.) techniques whereby he was able to assess the rotameric situation in this series (22). Ephedrine, as the free base, can exist in three different staggered rotational conformations of which a definite preference for conformer **A** is apparent from the various coupling constants. Conformer **B** makes a small contribution whereas **C**, which is not capable of stabilization by intramolecular hydrogen bonding, is not present in significant amounts. In acidic solution, the conformational preference



for **A** is reinforced at the expense of conformer **B** even though the hydrogen bonding is probably contributed by a different donor (**D**). Except for greater dilution, the conditions utilized in this study are similar, so these factors suggest that the o.r.d.–c.d. effects reported here are largely attributable to conformer **D**. Lesser amplitude observed with the free base may be due to an increased, and competing, contribution by conformer **B** and perhaps **C**. With pseudoephedrine, the corresponding most populous configuration is that of **E** which is closely analogous to rotamer **D** for ephedrine. This

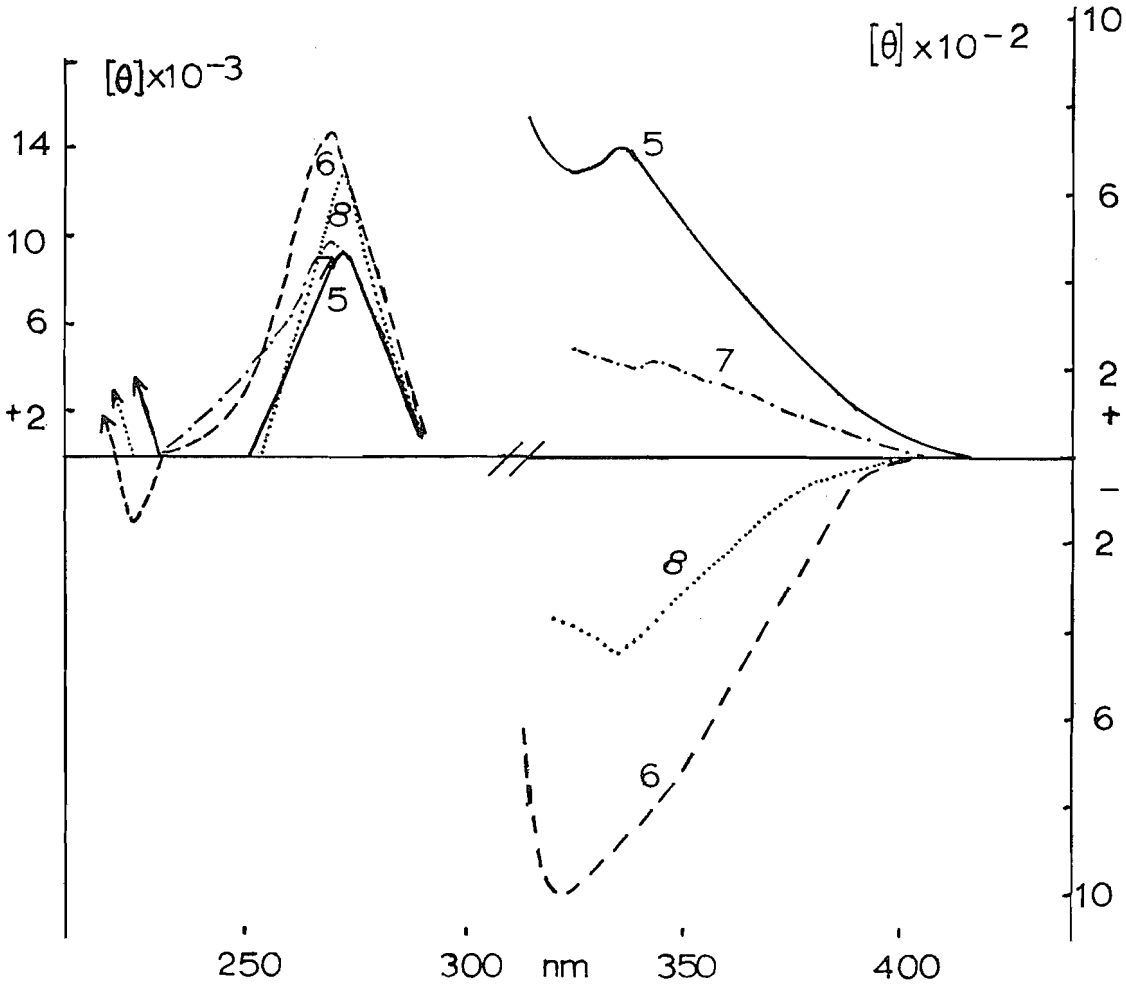


FIG. 3. Circular dichroism curves of the four isomeric chloramphenicol antibiotics **5–8**.

rotamer is strongly preferred for both the free base and the salt and in fact amplitude differences between the two forms are not sizable. The most notable difference between **D** and **E**, of course, is that the methyl group is on opposite sides of the chromophoric phenyl ring and may well distort the perpendicular magnetic moment (26) giving rise to the amplitude differences observed through its steric bulk effect.

These considerations make it extremely tempting to attribute the c.d. effects to the preference for a particular rotamer which has a dominant influence on the sign and intensity of the ^1L_b Cotton effect. In order to test this hypothesis we turned our attention to the chloramphenicols (**5–8**) where a series of apparently closely related isomers is available. The chloramphenicols have also been studied by n.m.r. techniques with regard to preferred conformation in solution (27). The appropriate c.d. curves are reproduced in Fig. 3. It will immediately be perceived that all 4 isomers have a Cotton effect of *the same sign* in the 260 mμ region! However, this is *not* the same transition which occurs in this region with the ephedrines but rather is the hitherto unavailable ^1L_a band which has now been shifted to higher wavelength due to the auxochromic effect of the *p*-nitro group. Now that this band is present in a relatively accessible spectral region and can be examined, it is clearly evident that

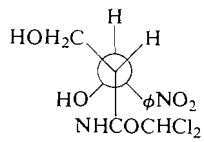
the sign and intensity of this transition does *not* reflect the absolute configuration of the side-chain in any clearly discernible manner any more than it seemed to in the ephedrine series. This finding can serve to rationalize difficulties others have experienced trying to correlate o.r.d. disappearance slopes and absolute configuration (12). The ^1L_b transition is now to be found at about 320–340 mμ and, as usual, is much less intense than the ^1L_b band and could be easily overlooked. Obviously in measuring c.d. spectra of compounds carrying auxochromic functions, then, appropriate wavelengths must be selected for comparison purposes.

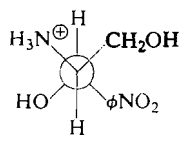
The sign of the ^1L_b transition of the chloramphenicols is a reliable indicator of absolute configuration. The signs of the respective Cotton effects are the same and the relative intensities are parallel to the corresponding ephedrines.

It should be pointed out that the possibilities for hydrogen bonding are quite different in the chloramphenicol series as opposed to the ephedrines because of the addition of the primary hydroxyl group on C-3. Indeed, according to Jardetzky (27), it is the interaction between this function and the secondary hydroxyl on C-1 which exerts a dominant influence on the rotamer population.

Jardetzky's preferred rotamer for natural chloramphenicol (**7**; 1R,2R) (**F**) looks rather more like that of (−)-(1R,2S)-ephedrine (**D**) than that of (−)-(1R,2R)-pseudoephedrine (**E**) to which it correlates directly by virtue of its absolute configuration and c.d. spectrum. This apparent noncorrelation between preferred rotamer and sign of Cotton effect is disappointing. The present state of knowledge, then, does not seem sufficient to allow generalizations based on



F



G

comparison of c.d. spectra and presumed rotamer population densities.

A great many more measurements will be needed on compounds of known absolute configuration and reasonably clear rotameric preference before generally useful empirical rules can be established in complicated cases of this type. These considerations are guiding extensions of this work currently under way in this laboratory.

Experimental

The o.r.d. and c.d. measurements were carried out using a Durrum–Jasco model ORD/UV-5 instrument equipped with a c.d. attachment and operating at ambient temperature (cell compartment temperature 29 °C). The solvent used was spectra grade methanol unless otherwise specified and concentrations were chosen so that peak absorption, as reflected by the photomultiplier voltage readings, did not exceed 0.8.

Quantitative aspects of base-catalyzed Michael addition: Mechanistic study of structural and medium effects on rate[1]

JOHN A. MARKISZ AND JOSEPH D. GETTLER
Department of Chemistry, Nichols Laboratory, New York University, Bronx, New York 10453

Received September 10, 1968

The quantitative kinetics of the reactions of acrylonitrile and methyl vinyl ketone with ethyl acetoacetate and 2,4-pentanedione, and those of acrylonitrile with ethanol and methanol in basic solution were studied as functions of base concentration, temperature, ionic strength, and solvent composition. An expression is obtained which relates the observed rates to the basicity of the solution for the 2,4-pentanedione reactions by the amount of anion in solution. For the other systems, reasonable values of ionization constants obtained empirically, similarly correlate observed rates with the concentration of base in the system. A quantitative correlation with activity coefficients as expressed by the expanded form of the Debye–Hückel equation gave good agreement for most of the experimental data with ionic strength. A derivation for the particular type of system employed indicated that the activity coefficient for the double-bonded compounds appears to have to be treated as an ion with partial ionic charge. On the basis of experimental data reported, the mechanism proposed involves, (*i*) anion attack on a polarized double bond, (*ii*) formation of a cyclic intermediate, severely restricted because of π orbital overlap, and (*iii*) protonation of this intermediate to form product.

Canadian Journal of Chemistry, 47, 1965 (1969)

Introduction

The Michael condensation denotes nucleophilic addition to a carbon–carbon double bond and is important synthetically for its versatility and characteristic high product yields (1). Although a large number of specific reactions of this type occur in basic solution, quantitative mechanistic studies in basic media or, for that matter, in any medium are quite rare.

In the almost complete absence of mechanistic studies (2), it has been presumed that an α-hydrogen is abstracted from a donor species generating a carbanion.

[1] 
The carbanion, with the importance of resonance stabilization depending upon the substituents, attacks the β-carbon of a multiple bond system.

[2] 
[1]Abstract of a dissertation submitted by John A. Markisz to the faculty of the Graduate School of Arts and Science, New York University, in partial fulfillment of the requirements for the degree of Doctor of Philosophy, June, 1966.

The resulting adduct can then be represented by the resonance structure, [3].

[3] 
This species can accept a proton from a protonated base, a solvent molecule, or another donor molecule, and the resulting protonated enol then rearranges to give the more stable keto form, a 1,4 addition becoming essentially a 1,2 addition. The varieties of donor compounds which react in this way are numerous and include amines, amides, alcohols, mercaptans, aldehydes, ketones, esters, inorganic acids, and salts (3, 4).

Few quantitative kinetic or mechanistic studies have been reported on the Michael condensation, even though a large number of reactions of this type have been studied synthetically. Some very early work by Jones (5) on the rate of addition of hydrogen cyanide across a conjugated double bond was found to be dependent upon the concentration of cyanide ion. Kamlet and Glover (6*a*, *b*), studied the reaction of barbituric acid with β-nitro styrene in non-alkaline media, while Hine and Kaplan (7*a*) studied the addition of nitroform to β-nitro styrene in acidic methanol. Both of these investigations proposed mutually consonant mechanisms which involved carbanion attack on the β-nitro styrene, but they presented no

For personal use only.

additional mechanistic information on base-catalyzed reactions. Kinetics of the reverse Michael reaction have been studied (*7b*), and Oda and Shono (*7c*) have attempted, with moderate success, to relate reactivity of Michael adducts to configuration and K_a with localized molecular orbital calculations for π electrons.

The present investigation was undertaken to elucidate the quantitative kinetics and mechanism of a number of base-catalyzed Michael condensations. All reaction systems investigated during the course of the current research were characterized by a double-bonded compound reacting with an α-hydrogen donor molecule. The kinetics of the following Michael additions were investigated:

reaction [4], methyl vinyl ketone (1 mole) with ethyl acetoacetate (1 mole) to yield ethyl 2-acetyl-5-keto hexanoate;

reaction [5], methyl vinyl ketone (2 moles) with ethyl acetoacetate (1 mole) to yield ethyl 2-acetyl-2-(4′-butanone)-5-keto hexanoate;

reaction [6], methyl vinyl ketone (1 mole) with 2,4-pentanedione (1 mole) to yield 3-acetyl-2,6-heptanedione;

reaction [7], methyl vinyl ketone (2 moles) with 2,4-pentanedione (1 mole) to yield 5,5-diacetyl-2,8-nonanedione;

reaction [8], acrylonitrile (1 mole) with ethyl acetoacetate (1 mole) to yield ethyl 2-(2′-cyanoethyl)-3-keto butanoate;

reaction [9], acrylonitrile (2 moles) with ethyl acetoacetate (1 mole) to yield ethyl 2,2-di(2′-cyanoethyl)-3-keto butanoate;

reaction [10], acrylonitrile (1 mole) with 2,4-pentanedione (1 mole) to yield 3-(2′-cyanoethyl)-2,4-pentanedione;

reaction [11], acrylonitrile (2 moles) with 2,4-pentanedione (1 mole) to yield 3,3-di(2′-cyanoethyl)-2,4-pentanedione;

reaction [12], acrylonitrile (1 mole) with methanol (1 mole) to yield methyl-2-cyanoethyl ether;

reaction [13], acrylonitrile (1 mole) with ethanol (1 mole) to yield ethyl-2-cyanoethyl ether.

Experimental

Materials

All chemicals employed in this research were commercially available. All organic reagents were liquids and were distilled before use, under nitrogen when necessary. All other compounds were reagent grade and used without further purification.

Preparation of Solutions

Buffer solutions were prepared in the conventional manner according to the formulations of Clark and Lubs (cited in ref. 8). The nominal values of buffer solutions were confirmed with a Sargent pH meter which had been previously standardized against commercially available buffer powders and buffer solutions of known pH. The pH meter was standardized with reference buffers at each of the temperatures at which rate constants were determined and the pH of each reaction mixture was measured before, during, and after the kinetic experiment at the relevant temperature. No variation was observed.

Standard solutions of base were prepared and standardized against standard hydrochloric acid solutions in the conventional manner. Salt solutions for ionic strength experiments were prepared by weighing portions of the desired salts into a tared volumetric flask, dissolving in distilled water, and diluting to the appropriate volume. Potassium chloride, sodium chloride, and lithium chloride were used in ionic strength experiments and no specific salt effects were observed.

Apparatus

The timing of kinetic experiments was done with an A.R. and J.E. Meylan one-fifth split second timer. Calibration of volumetric glassware and analytical weights met customary standards for precision experimentation. Reaction vessels were 250 ml Pyrex flasks fitted with 50 ml side-bulbs and standard tapered ground glass stoppers. The thermostats were of conventional design, and the temperature could be maintained to within ± 0.01 °C at 25 and 35°, and to within ± 0.05 °C at 50°. The composition of various reaction mixtures from kinetic experiments was studied, after suitable treatment, by gas–liquid chromatography (g.l.c.) on a Carbowax column.

Analytical Method

The analytical procedure employed during this research was based on the cyanoethylation of dodecyl mercaptan. This method is generally suited for the quantitative determination of acrylonitrile in dilute solutions (9), is unaffected by the presence of other species in the kinetic systems investigated, and is useful to determine as little as 2 mg (10). It was found here to be equally well suited for the determination of methyl vinyl ketone. Necessary reagents were prepared as follows:

(a) Basic Catalyst

Twenty-eight grams of potassium hydroxide were dissolved in 1 l of 95% ethanol, to prepare an approximately 0.5 *N* solution.

(b) Mercaptan Reagent

Twenty-five grams (31 ml) of crude *n*-dodecyl mercaptan were dissolved in 1 l of isopropyl alcohol (99%), and the resulting solution allowed to stand for at least two days before using.

(c) Standard Iodine Solution

An iodine–iodide (triiodide) solution was prepared in water and standardized against a solution of sodium thiosulfate, which had been standardized with potassium iodate.

(d) Acid Stop-Solution

Sixteen ml of concentrated hydrochloric acid were added to enough isopropyl alcohol to make 1 l.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In all analyses the following procedure was used. Twenty-five ml of mercaptan reagent were accurately transferred to a 250 ml iodine flask from a fast-flowing pipette. Similar mercaptan-containing flasks were prepared for each sample and one for a blank. A measured volume of an unknown sample was transferred into one of these flasks, which was then stoppered and the contents swirled. Two ml of the basic catalyst were added and the flask again stoppered and swirled to intermix the solutions. Two min after the catalyst addition, the reaction was suppressed by adding 125 ml of the acid stop-solution. The blank sample was afforded the same treatment, but in this case immediate titration was mandatory. Samples were titrated to a faint yellow color, permanent for at least 30 s of swirling, by the addition of standard triiodide solution.

Kinetic Procedure

Into the 50 ml side-bulb of a glass stoppered 250 ml reaction flask was pipetted an aliquot of acrylonitrile of known concentration in appropriate buffer and salt solution, and into the main section was pipetted the other reactant in a similar medium. The flask was then placed in a thermostat for a sufficient time to permit temperature equilibration. Reaction vessels for experiments with methyl vinyl ketone were prepared in a similar manner except that no base solution or basic buffer solution was mixed with the olefin while temperature equilibration was being affected. This procedural departure was necessary because methyl vinyl ketone reacts with the base itself. This complication is discussed more fully below. During this period, a series of iodine flasks containing mercaptan reagent was prepared, and the value of the blank determined. The reaction was initiated by removing the solution-containing reaction flask from the thermostat, inverting it, shaking vigorously to insure proper mixing, and returning it to the thermostat. This first inversion of the flask and mixing of the reactants was taken as zero time, the start of the reaction. Aliquots which were rapidly withdrawn using a fast-flowing pipette that had been sheathed in asbestos and kept in a glass well in the thermostat, were then delivered into the iodine flask containing mercaptan reagent. Resulting solutions were then analyzed for acrylonitrile or methyl vinyl ketone. The time was noted when the pipette started delivering solution, and to this was added the previously determined time of half-delivery for the pipette. This total time was used as the time t in kinetic calculations. Reaction mixtures were of sufficient volume so that 12–15 samples could be withdrawn for analysis during the course of a kinetic experiment.

Synthetic Experiments

The products of reactions [4] to [13] were synthesized by refluxing appropriate reaction mixtures over a steam bath for 3–4 h in the presence of approximately 1 g of sodium ethylate. Reaction mixtures of about 3:1 molar ratio of acrylonitrile or methyl vinyl ketone to α-hydrogen donor compound were used in reactions [5], [7], [9], and [11], while 1:3 molar ratios were used for the remaining reactions. Volatile components of reaction mixtures, essentially always the reactants, were expelled by gently heating, and the desired products were distilled under reduced pressure. Table I lists the boiling or melting points (experimental and reported) of the compounds prepared.

These compounds were used as standards to establish the identity of products formed in aqueous kinetic mixtures, extracted from such reaction mixtures, dried, and then subjected to g.l.c. analyses. The physical constants of products from reactions [6], [7], and [10] were not previously reported. Products from reactions [6] and [10], when treated with excess base and olefin, gave products from reactions [7] and [11], respectively. Elemental analysis confirmed their identity.

Calculations and Results

Although the Michael condensation is generally reversible (11), equilibrium constants under experimental conditions were so small that the reverse reaction could easily be neglected by selecting and imposing the proper conditions. The usual second-order irreversible rate expression was therefore used in rate calculations.

Thermodynamic activation quantities were calculated using the following equations (12):

$$[14] \qquad \Delta F^{\ddagger} = -RT \ln [kh/k_b T]$$

$$[15] \qquad \Delta H^{\ddagger} = RT^2 (\delta \ln k/\delta T) - RT$$

$$[16] \qquad \Delta S^{\ddagger} = [\Delta H^{\ddagger} - \Delta F^{\ddagger}]/T$$

where $F^{\ddagger}$, $H^{\ddagger}$, and $S^{\ddagger}$ are the activation free energy, enthalpy, and entropy, respectively, k is the rate constant, k_b is Boltzmann's constant, h is Planck's constant, R is the gas constant, T is the absolute temperature and $k_b T/h$ is the frequency factor of transition state theory.

Table II lists the experimentally observed rates of reaction for reactions [4]–[11] in aqueous solution. Table III lists the observed rates for reactions [4]–[12] which were run in methanol,

and Table IV lists the observed rates for reactions [4]–[11] and [13] which were run in ethanol. Table V lists the rates of reaction for the first-order basic decomposition of methyl vinyl ketone.

Discussion

Rate data accumulated during the present research indicate that all but reactions [12] and [13] are experimentally reversible. The rates of the reverse steps, however, are so slow that the extent of reversibility is easily controlled by the selection of proper experimental conditions. Consequently, forward specific rate constants can be readily determined. The production of the cyanoalkyl ethers, reactions [12] and [13], on the other hand, appear to be irreversibly second order under all conditions employed, since no measurable concentrations of reactants could be detected in basic solutions of these ethers over extended periods of time at any of the temperatures used. In any single kinetic experiment values of specific rate constants exhibit no noticeable trend with time. Practically all kinetic experiments were carried to approximately 75% completion, and a minimum of 10, and usually 12–15, experimental points were employed in the calculation of any particular rate constant.

An inspection of Tables II, III, and IV reveals that specific reaction rates of all reactions studied increase at higher base concentrations in all solvents, or at higher pH values in water, decrease with increasing ionic strength, increase with decreasing dielectric constant, and do not uniformly show linear Arrhenius plots, i.e., the logarithm of the rate constant versus the reciprocal of the absolute temperature. Some of the reactions investigated actually show inverted Arrhenius plots. Since this requires impossible negative activation energies, the reaction between uncharged reactant molecules, which is implied by using stoichiometric concentrations of reactants in the rate equations, cannot be considered valid.

Since all but two of the reactions investigated are reversible, forward reactions were studied under carefully controlled experimental conditions in an effort to suppress kinetic complications generally concomitant with reverse reactions. For this reason, either experimental conditions were selected so that a large excess of the α-hydrogen donor compound was present to suppress reversal tendency, or kinetic measurement was stopped at about 75% completion, up to which point the reverse reaction, because of its slower rate, imposed no measurable effect on the kinetic results. Gas–liquid chromatographic analyses of kinetic reaction mixtures showed the investigated reactions to be the expected ones, since no unexplained product peaks were observed. No change in concentration of acrylonitrile or methyl vinyl ketone, in the absence of other reactants, but with all other reaction conditions prevailing, except as noted below, was detected in a period greater than seven half-lives of the slowest reaction, which suggested the impossibility of hydrolysis or polymerization of these compounds during a kinetic experiment. The possibility of radical reaction was discounted since no insoluble polymers were found in the reaction mixtures and these dilute solutions became only slightly colored after having reached equilibrium.

The reactions of methyl vinyl ketone at low pH values, 7 to 8, and low base concentrations were uncomplicated by side reactions, and the study of pertinent kinetics was essentially straightforward, being of the mixed second-order type, first-order in each of the reactants. At increased base concentrations, however, in addition to the condensation reactions [4]–[7] listed above, there was a first-order disappearance of methyl vinyl ketone to some undetermined product or products, which interfered quite significantly with the determination of rate constants for the principal reactions. This situation was handled with the aid of computer techniques which have been previously described (13). Briefly, the differential equation

$$[17] \qquad -\delta[a]/\delta t = k_1[a] + k_2[a][b]$$

was solved for k_2 by a series of six steps: (*1*) obtaining a polynomial which expressed the concentration of a, $[a]$, as a function of the time, t; (*2*) differentiation of the function found in (*1*) to obtain $\delta[a]/\delta t$; (*3*) determination of k_1 experimentally under reaction conditions where the second-order reaction was quenched and then calculation of the amount of a decomposed in this reaction in the first second; (*4*) calculation from the function obtained in (*1*) of the total amount of a reacted after one second (for both reactions); (*5*) calculation of the difference between the quantities of a obtained in sections (*4*) and (*3*), which is equal to the amount of a and the amount of b disappearing by the second-

For personal use only.

order process; and (*6*) calculation of k_2 from eq. [17].

An inspection of the data in Tables II–V shows that for the reactions studied, at constant ionic strength, the specific rate constant increases with increasing concentration of base. A quantitative interpretation can be made if it is assumed that the anion, A^-, of the α-hydrogen donor molecule, HA, is the reactive species. This molecule, HA, would be in equilibrium with its conjugate base, A^-, as follows,

$$[18] \qquad HA \rightleftharpoons H^+ + A^-$$

for which there would be an equilibrium constant, K_a. The total concentration of HA, $[HA]_t$, would be equal to the sum of the un-ionized and anionic species,

$$[19] \qquad [HA]_t = [HA] + [A^-]$$

then,

$$[20] \qquad [A^-] = [HA]_t/(1 + [H^+]/K_a)$$

or,

$$[21] \qquad [A^-] = K_a[HA]_t[OH^-]/(K_w + K_a[OH^-])$$

where K_w is the ion product of water. If the rate determining step is represented by eq. [2], then the rate expression is,

$$[22] \qquad \delta[x]/\delta t = k[B][A^-]$$

where [B] is the concentration of olefin, and $[x]$ is the concentration of product. The values obtained in Tables II through IV were calculated using the total concentration of HA, $[HA]_t$,

$$[23] \qquad \delta[x]/\delta t = k'[B][HA]_t$$

where the observed rate constant, k', if eq. [2] correctly represents the rate determining step, would be equal to

$$[24] \qquad k' = k\,K_a[OH^-]/(K_w + K_a[OH^-])$$

K_w values used in this equation were those reported for the temperatures of kinetic experiments. The hydroxyl ion concentrations used were determined by measurement before, during and after a kinetic experiment. Salts were added initially to stock solutions of hydroxyl ion to prevent changes in ionic strength. K_a was assumed to be temperature independent over the temperature range investigated. This would introduce no error at 25° and a possible maximum error of about 4% at 50°. This latter error in k' would cause an error of about 0.3 cal/deg in activation entropy calculations, which is well within experimental limits.

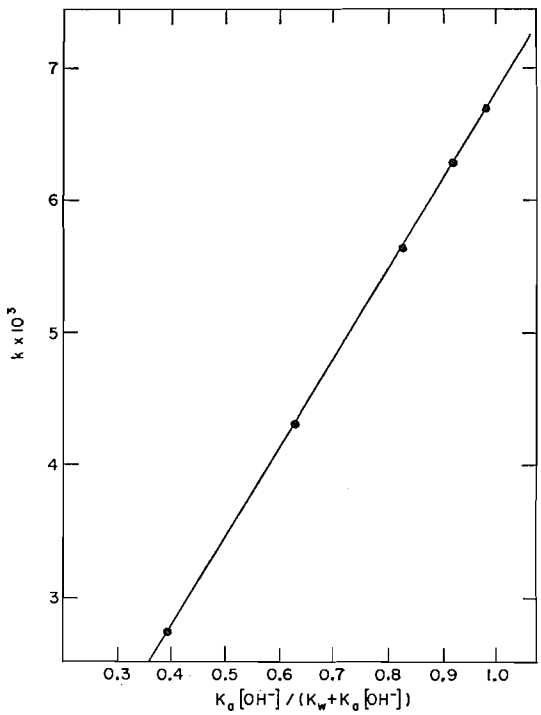

FIG. 1. k' vs. $K_a[OH^-]/(K_w + K_a[OH^-])$ for reaction [8], 25.00 °C; ionic strength = 1.05. Typical for the several reactions.

Equation [24] has been successfully employed for reactions [6] and [10], where K_a for 2,4-pentanedione (14) is 1.9×10^{-9}. A plot of k' against $K_a[OH^-]/(K_w + K_a[OH^-])$ is shown in Fig. 1 for these reactions at 25.00 °C. The assumption that K_a varies very little with temperature yielded satisfactory linear plots for data at all pertinent temperatures. The resultant specific rate constants, k, were found to be independent of base concentration. In the cases of reactions [5], [7], [9], and [11], occurring in water, K_a values are unavailable, so an alternate procedure was employed, which gave values of K_a for ethyl acetoacetate (reactions [4] and [8]) in very good agreement with reported values (7.1×10^{-11}) (14). Observed rates were plotted against $[OH^-]/(K_w + \beta[OH^-])$, where β is an empirically determined constant. This value is assumed equal to the ionization constant,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

K_a, and the slope, from eq. [24], thus becomes equal to k/K_a or k/β. Specific rate constants obtained in this way are independent of base concentration. Values of k corrected for the influence of base are listed in Table VI, along with calculated values of β. An analysis of the data in Table VI indicates that the β parameter is always essentially the same for a given nucleophile, independent of both the temperature and the particular olefinic compound involved in the reaction. These k values also yielded a normal, linear Arrhenius plot, which will be discussed below.

Although all of the reactions studied were base-catalyzed, no attempt was made to account quantitatively for this phenomenon in alcoholic solvents, since values of K_a and K_w were unavailable for all of the reactants under these conditions, and attempting to fit the data to a line determined by two empirical constants would have been completely meaningless. It was found in these solvents, as well as in pure ethanol and pure methanol, that equimolar solutions of different bases (sodium ethoxide, sodium methoxide, triethyl amine) had no specific effect on the rate of the reactions. In these rather dilute solutions, the basic ionization was probably complete.

It was established that methyl vinyl ketone is unstable in basic solution in a first-order manner, with the rate constant increasing linearly with the concentration of hydroxyl ion, Table V. This presumably indicates a second-order reaction in which the hydroxyl ion, itself a superior nucleophilic agent, competes with the other anion for addition to the double bond. A product analysis was not possible, since amounts of products recovered by extractive procedures, as described above, were obtained only in trace quantities, and the addition of base to concentrated solutions induced polymerization which was probably anionic. This competitive reaction was slow, but significantly large so as to interfere with the rate calculations of the Michael condensation at high pH values. No comparable reactions or complications were detected for acrylonitrile. Previously, data of a synthetic study (15*a*) of a Michael reaction involving methyl vinyl ketone indicated an increase in product yield followed by a decrease, as the concentration of base was steadily increased. It now appears that it is the increase in the rate of this incompletely described decomposition of methyl vinyl ketone with an increasing amount of base which is responsible for this phenomenon.

The mechanism of nucleophilic addition, then, as indicated by the results of the present investigation, appears to be consistent with that

presented in eqs. [1], [2], and [3], at least so far as the rate-determining step seems to be the addition of a nucleophile to the carbon–carbon double bond, eq. [2]. For the reaction of a donor substance bearing two α-hydrogens, there appears to be two separate and distinct nucleophilic additions, each with the mechanism proposed. The rate expression for these equations is

$$[25] \qquad \delta[x]/\delta t = k_1[a][b] + k_2[c][b]$$

where k_1 refers to the addition of the first mole of olefin to form the product c, and k_2 is the addition of a second mole of olefin to c. Since k_1 had been determined from weakly basic, dilute systems, the same procedure used to solve eq. [17] was employed here. Values of k_2 obtained agreed extremely well with second-order specific rate values obtained by reacting the products of reactions [4], [6], [8], and [10] with the appropriate olefin.

If the proposed mechanism is correct, a change of ionic strength would have little or no influence on the specific rate. Scatchard (16) has derived an expression, eq. [26], for the influence of ionic strength on the rate of reaction, where reactant molecules A and B, each with a charge z_a and z_b, respectively, form a complex X*, with a charge of $(z_a + z_b)$, which eventually yields products. The equation

$$[26] \qquad \ln k = \ln k_0 + 2z_a z_b A(I)^{1/2}$$

was derived assuming the natural logarithm of the activity coefficient to be the usual Debye–Hückel expression,

$$[27] \qquad \ln \gamma_a = -z_a^2 A(I)^{1/2}$$

where k is the rate constant at ionic strength I, k_0 is the rate constant at zero ionic strength, and A is a complex constant. Equation [26] would indicate no influence of ionic strength, since $z_b = 0$, a neutral molecule according to the mechanism of reaction [2]. However, an inspection of the data in Tables II–V shows a very pronounced decrease in rate with increasing ionic strength. Qualitatively, at least, this infers reaction between oppositely charged ions. For the systems of the present investigation it would mean that the rate-determining step could not be the one proposed, but should be rather the protonation of resonance structure [3]. This situation does not appear too reasonable, since protonation would be expected to occur very rapidly in the polar solvents employed (water, methanol, and ethanol), all of which are quite efficient proton donors as neutral molecules. The only other plausible alternate mechanism for these systems would be the rapid protonation of the double bond to form a carbonium ion, followed by the rate-determining step, reaction of the carbonium ion with the nucleophile. This possibility must also be rejected, firstly, because the rate would be expected to increase with decreasing base concentration and secondly, because from analyses of reaction products a primary carbonium ion must be generated, rather than the more stable secondary allylic carbonium ion.

A plot of log k against the square root of the ionic strength did not give a linear relationship in the case of any reaction studied, although this is not particularly surprising since the ionic strengths used in this investigation generally were outside the range of applicability of the Debye–Hückel equation used, [27]. Using a more precise equation (17):

$$[28] \qquad \log_{10} \gamma_a = -z_a^2 A(I)^{1/2}/(1 + \sigma B(I)^{1/2})$$

where $A = 1.8123 \times 10^6/(DT)^{3/2}$ and $B = 5.0288 \times 10^9/(DT)^{1/2}$. σ is a constant once considered to be the distance of closest approach of an oppositely charged field to the ion in question, but now considered to be purely an empirical parameter. D is the macroscopic dielectric constant and T is the absolute temperature. This would give the following expression for the influence of ionic strength on a specific rate constant.

$$[29] \qquad \log_{10} k = \log_{10} k_0 + 2z_a z_b A(I)^{1/2}/(1 + \sigma B(I)^{1/2})$$

It was found empirically that a value of $\sigma = 5$ gave a satisfactory linear plot of log k against the complex function on the right side of eq. [29], Fig. 2, for a sizeable fraction of the data at the low ionic strength portion of the curve, but the slope was much too small for an ionic reaction, being about 0.5 compared to a minimum of 2.0 for ionic reactions. Empirical equations of the type suggested by Debye and McAulay (18), such as

$$[30] \qquad \ln \gamma_a = \lambda_a I$$

for the influence of ionic strength on the activity coefficient of a neutral molecule, were applied to

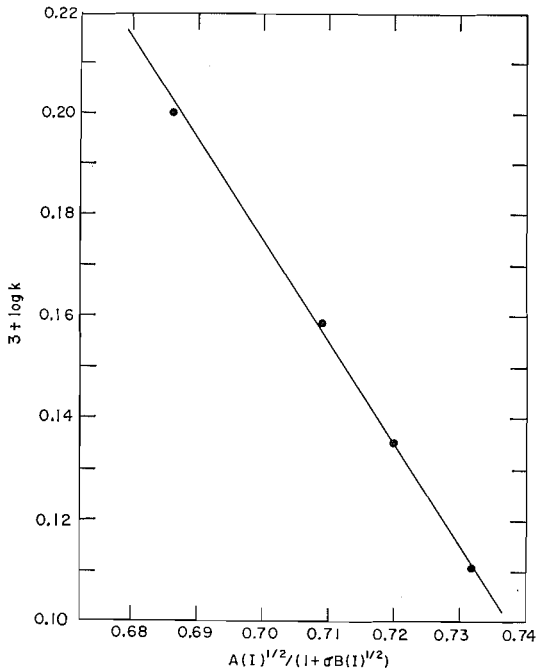

FIG. 2. Typical plot of log k against ionic strength function (eq. [29]), for reaction [8]; 25.00 °C; pH = 9.80.

the kinetic data without any success. The failure of these equations to correlate satisfactorily the data indicated the necessity for a new approach to the problem. With previous results pointing the way it was assumed that the olefin in eq. [2] was polarized prior to nucleophilic attack, and an attempt was made to treat theoretically this proposed mechanism to determine what effect, if any, ionic strength would have on rate.

The nucleophile, A^-, reacts with the positive end of the polarized double bonded compound, B, to form an activated complex, X*, in an equilibrium reaction. Ionic charges of the pertinent species are designated by z_a, z_b, and z_x, respectively, but now z_x is assumed equal only to z_a rather than the sum of z_a and z_b, since z_b is the charge at one end of a polarized molecule with no net charge on B, and the charge on the resulting complex, X*, will be that of the nucleophile A^-. Therefore,

$$[31] \qquad \text{rate} = k_0[X^*]$$

From the proposed equilibrium,

$$[32] \qquad K_x = \frac{[X^*]}{[A^-][B]} \cdot \frac{\gamma_x}{\gamma_a\gamma_b}$$

or,

$$[33] \qquad \text{rate} = (k_0K_x\gamma_a\gamma_b/\gamma_x)[A^-][B]$$

The observed rate constant, k, would then be given by,

$$[34] \qquad k = k_0K_x\gamma_a\gamma_b/\gamma_x$$

and since both A and X* are each singly negatively charged ions, it is to be expected that their activity coefficients, given by eq. [28], would be very similar and that the ratio of their activity coefficients, i.e., γ_a/γ_x, should be very close to unity. Then,

$$[35] \qquad k = k_0K_x\gamma_b$$

or,

$$[36] \qquad \log_{10} k = \log_{10} k' + \log_{10} \gamma_b$$

where k' is equal to k_0K_x, yielding

$$[37] \qquad \log_{10} k = \log_{10} k' - z_b^2A(I)^{1/2}/(1 + \sigma B(I)^{1/2})$$

if the polarized molecule behaves like an ion of partial electronic charge z_b, or,

$$[38] \qquad \log_{10} k = \log_{10} k' + \lambda_b I$$

if the polarized molecule behaves like a neutral molecule. Qualitatively, for the data in Tables II–V, eq. [38] predicts an increase in rate with increasing ionic strength (unless λ_b is negative) which was not found, and since no linear correlation of log k with ionic strength was found for any set of conditions, the possibility of eq. [30] accurately describing the behavior of the polarized molecule was discarded. Equation [37], however, not only correctly represents the influence of ionic strength on the rate, but also accurately describes the linearity predicted over most of the experimental range. That the upper ionic strength range does not fit to the desired curve, is probably due to non-ideal interactions in solution which limit the applicability of eq. [28] in this range. Although this function, eq. [37], may have no obvious theoretical validity for the systems under consideration, it is, nevertheless, useful for extrapolation back to zero ionic strength, yielding specific rate constants independent of the specific medium employed. The slopes of the lines for a given reaction are constant at different pH values or base concentrations within a given solvent. Table VII lists the slopes of the lines ($-z_b^2$)

for the various systems studied, which give values of z_b between 0.6–0.7 e.s.u. From these values it appears that the double bond is highly polarized by the groups conjugated to it, and must be treated as a positive ion with a fractional electronic charge, since its activity coefficient, in these reactions is unusually influenced, for a neutral molecule, by an ionic atmosphere.

There is a possibility that resonance might appreciably influence this treatment since the resonance structures of the nucleophile would not concentrate, strictly, a full negative charge on the carbon atom in question, but rather would tend to disperse it. If the charge dispersal effects were dissimilar for both the nucleophile and the transition state, the ratio of activity coefficients in eq. [34] would have a value other than unity, negating the validity of eq. [35] for the reactions treated here. The operation of such an effect is denied by an analysis of the data. Since 2,4-pentanedione has more important contributing resonance structures than does ethyl acetoacetate, the ratio of activity coefficients in eq. [34] would not be equal, and this would be evident from the differences in the slopes of the lines for their reactions with the same olefin (acrylonitrile or methyl vinyl ketone). Table VII shows that there is no such difference in slope, so that the effect of resonance in the nucleophile which would effectively reduce its charge and change its activity coefficient must also be operative in the resonance hybrid of eq. [3], thus maintaining the ratio at a value of unity. The values of the slopes for reactions [8] and [10] are almost identical to those for reactions [12] and [13] (all involving reactions with acrylonitrile), where the non-resonant methoxide and ethoxide ions are the nucleophilic reagents. Consequently the ratio of activity coefficients in these cases should also be unity.

It is not surprising that the absolute value of the slope should decrease with decreasing dielectric constant, if one considers z_b to be the partial positive charge on the primary carbon atom due to polarization by the conjugated electronegative groups. Water would be able to stabilize a positive charge much better than either ethanol or methanol, because it is much more polar, and would encounter much less steric hindrance. The carbon atom in question would therefore be able to accommodate a greater charge. The interpretation of the slopes of the lines for the ethanol and methanol systems is highly debatable, since in these much lower dielectric media there is a very great probability of ion-pair formation which would invalidate any quantitative treatment of the data. This possibility is further supported by the fact that only at very low ionic strengths does the data linearly fit eq. [37]. Table VIII lists the rate constants from Tables II–V, corrected for the influence of both base concentration and ionic strength.

Reactions [8], [10], [12], and [13] were investigated in methanol and in ethanol, as well as in aqueous solution, and it was found that a plot of log k against the reciprocal of the dielectric constant, $(1/D)$, was linear. The logarithm of the activity coefficient of an ion of radius ρ in a medium of dielectric constant D, relative to that of a vacuum, is given by (19):

$$[39] \quad \ln \gamma_a = -e^2 z_a^2 (1 - 1/D)/(2\rho k_b T)$$

where e is the electronic charge, z_a is the ionic charge, k_b is Boltzmann's constant, and T is the

absolute temperature. Assuming the proposed mechanism to be correct, and again using the method employed to obtain eq. [36],

$$[40] \quad \log_{10} k = \log_{10} k' - 2.303\, e^2 z_a^2 (1 - 1/D)/(2\rho k_b T)$$

or,

$$[41] \quad \log_{10} k = \text{const.} + 2.303\, e^2 z_a^2/(2\rho k_b T D)$$

Equation [41] predicts that the rate should increase with decreasing dielectric constant for the reactions studied, and this can be observed in Tables III and IV. The apparent linearity obtained is interesting in that it supports ionic strength measurements, indicating that the activity coefficients for the double bonded compounds can be treated as though they were those of ions of partial electronic charge. The limited scope of the present work, however, prohibits any conclusions beyond an interesting, although limited parallel. A more intensive study was attempted, without very much success, as shown below.

Reactions [12] and [13] were studied over a range of water–alcohol mixed solvents. Log k values were plotted against $1/D$, but no linear relationship was obtained. This result is probably due to a combination of contributing factors, such as non-uniform dielectric constant on a molecular level, increased importance of ion-pair formation as D decreases, variations in ionization constants over a range of mixed solvents, and appreciable changes in activity coefficient ratios as the dielectric constant is varied. For these reasons no detailed analysis of the slopes for any of these data was made.

The rates listed in Table VIII uniformly show a linear Arrhenius plot for log k vs. $1/T$. The activation entropy values reported in Table IX are apparently unusual in that they are abnormally large in a negative sense. Although highly negative entropy values have been assumed to be due to increased electrorestriction of solvent in the transition state, this would appear to be quite unlikely in this situation. These values should correspond to an intensely restricted transition state, which would most likely reflect a cyclic mechanism. Although these values are too negative to be consonant with earlier reported values for other cyclization processes (20), recent studies appear to agree with the present data in that Wulfman and co-workers (21) have reported an activation entropy of −55.6 e.u. for the reaction of diethyl malonate with methyl crotonate, leading them to a similar mechanistic interpretation.

Even though the entropies are highly unusual, they are quite plausible if the reaction course is considered in molecular detail. The anion, A^-, formed from HA, is a stable and readily formed species because of the formation of a resonance hybrid in which there is an overlap of π orbitals which restricts the 5 atoms (O—C—C—C—O) to a plane. The minimum energy path for anion attack and subsequent reaction requires that the

four π orbitals of the conjugated olefinic molecule be similarly parallel, for maximum overlap and delocalization enabling reaction. Thus, there is not only restricted rotation for the 9 atoms, but a condition for reaction arises whereby rotation for the 9 atoms involved is almost totally forbidden, due to the necessity for total π orbital overlap. Sufficient degrees of freedom of the entire system are therefore lost, with nine π orbitals parallel and overlapping, to account qualitatively for the apparently extremely negative entropy values.

Structural effects are also quite significant. As far as the polarization of the double bond is concerned, the acetyl group is seen to be more powerfully electron withdrawing than the cyano group on the double bond, as evidenced by the data in Tables II to IV and VIII. An examination of the data for the reactions of 2,4-pentanedione and ethyl acetoacetate with either methyl vinyl ketone or acrylonitrile reveals that although the anion of the former is more easily formed, the specific reaction rate constant is smaller for the reaction than for that of the latter compound. The 2,4-pentanedione is less reactive as a nucleophile than is the ethyl acetoacetate, since anionic charges would be dispersed to a greater extent. For this same reason, the dione is more acidic as reflected by its larger K_a value as listed in Table VI.

On the basis of experimental evidence reported here, the following mechanistic statements appear to apply without exception to all examples of the Michael condensation investigated during the course of this research:

(*i*) The reaction involves an anion attack on a double bond, which has been polarized, to form an activated complex.

(*ii*) The activated complex forms an intermediate through cyclization in which there are intensely hindered rotations because of π orbital overlap.

(*iii*) The cyclic intermediate reacts, most probably with the solvent, to accept a proton and form terminal products.

(*iv*) The polarized double bond, insofar as rate measurements are concerned, can be treated as a partial ion (i.e., an ion of partial positive electronic charge).

The observed variations of rate in various media and under different experimental conditions can then be explained, at least on a semi-quantitative basis, in terms of the above four statements.

Etude de la décomposition des diazo-2 dicétones-1,3. I. Cas du diazo-2 diméthyl-5,5 cyclohexanedione-1,3

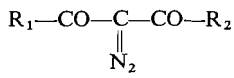
HENRI VESCHAMBRE[1] ET DANIEL VOCELLE[2]
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 16 octobre 1968

La décomposition thermique dans le xylène et les décompositions photochimiques dans le tétrachlorure de carbone, les alcools méthylique et éthylique, et le cyclohexène, du diazo-2 diméthyl-5,5 cyclohexanedione-1,3 (**2**) ont été étudiées. La thermolyse donne le composé **4**. La photolyse dans le CCl_4 fournit **4** et **5** tandis que dans le méthanol **6** et **7** sont obtenus. L'éthanol conduit aux composés **8**, **9**, **10** et **11**. Enfin la photolyse dans le cyclohexène donne les produits **5** et **12**. Un mécanisme, expliquant la formation de ces différents composés, sera proposé.

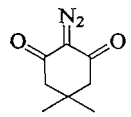
Canadian Journal of Chemistry, 47, 1981 (1969)

La décomposition de diazo-dicétones du type **1** est fort mal connue.



1

Quelques cas seulement ont été étudiés jusqu'à présent et souvent de façon incomplète (1, 2). Devant ces résultats fragmentaires, nous avons voulu faire une étude complète et approfondie de la décomposition des diazo du type **1** dans différents solvants. Pour ce faire, l'étude de la décomposition du diazo-2 diméthyl-5,5 cyclohexanedione-1,3 (**2**) a été entreprise.



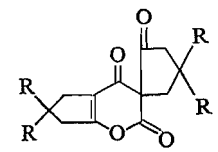
2

Le composé **2** a déjà été synthétisé. Pour notre étude nous avons utilisé la méthode mise au point par Yates *et al.* (3) en y apportant de très légères modifications (voir Partie expérimentale). Il existe deux modes principaux de décomposition de dérivés diazoïques (4): la thermolyse et la photolyse. Pour notre part, nous avons utilisé ces deux procédés; soit la thermolyse dans le benzène en présence de poudre de cuivre ou mieux encore dans le xylène, et la photolyse dans le tétrachlorure de carbone, dans les alcools méthylique et éthylique et dans le cyclohexène.

Résultats

Thermolyse

Le diazo **2**, porté à reflux dans le benzène en présence de poudre de cuivre pendant 30 h, n'a subi aucune décomposition. Toutefois à 140 °C et dans le xylène, sans poudre de cuivre, **2** a conduit au tétraméthyl-6,6,4′,4′ trioxo-2,4,2′ hexahydro-2,3,4,5,6,7 spiro[cyclopenta(*b*)pyran-3,1′ cyclopentane] (**4**) avec un rendement de 76%.



3, R = H **4**, R = CH_3

Ce composé présente les caractéristiques suivantes: spectre infrarouge (i.r.): bandes à 1647, 1678, 1752 et 1788 cm^{-1}. Stetter et Kiehs (1) attribuent au composé non méthylé **3** des bandes à 1647, 1672, 1744 et 1786 cm^{-1}. Le spectre u.v. de **4** dans le chloroforme possède un maximum à 278 mμ (ε_{max} = 7940) alors que pour **3** Stetter et Kiehs (1) ont obtenu λ_{max} = 277 mμ (ε_{max} = 7900).

Le spectre de résonance magnétique nucléaire (r.m.n.) est constitué par deux systèmes de bandes ayant les caractéristiques suivantes: un système localisé à 8.81, 8.78 et 8.72 τ répondant pour 12 protons (soit 4 CH_3) et un système comportant deux séries de bandes, l'une sous forme de deux pics mals séparés à 7.7 et 7.65 τ et l'autre sous

Schéma 1

forme de quatre pics mals résolus à 7.45, 7.37, 7.34 et 7.30 τ. L'ensemble de ce dernier système répond pour 8 protons (soit 4 CH_2). En outre l'analyse est en accord avec la formule brute de **4** soit $C_{16}H_{20}O_4$. L'ensemble de ces données vérifie bien la structure attribuée au composé **4** obtenu au cours de la thermolyse de **2** dans le xylène.

Photolyse

Les résultats de toutes les réactions photochimiques faites à partir de **2** paraissent au Schéma 1. Le même mode opératoire a été suivi dans presque tous les cas, soit une photolyse d'une heure sous atmosphère d'azote, avec une lampe Hanovia 450 W, sans filtre. Dans chaque cas, à la fin de la réaction, le solvant a été soigneusement éliminé par distillation. Le résidu obtenu consistait en un mélange de solides et de liquides qui furent séparés par filtration. Des analyses par chromatographie sur couches minces, suivies par des chromatographies sur colonne permirent d'isoler les produits réactionnels. Les pourcentages paraissant au Schéma 1 sont des pourcentages de récupération qui furent dans la presque totalité des cas supérieurs à 90%.

(a) Photolyse dans le tétrachlorure de carbone

Le solide obtenu de la photolyse (76%) a présenté un point de fusion et des spectres i.r., u.v. et de r.m.n. rigoureusement identiques à ceux obtenus pour le composé **4**; ce qui l'identifia.

Le liquide présentait après distillation une

For personal use only.

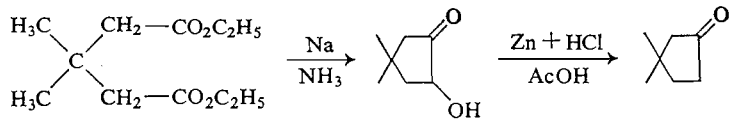

Schéma 2

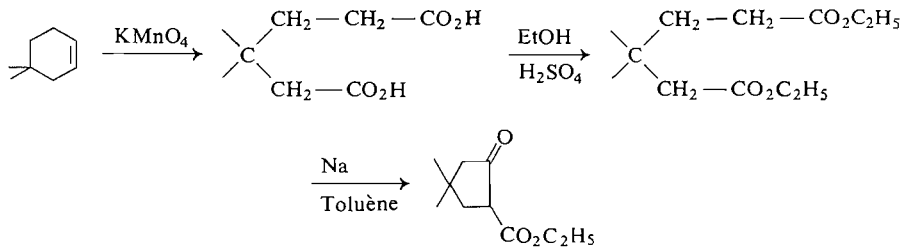

Schéma 3

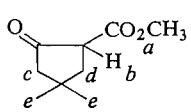
bande i.r. à 1745 cm^{-1}, un dérivé dinitro-2,4 phénylhydrazone fondant à 145–146 °C et une semicarbazone fondant à 180–181 °C. Ces dérivés se sont révélés identiques à ceux obtenus d'un échantillon authentique de diméthyl-3,3 cyclopentanone synthétisé selon le mode réactionnel décrit au Schéma 2. De la photolyse il a été tiré 18% de diméthyl-3,3 cyclopentanone (**5**).

(b) Photolyse dans les alcools

Les photolyses dans le méthanol et l'éthanol donnèrent essentiellement les mêmes types de composés.

Dans le méthanol purifié, la photolyse de **2** donne 70% de dérivé dimédonique du méthanal (**6**) et 20% de diméthyl-4,4 oxo-2 cyclopentanecarboxylate de méthyle (**7**). De plus la chromatographie sur colonne de silicagel permet d'isoler un mélange de liquides (4%) qui présente en i.r. des bandes hydroxyle et carbonyle. En outre le spectre de r.m.n. de ce mélange indique l'incorporation de groupements méthoxy. Ce mélange ne fut pas étudié plus à fond. Le composé **6** a été identifié à l'aide d'un échantillon authentique obtenu par réaction de la dimédone sur le formaldéhyde selon la méthode de Horning et Horning (5). Le céto-ester a été identifié comme étant le diméthyl-4,4 oxo-2 cyclopentanecarboxylate de méthyle (**7**), par ses bandes i.r. à 1750 et 1730 cm^{-1} et par son spectre de r.m.n. dont les valeurs sont données ci-dessous. De plus l'hydrolyse acide de **7** conduit à la diméthyl-3,3 cyclopentanone (**5**).



a: 6.24 τ (singulet)
b: 6.57 τ (triplet)
c: 7.78 τ (singulet)
d: 7.84 τ (doublet)
e: 8.77 et 8.93 τ (singulet)

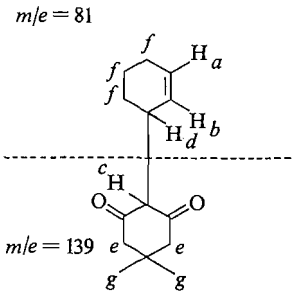
Dans l'éthanol, les mêmes types de produits ont été observés. Ainsi 40% de dérivé dimédonique de l'acétaldéhyde (**10**) et 10% de dioxo-4,5 pentaméthyl-2,2,7,7,9 octahydroxanthène (**9**) ont été obtenus. Ils ont été identifiés à l'aide d'échantillons authentiques obtenus par réaction de la dimédone sur l'acétaldéhyde (5). De plus, 24% de dimédone (**8**) étaient présents de même que 6% de diméthyl-4,4 oxo-2 cyclopentanecarboxylate d'éthyle (**11**). Ce dernier composé a été identifié de deux façons: d'une part à l'aide d'un échantillon authentique obtenu selon le mode opérationnel décrit au Schéma 3, et d'autre part au moyen d'une hydrolyse acide de **11** qui donna **5**. Il a également été trouvé un mélange de plusieurs produits liquides (14%) qui n'ont pas été identifiés.

(c) Photolyse dans le cyclohexène

Lorsque nous avons utilisé du cyclohexène parfaitement pur, la photolyse a conduit aux composés **5** et **12** dans des proportions respectives de 18 et 30%. Un important résidu gommeux s'est également formé (1 g). Le composé **12** a été identifié par son spectre i.r.: bandes à 3020, 1755 et 1720 cm^{-1}, par une détermination de masse moléculaire: 222 ± 2 (théorique 220.3),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

par analyse et par son spectre de r.m.n. dont les valeurs sont données ci-après:



12

a et *b*: 4.0 à 4.5 τ (multiplet)
c: 4.75 τ (singulet très large)
d: 6.63 τ (triplet)
e: 7.8 et 8.0 τ (singulet)
f: 8.1 à 8.7 τ (multiplet)
g: 8.78 et 8.94 τ (singulet)

De plus le spectre de masse montre des fragments importants à m/e = 81 et 139. Le pic parent n'est pas présent.

Discussion

Le décomposition thermique et photolytique des diazocétones est fort bien connue (4). Elle conduit généralement à un cétène selon le mécanisme ci-dessous (Schéma 4)

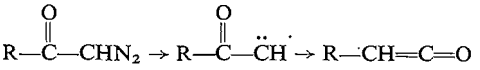


Schéma 4

Ce dernier n'est qu'un intermédiaire, car il réagit habituellement avec le solvant ou se réarrange pour donner des composés plus stables.

Dans le cas du diazo-2 diméthyl-5,5 cyclohexanedione-1,3 un tel mécanisme semble intervenir à la fois dans la thermolyse dans le xylène et dans la photolyse dans le tétrachlorure de carbone.

Ainsi Stetter et Kiehs (1), dans la décomposition thermique du diazo-2 cyclohexanedione-1,3, ont obtenu le composé **3** et préconisé un intermédiaire cétène pour expliquer leur résultat (Schéma 5, R = H).

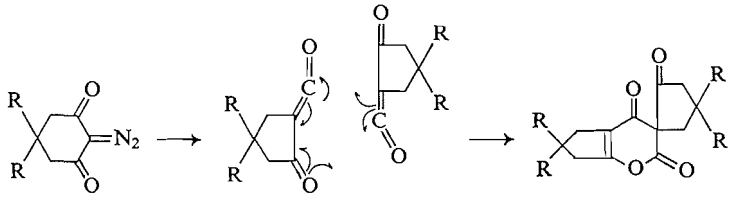

Schéma 5

La thermolyse de **2** donnant **4** (R = CH_3) a donc lieu selon le même mécanisme.

La photolyse du diazo **2** dans le tétrachlorure de carbone, conduisant à **4** et à la diméthyl-3,3 cyclopentanone (**5**), peut également s'expliquer par un mécanisme admettant le même cétène comme intermédiaire (Schéma 6).

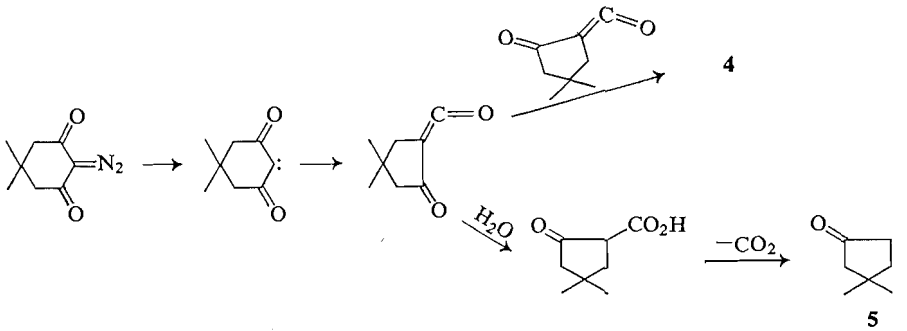

Schéma 6

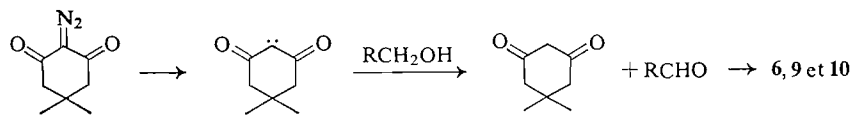
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

La formation de la cétone **5** par réaction du cétène avec l'eau, suivie d'une décarboxylation, semble être confirmée par le fait que, plusieurs photolyses de **2** dans le tétrachlorure de carbone contenant une proportion variable d'eau, donnèrent un pourcentage plus élevé de **5** à mesure que la proportion d'eau dans le solvant augmentait. En effet, selon que l'on utilise un tétrachlorure de carbone séché, non séché ou saturé d'eau, les pourcentages en composé **5** passent respectivement de 18 à 40% et à 57%. (Il faudrait moins de 0.003% d'eau dans le tétrachlorure de carbone pour éviter toute formation de **5**.)

Les résultats des photolyses du diazo **2** dans les alcools méthylique et éthylique montrent que le mécanisme décrit au Schéma 6 n'est pas le seul à intervenir. En effet, la formation des composés **6**, **9** et **10**, ne peut que provenir d'une réaction de la dimédone sur le formaldéhyde et l'acétaldéhyde. Ceci implique d'une part l'oxydation du méthanol en formaldéhyde et de l'éthanol en acétaldéhyde et d'autre part la réduction du carbène en dimédone. Le mécanisme proposé pour le système d'oxydo–réduction est le suivant (Schéma 7).

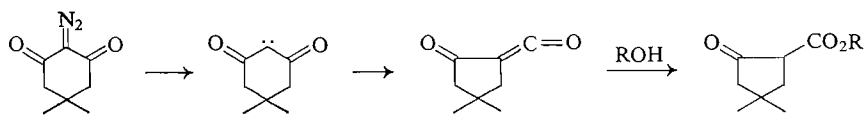


8

Schéma 7

Ce mécanisme est déjà confirmé par la présence de **8** dans les produits finaux de la réaction dans l'éthanol, et par la mise en évidence de la formation d'acétaldéhyde au cours de la réaction. Ainsi, lorsqu'on fait barbotter l'azote à la sortie de l'appareil de photolyse dans une solution de dinitro-2,4 phénylhydrazine, un précipité de dinitro-2,4 phénylhydrazone de l'acétaldéhyde est obtenu. Un système d'oxydo–réduction du même type a déjà été mentionné par Weygand, Schwenke et Bestmann (6).

Les céto-esters **7** et **11** sont obtenus par un réarrangement de Wolff classique (4) (Schéma 8).



7, R = H
11, R = CH_3

Schéma 8

La formation de carbène, normale dans ces réactions (4), a cependant été confirmée par la photolyse du diazo **2** dans le cyclohexène. Elle donne le composé **12** typique d'une réaction d'un carbène sur une oléfine (2, 4).

Conclusion

L'ensemble des mécanismes, proposé pour expliquer la formation des composés obtenus au cours des décompositions du diazo-2 diméthyl-5,5 cyclohexanedione-1,3, montrent que ces produits se forment: soit par une contraction de cycle provenant de la transposition du carbène en cétène, soit par un système d'oxydo-réduction faisant intervenir le solvant et le carbène lui-même.

Partie expérimentale

Les points de fusion ont été déterminés dans l'appareil Büchi Modèle Dr. Tottoli et sont donnés sans correction. Les spectres i.r. ont été enregistrés sur un spectrophotomètre Beckman IR 8 et les spectres u.v. sur "spectronic 505" de Bausch and Lomb. Les spectres de r.m.n. ont été réalisés sur un appareil Jéol type C 60 H dans le chloroforme deutérié comme solvant. Les spectres de masse ont été pris sur un appareil Hitachi Perkin–Elmer RMU-6D. Les microanalyses on été effectuées par "Schwarzkoff Microanalytical Laboratory," Woodside, New York, U.S.A. Les poids moléculaires ont été déterminés sur un appareil Hewlett–Packard type Mechrolab 301 A. Les chromatographies en phase gazeuse ont été

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

réalisées sur un appareil F et M modèle 810; et les chromatographies sur couches minces ont été faites sur des "chromagram" Eastman-Kodak No. 6060. Dans ce dernier cas l'éluant utilisé a toujours été le mélange cyclohexane – acétate d'éthyle 75:25 en volume.

Synthèse du diazo-2 diméthyl-5,5 cyclohexanedione-1,3 (2)

Selon la méthode décrite par Rosenberg, Yates, Hendrickson et Wolf (3) un mélange de diméthyl-5,5 cyclohexanedione-1,3 et d'azoture de tosyle a été mis en suspension dans l'éther anhydre sous agitation. Lorsque la température est inférieure à 10 °C on ajoute rapidement de la triéthylamine et on abandonne 15 min à froid. Après 1 h à température ambiante, un abondant précipité s'est formé, il est filtré et lavé à l'éther. La solution éthérée est lavée à la soude 10% et à l'eau. Après séchage et élimination du solvant, le solide restant est recristallisé dans l'alcool à 95°; rendement 75%; p.f. 106–108° (litt. p.f. 106–108° (3)).

Infrarouge ($CHCl_3$): 2180, 2130 et 1640 cm^{-1}; r.m.n.: 7.8 τ (singulet 4 H) et 8.88 τ (singulet 6 H).

Décomposition thermique du diazo-2 diméthyl-5,5 cyclohexanedione-1,3 (2)

En solution dans le benzène, et en présence de poudre de cuivre, le diazo **2** ne subit aucune décomposition apparente même après 30 h de reflux.

Dans le xylène la décomposition s'effectue facilement: dans un ballon de 100 ml à 2 tubulures, muni d'un réfrigérant et d'une ampoule à brome, 30 ml de xylène ont été placés. Lorsque la température du bain d'huile, dans lequel est placé le ballon, atteint 140°, on ajoute goutte à goutte une solution de 1.5 g de **2** dans 20 ml de xylène. Le dégagement gazeux cesse 15 min après la fin de l'addition de la solution de diazo. La solution encore chaude est traitée par du charbon actif et filtrée. On élimine le xylène sous vide partiel, il reste une huile jaune claire qui cristallise au refroidissement. Après recristallisation dans l'éther un solide blanc est obtenu, p.f. 110–120°. Les propriétés spectrales sont rapportées dans le texte.

Anal. Calc. pour $C_{16}H_{20}O_4$ (276.3): C, 62.59; H, 7.25. Trouvé: C, 62.29; H, 7.23.

Décomposition photochimique du diazo-2 diméthyl-5,5 cyclohexanedione-1,3 (2)

Toutes les photolyses ont été faites avec une lampe Hanovia 450 W et sous courant d'azote.

(a) Photolyse dans le tétrachlorure de carbone

Une solution de 5 g de diazo **2**, dans 1 000 ml de tétrachlorure de carbone (Anachemia Reagent) séchés sur des tamis moléculaires, a été photolysée pendant 1 h. Après quoi, le solvant est éliminé par distillation. On obtient 3.8 g de résidu qui cristallise partiellement au refroidissement et dont les spectres i.r. indique l'absence complète de **2**. Par filtration, il fut séparé 3.2 g d'un solide qui après recristallisation dans l'éther fut identifié comme étant **4** et 0.6 g d'un liquide qui s'avéra être la diméthyl-3,3 cyclopentanone (5).

Le solide blanc homogène en chromatographie sur couches minces, présentait les mêmes spectres i.r., u.v. et de r.m.n. qu'un échantillon authentique de **4**. En outre, le point de fusion mixte ne donna aucune dépression.

Le liquide également homogène en chromatographie en phase gazeuse (colonne de 8 pieds de polyester de Craig 20% sur chromosorb P; T °C: 160; temps de rétention: 11 min) présente en i.r. une bande à 1745 cm^{-1}. En outre il forme très facilement une dinitro-2,4 phénylhydrazone (p.f. 145–146 °C) et une semicarbazone (p.f. 180–181 °C). Ces deux dérivés possèdent les mêmes points de fusion et les mêmes caractéristiques spectrales que ceux obtenus de la diméthyl-3,3 cyclopentanone (**5**) synthétisée, via une condensation acyloïne du diméthyl-3,3 glutarate d'éthyle (voir plus loin).

Une photolyse de **2** dans un tétrachlorure commercial non séché nous permet d'isoler de la même manière 1.8 g de **4** et 1.7 g de **5**. Une photolyse de **2**, dans du tétrachlorure de carbone ayant séjourné 48 h sur de l'eau, fournit 1.5 g de **4** et 2.4 g de **5**.

(b) Photolyse dans l'alcool méthylique

Une solution de 5 g de diazo-2 diméthyl-5,5 cyclohexanedione-1,3, dans 1000 ml de méthanol purifié selon la méthode de Lund et Bjerrum (7), a été photolysée pendant 1 h. Le méthanol est par la suite soigneusement distillé et le résidu obtenu cristallise en partie. Une filtration permet de recueillir 3.1 g de solide et 1 g de liquide.

Le produit solide est homogène (chromatographie sur couches minces) après une recristallisation dans le méthanol. Il fut identifié comme étant le dérivé dimédonique du formaldéhyde (6). Il présente en effet les caractéristiques suivantes: p.f. 191–192 °C (litt. p.f. 191–192 °C (5)); i.r. ($CHCl_3$): bande large entre 3400 et 2400 cm^{-1}, 1611 et 1592 cm^{-1}; u.v. (ethanol 95%): λ_{max} = 258 mμ ε_{max} = 20 300; r.m.n.: 8.96 τ (12 H singulet); 7.75 τ (4 H, singulet), 6.83 τ (2 H, singulet), −1.23 τ (2 H singulet).

Ces caractéristiques sont rigoureusement identiques à celles obtenues pour le dérivé dimédonique du formaldéhyde synthétisé à partir de dimédone et de formaldéhyde selon la méthode de Horning et Horning (5).

Le produit liquide est en fait un mélange assez complexe de plusieurs composés (chromatographie en phase gazeuse: colonne 8 pieds de Polyester de Craig 20% sur chromosorb P; T °C = 190; temps de rétention de 6 à 40 min). Toutefois un produit est nettement majoritaire. Une chromatographie sur colonne de silicagel (Baker Analyzed 150 g), en utilisant le mélange cyclohexane – acétate d'éthyle 75:25 en volume comme éluant, permet d'isoler le diméthyl-4,4 oxo-2 cyclopentane-carboxylate de méthyle ((**7**), 0.540 g, 20%). Les caractéristiques spectrales sont rapportées dans le texte.

La structure de ce composé a été confirmée par une hydrolyse acide qui donna la diméthyl-3,3 cyclopentanone (**5**). Celle-ci fut identifié par le point de fusion mixte de sa semicarbazone et de son dérivé dinitro-2,4 phénylhydrazone.

La chromatographie sur colonne ne put séparer les autres constituants du mélange (0.160 mg) qui ne furent pas identifiés.

(c) Phololyse dans l'alcool éthylique

De la même façon que pour le méthanol, 5 g de diazo **2** dans 1 000 ml d'éthanol purifié selon la méthode de Lund et Bjerum (7) ont été photolysés pendant 1 h. Le solvant a été soigneusement distillé, le résidu obtenu cristallise en partie et fournit après filtration une phase solide (3.3 g) et une phase liquide (1.2 g).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Une chromatographie sur couches minces du solide montra que celui-ci contenait au moins 3 produits. Une chromatographie sur colonne de silicagel (Baker Analyzed 300 g) fournit deux fractions. En éluant avec un mélange de cyclohexane – acétate d'éthyle (75:25 en volume) les composés **9** et **10** furent obtenus en mélange (2.3 g) et dans les proportions respectives de 20 et 80. Une cristallisation fractionnée dans le méthanol aqueux permet d'isoler d'abord le pentaméthyl-2,2,7,7,9 dioxo-4,5 octahydroxanthène (**9**) p.f. 178–179 °C (litt. p.f. 176–177 °C (5)) dont es caractéristiques sont les suivantes: i.r.: 1660 et 1620 cm^{-1}; u.v. (ethanol 95%): λ_{max} = 232 mμ ε_{max} = 15 000; r.m.n.: 6.34 τ (1 H quadruplet); 7.62 et 7.80 τ (8 H singulet); 8.86 (12 H singulet); 8.88 (3 H doublet).

L'addition supplémentaire d'eau permet d'obtenir le dérivé dimédonique de l'acétaldéhyde (**10**) pur, p.f. 142–143 °C (litt. p.f. 141–142 °C (5)). Dont les caractéristiques sont les suivantes:

Infrarouge: bande large entre 3400 et 2400 cm^{-1} et 1595 cm^{-1}; r.m.n.: 5.84 τ (1 H quadruplet); 7.7 (8 H singulet); 8.22 τ (3 H doublet); 8.95 (12 H singulet); −3.5 τ (2 H singulet).

Ces deux composés se sont révélés identiques au dérivé dimédonique de l'acétaldéhyde et à l'octahydroxanthène synthétisés à partir de la dimédone et d'acétaldéhyde selon le mode opératoire de Horning et Horning (5).

Le composé **10** obtenu par photolyse se transforme complètement en **11** par action de l'acide chlorhydrique en milieu éthanolique. Il a pu être montré que **9** est obtenu non pas au cours de la photolyse mais essentiellement pendant la distillation du solvant. En effet si le solvant est éliminé à froid, l'étude des composés obtenus ne montrent plus que la présence de traces de **9**.

La deuxième fraction de la chromatographie sur colonne est obtenue en éluant avec de l'acétate d'éthyle pur. Elle fournit 1 g de diméthyl-5,5 cyclohexanedione-1,3 (**8**) identifiée par comparaison avec un échantillon authentique.

La fraction liquide (1.2 g) était constituée de plusieurs composés comme le montra la chromatographie en couches minces. Elle fut traitée par la soude 10%. La solution sodique, acidifiée par HCl 10% et extraite à l'éther, fournit 0.500 g de diméthyl-4,4 oxo-2 cyclopentanecarboxylate d'éthyle (**11**). Ce composé présente les caractéristiques suivantes:

Infrarouge: 1745 et 1730 cm^{-1}; r.m.n.: 5.80 τ (2 H quadruplet); 6.60 τ (1 H triplet); 7.80 τ (2 H singulet); 7.85 τ (2 H doublet); 8.72 τ (3 H triplet); 8.75 τ (3 H singulet); 8.92 τ (3 H singulet).

Ces caractéristiques sont rigoureusement identiques à celles obtenues pour le diméthyl-4,4 oxo-2 cyclopentanecarboxylate d'éthyle provenant d'une condensation de Dieckman sur le diméthyl-3,3 adipate d'éthyle (voir synthèse plus loin). En outre la structure de **11** a été confirmée de la façon suivante: 0.250 g de **11** a été chauffé en suspension dans une solution d'acide chlorhydrique 10%; après 3 h de reflux et extraction à l'éther, on isole la diméthyl-3,3 cyclopentanone (**5**) qui fut identifiée par le point de fusion mixte de son dérivé dinitro-2,4 phénylhydrazone. La fraction non soluble dans la soude 10% (0.7 g) est un mélange de plusieurs composés. La chromatographie en phase gazeuse (colonne 8 pieds Polyester de Craig 20% sur chromosorb P; T °C = 190) a montré la présence d'au moins 4 produits qui n'ont pas été identifiés. Le spectre de r.m.n. de ce mélange indique l'incorporation de groupements éthyles.

(d) Photolyse dans le cyclohexène

Cas du cyclohexène purifié—Diazo-2 diméthyl-5,5 cyclohexanedione-1,3 (5 g) a été photolysé en solution dans 1 000 ml de cyclohexène purifiés selon la méthode de Waterman et Van Wester (8). La pureté du solvant a été vérifiée par chromatographie en phase gazeuse. Pour que tout le diazo disparaisse il a été nécessaire d'effectuer la photolyse pendant 4 h. Le cyclohexène fut ensuite distillé et le résidu liquide, par distillation fractionnée fournit 2 fractions:

Fraction 1 ($p.e._7$ = 48–50 °C (0.600 g))—Ce composé s'avèra être la diméthyl-3,3 cyclopentanone (**5**). Elle fut identifiée par comparaison des spectres i.r. et de r.m.n. et par le point de fusion mixte de son dérivé dinitro-2,4 phénylhydrazone.

Fraction 2 ($p.e._7$ = 145–155 °C (2.6 g))—Le liquide légèrement souillé par deux autres composés (chromatographie sur couches minces) fut purifié par une chromatographie sur colonne de silicagel (200 g Baker Analyzed). En éluant avec un mélange cyclohexane – acétate d'éthyle 75:25 en volume on obtient en tête 2.0 g de liquide pur. Ce liquide répond à la structure du (cyclohexen-2)yl-2 diméthyl-5,5 cyclohexanedione-1,3 (**12**) dont les caractéristiques spectrales sont rapportées dans le texte.

Anal. Calc. pour $C_{14}H_{20}O_2$ (220.3): C, 76.33; H, 9.15. Trouvé: C, 76.14; H, 9.39.

Spectre de masse: pic important à 81 (100%) et 139 (30%). On a également obtenu un abondant résidu gommeux (1 g) non distillable.

Synthèse de la diméthyl-3,3 cyclopentanone (5)

La diméthyl-3,3 hydroxy-5 cyclopentanone est d'abord préparée par une synthèse acyloïne à partir de diméthyl-3,3 glutarate d'éthyle en présence de sodium dans l'ammoniac. La méthode utilisée est celle décrite par Kwart et Ford (9).

L'acyloïne obtenue a été réduite en diméthyl-3,3 cyclopentanone par la poudre de zinc et l'acide chlorhydrique en milieu acétique selon le procédé de Prelog, Frenkiel, Kolbe et Barman (10).

La distillation finale conduit à un liquide $p.e._{12}$ = 55–60 °C (litt. $p.e._{760}$ = 154–155 °C (11)); semicarbazone: p.f. 180–181 °C (litt. p.f. 178–179 °C (11)); dinitro-2,4 phénylhydrazone: p.f. 145–146.5°.

Synthèse du diméthyl-4,4 oxo-2 cyclopentanecarboxylate d'éthyle

L'acide diméthyl-3,3 adipique a été obtenu par oxydation du diméthyl-4,4 cyclohexène par le permanganate de potassium tel que décrit par Hibbitt et Linstead (12).

Le diméthyl-3,3 adipate d'éthyle a été ensuite transformé en diméthyl-4,4 oxo-2 cyclopentanecarboxylate d'éthyle par une réaction de Dieckman utilisant le sodium dans le toluène selon la méthode de Pinkney (13).

Par distillation, on obtient un liquide $p.e._7$ = 100–105 °C et dont les caractéristiques spectrales sont les suivantes:

Infrarouge (pur): bandes à 1745 et 1730 cm^{-1}; r.m.n.: bandes à 5.80 τ (2 H quadruplet); 6.60 τ (1 H triplet); 7.80 τ (2 H singulet); 7.85 τ (2 H doublet), 8.72 τ (3 H triplet); 8.76 τ (3 H singulet); 8.92 τ (3 H singulet).

Mise en évidence de la formation d'acétaldéhyde au cours de la photolyse de **2** *dans l'éthanol*

La formation d'acétaldéhyde au cours de la photolyse de **2** dans 'éthanol a été mise en évidence en faisant barbotter l'azote, à la sortie de l'appareil de photolyse, dans une solution de dinitro-2,4 phénylhydrazine. Après 1 h de photolyse, un abondant précipité jaune orangé, s'est formé dans la solution-piège. Ce précipité était le dérivé dinitro-2,4 phénylhydrazone de l'acétaldéhyde, p.f. 159–161 °C. Le point de fusion mixte n'a donné lieu à aucune dépression.

Remerciements

Nous remercions Monsieur le Professeur H. Favre qui a gracieusement mis son laboratoire à notre disposition et sans qui ce travail n'aurait pu avoir lieu. Nos remerciements vont également à Monsieur R. Mayer pour les spectres de résonance magnétique nucléaire, à Monsieur J. C. Regenass pour les spectres de masse et à Monsieur R. Favier pour les déterminations de masse moléculaire. Finalement nous tenons à remercier le Conseil National de Recherches du Canada pour l'aide financière accordée et pour une bourse de recherches post-doctorale (subvention A-14).

Approaches to the synthesis of triterpenoids. I. Methyl group migration to the 9β-position in steroids as a route to the cucurbitacins. A possible structural feature directing epoxide cleavage rearrangements[1,2]

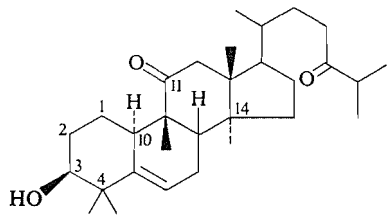
J. W. ApSimon, R. R. King, and J. J. Rosenfeld
Department of Chemistry, Carleton University, Ottawa, Canada

Received November 21, 1968

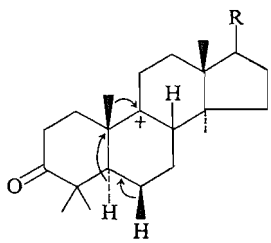
The BF_3 catalyzed cleavage of some steroidal 9α,11α-epoxides has been studied in an attempt to induce migration of the C-10 methyl group to C-9. In the case of 9α,11α-epoxyandrost-4-ene-3,17-dione, cleavage with BF_3 gas in benzene led to two major products. One of these was the required 3,11α-dihydroxy-9β-methylestra-1,3,5(10)-triene-17-one, thus leading to a novel class of steroids and possibly opening a route to the synthesis of compounds of the cucurbitacin class. The other main product was shown to be 11α-hydroxy-9β-androst-4,8(14)-diene-3,17-dione. A possible structural feature directing the rearrangement pathway to these materials is proposed from the study of other epoxide rearrangements and some reported in the literature.

Canadian Journal of Chemistry, 47, 1989 (1969)

The cucurbitacins (e.g. bryogenin **1** (1)) represent an interesting variation in the biogenetic pathways leading to the tetracyclic triterpenes, a migration of one methyl group from C-10 to C-9 in a lanostane precursor **2** (arrows) appearing to account for these compounds (2, 3). This series of compounds interested us from a synthetic point of view since there did not appear to be any direct correlation with other materials, and we felt that it was feasible to carry out such a methyl group migration chemically on a suitable triterpene precursor. This paper describes our initial studies in this direction.

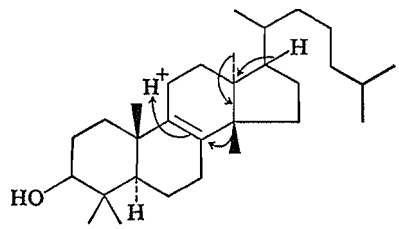


1

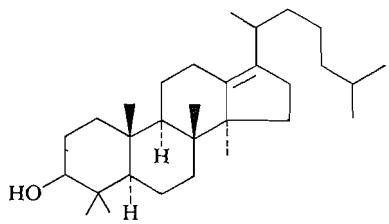


2

There are many reports of methyl group migrations in terpenoids usually initiated by protonation of a suitably situated double bond (4) such as the euphenol **3** to isoeuphenol **4** conversion (5).



3



4

At the outset we rejected this type of rearrangement for our studies since it involved the saturation of a double bond at one terminus of the pathway and hence loss of some functionality required for further elaboration of the molecule at a later stage. We therefore decided to study the creation of a cationic center next to the methyl

[1]Presented in part at the 50th and 51st Canadian Chemical Conferences, Toronto, June 1967 and Vancouver, June 1968 respectively. Preliminary communication of part of this work has appeared in ref. 36.

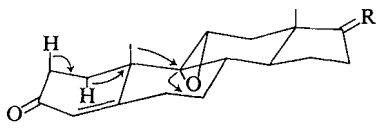
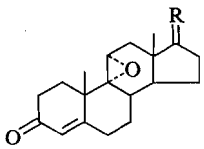
group of interest *via* the Lewis acid catalyzed cleavage of an epoxide. Thus, we reasoned that the methyl group could best be induced to migrate if it were *anti*-periplanar with respect to the opening end of an epoxide.[3] Since the systems required also have oxygenation at C-11, steroidal or tetracyclic triterpene 9α,11α-epoxides would appear to be the starting materials of choice. At first sight, the work of Henbest and Wrigley (7) appeared to militate against our ideas, since they had observed that the major product of BF_3-catalyzed opening of steroidal and some triterpene 9α,11α-epoxides was the corresponding 11-ketone. However, two factors induced us to continue. Firstly we felt that the particular model compound we wished to use, 9α,11α-epoxyandrost-4-ene 3,17-dione **5***a*, was ideally constructed for methyl migration, the expected concomitant aromatization of ring A acting as an extra driving force (arrows in **5**) to give the phenolic steroid **6***a*. Secondly, we were encouraged by reports on methyl group migrations, both single (8, 22) and multiple (9) induced by the acid-catalyzed cleavage of epoxides in steroids and triterpenes.



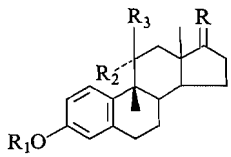
5



5*a* R = =O

b R = COCH$_3$ / H

The possibility that epoxides are involved in the biogenetic cyclization of squalene (10) suggested to us that perhaps this functional group could also play a role in further transformations of terpenoids in the plant. It is interesting to note that, at least in two cases where a triterpene series appears to have originated from a further methyl



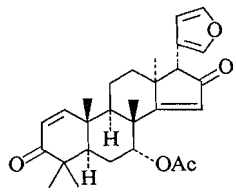
6*a* R = =O; R_1 = H; R_2 = OH; R_3 = H

b R = =O; R_1 = CH_3; R_2 = OH; R_3 = H

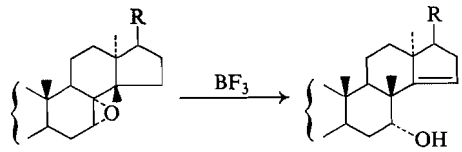
c R = =O; R_1 = CH_3; $R_2 + R_3$ = =O

d R = COCH$_3$ / H ; R_1 = H; R_2 = OH; R_3 = H

migration, there is an oxygen function at a position corresponding to the vestige of an epoxide. These are the cucurbitacins, e.g. **1**, and the meliacin series (11), e.g. **7**, this latter example being of particular note since there is a C-7α hydroxyl group having therefore the correct orientation for epoxide origin. In fact, since submission of our preliminary communication on this work,[2] two reports have appeared (12) describing the synthesis of this latter series by Lewis acid-catalyzed cleavage of a 7α,8α-epoxide, (**8** to **9**). Recent reports also suggest germacrane sesquiterpene epoxides as precursors of cyclized species (13).



7



8 **9**

The epoxide **5***a* (14) was prepared from commercially available androst-4-ene-3,11,17-trione (adrenosterone)[4] *via* epoxidation of androst-4,9(11)-diene-3,17-dione (15) assuming the stereochemistry of this last step to be controlled by the

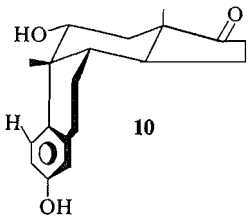
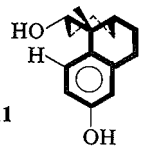
ease of approach of *m*-chloroperoxybenzoic acid to the 9(11)-double bond (16). Treatment of a dry benzene solution of this epoxide at room temperature with an excess of freshly distilled BF_3 etherate[5] for extended periods, or with $AlCl_3$ or $SnCl_4$ gave no indication of any reaction. Heating of these mixtures gave some cleavage products which could not be adequately characterized and appeared to be polymeric. However, when BF_3 gas was bubbled into a dry benzene solution of **5***a* at room temperature, a gel formed around the sides of the reaction flask characteristic of an epoxide–BF_3 complex (17). Immediate work-up of this solution gave only unchanged epoxide, but if the reaction mixture was left for 12 h at room temperature, the gel slowly turned purple and work-up gave phenolic and neutral products.

Phenolic Products

Extraction of the above reaction mixture followed by washing with 0.5 *N* sodium hydroxide yielded 30% phenolic material, m.p. 255–256°, analyzing for $C_{19}H_{24}O_3$. That this material can be assigned structure **6***a* follows from its spectral properties[6] and the predicted course of methyl migration in a *trans* and diaxial manner to the opening end of the epoxide. The phenol readily formed a monomethyl ether **6***b* with diazomethane which was not phenolic and which on oxidation yielded the diketone **6***c*. All of these compounds exhibited the required analytical and spectral properties. The stereochemistry assigned is supported by nuclear magnetic resonance (n.m.r.) since in **6***a* and **6***b* the C-1 proton is unusually deshielded, appearing at 8.1 δ. However, in the diketone **6***c* this signal appears at the more normal aromatic proton position of 6.5 δ. Considering the stereochemistry shown in **10** and viewing the molecule from end-on as in **11**, then it is apparent that there is a very strong nonbonded interaction between the C-1 proton and the hydroxyl group which can result in a strong compression effect evidenced as a large deshielding of that proton (19). On removal of this interaction by conversion to **6***c*, the C-1 proton is no longer subject to this Van der Waal's deshielding.[7] Through the kind cooperation of Professor R. A. Bell we have examined the nuclear Overhauser effects (n.O.e.) (20) of **6***b* in order to detect closely-spaced protons. Examination of **11** indicates that the 11α-hydroxyl proton is very close to H-1, at least some of the time and an Overhauser effect should be observable. When the signal for H-1 (8.12 δ) was integrated during irradiation of the 11α-hydroxyl proton signal (1.67 δ) a 10% increase in intensity was noted, supporting the stereochemistry assigned. It is also interesting to note that irradiation of the C-9 methyl group (1.43 δ) gives a 9% n.O.e. on H-1. No other possible structure for **6** appears consistent with these data.[8] A further indication of the proximity of the C-1 aromatic proton of **10** and the C-11α-hydroxy group is obtained from the n.m.r. spectrum of the phenol methyl ether of **10** (i.e. **6***b*) in pyridine-d_5. In this solvent, the H-1 doublet is deshielded by 0.85 p.p.m. appearing at 8.97 δ whereas the H-2 and H-4 signals were only deshielded by 0.2 p.p.m. This large deshielding effect is rationalized if an alcohol–pyridine association (probably by H bonding) is postulated, which leaves H-1 in the most highly deshielding region of the complex (21).



10



11

Neutral Products

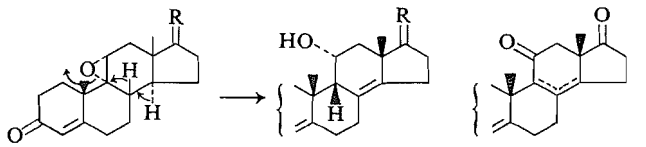
Column chromatography on alumina (grade III neutral) yielded, besides unchanged epoxide, two products which could be fully characterized. The major product from this fraction we assign as **12***a*[6] arising from the alternative mode of rearrangement of epoxide **5***a* as shown. The structure of **12***a* follows from its analysis and spectroscopic properties and is supported by its oxidation to **13***a* with Jones' reagent. We had hoped to

[5]In order for BF_3 to exert its full effect as a Lewis acid it must be freed of nucleophilic fluorine-containing species (18). In none of the cases reported here did we observe the formation of fluorohydrins.

[6]If the spectroscopic and other properties of new compounds are unexceptional we will not elaborate on them further, apart from full information in the experimental section.

[7]It is also possible to use magnetic anisotropy arguments in this case, and though we prefer the compression deshielding argument at this time we are not in a position to decide unequivocally between the two.

[8]We are at present attempting a synthesis of this material and hope to report on this at a later date.

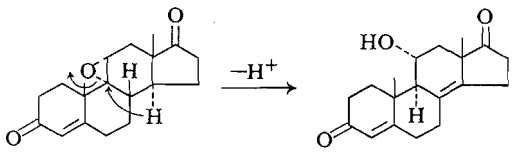


5*a*(or *b*) **12***a* R = =O, COCH$_3$ **13***a* $\Delta^{8,14}$, 9αH

b R = H *b* $\Delta^{8,9}$

isolate the 9β isomer of **13***a* thus confirming our assumption as to the stereochemistry of **12***a* at that position, but even on rapid treatment with Jones' reagent we were unsuccessful (22). On warming **13***a* with alcoholic hydrochloric acid, a di-α,β-unsaturated ketone **13***b* was obtained as evidenced by spectroscopy. Throughout this sequence, the only ethylenic proton observable in the n.m.r. spectra of the compounds prepared was that attributable to the C-4 proton. Thus, there is present in **12**, **13***a*, and **13***b*, a tetrasubstituted double bond, and hence the location of this unsaturation is as shown. There still exists some doubt as to the stereochemistry of **12***a* at C-9, although the C-8β hydrogen in **5***a* which would be expected to migrate in an *anti*-periplanar manner on epoxide cleavage would dictate this stereochemistry (23).

An alternative pathway leading to the 9α-isomer of **12***a* can also be formulated



5 **12***a* (9αH)

However, we prefer the pathway proceeding *via anti*-periplanar movements of the migrating atoms with loss of the C-14 proton, rather than the alternative shown which involves *cis*-attack at the reaction site as well as a 1,3 hydrogen transfer.[9] Whilst there are reported examples of openings of epoxides with retention of configuration at the cleaved bond, these have been observed only when some neighboring group participation is involved (25). Thus, we favor the first route to **12***a* and hence its stereochemistry as shown.

The structure of **12***a* is further supported by an n.m.r. study (100 MHz of the 11β-hydrogen signal ($CDCl_3/D_2O$) which appears as a 5-line multiplet centered at 4.4 δ. The ratio of these lines, all equally spaced at 5 Hz intervals, is 1:2:2:2:1. This signal is best accommodated by coupling constants of $J_{9\beta,11\beta} = 5$ Hz; $J_{11\beta,12\alpha} = 10$ Hz; $J_{11\beta,12\beta} = 5$ Hz, being assigned by inspection of Dreiding models of **12***a* where the observed approximate dihedral angles are Θ, 11βH–12αH, 120°; Θ, 11β–12βH, 0°; Θ, 9βH–11βH, 45°.[10] On the other hand the 9α-H isomer of **12***a* would appear, from Dreiding models, to exist in only one conformation with dihedral angles of Θ, 9β–11βH, 150°; Θ, 11βH–12αH, 180°; Θ, 11βH–12βH, 60°, leading to a substantially different signal pattern for 11βH in the n.m.r. spectrum of this isomer. The same observation was made for compound **12***b*.

When the rearrangement of **5** was performed on a large scale we were able to isolate about 4% of the ketone **14**, whose structure follows by base-catalyzed inversion at C-9 to adrenosterone (**14** with C-9α). It therefore appears that in the rearrangement of **5** there are two main pathways induced by epoxide cleavage, whilst the more common ketone formation (7) is suppressed.[11]

Assuming that our structural assignments are correct, we must now consider the factors dictating the two pathways observed. The first point of note is that the aromatization of ring A is not the dominant effect. This was emphasized by a

[9]There is a report of 1,3 hydrogen transfer (24) during epoxide cleavage. However, here again, the migrating group is *trans* disposed to the opening end of the epoxide.

[10]The models show this to be a very flexible molecule and it is also possible to make other likely conformations which would be expected to show similar coupling constants. However, the one used is that most closely giving correct coupling constants according to Karplus' equation (26).

[11]It is interesting to note that in Henbests' report (7), hydroxyl-containing materials up to about 50% yield were noted but not further characterized. We hope to repeat this work to see if these materials fit into our framework of observations.

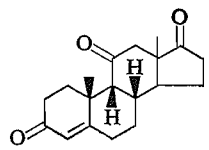
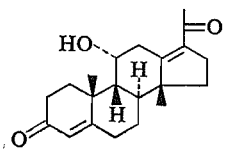
similar rearrangement of 9α,11α-epoxypregn-4-ene-3,20-dione, **5***b*, which might be expected to react in an analogous manner to **5***a* at least in that portion of the reaction leading to aromatization and methyl migration. In this case only 3% of rearrangement in this direction was noted yielding **6***d*, whilst the only other product present in detectable amount, **12***b*, was arising from formation of the 8,14 double bond. The structure was assigned in a similar manner to that used for **12***a*. Even in this latter case we were a little surprised since we had anticipated some concomitant migration of the C-13 methyl group to C-14 to give **15**, the formation of an α,β-unsaturated ketone driving this pathway.



14



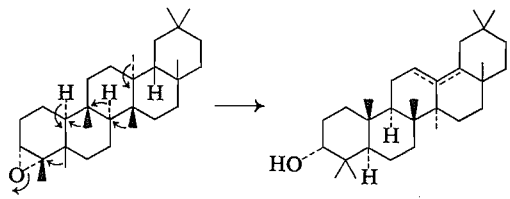
15

Thus, while the aromatization is probably responsible for directing the C-9 methyl migration, there must exist some other intrinsic structural feature acting in competition. We therefore believed that the alternate pathway (to **12***a* and **12***b*) represented a comparable energy barrier, the possibility of a concerted intramolecular process being favored.

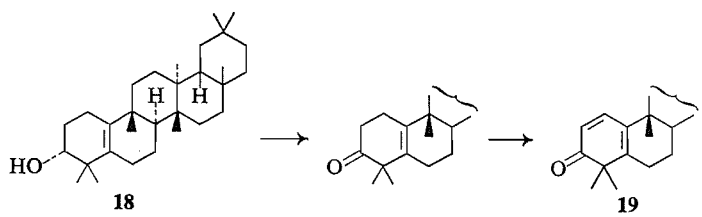
At this stage of our work, we studied two more examples of epoxide cleavage. The first was 9α,11α-epoxy-5α-androstan-3,17-dione (**5***a* with 4,5 double bond removed) (27). In this case we hoped to observe some C-10 methyl migration with the formation of a 9β-methylandrost-1-ene-3-one system (28), but again the major product was that resulting from formation of the 8,14 double bond (**12***a* with 4,5 double bond saturated), whose structure follows from oxidation and conjugation to an αβ unsaturated ketone (see Experimental). The second example was the cleavage of 3α,4α-epoxyfriedelane **16** (29). We anticipated that Lewis acid cleavage of this epoxide might lead to extensive backbone rearrangement to β-amyrin derivative **17** (29) (see arrows in **16**) although the possibility of rearrangement to an intermediate compound must not be ignored (30). In fact this latter course was observed, the only isolable product from the reaction of **16** with stannic chloride in dry benzene[12] was alnus-5(10)-ene-3α-ol, **18**, characterized by conversion to alnus-1,5(10)-diene-3-one, **19** (31) as shown in Scheme I.

On considering the above 4 cases of formation of homoallylic alcohols and examining the structures of the parent epoxides, one common structural feature is recognizable which could account for this mode of rearrangement. There is always a hydrogen atom in a 1,3-diaxial relationship to the departing end of the epoxide, and we find an intramolecular proton abstraction pathway an attractive explanation for the formation of such products as shown in Scheme II, assuming

[12] BF_3 also gave the same product but in lower yield and with more polymerization. This is in contrast to the steroidal examples where BF_3 was best.

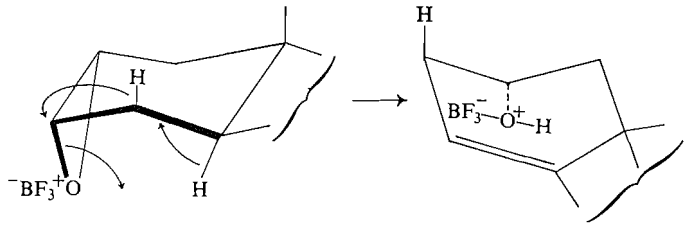


16 **17**



18 **19**

SCHEME I



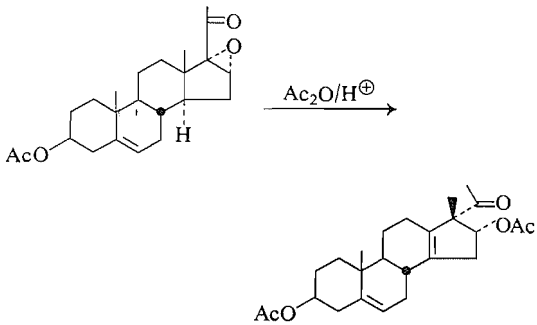
SCHEME II

of course that no major conformational factors lead to destabilization of this pathway.[13]

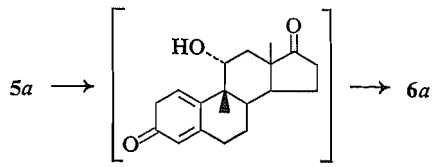
If it is borne in mind that in our cases only gaseous BF_3 or pure $SnCl_4$ in dry benzene was used as the Lewis acid, then the pathway shown could be favored since the only base available to aid in proton removal is the epoxide oxygen atom. By contrast, the more usual BF_3–etherate reagent used for epoxide rearrangements provides a proton acceptor in the ether and thus more varied reaction products may be anticipated. On considering our two initial cases, **5***a* and **5***b*, the only structural difference is in ring D at C-17. Examination of models shows that conversion of C-17 to a tetrahedral state introduces a new 1,3-diaxial interaction between the 17α- and the 12α- and 14α-hydrogens, as well as the introduction of further eclipsed cyclopentane vicinal interactions. If this effect is relieved by a slight flexing of the C and D rings then it becomes apparent from models that the C-14α hydrogen atom is pushed closer to the epoxide oxygen atom and is thus more available for abstraction on the basis of our hypothesis. This could then account for the large change in this direction of rearrangement, about 30% for **5***a* to **12***a* and about 75% for **5***b* to **12***b* and thus a corresponding reduction in the aromatization–methyl migration products.[14] Similar arguments account for some of the products observed in a number of published cases (12, 33), even where BF_3–etherate or mineral acid had at times been used for the cleavage. Such a pathway could even have biogenetic significance (11, 34).

We are at present exploring this concept of intramolecular proton abstraction in a number of other cases, especially with respect to earlier work (7). It is possible that this type of reaction could lead to some unique control in organic synthesis with suitably constructed epoxides.[15]

[13]This process may also be stepwise with the discrete formation of a carbonium ion. However, the example shown of a Wagner–Meerwein rearrangement on epoxide cleavage where the breaking bond is α to a carbonyl group (32) leads us to favor a generalized process in which there is little C—O bond cleavage before rearrangement, the BF_3 serving to increase bond polarization by complex formation. If a discrete carbonium ion was formed, this would necessitate the formation of a cationic center α to a carbonyl group whereas a cyclic process such as we envisage would not necessitate formation of such energetic species.



[14]In fact, the aromatization pathway can also be accounted for by this type of mechanism, the 1α hydrogen atom being in the correct orientation according to our proposal. This would then give **20** as the intermediate which by simple tautomerism would give **6**. The difference in the amounts of phenolic products from **5***a* and **5***b* is again a reflection of the ease of this 6-membered cyclic process in the two cases.



20

[15]For the present we have ignored the further effects of BF_3, such as complexation with keto groups present in some of the examples considered. Some of our examples quoted have no carbonyl groups, thus, if our hypothesis is correct, the complexation of BF_3 with keto groups distant from the epoxide grouping has little or no effect on the reaction pathway. We are, however, studying the effects of nearby carbonyl groupings.

Experimental

Infrared (i.r.) spectra were determined on Perkin–Elmer Infracord 137 and 237 spectrophotometers in Nujol mulls. Nuclear magnetic resonance spectra were determined at 60 MHz on a JEOLCO C-60, or at 100 MHz on a Varian HA 100 spectrometer. Chemical shifts are given in delta (δ) units relative to tetramethylsilane as internal standard. The following abbreviations were used to describe the signals—s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. Only signals deemed to be of interest in assigning structures have been quoted. Sample concentrations were approximately 10% (wt./vol.) in deuteriochloroform as a solvent. All optical rotations were taken at room temperature with absolute ethanol as solvent. Melting points are uncorrected and were determined on a Kofler hot stage. Thin-layer chromatography (t.l.c.) was carried out on silica gel plates. Mass spectra were obtained on the Perkin–Elmer–Hitachi instrument of McMaster University through the courtesy of Professors R. A. Bell and D. B. McLean. Microanalyses were determined by A. Spang, Ann Arbor, Michigan.

General Procedure for Epoxidation: Preparation of 9α,11α-Epoxyandrost-4-ene-3,17-dione (5)

Treatment of androst-4,9(11)diene-3,17 dione (6.1 g) with a slight excess of *m*-chloroperoxybenzoic acid (4.0 g) in spectra grade chloroform (200 cc) at 0 °C for 48 h gave complete reaction as indicated by t.l.c. (benzene – ethyl acetate 7:3). The chloroform solution was washed successively with sodium iodide in dilute sulfuric acid, dilute sodium sulfite, and saturated aqueous sodium bicarbonate, then dried and evaporated. Recrystallization of the product from acetone gave 5.3 g (87%) of pure (t.l.c.) epoxide **5***a*. Two more recrystallizations from acetone gave small colorless cubes, m.p. 273–275 °C; $[\alpha]_D$ +190°; ν_{max} 1740 (17 ketone), 1660 (3 ketone), 1620 cm^{-1} (Δ^4); λ_{max} 244 mμ, ε 15 800; n.m.r. signals at 6.85 (1H, s, 4-H), 3.27 (1H, t, 11βH).

Anal. Calcd. for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05. Found: C, 75.80; H, 8.07.

General Procedure for BF_3 Rearrangements: Rearrangement of 9α,11α-Epoxyandrost-4-ene-3,17-dione (5a)

Epoxide **5***a* (1.0 g) was dissolved in freshly dried and distilled benzene (175 ml). BF_3 gas was bubbled through the solution until epoxide–BF_3 complexation commenced as manifested by the formation of a slight reddish-brown gel around the sides of the flask. The mixture was allowed to stand for 12 h after which time t.l.c. analysis of the gel (benzene – ethyl acetate 7:3) showed the formation of two major products and the disappearance of most of the starting material. The reaction was taken up in ether (125 cm^3) to give an orange solution. The ether–benzene layer was washed three times with saturated aqueous sodium bicarbonate and twice with water. Extraction with 0.5 *N* aqueous sodium hydroxide, acidification of the aqueous layer with 2 *N* HCl, and back extraction with ether gave the phenolic material; the ether–benzene layer of the alkaline extractions contained the neutral fraction.

Phenolic Fractions

The phenolic fraction gave a yellow oil (300 mg) which was taken up in a small amount of chloroform. Upon standing, the chloroform solution deposited 140 mg fine colorless prisms **6***a*, m.p. 254.5–255 °C; $[\alpha]_D$ +32°; ν_{max} 3550 (hydroxyl), 3300 (phenol), 1730 (17 ketone), 1610 and 1575 cm^{-1} (aromatic); λ_{max} 281 mμ, ε 1950 changing to λ_{max} 298 mμ, ε 3160 in base; n.m.r. signals 8.1 (1H, d, 1-H), 6.56 (2H, d + s, 2-H + 4H), 4.05 (1H, q, 11βH, $J_{11\beta,12\alpha}$ = 12 c.p.s., $J_{11\beta,12\beta}$ = 4 c.p.s.), 1.4 and 1.0 (3H, s, C-9 and C-18 methyls).

Anal. Calcd. for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05. Found: C, 76.00; H, 8.02.

Methyl Ether of 6a

Treatment of **6***a* with dimethyl sulfate in methanolic potassium hydroxide gave **6***b* (65%). An analytical sample was prepared by crystallization from aqueous methanol followed by sublimation at 130 °C/10 mm to give colorless plates, m.p. 187–189 °C; ν_{max} 3550 (hydroxyl), 1730 (C-17 ketone), 1610 and 1575 cm^{-1} (aromatic); λ_{max} 278 mμ, ε 2140, no change in base; n.m.r. signals 8.12 (d, 1-H)4.00 (q, 11βH), 3.75 (3H, s, OMe), 1.43 (3H, s, C-9 CH_3), and 0.98 (3H, s, C-18 CH_3); *M* (mass spectral), 314.

Anal. Calcd. for $C_{20}H_{26}O_3$: C, 76.40; H, 8.33; Found: C, 76.13; H, 8.07.

9β-Methyl-3-hydroxy-1,3,5(10)-estratriene-11-one

Jones' oxidation of **6***a* followed by recrystallization from aqueous ethanol and sublimation at 200 °C/10 mm gave colorless plates, m.p. 278–280 °C; $[\alpha]_D$ +253°; ν_{max} 3400 (phenol), 1730 (17 ketone), 1695 (11 ketone), 1610 and 1595 cm^{-1} (aromatic); λ_{max} 282 mμ, ε 1980 changing to λ_{max} 300 mμ, ε 3010 in base; n.m.r. signals at 6.5 δ (3H, s, aromatic protons), 1.3 (3H, s, C-9 CH_3), 0.8 (3H, s, C-18 CH_3); *M* (mass spectral) 298. This compound was fairly unstable and it did not prove possible to obtain a sample pure enough for elemental analysis.

Neutral Fractions

The neutral fraction was chromatographed on neutral alumina. Elution with benzene gave **12***a* (260 mg, 26%) which was recrystallized from ethyl acetate. An analytical sample was obtained by further recrystallization from acetone to give colorless needles, m.p. 228–230 °C; $[\alpha]_D$ +350°; ν_{max} 3320 (hydroxyl), 1730 (17 ketone), 1650 (3 ketone); λ_{max} 245 mμ, ε 15 700; n.m.r. signals 5.58 (1H, s, 4H), 4.35 (1H, m, 11βH).

Anal. Calcd. for $C_{19}H_{24}O_3$: C, 75.96; H, 8.05. Found: C, 76.18; H, 8.05.

Repetition of the BF_3 catalyzed epoxide rearrangement on a 15 g scale gave 11.1 g of neutral material. Chromatography showed the presence of alcohol **12***a*, epoxide **5***a*, and triketone **14**. Chromatography on neutral alumina (Woelm) and elution with methylene chloride gave light-tan cubes (440 mg, 4%). Recrystallization from acetone gave colorless cubes (117 mg), m.p. 213–216 °C; ν_{max} 1749 (17 ketone), 1720 (11 ketone), 1660 (3 ketone), 1625 cm^{-1} (Δ^4); λ_{max} 245 mμ, ε 15 200; n.m.r. signals 5.78 (1H, s, 4H), 2.85 (1H, broad signal), 1.375 (3H, s), 1.28 δ (3H, s) (C_{18} + C_{19} methyl groups). Infrared, t.l.c., and n.m.r. indicated that this was not androst-4-ene-3,11,17-trione. Triketone **14** (40 mg) was treated with K_2CO_3 (30 mg) in methanol (3 cc). The solution was stirred overnight, poured into saturated salt solution (30 cm^3), extracted with ether, dried, and evaporated, to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

give androst-4-ene-3,11,17-trione (15 mg) identical in all respects (m.p. and mixed m.p.; i.r., t.l.c., and n.m.r.) with an authentic sample.

Oxidation of ***12a***

Oxidation of alcohol **12***a* with Jones' reagent gave a near quantitative yield of triketone **13***a*. With some difficulty a small portion of this triketone was eventually crystallized from aqueous ethanol giving large colorless needles, m.p. 211.5–213 °C; $[\alpha]_D$ +165°; ν_{max} 1735 (17 ketone), 1700 (11 ketone), 1660 cm^{-1} (3 ketone); λ_{max} 244 mμ, ε 16 100; n.m.r. signals 5.83 (1H, s, 4H), 3.1 (1H, s, 9βH), 1.45 (3H, s), 1.05 (3H, s, C-18 + C-19 methyl groups).

Conjugation of ***13a*** *to* ***13b***

Compound **13***a* (10 mg) was treated with a drop of HCl in absolute ethanol (10 cc) and was warmed on a steam bath for 2 h. Work-up and recrystallization from ethyl acetate gave 3 mg of slightly yellow-colored needles, m.p. 186–188 °C; ν_{max} 1735 (17 ketone), 1660 cm^{-1} (11 and 3 ketones); λ_{max} 246 mμ, ε 19 700. This was too unstable to obtain an analytical sample.

*9α,11α-Epoxypregn-4-ene-3,20-dione (****5b****)*

Treatment of pregn-4,9(11)-diene-3,20-dione (1.2 g) (35) with *m*-chloroperoxybenzoic acid (0.8 g) in spectral grade chloroform (45 cc) at 0 °C for 30 h followed by a work-up as described above gave **5***b* (925 mg, 78%), upon recrystallization from ethyl acetate. An analytical sample was recrystallized from ethyl acetate to give large colorless needles, m.p. 183–185 °C; $[\alpha]_D$ +126°; ν_{max} 1710 (20 ketone), 1665 (3 ketone), 1620 cm^{-1} (Δ^4); λ_{max} 240 mμ, ε 15 800; n.m.r. signals at 5.8 (1H, s, 4H), 3.18 (1H, t, 11βH).

Anal. Calcd. for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59. Found: C, 76.68; H, 8.54.

Rearrangement of 9α,11α-Epoxypregn-4-ene-3,20-dione

Rearrangement of **5***b* (450 mg) in freshly dried and distilled benzene was carried out as described above.

Phenolic Fraction

Recrystallization from benzene gave **6***d* (4 mg, 2%) as colorless flakes, m.p. 227–229 °C; $[\alpha]_D$ +77°; ν_{max} 3550 (hydroxyl), 3340 (phenol), 1690 (20 ketone), 1625 and 1590 cm^{-1} (aromatic); λ_{max} 282 mμ, ε 2020; n.m.r. signals at 8.2 (1H, d, 1H); 6.58 (1H, d, 2H), 6.47 δ (1H, s, 4H). This was too unstable to obtain an analytical sample.

Neutral Fraction

The neutral fraction was obtained in 89% yield (425 mg). Chromatography on neutral alumina and crystallization from acetone – petroleum ether gave **12***b* (290 mg, 61%) as fine white needles, m.p. 190–192 °C; $[\alpha]_D$ +376°; ν_{max} 3410 (hydroxyl), 1705 (20 ketone), 1650 (3 ketone), 1620 cm^{-1} (Δ^4); λ_{max} 242 mμ, ε 16 000; n.m.r. signals at 5.65 (1H, s, 4H), 4.45 (1H, m, 11βH).

Anal. Calcd. for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59. Found: C, 76.95; H, 8.65.

Oxidation of **12***b* (100 mg) with Jones' reagent (5 drops) in acetone (15 ml) was complete in 2 min. Work-up as described for the oxidation of **12***a* and crystallization from ether gave the triketone (**13***a*, acetyl for C-17 ketone) as fine rosettes, m.p. 166–168 °C; $[\alpha]_D$ +518°; ν_{max} 1695–1705 (11 and 20 ketone), 1665 (3 ketone), 1620 cm^{-1} (Δ^4); λ_{max} 241 mμ, ε 16 200.

Anal. Calcd. for $C_{21}H_{26}O_3$: C, 77.27; H, 8.03. Found: C, 77.14; H, 7.96.

This ketone was readily conjugated by warming in alcoholic HCl to give an unstable di-α,β-unsaturated ketone (**13***b*, acetyl for C-17 ketone); ν_{max} 1710 (20 ketone), 1665 (3 + 11 ketone), 1625 cm^{-1} (Δ^4 and Δ^8); λ_{max} 245 mμ, ε 19 100.

9α,11α-Epoxy-5α-androstan-3,17-dione

5α-Androst-9(11)-ene-3,17-dione (530 mg) (27) was treated with a slight molar excess of *m*-chloroperoxybenzoic acid (400 mg) in spectral grade chloroform at 0 °C. Work-up has been previously described. Crystallization from acetone gave pure epoxide (390 mg, 73%). A further recrystallization from acetone gave colorless prisms, m.p. 212–214 °C; $[\alpha]_D$ +108° (27), ν_{max} 1735 (17 ketone), 1705 cm^{-1} (3 ketone); n.m.r. signals at 2.28 (1H, t, 11βH).

Anal. Calcd. for $C_{19}H_{24}O_3$: C, 75.96; H, 8.67. Found: C, 75.66; H, 8.61.

Rearrangement of 9α,11α-Epoxy-5α-androstan-3,17-dione

9α,11α-Epoxy-5α-androstan-3,17 dione (350 mg) (**5***a*, $\Delta^{4,5}$ saturated) in freshly dried and distilled benzene (20 ml) was saturated with BF_3 gas. The reaction went to completion in 35 min (t.l.c.): Quenching with saturated aqueous sodium bicarbonate, ether extraction, and crystallization of the oily residue from acetone – petroleum ether gave 11α-hydroxy-5α,9β-androst-8(14)-ene-3,17-dione (260 mg, 74%) as fine colorless prisms, m.p. 196–198.5 °C; $[\alpha]_D$ −87°; ν_{max} 3410 (hydroxyl), 1735 (17 ketone), 1700 cm^{-1} (3 ketone); n.m.r. signals at 3.75 (1H, m, 11βH).

Anal. Calcd. for $C_{19}H_{26}O_3$: C, 75.46; H, 8.67. Found: C, 75.41; H, 8.55.

Oxidation of this product (70 mg) (**12***a*, Δ^4 reduced, 5αH) with Jones' reagent (3 drops) in acetone (10 ml) was complete in 3 min. Work-up as described above and crystallization from acetone – petroleum ether (60–80°) gave coarse prisms of the triketone (**13***a*, Δ^4 reduced, 5αH), m.p. 202–204 °C; $[\alpha]_D$ +206°; ν_{max} 1740 (17 ketone), 1715 (11 ketone), 1705 cm^{-1} (3 ketone). Conjugation was achieved by hot alcoholic HCl to give a low yield of the unstable α,β-unsaturated ketone (**13***b*, Δ^4 reduced, 5αH), m.p. 148–152°; ν_{max} 1740 (17 ketone), 1710 (3 ketone), 1665 (11 ketone), 1610 cm^{-1} (Δ^8); λ_{max} 246 mμ, ε 12 100.

*3α,4α-Epoxyfriedelane (****16****)*

Friedel-3-ene (24) (1.2 g) was treated with *m*-chloroperoxybenzoic acid (550 mg) in spectral grade chloroform (80 ml) at 0 °C for 12 h. Work-up of the chloroform solution as described above and crystallization from 95% ethanol gave **16** (910 mg, 76%), m.p. 234–236 °C; $[\alpha]_D$ +540°; n.m.r. signals at 2.85 (1H, t, 3βH).

Anal. Calcd. for $C_{30}H_{50}O$: C, 84.44; H, 11.81. Found: C, 84.47; H, 11.69.

Rearrangement of 3α,4α-Epoxyfriedelane

A solution of 3α,4α-epoxyfriedelane (400 mg) in dry benzene (20 cc) was treated with $SnCl_4$ (0.2 cc). Work-up and recrystallization from methanol, then from hexane gave fine powdery flakes, m.p. 225–227 °C (300 mg); $[\alpha]_D$ −36°; ν_{max} 3510 cm^{-1} (hydroxyl) (BF_3 gave similar results but with lower yield).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The alcohol (200 mg) was treated with Jones' reagent (0.2 ml) until oxidation was complete. Quenching with water, filtration, and recrystallization gave a near quantitative yield of a ketone. Further recrystallization from hexane gave fine colorless plates, m.p. 248–250.5 °C; $[\alpha]_D$ −84°; ν_{max} 1710 cm^{-1} (3 ketone).

Anal. Calcd. for $C_{30}H_{48}O$: C, 84.84; H, 11.39. Found: C, 85.06; H, 11.30.

Spring (27) gives m.p. 250–252°; $[\alpha]_D$ −90°, and Chapon (36) gives m.p. 248°; $[\alpha]_D$ −84°.

The ketone was converted into alnusa-1,5-(10)-diene-3-one using the method of Spring and co-workers (27), m.p. 212.5–215°; ν_{max} 1690 cm^{-1} (3 ketone); λ_{max} 320, ε 5000. Spring (27) gives melting points between 211–215° and 216–217°; λ_{max} 322 mμ, ε 5500. A comparison sample was not available.

Acknowledgments

We thank the National Research Council of Canada for continued generous support and for a scholarship to J. J. Rosenfeld. One of us (R. R. King) is thankful to the Government of Ontario for a Graduate Fellowship. We are grateful to the Upjohn Company which provided generous samples of adrenosterone and 11-ketoprogesterone, and to the Armstrong Cork Company which supplied the cork wax for the extraction of friedelin. We express our gratitude to Mr. R. Sampson (n.m.r. spectra), Dr. R. R. Fraser (100 MHz n.m.r.), Dr. R. A. Bell, Dr. D. B. Maclean (mass spectra and n.O.e.), and finally to Professor Guy Ourisson (Institut de Chimie, Strasbourg, France) for his hospitality during the preparation of this manuscript.

Pyridazino[4,5-*b*]indole derivatives

THOMAS NOGRADY AND LEESON MORRIS
Chemistry Department, Loyola College, Montreal 262, Quebec

Received March 13, 1968

A series of pyridazino[4,5-*b*]indole lactams and their reduction products was prepared in an attempt to uncover monoamine oxidase inhibitory activity. The reduction and nuclear magnetic resonance spectra of these compounds are dealt with. Some are weak analgesics but no other pharmacological activity was found.

Canadian Journal of Chemistry, 47, 1999 (1969)

In our attempts to uncover novel monoamine oxidase inhibitory compounds we synthesized some 2-indolylcarbohydrazide derivatives (1). It seemed interesting to close ring C by insertion of one more carbon atom and this way obtain the pyridazino[4,5-*b*]indole ring system which can be considered as an azacarboline. Since many carboline alkaloids related to harmine are strong reversible MAO inhibitors (2), the combination of the carboline system with hydrazine seemed to be attractive also from a pharmacological point of view.

Only basic information is available on pyridazinoindoles and very few derivatives known. The [3,4-*b*] isomer was described by Kobayashi and Furukava (3). The [4,5-*b*] isomer was first reported by King and Stiller (4) who obtained it by heating 2-carbethoxy-3-formylindole *p*-nitrophenylhydrazone to 300° and obtained the cyclic hydrazide. Other authors (5–7) used basically the same method of ring closure, while some (8, 9) started from 2- or 3-indolylmethylhydrazines and condensed them with aldehydes to obtain the cyclized product.

In our series the 4-oxopyridazino[4,5-*b*]-indoles and their 1,2,3,4-tetrahydro derivatives were prepared according to the scheme shown below.

It is quite remarkable that the sequence of basically identical reactions, i.e. formylation and condensation with hydrazine derivatives, used in preparing the compounds, is responsible for the formation or absence of the Δ^1 double bond. This is due to the unusual formation of the

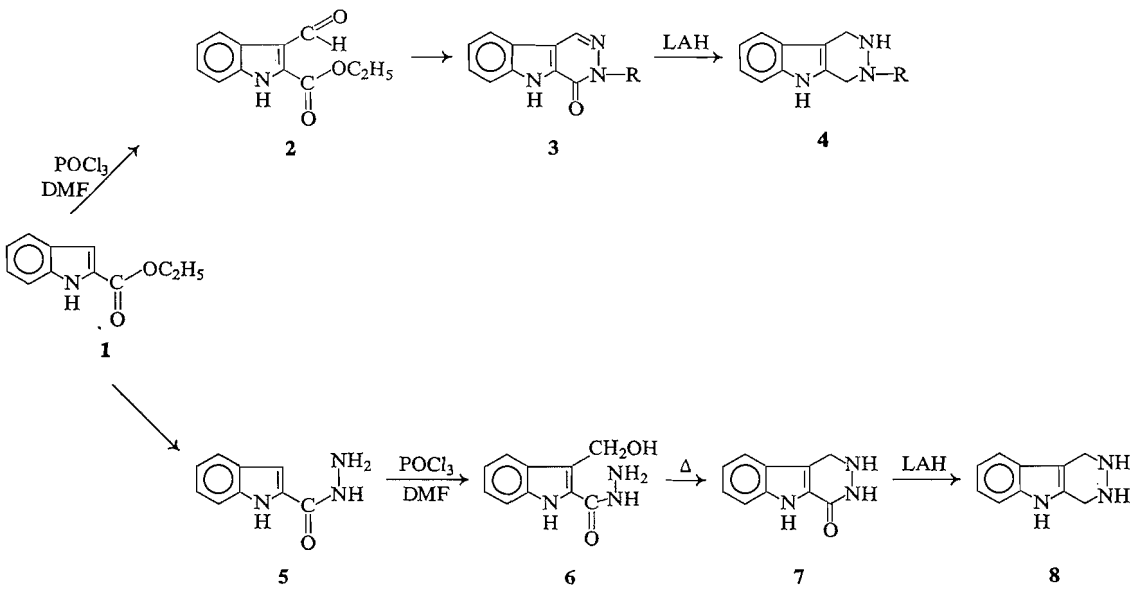

FIG. 1. Synthesis of pyridazoindoles.

TABLE I

3-Substituted 3,4-dihydro-4-oxo-pyridazino[4,5-*b*]indoles

Compound	R	Melting point (°C)	Solvent of crystallization	Nitrogen analysis Found	Nitrogen analysis Calcd.	Yield (%)	Method

*Method taken from ref. (7*a*).

3-hydroxymethylindole-2-carbohydrazine (**6**) during the DMF–$POCl_3$ formylation of indole-2-carbohydrazide (**5**) as described by Harradance and Lions (5), who obtained this compound in another way. The presence of the hydroxymethyl group (and the absence of any aldehyde proton) in **6** was proved by spectroscopy. The nuclear magnetic resonance (n.m.r.) spectrum of **6** (in DMSO-d_6) showed a CH_2 singlet at 2.80 p.p.m. (δ) integrating for two protons, an aromatic multiplet centered at 7.4 p.p.m., and two broad NH bands at 10.56 and 11.38 p.p.m., both exchangeable by D_2O. No aldehyde proton could be seen in the 9–10 p.p.m. region of the spectrum. The CH_2 singlet at 2.80 p.p.m. might appear more upfield than usual, since the corresponding resonance in benzyl alcohol is at 4.58. On inspecting the n.m.r. spectrum of 3-indolylmethanol however, one finds the CH_2 singlet at 3.83 p.p.m. (δ), also higher than expected.

In the ultraviolet (u.v.) spectrum, three maxima are visible: 306 (3.87), 251 (3.43), and 220 (3.69) mμ. In an alkaline medium practically no bathochromic shift could be seen, the maxima being at 310, 250, and 220 mμ. By comparison the ester-aldehyde **2** shows maxima at 322 (4.19), 253 (4.10), 245.5 (4.16), and 279.5 (4.22) mμ, which shift in an alkaline medium to 360 (4.79) and 273.5 (4.86), with strong tailing around 220–230 mμ. This bathochromic shift is due to the formation of the indolenine alcohol (cf. ref. 10).

The infrared (i.r.) spectrum (in KBr disk) shows a broad associated band in the OH/NH stretching region at 3.05–3.25 μ, the amide carbonyl at 6.40 μ, a fairly sharp, strong peak at 7.70 μ which could be O—H deformation, C—O stretching at 9.10 μ, and the disubstituted phenyl at 13.5 μ, as the principal peaks.

The condensation of 2-carbethoxy-3-formylindole (**2**) with hydrazine derivatives is more capable of variations in introducing a substituent in N-3, so our efforts were concentrated on preparing a series of 3,4-dihydro-4-oxopyridazines (Table I) rather than the tetrahydro derivatives and reduce them afterwards.

The reduction of the cyclic hydrazide (**3**) proved to be surprisingly facile considering reports on the failure to reduce aliphatic hydrazides (11) and 1-oxocarbolines (12) with $LiAlH_4$. The 4-oxopyridazino[4,5-*b*]indoles were refluxed overnight with a great excess of LAH in dioxane and excellent yields were obtained (Table II). After completion of our experiments the LAH reduction of 1-methyl-3-arylpyridaz-6-

TABLE II

3-Substituted 1,2,3,4-tetrahydro-pyridazino[4,5-*b*]indoles

Compound	R	Melting point (°C)	Solvent of crystallization	Nitrogen analysis Found	Nitrogen analysis Calcd.	Yield (%)
16	—H	235–237	Methanol	19.86	20.04	90
17	$-CH_3$	245–246	Methanol	18.29 (.HCl)	18.02	96
18	$-CH(CH_3)_2$	163–164	Methanol–water	19.65	19.52	95
19	—C$_6$H$_5$	222–223 (decomp.)	Acetone	16.55	16.99	95
20	$-CH_2-CH_2-N(CH_3)_2$	159–160	*i*-Propanol–hexane	22.66	22.93	90
21	$-CH_2-CH_2-CH_2-N(CH_3)_2$	146–147	Acetone	21.59	21.68	95
22	$-CH_2-CH_2-N$ piperazine NH	183–184	Benzene	24.66	24.54	86

one and related compounds was reported (13) but a 96 h reflux period yielded only 20% of pure reduced product.

In this reaction however the C=N double bond remains intact. In our reductions the C=N double bond is also reduced, as proved by n.m.r. spectra. In a representative example, the 1,2,3,4-tetrahydro-5*H*-pyridazino[4,5-*b*]indole (compound **17**), an N—CH_3 singlet is found at 2.88 p.p.m. (δ), and an aromatic multiplet centered at 7 p.p.m. The fairly well separated singlets at 4.16 and 4.23 p.p.m. (δ) are of equal intensity and integrate for 4 protons. They represent the 1- and 4-CH_2 groups; no olefinic protons are discernible. In the *N*-phenyl analogue, the corresponding protons are at 4.68 and 4.70 p.p.m. respectively.

In attempts to obtain the 4-methylpyridazino-[4,5-*b*]indole, the aza analogue of harmane, we tried the Bischler–Napieralski ring closure with phosphorus pentoxide, polyphosphoric acid, polyphosphate ester, and ethanolic HCl on 3-formylindole acetylhydrazone, without success.

Pharmacological Results

The only pharmacological effect shown by compounds **9**, **12**, **15**, and **16** was a weak analgetic activity (Median effective dose 50–150 mg/kg). No anti-histamine or central nervous system activity was noticed.

Experimental

All melting points were determined on a Gallenkamp block and are corrected; boiling points are uncorrected. The i.r. spectra were taken in KBr disks on a Beckman IR-8 instrument, and n.m.r. spectra were taken on a Varian A-60 spectrometer in trifluoracetic acid if not stated otherwise. Analyses were performed by Dr. C. Daesslé, Montreal.

3-Dimethylaminopropylhydrazine

Dimethylaminopropyl chloride·HCl (14.8 g) was dissolved in 75 ml ethanol, added slowly to 13.5 g refluxing hydrazine (anhydrous), and the solution refluxed for 4 h. After cooling, the precipitated hydrazine salt was filtered off, the solvent removed, and the residue distilled. The yield was 5.8 g (53.0%) b.p.$_{10}$ 75–80°; n_D^{20} 1.4611. The hydrochloride was prepared in ethanol–ether, and melted at 197–198°.

Anal. Calcd. for $C_5H_{15}N_3 \cdot 2HCl$: N, 22.05. Found: N, 21.78.

N-(β-Hydrazinoethyl)piperazine

N-(β-chloroethyl)piperazine (5 g) was dissolved in 10 ml water, 20 ml of anhydrous hydrazine added, and the solution refluxed for 4 h. After cooling, the solution was saturated with solid NaOH and the separated oil extracted with tetrahydrofuran. The organic phase was dried over K_2CO_3 and distilled; yield 3.2 g (95%), b.p.$_{12}$ 140–145°. The HCl salt, prepared in ethanol, melted at 107–109° (decomp.).

Anal. Calcd. for $C_6H_{16}N_4 \cdot 3HCl$: N, 22.09. Found: N, 21.70.

1,2,3,4-Tetrahydro-4-oxo-5H-pyridazino[4,5-b]indole (7) (5)

Indole-2-carbohydrazide **5** (ì) (0.5 g) was dissolved in 4 ml dimethyl formamide and added slowly to a solution of 0.5 ml $POCl_3$ in 4 ml dimethyl formamide. After 1 h at room temperature the solution was diluted with water and 0.41 g (77%) yellow crystals isolated by filtration, m.p. 195°. The melt resolidified and melted again at 285–288°. Recrystallized from *n*-butanol or dioxane they melted directly at 294–295°.

Anal. Calcd. for $C_{10}H_9N_3O$: C, 64.16; H, 4.85; N, 22.45. Found: C, 64.19; H, 4.63; N, 22.56.

The low melting compound is supposedly the 3-hydroxymethyl derivative **6** which cyclizes on heating in any way to **7**. Spectra of this compound were discussed in the theoretical part. The cyclized product shows a single carbonyl peak at 6.15 μ and broad indistinct bands in the 3–4 μ region.

*Method A. 3,4-Dihydro-3-methyl-4-oxo-5H-pyridazino[4,5-b]indole (**11**)*

A solution of 4.32 g 2-carbethoxy-3-formylindole and 7.5 ml methylhydrazine was refluxed gently in 50 ml glycerol for 15 min. The solution first became yellow, then colorless crystals separated. These were filtered off after cooling and dilution with water; yield 3.79 g (95%), m.p. 298–300°, unchanged after recrystallization from *n*-butanol.

Nuclear magnetic resonance spectrum: 4.30 (—CH_3) (3H), 7.2–8.2 (aromatic and C—H) (5H), 9.1 (N—H) (1H).

*Method B. 3,4-Dihydro-3-phenyl-4-oxo-5H-pyridazino[4,5-b]indole (**12**)*

2-Carbethoxy-3-formylindole (1.08 g) was dissolved in 20 ml glacial acetic acid and 2.5 ml freshly distilled phenylhydrazine were added. The solution became warm and yellow crystals of the phenylhydrazone separated, but dissolved upon heating. After refluxing for 1 h the crystals were filtered from the cooled reaction mixture and washed with water; yield 1.1 g (85%) m.p. 329–330° (from DMF–water).

Nuclear magnetic resonance spectrum: 7.6–8.6 (aromatic and C—H) (10H), 9.2 (N—H) (1H).

*Method C. 3,4-Dihydro-3-(γ-dimethylaminopropyl)-4-oxo-5H-pyridazino[4,5-b]indole (**14**)*

2-Carbethoxy-3-formylindole (1.08 g), 3.45 g 3-dimethylaminopropyl hydrazine, and 3 drops of glacial acetic acid were heated on the steam bath for 30 min until a gentle gas evolution ceased. The homogeneous mixture was now kept at 135–140° for 2 h more. On cooling, white needles separated which were filtered off, washed with water, and recrystallized from 50% methanol–water, yield 1.05 g (77%), m.p. 164–165°.

Reduction with $LiAlH_4$

The cyclic hydrazides were dissolved in 25–50 volumes of dry dioxane, an equal weight (5–8 moles) of $LiAlH_4$ was added cautiously, and the reaction mixture refluxed for 16 h. After cooling, 3 ml water were added for each gram of $LiAlH_4$ and worked up in the usual way. The pyridazines separated as solids in very good yields (see Table II).

Acknowledgments

This investigation was supported by Bristol Laboratories, Syracuse, New York. Pharmacological screening was performed by Dr. M. H. Pindell and his staff of Bristol Laboratories, to whom thanks are due.

Chemistry of the aminochromes. Part XI. Studies on 2-methylaminochromes[1,2,3]

O. HUTZINGER AND R. A. HEACOCK
Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

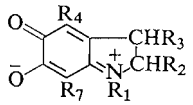
Received July 10, 1968

2-Methyladrenochrome and 1-ethyl-2-methylnoradrenochrome have been prepared by oxidation of 3,4-dihydroxyephedrine and 3,4-dihydroxyhomoephedrine with silver oxide. The corresponding 7-iodoaminochromes were obtained when the oxidations were carried out with potassium iodate. The expected 3,5,6-triacetoxyindoles were formed by treatment of these aminochromes with acetic anhydride and pyridine and the corresponding 5,6-dihydroxyindoles (isolated as their diacetyl derivatives) were obtained by reduction of the aminochromes with sodium borohydride or sodium hydrosulfite. An improved procedure for the synthesis of 3,4-dihydroxyephedrine (α-methyladrenaline) is also described.

Canadian Journal of Chemistry, 47, 2003 (1969

Only one 2-alkyl-substituted aminochrome had been isolated as a crystalline solid at the time that this investigation was begun. Bu'Lock and Harley-Mason obtained a deep-red crystalline product, described as 2-iodo-2-methylnoradrenochrome on oxidation of α-methylnoradrenaline (3,4-dihydroxynorephedrine) with potassium iodate (1). It has subsequently been shown that, like all other iodoaminochromes, this product is a 7-iodo derivative (i.e. 7-iodo-2-methylnoradrenochrome (**1**)) (2). 2-Methylnoradrenochrome (**2**) (1), 2-ethylnoradrenochrome (**3**) (3), and 2-methylnorepinochrome (**4**) (4) have been prepared in solution and a monosemicarbazone of **2** has been isolated as a crystalline solid (1).

The synthesis and some properties of 4-methyladrenochrome (**5**) and 7-methyladrenochrome (**6**) have recently been reported by the authors (5). This paper reports some of the results of a general extension of this research to aminochromes alkylated in the 2-position; in particular to 2-methyladrenochrome (**7**) and 2-methyl-1-ethylnoradrenochrome (**8**) and their 7-iodo derivatives **9** and **10**.



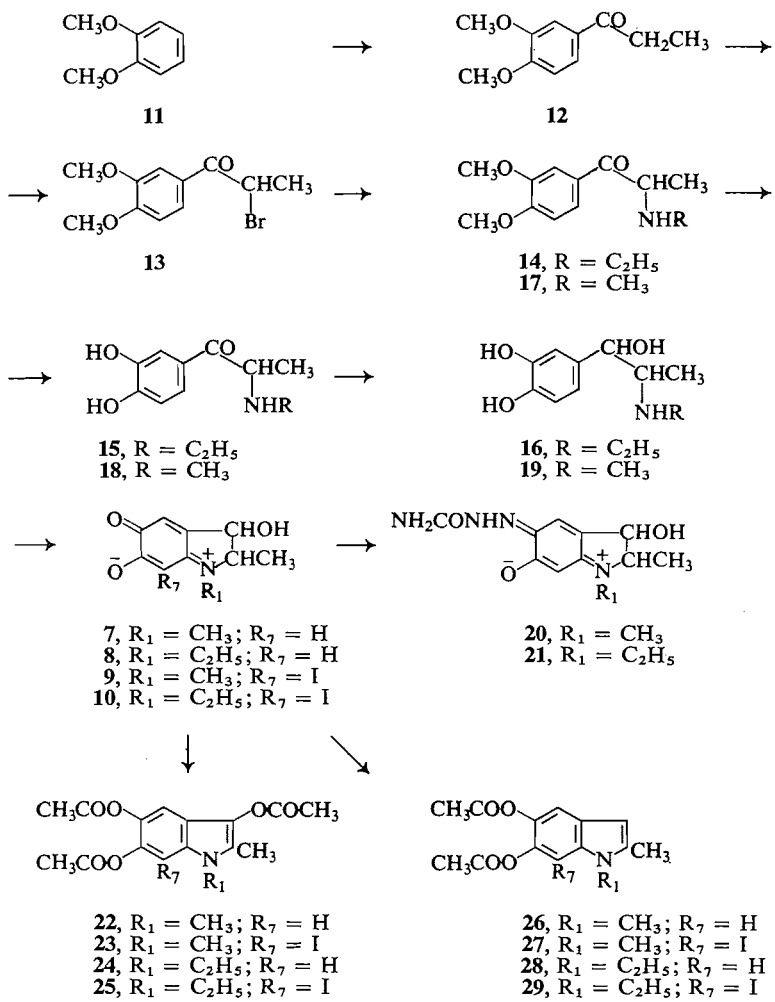
1, $R_1 = R_4 = H$; $R_2 = CH_3$; $R_3 = OH$; $R_7 = I$.
2, $R_1 = R_4 = R_7 = H$; $R_2 = CH_3$; $R_3 = OH$.
3, $R_1 = R_4 = R_7 = H$; $R_2 = C_2H_5$; $R_3 = OH$.
4, $R_1 = R_3 = R_4 = R_7 = H$; $R_2 = CH_3$.
5, $R_1 = R_4 = CH_3$; $R_2 = R_7 = H$; $R_3 = OH$.
6, $R_1 = R_7 = CH_3$; $R_2 = R_4 = H$; $R_3 = OH$.
7, $R_1 = R_2 = CH_3$; $R_3 = OH$; $R_4 = R_7 = H$.
8, $R_1 = C_2H_5$; $R_2 = CH_3$; $R_3 = OH$; $R_4 = R_7 = H$.
9, $R_1 = R_2 = CH_3$; $R_3 = OH$; $R_4 = H$; $R_7 = I$.
10, $R_1 = C_2H_5$; $R_2 = CH_3$; $R_3 = OH$; $R_4 = H$; $R_7 = I$.

Neither of the catecholamines required for the preparation of these aminochromes was available commercially. 3,4-Dihydroxyhomoephedrine (i.e. *N*-ethyl-α-methylnoradrenaline (**16**)) the precursor of **8** and **10** was prepared from veratrole (**11**) using essentially the method previously described by Lespagnol and Cuingnet (6) (i.e. **11** → **12** → **13** → **14** → **15** → **16**). An analogous route, used for the preparation of 3,4-dihydroxyephedrine (i.e. α-methyladrenaline (**19**)) is similar to a synthesis of this compound described in the patent literature (7). In the present case, however, the bromination reaction (i.e. **12** → **13**) was carried out in ether solution (cf. 6); the demethylation (**17** → **18**) by refluxing with concentrated hydrobromic acid, and a palladium–carbon, rather than a platinum catalyst was employed for the hydrogenation (**18** → **19**).

2-Methyladrenochrome (**7**) and 1-ethyl-2-methylnoradrenochrome (**8**) were both obtained, similarly to adrenochrome, as deep-red needles on oxidation of **19** and **16** with silver oxide in methanol (cf. 8). The monosemicarbazones **20** and **21** were obtained from aqueous solutions of the aminochromes **7** and **8**, prepared by oxidation of **19** and **16** with potassium ferricyanide in an aqueous sodium bicarbonate buffer (cf. 1). 7-Iodo-2-methyladrenochrome (**9**) and 1-ethyl-7-iodo-2-methylnoradrenochrome (**10**) were obtained as dark violet-brown crystalline solids

---

[1]NRCC No. 10375.
[2]Part X. W. Powell, R. A. Heacock, G. L. Mattok, and D. L. Wilson. Can. J. Chem. 47, 467 (1969).
[3]The preliminary phases of the work described in this paper were carried out by the authors in the laboratories of the Psychiatric Research Unit, University Hospital, Saskatoon, Saskatchewan.



when **19** and **16** were oxidized with potassium iodate in aqueous solution.

The deep-red colors of aqueous solutions of the aminochromes **7** and **8** were rapidly discharged by alkali or aqueous zinc acetate; the resulting pale-yellow solutions probably contained the corresponding 5,6-dihydroxyindoxyls since, in ultraviolet light, they exhibited an intense yellow-green fluorescence, characteristic of this class of compounds (cf. ref. 9, p. 239). 3,5,6-Triacetoxyindoles are readily obtained from aminochromes with an OH group in the 3-position by treatment with a mixture of acetic anhydride and pyridine (cf. ref. 9, p. 242). 3,5,6-Triacetoxy-1,2-dimethylindole (**22**), 3,5,6-triacetoxy-7-iodo-1,2-dimethylindole (**23**), 3,5,6-triacetoxy-1-ethyl-2-methylindole (**24**), and 3,5,6-triacetoxy-1-ethyl-7-iodo-2-methylindole (**25**) were prepared in this manner from **7**, **8**, **9**, and **10** respectively.

5,6-Dihydroxyindoles are usually obtained on reduction of 3-hydroxy-substituted aminochromes (cf. ref. 9, p. 249). Because dihydroxyindoles of this type undergo oxidative polymerization in air to melanins, they are often more conveniently isolated as their diacetyl derivatives. 5,6-Diacetoxy-1,2-dimethylindole (**26**) and 5,6-diacetoxy-1-ethyl-2-methylindole (**28**) were obtained by acetylation of the corresponding 5,6-dihydroxyindoles, which, in turn, were prepared by reduction of the aminochromes **7** and **8** with sodium borohydride. The 5,6-diacetoxyindoles were prepared without the isolation of either the intermediate amino-

For personal use only.

chromes or 5,6-dihydroxyindoles. 5,6-Diacetoxy-7-iodo-1,2-dimethylindole (**27**) and 5,6-diacetoxy-1-ethyl-7-iodo-2-methylindole (**29**) were prepared in an analogous manner from the 7-iodoaminochromes **9** and **10**. Here the oxidations were carried out in dilute aqueous solution with potassium iodate, and the reductions carried out with sodium hydrosulfite.

As would have been expected the presence of a 2-alkyl substituent in the aminochrome nucleus has little effect on the physical and chemical properties of the aminochromes. Further studies will be required to ascertain if the 2-alkyl group has any effect on the physiological activity of either the parent aminochromes (cf. ref. 9, p. 279) or the derived 5,6-dihydroxyindoles.

Experimental

*α-Methylamino-3,4-dimethoxypropiophenone Hydrochloride (**17**)*

A suspension of α-bromo-3,4-dimethoxypropiophenone (**13**) (119 g), prepared by the method of Lespagnol and Cuingnet (6), in a mixture of methanol (229 ml) and 30% w/v aqueous methylamine (150 ml), contained in a tightly stoppered flask, was stirred (magnetically) at room temperature until the solid had completely dissolved (ca. 45 min). The reaction mixture was then maintained at 37° overnight, after which time it was cooled and a mixture of 30% aqueous sodium hydroxide (200 ml) and ether[4] (200 ml) was added, with vigorous stirring. The system was allowed to separate into two phases and the ether layer was removed. The aqueous mother liquors were further extracted with ether (2 × 150 ml). The ether solutions were dried (K_2CO_3) and evaporated *in vacuo*. The oily residue was repeatedly evaporated with benzene to remove traces of water and was then dissolved in acetone (300 ml) and the solution saturated with dry hydrogen chloride gas. The hydrochloride (41.5 g; m.p. 207–209.5°) which separated as a colorless solid was removed by filtration and washed with a little cold acetone. The crude product was sufficiently pure to be used in the next stage of the synthesis.

An analytical sample of α-methylamino-3,4-dimethoxypropiophenone hydrochloride was obtained as colorless needles (m.p. 208–208.5° decomp.)[5] after repeated recrystallization from ethanol – ethyl acetate.

Anal. Calcd. for $C_{12}H_{18}ClNO_3$: C, 55.50; H, 6.98; N, 5.39; Cl, 13.65. Found: C, 55.25; H, 6.85; N, 5.49; Cl, 13.79.

*α-Methylamino-3,4-dihydroxypropiophenone (**18**)*

A solution of α-methylamino-3,4-dimethoxypropiophenone hydrochloride (40 g) in concentrated hydrobromic acid (124 ml) was boiled under reflux for 3 h. The dark solution was allowed to cool in a carbon dioxide atmosphere and then evaporated *in vacuo*. The dark residue was dissolved in methanol and decolorized with charcoal in a carbon dioxide atmosphere; after removal of the charcoal by filtration, dry ether was added to the yellowish-brown filtrate until a slight turbidity persisted. The solution was then saturated with dry ammonia gas. The impure base (mixed with ammonium bromide) which separated was filtered off, washed with a little cold acetone, and dried in a current of air. The crude material (17 g) was triturated with water (16 ml); the sludge so obtained was filtered and the remaining solid washed with water (5 × 10 ml) and acetone (2 × 25 ml). The α-methylamino-3,4-dihydroxypropiophenone (11.5 g), m.p. 191.5° (decomp.) obtained in this manner was sufficiently pure for the next stage in the synthesis and was not further purified.

*α-Methyladrenaline Hydrochloride (3,4-Dihydroxyphedrine Hydrochloride) (**19**)*

A suspension of α-methylamino-3,4-dihydroxypropiophenone (1.95 g) and 5% palladium–charcoal (1 g) in water (90 ml) and *N* hydrochloric acid (10 ml) was shaken in an atmosphere of hydrogen at atmospheric pressure and room temperature for 20 h. The reaction mixture was filtered and the filtrate evaporated *in vacuo* (T < 30°). The pale-violet residue (m.p. 182–182.5° decomp.) was repeatedly recrystallized from methanol – methyl acetate mixtures and gave α-methyladrenaline hydrochloride (1.5 g) in very small colorless plates, m.p. 190–191°; lit. m.p., 190–191° (10); 191–191.5° (11).

Anal. Calcd. for $C_{10}H_{16}ClNO_3$: C, 51.39; H, 6.90; N, 5.99; Cl, 15.17. Found: C, 51.50; H, 7.17; N, 5.71; Cl, 15.30.

*N-Ethyl-α-methylnoradrenaline Hydrochloride (3,4-Dihydroxyhomoephedrine Hydrochloride) (**16**)*

A suspension of α-ethylamino-3,4-dihydroxypropiophenone (2.09 g), prepared by the method of Lespagnol and Cuingnet (6), and 5% palladium–charcoal (1.0 g) in water (90 ml) containing *N* hydrochloric acid (10 ml) was shaken overnight in an atmosphere of hydrogen at atmospheric pressure and room temperature. After removal of the catalyst by filtration the solution was evaporated *in vacuo* (T < 50°). The white crystalline residue was repeatedly recrystallized from methanol–ether and gave *N*-ethyl-α-methylnoradrenaline hydrochloride as colorless prisms (1.15 g; m.p. 211–212°). Lespagnol and Cuingnet (6), who carried out the reduction in a slightly different manner reported m.p. 212–214°.

Anal. Calcd. for $C_{11}H_{18}ClNO_3$: C, 53.34; H, 7.32; N, 5.66; Cl, 14.32. Found: C, 53.36; H, 7.40; N, 5.52; Cl, 14.37.

*2-Methyladrenochrome (**7**)*[6]

Freshly prepared silver oxide (3.6 g) was added to a vigorously stirred solution of α-methyladrenaline hydrochloride (1.0 g) in methanol (20 ml). The stirring was continued for 3 min, after which time the reaction mixture

[4]Peroxide-free ether was used throughout this investigation.

[5]All melting points quoted in this paper are uncorrected.

[6]See preparation of adrenochrome by Heacock *et al.* (8).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was filtered through a Dowex-1 (Cl^-) resin bed[7] (diameter, 2.5 cm; height, 1.8 cm). Dry ether (30 ml) was added to the filtrate and 2-methyladrenochrome (0.22 g; totally decomposed without melting by 128°)[8] was obtained as dark-red needles after the solution had stood overnight at −20°.

Anal. Calcd. for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.74; N, 7.25. Found: C, 62.11; H, 5.94; N, 7.10.

*1-Ethyl-2-methylnoradrenochrome (**8**)*

Oxidation of α-methyl-*N*-ethylnoradrenaline hydrochloride (1.0 g) with silver oxide (3.6 g) gave deep-red needles of 1-ethyl-2-methylnoradrenochrome (0.29 g; totally decomposed by 110°) when the product was isolated in the manner described above.

Anal. Calcd. for $C_{11}H_{13}NO_3$: C, 63.75; H, 6.32; N, 6.76. Found: C, 63.75; H, 6.34; N, 6.75.

*2-Methyladrenochrome Monosemicarbazone (**20**)*

A solution of α-methyladrenaline hydrochloride (0.5 g) in water (2.5 ml) was treated with potassium ferricyanide (2.35 g) and sodium bicarbonate (0.75 g) in water (6.25 ml). A solution containing semicarbazide hydrochloride (0.25 g) and sodium acetate (0.25 g) in water (2 ml) was added to the resulting deep-red 2-methyladrenochrome solution; after stirring at room temperature for 5 min the crude semicarbazone separated as an orange-brown solid (0.43 g). A pure sample of 2-methyladrenochrome monosemicarbazone was obtained as bright orange needles (totally decomposed by 222°) after repeated recrystallization of the crude product from aqueous pyridine.

Anal. Calcd. for $C_{11}H_{14}N_4O_3$: C, 52.79; H, 5.64; N, 22.39. Found: C, 52.80; H, 5.68; N, 22.19.

*1-Ethyl-2-methylnoradrenochrome Monosemicarbazone (**21**)*

1-Ethyl-2-methylnoradrenochrome monosemicarbazone (0.42 g) (orange-red prisms; m.p. 234° decomp.) was prepared from a solution of *N*-ethyl-α-methyladrenaline hydrochloride (0.5 g) (in 5 ml of water) in an analogous manner to that described above for the corresponding *N*-methyl derivative.

Anal. Calcd. for $C_{12}H_{16}N_4O_3$: C, 54.55; H, 6.10; N, 21.20. Found: C, 54.59; H, 6.26; N, 21.21.

*7-Iodo-2-methyladrenochrome (**9**)*

Potassium iodate (0.8 g) was added to a solution of α-methyladrenaline hydrochloride (0.5 g) in water (150 ml) and the reaction mixture stirred at room temperature for 1 h. 7-Iodo-2-methyladrenochrome (0.38 g) was obtained as a dark violet-brown crystalline solid (totally decomposed without melting by 96°) after the solution had stood at 4° for 2 h.

Anal. Calcd. for $C_{10}H_{10}INO_3$: C, 37.64; H, 3.16; N, 4.39; I, 39.78. Found: C, 37.57; H, 3.19; N, 4.22; I, 39.60

*1-Ethyl-7-iodo-2-methylnoradrenochrome (**10**)*

Potassium iodate (0.8 g) was added to a stirred solution of α-methyl-*N*-ethylnoradrenaline hydrochloride (0.5 g) in water (150 ml); the reaction mixture was stirred at room temperature for 1.5 h, and was then cooled in the refrigerator for a further 4.5 h. 1-Ethyl-7-iodo-2-methylnoradrenochrome (0.4 g) was obtained as a deep violet (almost black) crystalline solid (totally decomposed without melting by 97°).

Anal. Calcd. for $C_{11}H_{12}INO_3$: C, 39.66; H, 3.63; N, 4.20; I, 38.12. Found: C, 39.60; H, 3.74; N, 4.16; I, 38.26.

*3,5,6-Triacetoxy-7-iodo-1,2-dimethylindole (**23**)*

7-Iodo-2-methyladrenochrome (0.3 g) was dissolved in a mixture of acetic anhydride (5 ml) and dry pyridine (5 ml). The solution was allowed to stand overnight at room temperature and then added dropwise, with stirring, to an ice–water mixture. The aqueous product was extracted with ether (4 × 100 ml). The combined ether extracts were washed with 5% sodium bicarbonate solution (3 × 100 ml) and water (200 ml); benzene (100 ml) was added to the dried (Na_2SO_4) ethereal solution, and the ether removed *in vacuo*. The crude product, obtained in benzene solution, was purified chromatographically on a silica gel[9] column (3 in. × ¾ in.). Elution with benzene (600 ml) gave no identifiable products. Elution with ethyl acetate – benzene (5:95) (500 ml) gave a pale-pink solid which on recrystallization (charcoal) from benzene – light petroleum (b.p. 80–100°) gave colorless elongated prisms of 3,5,6-triacetoxy-7-iodo-1,2-dimethylindole (0.02 g; m.p. 186°).

Anal. Calcd. for $C_{16}H_{16}INO_6$: C, 43.15; H, 3.62; N, 3.15; I, 28.51. Found: C, 43.08; H, 3.65; N, 3.03; I, 28.75.

By analogous procedures the following compounds were prepared:

*3,5,6-Triacetoxy-1-ethyl-7-iodo-2-methylindole (**25**)*

Prepared from 1-ethyl-7-iodo-2-methylnoradrenochrome, as colorless prisms, m.p. 213°.

Anal. Calcd. for $C_{17}H_{18}INO_6$: C, 44.45; H, 3.95; N, 3.05. Found: C, 44.49; H, 4.04; N, 3.35.

*3,5,6-Triacetoxy-1,2-dimethylindole (**22**)*

Prepared from 2-methyladrenochrome, as colorless elongated prisms, m.p. 171°.

Anal. Calcd. for $C_{16}H_{17}NO_6$: C, 60.18; H, 5.37; N, 4.39. Found: C, 60.22; H, 5.30; N, 4.32.

*3,5,6-Triacetoxy-1-ethyl-2-methylindole (**24**)*

Prepared from 1-ethyl-2-methylnoradrenochrome, as colorless prisms, m.p. 152°.

Anal. Calcd. for $C_{17}H_{19}NO_6$: C, 61.25; H, 5.75; N, 4.20. Found: C, 61.05; H, 5.59; N, 4.14.

*5,6-Diacetoxy-1,2-dimethylindole (**26**)*

A solution of α-methyladrenaline hydrochloride (0.5 g) in water (10 ml) was oxidized by adding potassium ferricyanide (2.5 g) and sodium bicarbonate (0.8 g) in water (10 ml). Ether (50 ml) was added to the deep red aminochrome solution and solid sodium borohydride was then added portionwise until the red color of the aqueous phase had been totally discharged. The reaction mixture

[7]The resin (200/400 mesh size) was prepared by extensive washing with: (*1*) 3 *N* hydrochloric acid, (*2*) with water until neutral to litmus, and finally (*3*) with dry methanol.

[8]The decomposition points of all the aminochromes and aminochrome monosemicarbazones described in this paper were measured on a Leitz hot-stage instrument.

[9]In this and subsequent experiments the chromatographic silica gel used was obtained from the Koch-Light Laboratories Ltd. (200/300 mesh size).

was cautiously acidified with 2 *N* sulfuric acid; the ether layer was removed, and the mother liquors were extracted with a further quantity of ether (3 × 50 ml). A mixture of acetic anhydride (5 ml) and dry pyridine (5 ml) was added to the dried (Na_2SO_4) ethereal solutions. The ether was removed *in vacuo* (T < 30°) and, after standing at room temperature overnight, the acetylation mixture was added dropwise, with stirring, to an ice–water mixture. The product was extracted with ether (5 × 50 ml); the combined extracts were washed free of acetic acid with 5% aqueous sodium bicarbonate and water, and dried (Na_2SO_4). Evaporation *in vacuo* (T < 30°) gave a pale-yellow oil which slowly crystallized on standing. Recrystallization of the crude product from benzene – light petroleum (b.p. 80–100°) and finally from light petroleum alone gave very pale-yellow prisms of 5,6-diacetoxy-1,2-dimethylindole (0.01 g), m.p. 134–135°.

Anal. Calcd. for $C_{14}H_{15}NO_4$: C, 64.36; H, 5.79; N, 5.36. Found: C, 64.28; H, 5.76; N, 5.26.

5,6-Diacetoxy-1-ethyl-2-methylindole (28)

5,6-Diacetoxy-1-ethyl-2-methylindole (0.08 g) was obtained from *N*-ethyl-α-methylnoradrenaline hydrochloride (0.5 g) by an analogous procedure to that described above for the corresponding 1-methylindole (very pale-yellow needles from light petroleum (b.p. 100–120°), m.p. 137–138°.)

Anal. Calcd. for $C_{15}H_{17}NO_4$: C, 65.44; H, 6.22; N, 5.09. Found: C, 65.45; H, 6.22; N, 5.14.

5,6-Diacetoxy-7-iodo-1,2-dimethylindole (27)

Potassium iodate (0.9 g) was added to a solution of α-methyladrenaline hydrochloride (0.5 g) in water (400 ml) and the reaction mixture was stirred at room temperature for 2.5 h. Solid sodium hydrosulfite was added until the deep-violet color of the solution was completely discharged and the reaction mixture was extracted with ether (5 × 100 ml). A mixture of acetic anhydride (30 ml) and dry pyridine (30 ml) was added to the dried (Na_2SO_4) extract and the ether was removed *in vacuo* below 30°. After 16 h at room temperature, the reaction mixture was poured into an ice–water mixture; a white solid separated (0.25 g). On recrystallization from light petroleum (b.p. 80–100°) containing a little benzene this solid afforded 5,6-diacetoxy-7-iodo-1,2-dimethylindole (0.1 g) as colorless needles, m.p. 170–172°.

Anal. Calcd. for $C_{14}H_{14}INO_4$: C, 43.43; H, 3.65; N, 3.63; I, 32.79. Found: C, 43.48; H, 3.62; N, 3.58; I, 32.50.

5,6-Diacetoxy-1-ethyl-7-iodo-2-methylindole (29)

5,6-Diacetoxy-1-ethyl-7-iodo-2-methylindole was prepared from α-methyl-*N*-ethylnoradrenaline hydrochloride (0.5 g) in a similar manner to that described above for the corresponding 1-methyl compound. The product, (crude yield, 0.24 g) was obtained as colorless plates from benzene, m.p. 158–160°.

Anal. Calcd. for $C_{15}H_{16}INO_4$: C, 44.91; H, 4.02; N, 3.50; I, 31.64. Found: C, 44.97; H, 4.04; N, 3.53; I, 31.78.

Chemistry of the aminochromes. Part XII. Some new aminochromes and their derivatives[1-3]

R. A. HEACOCK AND O. HUTZINGER
Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received August 9, 1968

The synthesis of a number of new aminochromes (and their monosemicarbazones) derived from catecholamines containing: (*a*) a primary amino group and (*b*) an alkoxy group in the β-position of the ethylamine side chain is reported. Improved procedures for the preparation of some previously described aminochromes of these types including 7-iodonorepinochrome and adrenochrome methyl and ethyl ethers are also given.

Canadian Journal of Chemistry, 47, 2009 (1969)

In previous publications in this series the preparation, physical properties, and chemical reactivity of several new aminochromes have been described (1–3). This paper describes attempts to isolate a number of other new aminochromes as crystalline solids from catecholamines with: (*a*) a primary amino group and (*b*) an alkoxy group in the β-position of the ethylamine side chain.

Whilst the preparation of aminochromes from catecholamines containing a secondary amino group presents no particular problems (cf. review by Heacock, (4)) no simple non-halogenated aminochromes have, as yet, been obtained, as fully characterized crystalline solids, from primary catecholamines. Marquardt and Carl (5) reported that noradrenochrome (**1**) could be obtained as an ill-defined red-brown powder or as "red rings on the side of the flask" when noradrenaline (**2**) was oxidized with silver oxide in acetonitrile. The ultraviolet–visible absorption spectrum of **1** was described, but no other physical or analytical data were reported (5).

In view of the interest that has developed in recent years in the physiological activity of adrenochrome (cf. ref. 4, p. 279) it was considered desirable to investigate also the physiological activity of pure samples of noradrenochrome (**1**). However, attempts in the hands of the authors, to repeat and improve on the procedure of Marquardt and Carl for the preparation of **1** have met with little success. It was also not possible to obtain crystalline **1** by the oxidation of noradrenaline (**2**) with silver oxide in methanol, using the method commonly employed for the preparation of adrenochrome from adrenaline (6) or by oxidation of the base with the calculated quantity of iodic acid in aqueous methanol (cf. 7), a method that has been successfully used for the preparation of adrenochrome. Whilst red solutions were obtained using both of these procedures, only unidentified black amorphous solids could be isolated in either case. Similarly all attempts to prepare crystalline 2-methylnoradrenochrome (**3**) by the oxidation of 3,4-dihydroxynorephedrine (**4**) were unsuccessful.

7-Iodonoradrenochrome (**5**) was first prepared by Bu'Lock and Harley-Mason in 1951 (8) by the oxidation of noradrenaline (**2**) with potassium iodate in aqueous solution. It was later shown that the copious formation of tarry by-products, that invariably occurred in this reaction, could be avoided if the reaction was carried out in more dilute solution under fairly strong acid conditions (9). A number of 7-halogenated aminochrome

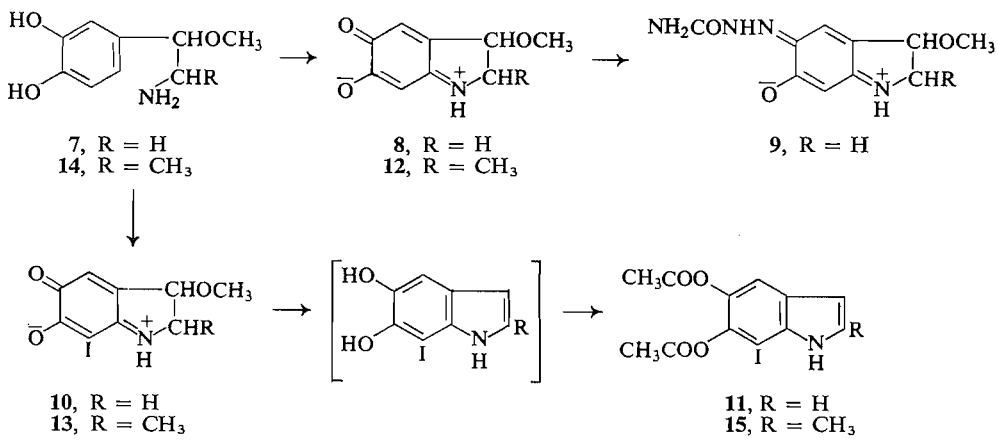
[3]The preliminary phases of the work described in this paper were carried out by the authors in the laboratories of the Psychiatric Research Unit, University Hospital, Saskatoon, Saskatchewan.



monosemicarbazones have recently been prepared by direct halogenation of the corresponding aminochrome monosemicarbazones and shown to exhibit potent hypotensive activity (10). A potentially very interesting member of this series, from the physiological standpoint, which was not reported in the original patent (10), is 7-iodonoradrenochrome monosemicarbazone (**6**). This compound has now been prepared by direct condensation of 7-iodonoradrenochrome (**5**) with semicarbazide.

Whilst red products were definitely obtained on the oxidation of noradrenaline methyl ether (**7**) with silver oxide either in methanol or acetonitrile it was not possible to isolate noradrenochrome methyl ether (**8**) as a crystalline solid from such solutions. However, noradrenochrome methyl ether monosemicarbazone (**9**) was obtained as a red microcrystalline solid from aqueous solutions of noradrenaline methyl ether (**7**) which had been oxidized with potassium ferricyanide. All attempts to prepare crystalline 7-iodonoradrenochrome methyl ether (**10**) by the oxidation of **7** with potassium iodate in aqueous solution were unsuccessful. There appears to be little doubt however that the iodoaminochrome **10** had formed, since the violet color of the solution was rapidly discharged by ascorbic acid, a reagent known to reduce aminochromes (cf. ref. 4, p. 253). 5,6-Diacetoxy-7-iodoindole (**11**) could be obtained by the acetylation of the ether-soluble reduction products. This product would have been expected since it is known that aminochromes with a 3-alkoxy group, like those with a 3-hydroxy group, give 5,6-dihydroxyindoles on reduction (11).

Similarly, all attempts to isolate crystalline 2-methylnoradrenochrome methyl ether (**12**) or 7-iodo-2-methylnoradrenochrome methyl ether (**13**) from solutions of oxidized α-methylnoradrenaline methyl ether (**14**) were not successful. As in the case of the oxidation products of noradrenaline methyl ether (**7**) however, it appeared that 7-iodo-2-methylnoradrenochrome methyl ether (**13**) was formed during the aqueous iodate oxidation since 5,6-diacetoxy-7-iodo-2-methylindole (**15**) was obtained on acetylation of the ether-soluble reduction products of **13**.

The formation of a crystalline iodo derivative of norepinochrome was first reported in 1951 (12). At that time neither the details of the preparative procedure nor the position of the iodine atom in the molecule was defined. This compound has now been obtained as a well-characterized violet-brown crystalline solid by the oxidation of dopamine (**16**) with potassium iodate under the conditions used to prepare 7-iodonoradrenochrome (**5**) (cf. 9). In common with all other iodoaminochromes the iodo derivative of norepinochrome is a 7-iodo derivative (i.e. **17**) since it gave 5,6-diacetoxy-7-iodoindole (**11**) on treatment with acetic anhydride and pyridine (cf. ref. 4, p. 242).

The iodoaminochrome **17** is probably the primary product obtained on oxidation of dopamine (**16**) with iodine, the reaction employed as the first stage of the commonly used estimation of dopamine in clinical chemistry. The chemistry of this method does not appear to be clearly understood (cf. ref. 4, p. 282).

The methyl and ethyl ethers of adrenochrome (**18** and **19**) were first isolated as their mono-

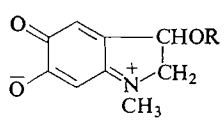
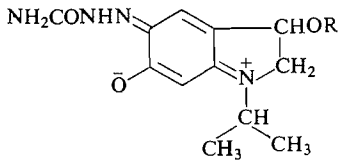
16 17 11

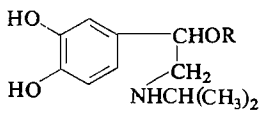
semicarbazones (13); the preparation of the crystalline aminochromes **18** and **19** in relatively poor yield was later reported by Heacock and Scott (1) who carried out the oxidation of adrenaline methyl and ethyl ether in acetonitrile with silver oxide. It has now been shown that **18** and **19** can be readily prepared by carrying out the oxidation in a methanol–ether medium.



18, R = CH_3
19, R = C_2H_5



22, R = CH_3
23, R = C_2H_5



20, R = CH_3
21, R = C_2H_5

The preparation of the methyl and ethyl ethers of *N*-isopropylnoradrenaline (i.e. **20** and **21**) has recently been described (14). In view of the relatively small amount of research that has been carried out into the chemistry of the aminochrome ethers, attempts were made to prepare aminochromes (and their 7-iodo derivatives) from **20** and **21**. Whilst it was not possible to obtain these aminochromes in crystalline form it was possible to isolate crystalline monosemicarbazones of 1-isopropylnoradrenochrome methyl ether and 1-isopropylnoradrenochrome ethyl ether (i.e. **22** and **23**).

The results reported in this paper indicate some of the difficulties that are encountered in the synthesis of aminochromes derived from catecholamines containing a primary amino group or a β-alkoxy group in the ethylamine side chain.

Experimental

7-Iodonorepinochrome (17)

Potassium iodate (0.8 g) was added to a solution of dopamine hydrochloride (0.5 g) in water (150 ml). The reaction mixture was stirred at room temperature for 1 h, after which time the pH of the solution was adjusted to 2 by the dropwise addition of concentrated hydrochloric acid; 7-iodonorepinochrome (0.28 g; totally decomposed without melting by 106°[4]) was obtained as a violet-brown crystalline solid after the deep red-violet solution had been allowed to stand in the refrigerator overnight.

Anal. Calcd. for $C_8H_6INO_2$: C, 34.94; H, 2.20; N, 5.09; I, 46.15. Found: C, 34.85; H, 2.11; N, 5.16; I, 45.97.

Acetylation of 7-Iodonorepinochrome (17); Preparation of 5,6-Diacetoxy-7-iodoindole (11)

7-Iodonorepinochrome (1.2 g) was dissolved in a mixture of acetic anhydride (35 ml) and dry pyridine (35 ml) and the solution was allowed to stand at room temperature overnight. The reaction mixture was then added dropwise to a stirred ice–water mixture (1500 ml) and the aqueous reaction product was extracted with ether[5] (6 × 150 ml). The combined ether extracts were washed with saturated aqueous sodium bicarbonate (until free of acetic acid) and with water (2 × 100 ml). The yellow oily residue, which remained on concentration of the dried (Na_2SO_4) solution, *in vacuo*, gave after recrystallization from benzene – light petroleum (b.p. 80–100°), pale-fawn colored crystals (0.41 g; m.p. 123–126°) of crude 5,6-diacetoxy-7-iodoindole. This product was purified first by chromatography on a short silica gel[6] column with benzene – light petroleum (b.p. 60–80°) (2:1) as eluant and finally by further recrystallization from benzene – light petroleum (b.p. 80–100°). In this manner a pure sample of 5,6-diacetoxy-7-iodoindole (0.25 g; m.p. 127–128°) was obtained as a colorless crystalline solid. The melting point of a sample of 5,6-diacetoxy-7-iodoindole prepared by acetylation of the reduction product of 7-iodoadrenochrome (cf. 15) was undepressed on admixture with a sample of the same compound, prepared by the method described above.

7-Iodonoradrenochrome Monosemicarbazone (6)

A suspension of 7-iodonoradrenochrome (0.3 g), prepared by the method of Heacock and Scott (9), sodium acetate (0.5 g; anhydrous), and semicarbazide hydrochloride (0.5 g) in water (2.5 ml) was stirred at room temperature for 2 h. The crude product, an orange-brown solid (0.23 g), was filtered off, washed with a little cold water, and air dried. The residue was repeatedly extracted with boiling ethanol. The combined extracts were concentrated to small volume and an equal quantity of dry

[4]The decomposition points were measured on a Leitz hot-stage instrument.

[5]Peroxide-free ether was used throughout this investigation.

[6]In this and subsequent experiments the chromatographic silica gel used was obtained from the Koch-Light Laboratories Ltd. (200/300 mesh size).

benzene added. 7-Iodonoradrenochrome monosemicarbazone (0.04 g) was obtained as a deep cherry red crystalline solid (totally decomposed by 158°).

Anal. Calcd. for $C_9H_9IN_4O_3$: C, 31.05; H, 2.61; N, 16.10; I, 36.40. Found: C, 31.30; H, 2.73; N, 16.41; I, 36.49.

Oxidation of Noradrenaline Methyl Ether (7)

(i) Oxidation with Silver Oxide

No crystalline products could be isolated from solutions of noradrenaline methyl ether hydrochloride, in either methanol or acetonitrile, which had been oxidized with silver oxide.

(ii) Oxidation with Potassium Ferricyanide; Preparation of Noradrenochrome Methyl Ether Monosemicarbazone (9)

A solution of noradrenaline methyl ether hydrochloride (0.5 g, (14)) in water (2.5 ml) was oxidized with a solution of potassium ferricyanide (2.35 g) and sodium bicarbonate (0.75 g) in water (6.2 ml). After the oxidation had been allowed to proceed for 5 min a solution of semicarbazide hydrochloride (0.25 g) and sodium acetate (0.25 g) in water (1.5 ml) was added to the deep-red solution containing noradrenochrome methyl ether. A brown precipitate (0.25 g) separated after the reaction mixture had been allowed to stand at 4° overnight. Eventually a small quantity of noradrenochrome methyl ether monosemicarbazone was obtained as a deep-red microcrystalline powder (totally decomposed by 208°) by repeated recrystallization of the crude product from aqueous alcohol.

Anal. Calcd. for $C_{10}H_{12}N_4O_3$: C, 50.84; H, 5.12; N, 23.72. Found: C, 50.52; H, 5.29; N, 23.55.

(iii) Oxidation with Potassium Iodate

(*a*) Potassium iodate (0.8 g) was added to a solution of noradrenaline methyl ether hydrochloride (0.5 g; (14)) in water (150 ml). The reaction mixture was stirred at room temperature for 3½ h, after which time the deep-purple solution was filtered from a little dark-colored amorphous insoluble material. No significant precipitation occurred after the reaction mixture had been allowed to stand in the refrigerator overnight. The pH of the solution was then adjusted to 2 and it was allowed to stand at 4° for several hours; however, no crystalline iodoaminochrome was obtained.

The solution, presumed to contain 7-iodonoradrenochrome methyl ether (**10**), was treated with an excess of ascorbic acid and rapidly extracted with ether (4 × 60 ml). A mixture of acetic anhydride (10 ml) and dry pyridine (10 ml) was added to the dried (Na_2SO_4) ethereal extracts. After removal of the ether *in vacuo* the acetylation mixture was allowed to stand at room temperature overnight and was then poured dropwise with stirring into an ice–water mixture. The aqueous reaction mixture was ether extracted (4 × 60 ml) and the combined ether extracts washed free of acetic acid with 5% aqueous sodium bicarbonate and water. Benzene (50 ml) was added to the dried (Na_2SO_4) ether solution and the ether removed *in vacuo*. The crude product (in benzene solution) was purified chromatographically on a short silica gel column by adsorption from benzene – light petroleum (b.p. 60–80°) (1:1) and elution with a mixture (5:1) of these solvents. 5,6-Diacetoxy-7-iodoindole (0.13 g; m.p. 126–127°) was obtained when the partially purified product, obtained on concentration of the combined eluates, was recrystallized from benzene – light petroleum (b.p. 80–100°). This material did not depress the melting points of samples of 5,6-diacetoxy-7-iodoindole obtained from dopamine (see above) or noradrenaline (15).

(*b*) No crystalline products were obtained when more concentrated aqueous solutions of noradrenaline methyl ether hydrochloride were oxidized with potassium iodate in water at 0°. Repeated filtration from initially formed tarry by-products and adjustment of the pH of the solution to 2 were of no avail.

Oxidation of α-Methylnoradrenaline Methyl Ether (14)

An attempt to prepare 7-iodo-2-methylnoradrenochrome methyl ether (**13**) from α-methylnoradrenaline methyl ether hydrochloride (0.5 g), by a method analogous to that described above for the corresponding noradrenaline derivative was also unsuccessful. The deep-purple solution of the crude iodoaminochrome was reduced and the products acetylated as described previously. On pouring the acetylation mixture into ice–water a pale-brown solid was obtained. The product was dissolved in a mixture of benzene and light petroleum (b.p. 80–100°) (1:1) and adsorbed on a short silica gel column (2.5 × 2.2 cm). Elution of the column with benzene – light petroleum (b.p. 80–100°) (5:1) gave a solid product, which, on recrystallization from benzene – light petroleum (b.p. 100–120°), gave 5,6-diacetoxy-7-iodo-2-methylindole (0.055 g), m.p. 161–162°, undepressed on admixture with a sample prepared from α-methylnoradrenaline hydrochloride (16).

Adrenochrome Methyl Ether (18)

Freshly prepared silver oxide (5 g) was added to a solution of adrenaline methyl ether hydrochloride (1 g; (13)) in dry methanol (10 ml). The reaction mixture was shaken vigorously for 3–4 min and then filtered with suction through a Dowex-1 (Cl^-) resin bed.[7] Dry ether (30 ml) was added to the deep-red filtrate, which was cooled to −80°. After standing for several hours at this temperature adrenochrome methyl ether was obtained as a deep-red microcrystalline solid (m.p. softens at 81°; totally decomposed by 86°; undepressed on admixture with a sample of this compound prepared by the method previously described (1)). A second crop was obtained from the mother liquors after they had been allowed to stand at −80° overnight (total yield, 0.19 g).

Anal. Calcd. for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.74. Found: C, 62.04; H, 5.71.

Adrenochrome Ethyl Ether (19)

Adrenochrome ethyl ether (0.25 g) was prepared as a deep-red microcrystalline solid (m.p. 79.5–81.5° with decomposition, undepressed on admixture with a sample of this compound prepared by the method previously described (1)) from adrenaline ethyl ether hydrochloride (1 g) by a method analogous to that described above for the preparation of adrenochrome methyl ether.

Anal. Calcd. for $C_{11}H_{13}NO_3$: C, 63.75; H, 6.32; N, 6.76. Found: C, 63.60; H, 6.32; N, 6.77.

---

[7]The resin (200/400 mesh size) was prepared by extensive washing with: (*1*) 3 *N* hydrochloric acid; (*2*) with water until neutral to litmus; and (*3*) finally with dry methanol. Column diameter, 2.5 cm; height, 1 cm.

1-Isopropylnoradrenochrome Methyl Ether Monosemicarbazone (22)

A solution of *N*-isopropylnoradrenaline methyl ether hydrochloride (0.25 g; (14)) in water (1.3 ml) was oxidized with a solution of potassium ferricyanide (1.17 g) and sodium bicarbonate (0.37 g) in water (3.1 ml). A solution containing semicarbazide hydrochloride (0.13 g) and sodium acetate (0.13 g) in water (0.7 ml) was added to the deep-red aminochrome solution; the resulting orange-colored solution deposited an orange-brown crystalline solid, m.p. 184–185° (decomp.) after being allowed to stand at 4° overnight. Recrystallization from water afforded 1-isopropylnoradrenochrome methyl ether semicarbazone (0.2 g) in reddish-orange elongated prisms, m.p. 190.5–191° (decomp.).

Anal. Calcd. for $C_{13}H_{18}N_4O_3$: C, 56.10; H, 6.52; N, 20.13. Found: C, 55.95; H, 6.56; N, 19.96.

1-Isopropylnoradrenochrome Ethyl Ether Monosemicarbazone (23)

1-Isopropylnoradrenochrome ethyl ether monosemicarbazone (0.21 g) (very small orange prisms; m.p. 187.5–188.5° (decomp.) was prepared from *N*-isopropylnoradrenaline ethyl ether hydrochloride (0.25 g; (14)) in a manner analogous to that described above for the corresponding methyl ether.

Anal. Calcd. for $C_{14}H_{20}N_4O_3$: C, 57.52; H, 6.90; N, 19.17. Found: C, 57.32; H, 6.84; N, 19.07.

Dimethyl sulfoxide as a solvent in the Williamson ether synthesis[1]

RUSSEL G. SMITH, ALAN VANTERPOOL, AND H. JEAN KULAK[2]
Research Department, Canadian Chemical Company, P.O. Box 99, Edmonton, Alberta

Received September 9, 1968

Using the conventional Williamson ether synthesis, *n*-butyl ether was prepared from sodium hydroxide, *n*-butyl alcohol, and *n*-butyl chloride using excess of the alcohol as solvent in 61% yield after 14 h reaction time. However, when the excess alcohol was replaced by dimethyl sulfoxide, the yield of ether rose to 95% with 9.5 h reaction time. Other primary alkyl chlorides exhibited similar behavior to *n*-butyl chloride, but secondary alkyl chlorides and primary alkyl bromides gave little etherification, elimination being the major reaction. Unreactive halides, such as vinyl chloride, phenyl bromide, and 2,4-dinitrobromobenzene, were not etherified in dimethyl sulfoxide. The reaction products obtained from aliphatic dichlorides depended upon the relative positions of the chlorine atoms. Secondary alcohols reacted to give ethers, but tertiary alcohols were very unreactive. Polyols generally gave high yields of ethers, the major product being that in which all but one of the hydroxyl groups became etherified. Under forcing conditions, however, completely etherified polyols could be obtained.

Canadian Journal of Chemistry, 47, 2015 (1969)

Introduction

It has been shown by Cram and co-workers (1) that dimethyl sulfoxide (DMSO) is a useful solvent for the Williamson reaction (2). Working with phenyl bromide and potassium *t*-butoxide these authors obtained a greatly enhanced rate and a better overall yield of *t*-butyl phenyl ether in DMSO as compared to the conventional synthesis in *t*-butyl alcohol.

Later, workers studied the mechanism of the rate enhancement in greater detail and extended the application of the reaction in DMSO. Thus, ethers have been prepared from alkoxides and alkyl sulfonate esters (3, 4), from carbohydrates and dimethyl sulfate or methyl iodide (5, 6), from phenoxides and butyl halides (7), from methoxide and benzyl chlorides (8), from diphenoxides and dihaloaromatic compounds (9), and from methoxide and phenolates with poly[3,3-bis(chloromethyl)oxacyclobutane] (10). Zimmerman and Dathe (11) have shown polyol ethers can be obtained by reaction of the sodium alkoxide formed from the polyol and sodium hydroxide with alkyl chlorides.

The rate enhancement which occurs on transfer of a nucleophilic reaction from a protic solvent such as *t*-butanol to a dipolar aprotic solvent such as DMSO has been discussed in a review article by Parker (12). The rate enhancement is explained on the basis of the much greater solvation of anions in protic solvents along with the much greater solvation of polarized charged transition states in dipolar aprotic solvents. Consequently, for nucleophilic reactions the activation energy is less in dipolar aprotic solvents than in protic solvents. Rate enhancements by factors as large as 1×10^{10} have been observed for some nucleophilic reactions on transfer from protic solvents to dipolar aprotic solvents.

The use of sodium hydroxide to form alkoxides and subsequent reaction with alkyl chlorides as reported by Zimmerman and Dathe (11) is of interest since it is considerably less expensive than the conventional use of sodium metal and alkyl bromides. The purpose of the work reported here was to determine the limitations and advantages of this method of ether synthesis.

Experimental

In a typical preparation the hydroxyl containing compound, a stoichiometric excess of sodium hydroxide and DMSO (ca. 300 ml per mole of hydroxylic compound) was mixed and heated, with stirring. The temperature chosen was 5–10 °C below that at which discoloration occurred (usually 90–110 °C). When the precipitate had changed in physical appearance from a slimy to a granular form, the halide (in stoichiometric equivalence with caustic) was slowly added at such a rate that the temperature could be maintained at ca. 100 °C. Stirring and heating were maintained for 2–3 h after the addition was complete. The mixture was then cooled, and sufficient water added to dissolve the precipitated solids. The liquid layers were extracted with ethyl ether, the extracts combined, dried (sodium sulfate), and the ether removed by distillation. The residue was vacuum flashed, and the distillate analyzed by hydroxyl value and gas chromatography. Peak assignment, where possible, was made

using known compounds. When these were not available, the assignment was chosen so as to agree with the determined hydroxyl value.

Volatile by-products were trapped in a dry ice – acetone bath and analyzed by mass spectrometry.

Results and Discussion

In general, it proved difficult to prepare alkoxides at practical synthetic levels in DMSO since both sodium hydroxide and the alkoxides studied had very limited solubility in DMSO. Consequently, long reaction times and high temperatures were necessary for the alkoxide production stage of the synthesis. Once the alkoxide had been formed, reaction with alkyl chlorides was rapid and ethers could be obtained in good yields. When *n*-butyl ether was prepared (Table I), it was obtained in 95% yield after a total of 9.5 h reaction time of which 7.0 h were required for alkoxide formation. This result compares favorably with a 61% yield obtained after 14 h reaction time, when *n*-butyl alcohol was used as the solvent instead of DMSO. When a reaction time of only 2.5 h for alkoxide formation in DMSO was allowed, the yield of the ether was only 62%.

In the synthesis of *n*-butyl ether in DMSO, a portion of the excess *n*-butyl chloride employed was converted to 1-butene. This elimination reaction did not occur in *n*-butyl alcohol solvent or when aqueous DMSO was employed. If stoichiometrically equivalent quantities of *n*-butyl alcohol, sodium hydroxide, and *n*-butyl chloride were used in the synthesis, a low yield of *n*-butyl ether was obtained due to this competing elimination. However, good yields of *n*-butyl ether could be obtained if a 1.5 fold excess of sodium hydroxide and *n*-butyl chloride was used over the *n*-butyl alcohol.

The synthesis gives good results when other primary alcohols and other primary chlorides are used. Thus, *n*-dodecyl ether was prepared (Table II) in 54% yield from *n*-dodecyl alcohol and *n*-dodecyl chloride.

A series of halides was reacted with *n*-butyl alcohol to determine the limitations to the type of halide which could be used in the synthesis. With isopropyl chloride (Table II), *t*-butyl chloride, and *n*-butyl bromide, the elimination reaction was sufficiently pronounced that little, if any, etherification occurred. On the other hand, vinyl chloride, 2,4-dinitrobromobenzene, and phenyl bromide failed to react at all (unreported experiments). This result is in contrast to the work of Cram *et al.* (1) where however, rigorously anhydrous conditions were employed.

Secondary alcohols, e.g., isopropyl alcohol, cyclohexyl alcohol, were found to be less reactive than *n*-butyl alcohol, while *t*-butyl alcohol was very unreactive (cf. Cram *et al.* (1)) (Table II). This lack of reactivity probably relates more to a difficulty in forming the alkoxide than to a difficulty in reacting the alkoxide with the halide. With phenol the reaction was particularly satisfactory since sodium phenoxide formed easily and was soluble in DMSO.

The reaction products obtained from aliphatic dichlorides depended on their structure. Thus, the *vicinal* dihalides studied (Table III) gave no ethers. Instead, appreciable amounts of acetylenes were formed, together with minor amounts of vinyl chlorides. With 1,3-dichloropropane

there was a substantial amount of elimination to give allyl chloride, much of which reacted to form a mixture of ethers. However, there was also an appreciable degree of hydrolysis of the halides resulting, after subsequent reaction, in allyl ether and γ-hydroxypropyl butyl ether. 1,4-Dichlorobutane on the other hand, gave 1,3-butadiene as the major product with minor amounts of 1,4-dibutoxybutane and δ-chlorobutyl butyl ether. All these aliphatic dichlorides, however, were considerably less reactive than *n*-butyl chloride, as shown by the amount of unreacted *n*-butyl alcohol detected in the reaction product.

The reaction of several polyols with *n*-butyl chloride demonstrated (Table IV) that they were more reactive than the monohydric alcohols examined. This was to be expected on the basis of their higher acidity (13). However, mixtures of products were invariably obtained. Thus, ethylene glycol gave 22% monoether and 66% diether. With 1,2-propylene glycol, 27% of the fully etherified material was obtained along with 55% of the monoether. There were two monoethers formed, however; one, presumably 1-butoxy-2-hydroxypropane, to a much greater extent than the other (49% vs. 6%). With glycerol, no monoether was formed, only a mixture of diethers (34% of one isomer and 7% of the other) and the triether (24%). Trimethylolpropane and pentaerythritol also formed ethers in high conversion. The major product was that in which all but one of the hydroxyl groups had been etherified. *n*-Octyl chloride reacted with pentaerythritol in a similar manner to *n*-butyl chloride, while benzyl and methallyl chlorides gave results more similar to allyl chloride.

An appreciation of the selectivity of the reaction system, using pentaerythritol as an example can be gained from Table V. With either butyl or allyl chloride, no conditions were found which gave any appreciable amount of monoether. Diethers were obtained in modest conversions by using short reaction times for alkoxide formation and by reducing the moles of base and halide per mole of pentaerythritol. High conversion to tri-ether resulted when additional water was added to the solvent or by control of the stoichiometry. Tetra-ethers resulted when a large excess of alkyl chloride was employed with or without concomitant removal of water from the system. Previously it had not been found possible to make pentaerythritol tetraether in one step (14). The reaction using *n*-butyl chloride in DMSO resulted in production of 1-butene, *n*-butyl alcohol, and *n*-butyl ether by-products, but these were absent when the solvent was aqueous DMSO.

Polyallyl ethers of several other polyols were prepared. The mixed products were analyzed by determining hydroxyl number and iodine number. For materials, such as, sucrose, sorbitol, and inositol, which contain both primary and secondary hydroxyl groups, there was a low conversion (i.e., 10 to 30%) to highly etherified products. In each case, there was on an average, less than one free hydroxyl group remaining. Glucose was resinified by the highly alkaline reaction medium.

Reactions of cysteine with *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide and *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine

UWE SCHULZ AND D. R. MCCALLA
Department of Biochemistry, McMaster University, Hamilton, Ontario

Received December 10, 1968

The reaction between cysteine and *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide affords almost quantitative yields of cystine and *N*-methyl-*p*-toluenesulfonamide. A mechanism based on the intermediacy of the *S*-nitroso derivative of cysteine and the intermediate formation of nitric oxide is proposed. Nitrous oxide is shown to be a final product. In the reaction of cysteine with *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine a substantial yield of 2-nitramino-4-carboxyl-thiazoline is obtained. Cystine, *N*-methyl-*N'*-nitroguanidine and *S*-methylcysteine are formed in lesser amounts. The major product arises from nucleophilic attack on the imino carbon of *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine. Concomitant elimination of the methylnitrosamino group accounts for the methylating ability of the system.

Canadian Journal of Chemistry, 47, 2021 (1969)

Previous work in this laboratory has shown that deoxyribonucleic acid (DNA) becomes methylated when it is allowed to react *in vitro* with either *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (NG) or with *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (MNTS) (1). Addition of cysteine to the reaction mixture was found to increase methylation by NG but to decrease dramatically methylation by MNTS, results which are of considerable interest in view of biological studies showing that cysteine has a protective action against certain types of alkylating agents (2).

Both NG and MNTS are well-established sources of diazomethane in their reactions with aqueous base (3, 4). For the reactions of NG and MNTS with nucleophilic reagents other than oxygen nucleophiles, a variety of products are reported. McKay and Wright (5) demonstrated that primary alkyl or aryl amines react with NG with the elimination of the methylnitrosamino group and the formation of *N*-substituted nitroguanidines. The only secondary amine to react with NG to give a *N*-disubstituted-*N'*-nitroguanidine is dimethylamine. Reaction of NG with other secondary amines resulted in denitrosation (6). In the reaction of NG with azide ion the methylnitrosamino group is eliminated and 5-nitroaminotetrazole is formed by cyclization of the intermediate nitroguanylazide (7). The reaction between MNTS and piperidine results in transfer of the nitroso group to form *N*-nitrosopiperidine without the formation of any diazomethane (4). Low yields of diphenylnitrosamine are reported to result from reaction of MNTS with diphenylamine (8).

Thus, while the existing literature pointed to the fact that the *N*-methyl-*N*-nitroso compounds under consideration exhibit two centers susceptible to nucleophilic attack, resulting in loss of the methylnitrosamino group and the nitroso function respectively, no information was available on their reactions with mercaptans. We report here data that provide a reasonable explanation for the difference in the behavior of NG and MNTS in the presence of cysteine.

Results and Discussion

Reactions of Cysteine with MNTS

The reactions of cysteine with MNTS were carried out at room temperature in aqueous 25% ethanol at pH 7 in an atmosphere of nitrogen. An ethanolic solution of MNTS was added to a magnetically stirred aqueous solution of cysteine at such a rate that the solution remained homogeneous. Upon addition of MNTS, the reaction mixture turned light-red and evolved gas. After most of the MNTS was added, a white solid precipitated. Preliminary experiments using a 1:1 ratio of reagents resulted in partial recovery of MNTS after an extended reaction period. Subsequently all experiments were carried out using a 1:2 ratio of MNTS and cysteine. Filtration after a reaction period of 20 h afforded an 85% yield of cystine. On ether extraction of the filtrate, *N*-methyl-*p*-toluenesulfonamide was isolated in 93% yield. The products were identified by their infrared spectra and their chromatographic behavior in comparison with that of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

authentic samples. The amount of gas collected in a measuring cylinder during the reaction corresponded to 53 mole % based on the amount of MNTS. On exposure of the collected gas to air, brown fumes developed accompanied by a characteristic smell of nitrogen dioxide. This behavior pointed to the presence of nitric oxide. When the reaction was carried out in a closed system flushed with nitrogen and evacuated by means of an aspirator prior to addition of MNTS, the yield of cystine increased to 91%. The gaseous products at the end of the reaction were analyzed by mass spectrometry. The predominant peak was found at *m/e* 44 and was assigned to nitrous oxide. No peak was observed at *m/e* 30 corresponding to nitric oxide.

The observations described can be accounted for by the following mechanism:

[1] 
[2] $R{-}S{-}N{=}O \rightarrow R{-}S\cdot + \cdot N{=}O$

[3a] $R{-}S\cdot + R{-}S\cdot \rightarrow R{-}S{-}S{-}R$

[3b] $R{-}S\cdot + R{-}S{-}N{=}O \rightarrow R{-}S{-}S{-}R + \cdot N{=}O$

[4] $RSH + \cdot N{=}O \rightarrow R{-}S\cdot + HNO$

[5] $2HNO \rightarrow N_2O + H_2O$

$$R = H_2N{-}\underset{\displaystyle COOH}{\underset{|}{CH}}{-}CH_2$$

Initial nucleophilic attack by the sulfhydryl function on the nitroso group of MNTS results in the formation of *N*-methyl-*p*-toluenesulfonamide and of the *S*-nitroso derivative of cysteine. Subsequent reactions leading to the observed products involve radical intermediates formed by homolytic decomposition of the thionitrite.

Although in its entirety this mechanism is without precedent, the individual steps are supported by literature data and by additional experimental results described below. Isolation of *N*-methyl-*p*-toluenesulfonamide and appearance of a red color are considered sufficient evidence for eq. [1]. Solutions of thionitrites are known to be red (9, 10), though there is one report of green solutions of this class of compounds (11). Furthermore, the electronic spectrum of the reaction mixture shortly after mixing agreed closely with those reported for other thionitrites (12, 13). Thionitrites are relatively unstable compounds and are generally prepared in solution by action of nitrous acid (10) or nitrosyl chloride (9, 14) on the mercaptan. Thus, the reaction of a mercaptan with MNTS represents an alternative route to this class of compound and might have some practical value where strongly acidic (10) and anhydrous conditions (9, 14) are not expedient. Formation of a thiyl radical and nitric oxide has been reported in photolysis of thionitrites (12, 13). The thermal instability of the *S*-nitroso derivative of cysteine was indicated by our observation that exclusion of light had no noticeable effect on the rate of the reaction.

A somewhat disturbing fact was the report of a half-life of approximately 50 h for the *S*-nitroso derivative of cysteine when prepared from sodium nitrite in sulfuric acid in the presence of ammonium sulfamate (10). We therefore prepared the thionitrite in question by this latter method, but without addition of ammonium sulfamate. A deep red color resulted and persisted over a period of several hours. However, when the reaction mixture was adjusted to pH 7 immediately after mixing of the reagents, a vigorous evolution of gas set in within minutes, accompanied by precipitation of cystine and fading of the color. After 40 min a 78% yield of cystine was obtained. Thus, eq. [2] in the proposed reaction scheme is consistent with the behavior of the *S*-nitroso derivative of cysteine produced by an independent route.

The efficiency of eq. [2] does not have to be exceedingly high in view of a possible subsequent step [3*b*], a reaction that has precedence in the literature (12). Hydrogen atom abstraction from the sulfhydryl function of cysteine by nitric oxide should be an energetically favorable process considering the energy contents of the chemical bonds involved (15), and indeed reaction between an aqueous solution of cysteine and nitric oxide produced an almost quantitative yield of cystine. Preparation of disulfides in excellent yields has been reported for reactions of mercaptans with nitric oxide in the presence of hydroxide (16) and methoxide (17) ion. The

For personal use only.

dimerization reaction of nitroxyl and subsequent decomposition follow from the work of Harteck (18) and seem to explain the formation of nitrous oxide. In this connection mention should be made of an investigation of the gas formation by cysteine during nitrite azotometry (19). Nitrous oxide was identified as product and the reaction mechanism was assumed to be as follows:

$$RSH + HNO_2 \rightarrow RSNO + H_2O$$

$$2RSNO \rightarrow RSSR + 2NO$$

$$2NO \rightarrow N_2O + O$$

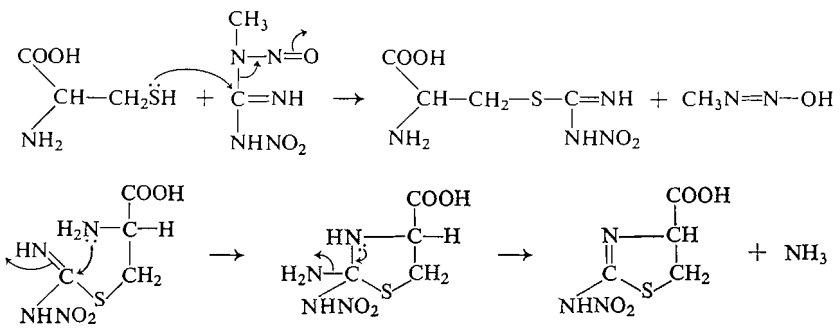
Regarding the last step of this scheme we prefer our mechanistic proposal as it avoids the intermediacy of atomic oxygen which certainly would enter into further reactions.

Strong supporting evidence for the mechanism presented in this paper derives from variations in the stoichiometry under different reaction conditions. The fact that considerable amounts of unchanged MNTS could be recovered from reactions using a 1:1 ratio of MNTS and cysteine seems to indicate that the reaction steps [3–5] in our scheme involving radicals are fast compared to the initial nucleophilic attack on MNTS. The observed intermediacy of nitric oxide and the failure to detect any nitric oxide at the end of the reaction also support this notion. Finally, the decreased yield of cystine when the evolving gas is taken out of the reaction system during the reaction is in good agreement with the proposed mechanism.

Reactions of Cysteine with NG

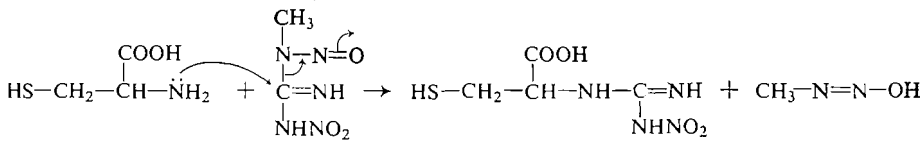
The reactions of cysteine with NG were carried out in a manner analogous to that described for the reactions of cysteine with MNTS. Again a red color developed, gas evolved and precipitation of cystine took place. However, the yield of cystine (36%) was considerably lower and the amount of gas collected considerably higher than observed for the reaction of cysteine and MNTS. When the reaction was carried out in a closed system, the yield of cystine increased to 41%. Continuous extraction of the aqueous phase with ethyl acetate afforded a 22% yield of *N*-methyl-*N'*-nitroguanidine. When the aqueous phase was acidified and again extracted with ethyl acetate, a material was obtained which was shown to be homogeneous by thin-layer chromatography. After recrystallization from water the compound melted at 190–191°. Infrared spectroscopy indicated the presence of a nitro group and of a carbonyl function. The mass spectrum showed a molecular ion at *m/e* 191 and peaks at *m/e* 145 due to loss of the nitro group and at *m/e* 100 due to additional loss of the carboxyl group.

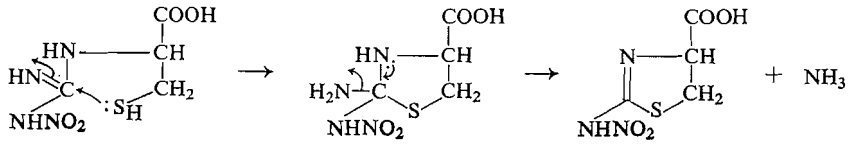
These findings suggested structure [**1**] for the material and the following pathway can account for its formation.



1

Elemental analysis and the nuclear magnetic resonance spectrum were in agreement with structure **1**. Another possible route for the formation of **1** is indicated in the sequence below:





1

A comparison of the nucleophilic reactivities of the thiol and amino functions of cysteine should cast some light on the relative merits of these two alternatives. Ross has reported that the effective competition factor for the sulfhydryl group in cysteine is approximately 1000 times larger than that of α-amino groups (20). We therefore conclude that the thiazoline derivative is formed by almost exclusive operation of the first of the two sequences above.

Formation of the thiazoline derivative is reminiscent of the preparation of cyclic nitroguanidine derivatives from diamines and nitroguanidine with liberation of ammonia (21, 22). The possibility that 2-nitramino-4-carboxylthiazoline might arise from reaction of cysteine with *N*-methyl-*N'*-nitroguanidine can be eliminated, since no reaction took place on mixing cysteine and *N*-methyl-*N'*-nitroguanidine for 20 h at room temperature in aqueous ethanol.

The experiments indicate that the sulfhydryl function of cysteine can react with NG by nucleophilic attack at two reactive centers. Attack on the imino carbon of NG gives rise to the thiazoline derivative while attack on the nitroso group accounts for the formation of *N*-methyl-*N'*-nitroguanidine and cystine. The relative proportion of these two modes of attack can be assessed by the yields of the respective reaction products, if the products are stable under reaction conditions and if they do not arise from other reactions.

Based on the results from the reaction of cysteine with MNTS the two products from attack of the sulfhydryl function on the nitroso group were expected to be formed in equimolar amounts. However, *N*-methyl-*N'*-nitroguanidine was obtained in 22% yield while cystine was obtained in 41% yield. The reported decomposition of *N*-methyl-*N'*-nitroguanidine in aqueous solution at reflux (23), prompted us to check whether continuous extraction over 80 h in ethyl acetate saturated with water could cause decomposition of *N*-methyl-*N'*-nitroguanidine. A blank run resulted in recovery of 91% of *N*-methyl-*N'*-nitroguanidine and showed that decomposition if taking place at all could not be substantial enough to account for the observed imbalance of products in the reaction under investigation.

Chromatographic analysis of the aqueous solution after two continuous extractions with ethyl acetate revealed the presence of three compounds, one of which was identified as *S*-methylcysteine. Formation of this product serves as further evidence for the elimination of the methyl nitrosamino group from NG. The other two spots were shown to absorb ultraviolet light, but were not further identified.

Since the amount of nucleophilic attack by the sulfhydryl function on the nitroso group was not established with certainty, the respective yields of 22 and 41% can only be taken as lower and upper limits of the amount of this mode of attack. However, the 57% yield of the thiazoline derivative is believed to represent the percentage of attack on the imino carbon.

The results of our studies indicate a marked difference in mode of attack of cysteine on the two *N*-methyl-*N*-nitroso compounds under investigation. The reasons for this behavior are not obvious and are not discussed here. The interaction of *N*-methyl-*N*-nitrosourethane with cysteine in aqueous ethanol at room temperature is reported to afford a variety of compounds arising from nucleophilic attack of the thiol on the carbonyl group. Denitrosation reactions were not considered (24). We have conducted preliminary experiments in which *N*-methyl-*N*-nitrosourethane and *N*-methyl-*N*-nitrosourea in their reactions with cysteine in aqueous ethanol failed to yield any of the red color characteristic of *S*-nitroso compounds. Thus, it seems likely that at least under the conditions used, attack takes place exclusively on the carbonyl group of these compounds. Factors governing the relative proportion of nucleophilic attack on the nitroso group and the carbonyl carbon have been discussed recently for reactions of nitrosoalkylamine derivatives with alkoxide ions (25).

Our findings provide a possible explanation for the effects of added cysteine in the reactions of DNA with MNTS and NG. The reaction of cysteine with MNTS proceeds exclusively via attack on the nitroso group, a process that results in denitrosation and prevents MNTS from functioning as a methylating agent. This can explain the large decrease in methylation of DNA by MNTS when cysteine is added (1). In the reaction of cysteine with NG attack on both the nitroso group and the imino carbon are observed with the latter predominating. Nucleophilic attack on the imino carbon produces a fragment capable of methylation and thus allows qualitative rationalization of the increase in methyl incorporation into DNA in the presence of cysteine.

Experimental

Melting points were taken on a Gallenkamp apparatus and are uncorrected. Infrared spectra were recorded with a Beckman model IR5A spectrophotometer; nuclear magnetic resonance (n.m.r.) spectra with a Varian Associates model A-60 spectrometer; electronic spectra with a Beckman model DB spectrophotometer; mass spectra with a Hitachi model RMU-6A mass spectrometer. Microanalyses were by Galbraith Laboratories, Knoxville, Tennessee.

Thin-layer chromatograms were carried out on glass plates coated with silica gel H (E. Merck, Darmstadt) and were developed with iodine vapor. Paper chromatograms were run by the ascending method using the following solvent system (v/v/v): isopropanol – aqueous ammonia – water, 25:2:12. Spots were located in ultraviolet light or after spraying with a ninhydrin solution.

Nitrogen (Canadian Liquid Air) and nitric oxide (Matheson) were used as received. The following compounds were obtained from commercial sources: *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (Aldrich), *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (Aldrich) and cysteine hydrochloride (Baker).

Reaction of Cysteine with N-Methyl-N-nitroso-p-toluenesulfonamide (MNTS)

A 500 ml three-necked flask was equipped with an inlet tube for nitrogen, a dropping funnel, a magnetic stirring bar and a connecting tube leading to a measuring cylinder for the collection of evolved gas. The system was thoroughly flushed with nitrogen and 1.404 g (8.0 mmole) of cysteine hydrochloride monohydrate dissolved in 300 ml of water was placed into the flask. The pH of the solution was adjusted to 7 by addition of sodium hydroxide solution. The nitrogen inlet tube was quickly disconnected, the connecting tube opened and a solution of 0.860 g (4.0 mmole) of MNTS in 100 ml of 95% ethanol was added dropwise with magnetic stirring over a period of 40 min. Towards the end of the addition the slightly red solution turned cloudy due to precipitation. Evolution of gas (47 ml at STP) had ceased completely after an additional 2 h of stirring. When the collected gas was exposed to air, dark brown fumes with the characteristic smell of nitrogen dioxide formed immediately. Stirring of the aqueous reaction mixture was continued and after a total of 20 h the white precipitate was collected on a Buchner funnel (814 mg, corresponding to a yield of 85%). The material was identified as cystine by the R_f value of 0.3 on a paper chromatogram (ninhydrin) and by the infrared spectrum in comparison with an authentic sample (Sigma).

The filtrate was extracted with ether and the dried ether phase (sodium sulfate) was evaporated to dryness under vacuum. When the white residue was chromatographed on a neutral alumina column with petroleum ether – chloroform (1:1) as eluent, 692 mg, 93% yield of *N*-methyl-*p*-toluenesulfonamide was obtained. The infrared spectrum was identical to that of an authentic (26) sample. The melting point of 77–78° (lit. (27) 77.5–78.5) and a thin-layer chromatogram in chloroform, R_f 0.55, were confirmatory.

In another experiment, a similar apparatus was used except that the connecting tube was replaced by a gas trap that could be attached to the mass spectrometer. The system was evacuated by means of an aspirator prior to the reaction. Identical quantities were employed and the reaction was carried out as mentioned above. After 20 h the gaseous materials in the system were collected in the gas trap with the aid of liquid nitrogen. The mass spectrum of the gas sample showed a predominant peak at *m/e* 44 and did not show a peak at *m/e* 30. The described work-up yielded cystine in 91% yield (876 mg) and *N*-methyl-*p*-toluenesulfonamide in 93% yield (690 mg).

In an experiment on a smaller scale the colored solution of an early stage of the reaction was monitored spectrophotometrically in the visible region. Absorption maxima were observed at 340 and 550 mμ which agreed well with maxima of 340 and 550–560 mμ reported for other thionitrites (12, 13).

In a preliminary experiment employing a 1:1 ratio of cysteine and MNTS the reagents were allowed to react in 25% ethanol at room temperature for 20 h under a nitrogen atmosphere. The reaction mixture was extracted with ether and thin-layer chromatography showed the concentrate to contain considerable amounts of MNTS, R_f 0.55 in toluene

Reaction of Cysteine with Nitrous Acid

A 1 l three-necked flask was equipped with a connecting tube with parallel side arm, three dropping funnels and a gas inlet tube. The system was thoroughly flushed with nitrogen and 1.756 g (10 mmole) of cysteine hydrochloride hydrate dissolved in 180 ml of water was placed into the flask. To this solution was added 1 ml of concentrated sulfuric acid. The nitrogen stream was turned off and a solution of 0.69 g (10 mmole) of sodium nitrite in 30 ml of water was added within 2 min, followed by the rapid addition of 70 ml of 95% ethanol. The pH of the solution was then adjusted to 7 by addition of sodium hydroxide solution with moderate cooling. After a further 3 min a vigorous evolution of gas set in and the deep red solution turned cloudy due to precipitation accompanied by fading of the color. After 40 min the reaction mixture was filtered and 938 mg of cystine was collected corresponding to a 78% yield.

TABLE I

Paper chromatographic behavior of products in aqueous filtrate from reaction of cysteine with NG

R_f	Method of detection	Identity of spot
0.19	Ultraviolet light	Unknown
0.24	Ultraviolet light, ninhydrin	Unknown
0.29	Ninhydrin	Cystine
0.50	Ultraviolet light	2-Nitramino-4-carboxyl-thiazoline
0.62	Ninhydrin	S-Methylcysteine
0.75	Ultraviolet light	*N*-Methyl-*N'*-nitroguanidine

Reaction of Cysteine with Nitric Oxide

Into a 1 l three-necked flask equipped with three gas inlet tubes and a magnetic stirring bar was placed 1.756 g of (10 mmole) cysteine hydrochloride hydrate dissolved in 200 ml of water–ethanol (3:1). The system was thoroughly flushed with nitrogen and the solution was adjusted to pH 7 with sodium hydroxide. After repeated alternate flushing with nitrogen and evacuating by means of an aspirator the system was evacuated and a measured amount (10 mmole at STP) of nitric oxide was transferred in the reaction vessel. The solution was vigorously stirred for 20 h and the resulting precipitate was filtered off, 1.13 g, corresponding to a 94% yield of cystine. The material was identified by the infrared spectrum and by its paper chromatographic behavior.

Reaction of Cysteine with N-Methyl-N'-nitro-N-nitrosoguanidine (NG)

The reaction between 3.51 g (20 mmole) of cysteine hydrochloride monohydrate dissolved in 225 ml of water and 1.47 g (10 mmole) of NG dissolved in 75 ml of 95% ethanol was carried out as described for the reaction of cysteine with MNTS. Gas evolution amounted to 9 mmole at STP and the yield of cystine to 36% (0.869 g).

When the reaction was carried out in a closed system, cystine was obtained in 41% yield (0.989 g). A paper chromatogram of the aqueous filtrate indicated the presence of at least six compounds as shown in Table I. The major components of this reaction mixture could be identified as described below.

The filtrate was subjected to a continuous extraction with ethyl acetate over a period of 80 h. Evaporation of the organic phase to dryness gave 257 mg of a white solid, which was identical (infrared spectrum, thin-layer chromatogram in methanol, R_f 0.62) with authentic *N*-methyl-*N'*-nitroguanidine (5). After recrystallization from 95% ethanol the compound melted at 158–159°. Reported (5) m.p. 160–161°. The yield corresponded to 22%.

The aqueous layer was acidified to pH 1 by addition of concentrated hydrochloric acid and extracted with ethyl acetate over a period of 20 h. Concentration of the organic phase by rotary evaporation afforded 1.1 g of solid material which was shown to be homogeneous by thin-layer chromatography in 70% ethanol, R_f 0.78. After recrystallization from water the material melted at 190–191°. The infrared spectrum (Nujol) showed significant absorption at 1720 cm^{-1} (C=O) and at 1540 and 1260 cm^{-1} (nitro). The mass spectrum exhibited predominant peaks at *m/e* 191, 145 and 100. The n.m.r. spectrum (deuterium oxide) showed a quartet at τ 5.15 (J = 8.5 c.p.s., J = 6.5 c.p.s.) and doublets at τ 6.35 (J = 8.5 c.p.s.) and τ 6.42 (J = 6.5 c.p.s.). The ratio of the quartet at τ 5.15 and the sum of the doublets at τ 6.35 and 6.42 was 1.02:2. The yield corresponded to 57% of 2-nitramino-4-carboxyl-thiazoline.

Anal. Calcd. for $C_4H_5N_3O_4S$: C, 25.14; H, 2.64; N, 21.98; S, 16.77. Found: C, 25.20; H, 2.66; N, 21.88; S, 16.78.

A paper chromatogram of the aqueous phase indicated the presence of *S*-methylcysteine identified by comparison with authentic material (Sigma) and of unknown materials of R_f 0.19 and 0.24.

A sample of 100 mg of *N*-methyl-*N'*-nitroguanidine in 100 ml of ethyl acetate saturated with water was refluxed for 80 h. On concentration by rotary evaporation 91 mg of material was obtained which was found identical (infrared spectrum, thin-layer chromatogram in methanol, R_f 0.62) with authentic *N*-methyl-*N'*-nitroguanidine.

To a solution of 351 mg (2 mmole) of cysteine hydrochloride in 150 ml of water adjusted to pH 7 with sodium hydroxide was added 236 mg (2 mmole) of *N*-methyl-*N'*-nitroguanidine dissolved in 50 ml of 95% ethanol. The clear solution was stirred in a nitrogen atmosphere for 20 h and then concentrated to a volume of 30 ml by rotary evaporation. Paper chromatography showed only two spots which were identified as *N*-methyl-*N'*-nitroguanidine and cystine by comparison with authentic samples.

Chloral–ketone condensations in acetic anhydride. Reaction of chloral with butanone, 3-pentanone, cyclohexanone, and 4-methyl-2-pentanone

EBERHARD KIEHLMANN AND PUI-WAH LOO
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia
Received November 5, 1968

In the presence of sodium acetate as catalyst, chloral hydrate undergoes a mixed aldol condensation with aliphatic and alicyclic ketones in acetic anhydride as solvent. Contrary to previous literature reports, reaction occurs at both the methyl and the methylene group in α-position to the carbonyl group of butanone, to give a mixture of 1,1,1-trichloro-2-hydroxy-4-hexanone (**1**) and 1,1,1-trichloro-2-hydroxy-3-methyl-4-pentanone (**2***a* and **2***b*, diastereomers). 3-Pentanone, cyclohexanone, and 4-methyl-2-pentanone yield 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanone (**3***a* and **3***b*, diastereomers), 2-(1-hydroxy-2,2,2-trichloroethyl-)cyclohexanone (**4***a* and **4***b*, diastereomers), and 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**5**), respectively. Compound **5** is the exclusive product formed from chloral hydrate and 4-methyl-2-pentanone since attack at the methylene group is sterically hindered. The low-melting diastereomers **2***a*, **3***a*, and **4***a* which have not been characterized before, exhibit strong intramolecular hydrogen bonding and have been assigned the *threo* configuration on the basis of nuclear magnetic resonance and molecular model studies.

The condensation of chloral hydrate with aliphatic and alicyclic ketones is known to give aldol addition products which do not readily undergo dehydration when the reaction is carried out in acetic anhydride in the presence of sodium acetate as catalyst. According to Caujolle and co-workers (1), acetone, butanone, 3-pentanone, cyclohexanone, benzalacetone, and camphor yield only one addition product, respectively, under these experimental conditions although two asymmetric centers are generated, i.e., two diastereomeric products are possible when reaction occurs at the α-methylene group of butanone, 3-pentanone, or cyclohexanone. It has been postulated but not experimentally verified by the same authors (1), that chloral adds preferentially at the methylene group if a ketone e.g., butanone, contains both a methyl and a methylene group in α-position to the carbonyl function. The opposite view is held by Breusch and Keskin (2), who prepared a series of fourteen 1,1,1-trichloro-2-hydroxy-4-alkanones by refluxing the appropriate ketone, $R—CH_2—CO—CH_3$, with anhydrous chloral in glacial acetic acid. They determined the structure of the condensation product of 4-methyl-2-pentanone and chloral by synthesis and mixture melting point determination of 6-methyl-4-oxoheptanoic acid by two different routes, one of which involved 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**5**) as an intermediate. On the basis of this experiment, the general structure $R—CH_2—CO—CH_2—CHOH—CCl_3$ resulting from addition of chloral at the ketone methyl group was assigned to all 14 reaction products.

Although the structure of **5** was subsequently verified by spectroscopic means (3), it appeared strange to us that the site of aldol addition changes from the α-methylene to the α-methyl group of a 2-alkanone when anhydrous chloral and glacial acetic acid are used instead of chloral hydrate and acetic anhydride. Therefore, we decided to reinvestigate the reaction of chloral hydrate with ketones in acetic anhydride in the presence of sodium acetate placing particular emphasis on the number and structure of the reaction products formed. This product study which made extensive use of modern techniques (vapor phase chromatography (v.p.c.) and nuclear magnetic resonance (n.m.r.)) not available to the authors of the original papers (1, 2) was also desirable as a first step toward future kinetic investigations of the addition step in mixed aldol condensations.

Results and Discussion

Chloral (trichloroacetaldehyde) appears to be a particularly suitable aldehyde component for studying the mechanism of mixed aldol condensations since due to the absence of α-hydrogens no self-condensation products are possible; thus, the desired mixed condensation product with the ketone component is expected to be formed exclusively. However, due to the inductive effect of the three chlorine atoms, the carbonyl group of chloral surpasses that of other aldehydes

TABLE I

Reaction products from chloral hydrate and various ketones*

Ketone	Reaction time (h)	Product yield (mole %)†‡ A	B	C	6	Literature‡§ yield (%)

in additive ability and is readily attacked even by weak nucleophiles. It adds water to form a stable gem-diol (chloral hydrate), and acetic anhydride (4) to form 1,1-diacetoxy-2,2,2-trichloroethane (**6**) (trichloroethylidene diacetate). The latter is a stable compound which was obtained as the exclusive product in an attempt to prepare **5** from 4-methyl-2-pentanone and anhydrous chloral in acetic anhydride as solvent.

$$(CH_3)_2CHCH_2COCH_3 + CCl_3CHO + Ac_2O + NaOAc \rightarrow CCl_3CH(OAc)_2\ (71\%)$$
6

$$(CH_3)_2CHCH_2COCH_2CHOHCCl_3 \quad \text{(not observed)}$$
5

Chloral hydrate, on the other hand, is less reactive than anhydrous chloral as expected from its structure. It forms **6** in 5% yield when treated with acetic anhydride and sodium acetate for 52 h at 100°.

$$CCl_3CH(OH)_2 + Ac_2O \xrightarrow{NaOAc} HOAc + CCl_3CH(OAc)_2$$
6

Thus under the experimental conditions reported in the literature (1), i.e., treatment of a ketone with chloral hydrate, acetic anhydride and sodium acetate at 70° for several hours, we expected to obtain substantial quantities of **6** in addition to the desired chloral–ketone condensation products. The experimental results reported below were essentially in agreement with these expectations.

In contrast to the results reported by Caujolle and co-workers (1), we obtained three isomeric condensation products from butanone, two diastereomeric products each from 3-pentanone and cyclohexanone, respectively, and one product each from 4-methyl-2-pentanone, acetone and benzalacetone; considerable amounts of 1,1-diacetoxy-2,2,2-trichloroethane were found in all product mixtures, but no dehydration products of the type R—CO—CR′=CH—CCl_3 or acetylation products of the type R—CO—CHR′—CHOAc—CCl_3 were detected. This demonstrates that in general the aldol reaction between ketones of the type R—CO—CH_2—R′ (except when R′ is bulky, *vide infra*) and chloral hydrate leads to the formation of all possible isomeric condensation products resulting from attack at both the α-methyl (R = CH_3) and the α-methylene group of the ketone. Yields and product composition data for the condensation reaction [1] are summarized in Table I.

[1] $$RCOCH_2R' + CCl_3CH(OH)_2 \xrightarrow[70°]{Ac_2O,\ NaOAc} RCOCHR'—CHOH—CCl_3$$

and acetic anhydride, the desired condensation products were formed in higher yields.

The tabulated results (Table I) show that cyclohexanone and benzalacetone are less reactive than the other ketones studied, and that the α-methyl groups of acetone and 4-methyl-2-pentanone are approximately of equal reactivity toward chloral hydrate (taking into account a statistical factor of two for acetone). When two diastereomeric condensation products are possible, the high-melting isomer (**2***b*, **3***b*, **4***b*) is generally formed in higher yield than the low-melting compound (**2***a*, **3***a*, **4***a*).

The reaction between chloral hydrate and the 6 ketones listed in Table I is not accompanied by dehydration or acetylation of the condensation products. Only traces of unexpected by-products were detected by v.p.c. analysis of the slightly yellow, crude reaction mixtures; the ketone peak areas were found to correspond to 98–99% of the amount of unreacted ketone as calculated from the yield of condensation product. Thus, unreacted starting material, acetic acid, and the products listed in Table I account for more than 98% of the weight of the final reaction mixtures.

Butanone and Chloral Hydrate

Butanone reacts with chloral hydrate to form three isomeric condensation products and 1,1-diacetoxy-2,2,2-trichloroethane (**6**):

$$CH_3CH_2COCH_3 + CCl_3CH(OH)_2 \xrightarrow{Ac_2O} CH_3CH_2COCH_2CHOHCCl_3$$

1

$$+ CH_3COCH(CH_3)—CHOHCCl_3$$

2*a* and **2***b* (diastereomers)

$$+ CCl_3CH(OAc)_2$$

6

This demonstrates that contrary to a report in the literature (1), butanone undergoes condensation at both the methylene and the methyl group in α-position to the carbonyl function. Melting point and ease of crystallization indicate that the only product isolated by Caujolle and co-workers was ketol **1** and not the postulated isomeric ketol **2**. All three ketols are stable compounds which neither isomerize nor cleave to yield butanone and chloral when treated with acetic anhydride and sodium acetate under the preparative experimental conditions. The crude product mixture contains the straight-chain isomer (**1**) and the branched-chain isomers (**2***a* and **2***b*) in the approximate molar ratio 4:7 indicating that reaction occurs preferentially but not exclusively at the methylene group. However, the greater reactivity of the methylene group relative to the methyl group toward chloral hydrate appears to be specific for butanone (*vide infra*).

The n.m.r. and infrared (i.r.) spectra of the three isomeric condensation products exhibit a number of special features which permit conclusions to be drawn with respect to hydrogen-bonding and conformational interactions in these compounds. At a mole fraction of 0.08 in deuteriochloroform, the hydroxylic proton of **1**, **2***a*, and **2***b* appears as a sharp doublet at τ 5.83, 4.30, and 6.23, respectively. The coupling of this proton with the geminal proton (4.9–8.5 c.p.s.) suggests hydrogen-bonding association in $CDCl_3$ solution and a slow rate of proton exchange. Middleton and Lindsey (6) have reported similar retention of OH—H coupling for certain hydrogen-bonded solute–solvent complexes of 2*H*-hexafluoro-2-propanol.

The n.m.r. dilution shift data and i.r. absorption bands summarized in Table II provide evidence for different types of hydrogen bonds in the isomeric condensation products of butanone and chloral. Decreasing the mole fraction of the product in $CDCl_3$ from 0.25 to 0.04 results in an upfield shift of 36, 0, and 54 c.p.s. for the hydroxylic proton of **1**, **2***a*, and **2***b*, respectively. All three isomers exhibit an i.r. absorption band at 3600 cm^{-1} ("free" OH).[1] The "bonded" OH peak for **1** and **2***b* appears at 3470 to 3480 cm^{-1} (Δ_ν between "free" and "bonded" OH 120–130 wavenumbers) while the corresponding band for **2***a* is found at 3380 cm^{-1} ($\Delta_\nu = 220$ wavenumbers). The effect of concentration changes on the relative intensities of these i.r. absorption peaks is markedly different for **2***a* on one hand and **1** and **2***b* on the other hand. The "free" OH band of **2***a* is much less intense than the bonded OH band, and the ratio of peak intensities of the two bands remains essentially constant over the concentration range 0.5 *M* to 0.04 *M* in CCl_4. In contrast, dilute solutions (0.04 *M* in CCl_4) of **1** and **2***b* show a sharp, intense "free" OH band at 3600 cm^{-1} and a weak "bonded" OH band at 3475

[1]This band may be due to weakly hydrogen-bonded OH involving Cl as acceptor site, see ref. 9.

TABLE II

cm^{-1}. As the concentration is increased, the intensity of the bonded OH band increases at the expense of the "free" OH band. The absorption peak at 3600 cm^{-1} is entirely absent from the i.r. spectrum of a pure liquid (melt) film of **1** and **2***b* on sodium chloride plates.

It is apparent from these data that **2***a* is intramolecularly hydrogen-bonded involving the hydroxyl group as donor and the carbonyl oxygen as acceptor site (7, 8), while the isomeric ketols **1** and **2***b* form intermolecular hydrogen bonds at high concentrations. The possibility of weak Cl . . . . HO hydrogen bond interactions (9, 10) cannot be entirely excluded.

Molecular models show that only a limited number of conformations will satisfy the hydrogen-bonding requirements of the three isomeric condensation products **1**, **2***a*, and **2***b* if these assumptions are correct. These considerations prompted a conformational analysis of the two diastereomeric products **2***a* and **2***b*.

It is well known (11) that the coupling constant J_{ab} for the H_a—C—C—H_b fragment of ethane derivatives depends on the dihedral angle ϕ between the H_a—C—C and C—C—H_b planes. Although indiscriminate application of the theoretically derived correlation curve between J_{ab} and ϕ may lead to incorrect structural assignments (12), it may be used to estimate bond angles and conformations of organic molecules. Stiles and co-workers (13) investigated hydrogen bonding and conformational interactions in the diastereomeric condensation products of butanone with aromatic aldehydes by i.r. spectroscopy and measurement of the coupling constant J_{ab} between the tertiary hydrogens of CH_3—CO—$CH_a(CH_3)$—CH_bOH—Ar. They found intramolecular hydrogen bonding for both diastereomers and coupling constants of 8.0 and 3.0 c.p.s. for the *threo* (tertiary hydrogens *trans*) and *erythro* structure (tertiary hydrogens *gauche*), respectively.

After deuterium exchange, the n.m.r. spectrum of CH_3—CO—$CH_b(CH_3)$—CH_aOD—CCl_3 (**2***a* or **2***b*) exhibits a simple doublet due to the tertiary proton (H_a) of the —CH_aOD— group and a multiplet due to the tertiary proton (H_b) of the methyl-substituted carbon. Measurement of the H_b-methyl coupling in the methyl doublet and the H_a—H_b coupling in the H_a doublet allowed a satisfactory interpretation of the H_b signal, based upon simple splitting rules. The chemical shifts of the tertiary hydrogens and the coupling constants are summarized in Table III.

It is concluded from the magnitude of the splitting and from the inspection of molecular models that the H_a—C—C—H_b dihedral angle ϕ in the preferred conformation of **2***a* is close to 60 or 120° (Fig. 1, structures T-1 and T-2) while

2*b* (and **1**) prefers a conformation with ϕ close to 140° (Fig. 1, structure E-1). Based on these results and the hydrogen-bond studies, the *threo* configuration has been assigned to **2***a* and the *erythro* configuration to **2***b*.[2]

The *erythro* configuration has been ruled out for the hydrogen-bonded structure **2***a* because molecular models of the two conformers obtained by 80° counterclockwise or 160° clockwise rotation of the rear carbon of structure E-1 (Fig. 1) indicate serious steric hindrance due to the eclipsing effect of the methyl and the trichloromethyl group, and all other conformers with an H_a—C—C—H_b dihedral angle of 60 or 120° (corresponding to the observed coupling constant J_{ab} = 1.9 c.p.s.) do not permit intramolecular hydrogen bonding. To minimize steric interaction between the R—CO— and the bulky trichloromethyl group of **2***b* (structure E-1, Fig. 1), a dihedral angle of 140° between the tertiary hydrogens is preferred to a 180° angle corresponding to a completely staggered conformation. For the same reason, the alternative *erythro* conformation with ϕ 140° (obtained by 80° clockwise rotation of the rear carbon of the structure E-1, Fig. 1) and all conformers with the alternative dihedral angle of 35° (corresponding to the observed coupling constant J_{ab} = 5.5 c.p.s.) are unfavorable for ketol **2***b*. It is therefore concluded that in contrast to the flat aryl groups of the compounds studied by Stiles and coworkers (13), the bulkiness of the trichloromethyl group prevents intramolecular hydrogen bonding in the *erythro* structure **2***b*, and in the straight-chain isomer **1** (see Table II).

It is hoped that high-resolution i.r. and n.m.r. spectral studies of very dilute solutions of **1**, **2***a*, and **2***b* in nonpolar solvents (presently in progress) will permit a quantitative estimate of the relative contribution of Cl . . . . H—O hydrogen-bonded structures and of conformational energy differences.

3-Pentanone and Chloral Hydrate

3-Pentanone reacts with chloral hydrate in acetic anhydride to form 1,1-diacetoxy-2,2,2-trichloroethane (**6**) and 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanone (**3***a*, m.p. 37–38°, and **3***b*, m.p. 57.5–58.5°). Pure samples of the two diastereomeric condensation products were obtained by partition chromatography of selected fractions of the high vacuum distillate on silicic acid using benzene as eluent.

Apparently Caujolle *et al.* (1) isolated only the high-melting isomer of this diastereomeric pair (m.p. 58.5°). We found that **3***a* and **3***b* are formed in the approximate molar ratio 5:6. The composition data of Table I show that the two methylene groups of 3-pentanone and cyclohexanone (*vide infra*) are less reactive toward chloral hydrate than the two methyl groups of acetone which is attributed to decreased nucleophilicity of the alkyl-substituted α-carbons.

The n.m.r. and i.r. spectra of the two diastereomers (Tables II and III) exhibit the same general features as the spectra of **2***a* and **2***b*, i.e. coupling of the hydroxylic proton with the geminal proton of the CHOH group, downfield position of the OH chemical shift of **3***a* relative to **3***b*, upfield shift of the OH proton signal of **3***b* (but not **3***a*) on dilution, concentration dependence of the i.r. absorption intensity ratio "free" OH: "bonded" OH for **3***b* only, and largely different coupling constants J_{ab} for the tertiary protons of **3***a* (2.0 c.p.s.) and **3***b* (5.5 c.p.s.), respectively. Applying arguments analogous to those advanced for the structural analysis of 1,1,1-trichloro-2-hydroxy-3-methyl-4-pentanone (**2***a* and **2***b*), it is concluded from these spectral data that **3***a* is an intramolecularly hydrogen-bonded *threo* structure (Fig. 1, conformer T-1 or T-2), and **3***b* is the *erythro* isomer existing predominantly in a conformation with ϕ close to 140° (Fig. 1, conformer E-1).

Cyclohexanone and Chloral Hydrate

The reaction between cyclohexanone and chloral hydrate in acetic anhydride has been reported (1) to give a 70% yield of a condensation product melting at 105°. Under the same reaction conditions we obtained a product mixture (47% yield) containing 1,1-diacetoxy-2,2,2-trichloroethane (**6**) as major component, and the two diastereomers of 2-(1-hydroxy-2,2,2-trichloroethyl-)cyclohexanone (**4***a* and **4***b*) in the approximate molar ratio 2:7. Ketol **4***b* (m.p. 101–102°) crystallized readily from the high-vacuum distillate of the crude product mixture but the isolation and purification of **4***a* (m.p. 43–44.5°) was found to be extremely difficult.

In close similarity to the structural features

[2]The *erythro*/*threo* nomenclature is used in this paper with reference to the two adjacent tertiary hydrogen atoms considering CCl_3—CH_a—CH_b—R′ as the main chain of the molecule and —OH and —CO—R as substituents.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

observed for 1,1,1-trichloro-2-hydroxy-3-methyl-4-pentanone (**2***a* and **2***b*) and 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanone (**3***a* and **3***b*), i.r. and n.m.r. spectral data (Tables II and III) indicate strong intramolecular hydrogen bonding in **4***a* with the OH proton signal (381 c.p.s.) appearing considerably downfield from the position of the corresponding proton in **2***a* and **3***a* (342 and 345 c.p.s., respectively), and intermolecular hydrogen bonding in concentrated solutions of the more stable *erythro* structure **4***b*. The coupling constant J_{ab} between the two tertiary hydrogens was found to be 2.0 c.p.s. for **4***a* and 2.5 c.p.s. for **4***b* suggesting dihedral angles close to 60 or 120°. In order to satisfy these conformational requirements and to permit intramolecular C=O . . . H—O hydrogen bonding in **4***a*, the two diastereomers are believed to exist predominantly in the eclipsed conformations T-2 and E-2 (Fig. 1), respectively.

The rigidity of the cyclohexane ring prevents free rotation about the CHR′—CO single bond thus forcing the molecule into an eclipsed conformation in order to minimize steric interaction of the bulky CCl_3CHOH group with axial ring hydrogens or with the carbonyl group.

4-Methyl-2-pentanone and Chloral Hydrate

4-Methyl-2-pentanone yields only one condensation product, 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**5**), when treated with chloral hydrate and acetic anhydride at 70°. In addition, 1,1-diacetoxy-2,2,2-trichloroethane is formed in low yield. It was not possible to detect any isomeric product by v.p.c. analysis using three different analytical columns. This finding, in conjunction with the experimental observation that 4,4-dimethyl-2-pentanone also undergoes condensation with chloral at the methyl group only, is indicative of steric factors being predominant in determining the product structure in crossed aldol condensations of unsymmetrical aliphatic ketones with chloral. Assuming that the reaction proceeds through an enol-like transition state rather than through an enolate intermediate, these results are in qualitative agreement with recent literature reports on the rate and orientation of the acid- and base-catalyzed deuteration of methyl ketones (5, 14, 15). The unusually high reactivity of the methylene group of butanone (see Table I) as compared to other methyl ketones of the general structure $CH_3—CO—CH_2—R$ has been attributed by Warkentin and Barnett (15) to a rate-accelerating polar effect of the alkyl group which "opposes the steric effect and is swamped by it in all the ketones except butanone". The same authors have shown that in the base-catalyzed deuteration of 4-methyl-2-pentanone in aqueous dioxane, enolization toward the methyl group is favored over enolization toward the methylene group by a factor of 2.38. The exclusive formation of **5** from chloral hydrate and 4-methyl-2-pentanone therefore indicates that this reaction cannot be simply interpreted in terms of two competitive rate-determining enolization steps, and that indiscriminate quantitative comparison of results obtained in different reaction media leads to incorrect predictions.

Further work will be needed to establish whether the transition state resembles ketone, enol or enolate, and to assess the importance of solvent effects and catalyst structure in determining the orientation of enolization of unsymmetrical aliphatic ketones and the rate of chloral addition. We are presently investigating the rate of acetate-catalyzed deuteration of ketones in acetic acid-d_4 and the kinetics of the reaction of anhydrous chloral with various methyl ketones in glacial acetic acid in order to gain further insight into the mechanism of this crossed aldol condensation.

On the basis of closely similar i.r. and n.m.r. spectra of **5** and **1**, intramolecular hydrogen bonding is believed to be weak or absent in straight-chain compounds of the type $R—CO—CH_2—CHOH—CCl_3$. In contrast to the spectral properties of the condensation products of butanone, 3-pentanone, and cyclohexanone with chloral hydrate, the OH proton signal of **5** appears as a broad singlet in the n.m.r. spectrum.

Experimental

Melting points are uncorrected. Analyses were performed by A. Bernhardt, Microanalytical Laboratory, Mülheim, Germany.

Infrared spectra were recorded on a Beckman IR-12 or a Perkin–Elmer 457 spectrometer using a CCl_4 solution or a thin film of neat liquid (melt) between sodium chloride plates. Ultraviolet (u.v.) spectra were run in 95% ethanol using a Unicam SP-200 spectrometer. Nuclear magnetic resonance spectra were recorded on a Varian A56/60 spectrometer using TMS as internal standard and $CDCl_3$ as solvent (unless specified otherwise). Chemical shifts are reported in c.p.s. downfield from TMS or in τ units. All spectral measurements were performed at room temperature.

Vapor-phase chromatographic analyses were carried out on a Varian Aerograph Model 1200-1 HY-FI III gas

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

chromatograph using a 5 ft × ⅛ in. column packed with 5% SE-30 on Aeropak 30 (column temperature 120–140°) and nitrogen as carrier gas (35 ml/min). All quantitative estimates of the composition of product mixtures by gas–liquid chromatographic (g.l.c.) analysis (Table I) are based on comparison of integrated peak areas obtained for the various components of a crude product mixture with those obtained for standard mixtures prepared from the pure components. The v.p.c. peak areas were measured planimetrically. For the purpose of analysis and identification, pure samples of all components of a product mixture were isolated by fractional distillation, crystallization and/or liquid partition chromatography on silica (Mallinckrodt, Silicic Acid A.R. 100 Mesh, Chromatographic Grade).

Butanone, 3-pentanone, cyclohexanone, and 4-methyl-2-pentanone (Matheson, Coleman, and Bell) were purified by fractional distillation; chloral hydrate (Matheson, Coleman, and Bell) and acetic anhydride (Baker and Adamson, Reagent grade) were used without further purification.

Reaction of Chloral Hydrate with Butanone

A mixture of 22.5 g (0.31 moles) of butanone, 41.1 g (0.25 moles) of chloral hydrate, 25.5 g (0.25 moles) of acetic anhydride, and 9.9 g (0.12 moles) of anhydrous sodium acetate was heated in a 200-ml pressure bottle at 70° for 58 h. Solvent, unreacted starting materials, and acetic acid were removed by distillation under reduced pressure. The yellow distillation residue was dissolved in 100 ml of ether, washed with water and sodium bicarbonate solution, and dried ($MgSO_4$). Evaporation of the ether gave 24.7 g of crude product (yellow) containing 30% (by weight) of ketol **1**, 23% of ketol **2***a*, 30% of ketol **2***b*, and 17% of 1,1-diacetoxy-2,2,2-trichloroethane (**6**) (analysis by v.p.c.). No dehydration or acetylation products and only trace amounts of other by-products were detected in the gas chromatogram. To separate **6** from the condensation products, the crude product mixture was distilled in high vacuum; ketols **1**, **2***a*, and **2***b* (total weight 15.4 g) were collected at 75–90°/0.02 mm (lit. (16), 135–138°/17 mm). Small samples of the pure components were isolated by liquid partition chromatography on silica using 20% (by volume) petroleum ether (30–60°) in benzene as eluent. Larger quantities of pure **2***a* and **2***b* were obtained by redistillation of the product mixture through a Vigreux column at high vacuum, v.p.c. analysis of each of the 15 fractions collected, seeding of selected fractions with **2***a* and **2***b*, respectively, filtration, and recrystallization from cyclohexane. Crystallization of **2***a* was extremely slow and inhibited by small amounts of impurities.

Characterization of **1**: m.p. 56–56.5° (lit. (1) 57°), b.p. 88–89°/0.02 mm.

Reaction of Chloral Hydrate with 3-Pentanone

Following the procedure described in the preceding experiment (reaction time 102 h), 19.3 g of crude product (yellow) was obtained from 26.9 g (0.31 moles) of 3-pentanone, 41.1 g (0.25 moles) of chloral hydrate, 25.5 g (0.25 moles) of acetic anhydride, and 9.81 g (0.12 moles) of anhydrous sodium acetate. The crude product was found by v.p.c. analysis to contain 37% (by weight) of ketol **3***a*, 43% of ketol **3***b*, and 20% of **6**. High-vacuum distillation gave 13.4 g of a mixture of **3***a* and **3***b*, b.p. 79–89°/0.07 mm. Pure samples of the two diastereomers were obtained by fractional high-vacuum distillation and liquid partition chromatography with benzene as eluent (see preceding experiment for procedural details).

Characterization of **3***a*: m.p. 37–38°, b.p. 79–83°/0.07 mm.

Anal. Calcd. for $C_7H_{11}O_2Cl_3$: C, 36.00; H, 4.75; Cl, 45.55. Found: C, 36.05; H, 4.57; Cl, 45.45.

Ultraviolet: ν_{max}(EtOH) 213 mμ (ε 59), 279 mμ (ε 34); n.m.r. ($CDCl_3$): τ 8.95, triplet (3, CH_3CH_2); 8.61, doublet (3, CH_3CH); 7.33, quartet (2, CH_3CH_2); 6.53, multiplet (1, CH_3CH); 5.89, multiplet (1, CHOH); 4.17, doublet (1, OH).

Characterization of **3***b*: m.p. 57.5–58.5° (lit. (1) 58.5°), b.p. 85–89°/0.07 mm.

Ultraviolet: ν_{max}(EtOH) 213 mμ (ε 51), 280 mμ (ε 31); n.m.r.: τ 8.93, triplet (3, CH_3CH_2); 8.71, doublet (3, CH_3CH); 7.37, quartet (2, CH_3CH_2); 6.78, multiplet (1, CH_3CH); 5.55, doublet (1, OH); 5.33, multiplet (1, CHOH).

Reaction of Chloral Hydrate with Cyclohexanone

Following the procedure described before, 28.9 g of crude product (yellow) was obtained by heating a mixture of 30.7 g (0.31 moles) of cyclohexanone, 41.1 g (0.25 moles) of chloral hydrate, 25.5 g (0.25 moles) of acetic anhydride, and 10.8 g (0.132 moles) of anhydrous sodium acetate at 70° for 45 h. The crude product mixture was found by v.p.c. analysis to contain 11% (by weight) of ketol **4***a*, 39% of ketol **4***b*, and 50% of **6**. High-vacuum distillation gave 10.4 g of a mixture of the two diasteromeric condensation products **4***a* and **4***b*. A pure sample of **4***b* was isolated by recrystallization of the solidified portion of the distillate from carbon tetrachloride. Purification of **4***a* was accomplished by liquid partition chromatography on silica using 20% (by volume) petroleum ether in benzene as eluent.

Characterization of **4***b*: m.p. 101–102° (lit. (1) 105°), b.p. 119–120°/0.04 mm.

Anal. Calcd. for $C_8H_{11}O_2Cl_3$: C, 39.13; H, 4.52; Cl, 43.32. Found: C, 39.22; H, 4.68; Cl, 43.23.

Ultraviolet: ν_{max}(EtOH) 214 mμ (ε 49), 283 mμ (ε 21); n.m.r.: τ 6.93, multiplet (1, C*H*—CHOH); 6.40, doublet (1, OH); 4.99, multiplet (1, C*H*OH).

1,1,1-Trichloro-2-hydroxy-6-methyl-4-heptanone (5)

Following the procedure outlined before (reaction time 52 h), 14.23 g of crude product (light yellow, partially solidified) was obtained from 31.25 g (0.31 moles) of 4-methyl-2-pentanone, 41.1 g (0.25 moles) of chloral hydrate, 25.5 g (0.25 moles) of acetic anhydride, and 10.9 g (0.133 moles) of anhydrous sodium acetate. The crude product mixture was found by v.p.c. analysis to contain 77% (by weight) of **5** and 23% of **6**. The residue left after removal of **6** by high vacuum distillation was recrystallized from carbon tetrachloride and cyclohexane to give 8.0 g of pure 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**5**), m.p. 86–87° (lit. (3) 86–87°). Ketol **5** was shown by mixed melting point determination to be identical with a sample of the same compound prepared by the procedure described in the literature (3).

Characterization of **5**: u.v.: ν_{max}(EtOH) 213 mμ (ε 47), 239 mμ (ε 33), 280 mμ (ε 27); n.m.r. ($CDCl_3$): τ 9.07, doublet (6, $(CH_3)_2C$); 7.60, multiplet (3, $CHCH_2CO$); 7.05, multiplet (2, CH_2CHOH); 5.97, broad singlet (1, OH); 5.37, multiplet (1, C*H*OH).

1,1,1-Trichloro-2-hydroxy-4-pentanone (7)

Following the procedure outlined before (reaction time 50 h), 20.5 g of crude product (yellow, partially solidified) was obtained from 18.1 g (0.31 moles) of acetone, 41.1 g (0.25 moles) of chloral hydrate, 25.5 g (0.25 moles) of acetic anhydride, and 9.4 g (0.114 moles) of anhydrous sodium acetate. The crude product mixture containing 85% (by weight) of the desired ketol (7) and 15% of **6** was distilled at high vacuum to give 14.4 g of **7**, b.p. 100–105°/0.4 mm (lit (3) 100–105°/1 mm), m.p. 73.5–75° (lit. (1, 3, 17) 75–76°) after recrystallization from cyclohexane.

Characterization of **7**: u.v.: ν_{max}(EtOH) 219 mμ (ε 41), 275 mμ (ε 17); n.m.r. ($CDCl_3$): τ 7.75, singlet (3, CH_3CO); 7.00, multiplet (2, $COCH_2$); 5.90, doublet (1, OH); 5.35, multiplet (1, C*H*OH).

Reaction of Benzalacetone with Chloral Hydrate

Only trace amounts of 1,1,1-trichloro-2-hydroxy-6-phenyl-5-hexen-4-one (**8**) were obtained when a mixture of 45.6 g (0.31 moles) of benzalacetone, 41.1 g (0.25 moles) of chloral hydrate, 25.5 g (0.25 moles) of acetic anhydride, and 12.5 g (0.152 moles) of anhydrous sodium acetate was heated at 70° for 21 h. The usual work-up procedure (see before) gave a crude product mixture which was found by n.m.r. analysis (methyl peaks) to contain approximately 75 mole-% of benzalacetone and 25 mole-% of 1,1-diacetoxy-2,2,2-trichloroethane (**6**).

1,1-Diacetoxy-2,2,2-trichloroethane (**6**)

Compound **6** was obtained as the exclusive reaction product (71% yield) when a mixture of 31.25 g (0.31 moles) of 4-methyl-2-pentanone, 36.8 g (0.25 moles) of anhydrous chloral,[3] 25.5 g (0.25 moles) of acetic anhydride, and 5.2 g (0.063 moles) of anhydrous sodium acetate was heated at 100° for 52 h and worked up as described before. None of the desired 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**5**) was detected by n.m.r. and v.p.c. analysis of the crude product mixture (44.4 g).

Characterization of **6**: b.p. 217–218°/750 mm, (lit. (18) 225°/750 mm); n.m.r. ($CDCl_3$): τ 7.81, singlet (6, CH_3); 2.28, singlet (1, CH); n_D^{23} 1.4570 (lit. (14), n_D^{20} 1.4567).

Reactions of some 1,3-dipolarophiles with 1,2-dithioles and 1,2,4-dithiazoles

J. M. BUCHSHRIBER, D. M. MCKINNON, AND M. AHMED
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received November 27, 1968

The reactions of 1,2-dithiole-3-thiones and 1,2,4-dithiazole-3-thiones with acetylenic esters provide initial 1,3-dithiole products by 1,3-dipolar additions. 3-Imino-1,2-dithioles react similarly to form thiazoles. Both these initial adducts react further with more acetylenic ester to form spiran type structures. The stereochemistry of these is discussed briefly and applied to their reactivity and spectroscopic properties.

Canadian Journal of Chemistry, 47, 2039 (1969)

1,2-Dithiole-3-thiones (**1**) have been shown to undergo 1,3-dipolar reactions with activated acetylenes (1–3). The reaction provides 1:1 adducts, formulated as 2-(2-thioacylmethylene)-1,3-dithioles (**2**). Further reaction may provide spirans (**3**) by further 1,4-addition of the activated acetylene with the initially formed adduct. Similarly, 1,2,4-dithiazole-3-thiones (**4**) react with activated acetylenes to give 2-thioacylimino -1,3-dithiole (**5**) initial products (3–5) which may react further with more acetylene to give spiran structures (6) (**6**).

We were interested in the reactions of some dipolarophilic acetylenes with other such thiones and also with 3-imino-1,2-dithioles (**7***a*,*b*) which might be expected to undergo reactions similarly to the thiones, since partial ionic structures may be also written for these. Behringer reports (7) obtaining adducts by reaction of 5-iminoisothiazoles with dimethyl acetylenedicarboxylate. Probably the reaction of a 3-imino-1,2,4-dithiazole with dimethyl acetylenedicarboxylate (3) proceeds similarly.

4,5-Diphenyl-1,2-dithiole-3-thione (**1***a*) reacted with the three acetylenic esters studied; dimethyl acetylenedicarboxylate, ethyl propiolate, and ethyl phenylpropiolate. The first of these gave first a mono-adduct (**2***a*). The nuclear magnetic resonance (n.m.r.) spectrum of this showed two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

singlets assigned to the methyls of the carbomethoxy groups which are not equivalent in this molecule. It is reported (4) however, that in the related thioacylimino-1,3-dithiole (**5***a*) the two carbomethoxy groups are equivalent. It is also found in 4,5-bistrifluoromethyl-2-thiobenziminо-1,3-dithiole (**5***b*) prepared by reaction of hexafluoro-2-butyne with 5-phenyl-1,2,4-dithiazole-3-thione (**4**) that the two trifluoromethyl groups are equivalent as indicated by n.m.r. It was initially suggested that the equivalence of the methyls was fortuitous, but it now appears more likely that they are in fact equivalent due to ready rotation of the side chain by a means which is not yet clear. Similarly, the n.m.r. spectrum of the ethyl ester (**5***c*) (4) showed the presence of only one carbethoxy group, instead of the two expected if two geometrical isomers had been obtained. Probably the greater electronegativity of the side chain nitrogen in these compounds (**5***a,b,c*) compared to the side chain carbon in compound **2***a* makes the exocyclic double bond acquire more single bond character, permitting free rotation. Such free rotation should be temperature dependent, but even at $-60°$, the n.m.r. spectrum of compound **5***c* indicated that only one compound was present. Further treatment of the mono-adduct (**2***a*) with dimethyl acetylenedicarboxylate provided a di-adduct (**3***a*). The two carbomethoxy groups in the five-membered ring are equivalent in the di-adduct, and this is confirmed by the n.m.r. A small amount of unidentified violet material was also isolated from this reaction.

With ethyl propiolate the thione (**1***a*) gave both mono- and di-adducts. The n.m.r. spectrum of the former (**2***b*) indicated that it was a mixture of two geometrical isomers. This has been previously suggested (8) for a related 1,3-dithiole ketone (**2***c*) and for some other thioacylmethylene-1,3-dithioles (3). These isomers could not be separated. The n.m.r. showed two different singlets at 2.26 τ and 2.13 τ due to the different protons on the five-membered rings of the mono-adducts. A possible mechanism for the 1,3-addition would involve initial β-addition of the thione group to the ethyl propiolate. This is inconsistent with the production of two isomers. Possibly these could interconvert under the conditions of the reaction, but Campaigne (8) has shown that for two such acylmethylene-1,3-dithiole isomers there was no interconversion at 140°.

The n.m.r. spectrum of the di-adduct (**3***b*) obtained was consistent with the presence of two enantiomers, both derived from the geometrical isomers of the mono-adduct. The two protons on the 1,3-dithiole rings absorbed at τ 3.5 and are equivalent in the enantiomers. The carbethoxy group of the thiopyran ring may be α or β to the sulfur atom, depending on the mode of addition of the acetylenic ester to the α,β-unsaturated thioketonic side chain of the initial adduct (**2***b*). Only one singlet for the proton on the thiopyran ring is apparent, hence only one isomer has been formed. Probably the mechanism again involves β-addition of the thione sulfur (from a vinylogous 1,3-dithiole-2-thione) to the acetylenic ester. Even the meribicyclic **6***a*, thiathiophthene system exhibits vinylogous 1,2-dithiole-3-thione properties in its reaction with methyl iodide (9). A 1,4-dipolar mechanism has been proposed (10) for this second addition of acetylenic ester.

A mixed di-adduct (**3***c*) was prepared by reaction of the mono-adduct (**2***a*) with ethyl propiolate to allow proper assignment of the protons in the different rings of the di-adduct (**3***b*). It demonstrated that the protons on the thiopyran ring of the di-adducts absorb at lower fields than those on the 1,3-dithiole ring.

The reaction of the thione (**1***a*) with ethyl phenylpropiolate provided a mono-adduct (**2***d*) only. Possibly steric hindrance or reduced reactivity of the acetylene made formation of a di-adduct more difficult. Examination of the n.m.r. spectrum again indicated that two geometrical isomers were present.

Reaction of two 3-phenylimino-1,2-dithioles (**7***a,b*), prepared (11) by reaction of 3-methylthio-1,2-dithiolium salts with aniline, with dimethyl acetylenedicarboxylate gave no mono-adducts (**8**). Instead di-adducts were obtained. These may be formulated as spiran structures (**9***a,b*) respectively which have a thiazole nucleus joined to a thiopyran nucleus. Even when equivalent quantities of reagents were used, no mono-adducts (**8***a, b*) were isolated. Presumably these reacted more rapidly than the starting material with the acetylenic ester. However, Behringer (7) reports obtaining mono-adducts by reaction of isothiazole-3-imines with dimethyl acetylenedicarboxylate. In this case steric interference by phenyl groups on the nitrogen atoms of the side chain of the mono-adduct may hinder reaction with more acetylenic ester.

With the less reactive propiolic and phenylpropiolic esters, only 5-phenyl-3-phenylimino-1,2-dithiole (**7***a*) reacted. Mono-adducts (**8***c,d*) respectively were obtained. The n.m.r. spectrum was inconclusive in deciding whether the products were single compounds or mixtures of two geometrical isomers. Apparently, the ester groups are equivalent in the pairs of geometrical isomers in each case. 4,5-Diphenyl-3-phenylimino-1,2-dithiole (**7***b*) failed to react, probably due to steric hindrance. In these imines (**7***a,b*) the *N*-phenyl group may be "*cis*" or "*trans*" to the sulfur atoms. In the compound (**7***b*) however, steric hindrance by the 4-phenyl group makes the "*cis*" form more likely, and this form would in turn be less susceptible to approach by the acetylenic ester.

Also, the mono-adducts (**8***c,d*) formed may be either thiazole-4- or -5-carboxylic esters. They are formulated as the former since these would be the expected products of initial β-addition to the acetylenic ester.

Experimental

Thin-layer chromatography was performed on "Camag" silica gel type D.S.F. 5, supplied by Mondray Ltd. Development of plates was carried out using benzene with increasing proportions of chloroform and nuclear magnetic resonance spectra were obtained on a Varian model 56/60A spectrometer, in deuteriochloroform solution using tetramethylsilane as an internal standard.

Reaction of 4,5-Diphenyl-1,2-dithiole-3-thione with Dimethyl Acetylenedicarboxylate to form the Mono-adduct (2a)

4,5-Diphenyl-1,2-dithiole-3-thione (12) (381 mg) and dimethyl acetylenedicarboxylate (185 mg) in benzene (60 ml) were stirred together at room temperature for 18 h. The solution was evaporated to give a dark-green solid which was further purified by thin-layer chromatography. Dark-green needles m.p. 158.5–160.5° from chloroform (70%).

Anal. Calcd. for $C_{21}H_{16}O_4S_3$: C, 58.88; H, 3.74; S, 22.43. Found: C, 58.84; H, 3.72; S, 22.24.

Nuclear magnetic resonance 6.19 τ (3H singlet); 6.07 τ (3H singlet); 2.95 τ (5H singlet); 2.79 τ (5H singlet).

Reaction of 4,5-Diphenyl-1,2-dithiole-3-thione with Dimethyl Acetylenedicarboxylate to form the Di-adduct (3a)

4,5-Diphenyl-1,2-dithiole-3-thione (12) (285 mg) and dimethyl acetylenedicarboxylate (282 mg) in benzene (30 ml) were refluxed together for 15 h. The reddish-brown product obtained on evaporation was further purified by thin-layer chromatography. Two bands were obtained. The main product was the di-adduct. Yellow prisms m.p. 111–113° from ethanol (66%).

Anal. Calcd. for $C_{27}H_{22}O_8S_3$: C, 56.84; H, 3.86; S, 16.86. Found: C, 56.96; H, 3.75; S, 16.80.

Nuclear magnetic resonance 6.32 τ (6H singlet); 6.19 τ (3H singlet); 6.13 τ (3H singlet); 3.03–2.70 τ (5H multiplet); 2.77 τ (5H singlet).

A minor product was separated and crystallized from ethanol. Violet powder m.p. 161–163° (10 mg).

Reaction of 4,5-Diphenyl-1,2-dithiole-3-thione with Ethyl Propiolate (2b) and (3b)

The thione (213 mg) and the ester (74 mg) in benzene (50 ml) were refluxed 24 h. After evaporation the crude mixture was treated by thin-layer chromatography to separate the mono- and di-adducts.

Mono-adduct

Brownish-green powder from chloroform (29%) m.p. 175–178°.

Reaction of Dimethyl 2-(α-phenylthiophenacylidene)-1,3-dithiole-4,5-dicarboxylate with Ethyl Propiolate (3c)

The 1,3-dithiole dicarboxylic ester (151 mg) and ethyl propiolate (51 mg) in benzene (40 ml) were refluxed together for 4 days. The crude product was purified by thin-layer chromatography. Yellow needles from ethanol (62%) m.p. 148–150°.

Anal. Calcd. for $C_{26}H_{22}O_6S_3$: C, 59.32; H, 4.18; S, 18.25. Found: C, 59.12; H, 4.04; S, 18.17.

Nuclear magnetic resonance 8.77 τ (3H triplet, J = 7.0 c.p.s.); 6.38 τ (6H singlet); 5.63 τ (2H quartet, J = 7.0 c.p.s.); 3.02–2.50 τ (10H multiplet); 2.45 τ (1H singlet).

Reaction of 4,5-Diphenyl-1,2-dithiole-3-thione with Ethyl Phenylpropiolate (2d)

The thione (325 mg) and the ester (195 mg) in xylene (25 ml) were refluxed for 24 h. The solvent was removed under reduced pressure, and the crude product recrystallized from ethanol (56%) m.p. 183–185°.

Anal. Calcd. for $C_{26}H_{20}O_2S_3$: C, 67.82; H, 4.35; S, 20.87. Found: C, 67.62; H, 4.30; S, 20.85.

Nuclear magnetic resonance 8.92 τ (3H triplet, J = 7.2 c.p.s.); 8.80 τ (3H triplet, J = 7.2 c.p.s.); 5.90 τ (2H quartet, J = 7.2 c.p.s.); 5.78 τ (2H quartet, J = 7.2 c.p.s.); 3.05–2.53 τ (15H multiplet).

Reaction of 5-Phenyl-3-phenylimino-1,2-dithiole with Dimethyl Acetylenedicarboxylate (9a)

5-Phenyl-3-phenylimino-1,2-dithiole (**11**) (120 mg) and excess dimethyl acetylenedicarboxylate in benzene (50 ml) were refluxed for 18 h. The crude product obtained on evaporation was purified by thin-layer chromatography and crystallized from ethanol, orange prisms m.p. 173–175° (63%).

Anal. Calcd. for $C_{27}H_{23}NO_8S_2$: C, 58.59; H, 4.16; N, 2.53; S, 11.58. Found: C, 58.46; H, 4.10; N, 2.68; S, 11.68.

Nuclear magnetic resonance 6.42 τ (3H singlet); 6.32 τ (3H singlet); 6.20 τ (3H singlet); 6.12 τ (3H singlet); 3.75 τ (1H singlet); 2.83–2.62 τ (5H multiplet); 2.73 τ (5H singlet).

When the reaction was performed with equimolar quantities of reagents, the product was a mixture of di-adduct and unreacted imine.

Reaction of 5-Phenyl-3-phenylimino-1,2-dithiole with Ethyl Propiolate (8c)

The imine (400 mg) and the ethyl propiolate (150 mg) in benzene (20 ml) were refluxed for 18 h. The product obtained on evaporation was purified by thin-layer chromatography and crystallized from ethanol, dark orange needles, m.p. 221–223° (75%).

Anal. Calcd. for $C_{20}H_{17}NO_2S_2$: C, 65.39; H, 4.63; N, 3.82; S, 17.44. Found: C, 65.23; H, 4.66; N, 3.95; S, 17.47.

Nuclear magnetic resonance 8.70 τ (3H triplet, J = 7.2 c.p.s.); 5.83 τ (2H quartet, J = 7.2 c.p.s.); 3.12–2.59 τ (11H multiplet, due to 10 protons on the two benzene rings and one single proton on the thiazole ring); 2.47 τ (1H singlet; proton on side chain).

Reaction of 5-Phenyl-3-phenylimino-1,2-dithiole with Ethyl Phenylpropiolate (8d)

5-Phenyl-3-phenylimino-1,2-dithiole (11) (329 mg) and the ester (200 mg) in xylene (20 ml) were refluxed for 14 h. The solvent was removed under reduced pressure and the yellowish-orange residue was extracted with boiling ethanol (80 ml) to remove unreacted thione, and recrystallized from chloroform. Dark orange needles m.p. 261–263° (64%).

Anal. Calcd. for $C_{26}H_{21}NO_2S_2$: C, 70.43; H, 4.74; N, 3.16; S, 14.45. Found: C, 70.24; H, 4.86; N, 3.26; S, 14.26.

Nuclear magnetic resonance 8.80 τ (3H triplet, J = 7.0 c.p.s.); 5.77 τ (2H quartet, J = 7.0 c.p.s.); 2.97–2.28 τ (16H multiplet, due to 15 protons on the benzene rings and one proton on the thiazole ring).

Reaction of 4,5-Diphenyl-3-phenylimino-1,2-dithiole with Dimethyl Acetylenedicarboxylate (9b)

4,5-Diphenyl-3-phenylimino-1,2-dithiole (11) (330 mg) and the ester (132 mg) in xylene (30 ml) were refluxed for 72 h. The orange residue remaining after removal of the solvent under reduced pressure was recrystallized from ethanol. Yellow prisms m.p. 230–232° (75%).

Anal. Calcd. for $C_{33}H_{27}NO_8S_2$: C, 62.97; H, 4.29; N, 2.33; S, 10.17. Found: C, 62.73; H, 4.47; N, 2.17; S, 10.21.

Nuclear magnetic resonance 6.57–6.37 τ (12H, two main peaks but not properly resolved). 3.05–2.67 τ (15H multiplet, not properly resolved).

Reaction of 4,5-Diphenyl-3-Phenylimino-1,2-dithiole with Ethyl Propiolate

The imine was treated with excess ester in boiling xylene for 1 week. A thin-layer chromatography separation of the mixture indicated only unreacted starting materials.

Reaction of 4,5-Diphenyl-3-phenylimino-1,2-dithiole with Ethyl Phenylpropiolate

The imine was treated with excess ester in boiling xylene for 1 week. A thin-layer chromatography separation of the mixture indicated only unreacted starting materials.

Reaction of 5-Phenyl-1,2,4-dithiazole-3-thione with Hexafluoro-2-butyne (5b)

The thione (500 mg) was heated with excess hexafluoro-2-butyne in benzene (20 ml) in a sealed glass tube at 70° for 7 h. The benzene was evaporated and the product recrystallized from ethanol. Greenish needles m.p. 128–129° (89%).

Anal. Calcd. for $C_{12}H_5F_6NS_3$: C, 38.70; H, 1.30; F, 30.31; N, 13.69; S, 25.52. Found: C, 38.70; H, 1.53; F, 30.47; N, 3.81; S, 25.72.

Nuclear magnetic resonance gave a singlet at +3133 τ.

Low Temperature Nuclear Magnetic Resonance Study of Ethyl 2-Thiobenzimino-1,3-dithiole-4-carboxylate

The ester (4) was examined in saturated deuteriochloroform solution at temperatures to −60°. The absorption of the proton on the 1,3-dithiole ring at 1.98 τ remained a singlet over the temperature range studied.

Photolysis of benzil in 2-propanol and in cumene

DAVID L. BUNBURY AND TZE TANG CHUANG[1]
Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received October 9, 1968

Benzil has been irradiated in 2-propanol and in cumene with a mercury lamp filtered through Pyrex. The principal products are benzoin, 1,2,3,4-tetraphenyl-2,3-dihydroxybutane-1,4-dione (**3**), benzoin benzoate, benzaldehyde, benzoic acid, 1,2,3,4-tetraphenyl-2,3-dihydroxybutane-1,4-dione dibenzoate (**5**), and some unidentified high molecular weight compounds. The yield of **3** is strongly dependent on initial benzil concentration and temperature and on the solvent used. The quantum yield of benzil disappearance depends on initial benzil concentration to a lower limit which varies with solvent. At an initial benzil concentration of 0.083 moles/l, the quantum yield of benzil disappearance is 0.11 in 2-propanol and 0.018 in cyclohexane. Compound **3** does not appear to be formed by a coupling of the appropriate ketyl radicals, as in the benzophenone case but instead, a complex is formed between a benzil molecule and the ketyl radical. Compound **3** decomposes at temperatures as low as 25°. The principal path for the formation of benzaldehyde and benzoyl radicals is the dissociation of the ketyl radical. Excited benzil abstracts a hydrogen from 2-propanol at least ten times faster than it dissociates into two benzoyl radicals.

Canadian Journal of Chemistry, 47, 2045 (1969)

Introduction

The photo-reaction of benzil in cyclohexane has already been reported (1). This study has been extended using 2-propanol and cumene as solvents. Differences in kinds of products formed, in product distribution, and in concentration dependence, result when different solvents are used, particularly in the appearance of benzil pinacol (1,2,3,4-tetraphenyl-2,3-dihydroxy-1,4-butanedione). These differences seem to be related to the ease with which a hydrogen atom may be abstracted from the solvent. Benzoic acid appears as a product in all solvents used despite exclusion of oxygen during irradiation. Although similar to the photo-reduction of benzophenone (**2**) in the initial chemical step, subsequent reactions are more complicated.

Experimental

Materials

Benzil was from Eastman Organic Chemicals, and benzoin was Matheson, Coleman, and Bell, reagent grade. These were twice recrystallized from methanol. 2-Propanol and benzene, Fisher certified reagents, were freshly distilled. Cumene, Eastman Organic Chemicals, was distilled each time immediately before use. The silica gel used in column chromatography was 100–200 mesh Fisher certified grade, heated to 150 °C for 1 h and cooled to room temperature in a desiccator. Eastman Chromagram Sheet 6060 (silica gel with fluorescent indicator) was used in thin-layer chromatography (t.l.c.) and was heated to 100° for 20 min before use. Naphthalene, anthracene, and pyrene were chromatographed through activated alumina (3). Tri-*n*-butyltin hydride was prepared from tri-*n*-butyltin chloride (Aldrich Chemical Co. Inc.) by reduction with lithium aluminium hydride and vacuum distilled prior to use (4). Benzoin benzoate had been prepared previously. All other solvents used were freshly distilled.

Apparatus

All melting points were taken on a Fisher–Johns melting point apparatus and/or checked with a Mel-Temp melting point apparatus. Infrared (i.r.) spectra were determined on a Beckman IR 8 double beam spectrophotometer. Elemental analyses were done by Schwarzkopf Microanalytical Laboratory, 56–19 37th Avenue, Woodside, New York 11377, except for the dibenzoate analysis which was done by Dr. C. Daessle, Montreal, Quebec. Molecular weights were determined on a Hitachi Perkin–Elmer Model 115 molecular weight apparatus which uses an isopiestic method. Gas–liquid chromatography (g.l.c.) was performed on a Burrell model K-1 with a thermal conductivity detector. A 250 cm × ¼ in. internal diameter column filled with 20% Dow Corning high vacuum silicone grease on 80–100 mesh Chromosorb W was used for all compounds except acetone, for which 15% Apiezon L on the same supporting material was used. Standard solutions were run alternately with the irradiated solution for each peak of interest. Nuclear magnetic resonance (n.m.r.) spectra were obtained on a Varian A-60-A spectrometer, by courtesy of Dr. B. M. Lynch.

Three Raymaster Uviarc high pressure mercury lamps 420-UI (George W. Gates and Co., Inc., Franklin Square, Long Island, New York 11 010) were used in all irradiations except the actinometry runs. For these an Osram HBO 100 W/2 mercury super (high) pressure lamp (George W. Gates) with an arc size of 0.3 mm × 0.3 mm was used. Quantitative measurements were made on thin-layer chromatograms by a Photovolt Densicord, model 542 densitometer with a light source of 254 mμ.

Irradiation

Three types of irradiation were carried out. In the first type, 0.6 g of benzil were weighed into a 50 ml tube and made up to 35 ml with 2-propanol. This was attached to a vacuum line and, after degassing by at least three freeze pump thaw cycles, was sealed off the line and allowed to warm to room temperature. After solution of the benzil, it was irradiated for 7 min with external water cooling.

In the second type, 34.2 g of benzil were dissolved in 2 l of 2-propanol. The resulting solution was poured into a 3 l three-necked round bottom Pyrex flask fitted with reflux condenser and nitrogen sparger connections. The flask was surrounded by the 3 Uviarc mercury lamps and, after thorough flushing with nitrogen, it was irradiated. The temperature during irradiation was the boiling point of 2-propanol (82–85 °C).

Most of the irradiations were carried out using the third arrangement. In this, varying amounts of benzil and sometimes other reagents were dissolved in 500 ml of 2-propanol or other solvent and placed in a Vycor cylinder with a 600 ml capacity. This cylinder was placed inside a larger Pyrex cylinder and distilled water (25 °C) circulated through the Pyrex cylinder by means of a vibrostatic pump. Nitrogen was flushed through the solution for 30 min before irradiation and during the course of the irradiation. The few runs where nitrogen was not used are indicated.

Thin–Layer Chromatography

Standards were run at the same time as the irradiated solution. The developing solvent was hexane:ethyl ether (2:1). Quantitative analysis was carried out by measuring the area recorded on the densitometer and comparing it to the area produced by a standard solution. Using standard solutions, it was seen that there was a linear relationship between the area and amount of substance.

Column Chromatography

A check by t.l.c. showed no difference in the kinds of products between the sealed tube photolyses and the nitrogen flushed ones, so no further work was done on the sealed tube runs. In those runs in which a precipitate appeared, it was first filtered off and the filtrate treated the same as in those runs where there was no precipitate.

The 2-propanol was removed from the clear solution under reduced pressure. About 5 g of the residue were redissolved in 50 ml of ethyl ether and were added to 15 ml of saturated sodium bisulfite solution with continuous shaking. After separation, the ether layer was washed with 30 ml of saturated sodium bicarbonate twice, followed by two 50 ml portions of distilled water, and then dried over anhydrous sodium sulfate. The ether solution was then added to 30 g of silica gel, and the ether removed in a rotary evaporator. The dried residue was ground in a mortar with *n*-hexane and the mixture placed on top of 300 g of silica gel in a packed column. The column was eluted with 6 l of ethyl ether – hexane which varied in concentration from 0 to 60% ether (v/v), then 2.5 l of acetone. Each fraction was examined by either t.l.c. or g.l.c. Ether (5%) eluted the unreacted benzil and ether (15%) eluted the benzoin benzoate. The fractions eluted by 25–35% ether were combined for further column chromatography and yielded benzoin and dibenzoin dibenzoate.

The material eluted from the first column by 50% ether and by acetone could not be separated any further and was brownish in color; presumably this material was a high molecular weight product. There was also a very little material which could not be removed from the column. Runs made after identification of all the products had been completed were analyzed by t.l.c. after removal of the benzaldehyde and benzoic acid.

Determination of Quantum Yield

The actinometer used was that of Hatchard and Parker (5) and was stirred by a current of nitrogen during irradiation. The light from the lamp was passed through a collimating hole and then a No. 7-83 filter from Corning glass works. This filter has a peak at 368 mμ and a half band width of 22 mμ. The percentage transmission at the maximum is 16%. The same cell with plane glass windows was used both for the benzil solutions and for the actinometer. Complete absorption of light, as measured by a photocell, took place in the benzil solutions.

Isolation, Identification, and Estimation of Products

Benzil Pinacol

This compound appeared as a white precipitate after some irradiations. As there was sometimes supersaturation, the solution was always allowed to stand for several hours after irradiation before filtration. After filtering, the precipitate was purified by immersion in acetone for 24 h, filtered again, and dried in a vacuum desiccator. The i.r. spectrum showed a strong hydroxy peak at 3400 cm^{-1} and a carbonyl absorption at 1650 cm^{-1}. The melting point was 204° measured on a Koffler hot bench but decomposed at 130° when heated slowly in a capillary tube. If air was present, the decomposition product was benzil. When heated in a sealed degassed tube the decomposition products were benzoin and benzil. Quantitative analysis (weighing the total decomposition product and measuring the benzil by ultraviolet (u.v.) spectrometry) showed that the two were present in a 1:1 mole ratio.

Anal. Calcd. for $C_{28}H_{22}O_4$: C, 79.60; H, 5.25. Found: C, 79.14, 79.19; H, 5.20, 5.18.

The formula weight is 422. An outside laboratory reported a molecular weight of 278. Using tetrahydrofuran as solvent, we found the molecular weight to be 403 when measured as soon as the solution was made up. After standing for 4 h in tetrahydrofuran (0.9 g/100 ml at room temperature) the compound changed completely to benzil. The compound also dissolved in dioxane (0.7 g/100 ml at room temperature), and slightly in dimethyl sulfoxide. It was insoluble in all other solvents tried, changing in some of them to benzil (DMF 5 min, diphenylmethane 24 h). Alcohols and acetone at room temperature had absolutely no effect on either, neither did 1 *N* alcoholic NaOH. The fact that it changes to benzil over a period of hours would explain the molecular weight results. The insolubility in NaOH and the white color exclude the enol structure which might be expected in analogy with the dimerization of triphenylmethyl radicals to produce 1-diphenylmethylene-4-trityl-2,5-cyclohexadiene (6).

The n.m.r. spectrum in DMSO was run 6 times over a period of 135 min. The ratio of the area of the aromatic hydrogen and hydroxy hydrogen was plotted against

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

time and extrapolated to zero time. The intercept ArH/OH was 12. A ratio of 10 would be expected on the basis of the structure **3**. An excess of the compound was shaken with tetrahydrofuran, centrifuged, and the n.m.r. spectrum taken immediately. A value of 9.6 was obtained for the same ratio. When refluxed in 2-propanol or even just heated to 50 °C in 2-propanol, the compound changed to benzil. When added to styrene at room temperature the rate of polymerization increased. When added to a benzene solution of iodine which was then degassed and sealed, the color disappeared on warming to 50 °C. Apparently, the benzil pinacol dissociates very easily into two ketyl radicals. In the absence of oxygen, they disproportionate to benzil and benzoin. When O_2 is present, benzil is the sole product. Neckers and Schaap have recently reported that benzpinacol dissociates into free radicals at a temperature as low as 130 °C (7).

Benzaldehyde

This compound was measured by g.l.c. and its identity was checked by comparing its retention time with that of an authentic sample, and also by precipitating the 2,4-dinitrophenylhydrazone.

Unreacted Benzil

This compound was identified by its i.r. spectrum. It was measured by g.l.c.; one half of the benzoin had been subtracted. Benzoin disproportionates to benzil and deoxybenzoin on the g.l.c. column (8).

Benzoic Acid

This was recovered by acidification of the bicarbonate extract to pH 2 followed by two extractions with ether. The ether was washed, dried, and evaporated; the residue was identified by its m.p. and i.r. spectrum, and was weighed.

Benzoin Benzoate

The fraction eluted with 15% ethyl ether gave a substance which after recrystallization had m.p. 126 °C, lit. (17) 125 °C. The mixed m.p. with benzoin benzoate showed no depression and the i.r. and n.m.r. spectra were identical with authentic benzoin benzoate. The singlet at δ 7.19 in the n.m.r. spectrum is assigned to the aliphatic proton. It was measured either by weighing or by t.l.c.

Benzoin

This was obtained from column chromatography. It was identified by its m.p. and i.r. spectrum. It was measured either by weighing after column chromatography or by densitometry after t.l.c.

1,2,3,4-Tetraphenyl-2,3-dihydroxy-1,4-butanedione Dibenzoate (5) (di-(Benzoin Benzoate))

The second fraction after rechromatography yielded a compound which after recrystallization from *n*-hexane had m.p. 112–113 °C. It was first measured quantitatively by weighing and later by densitometry after t.l.c.

Anal. Calcd. for $C_{42}H_{30}O_6$ (mol. wt., 630.7): C, 79.98; H, 4.80. Found (mol. wt., 640): C, 78.82; H, 4.88.

The i.r. spectrum showed no aliphatic hydrogens or hydroxy groups and had the characteristic bands of the benzoyl group. The n.m.r. spectrum in dimethyl sulfoxide consisted only of unresolved aromatic absorption.

Further identification was made in two ways. The radicals produced by the abstraction of the aliphatic hydrogen of benzoin benzoate should couple to produce **5**. A mixture of benzoin benzoate with benzophenone was irradiated in a benzene–cyclohexane solvent (1:1, v/v). The solution was evaporated to dryness and the residue separated by column chromatography. One of the compounds obtained had an i.r. spectrum identical with that of **5** and m.p. 112 °C. A mixed m.p. with **5** showed no depression.

Rust *et al.* (9) found that heating benzaldehyde with *tert*-butyl peroxide leads to the formation of dihydrobenzoin dibenzoate by a mechanism involving the attack of benzoyl radicals on the oxygen of another benzaldehyde molecule, followed by a coupling of the resulting radicals. It was earlier reported by Bunbury and Wang (1) that adding benzil to the mixture of benzaldehyde and *tert*-butyl peroxide did not lead to the production of the dibenzoate. However, a careful check of the products from heating benzil, benzaldehyde, and *tert*-butyl peroxide leads to the isolation of several compounds. One of these compounds had m.p. 110–112 °C on recrystallization from *n*-hexane. The elementary analysis was C, 78.94; H, 4.80 and the measured molecular weight 648. A mixed m.p. with the product from the benzil in 2-propanol irradiation showed no depression. The n.m.r. spectrum showed only unresolved aromatic absorption.

Acetone

This was measured by g.l.c. and identified by its 2,4-dinitrophenylhydrazone.

Bicumyl

After irradiation of a cumene solution of benzil, the solvent was removed under reduced pressure, and the residue separated by column chromatography. The first fraction eluted with *n*-hexane was proved to be bicumyl by its m.p. and by comparison of its i.r. spectrum with that of an authentic sample. It was weighed.

Results and Discussion

The percentage of high molecular weight compounds appearing in Table I was obtained by difference. All runs in this table were carried to about 50% decomposition of the benzil.

Reducing the benzil concentration at constant light intensity has three effects: (1) the rate of benzil disappearance becomes steadily less until a constant value is reached, see runs 4–9, Table I and Fig. 1 curve A; (2) the percentage of benzil pinacol falls off to zero, see runs 4–9, Table I and Fig. 1 curve C; and (3) there is an increase in the amount of benzoin benzoate formed and even more in the amount of dibenzoin dibenzoate formed, see runs 4–9, Table I. Further, the initial concentration at which the benzil pinacol production becomes zero is the same as that at which the rate of benzil disappearance becomes constant.

Reducing the 2-propanol concentration with benzene leads to a marked reduction in rate and an elimination of benzil pinacol as a product, see run 13 Table I.

*Bath temperature was 25–30° in all runs except run 1; here it was 82–85°. The sample volume was 0.5 l except in run 1; here it was 2 l. Acetone (17 mmoles) was found in run 4, and 7 mmoles of bicumyl was found in run 11. There was weak light intensity in run 19. Runs were carried to 50% decomposition.

†Not measured.

‡None were found.

§High molecular weight compounds were obtained by difference.

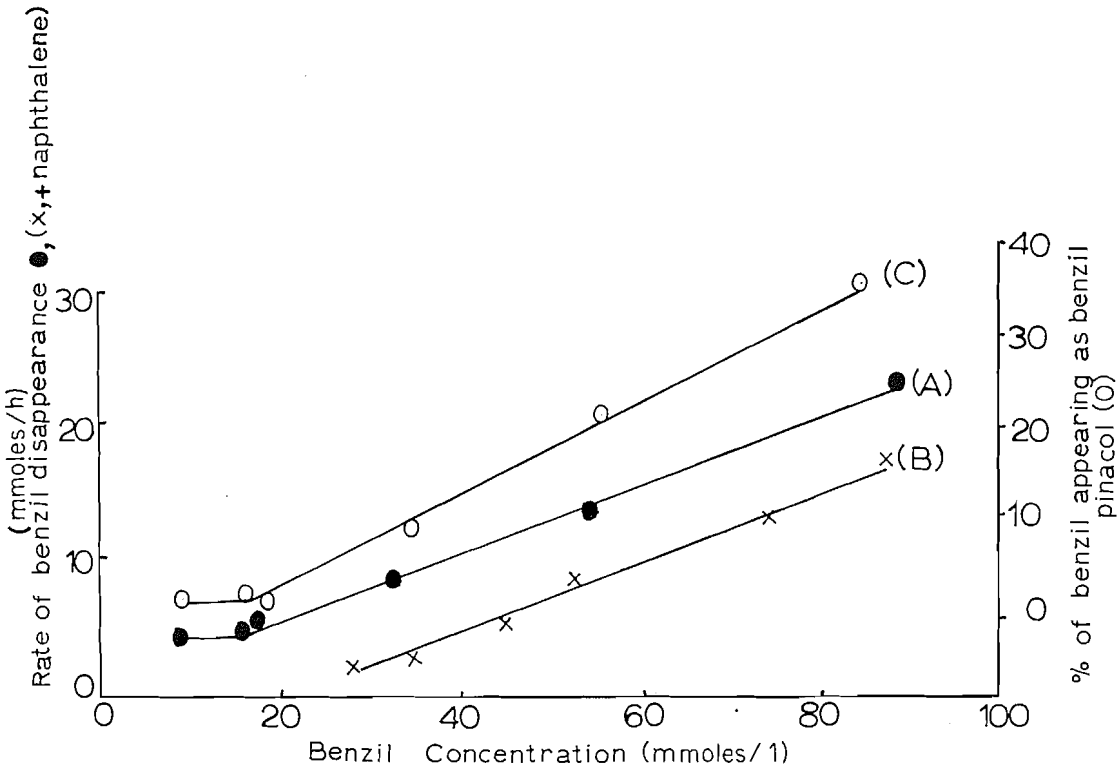

FIG. 1. Rate of benzil disappearance and pinacol formation as a function of benzil concentration in 2-propanol. Each curve was a separate series: curves A and B, 10% destruction of benzil; curve C, 40% destruction of benzil.

TABLE II

Reaction conditions and products of benzil photolysis in cumene

Run number*	Initial concentration of benzil (mole/l)	Rate of decomposition (mmole/h)	% benzil pinacol formed (% of decomposed benzil)	Benzoin	Benzoin benzoate	Benzaldehyde
1	0.405	3.54	23.0	7	3	†
2	0.362	3.15	15.7	7	5	†
3	0.272	2.50	9.4	10	5	†
4	0.248	2.38	0	14	10	†
5	0.226	2.33	0	13	13	†
6	0.092	2.60	0	†	†	†

*Total volume for irradiation is 50 ml of cumene solution. About 15% benzil was destroyed in each run. All runs were degassed.
†Not measured.

The behavior in cumene differs from that in 2-propanol in the following ways. The benzil concentration below which no benzil pinacol is formed is 250 mmoles/l in cumene as compared to 18 mmoles/l in 2-propanol. At a given concentration the rate is slower. The rate of change of the rate with concentration is 0.009 mmoles/h//mmoles/l while in 2-propanol it is 0.25 mmoles/h//mmoles/l. This is shown by runs 4, 10, and 11 in Table I, by Table II, and by Figs. 1 and 2.

The following series of steps seems best for rationalizing the results.

$$[1] \quad C_6H_5COCOC_6H_5 \xrightarrow{h\nu} {}^1C_6H_5COCOC_6H_5^*$$

$$[2] \quad {}^1C_6H_5COCOC_6H_5^* \rightarrow C_6H_5COCOC_6H_5$$

2

[5] **1** + $CH_3\dot{C}OHCH_3 \rightarrow$ **2** + CH_3COCH_3

After reaction [1] the excited benzil molecule can do three things; lose its energy and revert to the ground state [2], split into two benzoyl radicals [3], or abstract a hydrogen atom from the solvent to form the ketyl radical [4]. That reaction [2] does occur is shown by the fact that the quantum yield of benzil decomposed depends strongly on the ease with which hydrogen is lost by the solvent. At an initial concentration of 83.4 mmoles/l the quantum yield of benzil disappearance in 2-propanol is 0.11 and in cyclohexane, 0.018. Anthracene and pyrene which have triplet energies below that of benzil are much more effective in slowing down the reaction than is naphthalene, the triplet energy of which is greater (10*a*), see Table III.

Reaction [3] is a minor reaction. Assume for the sake of argument that the benzoyl radicals so produced either abstract hydrogen from the solvent or react with benzil as proposed by Bunbury and Wang (1). Then the proportion of benzaldehyde should increase with the ease of hydrogen abstraction from the solvent but no such correlation is found; cyclohexane 6.2%, cumene 7.4%, 2-propanol 6%. Further, at lower benzil concentrations there should be an increase in the amount of benzaldehyde as there is less benzil to compete with the solvent for the benzoyl radicals. No such increase is found (Table I). The rate of decomposition in pure benzene, where reactions [4] and [5] cannot occur was found to be 0.323 mmoles/h at a concentration of 8 mmoles/l, and 0.526 mmoles/h at a concentration of 82.8 mmoles/l, under the same conditions as the runs in Table IV.

With the exception of the formation of benzoic acid, reactions [4] and [5] are the principal ones leading to products.

Reactions [6]–[9] show the different possible fates of the ketyl radical (**2**).

Reaction [6] shows the formation of benzil in a manner analogous to the formation of benzpinacol in the photolysis of benzophenone, **2.**

Dimerization of two ketyl radicals does not occur to any extent in the benzil system. If the benzil pinacol was produced by the combination of two ketyl radicals, its rate of production compared to that of benzoin should drastically decrease with a reduction in light intensity as the steady state concentration of ketyl radicals was reduced. No such decrease was found (run 19, Table I). Added quenchers which also reduce the steady state concentration of excited benzil, reduced the rate but had no effect on the proportion of benzil pinacol produced (Table III).

Since reduction of the benzil concentration causes a marked decrease in the production of benzil pinacol, we postulate a reversible complex formed between the ketyl radical and an unexcited benzil molecule and that this complex can abstract a hydrogen atom to form the benzil pinacol, reaction [7]. Also, since formation of the pinacol by this route uses a benzil molecule that would not otherwise be used, part of the fall in the quantum yield of benzil disappearance with fall in initial benzil concentration is explained. If the complex between the ketyl radical and a benzil molecule is a poor hydrogen abstractor, there should be an effect of solvent on pinacol formation. If we compare the reaction in cyclohexane, cumene, and 2-propanol, it is seen that there is no pinacol production in cyclohexane, and that the pinacol production becomes zero in cumene at an initial benzil concentration of 0.25 moles/l, and zero in 2-propanol at an initial benzil concentration of about 0.018 moles/l.

Metzger (11), in a study of the thermal decomposition of 1,1,2,2-tetraphenylethanol and of α-benzhydrylbenzoin says ". . . the experimental evidence leads to the conclusion that benzil is forming π-complexes with the radical intermediates . . .". One of the radicals for which complexes are postulated is the same ketyl radical as we have here.

In a recent paper, Filipescu and Minn (12) have shown that there is a long-lived intermediate formed between the PhĊOH radicals and the Me_2ĊOH radical during the photolysis of benzophenone in 2-propanol. This intermediate undergoes a slow dark reaction with benzophenone in the absence of oxygen to produce two PhĊOH radicals. Since the benzil pinacol usually took some time to precipitate after irradiation, we thought that perhaps an intermediate was intervening in a similar way. Shaking the irradiated mixture with air immediately after turning out the lights had no effect on the amount of benzil pinacol produced.

As mentioned above, the hydrogen-donating properties of the solvent have no effect on benzaldehyde production, therefore, benzaldehyde does not appear to be produced by hydrogen abstraction of benzoyl radicals. Further, the rate of benzoyl radical production by reaction [3] (as measured in pure benzene) is not nearly great enough to account for the rate of production of benzoin benzoate and its dimer (Table IV). Therefore, another source of benzoyl radicals, as well as a route for the production of benzal-

For personal use only.

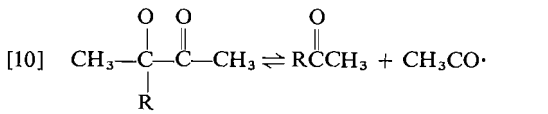
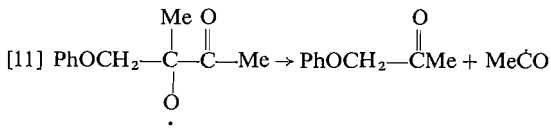
dehyde, is needed. Reaction [9] is suggested as a source of both benzaldehyde and benzoyl radicals. This reaction is similar to reaction [10]



[10] $CH_3—\underset{\underset{R}{|}}{\overset{O}{\overset{||}{C}}}—\overset{O}{\overset{||}{C}}—CH_3 \rightleftharpoons R\overset{O}{\overset{||}{C}}CH_3 + CH_3CO\cdot$

proposed by Bentrude and Darnall (13) in both biacetyl photochemistry and the reaction of biacetyl with thermally generated radicals, and



[11] $PhOCH_2—\underset{\underset{O\cdot}{|}}{\overset{Me\ O}{\overset{|\ \ ||}{C}}}—\overset{O}{\overset{||}{C}}—Me \rightarrow PhOCH_2—\overset{O}{\overset{||}{C}}Me + MeCO$

also to reaction [11] suggested by Baum and Norman (14) in a study of the photochemical reactions of biacetyl with some benzenoid compounds. In the photolysis of acetaldehyde, Zeldes and Livingston (15) propose reaction [12] which is the reverse of reaction [9] with methyls instead of phenyls

[12] $CH_3CO\cdot + CH_3CHO \rightarrow CH_3COCOHCH_3$

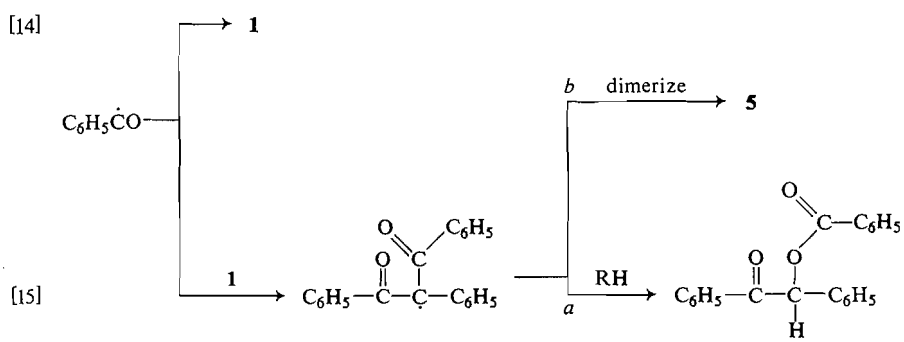
Reaction [9] is also supported by the finding that both benzoin and *benzoin benzoate* are produced by tri-*n*-butyl tin hydride acting on benzil in 2-propanol in the dark (Table III). Presumably, the tin hydride transfers a hydrogen atom to benzil forming the same ketyl radical, some of which then dissociates according to reaction [9]. In a given solvent the benzoin/benzaldehyde ratio would be expected to be independent of the benzil concentration as a certain fraction of the ketyl radicals would split and a certain fraction abstract hydrogen to form benzoin. On examining runs 4–7 in Table IV this is seen to be so. An increase in temperature would increase the rate of both reaction [8] and reaction [9] so the change in the ratio is not predictable. The ratio in fact shows slight if any change from 82–85 °C to 25–30 °C, 2.2 to 3.3. The more difficult it is to abstract a hydrogen atom from the solvent, the greater the amount of dissociation to benzoin formation would become. The benzoin/benzaldehyde ratio is 1.4 for cumene at 25°, and 1.1 for 10% 2-propanol in benzene at 25°.

If it is assumed that the rate of dissociation is the same in 2-propanol as in cumene, a comparison of the benzoin/benzaldehyde ratio in the two solvents gives the relative ease of hydrogen abstraction by the ketyl radical. The additional assumption that reaction [13]

[13] $\mathbf{2} + CH_3\dot{C}OHCH_3 \rightarrow \mathbf{4} + CH_3COCH_3$

does not take place to any appreciable extent must also be made. This appears to be so in the case of benzophenone; i.e. benzhydrol is not produced (10*b*).

With unsubstituted benzil, reaction [14] only results in a reduction of the quantum yield but it cannot be ruled out. Reaction [15] leads to benzoin benzoate, and di-(benzoin benzoate). Presumably, the high molecular weight compounds may be formed by other reactions involving benzoyl radicals. If reaction [9] was the only one forming benzoyl radicals, the moles of benzaldehyde should not be less than the moles of benzoin benzoate, plus twice the moles of benzoin benzoate dimer; further, the ratio of the two should remain constant. As can be seen from Table IV, the relative amount of benzoin benzoate and dimer increase with decreasing benzil concentration. Reaction [3] must be providing the additional benzoyl radicals. The thin-layer chromatogram of the pure benzene runs



showed only two product spots, one that did not move and one that had an R_f corresponding to the dimer of benzoin benzoate. Apparently the sequence [1], [3], [15*b*] is followed in benzene. If twice the rate of decomposition in pure benzene (about 0.4 mmoles/h) is subtracted from the sum of the rate of benzoin benzoate formation and twice that of its dimer, the difference is approximately the rate of benzaldehyde production: i.e. benzaldehyde to benzoin benzoate plus twice the dimer ratio becomes more or less constant.

Apparently then, at constant light intensity, benzil dissociates into benzoyl radicals at a certain slow rate that is concentration independent, and also abstracts hydrogen from the solvent at a much faster rate that is solvent and, in some cases, concentration dependent. Thus, the proportion of benzil dissociating into two benzoyl radicals would become progressively larger at lower benzil concentrations (until the steady value is reached) thus explaining the relative increase in products involving the benzoyl radical as starting concentrations of benzil are reduced.

The decrease in the quantum yield of benzil destruction with decreasing benzil concentration is more than can be accounted for by the decrease in pinacol production. If each mole of pinacol is formed from an excited benzil molecule and one in the ground state, the rate of benzil disappearance when pinacol production reaches zero should be 22.7 – 3.9 = 18.8 mmoles/h. Instead, it falls to about 5 mmoles/h (Table IV). If at high benzil concentrations, reaction [5] is important and at low benzil concentrations becomes much less so, the 2-hydroxy-2-propyl radicals disappearing by disproportionation, this could account for an additional fall in the rate to about 9 mmoles/h. In cumene, the concentration effect disappears at a much higher initial benzil concentration and is much less marked than in 2-propanol; 0.009 mmoles/h//mmoles/l compared to 0.25 mmoles/h//mmoles/l.

It was originally thought that the tri-*n*-butyl tin hydride would suppress benzil pinacol formation by giving a hydrogen to the benzoin radicals before they had a chance to dimerize. Since that is apparently not the path of benzil pinacol formation we have no explanation for the suppression of benzil pinacol formation or for the fact that the tin hydride also slows down the rate of photochemical reaction.

That such a small amount of iodine should suppress the photochemical reaction is surprising (Table III). The iodine must either be a very efficient quencher or reacting in such a way that it is constantly being regenerated. For example, the following steps, [16] and [17], would provide such a path

[16] $$\underset{(I)}{\mathbf{2}} + I_2 \rightarrow \mathbf{1} + \underset{(HI)}{HI} + I$$

[17] $$CH_3\dot{C}(OH)CH_3 + HI \rightarrow CH_3CHOHCH_3 + I$$

This sequence is the same as the one proposed by Cohen *et al.* (16) for inhibition by disulfides and thiols in low concentration, of the photo-reduction of benzophenone, reactions [18] and [19].

[18] $$Ph_2\dot{C}OH + RS\cdot \rightarrow Ph_2CO + \underset{(R_2S_2)}{} \underset{(RSH + RS\cdot)}{RSH}$$

[19] $$Me_2\dot{C}OH + RSH \rightarrow Me_2CHOH + RS\cdot$$

The path to benzoic acid remains obscure. It is produced in all solvents used so far, cyclohexane (1), 2-propanol, cumene, and in later work here[2], triethylamine. The poorer hydrogen donors produce a larger percentage of benzoic acid. On the other hand, the presence of the very strong hydrogen donor, tri-*n*-butyl tin hydride does not affect the percentage of benzoic acid formed in 2-propanol. The reaction leading to the benzoic acid precursor must be a rapid one. The fact that it can exist in the presence of the tin hydride argues against it being a radical. It is not produced by oxygen during the reaction. When carried out in sealed degassed tubes, the same products were found comparable to run 4, Table I, benzil pinacol (not measured), benzoin 20%, benzoin benzoate 15%, benzoic acid 10% (analysis by t.l.c. only), and dibenzoin dibenzoate. Varying the flushing period before irradiation to a minimum of 15 min had no effect on the products. The u.v. spectrum (360–480 mμ) of a degassed sample was taken before irradiation, after irradiation, and after being opened to the air. The changes were not pronounced. Deliberately adding oxygen to the reaction mixture during irradiation leads to benzoic acid as the sole identifiable product with a reduction in rate

[2]Runs by Miss Han Ping Mak.

from 22.7 mmoles/h to 16.5 mmoles/h.[3] In oxygen-free solutions, the compound leading to benzoic acid might be an intermediate of the type proposed by Filipescu and Minn (12). In the case of benzophenone, it regenerates benzophenone on exposure to oxygen. In the case of benzil, it could lead to benzoic acid.

Acknowledgments

The authors thank the National Research Council of Canada for generous support and St. Francis Xavier University for help in the purchase of the densitometer.

Polymerization behavior of 2,6-dimethoxystyrene

W. Y. Lau and C. M. Burns
Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario
Received November 18, 1968

Free radical, cationic, and anionic initiators were investigated as possible agents for the polymerization of 2,6-dimethoxystyrene. Polymerization was observed in all three cases, with rapid cross-linking apparently occurring with the cationic catalyst. Attempts at copolymerization with styrene and with methyl methacrylate resulted in the formation of homopolymers of 2,6-dimethoxystyrene, in the cationic cases, and of methyl methacrylate in the anionic cases. Random copolymers were obtained in the anionic case with styrene and in the free radical case with both comonomers. Monomer reactivity ratios were calculated, and the polymerization behavior was interpreted in terms of the molecular structure of 2,6-dimethoxystyrene.

Canadian Journal of Chemistry, 47, 2057 (1969)

In an investigation into graft copolymerization using cationic catalysts, we recently reported (1) an improved synthesis of 2,6-dimethoxystyrene. Using organometallic reagents it was possible to prepare this styrene derivative in high purity under relatively mild conditions in two steps, rather than in seven steps using the synthesis of Shamshurin (2) which was difficult to reproduce (3).

The methoxy groups in 2,6-dimethoxystyrene are electron-donating substituents which have been shown to increase greatly the susceptibility of the phenyl ring of styrene to electrophilic attack, while the solubility characteristics of the poly(2,6-dimethoxystyrene) surprisingly remain almost identical to those of the unsubstituted polystyrene (1). In this paper we report on the polymerization and copolymerization of this practically new monomer, and on the effects of these methoxy substituents upon the reactivity of this monomer in the presence of free radical, cationic, and anionic catalysts.

Experimental

2,6-Dimethoxystyrene

The synthesis followed our previous method (1) in which commercial 2,6-dimethoxyphenyllithium (Alfa Inorganics) was allowed to react with *N*-methylformanilide to form 2,6-dimethoxybenzaldehyde. The aldehyde was converted to 2,6-dimethoxystyrene by a Wittig reaction (4). An improved yield (97%) of the aldehyde was attributed to greater purity of 2,6-dimethoxyphenyllithium when received. The purity of the monomer was checked by infrared spectroscopy and gas–liquid chromatography.

The comonomers, styrene and methyl methacrylate, were purified by caustic extraction and distillation at reduced pressure.

Free Radical Polymerization

Measured quantities of bulk monomer (or comonomers) and 2,2′-azobis(2-methylpropionitrile) were added to a polymerization tube of about 8 ml capacity. The monomer was degassed by freezing and thawing and then sealed under vacuum. The tube was heated to 60 ± 1° for a pre-estimated period of time to give a desired conversion (below 10% in copolymerization experiments). The polymer was then precipitated in methanol, filtered, and dried. Three times the polymer was redissolved in 2-butanone, precipitated in methanol, filtered, and dried under vacuum at 50°.

Cationic Polymerization

Under dry nitrogen a solvent mixture was made up from freshly distilled nitrobenzene and carbon tetrachloride in a 1:1 mole ratio. The freshly distilled monomers were kept over silica gel. The polymerization vessel was a 15 ml glass bottle which had been heated and flushed with dry nitrogen and fitted with a self-sealing serum cap. Calculated quantities of materials were transferred to the polymerization vessel with syringes. The reaction was initiated when a calculated quantity of anhydrous stannic chloride in the solvent mixture was injected into the vessel at 0°. Of the remaining mixture stannic chloride was 0.5 wt. % and the solvent mixture was 85 wt. %. The polymers formed were purified as mentioned before.

Anionic Polymerization

Tetrahydrofuran was refluxed overnight with lithium aluminium hydride and distilled before use as solvent at a concentration of 60 wt. % of the polymerization mixture. *n*-Butyllithium in hexane was the anionic initiator so that the resulting initiator concentration was 1.6% by wt. The temperature was 30°. Techniques similar to those mentioned for cationic polymerization were used.

In order to determine whether polymers of reasonably high molecular weights were being produced, intrinsic viscosities of the polymers were measured in toluene at 30° in a Cannon-Ubbelohde viscometer with a flow-time for pure solvent of 153.0 s. The values of the intrinsic viscosities ranged between 0.1 and 1.1 dl/g, with the lower values about 0.1 being obtained in the ionic cases, and the higher values in the free radical cases.

Ultraviolet absorption spectroscopy was used to analyze quantitatively the compositions of the copolymers formed. Spectra were determined in methylene chloride at room temperature using a Cary 14 recording spectrophotometer.

Results

Ultraviolet Absorption Spectroscopy

Profiles of the absorption spectra in the ultraviolet region for the monomers and polymers studied show that at 278 mμ poly(2,6-dimethoxystyrene) absorbs strongly while polystyrene and poly(methyl methacrylate) absorb negligibly. Therefore the absorbances at 278 mμ of the copolymers were concluded to be entirely due to the presence of 2,6-dimethoxystyrene units in the copolymers. The absorbance at 278 mμ for poly(2,6-dimethoxystyrene) was found to increase linearly with concentration up to 0.16 g/l, with a specific extinction coefficient of 3.88 l g^{-1} cm^{-1}. Thus the amount of 2,6-dimethoxystyrene present in the copolymer was determined readily. The amount of comonomer (styrene or methyl methacrylate) present in the copolymer could then be obtained by difference.

Homopolymerization

It was found that the 2,6-dimethoxystyrene could be homopolymerized by free radical, cationic, and anionic catalysts. Very rapid polymerization was observed with the cationic system. The cross-linked material which was obtained may have been a result of a considerable amount of cationic grafting (1) or of cationic reaction with the polymeric main chain (5). Cross-linking had also resulted when 2,5-dimethoxystyrene had been polymerized cationically (6).

Copolymerization

For the cases of free radical copolymerization of 2,6-dimethoxystyrene with styrene and methyl methacrylate and of anionic copolymerization with styrene, the mole fraction of the 2,6-dimethoxystyrene taken up into the copolymer was found to be a monotonically increasing function of the mole fraction of the 2,6-dimethoxystyrene in the mixture of comonomers (Fig. 1).

This behavior was not observed in the other cases of copolymerization attempted. In the case of anionic polymerization of 2,6-dimethoxystyrene with methyl methacrylate, only pure poly(methyl methacrylate) was produced. In the case of cationic copolymerization of 2,6-dimethoxystyrene with unsubstituted styrene, only pure poly(2,6-dimethoxystyrene) was produced.

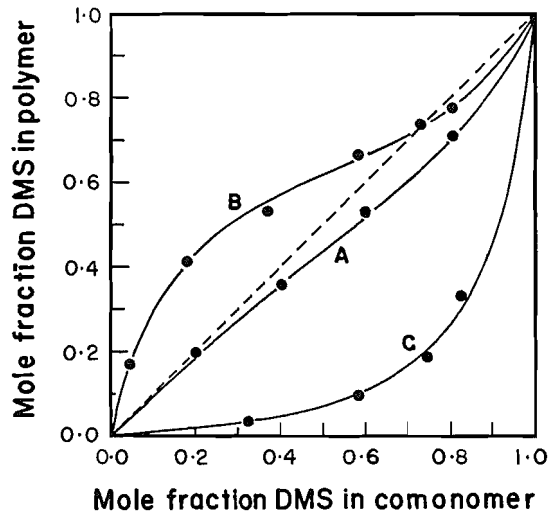

FIG. 1. Variation of copolymer composition with composition of comonomers: **A**, free radical copolymerization of 2,6-dimethoxystyrene (DMS) with styrene: **B**, free radical copolymerization of DMS with methyl methacrylate; **C**, anionic copolymerization of DMS with styrene.

Discussion

The presence of the two methoxy groups would be expected to increase the electron density of the vinyl group in styrene, so that it is noteworthy that 2,6-dimethoxystyrene can be homopolymerized by the anionic catalyst. The rapid polymerization and cross-linking in the cationic homopolymerization can be attributed to the increased electron density also, since it has been shown for *p*-methoxystyrene that the single methoxy substituent increases the reactivity of the phenyl ring to electrophilic attack one hundred times and the reactivity of the vinyl group four hundred times (7). The methoxy substituents in the 2- and 6-positions apparently do not sterically hinder the polymerization reaction although methyl substituents in the same positions had been observed to impede the polymerization (3).

In the cationic copolymerization of 2,6-dimethoxystyrene with styrene, the fact that only homopolymers of 2,6-dimethoxystyrene were formed indicates that the presence of the methoxy groups has made the vinyl group so electronegative that in the presence of cations it reacts preferentially to the exclusion of the styrene molecules. If cationic copolymerization had been attempted with 2,6-dimethoxystyrene and methyl methacrylate, homopolymers of 2,6-dimethoxystyrene would also be expected since methyl

TABLE I

Reactivity ratios and Q–e values of 2,6-dimethoxystyrene and copolymerization at 60°

Comonomers 1;2	r_1	r_2	Q	e
2,6-Dimethoxystyrene; styrene	0.55 ± 0.001	0.98 ± 0.004	1.9 ± 0.01	-1.6 ± 0.003
2,6-Dimethoxystyrene; methyl methacrylate	0.74 ± 0.04	0.14 ± 0.05	2.6 ± 0.7	-1.1 ± 0.1

methacrylate has an even more electropositive vinyl group than styrene.

The electropositive nature of the vinyl group of methyl methacrylate causes strong electrostatic attraction between it and anions, so that under anionic conditions methyl methacrylate is polymerized preferentially in mixtures with 2,6-dimethoxystyrene, in fact, to the complete exclusion of any 2,6-dimethoxystyrene. Copolymers of 2,6-dimethoxystyrene were formed anionically when styrene was used as the comonomer, but the electronegativity of the 2,6-dimethoxystyrene is so much greater that it is incorporated into the copolymer rather reluctantly and, at all relative concentrations of comonomers, the relative amount of 2,6-dimethoxystyrene in the copolymer is less than its relative amount in the comonomer (Fig. 1).

Copolymers of 2,6-dimethoxystyrene were obtained with both styrene and methyl methacrylate when a free radical catalyst was used. Computer techniques were used to show that the copolymerization data obtained in both the free radical and anionic cases were best described by the mechanism proposed by Mayo and Lewis (8), rather than the mechanisms of Wall (9) or Fontana and Kidder (10). At low conversions, the molar ratio of monomers being assimilated into the copolymer, m_1/m_2, is a function of the molar ratio of the monomers present, M_1/M_2, according to the following equation

$$\frac{m_1}{m_2} = \frac{r_1 \frac{M_1}{M_2} + 1}{1 + \frac{r_2 M_2}{M_1}}$$

r_1 ($= k_{11}/k_{12}$) and r_2 ($= k_{22}/k_{21}$) are called the monomer reactivity ratios.

The values of r_1 and r_2 were obtained after the equation was rearranged according to Fineman and Ross (11) and are given in Table I.

Since the reactivity ratios were all found to be less than one, all the radicals show a tendency to alternate, i.e. to add the other monomer. This tendency is strongest with the methyl methacrylate radical, apparently due to the large difference in its electronegativity with that of 2,6-dimethoxystyrene. The alternation tendency is much less pronounced in the styrene system.

Several schemes have been developed to assign to monomers characteristic parameters from which monomer reactivity ratios can be predicted (12). The Q–e scheme proposed by Alfrey and Price (13) is widely used. For the reaction of monomer j with radical i, the rate constant, k_{ij}, is considered in this scheme to be given by

$$k_{ij} = P_i Q_j \exp(- e_i e_j)$$

where P and Q refer to the resonance stabilization of radical and monomer, respectively, and e refers to the polar nature of the radical and monomer. The Q and e values for 2,6-dimethoxystyrene have been determined from the present copolymerization studies (Table I).

The standard deviations in the reactivity ratios determined in the styrene system (Table I) were much less than in the methyl methacrylate system so that the Q and e values determined from the styrene system are considered more reliable, and more likely to represent the monomer. Better agreement is obtained in the case of the Q values than in the case of the e values. A comparison of those Q and e values with those of other monomers (Table II) shows that the Q value for 2,6-dimethoxystyrene is remarkably large, indicating that the vinyl group of this monomer is considerably stabilized by resonance, while the e value for 2,6-dimethoxystyrene is quite negative, indicating that the vinyl group of this monomer has been made strongly electronegative by the electron-donating methoxy substituents in the 2- and 6-positions.

The small Q value of pentachlorostyrene has been attributed to the bulky substituents forcing the vinyl group out of coplanarity with the phenyl ring (15). A similar effect is believed to occur also with 2,6-dichlorostyrene as indicated by indirect evidence (16). The large Q value of 2,6-dimethoxystyrene indicates that the vinyl

Azaindoles. Part I. The syntheses of 5-aza- and 5,7-diazaindoles by the non-catalytic thermal indolization of 4-pyridyl- and 4-pyrimidylhydrazones respectively[1]

P. A. Crooks and B. Robinson
Department of Pharmacy, The University, Manchester 13, England

Received October 22, 1968

The thermal indolization of a series of 4-pyridyl- and 4-pyrimidylhydrazones has been investigated. Under these conditions, isobutyraldehyde and 2-methylbutyraldehyde 4-pyridylhydrazones afford only 5-aza-2,3-dimethylindole and 5-aza-2-ethyl-3-methylindole respectively, and both ethyl methyl ketone and isobutyraldehyde 4-pyrimidylhydrazones afford only 5,7-diaza-2,3-dimethylindole. Several attempts to effect a Chichibabin amination on 5-aza-2,3-dimethyl- and 5-aza-1,2,3-trimethylindole led only to the recovery of starting material.

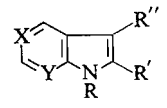
Canadian Journal of Chemistry, 47, 2061 (1969)

Several synthetic approaches to the 5-azaindole system have been developed (1), but that involving the acid-catalyzed Fischer indolization (2) of 4-pyridylhydrazones has either failed or only succeeded under much more drastic conditions than employed for the indolization of the corresponding phenylhydrazones (1, 2). These limitations with 4-pyridylhydrazones are caused by deactivation of the pyridine nucleus towards intramolecular electrophilic attack, one of the stages in the mechanism of the Fischer indole synthesis, both by the inductive effect of the hetero-nitrogen atom and by protonation of this atom in the acidic reaction media (2). Recently (3, 4) protonation of this nitrogen atom during such indolizations has been prevented by employing the non-catalytic thermal indolization technique (5), several 2-pyridylhydrazones (3, 4) and cyclohexanone 4-pyridylhydrazone (3) having been converted into the corresponding 7-azaindoles and 6-aza-1,2,3,4-tetrahydrocarbazole respectively by boiling in di- or triethylene glycol. We have now investigated the application of this technique to the indolization of further 4-pyridylhydrazones.

The introduction of another nitrogen atom into the aromatic ring of a pyridylhydrazone affords, amongst other possible compounds, 4-pyrimidylhydrazones, in which the second hetero-nitrogen atom further reduces the nucleophilicity of the aromatic ring. This, however, does not prevent their non-catalytic thermal indolization to 5,7-diazaindoles in the examples which have been investigated in the present studies. Although syntheses of the 5,7-diazaindole ring system (6–8) and of 5,7-diazaindole itself (7,8) have been published, these are the first reports of such syntheses using Fischer indolizations, an approach which offers a versatile preparation of 5,7-diazaindoles having alkyl or aryl substituents in the 2- and/or 3-position(s), since 4-hydrazinopyrimidine is readily available (9, see also the Experimental).

The 4-pyridylhydrazones (Table I) were prepared by addition of the appropriate carbonyl compound to an aqueous or aqueous ethanolic solution of 4-hydrazinopyridine hydrochloride (10). Attempted preparation of ethyl pyruvate 4-pyridylhydrazone by condensation of ethyl pyruvate and 4-hydrazinopyridine hydrochloride under these conditions afforded only pyruvic acid 4-pyridylhydrazone. The 4-pyrimidylhydrazones (Table II) were prepared by condensation of the appropriate carbonyl compound with 4-hydrazinopyrimidine (9) in methanolic solution.

Attempted indolization of pyruvic acid 4-pyridylhydrazone by boiling a solution of it in mono-, di-, or triethylene glycol was unsuccessful, as were the similar attempts to prepare 5-aza-2-methylindole (**1**, R = R″ = H, R′ = CH_3, X = N, Y = CH) from acetone 4-pyridylhydrazone.



1

These results are analogous to those obtained from the previous unsuccessful attempts (4) to thermally indolize pyruvic acid and acetone 2-pyridylhydrazones: however, 5-aza-3-methylindole (**1**, R = R′ = H, R″ = CH_3, X = N, Y = CH) is produced by boiling a solution of

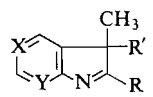
propionaldehyde 4-pyridylhydrazone in diethylene glycol.

Since both cyclohexanone phenylhydrazone and 4-pyridylhydrazone have been indolized (3) in high yields using non-catalytic thermal conditions, the first attempted thermal indolization of a 4-pyrimidylhydrazone was effected on that of cyclohexanone in boiling diethylene glycol, a reaction which afforded a 32% yield of 6,8-diaza-1,2,3,4-tetrahydrocarbazole (**1**, R = H, R′ + R″ = $(CH_2)_4$, X = N, Y = CH). Boiling solutions of ethyl methyl ketone 4-pyridyl- and 4-pyrimidylhydrazones in diethylene glycol afforded only 5-aza- and 5,7-diaza-2,3-dimethylindoles (**1**, R = H, R′ = R″ = CH_3, X = N, Y = CH, and X = Y = N) respectively. These indolizations occurred as expected (2) exclusively on the methylene group of the ethyl group and not on the methyl group of the ketonic moiety.

In an attempt to extend this synthesis to the preparation of 5-aza- and 5,7-diaza-3*H*-indoles, solutions of isobutyraldehyde 4-pyridyl- and 4-pyrimidylhydrazones in monoethylene glycol were boiled, but no indolization of these compounds under these conditions could be detected, whereas in boiling diethylene glycol the hydrazones afforded only 5-aza- and 5,7-diaza-2,3-dimethylindoles (**1**, R = H, R′ = R″ = CH_3, X = N, Y = CH, and X = Y = N) respectively. Presumably, both these indoles are formed by a thermally-induced (11) Plancher rearrangement (12) of the initially-formed 5-aza- and 5,7-diaza-3,3-dimethyl-3*H*-indoles (**2**, R = H, R′ = CH_3, X = N, Y = CH, and X = Y = N) respectively. To eliminate the possibility that



2

methyl group migration had occurred in the isobutyraldehyde 4-pyridyl- and 4-pyrimidylhydrazones (**3**, X = CH and N respectively) during their synthesis, the proton magnetic resonance (p.m.r.) spectra of these compounds were ex-

3

amined. Both spectra showed 6-proton doublets (J = 7 and 8 c.p.s. respectively) centered at τ 8.80 and 8.87 respectively (the two equivalent methyl groups on C_{10}), a 1-proton multiplet between τ 6.90–7.90 and τ 6.97–7.82 respectively [C_{10}—H], and a 1-proton doublet (J = 6 and 5 c.p.s. respectively) centered at τ 2.84 and τ 2.77 respectively [C_9—H]. In each case signals attributable to the N—H and aromatic protons were also obtained. In both spectra, after irradiation of the C_{10}—H one-proton multiplet, the 1- and 6-proton doublets collapsed to singlets. Boiling a solution of methyl isopropyl ketone 4-pyridylhydrazone in monoethylene glycol did, however, afford 5-aza-2,3,3-trimethyl-3*H*-indole (**2**, R = R′ = CH_3, X = N, Y = CH) in which a Plancher rearrangement to an indole is impossible.

It has been claimed (4), without the evidence of physical data, that the product obtained by thermal indolization of isobutyraldehyde 2-pyridylhydrazone in boiling diethylene glycol is 7-aza-3,3-dimethyl-3*H*-indole (**2**, R = H, R′ = CH_3, X = CH, Y = N); however, this product has an almost identical melting point to that of 7-aza-2,3-dimethylindole (**1**, R = H, R′ = R″ = CH_3, X = CH, Y = N), prepared by thermal indolization of ethyl methyl ketone 2-pyridylhydrazone in boiling diethylene glycol (4). In view of this and the above mentioned rearrangements it seems probable that the compound thought (4) to be 7-aza-3,3-dimethyl-3*H*-indole is, in fact, 7-aza-2,3-dimethylindole, a possibility which has now (13) been verified as correct.

2-Methylbutyraldehyde 4-pyridylhydrazone upon indolization in boiling diethylene glycol affords only 5-aza-2-ethyl-3-methylindole (**1**, R = H, R′ = C_2H_5, R″ = CH_3, X = N, Y = CH). In this case the intermediate 5-aza-3-ethyl-3-methyl-3*H*-indole (**2**, R = H, R′ = C_2H_5, X = N, Y = CH) has also undergone thermally-induced Plancher rearrangement under the indolization conditions. The exclusive formation of **1** (R = H, R′ = C_2H_5, R″ = CH_3, X = N, Y = CH) is in accord with the observation (14) that an ethyl group has a higher migratory aptitude than a methyl group and migrates preferentially to it in a Plancher rearrangement.

It has been suggested (15) that the "essential" molecular features of a purine antimetabolite are contained in a 1-unsubstituted 5-azaindole having a 4-substituent which is capable of forming a hydrogen bond, by hydrogen donation, with a nitrogen p-electron pair of a pyrimidine nucleus. Attempts have been made to synthesize a compound having these requirements by effecting a Chichibabin reaction (16) on **1** (R = H, R′ = R″ = CH_3, X = N, Y = CH), which, by analogy with this reaction on isoquinoline which affords (17) exclusively 1-amino-isoquinoline, would be expected to afford 4-amino-5-aza-2,3-dimethylindole. However, attempted amination of 5-aza-2,3-dimethylindole with sodamide in xylene and in *N*,*N*-dimethylaniline under various conditions failed, only starting material being recoverable from such reactions [cf. the failure to aminate 7-azaindole (18)]. It appeared likely that the failure of this reaction could be caused by the heterogeneous nature of these reaction mixtures owing to the insolubility of the sodium salt of the indole which is formed and precipitated out and/or by the presence of the negative charge on the indolic nucleus of this salt which would prevent attack on the nucleus by amide anion. This salt formation was overcome by 1-methylation of **1** (R = H, R′ + R″ = CH_3, X = N, Y = CH), with sodamide and methyl iodide (19) to afford **1** (R = R′ = R″ = CH_3, X = N, Y = CH), but attempted amination of this *N*-methylated derivative with sodamide in boiling decalin or xylene or with barium amide in liquid ammonia (20) again failed and led only to the recovery of starting material.

Experimental

Melting points were determined on a Köfler hot-stage apparatus and are uncorrected. Infrared (i.r.) spectra were recorded on a Perkin–Elmer 237 spectrophotometer, ultraviolet (u.v.) spectra were measured on a Perkin–Elmer 137 spectrophotometer, and p.m.r. spectra were recorded on a Varian A 60 spectrometer in deuteriochloroform solution (unless otherwise stated) using tetramethylsilane as internal standard. Solutions were dried over anhydrous magnesium sulfate and, unless otherwise stated, solvents were removed on a steam-bath under reduced pressure (water pump).

4-Pyridylhydrazones

4-Hydrazinopyridine hydrochloride (4.0 g) (10) was dissolved in water (10 ml) and the appropriate aldehyde or ketone (4 ml) was added. Ninety-five percent ethanol

(8 ml) was added, if required, to effect a homogeneous reaction mixture. After standing at room temperature for 4 h, the solution was basified with sodium hydroxide solution and the liberated oil extracted with ether (2 × 20 ml). The combined ethereal extracts were washed with water (2 × 20 ml), dried, and the solvent removed to afford the 4-pyridylhydrazones as oils which completely crystallized and which were recrystallized (except propionaldehyde and 2-methylbutyraldehyde 4-pyridylhydrazones) (Table I).

In the case of acetone 4-pyridylhydrazone a precipitate, and not an oil, was formed upon basification. This was collected, washed with water until the washings were neutral, dried over P_2O_5 *in vacuo*, and recrystallized (Table I).

4-Hydrazinopyridine hydrochloride was reacted with pyruvic acid and ethyl pyruvate as above, but after standing the reaction mixture at room temperature for 4 h, the ethanol was removed and the solid which separated was collected, washed with water, dried over P_2O_5 *in vacuo*, and recrystallized (Table I).

4-Hydrazinopyrimidine

The previously published (9, 21) method for the preparation of 4-hydrazinopyrimidine from 4-hydroxypyrimidine (22) was modified as follows to afford an increase in the yield of product.

A mixture of phosphoryl chloride (50 ml) and 4-hydroxypyrimidine (22) (14 g) was boiled under reflux on an oil-bath for 40 min. The cooled reaction mixture was then shaken with sodium-dried petroleum (6 × 40 ml, b.p. 40–60°) and to the resulting brown gum was carefully added dry methanol (120 ml) dropwise. After the vigorous reaction had ceased the resulting yellow-brown solution was poured into a methanolic solution of sodium methoxide (20 g of sodium in 250 ml of dry methanol) and the resulting suspension was boiled under reflux for 30 min. After cooling, carbon dioxide was passed through the suspension until it was saturated (3 h), the mixture was filtered, the precipitate was washed with dry methanol (2 × 20 ml), and the total methanolic filtrate was evaporated to dryness on a rotating evaporator at 25°. To the residue was added dry methanol (15 ml) and the methanol was again completely evaporated at 70°, this procedure being repeated one further time. The total methanolic distillate was then evaporated at room temperature on a rotating evaporator to a volume of approximately 30 ml, hydrazine hydrate (5 ml) was added, the mixture boiled under reflux for 2 h, a further quantity of hydrazine hydrate (5 ml) was added and the boiling under reflux continued a further 2 h. The solution was left standing at room temperature overnight and the solvent evaporated to afford 4-hydrazinopyrimidine as a pale-yellow crystalline solid (6.90 g, 41%) [lit. yield 15% (9, 21)] which was used to prepare the 4-pyrimidylhydrazones below without recrystallization. A small sample was recrystallized from methanol–benzene to afford pale-yellow prisms, m.p. 133–134° (decomp.) [lit. m.p. 132–134° (9)].

4-Pyrimidylhydrazones

4-Hydrazinopyrimidine (1.6 g) was dissolved in dry methanol (10 ml) and the ketone or aldehyde (3 ml) was added. An exothermic reaction occurred, after which the solutions were left standing overnight at room temperature.

Evaporation of the solvent then left the 4-pyrimidylhydrazones (Table II) as crystalline solids which were purified by recrystallization.

5-Aza-3-methylindole

A solution of propionaldehyde 4-pyridylhydrazone (3.0 g) in diethylene glycol (30 ml) was boiled under reflux for 10 h, then cooled to room temperature, and poured into cold water (250 ml). The liberated oil was extracted with chloroform (2 × 200 ml) and the combined chloroform extracts were washed with water (2 × 300 ml), dried, and the solvent removed to afford a tan-colored solid which after recrystallization from ethanol–ether afforded light-tan prisms (1.14 g, 34.5%), m.p. 144–145°.

Anal. Calcd. for $C_8H_8N_2$: C, 72.7; H, 6.1. Found: C, 72.5; H, 6.2.

λ_{max}(EtOH) 222 mμ, log ε 4.53; 275 mμ, log ε 3.39. λ_{Infl}(EtOH) 283 mμ, log ε 3.28. λ_{min}(EtOH) 245 mμ, log ε 3.04. λ_{max}(EtOH–HCl) 227.5 mμ, log ε 4.57; 284 mμ, log ε 3.34. λ_{Infl}(EtOH–HCl) 312 mμ, log ε 3.04. λ_{min} (EtOH–HCl) 246 mμ, log ε 2.92. These u.v. spectral data are similar to those reported (1) for 5-azaindole, the dissimilarities probably being caused by the bathochromic effect of the 3-methyl substituent. The p.m.r spectrum showed a 3-proton singlet at τ 7.83 [C_3—CH_3], a 1-proton singlet at τ 2.96 [C_2—H] (24), a 1-proton doublet (J = 5 c.p.s.) (ortho coupling) centered at τ 2.80 with each peak split into another doublet (J = 1.5 c.p.s.) (para coupling) [C_7—H], a 1-proton doublet (J = 5 c.p.s.) (ortho coupling) centered at τ 1.90 [C_6—H], a 1-proton doublet (J = 1.5 c.p.s.) (para coupling) centered at τ 1.25 [C_4 —H], and a broad 1-proton singlet at τ −1.36 which disappeared upon addition of D_2O (N—H).

5-Aza-2,3-dimethylindole

Ethyl methyl ketone 4-pyridylhydrazone (3.0 g) was boiled in diethylene glycol solution (30 ml) for 15 h, the reaction mixture cooled, and then poured into cold water. The resulting light-brown precipitate was collected, washed well with water followed by a little ether, and recrystallized from ethanol to afford light-tan prisms (1.41 g, 52.5%), m.p. 214–215°.

Anal. Calcd. for $C_9H_{10}N_2$: C, 73.5; H, 6.9. Found: C, 74.15; H, 6.85.

λ_{max}(EtOH) 226 mμ, log ε 4.54; 278 mμ, log ε 3.67. λ_{Infl}(EtOH) 286 mμ, log ε 3.54. λ_{min}(EtOH) 250 mμ, log ε 3.17. λ_{max}(EtOH–HCl) 231.5 mμ, log ε 4.62; 290 mμ, log ε 3.53. λ_{Infl}(EtOH–HCl) 314 mμ, log ε 3.17. λ_{min} (EtOH–HCl) 250 mμ, log ε 3.02. The p.m.r. spectrum included two 3-proton singlets at τ 7.80 and τ 7.68 [C_3—CH_3 and C_2—CH_3 respectively] (the high-field singlet is attributed to the C_3—CH_3 protons by comparison with the τ value of the singlet caused by the protons of this group in the spectrum of 5-aza-3-methylindole quoted above), a 1-proton doublet (J = 5.5 c.p.s.) (ortho coupling) centered at τ 2.76 with each peak split into further doublets (J = 1.5 c.p.s.) (para coupling) [C_7—H], a 1-proton doublet (J = 5.5 c.p.s.) (ortho coupling) centered at τ 1.89 [C_6 —H], a 1-proton doublet (J = 1.5 c.p.s.) (para coupling) centered at τ 1.32 [C_4 —H], and a 1-proton broad singlet between τ −1.33 and τ −0.93 which disappeared upon addition of D_2O (N—H).

For personal use only.

When this reaction was repeated using isobutyraldehyde 4-pyridylhydrazone in place of ethyl methyl ketone 4-pyridylhydrazone, 5-aza-2,3-dimethylindole (identical m.p., mixture m.p., u.v., i.r., and p.m.r. spectra with that prepared above) was produced in 14.5% yield.

5-Aza-2,3,3-trimethyl-3H-indole

A solution of methyl isopropyl ketone 4-pyridylhydrazone (3.0 g) in diethylene glycol (30 ml) was boiled under reflux under an atmosphere of nitrogen for 6 h, and the reaction mixture worked up as described above for the preparation of 5-aza-3-methylindole. Evaporation of the chloroform extract afforded a dark-brown gum from which no recognizable product could be isolated.

The reaction was repeated in monoethylene glycol and after boiling for 6 h, the reaction mixture was cooled, poured into cold water (250 ml), and the aqueous suspension extracted with ether (3 × 150 ml). The combined ether extracts were washed with water (2 × 250 ml), dried, and the solvent removed to afford a brown oil (1.21 g) which could not be induced to crystallize and which had an u.v. spectrum (in EtOH) almost identical to that of the starting material. The aqueous phase remaining from the above ether extraction was extracted with chloroform (2 × 100 ml), the combined chloroform extracts washed with water (2 × 100 ml), dried, and the chloroform removed to afford a crystalline residue which upon sublimation [60–80° (bath temperature) at 74 mm] gave 5-aza-2,3,3-trimethyl-3*H*-indole as colorless needles (0.29 g, 10.5%), m.p. 86–87° [reported m.p. 81–81.5° (25)].

λ_{max}(EtOH) 243.5 mμ, log ε 3.56. λ_{infl}(EtOH) 299 mμ, log ε 2.78. λ_{min}(EtOH) 224 mμ, log ε 3.48. λ_{max}(EtOH–HCl) 277.5 mμ, log ε 3.85. λ_{infl}(EtOH–HCl) 308 mμ, log ε 2.94. λ_{min}(EtOH–HCl) 240 mμ, log ε 3.05. λ_{max} (conc. HCl) 256 mμ, log ε 3.84. λ_{infl}(conc. HCl) 313 mμ, log ε 2.43. λ_{min}(conc. HCl) 227 mμ, log ε 3.64. The p.m.r. spectrum showed a 6-proton singlet at τ 8.68 [C_3 $(CH_3)_2$], a 3-proton singlet at τ 7.75 [C_2 CH_3], a 1-proton doublet (J = 5 c.p.s.) (ortho coupling) centered at τ 2.75 with each peak split into further doublets (J = 1.5 c.p.s.) (para coupling) [C_7 —H], a 1-proton doublet (J = 1.5 c.p.s.) (para coupling) centered at τ 1.73 [C_4 —H], and a 1-proton doublet (J = 5 c.p.s.) (ortho coupling) centered at τ 1.70 [C_6 —H].

5-Aza-2-ethyl-3-methylindole

2-Methylbutyraldehyde 4-pyridylhydrazone (3.0 g) was indolized as described above for propionaldehyde 4-pyridylhydrazone, the boiling in diethylene glycol being continued for 16 h. The brown oil obtained by evaporation of the chloroform extract was subjected to column chromatography on alumina (grade 'H'). A light-brown band was eluted with ether, evaporation of the eluate yielding a light-brown oil which could not be crystallized and which showed no significant u.v. absorption. Elution with chloroform/ether (1:5 vol:vol) and then with chloroform, followed by evaporation of the eluates, afforded in each case a crystalline residue which after recrystallization from ethanol–ether gave light-tan prisms (0.54 g, 20%), m.p. 155–156°.

Anal. Calcd. for $C_{10}H_{12}N_2$: C, 75.0; H, 7.55. Found: C, 75.0; H, 7.25.

λ_{max}(EtOH) 227.5 mμ, log ε 4.57; 278 mμ, log ε 3.70. λ_{infl}(EtOH) 286 mμ, log ε 3.65. λ_{min}(EtOH) 250 mμ, log ε 3.51. λ_{max}(EtOH–HCl) 232 mμ, log ε 4.65; 289 mμ, log ε 3.65. λ_{infl}(EtOH–HCl) 316 mμ, log ε 3.28. λ_{min} (EtOH–HCl) 250 mμ, log ε 3.29 (these u.v. spectral data are almost identical with those recorded for 5-aza-2,3-dimethylindole recorded above). The p.m.r. spectrum (recorded in hexadeuteriodimethylsulfoxide) showed a 3-proton triplet (J = 7 c.p.s.) and a 2-proton quartet (J = 7 c.p.s.) centered at τ 8.75 and τ 7.26 respectively [C_2 C_2H_5], a 3-proton singlet at τ 7.78 [C_3 CH_3] [cf. the value of τ 7.83 and τ 7.80 for the protons of the C_3 CH_3 groups in 5-aza-3-methylindole and 5-aza-2,3-dimethylindole respectively], a 1-proton doublet (J = 5.1 c.p.s.) (ortho coupling) centered at τ 2.75 with each peak split into a further doublet (J = 1.5 c.p.s.) (para coupling) [C_7 —H], a 1-proton doublet (J = 5.1 c.p.s.) (ortho coupling) centered at τ 1.90 [C_6 —H], a 1-proton doublet (J = 1.5 c.p.s.) (para coupling) centered at τ 1.30 [C_4 —H], and a broad singlet between τ −1.40 and τ −0.92 which disappeared upon addition of D_2O (N—H).

The mother liquors remaining from the recrystallization of the 5-aza-2-ethyl-3-methylindole were evaporated and the p.m.r. spectrum of the residue was recorded (in hexadeuteriodimethylsulfoxide) and showed no trace of a singlet signal at ≏ τ 7.7, indicating the absence of a 2-methyl substituted 5-azaindole nucleus, since the C_2 CH_3 protons in 5-aza-2,3-dimethylindole give rise to a singlet at τ 7.68.

6,8-Diaza-1,2,3,4-tetrahydrocarbazole

Cyclohexanone 4-pyrimidylhydrazone (3.0 g) was dissolved in diethylene glycol (30 ml), the solution boiled under reflux for 5 h, and then worked up as described above for the preparation of 5-aza-3-methylindole. Evaporation of the chloroform extract afforded a light-brown oil which crystallized. Recrystallization from chloroform–ether afforded light-tan prisms (0.87 g, 32%), m.p. 233–235°.

Anal. Calcd. for $C_{10}H_{11}N_3$: C, 69.4; H, 6.4. Found: C, 69.2; H, 6.45.

λ_{max}(EtOH) 232.5 mμ, log ε 4.50; 274–275 mμ, log ε 3.38; 305 mμ, log ε 3.35. λ_{min}(EtOH) 251 mμ, log ε 3.24; 290 mμ, log ε 3.33. λ_{max}(EtOH–HCl) 236–237 mμ, log ε 4.47; 292–293 mμ, log ε 3.44. λ_{infl}(EtOH–HCl) 325 mμ, log ε 3.03. λ_{min}(EtOH–HCl) 258 mμ, log ε 3.23. λ_{max}(conc. HCl) 241.5 mμ, log ε 4.50; 299.5 mμ, log ε 3.73. λ_{infl}(conc. HCl) 320–330 mμ, log ε 3.50. λ_{min}(conc. HCl) 275 mμ, log ε 3.55. The p.m.r. spectrum (recorded in hexadeuteriodimethylsulfoxide) showed two 4-proton multiplets between τ 7.93 and τ 8.46 [C_2 H_2 and C_3 H_2] and τ 7.13 and τ 7.58 [C_1 H_2 and C_4 H_2], 1-proton singlets at τ 1.37 and τ 1.25 [C_5 H and C_7 H], and a 1-proton broad singlet at τ −1.66 which disappeared upon addition of D_2O (N—H).

5,7-Diaza-2,3-dimethylindole

Ethyl methyl ketone 4-pyrimidylhydrazone (1.60 g) was dissolved in monoethylene glycol (25 ml) and the solution was boiled under reflux for 12 h. After working up as described above for the preparation of 6,8-diaza-1,2,3,4-tetrahydrocarbazole, a brown oil was obtained but all attempts to obtain a crystalline or recognizable product from this failed.

The above procedure was repeated using diethylene glycol instead of monoethylene glycol and the brown oil obtained was subjected to column chromatography on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

alumina (grade 'H') using chloroform as eluant. A brown band was initially eluted which upon removal of the solvent afforded a brown gum which could not be induced to crystallize and which had no significant u.v. absorption. A deep-yellow band was then eluted, removal of the solvent from which affording a pale-yellow crystalline solid (0.15 g, 10.5%) which after recrystallization from chloroform–ether and sublimation [140–160° (bath temperature) at 0.4 mm] yielded colorless prisms, m.p. 172–173°.

Anal. Calcd. for $C_8H_9N_3$: C, 65.3; H, 6.15. Found: C, 64.55; H, 6.0.

λ_{max}(EtOH) 231.5 mμ, log ε 4.39; 274–276 mμ, log ε 3.28; 307–308 mμ, log ε 3.26. λ_{min}(EtOH) 249 mμ, log ε 3.16; 290 mμ, log ε 3.24. λ_{max}(EtOH–HCl) 235 mμ, log ε 4.38; 293 mμ, log ε 3.30. λ_{infl}(EtOH–HCl) 323 mμ, log ε 3.15. λ_{infl}(EtOH–HCl) 323 mμ, log ε 3.15. λ_{min}(EtOH–HCl) 259 mμ, log ε 3.16. λ_{max}(conc. HCl) 241 mμ, log ε 4.38; 296 mμ, log ε 3.50. λ_{infl}(conc. HCl) 320–331 mμ, log ε 3.22. λ_{min}(conc. HCl) 275 mμ, log ε 3.28. The p.m.r. spectrum showed two 3-proton singlets at τ 7.73 [C_3CH_3] and τ 7.53 [C_2CH_3], a 2-proton singlet at τ 1.23 [C_4H and C_6H] and a 1-proton broad singlet at τ −1.93 which disappeared upon addition of D_2O (N—H).

The u.v. spectra reported above for 6,8-diaza-1,2,3,4-tetrahydrocarbazole and 5,7-diaza-2,3-dimethylindole are, as would be expected, closely similar to each other but bear no resemblance to the spectrum previously reported (8) for 5,7-diazaindole (i.e. λ_{max}(pH 6.8) 271 mμ, log ε 3.60. λ_{max}(HCl) 225 mμ, log ε 4.44; 265 mμ, log ε 3.49; 299 mμ, log ε 3.18. λ_{max}(NaOH) 273 mμ, log ε 3.59), although the spectrum of 5,7-diazaindole in hydrochloric acid solution as previously reported (8) and quoted above is closely similar to those of the two 5,7-diazaindoles presently reported in ethanolic solution. Since the structures of these two 5,7-diazaindoles are definitely established by their mode of synthesis and from their p.m.r. spectra, it appears that the solvents quoted in the published (8) u.v. spectrum of 5,7-diazaindole are erroneous.

Isobutyraldehyde 4-pyrimidylhydrazone (1.6 g) was indolized in boiling diethylene glycol by a procedure analogous to that described above for the indolization of ethyl methyl ketone 4-pyrimidylhydrazone. The column was initially eluted with ether–chloroform (1:1 vol:vol) until the eluate was colorless and a brown band was subsequently eluted with chloroform. Both these eluates upon evaporation of the solvents afforded crystalline residues (total 0.23 g, 16%) which after recrystallization from chloroform–ether and sublimation [140–160° (bath temperature) at 0.4 mm] gave colorless prisms which were identical (m.p., mixture m.p., and i.r., u.v., and p.m.r. spectra) to 5,7-diaza-2,3-dimethylindole described above.

Attempted Aminations of 5-Aza-2,3-dimethylindole

After boiling mixtures of 5-aza-2,3-dimethylindole (0.50, 0.30, and 0.30 g respectively) and sodamide (0.28, 0.20, and 0.80 g respectively) in dry xylene (6 ml) for 5 h, and *N,N*-dimethylaniline (6 ml) for 1 h and 5 h respectively, the only product which could be isolated from the reaction mixtures was unchanged 5-aza-2,3-dimethylindole (0.41, 0.12, and 0.17 g respectively).

5-Aza-1,2,3-trimethylindole

To a solution of sodamide in liquid ammonia (prepared from 8.0 g of sodium in 150 ml of liquid ammonia) was added 5-aza-2,3-dimethylindole (10 g). After stirring for 1.5 h, methyl iodide (20 ml) was added dropwise with stirring over 30 min, the stirring continued for 2.5 h, the ammonia and unreacted methyl iodide removed (steam-bath), and the residue shaken with water (150 ml).

The aqueous solution was basified with sodium hydroxide solution, the precipitate extracted with chloroform (3 × 200 ml), the combined extracts washed with water (2 × 200 ml), dried, and the solvent evaporated to afford a brown oil which was distilled (b.p. 160–164° at 1.5 mm) to give a pale-yellow oil which soon completely crystallized. Recrystallization afforded 5-aza-1,2,3-trimethylindole (7.20 g, 68%) as cream-colored prisms, m.p. 69–71°.

Anal. Calcd. for $C_{10}H_{12}N_2$: C, 75.0; H, 7.5. Found: C, 75.0; H, 7.85.

Attempted Aminations of 5-Aza-1,2,3-trimethylindole

Mixtures of 5-aza-1,2,3-trimethylindole (0.75 g) with sodamide (0.5 and 1.0 g respectively) were boiled in dry decalin (15 ml) for 1.5 h and dry xylene for 4 h respectively, and a mixture of 5-aza-1,2,3-trimethylindole (1.9 g) and barium nitrate (0.90 g) in a solution of barium amide in ammonia [prepared from barium (2.1 g), liquid ammonia (50 ml), and a trace of ignited barium oxide] was stirred for 24 h. The only product which could be isolated from all three reactions was 5-aza-1,2,3-trimethylindole (0.50, 0.46, and 1.62 g respectively).

Configuration of echinulin. II.[1] Optical rotatory dispersion of echinulin, hydroechinulin, and the stereoisomeric 3-methyl-6(indolyl-3-methyl)-piperazine-2,5-diones[2,3]

R. NAKASHIMA[4] AND G. P. SLATER

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

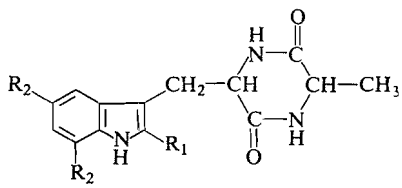
Received November 29, 1968

The optical rotatory dispersion spectra of echinulin and hydroechinulin have been compared with the spectra of the 4 stereoisomers of *cyclo*-alanyltryptophan. The results indicate appreciable differences in the spectra of the *cis*- and *trans*-piperazinediones and that echinulin has the *cyclo*-L-alanyl-L-tryptophan configuration.

Canadian Journal of Chemistry, 47, 2069 (1969)

Echinulin (**1***a*) is a white crystalline compound which was first isolated from a culture of *Aspergillus echinulatus* (Delacr) Thom & Church (1). The structure (**1***a*) was established by a series of degradations and partial synthesis (2) and is supported by nuclear magnetic resonance (n.m.r.) (3) and biochemical (4) studies.

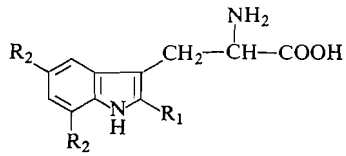
Acid hydrolysis (5) of hexahydroechinulin (hydroechinulin) (**1***b*) gave L-alanine and the amino acid hexahydroechinin (hydroechinin) (**2***b*). Echinulin (**1***a*) may be regarded then as a piperazinedione formed by the condensation of L-alanine and the amino acid echinin (2′-(1,1-dimethylprop-2-enyl)-5′,7′-di-(3-methylbut-2-enyl)-tryptophan) (**2***a*) of unknown configuration.



1

(*a*) $R_1 = -C(CH_3)_2-CH=CH_2$;
$R_2 = -CH_2-CH=C(CH_3)_2$

It has been found (6) that the absolute configuration of amino acids is indicated by their optical rotatory dispersion (o.r.d.) between 200 and 225 mμ. The configuration of echinin (**2***a*) could presumably be determined in this way also.



2

(*b*) $R_1 = -C(CH_3)_2-CH_2CH_3$;
$R_2 = -CH_2-CH_2-CH(CH_3)_2$

However, echinin (**2***a*) could not be obtained (5) by acid hydrolysis of echinulin (**1***a*) although hydroechinulin (**1***b*) gave hydroechinin (**2***b*) under the same conditions. The acid hydrolysis of hydroechinulin was previously used in this laboratory in connection with biosynthetic studies (7) but did not give a pure product. In view of this, and the observation (8) that the configuration of a piperazinedione can be determined by o.r.d., it was decided to compare the o.r.d. spectra of echinulin and the model *cyclo*-alanyltryptophans (**1**, $R_1 = R_2 = H$).

The piperazinediones were prepared by the cyclization (9) of alanyltryptophan or tryptophylalanine as shown in Fig. 1. In practice it was found more convenient to use the latter compound, as the synthesis of benzyloxycarbonyltryptophan presented less difficulty than the synthesis of tryptophan benzyl ester. Our investigations showed that the intermediate protected dipeptides obtained by the carbodiimide method (10) were identical in m.p. and specific rotation with the corresponding compounds prepared by the azide method (11). The various intermediates were obtained in good yield but since the carbodiimide method requires fewer steps than the azide method, the preferred synthesis of *cyclo*-alanyltryptophan is that shown in Fig. 1, route A.

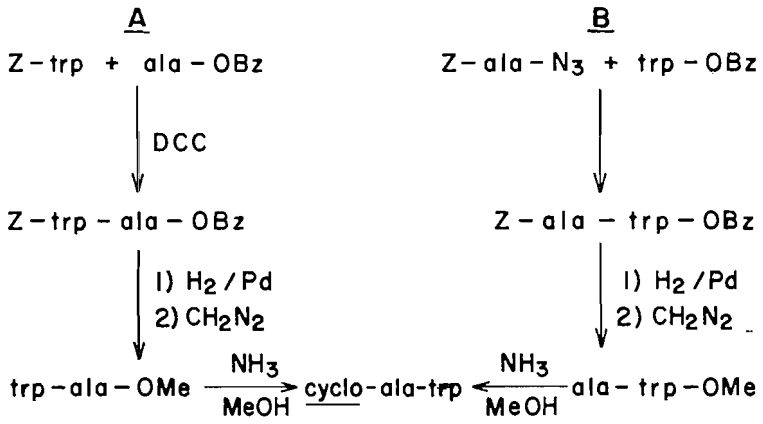

FIG. 1. Synthesis of *cyclo*-alanyltryptophan. Z = benzyloxycarbonyl, DCC = *N,N'*-dicyclohexylcarbodiimide.

Since this work was completed, two methods of preparing sterically pure piperazinediones have been reported (12, 13). A number of piperazinediones synthesized by Fischer's method (9) were found (13) to contain varying amounts of racemic material. However, thin-layer chromatography (t.l.c.) (13) of the piperazinediones used in the present work did not indicate racemization. The racemization may have been avoided by using shorter reaction times (5 h) than those (1–5 days) used by Nitecki *et al.* (13).

In a preliminary communication (14) the o.r.d. spectra of echinulin in chloroform and hydroechinulin in ethanol were compared with the o.r.d. spectra of *cyclo*-L-alanyl-L-tryptophan and *cyclo*-L-alanyl-D-tryptophan in diglyme–water (4:1) from 700–300 mμ. The similarity of the curves for *cyclo*-L-alanyl-D-tryptophan, echinulin, and hydroechinulin prompted the suggestion that the tryptophan moiety in echinulin has the D-configuration. The spectra of these compounds and the other stereoisomeric piperazinediones, *cyclo*-D-alanyl-D-tryptophan, and *cyclo*-D-alanyl-L-tryptophan, in ethanol are presented in Figs. 2–5. In the 650–350 mμ region these compounds possess plain dispersion curves as previously described (14). Below 350 mμ the spectra are more complex and more valuable in determining configuration, and only spectra covering this region have been reproduced. The spectra of the piperazinediones (Figs. 2–5) are divided into two parts (200–250 mμ and 230–320 mμ) with the ordinates in the ratio of 10:1. This method of presentation has been used because of the large differences in the molecular rotations and

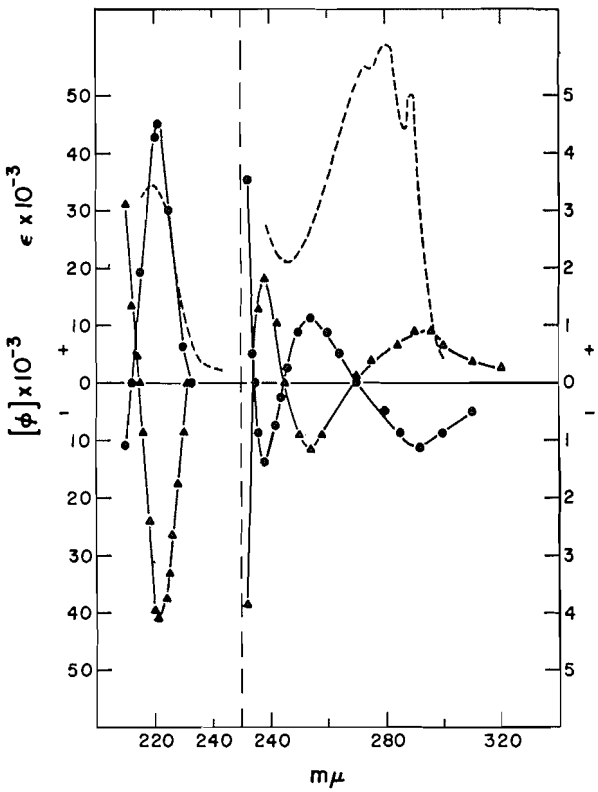

FIG. 2. Optical rotatory dispersion spectra of *cyclo*-L-alanyl-L-tryptophan (▲) and *cyclo*-D-alanyl-D-tryptophan (●) in ethanol. Ultraviolet spectrum in ethanol (– – –).

ultraviolet (u.v.) absorptions in these two regions. The spectra of echinulin (Fig. 4) and hydroechinulin (Fig. 5) have likewise been presented in two parts (200–280 mμ and 230–320 mμ)

which allow for comparison with the spectra of the piperazinediones.

The o.r.d. spectra of the piperazinediones, echinulin, and hydroechinulin, show a number of differences in the 350–230 mμ region (cf. Figs. 2–5). The absence of a complex Cotton effect at 230–320 mμ in the spectra of the *trans*-piperazinediones may be due to the extrema near 246 mμ (Fig. 3) which mask the weak Cotton effects shown by the *cis*-piperazinediones (Fig. 2) in this region (the rotations of the *trans* compounds are almost three times the rotations of the *cis* compounds at these wavelengths). Echinulin (Fig. 4) and hydroechinulin (Fig. 5) also do not possess complex Cotton effects at 300–230 mμ but have instead a rather broad Cotton effect. The rotations of echinulin, hydroechinulin, and the *cis*-alanyltryptophans are of similar magnitude and the difference in the complexity of the spectra may be related to the steric effects of the alkyl substituents of echinulin and hydroechinulin.

Proton magnetic resonance (p.m.r.) studies (15) indicate that the preferred conformation of *cyclo*-alanylphenylalanine is such that the benzene and piperazinedione rings face each other. A similar folding would be expected of the *cyclo*-alanyltryptophans. Construction of models (Corey–Pauling–Koltun) (16) indicates that in the *cis* compounds, the indole nucleus can lie over the piperazinedione ring so that a hydrogen atom of the alanine methyl group is close to the mid-point of the bond common to the five- and six-membered rings (a model of *cis*-alanylphenylalanine shows that the corresponding hydrogen atom is near the center of the benzene ring). A model of echinulin in the folded form is very difficult to construct because of interference from the alkyl substituent in the α-position of the indole nucleus. The strain is not affected by placing the alanine methyl group in the *trans* position but is relieved by swinging the indole nucleus away from the

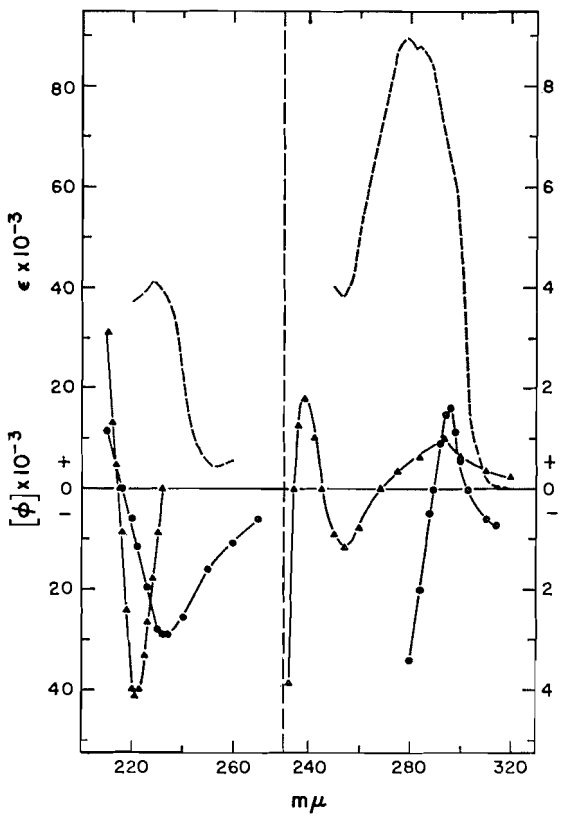

FIG. 4. Optical rotatory dispersion spectra of echinulin (●) and *cyclo*-L-alanyl-L-tryptophan (▲) in ethanol. Ultraviolet spectrum of echinulin in ethanol (– – –).

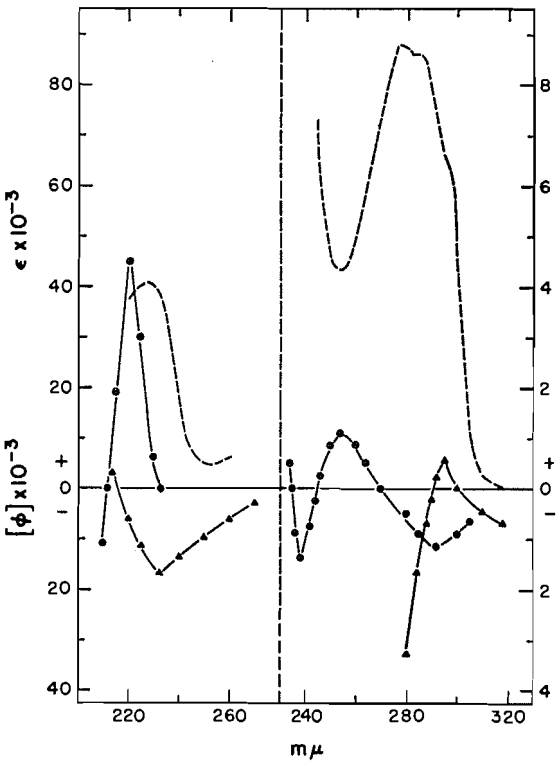

FIG. 5. Optical rotatory dispersion spectra of hydroechinulin (▲) and *cyclo*-D-alanyl-D-tryptophan (●) in ethanol. Ultraviolet spectrum of hydroechinulin in ethanol (– – –).

piperazinedione ring. Thus the molecular models indicate that interaction between the π-electrons of the indole and carbonyl groups would be expected to decrease in the order *trans-cyclo*-alanyltryptophan > *cis-cyclo*-alanyltryptophan > echinulin. Klyne *et al.* (17) have shown that the Cotton effects at 250–230 mμ of the heteroyohimbine alkaloids are influenced by the relative positions of the indole and carbomethoxy groups. Other examples of Cotton effects being related to the interaction of two π-electron systems are also known (18), and the results of the present study may be another instance of this type of relationship.

The o.r.d. spectra of echinulin (Fig. 4) and hydroechinulin (Fig. 5) possess the same broad positive Cotton effect in the 300–220 mμ region. These spectra are compared with the spectra of *cyclo*-L-alanyl-L-tryptophan (Fig. 4) and *cyclo*-D-alanyl-D-tryptophan (Fig. 5), respectively. The trough of the Cotton effects of echinulin and hydroechinulin are at longer wavelength (232 mμ) than the trough of the Cotton effect of *cyclo*-L-alanyl-L-tryptophan (221 mμ) (Fig. 4), or the corresponding trough of *cyclo*-D-alanyl-L-tryptophan (224 mμ) (Fig. 3). However, the troughs of these Cotton effects coincide with the relevant u.v. absorption maxima (cf. Figs. 2–5) and would thus appear to be related to the same chromophores. Comparison of the o.r.d. spectra of hydroechinulin and *cyclo*-D-alanyl-D-tryptophan (Fig. 5) shows that the latter has Cotton effects of opposite sign to the former. The o.r.d. spectra below 300 mμ therefore indicate that echinulin has the *cyclo*-L-alanyl-L-tryptophan configuration, and not the *cyclo*-L-alanyl-D-tryptophan configuration as previously suggested (14). This conclusion is supported by a recent o.r.d. study (19) of two *cyclo*-alanyltryptophans carrying a 1,1-dimethylprop-2-enyl substituent in the α-position of the indole nucleus (**1**, R_1 = —C$(CH_3)_2CH{=}CH_2$, R_2 = H).

The configuration of echinulin has also been investigated (20) by the t.l.c. method used to determine the steric purity of piperazinediones (13). Nitecki *et al.* (13) found that *cis*-piperazinediones have a lower R_f value than the corresponding *trans* compounds. Echinulin and *cyclo*-L-alanyl-L-tryptophan were racemized separately in boiling ethanol–triethylamine and the products, starting materials, and *cyclo*-L-alanyl-D-tryptophan were examined by t.l.c. The results (20) indicated that echinulin behaves like a *cis*-piperazinedione, and since the alanine portion has the L-configuration it follows that the tryptophan moiety must also have the L-configuration. Racemization experiments using the above-mentioned compounds and hydroechinulin gave results identical to those of Westley *et al.* (20).

Experimental

The optical rotatory dispersion (o.r.d.) measurements were made on a Jasco ORD/UV-5 spectropolarimeter. Optical rotations at the sodium-D line were measured at 25° on a Perkin–Elmer141 polarimeter. Ultraviolet absorption spectra were obtained with a Beckman DK-2 spectrometer. Melting points were determined on a Leitz hotstage and are uncorrected. Echinulin and hydroechinulin were obtained as previously described (7). The amino acids were obtained from the Sigma Chemical Company and had specific rotations in agreement with literature values and were used as supplied. The protected amino acids were synthesized by known methods and those previously described had melting points and specific rotations corresponding to the published values. The following derivatives do not appear to have been described previously: D-alanine benzyl ester benzene sulfonate (21), m.p.

120–121° (EtOH–Et_2O), $[\alpha]_D$ −8.1° (*c*, 3.1 pyridine); benzyloxycarbonyl-L-tryptophan hydrazide (24), m.p. 210–212° (EtOH–EtOAc), $[\alpha]_D$ −9.7° (*c*, 1.27 HOAc); D-isomer, m.p. 209–211°, $[\alpha]_D$ +9.2° (*c*, 1.31 HOAc); D-alanine ethyl ester hydrochloride (25*b*), m.p. 75–76° (EtOH–Et_2O), $[\alpha]_D$ +11.1° (*c*, 2.1 in 5 *N* HCl); D-tryptophan benzyl ester hydrochloride (23), m.p. 213–215° (EtOH–Et_2O), $[\alpha]_D$ −4.1° (*c*, 2.1 MeOH).

Benzyloxycarbonyltryptophylalanine Benzyl Ester

N,N'-dicyclohexylcarbodiimide (1.36 g, 0.006 mole) (23) was added to a mixture of benzyloxycarbonyltryptophan (22) (2.0 g, 0.0059 mole), alanine benzyl ester benzenesulfonate (21) (2.0 g, 0.0059 mole), and triethylamine (0.85 ml, 0.006 mole) in dichloromethane (25 ml). After stirring at room temperature for 4 h, acetic acid (0.2 ml) was added and the mixture filtered to remove dicyclohexylurea. The filtrate was washed with 0.5 *N* HCl, 0.5% $NaHCO_3$, and water. Evaporation of the dried ($MgSO_4$) solution left a mixture of dicyclohexylurea and an oil which was taken up in acetone and filtered. Addition of petroleum ether to the filtrate, and cooling, gave the product in 70–75% yield.

Benzyloxycarbonyl-L-tryptophyl-L-alanine benzyl ester, m.p. 150–152°, $[\alpha]_D$ −28.4° (*c*, 0.54 MeOH) (lit. (23) m.p. 153°, $[\alpha]_D^{25}$ −27° (*c*, 1 MeOH)).

Benzyloxycarbonyl-D-tryptophyl-D-alanine benzyl ester, m.p. 146–149°, $[\alpha]_D$ +27.4° (*c*, 0.58 MeOH).

Benzyloxycarbonyl-L-tryptophyl-D-alanine benzyl ester, m.p. 163–164°, $[\alpha]_D$ +9.8° (*c*, 0.59 MeOH).

Benzyloxycarbonyl-D-tryptophyl-L-alanine benzyl ester, m.p. 161–163°, $[\alpha]_D$ −9.2° (*c*, 0.72 MeOH).

Anal. Calcd. for $C_{29}H_{29}N_3O_5$: C, 69.7; H, 5.9; N, 8.4. Found: C, 69.5; H, 5.9; N, 8.7.

Coupling of benzyloxycarbonyltryptophan hydrazide (24) and alanylbenzyl ester (21) by the azide method (24) gave products identical to those from the carbodiimide method, although in lower yield (50–55%).

Cyclo-alanyltryptophan

A stream of hydrogen was passed through a stirred solution of benzyloxycarbonyltryptophylalanine benzyl ester (0.56 g, 0.0011 mole) in methanol (50 ml) containing palladium black (approximately 0.1 g) until carbon dioxide was no longer evolved (25*a*). If free peptide precipitated during hydrogenolysis it was dissolved by addition of water. The reaction mixture was filtered and the filtrate evaporated to dryness under reduced pressure at 50° to give tryptophylalanine as a white solid (90–95%) which was chromatographically pure (23). The tryptophylalanine tended to decompose (judged by the development of a yellow-brown color) when subjected to recrystallization procedures and the product obtained from hydrogenolysis was used directly in the following step.

The alanyltryptophan in methanol (50 ml) at room temperature was treated with an ether solution of diazomethane over 1 h. After stirring for a further 1 h the solvent was removed under reduced pressure and the residue dissolved in methanol (100 ml). The solution was cooled to 0° and saturated with dry ammonia gas (9). After stirring for 5 h the solvent was removed under reduced pressure at 40° and the product crystallized from ethanol – ethyl acetate in yields of 60–65%.

Cyclo-L-alanyl-L-tryptophan, m.p. 282–284° (decomp.) $[\alpha]_D$ +10.4°, (*c*, 0.48 EtOH).

Cyclo-D-alanyl-D-tryptophan, m.p. 281–283° (decomp.) $[\alpha]_D$ −10.2° (*c*, 0.048 EtOH).

Cyclo-D-alanyl-L-tryptophan, m.p. 265–267° (decomp.) $[\alpha]_D$ +75.6° (*c*, 0.049 EtOH).

Cyclo-L-alanyl-D-tryptophan, m.p. 264–267° (decomp.) $[\alpha]_D$ −74.2° (*c*, 0.051 EtOH).

λ_{max} (EtOH) 220 (35 700), 274 (5 790), 280 (5 870), 290 (5 080), mμ.

Anal. Calcd. for $C_{14}H_{14}N_3O_2$: C, 65.4; H, 5.9; N, 16.3. Found: C, 65.2; H, 5.8; N, 16.1.

Benzyloxycarbonylalanyltryptophan Benzyl Ester

Benzyloxycarbonylalanine hydrazide (24) (2.43 g, 0.0103 mole) in a mixture of acetic acid (12 ml), water (50 ml) and 5 *N* hydrochloric acid (5 ml) was treated with a solution of sodium nitrite (0.8 g, 0.0116 mole) in water (2.5 ml) as previously described (24). The dry ether solution of the azide was added to a solution of tryptophan benzyl ester (prepared by treating the hydrochloride (3.4 g, 0.0103 mole) in chloroform (20 ml) with triethylamine (5 ml, 0.0358 mole) at room temperature for 20 min, filtering, and evaporating to dryness). After standing at room temperature overnight, the reaction mixture was worked up in the usual way (24) and the solid product recrystallized from acetone – petroleum ether in yields of 75–80%.

Benzyloxycarbonyl-L-alanyl-L-tryptophan benzyl ester, m.p. 105–106°, $[\alpha]_D$ −23.2° (*c*, 1.1 MeOH) (lit. (23) m.p. 105°, $[\alpha]_D^{25}$ −22° (*c*, 1 MeOH)).

Benzyloxycarbonyl-D-alanyl-D-tryptophan benzyl ester, m.p. 104–105°, $[\alpha]_D$ +20.2° (*c*, 1.2 MeOH).

Benzyloxycarbonyl-D-alanyl-L-tryptophan benzyl ester, m.p. 158–160°, $[\alpha]_D$ +12.8° (*c*, 0.57 MeOH).

Benzyloxycarbonyl-L-alanyl-D-tryptophan benzyl ester, m.p. 158–160°, $[\alpha]_D$ −12.4° (*c*, 0.46 MeOH).

Anal. Calcd. for $C_{29}H_{29}N_3O_5$: C, 69.7; H, 5.9; N, 8.4. Found: C, 69.5; H, 5.8; N, 8.5.

Products identical to the above were obtained in 75–80% yield by treating benzyloxycarbonylalanine (26) and tryptophan benzyl ester with dicyclohexylcarbodiimide (23).

Cyclo-alanyltryptophan

Benzyloxycarbonylalanyltryptophan benzyl ester (2 g, 0.004 mole) in methanol (50 ml) containing palladium black (0.5 g) was hydrogenolyzed (25*a*) as for the benzyloxycarbonyltryptophylalanine benzyl ester to give alanyltryptophan in 90% yield. The peptide was methylated as before and the oily product treated with dry ammonia gas (9) as for the tryptophylalanine, to give *cyclo*-alanyltryptophan in yields of 65–70%. The piperazinediones prepared by this method were identical to the corresponding compounds synthesized from tryptophylalanine.

Racemization and Thin-Layer Chromatography

Samples (25 mg) of echinulin, hydroechinulin, and *cyclo*-L-alanyl-L-tryptophan in ethanol–triethylamine (1:1, 10 ml) were boiled under reflux for 3 days (20). The solvent was removed under reduced pressure and the residues, starting materials, and *cyclo*-L-alanyl-D-tryptophan examined by t.l.c. on silica gel G using diisopropyl ether – chloroform – acetic acid (6:3:2) (Nitecki *et al.* (13) used the ratio 6:3:1 but this was not sufficiently polar for our purpose). The spots were detected by exposing the air-dried plates to iodine vapor, which was

superior to the method of Nitecki *et al.* (13) for the compounds in this study.

Lignans and related phenols. Part IX.[1] Observations on the spectroscopic characterization and conformational analysis of apo-compounds of the arylnaphthalene class

D. C. AYRES

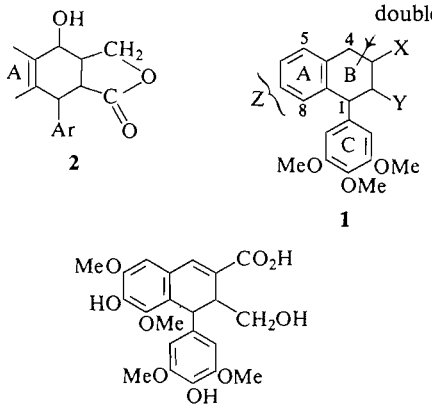
Department of Chemistry, Westfield College, University of London, Hampstead, London, N.W.3, England

Received December 2, 1968

The need for further spectroscopic characterization of apo-compounds of type **1** is discussed and details of proton magnetic resonance (p.m.r.) and optical rotatory dispersion (o.r.d.) spectra are given. Analysis of these spectra is relevant to the assignment of structure to the recently isolated thomasic acid and also reveals unusual conformational features in compounds of this group.

Canadian Journal of Chemistry, 47, 2075 (1969)

The presence of a carbon–carbon double bond in the B ring of these compounds (see Scheme 1[2]) may be indicated by weak infrared (i.r.) absorption. In apo-lactones (**1**, X → Y, CH_2—O—C=O) derived from picropodophyllin, (from **2** by elimination of —OH) this lies (7) at 1648(γ) or 1698 cm^{-1}(β). The intensity is not sensibly affected by conjugation and the absorption in methyl α-apopicropodophyllate (**1**, X = CH_2-OH, Y = CO_2Me) and its reduction product (α-apopicropodophyllol, X = Y = CH_2OH) lies at 1700 cm^{-1}. The peak due to the B ring unsaturation is obscured in the α-apo-lactone (1) and in acetyl α-apopicropodophyllol (2) and, when resolved, may not be readily correlated with structure. Thus the retro-system of thomasic acid (**3**) leads to absorption at 1695 cm^{-1} (3) close to that of α-apopicropodophyllate and of β-apopicropodophyllin, which in turn differ little from the γ-methyl ester (**1**, X = CH_2OH, Y = CO_2Me) absorbing at 1700 cm^{-1}.



2 **1** **3**

SCHEME 1

In the ultraviolet (u.v.) spectra the effect of twisting the olefinic chromophore in the strained B ring of isomeric α- and γ-lactones has been referred to (4). Opening of the lactone ring causes only a slight blue shift (3 mμ) at longer wavelength when the α-lactone is converted into the corresponding methyl ester (**1**, X = CH_2OH, Y = CO_2Me; λ_{max} 310 mμ, log ε 3.80), but the carbonyl group is evidently much less effectively conjugated in methyl γ-apopicropodophyllate (λ_{max} 332.5 mμ, log ε 4.04) than in the corresponding lactone (λ_{max} 350, log ε 4.10); this must result from steric interaction between the methoxycarbonyl group and the adjacent aryl substituent. Provided regard is paid to this shift γ-apo-compounds can be characterized by their u.v. spectra. However, a distinction between α and β apo-derivatives by comparison of these spectra may not be possible; for example α-apopicrosikkimotoxin [**1**, Z = 6,7-dimethoxy, (5)] absorbs at shorter wavelength (λ_{max} 285 mμ) than either β-apopicropodophyllin (**1**, Z = 6,7-methylenedioxy) or its desmethylene derivative (λ_{max} 292 and 287.5 mμ respectively).

Opposition between factors favoring conjugation and those favoring strain relief leads to other uncertainties in the interpretation of u.v. spectra. Thus artifacts may arise in the presence of weak bases which readily isomerize α- to β-lactones

[1]For Part VIII see ref. 10.

[2]In the general structure **1**, α-apo implies unsaturation between C-3 and C-4, β-apo between C-2 and C-3, and γ-apo between C-1 and C-2; Z substituents on ring A are specified where relevant.

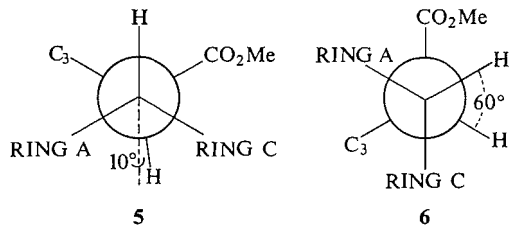
with reversion to the α-hydroxyacid on hydrolysis (1), whilst stronger bases may cause dehydrogenation to fluorescent arylnaphthalenes in non-hydrolytic media (6).

In their fundamental paper Schrecker and Hartwell (7) assigned configurations to the diastereoisomers of the desoxypicropodophyllin group (**2**, C-4 desoxy); their method depended on the hydrogenation of apo-precursors which were characterized in the u.v. It is apparent from the above remarks that additional evidence of the structures of these precursors is desirable. The following evidence of proton magnetic resonance (p.m.r.) spectroscopy confirms Schrecker and Hartwell's assignment and complements data given recently (3) for thomasic acid (**3**), the first fully characterized α-apo-compound of natural occurrence.

The p.m.r. spectrum of a model for γ-apopicropodophyllin (**1**,X,Y = CH_2—O—CO, rings A and C unsubstituted) has been recorded (8).[3] Points of interest in the spectrum of methyl γ-apopicropodophyllate (see Table I) are the shielding of the C-8 proton by the pendant aromatic ring, which also shields the ester protons, whose resonance lies about 18 Hz above the normal for an acrylic methyl ester (cf. Fig. 1). The shielded ester group must be forced above the plane of the aromatic ring and this is consistent with the blue shift in the u.v. spectrum noted above.

In the p.m.r. spectrum of β-apopicropodophyllin the C-4 protons and the C-1 proton form an ABX system, but the AB part is largely obscured beneath the ether peak (τ 6.25) in deuteriochloroform and although the high field portion is detectable in dimethyl sulfoxide-d_6 the resolution was not further improved on solution in trifluoroacetic acid. The X part of the spectrum appears at τ 5.20 in the less polar solvents, resonating at lower field than normal for a diphenylmethyl proton owing to deshielding by the C-2, C-3 unsaturation; in these solvents the resonance of the lactone protons is coincident with that at C-1. In trifluoroacetic acid the C-1 proton is resolved from the broad lactone peak at τ 4.95 as a multiplet (τ 5.14). The splitting of the methylenedioxy resonance must result from shielding of one of them by the pendant ring (9) when it occupies an axial conformation on the same face of the molecule; models show that these conformers are easily interconverted.[4]

Figure 1 shows the 100 MHz spectrum of methyl α-apopicropodophyllate (4). The broad peak at τ 5.80 was allocated to the hydroxymethylene protons as it was split on irradiation at τ 3.50 and the vinyl proton located here sharpened on irradiation at 5.80. Irradiation of the water peak in deuteriochloroform (τ 8.25) also sharpened the hydroxymethylene resonance because of exchange of the saturated water protons with those of the alcohol (11). The pair of doublets centered at τ 5.54 and 6.47 are allocated to C-1 H and C-2 H respectively. The former corresponds to the resonance C-1 H (τ 5.92) reported by Wallis (12) in a related structure (**1**, X = Y = Me, Z = 6,7,8-trimethoxy) and the latter to the resonance of C-2 H in thomasic acid dimethyl ether (τ 6.65 in $CDCl_3$) allowing for deshielding by the C-2 CO_2Me group of α-apopicropodophyllate (**4**). The coupling of 4 Hz between these protons was confirmed by irradiation at τ 5.54 and 6.47 and is small for a diaxial pair (**5**, Scheme 2). Chemical evidence for the *trans* configuration at C-1 and C-2 has been presented by a number of independent workers (e.g. 1, 5, 13, 14) and we must conclude that the conformation (**6**), having an axial aromatic substituent, contributes significantly to the equilibrium. Seikel[5] has



5 6

SCHEME 2

revised the structure of thomasic acid on chemical grounds and finds that its *trans*-1:2 configuration leads to a smaller coupling than that reported here for the α-apopicropodophyllate-ester, since the resonance of C-1 H (τ 5.16 in acetone) is broadened but not split. Wallis found a similar C-1 H resonance in the spectrum of his analogue [**1**, X = Y = Me, Z = $(MeO)_3$] which also had

[3]Some proton magnetic resonance data are also available for the γ-lactone, collinusin (**1**, X → Y CH_2—O—CO, Z = 6,7-dimethoxy, ring C 3,4-dimethoxyphenyl), see ref. 18.

[4]The conformational analysis of a related model is detailed in Part VIII of the series (10).

the *trans*-1,2 configuration. It may be noted that when the aryl substituent adopts a quasi-axial conformation its interactions with an equatorial substituent at C-2 and with a hydrogen atom, or other group, at C-8 are diminished; further, no 1–3 interactions are established. The compounds described by Seikel *et al.* (3) and by Wallis (12) with a C-8 OMe substituent are expected to have an increased, even preponderant, proportion of axial substitution at C-1; this is in keeping with the smaller coupling constant $J_{H_1H_2}$ relative to that of methyl α-apopicropodophyllate.

In an attempt to evaluate the diaxial coupling constant $J_{H_1H_2}$ we examined the spectrum of α-apopicropodophyllin (**1**; X,Y = CH_2—O—CO, Z = 6,7-methylenedioxy) because the fused lactone ring prevents equilibration of conformers. Unfortunately the low solubility of this compound prevented its examination in chloroform. In deuteriodimethyl sulfoxide-d_6 the C-1 H resonance occurred at τ 5.96 as a broadened singlet whose intensity diminished during 15 min at 90° owing to isomerization to the β-apo-isomer; the C-2 H peak was obscured by the methoxyl proton resonances. The α-apo-lactone was unaffected (i.r. spectrum) after several hours in trifluoroacetic acid although it does react to give colored products on long-standing; in this solvent both the C-1 and C-2 H peaks were largely obscured by the methoxyl proton resonances.

Nitrobenzene gave a cold concentrated solution which did not deteriorate on keeping; here the C-1 H peak was identified (Fig. 2), and the protons of the lactone and the vinyl carbon were located at τ 4.88 and 3.56 respectively. The resonances of the aromatic ring protons are recorded in Table I, but their position is affected by the solvent so as to confuse the shielding correlation between C-8 H and the ring C conformation. The small coupling between C-1 H and C-2 H in the *trans* lactone must result from reduction in the dihedral angle (compare **5**) by rotation about the bond linking these carbon atoms, thus imparting axial character to the aryl substituent and bringing the C-3—C-4 double bond into more effective conjugation with ring A. This torsional effect also imparts axial character to the C-2 substituent so further straining the lactone ring, which in fact absorbs in KBr at a higher frequency (1770 cm^{-1}) in the i.r. than the strained lactone ring of podophyllotoxin (**2**, 1750 cm^{-1}); the conjugated lactones absorb at appreciably lower wavelengths (β-lactone 1750, γ-lactone 1745 cm^{-1}).

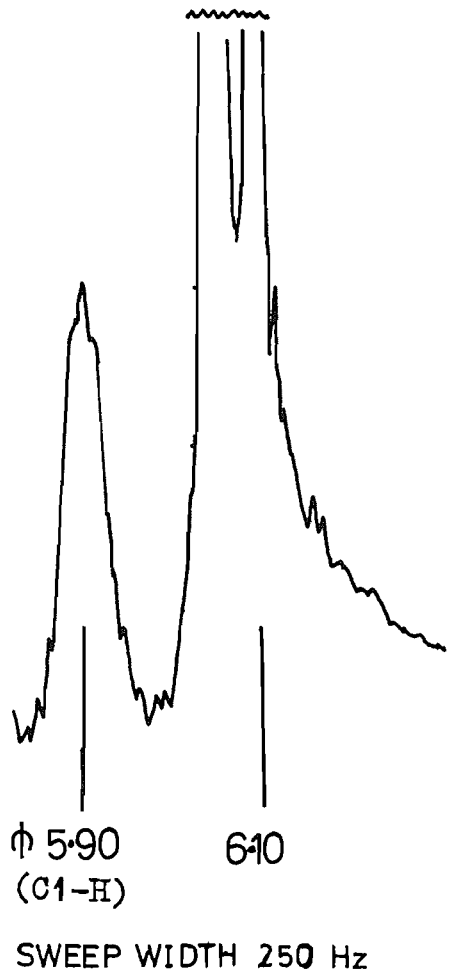

FIG. 2. The 60 MHz proton magnetic resonance spectrum of α-apopicropodophyllin (C-1 H peak).

The form of the optical rotatory dispersion (o.r.d.) curves (Fig. 3) of α-apopicropodophyllin (**7**) and of α-apopicropodophyllic acid (**8**) indicates that there are overlapping Cotton effects and that for fuller assignments circular dichroism measurements are required. However the considerable differences in the two curves cannot arise from minor differences in substituents at C-2 and C-3 (15), and must be due to differences in the conformation of the B ring: this is consistent with the interpretation of the p.m.r. spectra. The amplitude of the apparent Cotton effect near 285 mμ is much greater in the α-apo-acid and this can be attributed to the greater skewing between the aromatic chromophores (cf. 16) when the C ring adopts the quasi-axial conformation in this compound.

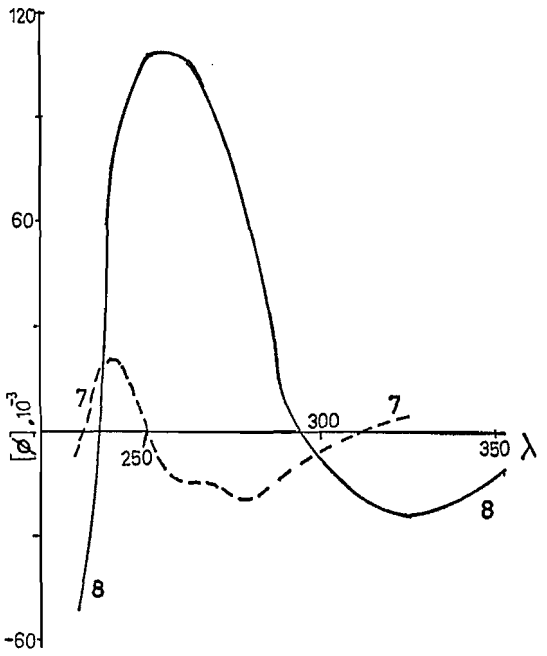

FIG. 3. Optical rotatory dispersion curves.

Experimental

With two exceptions the nuclear magnetic resonance (n.m.r.) spectra were measured on a Varian HA-100 spectrometer by the S.R.C. Spectroscopy Unit at Imperial College. Infrared (i.r.) spectra were measured with a Perkin–Elmer 127 spectrometer and ultraviolet (u.v.) spectra with a Unicam SP800 instrument. The optical rotatory dispersion measurements were made in methanol–dioxan 1:1 with the Bellingham and Stanley/Bendix Ericsson spectropolarimeter, Polarmatic 62, at a similar temperature (25–30°) to the proton magnetic resonance (p.m.r.) determination.

α-Apo-compounds

These were prepared and characterized as previously described. The method of Schrecker and Hartwell (1) was used for α- and β-apopicropodophyllin, α-apopicropodophyllic acid, and its methyl ester, while that of Haworth and Richardson (17) was used for γ-apopicropodophyllin, and the method of Ayres and Mundy (10) was used for methyl γ-apopicropodophyllate.

α-Apopicropodophyllin was obtained in almost quantitative yield without any discoloration by reducing the reaction time (1) of picropodophyllin in acetic anhydride/sulfuric acid to 2 min at 80–100°. The i.r., u.v., and p.m.r. spectra establish the structure of the product but the recorded (1) melting point was not observed on a heated microscope stage. Here the product was seen to melt at 161–163° and to crystallize at 165° on further slow heating; the material re-melted at 220–222° (cf. β-apopicropodophyllin). A sample of α-apopicropodophyllin kindly supplied by Dr. A. W. Schrecker behaved similarly.

Acknowledgments

We thank Dr. J. Feeney, Varian Associates Ltd., for the 100 MHz spectrum of **4** in $CDCl_3$ and Mr. P. B. Hulbert, Westfield College for the o.r.d. results. Dr. J. W. Mundy is thanked for the u.v. spectra.

Gas–liquid chromatography of terpenes. Part XVIII. The volatile oil of the leaves of *Juniperus communis* L.[1]

E. VON RUDLOFF AND V. K. SOOD[2]

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received January 2, 1969

The volatile leaf oil of the local common juniper was found to consist mainly of α-pinene (73 to 83%) and smaller amounts (0.5 to 5%) of β-pinene, 3-carene, myrcene, limonene, methyl citronellate, bornyl acetate, myrtenal, myrtenol, myrtenyl acetate, α-terpineol, citronellol, citronellyl acetate, nerolidol, farnesol, and an unusual hydroxy ketone. Of the many trace constituents, β-phellandrene, citronellal, "iso-" citronellal, linalool, geraniol, isopulegol, 4-terpinenol, and ε-cadinene were isolated, whereas camphene, sabinene, α-phellandrene, γ-terpinene, terpinolene, *p*-cymene, fenchone, thujone, isothujone and δ-cadinene could only be tentatively identified.

There was little variation in the quantitative composition of the leaf oil from one plant to another. Since the composition of this oil differs significantly from that of other juniper leaf oils, chemotaxonomic studies by means of leaf oil analysis are feasible.

Canadian Journal of Chemistry, 47, 2081 (1969)

Introduction

The common juniper, *Juniperus communis* L., is one of the most widely distributed conifers, occurring throughout the temperate zone of the northern hemisphere. On the North American continent it is found from the Maritimes through the Great Plains as well as the boreal region of Canada to the Rocky Mountains and the Pacific Coast. On this continent it seldom grows to more than 2 ft in height and it is generally referred to as the variety *depressa*. Sargent (1) lists the common juniper occurring at higher altitudes (Appalachians, Rocky Mountains, as well as the coast of Greenland to New England) as the variety *montana*. Fraser and Russell (2) refer to the common juniper found in the Prairie Provinces as *J. sibirica* Burgsd., *syn. J. communis* L. var. *saxatilis* Pall. The correct varietal names of two low-growing forms found in Europe were discussed by Hunt and Welch (3) recently.

Whereas the volatile oil of the berries of the common juniper has been investigated in considerable detail (4–6), the leaf oil has received scant attention, Hegnauer (5) listing only α-pinene, camphene, and cadinene as constituents. The components of the wood were investigated in detail by Bredenberg (7).

In the previous papers of this series the analyses by gas–liquid chromatography (g.l.c.) of the leaf oils of the Savin juniper (8), Rocky Mountain juniper (9), creeping juniper (10), Ashe juniper (11), and red juniper (12) were described. This communication deals with a similar analysis of the leaf oil of the local common juniper. As in the previous work, both quantitative and qualitative aspects were studied and the variation from one plant to another was determined to permit conclusions on chemotaxonomic aspects.

Experimental

The gas–liquid chromatography (g.l.c.) analyses were carried out with an F & M model 500 gas chromatograph (linear temperature programming, thermal conductivity dectector; F & M Scientific Instrument Inc.) and a unit of conventional design (isothermal operation). An Aerograph model A-700 (Autoprep, Varian-Aerograph) instrument was employed for preparative g.l.c. Helium was used as carrier gas in all instruments. The peak area and percentage composition were determined with an Aerograph model 471 digital integrator, the instrumental error being less than 0.1% on full scale recorder (1 mV) deflection with no baseline drift. Retention times were measured from the time of injection to the initial emergence of the peaks and tentative identity was established by comparison of relative retention data or by co-injection of reference terpenes. The liquid phases employed in the g.l.c. columns were polyethylene glycol (PEG) (Carbowax 20 M, 5% on Aeropak 30, 70–80 mesh and 15% on Gaschrom P, 60–80 mesh), silicone gum polymer (SE–30) (5% on Gaschrom Q, 60–80 mesh), fluorinated silicone polymer (QF-1) (15% and 20% on Gaschrom P, 60–80 mesh), β,β-oxydipropionitrile (ODPN) (ethylene glycol *bis*-propionitrile; 15% on Gaschrom P, 60–80 mesh), C-modified polyphenyl ether (PPE) (Monosanto MCS 652; 15% on Gaschrom P, 60–80 mesh). The 5% columns were used for analytical experiments (90–120 ml He/min) whereas the more heavily loaded ones were employed for preparative work (40–70 ml He/min). A typical gas chromatogram of the leaf oil of the common

[1]NRCC No. 10604 (Part XVII see ref. 12).

[2]Colombo Plan Fellow, 1968; present address: C.F.P. Branch, Forest Research Institute and Colleges, Dehra Dun (U.P.) India.

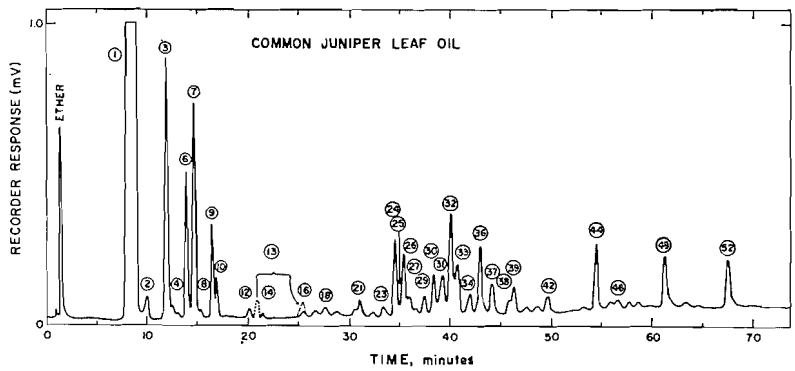

FIG. 1. Gas-liquid chromatogram of the leaf oil of *Juniperus communis* L. collected near Saskatoon, Saskatchewan; 5% PEG column (350 × 0.4 cm O.D.), 50° to 220° at 2.9°/min.

juniper as obtained on the 5% PEG column is shown in Fig. 1 and the individual components are numbered according to the sequence of elution on this column (50° to 220° at 2.9° per min). The isolated compounds were identified by comparison of the infrared (i.r.), proton magnetic resonance (p.m.r.), and ultraviolet (u.v.) spectra with those of authentic specimens. Infrared spectra were recorded as films between sodium chloride plates, using a Perkin–Elmer model 21 i.r. spectrophotometer. The p.m.r. spectra were obtained in carbon tetrachloride solution with tetramethyl silane as internal standard, using a Varian HA-100 (100 Hz) spectrometer. The u.v. spectra were determined in isooctane solution. Optical rotations were recorded in chloroform solution (2 to 5%) at 25° when a component was obtained in high purity and in sufficient amount (20 to 50 mg).

Plant Material and Recovery of the Volatile Oil

The foliage of the common juniper was collected along the eastern bank of the South Saskatchewan River 8 to 10 miles south of Saskatoon (Cranberry Flats to Beaver Creek area) during October and November, 1967, as well as April and May 1968. All woody branches were removed and the foliage was steam-distilled in 800 g batches in an all-glass apparatus (13) for 5 to 6 h. The oil was trapped in a small volume of ether and removed from time to time, a fresh aliquot of ether being added to the side-arm assembly after each withdrawal. After the distillation was completed, the residual water in the side-arm was extracted with ether. The ethereal extracts were combined and dried over anhydrous sodium sulfate and the ether was distilled off as described previously (12, 13). Small scale distillations (50 to 150 g foliage) were carried out in the same manner, but with a smaller apparatus (15). In later work it was discovered that the yield of the last component (farnesol, peak 53) could be increased by continuing the steam-distillation for a further 3 to 4 h. The yield of oil varied from 1.0 to 1.1% in the large scale distillation (same batch of plant material) and from 0.7 to 1.3% in the small scale work (individual plants); $[\alpha]_D$ −18 to −22°.

Prefractionation of the Volatile Oil

Aliquots (10.0 g) of the oil were chromatographed on modified silicic acid (120 g) as described previously (9–12). Elution of the column with petrol (Skellysolve F, b.p. 40–50°; 500 ml) gave a hydrocarbon fraction A (6.2 g), elution with methylene chloride (400 ml) a mid-fraction B (0.75 g), and elution with methanol (400 ml) a polar fraction C (2.0 g). Since the latter fraction was rather complex in composition attempts were made to separate this into distinct groups of compounds, but neither column chromatography nor preparative g.l.c. on QF-1 or SE-30 gave clear-cut separations.

Identification of Individual Compounds

a) Hydrocarbons

Analysis of the hydrocarbon fraction A on the analytical PEG, SE-30, PPE, and ODPN columns indicated that peaks 1 to 13 were monoterpene hydrocarbons with retentions corresponding to α-pinene, camphene, β-pinene, sabinene, an unknown, 3-carene, myrcene, α-phellandrene, limonene, β-phellandrene, γ-terpinene, *p*-cymene and terpinolene respectively. In some runs the camphene peak was partially resolved into two components, but the large amounts of α-pinene made separation and identification impossible. α-Pinene ($[\alpha]_D$ −20.2°), β-pinene ($[\alpha]_D$ −18.7°), 3-carene, myrcene, limonene and β-phellandrene were positively identified by their i.r. and nuclear magnetic resonance (n.m.r.) spectra, and *p*-cymene by its u.v. spectrum.

The relative amounts of component 13 (terpinolene) in the hydrocarbon fraction A were considerably lower than those recorded for the oil as a whole. On checking all analytical runs of the total oil and prefractionated material it could be found that a large portion of component 13 decomposed or rearranged during prefractionation. Also in most runs on the PEG columns a partial loss of component 13 with concomitant increase in the size of the double peak 15/16 was noticed. An attempt was made to isolate component 13 directly without prefractionation. The amount which could be collected barely sufficed for recording the i.r. spectrum in a micro cell (0.01 mm) path length. The weak spectrum was characterized by a broad CH peak (3000–2860 cm^{-1}), and relatively strong absorptions near 1730, 1645, 1455, 1380–1360 (doublet), 1260 (broad) and 870 cm^{-1} as well as a weak band near 3080 cm^{-1} ($\rangle C{=}CH_2$). Peak 13 must therefore consist mainly of a low boiling

labile ester containing a terminal methylene group and a trace of a hydrocarbon with the retention time of terpinolene.

The hydrocarbon fraction A also contained three trace peaks in the sesquiterpene range, retentions of which corresponded to those of ε-cadinene, δ-cadinene, and an unknown (peaks 34*b*, 36*b*, and 38*b* respectively). Only the first could be isolated in sufficient amount to give a weak i.r. spectrum and this was similar to that of the ε-cadinene isolated previously (15).

b) Midfraction

This fraction contained mainly peaks 21, 24, 26, 30, 31, 32, 34, and 35. Preparative g.l.c. on a QF-1 column (200 × 0.9 cm O.D.) gave these components as impure fractions and each was purified further on a PEG column (200 × 0.6 cm O.D.). In this manner components 24, 26, 30, 31, and 32 could be obtained practically pure and these were found to be methyl citronellate, bornyl acetate ($[\alpha]_D$ −30.5°), myrtenal ($[\alpha]_D$ +12.3°), citronellyl acetate, and myrtenyl acetate respectively. Refractionation of the methyl citronellate peak on a QF-1 column (180 × 0.9 cm O.D.) showed the presence of a small amount of an unknown alcohol (peak 25).

Component 21 was found to be an unknown aldehyde with a trisubstituted double bond; i.r. 1720 and 795 cm^{-1}, p.m.r. δ 9.73 Hz (1 H, partially split singlet, —CHO), 5.19 Hz (1 H, partially split singlet, $\rangle C=CH-$), 2.34 Hz (2 H complex multiplet, $-CH_2-C=C-$), 1.60 Hz (3 H, partially split singlet $CH_3-C=C$), 1.00 and 0.80 Hz (6 H, doublet, $(CH_3)_2CH-$).

Component 34 was found to be an unknown conjugated ketone with spectral properties differing from those of pulegone, piperitone, piperitenone, and carvone; i.r. bands near 2940 (s), 1760 (m), 1670 (s), 1615 (m), 1467 (m), 1432 (m), 1372 (m), 1335 (m), 1280 (m), 1240 (m), 1200 (m), 1030 (m), and 860 (m) cm^{-1}. The amount isolated was too small for recording a satisfactory p.m.r. spectrum.

Component 35 was isolated in very small amounts only and retention as well as the weak i.r. spectrum were in agreement with those of geranyl acetate. However, the isolated fraction was impure and since the i.r. spectrum of geranyl acetate does not contain a characteristic fingerprint region (it is very similar to that of neryl acetate) this identification is not entirely satisfactory. Subsequent refractionation of a concentrate of peaks 33 to 35 confirmed the presence of geranyl acetate. In addition a new ester was found in admixture with the conjugated ketone (peak 34).

c) Polar Fraction

This fraction consisted mainly of peaks 27, 33, 36, 37, 38, 44, 49 and 53. Preparative g.l.c. on a PEG column (200 × 0.6 cm O.D.) gave almost pure terpinen-4-ol (peak 27), α-terpineol (peak 33), citronellol (peak 36), myrtenol (peak 37), geraniol (peak 38), nerolidol (peak 44), and farnesol (peak 53).

Component 49 was obtained in what appeared to be a homogeneous main fraction (single peaks on QF-1, PEG and SE-30). The i.r. spectrum, 3430 (m), 2930 (s), 1705 (m), 1445 (m), 1375 (m); 820 and 795 (w) cm^{-1} suggested the main component to be a hydroxy ketone with at least one trisubstituted double bond. The p.m.r. spectrum differed from that of the known terpenoid hydroxy ketones (e.g. hydroxy camphor); δ 5.32 Hz (1 H, broad singlet, $\rangle C=CH-$), 5.05 Hz (1 H, triplet, J = 6, $\rangle C=CH-$), 4.22 Hz (1 H, broad, —OH), 1.95 Hz (4 to 6 H, unresolved multiplet), 1.66 Hz (3 H, singlet) and 1.62 Hz (3 H, singlet) (2 $CH_3-C=C$), and 1.08 Hz (3 H, singlet, $CH_3-C\langle$). The p.m.r. spectrum in deuterated dimethyl sulfoxide showed a sharp singlet near δ 3.80 Hz, which was removed on shaking with deuterium oxide (*tert* OH). The hydroxy ketone was hydrogenated in a Brown microhydrogenation apparatus. A slow uptake of approximately 2 mole equivalents of hydrogen was measured. The p.m.r. spectrum of the product showed singlets near δ 0.85, 0.90, 0.92, and 0.98 Hz, as well as a doublet near 1.02 Hz (J = 2) and a complex multiplet between δ 1.06 and 1.40 Hz. The amount available did not permit accurate integration.

Component 39 was isolated only in an impure state, the contaminant being geraniol (i.r., p.m.r.). The i.r. spectrum, 3460 (s), 3080 (w), 3000–2800 (s), 1635 (w), 1440 (s), 1375 (s), 1050 and 1025 (s), 950 (m), 880 (m), 810 (m), was indicative of an unsaturated alcohol containing a terminal methylene group. The p.m.r. spectrum showed resonance bands near δ 7.2 Hz (2 H, quartet as in estragol, or two doublets near 7.00 and 8.24, J = 16), 4.66 (1 H, singlet), 2.30 (2 H, doublet), 1.72 (4 H, multiplet), 1.58 and 1.55 (2 H and 1 H partially split doublet) and 1.48 Hz (3 H, singlet). The spectrum in deuterated dimethyl sulfoxide shifted the signals between 1.48 and 1.72 slightly upfield (by 0.03 to 0.09 Hz) and showed an unsymmetrical doublet at 4.80 Hz which was removed by shaking with deuterium oxide.

A small amount of component 50 was isolated and the i.r. (1720, 1705 cm^{-1}) and p.m.r. (δ 9.92 Hz (d)) spectra indicated this to be a conjugated keto aldehyde.

Results and Discussion

A typical gas–liquid chromatogram of the leaf oil of the common juniper as obtained on the standard 5% PEG column (12) is shown in Fig. 1. The individual components, identified by isolation and comparison of spectral properties as well as by retention data, and the percent composition are shown in Table I. This Table also lists the percent composition of five other leaf samples of common juniper collected in the same area along the South Saskatchewan River near Saskatoon. The results obtained show that there is little variation in the quantitative and qualitative composition of the leaf oil from one plant to another. The leaf oils of the local plants contain from 73 to 83% (−)-α-pinene. Since α-pinene has found extensive use in the synthesis of terpenes which are of value in the perfumery industry, this leaf oil may serve as a good source of this

monoterpene, especially where the yield of oil (0.7 to 1.3%) is relatively high. It is noteworthy that as with other conifer leaf oils (13) the composition was found to be rather constant during the fall and winter months.

Most of the minor and several of the trace constituents could be identified positively (see Table I). Of considerable interest from a phylogenetic point of view is the finding of myrtenal, myrtenol, and myrtenyl acetate. These terpenes are rarely found in essential oils and myrtenyl acetate does not appear to have been isolated previously from a natural source. These pinane derivatives may be readily identified by the characteristic chemical shifts of the *gem*-dimethyl groups in the p.m.r. spectra (14). It is possible that they may be detected in other oils containing smaller amounts of the pinanes by employing g.l.c. separation and p.m.r. spectroscopy.

From a chemical point of view the isolation of an isomer of citronellal (peak 21), and hydroxy ketone (peak 49) and what appears to be a ketoaldehyde (peak 50), are of interest. Retention and spectral characteristics showed component 21 to be an aliphatic aldehyde with a non-conjugated trisubstituted double bond. Since the p.m.r. spectrum indicates that one methyl group is situated next to the double bond whereas two more have the normal chemical shift (doublet at δ 1.00 and 0.80 Hz), of an isopropyl group the only acyclic terpenoid structure possible is 3,7-dimethyl-oct-3-en-1-al. However, the splitting constant of the two methyl groups ($J = 20$ c.p.s.) is very large for an isopropyl group (that in tetrahydro geraniol is only 7 c.p.s.). This aspect requires further study.

The retention time of the hydroxy ketone (peak 49) is typical for a monosubstituted sesquiterpene. Its i.r. spectrum shows the presence of a tertiary hydroxyl and a ketone group with strong indications that hydrogen bonding takes place. Internal hydrogen bonding between the hydroxyl and carbonyl functions would reduce the polarity sufficiently to account for the retention characteristics. The p.m.r. spectra confirmed the presence of a tertiary hydroxyl group and indicated the presence of an isopropylidene and at least one additional methyl group next to a double bond. Since all proton signals of the hydrogenated product were in the δ 0.85 to 1.0 Hz range none of the methyl groups can be adjacent to the oxygen functions. Although the spectra are fairly typical for terpenoid compounds (the single proton signals at low field as well as the methyl signals resembled those of farnesol) the above functions cannot be correlated with the basic farnesane, bisabolane, cadinane or eudesmane type of sesquiterpenes. The amounts of this hydroxy ketone, as well as the other partially characterized minor constituents which can be isolated in a fairly pure state by the present techniques are too small to permit structural investigations other than by spectral means. Large scale recovery of the oil and prefractionation by distillation may be an approach to obtain more of these compounds. Since several minor constituents of novel structure were also found in the leaf oils of the red, Ashe, Rocky Mountain and creeping junipers (9–12), new approaches to the isolation of larger amounts of such minor constituents are currently being studied.

Another minor constituent deserves attention in that it appears to rearrange during prefractionation. Component 13 has the retention time of terpinolene, but is almost completely lost in the prefractionation on silicic acid. Collection in a g.l.c. separation of the total oil gave only enough material for a weak i.r. spectrum. This indicated the compound to be an unsaturated acetate (bands at 1730, 1260, 1645, and 870 cm^{-1}) with a terminal methylene group. On reinjection to determine the purity two peaks with the retention time of peaks 13 and 15/16 were recorded, indicating that the ester was partially rearranged. The retention characteristics make it unlikely that it is a terpene acetate, but rather that a compound with six to eight carbon atoms is involved. Volatile aliphatic esters have been isolated from the leaf oil of the Douglas fir (16) and Sitka spruce (17), but component 13 differed from those reported.

The relatively small quantitative variation in the composition of the oil from one juniper plant to another (Table I, samples B1 to B5) make analysis of the leaf oil a suitable tool for chemotaxonomic studies. The common juniper is placed in the *Sectio oxycedrus*, whereas the junipers investigated previously by us (8–13) are all members of the *Sectio sabina*. This botanical difference is reflected in the chemical composition of the leaf oils. Whereas that of the common juniper is characterized by a large content of α-pinene and the presence of several terpenes belonging to the pinane (β-pinene, myrtenal,

myrtenol, and its acetate) and the acyclic (myrcene, linalool, citronellal, "iso"-citronellal, citronellol, geraniol, and possibly their acetates) groups, the oils of the other group of junipers contain mainly sabinene and its derivatives, elemol, the eudesmol isomers as well as safrole and other aromatic ethers. Hence, it appears relatively easy to distinguish between the two different groups on the basis of the types of terpenes found in their leaf oils. Noteworthy is, however, the finding of methyl citronellate in both groups. Since this ester is not widely found in conifer leaf oils, it may indicate the common ancestry of the two subsections of the genus *juniperus*. The fact that terpinen-4-ol and α-terpinenol, as well as several of the minor monoterpene hydrocarbons (and possibly the cadinenes) are also common to both sections, might at first sight also be listed in favor of common ancestry. However, since these terpenes are of widespread occurrence their phylogenetic value appears to be much more limited.

Finally, the occurrence of bornyl acetate in the oil of the common juniper deserves comment. Bornyl acetate is a typical constituent of the oils of the family Pinaceae, and with one noteworthy exception is absent from the members of the junipers (family Cupressaceae). The leaf oil of the Ashe juniper, *J. ashei* Buchh., was found to contain over 20% of bornyl acetate, as well as camphor, borneol and other terpenes which may be considered as typical of the family Pinaceae (11, 13). Hence, a biogenetic link between the conifers of the family Pinaceae, the Ashe juniper and the common juniper may be traced by the presence of bornyl acetate and related terpenes of the camphor group. Chemotaxonomic studies on this, as well as other North American junipers are in progress.

Acknowledgments

The grant of a Colombo Plan Fellowship by the Canadian International Development Agency to one of us (V. K. Sood) is gratefully acknowledged, as is the excellent technical assistance by Mr. M. Granat. The proton magnetic resonance and infrared spectra were recorded by Mr. M. Mazurek and Mr. W. C. Haid.

Structure of cryptosporiopsin: a new antibiotic substance produced by a species of *Cryptosporiopsis*[1]

G. M. STRUNZ, A. S. COURT, J. KOMLOSSY, AND M. A. STILLWELL
Canada Department of Forestry and Rural Development, Forest Research Laboratory, Fredericton, New Brunswick

Received November 13, 1968

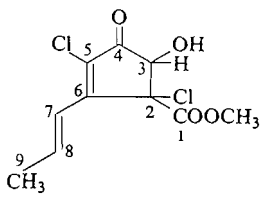
The structure of cryptosporiopsin, a novel chlorine-containing antifungal agent produced by a species of *Cryptosporiopsis*, has been elucidated on the basis of spectral and chemical studies.

Canadian Journal of Chemistry, 47, 2087 (1969)

It was observed by Stillwell (1) that antifungal properties were associated with *Cryptosporiopsis* sp., an imperfect fungus isolated from yellow birch, *Betula alleghaniensis* Britt. Isolation from culture filtrates of the organism of a pure crystalline metabolite has recently been reported by Stillwell *et al.* (2). This compound, which was named cryptosporiopsin, was found to inhibit *in vitro* the growth of a wide variety of microorganisms (2).

In this paper, evidence is presented which allows the assignment of the structure **1** to cryptosporiopsin.

The metabolite was obtained as colorless crystals from *n*-hexane – methylene chloride, m.p. 133–137°, $[\alpha]_D^{25}$ +129°, (*c*, 1.35, chloroform). The molecular formula was established as $C_{10}H_{10}O_4Cl_2$ by elemental analysis and high resolution mass spectrometry. The infrared



1

spectrum (KBr disk) of cryptosporiopsin exhibits bands at 1755 and 1730 cm^{-1}, attributed respectively to ester and conjugated five-membered ketone absorption. The relatively high frequency of both peaks is a consequence of chlorine substitution in the α-positions (3). A shoulder at 1737 cm^{-1} may be due to a rotational isomer of the chloroester in which the carbonyl group and the chlorine are staggered. The spectrum, measured at several concentrations in carbon tetrachloride, shows a strong sharp peak at 3500 cm^{-1} attributed to an intramolecularly hydrogen-bonded hydroxyl function. The carbonyl absorptions coalesce in the solution spectrum to a single sharp band at 1746 cm^{-1}.

The high resolution mass spectrum (see Experimental) shows, besides the molecular ion, peaks corresponding to loss from the latter of H_2O, Cl, $COOCH_3$ (base peak), and $COOCH_3$ plus CO.

The nuclear magnetic resonance (n.m.r.) spectrum of cryptosporiopsin (Fig. 1) shows a three-proton singlet at 6.12 τ attributable to the methyl ester hydrogens. A one-proton singlet at 5.31 τ slowly diminishes on addition of deuterium oxide and thus is assigned to the bonded hydroxyl hydrogen. A similar signal at 5.43 τ is shifted downfield to 4.91 τ on acetylation of the antibiotic, and clearly corresponds to the α-proton of a *secondary* alcohol. A three-proton doublet, centered at 7.99 τ (J = 6.2 c.p.s.) and a two-proton multiplet between 2.75 and 3.66 τ constitute an ABX_3-type pattern (4), in accord with the partial structure **2** (J_{AB} = 16.9 c.p.s.; no 1:3 coupling is evident). This assignment was corroborated by spin decoupling.

The metabolite exhibits an ultraviolet chromophore λ_{max}(95% EtOH) at 292 mμ (ε 22 800) indicating a system possessing extended conjugation, such as **3** (*vide infra*). The addition of alkali causes a negligible shift of the chromophore but gives rise to a time-dependent irreversible diminution of the extinction coefficient, demonstrating the lack of stability of the antibiotic in this medium. Since only two vinyl hydrogens appear in the n.m.r. spectrum, R_1 and R_2 must be alkyl substituents or chlorine atoms.

The molecular formula shows that the compound possesses five sites of unsaturation, four

[1]Presented at the Joint Meeting on the Chemistry of Natural Products, Fredericton, New Brunswick, August 1968.

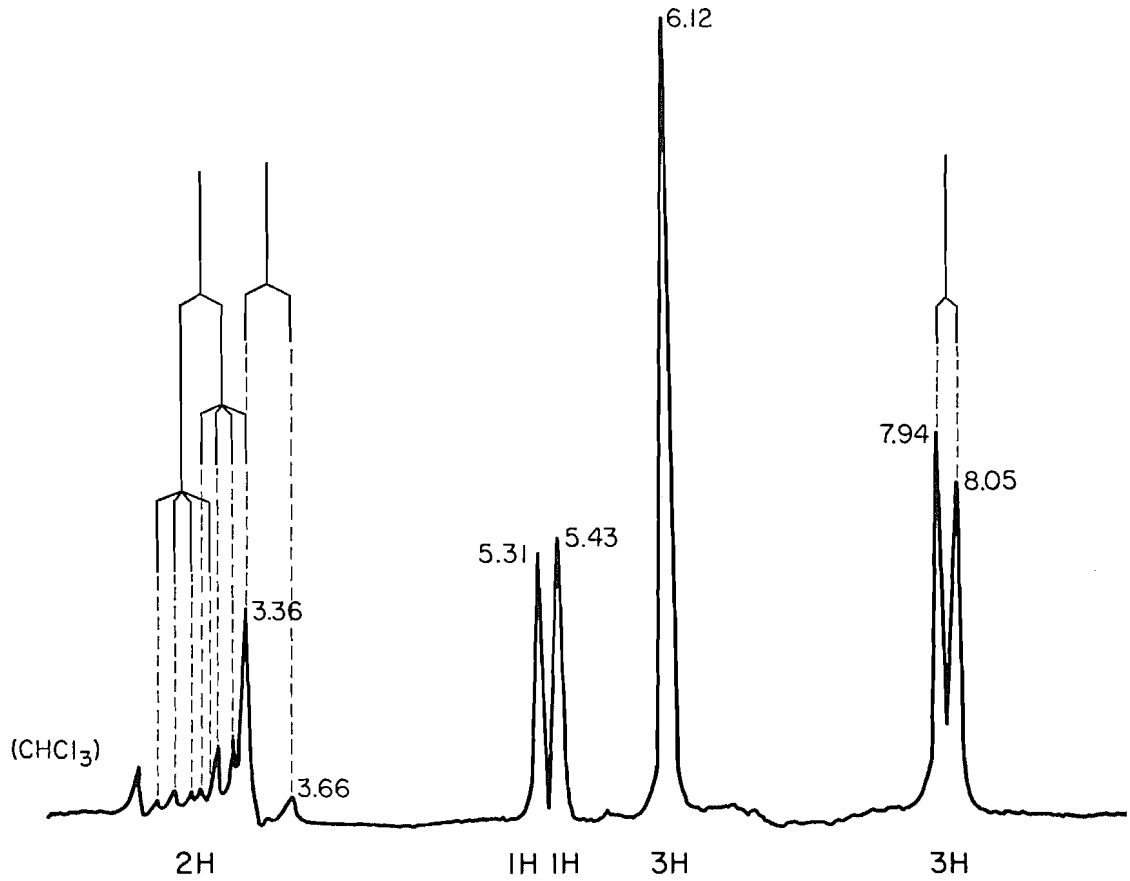

FIG. 1. The 56.4 Mc.p.s. nuclear magnetic resonance spectrum of cryptosporiopsin.

of these being accommodated in the ketone, ester, and double bonds; a ring accounts for the remaining unsaturation. The spectral data and degradative evidence (*vide infra*) eliminate structures possessing a conjugated ester group, and the remaining possiblities consistent with the cited information are represented in the partial formulae **4** and **5**.

Some structural features of the mould metabolite terrein **6** (5) suggested that the latter might be a useful model for spectroscopic comparison with cryptosporiopsin. Terrein shows ultraviolet absorption λ_{max}(EtOH) at 276 mμ (ε 25 000). The presence of a chlorine atom at the α-position would be expected to shift the maximum to 291 mμ (6), which coincides with the observed chromophore of cryptosporiopsin. Furthermore, infrared absorption (KBr disk) at 1635 and 1570 cm^{-1}, associated with the double bond system of cryptosporiopsin is also present in the terrein spectrum, as well as a peak at 965 cm^{-1} for the *trans* double bond (3).

Reduction of cryptosporiopsin with zinc in refluxing ethanol yielded an amorphous product, *m/e* 244, assigned the structure **7**. The relative abundance of the $M^+ + 2$ isotope peak demonstrates that **7** contains a single chlorine atom. The ultraviolet absorption λ_{max}(95% EtOH) at 285 mμ (ε 22 000) shows that the original chromophore is essentially unchanged. The presence of an *ethyl* ester is manifested in the n.m.r. spectrum, and in the mass spectral peak at *m/e* 171 (base peak) corresponding to the loss of the $COOC_2H_5$ fragment. The infrared spectrum (CCl_4) of **7** reveals again the presence of an internally-bonded hydroxyl group, and the carbonyl absorptions, in the absence of the chlorine α to the ester, now appear as a single band at 1730 cm^{-1}.

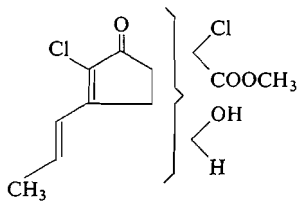
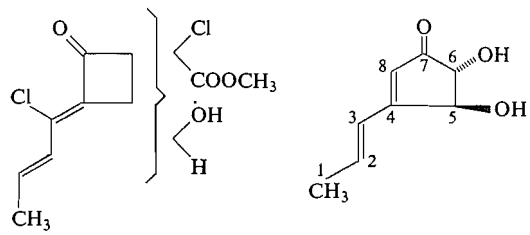
2 3



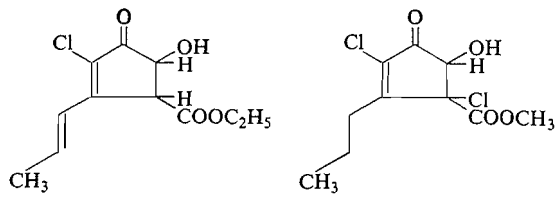
4



5 6

A dihydro product **8**, $C_{10}H_{12}O_4Cl_2$, *m/e* 266, was isolated from hydrogenation of cryptosporiopsin in ethyl acetate with a palladium-on-charcoal catalyst. Infrared absorption (KBr disk) at 1752 and 1738 cm^{-1} accounts for the chloroester and ketone respectively, while the double bond gives rise to a band at 1618 cm^{-1}. The hydroxyl shows again as a sharp peak at 3500 cm^{-1} in the spectrum measured in carbon tetrachloride solution. Ultraviolet absorption λ_{max} (absolute EtOH) at 244 mμ (ε 8300) agrees well with the predicted chromophore (6). The n.m.r. spectrum displays, *inter alia*, a two-proton multiplet at 7.35–7.61 τ, attributed to the allylic hydrogens of **8**. The methyl group appears as a poorly resolved triplet at 9.03 τ and no vinyl hydrogens are in evidence.

When hydrogenation with palladium-on-charcoal was conducted in ethanol, absorption ceased abruptly after uptake of 4 moles of hydrogen, and an oily product, *m/e* 182, corresponding to $C_{10}H_{14}O_3$ was obtained. Hydroxylic absorption is absent in the infrared spectrum



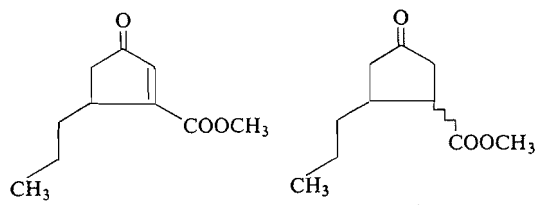
7 8

(CCl_4), and in addition to the carbonyl band at 1725 cm^{-1}, the spectrum surprisingly shows double bond absorption at 1610 cm^{-1}. Furthermore, the substance exhibits an ultraviolet maximum at 237 mμ (ε 10 000). This spectroscopic behavior can be readily interpreted in terms of the structure **9**. The primary reduction product is evidently the saturated hydroxy keto ester, which undergoes spontaneous dehydration on work-up.

Further support for structure **9** is found in the n.m.r. spectrum (4), in which the single vinyl hydrogen appears as a narrow doublet at 3.37 τ (J = 1.1 c.p.s.). A broad multiplet at 6.81 τ is attributed to the allylic proton; the low position of this resonance may be due to the anisotropy of the ester carbonyl. The two hydrogens on the saturated carbon α to the ketone constitute the AB part of an ABX system, and the appropriate pattern is discernible centered at 7.54 τ ($|J_{AB}|$ = 18.6 c.p.s.).

The mass spectrum exhibits, in addition to the molecular ion at *m/e* 182, peaks corresponding to the loss of methyl, ethyl, and propyl fragments, as well as $(M—OCH_3)^+$ and $(M—COOCH_3)^+$.

Reduction of **9** with zinc in acetic acid afforded a mixture of epimeric *cis* and *trans* keto esters **10**, not readily separable by thin-layer chromatography (t.l.c.). The mass spectrum of **10** shows



9 10

a molecular ion at *m/e* 184. A strong peak at *m/e* 114, and ions at *m/e* 97 and 87 can be rationalized in terms of the fragmentations shown in Fig. 2.

Separation of the *cis* and *trans* isomers could be effected by preparative vapor phase chromatography (v.p.c.), and the retention times of the

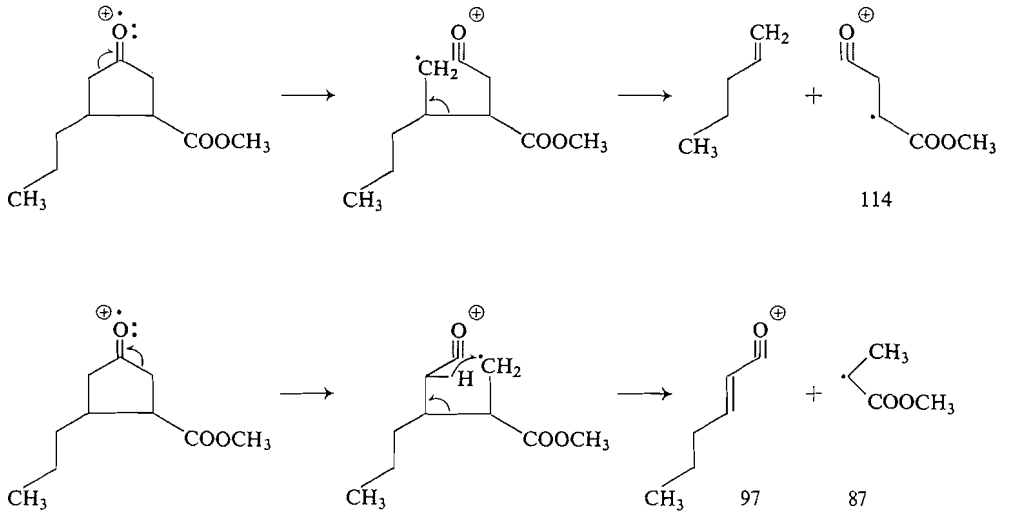


FIG. 2. The fragmentations of **10**

two fractions were identical with the major (*trans*) and minor (*cis*) constituents of a synthetic sample (*vide infra*). Comparison of the n.m.r., infrared, and mass spectra of the natural and synthetic *trans* keto esters confirmed their identities, and these compounds were further characterized as their 2,4-dinitrophenylhydrazones, $C_{16}H_{20}N_4O_6$.

Thus the skeletal structure of cryptosporiopsin is clearly defined, establishing the formulation **1** for the new antibiotic. Inspection of this structure suggests that, like terrein (7), it may arise from a polyketide chain precursor. In any scheme involving a purely polyketide route, the loss of one carbon atom must be accounted for. Birch *et al.* (7) has shown that terrein incorporates polyketide precursors with the unusual feature of two linked "carboxyl" carbons at the 6,7-positions (**6**), and attributes this distribution to a contraction of a six-membered precursor. It is reasonable to speculate that a common pathway is involved in the biosynthesis of cryptosporiopsin and terrein. Cyclization of a five-acetate unit chain with extrusion and the loss of one of the ring carbon atoms is seen to lead readily to the cryptosporiopsin system. Whereas the C-1 carboxyl is retained in cryptosporiopsin, this moiety is lost in the course of the terrein biosynthesis. Studies on further aspects of the chemistry, including stereochemistry, of cryptosporiopsin are in progress.

*Synthesis of 3-carbomethoxy-4-n-propyl Cyclopentanone **10**, cf. (8)*

2-Hexenoic acid, prepared from butyraldehyde and malonic acid by the Knoevenagel–Doebner reaction (9), was heated in a sealed vessel with butadiene to give the Diels–Alder adduct **11**, *m/e* 168. The product, after esterification, was cleaved by ozonolysis affording the ester diacid **13**, $C_{11}H_{18}O_6$. Esterification, followed by Dieckmann cyclization yielded the expected keto esters **15** (*a* and/or *b*). Hydrolysis and decarboxylation, followed by reesterification afforded *trans* and *cis* **10**, *m/e* 184, in the approximate ratio 25:4 (determined by v.p.c.).[2]

[2]This stereochemical assignment is based on the assumption that starting with predominantly *trans* 2-hexenoic acid (see Experimental), the preferred stereochemistry of the centers in question is *trans* throughout the synthetic sequence.

Experimental

Melting points were determined on a hot stage apparatus and are uncorrected. Infrared spectra were determined on a Beckmann IR-10 infrared spectrophotometer. Ultraviolet spectra were obtained on a Beckmann DK-2A spectrophotometer using 95% ethanol as solvent, except where otherwise indicated. Nuclear magnetic resonance spectra were measured in $CDCl_3$ solution with a Varian Associates 56.4 Mc.p.s. spectrometer.

The high resolution mass spectrum was obtained on a CEC 21-110B mass spectrometer, the other mass spectra were determined on a Hitachi Perkin–Elmer RMU-6D mass spectrometer. Microanalyses were performed by Spang Microanalytical Laboratory, Ann Arbor, Michigan, and by Dr. F. Pascher, Mikroanalytiches Laboratorium, Bonn, West Germany.

Cryptosporiopsin (1)

Isolation and purification of cryptosporiopsin have been described elsewhere (2). The metabolite is obtained as colorless crystals from methylene chloride – *n* – hexane, m.p. 133–137°, $[\alpha]_D^{25}$ +129° (*c*, 1.35, chloroform).

Anal. Calcd. for $C_{10}H_{10}O_4Cl_2$: C, 45.30; H, 3.80. Found: C, 45.45; H, 3.90.

Anal. Calcd. for $C_{10}H_{10}O_4Cl_2$ (high resolution mass spectrum): *m/e* 263.9956. Found: *m/e* 263.9943. Isotope peaks as percentages of M^+: $M^+ + 2$, 66%; $M^+ + 4$, 12%.

Acetylation of Cryptosporiopsin

Cryptosporiopsin (100 mg) was dissolved in acetic anhydride (6.0 ml). The solution was cooled to 0° and dry pyridine (0.6 ml) was added by syringe under nitrogen. The initially clear colorless solution was allowed to attain 25°, and was set aside with stirring in a nitrogen atmosphere for 22 h. The resulting brown reaction mixture was then evaporated to dryness and the residue was dissolved in an ether–water mixture. The organic phase was washed with 2% aqueous hydrochloric acid followed by water. The organic solution was subsequently dried over magnesium sulfate and the removal of the solvent under reduced pressure afforded 103 mg of brown gum. After chromatography on silica gel plates, 73 mg of pale-brown amorphous product was isolated. Infrared $\nu_{max}(CCl_4)$: 1741, 1759 cm^{-1} (no OH); n.m.r.: 2.78–3.77 τ (m, 2H), 4.83, 4.91 τ (s, ratio ca 0.4:1 for conformational or stereoisomers, 1H), 6.25 τ (s, 3H), 7.76, 7.83 τ (s, ratio ca 1:0.4 for conformational or stereoisomers, 3H) 7.97 τ (d, 3H); mass spectrum: M^+, 306; $M^+ + 2$, 66%; $M^+ + 4$ 12%.

Zinc–ethanol Reduction of Cryptosporiopsin

To cryptosporiopsin (100 mg, 0.377 mmole) in absolute ethanol (8 ml) was added zinc dust (131 mg, 0.002 g atom). The mixture was set aside with stirring at 25° for 20 h and was then refluxed for 7 h. Filtration removed the solid material, which was washed thoroughly with methylene chloride. The combined filtrates were washed with 2% sulfuric acid followed by water, and after drying over magnesium sulfate, removal of solvent yielded 85 mg of colorless gum. The product, 7, was chromatographed twice on preparative silica gel plates, but failed to crystallize. Infrared $\nu_{max}(CCl_4)$: 3515, 1730, 1642 cm^{-1}; ultraviolet λ_{max}(95% EtOH) 285 mμ (ε 22 000); n.m.r. 3.03–4.05 τ (m, 2H), 5.76 τ (q, J = 6.8 c.p.s., 2H), 6.01 τ (1H), 7.16, 7.22 τ (2H), 8.04 τ (d, 3H), 8.77 τ (t, J = 6.8 c.p.s., 3H); mass spectrum: M^+, 244; $M^+ + 2$, 34%.

Hydrogenation of Cryptosporiopsin, Palladium-on-charcoal – Ethyl Acetate

Cryptosporiopsin (70 mg) in ethyl acetate (30 ml) was stirred under hydrogen at atmospheric pressure and room temperature with a prehydrogenated 10% palladium-on-charcoal catalyst (30 mg) for 35 min. The catalyst was removed by filtration, and was washed thoroughly with ethyl acetate. The combined filtrates were evaporated to dryness furnishing 57 mg of colorless gum, which crystallized on standing. After recrystallization from ether–hexane the product, **8**, melted at 75–91° Spectral details are described in the text. Mass spectrum: M^+, 266; $M^+ + 2$, 66%; $M^+ + 4$, 12%.

Anal. Calcd. for $C_{10}H_{12}O_4Cl_2$: C, 44.96; H, 4.53; Cl, 26.55. Found: C, 45.00; H, 4.69; Cl, 26.49.

TABLE I

Cryptosporiopsin: accurate mass measurements of major peaks in the higher mass region of the spectrum

Peak*	Relative abundance	Observed mass	Composition	Calcd. mass (10)	Error (obs.–calcd.)	Fragment
264	36	263.9943	$C_{10}H_{10}O_4Cl_2$	263.9956	−0.0013	M^+
246	6	245.9865	$C_{10}H_8O_3Cl_2$	245.9850	+0.0015	$(M—H_2O)^+$
229	8	229.0268	$C_{10}H_{10}O_4Cl$	229.0268	0.0000	$(M—Cl)^+$
205	100	204.9828	$C_8H_7O_2Cl_2$	204.9823	+0.0005	$(M—COOCH_3)^+$
185	22	185.0375	$C_9H_{10}O_2Cl$†	185.0369	+0.0006	$(M—Cl \text{ and } CO_2)^+$
177	38	176.9871	$C_7H_7OCl_2$‡	176.9874	−0.0003	$(M—COOCH_3 \text{ and } CO)^+$

*Isotope peaks with appropriate relative intensities are present in each case.
†One of several plausible mechanistic rationales for a fragment with this composition involves migration of the ester methyl group to the carbon vacated by chlorine, through a four-center mechanism, with concomitant extrusion of CO_2. An alternative fragmentation pathway however appears also to be available for the $(M—Cl)^+$ ion. The spectrum shows a metastable peak at *m/e* 126.5 which corresponds to the decomposition 229 → 170, i.e. loss from $(M—Cl)^+$ of the $COOCH_3$ (mass, 59) fragment.
‡Metastable peak at *m/e* 153.5 (205 → 177).

Hydrogenation of Cryptosporiopsin, Palladium-on-charcoal – 95% Ethanol

Cryptosporiopsin (200 mg, 0.755 mmoles) in 95% ethanol (40 ml) was stirred under hydrogen at atmospheric pressure and 25° with a 10% prehydrogenated palladium-on-charcoal catalyst (90 mg). Absorption ceased abruptly after uptake of 4 moles of hydrogen. The catalyst was removed by filtration, and was washed thoroughly with ethanol. The combined filtrates upon the removal of solvent afforded 144 mg of pale-brown oil. Chromatography of 56 mg of this product on a silica gel preparative layer plate yielded 32 mg of colorless oily unsaturated keto ester **9**.

Spectral details are described in the text.

Due to asymmetric induction the hydrogenation product **9** was optically active, $[\alpha]_D^{30}$ −26.5° (*c*, 1.29, chloroform).

Zinc – Acetic Acid Reduction of 9

To a refluxing solution of the keto ester **9** (200 mg) in glacial acetic acid (30 ml) was added zinc dust (2.0 g) in three portions during 20 min. The resulting suspension was heated under reflux with stirring for 5 h. The solid material was removed by filtration, and was washed thoroughly with ether. The combined filtrates were evaporated to dryness, and the residue was redissolved in ether–water. The ether solution was washed with water and dried over magnesium sulfate. Removal of solvent *in vacuo* furnished 197 mg of pale-yellow gum. Chromatography on a preparative silica gel plate yielded 170 mg of colorless oil, consisting of a mixture of epimeric keto esters **10**. Although it was subsequently shown that t.l.c. did effect a partial separation of the isomers, their presence was not readily discernible on inspection of t.l.c. plates, but was however clearly manifested in the n.m.r. spectrum, in particular by the presence of two methoxyl peaks (6.24, 6.27 τ) together integrating for three protons. Separation of the epimers was effected by means of a Varian Aerograph Autoprep Model A-700; 20 ft by 3/8 in. column (30% SE 30 on Chromosorb W) at 205°, with helium as the carrier gas at 133 ml/min. Under these conditions the retention times of the two stereoisomers were (**10***a*) 21 min 15 s and (**10***b*) 22 min 55 s, identical with those of the major and minor epimeric constituents of an authentic synthetic product (considered to be *trans* and *cis* respectively—see text).

The infrared spectrum of **10***a* shows a broad carbonyl band at 1745 cm^{-1}. In the n.m.r. spectrum the methyl ester protons give rise to a sharp singlet at 6.28 τ, five deshielded hydrogens are included in a multiplet whose principal peaks are at 7.44 and 7.55 τ and the methyl protons of the propyl side chain appear as a poorly resolved triplet at 9.07 τ. The mass spectrum is similar to that of the epimer mixture **10**, and exhibits ions at *m/e* 184 (molecular ion, 5%), 114 (66%), 97 (7%), and 87 (32%) as described in the text. The base peak at *m/e* 55 corresponds to the ion $C_3H_3O^+$. In addition, peaks at *m/e* 155 (4%), 153 (5%), 141 (17%), and 125 (18%) correspond to the loss from the molecular ion of C_2H_5, OCH_3, C_3H_7, and $COOCH_3$ fragments respectively.

The infrared spectrum of the 2,4-dinitrophenylhydrazone of "natural" (dextrorotatory) **10***a*, was identical in all details with that of the derivative of racemic synthetic **10***a*.

An analytical sample, after four crystallizations from methanol, melted at 107–115°. Mass spectrum: *m/e* 364.

Anal. Calcd. for $C_{16}H_{20}N_4O_6$: C, 52.74; H, 5.53; N, 15.38. Found: C, 53.23; H, 5.61; N, 15.03.

2-Hexenoic Acid

2-Hexenoic acid was prepared according to the procedure of Niemann and Redemann (9). The crude reaction product crystallized on standing and was used in the subsequent Diels–Alder reaction without further purification. The n.m.r. spectrum indicates clearly that it consists principally of the *trans* isomer. A pair of partially superimposed triplets in the region 2.72–3.23 τ and a doublet at 4.25 τ (peaks slightly broadened due to 1,3-splitting) constitute the AB part of an ABX_2 spectrum. The coupling constant J_{AB} is 15.8 c.p.s., the correct magnitude for *trans* olefinic protons.

Preparation of 11 and 12

2-Hexenoic acid (14.3 g, 0.125 moles) was heated with butadiene (ca 7 g, 0.13 moles) and hydroquinone (100 mg) in a Parr bomb at 170–190° for 5 h.

Distillation of the brown reaction product afforded 11.7 g of colorless oily **11**, b.p. 140–150° /9 mm. In the

For personal use only.

n.m.r. spectrum the two vinyl protons appear as a somewhat broadened singlet at 4.39 τ; the mass spectrum shows a molecular ion peak at *m/e* 168.

Conversion to the methyl ester **12** was effected by refluxing **11** (7.1 g) with anhydrous methanol (40 ml) in the presence of concentrated sulfuric acid (3 ml), monitoring the progress of the reaction by t.l.c. After work-up in the usual manner, the product was distilled, and the pure ester **12** was collected at 99–102° /11 mm. Infrared $\nu_{max}(CCl_4)$ 1737, 1658 cm^{-1}; n.m.r.: 4.39 τ (broad s, 2H), 6.33 τ (s, 3H); mass spectrum: molecular ion *m/e* 182.

*Preparation of **13** and **14***

An ozone–oxygen mixture was passed by means of a sintered glass bubbler into a solution of **12** (3.75 g, 20.6 mmoles) in ethyl acetate (100 ml) cooled in a dry ice – acetone bath. (Welsbach Model T-23 ozonator, operating at 90 V, 8 lb pressure, flow rate 0.02 ft^3/min). The end point was indicated by the development of a blue color in the solution, whereupon the system was flushed with nitrogen to remove excess ozone. The solution was then stirred vigorously under hydrogen at atmospheric pressure with a prehydrogenated 10% palladium-on-charcoal catalyst (304 mg), until the calculated volume of hydrogen had been taken up. The catalyst was removed by filtration, and the solvent was stripped off *in vacuo* below 30°.

The resulting dialdehyde ($\nu_{max}(CCl_4)$ 2720 cm^{-1}, broad carbonyl 1738–1715 cm^{-1}) was dissolved in acetone (200 ml), and the solution was cooled in an ice-bath. A solution of potassium permanganate (4.88 g, 30.9 mmoles) in distilled water (200 ml) was added slowly with stirring during 40 min, and the reaction mixture was set aside with stirring at 0–10° for a further 30 min. After addition of 20% sulfuric acid (2 ml), sulfur dioxide gas was passed in until a clear solution resulted; this was extracted exhaustively with ether. After drying over magnesium sulfate, removal of solvent under reduced pressure furnished 3.767 g of colorless oil, which partially crystallized on standing. Recrystallization from ether – *n*-hexane afforded colorless crystals of **13**, m.p. 128–132°.

Anal. Calcd. for $C_{11}H_{18}O_6$: C, 53.65; H, 7.37. Found: C, 53.83; H, 7.38.

Esterification was effected by sulfuric acid-catalyzed reaction with anhydrous methanol in the usual manner.

The pure triester **14** was eluted from a silica gel column with benzene–ether (95:5).

A somewhat broadened singlet at 6.32 τ in the n.m.r. spectrum accounts for the nine methoxyl protons; $\nu_{max}(CCl_4)$ 1740 cm^{-1}.

The same product was obtained by direct oxidation of the potassium salt of **11** with aqueous permanganate, followed by esterification.

*Dieckmann Condensation of **14***

To sodium hydride (306 mg, 12.75 mmoles, washed free of mineral oil with light petroleum) was added anhydrous tetrahydrofuran (30 ml) containing 5 drops of absolute methanol. The suspension was cooled in an ice-bath, and a solution of triester **14** (1.75 g, 6.37 mmoles) in dry tetrahydrofuran (70 ml) was added during 20 min with stirring. Moderate evolution of hydrogen occurred. When the addition was complete, and effervescence ceased, a nitrogen atmosphere was introduced, and the mixture was stirred at 25° for 15 h; it was then heated under reflux for 7 h. After cooling, methanol was added cautiously to decompose any unreacted hydride, and the solution was poured on to ice. The pH was adjusted to 2–3 by addition of 5% hydrochloric acid, and the mixture was extracted thoroughly with ether. The extracts were washed with sodium bicarbonate solution, dried over magnesium sulfate, and evaporated, yielding 1.214 g of crude oily product **15** (*a* and/or *b*). The cyclized material, which was not purified further exhibits ultraviolet absorption at λ_{max}(95% EtOH) 250 mμ (ε 2000). The addition of 1 drop 5% sodium hydroxide solution shifts and enhances the chromophore to 279 mμ (ε 15 000).

*Preparation of **10***

The crude Dieckmann product **15** (*a* and/or *b*) (3.4 g) was hydrolyzed and decarboxylated by refluxing with 4 *N* hydrochloric acid (25.2 ml) for 18 h. When cool, the mixture was extracted with ether, and the combined extracts were shaken with saturated sodium bicarbonate solution. Acidification of the aqueous phase, and extraction afforded 1.97 g of acidic product **16**.

Esterification was effected by refluxing **16** (1.97 g) with methanol (75 ml) and concentrated sulfuric acid (4 ml) for 3 h. After removal of the methanol under reduced pressure, work-up in the usual manner yielded 1.5 g of pale-yellow oil, which appeared homogeneous on t.l.c.

Vapor phase chromatographic analysis of synthetic **10** thus obtained revealed the presence of two components in the approximate ratio 25:4, corresponding to the *trans* and *cis* epimers **10***a* and **10***b* respectively (*vide supra*).

The infrared, n.m.r., and mass spectra of synthetic **10***a* were completely identical with the purified "natural" dextrorotatory *trans* epimer **10***a*.

Similarly the infrared spectrum of the 2,4-dinitrophenylhydrazone of racemic synthetic **10***a* was identical with that of the corresponding derivative of the "natural" keto ester.

An analytical sample, after four crystallizations from methanol melted at 103–109°.

Anal. Calcd. for $C_{16}H_{20}N_4O_6$: C, 52.74; H, 5.53; N, 15.38. Found: C, 52.83; H, 5.55; N, 15.31.

Acknowledgments

The authors thank Dr. P. Levins, Arthur D. Little Inc., Cambridge, Massachusetts for the high resolution mass spectrum, and Mr. J. E. Anderson, Harvard University for the spin decoupling study. Gratitude is expressed to Mrs. H. Moore, Mr. H. J. Liu, and Mr. K. T. Kan, all of the University of New Brunswick, for their contributions to this work in the form of nuclear magnetic resonance, mass spectra, and optical rotation measurements respectively.

Pyrazolines VIII. Migration of a carbomethoxy group in a bromopyrazoline to pyrazole conversion[1]

D. E. McGreer and Y. Y. Wigfield
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

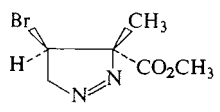
Received December 9, 1968

The stereoisomers of 4-bromo-3-methyl-3-carbomethoxy-1-pyrazoline (**1** and **2**) have been prepared and are both transformed readily into 3-methyl-4-carbomethoxypyrazole (**6**). This transformation requires preferential migration of a carbomethoxy group over a methyl group.

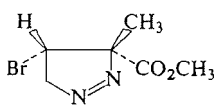
Canadian Journal of Chemistry, 47, 2095 (1969)

Pyrazolines substituted with halo, nitrile, hydroxyl, amino, or nitro groups readily undergo elimination reactions to yield pyrazoles (1). Evidence has been presented that indicates that this reaction is both acid- and base-catalyzed (2). Aromatization occurs in preference to the elimination of nitrogen and formation of cyclopropane and olefin products (3). We have prepared the stereoisomers of 4-bromo-3-methyl-3-carbomethoxy-1-pyrazoline (**1** and **2**) in the hope that double substitution at C-3 would favor the reaction leading to loss of nitrogen. This would then provide a means for evaluating the migrational aptitudes of bromine and hydrogen in the olefin-forming reaction. The only reaction which could be induced, however, was pyrazole formation. As described below pyrazoles were formed by migration of a carbomethoxy group in preference to a methyl group.

Addition of diazomethane to methyl β-bromo-α-methacrylate, (E)-[2] (**3**) and (Z)- (**4**) gave the pyrazolines **1** and **2**. Compounds **1** and **2** could not be isolated pure due to their instability; however, conclusive evidence for their structures is found in the nuclear magnetic resonance (n.m.r.) spectra of solutions in tetrachloroethylene and chloroform-*d* (see Table I and the Experimental).



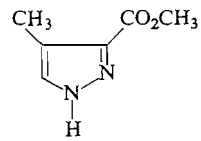
1



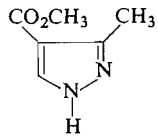
2

The magnitude of the coupling constant for the triplet and doublet multiplets is evidence that the carbon of the diazomethane has bonded to the β-carbons of **3** and **4**.

Warming of **1** or **2** neat or in solution led to an exothermic reaction which fumed apparently due to the hydrogen bromide formed. The reaction showed evidence of being autocatalytic due to a variable induction time with different samples and a sensitivity to the addition of traces of acid. The product from **1** and **2** was identical and was isolated as the hydrobromide and then converted to a pyrazole (m.p. 93–94 °C). Possibilities considered for the structure of this pyrazole were 3-carbomethoxy-4-methylpyrazole (**5**) and 3-methyl-4-carbomethoxypyrazole (**6**). An authentic sample of **5** (m.p. 171–171.5 °C, lit. (4) m.p. 172 °C) was prepared by the bromine oxidation of 3-carbomethoxy-4-methyl-2-pyrazoline (5) and proved different in many ways from our product. The pyrazole from **1** and **2** was converted to its ethyl ester (m.p. 46–48 °C, lit. (6) for the ethyl ester of **6**, m.p. 46 °C) confirming structure **6** for it.



5



6

Treatment of **1** or **2** with base might permit isolation of a 3-methyl-3-carbomethoxy-(3*H*)-pyrazole. Attempts towards this end with pyridine or quinoline, however, yielded only intractable tars.

[1]Presented at the 51st meeting of the Chemical Institute of Canada Vancouver, British Columbia, June 1968.
[2]See ref. 12 for the use of this nomenclature.

TABLE I

The nuclear magnetic resonance spectra of **1** and **2** in C_2Cl_4 in τ units with external tetramethylsilane reference

Compound	C-5 (doublet)	C-4 (triplet)	CH_3-ester	CH_3 at C-3
1	5.12(J = 4.7 Hz)	5.28(J = 4.7 Hz)	6.21	8.09
2	4.96(J = 5.4 Hz)	5.80(J = 5.4 Hz)	6.15	8.48

The preferential migration of a carbomethoxy group over a methyl during acid-catalyzed aromatization is not without precedent. A number of dienones substituted on the 4 position by an alkyl group and a carboalkoxyl group undergo similar acid-catalyzed (7) and photochemical reactions (8). In the present case acid catalysis is presumably required to activate one molecule (by formation of its salt) towards elimination by another molecule of pyrazoline. We feel that elimination occurs as a distinct step prior to migration due to the fact that the same product is isolated from **1** and **2**. Concerted migration with elimination would be expected to lead to the migration of different groups from these different stereoisomers.

Experimental

Methyl β-Bromo-α-methacrylate, (E)- (3)

Methyl β-bromo-α-methacrylate, (E)- (b.p. 162–163 °C) was prepared by the procedure of Bieber (9) from methyl α,β-dibromoisobutyrate (10).

Methyl β-Bromo-α-methacrylate, (Z)- (4)

Methyl β-bromo-α-methacrylic acid, (Z)- was prepared from 50 g of *dl-erythro*-2,3-dibromo-2-methylsuccinic acid by the procedure of Rappe and Anderson (11). The acid obtained as an oil (2.8 g) contained 20% of the E form as determined by nuclear magnetic resonance (n.m.r.) spectroscopy. Treatment with 1 mole of diazomethane gave **4** and **3** in the ratio of 72:28 respectively. The equilibrium for these forms which can be achieved by heating to 120° or by acid catalysis is about 1:400 respectively as determined by vapor-phase chromatography.

Pyrazolines

All glassware for these preparations was conditioned by treatment with 10% aqueous sodium hydroxide followed by three washes with distilled water.

An excess of diazomethane in ether was added to **3** in ether and the solution let stand overnight. Evaporation of the ether at 0 °C gave an oily product. A solution in deuteriochloroform of the 3-carbomethoxy-3-methyl-4-bromo-1-pyrazoline (**1**), having the same *trans* orientation for the bromine and carbomethoxy groups as the starting material, showed n.m.r. signals at τ 5.00 (doublet, J = 4.7 Hz), τ 5.42 (triplet, J = 4.7 Hz), τ 6.27 and τ 9.02 against an internal TMS standard. No other physical properties could be determined as the pyrazoline even at room temperature readily reacted as described below.

Treatment in a similar manner of 1.9 g of **4** (containing 28% of **3**) yielded an oily pyrazoline mixture. The n.m.r. spectrum, given in Table I, indicated the presence of 55% of **2**, 20% of **1**, and 25% of unreacted **4**.

Pyrazoline Decomposition

On warming pyrazoline **1** a vigorous reaction took place with fuming due to hydrogen bromide gas which evolved and the hydrobromide of a pyrazole, m.p. 175–177.5 °C (white needles from ethanol) was formed. The n.m.r. spectrum taken in deuterium oxide showed peaks at τ 2.04 (1H), τ 6.30 (3H), and τ 7.68 (3H). Treatment of the hydrobromide with dilute sodium bicarbonate yielded a pyrazole (70%) which was extracted with chloroform. Evaporation of the chloroform gave a solid which when crystallized from methanol melted at 93–94 °C. The n.m.r. spectrum taken in deuteriochloroform gave peaks at τ 2.05 (1H), τ 6.17 (3H), and τ 7.46 (3H).

Anal. Calcd. for $C_6H_8N_2O_2$: C, 51.42; H, 5.75; N, 20.00. Found: C, 51.49; H, 5.85; N, 19.89.

In a similar way pyrazoline **2** (mixed with 28% of **1**) decomposed to the pyrazole hydrobromide, m.p. 175–177.5 °C. Treatment of this salt with dilute sodium bicarbonate yielded the pyrazole (76%), m.p. 93–94 °C, with n.m.r. peaks in deuteriochloroform at τ 2.00 (1H), τ 6.15 (3H), and τ 7.45 (3H).

3-Methyl-4-carboethoxypyrazole

A solution of 0.5 g of the pyrazole from **1** in 10 ml of 10% sodium hydroxide was heated under reflux for 3 h. After cooling and neutralization with concentrated hydrochloric acid, 0.3 g of the free acid was collected. A solution of the acid in 20 ml of absolute ethanol saturated with dry hydrogen chloride at 0 °C was refluxed for 3 h. After cooling the solution was made basic with sodium bicarbonate and the product was taken up into chloroform. Evaporation of the solvent gave 0.37 g of an oily material which crystallized, m.p. 46–48 °C, on standing. The melting point of 3-methyl-4-carboethoxypyrazole is 46 °C (4) thus identifying our pyrazole products from **1** and **2** as 3-methyl-4-carbomethoxypyrazole (6). The n.m.r. spectrum in deuteriochloroform showed peaks at τ 2.01 (1H), τ 5.67 (quartet, J = 7 Hz), τ 7.44, and τ 8.66 (triplet, J = 7 Hz).

Convenient new synthesis of 1,3-diaroylureas[1]

JAMES F. WOLFE AND GEORGE B. TRIMITSIS
Department of Chemistry, Virginia Polytechnic Institute, Blacksburg, Virginia 24061

Received January 14, 1969

It has been found that symmetrical 1,3-diaroylureas can be prepared in good yields by allowing urea to react with aromatic esters and excess sodium hydride in refluxing 1,2-dimethoxyethane. Applications of this method to the synthesis of unsymmetrical 1,3-diaroylureas and substituted monoaroylureas are also described.

Canadian Journal of Chemistry, 47, 2097 (1969)

In connection with a continuing study of base-catalyzed condensations involving nitrogen-containing carbonyl compounds (1, 2), we had occasion to investigate the reactions of urea and certain urea derivatives with aromatic esters, employing sodium hydride as the condensing agent. During the course of this investigation it became evident that these reactions provide a facile new method for the synthesis of 1,3-diaroylureas. Unlike several previously reported methods (3–6), which are either inconvenient or of untested generality, the present procedure utilizes readily available starting materials and appears to be quite general in scope.

Results

Treatment of urea with slightly more than two molecular equivalents of the appropriate aromatic ester and excess sodium hydride in refluxing 1,2-dimethoxyethane (DME) until hydrogen evolution was complete, produced symmetrical 1,3-diaroylureas **1***a–c*, eq. [1]. Similarly, dibenzoylurea (**1***a*) and unsymmetrical diaroylureas **2***a–b* were obtained from the reaction of benzoylurea

$$NH_2CONH_2 \xrightarrow[2.\ \text{Acid}]{1.\ ArCOOCH_3,\ NaH} ArCONHCONHCOAr \quad [1]$$

1*a*, Ar = C_6H_5
b, Ar = C_6H_4Cl-*p*
c, Ar = $C_6H_4OCH_3$-*p*

with methyl benzoate, methyl *p*-chlorobenzoate, and methyl anisate, respectively. In addition, this procedure was extended to the synthesis of monoaroylureas **3***a–b*, which were produced on treatment of methylurea and phenylurea with methyl

$C_6H_5CONHCONHCOAr$
2*a*, Ar = C_6H_4Cl-*p*
b, Ar = $C_6H_4OCH_3$-*p*

$RNHCONHCOC_6H_5$
3*a*, R = CH_3
b, R = C_6H_5

benzoate and sodium hydride in refluxing DME. The results of these experiments are presented in Table I where it may be seen that yields were generally good to excellent. Incidentally, in an attempt to effect dibenzoylation of biuret by the above method, cleavage of one of the amide groups occurred and dibenzoylurea, instead of the expected dibenzoylation product of biuret, was isolated from the reaction.

Structural assignments for new diaroylureas **1***b–c* and **2***a–b* were based on analyses (Table I)

and spectral data. The i.r. spectra of these compounds, which were similar to that of dibenzoylurea, had strong NH absorption at 3360–3400 and two intense carbonyl bands at 1670 and 1750 cm^{-1}. The nuclear magnetic resonance (n.m.r.) spectra had absorption for two NH protons at 12.1–13.2 and resonance for the appropriate number of aromatic protons at 7.8–8.5 p.p.m.; the methoxy protons of **1***c* (6H) and **2***b* (3H) appeared as singlets at 4.0 and 4.3 p.p.m., respectively.

Experimental[2]

Synthesis of Symmetrical Diaroylureas ***1****a–c*

These reactions were carried out in a 1 l two-necked flask equipped with a heating mantle, a magnetic stirring bar, and a reflux condenser, connected at its upper end through a cold trap (dry ice – acetone) to a Precision Scientific wet-test meter filled with water. The other neck of the flask was connected, through rubber tubing, to a 150 ml round-bottomed flask. The reaction flask was charged with 250 ml of DME[3] and 0.50 mole of sodium hydride,[4] and a slurry of 0.05 mole of urea and 0.125 mole of the appropriate ester in 60 ml of DME was placed in the addition flask. The system was then flushed with dry nitrogen and closed to the atmosphere. The sodium hydride – DME slurry was brought to reflux, and when thermal equilibrium had been established (15–20 min) an initial reading was taken on the test meter. The slurry of urea and ester in DME was then added during 5–7 min. Readings were taken periodically on the gas meter until hydrogen evolution had ceased.[5] Most of the solvent was then removed to give a pasty residue, which was cooled to 0° in an ice-water bath. Ether (150 ml) was added, and the resulting suspension was allowed to stir for 5–10 min. Cold water (100 ml) was added cautiously, and the solid which separated between the layers was collected by filtration and acidified with cold 6 *N* HCl. The resulting solid was collected, washed with 5% sodium bicarbonate solution, and recrystallized from the appropriate solvent (see Table I). Yields and analytical data for **1***a–c* are presented in Table I.

Synthesis of Unsymmetrical Diaroylureas ***2****a–b and Substituted Monoaroylureas* ***3****a–b*

These reactions were effected essentially as described above, employing 0.05 mole of the appropriate substituted urea, 0.08 mole of the appropriate aromatic ester, and 0.25 mole of sodium hydride. The reaction mixture was refluxed until hydrogen evolution ceased,[6] and the reaction mixture was processed in the usual manner. Recrystallization solvents, yields, and analytical data for the products obtained from these reactions are presented in Table I.

[2]Melting points were taken on a Thomas–Hoover "Uni-Melt" apparatus in open capillary tubes, and are corrected. Analyses were performed by Galbraith Laboratories, Knoxville, Tenn., and by Miss Q. H. Tan using an F & M model 185 C, H, and N analyzer. Infrared (i.r.) spectra were taken on a Beckman IR-5A infrared spectrophotometer using the potassium bromide pellet method. Nuclear magnetic resonance (n.m.r.) spectra were obtained on a Varian Associates A-60 spectrometer. Chemical shifts, relative to internal tetramethylsilane, were measured to the center of a singlet or multiplet. Dimethyl sulfoxide-d_6 was used as the n.m.r. solvent. Unless specified otherwise, chemicals were commercial reagent grade and were used without further purification.

[3]The DME was distilled from sodium ribbon immediately before use.

[4]This reagent was used as a 55% dispersion in mineral oil as obtained from Metal Hydrides, Inc., Beverly, Massachusetts.

[5]In all of these experiments four molecular equivalents of hydrogen were evolved.

[6]Three molecular equivalents of hydrogen were liberated in these experiments.

Attempted Dibenzoylation of Biuret

To a suspension of 0.50 mole of sodium hydride in 250 ml of refluxing DME was added a solution of 5.16 g (0.05 mole) of biuret and 17.02 g (0.125 mole) of methyl benzoate in 150 ml of DME. The reaction mixture was refluxed for 19.5 h and then processed in the usual manner to afford, after one recrystallization from absolute ethanol, 5.10 g (38%) of 1,3-dibenzoylurea (**1***a*), m.p. 215–217°; mixture m.p. 215–217°. The i.r. spectrum of this material was identical with that of a sample of **1***a* prepared from the dibenzoylation of urea.

Selective reduction of esters with sodium trimethoxyborohydride

R. A. Bell and M. B. Gravestock

McMaster University, Hamilton, Ontario

Received December 27, 1968

The rate of reduction of representative methyl esters with sodium trimethoxyborohydride decreases in the order primary > secondary > tertiary. Sodium trimethoxyborohydride reduces with 100% selectivity the secondary ester group in the alicyclic diester–acid **2***c*.

Canadian Journal of Chemistry, 47, 2099 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Since its first preparation and brief examination of its properties in 1953 by Brown and Mead (1), sodium trimethoxyborohydride appears to have received little attention by organic chemists (2). We now report the 100% selective reduction of the alicyclic diester–acid **2***c* with sodium trimethoxyborohydride in refluxing dimethoxyethane. In order to gauge the synthetic utility of this reagent in selective ester reductions, we have measured the rates of reduction of the primary, secondary, and tertiary methyl esters, methyl 3-phenylpropionate, methyl cyclohexylcarboxylate, and methyl abietate **4**.

The diester–acid **2***c* was prepared from the known compound (3) methyl 12-oxopodocarp-13-en-16-oate **1**. Ozonolysis of **1** in ethyl acetate at 0°, followed by treatment with hydrogen peroxide in acetic acid yielded a dicarboxylic acid **2***a*, which on methylation with diazomethane afforded the triester **2***b*. Selective hydrolysis with one mole-equivalent of sodium hydroxide in methanol (4) yielded the diester–acid **2***c* in 75% overall yield from **1**.

The selective reduction of the secondary ester function in **2***c* was accomplished by treatment with a three mole-equivalent excess of sodium trimethoxyborohydride in refluxing dimethoxyethane. The ester – acid – alcohol **3** was obtained in greater than 95% yield, either as the free alcohol or in the form of its δ-lactone. Careful examination of the crude reaction product by proton magnetic resonance (p.m.r.) spectroscopy showed that the C-15 carbomethoxy group at 3.64 p.p.m. had suffered no observable reduction. The

Reduction of esters by sodium trimethoxyborohydride*

Ester	Time for 50% reduction (min)	Time for 100% reduction (min)	Product
Methyl 3-phenylpropionate	17	40	3-Phenylpropanol
Methyl cyclohexylcarboxylate	27	60	Cyclohexylcarbinol
Diester–acid **2***c*	32	75	**3**
Methyl abietate **4**	255	600	Abietenol

*3 mole-equivalents excess in refluxing dimethoxyethane at 83°.

carboxyl function at C-12 was likewise completely unaffected as demonstrated by quantitative lactone formation.

To examine the general utility of sodium trimethoxyborohydride in dimethoxyethane in ester reductions, the rates of reaction of the esters, methyl 3-phenylpropionate, methyl cyclohexylcarboxylate, and methyl abietate were measured using the same procedure as above with three mole-equivalents excess of the reagent. Reduction times and products are summarized in Table I. The expected alcohols were all produced in essentially quantitative yield and were characterized by their p.m.r. spectra and as their 3,5-dinitrobenzoate derivatives.

Since sodium trimethoxyborohydride does not react with the carboxyl group (1, 2) (except to form the carboxylate anion) it would seem that the selective reduction of ester groups in the presence of carboxylic acids is readily achieved with this reagent. The relative rates of reduction of the primary and secondary esters methyl 3-phenylpropionate and methyl cyclohexanecarboxylate (1.6:1 respectively for 50% reduction) show that some selectivity (ca. 60%) may be achieved between them (5). This selectivity could probably be improved considerably by operating at lower temperatures, for example 0°. The very slow rate of reduction of the tertiary ester, methyl abietate, indicates that excellent selectivity can be achieved between primary and secondary esters in the presence of tertiary esters and that the reagent should be of synthetic use in these areas. The total non-reaction of the axial C-15 methyl ester in the diester–acid **2***c* arises because of the severe 1,3 diaxial interaction with the C-14 methyl group. This behavior may be compared with the more normal behavior of the tertiary, equatorial C-18 methyl ester in methyl abietate which, although slow, does undergo reduction.

Sodium borohydride in large excess in methanol (6) reduces aromatic carboxylic esters to alcohols in good yields, but results with aliphatic and alicyclic esters were less satisfactory. Lithium borohydride on the other hand reduces esters well, but also attacks carboxylic acids to varying extents (2, 7) so that selective reduction of esters in the presence of acids is rarely possible. It is likely that sodium trimethoxyborohydride, despite its reactivity, is more sensitive to the steric environment of the substrate than the tetrahydro reagents. Thus, like lithium tritertiarybutoxyaluminium hydride (8) it exhibits a wide range of relative reduction rates in its reaction with esters. A variety of selective reductions amongst different functional groups can be readily carried out with alkoxyaluminohydrides (8, 9). Lithium diethoxyaluminohydride has been reported to show some selectivity in the reduction of simple esters (10). However, on currently available evidence it would appear that sodium trimethoxyborohydride is the preferred reagent for achieving reasonable selectivity in ester reductions.

In view of Brown's report (1) that sodium trimethoxyborohydride reacted only slowly with esters in ethyl ether at reflux or in *n*-butyl ether at 110–140°, we are at present investigating the possibility of a specific solvent effect by dimethoxyethane. In addition, we are examining the effects of different alcohol moieties in the ester group with a view to further improving the selectivity between primary and secondary esters.

Experimental

Melting points are uncorrected and were determined on a Köfler hot-stage apparatus. Infrared spectra were recorded in chloroform. Proton magnetic resonance (p.m.r.) spectra were determined on Varian Associates HA-100 and A-60 spectrometers in deuteriochloroform with TMS as internal standard. Mass spectra were obtained on a Hitachi Perkin–Elmer RMU-6A spectrom-

eter. Carbon and hydrogen analyses were determined by Spang Microanalytical Laboratories, Ann Arbor, Michigan.

The sodium trimethoxyborohydride used in these experiments was obtained from Alfa Inorganics Inc., Beverly, Massachusetts.

4α,10-Dimethyl-4β-carbomethoxy-8α-carboxy-decahydro-9-naphthaleneacetic Acid 2a

The α,β-unsaturated ketone **1** (3) (1.00 g (3.45 mmoles)) m.p. 124–126°, was dissolved in 25 ml of dry ethyl acetate and oxygen containing ca. 2% ozone (Welsbach T-408 ozonizer) was passed through the solution at 0° for 30 min. After removal of excess ozone with a stream of nitrogen the solvent was removed *in vacuo* at 40°. To the residue were added 30 ml of acetic acid, 20 ml of 30% hydrogen peroxide, and 10 drops of concentrated hydrochloric acid and the mixture stirred at room temperature overnight and then heated for 1.5 h on the steam bath. The product was taken up in benzene, washed thoroughly with water, then with three 50 ml portions of saturated sodium carbonate solution, and finally once with 50 ml of water. The combined alkaline washings were acidified to pH 1 with 2 *N* sulfuric acid and extracted with benzene. The washed and dried (anhydrous sodium sulfate) benzene extract was evaporated *in vacuo* to give 0.90 g (80%) of **2a** as an oil which crystallized slowly on standing. Recrystallization from hexane – ethyl acetate (4:1) gave the diacid as colorless needles m.p. 182–184°; i.r. ν_{max}, 3500–2500 (COOH), 1730–1700 cm^{-1} (>CO, $COOCH_3$ and COOH); p.m.r. δ, 0.66 (s, 3H, C-14 CH_3); 1.20 (s, 3H, C-16 CH_3); 3.66 (s, 3H, $COOCH_3$); 10.5–11.5 p.p.m. (broad, 2H, COOH).

Anal. Calcd. for $C_{17}H_{26}O_6$: C, 62.56; H, 8.03. Found: C, 62.64; H, 8.11.

Methyl 4α,10-Dimethyl-14β,8α-dicarbomethoxy-decahydro-9-naphthalene-acetate 2b

Methylation of the diacid **2a** was carried out by the addition of a freshly prepared solution of diazomethane in ether to a stirred solution of 0.650 g (2 mmoles) of **2a** in ether–methanol at room temperature. Evaporation of the solvent *in vacuo* afforded 0.705 g (99–100%) of the crystalline triester **2b**. Recrystallization from hexane – ethyl acetate (9:1) yielded **2b** as colorless prisms m.p. 91.5–92.5°; i.r. ν_{max} 1740 (C-12 $COOCH_3$), 1735 (C-13 $COOCH_3$), 1725 (C-15 $COOCH_3$), 1220, and 1165 cm^{-1} (O—CH_3); p.m.r. δ, 0.59 (s, 3H, C-14 CH_3); 1.13 (s, 3H, C-16 CH_3), 3.53 (s, 3H, C-15 $COOCH_3$), 3.50 (s, 3H, C-13 $COOCH_3$), and 3.48 p.p.m. (s, 3H, C-12 $COOCH_3$); mol. wt. 354 (mass spectrum).

Anal. Calcd. for $C_{19}H_{30}O_6$: C, 64.38; H, 8.53. Found: C, 64.44; H, 8.11.

4α,10-Dimethyl-4β,8α-dicarbomethoxy-decahydro-9-naphthaleneacetic Acid 2c

To a sample of 1.00 g (2.83 mmoles) of triester **2b** (m.p. 89–91°) dissolved in 32 ml of methanol were added 2.85 ml of 1 *N* sodium hydroxide and 57.0 ml water (making the total solution 0.05 *N* in sodium hydroxide). The mixture was refluxed with stirring under nitrogen for 3.5 h. After removal of the majority of methanol *in vacuo*, the aqueous residue was washed with ether (3 × 50 ml) and the ethereal washings counterwashed with 50 ml of water. The aqueous phases were then combined and acidified to pH 1 with 2 *N* sulfuric acid and extracted with benzene. The benzene layer was washed with water, dried with anhydrous sodium sulfate, and after evaporation *in vacuo* yielded 875 mg (91%) of **2c** as an oil which crystallized on standing. Recrystallization from hexane – ethyl acetate (9:1) gave **2c** as colorless plates m.p. 138–139°; i.r. ν_{max} 3600–2600 (COOH), 1735 ($COOCH_3$), 1715 (COOH), 1220 and 1165 cm^{-1} (O—CH_3, CH_2—O); p.m.r. δ, 0.63 (s, 3H, C-14 CH_3), 1.16 (s, 3H, C-16 CH_3), 3.57 (s, 3H, C-15 $COOCH_3$), 3.54 (s, 3H, C-13 $COOCH_3$), 11.32 p.p.m. (broad, 1H, COOH).

Anal. Calcd. for $C_{18}H_{28}O_6$: C, 63.51; H, 8.29. Found: C, 63.54; H, 8.21.

Work-up of the neutral ether washings yielded 90 mg of crystalline unchanged starting material **2b**.

4α,10-Dimethyl-4β-carbomethoxy-8α-hydroxymethylene-decahydro-9-naphthaleneacetic Acid 3

A solution of 0.500 g (1.47 mmoles) of diester-acid **2c** in 50 ml dimethoxyethane (freshly distilled from calcium hydride) was added dropwise to 2.25 g (5.85 mmoles) of sodium trimethoxyborohydride in a 200 ml flask under a nitrogen atmosphere. After a short period of frothing and hydrogen evolution, the mixture was stirred and brought to reflux for 75 min. After cooling, the reaction mixture was poured into cold water, acidified with 2 *N* sulfuric acid and the liberated product extracted with benzene. The benzene extracts after washing with water, brine and drying (anhydrous sodium sulfate) afforded on evaporation *in vacuo* 0.45 g (98%) of crystalline hydroxy-acid **3**. However, recrystallization from hexane – ethyl acetate yielded colorless plates m.p. 136–137° which were found to be the δ-lactone of **3**. The impure crystalline **3** showed: i.r. ν_{max} 3600–2550 (COOH), 1730 ($COOCH_3$), 1720 cm^{-1} (COOH); p.m.r. δ, 0.68 (s, 3H, C-14 CH_3), 1.18 (s, 3H, C-16 CH_3), 3.64 (s, 3H, $COOCH_3$), 3.75 and 4.28 (m, 2H, AB part of an ABX, J_{AB} = 11 Hz, J_{BX} = 10 Hz, and J_{AX} = 5 Hz; C-13 CH_2), 8.70 p.p.m. (broad, 2H, COOH and OH). It was not possible to recrystallize **3** even from cold, nonpolar solvents without the loss of water and quantitative formation of the δ-lactone. The lactone showed: m.p. 136–137°; i.r. ν_{max} 1730 ($COOCH_3$), and 1725 cm^{-1} (δ-lactone); p.m.r. δ, 0.675 (s, 3H, C-14 CH_3), 1.16 (s, 3H, C-16 CH_3), 3.72 (s, 3H, $COOCH_3$), 3.66 and 4.20 (m, 2H, AB part of an ABX, J_{AB} = 11 Hz, J_{AX} = 5 Hz, and J_{BX} = 11 Hz; C-13 CH_2); mol. wt. 294 (mass spectrum).

Anal. Calcd. for $C_{17}H_{26}O_4$: C, 69.36, H, 8.90. Found: C, 69.38; H, 8.83.

The similarity in coupling constants for the ABX system formed by the C-13 protons (H_A and H_B) and the C-8 proton (H_X) for the δ-lactone and hydroxy-acid **3** suggests, not unexpectedly, that the hydroxyl group of **3** hydrogen bonds with the carboxyl and that **3** adopts a conformation very similar to that of the δ-lactone.

Reduction of Methyl Esters

The same procedure was followed for the three esters, methyl 3-phenylpropionate, methyl cyclohexylcarboxylate, and methyl abietate **4**.

To a solution of 5.0 mmoles of an ester in 50 ml of dimethoxyethane were added 20 mmoles of sodium trimethoxyborohydride and the mixture stirred under reflux under a nitrogen atmosphere. Five millilitre aliquots of the reaction mixture were withdrawn at appropriate times, quenched in dilute acid and examined by p.m.r. spectroscopy for the extent of reduction. In all three cases it was possible to observe the rate of disappearance of the ester group by integrating the area under the ester methyl absorption and comparing it with the area under absorptions arising from protons common to both the starting ester and the alcohol products. The results are shown in Table I. The 3,5-dinitrobenzoate derivatives of the products were prepared in the usual way and gave satisfactory melting points. The p.m.r. spectra of the products were consistent with expected alcohols.

Chemistry of the aminochromes. Part XIII. Some further observations on the reactions of the aminochromes with thioglycollic acid[1,2]

W. Powell[3,4] and R. A. Heacock[5]

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia and Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received September 16, 1968

Thioglycollic acid reacts with adrenochrome in aqueous solution to give 5,6-dihydroxy-1-methylindole and 4-*S*-carboxymethylthio-5,6-dihydroxy-1-methylindole, together with smaller amounts of the lactone obtained by intramolecular cyclization of the latter compound. When the reaction is carried out in the absence of water the relative amount of 5,6-dihydroxy-1-methylindole formed is markedly reduced. At lower temperatures 4-*S*-carboxymethylthio-5,6-dihydroxy-1-methylindole is the main product obtained, whilst at higher temperatures the corresponding lactone predominates.

The major products obtained by the action of thioglycollic acid on 4- and 7-methyladrenochrome in aqueous solution were 5,6-dihydroxy-1,4-dimethylindole and 4-*S*-carboxymethylthio-5,6-dihydroxy-1,7-dimethylindole respectively.

Canadian Journal of Chemistry, 47, 2102 (1969)

The reduction of adrenochrome (**1**) by thioglycollic acid was first reported in 1945 (1). Some years later an examination by paper chromatography of the products formed when this reaction was carried out in aqueous solution at room temperature, indicated that two major products were consistently obtained and that they were accompanied by lesser amounts of two other products (2). The two major products have subsequently been identified as 5,6-dihydroxy-1-methylindole (**2**) and 4-*S*-carboxymethylthio-5,6-dihydroxy-1-methylindole (**3**) (3). Analogous products also appear to be formed by the action of thioglycollic acid on related simple aminochromes (3).

reaction mixtures, obtained by the action of thiols on aminochromes, has usually been carried out either spectroscopically or chromatographically on paper, with 2% acetic acid in water as running solvent and with descending or radial development. Using the descending technique the products **2** and **3** had R_f values of ca. 0.45 and ca. 0.50 respectively (2, 3). Whilst the chromatographic separation of **2** and **3** was not very good the products could easily be separated on the basis of the solubility of **3** in aqueous sodium bicarbonate. The more important minor product observed in the aqueous adrenochrome – thioglycollic acid reaction mixtures had an R_f value of ca. 0.18 under these conditions (2, 3). On the basis of the previously reported (2,3) color reactions of this product and the fact that it is not soluble in aqueous sodium bicarbonate, it appeared likely that the substance does not contain a carboxylic acid group but contains divalent sulfur, an indole nucleus, and phenolic groups.

It was observed in the course of preliminary chromatographic studies of this and other reactions of adrenochrome (**1**) that thin-layer chromatography (t.l.c.) of these reaction mixtures on cellulose layers was in many ways superior to paper chromatography, giving faster and in many cases better separations of the products. Consequently t.l.c. on cellulose layers using 2% acetic acid in water was used exclusively in this investigation.

The reaction between adrenochrome and thioglycollic acid has been studied under a variety of conditions including (*a*) reaction in aqueous solution at room temperature, (*b*) reaction under anhydrous conditions (i.e. in the absence of solvent) at room temperature, and (*c*) reaction under anhydrous conditions at 120°. The products were separated on cellulose layers using 2% acetic acid in water as running solvent.

In the first case the chromatographic picture was, as would have been expected, essentially the same as that previously observed (2, 3). The two main products detected were **2** and **3** with R_f values of 0.45 and 0.49 respectively. In order to observe the products clearly it was necessary to effect a preliminary separation of the reaction mixture on the basis of the solubility of **3** in aqueous sodium bicarbonate. The minor product, which was insoluble in aqueous sodium bicarbonate, and which had an R_f value of ca. 0.13 in this system was also observed as a fairly intense spot.

When the reaction was carried out under anhydrous conditions, however, the relative amounts of the products formed were quite different; the amount of 5,6-dihydroxy-1-methylindole (**2**) formed was considerably less and the relative amounts of 4-*S*-carboxymethylthio-5,6-dihydroxy-1-methylindole (**3**) and the unknown (R_f, 0.13) considerably increased. At room temperature significant amounts of **3** were present but when the reaction was carried out at elevated temperatures and for longer periods (i.e. at 120° for 3 h) the product R_f, 0.13 was the only major product observed. A more extensive survey of the color reactions of this compound suggested that, together with an indole nucleus (positive reactions with Ehrlich's reagent, cinnamaldehyde, and *p*-*N*,*N*-bis(2-chloroethyl)-aminobenzaldehyde) and divalent sulfur (positive reaction with the alkaline sodium nitroprusside reagent (cf. 4)), it contained a monophenolic hydroxyl group rather than the catechol system. Positive reactions for a phenolic hydroxyl group were obtained with ferric chloride, the Folin–Ciocalteu reagent, and Gibb's phenol reagent. A strongly positive reaction was obtained with the 4-aminoantipyrene reagent only after overspraying with potassium ferricyanide, suggesting that a monophenolic hydroxyl rather than an *o*-diphenol group was present in the molecule (cf. 5). All the evidence available at this point

suggested that this product was the lactone **4** derived from 4-*S*-carboxymethylthio-5,6-dihydroxy-1-methylindole (**3**). This was confirmed by the isolation of the crystalline monoacetyl derivative of **4**, i.e. 6-acetoxy-4-*S*-carboxymethylthio-5-hydroxy-1-methylindole lactone (**5**). This product was identical in all respects to samples of **5** previously prepared by the treatment of **3** directly with acetic anhydride and pyridine (3).

An analogous lactone described as hydroquinone α-thioacetic acid lactone was obtained several years previously by Snell and Weissberger (6) when the crude products obtained by the action of thioglycollic acid on *p*-benzoquinone were either allowed to stand in a vacuum desiccator over phosphorous pentoxide or were heated to 150°.

The present investigation has confirmed previously reported preliminary results (3) which suggested that in general, thiols react with 4-alkyl substituted aminochromes to give only one significant product, namely the corresponding 4-alkyl-5,6-dihydroxyindole, whereas 7-alkyl substituted aminochromes give mainly the 7-alkyl-4-*S*-carboxymethylthio-5,6-dihydroxyindole derivative. 4-*S*-Carboxymethylthio-5,6-dihydroxy-1,7-dimethylindole (**6**) was the main product obtained by the action of thioglycollic acid on 7-methyladrenochrome (**7**) in aqueous solution. A smaller, but significant quantity of the corresponding lactone (i.e. **8**) was also formed at the same time; however, only minute amounts of a third product, which was probably 5,6-dihydroxy-1,7-dimethylindole (**9**), were detected in the reaction mixtures. The *O*-acetyl derivative (i.e. **10**) of the lactone **8** was isolated as a crystalline solid after treatment of the major product, i.e. 4-*S*-carboxymethylthio-5,6-dihydroxy-1,7-dimethylindole (**6**) with acetic anhydride and pyridine. 5,6-Dihydroxy-1,4-dimethylindole (**11**) was the only significant product formed by reduction of 4-methyladrenochrome (**12**) with thioglycollic acid.

Experimental

A. The Reaction of Adrenochrome with Thioglycollic Acid

Adrenochrome was prepared by the method of Heacock *et al.* (7).

I. Preliminary Reactions

(i) Non-aqueous reactions—Adrenochrome (3 mg) was dissolved in anhydrous thioglycollic acid (ca. 0.5 ml) and the resulting dark yellow-brown solution was divided into two approximately equal parts. After being allowed to stand at room temperature for ca. 1 h, one part of the reaction mixture was poured into water (3 ml) and excess solid sodium bicarbonate added; the reaction mixture was extracted with ether (4 × 2 ml) to remove phenolic but not acidic products (*extract A*). The mother liquors were acidified with 2 *N* hydrochloric acid and extracted with ether (4 × 2 ml) to remove acidic products (*extract B*). The second half of the original reaction mixture was heated on an oil-bath at 120° for 3 h, after which time it was cooled and poured into water (3 ml) and the products worked up in the manner described above, giving ether extracts containing phenolic (*extract C*) and acidic (*extract D*) products.

(ii) Aqueous reaction (cf. 2, 3)—Thioglycollic acid was added dropwise to a solution of adrenochrome (3 mg) in water (1 ml) until the red color of the solution was

‖The spot (R_f, 0.85), which was of variable intensity, was due to excess thioglycollic acid.

totally discharged. The aqueous reaction mixture was then treated with an excess of sodium bicarbonate and the products worked up in the manner described above to give ether extracts containing phenolic (*extract E*) and acidic (*extract F*) products.

(iii) Chromatography—The extracts *A*–*F* were examined by t.l.c. on cellulose layers (Eastman "Chromagram" sheet, 20 × 20 cm) using 2% acetic acid in water as running solvent. The developed chromatograms were dried and sprayed with several different chromogenic reagents. The results of the chromatographic examination of these extracts are shown in Table I.

*II. Isolation of 6-Acetoxy-4-S-carboxymethylthio-5-hydroxy-1-methylindole Lactone (**5**)*

A solution of adrenochrome (0.5 g) in thioglycollic acid (15 ml) was heated on an oil bath at 120° for 3 h. After cooling, the reaction mixture was poured into saturated aqueous sodium bicarbonate solution (200 ml) and the resulting suspension was extracted with ether (3 × 250 ml). A mixture of acetic anhydride (2.5 ml) and dry pyridine (2.5 ml) was added to the combined, dried (Na_2SO_4), ether extracts and the reaction mixture allowed to stand at room temperature overnight. After removal of the ether *in vacuo* the concentrated acetylation mixture was poured slowly, with stirring, into ice–water (250 ml). The pale-yellow gummy solid which was obtained was dissolved in benzene and purified chromatographically on a short silica gel[6] column (1.8 × 10 cm) with adsorption from and elution with benzene. The crude solid obtained on concentration of the benzene eluant gave 6-acetoxy-4-*S*-carboxymethylthio-5-hydroxy-1-methylindole lactone as colorless needles (125 mg; m.p. 156–159°). The identity of this product with samples of **5**, previously prepared, was established by the non-depression of m.p. and by the identity of their infrared and nuclear magnetic resonance spectra (cf. ref. 3).

Anal. Calcd. for $C_{13}H_{11}NO_4S$: C, 56.30; H, 4.00; N, 5.05; S, 11.57. Found: C, 56.69; H, 3.98; N, 5.07; S, 11.69.

[6]Malinckrodt "SilicaR" (100–200 mesh size) silica gel was used throughout this investigation.

B. The Reactions of 4- and 7-Methyladrenochrome with Thioglycollic Acid

4-Methyladrenochrome (**12**) and 7-methyladrenochrome (7) were prepared by the method of Heacock and Hutzinger (8).

I. Preliminary Reactions (cf. 2,3)

Thioglycollic acid was added dropwise to the aqueous aminochrome solution (2 mg/ml) until no further color changes occurred. The aqueous reaction mixtures were then treated with an excess of solid sodium bicarbonate and the products worked up in the manner described above for the reactions involving adrenochrome to give phenolic and acidic extracts.

The various extracts were examined by t.l.c. using the procedure described above. The results of the chromatographic investigations are given in Table II.

*II. Isolation of 6-Acetoxy-4-S-carboxymethylthio-5-hydroxy-1,7-dimethylindole Lactone (**10**)*

Thioglycollic acid (0.5 ml) was added, dropwise with stirring, to a solution of 7-methyladrenochrome (300 mg, prepared by the method of Heacock and Hutzinger (8)). The reaction mixture was stirred at room temperature for a further few minutes, after which time excess solid sodium bicarbonate was added. The neutralized reaction mixture was immediately extracted with peroxide-free ether (5 × 100 ml), cautiously acidified with 2 *N* hydrochloric acid, and further extracted with ether (5 × 100 ml). A mixture of acetic anhydride (1.5 ml) and pyridine (1.5 ml) was added to the combined, dried (Na_2SO_4) ether extracts of the acidified reaction mixture. The ethereal acetylation mixture was allowed to stand overnight at room temperature after which time the ether was removed *in vacuo* and the concentrated reaction mixture poured dropwise with stirring into ice–water (150 ml). The crude product, a light green tarry precipitate, was dissolved in benzene and purified chromatographically on a silica gel column (6 × 1.8 cm). The column was eluted with benzene and a series of 25 ml fractions collected. The fractions were monitored by t.l.c. using the F_1[7] reagent. The first three fractions did not react with

this reagent and were discarded; fractions 4–11, which reacted positively with the F_1 reagent were combined and the benzene removed *in vacuo*. Recrystallization of the crude white crystalline solid, so obtained, from light petroleum (b.p. 80–100°) gave 6-acetoxy-4-*S*-carboxymethylthio-5-hydroxy-1,7-dimethylindole lactone (**10**) as white needles (53 mg, m.p. 202–204°). The proton magnetic resonance spectrum of this product in $CDCl_3$ indicated the presence of two C—CH_3 groups at τ 7.62 and 7.45; an S—CH_2— group at τ 6.54; an N—CH_3 group at τ 5.98; the indole β-proton at τ 3.64 ($J_{2,3}$ = 3 Hz); and the indole α-proton at τ 3.03 ($J_{2,3}$ = 3 Hz).

Coupling reaction between 4-*t*-butyl-*o*-benzoquinone and methyl linoleate

TAKASHI KATO, MAKOTO TANIAI, KAZUYUKI YOKOO, AND JU KUMANOTANI

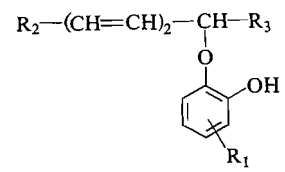
The Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Received January 2, 1969

This is the first report on the dehydrogenation-coupling reaction of an *o*-quinoid compound with a 1,4-diolefinic compound. The reaction of 4-*t*-butyl-*o*-quinone and methyl linoleate has been studied, and the product which has a 1-(2′-hydroxy-4′(or 5′)-*t*-butylphenoxy)-2,4-pentadienyl structure has been separated and identified.

Canadian Journal of Chemistry, 47, 2106 (1969)

Previously we reported that urushiol quinone reacts with the side chain of a triolefinic component of urushiol (3-(8′,11′,13′-pentadecatrienyl)-catechol) during the laccase-catalyzed oxidation process of Japanese lacquer, giving a coupling product with a phenyl ether linkage and a conjugated triene structure (1). As a further example of this type of reaction, we now describe the formation of a coupling product (**1**) in the reaction of 4-*t*-butyl-*o*-quinone with methyl linoleate at room temperature.



1

R_1 = *t*-butyl attached to 4 or 5 position

$\begin{cases} R_2 = (CH_2)_7—COOCH_3 \\ R_3 = (CH_2)_4—CH_3 \end{cases}$

and/or

$\begin{cases} R_2 = (CH_2)_4—CH_3 \\ R_3 = (CH_2)_7—COOCH_3 \end{cases}$

Concerning the reactions of *o*-quinones with unsaturated hydrocarbons, it is known that a high potential *o*-quinone, e.g., tetrachloro-*o*-quinone, abstracts hydrogen from the latter (2,3). It has been also reported that hydroquinone α-tetralyl ether derivatives were obtained by the reaction between the high potential *p*-quinone derivatives and tetralin (4,5). In those cases, however, an elevated temperature (4) or a radical initiator (5) was required. Therefore, this is the first report on the dehydrogenation-coupling reaction of an *o*-quinone with a 1,4-diene system.

The reaction product (**1**) was separated by thin-layer chromatography (t.l.c.) and identified. The results of the elemental analysis and the molecular weight measurement indicate that the compound is a coupling product between methyl linoleate and 4-*t*-butyl-*o*-quinone. The presence of a hydroxyl group and a benzene nucleus is obvious in view of the finding of the infrared (i.r.) absorptions at 3600–3200 cm^{-1}, and at 1599 and 1510 cm^{-1}, respectively. The conjugated diene structure was identified by the ultraviolet (u.v.) and i.r. absorptions at 234 mμ (ε 27 900) and 991

cm^{-1}, respectively. The nuclear magnetic resonance (n.m.r.) signal at τ 5.38 undoubtedly revealed the presence of the phenyl ether linkage by which two reactants were combined in this product (1, 6). Upon hydrogenation over 5% Pd-on-charcoal, this signal was observed to shift to an appreciably higher field at τ 5.73. This indicates that the phenyl ether bond is adjacent to the conjugated diene. Three different signals due to hydroxyl protons at τ 4.2–4.4 observed with the hydrogenated product may be attributed to the isomeric structures of the coupling product. However, the bonding position of the phenyl ether linkage in the olefinic chain and that of *t*-butyl in the benzene ring were not determined in this study.

Experimental

The infrared (i.r.) spectra were obtained with a Nihon-Bunko IR-spectrophotometer, model IR-S. The ultraviolet (u.v.) spectra were taken in ethanol with a Hitachi spectrophotometer, EPS-2. The nuclear magnetic resonance (n.m.r.) spectra were determined in deuteriochloroform at 60 Mc.p.s. with a Nihon-Denshi n.m.r. spectrometer, JMN C-60. The chemical shifts are described in τ values relative to tetramethylsilane as an internal standard. The molecular weights were measured in methyl ethyl ketone with a vapor pressure osmometer, model 301-A, Mechrolab., Inc. The silica gel layers used for thin-layer chromatography (t.l.c.) were made from Silica Rider (silica gel with 12–14% calcium sulfate, purchased from the Daiichi Pure Chemicals), and were activated at 105° for 1.5 h.

Materials

Methyl linoleate (93.8% with 6.2% of methyl oleate by gas–liquid chromatography (g.l.c.) was obtained from safflower oil. 4-*t*-Butyl-*o*-quinone was prepared from 4-*t*-butylcatechol (b.p. 129–131°/3 mm) by the method described in the literature (7).

Isolation of the Coupling Reaction Product between 4-t-Butyl-o-quinone and Methyl Linoleate

Methyl linoleate (7.19 g, 0.0245 mole) and 4-*t*-butyl-*o*-quinone (1.32 g, 0.0081 mole) were reacted at room temperature for 50 h. The reaction mixture was dissolved in *n*-hexane and applied as a spot on the silica gel layer (thickness, 0.25 mm). It was then chromatographed in an *n*-hexane–ether (4:1 v/v) solvent tank using the ascending technique. The developing distance was 12–14 cm. A filter paper (20 × 20 cm) impregnated with the developing solvent was inserted into the tank in order to saturate the atmosphere with the solvent vapor. The chromatogram gave, when sprayed with methanol – 1% $FeCl_3$ solution, the spots with R_f 0.43 (green, main) and 0.14 (dark brown), and the starting spot, and when further sprayed with an aqueous sulfuric acid solution (1:1) and heated at 150° for 30 min, it gave a new spot with R_f 0.60 (methyl linoleate). The compound with R_f 0.43 was collected by t.l.c. in the manner similar to that described previously (1), and a faintly yellow oil (**1**) was obtained (20% based upon the quinone).

Anal. Calcd. for $C_{29}H_{46}O_4$ (mol. wt. 458.7): C, 76.00; H, 10.12. Found (mol. wt. 514): C, 76.09; H, 10.06.

Infrared: ν_{max}(liquid film) 3600–3200 (m), 2930 (vs), 2870 (vs), 1745 (vs), 1657 (w), 1599 (w), 1510 (m), 1461 (m), 1435 (m), 1367 (m), 1279 (s), 1210 (vs), 1174 (s), 1125 (m), 991 (vs), 852 (w), 814 (w), and 727 cm^{-1} (w); u.v.: λ_{max} 234 (ε 27 900) and 283 mμ (3660); n.m.r.: τ 2.8–3.3 (3H, aromatic protons, multiplet), τ 3.3–5.0 (5H, olefinic and hydroxyl protons (1), multiplet), τ 5.38 (1H, phenoxymethine proton (6), broad), τ 6.33 (3H, protons of methyl ester, singlet), and τ 7.5–9.5 (34H, among broad signals were observed sharp signals at τ 8.69 due to methylene protons, τ 8.74 due to *t*-butyl protons and τ 9.13 due to methyl protons).

Hydrogenation of the Coupling Product

The coupling product (309 mg) was hydrogenated in ethyl acetate (10 ml) under an atmospheric pressure of hydrogen over 5% Pd-on-charcoal (51 mg) for 5 h; it absorbed 2.0 moles of hydrogen per mole. By removing the catalyst and the solvent from the reaction mixture the hydrogenated product resulted. It was further purified similarly by t.l.c. and a faintly yellow oil which gave one spot with R_f 0.52 was obtained.

Infrared: ν_{max}(liquid film, 1000–900 cm^{-1}) ca. 1005 cm^{-1} (m); u.v.: λ_{max} 231 (ε 5280, shoulder), and 283 mμ (2150); n.m.r.: τ 2.9–3.4 (3H, aromatic protons, quasi-triplet), τ 4.2–4.4 (1H, hydroxyl proton, quasi-triplet), τ 5.73 (1H, phenoxymethine proton, broad), τ 6.33 (3H, protons of methyl ester, singlet), τ 7.70 (2H, protons of the methylene adjacent to carbonyl, triplet, $J = 7$ c.p.s.), τ 8.0–9.0 (37H, methylene protons, signals were centered at τ 8.73), and τ 9.13 (3H, methyl protons, triplet, $J = 5$ c.p.s.).

Acknowledgment

The authors wish to express their gratitude to Dr. K. Yoshitomi (the Nisshin Oil Mills Ltd.) for the supply of methyl linoleate used in this study.

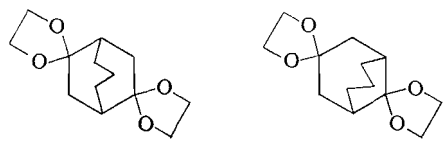
Mass spectral fragmentation of some bicyclic diketals. Evidence for ethylenedioxycarbene

GORDON WOOD AND E. P. WOO[1]
Department of Chemistry, University of Windsor, Windsor, Ontario
Received September 24, 1968

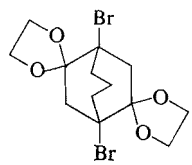
Some evidence is presented for a novel mass spectral fragmentation of certain bicyclic diketals.
Canadian Journal of Chemistry, 47, 2108 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In connection with the preparation and study of some bicyclic analogues of cyclohexane-1,4-dione (1) we had mass spectra of several intermediates determined.[2] We wish to report here some evidence for the loss of ethylenedioxycarbene (or its equivalent) as an important mode of fragmentation for diketals **1**, **2**, and **3**.



1 **2**



3

Table I lists the most abundant peaks of **1** and **2**, and selected peaks from **3**. It can be seen that both **1** and **2** show characteristic ketal peaks (2) at *m/e* 99 (base), 112, 125 etc. In addition, both show a significant peak at *m/e* 168. This peak corresponds to *P*-72 and if this peak arises directly from fragmentation of the parent, a metastable peak at *m/e* 117.6 would be anticipated. In both cases a metastable ion near *m/e* 118 is found.

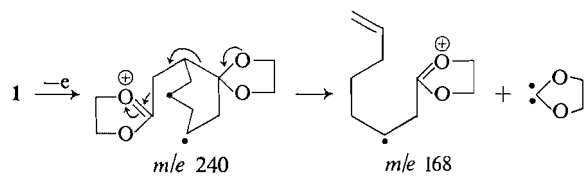
Although considerable study has been done of mass spectral fragmentation of ketals (2–6), and the usefulness of these derivatives has been pointed out (3, 5, 6), to our knowledge mass spectral fragmentation involving the loss of a neutral species equivalent to ethylenedioxycarbene has not previously been observed.[3] We tentatively conclude that expulsion of the carbene may require a second ketal group or other functionality suitably located.[4]

TABLE I
Mass spectra of some bicyclic diketals

	Relative abundance*		
m/e	**1**	**2**	**3**
28	8.3	38.7	
41	19.9	17.0	
43	9.3	10.7	
45	5.5	10.1	
55	29.4	32.2	
86	33.1	17.0	
99	100 (base)	100 (base)	11.8
100	11.0	17.0	
112	8.3	18.0	8.0
113	12.4	37.4	61.5
125	35.9	24.1	17.3
139	4.1	22.2	
153	2.4	18.0	
168	13.4	15.8	
195	3.3	10.6	
240	13.4	10.0	
241	2.4	1.7	
245			100 (base)
247			98.0
317			88.5
319			86.0

*For **1** and **2** all ions of relative abundance 10% or greater in one of them are tabulated. For **3**, only selected ions are shown.

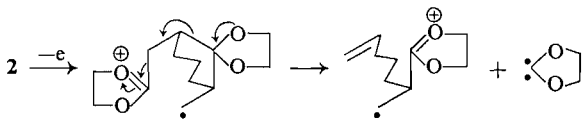
One rationale for the process does place positive charge on oxygen in the remaining ketal moiety.



[1]Holder of a Province of Ontario Fellowship 1965–1968. Present address: Department of Chemistry, University College, London, England.
[2]Mass spectra were determined by Morgan Schaffer Corporation, Montreal.
[3]Some evidence for formation of this carbene and related species from thermal decomposition has been presented (7).
[4]The mass spectra of diketals in ref. 4 show no evidence of this process.

A mechanism may be drawn for **2** with the same structure for the *m/e* 168 ion. However, the substantial difference in the relative abundances of the ions between *m/e* 99 and *m/e* 168 suggests that a different *m/e* 168 ion may be involved.

Compound **3** yields an extremely rich spectrum in which the characteristic ketal peaks (*m/e* 99, etc.) are relatively weak. The strong peaks at *m/e* 317, 319 represent a monobromo species which differs from the parent (*P* = 396, 398, 400) only in the loss of one bromine atom. The



m/e 240 *m/e* 168

presence of a similar doublet at *m/e* 245, 247 and the broad metastable ion centered at *m/e* 190.5 (calcd. *m/e* 189.3 and 191.3) provides some evidence that loss of the ethylenedioxycarbene is involved here as well. Note that here the *m/e* 245 peak is the base peak.

Structure and reactivity of the mono-oxime of 2,6-dimethoxy-1,4-benzoquinone

H. I. Bolker and F. L. Kung[1]

Department of Chemistry, McGill University, Montreal, Quebec and Organic Chemistry Division, Pulp and Paper Research Institute of Canada, Montreal, Quebec

Received August 9, 1968

Reaction of 2,6-dimethoxy-1,4-benzoquinone with hydroxylamine yielded 2,6-dimethoxy-4-oximino-2,5-cyclohexadienone-1 (**3**), as confirmed by spectroscopic analysis, and by independent synthesis from 5-nitro-1,2,3-trimethoxybenzene. Infrared and proton magnetic resonance spectra in solution showed no significant proportion of the tautomeric nitrosophenolic form of **3**. When **3** was heated for 3 min at 90–95° in 1.0 *N* HCl in $H_2{}^{18}O$, the N—OH group was stable, but the keto oxygen underwent complete exchange. Mass spectra of **3**, its ^{18}O- and deuterium-substituted derivatives indicated that a major process leading to fragmentation upon electron impact was loss of oxygen from N—OH to form the corresponding quinone imine.

Canadian Journal of Chemistry, 47, 2109 (1969)

In research aimed at elucidating the mechanism whereby 2,6-dimethoxy-1,4-benzoquinone (**1**) is formed by the action of nitrous acid on 1,2,3-trimethoxybenzene, we have found (1) that 2,6-dimethoxy-4-oximino-2,5-cyclohexadienone-1 (2,6-dimethoxy-1,4-benzoquinone-4-oxime) (**3**), a compound unknown until now, is an intermediate. Its relevance to current studies on the keto–enol equilibrium of nitrosophenols (2), and our findings concerning the exchangeability of its oxygen, have prompted separate publication of this part of the work.

Unsubstituted *p*-nitrosophenol is known to exchange 82% of one oxygen after only 5 min at

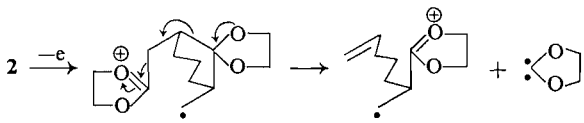
A mechanism may be drawn for **2** with the same structure for the *m/e* 168 ion. However, the substantial difference in the relative abundances of the ions between *m/e* 99 and *m/e* 168 suggests that a different *m/e* 168 ion may be involved.

Compound **3** yields an extremely rich spectrum in which the characteristic ketal peaks (*m/e* 99, etc.) are relatively weak. The strong peaks at *m/e* 317, 319 represent a monobromo species which differs from the parent (*P* = 396, 398, 400) only in the loss of one bromine atom. The



m/e 240 *m/e* 168

presence of a similar doublet at *m/e* 245, 247 and the broad metastable ion centered at *m/e* 190.5 (calcd. *m/e* 189.3 and 191.3) provides some evidence that loss of the ethylenedioxycarbene is involved here as well. Note that here the *m/e* 245 peak is the base peak.

100° in 0.2 *N* alcoholic hydrogen chloride, and 1-nitroso-2-naphthol exchanges 84% in 5 min at 80° in the same solvent (3). However, the existence of the tautomeric keto-oximes has complicated interpretation of these reactions by suggesting that two exchangeable oxygens could be present. Nevertheless, it is proposed that only the carbonyl group of the keto-oxime is exchanged (3,4). In the present work, application of mass spectroscopy to compound **3** and its derivatives has produced evidence to support the original proposal.

The Structure of the Oxime (3)

Although the product **3** obtained by treating **1** with hydroxylamine in pyridine (5) was clearly a monoxime, an alternative synthesis (6) from 5-nitro-1,2,3-trimethoxybenzene (**2**) proved that the oximino group had been introduced in position-4, and not position-1. The products of the two reactions were identical in all respects, and, on acetylation, yielded the same acetate (**4**).

The proton magnetic resonance (p.m.r.) spectrum of **3** in deuteriodimethylsulfoxide showed the expected singlet at δ 3.58 corresponding to the 6 hydrogens of the methoxyl groups, and another singlet at δ 12.62 (eliminated on deuteration) due to a single hydroxyl proton. However, neither the spectrum of **3** in pure deuteriodimethylsulfoxide nor that in deuteriodimethylsulfoxide containing 50% D_2O exhibited any trace of the single peak which might have been expected to arise from the two identical phenyl ring protons of the tautomeric nitrosophenol (**5**). Rather, spectra of the compound in both solvents had a doublet at δ 6.30 and δ 6.64, corresponding to two phenyl ring protons with $J_{3,5} = 1.5$ c.p.s. This AB pattern suggests that the protons at positions-3 and -5 are not equivalent, undoubtedly because of the rigidity and non-linearity of the C=N—O group on position-4. Hence, even in aqueous solution, the oxime form of **3** is overwhelmingly predominant, as would be predicted from the literature already cited (2).

The oxime **3**, treated with nitrous acid, produced no 2,6-dimethoxy-4-nitrophenol but only 2,6-dimethoxy-1,4-benzoquinone (**1**) in 98% yield. In contrast, treatment of 2-methoxy-4-nitrosophenol with nitrous acid gave rise to the corresponding nitro compound (although it forms an oxime acetate upon acetylation (7)). In general, most other quinone monoximes (or *p*-nitrosophenols) are reported to exhibit reactions of both tautomers (2*c*, 8). In this respect the behavior of **3** is unusual.

Interpretation of Mass Spectra

From the mass spectra of **3** (Fig. 1) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

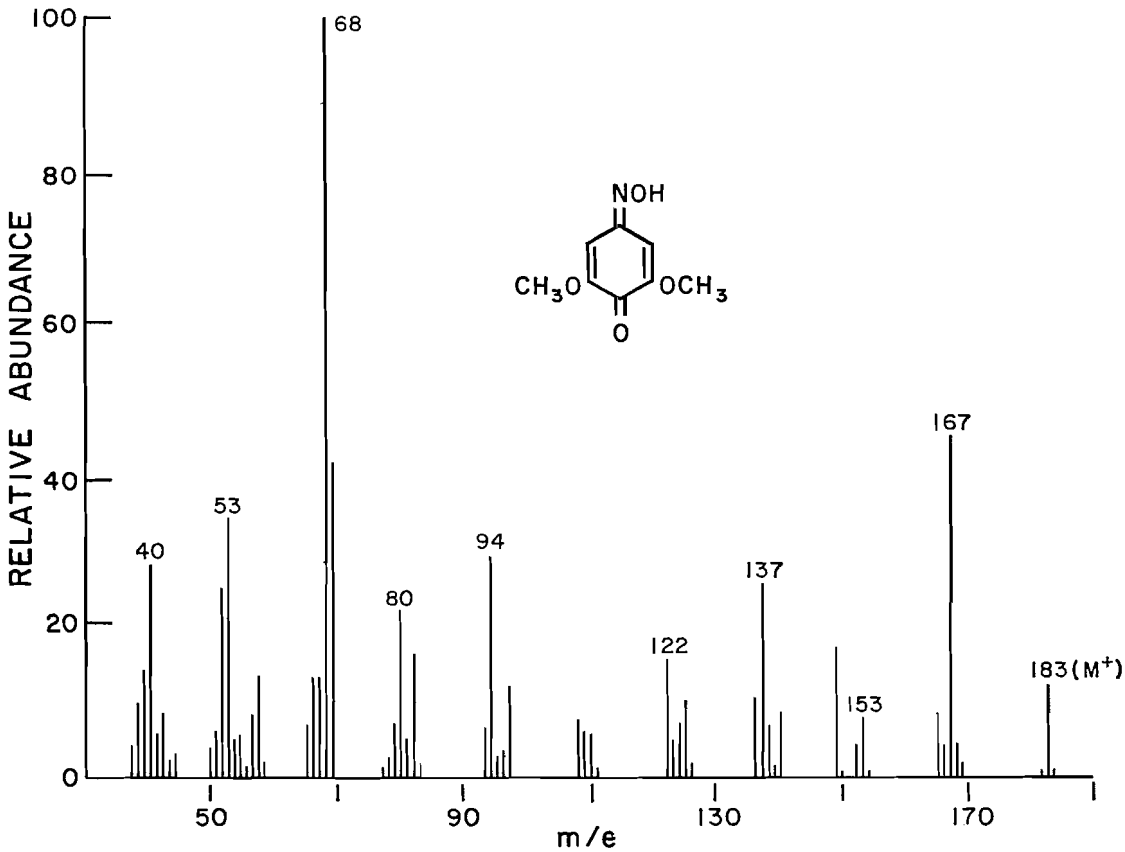

FIG. 1. Mass spectrum of 2,6-dimethoxy-4-oximino-2,5-cyclohexadienone-1 (**3**).

deuterated **3** (i.e. as =N—OD), we have deduced many of the details of the pattern of fragmentation (Scheme 1) arising from electron-impact, and have related this interpretation to the spectrum of the acetate (**4**), and hence deduced, in turn, the position of ^{18}O on compound **6** after exchange in acidified $H_2{}^{18}O$.

In the spectrum of deuterated **3**, all the peaks representing species listed in Scheme 1, except Path 3, exhibit intensification of the next higher mass unit ($m/e + 1$) over the corresponding peaks in the spectrum of the undeuterated **3** (Fig. 1). Therefore, these species have retained the deuterium introduced by exchange.

Thus, Path 1 demands tautomerization of species *a* to permit the expulsion of NO and formation of *e* ($m/e = 153$) without loss of label. In the light of the known tendency of **3** to retain its oxime form, Path 2 (by analogy with the fragmentation of benzophenone oxime (9)) requires transfer of the hydroxyl hydrogen to the ring, but may be a better interpretation for this compound. Paths 4, 5, and 6 have a common starting point, fragment *f*, which appears to have arisen in a one-step process (metastable ion is present) involving transfer of hydrogen to nitrogen simultaneously with the loss of oxygen. We have also observed the formation of a quinone imine corresponding to *f* in the fragmentation of the 4-monoxime of 2-methoxy-1,4-benzoquinone. We are therefore led to suggest that the quinone imine mechanism may prove to be common to the fragmentation processes of all quinone monoximes.

In the first step in each of the three pathways, 4, 5, and 6, whereby *f* undergoes further fragmentation, the products *h*, *i*, and *j* all retain their deuterium labels. The cleavage giving rise to *h* is similar to that of methoxybenzoquinones (10). In Path 5, the first two steps from *f* are the same

as those known for phenolic methyl ethers (11): loss of formaldehyde, then methyl. Two more steps are required to form *n* (*m/e* = 68), an isomer of *h*. The formation of *n* through two different paths, and the fact that it is resonance-stabilized, may account for *m/e* = 68 being the base peak of the spectrum.

In contrast with the other mechanisms, Path 3 alone leads to a product, *s*, which has lost its deuterium label.

With the exception of the transitions $183^+ \rightarrow 153^+ + 30$, $167^+ \rightarrow 68^+ + 99$, $153^+ \rightarrow 80^+ + 73$, all the fragmentation processes deduced from the spectra of **3** are further supported by the presence of appropriate metastable ions.

Exchange of Oxygen

For the experiment on the exchange of oxygen, **3** was dissolved in 1.0 *N* hydrochloric acid containing 10% of $H_2{}^{18}O$; the solution was rapidly heated to 90–95° and kept at that temperature for 3 min. Accurate measurement of the isotope content of the product by mass spectroscopic analysis (12) presented some difficulties, and it proved necessary to acetylate the compound to facilitate purification.

In the ^{18}O-containing acetate, the ratios of the peaks at *m/e* 225/227, 183/185, and 153/155 were all 100/12, while the same peaks in the unexchanged compound were in the ratio of 100/2. Thus 10% of ^{18}O had been incorporated in each of these species. (Natural relative isotopic abundance (13) of P_m/P_{m+2} for $C_{10}H_{11}NO_5$ (*m/e* 225) is 100/1.6, for $C_9H_9NO_4$ (*m/e* 183) is 100/1.2, and for $C_8H_9O_3$ (*m/e* 153) is 100/1.0.) The complete absence of spectral bands above *m/e* 225 + 2 clearly ruled out the possibility that ^{18}O might have been incorporated into more than one oxygen atom of **4**.

The main features of the spectra of the acetate are the same as those of the unacetylated oxime (Fig. 1), with the necessary exception that the first step in fragmentation is the loss of ketene (M-42), as has been observed in the spectra of *N*-acetyl alkylamines (14), and of sugar acetates (15). This loss occurred with retention of ^{18}O. Subsequent fragmentation through Paths 1, 2, 3, and 4 also led to retention of ^{18}O, as measured from the peaks for *c*, *e*, *i*, *s* (Scheme 1). However, in Paths 5 and 6, once the keto oxygen is lost (*h* in Path 6, *m* and subsequent fragments in Path 5) the ratios of *m/e*:*m/e* + 2 are the same for each *m/e* whether or not the compound originally contained ^{18}O.

The mass spectra of the oxime acetate (**4**), both with and without ^{18}O, thus serve on the one hand to confirm the previous interpretations of the spectrum of the free oxime, and, on the other, to demonstrate that, in accordance with earlier conjecture, the keto oxygen is the one which is exchangeable, in this instance, completely so.

Nucleophilic displacement of ring oxygen has also been reported to occur (16) as a minor pathway in the mechanism of direct alkylation of benzoquinone oxime by acidified alcohols (17). The major mechanism involves attack by protonated alcohol on carbonyl oxygen.

Experimental

All melting points were determined on a calibrated Fisher–Johns apparatus unless otherwise specified. Infrared (i.r.) spectra were recorded on a Perkin–Elmer spectrometer, model 337. The proton magnetic resonance (p.m.r.) spectra were recorded on a Varian A-60 spectrometer, with tetramethylsilane as an internal standard. Mass spectra were determined by the Morgan Schaffer Corp., Montreal, on a Hitachi Perkin–Elmer RMU60 mass spectrometer operating at 70 eV. Elemental analyses were done by Schwarzkopf Microanalytical Laboratory of Woodside, N.Y. Magnesium sulfate was used to dry all solvent extracts before concentration. Deuterium oxide and hydrogen oxide-^{18}O were products of Merck-Sharpe and Dohme. Known methods (1) were used to prepare 2,6-dimethoxy-1,4-benzoquinone (**1**) and 5-nitro-1,2,3-trimethoxybenzene (**2**). Solutions of nitrous acid were prepared according to the published procedure (18).

Preparation of 2,6-Dimethoxy-4-oximino-2,5-cyclohexadienone-1 (3) from 2,6-Dimethoxy-1,4-benzoquinone (1)

A solution of 20 g (0.12 mole) of **1** and 20 g (0.30 mole) of $NH_2OH \cdot HCl$ in 100 ml of anhydrous pyridine and 150 ml of anhydrous ethanol was boiled under reflux for 1 h with exclusion of moisture. The solution was then made alkaline with aqueous sodium hydroxide and concentrated by complete removal of the remaining pyridine under reduced pressure. Water (200 ml) was added and then the pyridine-free aqueous solution was extracted with methylene chloride (5 × 300 ml). Drying and evaporation of the combined extracts yielded 6.8 g (31%) of brown powder with m.p. 212–216°. Two recrystallizations from water containing 5% methanol gave 4.1 g, m.p. 218.8° (decomp.), of yellow plates. This compound was insoluble in ether and carbon tetrachloride, moderately soluble in cold water and chloroform, soluble in hot water, ethanol and methanol.

Anal. Calcd. for $C_8H_9NO_4$: C, 52.46; H, 4.92; N, 7.65. Found: C, 52.57; H, 5.01; N, 7.83.

The i.r. spectrum (KBr), 3270 cm^{-1} broad (OH), 1635 cm^{-1} (C=O), 1570 cm^{-1} (C=N), 1010 cm^{-1} (N—OH str.) and the absence of —N=O str. band at 1500 cm^{-1}, accorded with an oxime structure (19,20).

Preparation of 2,6-Dimethoxy-4-oximino-2,5-cyclohexadienone-1 (3) from 5-Nitro-1,2,3-trimethoxybenzene (2)

In a solution of 1.0 g of NH_4Cl in 50 ml of water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

containing 20% methanol, 1.5 g of **2** were dissolved. The solution was heated to 60–65°, and zinc powder (2.5 g) was added over a period of 10 min with stirring. After rapid filtration by suction, the filter cake was washed with hot ethanol, the filtrate was cooled, and then was poured with stirring into 200 ml of water containing 10% ferric chloride. Steam distillation led to the recovery of 80 mg of starting material, **2**, in the distillate. The residue in the still (pH 2) was cooled and extracted with chloroform (3 × 100 ml). Drying and evaporation of the extract gave 1.1 g (85%) of light brown solid material with m.p. 210–215° (decomp.). One recrystallization from water containing 5% methanol gave 0.85 g of yellow plates with m.p. 218.0–218.5° (decomp.). This material exhibited an i.r. spectrum identical to that of a sample of **3**, prepared according to the method described in the preceding section, and showed no depression of melting point upon admixture.

Reaction of 2,6-Dimethoxy-4-oximino-2,5-cyclohexadienone-1 (3) with Nitrous Acid

This reaction was conducted in a flask fitted with a reflux condenser, with the top of the condenser connected, by means of rubber tubing, to two wash bottles in series. The first wash bottle was empty, and acted as a safety bottle. The second contained water, and its purpose was twofold: (*a*) to inhibit the escape of gases so that decomposition of nitrous acid would be retarded, and (*b*) to trap whatever oxides of nitrogen might otherwise tend to escape. A suspension of 10 mg of **3** in 20 ml of nitrous acid (pH 1) was placed in the flask and boiled under reflux for 1 h. The reaction mixture was then extracted with chloroform (3 × 10 ml). After drying and evaporation of the solvent, the yellow solid residue, 9 mg (98%), m.p. 250–252° was identified as **1** (by mixture m.p. and i.r. spectrum).

Reaction of 2-Methoxy-4-nitrosophenol with Nitrous Acid

A suspension of 10 mg of 2-methoxy-4-nitrosophenol (18) in 20 ml of nitrous acid (pH 1) was boiled under reflux for 1 h in the apparatus described in the previous section. The product solution was then extracted with chloroform (3 × 10 ml). Drying and evaporation of the extract yielded 10 mg (91%) of yellow solid, m.p. 90–96°. Two recrystallizations from ether with a few drops of petroleum ether added each time gave 7.3 mg of yellow needles, m.p. 100.3–100.4°, which proved to be identical (i.r. spectrum and mixture m.p.) with a sample of 4-nitroguaiacol prepared according to Pollecoff and Robinson (21). Thin-layer chromatography (on silica gel with methanol:benzene:acetic acid:petroleum ether (8:45:3.5:20) showed that the crude yellow solid contained a trace of 4,6-dinitroguaiacol (18).

Preparation of 2,6-Dimethoxy-4-oximino-2,5-cyclohexadienone-1 Acetate (4)

A solution of 1.0 g of **3** in 25 ml of acetic anhydride was boiled under reflux for 2 h. The hot solution was poured into 200 ml of ice water and extracted with chloroform (4 × 50 ml). Drying and evaporation of the extract, yielded a residue, which, after thorough washing with methanol and subsequent drying, was a yellowish material weighing 0.85 g (69%) with m.p. 179–181°. After two recrystallizations from ethanol, the product (0.61 g) appeared as yellow prisms, m.p. 181.8–182.0°.

Anal. Calcd. for $C_{10}H_{11}NO_5$: C, 53.33; H, 4.89; N, 6.22. Found: C, 52.84; H, 4.83; N, 6.31.

The i.r. spectrum (KBr) exhibited a band at 1795 cm^{-1} corresponding to C=O stretching vibration of acetoxyl (22).

Oxygen-18 Exchange Reaction of 2,6-Dimethoxy-4-oximino-2,5-cyclohexadienone-1 (3) Followed by Acetylation

To a solution of 1 ml of 6 *N* aqueous hydrochloric acid in 8 ml of water containing 10.6% ^{18}O, **3** (400 mg) was added. The resulting mixture was heated to 90–95° with constant stirring for 3 min. Extraction with chloroform, drying of the extract, and evaporation gave a yellowish product which was then acetylated by the same procedure as described in the preceding section. The purified labeled oxime acetate weighed 150 mg, m.p. 178.5–181.8°. The i.r. spectrum of the ^{18}O-containing compound showed no detectable difference from its unlabeled precursor (**3**). However, its mass spectrum indicated that 10% ^{18}O had been incorporated into the molecule.

Deuterium Exchange Reaction of 2,6-Dimethoxy-4-oximino-2,5-cyclohexadienone-1 (3)

A suspension of 100 mg of **3** in 3 ml of deuterium oxide was heated to boiling and filtered. The filtrate was allowed to stand at room temperature and the partially deuterated oxime gradually separated as yellow plates, m.p. 216.0–218.5° (turns brown at 210°), yield 75%. The i.r. spectrum exhibited an O—D stretching band at 2400 cm^{-1} (23).

Electrochemical methoxylation of vinyl ethers: a novel anodic dimerization reaction

B. BELLEAU AND Y. K. AU-YOUNG
Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received March 24, 1969

Electrolysis of vinyl ethers in methanol using a platinum anode and nickel cathode was found to yield the corresponding 1,2-dimethoxylation products (60–66%) and products resulting from a tail-to-tail dimerization to succindialdehyde acetals (20–22%). A mechanism involving radical cation intermediates is proposed.

Canadian Journal of Chemistry, 47, 2117 (1969)

We have previously reported the electrochemical methoxylation of the isomeric dimethoxybenzene to *o*- and *p*-benzoquinone ketals (1), a class of substances inaccessible by other methods. Since benzene, simple ethers, and olefins react sluggishly or not at all under conditions which readily produce benzoquinone ketals from dimethoxybenzenes, it occurred to us that the only structural requirement in the latter for smooth anodic methoxylation could consist in the presence of vinyl ether units. Accordingly, a variety of aliphatic vinyl ethers were submitted to the conditions of electrochemical methoxylation described previously (1) using the same type of electrolysis cell (two concentric platinum gauze anodes and a nickel cathode; 1–0.5% KOH in methanol as the solvent). This work led to the discovery of two novel reactions of considerable practical and theoretical interest: (*a*) the dimethoxylation of the olefinic bond of vinyl ethers; and (*b*) the *dimerization* of vinyl ethers to succindialdehyde acetals.

A typical procedure was as follows. A one-litre electrolytic cell (160 cm^2 platinum gauze as anode and 240 cm^2 nickel as cathode) was charged with a solution of 42 g ethyl vinyl ether and 800 ml of methanol containing 5 g KOH. While stirring at $-5°$, a current of 4 A and 7 V was applied ($\sim$0.025 A/cm^2) for 24 h. The methanol was removed by distillation and the residue fractionated *in vacuo* (Todd column 30 cm) to give 1-ethoxy-1,2-dimethoxyethane, b.p. 58°/27 mm, n_D^{25}1.3954 (68% yield), 1,4-diethoxy-1,4-dimethoxylbutane, b.p. 110°/10 mm, n_D^{25}1.4148 (22% yield), and 2,4-dinitrophenylhydrazone m.p. 259–262° (decomp.). Other examples are assembled in Table I where it can be seen that the reaction is of general applicability.

The mechanism of this reaction is of considerable interest. The studies of Zweig *et al.* (2), revealed that the methoxybenzenes have remarkably low half-wave oxidation potentials. Their election spin resonance (e.s.r.) data show that anodic discharge readily produces absorbed radical cations, which they suggest could yield dimerization products. We have been unable to demonstrate this in our previous studies (1), presumably because of the very low discharge potential of the

methoxybenzene radical cations. It is logical to suggest similarly that vinyl ethers readily discharge at the anode to give the adsorbed radical cation **1***a* ↔ **1***b*. Subsequently, **1***a* would dimerize to yield **2** after reaction with the solvent, but for reasons unknown as yet, the resonance form **1***b* does not give dimerization products. Alternatively, **1***a* would react rapidly with the solvent but would simultaneously discharge to give cation **3** which would finally yield **4** after reaction with the solvent. We feel that this mechanism accounts adequately for the substrate specificity of the anode in this reaction and for the observed products. Only one other anodic dimerization reaction in the non-aromatic series has general utility: the Kolbe synthesis (3). The anodic dimerization of vinyl ethers (**1***a* ↔ **2**) constitutes a second example which, because of the nature of the products, may have broader synthetic utility.

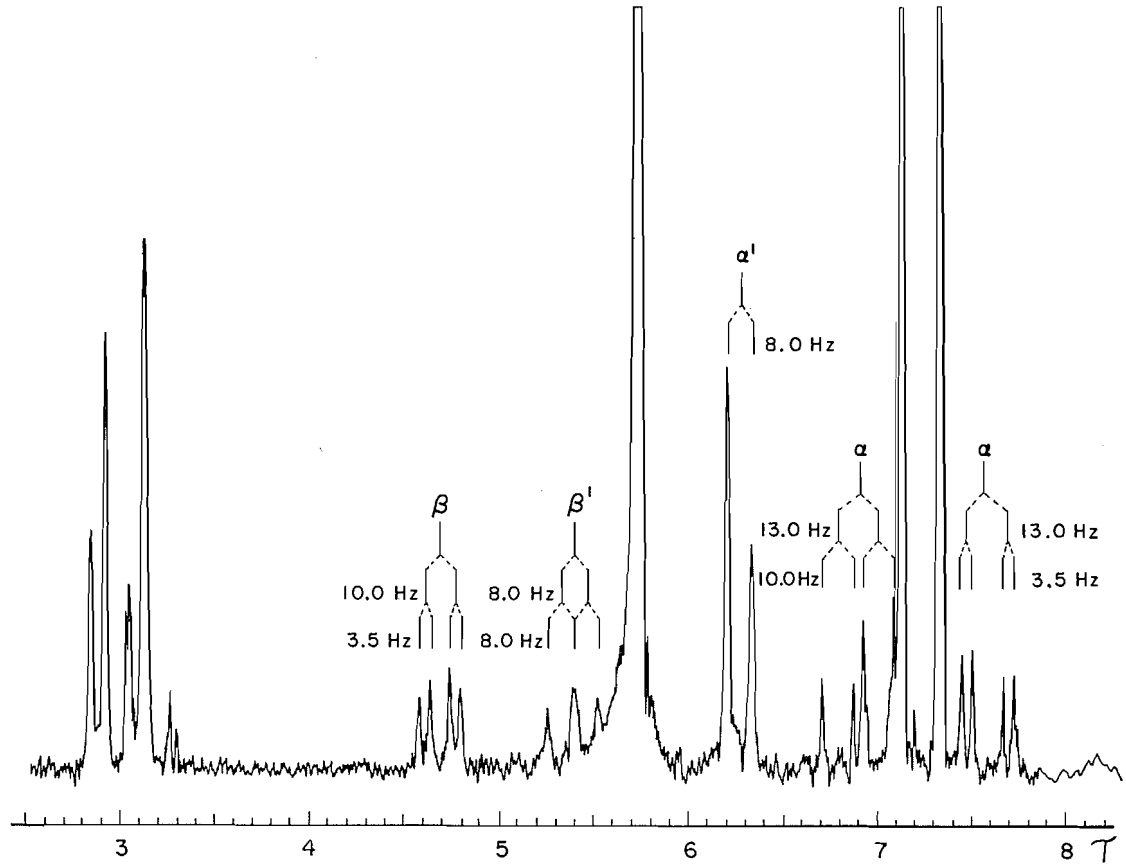

FIG. 1.

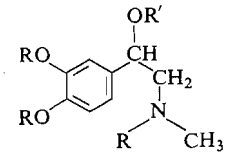
NOTE: The nuclear magnetic resonance spectrum of adrepine (**3**) dihydrochloride in D_2O with TMS as an external reference [τ 2.85 to τ 3.30, 5 aromatic protons; A_2X: τ 6.28 (d) and τ 5.40 (t); ABX: τ 7.75 (dd), τ 6.91 (dd), and 4.70 (dd); *N*—CH_3: τ 7.12 (s); *N*—CH_3: τ 7.32 (s)].

same product by the action of 20% aqueous hydrochloric acid on adrenaline (**1**) at 40° (2). The same product has also been detected chromatographically in solutions of adrenaline (**1**) in 10 *N* hydrochloric acid which have been allowed to stand for several days at room temperature (3).

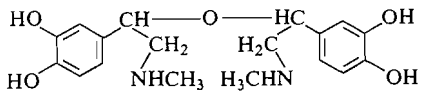
In the course of a systematic study of the nuclear magnetic resonance (n.m.r.) spectra of a number of catecholamine derivatives, the spectrum of the compound described as diadrenaline ether (**2**) was recorded (see Fig. 1). It was immediately apparent that this compound could not have the symmetrical ether structure **2**. The spectrum showed the presence of five aromatic protons per molecule instead of the six required by structure **2**, indicating that substitution had occurred on one of the aromatic rings. The presence of two *N*-methyl peaks in the spectrum confirmed that the structure **2** was incorrect.

We now propose the structure **3** [i.e. 6-(3′,4′-dihydroxy-α-methylaminomethylbenzyl)adrenaline] for this product, which is usually isolated as the dihydrochloride and suggest the trivial name adrepine for the base. The observed n.m.r. spectrum of this product is fully compatible with a structure such as **3**.

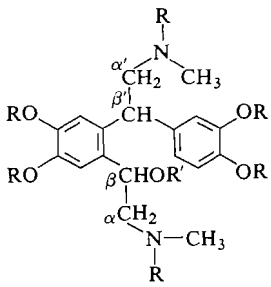
Acetylation of adrenaline (**1**) with acetic anhydride in aqueous sodium bicarbonate gives the triacetyl derivative **4**, in which the alcoholic OH group is not acetylated (4); acetylation of adrenaline under more vigorous conditions (acetic anhydride and pyridine) gives the tetra-acetyl derivative **5** (5). Similarly **3** gives the



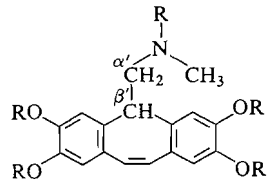
1 R = R′ = H
4 R = $COCH_3$; R′ = H
5 R = R′ = $COCH_3$



2



3 R = R′ = H
6 R = $COCH_3$; R′ = H
7 R = R′ = $COCH_3$



8 R = H

hexaacetate **6** ($C_{30}H_{36}N_2O_{11}$:[3] m.p. 91–92°; $\lambda_{max(EtOH)}$: 263; 272 mμ; $\nu_{max(Nujol)}$: 3300 (broad); 1770; 1630 cm^{-1}) under the former conditions of acetylation (cf. 4) and a heptaacetate **7** ($C_{32}H_{38}N_2O_{12}$: m.p. 167–170°; $\lambda_{max(EtOH)}$: 268; 274 mμ; $\nu_{max(Nujol)}$: 1775; 1755; 1735; 1640 cm^{-1}) under the latter, indicating that **3** contains an adrenaline type ethanolamine side chain. This fact can be verified by consideration of the n.m.r. spectra of **4**, **5**, **6**, and **7**. The signal due to the hydrogen atom on the β-carbon atom of the ethanolamine side chain in **6** is observed at τ 4.75 (the corresponding signal in **4** occurs at τ 5.10), whereas in **7** (in which the OH group on the β-carbon atom is acetylated) the corresponding peak is observed at τ 3.85, i.e. nearly 1 p.p.m. downfield. In tetraacetyladrenaline (**5**) the signal due to the β-proton is seen at τ 4.05, also ca. 1 p.p.m. downfield from its position in **4**. The heptaacetate **7** can also be obtained by acetylation of **6** with acetic anhydride and pyridine.

When **3** is heated above its melting point it decomposes and is converted to the dibenzocycloheptatriene derivative adnamine (**8**). This presumably accounts for the fact that all attempts to obtain a molecular ion in the mass spectrum of **3** have been unsuccessful; the highest mass fragment ion (*m/e* 299) observed appears to have been derived from **8**, formed by the thermal decomposition of **3** prior to ionization.

Kawazu had previously postulated the formation of **3** as a non-isolated intermediate in the formation of adnamine (**8**) from adrenaline (**1**) (6). The formation of **3** from **1** in acid solution can be readily explained mechanistically. It is well known that, in acid solution, the β-hydroxyl group in **1** is readily eliminated with the formation of the corresponding carbonium ion. The product **3** could then be formed by an electrophilic attack by this carbonium ion on the aromatic ring of a second adrenaline unit at a position *ortho* to the ethanolamine side chain.

The observed chemical shifts and coupling constants for the protons in the $-CH_2-CH<$ systems in **3**, **8** and a number of related β-arylepinines are very similar providing further evidence in support of structure **3**. The β′-proton is seen as a triplet in **3** (D_2O: τ 5.40; J = 8 Hz) and in **8** (D_2O: τ 5.90; J = 8 Hz). The α′-protons in **3** and **8** occur as doublets at τ 6.30 and τ 6.88 respectively.

This investigation is continuing and further details of the preparation and properties of a

On the mechanism of the Doebner–Miller reaction

T. P. FORREST, G. A. DAUPHINEE, AND W. F. MILES
Dalhousie University, Halifax, Nova Scotia

Received April 9, 1969

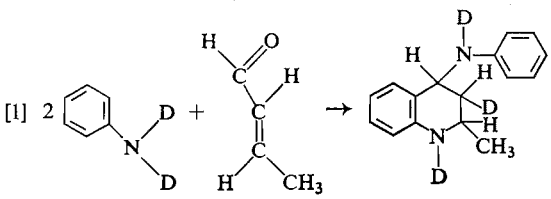
The reaction of acetaldehyde and aniline in deuterated media has led to substituted tetrahydroquinaldines. Analysis of the deuteration pattern indicates that the previously accepted mechanism of the reaction is incorrect. An alternative mechanism is proposed.

Canadian Journal of Chemistry, 47, 2121 (1969)

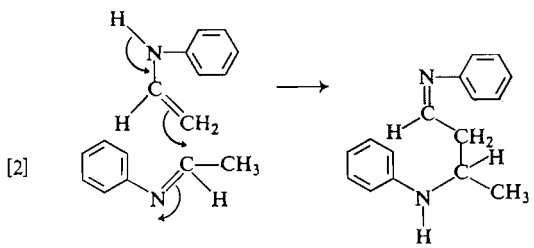
The mechanism of the Doebner–Miller synthesis of quinaldines has been the subject of many investigations, leading to the currently accepted mechanism which involves an aldol condensation forming an α,β-unsaturated aldehyde followed by Michael addition of the aromatic amine (1–3). We have carried out the reaction with acetaldehyde and aniline and present evidence that the reaction does not occur via the α,β-unsaturated aldehyde.

When acetaldehyde and aniline were reacted at low temperature in neutral or acidic medium a mixture of the *cis*- and *trans*-4-anilino-1,2,3,4-tetrahydroquinaldine (**1**) (4) could be isolated. The *cis* isomer is readily distinguished from the *trans* isomer by the coupling constants of the heterocyclic ring protons. In the *cis* isomer (m.p. 126°) the C-3 axial proton has coupling constants of 11.0 Hz with both vicinal protons indicating that the protons on C-2 and C-4 are both axial. In the *trans* isomer (m.p. 85°) the C-3 axial proton is coupled by 11.5 Hz to one of the vicinal protons and 4.0 Hz to the other indicating that one is axial and the other equatorial.

If the reaction is carried out in deuterated ethanol (C_2H_5OD) without acid, no deuterium is incorporated into either the *cis* or *trans* isomer of **1**. If the α,β-unsaturated aldehyde is an intermediate at least one deuterium atom would have to be incorporated at the C-3 position of the heterocyclic ring (eq. [1]).



The reaction in non-acidic medium therefore does not proceed via the aldol condensation, but probably involves the condensation of the enamine with the Schiff's base (eq. [2]).



2

When the reaction was carried out in D_2O, DCl at room temperature the *cis*-4-anilino-1,2,3,4-tetrahydroquinaldine (**1** *cis*) was isolated. Nuclear magnetic resonance analysis showed some deuterium in the 3-position and in the

number of related β-phenylethylamine derivatives will be published in due course.

On the mechanism of the Doebner–Miller reaction

T. P. FORREST, G. A. DAUPHINEE, AND W. F. MILES
Dalhousie University, Halifax, Nova Scotia

Received April 9, 1969

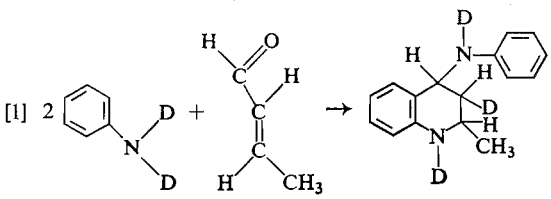
The reaction of acetaldehyde and aniline in deuterated media has led to substituted tetrahydroquinaldines. Analysis of the deuteration pattern indicates that the previously accepted mechanism of the reaction is incorrect. An alternative mechanism is proposed.

Canadian Journal of Chemistry, 47, 2121 (1969)

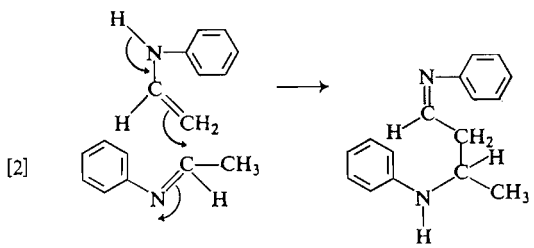
The mechanism of the Doebner–Miller synthesis of quinaldines has been the subject of many investigations, leading to the currently accepted mechanism which involves an aldol condensation forming an α,β-unsaturated aldehyde followed by Michael addition of the aromatic amine (1–3). We have carried out the reaction with acetaldehyde and aniline and present evidence that the reaction does not occur via the α,β-unsaturated aldehyde.

When acetaldehyde and aniline were reacted at low temperature in neutral or acidic medium a mixture of the *cis*- and *trans*-4-anilino-1,2,3,4-tetrahydroquinaldine (**1**) (4) could be isolated. The *cis* isomer is readily distinguished from the *trans* isomer by the coupling constants of the heterocyclic ring protons. In the *cis* isomer (m.p. 126°) the C-3 axial proton has coupling constants of 11.0 Hz with both vicinal protons indicating that the protons on C-2 and C-4 are both axial. In the *trans* isomer (m.p. 85°) the C-3 axial proton is coupled by 11.5 Hz to one of the vicinal protons and 4.0 Hz to the other indicating that one is axial and the other equatorial.

If the reaction is carried out in deuterated ethanol (C_2H_5OD) without acid, no deuterium is incorporated into either the *cis* or *trans* isomer of **1**. If the α,β-unsaturated aldehyde is an intermediate at least one deuterium atom would have to be incorporated at the C-3 position of the heterocyclic ring (eq. [1]).



The reaction in non-acidic medium therefore does not proceed via the aldol condensation, but probably involves the condensation of the enamine with the Schiff's base (eq. [2]).

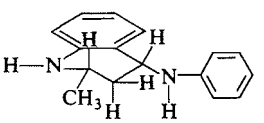


2

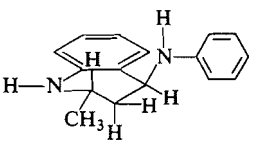
When the reaction was carried out in D_2O, DCl at room temperature the *cis*-4-anilino-1,2,3,4-tetrahydroquinaldine (**1** *cis*) was isolated. Nuclear magnetic resonance analysis showed some deuterium in the 3-position and in the

methyl group. Twenty-five percent of the compound contained no deuterium in the 3-position, thus showing that the α,β-unsaturated aldehyde is not required as an intermediate under acidic conditions.

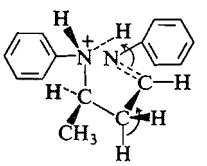
The incorporation of deuterium in both the equatorial (65% D) and axial (30% D) positions of C-3 was greater than that in the methyl groups (15% D). The exchange in the methyl group could take place in the free acetaldehyde or its Schiff's base. No incorporation of deuterium takes place when **1** is treated with acid under the conditions used in the reaction. This indicates that exchange takes place in an intermediate and in a manner which differentiates the protons of the methylene group.



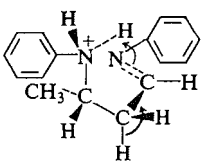
1 (*cis*)



1 (*trans*)



3



4

The differential exchange of the C-3 protons may be due to anchimeric assistance of the exchange through conformers **3** or **4**. The reactive *trans* proton of conformer **3** becomes the equatorial C-3 hydrogen in the final product (**1** *cis*). Conformer **3** should be more stable than **4** because of the greater non-bonded interaction of the methyl group in **4**. The predominance of conformer **3** therefore dictates that more deuterium appears in the C-3 equatorial position than in the C-3 axial position of **1** (*cis*).

Although it is true that crotonaldehyde can be used directly in this reaction our evidence indicates that it is not necessarily formed as an intermediate when acetaldehyde is used.

Polarography and coulometry of Rh(III) in a pyridine – pyridinium chloride electrolyte

LESLIE E. JOHNSTON[1] AND JOHN A. PAGE[1]

Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario

Received October 17, 1968

The polarography and coulometry of Rh(III) has been studied in an aqueous pyridine – pyridinium chloride – sodium chloride electrolyte at pH 5.30 and ionic strength 0.30 *M* at 25.0 °C. Two distinct types of polarographic behavior were noted as the total Py concentration was varied between 0.05 and 0.45 *M*, a "normal" wave with $E_{1/2}$ of −0.43 V vs. a standard calomel electrode, and a second catalytic wave which under some conditions masked the normal wave.

For both types of behavior, controlled potential electrolysis gave a well-defined two electron reduction but there was a definite H^+ consumption in the electrolyses. It is postulated that hydride species are involved in the reduction according to the scheme

$\longrightarrow$ $Rh(III) + 2e \rightarrow Rh(I)$
"normal", diffusion controlled wave at dropping mercury electrode

"enhanced" wave
$Rh(I) + PyH^+ \rightarrow Rh(III) + H^- + Py$

surface reaction at dropping mercury electrode
$xRh(I) + yH^+ \rightarrow$ Products where $y > x$
slow, bulk solution in controlled potential electrolysis

Canadian Journal of Chemistry, 47, 2123 (1969)

Introduction

Nearly all of the analytical polarography of rhodium has been carried out employing a pyridine supporting electrolyte. The first investigations by Willis (1) and Repin (2) employed a Rh(III)–Py–KX(X = Cl^- or Br^-) system, and their work defined the position of the cathodic step on the potential axis. Pantani (3) examined their postulates on the number of electrons involved in the step and provided dubious evidence for a two electron reduction of the Rh(III). The nature of the solution species (oxidized or reduced) was not characterized. In another connection, Gillard *et al.* (4) have investigated the polarographic reduction of a number of Rh(III) complexes, among them $RhPy_4Cl_2{}^+Cl^-$. They postulated a two electron reduction step, but this was based on an estimate for the diffusion coefficient of the reducible species. The nature of the products of the reduction was not definitely established, but other work by these authors (5–7) indicated a Rh(III)-hydride as a possible product along with the more obvious Rh(I).

This study delineates the polarographic behavior, emphasizing the effect of solution composition on the wave. The nature of the reduction is characterized by analytical coulometry, half-wave potential measurements, and identification experiments on the oxidized and reduced solutions.

Experimental

All potentials reported are in volts relative to a mercury calomel electrode (m.c.e.) filled with saturated NaCl solution. The reference used throughout was a Metrohm EA-402 calomel electrode, or equivalent, containing saturated NaCl solution.

The polarograms were normally recorded on a Sargent Model XV polarograph with the damping set in the number one position. A conventional jacketed H-cell, thermostated at 25.0 °C, and employing a frit/NaCl agar

TABLE I

Determination of Py groups in the Rh(III) complex

Rh taken (moles × 10^5)	Py taken (moles × 10^5)	Py found (moles × 10^5)	Py groups per Rh(III)
1.134	126.1	121.3	4.2
2.831	126.1	115.3	3.8
2.831	126.1	115.1	3.9
2.831	126.1	114.6	4.0

gel to separate the working and counter (reference) compartments, was used. The dropping mercury electrode (d.m.e.) used for quantitative work had a flow rate of 1.597 mg s^{-1} with a drop time of 3.97 s at −0.60 V in a solution that was 0.453 m*M* in Rh(III) and 0.45 *M* in total Py at the chosen ionic strength and pH.

For the determination of the $E_{1/2}$ and wave form parameters, a three electrode system was used. This employed a Wenking Model 61 RS potentiostat, accurately calibrated for potential, to control the potential of the d.m.e. relative to a reference electrode in the working electrode compartment of the H-cell. The current was measured as the potential drop across a 10 KΩ load resistor; a Hewlett–Packard Model 7100B recorder with a response time of 0.5 s was used to record the current as a function of time over a series of mercury drops at a fixed potential.

Controlled potential coulometry was carried out in the H-cell with the three electrode system, but a Hg pool of 17.3 cm^2 area was used in place of the d.m.e. The pool was stirred mechanically in a reproducible fashion. The electrolysis current was integrated using an operational amplifier circuit with capacitance feedback (8). Background corrections, equal to the product of the final residual current and electrolysis time, were deducted from the total quantity of electricity.

For the measurement of pH, a Beckman Model G, or in the case of the precise electrolysis experiments involving H^+ consumption, a Beckman Research pH meter, was used. The glass electrode was a Beckman 40498 or equivalent and the meter was standardized against a KH phthalate solution prepared according to the directions of the National Bureau of Standards from their sample 185c (pH = 4.008 at 25.0 °C).

All solutions for polarography and coulometry were deaerated with nitrogen gas. Before use, the N_2 (Linde, less than 10 p.p.m. O_2) was passed through an acid vanadium(II) solution (9), scrubbed with water, then equilibrated with pyridine vapor by passage through three successive towers filled with supporting electrolyte at 25.0 °C.

Spectra in the ultraviolet (u.v.) and visible regions were obtained on either a Bausch and Lomb 505 Spectrophotometer using 10 cm quartz cells or on a Beckman DU Spectrophotometer using 1 cm quartz cells. The infrared (i.r.) spectra were obtained on a Perkin–Elmer Model 521 Grating i.r. spectrophotometer using Nujol mulls. Nuclear magnetic resonance (n.m.r.) information was obtained from the Varian Associates Model HR-100 n.m.r. spectrophotometer.

All chemicals used were reagent grade, and the pyridine was redistilled before use. The stock Rh(III) solutions were prepared by dissolution of $Na_3RhCl_6 \cdot 12H_2O$ (Alpha Inorganics Rh-103) in a 6 *M* HCl solution. Standardization of the resultant well characterized red $RhCl_6^{3-}$ species (10) was effected by controlled potential coulometry according to the method of Van Loon and Page (11). Typical analyses gave rhodium concentrations of 22.72 ± 0.04 m*M*.

The solutions for polarography and coulometry were prepared by refluxing aliquots of the stock Rh(III) solution with varying amounts of a 2.5 *M* aqueous Py solution for 15–20 min. The resulting pale yellow solution was diluted, and then neutralized to the appropriate pH by the addition of a 3 *M* HCl solution. The ionic strength was adjusted by the addition of the appropriate amount of a 2 *M* NaCl solution to give a final total ionic strength of 0.30 *M* on dilution to a volume of 100 ml. Spectrally, the complex prepared in this way was identical to $RhPy_4Cl_2^+$. Although the excess Py of the supporting electrolyte masked the u.v. region, the visible peak concurred with that reported. When the excess Py was removed by cryogenic distillation in the presence of NaOH in a closed evacuated system, and the residue taken up in water and acidified to pH 5, the absorbances found in the u.v. corresponded to those found in the literature for this complex (12, 13). Previous workers (14, 15) have indicated that a hydridic catalyst is necessary for the formation of this complex from Rh(III) chloro species.

Further confirmation of the number of Py groups coordinated to the Rh(III) was obtained by analysis; the total Py added in the preparation was compared to the free Py after reaction with the Rh(III). In each case the Py was separated from an aliquot of solution by a cryogenic distillation in a closed evacuated system after the addition of excess NaOH. The Py and water that distilled over were reacted with acetic anhydride, and then neutralized by excess standard $HClO_4$ in an HOAc solvent under non-aqueous conditions. Special care was required in the hydrolysis of the acetic anhydride. It was found that the reaction should be allowed to proceed overnight in the cold before completion through catalysis by addition of the excess standard $HClO_4$. The acid in excess was determined by a back titration with standard NaOAc solution to a potentiometric end point according to Kucharsky and Safarik (16). The results appear in Table I and clearly indicate four Py groups per Rh(III).

Results

Polarographic Reduction of $RhPy_4Cl_2^+$

The outlined method was used to prepare a series of Rh(III)–Py solutions, all with a final pH

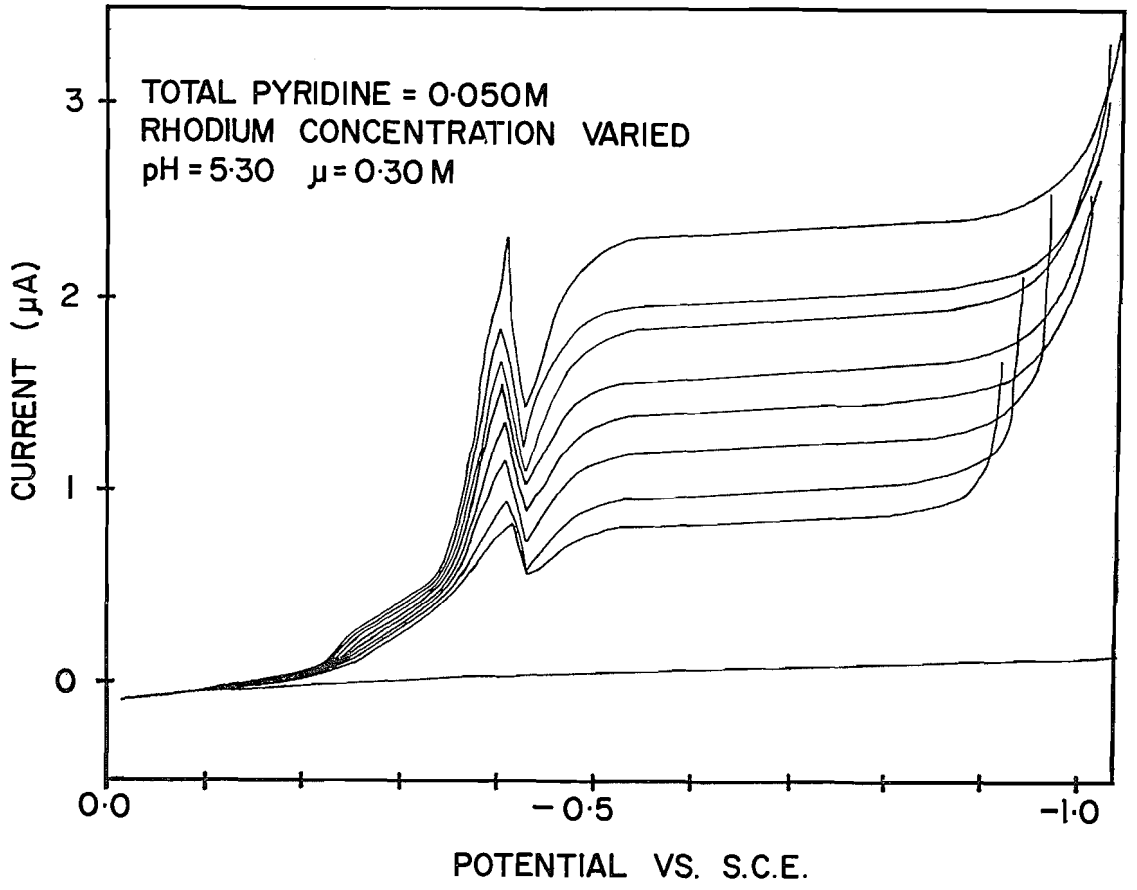

FIG. 1. Polarography at low total Py concentration. Curves from bottom to top are for 0.150, 0.180, 0.226, 0.270, 0.359, 0.385, and 0.453 m*M* Rh(III).

of 5.30. Two types of polarographic behavior were noted: a wave with normal parameters except for a spike on the rising part of the wave (Fig. 1) and a wave with abnormal parameters, the most apparent being the current enhancement over the normal wave (Fig. 2). The transformation from "normal" to "enhanced" behavior was noted as the Py concentration increased; both the spike width and a hump on the limiting current plateau grew until they merged to form the abnormal wave (Fig. 3). The decrease in current just prior to the discharge of the supporting electrolyte was also characteristic. The merging process was also a function of Rh(III) concentration in that at lower concentrations the abnormal wave formed more readily (Fig. 4).

The limiting current (i_l) of the "normal" wave exhibited a linear concentration dependence (Fig. 5*a*) and a temperature coefficient of +1.6% per °C over the range 15–30 °C. Diffusion control was indicated by the constancy of $i_l/h_{corr}{}^{1/2}$ (9) and also by the fact that the current–time curves for individual drops on the limiting plateau showed a $t^{1/6}$ behavior. The square root of the diffusion coefficient, calculated from the Ilkovic equation and an assumed 2 electron reduction, was 2.4×10^{-3} cm $s^{-1/2}$ compared with the value of 2.1×10^{-3} given by Gillard *et al.* (4) for $RhPy_4Cl_2{}^+$.

A solution 0.15 *M* in total Py and 0.38 m*M* in Rh(III) gave a "normal" wave with $E_{1/2} = -0.43$V. For this solution, the irreversibility of the assumed 2 electron reduction was noted from the slope of 57.7 mV for the plot of $E_{d.m.e.}$ vs. log $i/(i_d - i)$ and from the temperature coefficient of +1.6 mV per °C for $E_{1/2}$. In these, and in other cases, the log plot analysis was applied

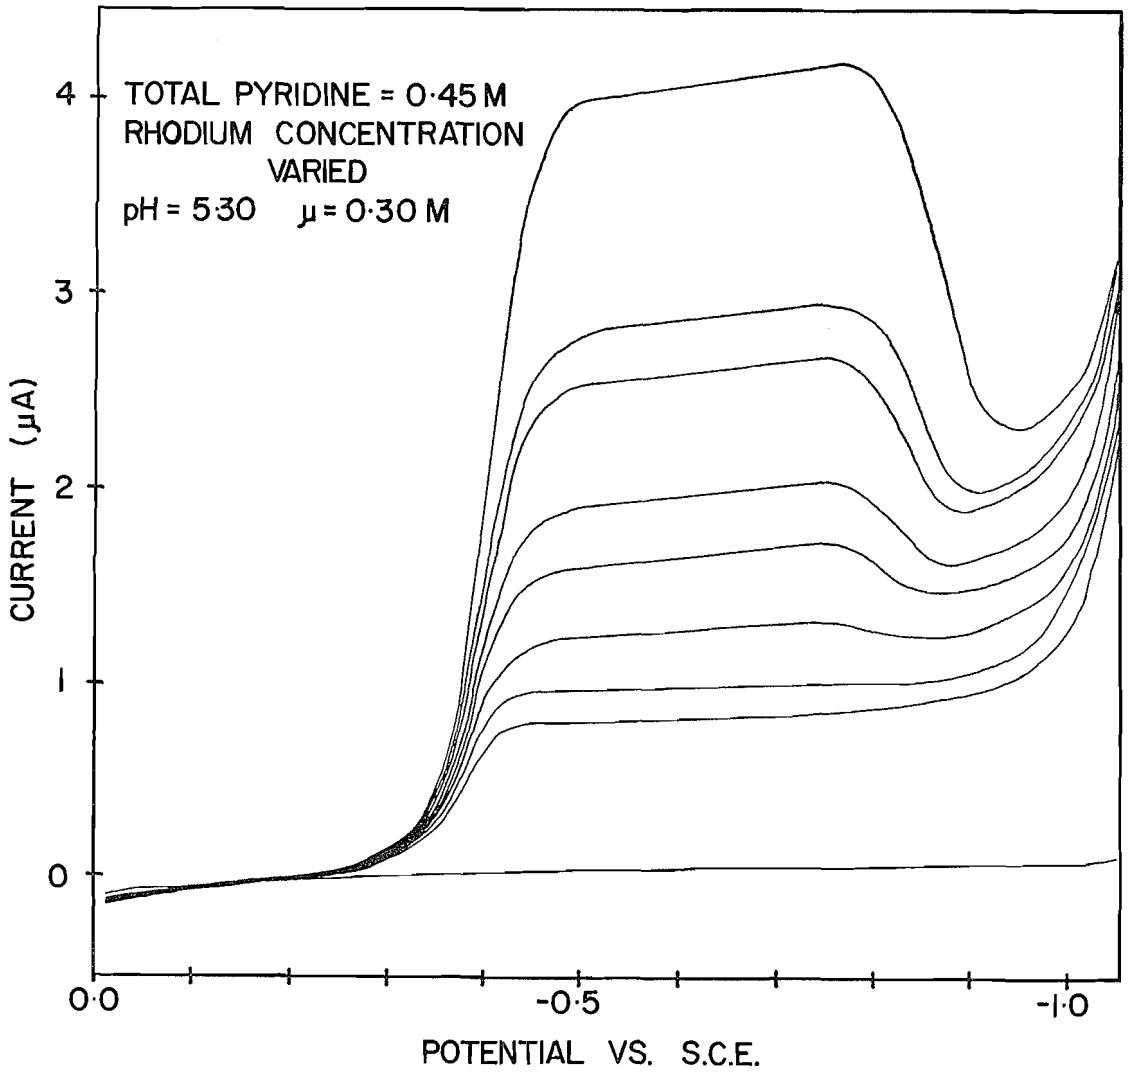

FIG. 2. Polarography at high total Py concentration. Rh(III) concentrations as in Fig. 1.

only on the part of the wave where the spike did not interfere.

The current on the plateau of the "enhanced" wave did not exhibit a linear concentration dependence (Fig. 5*a*), although the current at the minimum just prior to the discharge of the supporting electrolyte did show a linear dependence (Fig. 5*b*). Measurements on the limiting current plateau showed that i_l was invariant with h_{corr}. The temperature coefficient of i_l was +2.8% per °C. The current–time curves for individual drops on the plateau showed exponents of time increasing during drop life and tending to a $t^{2/3}$ behavior.

Lowering the temperature was found to result in a transformation from "enhanced" to "normal" behavior in a manner that was the reverse of that achieved with increasing Py concentration; the exact temperature range for the transformation was a function of both the Py and Rh(III) concentrations.

A solution 0.45 *M* in total Py and 0.45 m*M* in

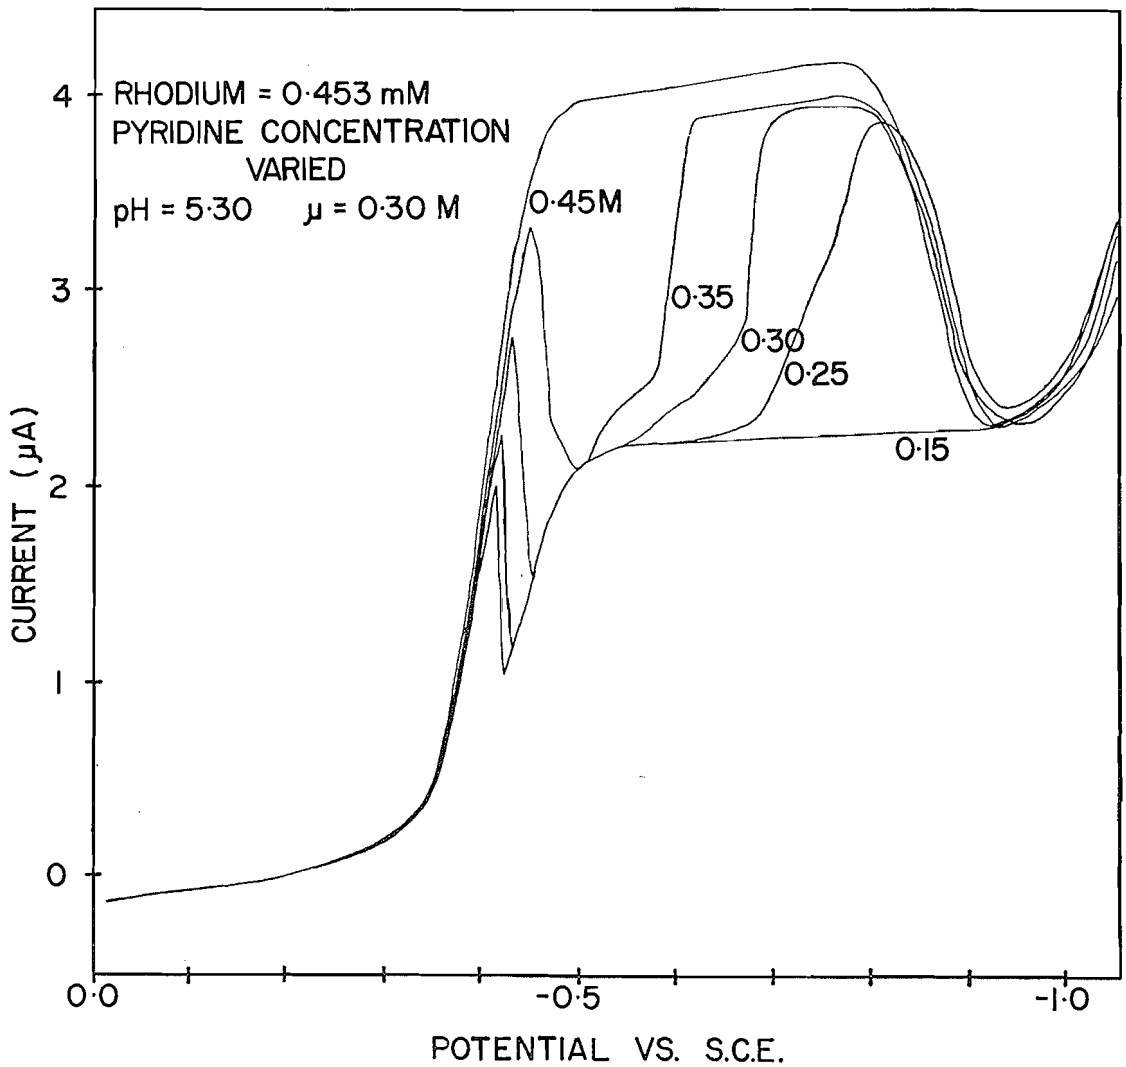

FIG. 3. Formation of "enhanced" polarographic wave.

Rh(III) gave an enhanced wave with $E_{1/2} = -0.40$ V. The plot of $E_{d.m.e.}$ vs. $\log i/(i_l - i)$ had a slope of 55.6 mV.

The effect of pH was investigated using solutions of fixed total Py and Rh(III) concentrations. The "normal" wave was found to break into two steps at pH > 5.8 (Fig. 6), although the total i_l measured just prior to the discharge of the supporting electrolyte remained constant with diffusion control demonstrated through the invariance of $i_l/h_{corr}^{1/2}$. For the first step at high pH, i_l showed neither diffusion or kinetic control when tested at various values of h_{corr}.

At pH > 10, the spike character of the first step disappeared. The wave height of this step was found to be insensitive to the Rh(III) concentration above a certain low value, and the current time curves for individual drops on the limiting current plateau exhibited a $t^{-1/3}$ behavior. This indicates an adsorption of the reduction product formed in the first step.

For the "normal" wave, the parameter $E_{1/2}{}^0$ was evaluated over a selected range of pH according to Meites (9) (Table II and Fig. 7). The linear variation from pH 4.1 to 5.8 shows a slope of 3.5 mV per pH unit; the experimental value of

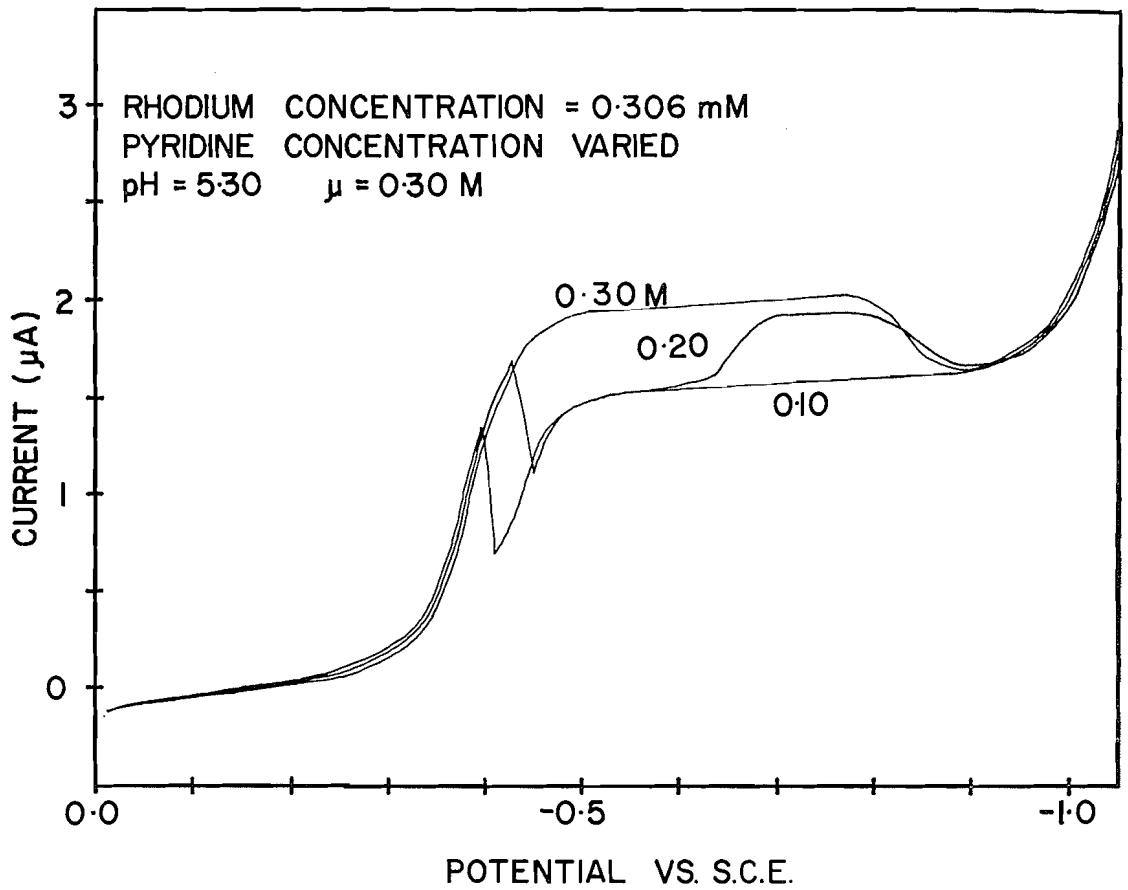

FIG. 4. Formation of "enhanced" polarographic wave at low Rh(III) concentration.
The wave at total Py > 0.30 *M* coincides with that at 0.30 *M*; for total Py < 0.10 *M* the wave coincides with that at 0.10 *M*.

αn over this pH range was 1.05. This independence on hydrogen ion concentration indicates that if the electron transfer step involves two electrons, the product of the reduction is a Rh(I) species rather than a Rh(III)-hydride species as suggested by Gillard *et al.* (4). While the variation of $E_{1/2}{}^0$ at pH > 5.8 seems to indicate hydrogen ion involvement, interpretation is difficult as the "normal" wave has begun to split.

Variation of $E_{1/2}$ with Cl^- concentration*

Cl^- (moles l^{-1})	Slope of log plot (−mV)	$E_{1/2}{}^0$ (V)
0.300	49.8	-0.441_3
0.250	50.0	-0.436_5
0.200	49.9	-0.430_3
0.150	50.2	-0.423_2
0.100	50.4	-0.413_2
0.0682	53.1	-0.405_1

*$RhPy_4Cl_2{}^+$ = 0.681 m*M*, total Py = 0.108 *M*, pH 5.0, μ = 0.30 *M* ($NaNO_3$).

The parameter $E_{1/2}{}^0$ was also evaluated for the second wave at high pH (Table III) and found to be relatively constant.

The effect of Cl^- concentration on the "normal" wave was also investigated at pH 5.0 and fixed total Py and Rh(III) concentrations (Table IV and Fig. 8). The data were analyzed according to the relation of Matsuda and Ayabe quoted in ref. 17

$$\frac{-dE_{1/2}{}^0}{d \ln [Cl^-]} = (m - i)\frac{RT}{\alpha n F}$$

where m is the number of Cl^- species on the Rh(III) species in bulk solution and i the number of Cl^- species on the electroactive species. The linear plot had a slope of −25.2 mV with αn = 1.08 yielding i = 0.94 for m = 2. This indicates that a fast reaction of the type

$$RhPy_4Cl_2{}^+ + X \rightleftharpoons RhPy_4ClX^{2+} + Cl^-$$

occurs prior to the assumed two electron reduction

$$RhPy_4ClX^{2+} + 2e \rightarrow RhPy_4ClX^0$$

The nature of X is not indicated by the experiment.

Controlled Potential Reduction of $RhPy_4Cl_2{}^+$

Hg cathode controlled at -0.55 V and using conditions that produced either the "normal" or "enhanced" polarographic wave. In each case, the reduction proceeded to a negligible residual current (10–40 μA) and the quantity of electricity, when corrected for background effects, corresponded closely to 2 F per mole of Rh(III). The results, of analytical accuracy, are shown in Table V. Preelectrolysis to purify the electrolyte was not feasible because of the method of preparation of the complex, but blank electrolyses showed a negligible consumption of electricity.

When dealing with conditions that produced a "normal" polarographic wave, plots of ln i vs. time were always linear, indicating diffusion control. Slopes of the plot ran typically from 5×10^{-4} s^{-1} at 10 °C ($t_{1/2}$ = 1400 s) to 8×10^{-4} s^{-1} at 25 °C ($t_{1/2}$ = 850 s). In contrast, at high total Py concentration, a condition that showed an "enhanced" polarographic wave, the behavior was significantly different. The electrolysis current would decay to about 70% of the initial value, then jump back to about the initial value before decaying to the final background value. The effect was reproducible, but could be made to disappear by increasing the stirring to a much more rapid rate. Under this condition the plot of ln i vs. time was linear with slope typically 9×10^{-4} s^{-1} at 25 °C.

Hydrogen ion involvement in the Hg cathode electrolyses was studied in two series of runs. In the first, electrolyses were carried out at pH 4.5, a value somewhat less than that of the optimum buffer capacity of the Py system. Standard 0.01 M HCl solution was added to the system as necessary through the electrolysis to maintain the pH within ±0.001 unit of the initial value. Titrations of about 10 ml with a discrimination of 0.2 ml were typical. The moles of acid added were plotted against the quantity of electricity (Fig. 9), and the slope found for three such runs was $+0.68 \pm 0.03$ moles H^+ per F. This indi-

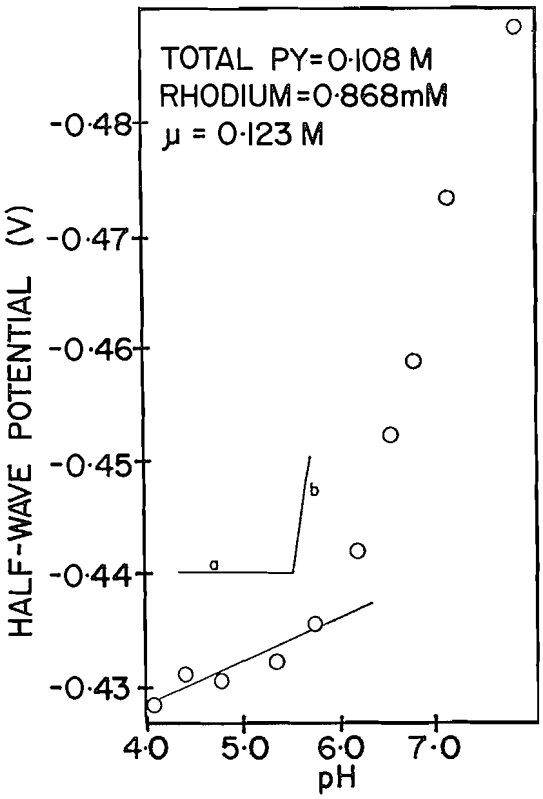

FIG. 7. Variation of $E_{1/2}$ with pH. Slope *a* corresponds to non-involvement of H^+; slope *b* corresponds to involvement of one H^+ in electrode reaction.

cates that 1.4 moles of H^+ are consumed during the reduction of each mole of Rh(III).

A second series of runs was carried out at pH 7.0, a value considerably above that of optimum buffer capacity. In these electrolyses, the meter was used to monitor the pH throughout the reduction. The total concentration of Py was determined by analysis of an aliquot of the solution before the run and checked by analysis of the reduced solution at the end of the run.

The concentration of H^+, calculated from the pH meter reading was plotted against the quantity of electricity (Fig. 10) and the slope found for 6 such runs was $-7.7 \pm 0.2 \times 10^{-4}$ moles l^{-1} H^+ per F. The rate of change of concentration of PyH^+ was then calculated

$$\frac{[Py][H^+]}{[PyH^+]} = K_a = 5.7 \times 10^{-6}$$

$$[Py] + [PyH^+] = C; [H^+] \approx 10^{-7}$$

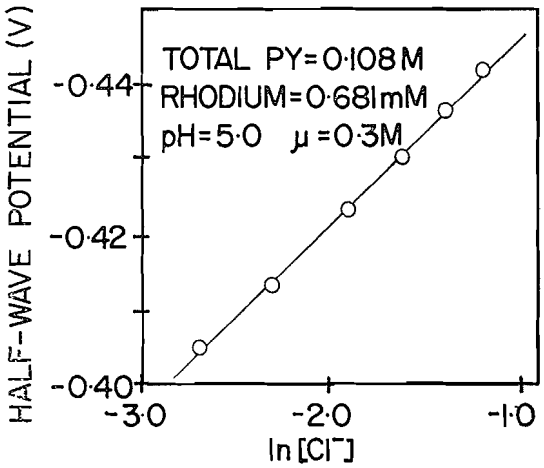

FIG. 8. Variation of $E_{1/2}$ with Cl^- concentration.

$$\frac{d[PyH^+]}{dQ} = \left\{\frac{C}{K_a + [H^+]} - \frac{[H^+]C}{(K_a + [H^+])^2}\right\}\frac{d[H^+]}{dQ}$$

and found to be -7.9 ± 0.2 moles l^{-1} per F. For the 90 ml electrolysis volume, this again indicated that 1.4 moles of protonic strength is consumed during the reduction of each mole of Rh(III).

Characterization of the Reduced Species

The reduced solution prepared by electrolysis was colorless. No adsorption peaks were found in the u.v.–visible spectrum other than the strong adsorption of the excess Py ($\lambda < 330$ mμ).

Since Gillard *et al.* (4) in their studies on rhodium hydrides found evidence that some metallic Rh was formed in the chemical reduction of Rh(III), the actual rhodium content of the reduced solutions was determined. The complex was destroyed by fuming the solution with a 1:1 mixture of nitric and perchloric acids in the presence of a metavanadate catalyst according to Smith (18). The resultant Rh(III) species was anated in hot 6 *M* HCl solution and determined coulometrically (11). A vanadium correction was determined by blank electrolyses. The results as shown in Table VI confirm the presence of all the rhodium in solution after reduction.

The reduced solutions on polarography yielded an oxidation wave with $E_{1/2} = -0.32$ V, but the limiting current of this wave was only about

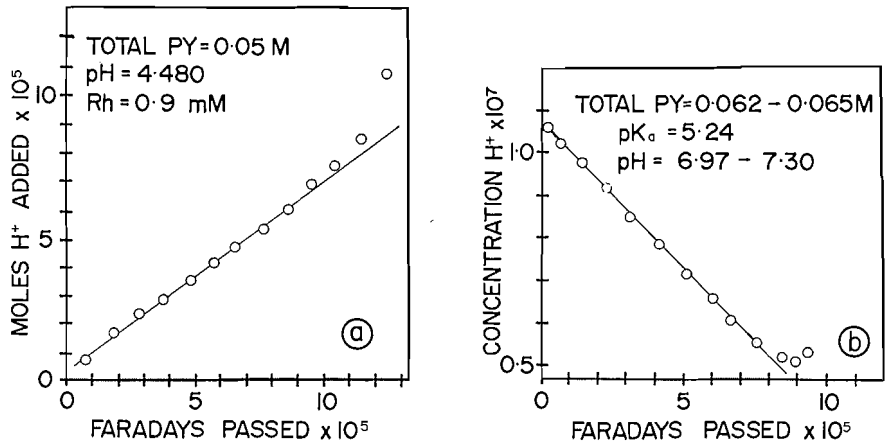

FIG. 9. Consumption of H^+ on electrolysis. (*a*) Electrolysis at fixed pH, (*b*) pH monitored through electrolysis.

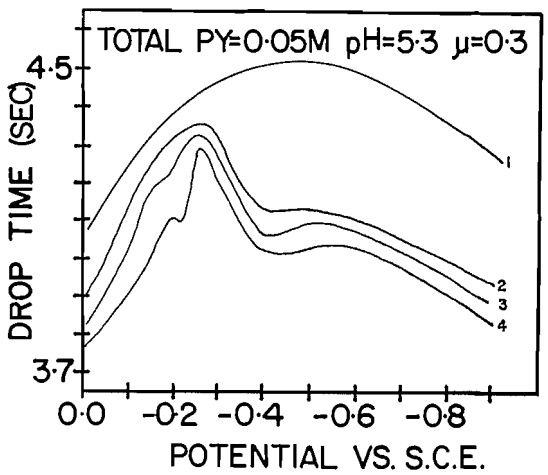

FIG. 10. Droptime vs. potential in 0.05 *M* total Py electrolyte. 1, 0; 2, 0.18; 3, 0.27; 4, 0.45 m*M* Rh(III).

15% of the reduction wave in the original unreduced solution. Investigations with a rotating Pt microelectrode showed no other reduction steps up to +0.9 V, indicating that this unexpectedly small wave at −0.32 V was not an absorption prewave.

Controlled potential electrolyses of the reduced solutions at a Hg anode at −0.1 V proceeded smoothly but required only about 15% of the quantity of electricity used in the original reduction. Subsequent re-reduction at −0.55 V after this oxidation required only the 15% quantity of electricity; if the solution was then electrolyzed again at −0.1 V there was a negligible consumption of electricity. This would indicate that each

TABLE VII

Reoxidation of reduced Rh solutions by reflux

6.82	6.69

reduction produces a small proportion of an electroactive rhodium species, and a large proportion of an electroinactive species.

On the other hand, when the reduced solutions were refluxed under air, there was a complete reconversion to $RhPy_4Cl_2^+$. The refluxed solutions had the correct u.v.–visible spectrum and exhibited the proper coulometric behavior as summarized in Table VII.

The reduced solutions were also tested for catalytic activity as regards substitution of Py in a $RhCl_6^{3-}$ species. This experiment was suggested by the work of Rund *et al.* (19, 20) who distinguished between Rh(I) and Rh(III)-hydrides on the basis of such activity. The reaction was followed amperometrically using a Hg drop J-tube indicator electrode polarized at −0.20 V in a well stirred solution; the current at this potential was found to be proportional to the $RhCl_6^{3-}$ concentration. The catalyst was freshly prepared by electrolysis and added to the reaction mixture by pipette at zero time. The pyridination was found to be pseudo first order in $RhCl_6^{3-}$, but the catalytic activity of the electrolytically

reduced rhodium solution was consistently much greater than that found by Rund for his active Rh(I) species (Table VIII).

It was hoped that further information could be obtained from i.r. and n.m.r. spectroscopy on the reduced solutions. A rhodium containing material was precipitated from the reduced dilute solution with tetraphenylborate but no peak was observed in the range 2000–2100 cm^{-1} where Rh—H stretches have previously been reported (5–7). Similarly, the high field line reported for Rh—H in the same papers could not be detected in the n.m.r. spectrum of a reduced saturated (ca. 0.01 M) $RhPy_4Cl_2^+$ solution, although the concentration range approached the detection limit for the n.m.r. configuration.

Discussion

The polarographic reaction of the $RhPy_4Cl_2^+$ species at the d.m.e. is complex but a possible scheme is given by

[1] $\longrightarrow$ Rh(III) + 2e → Rh(I)
"normal" diffusion controlled wave

[2] Rh(I) + PyH^+ → Rh(III) + Py + H^-

surface reaction at d.m.e.

The "normal" polarographic wave produces a Rh(I) species according to reaction [1]; this is consistent with the apparent 2 F per mole reduction. Since H^+ concentration appears to have little effect on $E_{1/2}{}^0$, the product of this electron transfer step is presumably not a hydride. However, the reaction is not completely "normal" in that there appears to be a strong adsorption of both the Rh(III) species and also of the product of the reduction. This can be concluded from Fig. 10 where the drop time of the d.m.e. in the presence of the Rh(III) species is plotted as a function of applied potential; it can also be inferred from the effect of temperature on the "enhanced" polarographic wave.

Under certain conditions, another reaction [2] may follow to produce an "enhanced" wave. The process envisioned would take place on the surface of the d.m.e.; it would involve a hydride intermediate which would decompose to regenerate Rh(III) and produce an enhanced polarographic current as the result of a cyclic or catalytic process.

The fact that a detectable enhancement is observed only over a restricted range of polarographic potentials can be explained if it is assumed that reaction [2] can only take place between adsorbed Rh(I) and adsorbed PyH^+ species. Three conditions could then result in a "normal" wave:

(*1*) No specific adsorption of either Rh(I) or PyH^+.

(*2*) A relatively strong adsorption of the Rh(I) produced by reaction [1]. If this was the case, the surface of the growing mercury drop would be saturated with Rh(I) to the exclusion of PyH^+ from almost the very beginning of the life of each drop.

(*3*) A relatively strong adsorption of the PyH^+. If this was the case, the Rh(I) formed by reaction [1] could not successfully compete for adsorption sites on a drop over its finite lifetime.

Intermediate situations could arise depending on the relative tendency of the Rh(I) and PyH^+ to be adsorbed. Thus it would be possible to have a catalytic process early in the life of a drop, but an increasing surface concentration of Rh(I) would finally result in an adsorption of this species to the exclusion of PyH^+. Thus only reaction [1] could proceed towards the end of the drop life.

The spike behavior of the "normal" wave would result from reaction [2] with the cyclic process inhibited by an increasingly strong adsorption of the Rh(I) as the potential of the d.m.e. becomes more negative. With electrolytes of low total Py concentration, the spike is followed by an enhancement at still more negative electrode potentials; this would follow from a change in relative adsorption characteristics with potential such that both species are again adsorbed. With electrolytes of high total Py concentration the spike and the enhancement are merged; this would follow if the higher concentration of PyH^+ in the electrolyte resulted in its adsorption, together with the Rh(I), over the given range of potential.

The final decrease to a "normal" current that is observed just prior to the discharge of the supporting electrolyte would again represent a change in relative adsorption or even a complete desorption of the two species.

In the large scale electrolysis, the coulometry shows a precise reduction of 2 F per mole of Rh(III). Thus there cannot be any appreciable net amount of the catalytic process represented by reaction [2], even under the same electrolyte conditions that produced an "enhanced" wave in polarography. It has been argued that this wave is associated with adsorption phenomena at the renewable surface of the d.m.e.; reaction [2] can proceed only when both Rh(I) and PyH^+ are present in the adsorbed state. It is possible that some of reaction [2] may indeed occur at the very beginning of a large scale electrolysis, but after passage of a small quantity of electricity, sufficient Rh(I) is produced to passivate the electrode by an adsorption of this species with an accompanying complete desorption of PyH^+. The quantity of electricity consumed in any accompanying cyclic process up to this point would be negligibly small relative to the total consumed in the quantitative reduction.

A possible scheme for the large scale reduction would require an electron transfer process followed by a protonation of part of the products of the electrode reaction

$$[3] \qquad \text{Rh(III)} + 2e \rightarrow \text{Rh(I)}$$

$$[4] \qquad x\text{Rh(I)} + y\text{H}^+ \rightarrow \text{Products} \quad \text{where } y > x$$

the nature of the protonated products being unknown. This scheme is supported by the precise 2 F per mole of Rh(III) reduced, the consumption of H^+ in the electrolysis, and evidence of a pair of products in that part of the reduced rhodium was present in an easily oxidized form (15%), the remainder in an electroinactive form (85%). The presence of some Rh(I) as a product follows from the proposal of Rund while a Rh(III)-hydride similar to the monohydride isolated by Wilkinson is an obvious possibility for a protonated product.

However, the observed consumption of 1.4 moles of H^+ per mole of Rh(III) reduced is not consistent with a single Rh(III)-hydride product, since even complete conversion to this species would require only one mole of H^+ per mole of Rh(III).

$$\text{Rh(III)} + \text{H}^+ + 2e \rightarrow \text{Rh(III)-H}$$

It is possible to explain the H^+ consumption at pH 4.5 if one proposes that one or more Py groups are displaced from the Rh(III) on reduction, the displaced Py being largely protonated at this pH. However, the same consumption of H^+ was noted at pH 7 where any displaced Py would be very largely unprotonated.

The difference between the consumption expected for the formation of Rh(III)-hydride and the value actually found appears to be significant and requires the formation of a more complex species as shown in reaction [4].

The failure to find a Rh—H stretch in the i.r. spectrum may or may not be significant in this regard. Some may have been formed but unobserved because of the relatively small quantities of this product; it may be that the proportion of stable Rh(III)-hydride is negligibly small.

Kinetics and mechanism of the addition of dimethylarsine to hexafluorobutyne-2

W. R. CULLEN AND W. R. LEEDER
Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received November 5, 1968

The addition of dimethylarsine to hexafluorobutyne-2 follows second order kinetics with activation energy, 6.09 ± 0.20 kcal/mole, and activation entropy, −48 ± 1 e.u. The product distribution of the competitive reaction of dimethylarsenic deuteride and diethylarsine with the acetylene shows that the addition mainly involves an intermolecular proton transfer. The mechanism of the addition is discussed.

Canadian Journal of Chemistry, 47, 2137 (1969)

Many investigations have been made of nucleophilic additions to acetylenes and a general rule of "*trans* addition" was postulated by Truce and Simms (1) and independently by Miller (2). This rule of stereospecific *trans* addition was based on product configuration. However, recently *cis* addition products have also been isolated (3, and references therein), mainly from reactions of primary and secondary amines, and with this discovery, the question of the mechanism of nucleophilic addition to alkynes has become of great interest. The mechanism suggested for these *cis* additions involves an intramolecular proton transfer (4). In general, the steric course of the reaction seems to depend on many variables such as the nature of the alkyne and amine (3), and the solvent (5, 6).

A predominantly *trans* addition product (90–98%) is obtained from the quantitative addition of dimethylarsine to hexafluorobutyne-2 (7) (reaction [1], R = R′ = CH_3). This reaction is clearly related to the amine additions and the present investigation was undertaken to establish if the mechanism of the arsine reaction involved a nucleophilic addition to form both products. It was also important to establish whether the hydrogen atom is transferred inter- or intra-molecularly.

Experimental

Volatile reagents and products were manipulated in a conventional vacuum system. Unless otherwise indicated, reactions were carried out in sealed Pyrex tubes. Nuclear magnetic resonance (n.m.r.) spectra were run on Varian A-60 and HA-100 instruments and are reported in p.p.m. downfield from external TMS. Ultraviolet (u.v.) spectra were recorded using a Cary Model 14 spectrophotometer; this was also used for the kinetic studies. Infrared (i.r.) spectra were run on a Perkin–Elmer Model 457 instrument.

Preparation of Dimethylarsine

The method used is a modification of that of Dehn and Wilcox (8). A 1-liter 3-necked flask was fitted with a dropping funnel, water-cooled condenser, stirrer, nitrogen purge, and cold traps (−196°) to condense any volatile products coming through the condenser. Mercuric chloride (30 g) and zinc dust (290 g) were placed in the flask and stirred vigorously with 100 ml of water. A solution of dimethylarsinic acid (50 g) in water (100 ml) was purged with nitrogen, transferred to the dropping funnel using a syringe, and combined with the slurry in the reaction flask. In a similar way 12 *N* hydrochloric acid (250 ml) was slowly added to the vigorously stirred flask. After 6 h, the contents of the traps were taken into the vacuum system and dried over P_2O_5. The yield of dimethylarsine was 34.1 g (89%). It had a very strong As—H stretching frequency at 2085 cm^{-1} and the n.m.r. spectrum showed a doublet at 0.82 p.p.m. (6H) and a septet at 2.82 p.p.m. (1H) (J_{CH_3H} = 7.0 Hz).

Preparation of Dimethylarsenic Deuteride

Dimethylarsine (10.8 g) was shaken with D_2O (30 g) and a trace of HCl (to speed exchange) for one week in a sealed tube. The arsine was separated and re-equilibrated with fresh D_2O. This yielded a product which is ~ 100% $(CH_3)_2AsD$ as detected by n.m.r.; (1:1:1 triplet at 0.82 p.p.m. (J_{CH_3D} = 1 Hz)). The i.r. spectrum showed a strong As—D stretching band at 1502 cm^{-1}.

Preparation of Diethylarsine

Chlorodiethylarsine was prepared from arsenic trichloride and tetraethyllead (9). The chloroarsine was then

[1] $$RR'AsH + CF_3C{\equiv}CCF_3 \longrightarrow \underset{90\text{–}98\%}{\overset{CF_3}{\underset{RR'As}{\diagdown C{=}C \diagup}}\overset{H}{\diagup\diagdown}\overset{}{CF_3}} + \underset{2\text{–}10\%}{\overset{CF_3}{\underset{RR'As}{\diagdown C{=}C \diagup}}\overset{CF_3}{\diagup\diagdown}\overset{}{H}}$$

For personal use only.

reduced using lithium aluminium hydride (10). Diethylarsine had a very strong As—H stretching frequency at 2085 cm^{-1}. The n.m.r. spectrum showed a quintet at 2.43 p.p.m. (1H) (J = 6 Hz) and two multiplets (10H) at 1.42 and 1.15 p.p.m. respectively.

Reaction of Dimethylarsenic Deuteride with Hexafluorobutyne-2

Dimethylarsenic deuteride (0.95 g) and the acetylene (2.8 g) were left at 20° for 1 h. The product, 2-dimethylarsino-3-deutero-1,1,1,4,4,4-hexafluorobutene-2, condensed in a trap at −78°. The purity of the product was established by its n.m.r. spectrum which showed a quartet at 0.96 p.p.m. ($J \sim 1$ Hz). A small upfield quartet presumably corresponding with the *cis* adduct was also present. The amount of this was about 5% of the total product.

Reaction of Diethylarsine and Hexafluorobutyne-2

The arsine (2.43 g) and the acetylene (3.68 g) were left for 2 days at 20°. The product, 2-diethylarsino-1,1,1,4,4,4-hexafluorobutene-2, b.p. 146°, condensed in a trap cooled to −46°. The identity of the compound was established by its n.m.r. spectrum. This showed in the downfield region a quartet of quartets centered at 6.58 p.p.m. (J = 8 and 2 Hz) and another quartet at 5.85 p.p.m. (J = 8.3 Hz). The relative intensity of the two absorptions, 22:1, was the ratio of the *trans* to *cis* adducts (7). Upfield was a triplet (CH_3—CH_2—) at 0.94 p.p.m. (J = 7 Hz) and a complex multiplet at about 1.6 p.p.m. (CH_3—CH_2—). The relative areas of all multiplets were as expected.

Equilibrium Reaction of Diethylarsine and 2-Dimethylarsino-3-deutero-1,1,1,4,4,4-hexafluorobutene-2

Equal volumes of diethylarsine and the arsinobutene were sealed in an n.m.r. tube. The spectrum after 3 h at 20° showed no downfield absorption so that no exchange of D and H occurred.

Stability of the Products of the Dimethylarsine – Hexafluorobutyne-2 Reaction

The products from the reaction of reaction [1] (R = R′ = CH_3) can be separated by vapor-phase chromatography (v.p.c.) (silicone oil at 92°). The *trans* isomer was stable to air, diethyl ether, dimethylarsine, and mixtures of dimethylarsine and diethyl ether for extended periods of time (4 weeks). No isomerization to the *cis* isomer occurred. Similarly the *cis* isomer was stable and did not isomerize under the same conditions.

Kinetics of Secondary Arsine Additions to Hexafluorobutyne-2

The kinetics of the addition reactions were determined by following product formation using n.m.r. and u.v. spectroscopy.

In a typical n.m.r. monitored experiment, 0.1805 g of hexafluorobutyne-2, dimethylarsine (0.0554 g), and diethyl ether (total volume at 20° was 1.12 ml) were condensed into an n.m.r. tube. The tube was sealed. The sample was warmed to −35° and shaken just before placing it into the cooled probe (−30°) of the spectrometer. The rate of formation of the products was followed by integration. The results shown in Table I were found for the *trans* adduct.

The rate of formation of *cis* adduct was the same as the *trans* as the relative amounts of *trans* and *cis* products remained constant throughout the experiment.

TABLE I

Rate of *trans* product formation

t* (s)	Concentration of *trans* product (moles/l)
260	0.120
344	0.147
830	0.237
780	0.246
1587	0.337
1620	0.340
2420	0.388
2445	0.394
∞	0.493

*t = 0 is arbitrary.

Assuming that the reaction is bimolecular and first order in each of the starting materials, the following rate eq. [2] can be derived

$$[2] \qquad \log\left(\frac{A_0 - U}{B_0 - U}\right) = \frac{k_T(A_0 - B_0)}{2.303}\,t$$

where t = time, A_0 = initial concentration of acetylene, B_0 = initial concentration of dimethylarsine, U = concentration of one product formed, and k_T = rate constant at temperature T. Plotting t against $\log (A_0 - U/B_0 - U)$ for *trans* product formation gives a straight line (Fig. 1).

The experiments monitored by u.v. absorption were followed by measuring the increase in absorbance at 2610 Å (the products absorb there but not the reactants (11)). The reactants were condensed via a metal valve into a cold finger attached to a 1 or 0.1 mm path length silica cell. The arsine and ether (10 ml) were added first, mixed at room temperature, and then frozen. The hexafluorobutyne-2 was then condensed into the cold finger well above the arsine–ether mixture. The lower layer was quickly warmed and then vigorously shaken onto the still frozen acetylene. When the whole apparatus was at room temperature, it was placed in the adapted cavity of the spectrometer.

Second order kinetics were observed for all reactions until at least 50% completion. Allowance has been made for the solubility of hexafluorobutyne-2 determined below (Fig. 2). A summary of the experimental conditions used for the kinetic experiments is given in Table II. The rate constants obtained from each run are also listed.

Kinetics of the Addition of Diethylarsine to Hexafluorobutyne-2

This reaction was monitored by n.m.r. techniques as described above. Diethylarsine (0.052 g), the acetylene (0.1882 g), and diethyl ether were sealed in an n.m.r. tube. A plot for second order kinetics, first order in each of the starting materials, was linear. The rate was calculated to be 1.528×10^{-3} l $mole^{-1}s^{-1}$ at −10° in diethyl ether.

Competitive Reaction of Diethylarsine and Dimethylarsenic Deuteride with Hexafluorobutyne-2

Dimethylarsenic deuteride, diethylarsine, and hexafluorobutyne-2 were frozen into a Carius tube. The tube

was warmed under water (15°) and vigorously shaken. After 5 min, the tube was frozen down, opened, and the contents taken into a vacuum system. The fraction which condensed at −78° was separated by v.p.c. (silicone, 128°). Four major fractions were found. These fractions were identified by n.m.r. to be *cis* and *trans* isomers of the arsine–butyne adducts. The weight of the separated isomers indicated that the reaction went 93% *trans*, 7% *cis* for adduct formations. The ratio of the products before and after separation was identical so no isomerization occurred while separating. From the integrals of the n.m.r. spectra, the percentage of hydrogen could be calculated for the separated fractions and from this the deuterium percentage could be found.

The results of two experiments are tabulated in Tables III and IV.

Reaction of Dimethylarsine and Hexafluorobutyne-2 in the Gas Phase

Gaseous hexafluorobutyne-2 and dimethylarsine were isolated separately in two evacuated bulbs separated by a valve. The valve was opened and the gas allowed to mix at room temperature. The extent of reaction could be followed by the pressure decrease in the system. In the absence of light, complete reaction required 3 days. Under identical initial conditions, but upon irradiation with u.v. light (100 W lamp, 20 cm from the air-stream cooled bulbs), the reaction required only 1 day to go to completion.

The analysis of the products from the two reactions showed 92% *trans* and 8% *cis* adducts from the u.v.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

irradiated experiment, and 94% *trans* and 6% *cis* in absence of light. The small difference is not significant.

Solubility of Hexafluorobutyne-2 in Diethyl Ether

Hexafluorobutyne-2 (0.02615 g), trifluoroacetophenone (0.1295 g), and diethyl ether were sealed in an n.m.r. tube. The total volume was 1.0 ml and the concentration of gas corresponded closely with that of the n.m.r. kinetic studies. The trifluoroacetophenone was introduced as an internal standard. The ratio of the integrals in the ^{19}F n.m.r. spectrum of the sample was observed at various temperatures. At $-76°$ two phases appeared. The percentage of hexafluorobutyne-2 dissolved in the ether is plotted in Fig. 2.

In a separate experiment the vapor pressure increase found on adding the acetylene to ether solutions of the acetylene indicated that at 24°, 12% of the acetylene does not dissolve. This corresponds well with the n.m.r. results.

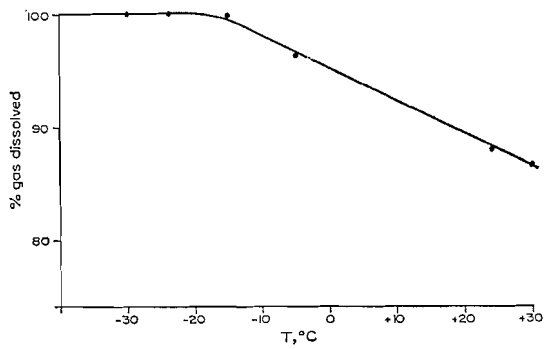

FIG. 2. Plot of % hexafluorobutyne-2 dissolved in diethylether as a function of temperature.

Discussion

Dimethylarsenic deuteride and diethylarsine have been found to add easily to hexafluorobutyne-2 in the same way as dimethylarsine (reaction [1], R = R′ = CH_3). The diethylarsine adduct is about 96% *trans* and the dimethylarsenic deuteride adduct is much the same. The n.m.r. spectrum of the deutero adduct shows that the peak due to the $(CH_3)_2As$ group is split into a quartet as has been observed previously for compounds with this type of structure (7, 12).

Kinetic Results

The addition of dimethylarsine to hexafluorobutyne-2 in ether solution is first order in both arsine and acetylene (Table II and Fig. 1). The rate constants determined from the n.m.r. monitored experiments are reproducible and an activation energy of 6.09 ± 0.20 kcal/mole for the reaction can be obtained from the variation of k_T with temperature. The activation entropy is -48 ± 1 e.u. at $-30°$ (13).

Although the u.v. monitored experiments gave good second order plots, the rate constants were inconsistent (Table II). This is probably due to the formation of variable amounts of polymeric $(CF_3C)_n$, visible in some cases. A small accelerating effect due to the u.v. radiation might also be expected since the slow gas phase addition rate is about three times faster when the reactants are irradiated with u.v. light. Good temperature control was not possible in the u.v. monitored experiment, so the rates would be expected to be nonreproducible on this account also. However, the greatly increased rate found when methanol was used as solvent is a real effect (*q.v*).

The product distribution of the liquid phase reaction is the same in a solvent as when the reactants are mixed neat, and is apparently unchanged when the reaction is done at lower temperatures. The rate of formation of the *cis* product always parallels that of the *trans*, suggesting that they are produced from the same intermediate.

In an attempt to determine if the As—H bond was involved in the rate determining step of the reaction, the rate of the addition of dimethylarsenic deuteride to the butyne was measured. However, this experiment, necessarily monitored by u.v. absorption, was inconclusive. The rate is similar to that found for the majority of the u.v. monitored experiments, (Table II).

The rate of addition of diethylarsine to the butyne is probably very little different from the rate of the addition of dimethylarsine. This can be deduced from the result that the diethylarsine rate at $-10°$ almost lies on the linear plot of log k_T against $1/T$ used to obtain the activation energy for the dimethylarsine addition.

Reaction Mechanism

Four general reaction paths can be considered for reaction [1]. The first, involving free radicals, can be eliminated mainly on the basis that the rate of addition of dimethylarsine to the acetylene is not significantly altered in the presence of an inhibitor and that the *cis* and *trans* isomers were again formed at the same rate. The increase in rate in methanol solution is against a free radical mechanism as is, to a lesser extent, the slight increase in the gas phase reaction found when the reactants are irradiated with u.v. light. The methanol experiment, monitored by u.v. spectroscopy, was checked against control unirradiated experiments. After a given time the reactions had proceeded to almost the same extent. The products from the gas phase reactions also have the same

For personal use only.

isomer distribution as both the neat liquid reactions and the solution reactions, which indicates that the same sort of mechanism is operating in all cases.

A second possible mechanism involves pre-ionization of the arsine (reaction [3]). The rate law would be dependent on either the square root

[3] $(CH_3)_2AsH \rightleftarrows (CH_3)_2As^- + H^+$

of the arsine concentration or would be zero order in acetylene depending on the rate controlling step of the mechanism. The more likely pre-ionization step of reaction [4], could result in second

[4] $2(CH_3)_2AsH \rightleftarrows (CH_3)_2As^- + (CH_3)_2AsH_2^+$

order kinetics, first order in each of the starting materials, if addition of the arsine anion to the butyne is slower than the reverse step of reaction [4]. However, this pre-ionization step is not likely to contribute significantly to the overall mechanism of the addition reaction since the maximum rate of exchange of the label of diethylarsine with dimethylarsenic deuteride, regardless of mechanism, is 10^3 times slower than the rate of the addition reaction (11).

The third possible mechanism would involve electrophilic attack by the arsine which seems unlikely on chemical evidence. Haszeldine (14) has shown that electrophilic addition to hexafluorobutyne-2 is difficult and often needs a catalyst.

Considerable chemical evidence supports the fourth possible mechanism, nucleophilic attack by the arsine. Thus hexafluorobutyne-2 reacts easily with alkoxides and other nucleophiles (14, 15) and the ease of nucleophilic attack on hexafluorobutyne-2 is greater than on 3,3,3-trifluoropropyne, $CF_3C{\equiv}CH$ (14). It has already been shown that dimethylarsine reacts faster with the butyne than the propyne (7). Another piece of evidence pointing to nucleophilic attack is the result that as the groups R (reaction [1]) become more electronegative the reaction becomes more difficult. Thus the reaction rate decreases in the order (7)

$$(CH_3)_2AsH > (C_6H_5)(CH_3)AsH > (CF_3)_2AsH$$

an order which reflects the decreasing availability of the arsenic lone pair for nucleophilic attack because of the electron withdrawing effect of the groups attached to it (16).

In many amine additions to acetylenes the postulated mechanism involves an *intramolecular* proton transfer.

[5] $$R_2AsH + CF_3C{\equiv}CCF_3 \longrightarrow \begin{matrix} CF_3 & & CF_3 \\ & C{=}C & \\ R_2As\cdots\cdots & & H \end{matrix} \longrightarrow \begin{matrix} CF_3 & & CF_3 \\ & C{=}C & \\ R_2As & & H \end{matrix}$$

[6] $$\left.\begin{matrix}(C_2H_5)_2AsH \\ + \\ (CH_3)_2AsD\end{matrix}\right\} + CF_3C{\equiv}CCF_3 \longrightarrow \begin{matrix}(C_2H_5)_2AsC(CF_3){=}C(^{H}_{D})CF_3 \\ (CH_3)_2AsC(CF_3){=}C(^{H}_{D})CF_3\end{matrix}$$

This possibility (reaction [5]) must be considered for the arsine additions especially for the formation of the *cis* adduct. To check on this, the competitive experiment of reaction [6] was carried out on a preparative scale so that the *cis* and *trans* isomers of the products could be separated. The results are listed in Tables III and IV. The hydrogen–deuterium exchange reaction of reaction [7] when studied with neat liquids takes about 15 min for 50% equilibration at 35°, and in dilute solution is so slow compared with the rate of addition to the acetylene, that preequilibration of the arsines can be ignored (11).

[7] $(C_2H_5)_2AsH + (CH_3)_2AsD \rightleftarrows (CH_3)_2AsH + (C_2H_5)_2AsD$

Moreover, there is no exchange of the deuterium label on the products with another product or with a reactant, and there is no isomerization of the reaction products once they are formed even in the presence of unreacted arsine[1]. Thus the distribution of the deuterium label is significant and can be used as an aid to establish a mechanism for the reaction. Table V shows some of the mechanistic possibilities for the *trans* addition.

A similar table can be drawn up for the *cis* adducts. The results show that an *intramolecular* process is most unlikely for the formation of both isomers.

[1]Isomerization of tin hydride – acetylene adducts does occur in the presence of tin hydride (17).

TABLE V

Mechanistic possibilities for *trans* addition

trans Product	Exp. 1, %D		Exp. 2, %D		Mechanism
	Expt.	Calcd.	Expt.	Calcd.	
$(CH_3)_2As$	77	100	40	100	Intramolecular proton transfer

[8] $$R_2AsH + CF_3C{\equiv}CCF_3 \xrightarrow{\text{slow}} \left[\begin{array}{c} CF_3 \quad\quad \bar{C} \\ \diagdown \quad / \\ C{=}C \\ / \quad \diagdown \\ R_2\overset{+}{A}sH \quad CF_3 \end{array} \rightleftarrows \begin{array}{c} CF_3 \quad\quad CF_3 \\ \diagdown \quad / \\ C{=}\underline{C} \\ / \quad \diagdown \\ R_2\overset{+}{A}sH \end{array} \right] \xrightarrow{R_2'AsH'} \begin{array}{c} CF_3 \quad\quad H' \\ \diagdown \quad / \\ C{=}C \\ / \quad \diagdown \\ R_2As \quad CF_3 \end{array} + \begin{array}{c} CF_3 \quad\quad CF_3 \\ \diagdown \quad / \\ C{=}C \\ / \quad \diagdown \\ R_2As \quad H' \end{array} + R_2'AsH$$

[9] $$R_2\overset{+}{A}sHC(CF_3){=}\bar{C}CF_3 + R_2'AsH' \rightarrow R_2\overset{+}{A}sHC(CF_3){=}CH'CF_3 + R_2'\bar{A}s$$

$$R_2'\bar{A}s + CF_3C{\equiv}CCF_3 \rightarrow R_2'AsC(CF_3){=}\bar{C}CF_3 \text{ etc.}$$

$$R_2\overset{+}{A}sHC(CF_3){=}CH'CF_3 \rightarrow R_2AsC(CF_3){=}CH'CF_3 + \overset{+}{H} \text{ (or } R_2\overset{+}{A}sH_2)$$

$$\overset{+}{H} \text{ (or } R_2\overset{+}{A}sH_2) + R_2'\bar{A}s \rightarrow R_2'AsH \text{ (+ } R_2AsH)$$

The following mechanism which most closely fits experimental results is proposed for the addition.

The *cis–trans* interconversion could proceed through a hyperconjugated intermediate as previously suggested (18). It is possible that at very low concentration the *cis* addition does go by an intramolecular process because of the lack of a second arsine molecule to donate its proton.

The low activation energy (6.09 kcal/mole) for the formation of the *trans* (and possibly *cis*) adduct fits in well with the idea of the arsenic atom easily donating its lone pair to the very electron defficient carbon–carbon triple bond. The activation entropy which is highly negative could be consistent with a charged transition state. The latter would account for the large increase in the rate of addition found when methanol is the solvent.

It should be noted that little can be said about the second part of the reaction, i.e. the formation of $R_2'AsH$. In fact it might not be formed at all since the anion $R_2'As^-$ might be stable enough to act as the nucleophile for further additions. This and some other possibilities are shown in reaction [9].

Solvolysis of alkyl chlorosulfates. Part III. Alcoholysis of *n*-propyl chlorosulfate

E. BUNCEL AND J. P. MILLINGTON
Department of Chemistry, Queen's University, Kingston, Ontario
Received November 25, 1968

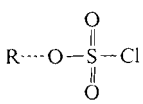
The propanolysis reaction of *n*-propyl chlorosulfate has been examined quantitatively. Reaction at 25° yields the following products: di-*n*-propyl ether, *n*-propyl chloride, isopropyl chloride (trace), *n*-propyl hydrogen sulfate, di-*n*-propyl sulfate, and hydrogen chloride. It is found that the product distribution bears a direct relationship to the initial concentration of *n*-propyl chlorosulfate.

It is concluded that only di-*n*-propyl ether and di-*n*-propyl sulfate are formed in primary processes, that is solvolytic displacement at carbon and sulfur respectively, and that the other products arise through secondary reactions. Carbon displacement is the predominant primary process.

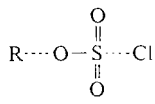
Canadian Journal of Chemistry, 47, 2145 (1969)

The alcoholysis of an alkyl chlorosulfate was first examined in 1879 by Claesson (1) who reported the formation of a variety of products. Thus ethyl chlorosulfate on treatment with ethanol gave rise to diethyl ether, ethyl chloride, diethyl sulfate, ethyl hydrogen sulfate, and hydrogen chloride (1). Subsequently the reaction of methyl chlorosulfate with methanol was reported to yield analogous products, but with the exception of dimethyl ether (2).

In our first systematic study of nucleophilic substitution in alkyl chlorosulfates (3, 4) the kinetics of hydrolysis in aqueous dioxan of a series of primary alkyl chlorosulfates was reported on (see also ref. 5). The relative rates of hydrolysis were in accord with a solvolytic displacement process at carbon (**1**) but the entropies of activation suggested the possibility of multiple bond fission (**2**) (cf. refs. 6, 7). The reaction of



1



2

n-propyl chlorosulfate with some nucleophiles in aqueous dioxan was similarly interpreted as proceeding by displacement at carbon with $^-OSO_2Cl$ as the leaving group (8). In the alcoholysis of an alkyl chlorosulfate, the formation of dialkyl ether is indicative of carbon displacement, while the simultaneous formation of dialkyl sulfate would then suggest that nucleophilic displacement at sulfur has become an important competing process. The origin of the other products observed in the earlier studies (1, 2) is not so clear. The present study was initiated with the aim of elucidating these aspects and particularly to evaluate quantitatively the nucleophilicities towards carbon and towards sulfur in this system.

Results

The system chosen for study was that of *n*-propyl chlorosulfate with *n*-propanol, in which quantitative estimation of the various possible products should be readily feasible. As anticipated, gas–liquid chromatography (g.l.c.) allowed the quantitative analysis of di-*n*-propyl ether, *n*-propyl chloride, isopropyl chloride, and di-*n*-propyl sulfate, in *n*-propanol solvent. Hydrogen chloride was analyzed as chloride ion with silver nitrate, and *n*-propyl hydrogen sulfate was determined as the difference between the total acid, as titrated with sodium hydroxide, and the hydrogen chloride. Reaction was allowed to go to completion at 25° prior to product analysis. The effect of varying the initial chlorosulfate concentration on the proportion of the various products was evaluated.

The results of the product analyses are given in Tables I–III. For clarity the data are presented separately for the constituent portions of the substrate: the *n*-propyl residue (Table I), the chloride residue (Table II), and the sulfate moiety (Table III), in mole % throughout. The *n*-propyl hydrogen sulfate data are not included in Table I since, as is shown later, the alkyl moiety of this product originates not from the substrate but from the solvent through a secondary reaction. Isopropyl chloride constitutes only a very small proportion of the total alkyl halide and is formed

only with the highest *n*-propyl chlorosulfate concentration. Due to the very small yield of di-*n*-propyl sulfate and the consequent poor precision in analysis, it is not clear whether the apparent initial increase and subsequent decrease in the yield of this material is real, or whether its yield should be considered as invariant, within experimental error (i.e. a yield of 6 ± 2.5 mole%). The material balance in the various experiments is generally better than 90% of theoretical.

The effect of increasing the initial concentration of *n*-propyl chlorosulfate on the product distribution is seen more clearly with reference to the graphical representation in Figs. 1 and 2, for the volatile and the ionic products of reaction, respectively. Figure 1 shows that on increasing the initial substrate concentration from ca. 0.01 to 2 *M* the yield of di-*n*-propyl ether decreases, rapidly at first and then more gradually, while the yield of *n*-propyl chloride increases correspondingly. The di-*n*-propyl sulfate yield remains small throughout. Figure 2 shows that the decrease in the hydrogen chloride yield with increasing substrate concentration mirrors the trend with respect to di-*n*-propyl ether. The *n*-propyl hydrogen sulfate yield remains approximately constant.

Discussion

The results presented in Tables I–III and Figs. 1 and 2 show that there is a relationship between the spectrum of products and the initial substrate concentration. The proposed mechanistic rationale of the observations is as follows. The near quantitative formation of di-*n*-propyl ether in the most dilute reaction media indicates that the principal primary process, in the absence of complicating reactions which arise as the substrate concentration is increased, is solvolytic displacement by *n*-propanol nucleophile on carbon, with $^-OSO_2Cl$ as the leaving group. The near constancy in the di-*n*-propyl sulfate yield

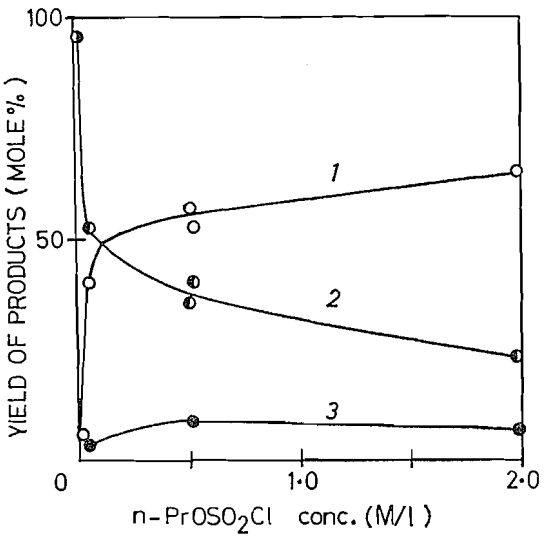

FIG. 1. Yield of gaseous products (mole %) in the propanolysis of *n*-propyl chlorosulfate at 25° as function of initial concentration. Curve 1, *n*-propyl chloride; curve 2, di-*n*-propyl ether; curve 3, di-*n*-propyl sulfate.

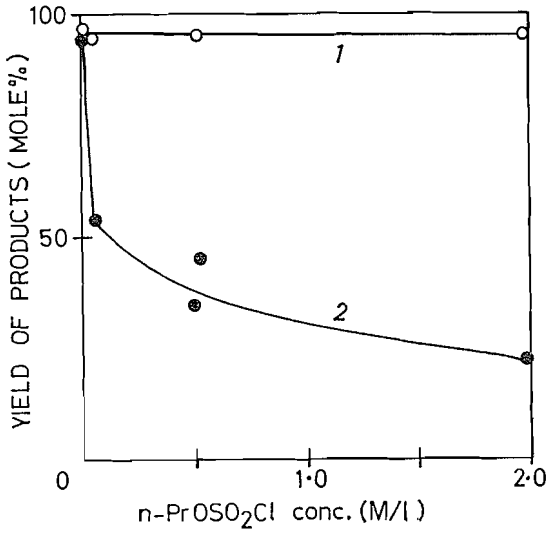

FIG. 2. Yield of ionic products (mole %) in the propanolysis of *n*-propyl chlorosulfate at 25° as function of initial concentration. Curve 1, *n*-propyl hydrogen sulfate; curve 2, hydrogen chloride.

over the range of substrate concentrations suggests that this compound is formed by a minor concurrent (parallel) process, that is, displacement by *n*-propanol nucleophile on sulfur, with chloride ion as the leaving group. The two primary processes, solvolytic displacement at carbon and at sulfur, are depicted in reactions [1] and [2]

[1] $PrOH + Pr\overset{\frown}{O}SO_2Cl \longrightarrow Pr_2O + HOSO_2Cl$

[2] $PrOH + PrOSO_2\overset{\frown}{Cl} \longrightarrow PrOSO_2OPr + HCl$

It is proposed that the other observed products arise as follows. The chlorosulfonic acid formed in the principal solvolytic process (reaction [1]) will be rapidly solvolyzed to form *n*-propyl hydrogen sulfate and hydrogen chloride (reaction [3]); this would account for the initial formation of hydrogen chloride in ca. 95% yield, as well as *n*-propyl hydrogen sulfate. Now as the concentration of hydrogen chloride increases, with increasing initial substrate concentration, chloride ion will effectively compete with *n*-propanol in nucleophilic displacement at the carbon center of *n*-propyl chlorosulfate (reaction [4]). (This reaction may be acid catalyzed, with protonation occurring on the ester oxygen, and may also account for the formation of isopropyl chloride through a minor ionization process.) Since

[3] $PrOH + HOSO_2\overset{\frown}{Cl} \longrightarrow PrOSO_2OH + HCl$

[4] $HCl + Pr\overset{\frown}{O}SO_2Cl \longrightarrow PrCl + HOSO_2Cl$

reaction [4] also consumes the substrate, the formation of propyl chloride must occur at the expense of the propyl ether (reaction [1]), as is in fact observed experimentally (Fig. 1). (Some *n*-propyl chloride may also be formed by reaction of hydrogen chloride with solvent but this should be a very minor process under the mild reaction conditions.) The chlorosulfonic acid formed in the latter reaction (reaction [4]) will react with solvent to give more *n*-propyl hydrogen sulfate, whose total yield will therefore equal the sum of the yields of propyl ether and propyl chloride. This also is borne out by the experimental findings.

The conclusion of the preceding discussion hence is that the primary processes in the propanolysis of *n*-propyl chlorosulfate are solvolytic displacements at carbon (reaction [1]) and at sulfur (reaction [2]), leading to propyl ether and propyl sulfate, respectively. Propyl chloride, propyl hydrogen sulfate, and hydrogen chloride are formed in secondary, consecutive, reactions (reactions [3] and [4]). Of the two primary processes, the predominance of solvolytic displacement at carbon requires comment. One factor
