The far infrared spectrum of Pd_2(*trans*-ED)$_4$-$Cl_4 \cdot 3H_2O$, **7**, (M = Pd), shows no absorptions that are altered by substitution of Cl^- with Br^-. This suggests that in the solid state, complex **7** (M = Pd) contains no coordinated Cl^- ions. The fact that both the Cl^- and Br^- derivatives are the same color supports this conclusion, because substitution of Cl^- with Br^- in Pd(II) complexes normally results in a deepening color as the charge transfer absorptions move to lower energies. In agreement with this, when water is removed from complex **7** (M = Pd), the color deepens and a new absorption appears at 285 cm^{-1}, suggesting that Cl^- ions have moved into the first coordination sphere.

The complex, Pd(*cis*-ED)$_2Cl_2 \cdot 3H_2O$, shows a single absorption in this region, at 296 cm^{-1}. This band is not altered upon substitution of Cl^- with Br^- and it is concluded that there is no positive evidence for five- or six-coordinate Pd(II) in the solid state. The complex, Pd(*cis*-ED)Cl_2, shows three bands in this region, at 322, 293, and 262 cm^{-1}, none of which appear in Pd(*cis*-ED)Br_2. From the evidence above, the absorption at 293 cm^{-1} could be considered a

For personal use only.

ligand absorption and it is not clear why it disappears with the removal of Cl^- ions. The number and position of the M—X absorptions, however, do support the structure **9** (11).

Reactions

It was reported (1) that ultraviolet irradiation of solutions of $Pt_2(trans\text{-}ED)_4Cl_4 \cdot 3H_2O$ in a variety of solvents caused a *trans*-to-*cis* conversion of the ligand, to yield the complex, $Pt(cis\text{-}ED)_2Cl_2$. With the complex, $Pd_2(trans\text{-}ED)_4Cl_4 \cdot 3H_2O$, irradiation of an aqueous solution for two days caused no change in the n.m.r. spectrum of that solution, nor in its color. In other solvents (ethanol, acetonitrile), in the presence of excess *trans*-ED to stabilize the starting material, irradiation for 7 h through a Pyrex filter did cause a decoloration of the solution and conversion of the ligand according to the following equation

$$[2]\quad Pd_2(trans\text{-}ED)_4Cl_4 \cdot 3H_2O \xrightarrow{h\nu} 2\,Pd(cis\text{-}ED)_2Cl_2 \cdot 3H_2O$$

(Extra water is picked up during the reaction or during the work-up. Isolation of the product complex in the absence of water yields an extremely hygroscopic yellow powder that is difficult to handle.)

The stability of the complex **7** (M = Pd) in water and its instability in other solvents is evidence for the weaker coordinating power of tertiary arsine and chloride ions for palladium(II) compared to platinum(II). The following points give evidence that in these complexes there is a strong competition between tertiary arsine and Cl^- ion for the metal coordination sites.

(*a*) The ease with which ligands can be removed from solid $M_2(trans\text{-}ED)_4Cl_4 \cdot 3H_2O$ (M = Pd, Pt), i.e.

$$[3]\quad M_2(trans\text{-}ED)_4Cl_4 \cdot 3H_2O \rightleftharpoons M_2(trans\text{-}ED)_2Cl_4 + 2\,trans\text{-}ED + 3H_2O$$

In the case of the palladium derivative, simple loss of water at atmospheric pressure will shift this equilibrium to the right, while for M = Pt(II), heating at high vacuum to 95 °C is required before the internal attack of Cl^- ions causes the M—As bonds to rupture.

(*b*) Stability in non-aqueous solvents. The platinum(II) complex in (*a*) above can be dissolved and recovered unchanged from non-aqueous solvents that are not strongly coordinating (e.g. ethanol). With the corresponding palladium(II) complex, dissolution in solvents in which the halide ion is not strongly solvated causes the immediate elimination of two molecules of ligand and the precipitation of the dimeric, 1:1 complex **6** (M = Pd), see reaction 1. (The process occurs immediately in ethanol, nitromethane, and acetonitrile.) The solvating properties of the solvent favor dissolution of the ligand rather than the chloride ion and this, along with the insolubility of complex **10**, helps to drive the reaction forward.

(*c*) Stability in aqueous solution. Here, the positions of palladium(II) and platinum(II) are reversed. The important equilibrium is

$$[4]\quad M_2(trans\text{-}ED)_4Cl_4(aq) \rightleftharpoons [M_2(trans\text{-}ED)_4]^{(4-x)+}Cl_x(aq) + (4-x)Cl^-(aq)$$

For M = Pd(II), conductivity measurements show that the value of x approaches 0 in dilute solutions, and that there is very little competition between AsR_3 and Cl^- in these solutions. The fact that the corresponding bromide derivative is the same color as the chloride indicates the ionic nature of the halides even in the solid state. The isomerization of *trans*-ED to *cis*-ED requires a rupture of the M—As bond, and in this case the chloride ion is prevented from causing this rupture. For M = Pt(II), however, the complex is much less soluble in water, suggesting that x approaches the value 4 in reaction [4]. Upon exposure to ultraviolet light, the rupture of the M—As bond is greatly assisted by the strongly coordinating chloride ion, and isomerization occurs.

Calculation of reaction order for the homogeneous pyrolysis of organic vapors

JOHN TOROK[1] AND SAMUEL SANDLER
Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario
Received November 1, 1968

A method is proposed for the derivation of a mathematical equation that relates the kinetic parameters of the propagation reactions of homogeneous free-radical chain reactions to the overall order of the reaction. The equation may be used in evaluating the predominant chain-termination reaction, provided that the mechanism of propagation of the chain is well understood. Application of the technique is demonstrated for the pyrolysis of *n*-butane. It predicts the predominance of the methyl–methyl radical recombination reaction.

Introduction

Goldfinger, Letort, and Niclause (1) have shown that, for pyrolytic reactions, the overall order of the reaction depends on: (*a*) the order of initiation (first or second order), (*b*) the order of termination (second or third order), and (*c*) the type of radical participating in the chain-termination process. They referred to radicals involved in bimolecular propagation reactions as β radicals, and radicals undergoing unimolecular reactions in the propagating steps as μ radicals. The various possibilities for the overall orders of such reactions are summarized in Table I.

TABLE I

Overall orders of reaction for various types of initiation and termination reactions

First-order initiation		Second-order initiation		
Simple termination	Third-body termination	Simple termination	Third-body termination	Overall order
		ββ		2
ββ		βμ	ββM	3/2
βμ	ββM	μμ	βμM	1
μμ	βμM		μμM	1/2
	μμM			0

Although Goldfinger's rule is helpful in establishing which chain-termination reaction is predominant, it neglects the treatment of the homogeneous reaction phenomena frequently encountered in chain reactions and affecting the overall order of such reactions. These include observations such as: (*a*) the rates of unimolecular initiation, propagation, or bimolecular termination reactions are proportional to a fractional power of the reaction pressure when in their pressure-dependent region, (*b*) some radicals, such as ethyl and isopropyl, may act both as β and as μ radicals, and (*c*) with certain reaction conditions 2 or more chain-termination reactions may have comparable rates.

The present paper is concerned with the mathematical treatment of the above phenomena. One study of the pyrolysis of *n*-butane is used to illustrate the effect of the first 2 points, while the third will be treated in a subsequent publication.

Derivation of Order Equation

Equations permitting the prediction of the overall reaction order for a simple pyrolysis mechanism will be derived first. It will be assumed initially that the initiation and termination reactions are in their pressure-dependent regions in the following generalized scheme.

Initiation

[1] $$a\mathrm{AH} \rightarrow 2 \text{ free radicals} + (a-1)\mathrm{AH}$$

Propagation

[2] $$\mathrm{A}\cdot \rightarrow \mathrm{B}\cdot + \mathrm{C}$$

[3] $$\mathrm{B}\cdot + \mathrm{AH} \rightarrow \mathrm{BH} + \mathrm{A}\cdot$$

Reactions [2] and [3] participate in a cyclic process.

Termination

[4] $$\mathrm{A}\cdot + \mathrm{A}\cdot + b\mathrm{AH} \rightarrow \mathrm{A_2} + b\mathrm{AH}\ (\mu - \mu \text{ termination})$$

[5] $$\mathrm{A}\cdot + \mathrm{B}\cdot + c\mathrm{AH} \rightarrow \mathrm{AB} + c\mathrm{AH}\ (\beta - \mu \text{ termination})$$

[6] $$\mathrm{B}\cdot + \mathrm{B}\cdot + d\mathrm{AH} \rightarrow \mathrm{B_2} + d\mathrm{AH}\ (\beta - \beta \text{ termination})$$

Here A· and B· are free radicals while AH,

[1]Present Address: Norton Research Corporation, Chippawa, Ontario.

For personal use only.

BH, A_2, B_2, AB, and C are organic compounds.

In the following derivation the following assumptions are made.

Assumption 1, the fundamental hypothesis of Bodenstein that the intermediate products of the reaction are of almost stationary concentration is valid.

Assumption 2, the chain lengths are large.

Since the rate of chain initiation is equal to the rate of chain termination

$$[7]\quad k_1[\mathrm{AH}]^a = k_4[\mathrm{A}\cdot]^2[\mathrm{AH}]^b + k_5[\mathrm{A}\cdot][\mathrm{B}\cdot][\mathrm{AH}]^c + k_6[\mathrm{B}\cdot]^2[\mathrm{AH}]^d$$

Based on assumption 2 the rates of the two propagating reactions, [2] and [3], are approximately equal and equivalent to the overall rate of reaction, r, that is

$$[8]\quad r = k_2[\mathrm{A}\cdot] = k_3[\mathrm{B}\cdot][\mathrm{AH}]$$

From eqs. [7] and [8] the steady-state concentration of radical A· is

$$[9]\quad [\mathrm{A}\cdot] = k_1^{1/2}k_3[\mathrm{AH}]^{a/2}/(k_3^2k_4[\mathrm{AH}]^b + k_2k_3k_5[\mathrm{AH}]^{c-1} + k_2^2k_6[\mathrm{AH}]^{d-2})^{1/2}$$

The overall order of the reaction is equivalent to the slope of the ln rate vs. ln pressure relationship, or

$$[10]\quad \text{Order} = \mathrm{d}\ln r/\mathrm{d}\ln[\mathrm{AH}]$$

Substitution of the first part of eq. [8] into eq. [10] results in

$$[11]\quad \text{Order} = \frac{[\mathrm{AH}]}{k_2[\mathrm{A}\cdot]}\cdot\frac{\mathrm{d}(k_2[\mathrm{A}\cdot])}{\mathrm{d}[\mathrm{AH}]} = \frac{[\mathrm{AH}]}{[\mathrm{A}\cdot]}\cdot\frac{\mathrm{d}[\mathrm{A}\cdot]}{\mathrm{d}[\mathrm{AH}]}$$

Equation [9] and its derivative with respect to AH may be substituted into eq. [11]. After rearrangement, one gets

$$[12]\quad \text{Order} = \frac{a-1}{2} + \frac{(0.5 - b/2)k_3^2k_4[\mathrm{AH}]^b + (1.0 - c/2)k_2k_3k_5[\mathrm{AH}]^{c-1} + (1.5 - d/2)k_2^2k_6[\mathrm{AH}]^{d-2}}{k_3^2k_4[\mathrm{AH}]^b + k_2k_3k_5[\mathrm{AH}]^{c-1} + k_2^2k_6[\mathrm{AH}]^{d-2}}$$

By substituting into eq. [12] the rate expressions for reactions [4], [5], and [6], as modified by substitution of the second equality in eq. [8], the following expression is obtained,

$$[13]\quad \text{Order} = \frac{a-1}{2} + \frac{(0.5 - b/2)r_4 + (1.0 - c/2)r_5 + (1.5 - d/2)r_6}{r_4 + r_5 + r_6}$$

where r_i = rate of reaction i. Goldfinger's table (Table I) may be generated from eq. [13] when conditions such that only one of the three possible termination reactions, that is [4], [5], or [6], may be concerned and, when a equals 1 or 2 and either b, c, or d is equal to 0 or 1.

For most pyrolytic reactions the initiation reaction is first order and the predominant termination reactions are second order. Under these circumstances a third assumption may be made.

Assumption 3, the rate constant for the cross combination of free radicals can be calculated from their individual recombination rates. According to the simple collision theory of chemical kinetics

$$[14]\quad k_5 = 2(k_4k_6)^{1/2}$$

Equation [13] then simplifies to the following expression

$$[15]\quad \text{Order} = \frac{(0.5k_4^{1/2}/k_2)[\mathrm{AH}] + 1.5(k_5^{1/2}/k_3)}{(k_4^{1/2}/k_2)[\mathrm{AH}] + (k_5^{1/2}/k_3)}$$

It should be noted that the order in eq. [15] is a function of ratios of rate constants of the form $k_3/k_5^{1/2}$ and $k_2/k_4^{1/2}$. Photolytic investigations of free-radical reactions produce a ratio of rate constants of the form $k_m/k_u^{1/2}$, where k_m is the rate constant of a propagation step involving a free radical as a reactant and k_u is the rate constant of a chain-termination step involving the recombination of two of the same radicals. In the above mechanism $m = 2$ or 3 and $u = 4$ or 5. Thus, a prediction of the overall order may be made if the kinetic parameters for the chain-propagation reactions are known.

Reaction Order when One of the Radicals Acts both as a β and as a μ Radical, e.g., Pyrolysis of n-Butane

The ethyl radical may act both as a β and as a μ radical. For example, in *n*-butane pyrolysis, it acts as a β radical in the following reaction

[16] $C_2H_5\cdot + C_4H_{10} \rightarrow C_2H_6 + C_4H_9\cdot$

and as a μ radical in

[17] $C_2H_5\cdot \rightarrow C_2H_4 + H\cdot$

According to Purnell and Quinn (2) reaction [17] is in its pressure-dependent region at the conditions of their investigation (420–530 °C). It can more properly be represented by the following reaction

[18] $C_2H_5\cdot + e\,n\text{-}C_4H_{10} \rightarrow C_2H_4 + H\cdot + e\,n\text{-}C_4H_{10}$

where $1 > e > 0$

Derivation of the order equation for *n*-butane pyrolysis will demonstrate the effect of an ambivalent radical such as the ethyl radical on the overall order of reaction.

The following mechanism differs from the ones proposed by previous investigators (2, 3) in that primary (p-$C_4H_9\cdot$) and secondary (s-$C_4H_9\cdot$) butyl radicals are treated separately. Investigations of *n*-butane-2,2,3,3-d_4 pyrolysis (4) and comparison of the kinetic parameters for relative p- and s-hydrogen abstraction from *n*-butane (5, 6) with the kinetic parameters for product distribution in *n*-butane pyrolysis (2) indicate that the rate of isomerization is negligible compared to the rate of decomposition of butyl radicals in the 400–500 °C range. The results of an investigation by Kerr and Trotman-Dickenson (7) in this area indicate an appreciable rate of butyl radical isomerization. However, these results do not agree with the findings of other investigators of butyl radical decomposition kinetics (8–10).

Mechanism of n-Butane Pyrolysis

Initiation

[19] $C_4H_{10} \rightarrow 2C_2H_5\cdot$

Propagation

[20] p-$C_4H_9\cdot \rightarrow C_2H_4 + C_2H_5\cdot$

[21] s-$C_4H_9\cdot \rightarrow C_3H_6 + CH_3\cdot$

[16] $C_2H_5\cdot + C_4H_{10} \rightarrow C_2H_6$ + s- or p-$C_4H_9\cdot$

[22] $CH_3\cdot + C_4H_{10} \rightarrow CH_4$ + s- or p-$C_4H_9\cdot$

[18] $C_2H_5\cdot + eC_4H_{10} \rightarrow C_2H_4 + H\cdot + eC_4H_{10}$

[23] $H\cdot + C_4H_{10} \rightarrow H_2$ + s- or p-$C_4H_9\cdot$

Termination

Assuming that all of the 5 free radicals can participate in recombination and cross-combination reactions and neglecting disproportionation reactions, the following recombination reaction equations may be written

[24] $2CH_3\cdot \rightarrow C_2H_6$

[25] $2C_2H_5\cdot \rightarrow C_4H_{10}$

[26] $2s\text{-}C_4H_9\cdot \rightarrow C_8H_{18}$

[27] $2p\text{-}C_4H_9\cdot \rightarrow C_8H_{18}$

[28] $2H\cdot \rightarrow H_2$

For the free-radical, cross-combination reactions assumption 3 may be applied and the appropriate rates may be expressed in terms of the rates of reactions [24] to [28].

The relative rates of s- and p-butyl radical formation may be obtained from the product distributions

$$[29] \qquad \frac{r_{20}}{r_{21}} = \frac{[C_2H_4] + [C_2H_6]}{[CH_4] + [C_3H_6]} = Q$$

where $Q = f(T)$ only.

Using the three assumptions which were applied to the simple pyrolysis mechanism, the rate of initiation = rate of termination

$$[30] \quad k_{19}C = (k_{24}^{1/2}R1 + k_{25}^{1/2}R2 + k_{26}^{1/2}SR4 + k_{27}^{1/2}PR4 + k_{28}^{1/2}H)^2 = J^2$$

where $R1 = [CH_3\cdot]$, $R2 = [C_2H_5\cdot]$, $SR4 = [s\text{-}C_4H_9\cdot]$, $PR4 = [p\text{-}C_4H_9\cdot]$, $H = [H\cdot]$, $C = [C_4H_{10}]$, and J = a parameter defined as the square root of the rate of initiation (or termination). Since the rate of production of a radical equals the rate of its removal (in propagation reactions only) then

$$r_{21} = r_{22}$$

and

$$[31] \qquad k_{21}SR4 = k_{22}R1C$$

$$r_{20} = r_{16} + r_{18}$$

$$[32] \qquad k_{20}PR4 = k_{16}R2C + k_{18}R2C^e$$

$$r_{18} = r_{23}$$

$$[33] \qquad k_{18}R2C^e = k_{23}HC$$

From eq. [29]

[34] $$k_{20}PR4 = Qk_{21}SR4$$

From eqs. [31]–[34]

[35] $$R1 = (k_{20}/k_{22})(1/CQ)PR4$$

[36] $$R2 = (k_{20}/(k_{16}C + k_{18}C^e))PR4$$

[37] $$SR4 = (k_{20}/k_{21})(1/Q)PR4$$

[38] $$H = (k_{20}/k_{23}C) \times (k_{18}C^e/(k_{16}C + k_{18}C^e))PR4$$

Taking derivatives with respect to C of eqs. [35]–[38], the following relationships are obtained.

---

[39] $$\frac{dR1}{dC} = \frac{k_{20}}{k_{22}}\frac{1}{QC}\frac{dPR4}{dC} - \frac{k_{20}}{k_{22}}\frac{1}{QC^2}PR4$$

[40] $$\frac{dR2}{dC} = \frac{k_{20}}{k_{16}C + k_{18}C^e}\frac{dPR4}{dC} - \frac{k_{16}k_{20} + nk_{18}k_{20}C^{e-1}}{(k_{16}C + k_{18}C^e)^2}PR4$$

[41] $$\frac{dSR4}{dC} = \frac{k_{20}}{k_{21}Q}\frac{dPR4}{dC}$$

[42] $$\frac{dH}{dC} = \frac{k_{20}}{k_{23}C}\frac{k_{18}C^e}{k_{16}C + k_{18}C^e}\frac{dPR4}{dC} - H\frac{e}{C} - \left(\frac{2k_{16} + (n+1)k_{18}C^{e-1}}{k_{16}C + k_{18}C^e}\right)$$

Taking the derivative of eq. [30] with respect to C results in the following expression

[43] $$k_1 = 2J\left(k_{24}^{1/2}\frac{dR1}{dC} + k_{25}^{1/2}\frac{dR2}{dC} + k_{26}^{1/2}\frac{dSR4}{dC} + k_{27}^{1/2}\frac{dPR4}{dC} + k_{28}^{1/2}\frac{dH}{dC}\right)$$

Substitution of eqs. [39], [40], [41], [42], and finally eq. [30] into eq. [43] results in

[44] $$J^2 = 2J^2\frac{C}{PR4}\frac{dPR4}{dC} - 2J\left[k_{24}^{1/2}\frac{k_{20}}{k_{22}}\frac{1}{QC} + k_{25}^{1/2}\left(\frac{k_{16}k_{20} + nk_{18}k_{20}C^{e-1}}{(k_{16}C + k_{18}C^e)^2}\right) + k_{28}^{1/2}H\left(\frac{2k_{16}C + (e+1)k_{18}C^e}{k_{16}C + k_{18}C^e} - e\right)\right]PR4$$

The rate of the overall reaction is equal to the rate of decomposition of butyl radicals.

$$r = r_2 + r_3 = k_2PR4(1 + 1/Q)$$

[45] $$\text{Order} = \frac{d\ln r}{d\ln C} = \frac{C}{r}\frac{dr}{dC} = \frac{C}{PR4}\frac{dPR4}{dC}$$

Substituting eqs. [35], [36], [37], [38], and [45] into eq. [44], then

[46] $$J^2 = 2J^2\,\text{order} - 2J(k_{24}^{1/2}R1 + k_{25}^{1/2}R2U + k_{28}^{1/2}H(U - e + 1))$$

where

[47] $$U = \frac{k_{16}C + ek_{18}C^e}{k_{16}C + k_{18}C^e} = \frac{\text{rate of reaction [16]} + e\ \text{rate of reaction [18]}}{\text{rate of reaction [16]} + \text{rate of reaction [18]}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Substitution of eq. [30] into eq. [46] and subsequent rearrangement results in an expression for the order

$$[48]\quad \text{Order} = \frac{\sum_{i=24}^{i=28}\sum_{j=24}^{j=28}(F_i + F_j)(r_i r_j)^{1/2}}{\sum_{i=24}^{i=28}\sum_{j=24}^{j=28}(r_i r_j)^{1/2}}$$

where the values for i, j, $2F_i$, and $2F_j$ are:

Radical	Value	
	i or j	$2(F_{i \text{ or } j})$
$CH_3\cdot$	24	1.5
$C_2H_5\cdot$	25	$0.5 + U$
s-$C_4H_9\cdot$	26	0.5
p-$C_4H_9\cdot$	27	0.5
$H\cdot$	28	$1.5 + U - e$

where $0 < U < 1$ and $0 < e < 1$

Recent investigators (2, 3) of this reaction in the 420–590 °C region have found the overall reaction order to be 1.5. Of the 5 radicals participating in the reactions, the recombination of only the methyl and ethyl radical and hydrogen could result in an order of approximately 1.5. Of these hydrogen is the most reactive since

$$k_{23} \gg k_{16} \text{ or } k_{22}$$

Its steady state concentration is thus expected to be much lower than that of methyl or ethyl radicals. Therefore

$$r_{28} \ll r_{24} \text{ or } r_{25}$$

The termination reaction

$$[49]\quad CH_3\cdot + C_2H_5\cdot \rightarrow C_3H_8$$

would be one of the predominant chain-termination reactions if the two participating radicals were at comparable concentrations. However, Purnell and Quinn (2) did not find propane among the primary reaction products. This indicates that either reaction [24] or reaction [25] is overwhelmingly operative.

It may be seen from eq. [48], that if reaction [24] predominates, the calculated order is 1.5. If, however, reaction [25] predominates then the value of U is needed to calculate the predicted order.

Calculation of the Value of U

From the expressions for the rate of production of ethane and ethylene by reactions [16], [18], and [20] and from eq. [32], the following expression may be derived.

$$[50]\quad \left(\frac{[C_2H_4]}{[C_2H_6]} - 1\right)C = 2\left(\frac{k_{18}C^e}{k_{16}}\right)$$

Purnell and Quinn reported values of the left side of eq. [50] at 518.0 °C between 15 and 120 mm of Hg reaction pressure. They plotted these values as a function of pressure and fitted them with a curve calculated from Kassel's model. This treatment of the data illustrated the pressure dependence of reaction [18].

If natural logarithms of eq. [50] are taken the following relationship is obtained

$$[51]\quad \ln\left[\left(\frac{[C_2H_4]}{[C_2H_6]} - 1\right)C\right] = e \ln C + \ln\left(\frac{2k_{18}}{k_{16}}\right)$$

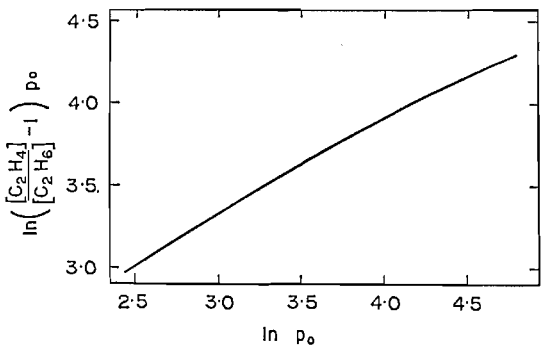

FIG. 1. The variation of the function $\ln\{[C_2H_4]/[C_2H_6]-1\}p_0$ with ln initial pressure, p_0, in the pyrolysis of *n*-butane at 518 °C (from Purnell and Quinn (2)).

Figure 1 shows a plot of $\ln\{[C_2H_4]/[C_2H_6] - 1\}p_0$ vs. $\ln p_0$ calculated from the curve of Purnell and Quinn. Equation [51] indicates that the slope of the curve is equivalent to the value of e. From the values of e, $2(k_{18}C^e/k_{16})$, and C, values of U were calculated and are listed in Table II along with the predicted overall reaction orders (assuming the predominance of the ethyl–ethyl termination reaction).

With an increase in reaction pressure the rate of reaction [16] increases relative to the rate of reaction [18]. This has the effect of increasing the overall order of the reaction. The order of reaction [18] on the other hand decreases with an increase in pressure and thus compensates for the above effect. The predicted overall order is approximately 1.35 and is relatively independent of

TABLE II

Overall reaction orders at 518 °C calculated by assuming reaction [25] as the predominant chain-termination reaction*

16	0.63	2.5	0.84	1.34
37	0.58	2.1	0.85	1.35
53	0.55	1.9	0.85	1.35
90	0.47	1.7	0.86	1.36
110	0.44	1.6	0.86	1.36

*Calculations are based on the experimental results of Purnell and Quinn (2).

pressure. However, it is significantly lower than the experimental value of 1.5 reported by Purnell and Quinn (2) and Sagert and Laidler (3).

Based on the pressure dependence of the activation energies for the formation of the major products, Purnell and Quinn (2) predicted the predominance of the ethyl–ethyl radical termination reaction (reaction [25]). On the basis of the overall reaction order and using the results of the same investigators, the above treatment predicts the predominance of the methyl–methyl radical termination reaction. In view of this contradictory evidence, further work is necessary for the establishment of the exact termination mechanism for *n*-butane pyrolysis.

Conclusion

The overall order of a pyrolytic reaction can quite easily be determined in any kinetic study. Its variation with temperature and pressure can be compared with the mathematical analysis outlined above for any proposed mechanism, which then can provide an additional criterion for the proper choice of the chain-termination reaction. Such an analysis of the pyrolysis of *n*-butane has indicated that the methyl–methyl radical recombination is the major chain-termination process.

The validity of a derived order equation hinges on the choice of a correct chain-propagation mechanism. Throughout the above analysis all simple reactions were assumed to be homogeneous. If the experimental order can not be predicted by the calculation procedure outlined, it is likely that some of the simple reactions are partially or completely heterogeneous, or alternatively that incorrect chain-propagation reactions have been assumed.

The method outlined may be quite useful when chain-termination products are identical to the reactant or to products of the propagation reactions, making it necessary to determine the chain-termination process indirectly, as in *n*-butane pyrolysis.

The order equation derived in this publication may also be used for the quantitative interpretation of the order change resulting from a change in the termination mechanism. The results of a study of the kinetics of the thermal decomposition of *n*-butane at low temperatures indicate that, at temperatures below 400 °C, the overall reaction order decreases with a decrease in reaction temperature. This drop in reaction order may be explained by the increasing importance of reaction [26] relative to reaction [24] at lower temperatures. The results of this investigation will be presented in a subsequent publication.

NOTES

Crystal field splitting in the far infrared spectrum of rhombic sulfur

A. ANDERSON AND L. Y. WONG
Department of Physics, University of Waterloo, Waterloo, Ontario

Received February 18, 1969

The infrared (i.r.) spectra of thin polycrystalline samples of orthorhombic sulfur at 95 °K in the range 50–500 cm^{-1} have been recorded. The three i.r. active fundamentals ν_4, ν_5, and ν_6 are observed to be split into 2, 3, and 3 components, respectively, as predicted from a group theoretical analysis of the unit cell symmetry, thus confirming the assignment of ν_4 and ν_6. Several weaker absorptions are assigned by comparison with recent Raman results and a normal coordinate analysis. No peaks assignable to lattice vibrations are observed.

Canadian Journal of Chemistry, 47, 2713 (1969)

Introduction

Of the 11 fundamental vibrations of the S_8 ring molecule only 3 are infrared active. According to Herzberg's notation (1), these are ν_4 (b_2), ν_5 (e_1), and ν_6 (e_1). For many years, incorrect assignments of ν_4 and ν_6 were made on the basis of the early low resolution far infrared studies of Barnes (2), but in 1964 two independent investigations (3, 4) of sulfur in solution established that there are two strong absorptions in the region 175–250 cm^{-1} which should be assigned to these fundamentals. In addition, a normal coordinate analysis (3) based on a modified Urey–Bradley field, showed that the lower frequency band corresponded to the degenerate vibration, ν_6, and the higher one to the non-degenerate ν_4. However, since the separation of the peaks is only about 50 cm^{-1}, an independent check on the assignment of these two modes would seem desirable.

Such a check is possible by consideration of the crystal field splittings expected for the two bands. A recent Raman study (5) of orthorhombic sulfur at liquid nitrogen temperature showed that for the strong Raman peaks, very good agreement is obtained with the predictions of a group theoretical analysis based on the known molecular, site, and unit cell symmetries (6, 7). This suggests that a similar analysis of the strong i.r. spectral features may be confidently used to confirm the assignments. As shown in the previous work (5), the non-degenerate ν_4 should be split into two i.r. components as a result of coupling within the unit cell, whereas ν_5 and ν_6 experience an additional effect, the removal of their degeneracies by the lower site symmetry, resulting in three i.r. active compounds for each. Other molecular vibrations and lattice modes are predicted to have i.r. activity, but should be weak relative to these three fundamentals.

Experimental

Because of low intensity sources and relatively insensitive dectectors in the far i.r. region, coupled with the strong absorption by sulfur, considerable experimental difficulties were experienced before good quality spectra of sufficient resolution to observe the expected fine structure were obtained. Earlier work on sulfur pellets at room temperature was inconclusive in this respect, although some splitting was observed (4). In this research a variety of sampling techniques was tried, including Nujol mulls, KBr pellets, and attenuated total reflection using KRS 5 plates. The most reproducible and reliable spectra were obtained with very thin pressed discs (0.004 in. thick, 0.75 in. diameter) for the region below 400 cm^{-1}, where an RIIC-Beckman 620 Fourier spectrophotometer with direct on-line hook-up to an IBM 360 model 44 computer was used, and a thin uniform layer of finely powdered sulfur on a silver bromide plate for the region 400–500 cm^{-1}, where a Beckman IR-9 instrument was used. The pellet and backing plate were mounted in a conventional glass cryostat with polyethylene windows, and cooled with liquid nitrogen. Sample temperatures in the beam, as measured by a copper–constantan thermocouple, were around 95 °K.

Results

Identical spectra were obtained for sulfur from Fisher (U.S.P. grade) and Gallard–Schlesinger (99.9999% pure). The low-temperature spectra of polycrystalline sulfur are shown in Fig. 1. These differ from those at room temperature in two important respects: the overall width of the strong peaks is reduced, and the fine structure is more apparent, particularly for the ν_5 absorption.

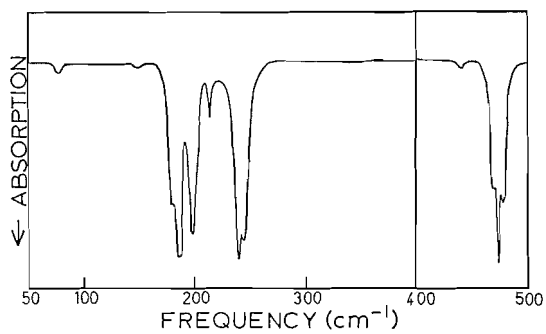

FIG. 1. The i.r. absorption spectrum of orthorhombic sulfur at 95 °K.

The spectral resolution is about 1 cm^{-1} for this band, and 2.5 cm^{-1} for the lower frequency range. Higher resolution (but noisier) spectra were obtained with the interferometer, but no further sharpening was observed. Spectra of sulfur in solution (polyethylene cell, 1 mm thick, saturated solution in CS_2) were also run, under identical resolution conditions. No fine structure was apparent in the strong bands, and the weaker absorptions in the crystal were absent. The frequencies of maximum absorption for crystal and solution are listed in Table I, and are estimated to be accurate to ± 1 cm^{-1}. These are compared with previous values (3, 4) and the relevant Raman data for the crystal at approximately the same temperature (5). Spectra were also obtained for thicker samples, but because of the extent of the wings of the strong bands, these were of poor quality and no reproducible additional features were found. In any case, since there is evidence (8) that orthorhombic sulfur often contains small amounts of S_n chain molecules, the assignment of very weak features is open to question. The region below 75 cm^{-1} was investigated with a thicker beam divider, which is more efficient at low frequencies (9), but no new peaks were found.

Discussion

The predicted numbers of components for the three i.r. fundamentals are observed: ν_4 (2), ν_5 (3), and ν_6 (3). Hence the assignment of Scott *et al.*

(3) is confirmed, as is the explanation of the splittings in terms of the static and correlation fields. The splittings range from 2.5–11 cm^{-1}, compared to 3–7 cm^{-1} in the Raman spectrum (5). The weaker bands, resulting from activity induced by the perturbing crystal field, are readily assigned by reference to the Raman data and the normal coordinate analysis (3): the sharp symmetric peak at 214 cm^{-1} is the predicted i.r. singlet for ν_2; the other bands are broader, and represent the unresolved triplets of ν_9 (78 cm^{-1}), ν_8 (149 cm^{-1}), and ν_{10} (442 cm^{-1}). The absence of lattice modes indicates that their interaction with the electromagnetic field is a factor of at least 20 less than that of the intramolecular fundamentals, which is not unusual for such a symmetric molecule.

A final point of interest is that a comparison of the frequencies of bands observed in both i.r. and Raman shows evidence for coincidences within experimental error. This is especially noticeable for ν_6, and the only exception is ν_4, where there is a 4 cm^{-1} difference. From spectroscopic evidence alone, one might conclude that the crystal does not possess a center of symmetry, whereas the X-ray data show that the opposite is true (6). Infrared and Raman data are often used to aid in crystal structure determinations, especially of hydrogenic molecules, when X-ray, electron, or neutron diffraction measurements are not available (10). The above result shows that this procedure must be used with extreme caution, if spurious deductions are to be avoided.

Thermal reactions of O_2^+ and O^- ions in gaseous ammonia

D. K. Bohme[1] and F. C. Fehsenfeld

Environmental Science Services Administration, Research Laboratories, U.S. Department of Commerce, Boulder, Colorado 80302

Received March 10, 1969

The reaction channels and rate coefficients for the reactions of O_2^+ and O^- ions with NH_3 have been determined at 21.4 °C in a flowing afterglow of pure oxygen and a mixture of helium and oxygen. Charge-transfer was found to be the dominant O_2^+ reaction channel whereas hydrogen atom abstraction was found to be the dominant O^- reaction channel. The secondary NH_3^+ ions were found to react further with NH_3 by hydrogen abstraction to yield NH_4^+ ions, which readily associated with NH_3 to yield cluster ions. The further reaction of secondary OH^- ions with NH_3 was not observed suggesting that the electron affinity of NH_2 may be less than 1.10 eV.

Canadian Journal of Chemistry, 47, 2715 (1969)

The flowing afterglow technique developed in the Environmental Science Services Administration Research Laboratories principally for the investigation of thermal ion–molecule reactions of interest on the earth's ionosphere has recently been employed to study the reactions of O_2^+ and O^- ions in gaseous ammonia.

Details of the operation of the flowing afterglow system and the related data analysis have been described elsewhere (1). In the present experiment, pure oxygen or a helium–oxygen

TABLE I

Measured rate constants

Reaction	k
$O_2^+ + NH_3 \rightarrow NH_3^+ + O_2$	2.6 (−9)* cm^3/s
$NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2$	1.6 (−9) cm^3/s
$NH_4^+ + NH_3 + O_2 \rightarrow NH_4^+ \cdot NH_3 + O_2$	1.8 (−27) cm^6/s
$O^- + NH_3 \rightarrow OH^- + NH_2$	1.2 (−9) cm^3/s

*(−9) denotes 10^{-9}.

mixture is introduced into the excitation region of the flow tube. The gas is excited by the energetic electrons from an electron gun producing O^- and O_2^+ by electron impact with O_2. In addition some O_2^+ is produced by reaction of O_2 with O^+ and excited and ionized helium.

In the region following the excitation region the secondary reactions forming O_2^+ go to completion. Also, O_2^+ ions formed in electronically or vibrationally excited states are de-excited. The O^- and O_2^+ ions are carried with the flowing gas past a downstream port where measured quantities of ammonia are added. In the region following this reactant inlet the characteristic reactions between the ions and ammonia take place. This reaction region is terminated by the sampling port of a quadrupole mass spectrometer. The decline of the primary ion signal and the increase of the secondary ions as a function of the rate of addition of the ammonia allows the determination of a reaction rate constant and reaction channel designation. The rates so determined by this technique should possess an absolute accuracy of 30% with a relative accuracy of better than 10%.

Figure 1 shows a sample run of data for the reaction sequence beginning with O_2^+ in reaction with ammonia. This data was taken at a gas temperature of 21.4 °C. Pure oxygen was introduced into the excitation region and the steady state gas pressure was 0.224 Torr. As the ammonia is added the O_2^+ signal declines and there is a corresponding rise in the NH_3^+ signal due to the reaction

[1] $$O_2^+ + NH_3 \rightarrow NH_3^+ + O_2$$

The reaction channel between NH_3 and O_2^+ to produce NH_2^+ and O_2H is endothermic at room temperature for ground state O_2^+ and was not observed.

The NH_3^+ product signal peaks and then declines corresponding to the production of

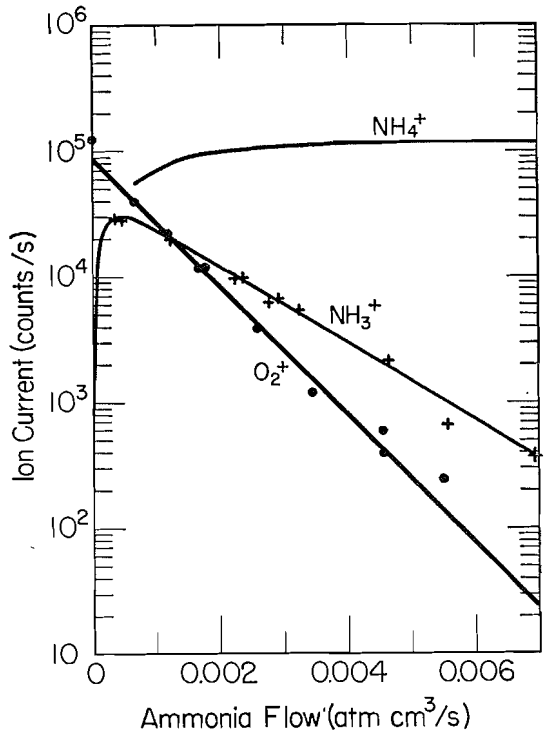

FIG. 1. Ion currents for reactions of O_2^+ and NH_3^+ with NH_3 in an oxygen ion afterglow.

NH_4^+. Since the decline of the NH_3^+ signal is slower than that of the precursor ion O_2^+, a rate coefficient may be determined for the reaction

[2] $$NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2$$

from the slope of the NH_3^+ signal. With large additions of NH_3 the cluster ions $NH_4^+ \cdot (NH_3)$, $NH_4^+ \cdot (NH_3)_2$, and $NH_4^+ \cdot (NH_4)_3$ were observed, and the rate constant for the first step in the formation of these clusters

[3] $$NH_4^+ + NH_3 + O_2 \rightarrow NH_4^+ \cdot NH_3 + O_2$$

was determined. Table I lists the rate coefficients

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

determined for [1], [2], and [3], along with the rate coefficient for the fast reaction between O^- and NH_3 found to proceed by hydrogen abstraction to form OH^-. The product ion OH^- accounted for essentially 100% of the disappearing O^- ions. Electron transfer will not compete since NH_3 has no affinity for electrons (2). Also, there was no indication of a residual signal at $m/e = 16$. This means that no NH_2^- was produced by the reaction and suggests that this channel for the reaction is endothermic at room temperature, implying that the electron affinity of NH_2^- is less than 1.61 eV. This observation is compatible with the electron affinity of NH_2 of 1.21 eV reported by Vedeneyev *et al.* (3). The further reaction of OH^- with NH_3 to yield NH_2^- and H_2O was not observed suggesting that the electron affinity of NH_2 may be less than 1.10 eV.

Gupta *et al.* (4) have measured the thermal (or zero field) rate constant for reaction [2] using a pulsed-beam technique. The rate of 1.0×10^{-9} determined by Gupta *et al.* at 373 °K is somewhat smaller than the value of 1.6×10^{-9} determined in the present experiment at 295 °K. There are no other published rates for the other reactions with which we may compare.

Thermal reactions of O^- ions with saturated hydrocarbon molecules

D. K. BOHME[1] AND F. C. FEHSENFELD

Environmental Science Services Administration Research Laboratories, U.S. Department of Commerce, Boulder, Colorado 80302

Received March 20, 1969

The thermal energy reactions of O^- ions with saturated hydrocarbon molecules have been investigated in a flowing afterglow of pure oxygen and a mixture of helium and oxygen. Hydrogen atom abstraction was found to be the dominant reaction channel. The reaction probability was found to increase for the higher members of the homologous series. The further reaction of the product OH^- ions with saturated hydrocarbon molecules was not observed. This result was used to estimate an upper limit to the electron affinity of the free radicals CH_3, C_2H_5, C_3H_7, and C_4H_9.

Canadian Journal of Chemistry, 47, 2717 (1969)

The flowing afterglow technique developed in the Environmental Science Services Administration Research Laboratories has been used extensively for the study of thermal energy ion–neutral reactions of interest in aeronomy, and has been employed to investigate the reactions of O^- ions with the homologous hydrocarbon series C_nH_{2n+2}, $n = 1$ to 4. The results suggest a fairly general behavior which is that the reaction of O^- ions with saturated hydrocarbon molecules proceeds by hydrogen atom abstraction

[1] $$O^- + RH \rightarrow OH^- + R$$

and that the reaction probability for this process increases for higher members of the homologous series.

The details of the experimental apparatus, its operation, and the related data analysis have been described in detail elsewhere (1). The flow system is a stainless steel tube about 100 cm long and 8 cm in diameter in which the products of an electron impact ion source are pumped down the tube at a velocity of about 10^4 cm/s. In the present experiments either pure O_2 or O_2 in small fractional quantities in a helium buffer gas is introduced into the excitation region. The O^- ion is then produced by the dissociative ionization reaction, $e + O_2 \rightarrow O^- + O^+ + e$, and, probably to a lesser extent, the dissociative

determined for [1], [2], and [3], along with the rate coefficient for the fast reaction between O^- and NH_3 found to proceed by hydrogen abstraction to form OH^-. The product ion OH^- accounted for essentially 100% of the disappearing O^- ions. Electron transfer will not compete since NH_3 has no affinity for electrons (2). Also, there was no indication of a residual signal at $m/e = 16$. This means that no NH_2^- was produced by the reaction and suggests that this channel for the reaction is endothermic at room temperature, implying that the electron affinity of NH_2^- is less than 1.61 eV. This observation is compatible with the electron affinity of NH_2 of 1.21 eV reported by Vedeneyev *et al.* (3). The further reaction of OH^- with NH_3 to yield NH_2^- and H_2O was not observed suggesting that the electron affinity of NH_2 may be less than 1.10 eV.

Gupta *et al.* (4) have measured the thermal (or zero field) rate constant for reaction [2] using a pulsed-beam technique. The rate of 1.0×10^{-9} determined by Gupta *et al.* at 373 °K is somewhat smaller than the value of 1.6×10^{-9} determined in the present experiment at 295 °K. There are no other published rates for the other reactions with which we may compare.

Thermal reactions of O^- ions with saturated hydrocarbon molecules

D. K. BOHME[1] AND F. C. FEHSENFELD

Environmental Science Services Administration Research Laboratories, U.S. Department of Commerce, Boulder, Colorado 80302

Received March 20, 1969

The thermal energy reactions of O^- ions with saturated hydrocarbon molecules have been investigated in a flowing afterglow of pure oxygen and a mixture of helium and oxygen. Hydrogen atom abstraction was found to be the dominant reaction channel. The reaction probability was found to increase for the higher members of the homologous series. The further reaction of the product OH^- ions with saturated hydrocarbon molecules was not observed. This result was used to estimate an upper limit to the electron affinity of the free radicals CH_3, C_2H_5, C_3H_7, and C_4H_9.

Canadian Journal of Chemistry, 47, 2717 (1969)

The flowing afterglow technique developed in the Environmental Science Services Administration Research Laboratories has been used extensively for the study of thermal energy ion–neutral reactions of interest in aeronomy, and has been employed to investigate the reactions of O^- ions with the homologous hydrocarbon series C_nH_{2n+2}, $n = 1$ to 4. The results suggest a fairly general behavior which is that the reaction of O^- ions with saturated hydrocarbon molecules proceeds by hydrogen atom abstraction

[1] $$O^- + RH \rightarrow OH^- + R$$

and that the reaction probability for this process increases for higher members of the homologous series.

The details of the experimental apparatus, its operation, and the related data analysis have been described in detail elsewhere (1). The flow system is a stainless steel tube about 100 cm long and 8 cm in diameter in which the products of an electron impact ion source are pumped down the tube at a velocity of about 10^4 cm/s. In the present experiments either pure O_2 or O_2 in small fractional quantities in a helium buffer gas is introduced into the excitation region. The O^- ion is then produced by the dissociative ionization reaction, $e + O_2 \rightarrow O^- + O^+ + e$, and, probably to a lesser extent, the dissociative

attachment reaction, $e + O_2 \rightarrow O^- + O$. At the end of the tube the ion composition is sampled, mass analyzed by means of a quadrupole mass spectrometer, and counted. The hydrocarbon reactant gases are added downstream of the excitation region. They had the following minimum purity in mole%: methane, 99.95; ethane, 99.0; propane, 99.5; *n*-butane, 99.5. The decline of the reactant O^- ion signal as a function of hydrocarbon gas addition constitutes the raw data from which rate coefficients are determined with an absolute accuracy of about 30% and a somewhat better relative accuracy. The experiments were performed at 22.5 °C at a total steady state pressure of 0.23 Torr.

A list of the reactions investigated and the measured rate constants are given in Table I. The major product ion in each case was OH^-, indicating that hydrogen abstraction, i.e. reaction [1], is the dominant reaction channel. The reaction energies listed in Table I apply if the products are in their ground states and are given only to show that the reactions are exothermic at 22.5 °C. It is of course not unlikely that the products are formed in vibrationally excited states. Electron affinities of 1.465 and 1.78 eV were used for O and OH respectively (2). Bond energies were taken from Vedeneyev *et al.* (3).

A consideration of the ground state reaction energetics complemented by experimental observations allows an estimation of upper limits to the electron affinity of several hydrocarbon radicals. It is observed in these experiments that the OH^- ions produced by the hydrogen abstraction reactions listed in Table I do not react efficiently with the added hydrocarbon molecules (rate coefficient $\leq 10^{-12}$ cm³/s). This strongly suggests, but does not prove, that the reaction channel

[2] $$OH^- + RH \rightarrow R^- + H_2O$$

is endothermic since most exothermic ion–molecule reactions proceed rapidly with little or no activation energy. Accordingly, an upper limit to the value of the electron affinity of CH_3, C_2H_5, C_3H_7, and C_4H_9 may be estimated. The results are given in Table II together with values reported in the literature.

It is instructive to compare the experimentally measured reaction rate constant, k, with the theoretical collision rate constant, k_c. For an ion colliding with a neutral molecule, the theoretical collision rate constant is given by the expression

[3] $$k_c = 2\pi e\left(\frac{\alpha}{\mu}\right)^{\frac{1}{2}}$$

Here μ is the reduced mass of the reactants and α is the polarizability of the neutral reactant. Equation [3] is derived on the assumption that the total collision cross-section is determined solely by the long range ion-induced dipole interaction which results in orbiting or spiralling (6). The ratio k/k_c is a measure of the reaction probability. The calculated reaction probabilities for hydrogen abstraction from saturated hydrocarbon molecules by O^- ions are given in Table I. Polarizabilities for the neutral hydrocarbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

molecules were taken from Rothe and Bernstein (7). As indicated in Table I, the experimental rate constant for the reaction of O^- with CH_4 is considerably lower than predicted by theory, and accordingly a significant fraction (0.92) of the orbiting collisions does not lead to a reaction. It is also apparent from the reaction probabilities given in Table I that the number of hydrogen abstraction reactions per orbiting collision increases for the reaction of O^- with higher members of the homologous series. Equation [3] neglects the dispersion energy between the two mutually induced dipoles in the ion–molecule collision. Inclusion of such a term in the interaction potential for O^- and the very polarizable hydrocarbon molecules could increase the theoretical collision rate constant, k_c, by as much as 10%. This in turn would decrease the reaction probability by as much as 10%.

Photo-initiated reactions of thiols and olefins. IV. Inhibition of butene-2 isomerization by butadiene-1,3

D. M. GRAHAM AND J. F. SOLTYS
Department of Chemistry, University of Western Ontario, London, Ontario

Received December 2, 1968

The kinetics of inhibition of the thiyl radical catalyzed isomerization of *cis*-butene-2 has been investigated. The results yielded the value 6.9×10^7 *l* $mole^{-1}$ s^{-1} for the rate constant for CH_3S attack on butadiene. It is proposed that this technique could be generally useful in determining attack constants for conjugated olefins.

Canadian Journal of Chemistry, 47, 2719 (1969)

Introduction

It was shown previously that the rate constant for thiyl radical attack on butadiene cannot be obtained from the measurement of addition rates (1). The adduct radical produced is not sufficiently reactive for thiol dehydrogenation to compete successfully with termination reactions, and no chain character was observed. This behavior is probably typical of conjugated olefins, and it appeared desirable to find a technique for determining reactivities in such cases. In earlier work on thiyl radical catalyzed isomerization of butene-2, it was found necessary to purify the olefin by gas chromatography in order to obtain consistent kinetic data over the entire concentration range used (2). The effects observed with the non-purified samples were attributed to the presence of very small quantities of butadiene in the olefin. As a result of further investigation of these effects, a new method for determining relative attack constants for conjugated olefins has been obtained.

Experimental

The techniques used were as previously described (1, 2). All results given here were obtained using a quartz reaction cell, 5 cm diameter × 10 cm length.

Results

The isomerization curves given in Fig. 1 show that addition of small amounts of butadiene to *cis*-butene-2 produces an initial retardation in rate which disappears, presumably, when the butadiene is used up. Figure 2 indicates that the initial inhibited rate of isomerization ($R_{ic} = (d[T]/dt)_0$) is inversely proportional to the initial

Photo-initiated reactions of thiols and olefins. IV. Inhibition of butene-2 isomerization by butadiene-1,3

D. M. GRAHAM AND J. F. SOLTYS
Department of Chemistry, University of Western Ontario, London, Ontario

Received December 2, 1968

The kinetics of inhibition of the thiyl radical catalyzed isomerization of *cis*-butene-2 has been investigated. The results yielded the value 6.9×10^7 *l* $mole^{-1}$ s^{-1} for the rate constant for CH_3S attack on butadiene. It is proposed that this technique could be generally useful in determining attack constants for conjugated olefins.

Canadian Journal of Chemistry, 47, 2719 (1969)

Introduction

It was shown previously that the rate constant for thiyl radical attack on butadiene cannot be obtained from the measurement of addition rates (1). The adduct radical produced is not sufficiently reactive for thiol dehydrogenation to compete successfully with termination reactions, and no chain character was observed. This behavior is probably typical of conjugated olefins, and it appeared desirable to find a technique for determining reactivities in such cases. In earlier work on thiyl radical catalyzed isomerization of butene-2, it was found necessary to purify the olefin by gas chromatography in order to obtain consistent kinetic data over the entire concentration range used (2). The effects observed with the non-purified samples were attributed to the presence of very small quantities of butadiene in the olefin. As a result of further investigation of these effects, a new method for determining relative attack constants for conjugated olefins has been obtained.

Experimental

The techniques used were as previously described (1, 2). All results given here were obtained using a quartz reaction cell, 5 cm diameter × 10 cm length.

Results

The isomerization curves given in Fig. 1 show that addition of small amounts of butadiene to *cis*-butene-2 produces an initial retardation in rate which disappears, presumably, when the butadiene is used up. Figure 2 indicates that the initial inhibited rate of isomerization ($R_{ic} = (d[T]/dt)_0$) is inversely proportional to the initial

For personal use only.

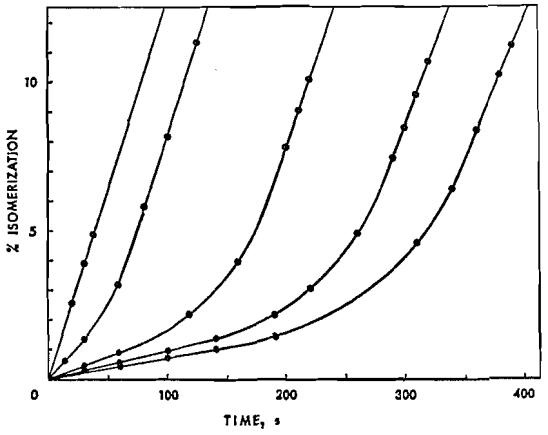

FIG. 1. Inhibition of isomerization. $[CH_3SH] = 1.08 \times 10^{-3}$ mole l^{-1}; [*cis*-butene-2] $= 5.38 \times 10^{-4}$ mole l^{-1}; from left to right, [butadiene] = 0, 2.07, 8.87, 15.5, and 19.9×10^{-7} mole l^{-1}.

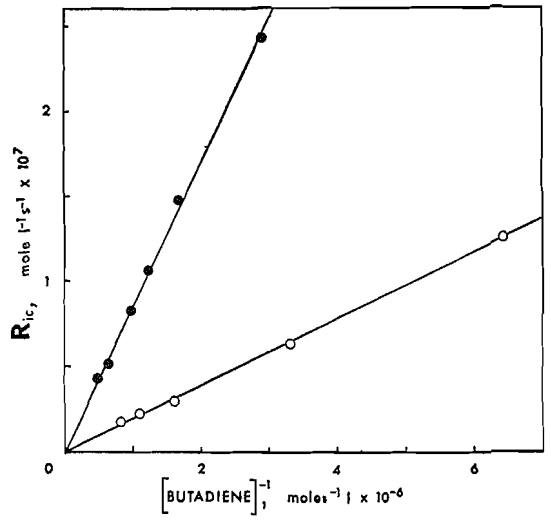

FIG. 2. Dependence of the inhibited rate on butadiene. [*cis*-butene-2] $= 5.38 \times 10^{-4}$ mole l^{-1}; ○, $[CH_3SH] = 2.15 \times 10^{-4}$; ●, 1.08×10^{-3} mole l^{-1}.

butadiene concentration. The slopes of the two lines are approximately in the ratio of the thiol pressures, and, since the rate of thiol photolysis is roughly proportional to the thiol concentration at low pressures, a first order dependence on the rate of generation of CH_3S is indicated. This was confirmed for the higher thiol concentration using calibrated screens to show a first order dependence on incident light intensity.

An inhibition period may be determined by the point of intersection of the extrapolated initial and final rates. This represents the time that would be required for all the butadiene to react if the initial mechanism were continuous to [B] = 0, and then changed abruptly to the uninhibited mechanism. A plot of inhibition periods for the results of Fig. 1 is given in Fig. 3; the constant slope indicates that the rate of disappearance of butadiene is zero order on concentration (a first order plot is not linear).

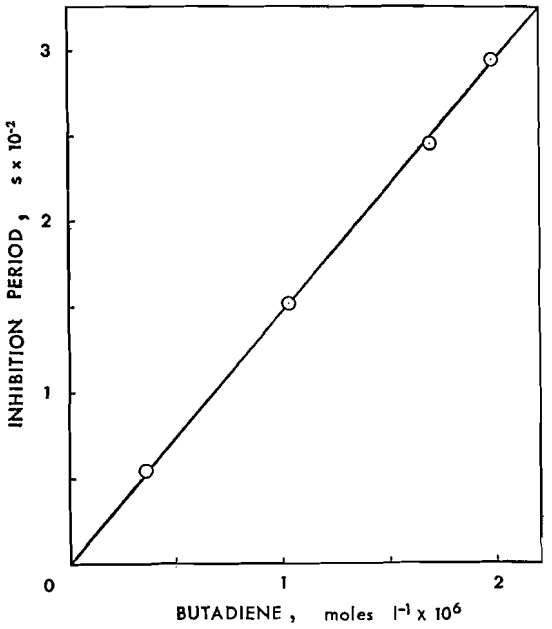

FIG. 3. Dependence of the inhibition period on butadiene. [*cis*-butene-2] $= 5.38 \times 10^{-4}$ mole l^{-1}; $[CH_3SH] = 1.08 \times 10^{-3}$ mole l^{-1}.

Discussion

The initial stages of the thiyl radical catalyzed isomerization of *cis*-butene-2 (C) to the *trans*-form (T) has been treated using the following mechanism (2)

$$CH_3SH \xrightarrow{h\nu} CH_3S \qquad (\text{rate} = r_i)$$

[1*c*] $\quad CH_3S + C \longrightarrow X$

[2] $\quad X + CH_3SH \longrightarrow XH + CH_3S$

[3] $\quad X \longrightarrow CH_3S + \rho_3 T + (1 - \rho_3)C$

[4] $\quad 2CH_3S \longrightarrow CH_3SSCH_3$

X is the adduct radical and ρ_3 is the probability that, when it decomposes, the *trans* isomer is formed. It has been established that the rate of reaction [2] is negligible compared with that of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

reaction [3] over the concentration ranges available to gas phase investigation. Since $[CH_3S] \gg [X]$ over the entire concentration range available to experiment, inhibition by butadiene (B) most probably occurs by competition for thiyl radicals as a result of the following reaction

[1b] $$CH_3S + B \rightarrow Y$$

The allyl-type adduct radical, Y, would be more stable than that obtained from butene by about 13 kcal (3). It is, therefore, very unlikely that the reverse reaction [3] need be considered for butadiene, since, at the pressures used, the radicals would be rapidly thermalized, and the activation energy for decomposition would then be at least 20 kcal.

Photolysis of methanethiol produces initially CH_3S and H almost exclusively; the hydrogen atom may subsequently attack thiol to give $CH_3S + H_2$, or add to olefin. Provided the radical produced by addition to olefin is sufficiently reactive to dehydrogenate thiol rapidly, and does not enter any other reaction, the overall initiation step may be considered to be the generation of two thiyl radicals. On the basis of the earlier study (2), this appears to be valid for the uninhibited reaction at the concentrations used here. Addition of a hydrogen atom to butadiene, however, should be very rapid and, since the resulting radical does not appear to dehydrogenate thiol very effectively (1), the following reactions should also be considered

$$CH_3SH \rightarrow CH_3S + H \qquad (\text{rate} = r_i/2)$$

[a] $$H + CH_3SH \rightarrow H_2 + CH_3S$$

[b] $$H + B \rightarrow Y$$

In terms of these reactions the initial rate of isomerization of *cis*-butene-2 is

[5] $$R_{ic} = \rho_3 k_{1c} [C][CH_3S]$$

This assumes that reaction [3] is the only fate of X. Since the inhibited rate was shown to be proportional to the rate of initiation, and to the inverse butadiene concentration, the steady-state thiyl radical concentration may be written

[6] $$[CH_3S] = \eta r_i/[B]$$

where η is the proportionality factor.

The rate of disappearance of butadiene is

[7] $$-\frac{d[B]}{dt} = \frac{r_i}{2} \cdot \frac{k_b[B]}{k_b[B] + k_a[CH_3SH]} + k_{1b}[B][CH_3S]$$

The second term of this expression must be independent of [B] because of eq. [6], and since it was concluded earlier that the rate of disappearance of butadiene was zero order on butadiene, the first term in eq. [7] must be negligible. This requires that, for these experiments, $k_b[B] \ll k_a[CH_3SH]$, which is not unreasonable since the thiol concentration is about 1000 times that of the butadiene. Omitting the first term and using eq. [6], eq. [7] may be integrated to obtain an expression for the inhibition period, defined as $t_i = t$ at $[B] = 0$

[8] $$t_i = [B]_0/\eta r_i k_{1b}$$

Combining eqs. [5], [6], and [8], one gets

[9] $$t_i R_{ic} = \rho_3 \frac{k_{1c}}{k_{1b}} [C]$$

The rate constant ratios calculated using this equation are given in Table I. The average is 0.0232, and since $\rho_3 k_{1c} = 1.6 \times 10^6$ l mole^{-1} s^{-1} (1), $k_{1b} = 6.9 \times 10^7$ l mole^{-1} s^{-1}.

TABLE I

Inhibition data obtained from Fig. 1

Butadiene mole l^{-1} × 10^7	R_{ic} mole l^{-1} s^{-1} × 10^8	t_i s	$\frac{\rho_3 k_{1c}}{k_{1b}}$
2.07	24.1	54	0.0242
8.87	8.16	152	0.0230
15.5	5.11	246	0.0234
18.9	4.25	294	0.0232

These equations do not depend upon the ultimate fate of the Y radicals; they may disappear by reaction with thiol, or more probably, on the basis of the addition kinetics (1), by termination. The only requirement for the use of this technique for measuring attack constants is that the added species decrease the thiyl radical concentration. This can occur only if decomposition of the resulting adduct radical is very slow. It has been shown, for example, that the presence of a large excess of ethylene has no effect on the rate of isomerization of butene-2, since reaction

[3] is very rapid for ethylene. It is highly probable that this reaction is negligible at 25 °C for butadiene but until this is experimentally verified, the value of the attack constant given above should perhaps be considered a lower limit.

The use of a saturation narrowed nuclear magnetic resonance spectrum to observe phase transitions in lithium stearate

W. R. JANZEN[1] AND B. A. DUNELL

Chemistry Department, The University of British Columbia, Vancouver 8, British Columbia

Received March 4, 1969

The phase transitions in solid lithium stearate have been observed using saturation narrowed spectra, whose high signal-to-noise ratio is advantageous particularly in cases where unfavorable packing factor for the sample or long T_1 makes the normal unsaturated absorption spectrum difficult to obtain. The saturation narrowed spectra are compared with unsaturated absorption spectra of lithium stearate and are discussed in terms of Provotorov's theory of saturation.

Canadian Journal of Chemistry, 47, 2722 (1969)

The use of broad line nuclear magnetic resonance (n.m.r.) spectra to investigate molecular motion and phase transitions in solids is well known (see, for example, ref. 1), and the method has been used in this laboratory to study a number of long chain fatty acids and their salts (2). During the course of these investigations we observed narrowing and intensification of the n.m.r. line with increasing intensity of the radio frequency (r.f.) field H_1. Our observations are in qualitative agreement with the saturation and line-shape theory of Provotorov (3) for solids at H_1 fields of intermediate intensity. The spectra shown in Fig. 1 were obtained for lithium stearate at room temperature using r.f. fields at 56.4 MHz with intensities of 0.45, 4.5, and 14.3 mG. It can be seen that as the H_1 intensity increases, the observed line shape goes in the direction of the Lorentzian shape, which is predicted by Provotorov theory as the limiting situation for high H_1, in agreement with Redfield's saturation theory (4). The fact that the line shape for lithium stearate at the highest available H_1 at 56.4 MHz is effectively Gaussian is thought to be entirely coincidental. In the strong saturation region the line shape can also be perturbed by absorption of energy by the spin system from the audio modulation field (4, 5). This rotary modulation saturation may account for the difference between the observed saturation narrowed line shape and that predicted by Provotorov. The great improvement in signal-to-noise ratio, which is evident in Fig. 1 as one goes to higher H_1 values, may be of considerable advantage in observing and recording spectra in cases where either an unfavorable packing factor for the sample in the spectrometer probe or a long T_1 makes the normal unsaturated absorption spectrum difficult to obtain.

It was of interest to determine how the saturation narrowed line would behave as one went through phase changes in the solid state of a substance for which such lines were obtainable. Lithium stearate had been observed to have two transitions between room temperature and 200 °C (2, 6). The lower temperature transition, near 115 °C, was attributed to a change from one crystalline form to another, and the higher temperature transition, near 187 °C, to a change from a crystalline to a waxy phase. It was also observed that the thermal history of

Received March 4, 1969

The phase transitions in solid lithium stearate have been observed using saturation narrowed spectra, whose high signal-to-noise ratio is advantageous particularly in cases where unfavorable packing factor for the sample or long T_1 makes the normal unsaturated absorption spectrum difficult to obtain. The saturation narrowed spectra are compared with unsaturated absorption spectra of lithium stearate and are discussed in terms of Provotorov's theory of saturation.

Canadian Journal of Chemistry, 47, 2722 (1969)

The use of broad line nuclear magnetic resonance (n.m.r.) spectra to investigate molecular motion and phase transitions in solids is well known (see, for example, ref. 1), and the method has been used in this laboratory to study a number of long chain fatty acids and their salts (2). During the course of these investigations we observed narrowing and intensification of the n.m.r. line with increasing intensity of the radio frequency (r.f.) field H_1. Our observations are in qualitative agreement with the saturation and line-shape theory of Provotorov (3) for solids at H_1 fields of intermediate intensity. The spectra shown in Fig. 1 were obtained for lithium stearate at room temperature using r.f. fields at 56.4 MHz with intensities of 0.45, 4.5, and 14.3 mG. It can be seen that as the H_1 intensity increases, the observed line shape goes in the direction of the Lorentzian shape, which is predicted by Provotorov theory as the limiting situation for high H_1, in agreement with Redfield's saturation theory (4). The fact that the line shape for lithium stearate at the highest available H_1 at 56.4 MHz is effectively Gaussian is thought to be entirely coincidental. In the strong saturation region the line shape can also be perturbed by absorption of energy by the spin system from the audio modulation field (4, 5). This rotary modulation saturation may account for the difference between the observed saturation narrowed line shape and that predicted by Provotorov. The great improvement in signal-to-noise ratio, which is evident in Fig. 1 as one goes to higher H_1 values, may be of considerable advantage in observing and recording spectra in cases where either an unfavorable packing factor for the sample in the spectrometer probe or a long T_1 makes the normal unsaturated absorption spectrum difficult to obtain.

It was of interest to determine how the saturation narrowed line would behave as one went through phase changes in the solid state of a substance for which such lines were obtainable. Lithium stearate had been observed to have two transitions between room temperature and 200 °C (2, 6). The lower temperature transition, near 115 °C, was attributed to a change from one crystalline form to another, and the higher temperature transition, near 187 °C, to a change from a crystalline to a waxy phase. It was also observed that the thermal history of

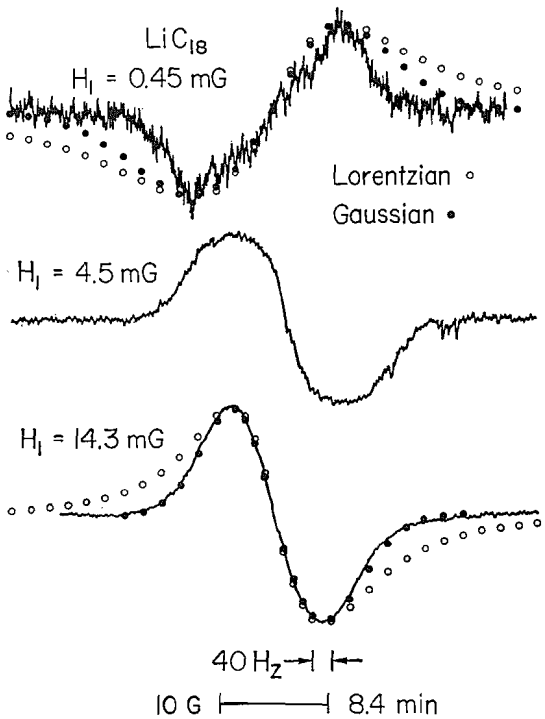

FIG. 1. The development of saturation narrowing with increasing H_1 in solid lithium stearate at room temperature. The observed spectra are compared with calculated Gaussian and Lorentzian line shapes of the same intensity (filled and open points, respectively). Modulation at 40 Hz was of the width indicated. Rate of scanning: 10 G in 8.4 min.

the sample, in particular the number of times the sample had been melted before a spectrum was run, had a strong effect on the line shape as one approached the crystalline to waxy phase transition. The intense, saturation narrowed n.m.r. line of lithium stearate has been observed between room temperature and 200 °C for a sample which was not fused during the course of preparation or subsequently. Preparative details have been given in the paper by Cyr, Janzen, and Dunell (2). Line widths of the saturation narrowed spectra, which were run at $H_1 = 14.3$ mG at 56.4 MHz and with a peak-to-peak modulation varying from 1.8 G at lower temperatures to 0.7 G near 200 °C, are shown in Fig. 2 together with the normal, unsaturated line widths obtained from spectra run at $H_1 = 0.45$ mG.

The line width vs. temperature curves of Fig. 2 show that the lithium stearate phase transitions

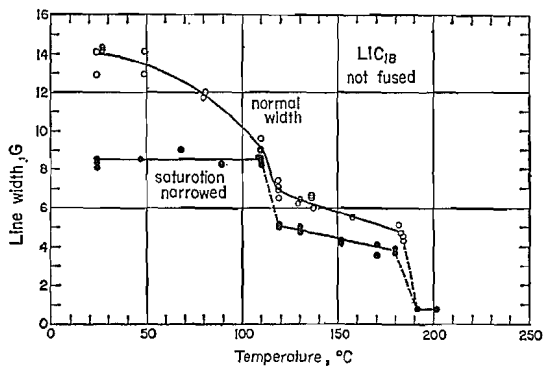

FIG. 2. Line widths of a never fused lithium stearate sample as a function of temperature: open circles, unsaturated, $H_1 = 0.45$ mG; filled circles, saturation narrowed, $H_1 = 14.3$ mG.

are equally observable from the saturation narrowed spectra as from the normal, unsaturated spectra, and that the temperature at which each transition is located is independent of the type of spectrum observed. Provotorov's equation 48 of ref. 3 for the absorption component of magnetic susceptibility can be written as

$$\chi'' = [\gamma^2\hbar\langle I_z\rangle_0\pi g(\Delta)/2][1 + \gamma^2 H_1^2\pi g(\Delta)T_1 \times (1 + T_D\hbar^2\Delta^2/T_1H_D^2)]^{-1}$$

where T_1 and T_D are the spin–lattice relaxation times for energy in the Zeeman system and the dipole–dipole interaction, respectively, $g(\Delta)$ is the unsaturated line shape, $H_D = \gamma\hbar H_L = \gamma\hbar\langle\Delta H^2\rangle^{1/2}/\sqrt{3}$, $\langle\Delta H^2\rangle$ being the second moment and H_L Redfield's local field (4), and $\Delta = \omega - \omega_0$, the distance from resonance. For large enough H_1, in the condition of strong saturation, this expression reduces to

$$\chi'' = (\hbar\langle I_z\rangle_0/2H_1^2T_1)(1 + T_D\hbar^2\Delta^2/T_1H_D^2)^{-1}$$

and we find the absorption line width under strong saturation to be

$$[1] \qquad \Delta H_{as} = (2/3)(T_1/T_D)^{1/2}\langle\Delta H^2\rangle^{1/2}$$

where this is measured from maximum to minimum slope of the absorption. One could expect to find, therefore, under conditions of strong saturation, a rapid change in the width of the saturation narrowed line wherever there is a rapid change in the second moment, $\langle\Delta H^2\rangle$, of the normal line unless there are compensating changes in the ratio of relaxation times T_1/T_D. An estimate of whether we have strong saturation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

can be obtained by considering the quantity $\gamma^2 H_1^2 \pi g(\Delta) T_1$. Saturation is strong at resonance ($\Delta = 0$) if this is large compared to unity. We take $\gamma = 2.68 \times 10^4$ for the proton, $H_1 = 14.3$ mG, and $T_1 = 16.8$ s, a value obtained for this sample by two independent techniques (7). The normalized, unsaturated line shape function at the center of resonance, $g(0)$, can be evaluated by integration of the unsaturated derivative absorption signal (the experimental, lock-in detector signal), called $v_1(\Delta)$ by Goldman (5). Since $g(\Delta)$ is normalized to unity, and $v_1(\Delta) \propto dg(\Delta)/d\Delta$ in the unsaturated condition, one has

$$g(0) = \int_{-\infty}^{\infty} v_1(\Delta)d\Delta/2 \int_{-\infty}^{\infty} \Delta v_1(\Delta)d\Delta$$

An average value of $g(0)$, obtained from three room temperature unsaturated absorption spectra of lithium stearate is 2.90×10^{-6} s (7). We thus obtain $\gamma^2 H_1^2 \pi g(0) T_1 = 22.4$, which is large compared with unity, and we can consider that saturation is strong. As Fig. 3 demonstrates, the second moment of the normal unsaturated spectrum decreases continually in the temperature range 24–110 °C, whereas the saturation narrowed line remains at constant width. Consequently the ratio T_1/T_D must change in this temperature range. Using eq. [1] and values of saturated line width and second moment shown in Figs. 2 and 3, we obtain $T_1/T_D = 7.4$ at 25 °C and 10.8 at 110 °C. Unfortunately this may not be a good method for measuring T_1/T_D ratios because of possible line shape perturbation by rotary modulation saturation mentioned earlier. The ratio can, however, be measured by pulse techniques (see, for example, ref. 8).

One may also note that Fig. 3 shows that the position of even the phase transition between crystalline forms of lithium stearate, as observed by n.m.r., depends on the thermal history of the sample. For the sample never fused the midpoint of the range of rapid decrease in line width and second moment corresponds to approximately 115 °C, which is the temperature of the transition according to dilatometry (9) and differential thermal analysis (10). In the previous experiments on a sample which had been fused during preparation, the transition temperature had been taken as the intersection of the extrapolated straight line portions of the line width or

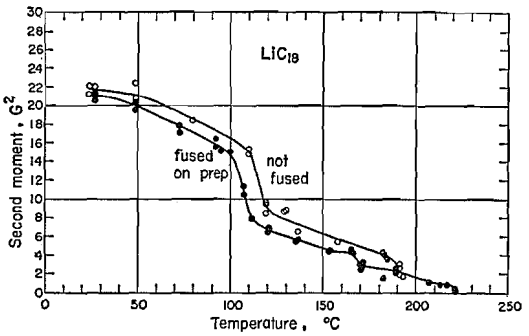

FIG. 3. Second moments for two lithium stearate samples, one never fused (open circles), and the other fused during preparation (filled circles).

second moment vs. temperature curves which lie just above and within the rapid decrease region. For the once melted sample, this corresponded to 114 °C.

The use of saturation narrowed n.m.r. spectra, having excellent signal-to-noise ratio, may be applicable to the examination of phase transitions in other solids. Before placing too much reliance on the method one should, however, investigate the dependence of the T_1/T_D ratio on temperature and on the existence of known phase transitions.

Thermal decomposition of hydrazoic acid as a possible source of NH radicals[1]

W. C. RICHARDSON AND D. W. SETSER[2]
Department of Chemistry, Kansas State University, Manhattan, Kansas 66502

Received November 26, 1968

The thermal decomposition of hydrazoic acid in the presence of methane, ethane, and propane investigated over the temperature range 285–470 °C gave only N_2, NH_3, and polymer as products. Limited experiments were done with ethene as a substrate, and products were formed which correspond to reactions of nitrogen containing radicals with C_2H_4. The pyrolysis of HN_3 is not a good source of NH radicals due to heterogeneity and complex secondary reactions of radicals with HN_3.

Introduction

Photolysis of HN_3 (1) and photolysis (2), pyrolysis (3), and mercury photosensitization (4) of HNCO have not provided a clean source of NH radicals. Previous work (5) suggested that NH is formed in the primary step in thermal decomposition of HN_3. Also formation of involatile acid–base complexes, a serious problem in HN_3 and HNCO systems, can be avoided because hydrazoic acid complexes are dissociated at temperatures above 100 °C, and complete decomposition of the HN_3 can be achieved before the sample is analyzed. Therefore, we investigated the pyrolysis of HN_3 with hydrocarbons as a source of NH radicals. Unfortunately, due to heterogeneous reactions, polymer formation, and complex secondary reactions, the thermal decomposition of HN_3 proved to be an unsatisfactory source of NH radicals. A brief summary of the results (6) from pyrolysis of HN_3 with CH_4, C_2H_6, C_3H_8, and C_2H_4 is presented.

Experimental

Hydrazoic acid was prepared in two ways: (*a*) by treating sodium azide (Fisher Laboratory Chemical, purified grade) with concentrated sulfuric acid and passing the effluent gas through phosphorous pentoxide, and (*b*) by passing hydrogen chloride gas through an 18 cm column packed with NaN_3. The former preparation contained a trace of SO_2 impurity; the latter preparation gave a poor yield and unreacted HCl had to be removed from the HN_3. The pyrolysis results were the same using HN_3 from either preparation. The hydrocarbons were obtained from standard sources.

Reactions were run by placing 1 cc (at S.T.P.) of HN_3 and 10 cc of substrate in a 10 cc Pyrex bulb. After mixing, the reaction bulb was introduced into a furnace and the temperature was monitored with a calibrated thermocouple. After complete decomposition of HN_3, condensable and noncondensable (−196 °C) products were separated using standard vacuum techniques. Products divided into 2 fractions in this manner were further separated and identified by gas–liquid chromatography (g.l.c.) or in some cases taken directly for mass spectrometric analysis. Using a variety of g.l.c. columns, quantitative analysis could be carried out for NH_3, N_2, CH_4, C_3H_8, C_3H_6, C_4H_{10}, and butenes. Analyses for H_2 and N_2H_4 were made with a Bendix time-of-flight mass spectrometer.

Results

One hundred pyrolyses using a variety of reaction vessels, reaction times, and temperatures from 285–470 °C were carried out with CH_4. In all pyrolyses the total pressure was about 2 atm. No explosions occurred as long as CH_4 was present. The products at complete HN_3 decomposition were nitrogen, ammonia, and nonvolatile polymer and the measured gaseous products were reproducibly the same at complete HN_3 decomposition over the temperature range studied. Within the experimental error, the initial quantity of methane was always recovered. Due to the polymer, direct mass balance could not be achieved. But from the amount of starting material and measurement of N_2 and NH_3 at complete HN_3 decomposition, the polymer was assigned by difference. Starting with 100 molecules of HN_3 the product molecules were 115 N_2, 15 NH_3, and 55 NH. Extensive searches were made for H_2, CH_3NH_2, and N_2H_4 by mass spectrometric and g.l.c. techniques with negative results.

The rate of production of N_2 depended upon the history of the vessel and seemed to be between zero and first order in $[HN_3]$. For example at 355 °C in a freshly cleaned Pyrex vessel

the time for half decomposition of HN_3 was 45 min, but in vessels that had been "seasoned" by propene pyrolysis, the half life was too rapid to be measured. At 285 °C in a "seasoned" vessel the half life was 40 min, while at this temperature in a fresh vessel appreciable decomposition did not occur. In contrast at 450 °C, complete decomposition occurred in less than 2 min for both types of vessels[3].

A limited number of experiments were done with C_2H_6 and C_3H_8 as substrates because the lower C—H bond energies relative to CH_4 might have permitted reaction with NH radicals. However, no amine formation could be detected for pyrolysis at 430 °C and the proportions of N_2 and NH_3 formed at complete HN_3 decomposition were similar to the methane system.

From the results described it was not obvious that NH radicals were a significant feature of HN_3 pyrolysis, although other work (5) certainly suggests this. A limited number of experiments with HN_3 and C_2H_4, and HN_3 and C_2D_4 were done because some characteristic products[4] have been reported for the reaction of NH with C_2H_4 (1*b*, 2*a*, 7, 8). Major reaction products (especially CH_3CN) were found which undoubtedly resulted from reaction of C_2H_4 and NH containing radicals. But ammonia was still formed and probably originated from radical reaction with HN_3 which, if true, questions the use of C_2H_4 as an efficient scavenger for NH. Also propane, propene, butane, and butenes were observed as reaction products. Another expected product from NH + C_2H_4 is HCN, but it would not have been detected due to formation of NH_4CN with the NH_3 product. A few experiments were done with C_2D_4. The g.l.c. effluent peaks were trapped and analyzed mass spectroscopically. The mass spectra were very complex, but there was evidence for the presence of H-atoms in fragment ions of propane, propene, and butane.

[3]Assuming a HN_3 diffusion coefficient similar to alkanes, the results at 450 °C imply that decomposition could not occur completely on the surface because, for the pressures of this study, complete diffusion of HN_3 to the surface is impossible in less than 2 min.

[4]Confusion exists in the literature regarding production of HCN and CH_3CN in the reaction of NH with C_2H_4. In some studies both products are observed (1*b*), in others either HCN (2*a*) or CH_3CN (7) or neither (8) has been detected. Careful work is needed to clarify this problem.

Discussion

The severe loss of NH in the overall stoichiometry and the dependence of the decomposition rate on vessel history in the NH_3–CH_4 studies point to a system plagued by heterogeneity. The obvious conclusion of this study is that the thermal pyrolysis of hydrazoic acid is unsuitable as a clean source of NH radicals.

Hydrazoic acid decomposition[5] in the presence of various alkanes gave the same products as those reported for the low temperature pyrolysis work of pure HN_3 (5*a*). No evidence was found for the reaction of NH or other radical intermediates with CH_4, C_2H_6, and C_3H_8, although the formation of CH_3CN in the HN_3–C_2H_4 system implies some gas phase reaction of NH with C_2H_4. Since the reaction of NH with C_2H_4 should be relatively fast, the concomitant formation of NH_3 as a product implies that it arose from an addition reaction (or some other low activation process) of NH with HN_3. The nature of the hydrocarbon products found from the C_2H_4 system, and the isotopic distribution from the C_2D_4 experiments suggest reactions of H-atoms presumably from HN_3. A great deal of further work is necessary before a mechanism (6) can be discussed with any certainty. The results of this work emphasize the need for clean sources of NH and NH_2 radicals so that their elementary reactions can be identified. Then a better understanding of the complex chemistry of nitrogen–hydrogen radical systems should be possible.

[5]The energy separation between the NH ($a^1\Delta$) and ($X^3\Sigma^-$) states has recently been measured (9) as 36 kcal. Hence the homogenous thermal decomposition of HN_3 would be expected to give triplet NH which may explain the lack of reaction with saturated alkanes found in this work.

Circular dichroism of copper(II) carboxylates

ANTHONY A. SMITH AND ROLAND A. HAINES
Department of Chemistry, University of Western Ontario, London, Ontario

Received December 23, 1968

The circular dichroism (c.d.) spectra of anhydrous copper(II) acetate, copper(II) isobutyrate, and copper(II) allylacetate in *d*-1,2-propanediol are interpreted as showing that all the d → d transitions are contained in a single band envelope with relative energies of the d orbitals being $d_{x^2-y^2} > d_{z^2} > d_{xy} > d_{xz} \simeq d_{yz}$. A possibility for the origin of a c.d. band at ~ 300 mμ is suggested.

Canadian Journal of Chemistry, 47, 2727 (1969)

The crystal structure of copper(II) acetate has been known for some time to be binuclear with the copper atoms joined by 4 bridging carboxylate ligands (1). However, there is still much controversy over the interpretation of its electronic absorption spectrum and that of related compounds. We wish to report a c.d. study of 3 of these compounds in an optically active solvent, *d*-1,2-propanediol, the results of which may give support for a particular assignment of the absorption spectra. The study was carried out on anhydrous copper acetate, copper isobutyrate, and copper allylacetate. The c.d. curves obtained in *d*-1,2-propanediol were virtually the same for all 3 complexes, with very slight differences in peak wavelengths and intensities, and are shown together with the absorption spectra in Fig. 1.

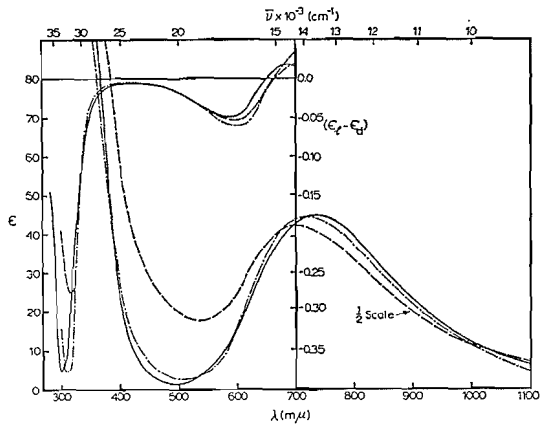

FIG. 1. Circular dichroism and absorption spectra in *d*-1,2-propanediol: (——), copper acetate; (---), copper isobutyrate; (-·-·-), copper allylacetate.

The absorption spectrum of copper acetate at 77 °K has shown 3 bands: a *z*-polarized band at 11 000 cm^{-1}, an *xy*-polarized band at 14 400 cm^{-1}, and another *z*-polarized band at 27 000 cm^{-1} (2). At room temperature, however, the 11 000 cm^{-1} band is seen only as a broadening of the more intense 14 400 cm^{-1} band. The lower energy bands are assigned as d → d transitions, while it is uncertain as to whether or not the high energy band is of this type (2–5). Hansen and Ballhausen (3), using a molecular orbital method of calculation in which the dimeric complex is treated as two weakly coupled chromophores, have assigned the 27 000 cm^{-1} band as a transition to a doubly excited state. On the other hand, Kokoszka, *et al.* (2) have favored the single excitation $d_{z^2} \rightarrow d_{x^2-y^2}$, while Boudreaux (4), and Dubicki and Martin (5) considered it as a charge transfer band.

The close proximity of the Cu atoms (2.64 Å) in each molecule of the complex indicates there is some interaction between them and this may be either a σ or a δ interaction. The σ-bonded

$d_{xy} \rightarrow d_{x^2-y^2}$	—	Allowed	—	Allowed
$d_{xz} \rightarrow d_{x^2-y^2}$	x	Allowed	—	Allowed
$d_{yz} \rightarrow d_{x^2-y^2}$	y	Allowed	—	Allowed

system requires that all d → d transitions terminate on the d_{z^2} orbital and all these transitions should thus be solvent sensitive, but this does not seem to be the case (6). For the δ-bonded configuration, the highest energy orbital is the $d_{x^2-y^2}$ level.

Two possibilities exist for this compound in solution, one in which the binuclear species is maintained, and the other in which the dimeric structure is broken down to give the monomer. A close examination of the crystal structure (1) shows that the planes containing the O—Cu—O bonds are not exactly at right angles, but are 7° from orthogonality. This would give a C_{2v} symmetry about each copper atom in the dimeric molecule. The monomer may be considered as a square planar structure with two acetate ligands (7), therefore having D_{2h} symmetry. In each case, a polarization can be predicted for the d → d transitions. Moreover, the c.d. activity of a transition can be predicted, since the requirement for this is met when the direct product of the symmetries of the electronic wave functions belongs to a representation containing a rotation. These predictions are shown in Table I.

The observed c.d. spectrum shows a positive peak around 700 mμ and a broad negative peak centered at ~590 mμ. We propose that the positive c.d. band corresponds to the $d_{xy} \rightarrow d_{x^2-y^2}$ transition and the negative band to the $d_{xz} \rightarrow d_{x^2-y^2}$ and $d_{yz} \rightarrow d_{x^2-y^2}$ transitions. The $d_{z^2} \rightarrow d_{x^2-y^2}$ transition would be at much lower energy and should correspond to the 11 000 cm^{-1} absorption band. It can be seen that this assignment is consistent with both C_{2v} and D_{2h} symmetries, and it is therefore impossible to distinguish which species is in solution from the c.d. spectrum. However, the absorption spectrum of copper acetate in 1,2-propanediol shows a large decrease in the extinction coefficient from that in non-polar solvents, thus suggesting that the species in solution in this case is the monomer. Similar decreases are exhibited by copper allylacetate and copper isobutyrate. The absorption band at 27 000 cm^{-1}, which has been thought to be indicative of dimeric species, is also absent from our spectra (6, 9). Dubicki and Martin (5) have stated that the energy states of the dimer correspond closely to those of the monomer, so it is reasonable that our assignment is also valid for the dimeric molecule.

Our assignment is consistent with the idea that all the d → d transitions are contained in one absorption band envelope (3, 5). Hansen and Ballhausen (3) employed this idea in their calculations using energies of the 3 bands derived from a Gaussian analysis of the absorption spectrum of $CuSO_4 \cdot 5H_2O$ by Holmes and McClure (8). The former authors used C_{4v} symmetry, thus predicting three d → d transitions, while the latter used a model in which 4 such transitions were expected, only 3 of which were indicated as being under the one absorption band. Dubicki and Martin (5), also using C_{4v} symmetry, concurred with the assignment of Hansen and Ballhausen. Our work definitely indicates the presence of all four d → d transitions predicted for both C_{2v} and D_{2h} symmetry under the main absorption band at 700 mμ.

The similarity of the c.d. spectra of copper isobutyrate and copper allylacetate to that of copper acetate indicates that the relative d-orbital energies for all these complexes are the same, i.e., $d_{x^2-y^2} > d_{z^2} > d_{xy} > d_{xz} \simeq d_{yz}$, with the d → d transitions contained in a single absorption envelope.

Edmondson and Lever (6) have noted that if the 14 400 cm^{-1} band is assigned as $d_{xy} \rightarrow d_{x^2-y^2}$, this band should be independent of solvent, but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

such is not the case. Assuming that a direct parallel can be drawn between the energy levels of the monomer and dimer and using our assignment, the solvent dependence could be explained as being due to the presence of the $d_{xz} \rightarrow d_{x^2-y^2}$ and $d_{yz} \rightarrow d_{x^2-y^2}$ transitions, which would be solvent dependent, in the near vicinity of the absorption maximum. Similarly, the *xy* polarization of the 14 400 cm^{-1} band in the dimer may be explained as being due to the polarizations of the underlying $d_{xz} \rightarrow d_{x^2-y^2}$ and $d_{yz} \rightarrow d_{x^2-y^2}$ bands.

The c.d. spectrum of copper acetate also shows a strong negative peak at 305 mμ and an analogous band is observed for the other 2 complexes at slightly higher wavelengths (~ 310 mμ). This band is almost certainly a charge transfer band, most probably one of the $n(s,p) \rightarrow \sigma^*_{x^2-y^2}$ transitions. Due to the large number of charge transfer transitions which could be optically active, however, it is obvious that an unambiguous assignment cannot be made for the c.d. band at 300 mμ.

Experimental

Optically active *d*-1,2-propanediol was obtained from Aldrich Chemical Co., Milwaukee, Wisconsin. The solutions were prepared by weighing both solvent and solute into a weighing bottle and calculating concentrations on the basis of solvent density. The solutions were all $\sim 10^{-2}$ *M* based on the monomeric formula for each complex. Circular dichroism spectra were measured on a Durrum–Jasco ORD-UV-5 spectropolarimeter and absorption spectra on a Beckman DK-1 spectrophotometer. Cupric acetate monohydrate was dried for 34 days at 50° under slight vacuum. If the complex was dried at a higher temperature, acetic acid was given off from the solid and the color changed to a lighter green than that of the monohydrate. Solutions of copper acetate monohydrate in *d*-1,2-propanediol showed evidence of decomposition and gave inconclusive c.d. data.

Explosive sensitivity of cobalt(III) ammine complexes

Taylor B. Joyner
Chemistry Division, Naval Weapons Center, China Lake, California 93555

Received February 11, 1969

Unexpected uniformities in the explosive sensitivities of a number of coordination compounds have been observed. These suggest that the kinetics of reaction within the hotspot (as distinct from either generation of the hotspot or propagation from the hotspot to macroscopic proportions) play a critical role in determining the sensitivity of an explosive to initiation by impact.

Canadian Journal of Chemistry, **47**, 2729 (1969)

This note reports unexpected uniformities in the explosive sensitivity of several coordination compounds. Previously, Tomlinson *et al.* reported sensitivities for coordination compounds (1) and we discussed complex azides (2). Of present interest are the perchlorates, chlorates, bromates, and permanganates of Table I. Despite the difficulties inherent in impact testing (Boyars and Levine (3) have recently reviewed the subject) and variations from strong to very weak, underoxidized explosives, the sensitivities of salts of a given anion are quite uniform. Irregularities, shown by nitrates, nitrites, and $[Co(en)_2Cl_2]ClO_4$, were expected. The more surprising uniformities suggest that for these compounds a factor associated with the anion is critical to sensitivity.

*The reactions were characterized as strong (s), more than 75% of sample consumed, loud report, visible flame; medium (m), 25–75% of sample consumed, audible report, occasionally visible flame; weak (w) less than 25% of sample consumed, usually no audible report, and little or no visible flame.

†Ethylenediamine is represented by "en".

Hotspot theory (4) permits some localization of this factor. Ignition involves: (*1*) generation and concentration of energy in small hotspots, (*2*) growth of reaction within these areas, and (*3*) growth to visible proportions. Failure can result from inadequate energy in (*1*) or the reaction rate during (*2*) or (*3*) not compensating for heat loss. Since the heat of reaction (roughly indicated by oxygen balance and reaction violence) supports propagation through the cool regions of the crystal, the observed independence suggests that the critical factor does not operate during (*3*)[1]. Although the events of (*1*) are complex (crushing, melting, entrapment of gas, etc.), the uniformities again suggest that properties dependent on crystal structure or the nature of the cation are not decisive.

However, during reaction *within* the hotspot the anion, and specifically, the kinetics of its reaction with the ammine, may be decisive. It thus seems reasonable to identify the factor critical to sensitivity with this aspect of the ignition process. This is in encouraging accord with the recent theoretical treatment of Bruckman and Guillet (5) who find that the Arrhenius parameters of the decomposition reaction exercise a dominant effect on the sensitivity of an explosive compound.

The independence of heat of reaction merits brief comment. If impact produces an adequate temperature, decomposition will commence. For success, the rate must be sufficient to maintain the hotspot temperature and reaction. Although growth within the hotspot is relatively easy (compared to the cool surroundings) it still depends on heat of reaction and weaker explosives will require faster rates to overcome heat loss. However, the temperature increase necessary for a two- or three-fold acceleration (a few tens of degrees) is small relative to hotspot temperature (ca. 500°) (4) and the crude tests would be unlikely to differentiate between impacts causing temperature rises of say 500 and 550°. Detailed consideration of the events and reaction mechanisms occurring within the hotspot would, at present, be highly speculative. However, it is hoped that current kinetic studies will permit insight into these problems.

Experimental

Preparations were conventional (6). Some compounds, notably $[Co(NH_3)_6](MnO_4)_3$, are treacherous. The "Type 12" test (3) with a 2 kg hammer and 25 mg of explosive loosely coned on sandpaper was used. The drop heights for 50% successful ignitions based on 20 tests are reported. For purposes of comparison, our machine yields 50% points of 10, 25, and 145 cm for lead azide, RDX, and TNT, respectively.

[1]Presumably, decomposition of a hotspot initiates adequate reactions in even weak explosives. However, propagation failure could explain some of the exceptions.

Spectroscopic and acoustic measurements in relation to the conformation of a cyclic sulfite and a cyclic sulfate

P. C. HAMBLIN AND R. F. M. WHITE
Chemistry Department, Sir John Cass College, Jewry Street, London, E.C.3, England

AND

G. ECCLESTON AND E. WYN-JONES[1]
Department of Pure and Applied Chemistry, University of Salford, Salford 5, Lancashire, England

Received December 16, 1968

In the investigation of certain types of conformational equilibria, the ultrasonic absorption technique can be used to supplement information derived from more conventional spectroscopic techniques, and thereby lead to a more detailed analysis of molecular configuration.

Nuclear magnetic resonance, infrared spectra, and ultrasonic absorption measurements indicate that both 4-methyl trimethylene sulfite and 4-methyl trimethylene sulfate exist as equilibrium mixtures of two chair isomers. In each case one isomer is strongly predominant.

Canadian Journal of Chemistry, 47, 2731 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

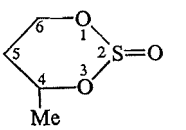
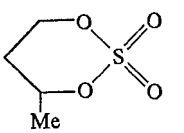
The conformational analysis of heterocyclic molecules has been studied with a variety of physical techniques including nuclear magnetic resonance (n.m.r.), infrared (i.r.), dipole moment (1, and references therein), and more recently the ultrasonic absorption method (2, 3). Spectroscopic and dipole moment studies, together with X-ray investigation of the solid phase (4), have demonstrated that in trimethylene sulfites the chair form is favored with the S=O bond in an axial orientation (5, 6).

The preference for the SO bond axial as against the SO equatorial orientation is estimated to be about 3.5 ± 1 kcal (6). Since the spectroscopic and dipole methods may not be discerning enough to detect conformers present in small percentages in "anancomeric" systems (7), the ultrasonic method (2, 3) constitutes a valuable additional technique since it is sensitive to ~1% of the higher energy rotamer (8).

As a further example of this type of conformational behavior we present spectroscopic and ultrasonic data which have been used to elucidate the conformations of 4-methyl trimethylene sulfite (**1**), and also 4-methyl trimethylene sulfate (**2**). The n.m.r spectra (10) of both **1** and **2** were found to be complex and first order analysis of the spectra gave the values for the coupling constants between the proton at C_4 and the two protons at C_5 as in Table I. A complex n.m.r. spectrum (9) and the above figures (5, 6) are compatible with a chair conformation for



1



2

TABLE I
Coupling constants between protons

Compound	Coupling constant	Value (Hz)
1	J_{aa}	12
	J_{ae}	2.6
2	J_{aa}	12.3
	J_{ae}	2.5

both molecules with the methyl group in an equatorial position in each case. In addition a strong absorption band at 1190 cm^{-1} in the i.r. spectrum of **1** indicates that the S=O is axial (6). There is no evidence for the corresponding equatorial S=O absorption band in the region 1230–1250 cm^{-1} (6). This combined spectroscopic evidence points to a rigid chair structure for both molecules with the methyl groups in an equatorial position and the S=O bond of **1** being axial. In practice, however, this type of statement can be qualified by postulating an anancomeric chair form for these molecules.

[1]To whom correspondence should be addressed.

More details about the conformation can be obtained from ultrasonic absorption measurements.

When there is an equilibrium between energetically different conformers in a molecule, this can sometimes be detected by ultrasonic measurements (8). If the appropriate frequency range is chosen, the temperature fluctuations accompanying sound waves can perturb the conformational equilibrium resulting in ultrasonic relaxation. When this occurs the quantity α/f^2 (α is the sound absorption coefficient at frequency f) decreases with increasing frequency (8).

Using a pulse apparatus operating in the frequency range 15–105 MHz we have observed an ultrasonic relaxation in **1**, and also in **2** which was examined as a 30% (wt./v.) solution in two solvents: *p*-xylene and 1,4-dioxan.

The results obtained are shown in Table II and are interpreted in each case as a perturbation of the equilibrium between two chair conformers.

1 $CH_3(e),\ S{=}O(a) \rightleftharpoons CH_3(a),\ S{=}O(e)$

2 $CH_3(e) \rightleftharpoons CH_3(a)$

These conclusions are supported by the following evidence. (*a*) Physico-chemical evidence indicates that in these molecules, the chair conformers are energetically favored compared with other extreme conformations. (*b*) The relaxation frequencies for both solutions of **2** are sensibly the same, indicating that the relaxation is due to an intramolecular mechanism. (*c*) Examination of solutions of **1** produces relaxation frequencies similar to those found in the pure liquid. (*d*) No relaxation (2) was found in solutions of trimethylene sulfate where ring inversion results in chair conformers of equal energy.

TABLE II

Ultrasonic relaxation data

Compound	Relaxation frequency (MHz)	Temperature (°C)
1	40	−10
2 (in *p*-xylene)	13.6	24
(in 1,4-dioxan)	13.3	24

A limitation of the spectroscopic methods is that they are sometimes unable to distinguish between a molecule involved in an anancomeric conformation equilibrium and a rigid molecule. On the other hand the ultrasonic method can detect an equilibrium between conformers differing in energy, in which only ~1% of the higher energy form is present. A preliminary analysis of the ultrasonic data in solutions of **2** in *p*-xylene shows that ΔG (at 298 °K) (axial–equatorial) $\approx$ 2 kcal/mole indicating 97% of the methyl equatorial chair isomer. The ultrasonic relaxation frequencies quoted indicate that the n.m.r. spectra are time averaged spectra.

Structure of rhodocladonic acid

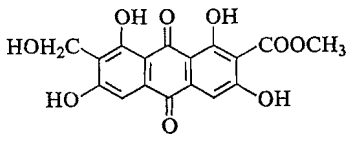
PAUL M. BAKER AND E. BULLOCK
Department of Chemistry, Memorial University, St. John's, Newfoundland

Received May 26, 1969

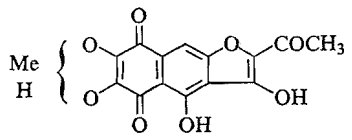
The currently accepted formulation of rhodocladonic acid, the red pigment from numerous lichens of the genus *Cladonia*, is revised. The compound is a naphthoquinone derivative, apparently the first isolated from a lichen.

Canadian Journal of Chemistry, 47, 2733 (1969)

Rhodocladonic acid is the characteristic pigment present in the red apothecia of numerous lichens of the genus *Cladonia* (**1**). Shibata (2) proposed a molecular formula $C_{17}H_{12}O_9$ and structure **1** for this substance. Reinvestigation of the compound, obtained from local cladonia species, leads us to propose **2** for the structure of rhodocladonic acid. The compound was isolated by established methods and recrystallized from nitrobenzene (2).



1



2

Rhodocladonic acid, $C_{15}H_{10}O_8$ (3), (molecular ion at *m/e* 318.0375; calcd. for $C_{15}H_{10}O_8$, 318.0376) has one *O*-methyl group (Zeisel). It gives a trimethyl ether, $C_{18}H_{16}O_8$, m.p. 192–193°, with methanolic diazomethane, and a triacetate, $C_{21}H_{16}O_{11}$, m.p. 210–212°, with acetic anhydride – pyridine. The triacetate can be reductively acetylated to a leucopentaacetate, m.p. 223–225°, with zinc – acetic anhydride. The nuclear magnetic resonance (n.m.r.) spectrum of the trimethyl ether (in $CDCl_3$) shows absorption due to one *C*-methyl group at τ 7.42 and a single aromatic proton at τ 1.98. These data preclude the anthraquinone formula **1**, but support the presence of a trihydroxyquinonoid system in the molecule. The infrared spectrum of the reduced pentaacetate (in $CHCl_3$) has a sharp band at 1690 cm^{-1}; thus the molecule appears to contain an aromatic methyl ketone (cf. 4).

Rhodocladonic acid is readily degraded by refluxing 3% potash solution to a mixture of products. One of these (mol. wt. 236) (**3***a*) gives a trimethyl ether (mol. wt. 278), with alcoholic diazomethane, whose mass spectrum is identical with that of spinochrome B tetramethyl ether (**3***b*).

A second degradation product, $C_{13}H_8O_7$ (**4**) (molecular ion at *m/e* 276.0264, required *m/e* 276.02701) has formula and properties corresponding to the loss of CH_3CO from rhodocladonic acid. Thus it gives a trimethyl ether (mol. wt. 318) with alcoholic diazomethane, which shows no *C*-methyl absorption in the n.m.r. spectrum ($CDCl_3$), but has 2 low field protons

(τ 2.06 and 2.63), which are not coupled, and 4 methoxyl signals.

Both **3***a* (max. at 311.5, 384.6, and 454.5 mμ) and **4** (max. at 306, 379, and 457 mμ) show typical hydroxy juglone electronic spectra, and give green colors with neutral magnesium acetate solution; hence both possess a free "peri"-hydroxyl group. Further, **3***a* was shown to be different from **3***c*, (obtained from **3***b* by alkaline hydrolysis to demethylate one ether of the quinonoid ring and treatment with ethereal magnesium iodide solution (5) to remove the second methyl from the quinonoid ring and the "peri"-methyl group), and is thus formulated as **3***a*.

The low-field single proton signal observed for rhodocladonic acid trimethyl ether suggests that a peri-aromatic proton is present in the molecule (cf. 6). Thus, rhodocladonic acid may be formulated as arising from addition of a 4 carbon unit at C-6 of **3***a* which, from the hydrogen content of the acid and of **4**, must form a cyclic structure. On the basis of an acetate-type biogenesis, **2** is proposed as the most reasonable formulation. The substituted furan ring in **2** is the analogue of isomaltol ((**5**) (7)). Final assignment of the position of the methyl ether in **2** must await crystallographic analysis, but a characteristic (M-71) peak in the mass spectra of **2**, **3***a*, and **4** supports the presence of a methoxyl substituent adjacent to a quinoid carbonyl (8).

The formulae given are substantiated by accurate mass data or analysis or both and are consistent with all spectroscopic data. This appears to be the first report of a naphthoquinone derivative in a lichen (cf. 9).

A rigorous, purely chemical structure proof for aconitine and delphinine

K. Wiesner, Wen-ling Kao, and Ernest W. K. Jay
Natural Products Research Center, University of New Brunswick, Fredericton, New Brunswick

Received May 20, 1969

A reaction sequence is described which allows the conversion of the aconitine degradation product (**8**) to the previously synthesized compounds **9** and **10** (10), thus providing a complete chemical proof of structures for aconitine **2** and delphinine **1**.

Canadian Journal of Chemistry, 47, 2734 (1969)

Ten years ago we have deduced the structure (**1**) for delphinine (1) and (jointly with the group of Professor G. Büchi) the structure (**2**) for aconitine (2). Shortly after the appearance of our papers in press the structure of desmethanolaconinone (**3**) was derived as a result of an independent crystallographic study (3). This X-ray work, besides corroborating our proposals, helped to orient the substituents in ring A and defined the stereochemistry of all substituents except those located in ring A. Since we have succeeded to correlate (4) aconitine and delphinine, the crystallographic work corroborated the structure of both alkaloids. The orientation and also the configuration of the ring A substituents in aconitine was proved chemically by Professor Büchi (5) and we have derived the configuration of the ring A methoxyl in delphinine (6). Thus the full structure and configuration of both alkaloids may be portrayed by the formulae **4** and **5**. The

chemical evidence for our original structure proposals (1,2,7,8) involved a rigorous proof of the structure and substitution of the C/D ring system and of its relationship to the nitrogen. If we add to this the chemical proof of the orientation and configuration of the ring A substituents in aconitine (5), we can represent the situation, in the chemistry of the two alkaloids, by the formulae **6** and **7**. The partial structure drawn by solid lines in **6** and **7** is rigorously established, while the dotted part of the formulae is in good agreement with a considerable number of experimental data, but not rigidly proved. In fact, this chemically unproved part of the molecule was not difficult to guess. It is common to all known diterpene alkaloids and it was known for a long time since we first proposed this structural feature as a part of the structure of veatchine and atisine (9). Nevertheless, we were interested to provide rigorous purely chemical evidence for the complete structure. Since we wished to accomplish this *via* a total synthesis, this work was simultaneously intended to serve as a stepping stone for the synthesis of the complex diterpene alkaloids themselves.

In our original work on aconitine (2, 8) we have shown that this alkaloid may be simply degraded to the aromatic compound **8**. In this

derivative the anisole ring originated from the C–D ring system of aconitine, while the rest of the molecule remained completely intact. Recently we have described (10) a total synthesis of the compounds **9** and **10**. In the present communication we wish to disclose the preparation of the optically active form of compounds **9** and **10** from the "natural" aromatization product **8** and a rigorous identification of these materials with the totally synthetic racemates. Since the position and configuration of the ring A substituents in aconitine is fully established by chemistry alone (5) this work represents a rigorous structure proof for aconitine and delphinine. The correlation provides also a chemical proof for the configuration of the ring B methoxyl which is known to be *exo* in the synthetic products (10).

Jones oxidation of compound **8** gave the dike-

tone **11** as a chromatographically homogeneous foam in a 91% yield. Infrared (i.r.) (CCl_4): 1720, 1690 cm^{-1} (ketones); nuclear magnetic resonance (n.m.r.): singlets (3H each) τ = 6.14, 6.69, 6.72, 6.80 p.p.m. (4 —OCH_3); *m/e* = 429.

As depicted in Scheme 1, the diketone **11** was heated under reflux with methanolic hydrochloric acid. The basic product **12** was purified by chromatography on alumina and was homogeneous in thin-layer chromatography (t.l.c.). It was obtained in a yield of 75%. Infrared ($CHCl_3$): 3500–3460 cm^{-1} (NH), 1675 cm^{-1} (both ketones); n.m.r.: singlets (3H each) τ = 6.20, 6.68 and 6.76 p.p.m. (3 —OCH_3); *m/e* = 369.1572.

Acetylation of **12** with acetic anhydride and pyridine gave a quantitative yield of the acetyl derivative **13**. It was purified by chromatography and was homogeneous in t.l.c. Infrared (CCl_4): 1700, 1690 cm^{-1} (ketones), 1670 cm^{-1} (N—C—CH_3); n.m.r.: singlets (3H each) τ =

6.14, 6.65, 6.79 p.p.m. (3 —OCH_3), τ = 8.09 p.p.m. (N—C—CH_3); *m/e* = 411.

The acetyl derivative **13** was hydrogenated with platinum oxide in ethanol and the diol **14** thus obtained was immediately oxidized by the Jones reagent to the diketone **15**. After chromatography on alumina compound **15** was homogeneous in t.l.c. and was obtained in a yield of 90%. Infrared (CCl_4): 1720, 1695 cm^{-1} (ketones), 1650 cm^{-1} (N—C—CH_3); n.m.r.: singlets (3H each) τ = 6.18, 6.70, 6.86 p.p.m. (3 —OCH_3), τ = 8.01 p.p.m. (N—C—CH_3); *m/e* = 413.

The diketone **15** was converted quantitatively to the dithioketal **16** by treatment with ethanedithiol and boron trifluoride in glacial acetic acid. The course of this transformation was followed by t.l.c. and by the disappearance of both ketonic absorptions in the i.r. spectrum. Compound **16** was now desulfurized with Raney nickel in alcohol and the product of this reaction was hydrogenated in glacial acetic acid with platinum oxide to reduce a certain amount of material containing a double bond in ring A. Preparative t.l.c. repeated twice yielded the pure "natural" compound **9**. It was homogeneous in six t.l.c. systems using two adsorbents and indistinguishable from the totally synthetic sample (10). The i.r. (CCl_4 and $CHCl_3$), n.m.r. and mass spectra of both materials were superimposable; *m/e* = 385.2252.

Jones oxidation of the "natural" compound **9** yielded the "natural" final product **10** in a 90% yield. It was purified by preparative t.l.c. and it was indistinguishable from the totally synthetic sample (10) of **10** in the same t.l.c. systems used previously. The i.r., mass, n.m.r. and ultraviolet (u.v.) spectra of both materials were identical in every detail; *m/e* = 399.2042.

Method for the accurate determination of specific rotation. Specific rotation of valine and leucine[1]

J. C. MacDonald

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received November 27, 1968

The optical rotation of various concentrations of L-valine and L-leucine, dissolved in glacial acetic acid, or 5 or 6 *M* HCl, was measured with a photoelectric polarimeter at the nominal wavelengths 589, 578, 546, 436, and 365 nm and temperatures of 20, 25, and 30 °C. The specific rotation for any one wavelength, solute, and solvent could be defined by the equation $[\alpha]_\lambda^T = A(1 + D(T - 25)) + BC$, where T is temperature in °C, C is concentration in grams of solute per 100 ml of solution, and A, B, and D are constants. The best fit values of the constants were determined by computer calculation and are listed. Constants are also given for calculating a specific rotation based on grams of solute per 100 g of solution.

Canadian Journal of Chemistry, 47, 2739 (1969)

Introduction

Hayashi and co-workers (1) investigated the specific rotation of amino acids at the sodium D spectral lines (589.3 nm), and the effect of the concentration of solute, molarity of the solvent (aqueous HCl), and temperature on the specific rotation. They found that the specific rotation of leucine and valine increased with increases in the molarity of the HCl and in the concentration of the amino acids. If this is true, few of the specific rotations found in the literature for either of these two compounds can be directly compared, for it is seldom that different workers have used the same temperature, and the same concentrations for HCl and amino acid.

In the work reported here, a formula is developed by which specific rotations of L-valine and L-leucine measured under different conditions can be compared. The solvents used were 5 and 6 *M* HCl, which are frequently employed in optical rotation measurements of amino acids, and glacial acetic acid, which is employed less frequently.

[1]NRCC No. 10648.

Materials and Methods

Solutes

Sucrose was a standard sample obtained from the National Bureau of Standards, Washington, D.C. Amino acid samples were obtained from commercial sources and checked for the content of other amino acids with a Beckman model 120 C amino acid analyzer, using relatively high loads of amino acid. The amino acid samples used in the main part of this work were tested for possible presence of the D-isomer, using a modification of the method of Meister and co-workers (2) and a lyophilized enzyme preparation (3) of D-amino acid oxidase. The modification consisted of the use of 6 ml of buffer instead of 1.5–3.5 ml to dissolve 1 mmole of leucine, because this amount of leucine could not be dissolved in the smaller volume.

Solutions of the amino acids in glacial acetic acid had no appreciable turbidity, and solutions were used directly for optical rotation measurements. Solutions in HCl were slightly hazy at the highest concentration used, so generally the amino acid was recrystallized from ethanol–water prior to making up the stock solution. The weight of material causing the slight haze was found to be negligible in comparison to the weight of amino acid.

A small amount of methionine contaminating the sample of leucine was removed by converting the methionine to the more soluble sulfoxide which was removed by recrystallization. To do this, the leucine was dissolved in water, H_2O_2 added to give a concentration of 0.3%, and the solution allowed to stand overnight. The solution was evaporated *in vacuo* to near dryness

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

with a rotary evaporator, the solid washed with ethanol, and recrystallized from water–ethanol.

Solvents

Reagent grade glacial acetic acid was purified by crystallization (4), and used as a solvent for optical rotation measurements. A smaller amount was purified further by drying it for 20 min over one-tenth of its weight of phosphorus pentoxide. The acetic acid was poured off and fractionally distilled until fractions of constant refractive index (measured with a Bausch and Lomb precision refractometer, 25 °C, Na lamp) were obtained. Such fractions of constant refractive index were combined. The refractive index of this standard sample was compared to that of the standard sample plus 0.3% and 0.9% (w/w) water, and to that of the acetic acid used for optical rotations, and the possible content of water in the latter calculated.

Reagent grade HCl was diluted with distilled water, titrated against standard sodium carbonate (5), the concentration readjusted to 5 or 6 M, and the final solutions retitrated.

Concentrations

Stock solutions of solutes in solvents were made up by weight, and dilutions made by weight, to give various values of W (g solute/100 g solution). Densities *in vacuo* were determined as described by Lipkin and co-workers (6) using a thermostatically controlled (±0.05 °C) water bath, and a 5 ml pycnometer modified to give a longer length of capillary below the hook to enable easier filling from a small flask and hence to minimize evaporation. Containers and their contents were equilibrated to balance-room temperature and static charges allowed to dissipate before weighing. All weights of solutes and solvents were corrected to weights *in vacuo* wherever such corrections made a difference of more than 0.05% in the final concentration as compared to uncorrected weights.

The concentration, C, of sucrose solutions in water was calculated from W by eq. [1] (see below), with ρ' values for 20.0, 25.0, and 30.0 °C calculated from Tables 113 and 119 of reference 7 for the appropriate W value. The apparent solution volume, V, of either amino acid in various solvents was calculated from eq. [2] from the density of the solution at the highest W value studied, and checked by appropriate measurements at a lower W value to make sure that it was constant, within experimental error, at differing concentrations. Equation [3] was derived from eqs. [1] and [2], and can be used to calculate C without repeating density determinations for every concentration.

$$[1] \qquad C = \rho' W$$

$$[2] \qquad \frac{1}{\rho'} = \frac{1 - 0.01W}{\rho} + 0.01VW$$

$$[3] \qquad C = \frac{W}{\dfrac{1 - 0.01W}{\rho} + 0.01VW}$$

C = g solute/100 ml solution; W = g solute/100 g solution; ρ' = absolute density of solution (g/ml) at specified temperature; ρ = absolute density of solvent at specified temperature; V = apparent solution volume of solute in solvent (ml/g solute) at specified temperature.

Polarimeter Readings

Optical rotations were measured with a Model 140 Perkin–Elmer photoelectric polarimeter equipped with sodium and mercury lamps and filters to isolate spectral lines at the nominal wavelengths of 589, 578, 546, 436, and 365 nm. The polarimeter cell used was of one-piece glass construction with a length of 1 dcm, a filling volume of 5.7 ml, wide filler ports (0.7 cm diameter) for rapid filling, and a jacket through which water from a thermostatically controlled bath was rapidly circulated. In the experiments with amino acids in glacial acetic acid the temperature of the solution was maintained to ±0.07 °C, and in other experiments the apparatus was improved to give a fluctuation of ±0.03 °C or less. Between different samples, the tube was washed with water and ethanol and dried with an air stream. The outside of the cell windows was wiped with lens tissue moistened with alcohol before each reading.

Amino acid stock solutions were made up by weight, and 5 dilutions made by weight to cover the range of concentrations investigated (Table II). The optical rotation of the stock solution was measured at five wavelengths at a nominal 20 °C (the thermometers were later calibrated against a National Bureau of Standards calibrated thermometer). The rotation with no cell in the light path (instrument blank) was then measured at the 5 wavelengths, and subtracted from the appropriate readings of the solution to obtain observed rotations, α_o The cell blank (i.e., α_o for the cell filled with solvent) was 0.000° for the cell and solvents used, so no corrections for cell blank were necessary. The temperature was readjusted, in turn, to a nominal 25 and 30 °C and the readings were repeated. The whole procedure was repeated for each dilution and all readings were done on the day of preparation of the solutions. The data were transferred to punched cards for computer calculations.

Calculation Methods and Equations

Results were calculated with an I.B.M. 360 computer. W was calculated from weight data, C from eq. [3], and $[\alpha]$ from eq. [4] (see below), using appropriate input data. Then data was separated into sets in which the solvent–solute system and wavelength were constant. From each data set with only C and α_o variable, and eq. [6] (8), which is derived from eqs. [4] and [5], the value of the constants A and B was calculated by a least squares method (eq. [7] and [8]) valid for a polynomial of degree 2 (9). This method gives more exact values of A and B for solutions having low rotations than would a linear regression analysis based on eq. [5]. The polarimeter tube length (0.9999 dcm) was so close to 1.0 dcm that it was treated as such and eliminated from the calculations and equations.

Equation [9] (see below) was found by inspection to fit data with C and T as independent variables, and was combined with eq. [4] to give eq. [10]. In this equation (and eqs. [6] and [13]), α_o has been changed to α_c to distinguish between an observed and calculated rotation. Approximate values of A, B, and D were substituted in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

eq. [10] and varied systematically in a computer program to obtain the best fit between α_0 and α_c values, as calculated from 'weighted degree difference' (w.d.d.) values (see Table II, footnote). The final values of A, B, and D were those which gave the lowest value for the sum of the squares of the w.d.d. values. The weighting of optical rotation values was necessary because the polarimeter had two specified accuracies: $\pm 0.002°$ for readings below 1°, and 0.2% (0.002 parts/degree) for readings greater than 1°.

$$[4] \quad [\alpha] = 100\alpha_0/CL$$

$$[5] \quad [\alpha] = A + BC$$

$$[6] \quad \alpha_c/L = 0.01AC + 0.01BC^2 = \alpha_c \quad (\text{if } L = 1 \text{ dcm})$$

$$[7] \quad a = \frac{\Sigma y \Sigma x^3 - \Sigma xy \Sigma x^2}{\Sigma x \Sigma x^3 - (\Sigma x^2)^2}$$

$$[8] \quad b = \frac{\Sigma y \Sigma x^2 - \Sigma xy \Sigma x}{(\Sigma x^2)^2 - \Sigma x \Sigma x^3}$$

$$[9] \quad [\alpha] = A(1 + D(T - 25)) + BC$$

$$[10] \quad \alpha_c/L = 0.01\,AC\,(1 + D(T - 25)) + 0.01\,BC^2 = \alpha_c \quad (\text{if } L = 1 \text{ dcm})$$

$$[11] \quad [\alpha_w] = 100\alpha_0/WL$$

$$[12] \quad [\alpha_w] = A'(1 + D'(T - 25)) + B'W$$

$$[13] \quad \alpha_c/L = 0.01A'W(1 + D'(T - 25)) + 0.01B'W^2 = \alpha_c \quad (\text{if } L = 1 \text{ dcm})$$

$[\alpha]$ = specific rotation as usually defined; $[\alpha_w]$ = a specific rotation defined by eq. [11]; α_0 = observed rotation of solution; α_c = rotation of solution as calculated from the equation; L = length of polarimeter tube in decimeters; A or A' = constants, the specific rotations at infinite dilution, or intrinsic rotation (8); B or B' = constants, concentration coefficient of specific rotation; D or D' = constants, temperature coefficient of specific rotation. T = temperature at which rotations were measured, °C.

$$a = 0.01A$$

$$b = 0.01B$$

$$y = \alpha_0/L = \alpha_0 \quad (\text{if } L = 1 \text{ dcm})$$

$$x = C$$

C and W have been defined above (see eqs. [1]–[3]).

For some work, a newly-defined specific rotation, $[\alpha_w]$ was calculated by eq. [11], which was used to derive eqs. [12] and [13]. The latter equation was used in the computer programs to find the best fit values of A', D', and B', by procedures similar to those mentioned above.

Results and Discussion

In general, the validity and accuracy of polarimetric results depends on three factors; the purity of the compounds used, the accuracy of the determination of concentration, and the accuracy of the polarimetric readings.

Purity of Compounds

The samples of L-leucine and L-valine used to obtain the data in Tables I, II, and III contained no detectable amount (<0.1%) of D-isomer. The L-valine contained no detectable amount (<0.1%) of any other amino acid but the L-leucine contained a trace (about 0.4%) of L-methionine. To check the validity of data obtained with this L-leucine sample, it was purified to remove methionine, but the rotations obtained in HCl (see below) did not differ significantly from those obtained with the original sample.

Small additions of water to purified acetic acid were found to increase the refractive index in a linear fashion. Analysis by refractive index of the acetic acid used for optical rotation measurements showed that it had a water content of about 0.1%. The acetic acid showed only one peak on gas–liquid chromatography.

Determination of Concentration

Since it is much easier to weigh solutions to an accuracy of 1 mg or better than it is to adjust their volumes to an accuracy of 1 µl or better (which would give comparable accuracy), concentrations were determined by weight and density (see Materials and Methods), and the appropriate factors are given in Table I. The density determinations, as checked with sucrose solutions and tabulated densities (7), were accurate to $\pm 0.02\%$. Good agreement was obtained between the densities of HCl and the data of Akerlof and Teare (10); other published densities for HCl (11, 12) are not so accurate (10). The method used allows for the change of concentration of solute caused by expansion of the solution with change in temperature. There is also a change in the molarity of HCl with change in temperature, but this affects optical rotations to a lesser extent, and may be corrected for as described later.

If an error of 1 mg was made in weighing the solute and solution in making up the stock solutions used to obtain data in Tables II and III,

the maximum error in concentration of the stock solutions would be from 0.07% to 0.19% for the various solvent–solute combinations. Similar small errors in dilutions would have an effect on the fit of data to eq. [10] or [13], but if the errors were random, they would be evened out to some extent in obtaining the best fit to these equations.

Polarimeter Readings

The Perkin–Elmer model 140 polarimeter has a specified accuracy of ±0.2% if $\alpha_0 > 1°$, and ±0.002° if $\alpha_0 < 1°$. The following checks with sucrose solutions of various concentrations from $C = 1.0313$ to $C = 25.974$, indicated that these specifications were correct. The readings were taken at 5 spectral regions, which probably have the effective wavelengths (13): 589.3, 577.9, 546.1, 535.7, and 365.4 nm. The dependence of $[\alpha]_{589.3}^{20}$ on concentration of sucrose can be calculated from the formula (7):

$$[\alpha]_{589.3}^{20} = 66.462 + 0.0087C - 0.000235C^2$$

The $[\alpha]_{589.3}^{20}$ values with the Perkin–Elmer polarimeter agreed within 0.05% with values calculated from this equation for solutions which had $\alpha_0 > 1°$, and within 0.001° where $\alpha_0 < 1°$. Over the range of concentrations studied, the change of specific rotation calculated from the above formula is not large (a maximum difference of 0.11%), which agrees with the finding that there was no significant dependence of specific rotation on concentration of sucrose (B coefficients were 0.000, Table II).

The rotation at other wavelengths can be calculated from the one-term Drude equation (14): $[\alpha]_\lambda^{20} = 21.676/(\lambda^2 - 0.0213)$. This formula is for sucrose in water, $C = 17.218$, and λ is the wavelength in microns. The $[\alpha]_\lambda^{20}$ values obtained with the Model 140 polarimeter at $C = 19.3352$ and the wavelengths mentioned above, were within 0.16% of the calculated values.

Formula for $[\alpha]_\lambda^T$

The formula and constants for specific rotation are shown in Table II. In general, constants were obtained by computer calculation from 18 different readings (6 solutions of different weight percent and 3 temperatures) at each wavelength.

The numbers in Table II labeled 'formula fit' show the minimum (−) and maximum (+) w.d.d. values in each set of 18 readings. If $\alpha_0 > 1°$, a figure of 0.002 represents a difference of 0.2% between α_c and α_0, and between calculated and observed specific rotations. If $\alpha_0 < 1°$, a figure of 0.002 represents a difference of 0.002° between α_c and α_0, and a difference of $0.2\%/\alpha_0$ or >0.2% between calculated and observed specific rotations. The accuracy of the polarimeter, as specified by the manufacturer, corresponds to ±0.002 w.d.d., and the above examples show that the best accuracy for specific rotation values is obtained if conditions are chosen so that $\alpha_0 > 1°$. A satisfactory fit to the equation is represented by ±0.002 w.d.d. The maximum absolute value under 'formula fit' in Table II was 0.0031, and the data in general fits the proposed formula and constants very well. In the following discussions the error limits of this formula will be considered to be ±0.003 w.d.d., plus a possible ±0.1% error in determining the concentration of the stock solution from which dilutions were made.

Studies with L-leucine and L-valine in aqueous HCl at one concentration and one temperature (15) showed that a two-term Drude equation (which contains 4 constants) was necessary to describe the variation of specific rotation with wavelength. My results with these compounds cannot usefully be expressed in terms of such an equation, because the range of wavelengths studied does not give sufficient data to evaluate the constants with any certainty.

Specific Rotation of Sucrose in Water

For temperatures near 20 °C, the temperature coefficient, D, of the specific rotation of sucrose in water at 589.3 nm. is known to be −0.00018 (13). This is quite close to the calculated value of D (−0.00015, Table II). The finding that the temperature coefficient 'D' changes with wavelength, if true, requires different constants in the one-term Drude equation at different temperatures. For example, the following equations describe my results quite well:

$$[\alpha]_\lambda^{20°} = 21.676/(\lambda^2 - 0.0213)$$

$$[\alpha]_\lambda^{25°} = 21.653/(\lambda^2 - 0.0214)$$

$$[\alpha]_\lambda^{30°} = 21.627/(\lambda^2 - 0.0215)$$

λ = wavelength in microns.

Specific Rotations of L-Leucine and L-Valine in Glacial Acetic Acid

The specific rotations of L-leucine and L-valine in glacial acetic acid were markedly decreased by the presence of water in the acetic acid. The specific rotation of L-leucine (C = 1.976) was 6.9–8.8% lower (depending on wavelength) in acetic acid containing 1% (w/w) water than in the pure solvent. This result disagrees with those of Greenstein and co-workers (4), who reported that up to 2% water could be present in the acetic acid without appreciably affecting the specific rotation of L-leucine. The specific rotation of L-valine (C = 1.064) was 4.7–5.5% lower in the solvent containing 1% water.

The specific rotation of these amino acids in glacial acetic acid was decreased also by heating. With L-leucine the decrease was about 2%/h at 70 °C and 0.01–0.02%/h at room temperature, and with L-valine was 0.4%/h at 70 °C, and 0.04–0.07%/day at room temperature. To establish the reason for such change, L-leucine was heated in glacial acetic acid for 5 days at 70 °C. After evaporation of the solvent and extraction of the residue with alcohol, a yield of 76% DL-leucine (alcohol-insoluble, identified by infrared spectroscopy) and 24% *N*-acetyl leucine (alcohol-soluble, identified by nuclear magnetic resonance (n.m.r.) spectroscopy) was obtained. The decrease in rotation on heating was therefore due in part to racemization of the amino acid.

For the results in Table II, the heating necessary to dissolve the amino acids was kept to a minimum (at most, 50 min at 50 °C plus 5 min at 60 °C), and the water content of the acetic acid was low (<0.1%). A check of the specific rotation of these amino acids in water-free acetic acid gave results which agreed within 0.54% (0.0028 w.d.d.) with those calculated from Table II, and therefore the results with this solvent can be reproducible. However, acetic acid should not be used where high accuracy is needed, because it may be difficult to obtain and maintain it free of water, and because differing amounts of heating may cause differing amounts of racemization and differing results even with the same sample.

Specific Rotations of L-Leucine and L-Valine in HCl

L-Leucine and L-valine in 5 *M* HCl showed no significant change in optical rotation when heated 1.5 h at 70 °C, or when left for 10 days at room temperature, provided that 5 *M* HCl was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

added to make up for slight evaporation losses. These amino acids are therefore stable in HCl under the conditions used here. The specific rotation results (Table II) agree qualitatively with those of Hayashi and co-workers (1) as outlined in the 'Introduction' section above, but in addition have been extended to other wavelengths and defined in terms of an equation with appropriate constants.

Literature values for specific rotation of these amino acids usually specify 5 or 6 *M* HCl. My results were obtained with HCl which was not exactly 5.00 or 6.00 *M*. One can calculate the specific rotation at exactly these molarities as follows. First find the actual molarities at the desired temperature from Table I (e.g. for 25 °C these were 4.98 and 6.05 *M*) and then calculate the specific rotations at these molarities from the formula and constants of Table II. Next interpolate mathematically to find the specific rotation at either 5.00 or 6.00 *M*, as desired. This linear interpolation is justified by the finding of Hayashi and co-workers (1) that the change of $[\alpha]_D^{20^\circ}$ of these amino acids was approximately linear from 3 to 8 *M* HCl. The interpolation is only over a small range — at most from 6.06–6.00 *M* — and the maximum correction necessary (found for L-leucine $[\alpha]_{589.3}^{20^\circ}$, $C = 8$ in 6.06 *M* HCl as compared to $C = 8$ in 6.00 *M* HCl) was calculated to be 0.24%.

Weight % Specific Rotations $[\alpha_w]$

The determination of concentration on a w/w % basis is undoubtedly more accurate for small amounts of amino acid solutions usually made up for optical rotation measurements than is determination on a w/v % basis. Therefore, it is useful to define a new specific rotation $[\alpha_w]$, eq. [11] on the basis of weight percent, *W*, and eliminate calculations involving density. Some of my data was recalculated with the appropriate equations for $[\alpha_w]$ (see Materials and Methods) to give the results in Table III. The formula fit values (Table III) are within ±0.003 w.d.d. and are satisfactory.

The optical rotations, α_0, of specially purified, methionine-free L-leucine were determined at two concentrations (approximately $W = 7.0$ and 3.5) for the two concentrations of HCl, three temperatures (20, 25, and 30 °C), and the five wavelengths. The results agreed with the α_c values calculated from the constants of Table III and eq. [11] within the range −0.0024 to +0.0028 w.d.d., showing that the optical rotations were not significantly changed by this purification and that the L-leucine used to obtain the data for Tables II and III was pure enough to give reliable results within the accuracy of the method. The rotations of L-valine were checked in a similar way with another commercial sample which contained no detectable amount (<0.1%) of any other amino acid, and satisfactory agreement (−0.0037 to +0.0008 w.d.d.) was obtained also.

Comparison of Specific Rotations with Published Values

Thomas and Nieman (16) reported that the $[\alpha]_D^{25^\circ}$ values for L-leucine in glacial acetic acid increased with a decrease in *C*, and that this increase was more rapid at low *C* values. To check this, the range of concentrations investigated (Table II) was extended by including a measurement at $C = 0.22$. My results showed that the increase of specific rotation with decrease in concentration (*B* constants are negative, Table II) was linear, and the linearity did not change at low *C* values. These authors also reported that the $[\alpha]_D^{25^\circ}$ value for L-leucine in 6.02 *M* HCl was independent of concentration from $C = 2$–5, but this is contradicted both by my results and those of Hayashi and co-workers (1).

Various published specific rotations at the D line of sodium (589.3 nm) for L-valine and L-leucine are compared in Table IV with those calculated from Table II with interpolations to 5.00 or 6.00 *M*, as described above. Greenstein and Winitz (17) stated the concentration for L-valine in acetic acid or in 5 *M* HCl as $C = 1$–2, so the choice of *C* for calculations in comparison with their results is therefore arbitrary. Hayashi and co-workers (1) published specific rotations at what they termed 'optimal conditions of measurement'. Their observed rotations, expressed as α_0/dcm, agree within 0.003° with my calculated values (Table IV), and this agreement is within my experimental error. Because Hayashi and co-workers were aware of the effects of concentration of solute, molarity of HCl, and temperature on the specific rotation of these amino acids, their results are probably much more accurate than those of other investigators, and the other results in Table IV confirm this.

TABLE IV

Comparison of published specific rotations for L-leucine and L-valine with those calculated from Table II

	Published values and conditions						Calculated values	
Solute	Solvent	T, °C	C	$[\alpha]_D$	α_0/dcm	Ref.	$[\alpha]_D$	α_0/dcm
L-Leucine	Acetic acid	25	2	22.5	0.450	17	23.26	0.465
L-Leucine	6 *M* HCl	20	4	15.1	0.604	1	15.17	0.607
L-Leucine	5 *M* HCl	25	2	15.6	0.312	18	15.10	0.302
L-Leucine	5 *M* HCl	25	2	16.0	0.320	17	15.10	0.302
L-Valine	Acetic acid	25	1?	62.0	0.620	17	48.23	0.482
L-Valine	6 *M* HCl	20	8	28.0	2.240	1	28.02	2.242
L-Valine	6 *M* HCl	20	3.4	26.7	0.908	18	27.44	0.933
L-Valine	5 *M* HCl	25	2?	28.3	0.576	17	26.61	0.532

If only a small amount of valine or leucine is available for measurements, so that the observed rotation is small at 589.3 nm, improved accuracy can be obtained by measurements at a lower wavelength where the observed rotation is larger. The data of Tables II or III is useful in evaluating what these rotations should be.

Acknowledgments

I thank Dr. A. J. Finlayson and Mr. D. M. Tenaschuk, Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan for amino acid analyses and technical assistance, respectively. I also thank Mr. B. Molaro, Computer Centre, University of Saskatchewan, for assistance in programming.

Aminodideoxy sugars. Methyl 3-acetamido-2,3-dideoxy-α-D-*arabino*-hexopyranoside and methyl 2-acetamido-2,3-dideoxy-α-D-*ribo*-hexopyranoside

ALEX ROSENTHAL AND P. CATSOULACOS
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received February 26, 1969

Oxidation of methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*arabino*-hexopyranoside (**2**) with methyl sulfoxide and acetic anhydride yielded methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*erythro*-hexopyranosid-2-ulose (**3**) in an 80% yield. Reduction of the oximino derivative of **3** with lithium aluminium hydride in tetrahydrofuran or with diborane afforded, after acetylation, methyl 2-acetamido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*ribo*-hexopyranoside (**6**) in a 44% yield. The latter was also debenzylidenated with aqueous acetic acid. In a parallel reaction, methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-oximino-α-D-*erythro*-hexopyranoside yielded mainly methyl 3-acetamido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*arabino*- (and a minor amount of the *ribo*-epimer)-hexopyranoside.

The preparation of methyl 2- and 3-amino-2,3-dideoxy-α-D-glycosides has posed a problem of considerable difficulty. Attempted reduction of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-oximino-α-D-*erythro*-hexopyranoside with either a palladium or a platinum catalyst, or by zinc and acetic acid, failed (1). On the other hand, methyl 2-deoxy-2-oximino-α-D-glycosides were reduced, to yield 2-amino-2-deoxy glycosides (2). Although methyl 2- and 3-aminodideoxy-α-D-glycosides have been prepared *via* the 2,3-epimine intermediates, this synthesis can not be considered to be attractive owing to the fact that the over-all yield is very low, and furthermore, great difficulty is encountered in separating the mixtures of isomers in the last step (3). For example, methyl 4,6-*O*-benzylidene-2,3-dideoxy-2,3-epimino-α-D allopyranoside afforded syrupy compounds which were assumed to be methyl 3-acetamido (and 2-acetamido)-2,3-dideoxy-α-D-*ribo*-hexopyranoside. 3-Azido derivatives have been successfully reduced with sodium borohydride to afford 3-amino carbohydrates (4). Finally, hydrazino compounds have been cleaved catalytically to yield amino carbohydrates in low over-all yield (5), dideoxyoximino glycosides have been reduced to yield aminodideoxy glycosides (4*c*),[1] and nitro carbohydrates have been used to prepare aminodideoxy carbohydrates (1).

In view of the importance of the amino sugars (6) it was decided to reinvestigate the reduction of the oximino compounds, because the latter can now be readily prepared from ketoses. The latter have now become readily accessible through use of the excellent oxidizing agent methyl sulfoxide in the presence of either acetic anhydride or phosphorus pentoxide.

Reduction of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-*manno*-hexopyranoside (**1**) with lithium aluminium hydride in tetrahydrofuran (7, 8)[2] gave an 88% yield of methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*arabino*-hexopyranoside (**2**). Subsequent oxidation of **2** with anhydrous methyl sulfoxide and acetic anhydride afforded methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*erythro*-hexopyranosid-2-ulose (**3**) in 80% yield. Treatment of **3** with hydroxylamine hydrochloride and sodium hydroxide at room temperature gave the oxime **4** in 60% yield. Reduction of **4** with lithium aluminium hydride in tetrahydrofuran or ether followed by acetylation of the amine with acetic anhydride, gave methyl 2-acetamido-2,3-dideoxy-α-D-*ribo*-hexopyranoside (**6**) contaminated with a trace of a compound which was presumed to be the *arabino* isomer. By fractional crystallization of the acetamido derivatives from ether – ethyl acetate, pure **6** was obtained in crystalline form in 44% yield having m.p. 263–264° and $[\alpha]_D = +52°$. Reduction of the 2-acetoximino derivative **5** with diborane in tetrahydrofuran also gave **6**, and in addition, a substance which was presumed to be an un-

[1]These authors reported (after our manuscript was in press) that the lithium aluminium hydride reduction of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-oximino-α-D-*erythro*-hexopyranoside yields only one substance which was presumed to be the *ribo* isomer.

[2]W. W. Zorbach used lithium aluminium hydride in tetrahydrofuran. Personal communication.

decomposed complex of the product. Debenzylidenation of **6** with aqueous acetic acid afforded crystalline methyl 2-acetamido-2,3-dideoxy-α-D-*ribo*-hexopyranoside. Buss *et al.* (3) had previously reported the isolation of a syrupy substance which was presumed to be **6** having $[\alpha]_D = +80°$.

The structure of debenzylidenated **6** was deduced from its nuclear magnetic resonance (n.m.r.) spectrum. The axial C-3 hydrogen signals centered at τ 8.56 which appear as a quartet have a total width of 34.5 Hz. This width is practically equal to the sum of the three coupling constants ($J_{3a,3e}$, $J_{3a,2a}$, and $J_{3a,4a}$) with which the axial C-3 hydrogen is coupled to the equatorial C-3 hydrogen and to the two neighboring hydrogens on C-2 and C-4. Thus, the sum of $J_{3a,4a}$ and $J_{3a,2a}$ may be calculated to be approximately 22 Hz. To account for this large value, as well as for the splitting pattern observed, the C-2 hydrogen is assigned an axial configuration as in **6**, and therefore, the acetamido group is equatorially oriented.

Similar consideration of the n.m.r. spectrum of the benzylidene derivative **6** also indicates the presence of an axial hydrogen on C-2. The singlet peak at τ 8.08 also indicates that the acetamido peak is in an equatorial orientation (9). The C-1 anomeric H of **6** appears as a doublet at τ 5.43 having $J_{1,2} = 3.5$ Hz. In general, 4,6-*O*-benzylidene compounds with the α-D-altro and α-D-*manno* configurations give spectra with first-order $J_{1,2} = 1.2$ Hz or less, so that the signal for H-1 frequently appears as a singlet. The fact that $J_{1,2}$ of **6** is much larger than 1.2 Hz indicates that H-2 is probably in an axial orientation. Irradiation experiments confirmed all assignments shown in the Experimental. Finally, indirect additional support for the assignment of structure **6** follows from the fact that methyl 2-acetamido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*arabino*-hexopyranoside has m.p. 171–173° (3), whereas compound **6** has m.p. 263–264°. Therefore, compound **6** is undoubtedly methyl 2-acetamido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*ribo*-hexopyranoside.

In an analogous way, methyl 4,6-*O*-benzylidene-α-D-*erythro*-hexopyranoside-3-ulose was oximinated, and the oxime then acetylated to afford the 3-acetoximino derivative. Lithium aluminium hydride reduction of the oximino or acetoximino derivative, followed by acetylation of the amines, gave a mixture of 3-acetamido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*arabino*-(and *ribo*)-hexopyranoside in 60% yield in the ratio of 3:1, respectively. Fractional crystallization of acetamido derivatives readily afforded crystalline methyl 3-acetamido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*arabino*-hexopyranoside. The 3-acetamido-α-D-*ribo* derivative was not characterized because of the difficulty of obtaining a pure substance. The n.m.r. and infrared (i.r.) spectra of the major component were similar to those of an authentic sample, kindly furnished by Dr. A.C. Richardson, of methyl 3-acetamido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*arabino*-hexopyranoside (4), although there is some discrepancy between the physical properties of our compound and those reported previously. It is interesting to note that the n.m.r. spectrum of the crude mixture of 3-acetamido epimers revealed that the equatorial acetamido group resonates at a higher field (about 0.1 p.p.m.) than the corresponding axially oriented counterpart, a finding in agreement with a previous report (9).

Experimental

The melting points were determined on a microstage and are uncorrected. Spectra were measured with a Varian Associates 100 MHz HA spectrometer with deuteriochloroform as a solvent (unless otherwise stated) and tetramethylsilane as the internal standard set at τ = 10. Thin-layer chromatography was performed on silica gel G plates using chloroform – methanol (97:3 v/v) as developer. The optical rotations were measured in a 1 decimeter tubes at the D line of sodium and room temperature (about 22–23°). The microanalyses were carried out by the University of British Columbia Microanalytical Laboratory.

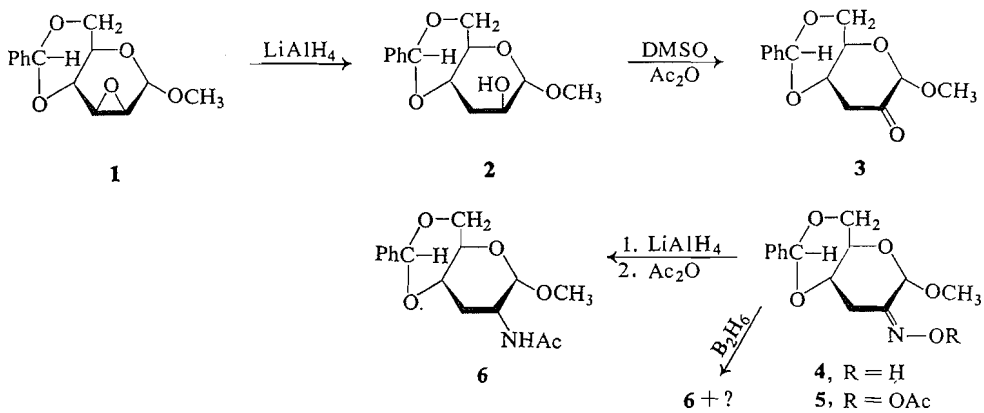
Methyl 4,6-O-Benzylidene-3-deoxy-α-D-arabino-hexopyranoside (2)

Lithium aluminium hydride reduction of **1** in tetrahydrofuran according to a previously described procedure (7) gave **2** in an 88% yield. Compound **2** was recrystallized from ether – petroleum ether (b.p. 35–60°), m.p. 110–112° (lit. (8), m.p. 111–112°).

Methyl 4,6-O-Benzylidene-3-deoxy-α-D-erythro-hexopyranosid-2-ulose (3)

To a solution of 5.74 g of compound **2** in freshly distilled (over calcium hydride) methyl sulfoxide (150 ml) was added anhydrous acetic anhydride (30 ml) and the resulting solution was kept at room temperature for 2 days. The product was worked-up as described previously (7), and recrystallized from ether – petroleum ether b.p. 35–60°), yield 4.6 g (80%), m.p. 114–115°; $[\alpha]_D^{22}$ +109° (*c* 2, in chloroform).

Anal. Calcd. for $C_{14}H_{16}O_5$: C, 63.63; H, 6.06. Found: C, 63.36; H, 6.20.



*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-oximino-α-*D*-erythro-hexopyranoside*

The ketose **3** (0.88 g) was added to an ethanol (75 ml) solution of hydroxylamine hydrochloride (0.240 g) and sodium hydroxide (0.135 g). After the mixture was maintained at room temperature for 24 h with stirring, water was added and the mixture left to stand for 3 h. The oxime was removed by filtration and recrystallized from ether – ethyl acetate to yield pure oxime (0.55 g, 60% yield), m.p. 138–139°; $[\alpha]_D^{22}$ +88° (*c* 1, in chloroform).

Anal. Calcd. for $C_{14}H_{17}NO_5$: C, 60.21; H, 6.09; N, 5.02. Found: C, 60.20; H, 6.32; N, 5.0.

*Reduction of Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-oximino-α-*D*-erythro-hexopyranoside to Yield Methyl 2-Acetamido-4,6-O-benzylidene-2,3-dideoxy-α-*D*-ribo-hexopyranoside (6)*

To a solution of methyl 4,6-*O*-benzylidene-2,3-dideoxy-2-oximino-α-D-*erythro*-hexopyranoside (0.44 g) in 50 ml of anhydrous tetrahydrofuran (or ether) was added lithium aluminium hydride (0.80 g) in portions during a period of 5 min. After the reaction mixture was kept under reflux for 4 h, excess lithium aluminium hydride was destroyed with ethyl acetate followed by water. The flocculent precipitate was separated by centrifugation or removed by filtration and washed several times with chloroform. The combined filtrates were washed twice with water (100 ml), dried over magnesium sulfate, and evaporated to yield 0.41 g of syrup. This syrup was acetylated with a mixture of 3 ml of acetic anhydride and 2 ml of pyridine for 10 h at room temperature. The reaction mixture was poured into a mixture of ice and water, and the product, removed by filtration, was recrystallized from ether – ethyl acetate, yield 0.205 g (44%), m.p. 264–264°; $[\alpha]_D^{22}$ +52° (*c* 1, chloroform). The product was homogeneous by chromatography R_f 0.56, τ ($CDCl_3$) 4.5 (s, CHPh), 5.43 (d, H-1, $J_{1,2}$ = 3.5 Hz), 5.5–6 (m), 6.1–6.5 (m), 6.6 (s, OCH_3), 7.83

(m, H3e), 8.08 (s, CH_3C—N), 8.16 (q, partly obscured by CH_3CO, total width 34 Hz, $J_{H3a,3e}$ = 11.5 Hz, $J_{H3a,2a}$ = 11 Hz). Irradiation at τ 8.2 collapsed the H-2 signal at τ 5.62. Irradiation at τ 7.8 also collapsed H-2 signal to a doublet. Irradiation at τ 5.70 affected the H-3a and H-3e signals.

Anal. Calcd. for $C_{16}H_{21}NO_5$: C, 62.54; H, 6.84; N, 4.56. Found: C, 62.33; H, 6.92; N, 4.61.

*Methyl 2-Acetamido-2,3-dideoxy-α-*D*-ribo-hexopyranoside*

Compound **6** was debenzylidenated with aqueous acetic acid on the steam bath and the product worked-up in the usual way. Recrystallization of the product from ethanol – ethyl acetate gave pure material, m.p. 204–206°; $[\alpha]_D^{22}$ +80° (*c* 1, in water).

τ (D_2O) 6.60 (s, OCH_3), 8.02 (s, acetyl), 7.8 (m, H-3e, partly obscured by the acetyl peak), 8.56 (q, H-3a, total width 34.5 Hz, $J_{3a,3e}$ = 11.5 Hz, $J_{3a,2a}$ = 11.5 Hz, $J_{3a,4a}$ = 11.5 Hz).

Anal. Calcd. for $C_9H_{17}NO_5 \cdot 1/2H_2O$: C, 47.45; H, 7.87; N, 6.14. Found: C, 47.52; H, 7.42; N, 6.05.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-oximino-α-*D*-erythro-hexopyranoside*

Methyl 4,6-*O*-benzylidene-α-D-*erythro*-hexopyranosid-3-ulose (1.32 g) (7) was converted into the oxime in 74% yield and recrystallized from methanol – ether, m.p. 208–209°, $[\alpha]_D^{22}$ +170° (*c* 1, in chloroform) (lit. (1), m.p. 203°, $[\alpha]_D$ +172°).

Anal. Calcd. for $C_{14}H_{17}NO_5$: C, 60.21; H, 6.14. Found: C, 60.41; H, 6.40.

*Methyl 3-Acetoximino-4,6-O-benzylidene-2,3-dideoxy-α-*D*-erythro-hexopyranoside*

The 3-oxime was acetylated in the usual way, and the product recrystallized from methanol – ethyl acetate, m.p. 201–202° (in agreement with the lit. value (1)).

*Reduction of Methyl 3-Acetoximino (and oximino)-4,6-O-benzylidene-2,3-dideoxy-α-*D*-erythro-hexopyranoside to Yield Methyl 3-Acetamido-4,6-O-benzylidene-2,3-dideoxy-α-*D*-arabino-(and ribo)-hexopyranoside*

(a) With Lithium Aluminium Hydride

The 3-acetoximino derivative (0.200 g) was reduced in a manner analogous to that already described in Experimental, and the syrupy amine was treated with acetic anhydride in ethanol to give the corresponding *N*-acetyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

derivative; yield 0.115 g (60%); τ (pyridine-d_5) (of crude acetamido compounds) 8.08 (s, equatorial $CH_3C(=O)-N$), 7.98 (s, axial $CH_3C(=O)-N$), in the ratio of 3:1, approximately. Fractional crystallization of the product from methanol – ethyl acetate afforded methyl 3-acetamido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*arabino*-hexopyranoside, m.p. 284–285°, $[\alpha]_D^{22}$ +64° (*c* 1, in ethanol), R_f 0.5; τ (pyridine-d_5) 4.40 (s, CHPh), 5.15 (NH), 5.23 (q, H-1, $J_{1,2a}$ = 3.5 Hz), 5.65–6.35 (m), 6.78 (s, OCH_3), 7.42 (m, H-2e, $J_{2e,2a}$ = 13 Hz), 8.1 (m, H-2a, partially obscured by CH_3CO), 8.08 (s, *N*-acetyl). Irradiation at τ 7.42 changed the H-1 signal to a doublet having $J_{1,2a}$ = 3.5 Hz. Irradiation at τ 5.23 altered the signals at τ 7.42.

The n.m.r. and i.r. spectra of the above 3-acetamido compound were identical to those of a sample of methyl 3-acetamido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*arabino*-hexopyranoside furnished by Dr. A.C. Richardson.

Anal. Calcd. for $C_{16}H_{21}NO_5$: C, 62.54; H, 6.84; N, 4.56. Found: C, 62.36; H, 7.04; N, 4.64.

Lithium aluminium hydride reduction of the oximino compound gave approximately the same yield (61%) of amine.

(b) With Diborane

Into an ice-cold solution of methyl 3-acetoximino-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*erythro*-hexopyranoside (0.50 g) in anhydrous tetrahydrofuran (25 ml) was bubbled diborane for 10 min. After the reaction mixture was left to stand at room temperature for 3 h, the solvent was removed under reduced pressure to yield a syrup which was then treated with 10% aqueous sodium hydroxide at 10–15°. The reaction mixture was then extracted twice with chloroform (150 ml), the chloroform extract washed twice with water (100 ml), and dried over magnesium sulfate. After the solvent was removed the product was acetylated with acetic anhydride and pyridine and the product worked-up in the usual way to yield 0.36 g of syrup. This syrup was crystallized from ethanol to give crystalline material (0.09 g), m.p. 150–152°, R_f 0.72 (chloroform). After evaporating off one-half of the solvent, 0.030 g of methyl 3-acetamido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-*arabino*-hexopyranoside, m.p. 284–285°, was obtained. The mother liquor contained about equal amounts of the two fractions. The first fraction was presumed (from its i.r. spectrum) to be an undecomposed borane complex.

Acknowledgments

This work was supported in part by Public Health Service Research Grant No. CA-08382 from the United States National Cancer Institute and by the National Research Council of Canada.

The author (A.R.) wishes to thank Dr. A.C. Richardson for a sample of methyl 3-acetamido-2,3-dideoxy-α-D-*arabino*-hexopyranoside. The technical assistance of Mrs. M. Ong is acknowledged.

Internal addition of acyl nitrenes to olefins[1]

IVOR BROWN,[2] O. E. EDWARDS, J. M. MCINTOSH,[2] AND D. VOCELLE[2]
Division of Biochemistry and Molecular Biology, National Research Council of Canada, Ottawa, Canada

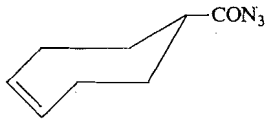
Received February 24, 1969

Photolysis of cycloheptene-5-carbonyl azide, *endo*-norbornene-5-carbonyl azide and *o*-vinylbenzoyl azide gave very reactive acyl aziridines by internal addition of acyl nitrenes to the olefinic double bonds. Derivatives of 6-azabicyclo-[3,2,2]nonane and 1,2-dihydroisoindol-1-one were prepared. *cis*-2-Vinylcyclopropyl isocyanate, prepared photochemically at −78°, underwent Cope rearrangement at room temperature to 2,3-dihydro-1*H*-azepin-2-one. The mass spectra of a series of lactams are interpreted.

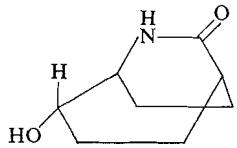
Canadian Journal of Chemistry, 47, 2751 (1969)

The generality of internal CH insertion of what appear to be excited singlet acyl nitrenes, to give lactams, is well documented. Some years ago we undertook to examine the irradiation of molecules containing both an acyl azide group and an olefinic double bond potentially close in space. Previous and subsequent work has shown that azidoformates (alkoxycarbonyl azides) when irradiated in solutions of olefins give the aziridines expected from nitrene addition to the double bond (1). Lwowski and co-workers (2) demonstrated that irradiation of pivaloyl azide in cyclohexene gave 45% of 7-pivaloyl-7-azabicyclo[4,1,0]heptane. Recently Masamune and co-workers (3) have reported intramolecular addition of an acyl nitrene to a carbon–carbon double bond.

Despite the fact that cycloheptene-5-carbonyl azide **1** undoubtedly exists mainly in the conformation illustrated, with the functions remote, its symmetry made it an attractive subject for study.

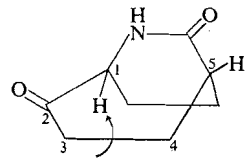


1



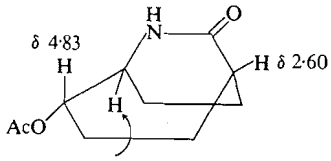
2

Irradiation of hexane solutions of the azide with a high pressure mercury lamp at 0° resulted in its conversion to isocyanate, an insoluble amide polymer (ν_{max} 1650 cm^{-1}) and a soluble substance with ν_{max} 1745 cm^{-1}. When the hexane solution was shaken with water the substance giving the band at 1745 cm^{-1} was destroyed and amides appeared in the water layer. From the latter a crystalline hydroxy lactam analysing correctly for **2** (4-hydroxy-7-oxo-6-azabicyclo[3,2,2]nonane) was isolated in around 12% yield. Its mass spectrum (see below) was consistent with structure **2**. The hydroxy lactam could be oxidized in poor yield to the keto lactam **3**, with ν_{max} 1713 and 1671 cm^{-1}. Again its mass spectrum could be readily reconciled with this structure (see below). The nuclear magnetic resonance (n.m.r.) spectra of the acetate (**4**) of the hydroxy lactam and the keto lactam were also consistent with these structures (see formulas).



δ 3.82($w_{\frac{1}{2}}$13 c.p.s.)

3

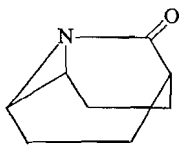


δ 3.50($w_{\frac{1}{2}}$13 c.p.s.)

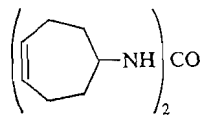
4

The half-band width of the signal at δ 3.50 in the spectrum of **4** was reduced to 7 c.p.s. when D_2O was added, confirming the assignment to H-1. It follows that the reactive photolysis product is the acylaziridine **5**. The amide resonance in this would be completely suppressed because of

[1]NRCC No. 10700. Presented in part at the Symposium on Reactive Intermediates in Organic Chemistry, Quebec City, Quebec, September, 1964.
[2]NRCC Postdoctorate Fellow.



5

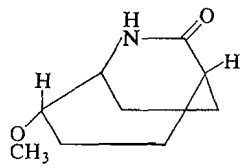


6

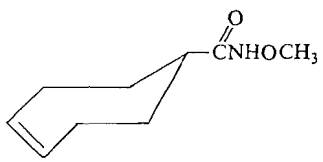
orthogonality of the carbonyl π orbitals and the unshared pair on nitrogen. This accounts for the high carbonyl frequency (1745 cm^{-1}). Because of its sensitivity to hydroxylic solvents, and the mixture in which it was formed, we were unable to isolate **5**. As far as we are aware, **2**, **3**, and **4** are the first derivatives of 6-azabicyclo[3,2,2]nonane to be described.

Photolysis of **1** in aqueous dioxane suppressed the polymer formation, but no increase in yields of **2** was noted. Crystals of the urea **6** separated if the solution was allowed to stand overnight.

When the photolysis of **1** was carried out in dry methanol at 0° isocyanate was again the major product (urethane formation was slow). As expected the methoxy lactam **7** (4-methoxy-7-oxo-6-azabicyclo[3,2,2]nonane) was formed, and in addition an isomer of the methyl urethane. The spectra of the latter suggested that it was



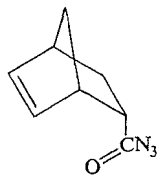
7



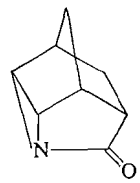
8

N-methoxycycloheptene-5-carboxamide (**8**). This was substantiated by its hydrogenolysis to cycloheptanecarboxamide and confirmed by comparison with a sample synthesized from cycloheptene-5-carbonyl chloride and methoxyamine.

Since considerable cyclization occurred in the case of **1** we expected that *endo*-norbornene-5-carbonyl azide **9**, with the function in close proximity, might give high yields of acyl aziridine. Actually only 20% of aziridine **10** was formed, estimated by the amount of hydroxy lactam produced on its hydrolysis. It again had its CO stretching vibration at very high frequency (ν_{max} 1776 cm^{-1}), accountable for as in the case of

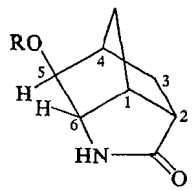


9

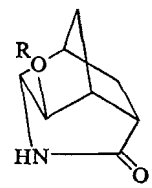


10

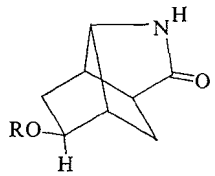
5. The structure of the hydroxy lactam could *a priori* have been **11** (5-*exo*-hydroxy-6-*endo*-amino-2-*endo*-norbornane carboxylic acid lactam), **12** or **13** (R = H).



11



12



13

We discount the possible structure **12** on the basis of the strain involved. The acetate of the hydroxy lactam was prepared. The signal at lowest field, attributable to the hydrogen on the carbon carrying the acetoxy group at δ 4.33 was fairly sharp ($w_{\frac{1}{2}}$ 3 c.p.s.) whereas the signal for the hydrogen on the carbon carrying the nitrogen was a broad doublet at δ 3.43 and 3.51. These values are only consistent with **11** (R = Ac) in which the coupling of the 5-hydrogen to both the 4- and 6-hydrogens should be very small, while the 6-hydrogen should couple with the 1-hydrogen with $J \simeq 4$.

A minor product of the photolysis reaction had a weak band at 3350 cm^{-1} and strong ones at 1705 and 1600 cm^{-1}. A broad signal centered at

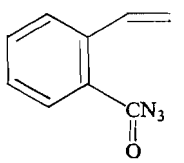
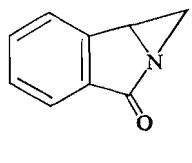
14

δ 6 indicated the presence of olefinic hydrogens. If the photolysis solution was heated prior to hydrolysis the amount of this product increased. It was not further characterized because of the small quantity available, but can tentatively be assigned structure **14.**

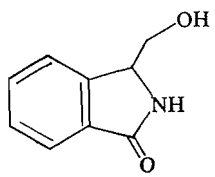
To extend the scope of the reaction we next examined the photolysis of *o*-vinylbenzoyl azide **15.** Due to the competitive absorption of light by the aromatic system, the decomposition of the azide was slow relative to the aliphatic examples. Considerable polymer separated as the photolysis proceeded. As the acyl azide bands at 1702 and 2140 cm^{-1} disappeared they were replaced by the isocyanate band at 2280 cm^{-1} and a carbonyl band at 1750 cm^{-1}. The latter seems consistent only with the presence of the aziridine **16.** Part of the material responsible for this absorption was rapidly destroyed when the reaction mixture was shaken with water. From the aqueous phase a



15

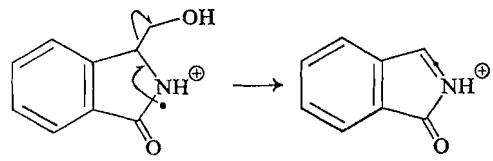


16



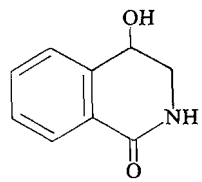
17

10% yield (calculated as hydroxy lactam) of product was obtained. This consisted of two major and three very minor components. The main product (4.5%) had a molecular weight (mass spectrum) of 163 and was a γ-lactam (ν_{max} (Nujol) 1710 cm^{-1}). Its base peak in the mass spectrum was at *m/e* 132 ($M—CH_2OH$) with *m/e* 133 almost as intense ($M—CH_2O$). On this basis we assign with confidence the structure **17** (3-hydroxymethyl-1,2-dihydroisoindolone) to this hydroxy lactam. The fragmentation on electron impact is undoubtedly as illustrated

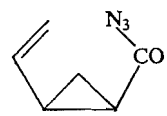


m/e 132

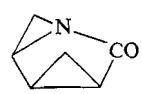
The next most abundant product from the aqueous layer was present in about 1% yield. It was not obtained completely pure. It had ν_{max} 1660 cm^{-1} (δ-lactam) and a molecular weight by mass spectrum of 163. A strong peak at *m/e* 145 (M-18) indicated facile loss of water. On this evidence we consider it probable that it has structure **18** (4-hydroxy-1,2,3,4-tetrahydroisoquinol-1-one) arising from the alternate mode of hydration of the aziridine ring of **16.**



18



19



20

Finally, *cis* 2-vinylcyclopropylcarbonyl azide **19** was irradiated in the hope of generating **20** or its rearrangement products. A weak band at

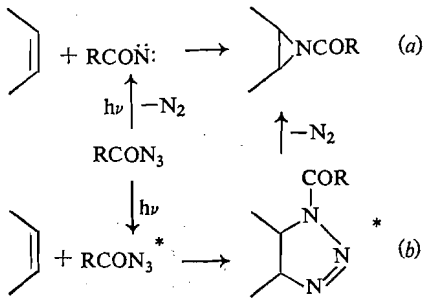
21

1764 cm^{-1} appeared in the infrared (i.r.) spectrum as photolysis proceeded. The compound corresponding to it was destroyed by water, but we were unable to isolate a hydroxy lactam from the mixture of water soluble products. As usual the major product when the photolysis was conducted at −78° was the isocyanate. This gave us a unique opportunity to test the postulate of Vogel *et al.* (4) that the isocyanate underwent Cope rearrangement to 2,3-dihydro-1*H*-azepinone (**21**). When the mixture containing the isocyanate warmed to room temperature, the characteristic i.r. absorption at 2270 cm^{-1} steadily diminished in strength, and a band at 1686 cm^{-1} grew in intensity. The transition was complete in several hours at room temperature, or in 15 min in the i.r. spectrometer beam. The dihydroazepinone was isolated, and proved identical with the product of thermal rearrangement of **19** (4).

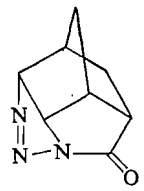
Photosensitized decomposition of azide **9** using energy transfer from triplet acetophenone led to an intractable mixture of products. As in a previous study (5), the free radical nature of the process was demonstrated by the presence of cyclohexene and bicyclohexyl derived from the solvent cyclohexane.

Discussion

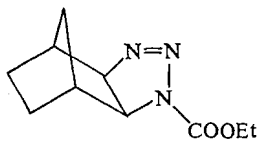
One of the unanswered questions in the mechanism of the photolytic reaction of acyl azides is whether the reaction with olefins is a nitrene addition (*a*) or involves an intermediate triazoline (*b*)



In the cycloheptanecarbonyl azide case a 12% yield of cyclization product was obtained despite the minor fraction of the molecules likely to be in the required conformation for this internal reaction. This suggests that a triazoline is formed, since the nitrene would seem likely to attack solvent or other molecules or rearrange before conformational inversion. However, the yield of cyclized product in the case of **9** was still quite low (20%). Since the triazoline **22** seems strainless while the aziridine is strained, this result leads



22



23

to the opposite conclusion, that the low yield is due to direct aziridine formation from the nitrene.

Difference between the product composition on photolysis of triazoline **23** and that of a mixture of norbornylene and ethyl azidoformate (6) also supports the contention that an acyl nitrene is involved in the acyl azide additions to olefins (see also 2).

The ease of solvolytic opening of the acyl aziridines described above is striking. This reactivity can be understood if the transition state for the solvolyses resembles product. In these aziridines the amide resonance is absent as discussed above, while in the product it is completely restored. Since around 20 kcal/mole would be gained on reestablishing the amide resonance, this would markedly accelerate the ring opening.

Mass Spectra

The fragmentation of the various products described above lent some support to the assigned structures. However, some of the ions had complex and obscure origins. Tentative assignments based mainly on single mass unit resolu-

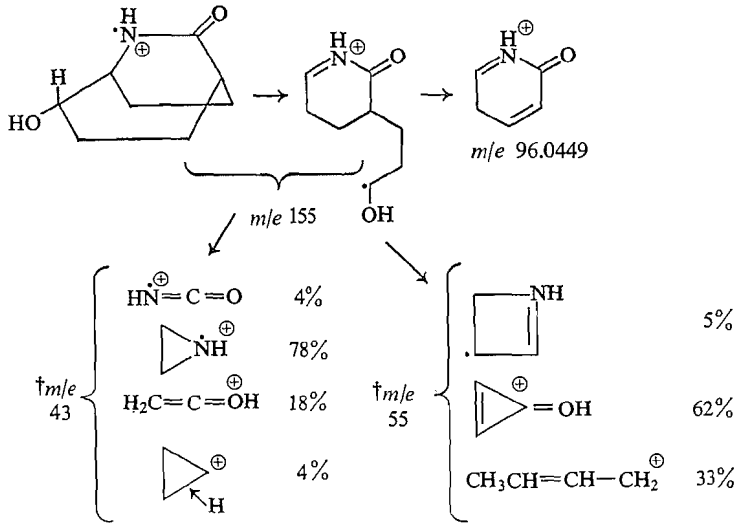
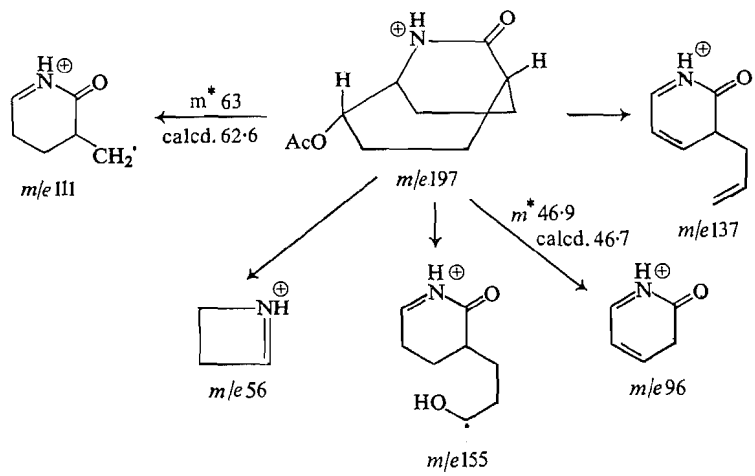
For personal use only.

tion are offered for the most abundant fragments. In the case of ions marked with a dagger (†), however, accurate *m/e* ratios[3] makes the composition certain. The hydroxy lactam **2** gave the following ions



The fragmentation of the acetate of **2** had some interesting features. The base peak was now at *m/e* 96 instead of *m/e* 43, hence the formation of $CH_3C{\equiv}O^{\dagger}$ was not important. The important fragment with *m/e* 56 replaces one at *m/e* 55 in the spectrum of the hydroxy lactam. This suggests transfer of one hydrogen of the acetoxy group to the nucleus with loss of ketene (see also the spectrum of **11** discussed below).

Suggested structures for some of the important ions follow



In the methoxy analogue **7**, because of the greater ease of formation of $CH_3\cdot$ over H·, the ion M-15 (*m/e* 154) became an intense peak.

[3]Kindly provided by Dr. W. D. Jamieson, Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia. The cited values are based on *C* = 12.0000.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

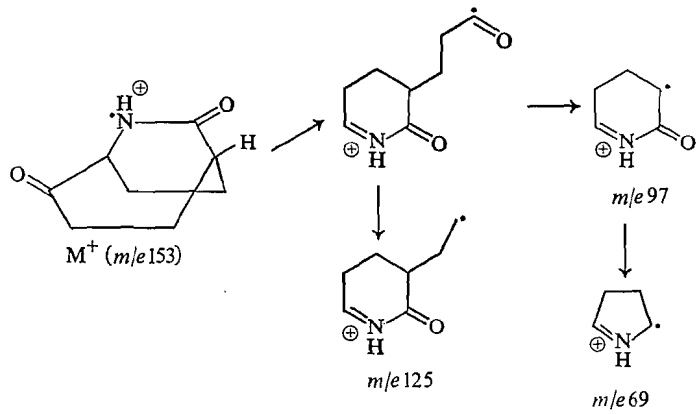
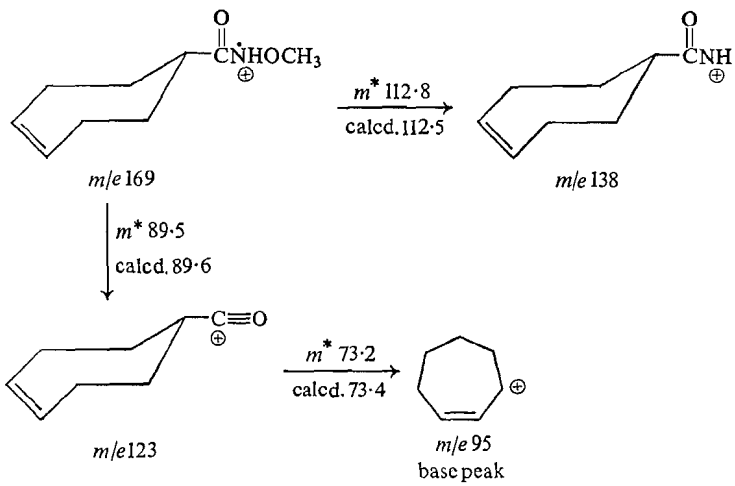
The *m/e* 96 peak was the base peak although *m/e* 43 was still strong.

The ketolactam **3** gave some interesting variations although *m/e* 96, 55, and 43 were still intense. The postulated ions are



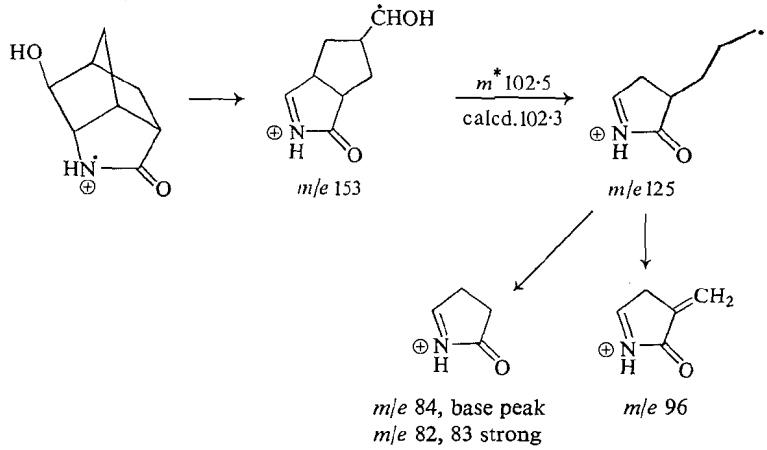
The fragmentation of the *N*-methoxyamide **8** left little doubt about its identity. In this case the metastable peaks were clear and proved very informative.



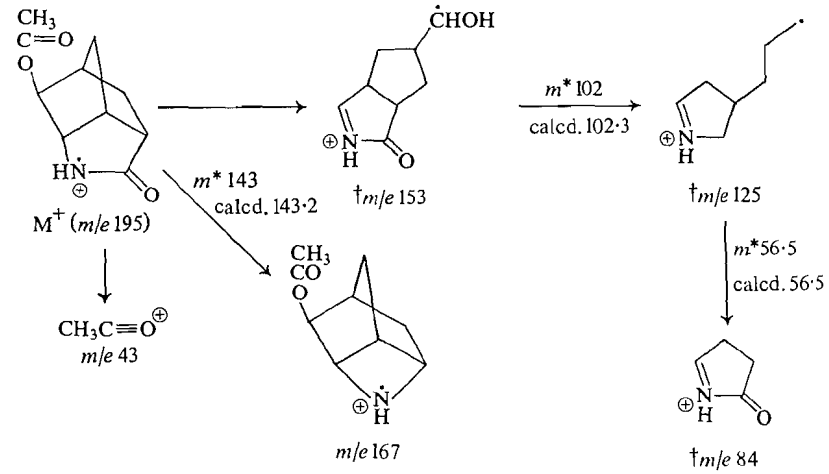
The ions from the hydroxy and acetoxy lactams **11** (R = H or Ac) could be accounted for, but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

not without invoking intramolecular hydrogen transfer (see the analysis of the spectrum of the acetate)



In the case of the acetate (**11**, R = Ac) the ion with *m/e* 84 was again the base peak, and ions at *m/e* 153 and 125 were prominent. The identity of these three ions was established by high resolution mass spectrometry to be $C_4H_6NO^+$, $C_8H_{11}NO_2{}^+$, and $C_7H_{11}NO^+$ respectively. Metastable peaks were found for three transitions, and are consistent with the following fragmentation



The transitions from *m/e* 153 to *m/e* 125 and from the latter to *m/e* 84 are surprising. The fragmentation of the corresponding trideuterioacetate was examined in an attempt to clarify these. The detail of the transitions is obscure, but the three ions in question probably have the structures illustrated

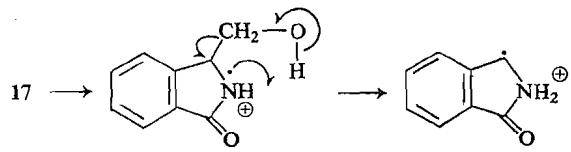
An additional fragmentation mode for hydroxy lactam **17** led to *m/e* 133. We formulate this as shown



m/e 133

Experimental

Infrared spectra were determined in solution on a Model 257 Perkin–Elmer grating spectrometer or as Nujol mulls using a Model 21 prism spectrometer, and n.m.r. spectra on a Varian A-60A spectrometer. Photolyses were performed, unless otherwise specified, using a 100 W Hanovia high-pressure immersion lamp in a water-jacketed Vycor well surrounded by a thin annular layer of photolyzing solution in a Pyrex container. Analytical thin-layer chromatography (t.l.c.) was done using silica gel G on microscope slides. Mass spectra were obtained using a Hitachi single focusing spectrometer using a direct inlet and a 75 V electron beam. The relative abundance of ions is given in brackets after the *m/e* ratio.

Photolysis of ***1*** *in Aqueous Dioxane*

Oxalyl chloride (3 ml) was added dropwise to a stirred suspension of 2.5 g of powdered, dried (80°, 0.5 mm) sodium salt of cycloheptene-5-carboxylic acid in 20 ml of pentane under a reflux condenser. After 1.5 h of stirring at room temperature, the solid was removed by filtration. The mixture was finally distilled at 80°, 10 mm in a Späth bulb assembly, giving 2.3 g of acid chloride. This had ν_{max} (hexane) 1795 cm^{-1}. The acid chloride was added to an ice-cold solution of 6 g of sodium azide in 20 ml of water. After 1.5 h of stirring at 0° the conversion to azide was complete. Sodium carbonate was added, then the acyl azide was extracted into pentane. The dried pentane solution was evaporated in a rotating evaporator below room temperature at water pump pressure. The oil was allowed to come to room temperature *in vacuo*. The residual colorless oil weighed 2.3 g and had ν_{max} (pentane) 2130, 1715, and 1650 (weak) cm^{-1}. A peak at 2250 cm^{-1} indicated the formation of 5–10% of isocyanate. The azide was dissolved in 40 ml of cold 80% dioxane–20% water and photolyzed at 0°. Gas evolution was complete in 4 h. To the clear solution, 20 ml of water was added. The mixture was then extracted twice with 15 ml portions of pentane and the pentane back-washed with water.

The aqueous dioxane solution was concentrated on a rotating evaporator at 80°, 15 mm pressure, leaving 619 mg of oil. This was dissolved in 5 ml of methylene chloride and seeded with hydroxy lactam. It slowly deposited 233 mg of fairly pure crystals of hydroxy lactam **2**. The methylene chloride soluble products were partially separated by chromatography on a 20-fold ratio of alumina, activity I. However, at least eight readily eluted components were indicated by t.l.c. The methanol in chloroform eluates crystallized in part from methylene chloride giving 32 mg of fairly pure hydroxy lactam. The total yield of hydroxy lactam **2** containing small amounts of components with higher R_f was 265 mg (12% based on azide).

Similar photolysis in 50% aqueous dioxane gave a 9% yield of hydroxy lactam **2**. When the photolysis mixture was allowed to stand overnight crystals of *N,N'*bis(cyclohepten-5-yl)urea **6** were deposited.

Photolysis of ***1*** *in Pentane and Methylene Chloride*

The acid chloride (1.26 g) was prepared from 1.5 g of sodium 4-cycloheptenecarboxylate, and this converted to the azide as described above. The azide was taken up in 350 ml of dry pentane, and photolyzed in an ice-salt bath. After 3.5 h the azide had all reacted. The solution had strong i.r. absorption at 2250 cm^{-1} (isocyanate), 1745 cm^{-1} (acyl aziridine), and broad weak absorption below 1600 cm^{-1} (other lactams). An insoluble solid had separated which had ν_{max} ($CHCl_3$) 1650 cm^{-1}. The filtered solution was extracted three times with distilled water (total 40 ml). The aqueous layer was taken to dryness under reduced pressure, giving 288 mg of residue. This crystallized from chloroform giving 167 mg of quite pure hydroxy lactam **2**, m.p. 220° (13.5% overall yield).

An equivalent experiment was performed using methylene chloride as solvent for the photolysis. At completion the solution had broad i.r. absorption centered at 1695 cm^{-1} with a shoulder near 1720 cm^{-1}, as well as an intense isocyanate band at 2265 cm^{-1}. The aqueous extract of the photolyzed solution gave a 10% yield of crude hydroxy lactam based on the volume of nitrogen evolved.

Hydroxy Lactam ***2*** *and its Acetate (4)*

Hydroxy lactam **2** was purified by chromatography on a 20-fold ratio of neutral alumina, activity III using chloroform and methanol in chloroform as eluting solvents. Fractions with m.p. 205–220° (Pyrex capillary) were recrystallized from benzene — chloroform, giving m.p. 230°. It had ν_{max} 3330, 3190, and 1660 cm^{-1}.

Anal. Calcd. for $C_8H_{13}NO_2$: C, 61.91; H, 8.44; N, 9.03. Found (after sublimation at 150 °C, 5×10^{-4} mm): C, 62.11; H, 8.95; N, 9.11.

Its mass spectrum had strong peaks at *m/e* 28(33), 39(55), 41(63), 43(100), 44(71), 55(57), 56(43), 96(89), 98(69), 99(63), and 155(45).

A solution of 109 mg of the hydroxy lactam in 2 ml of pyridine and 2 ml of acetic anhydride was left for 20 h at room temperature. The reagents were removed under reduced pressure. The residue was dissolved in methylene chloride and the solution washed with dilute sulfuric acid followed by dilute sodium carbonate. The dried solution yielded 140 mg of crystalline solid. After two recrystallizations from acetone – hexane, it melted at

120–121° and had ν_{max} ($CHCl_3$) 3420, 1728, and 1675 cm^{-1}.

Anal. Calcd. for $C_{10}H_{15}NO_3$: C, 60.89; H 7.67; N, 7.10. Found: C, 60.91; H, 7.50; N, 7.26.

Its n.m.r. spectrum had signals at δ 7.1(NH), 4.83(1H), 3.50(1H), 2.60(1H), 2.05(CH_3CO) and its mass spectrum had strong peaks at *m/e* 28(76), 55(16), 56(30), 83(20), 96(100), 97(12), 98(19), 99(27), 111(9), 136(8), 137(6), 154(9), 155(25), and 197(2.6).

Keto Lactam 3

Jones' reagent (7) (0.14 ml) was added to a solution of 86 mg (0.55 mmole) of hydroxy lactam **2** in 5 ml of pure acetone at 0°. The small excess of reagent was destroyed using methanol, the mixture filtered, and the filtrate taken to near dryness. The residue was taken up in methylene chloride plus dilute sodium carbonate solution. The aqueous layer was washed twice with methylene chloride. The organic layers were dried and distilled, leaving 22 mg of crystalline residue. After recrystallization and sublimation at 110°, 5×10^{-4} mm, it melted at 128–130° and had ν_{max} (Nujol) 3220, 3100, 1713, and 1672 cm^{-1}. Its n.m.r. spectrum had peaks at δ 7.2(NH) and 3.81(1H)($w_{1/2}$ 13 c.p.s.).

Its mass spectrum had strong peaks at *m/e* 28(100), 32(10), 39(9), 41(12), 42(7), 43(13), 54(5), 55(10), 56(7), 67(6), 68(12.5), 69(24), 82(7), 96(30.5), 97(23), 125(5), and 153(8).

Anal. Calcd. for $C_8H_{12}NO_2$: C, 67.72; H, 7.24. Found: C, 62.88; H, 7,06,

Photolysis of 1 in Methanol

Azide **1** (425 mg) was dissolved in 100 ml of methanol and irradiated for 3 h at 0°. The methanol was distilled under water-pump vacuum, leaving 337 mg of residue. This was adsorbed from hexane onto 6 g of neutral alumina, activity IV. The eluant was examined using t.l.c. on silica gel with ether as developing solvent.

The early eluates (hexane) gave spots on t.l.c. corresponding to cycloheptenyl isocyanate and the methyl urethane of 5-aminocycloheptene. The middle eluates (ether in hexane, ethyl acetate) (148 mg) contained two main components and two minor ones. After distillation at 125°, 0.1 mm, to remove polymer, and separation on a preparative thin layer plate using iodine vapor to locate the bands, the main components and one minor one were obtained pure.

N,N'-bis(cycloheptenyl)urea

The yield was 2% and its R_f was 0.75. After recrystallization from methanol it melted at 228–229° and had ν_{max} (Nujol) 3340, 3025, 1623, and 1573 cm^{-1}.

Anal. Calcd. for $C_{15}H_{24}N_2O$: C, 72.54; H, 9.74; N, 11.28. Found: C, 72.22; H, 10.02; N, 11.43,

Lactam 7

The yield was 7.5% based on the sodium salt used. After recrystallization from ether it changed crystal form to flat needles around 120° and melted at 139–140°. It was sublimed for analysis.

Anal. Calcd. for $C_9H_{15}NO_2$: C, 63.88; H, 8.93. Found: C, 64.41; H, 9.52.

It had ν_{max} ($CHCl_3$) 3430 and 1670 cm^{-1}, and n.m.r. signals at δ 8.05 (NH), 3.32 (OCH_3), ca. 3.4 (broad, N—CH<) 2.52 (broad, CO—CH<). Its mass spectrum had intense peaks at *m/e* 28(9), 39(8), 41(14), 43(13), 44(7.5), 55(12.5), 56(10), 58(15), 82(7.5), 83(6), 96(100), 97(7), 98(31), 136(3), 154(17.5), and 169(M^+) (17).

N-Methoxycycloheptene-5-carboxamide 8

The yield was 5% overall. After crystallization from acetone – hexane it formed needles with m.p. 90–92°. Its n.m.r. spectrum had peaks at δ 8.7(NH), 5.8 (two vinyl H's), 3.74 (OCH_3). A sample was sublimed for analysis.

Anal. Calcd. for $C_9H_{15}NO_2$ (molecular weight 169): C, 63.88; H, 8.93, N, 8.28. Found (molecular weight, (mass spectrum) 169): C, 64.52; H, 9.36; N, 8.58.

An ethanol solution of **8** in the presence of Adam's platinum catalyst rapidly absorbed one mole of hydrogen. The product was hydrogenolyzed slowly in acetic acid over Adam's catalyst. The product was recrystallized from benzene – hexane then sublimed, giving needles with m.p. 195–197°. This proved identical (mixed m.p. and X-ray powder pattern) with an authentic sample of cycloheptanecarboxamide (8). An authentic specimen of *N*-methoxy-cyclohexene-5-carboxamide was prepared from cycloheptene-5-carbonyl chloride and ether solution of methoxyamine. After recrystallization from acetone – hexane it formed needles with m.p. 92–93°. It had ν_{max} ($CHCl_3$) 3400, 3230, 2850, 1680, 1440, 1080, 1040, 935, and 912 cm^{-1}. The i.r. spectrum of the photolysis product was nearly identical to this, and they showed no mixed m.p. depression.

Methyl Urethane of 5-Aminocycloheptene

A methanol solution of cyclohepten-5-yl isocyanate was refluxed for 16 h. The product was recrystallized twice from hexane, filtering from less soluble products. After sublimation at 75°, 1×10^{-3} mm, and further recrystallization from hexane it separated as needles with m.p. 86–87°. It had ν_{max} ($CHCl_3$) 3440, 1712, and 1512 cm^{-1}.

Anal. Calcd. for $C_9H_{15}NO_2$: C, 63.88; H, 8.94; N, 8.28. Found: C, 63.85; H, 9.13; N, 8.46.

Endo-norbornene-5-carbonyl Azide 9

The *endo* acid was prepared following Diels and Alder (9) and purified via the iodolactone (10). Its sodium salt suspended in hexane was converted to the acid chloride using oxalyl chloride, then distilled at 78–80°, 17 mm.

A cold solution of 1.76 g (0.011 mole) of acid chloride in 5 ml of acetone was added to 10 ml of a cold saturated solution of sodium azide in water. More acetone was added until the cloudiness nearly disappeared. The solution was stirred at 0° for 2 h. It was then extracted with three 15 ml portions of cyclohexane and the combined extracts were washed with two 15 ml portions of saturated sodium bicarbonate solution, two 15 ml portions of water, and two 15 ml portions of saturated sodium chloride solution. The cyclohexane solution was then dried for 1 h over magnesium sulphate (large excess) at 0° in the dark. The yield of azide increased if the temperature of all solutions was kept as low as possible.

A 500 μl aliquot of the cyclohexane solution was removed and mixed with 30 μl of chloroform in a n.m.r. tube. Integration of the signals due to the olefinic protons in the azide and the signal due to the proton in the chloroform gave the amount of azide present in the solution. In most cases, this gave approximately 1.25–1.4 g/40 ml of solution. Infrared spectroscopy showed that a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

slight amount of isocyanate had been formed before the photolysis could be started.

Photolysis of endo-Norbornene-5-carbonyl Azide **9**

The photolysis was carried out in a Rayonet apparatus,[4] using a double-walled quartz vessel which contained the solution in the inner chamber and had circulating ice-water in the outer one to minimize thermal reaction of the azide. Lamps with peak radiation at 2537 Å were used.

The photolysis was carried out until the complete disappearance of the i.r. absorption at 2110 cm^{-1} occurred. This required from 3–4 h. As the reaction proceeded, a band at 2250 cm^{-1} developed rapidly. The band at 2110 cm^{-1} decreased more slowly as did the carbonyl absorption at 1700 cm^{-1}. At the same time, a triple peak at 1793, 1776, and 1765 cm^{-1} appeared. Of these, the central band was by far the most intense. This triplet increased steadily and reached a maximum at the disappearance of the azide absorption.

In some cases, a large amount of an amorphous yellow precipitate formed which slowed the photolysis drastically. It was necessary to stop the photolysis and filter the reaction mixture before continuing. Efficient drying of the starting solution eliminated this problem to a major extent.

After completion of the photolysis, the solution was stirred with 5 ml of water for 5 min, the layers were separated, and the procedure was repeated. The combined aqueous extracts were washed with cyclohexane and then poured into 100 ml of methylene chloride. Enough sodium sulfate was added to absorb all the water. This was allowed to stand for 12 h and then, after breaking up the lumps of drying agent, was filtered. The residue was washed well with methylene chloride by decantation (see 'Water-soluble Products').

The combined cyclohexane layers were dried over sodium sulphate. The i.r. spectrum revealed the complete absence of any absorption at 1776 cm^{-1}. Thin-layer chromatography showed one major component and three minor, slower-moving spots. The solution was diluted with 15 ml of anhydrous methanol and heated under vigorous reflux for 24 h. At the end of this period, the fast major spot had disappeared and another slower-moving spot had appeared. None of the three minor components was affected by this treatment.

Evaporation of the cyclohexane – methanol mixture gave a white solid which, after recrystallization from hexane or methanol – water, gave a white solid, m.p. 68–70°, which was identical to methyl 5-*endo*-norborn-2-enyl carbamate (11). The yield of this component based on starting azide was calculated to be 71%. The total amount of the three minor components was estimated to be not more than 2% of the total reaction mixture. By t.l.c. comparison with authentic materials (see below) it was shown that these components were not the amide or *N*-cyclohexylamide of *endo*-norbornylene-5-carboxylic acid.

Water-soluble Products

The methylene chloride solution of the water-soluble products was concentrated to small volume. Hydroxy lactam **11** (R = H) crystallized and proved to be sparingly soluble in methylene chloride or chloroform. The mother liquors contained a complex mixture. More hydroxy lactam was recovered by preparative t.l.c. (R_f 0.3 using 10% methanol in chloroform) but no other component was obtained pure.

Hydroxylactam **11** *(R = H) and its Acetate*

This was sparingly soluble in aprotic solvents. The yield was ca. 20% based on azide. After three recrystallizations from acetone and sublimation at 125°, 5×10^{-4} mm it had m.p. 181–182° and ν_{max} (Nujol) 3215 and 1680 cm^{-1}; n.m.r. signals (in D_2O) at δ 3.80 (1H singlet), 3.74–3.55 (1H, doublet?), 3.51–3.28 (1H multiplet), and 2.75–1.40 (6H multiplet). Its mass spectrum had intense peaks at *m/e* 153(12), 125(32), 96(36), 84(100), 83(41), 82(15), 69(20), 67(15), 41(31), 39(35), and 28(37).

Anal. Calcd. for $C_8H_{11}NO_2$: C, 62.72; H, 7.24. Found: C, 62.58; H, 7.31.

The acetate **11** (R = $COCH_3$) was prepared from the hydroxy lactam using acetic anhydride – pyridine at room temperature. It crystallized from acetone – hexane as hexagonal plates, m.p. 156°. It had ν_{max} 3435, 1720, 1700, and 1240 cm^{-1}. Its n.m.r. spectrum had signals at δ 6.4 (1H, broad), 4.33 (1H, doublet $J = 1$ c.p.s.), 3.54–3.39 (1H, broad doublet), 3.22–2.91 (1H, multiplet), 2.66–1.34 (6H multiplet), and 2.06 (3H, singlet). It was sublimed at 115°, 5×10^{-4} mm, for analysis.

Anal. Calcd. for $C_{10}H_{13}NO_3$: C, 61.52; H, 6.71. Found: C, 61.63; H, 6.79.

Its mass spectrum had strong peaks at *m/e* 28(74), 43(96), 81(92), 83(41), 84(100), 96(4), 124(34), 125(70), 152(5), 153(52), 167(14), and 195(M^+, 28).

Trideuterioacetate **11** *(R = $COCD_3$)*

This was prepared using trideuterioacetic anhydride in pyridine at room temperature. It crystallized from acetone – hexane as hexagonal plates m.p. 155–156°. Its n.m.r. spectrum was identical to that of the acetate except for complete absence of the signal at δ 2.06. Its mass spectrum had the following major peaks displaced from that of the acetate: *m/e* 46, 85, 97, 126, 154, 170, and 198.

Methyl 5-endo-Norborn-2-enyl Carbamate

5-*endo*-Norbornenyl isocyanate prepared by thermal rearrangement of the azide was refluxed in methanol for 24 h. The carbamate was recrystallized from hexane. It had m.p. 68–70° [lit. m.p. 70° (11)]. It had n.m.r. signals at δ 6.50–5.90 (2H, octet), 4.32 (1H, broad) 3.67 (3H, singlet) 3.18–2.72 (2H, broad doublet), 2.47–1.95 (1H, multiplet), 1.35 (2H, multiplet), and 0.9–0.45 (1H, very broad doublet). It had ν_{max} 3440, 1705, and 1510 cm^{-1}.

N-Cyclohexyl-5-endo-norbornenylcarboxamide

A hexane solution of 5-*endo*-norbornenylcarbonyl chloride was added to an ice-cold solution of excess cyclohexyl amine in benzene. The neutral product was recrystallized twice from aqueous ethanol. It had m.p. 170–172° and ν_{max} 3440, 1660, and 1500 cm^{-1}.

Anal. Calcd. for $C_{14}H_{21}NO$: C, 76.66; H, 9.65; N, 6.39. Found: C, 76.42; H, 9.23; N, 6.25.

2-Vinylbenzoyl Azide

2-Vinylbenzoic Acid

This was prepared by carbonation of 2-vinylphenylmagnesium bromide (see ref. 12). It had m.p. 93–96°,

[4]Product of the Southern New England Ultraviolet Company, Middletown, Connecticut.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ν_{max} ($CHCl_3$) 1690 cm^{-1} and λ_{max} 214(21 000), 246(12 100), and 292(1430) mμ.

Preparation of 2-Vinylbenzoyl Azide

To a slurry of the sodium salt of 2-vinylbenzoic acid (11) (1.0 g, 5.9 mmoles) in 25 ml of dry *n*-hexane was added 2.0 ml of oxalyl chloride. This was stirred at room temperature for 5 h. After filtering, the solution was evaporated to dryness under reduced pressure to give *o*-vinylbenzoyl chloride as a pale yellow oil, i.r. ($CHCl_3$) 1780 and 1740 cm^{-1}.

To a cold saturated aqueous solution of sodium azide (40 ml) was added a cold solution of the acid chloride in 10 ml of dry acetone. The heterogeneous mixture was stirred at 0–5° in the dark for 2 h. The solution was then diluted with 50 ml of cold water and extracted with three 20 ml portions of pure cyclohexane. The combined extracts were washed with two 20 ml portions of saturated sodium bicarbonate solution, two 20 ml portions of water, and two 20 ml portions of saturated sodium chloride solution. The cyclohexane solution was dried over magnesium sulfate at 0–5° in the dark for 2 h. After filtration, the i.r. spectrum of the cyclohexane solution showed no hydroxyl absorption, a clean single peak in the carbonyl region (1702 cm^{-1}), a strong azide absorption (2140 cm^{-1}), and a very small amount of isocyanate absorption (2280 cm^{-1}).

No acid was obtained by acidification of the basic extracts and extraction of these with ether. Therefore, for calculation of yields the conversion to azide was taken as quantitative. It was necessary to maintain the temperature of the solution below 10°. If it was left at 20° for 30 min a large portion of the azide was converted to isocyanate.

Photolysis of 2-Vinylbenzoyl Azide

A cyclohexane solution of azide from 1.0 g of sodium salt was diluted to 80 ml and photolyzed at 0° in a Vycor apparatus using a 450 W Hanovia immersion lamp in a water jacketed well. The polymer which deposited on the immersion unit was removed at intervals. As the photolysis proceeded, the i.r. absorption of the solution at 1702 and 2140 cm^{-1} decreased in intensity and new bands at 2280 and 1750 cm^{-1} appeared. After 7.5 h, i.r. analysis showed that reaction was complete. The solution was filtered and shaken with four 10 ml portions of water for 30 min each. The combined water phases were reduced in volume to ca. 5 ml and poured into 100 ml of methylene chloride. Enough anhydrous sodium sulfate was added to absorb the water. After 2 h, the solution was filtered and the drying agent washed well by grinding with methylene chloride. Evaporation of the solvent gave 90 mg (9.4% as hydroxylactams) of water-soluble material which showed two major spots on t.l.c.

The cyclohexane solution showed only one spot of any intensity on t.l.c. The solution was dried over sodium sulphate, diluted with an equal volume of dry methanol, and heated under reflux for 18 h. Evaporation of the solvent and recrystallization of the residue from *n*-hexane gave white crystals of methyl 2-vinylphenylcarbamate (502 mg, 50%) with m.p. 50.5–52.0. The polymeric material that formed in the reaction was estimated to account for ca. 25–30% of the starting azide.

The separation of the water-soluble products was done by preparative t.l.c. using 10% methanol in chloroform. The plates were developed twice. A total of 130 mg of material from photolyses was spotted. The adsorbent was scraped from the plate and the scrapings were extracted with three 10 ml portions of boiling 50% methanol in chloroform. Evaporation of the extracts gave 20.4 mg of the faster-moving material (**18**?) and 58.3 mg of the slower-moving one (**17**), both of which were slightly brown solids. In addition, several other minor products (weight = less than 5 mg each) were isolated. These were not investigated.

*3-Hydroxymethyl-1,2-dihydroisoindol-1-one (**17**)*

The major slow-moving component (yield 4.5% based on sodium salt) crystallized from methylene chloride. After three recrystallizations from acetone it separated as fine needles, m.p. 148°. It had ν_{max} (Nujol) 3440, 3200, 3080, 1705, 1060, and 740 cm^{-1}. Its mass spectrum had M and M + 1 peaks at *m/e* 163 and 164 and strong peaks at *m/e* 133, 132 (base peak), 104, and 77. After sublimation at 120°, 5×10^{-4} mm, it was analyzed.

Anal. Calcd. for $C_9H_9NO_2$: C, 66.24; H, 5.56. Found: C, 66.06; H, 5.78.

*4-Hydroxy-1,2,3,4-tetrahydroisoquinolin-1-one (**18**?)*

The major faster-moving component could not readily be purified. Its m.p. was 130–135°, and from its i.r. spectrum, it was estimated to be around 75% pure. It had ν_{max} 3420 and 1660 cm^{-1} and its mass spectrum had a prominent parent ion at *m/e* 163 and a strong peak at *m/e* 145 (M-18).

Methyl 2-Vinylphenylcarbamate

A methanol solution of *o*-vinylphenyl isocyanate, produced by thermal decomposition of *o*-vinylbenzoyl azide, was refluxed for 18 h. Removal of the solvent under reduced pressure left the crystalline carbamate. After recrystallization from hexane its m.p. was 50.5–52°; ν_{max} ($CHCl_3$) 3440 and 1740 cm^{-1}; λ_{max} 221 mμ (20 500), 247 mμ (14 200), and 295 mμ (1100).

Anal. Calcd. for $C_{10}H_{11}NO_2$: C, 67.78; H, 6.26; N, 7.91. Found: C, 67.86; H, 6.56; N, 8.02. Its n.m.r. spectrum had bands at 8.0–6.5 (6H, multiplet), 5.50 (2H, sextet), and 3.83 (3H, singlet).

cis-Vinylcylopropane Carboxylic Acid

A mixture of the *cis* and *trans* acids was prepared following Vogel *et al.* (4). The sodium salts were treated with iodine to convert the *cis* acid to iodolactone. The crystalline iodolactone was converted to the *cis* acid by zinc spangles in 95% ethanol. This was converted to its sodium salt using sodium hydroxide in ethanol and then dried *in vacuo*.

*Photolysis of **19***

Sodium salt of *cis*-vinylcyclopropane carboxylic acid (475 mg) was suspended in 5 ml of pentane and 1.5 ml of oxalyl chloride added cautiously. After 2 h of stirring, gas evolution had ceased. The suspension was filtered through cotton wool into a chain of bulbs, using pentane as wash liquid. The acid chloride was distilled at 70°, 25 mm, giving 394 mg of colorless oil.

The acid chloride was added to 10 ml of saturated aqueous sodium azide at 0°. After 1.5 h of vigorous stirring at 0° no acid chloride remained. A little sodium carbonate was added, then the azide extracted into pentane. After drying over sodium sulfate the pentane solution was filtered and made up to 45 ml with cold pentane.

The azide solution (ν_{max} 2150 and 1717 cm^{-1}) was cooled to −78°. A 100 W Hanovia lamp was introduced in a Vycor well, cooled by a stream of dry air through the well and a stream of dry nitrogen through a jacket surrounding the well. After 1.5 h of irradiation at −78°, the azide band was weak. A little polymer was washed off the well, then the irradiation continued for 0.5 h decomposing the remaining azide. The solution now contained isocyanate and carbonyl compounds with i.r. maxima at 1768, 1715, and 1690 cm^{-1}.

The pentane solution of the products was allowed to warm to 0°, then extracted with 2 × 5 ml of ice-water, and dried. It now contained mainly isocyanate (ν_{max} 2275 cm^{-1}). At room temperature this steadily rearranged to amide with ν_{max} 1689 and 1595 cm^{-1} (rapid in the i.r. beam). The solution was left at room temperature overnight, when the isocyanate was all isomerized. On careful distillation the pentane left 93 mg of strong-smelling oil. This was put on a 20 × 20 cm silica gel plate (0.5 mm thick when wet) containing a fluorescent indicator (Merck GF_{254}). When developed with ether 4 bands were detected: zone 1, R_f 0.81, 7 mg with a strong odor; zone 2, R_f 0.64, 5 mg; zone 3, R_f 0.54, 59 mg; zone 4, R_f 0.17, 14 mg.

The 59 mg extracted from zone 3 crystallized when seeded with 2,3-dihydro-1*H*-azepin-2-one. It was distilled at 100°, 1 mm, over a short path, giving a colorless oil which crystallized. When recrystallized from pentane this had a m.p. of 47–48.5°. It had λ_{min} 230 mμ, λ_{max} 255 mμ (ε 4400). It showed no mixed m.p. depression with 2,3-dihydro-1*H*-azepin-2-one (3) and the compound had an i.r. spectrum (ν_{max} ($CHCl_3$) 3400, 3220, 1683 (strong), 1640 (weak), and 1594 (medium) cm^{-1}) identical to that of an authentic sample prepared by refluxing a hexane solution of the isocyanate.

A methylene chloride extract of the above water washings, and of the gum which separated during photolysis gave 65 mg of gum. A hot hexane extract of this gave 10 mg of gum which by its i.r. spectrum and t.l.c. was rich in the dihydroazepinone.

No pure compound was isolated from the water-soluble products.

Acknowledgments

We are grateful to Dr. W. D. Jamieson, Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia, for obtaining accurate masses of many ions and advice on interpretation of mass spectra, to Mr. R. Pilon for mass spectra, and Mr. H. Seguin for microanalyses.

Synthesis of D-*glycero*-D-*gulo*-heptose, D-*glycero*-D-*ido*-heptose, and 2-deoxy-D-*gluco*-heptose from D-glucose[1]

D. T. WILLIAMS[2] AND M. B. PERRY
Division of Biochemistry and Molecular Biology, National Research Council of Canada, Ottawa, Canada

Received March 31, 1969

D-Glucose was condensed with nitromethane to yield 1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol and 1-deoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol which were converted *via* the Nef reaction to D-*glycero*-D-*ido*-heptose and D-*glycero*-D-*gulo*-heptose respectively. The acetylated 1-deoxy-1-nitro-D-*glycero*-(D-*ido*- and D-*gulo*-)-heptitols were converted to 3,4,5,6,7-penta-*O*-acetyl-1,2-dideoxy-1-nitro-D-*gluco*-hept-1-enitol and reduction of this derivative afforded 3,4,5,6,7-penta-*O*-acetyl-1,2-dideoxy-1-nitro-D-*gluco*-heptitol which underwent the Nef reaction to give 2-deoxy-D-*gluco*-heptose.

Canadian Journtal of Chemistry, 47, 2763 (1969)

The application of the Sowden–Fischer (1) method for the extension of the carbon chain of glycoses has not, in the case of D-glucose and its derivatives, proved as successful a procedure as in the case of many other glycoses. Sowden and Fischer (2) were able to prepare 3,4,5,6,7-penta-*O*-acetyl-1,2-dideoxy-1-nitro-D-*gluco*-hept-1-enitol in 5% yield from D-glucose but they were unable to isolate the intermediate 1-deoxy-1-nitroheptitol derivatives resulting from the condensation of the D-glucose with nitromethane. 1-Deoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol has been prepared by the mild hydrolysis of 5,7-*O*-benzylidene-1-deoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol prepared in 21% yield by the action of nitromethane on 4,6-*O*-benzylidene-D-glucose (3). In this note we record details of the condensation of nitromethane with D-glucose under modified conditions which leads to the practical synthesis of some derived heptose and heptitol derivatives.

D-Glucose was condensed with nitromethane in the presence of sodium methoxide and the collected insoluble product was composed of at least 24% 1-deoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol and 19% 1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol, the remainder being unreacted D-glucose. Fractional crystallization of the decationized product afforded pure crystalline 1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol and, 1-deoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol which were converted *via* the Nef reaction (4) to D-*glycero*-D-*ido*-heptose and D-*glycero*-D-*gulo*-heptose in 9 and 10% overall yields respectively.

[1]NRCC No. 10741.
[2]NRCC Postdoctorate Fellow 1967–1969.

The mixed 1-deoxy-1-nitro-D-*glycero*-(D-*ido* and D-*gulo*)-heptitols were acetylated and refluxing the product in benzene in the presence of sodium bicarbonate yielded 3,4,5,6,7-penta-*O*-acetyl-1,2-dideoxy-1-nitro-D-*gluco*-hept-1-enitol which was reduced with hydrogen in the presence of palladium black to yield 3,4,5,6,7-penta-*O*-acetyl-1,2-dideoxy-1-nitro-D-*gluco*-heptitol. The 3,4,5,6,7-penta-*O*-acetyl-1,2-dideoxy-1-nitro-D-*gluco*-heptitol was converted *via* the Nef reaction to crystalline 2-deoxy-D-*gluco*-heptose. The glycose can be readily characterized as its 1,3,4,5,6,7-hexa-*O*-acetyl-2-deoxy-D-*gluco*-heptitol derivative.

Experimental

Paper chromatography was performed by the descending method on Whatman No. 1 filter paper using (*a*) pyridine – ethyl acetate – water (2:5:5 v/v top layer) or (*b*) butan-1-ol – ethanol – water (3:1:1 v/v) as the mobile phase. Compounds were detected with an alkaline silver nitrate spray reagent (5) and their rates of movement are quoted relative to D-glucose (R_G).

Gas–liquid partition chromatography was carried out using a Hewlett–Packard 402 gas chromatograph with a hydrogen flame detector and fitted with glass U tubes (4 ft × 6 mm × 3 mm internal diameter) packed with (A) 10% (w/w) neopentylglycol sebacate polyester on 80–100 mesh acid washed Chromosorb W, (B) 3% (w/w) ECNSS-M (Applied Science Laboratories Inc., Pa.) on 80–100 mesh acid washed Chromosorb W, or (C) a mixture of 1.5% (w/w) GE-XF 1150 (Applied Science Laboratories Inc., Pa.) and 1.5% (w/w) neopentyl–glycol sebacate polyester on 80–100 mesh acid washed Chromosorb W. Retention times are quoted relative to penta-*O*-acetyl-L-arabinitol (T_A).

Melting points were determined on a hot stage and are corrected. Optical rotations were determined at 22 °C with a Perkin–Elmer 141 polarimeter. Solutions were concentrated under reduced pressure below 40 °C.

*1-Deoxy-1-nitro-*D*-glycero-*D*-gulo-heptitol and 1-Deoxy-1-nitro-*D*-glycero-*D*-ido-heptitol*

Anhydrous D-glucose (100 g) suspended in nitromethane (280 ml) was vigorously stirred and 1.88 *N* sodium methoxide in methanol (630 ml) followed by methanol (125 ml) were added. After stirring for 24 h at room temperature, the precipitated material was collected by filtration, washed with methanol and ether, and dried to leave a light-yellow powder (150 g). The product (150 g) in water (500 ml) was passed down a column of Rexyn 101(H^+) ion-exchange resin (2 l) and the eluate and washings were concentrated to a syrup which was dissolved in ethanol (300 ml) and kept at 0 °C. The first crystalline product obtained was 1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol (11 g) which after recrystallization from a methanol – ethanol mixture had m.p. 135–136 °C, $[\alpha]_D$ −1.4° (*c*, 3.3 in water), and on paper chromatography gave a single spot with R_G 1.60 (solvent *b*).

Anal. Calcd. for $C_7H_{15}NO_8$: C, 34.85; H, 6.27; N, 5.80. Found: C, 34.59; H, 6.37; N, 5.65.

The mother liquors on concentration afforded a crystalline mixture of 1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol and 1-deoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol (7.2 g). A third crop of crystals proved to be 1-deoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol (13.4 g) which after recrystallization from a methanol – ethanol mixture had m.p. 139–140 °C, $[\alpha]_D$ +2.8° (*c*, 3.1 in water) (lit. (3) m.p. 138–139 °C and $[\alpha]_D$ +3.1°), and on paper chromatography gave a single spot with R_G 1.90 (solvent *b*).

Anal. Calcd. for $C_7H_{15}NO_8$: C, 34.85; H, 6.27; N, 5.80. Found: C, 34.54; H, 6.26; N, 5.70.

A portion of the original nitromethane condensation product (1 g) was treated under the conditions of the Nef reaction and the resulting glycose mixture was reduced with sodium borohydride and acetylated to give the corresponding glycitol acetate derivatives. Following the addition of inositol acetate as an internal standard, the mixture was analyzed by gas–liquid chromatography on column B (189 °C) and showed peaks from hexa-*O*-acetyl-D-glucitol (T_A 3.52), hepta-*O*-acetyl-D-*glycero*-D-*gulo*-heptitol (T_A 8.50), and hepta-*O*-acetyl-D-*glycero*-D-*ido*-heptitol (T_A 9.45). The hexa-*O*-acetyl-D-glucitol arises from unreacted D-glucose present in the crude reaction product and quantitative analysis of the gas chromatograms indicates that it is composed of 24% 1-deoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol and 19% 1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol assuming that these derivatives are quantitatively transformed to aldoheptoses in the Nef reaction.

D-*glycero*-D-*ido-Heptose*

1-Deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol (0.5 g), dissolved in *N* sodium hydroxide (5 ml), was added dropwise with stirring to 6 *N* sulfuric acid (6.5 ml) cooled externally with ice. After 30 min the solution was diluted with water (15 ml) and neutralized with barium carbonate. The mixture was filtered and the filtrate was passed down columns of Rexyn 101 (H^+) (20 ml) and Duolite A4(OH^-) (10 ml) ion-exchange resins and the eluate and washing were concentrated to a syrup (0.4 g). Paper chromatographic examination of the product showed a major spot (R_G 1.85, solvent *a*) corresponding with authentic D-*glycero*-D-*ido*-heptose. A portion of the product after reduction with borohydride, on acetylation, gave hepta-*O*-acetyl-D-*glycero*-D-*ido*-heptitol which on gas–liquid chromatography gave a single peak (T_A 9.45, column A, 189 °C) having the same retention time as an authentic sample. A second portion of the D-*glycero*-D-*ido*-heptose (0.2 g) was converted to crystalline D-*glycero*-D-*ido*-heptose dibenzyldithioacetal (0.15 g) which had m.p. 130–131 °C and $[\alpha]_D$ +67° (*c*, 1.6 in pyridine) (lit. (6) m.p. 130–131 °C and $[\alpha]_D$ +71.4° (pyridine)).

D-*glycero*-D-*gulo-Heptose*

1-Deoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol (0.5 g) was converted in the way described above to yield crystalline D-*glycero*-D-*gulo*-heptose (0.26 g) which had m.p. and mixture m.p. 193–194 °C and $[\alpha]_D$ −22° → −18.5° (*c*, 2.5 in water) (lit. (7) m.p. 193 °C and $[\alpha]_D$ −20° (equil. in water)), and gave a single spot on paper chromatograms R_G 0.91 (solvent *a*).

*2-Deoxy-*D*-gluco- heptose*

*3,4,5,6,7-Penta-O-acetyl-1,2-dideoxy-1-nitro-*D*-gluco-hept-1-enitol*

The mixture of 1-deoxy-1-nitro-D-*glycero*-(D-*gulo* and D-*ido*)-heptitol (10.5 g) in acetic anhydride (100 ml) was treated with 2 drops of concentrated sulfuric acid and the mixture was heated for 40 min on a boiling water bath. The cooled reaction mixture was poured into an ice and water mixture (500 ml), and the product was extracted with chloroform in the usual way. The acetylated 1-deoxy-1-nitro-heptitol mixture (21 g) in dry benzene (250 ml) was boiled under reflux for 2.5 h with sodium bicarbonate (25 g). The cooled reaction mixture was filtered and the filtrate was concentrated to a syrup. The syrup was dissolved in ethanol (100 ml) and, when the solution was kept overnight at 0 °C, it gave a crystalline product (15 g) which after recrystallization from ethanol afforded pure 3,4,5,6,7-penta-*O*-acetyl-1,2-dideoxy-1-nitro-D-*gluco*-hept-1-enitol having m.p. 106–107 °C and $[\alpha]_D$ +15° (*c*, 3.55 in chloroform) (lit. (2) m.p. 106–107 °C and $[\alpha]_D$ +18° (in chloroform)).

*3,4,5,6,7-Penta-O-acetyl-1,2-dideoxy-1-nitro-*D*-gluco-heptitol*

3,4,5,6,7-Penta-*O*-acetyl-1,2-dideoxy-1-nitro-D-*gluco*-hept-1-enitol (6 g) in ethanol (400 ml) was shaken with hydrogen at room temperature and pressure in the presence of palladium black (0.5 g). One mole equivalent of hydrogen was absorbed in 30 min and the rate of reduction then became very slow. At this point the reaction mixture was filtered; the filtrate was concentrated to a small bulk and, when cooled to 0 °C, it afforded crystalline 3,4,5,6,7-penta-*O*-acetyl-1,2-dideoxy-1-nitro-D-*gluco*-heptitol (5 g) which after recrystallization from methanol had m.p. 119–120 °C and $[\alpha]_D$ +7.5° (*c*, 3.6 in chloroform).

Anal. Calcd. for $C_{17}H_{25}NO_{12}$: C, 46.89; H, 5.79; N, 3.22. Found: C, 46.51; H, 5.96; N, 3.16.

*2-Deoxy-*D*-gluco-heptose*

3,4,5,6,7-Penta-*O*-acetyl-1,2-dideoxy-1-nitro-D-*gluco*-heptitol (5 g) was dissolved at 36 °C in *N* sodium hydroxide solution (63 ml) and the mixture, after being kept at 20 °C for 1 h, was added dropwise to a cooled stirred solution of sulfuric acid (20 ml) in water (180 ml). After 2 h, the reaction mixture was neutralized with barium carbonate and following centrifugation and filtration, the solution was passed down columns of Rexyn

101(H^+) (150 ml) and Duolite A4(OH^-) (30 ml) ion-exchange resins and the eluate and washings were concentrated to a syrup. The syrup was taken up in a little ethanol and, on cooling, crystalline 2-deoxy-D-*gluco*-heptose was obtained (1.3 g) which after recrystallization from aqueous ethanol had m.p. 174.5–175.5 °C and $[\alpha]_D$ +7.6° (5 min) → +11.1° (30 min equil. value) (*c*, 5 in water).

Anal. Calcd. for $C_7H_{14}O_6$: C, 43.30; H, 7.27. Found: C, 43.16; H, 7.32.

The 2-deoxy-D-*gluco*-heptose gave a single spot on paper chromatograms having R_G 1.67 (solvent *a*) and R_G 2.00 (solvent *b*), and the trimethylsilylated crystalline material on gas chromatography gave a single peak T_A 0.15 (column A, 208 °C) whereas the trimethylsilated product obtained from the glycose, after equilibration in water, on gas–liquid chromatography gave two peaks having T_A 0.15 and 0.20 (very minor).

*1,3,4,5,6,7-Hexa-O-acetyl-2-deoxy-*D*-gluco-heptitol*

2-Deoxy-D-*gluco*-heptose (0.1 g) was reduced with sodium borohydride to 2-deoxy-D-*gluco*-heptitol which on acetylation afforded 1,3,4,5,6,7-hexa-*O*-acetyl-2-deoxy-D-*gluco*-heptitol (0.15 g). The product, after recrystallization from ethanol, had m.p. 106–107 °C and $[\alpha]_D$ +11° (*c*, 2.9 in chloroform).

Anal. Calcd. for $C_{19}H_{28}O_{12}$: C, 50.89; H, 6.29. Found: C, 50.95; H, 6.29.

On gas–liquid chromatography the acetate gave a single peak T_A 4.35 (column C, 209 °C), and T_A 3.64 (column A, 232 °C).

Effect of substituents on the chemical shift of benzylic protons

ROBERT R. FRASER, GURUDATA, ROGER N. RENAUD, CESAR REYES-ZAMORA, AND ROBERT B. SWINGLE
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received December 13, 1968

The chemical shift of the benzylic protons in fifteen series of *para*-substituted toluenes bearing different groups in the alpha position are reported. In each series a plot of the chemical shift in tau units of the benzylic protons against the Hammett σ value of the *para* substituent is linear. The slopes of these plots vary from −0.20 to +0.01 p.p.m./σ. The variation of slopes appears to be conformationally dependent, an observation at odds with current theory. In two rigid systems having the same geometry the slope has been found to vary from −0.12 to −0.18 indicating a dependence on other factors as well. The effect of solvent on the slopes has been determined, and shows no correlation with solvent dielectric properties.

In recent years many examples of correlations between the effect of substituents on the chemical shift (abbreviated to SCS) of a proton on a benzene ring and the Hammett sigma value of the substituents have been found (1–3). In addition similar correlations have been observed for protons in the side chains of toluenes (4–7), phenols (8), anisoles (9), dihydrocinnamic acids (10), cyclopropanes (11), and benzonorbornenes (12). The mechanism by which a substituent exerts its effect is a subject of some contention. It is usually assumed that the substituent alters the electron density of the aromatic ring by both inductive and resonance interactions and that this effect is relayed to the protons on the ring or in the side chain by polarization of the intervening sigma electrons. An alternative explanation involving field and mesomeric effects has been put forward by Dewar and Takeuchi (13). Yet Wittstruck and Trachtenberg examined the shifts in a series of cinnamic and dihydrocinnamic acids and concluded that both field and anisotropy effects of the substituent were negligible (10). Taft has shown that aromatic fluorine shifts correlate well with σ_R^o values (14) and that these parameters can be related by theoretical calculations to the excess π charge density introduced by a substituent (15). While the sensitivity of fluorine and proton nuclei to substituent effects is different, many similarities in their correlations do exist. In the case of aromatic protons, they too are influenced to a large extent by the resonance effect of the substituent as measured by σ_R^o (1).

We wish to report the results of a study of the correlation of SCS with σ for the methylene protons in a series of toluene derivatives. We believe that the observations made on these compounds provide some evidence pertaining to the mechanism by which substituents alter proton shifts. A brief communication of our results has already appeared (16). This paper will provide the details of our communication and will describe additional results on other toluene derivatives.

We have determined the chemical shifts of the benzylic protons in fifteen series of *para*-substituted compounds of the general formula $X—C_6H_5—CH_2—Z$. For each Z, at least four *para* substituents having a range of σ values of 0.95 or more were studied. The extent to which the chemical shifts are correlated by σ is well illustrated by a graph given in our earlier paper (16). Almost all points except that for chlorine fall within 1 Hz of the best straight line.[1] We have presented in Fig. 1 the correlation for the most interesting series of compounds, the *para*-substituted benzyl phenyl sulfoxides. In the sulfoxides the benzylic protons are magnetically non-equivalent and each proton shows a completely different sensitivity to the *para* substituent, X. One of the diastereotopic protons shows a large variation with X, the slope (ρ) of the τ versus σ plot being 0.20 p.p.m./σ and negative.[2]

[1]As has been noted elsewhere (7), the deviations from linearity in one series are usually reproduced in the same way in a second series. For example, a least squares analysis of a plot of the τ values for the *para* substituted benzyl tetrahydropyranyl ethers versus toluenes shows an excellent linear correlation with ρ = .759, r = .993 and s = .0095, less than a 2% uncertainty in ρ. An obvious way to improve the linearity of these σ–τ plots would be to avoid the use of all halogen substituents rather than only chlorine which shows the worst deviations from linearity.

[2]The sigma constants are taken from ref. 40.

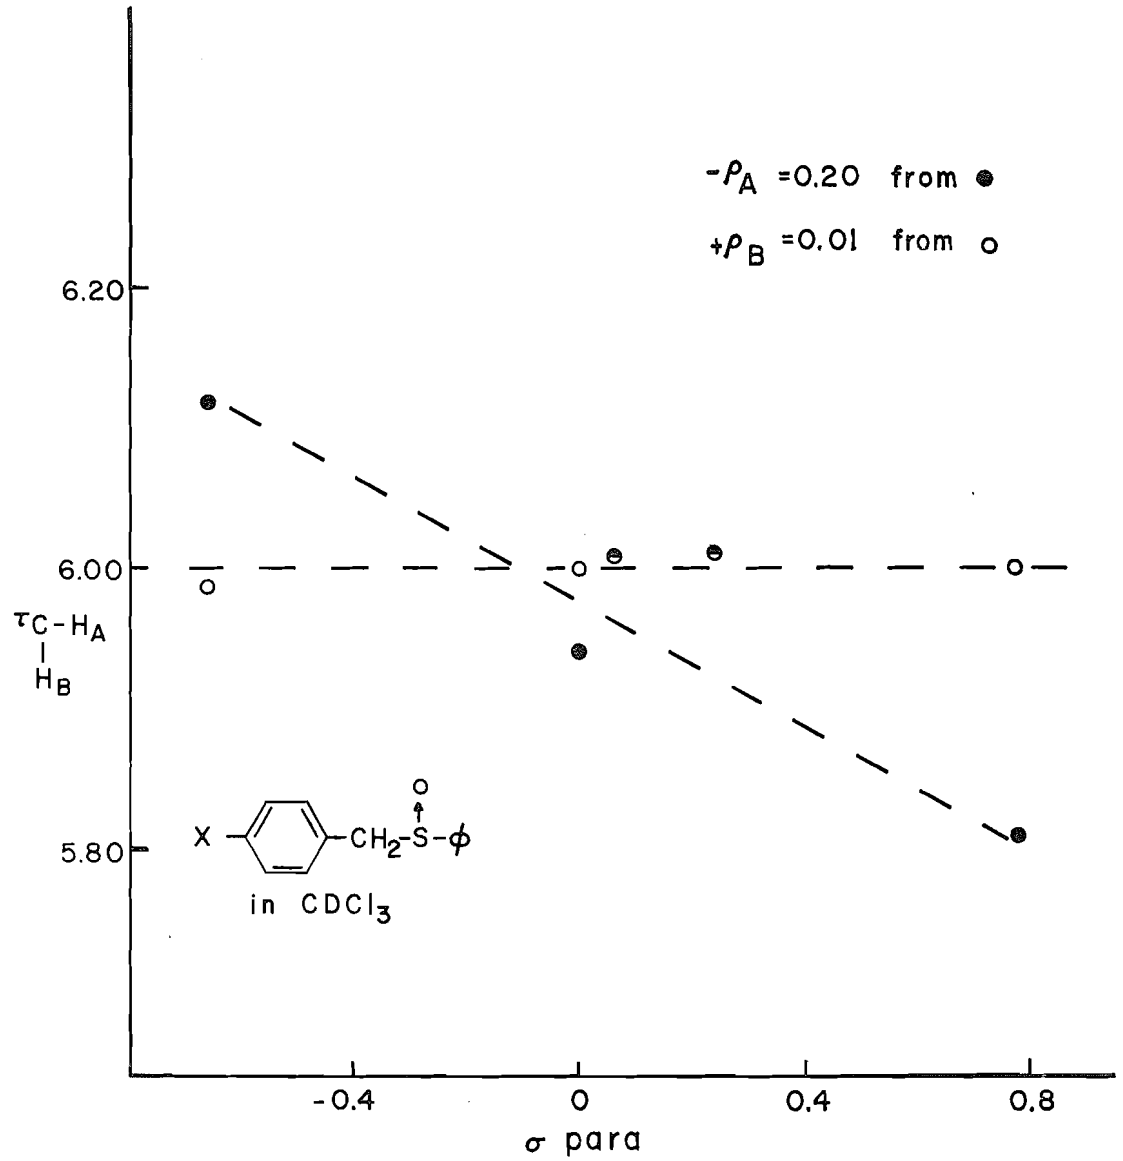

FIG. 1. A plot of the chemical shift of each diastereotopic proton in a series of five *para*-substituted benzyl phenyl sulfoxides versus the Hammett sigma value of the substituent. There is an uncertainty of ±1.5 Hz in the points for fluorine and chlorine since the diastereotopic protons appeared as a broad singlet in these compounds.

The other proton has a ρ or slope of plus 0.01. That the assignments to the diastereotopic protons of the amino derivative are opposite (in terms of relative field strengths) to those in the nitro compound was proven experimentally. A sample of *p*-nitrobenzyl phenyl sulfoxide was partially deuterated (17) by treatment with NaOD in a mixture of chloroform and heavy water.[3] The nuclear magnetic resonance (n.m.r.) spectrum of the product in $CDCl_3$ showed that the low field proton had exchanged more rapidly under these conditions i.e. had less intensity. The sulfoxide was then reduced by stannous

[3]A similar observation of preferential exchange in *p*-chlorophenyl benzyl sulfoxide has been reported (18).

[a] ρ, *r* and *s* represent the slope in p.p.m./σ, the correlation coefficient and the standard deviation as derived from a least squares treatment of the data (32). The points for chlorine have not been used in the calculations.
[b] Values of the van der Waal's radius of the atom attached to the methylene group are quoted from reference 19.
[c] *n* is the number of compounds studied in each series.
[d] Calculated from the data of Miller *et al.* (4).
[e] Calculated from the data of Williamson (5).
[f] Calculated from the data of Trachtenberg (10).
[g] Calculated from the data in reference 7.
[h] THP stands for tetrahydropyranyl ether.
[i] A van der Waal's radius is, by definition, limited to atoms. For the methyl group we have listed its "interference radius" as estimated from ultraviolet shifts (33).

chloride to the *para*-amino derivative whose n.m.r. in $CDCl_3$ showed that the high field proton had less intensity. There is an uncertainty regarding assignments for the unsubstituted compound in this series, but either assignment would give essentially the same slopes. Chlorine again shows its customary high field deviation. The slopes or ρ values for all series of compounds studied are listed in Table I along with all ρ's reported in the literature. It can be seen that ρ varies widely as Z is altered.

Before discussing these ρ values, it is important to consider the accuracy and reliability of the Hammett correlation. All the data in Table I has been obtained by a least squares analysis of the plots for each series. The correlation is generally good, the criterion of acceptability being that *r*, the correlation coefficient, be greater than 0.90 (32). For our purposes *s* is much more meaningful since *r* decreases as ρ decreases. For instance the plot of the benzyl bromides gives $\rho = 0.01 \pm$ an *s* of 0.02 even though $r = 0.544$. It can be seen that most of the standard deviations are 0.03 or less and this is a reliable limit of accuracy of ρ. It is thus established that the variation in ρ with a change in Z is statistically significant. At the same time the appreciable error in ρ requires that only a qualitative discussion of these initial results is warranted at present.

We wish to assume, as has been done for every Hammett correlation (4, 19), that a *para*-substituent affects only the π electron distribution of the benzene ring, and that no steric factors are involved. Then a change in ρ from series to series must be attributed to a change in some property or properties of Z. It can be seen at a glance that there is no correlation between the size of ρ and the electronegativity of Z. On the other hand, with the exception of the sulfones, there is a reasonably consistent parallel between ρ and the size of Z as estimated by its Van der Waal's radius. We interpret this parallel behavior as evidence that ρ depends, to a significant degree, on the conformation of the methylene group with respect to the benzene ring. This interpretation is strongly supported by the sulfoxide data. Here the two diastereotopic protons have a common Z but will almost certainly possess different orientations with respect to the benzene ring. The most probable conformation, as shown in **1**, should have the bulky phenyls *trans* to one another. The large asymmetric sulfur atom will

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

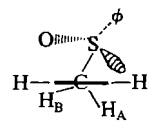
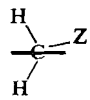
then prefer to tilt from the symmetrical arrangement in **3** to that shown in **1**. If the substituent effect is maximal when the benzylic C—H bond is colinear with the adjacent p orbital and minimal when perpendicular to it then the results for this sulfoxide and for the decrease in ρ with increasing size of Z can be accounted for.[4] Or, to rephrase the explanation we can say that a decrease in ρ represents a shift of conformational population from that shown in **2** to that shown in **3**. Our previous results on the effect of substituents on geminal coupling constants in the tetrahydropyranyl ethers and sulfoxides led to the same conclusions (20).



1

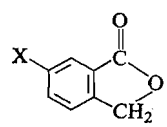


2

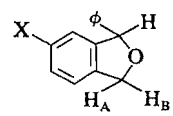
3

We have sought some experimental verification for this explanation by determining the ρ values for the benzyl phenyl sulfoxides at 90 °C. At this temperature the ρ values for the protons were −0.02 and −0.18. Unfortunately, this lack of a temperature effect on ρ is neither evidence for nor against our explanation.

Very little data exists at present which bears on the problem of rotation about a benzene to carbon bond. In toluene, the barrier to rotation has not been measured but has been calculated to be about 100 calories (21). A change from a 6-fold to a 2-fold axis of symmetry for benzyl derivatives will undoubtedly raise this barrier. Recently, in two different 2,6-di-substituted benzyl derivatives bearing either *ortho* chlorines or *ortho t*-butyl groups, the barrier was reported to be large enough (15–20 kcal) to have been determined by n.m.r. studies (22, 23). For the compounds in Table I a much smaller barrier will be present, perhaps of the order of a few kcals. The only other system for which experimental evidence on the rotational barrier is available is that of phenyl cyclopropane for which a "bisected" structure has been proposed as the most favorable conformation (24). It is obvious that in order to prove a relation between the CH_2 group's conformation and ρ, these values must be measured in systems of known rigid geometry. Thus far we have obtained data for only two structures of this class, the 6-substituted phthalides and a series of 3-phenyl phthalans. For a series of six phthalides, **4**, ρ was found to be −0.18, a value essentially equivalent to that found in the open chain ethers. For the phthalans, **5**, ρ was −0.12.[5] The similarity in ρ values of the phthalides to the ethers and acetates would indicate that the open chain ethers have **2** as their predominant conformation. The analogous conformation has been found to be the most favorable one in allyl methyl ether (26). However the appreciably lower ρ value for the CH_2 protons of the phthalans lessens the reliability of this conclusion. It indicates that other factors are also influencing the magnitude of ρ. The nature of these factors, electronegativity, strain, etc., cannot be determined at this time. Additional series of benzyl derivatives of fixed geometry are currently being synthesized to provide more evidence about the reliability of using ρ as an indication of conformation.



4



5

As we mentioned previously there does not appear to be any way to explain a conformational dependence of ρ within the present framework of proton shift theory. Three main factors are recognized which determine proton chemical shifts. These are (*a*) the diamagnetic shielding of the electrons which surround the nucleus, (*b*) the anisotropy of other atoms or groups of atoms within the molecule, and (*c*) solvent effects. The diamagnetic shielding of a benzylic proton can be

[4]It is also possible that H_A, because it is *trans* to the sulfoxide oxygen, has a different ρ than H_B which is *gauche* to the oxygen. However this explanation cannot explain the other data in Table I and is therefore less likely.

[5]Details of the preparation, analysis of spectra, and correlation of the data for this series will be described in a separate paper (25).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

influenced through either a field or inductive effect. Neither of these are capable of accounting for the large change in the benzylic shifts. As an example, we have calculated the direct field effect (27) on the benzylic proton shift when a nitro group is substituted for a hydrogen in the *para* position. It amounts to 0.05 p.p.m. and is independent of conformation. Moreover a field effect should correlate with σ_I not σ (28). The inductive effect acting through bonds would not show a conformational dependence. Anisotropy effects are also unable to account for the observed SCS's. Normally the effect is either assumed negligible (29) or variable as Figeys and Flammang propose (30) but much too small. For instance, if one assumes Figeys and Flammang's estimate that $\Delta\chi$ can vary by ten percent from -50×10^{-6} to -45×10^{-6} cm^3/mole, it can be shown that the decrease would alter the screening of a benzylic proton in the plane of the benzene ring by 0.045 p.p.m., and the screening of a benzylic proton as far away from the plane as possible by 0.032 p.p.m. Thus this effect would be far too small, not particularly sensitive to conformation and not related to Hammett σ values. The third factor, solvent effects, has been kept constant throughout the investigation. We must therefore seek a new explanation for our results. It is proposed that either the paramagnetic shielding term in the Ramsay formula is not negligible as normally assumed (31), or that a hyperconjugative interaction between the benzylic hydrogens and the π system of the aromatic ring is responsible for the variations in chemical shifts. A somewhat analogous explanation involving homobenzylic resonance has been proposed by Tanida and co-workers (12) to account for the stereochemical difference between the ρ's for the *syn* and *anti* 7-hydrogens in a series of benzonorbornenes. We hope that additional results will provide further evidence regarding the mechanism by which an SCS is produced.

The subject of solvent effects should be mentioned briefly. We purposefully avoided any change in solvent in the above measurements. We have, nevertheless, studied the solvent effect on ρ in several series including the rigid phthalides. The findings are given in Table II. It is apparent that the solvent can have a large effect on the size of ρ. The data for the phthalides shows that the variation of ρ is not due to an effect of solvent on conformational equilibria. Furthermore in this series, there is no correlation between the solvent effect on ρ and the dielectric constant of the medium. It would appear that specific solvent–solute interactions have a large influence on ρ. We cannot derive any more definitive information from these solvents effects. They do provide the information that ρ is very sensitive to its medium and therefore serve as a warning that the solvent must be kept constant if any meaningful interpretations are to be derived from studies of ρ in different series.

Experimental

Microanalyses were performed by Scandinavian Microanalytical Lab., Herlev, Denmark. The n.m.r. spectra were measured in deuterochloroform on either a

Varian DA-60 or on a Varian HA-100 spectrometer. Spectra of benzyl derivatives having non-equivalent methylene protons were determined using 0.3 *M* solutions at 60 MHz and using 0.1 *M* solutions at 100 MHz. All other spectra of the benzyl series were run using 0.2 *M* solutions and for at least three compounds in each series 0.1 *M* solutions were also measured, no dilution effect being detectable. In the phthalans and phthalides only 0.1 *M* solutions were studied. All line positions are reported as the average of at least five determinations with a standard deviation of less than 0.2 Hz. The following is a list of the tau values of the methylene protons in each series of benzyl derivatives studied. The values are given in brackets after the *para* substituent, X. For Z = CN; H (6.257), NH_2 (6.390), OH (6.330), CH_3 (6.312), Cl (6.287), Br (6.299), NO_2 (6.111). For Z = COOH; H, (6.361), OCH_3 (6.429), CH_3 (6.405), NO_2 (6.232). For Z = OH; H (5.312), OCH_3 (5.396), F (5.361), Cl (5.351), CN (5.228), NO_2 (5.171). For Z = OCH_3; H (5.544), OCH_3 (5.616), F (5.582), Cl (5.580), CN (5.490), NO_2 (5.439). For Z = OTHP (2-tetrahydropyranyloxy); H_A in H (5.222), NH_2 (5.345), OCH_3 (5.288), CH_3 (5.269), F (5.259), Cl (5.269), CF_3 (5.170), CN (5.162), NO_2 (5.115): H_B in H (5.507), NH_2 (5.623), OCH_3 (5.567), CH_3 (5.553), F (5.544), Cl (5.545), CF_3 (5.454), CN (5.446), NO_2 (5.390). For Z = $SOCH_3$ at 0.1 *M* concentration; H_A in H (5.942), NH_2 (6.025), OCH_3 (6.009), Cl (6.066), NO_2 (5.907): H_B in H (6.075), NH_2 (6.192), OCH_3 (6.119), Cl (6.066), NO_2 (6.008). J_{AB} was 12.80 in the OCH_3, NH_2 and unsubstituted compounds and 12.95 in the nitro derivative. For Z = SO_2CH_3; H (5.766), NH_2 (5.887), OCH_3 (5.827), Cl (5.799), NO_2 (5.656). For Z = SC_6H_5; H (5.886), NH_2 (5.970), F (5.925), Cl (5.949), NO_2 (5.865). For Z = SOC_6H_5 at 0.3 *M* concentration: H_A in H (5.94), NH_2 (6.12), F (6.02), Cl (6.02), NO_2 (5.80); H_B in H (6.00), NH_2 (5.99), F (6.02), Cl (6.02), NO_2 (5.99). For Z = SOC_6H_5 at 0.1 *M* concentration; H_A in H (5.921), NH_2 (6.110), F (6.005), Cl (6.013), NO_2 (5.811); H_B in H (6.004), NH_2 (5.980), F (6.005), Cl (6.013), NO_2 (6.005). J_{AB} was 12.60 for the unsubstituted and *p*-amino derivative, 12.75 for the *para*-nitro derivative. For Z = $SO_2C_6H_5$; H (5.699), NH_2 (5.828) F (5.734), Cl (5.740), NO_2 (5.599). For Z = Br; H (5.536), OCH_3 (5.519), CH_3 (5.546), CN (5.530), NO_2 (5.505).

The chemical shifts of the benzylic protons in the phthalides **4**, were as follows; H (4.668), NH_2 (4.803), OCH_3 (4.759), F (4.709), Cl (4.711), CN (4.604), NO_2 (4.526).

Preparation of Compounds

The majority of the compounds studied were available commercially. When necessary, the compound was purified by standard techniques until its physical constants were in agreement with literature values. With the exception of the phthalans, **5**, compounds which have been prepared for the first time are described below:

p-Methoxybenzyl Methyl Sulfoxide

This compound was prepared by oxidation of the corresponding sulfide (34) with sodium meta periodate (35). The product was a solid which, after recrystallization from ethyl acetate, had m.p. 60–61° (Previously reported to be 54–55° (37)).

Anal. Calcd. for $C_9H_{12}SO_2$: C, 58.7; H, 6.6. Found: C, 58.7; H, 6.6.

p-Methoxybenzyl Methyl Sulfone

This compound was prepared by oxidation of the sulfoxide with hydrogen peroxide in acetic acid. The sulfone after purification by recrystallization from ethyl acetate was a white solid, m.p. 108–109°.

Anal. Calcd. for $C_9H_{12}SO_3$: C, 54.0; H, 6.0. Found: C, 53.6; H, 6.0.

p-Chlorobenzyl Methyl Sulfoxide

Oxidation (35) of the corresponding sulfide (34, 36) gave a solid which after recrystallization from ethyl acetate had m.p. 98.5–100°.

Anal. Calcd. for C_8H_9ClSO: C, 50.9; H, 4.8. Found: C, 50.9; H, 4.8.

p-Aminobenzyl Methyl Sulfoxide

This sulfoxide was obtained by reduction of the corresponding *p*-nitro sulfoxide (37) in methanol with hydrogen (20 p.s.i.) and palladium (10% on charcoal) for 2 h. The product after recrystallization from ethyl acetate had m.p. 99–101.5°.

Anal. Calcd. for $C_8H_{11}NSO$: C, 56.8; H, 6.6. Found: C, 56.8; H, 6.7.

p-Aminobenzyl Methyl Sulfone

The corresponding *p*-nitro sulfone (35) was reduced with hydrogen and palladium (10% on charcoal) to give the *p*-amino sulfone, m.p. 161.5–162.5.

Anal. Calcd. for $C_8H_{11}NSO_2$: C, 51.9; H, 6.0. Found: C, 51.7; H, 6.0.

p-Aminobenzyl Phenyl Sulfoxide

A solution of 0.5 g of *p*-aminobenzyl phenyl sulfide (39) in 50 ml ethanol was treated dropwise with 0.5 g sodium meta periodate in 50 ml methanol. After stirring overnight the solution was filtered, the solvent evaporated, and chloroform was added. The chloroform solution was washed with water, dried and concentrated. The residue, after recrystallization from ethanol, was a light yellow solid, m.p. 155–156° which oxidized slowly on exposure to the atmosphere.

Anal. Calcd. for $C_{13}H_{13}NOS$: C, 67.5; H, 5.7; N, 6.0. Found: C, 67.0; H, 5.6; N, 5.1.

Transmission of polar effects. Part XI[1]. Polar and steric effects in the reactions of arylaliphatic carboxylic acids

KEITH BOWDEN AND R. C. YOUNG
Department of Chemistry, The University of Essex, Wivenhoe Park, Colchester, Essex, England

Received March 28, 1969

The rate coefficients for the reaction with diazodiphenylmethane in ethanol at 30° and the acid-catalyzed esterification with methanol at 60° of a number of arylaliphatic carboxylic acids and their pK_a values in 80% 2-methoxyethanol–water have been measured. Rate coefficients have also been measured for the alkaline hydrolysis in 70% dioxan–water of their 2-diethylaminoethyl esters at 45°. The pK_a values and diazodiphenylmethane esterification rate coefficients were also measured for a series of 2-substituted fluorene-9-carboxylic acids. The latter results have been correlated by Hammett equations and the transmission of polar effects in fluorene is discussed. Polar and steric substituent constants are evaluated for the arylaliphatic systems. These values are used to successfully correlate the hydrolysis and ionization reactions using the Taft–Ingold equation.

Canadian Journal of Chemistry, 47, 2775 (1969)

Introduction

An analysis of the activity of a series of antagonists of acetylcholine and histamine (2) required measurements of the polar and steric effects in the relevant arylaliphatic carboxylic acids. Taft (3) has described a separation of polar and steric effects in the arylaliphatic and aliphatic system using the polar and steric substituent constants, σ^* or σ_I, (4–6) and E_s respectively. Taft instituted the equations [1], [2], and [3] to correlate reactions controlled by polar, steric, or both effects, respectively.

$$[1] \qquad \log (k/k_0) = \rho^*\sigma^* \text{ (or } \rho_I\sigma_I)$$

$$[2] \qquad \log (k/k_0) = \delta E_s$$

$$[3] \qquad \log (k/k_0) = \rho^*\sigma^* \text{ (or } \rho_I\sigma_I) + \delta E_s$$

The relation [3], involving both polar and steric terms, has been called the Taft–Ingold equation (3). Several studies have used these relations successfully to correlate and separate the reactivity of arylaliphatic and aliphatic systems.

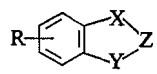
The Hammett equation [4] has been used extensively to correlate the reactions of meta- and para-substituents in benzene and similar systems (7). The transmission of polar effects

$$[4] \qquad \log (k/k_0) = \rho\sigma$$

has been investigated by a comparison of the reaction constants of a number of systems undergoing a common reaction (8). Jaffé (9) has adapted the Hammett equation to correlate reactivity in systems where the substituent can be considered formally as having both meta and para orientation with regard to the reaction site. This relation [5] correlates the transmission through the two links X and Y to a reactive site Z (**1**), where σ_X and σ_Y are the appropriate

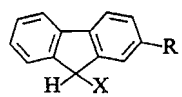
$$[5] \qquad \log (k/k_0) = \rho_X\sigma_X + \rho_Y\sigma_Y$$

Hammett σ values. Thus, ρ_X and ρ_Y describe the transmission by the links X and Y. A 2-sub-



1

stituent in fluorene (**2**, R) can be regarded as being a meta-substituent (direct) and a para-substituent (through the interannular link), with regard to a reactive site at the 9-position (**2**, X).



2

In the present study, the polar and steric substituent constants of a number of arylaliphatic groups have been estimated. These have been used to analyze and separate the factors controlling reactivity in other reactions. The transmission of polar effects in fluorene has been examined.

Results and Discussion

The rate coefficients for the reaction with diazodiphenylmethane (DDM) in ethanol at 30° and the acid-catalyzed esterification with methanol at 60°, and the pK_a values in 80% w/w 2-methoxyethanol–water (80% MCS) at 25° of a series of arylaliphatic carboxylic acids are shown in Table I. The rate coefficients for the alkaline hydrolysis of the 2-diethylaminoethyl esters in 70% v/v dioxan–water at 45° (where measurements could be made) are also shown in this Table.

Effect of 2-Substituents in Fluorene

In 2-substituted fluorene-9-carboxylic acids (Table I, acids 9, 18–23), the 2-substituent, relative to the reaction site, may be regarded as analogous to a meta-substituent in benzene (12). Using meta- σ values (13), good Hammett correlations are obtained for both the ionization and DDM reaction, as shown in Table II. However, the position of the substituent relative to the interannular link is analogous to the para-position in benzene. The extent of transmission by the latter route can be estimated by applying the Jaffé-adapted Hammett equation [5]. Somewhat better correlations are observed as shown in Table II. The much smaller contribution (11–23% of the total) for transmission "via the link" indicates the mainly meta-character of the 2-substituent effect in accord with the findings of earlier workers (12).

It is of interest to calculate the reaction constant ratio, ρ/ρ_0, (8), for the 2-substituted fluorene-9-carboxylic acid compared to the meta- and para-substituted benzoic acid system. This ratio is 0.68 (DDM esterification) and 0.71 (ionization in 80% MCS). The corresponding values for the phenylacetic acid system are 0.43 and 0.56 (in water) respectively (8). The increased transmission in the fluorene-9-carboxylic compared to the phenylacetic acid system could be due to either the extra route through the interannular link or the increased low dielectric cavity of fluorene transmitting the field effect.

Esterification of the Arylaliphatic Carboxylic Acids with Diazodiphenylmethane

The rate coefficients for the esterification of the arylaliphatic carboxylic acids with diazodiphenylmethane in ethanol at 30° are shown in Table I (acids 1–17).

Previous studies (11, 6) have demonstrated the absence of any significant primary steric effects on the rates of this reaction. The Taft equation [1] has been used to correlate the rate coefficients for this reaction of monosubstituted acetic acids with σ_I values very successfully. In this study, this relation [6] (6) has been used to calculate the σ_I values of the

$$[6] \qquad \log k = 2.441\,\sigma_I - 0.227$$

substituents which are shown in Table III. The additivity of similar substitutions has been discussed before (11). Noteworthy points from the present study are that the σ_I value of the 9-xanthene is significantly greater than

TABLE II

†Lit. values (6, 11).

the 9-thioxanthene system and that both are more electron-withdrawing than the systems (Table III; substituents 2, 8, 9) not having a heteroatom substituent. The first point is possibly due to the planar xanthene having a more favorable disposition of the dipolar substituent with regard to the reaction site. Substituents such as the *para*-MeO and -MeS are normally electron-releasing (13). The effect of insulating the reaction site, as in fluorene, and the symmetrical *ortho*-type substitution of the heteroatom probably easily outweighs any second-order resonance effects.

Acid-catalyzed Esterification of the Arylaliphatic Carboxylic Acids in Methanol

The rate coefficients for the acid-catalyzed esterification of the arylaliphatic carboxylic acids in methanol at 60° are shown in Table I. Steric substituent constants, E can be calculated from these rate coefficients and that for acetic acid (3, 11), as shown below [7], where log k_0 equals 1.34 (11). These steric parameters are shown in Table III and follow closely the pattern of those found previously (11). The small value found for 9-hydroxyfluorene-9-carboxylic acid (−0.90) appears to be due to hydrogen-bonded stabilization or "solvation" of the transition state. This E_s value will probably be applicable to reactions, such as alkaline hydrolysis and ionization, where similar interactions favor the reaction.

$$[7] \qquad E_s = \log (k/k_0)_A$$

Alkaline Hydrolysis of the 2-Diethylaminoethyl Esters of the Arylaliphatic Carboxylic Acids

The rate coefficients for the alkaline hydrolysis of the esters in 70% v/v dioxan–water at 45° are shown in Table I. A correlation of the results with polar and steric substituent constants using the Taft–Ingold equation [3] is very successful as shown in Table II. The polar and steric reaction constants, ρ_I and δ equal to 4.39 and 0.91 respectively, compare closely to those found previously for similar reactions (3, 14, 15). The 2-diethylaminoethyl esters studied here are hydrolyzed more rapidly than their methyl counterparts (14). All the esters in this report can be studied under similar conditions and near to ambient temperature. Only small extrapolations are necessary to obtain rate coefficients at a common temperature. An earlier investigation (14) of a more limited series of methyl esters gave a less well-defined and less general correlation. The present study confirms the Taft separation (3) of polar and steric effects in the alkaline hydrolysis reactions of arylaliphatic carboxylic esters.

Ionization of the Arylaliphatic Carboxylic Acids

The pK_a values of the arylaliphatic carboxylic acids in 80% MCS at 25° are shown in Table I. Our previous study (6) has demonstrated a good correlation of the pK_a values of a series of mono-substituted acetic acids in 80% MCS with σ_I values. A number of workers (16, 14) have shown that bulky groups inhibit the solvation of the carboxylate anions of aliphatic and arylaliphatic carboxylic acids. This causes acid weakening. An earlier investigation (14) indicated that the Taft–Ingold equation [3] could be used to correlate such systems. The more extensive results presented here are correlated excellently by this relation as is shown in Table II. The polar reaction constant, ρ_I equal to 4.02, compares closely with that for the mono-substituted acetic acids where ρ_I equals 4.04 (6). This confirms the meaningful nature of the correlation. The small size of the steric reaction constant, δ equal to 0.13, indicates the small role of steric effects unless the bulk of the substituent is very large.

The dominance of polar effects in this reaction is shown by the large ratio of the reaction constants, δ/ρ equal to 0.03, compared to that for the alkaline hydrolysis where δ/ρ equals 0.21.

Experimental

Materials

The acids were commercial samples or were prepared by standard methods. They were purified in order to give physical constants in good agreement with literature values. Neutralization equivalents were determined and were within 2% of the theoretical values, with the exception of 9-phenylfluorene-9-carboxylic acid (see Measurements). The 2-diethylaminoethyl esters of these acids were prepared as their hydrochlorides by reaction of either the acid chloride with 2-diethylaminoethanol or the acid with 2-diethylaminoethyl chloride (2).

Diazodiphenylmethane the solvents and reagents were prepared, purified, and stored as stated previously (6, 17).

Measurements

Rate Coefficients for Diazodiphenylmethane Esterification

These were determined, at 30° (±0.1°), as described previously (6), using a 10-fold excess acid concentration (0.06 *M*). 2-Aminofluorene-9-carboxylic acid was sparingly soluble in ethanol and was studied at equal acid and DDM concentrations (0.006 *M*).

pK_a Values

The pK_a values were determined, at 25° (±0.1°), as described previously (6). 9-Phenylfluorene-9-carboxylic acid was found to decarboxylate on neutralization and could not be measured in the usual manner. Therefore, pH readings were taken in rapid succession in the region of half-neutralization and the pK_a value estimated from the calculated half-neutralization point. This value is thus much more uncertain (±0.07). 9-*t*-Butylfluorene-9-carboxylic acid behaves similarly but at a much higher temperature. These two factors probably caused significant errors in a previous study (14).

Rate Coefficients for Acid-catalyzed Esterification

These were determined, at 60° (±0.1°), by a minor modification of the method described previously (17). The titrimetric apparatus used for the pK_a determinations (6) was used to titrate 1 ml samples of the reaction solution.

Rate Coefficients for Alkaline Hydrolysis of the Esters

These were determined, at 45° (±0.1°), by a titrimetric method using the apparatus described previously (6). The ester hydrochloride (0.02 *M*) was mixed thoroughly with "carbonate-free" sodium hydroxide (0.04 *M*) in 70% v/v dioxan–water at the reaction temperature. Immediately, a 1 ml sample of the reaction solution was withdrawn and placed in the titration vessel at 20°. Timing was commenced at half-addition of the latter and titrated immediately and swiftly with aqueous hydrochloric acid (0.05 *M*) from the micrometer syringe to an end point characterized by a sharp decrease in pH at approximately pH 11.6. Further samples were withdrawn at timed intervals and titrated immediately. This technique required an interval between measurements of approximately 4 min. It was necessary to make measurements at lower temperatures for the two most reactive esters and, also, to thermostat the titration vessel at these temperatures. The rate coefficients can be calculated in the manner previously described (17).

It was found impossible to measure satisfactorily the rates of alkaline hydrolysis of the esters of fluorene-9-carboxylic acids having an unsubstituted 9-position. A competing process produces the corresponding carbanion.

Photochemical behavior of some α,β-unsaturated lactams. Dependence of reaction path on multiplicity

E. CAVALIERI[1] AND S. HOROUPIAN

Department of Chemistry, University of Montreal, Montreal, Quebec

Received November 15, 1968

Whereas direct irradiation (2537 Å) of 5,6-dihydro-4,6,6-trimethyl-2(1*H*)-pyridone **1** (1*a*) produced almost exclusively the cleavage products **2** and **3**, the acetophenone sensitized reaction (3500 Å) gave a single cyclobutane dimer. In contrast, direct (2537 Å) or sensitized (acetophenone, 3500 Å) irradiation of the *homo* derivative **7** of compound **1** gave approximately the same mixture of two cyclobutane dimers. It was thus demonstrated that dimer formation proceeded by way of a triplet excited state and that the cleavage reaction most probably occurred *via* an excited singlet state.

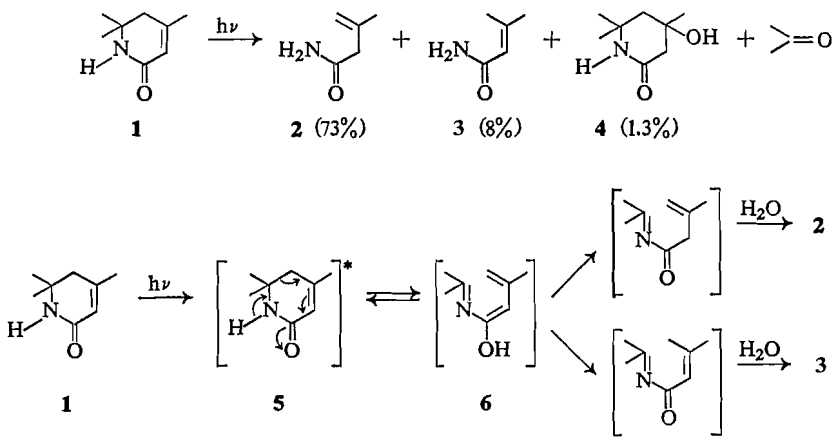
A structure for each cyclobutane dimer in the seven-membered series was proposed on the basis of its spectral properties.

Canadian Journal of Chemistry, 47, 2781 (1969)

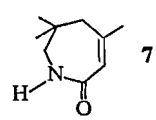
Introduction

We have recently shown (1*a*) that irradiation (2537 Å) in water of 5,6-dihydro-4,6,6-trimethyl-2(1*H*)-pyridone **1** produced the amides **2** and **3** together with a small amount of the photohydrate **4**.

The mechanism of this photochemical reaction was demonstrated to occur as depicted below (1*b*):



The proposed intermediate **6** was not isolable under the reaction conditions as it was rapidly hydrolyzed to compounds **2** and **3** and acetone. On the other hand, compound **4** was very probably derived from the addition of water to the electronically excited intermediate **5** or a strained ground-state molecule directly derived from it (2). When this photochemical reaction was carried out in dry *t*-butyl alcohol the cleavage reaction occurred very slowly (1*a*, 1*b*). Moreover, no traces of dimer were recovered. Based on the above mechanism it was anticipated that the *homo* derivative **7** would probably not undergo a



7

photochemical cleavage reaction analogous to that observed for the δ-lactam **1**. Indeed, one might have expected a dimerization of the type observed for carbostyril (3), isophorone (4), and many other α,β-unsaturated carbonyl compounds, or cyclization to a bicyclic β-lactam in a

[1]Present address: University of California, Chemical Biodynamics Laboratory, Lawrence Radiation Laboratory, Berkeley, California 94720.

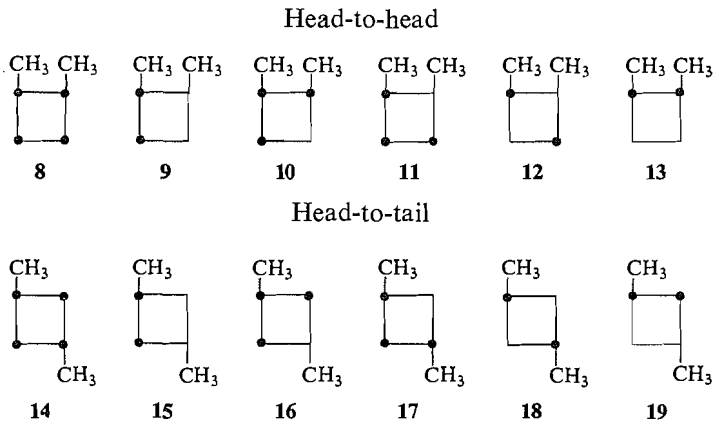


FIG. 1. Possible isomeric forms of dimers.

process similar to that demonstrated to occur on irradiation of certain acrylamides (5).

Results

Unsensitized Irradiation

Irradiation of a dilute (8.7×10^{-2} *M*) aqueous solution of the ε-lactam **7** at 2537 Å for 15 h resulted in the precipitation of an insoluble solid in 82.5% yield which could be separated into two components by virtue of their different solubility in dichloromethane.

The major, soluble product (96%) had m.p. 259–265°.[2] The molecular weight, parent peak at *m/e* 306 in the mass spectrum, and the combustion analysis established the dimeric nature of this compound. The infrared spectrum possessed absorptions at 3450 and 1665 cm^{-1} attributable respectively to the NH and carbonyl vibrations of a lactam.

The nuclear magnetic resonance (n.m.r.) spectrum in deuteriochloroform showed the methyl hydrogens as a complex multiplet centered at δ 1.25, the methylene protons as a series of multiplets absorbing between δ 2.15 and 3.80, the cyclobutane hydrogens as singlets at δ 4.89 and 5.00 ($\Delta\nu$ = 7.0 c.p.s.), and the two NH protons as a broad multiplet centered at δ 6.05. When the solvent was changed to trifluoroacetic acid, the spectrum was largely similar except that the absorptions were shifted by about 0.2 p.p.m. to lower field, the NH protons occurred as two broad singlets at δ 7.4 and 8.0 and the singlets assigned to the cyclobutane protons were now separated by 12.8 c.p.s. At 100 Mc.p.s. in deuteriochloroform the line spacing between the two singlets was 11.6 c.p.s. Furthermore, the expanded scale revealed that the peaks corresponding to each proton were split by 0.5 c.p.s.; a decoupling experiment showed this to be a weak coupling constant.

Given the non-equivalence of and the very weak coupling constant between these protons, all those dimers possessing adjacent cyclobutane hydrogens or symmetry elements can be excluded (6). Consequently only dimers **16** and **17** (see Fig. 1) are thus left for consideration. Inasmuch as *trans*-1,3-protons on a cyclobutane ring are known to be weakly coupled (J = 0.5 c.p.s.) (7), the dimer possessing *cis*-1,3-hydrogens **16** is disregarded over the alternative *trans* formulation **17**.

The minor, dichloromethane insoluble, material, m.p. 346–347° (homogeneous on t.l.c.), was also shown to be dimeric. Its infrared spectrum (Nujol mull) had absorption bands at 3320, 1645, and 1625 cm^{-1} ascribable to the NH and carbonyl moieties respectively of a lactam. The n.m.r. spectrum in trifluoroacetic acid showed the methyl hydrogens as a complicated multiplet centered at δ 1.38, the methylene protons as a series of multiplets between δ 2.40 and 4.00, the cyclobutane protons as two singlets at δ 5.10 and 5.18 ($\Delta\nu$ = 5.2 c.p.s.)[3] and

[2]The melting point remained unchanged after repeated recrystallization. The compound was shown to be homogeneous by thin-layer chromatography (t.l.c.) in alumina using two different solvent systems.

[3]At 100 Mc.p.s., in trifluoroacetic acid, the spacing was 8.4 c.p.s. and the expansion trace showed again the two protons as singlets.

the NH protons as two broad absorptions centered at δ 8.40 and 9.28. For the same principle applied above, all those dimer possessing adjacent, cyclobutane hydrogens or symmetry elements can be excluded. Furthermore, considering the lack of a weak coupling constant (7), it follows that only **16** (Fig. 1) remains as a possible structure.

Sensitized Irradiations

The acetophenone (E_T 73.5 Kcal/mole) sensitized photolysis of the ε-lactam (E_T 69 Kcal/mole, see Experimental) in water produced the same two dimers in approximately the same proportion as was obtained in the unsensitized experiment. Whereas in this series, both the sensitized and unsensitized photolysis provided the same products (dimers), in the six-membered series (δ-lactam **1**, E_T 68 Kcal/mole, see Experimental) only the sensitized irradiation (3500 Å, acetophenone sensitizer) provided dimeric material (for the products of the unsensitized photolysis, see Introduction). The rate of sensitized disappearance of the ε-lactam was about ten times greater than that observed for the corresponding δ-lactam (Fig. 2). In the latter case a single dimer, m.p. 343–345°, was isolated in 48% yield.[4] Its infrared spectrum had absorptions at 3380 and 1640 cm^{-1} for the NH and carbonyl vibrations of a lactam. The n.m.r. spectrum showed the *geminal* methyl groups as two closely spaced singlets at δ 1.22 and 1.25, the remaining methyl groups as a singlet at δ 1.57, the methylene protons as a singlet at δ 1.74, the cyclobutane hydrogens as a sharp singlet (even at high resolution) at δ 2.44, and the NH protons at δ 6.23.

If one excludes those dimers with structures **12**, **13**, **18**, and **19** on the basis of strain and **10**, **11**, **16**, and **17** on symmetry principles then the two head-to-head dimers **8** and **9**, and the two head-to-tail dimers **14** and **15** are equally compatible with a singlet absorption for cyclobutane hydrogens (6).

Discussion

Since the sensitized and unsensitized[5] photolysis of the ε-lactam gave the same two dimers in about the same proportion, their formation might have occurred *via* the triplet state. A valid support to this assertion was provided by the lack of fluorescence of the ε-lactam (in the same way as the δ-lactam) at room temperature in absolute ethanol. The non-emitting singlet excited state means that the rate of decay of this state must be higher than 5×10^{10} s^{-1}. Having observed dimerization of the ε-lactam even in very dilute solutions, i.e. 10^{-3} *M*, and considering this reaction to be diffusion-controlled ($K_{dim} \leq 5 \times 10^9$ M^{-1} s^{-1}), it then follows that the maximum quantum yield for dimer formation from the singlet state would be 10^{-4}. In other words, the very short lifetime of the excited singlet makes it an unlikely precursor for the dimer at room temperature because of the longer times required for the monomers to diffuse together. Besides, the relatively high rate of disappearance of this lactam in the unsensitized reaction (see Fig. 3) indicates that singlet–triplet intersystem crossing is probably quite efficient.

On the other hand, the complete lack of dimer formation during direct irradiation of δ-lactam in water and especially in *t*-butyl alcohol (see Introduction) suggested that singlet–triplet intersystem crossing was inefficient as compared to the cleavage reaction observed from the singlet state (see below). The fact that δ-lactam phosphoresced in ethanol at low temperature conflicted

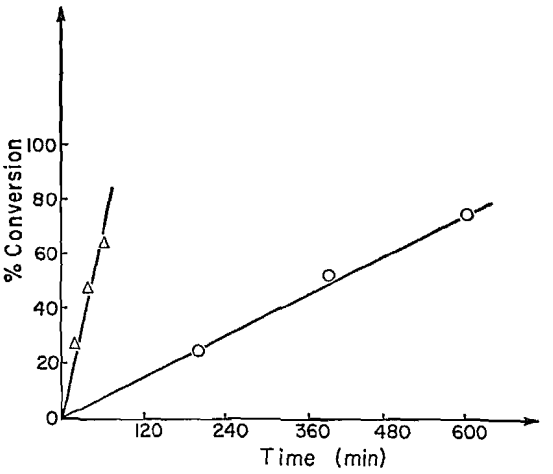

FIG. 2. Rate of acetophenone (2×10^{-2} *M*) sensitized disappearance in water – *t*-butanol 9: 1 at 3500 Å for the ε-lactam **7** (2×10^{-2} *M*, Δ) and δ-lactam **1** (2×10^{-2} *M*, O).

[4]The absence of photoamides **2** and **3** (see Introduction) in the crude product was clearly shown by thin-layer chromatography, and infrared and nuclear magnetic resonance spectroscopy.

[5]The same unsensitized irradiation of the ε-lactam in *t*-butyl alcohol produced dimers at about the same rate as in water.

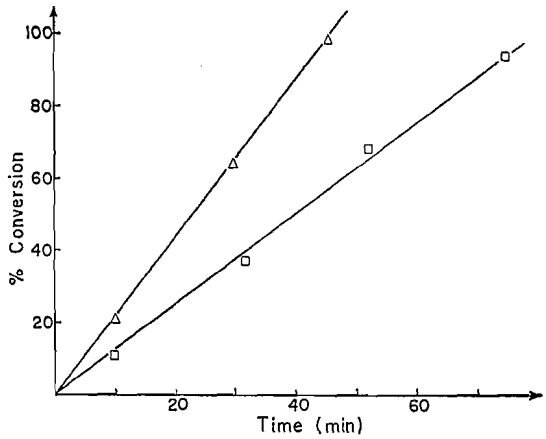

FIG. 3. Rate of disappearance of (2×10^{-2} *M*) lactams **1** (□) and **7** (△) in water.

with this explanation. We therefore think that the cleavage of the C—C bond provides a pathway for radiationless loss of singlet excitation energy which competes successfully with intersystem crossing. At 77 °K in frozen solvent the breaking of the C—C bond might be somehow prevented and the intersystem crossing then becomes a competitive process giving rise to phosphorescence (8). Inasmuch as the sensitized irradiation of the δ-lactam gave exclusively dimer formation, one can conclude that this reaction must proceed through a triplet state. The ring cleavage reaction which occurred upon direct photolysis, therefore must probably involve an excited singlet state.

As previously stated, the spectroscopic properties of the dimers were sufficient to establish the precise stereochemistry in the seven-membered series only. It was indeed found that the two cyclobutane dimers were formed by head-to-tail combination and that both possessed a *cis* (between the seven- and four-membered rings) and a *trans* (between the seven- and four-membered rings) junctions (see **16** and **17**, Fig. 1).[6] A knowledge of the stereochemistry of the dimer in the six-membered series is equally important because it may provide information concerning the nature of triplet state(s) which led to their formation (4). A chemical proof of the structure of the dimers in both series is therefore now in progress.

[6]Other products with *trans*-fused four- and six-membered rings have already been observed in photocycloaddition reactions (9, 10).

Experimental

The ultraviolet spectra were recorded in water using a Cary model 14 recording spectrophotometer.

The fluorescence and phosphorescence spectra were scanned in absolute ethanol at room temperature and at 77 °K respectively using an Aminco–Bowman spectrophotofluorometer (the solvent was distilled twice with a fractionating column and the lactams were sublimated after repeated recrystallizations).

The nuclear magnetic resonance (n.m.r.) spectra were determined on Varian A60 and HR-100 spectrometers using deuteriochloroform (unless otherwise specified) with tetramethylsilane as the internal standard.

The infrared spectra were recorded in chloroform (unless otherwise specified) on a Perkin–Elmer 621 and a Beckman IR-8 spectrophotometer.

The mass spectra were recorded on a Hitachi – Perkin – Elmer RMμ-D mass spectrometer.

The melting points were taken on a Büchi *Schmelzpunktbestimmungapparat* and are uncorrected.

The photolyses were carried out using a Rayonnet photochemical reactor. Prior to irradiation the solutions were flushed with oxygen-free nitrogen for at least 10 min.

The analyses were performed by Dr. C. Daesslé, Organic Microanalyses, Montreal.

5,6-Dihydro-4,6,6-trimethyl-2(1H)-pyridone **1**

This compound was prepared according to the method of Hall (11) and after purification in the manner to be described (sublimation) by Cavalieri and Gravel (1*b*) it had m.p. 118° (reported (11) m.p. 116.5–118°). The ultraviolet spectrum had an absorption maximum at 2128 Å (ε = 15 600) with a shoulder at 2300–2400 Å (ε = ~4300). The phosphorescence spectrum was measured in absolute ethanol at 77 °K and gave a triplet energy (0,0 band maximum) of 68 Kcal/mole.

6,7-Dihydro-4,6,6-trimethyl-2(1,5-H)-azepinone **7**

This lactam was prepared in the manner described by Mazur (12). After three recrystallizations from hexane–acetone and sublimation *in vacuo* at 95°/0.05 mm it had m.p. 109–110° (reported (12), m.p. 112–113°, and (13) m.p. 108.8–109.1°). The infrared spectrum had absorptions at 3440, 1657, and 1616 cm^{-1}. The n.m.r. spectrum showed peaks at δ 0.97 (6H, singlet), 1.92 (3H, doublet, J = 1.2 c.p.s.), 2.04 (2H, singlet), 2.82 and 2.92 (2H, singlets), and 5.74 (1H, quadruplet, J = 1.2 c.p.s.).

The ultraviolet spectrum had a maximum at 2203 Å (ε = 13 000), with no observable shoulder.

The phosphorescence spectrum in absolute ethanol at 77 °K gave a triplet energy (0,0 band maximum) of 69 Kcal/mole.

Irradiation of ε*-Lactam* **7**

(a) Unsensitized

A solution of lactam **7** (4 g) in 300 ml of distilled water was irradiated at 2537 Å for 15 h. A white precipitate of dimeric material separated from the solution during the photolysis. After filtration and drying the residue

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

weighed 3.33 g (82.5%) and had m.p. 256–261°. A small amount (180 mg, 5.5%) of this solid was not soluble in dichloromethane. The soluble portion was obtained on evaporation of the solution *in vacuo*. After two recrystallizations from methanol–water a white solid with m.p. 259–265° was obtained.

Anal. Calcd. for $C_{18}H_{30}N_2O_2$: C, 70.58; H, 9.87; N, 9.14. Found: C, 70.79; H, 9.87; N, 8.90.

The mass spectrum showed the parent peak at *m/e* 306. The infrared spectrum had bands at 3450 and 1665 cm^{-1}. The n.m.r. spectrum possessed absorptions at δ 0.80–1.50 (18 H, methyl hydrogens), 2.15–3.80 (8 H, methylene hydrogens), 4.83 and 5.00 (2H, singlets $\Delta\delta$ = 7.0 c.p.s. methyne hydrogens) and 6.05 p.p.m. (2H, NH, broad multiplet).

The dichloromethane insoluble solid was washed with methanol; it then had m.p. 346–347° (decomp.) and was shown to be homogeneous by thin-layer chromatography, infrared and nuclear magnetic resonance spectroscopy.

Anal. Calcd. for $C_{18}H_{30}N_2O_2$: C, 70.58; H, 9.87; N, 9.14. Found: C, 70.61; H, 10.03; N, 8.94.

The mass spectrum gave the parent peak at *m/e* 306. The infrared spectrum (Nujol mull) showed bands at 3320, 1645, and 1625 cm^{-1}. The n.m.r. spectrum (CF_3COOH) had absorptions at δ 0.97–1.82 (18H, methyl hydrogens), 2.40–4.00 (8 H, methylene hydrogens), 5.10 and 5.18 (2 H, singlet, $\Delta\nu$ = 5.2 c.p.s., methyne hydrogens), 8.40 and 9.28 (2 H, NH broad bands).

(b) Sensitized

A 6.54 × 10^{-2} *M* solution (100 ml: 90 ml of distilled water and 10 ml of distilled *t*-butanol) of the ε-lactam which was 2 × 10^{-2} *M* in acetophenone was irradiated at 3500 Å for 4.33 h.

The precipitated dimeric solid was separated by filtration and after drying it weighed 566 mg. The product was separated into dichloromethane insoluble and soluble fractions as before. The insoluble portion after washing with methanol and drying weighed 30 mg and had m.p. 346–347° (decomp.). The infrared and n.m.r. spectra were identical to that of the minor dimer produced in the unsensitized photolysis.

The dichloromethane soluble fraction after usual work-up gave a solid (536 mg) which had m.p. 259–264°. The infrared and n.m.r. spectra were indistinguishable from that of the major dimer obtained in direct photolysis experiment.

Irradiation of the ε-lactam at 3500 Å in the absence of acetophenone but under otherwise identical conditions resulted in the complete recovery of starting material.

Photosensitized Dimerization of δ-Lactam ***1***

A solution of the δ-lactam **1** (2 g, 1.44 × 10^{-2} moles) in 180 ml of distilled water and 20 ml of distilled *t*-butanol which was 1 × 10^{-2} *M* in acetophenone were irradiated at 3500 Å for 27 h. The *t*-butanol was removed *in vacuo* and the residue was extracted with ether to remove the acetophenone. The aqueous phase was saturated with ammonium sulfate and the product was then extracted into chloroform. The extract was dried over sodium sulfate and on evaporation *in vacuo* 1.725 g of crude product remained.

On recrystallization from dichloromethane ether 0.960 g (48%) of the pure dimer, m.p. 343–345° (decomp.) was obtained.

Anal. Calcd. for $C_{16}H_{26}N_2O_2$: C, 69.02; H, 9.41; N, 10.06. Found: C, 69.09; H, 9.29; N, 10.21.

The infrared spectrum had bands at 3380 and 1640 cm^{-1}. The n.m.r. spectrum had absorptions at δ 1.22 and 1.25 (12 H, 2 singlets, *geminal* methyl protons), 1.57 (6 H, singlet, methyl protons), 1.74 (4 H, methylene protons), 2.44 (2 H, singlets, methyne protons on cyclobutane ring), and 6.23 p.p.m. (NH, relatively sharp).

Measurement of the Rate of Photochemical Disappearance of Lactams ***1*** *and* ***7***

Solutions (2 × 10^{-2} *M*) of the lactams **1** and **7** in distilled water were irradiated in two separate quartz vessels at 2537 Å at near 30°. Aliquots were removed periodically, saturated with ammonium sulfate, extracted with chloroform, and dried over sodium sulfate. The extracts were evaporated *in vacuo* and the residue was dissolved in a standard amount of chloroform and the optical density of the infrared double band absorption (1623 cm^{-1} for **1** and 1616 cm^{-1} for **7**) was determined. The data thus obtained are recorded graphically in Fig. 3.

Measurement of the Rate of Acetophenone Sensitized Disappearance of Lactams ***1*** *and* ***7***

Solutions (2 × 10^{-2} *M*) of lactams ***1*** and ***7*** in distilled water and distilled *t*-butanol (9:1) were irradiated at 3500 Å in separate runs which were both 2 × 10^{-2} *M* in acetophenone. Aliquots were removed periodically and treated the same as above.

The data thus obtained are recorded graphically in Fig. 2.

Synthesis of highly hindered diphenyl ethers[1]

GEORGE A. NEVILLE
Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada

AND

ROBERT Y. MOIR
Department of Chemistry, Queen's University, Kingston, Ontario

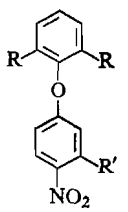
Received February 11, 1969

A new modification of the Hems synthesis for diphenyl ethers is reported. The preparation of 11 tetra-ortho-substituted, 12 tri-ortho-substituted, and 4 di-ortho-substituted diphenyl ethers is described for the action of various phenols on *N*-(4′-carbomethoxy-2′,6′-dinitro)phenylpyridinium chloride. Some factors governing product formation are discussed on the basis of the extensive number of successful as well as unsuccessful reactions.

Canadian Journal of Chemistry, 47, 2787 (1969)

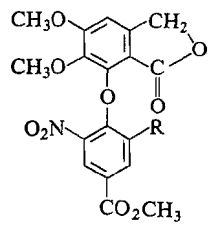
Introduction

Highly hindered diphenyl ethers form an admirable series for the study of aromatic conformations (1–3). Since most of the conformational conclusions are reached by difference or by double-difference techniques (2), the synthesis of large numbers of related ethers is required. We have reviewed the available synthetic methods (1), and now draw attention to the ethers of type **1** recently reported by Wright and Jorgensen (4) in which two very bulky groups were placed in the ortho-positions. These were made by the action of phenolates on activated aryl halides in dimethyl sulfoxide.



1, R = Me, *i*-Pr, *sec*-Bu, *t*-Bu, R′ = H, Me

In this paper there is described the synthesis of a large number of much more hindered diphenyl ethers by a new modification of the Hems synthesis. In former papers (5, 1, 2) we reported the synthesis of ethers such as **2**, already respectably hindered. By the new modification, it was possible to insert much larger ortho-groups to produce



2, R = NO_2, NH_2, NHOAc

compounds of great interest for continuing investigations of the limits of the Hems synthesis, the lifetime of ether enantiomers (1), and the determination of conformation by spectroscopy (2).

Synthesis of Hindered Diphenyl Ethers

The *Hems synthesis* of diphenyl ethers is based on a reaction discovered by Borrows *et al.* (6) which has as its essential step the reaction of a phenol with an activated *N*-phenyl pyridinium salt, e.g. **3***a*. Allen and Moir (1), in discussing the superiority of this synthetic route for the preparation of quadruply ortho-substituted diphenyl ethers, cited many failures of the Ullmann reaction (7, 8) and showed that the lower requirements for activation (6, 5) in the Hems synthesis make it more promising for the preparation of such highly hindered ortho-substituted diphenyl ethers than the well-known reaction of a phenol, a base, and an activated aryl halide (9–11).

A major problem with the Hems synthesis of diphenyl ethers having large steric hindrance in the ortho-positions has occurred when the reaction mixture was poured into ice water. A tar formed from which it was very difficult to extract

any diphenyl ether even when the preferred method (1) of first treating the tar or gum with dilute hydrochloric acid to decompose the pyridinium salts (precursor **3***a* and by-product **3***b*[2]).

By an embarrassingly simple modification to the Hems synthesis, involving addition of the reaction mixture to a mixture of acidified ice–water and chloroform and shaking of the combined mixture for ½ h before separating the phases, the synthesis and ordinarily unrewarding isolation of highly hindered diphenyl ethers has now been transformed into an operation of remarkable ease. Indeed, by this treatment, the product crystallizing from the ethanol–chloroform concentrate[3] (see Experimental) in yields ranging from 32–97% is comparable to a once recrystallized product from the unmodified synthesis.

4

Ethers Prepared by the Modified Hems Synthesis and Discussion of Some Factors Affecting Their Synthesis

The diphenyl ethers synthesized may be conveniently classified into six groups **5**, **6**, **7**, **8**, **9**, and **10** by virtue of the substitution derived from the phenolic moiety. In addition, five other diphenyl ethers, **11–15**, were prepared. All of these ethers were prepared using the conditions developed for the modified *Hems synthesis* (except **5***a* which was prepared using the unmodified Hems synthesis), and the percentage yield[4] (Table I) for each diphenyl ether from the chloro

[2]Invariably one obtains a small quantity of bright-yellow solid by-product (4 to 9% from the chloro ester) identified as *N*-(4-carbomethoxy-2,6-dinitrophenyl)pyridinium 4′-carbomethoxy-2′,6′-dinitrophenoxide (**3***b*) (1) in the Hems synthesis. Using the modified Hems synthesis we have found that when a reaction gives a good yield of diphenyl ether, a negligible quantity (0.5–1% from chloro ester) of by-product forms, but when no reaction occurs under the standard conditions, an appreciable quantity of the "yellow salt" normally forms.

[3]At the conclusion of our work, we noticed that Zenker and Jorgensen (12) had previously used a similar modification of the Hems synthesis, in which chloroform was introduced with the reactants, rather than at the isolation stage as in the present method. Although the difference may seem trivial at first sight, their method in the preparation of very hindered ethers led, in our hands, to a great decrease in the rate of reaction, with the consequent increased recovery of starting materials and by-products.

[4]Percentage yields varied with conditions in a complex fashion. When heating under reflux was performed with an oil bath instead of with a steam bath, the yield of **6***a* dropped from 77 to 72%, but the yield of **5***c* rose from 32 to 46%. Increasing the scale of the preparation sometimes depressed the yields, and prolonged contact with dilute acid during the isolation procedure had a distinctly deleterious effect.

ester[5] (except where noted) is that obtained by heating the reaction mixture under reflux for 1 h on a steam-bath.

Effect of Size of the R_1 and R_2 ortho-Substituents

When the size of the R_1 and R_2 ortho-substituents in class **6** diphenyl ethers was large, no isolation of diphenyl ether was possible as found for the following combinations:

TABLE II

Dependence of by-product on the size of the R_1 and R_2 ortho-substituents

R_1	R_2	% By-product (3*b*)
$C(CH_3)_3$	$C(CH_3)_3$	6.2*

CH_3	$CH_2CH_2CH_3$	None
NO_2	NO_2	28†

*11% of the chloro-ester reactant was recovered unchanged.
†40% of the phenolic reactant was recovered unchanged.

Steric factors alone may not provide an explanation for lack of diphenyl ether formation. Steric hindrance from the ortho-substituents of 2-methyl-6-*n*-propylphenol, which may not have reacted,[6] would be little different from that in 2-methyl-6-allylphenol, which did give a product (**6***c*) in moderately low yield. Similarly the steric hindrance of the nitro groups from 2,6-dinitrophenol is not especially large, particularly when these can be easily twisted out of the plane of the benzene ring (13). With ortho-nitro groups, an unfavorable factor seems to be the activation of

[5]The expression "chloro ester" is used for convenience and refers to methyl 4-chloro-3,5-dinitrobenzoate.
[6]No diphenyl ether was isolated from an intractable syrup in great contrast to the ease with which diphenyl ethers crystallized under the conditions of the modified Hems synthesis.

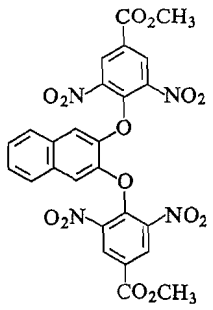
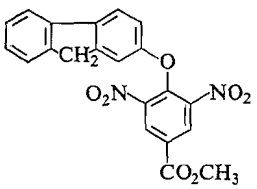
13



14

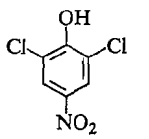


15

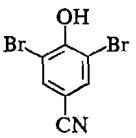
the resulting ethers for cleavage. The only example known to us where a report of the synthesis of a diphenyl ether with four ortho-nitro groups is that by Beckwith and Miller (14) for the preparation of 2,2′,4,6,6′-pentanitro-4′-methyldiphenyl ether in 87% yield by heating picryl chloride and potassium 2,6-dinitro-4-methylphenoxide under reflux with 1:1 aqueous acetonitrile for 5 min. In view of our failure to prepare 4-carbomethoxy-2,2′,6,6′-tetranitrodiphenyl ether either by the Hems synthesis or by the method of Barnes *et al.* (15), which is similar to the above method of Beckwith and Miller, it appears puzzling that Beckwith and Miller succeeded in synthesizing this sterically hindered compound; however, its synthesis was achieved by three different methods[7] and its composition was established by scission[8] with pyridine and with sodium methoxide. It is unlikely that the 2,2′,4,6,6′-pentanitro-4′-methyldiphenyl ether could be prepared by the Hems synthesis since the compound is highly activated for cleavage by pyridine. In contrast, diphenyl ethers with three ortho-nitro substituents appear to be insufficiently activated to suffer much competing scission by pyridine since Borrows *et al.* (6) were able to prepare 4-methyl-2,2′,4′,6-tetranitrodiphenyl ether (a yellow oil, b.p. 40–60°/10^{-4} mm Hg) in 38% yield using the Hems synthesis. Later Beckwith and Miller (14) obtained the same compound in solid form (m.p. 160°, 85%) after inducing crystallization of the dark oil resulting from the decomposition of *N*-(2,4-dinitrophenyl)-pyridinium-2′,6′-dinitro-4′-methylphenoxide in boiling anisole. More recently, Chandler[9] prepared 2-nitro-4-carbomethoxy-2′,6′-dinitro-4′-carbomethoxydiphenyl ether in 42% yield using the Hems synthesis.

Effect of para-Electronegative Substituents in the Phenol

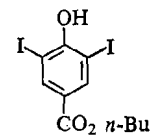
Whereas good yields were obtained for class **7** and **8** diphenyl ethers, it appears that the introduction of an electron-withdrawing conjugating substituent in the para-position of the phenols, **16**, **17**, and **18** prevented ether formation. The



16



17



18

high yields of the class **7** diphenyl ethers indicate that neither chlorine nor bromine ortho-substituents provide enough steric hindrance to interfere greatly with synthesis; moreover, the synthesis of 2′,6′-diiodo-4′-methyl-4-carbomethoxy-2,6-dinitrodiphenyl ether in 51% yield by Barnes *et al.* (15) shows that two ortho-iodine substituents can be accommodated with two ortho-nitro groups. Raiford and Colbert (16) have observed that 2,4-dinitrophenol fails to react with any of chlorobenzene, *o*-nitrochlorobenzene, or with *p*-nitrochlorobenzene. Although the combined mesomeric and inductive electron withdrawal by the nitro groups may lower the electron density of the phenolic oxygen to such an extent that 2,4-dinitrophenol is too weakly nucleophilic for the weakly activated chlorobenzenes above, Raiford and Colbert found that diphenyl ethers were always obtained regardless of the substituents on the phenol when 2,4-dinitrochlorobenzene is

[7]2,2′,4,6,6′-Pentanitro-4′-methyldiphenyl ether was prepared by Beckwith and Miller as above; in 21% yield by simply heating the above starting materials together for 30 min at 160° without a solvent, and in 49% yield by decomposition of *N*-picrylpyridinium 2,6-dinitro-4-methylphenoxide in boiling anisole.

[8]Scission with sodium methoxide gave 89% of 3,5-dinitro-*p*-cresol and 78% picryl methyl ether, whereas scission with pyridine gave a 95% yield of *N*-picrylpyridinium 2,6-dinitro-4-methylphenoxide.

used, and they cite the synthesis and yields of the following diphenyl ethers: 2,4-dinitro-4′-bromodiphenyl ether (100%), 2,4-dinitro-4′-chlorodiphenyl ether (97%), 2,4,2′-trinitrodiphenyl ether (89%), 2,4,3′-trinitrodiphenyl ether (77%), 2,4,4′-trinitrodiphenyl ether (97%), 2,4-dinitro-2′,4′,6′-tribromodiphenyl ether (28%), 2,4,2′-trinitro-4′-chlorodiphenyl ether (87%), and 2,4,2′-trinitro-4′-bromodiphenyl ether (95%). The synthesis and yield of 2,4,2′,4′-tetranitrodiphenyl ether are conspicuous by their absence from this list; however, Raiford *et al.* (16) may simply have omitted their experimental details since this diphenyl ether had been synthesized many years earlier by Willgerodt (17) by heating 2,4-dinitrochlorobenzene and potassium 2,4-dinitrophenolate together at 180–200°. A reasonable explanation for the lack of diphenyl ether formation from 2,6-dinitrophenol, 2,6-dichloro-4-nitrophenol, and 2,4-dibromo-6-nitrophenol with methyl-4-chloro-3,5-dinitrobenzoate by the Hems synthesis appears to be that any such diphenyl ether formed would be extremely easily cleaved by pyridine or water, due to the combined effects of steric compression and activation of the ethereal linkage for cleavage by the electron withdrawing substituents of both rings. In order to test this hypothesis, an attempt was made to synthesize the corresponding diphenyl ethers by the action of 2,6-dinitrophenol, 2,6-dichloro-4-nitrophenol, *n*-butyl-4-hydroxy-3,5-diiodobenzoate, 5-chloro-8-hydroxy-7-iodoquinoline, and 2,4-dibromo-6-nitrophenol on methyl 4-chloro-3,5-dinitrobenzoate using the mild conditions of Barnes *et al.* (15) which involve refluxing the reactants in methyl ethyl ketone with anhydrous potassium carbonate. In each case, no diphenyl ether was formed, and only the reactants or potassium salts derived from the reactants were recovered. Since the procedure of Barnes *et al.* (15) is successful for the synthesis of 2′,6′-diiodo-4′-methyl-4-carbomethoxy-2,6-dinitrophenyl ether but fails when the CH_3 group of this diphenyl ether is replaced by the carbo-*n*-butoxy group, one can only conclude that synthesis of highly hindered diphenyl ethers from strongly activated aryl halides and moderately activated phenols, either by the Hems synthesis or by the uncatalyzed, mild Ullmann-type condensation, involves a delicate system in which steric, polar, and dipolar factors must be accommodated to result in product formation.

Factors Affecting the Formation of bis-Diphenyl Ethers

It should be noted that even with reactant ratios favoring formation of the mono-ether, 3-methylcatechol gave only the bis-ether **12**. There are two ways to account for exclusive formation of the bis-ether. One explanation consistent with the view that the 2-hydroxyl group should have the greater electron density, is a two-step reaction involving initial rapid attack by the 2-hydroxyl group followed by attack by the 1-hydroxyl group on the pyridinium salt intermediate to give the bis-ether. If nucleophilic attack involved the 1-hydroxyl group first, then steric hindrance of this mono-ether would inhibit further reaction providing no rearrangement could occur. The second explanation rests on the assumption of a facile intranucleophilic attack on the ethereal linkage by the 2-hydroxyl group (Smiles' rearrangement)[10] to form a new ethereal linkage leaving a hydroxyl group in the 1-position with a minimum of steric hindrance (Fig. 1).

Another unexpected finding was that 2,3-dihydroxynaphthalene gave the bis-ether (**14**) exclusively with reactant ratios favoring formation of mono-ether, and gave the mono-ether (**13**) as the major product with reactant ratios favoring formation of the bis-ether. In addition, the bis-ether exhibited marked dimorphism which is of particular interest in view of the recent finding of two crystalline modifications of 1,1′-binaphthyl by Badar *et al.* (18) and of similar phenomena in other diphenyl ethers (2).

Experimental

All melting point (m.p.) determinations, except where noted, were obtained with Anschütz immersion thermometers using an electrically heated precision melting apparatus (19) containing Dow Corning 550 fluid. Thin-walled capillary tubes were drawn from cleaned $\frac{3}{4}$ in. Pyrex tubing. Some m.p. determinations were made using a Kofler hot stage apparatus and are reported uncorrected. Refractive indices were measured on a thermostatted Abbé refractometer, and all readings are reported corrected on the basis of readings of distilled water.

Purification of Phenols

The substituted phenols used in this work were obtained either from the Aldrich Chemical Co., or from Distillation Industries Products (Eastman). Solid phenols, whose

[10]An extensive study of this rearrangement had been made previously in these laboratories by W. D. Chandler.

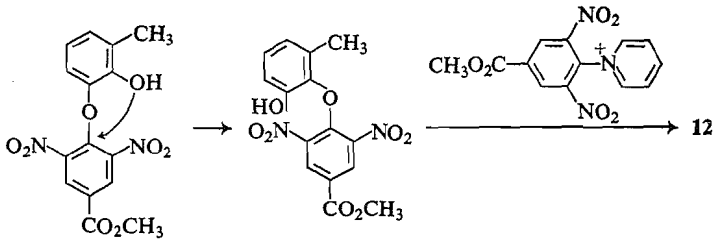

FIG. 1. A rationalization of bis-diphenyl ether formation by the Smiles' rearrangement.

melting range was less than 2°, and liquid phenols whose refractive index agreed with the known n_D by ±0.001, were used as obtained. Other phenols were first purified as follows: 2-chloro-6-methylphenol (80% technical, Aldrich) was fractionated to obtain a liquid, b.p. 81–84°/21 mm Hg, $n_D^{25.0}$ 1.5433; and 2,3,5,6-tetramethylphenol (m.p. 90–100°, Aldrich) was recrystallized twice from aqueous methanol to obtain a solid, m.p. 116.5–117.5°.

General Modified Hems Synthesis

The syntheses of all diphenyl ethers, except where noted, were performed using the following generalized procedure:

Methyl 4-chloro-3,5-dinitrobenzoate[11] (2.00 g, m.p. 104.5–106.0°) was dissolved in dry pyridine (10 ml, Fisher, 0.01% water) stored over anhydrous barium oxide. The stoppered mixture was heated for 5 min on a steam bath to enhance salt formation.

A 1.5 *M* excess of the chosen phenol was then added quantitatively to the pyridinium salt mixture by rinsing it in with minimal chloroform (Fisher spectranalyzed[12]). The mixture was heated for 1 h under reflux (with a $CaCl_2$ guard tube) on the steam bath.

The reaction mixture was cooled under the cold water tap and it was then poured into a conical flask (500 ml) containing ice (handful of chips), water (50 ml), and concentrated hydrochloric acid (15 ml, 12 *N*). Chloroform (25 ml, stock) was added, and the mixture was shaken for ½ h on a mechanical shaker. The mixture was then filtered to remove the insoluble yellow by-product, *N*-(4-carbomethoxy-2,6-dinitro)phenylpyridinium 4′-carbomethoxy-2′,6′-dinitrophenoxide (**3***b*), when present.

The chloroform phase was separated, treated with an equal volume of absolute ethanol, and the solution was reduced to the original volume, or less, by boiling. A copious solid generally crystallized when the concentrate was cooled in a salt–ice bath. The crude solid was collected and washed with petroleum ether (b.p. 30–60°) and dried over P_2O_5 in a desiccator under vacuum. The solid was recrystallized successively, until constancy of melting range was achieved, three recrystallizations normally being required.

All analytical samples received additional drying over P_2O_5 in a drying pistol. Microanalyses were performed by Alfred Bernhardt, 433 Mülheim (Ruhr), West Germany.

[11]Prepared by the method of Borrows *et al.* (6).

[12]Used as a convenient source of dry chloroform. The larger water content of stock chloroform led to increased yields of the by-product **3***b*.

All samples gave nuclear magnetic resonance (n.m.r.) and infrared (i.r.) spectra consistent with the assigned structures.

2-Methyl-4′-carbomethoxy-2′,6′-dinitrodiphenyl Ether (5a)

Freshly distilled *o*-cresol (1.25 g, b.p. 89–90°/13 mm Hg) was added to the pyridinium salt prepared as in general procedure above, and the mixture was heated on a steam bath for 90 min. The cooled mixture was poured onto ice in dilute hydrochloric acid (15 ml of 12 *N* HCl in 50 ml water). The gummy material which formed initially, changed into crystalline solid on standing for 3 h. The solid was recrystallized from acetone – petroleum ether to obtain crude product (1.72 g, 67% from chloro ester) melting mainly 128–133° (uncorrected, Kofler). The solid was recrystallized 4 times from absolute ethanol with successive elevation of the melting range (131.0–132.5, 134.5–135.2, 135.0–135.7, and 135.2–135.7°) before an analytical grade sample was obtained.

The pure compound was observed to turn brown on the surface when exposed to air and sunlight. No color change occurred on standing over sodium hydroxide and concentrated sulfuric acid in the vacuum desiccator. Admixture of the discolored compound with the unchanged compound resulted in a slight lowering of the melting range to 134.2–134.8°, but i.r. spectra of both samples in chloroform solution were identical.

2-(4′-Carbomethoxy-2′,6′-dinitrodiphenoxy)fluorene (**15**) was also observed to be very sensitive to light; the exposed surface of the pale-yellow solid would quickly turn to a pale-orange color.

2,3-bis(4′-Carbomethoxy-2′,6′-dinitrophenoxy)toluene (12)

The reaction was done according to the generalized procedure using 3-methylcatechol (1.43 g, i.e. 1.5 *M* excess over chloro-ester, m.p. 66.4–67.5°, Aldrich). No solid was isolated from this reaction, designed to give the mono-ether, except the unexpected bis-ether. The yield of crude dry solid was 0.20 g or 5% from the chloro-ester, m.p. 174–176°.

The reaction was repeated using conditions designed to favor formation of the bis-ether. A 2.5 *M* excess of the chloro-ester (5.24 g) over 3-methylcatechol (1.00 g) was used. The yield of crude dry product was 3.67 g (or 80% from 3-methylcatechol), m.p. 178.5–180.0°, and negligible **3***b* formed.

3-Hydroxy-2-(4′-carbomethoxy-2′,6′-dinitro)phenoxynaphthalene (13)

Reaction conditions of the generalized procedure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

favorable for synthesis of the bis-phenyl-naphthyl ether were employed, using 2,3-dihydroxynaphthalene (0.49 g, i.e. 1.0–2.5 *M* ratio of phenol to chloro-ester, m.p. 162.0–163.3°, Aldrich).

A small quantity of insoluble yellow solid (0.29 g) was collected from the acid treated reaction mixture. This solid was different from the usual yellow by-product *3b* in that it melted at 95–98° with the melt solidifying around 100° to give feathery crystals which melted at 121–130° (all m.p. determinations were made on a Kofler hot stage). Recrystallization of the solid in chloroform – absolute ethanol (1:1) using decolorizing charcoal gave a solid, m.p. 171.5–175° (Kofler) whose i.r. spectrum showed the presence of O—H stretching. A much larger quantity (1.60 g) of the same compound was obtained from the chloroform–ethanol concentrate by the usual treatment; 2 recrystallizations gave analytical quality material which analyzed for the mono-phenyl-naphthyl ether (**13**).

A small quantity of the bis-phenyl-naphthyl ether was isolated from the residual oil obtained from the chloroform–ethanol concentrate. Crystallization of the oil was induced by treating it with petroleum ether. After recrystallization the crude solid (0.09 g, m.p. 90–95°) was shown to be identical with **14** by comparison of i.r. spectra.

2,3-bis-(4′-Carbomethoxy-2′,6′-dinitrophenoxy)-naphthalene (14)

An attempt was made to synthesize the corresponding mono-naphthyl-phenyl ether by the reaction conditions of the generalized procedure using 2,3-dihydroxynaphthalene (1.85 g, i.e. a 1.5 *M* excess over chloro-ester, m.p. 162.0–163.3°, Aldrich).

A small quantity of the by-product **3b** (0.33 g) was obtained. A dirty yellow solid was obtained from the chloroform–ethanol concentrate with cooling. The crude solid (1.44 g) showed some melting around 110°, but most of the solid melted at 209.5–211.0°. After recrystallization from chloroform – absolute ethanol (2:1) using decolorizing charcoal, the dry solid melted almost completely at 114–116°, then the melt solidified from 151–155° forming feathery crystals which melted completely at 212–215° (Kofler). An i.r. spectrum of the recrystallized solid indicated that it was the bis-phenyl-naphthyl ether.

In view of the remarkable melting behavior of the solid above, a thermal transformation was performed by heating approximately half the recrystallized material in a glass thimble immersed in the vapor of anisole (b.p. 155°). Within 10 min of constant temperature heating, the solid melted and was transformed into a pale-yellow solid which was crusty and porous in nature. A sample of this solid melted at 211.5–214.0° (Kofler) with no melting at lower temperature. After recrystallization from chloroform – absolute ethanol, the thermally transformed solid was found to melt at 212.0–214.5° (Kofler) and 209.9–210.5°; this material was used for the analytical sample.

Received March 10, 1969

The reactions of 2(2-isopropanol)cyclobutanones with phosphorous pentoxide lead to ring opened carboxylic acids. Reaction of 2-isopropylidenecyclobutanones with polyphosphoric acid (PPA) gives ring cleavage rearrangement products. The mechanisms of these reactions are discussed in the light of the observed different reactions of the corresponding cyclopentanones.

Canadian Journal of Chemistry, 47, 2797 (1969)

Anomalous reactions and enhanced reactivities of small ring compounds have recently received considerable interest. The strain involved in bond angular distortions tends to offset "normal" reaction modes so that other pathways are often followed such that relief of this strain occurs. We wish to report some novel acid-catalyzed ring-cleavage and rearrangement of cyclobutanones.

Acid Catalyzed Ring Opening of 2(2-Isopropanol)cyclobutanone

The reaction of 2-isopropylidene-2′(2-isopropanol)cyclobutanone (**1**) with P_2O_5 in C_6H_6 gave the acid **2** (m.p. 50–51°) and an ester **3** in 55 and 35% yields, respectively. A trace amount of **4** was obtained and identified by comparison with an authentic sample (*1*). The structure of carboxylic acid **2** was based on the nuclear magnetic resonance (n.m.r.) spectrum which showed an exchangeable proton signal at 12.64 p.p.m. and vinyl methyl signals at 1.70 p.p.m. (6H), 1.90, and 2.14 p.p.m. The infrared (i.r.) spectrum of **2** showed the characteristic peaks for an α,β-unsaturated carboxylic acid.

Platinum catalyzed hydrogenation of **2** at 1 atmosphere resulted in the sole reduction of the γ–δ unsaturated bond giving **5**, which was also converted to **6** by catalytic hydrogenation at 3 atmospheres. Compound **6** had similar physical constants and spectra with those reported for 2-isopropyl-5-methylhexanoic acid (*2*). Compound **6** was also obtained from the catalytic pressure hydrogenation of 2-isopropylidene-5-methyl-Δ^4-hexenoic acid (**2**).

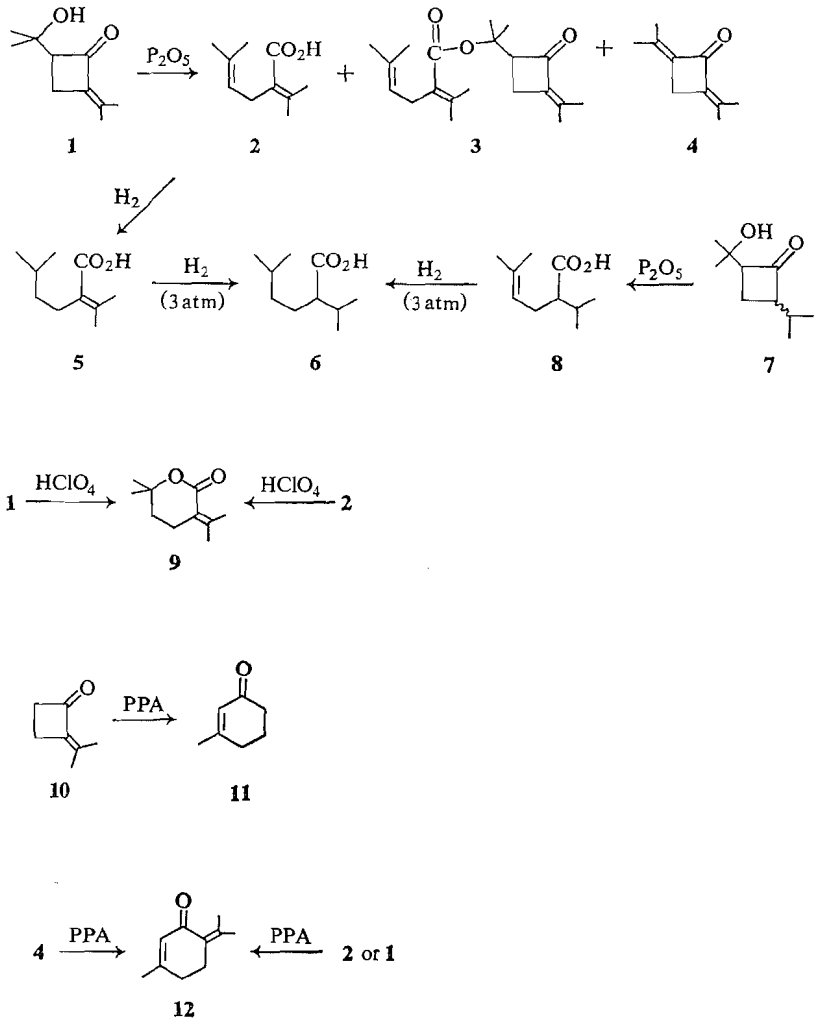
The structure of **3** was assigned on the basis of spectral and analytical data. Hydrolysis of **3** in a 10% methanolic sodium hydroxide solution gave equimolar amounts of the acid **2** and a mixture of the starting ketone **1** and dienone **4**.

Hydrogenation of 2-isopropylidene-2′(2-isopropanol)cyclobutanone (**1**) at 3 atmospheres yielded an isomeric mixture **7**. Reaction of **7** with P_2O_5 in benzene yielded **8**. The structure of **8** was supported by its spectral data and its ready catalytic hydrogenation at atmospheric pressure giving exclusively the saturated acid **6**.

The reaction of **1** with perchloric acid in benzene yielded the α,β-unsaturated lactone **9** quantitatively. Its structure was supported by spectral data and its synthesis from 2-isopropylidene-5-methyl-Δ^4-hexenoic acid (**2**). Treatment of **2** with 60% perchloric acid in benzene gave exclusively lactone **9** identical in all respects with that obtained from the perchloric acid reaction with **1** (Scheme I).

Rearrangement of 2-Isopropylidenecyclobutanones in PPA

Reaction of 2-isopropylidenecyclobutanone (**10**) with polyphosphoric acid (PPA) at 100° gave 3-methyl-Δ^2-cyclohexenone (**11**) in 82% yield. The n.m.r. and i.r. spectra of **11** were identical with those of an authentic sample. Reaction of 2,2′-diisopropylidenecyclobutanone with polyphosphoric acid at 100° gave piperitenone (**12**) and 3-methyl-Δ^2-cyclohexenone (**11**). The structure of **12** was assigned by comparison of its spectral data with those of an authentic sample (*3*, *4*). An identical mixture of piperitenone (**12**) and **11** was obtained by treating carboxylic



SCHEME I

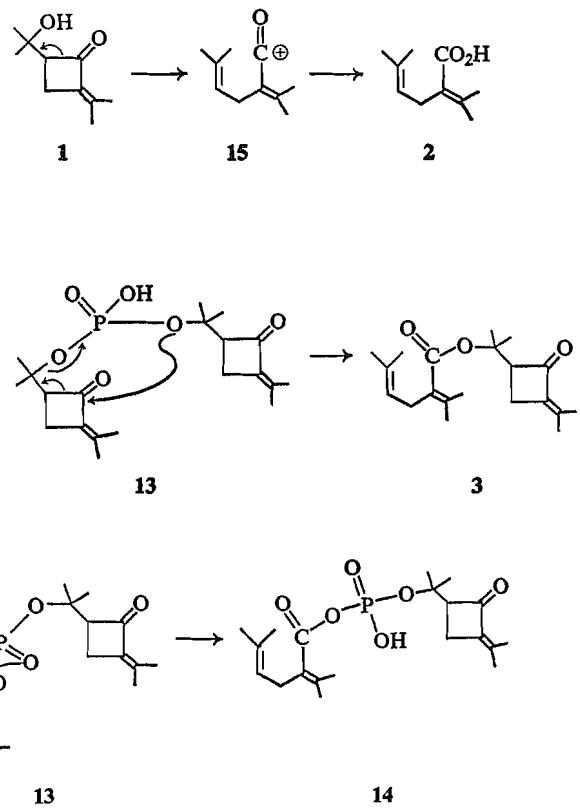
acid **2** with PPA under the same conditions. Similarly, ketone **1** gave piperitenone **12** with PPA.

Discussion

The acid-catalyzed ring opening of the 2-(2-isopropanol)cyclobutanones can be explained by the following mechanisms (Scheme II). The acylium ion can be generated by direct abstraction of the hydroxyl group by phosphorous pentoxide with subsequent rearrangement or by the initial formation of the phosphate diester **13** (5) with concomitant rearrangement and elimination. On the other hand, phosphate **13** can undergo a cyclic six-centered rearrangement to give the acyl phosphate **14**. The acyl phosphate **14** could also conceivably be formed from the acylium ion **15**. Under the work-up conditions the acyl phosphate would be readily converted to the carboxylic acid **2**. The formation of ester **3** can be envisaged as the reaction of an acylium ion with unreacted ketone **1** or by rearrangement of the phosphate diester **13** as illustrated. The former mechanism is less likely since the reaction of phosphorous pentoxide in a one-tenth dilute benzene solution of **1** gave identical yields of the carboxylic acid **2** and the ester **3**.

In the reaction of **1** with perchloric acid, the carboxylic acid **2** is apparently the precursor of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

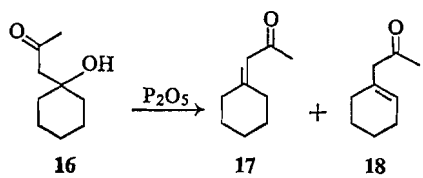


SCHEME II

lactone **9**, since, under the same conditions, **2** was readily converted to **9**. In this particular case only the acylium ion mechanism is tenable.

The phosphorous pentoxide reaction of **1** may proceed in part by the acylium ion mechanism. It was observed that the saturated 2-isopropyl-2(2-isopropanol)cyclobutanone (**7**) reacted much slower than **1**. This is reasonable since the acylium ion **15**, which is derived from **1**, is stabilized by α,β-unsaturation.

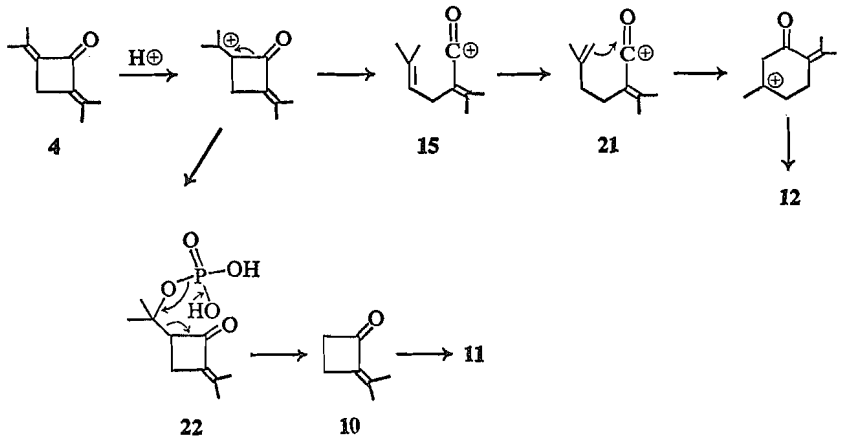
Reaction of **16** with phosphorous pentoxide in benzene (Scheme III) results in the normal dehydration products **17** and **18** and reaction of **19** under similar conditions gave **20**, indicating



SCHEME III

that the anomalous ring cleavage observed in the cyclobutanones is due to the strain in these derivatives. The polyphosphoric acid reaction of the 2-isopropylidenecyclobutanones may also involve the same acylium ion **15** as shown in the reaction Scheme IV. The acylium ion **15** could tautomerize under the experimental conditions to give acylium ion **21** which could undergo an intramolecular acylation to give ketone **12**. Such tautomerizations have been observed under similar reaction conditions (6). Evidence for the intervention of the acylium ion **15** was found by the observation that carboxylic acid **2** under the same conditions gave an identical mixture of ketones **11** and **12**. The formation of acylium ions from the reaction of α,β-unsaturated carboxylic acids with PPA is well documented (6). The formation of 3-methyl-Δ^2-cyclohexenone (**11**) in the reaction of **4** with PPA appears at first glance to be quite unusual. However, it is possible that phosphate **22** might be formed which could undergo a retro aldol condensation

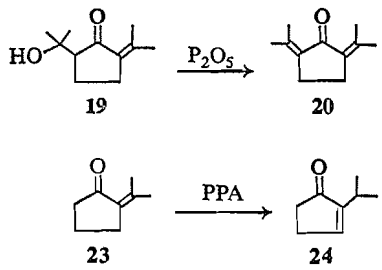
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



SCHEME IV

as shown, giving rise to 2-isopropylidenecyclobutanone (**10**). Ketone **10** could then be transformed into **11** in the usual manner. Treatment of ketone **1** with base resulted in a 10% yield of 2-isopropylidenecyclobutanone (**10**).

The unusual reactions of the cyclobutanones with PPA appear to be the result of ring strain. It was reported (7) that the reaction of 2-isopropylidene cyclopentanone (**23**) with PPA gave the α,β-conjugated cyclopentenone **24** (Scheme V).



SCHEME V

Experimental

All melting points were obtained on a Buchi melting-point apparatus and are uncorrected. The n.m.r. spectra were run on a Varian A-60A spectrometer (TMS, internal standard). Infrared spectra were run on a Perkin–Elmer model 137 spectrometer. Elemental analyses were obtained from Schwarzkopf Microanalytical Laboratories, Woodside, New York.

Reaction of 1 with Phosphorous Pentoxide

Ketone **1**[1] (800 mg) was dissolved in 15 ml of anhydrous benzene. To this solution was added 1 g of P_2O_5 and the mixture was stirred at room temperature for 3 h. Water was slowly added until all the P_2O_5 was destroyed. The solution was taken up in ether and the ether extract washed neutral with water and then with 25 ml of 10% sodium carbonate solution. The basic extract was acidified with concentrated HCl and washed with 25 ml of ether. The ether layer was washed neutral with water, dried, and evaporated to give 440 mg of carboxylic acid **2**; n.m.r.: (CCl_4, TMS internal) δ 1.70 (6H, s), 1.90 (3H, s), 2.14 (3H, s), 3.00 (2H, A_2X, d, J_{AX} = 7 Hz), 5.01 (1H, t, A_2X, J_{AX} = 7 Hz), 12.64 (1H, s, exchanged with D_2O); i.r.: λ_{max} (CCl_4) 1685 cm^{-1} (carboxylic acid); ultraviolet (u.v.): λ_{max} (pentane) 252 mμ (ε = 1150); (recrystallized from MeOH/H_2O) m.p. 50–51°.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.48; H, 9.52. Found: C, 71.32; H, 9.44.

The neutral ether fraction was dried with anhydrous magnesium sulphate and evaporated to give 340 mg of an oily residue which was chromatographed on 3 thin-layer chromatographic plates (10% ether – benzene). The less polar fraction (20 mg) was assigned structure **4** by comparison with an authentic sample (1). The major fraction was assigned structure **3** (300 mg) based on the following data: n.m.r.: 5.00 (1H, t), 3.1–2.3 (5H, m), 2.2–1.3 (24H, singlets); i.r.: λ_{max} (CCl_4) 3020 (C═C—H), 1725, 1699 (C═O), 1665 (C═C).

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.45; H, 9.45. Found: C, 75.36; H, 9.18.

Pressure Hydrogenation of 2

To 500 mg of **2** in 40 ml of ethyl acetate was added 200 mg of PtO_2. This solution was placed in the Parr hydrogenator at 50 lb/in.^{2} for 15 h. The platinum was filtered and the solvent evaporated to give 505 mg of oily **6** (*2a*, *b*). Boiling point (4 mm) 119–121°; lit. (2) b.p. (4 mm) 118–120° (ether pentane); n.m.r.: 0.93 (6H, 2d), 1.09–2.07 (7H, m), 13.04 (1H, s, exchanged with D_2O); i.r.: λ_{max} (neat) 1710 cm^{-1} (carboxylic acid).

Anal. Calcd. for $C_{10}H_{20}O_2$: C, 69.80; H, 11.63. Found: C, 70.04; H, 11.65.

[1]Ketone **1** was obtained by a modified method as described by J. M. Conia (1).

The amide of **6** was prepared in the standard way *via* the acyl chloride. The acyl chloride was obtained by reaction of **6** with thionyl chloride. Amide m.p. 111–113°; lit. (2) m.p. 112–114°.

Anal. Calcd. for $C_{10}H_{21}NO$: C, 70.10; H, 12.30; N, 8.20. Found: C, 69.65; H, 12.36; N, 8.02.

Atmospheric Hydrogenation of ***2***

To 102.7 mg of **2** in 10 ml of ethyl acetate was added 35 mg of PtO_2. The mixture was hydrogenated at atmospheric pressure for 6 h. The platinum was filtered off and the solvent evaporated to give 100 mg of oily **5**; n.m.r.: 0.98 (6H, 2 d), 1.29 (3H, m), 1.85 (3H, s), 2.08 (3H, s), 2.30 (2H, m), 12.40 (1H, s, exchanged with D_2O); i.r.: λ_{max} 1695 cm^{-1} (α,β-unsaturated carboxylic acid); *m/e* 170.

Pressure Hydrogenation of ***5***

To 90 mg of **5** in 25 ml of ethyl acetate was added 60 mg of PtO_2. The mixture was hydrogenated at 45 lb/in.^{2} for 10 h. The Pt was filtered off and the solvent evaporated to give 92 mg of **6** identical with a sample previously prepared.

Hydrolysis of Ester ***3***

300 mg of **3** was dissolved in 10 ml of methanol containing 2 ml of water and 1 g of sodium hydroxide. The solution was stirred for 20 min at room temperature. The mixture was taken up in 25 ml of ether, the ether layer washed neutral with water, dried, and evaporated to give 130 mg of an oily residue shown by n.m.r., i.r., and thin-layer chromatography (t.l.c.) to contain a mixture of **1** and **4**. The aqueous layer was acidified with concentrated HCl. This was extracted with 25 ml of ether and worked up in the usual manner to give 135 mg of carboxylic acid **2** identical in all respects with a sample obtained previously.

Pressure Hydrogenation of Ketone ***1***

To 1 g of **1** in 50 ml of ethyl acetate was added 300 mg of PtO_2. The solution was hydrogenated at 45 lb/in.^{2} on a Parr hydrogenator for 6 h. The Pt was filtered off and the solvent evaporated to give 980 mg of oily **7**; n.m.r.: 0.93 (6H, 2 d), 1.14 (3H, s), 1.26 (3H, s); i.r.: λ_{max} 1770 (C=O of cyclobutanone); *m/e* 170.

Phosphorous Pentoxide Reaction of ***7***

500 mg of **7** was dissolved in 5 ml of anhydrous benzene. To the solution was added about 500 mg of P_2O_5 and the mixture was stirred for 4 h. The excess P_2O_5 was quenched by slow addition of water. The mixture was taken up in 25 ml of ether which was washed neutral with water. The ether layer was then extracted with 3 × 8 ml of 10% aqueous sodium carbonate. The aqueous layer was acidified with concentrated HCl and reextracted with 25 ml of ether which was then washed neutral with water, dried over anhydrous $MgSO_4$ and evaporated to give 150 mg of oily carboxylic acid **8**; n.m.r.: 0.98 (6H, d), 1.60 (3H, s), 1.67 (3H, s), 1.80–2.40 (4H, m), 5.10 (1H, t), 13.14 (1H, s, exchanged with D_2O); i.r.: λ_{max} (CCl_4) 1710 (saturated acid C=O).

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.50; H, 10.60. Found: C, 70.52; H, 10.74.

Reaction of Ketone ***1*** *with* $HClO_4$

To 200 mg of ketone **1** dissolved in 5 ml of benzene was added 5 drops of concentrated perchloric acid. The solution was stirred at room temperature for 2 h. This was extracted with 25 ml of ether, the ether extract washed netural with water, dried, and evaporated to give 180 mg of **9**; *m/e* 168 (base peak *m/e* 118); n.m.r.: 1.32 (6H, s), 1.84 (3H, broad s), 2.18 (3H, broad s), 1.70 (2H, m), 2.50 (2H, m); i.r.: λ_{max} (CCl_4) 1710 cm^{-1} (C=O), 1630 (C=C), 1275 and 1110 cm^{-1} (C—O—C).

Reaction of Carboxylic Acid ***2*** *with Perchloric Acid*

To 25 mg of **2** in 5 ml of benzene was added 5 drops of concentrated perchloric acid. The solution was stirred at room temperature for 2 h. It was then taken up in 25 ml of ether and worked up in the usual manner to give 25 mg of **9** identical by n.m.r. and t.l.c. with the sample prepared above.

Reaction of Ketone ***10*** *(1) with PPA*

400 mg of **10** (1) was added to 8 g of PPA. The solution was vigorously stirred for 1 h at 100°. The reaction mixture was taken up in 4 ml of water. After cooling, it was extracted with ether and the extract washed with aqueous sodium bicarbonate and water, and dried over sodium sulfate. After evaporation of the solvent under reduced pressure, the residue was analyzed by vapor phase chromatography (v.p.c.) (XF-1150, 5.3 ft, 185°) and shown to consist of one product (retention time 9 min) (82% yield), 3-methylcyclohex-2-enone, **11**, whose i.r. and n.m.r. spectra were compared with those of an authentic sample.

Reaction of Ketone ***4*** *with PPA*

1.5 g of ketone **4** (1) was reacted with 25 g of PPA for 1 h at 100°. After working up in the same way as the procedure above the residue was analyzed by v.p.c. and shown to consist of two products. One was 3-methylcyclohex-2-enone (retention time 9 min) (10%); the other product was found to be piperitenone (**12**) (retention time 18 min) (71%) whose n.m.r. and i.r. spectra were identical with those described in the literature (3, 4).

Reaction of Carboxylic Acid ***2*** *with PPA*

The polyphosphoric acid was prepared by mixing 7 g of P_2O_5 with 3 ml of 85% phosphoric acid and heating at 100° for 12 h. 400 mg of **2** was added and the viscous solution was stirred for 1 h at 100°. 10 ml of water was slowly added and the reaction mixture cooled. This was extracted with 50 ml of ether. The ethereal extract was washed neutral with water, dried over anhydrous magnesium sulfate, and the solvent evaporated to give 320 mg of an oily residue which was separated into two components on v.p.c. (20% FFAP on Chrom W. 3 ft, 150°). The less polar material (retention time 2 min) (20 mg) was identical with 3-methylcyclohex-2-enone (**11**), the more polar product (retention time 4 min) (280 mg) was identical with piperitenone.

Reaction of Ketol ***16*** *with Phosphorous Pentoxide*

To 500 mg of ketol **16**[1] in 5 ml of benzene was added 1 g of P_2O_5. The mixture was stirred at room temperature for 2 h. This was worked-up in the usual manner to give

[1]**16** was obtained from the aldol condensation of acetone and cyclohexenone.

500 mg of an oily residue which showed two peaks (**17** and **18**) on v.p.c. (FFAP, 160°, 3 ft). The mixture showed the following spectral data: n.m.r.: 5.88 (1H, s), 5.50 (1H, m), 2.87 (2H, s), 2.75 (6H, m), 2.02 (3H, s), 1.99 (3H, s), 1.50 (12H, m); i.r. λ_{max} (CCl_4) 1680 (α,β-unsaturated C=O) 1710 (saturated C=O).

*Reaction of Ketol **19** with Phosphorous Pentoxide*

To 100 mg of ketol **19** in 5 ml of benzene was added 500 mg of P_2O_5. The reaction mixture was stirred for 8 h at room temperature. This was extracted with 5 ml of ether and worked up in the usual manner to give 95 mg of oily **20** whose n.m.r. and i.r. spectra were identical with those of an authentic sample (1).

Reaction of thionyl bromide with tropolone and phenol

S. D. SARAF
Defence Science Organization, Chaklala, West Pakistan

Received February 25, 1969

Tropolone and phenol react with thionyl bromide forming 3,7-dibromotropolone and 2,4-dibromophenol respectively.

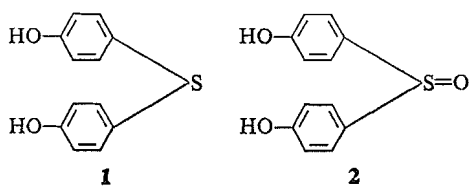
Canadian Journal of Chemistry, 47, 2803 (1969)

The reported synthesis (1, 2) of 2-chlorotropone from tropolone and thionyl chloride suggested that thionyl bromide might be used for a similar preparation of 2-bromotropone.

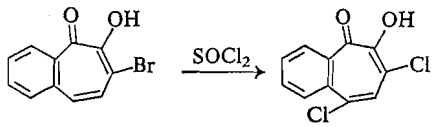
The reactions between thionyl bromide and organic compounds have been studied with only a few acids and alcohols. It has been reported (3) that on adding thionyl bromide to heptoic acid, a brisk reaction occured with the evolution of hydrogen bromide and sulfur dioxide and with the formation of acid bromide. It has also been reported (4) that thionyl chloride with tertiary alcohols gives only alkyl halides, whereas with other alcohols, a chlorosulfite is obtained as an intermediate. According to Darzens (4), the reaction of thionyl bromide with alcohols should follow the same course, but the intermediate ROSOBr is so unstable that it decomposes instantly and therefore has never been isolated.

The reaction of phenol with thionyl chloride has attracted a considerable amount of attention, and widely varying results have been obtained according to the experimental conditions chosen. Simply mixing the two reactants in the cold leads to the formation of a number of products, the main one being dihydroxydiphenyl sulfide (**1**) (5, 6). If the reaction takes place in carbon disulfide, dihydroxydiphenyl-*p*-sulfoxide (**2**) is the chief product (7).

Several unsuccessful attempts were made to prepare phenyl chlorosulfinate, but it was eventually obtained by the action of sodium phenoxide on thionyl chloride in toluene (8). This unusual behavior of thionyl chloride with phenol is not unique, since Ebine (9) has reported that 3-bromobenztropolone (**3**) with thionyl chloride gives 3,5-dichlorobenztropolone (**4**).

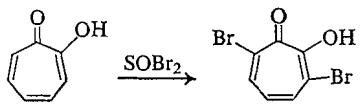


1 **2**



3 **4**

Addition of thionyl bromide to tropolone in dry benzene gave an immediate red precipitate, which redissolved on refluxing for 2 h to give a clear red solution. Work-up in the usual manner followed by sublimation and crystallization from petroleum ether (b.p. 60–80°) gave 3,7-dibromotropolone (**5**) as colorless needles m.p. 160–161° in 45% yield. This structure is based on the following facts.



5

The compound analyzed for $C_7H_4Br_2O_2$, a dibromotropolone. The product gave an intense green coloration with ferric chloride, and with sodium hydroxide it formed an insoluble sodium salt. The infrared (i.r.) and ultraviolet (u.v.) spectra were in agreement with the reported spectra of 3,7-dibromotropolone.

The methyl ether of 3,7-dibromotropolone, on treatment with 25% sodium hydroxide solution, rearranged to 2,6-dibromobenzoic acid. Similar treatment of the methyl ether with sodium methoxide gave methyl 2,6-dibromobenzoate. These results are in agreement to those of Nozoe *et al.* (10) and Cook *et al.* (11).

Addition of thionyl bromide to solid phenol at room temperature gave an immediate reaction

with the evolution of hydrogen bromide, sulfur dioxide, and the precipitation of sulfur. Work-up in the usual manner followed by distillation gave 2,4-dibromophenol as colorless needles in an 85% yield. Its structure was confirmed by its i.r. spectrum, melting point, mixed melting point, and by preparing several of its derivatives. The gas–liquid phase chromatography gave the same retention time to that of an authentic 2,4-dibromophenol.

Nothing definite can be said about the mechanism operating in these reactions at the present stage.

Experimental

Thionyl bromide was prepared by the method of Mayes and Partington (3). The product distilled as an orange liquid, b.p. 58–60°/40 mm.

3,7-Dibromotropolone

To a solution of tropolone (200 mg) in dry benzene (50 ml) was added thionyl bromide (0.15 ml) and the mixture was refluxed for 2 h, when a clear red solution was obtained. Removal of the solvent followed by sublimation at 120–125°/0.2–0.3 mm gave a yellow solid, m.p. 142–144°. Crystallization of the crude product from petroleum ether (b.p. 60–80°) gave 3,7-dibromotropolone (200 mg) as long colorless needles, m.p. 160–161°, (lit. (10) 159–160°); i.r. spectrum CH_2Cl_2): 1600 and 1550 cm^{-1}; u.v. spectrum (ethanol): E_{max} 264, 355, 373, and 391 mμ; log ε = 4.4, 3.38, 3.36, and 3.37.

Anal. Calcd. for $C_7H_4Br_2O$: C, 30.0; H, 1.43. Found: C, 29.8; H, 1.5.

3,7-Dibromotropolone Methyl Ether

To a solution of 3,7-dibromotropolone (200 mg) in dry ether (10 ml) was added a dry ethereal solution of diazomethane in small portions until the solution gave no color with ferric chloride. Removal of the solvent under reduced pressure left a yellow crystalline solid, which was crystallized from petroleum ether (b.p. 100–120°) as yellow plates of 3,7-dibromotropolone methyl ether (178 mg, 85%). It melted at 130–131° (lit. (10) 133.5°).

Anal. Calcd. for $C_8H_6Br_2O_2$: C, 32.65; H, 2.04; Br, 54.4. Found: C, 32.35; H, 2.1; Br, 54.7.

Reactions of 3,7-Dibromotropolone Methyl Ether

a) With 25% Sodium Hydroxide

3,7-Dibromotropolone methyl ether (50 mg) and 25% aqueous sodium hydroxide (20 ml) were heated at 60° for 30 min. After acidification and extraction with ether, 2,6-dibromobenzoic acid (23 mg) m.p. 146–148° was isolated. Upon admixture with an authentic specimen of 2,6-dibromobenzoic acid, the melting point remained unchanged.

b) With Sodium Methoxide

A solution of 3,7-dibromotropolone methyl ether (100 mg) in methanol (10 ml) was added to a saturated solution of sodium methoxide and the mixture was refluxed for 3 h. Work-up in the usual manner and recovery of the product in ether afforded methyl 2,6-dibromobenzoate (75 mg, 75%), which melted at 62–63° (lit. (10) 61–62°).

2,4-Dibromophenol

To phenol (5 g) was added thionyl bromide (4.4 ml). A brisk reaction occurred with the evolution of hydrogen bromide and sulfur dioxide. After the reaction had slowed down, the reaction mixture was heated on a steam bath for 30 min. Work-up in the usual manner followed by distillation gave 2,4-dibromophenol (10 g) as a colorless oil, which crystallized from petroleum – ether (b.p. 40–60°) as colorless needles m.p. 35–36°, undepressed with an authentic specimen.

2,4-Dibromo-1-phenoxy Acetic Acid

This compound was prepared by a known procedure (12) from sodium phenate and chloroacetic acid. Crystallization from hot water gave 2,4-dibromo-1-phenoxy acetic acid as colorless needles, m.p. 154–155° (lit. (12) 151.8–153.5°).

Anal. Calcd. for $C_8H_6Br_2O_3$: C, 30.9; H, 1.9; Br, 51.2. Found: C, 30.7; H, 2.0; Br, 51.2.

Reçu le 5 décembre 1968

Les groupements méthyle, méthoxyle et *tert*-butyle en position-2 dans les nitro-1 naphtalènes, perturbent les valeurs des déplacements chimiques du proton en position-8.

Cette perturbation est évaluée, par défaut à la règle d'additivité.

Par le calcul, on montre que le facteur responsable de cette perturbation est essentiellement lié à la variation de la contribution de l'anisotropie magnétique du groupement NO_2, suivant qu'il est ou non, dans le plan du cycle naphtalénique.

Canadian Journal of Chemistry, 47, 2805 (1969)

Introduction

Au cours d'études sur les substitutions électrophiles, Richer, Pepin, Baskevitch *et al.* (1–5) ont souligné certains effets d'encombrement stérique dûs aux groupements *tert*-butyle, méthoxyle et méthyle. En particulier, ils ont noté que de tels effets peuvent être mis en évidence par la résonance magnétique nucléaire (r.m.n.). Ceux-ci perturbent de façon sensible, les déplacements chimiques de certains protons du cycle naphtalénique. En ce qui concerne le groupe méthyle, Wells et Alcorn (6) sur le nitro-1 naphtalène, ont évalué à 0.64 p.p.m. la variation du déplacement chimique du proton H_8 lors d'une méthylation en 2. Ils attribuent cette différence à une modification de l'anisotropie magnétique du groupe nitro qui, gêné par le méthyle en 2, aurait tourné autour de la liaison CN.

Yamaguchi (7) a préconisé une relation empirique entre le déplacement chimique des protons du méthyle de l'*o*-méthyl-nitrobenzène et l'angle de rotation du groupe nitro. Il note que, pour les protons du méthyle, les variations de l'anisotropie magnétique causées par la rotation de NO_2 l'emportent sur celles d'un effet mésomère puisque, au cours de la rotation, la variation du déplacement chimique des protons du méthyle en *para* est seulement le 1/10 de celle du déplacement chimique des protons du méthyle en *ortho*. Gibbons et Gil (8) sur les mono-dérivés du mésitylène et du tri *tert*-butyl-1,3,5 benzène, concluent également à un effet stérique de ces groupements sur le déplacement chimique des protons du cycle; pour le dérivé nitré, ils observent un effet anormal sur le déplacement chimique du proton en *meta*, qui compenserait l'augmentation de densité électronique au cours de la rotation. Par ailleurs Franck et Williamson (9) ont montré, en série benzénique, que le déplacement chimique des protons aromatiques situés en position-2 par rapport à un groupe nitro est fonction de l'angle de torsion qui lui est imposé par les substituants méthyle, éthyle, propyle et *tert*-butyle situés en position-6. Sur une base d'observation qualitative ils attribuent cette variation de déplacement chimique à une diminution de l'anisotropie magnétique au cours de la rotation. A la suite d'un travail connexe sur la variation, en fonction du solvant, du déplacement chimique des protons aromatiques de nitrobenzènes substitués, Rae (10) a interprété ses résultats en terme d'une augmentation, dans le DMSO, de la grosseur effective du groupe nitro provoquant, dans les cas des produits

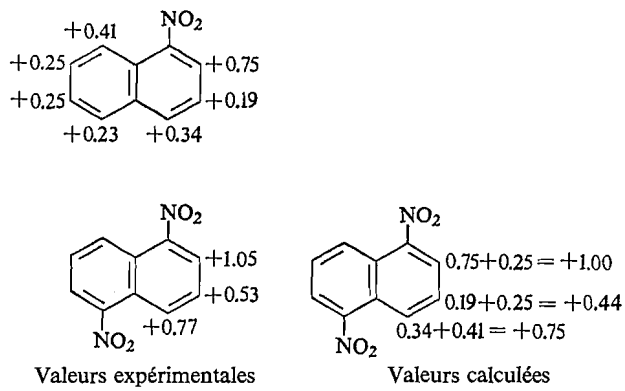

FIG. 1. Comparaison entre les valeurs calculées à l'aide de la loi d'additivité et les valeurs expérimentales (19) des déplacements chimiques par rapport au naphtalène, exprimées en p.p.m.

substitués par des groupes appropriés en *ortho* du groupe nitro, une rotation de ce groupe autour de l'axe Ar—N; cette interprétation tenait aussi compte implicitement d'une variation de l'anisotropie magnétique du groupe NO_2. Dans le cadre d'un travail théorique sur le déplacement chimique et la conformation des molécules, il s'avérait intéressant d'examiner systématiquement les mesures de déplacement chimique des protons des dérivés du nitronaphtalène rassemblés dans ces articles afin tout d'abord, d'estimer l'effet d'encombrement stérique des groupement *tert*-butyle, méthoxyle et méthyle sur la valeur du déplacement chimique δ^H, puis d'en analyser théoriquement le rôle tant du point de vue de l'effet mésomère que de celui de l'anisotropie magnétique.

Estimation de l'effet de l'encombrement stérique sur δ^H

Martin et Dailey (11) ont proposé une loi générale d'additivité des déplacements chimiques, qu'illustre en particulier la Fig. 1 sur les dérivés mono- et di-nitrés du naphtalène. La règle d'additivité suppose que l'apport d'un substituant supplémentaire ne modifie pas la géométrie de la molécule monosubstituée alors que, par effet stérique, le second substituant peut imposer une rotation au premier et rendre non valable l'application de la règle.

Aussi, nous proposons d'estimer l'effet stérique d'un groupement *tert*-butyle, méthoxyle ou méthyle sur le déplacement chimique des protons des dérivés correspondants du naphtalène, à l'aide de la différence entre la valeur expérimentale et celle que donnerait la loi d'additivité.

Dans la Fig. 3, sont rassemblés tous les résultats calculés selon le modèle explicité dans la Fig. 2. Les valeurs inférieures à 0.05 p.p.m. ne sont pas mentionnées.

On constate sur la Fig. 3: (*1*) que pour chaque groupement *tert*-butyle, méthoxyle et méthyle, l'effet est spécifique et prépondérant en position-8; (*2*) que l'effet décroit dans la série avec la dimension du groupement; (*3*) qu'il existe en position-3 un effet non négligeable inhérent au groupe méthoxyle, puisqu'il n'apparait pas pour les autres groupes; (*4*) qu'en position-4 et -5 rien de notable n'est à signaler; et (*5*) enfin, la Fig. 3 illustre assez bien la loi d'additivité lorsque les différents groupements, de par leurs positions relatives, ne peuvent être gênés stériquement.

Il semble que les déplacements chimiques des protons dans les positions 4 et 5 seraient insensibles à une diminution d'effet mésomère, provoquée par la rotation de NO_2. Cet effet devrait intervenir seul, puisqu'en raison de l'éloignement de ces protons du groupe nitro, la variation correspondante d'anisotropie magnétique est négligeable comme le montre le Tableau II.

Par contre, en position-8, contrairement à un proton en 5 ou en 4, une variation d'anisotropie magnétique occasionnée par la rotation, devrait contribuer de façon prépondérante à la variation de déplacement chimique observée.

Interprétation théorique de l'effet stérique du groupement *tert*-butyle sur le déplacement chimique δ^{H_8}

D'après la théorie de Pople (12) du déplacement chimique (dans le cadre de l'approximation des orbitales moléculaires à électrons indépendants,

TABLEAU II

Calcul de la contribution de l'anisotropie magnétique du groupe NO_2, à la constante d'écran des protons du nitro-1 naphtalène selon les deux modèles plan et non plan.

	$\sigma^{NO_2 plan}$	$\sigma^{NO_2 \perp plan}$
$\sigma^{H_3-NO_2}$	−0.05	−0.01≃0
$\sigma^{H_4-NO_2}$	−0.04≃0	−0.01≃0
$\sigma^{H_5-NO_2}$	−0.002=0	−0.01≃0
$\sigma^{H_8-NO_2}$	−0.65	+0.10

pour expliciter la fonction d'onde moléculaire) la constante d'écran σ^H d'un proton engagé dans une molécule cyclique, résulte de la contribution de trois termes: σ^{HH}, diamagnétique lié à la distribution électronique autour du proton; $\Sigma_X\sigma^{HX}$, anisotropie magnétique des atomes ou groupes d'atomes X, voisins; et σ^H_{CC} courant cyclique.

Si l'on prend le naphtalène comme référentiel dans la série de molécules étudiées, on peut négliger la variation de la contribution du courant cyclique vis à vis des deux autres et écrire:

$$[1] \qquad \delta^H = \sigma^H_{ref} - \sigma^H_{ech} = -\Delta\sigma^H = -(\Delta\sigma^{HH} + \Sigma_X\Delta\sigma^{HX})$$

Comme il l'a été mentionné, un groupe *tert*-butyle, au voisinage immédiat du groupe nitro doit avoir tendance à faire tourner d'un angle α le groupement NO_2 autour de la liaison C—N.

Quelle peut être alors la conséquence de cette rotation respectivement sur $\Delta\sigma^{H_8-H_8}$ et sur $\Delta\sigma^{H_8-NO_2}$? (Ce dernier terme est celui auquel on peut réduire la somme: $\Sigma_X\Delta\sigma^{H_8-X}$ lorsque l'on cherche à prévoir la variation de δ^{H_8} au cours de la rotation de NO_2.)

(*i*) *Influence de la rotation de NO_2 sur le terme diamagnétique* $\Delta\sigma^{H_8-H_8}$

Nous avons établi (13) théoriquement une relation qui permet le calcul de la variation du terme diamagnétique d'un proton indicé par *i* en fonction de la variation correspondante des charges π: Δq_i du carbone *i*, lié au proton *i*, $\Delta q_{i\pm1}$ des carbones voisins $i \pm 1$ et de l'indice de valence libre ΔF_i du carbone *i*.

$$[2] \quad \Delta\sigma^{H_iH_i} = 5\Delta q_i - 2\Delta F_i + 2(\Delta q_{i+1} + \Delta q_{i-1})$$

La détermination des charges et de l'indice de valence libre, résulte d'un calcul Hückel de fonction d'onde π. Pour ce calcul, les paramètres de l'azote et de l'oxygène sont connus; par contre, ceux du groupement *tert*-butyle, sont à déterminer.

D'après les travaux de Heilbronner (14) sur les spectres u.v., d'Ingold (15) sur les vitesses de nitration du toluène et du *tert*-butyl-benzène et de Gibbons et Gil (16) sur une étude comparée des déplacements chimiques des protons dans les 2 séries des méthyl- et *tert*-butyl-benzènes, le groupe *tert*-butyle semble interagir avec le cycle, par effet inductif, de la même façon que le groupe méthyle. Nous traitons l'effet inductif du *tert*-butyle en choisissant pour paramètre h_c du carbone qui lui est chimiquement lié, celui qui rend le mieux compte des déplacements chimiques, par rapport au naphtalène, des protons du cycle des 2,6- et 2,7-di-*tert*-butyl-naphtalènes. L'ajustement sur l'expérience se fait, en considérant l'anisotropie du *tert*-butyle comme négligeable, à l'aide de la formule [1]:

$$\delta^{H_i} = -\Delta\sigma^{H_i} = -\Delta\sigma^{H_iH_i}$$

et de la formule [2] pour le calcul de $\Delta\sigma^{H_iH_i}$. Les résultats rassemblés dans le Tableau I montrent qu'une valeur de h_c comprise entre −0.3 et −0.5 peut être retenue, ce qui confirme le caractère électro-donneur du *tert*-butyle comparable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

au méthyle. En effet, l'effet inductif du méthyle se traite habituellement avec un paramètre h_c égal à -0.5 (17), (dans le cadre de la méthode de Hückel).

Nous avons effectué le calcul Hückel de la fonction d'onde du di-*tert*-butyl-2,6 nitro-1 naphtalène en utilisant les paramètres suivants (17), $h_2 = h_6 = -0.3, h_{\dot{N}} = 1.5$, $h_{\dot{O}} = 1.00$, et $K_{CN} = 1.00 \cos\alpha$, avec $\cos\alpha = 1$ pour le modèle plan et $\cos\alpha = 0$ pour le modèle non plan.

Pour le proton en 8, il résulte du calcul sur les deux modèles plan et non plan, une différence de variation de constante d'écran diamagnétique, par rapport au naphtalène:

$$\Delta\sigma^{H_8H_8}_{\text{non plan}} - \Delta\sigma^{H_8H_8}_{\text{plan}} = +0.12 - 0.04 = +0.08 \text{ p.p.m.}$$

La rotation du groupement NO_2 induit donc une variation de la contribution diamagnétique au déplacement chimique du proton en 8 de l'ordre de:

$$(a) \quad \delta^{H_8H_8}_{\text{non plan}} - \delta^{H_8H_8}_{\text{plan}} = -0.12 - (-0.04) = -0.08 \text{ p.p.m.}$$

(ii) Influence de la rotation de NO_2 sur le terme d'anisotropie $\sigma^{H_8-NO_2}$

En adoptant la technique proposée par Pople (18) pour le calcul du terme d'anisotropie, nous avons calculé la contribution à la constante d'écran du proton en 8 de l'anisotropie du groupement NO_2 dans les deux cas où, NO_2 est dans le plan du cycle ou perpendiculaire à ce plan.

Le calcul, détaillé dans l'appendice, conduit aux résultats suivants:

$$\sigma^{H_8-NO_2}_{\text{plan}} = -0.65 \quad \text{et} \quad \sigma^{H_8-NO_2}_{\text{non plan}} = +0.10$$

soit

$$\Delta\sigma^{H_8-NO_2} = \sigma^{H_8-NO_2}_{\text{non plan}} - \sigma^{H_8-NO_2}_{\text{plan}} = +0.75$$

d'où

$$(b) \quad \delta^{H_8-NO_2}_{\text{non plan}} - \delta^{H_8-NO_2}_{\text{plan}} = -\Delta\sigma^{H_8-NO_2} = -0.75 \text{ p.p.m.}$$

En additionnant les deux contributions (*a*) et (*b*), l'effet d'une rotation de 90° du groupement NO_2 (gêné par le groupe voisin du *tert*-butyle), sur le déplacement chimique du proton H_8 est théoriquement égal à:

$$(c) \quad \delta^{H_8}_{\text{non plan}} - \delta^{H_8}_{\text{plan}} = -0.83 \text{ p.p.m.}$$

C'est l'ordre de grandeur de l'effet stérique estimé empiriquement dans la première partie. Il faut remarquer que ce chiffre calculé, est une borne supérieure de l'effet réel puisque l'on a supposé l'angle de rotation égal à 90°.

Conclusion

Cette analyse souligne le rôle important que peut jouer l'anisotropie magnétique d'un groupe d'atomes en vue de l'élaboration d'un modèle moléculaire. Elle est, en grande partie, responsable des variations de déplacement chimique, vers les champs forts, du proton, en position péri du groupement nitro, dans le cycle naphtalénique, lorsque —NO_2 se place hors du plan, sous la contrainte de l'encombrement stérique du groupe *tert*-butyle. Cette conclusion basée sur des calculs semi-empiriques rejoint précisément les observations qualitatives faites par Franck et Williamson (9).

C'est aussi l'anisotropie magnétique qui, dans certains cas, met en défaut la relation linéaire entre le déplacement chimique et la charge (au sens L.C.A.O.O.M.). Une telle relation n'est en effet valable, qu'appliquée à des séries de molécules pour lesquelles les termes d'anisotropie sont comparables ou nuls; le seul terme sensiblement variable d'une molécule à l'autre, se réduit alors au terme diamagnétique explicité par la formule [2].

Partie expérimentale

Les spectres r.m.n. ont été déterminés à la température ambiante pour des solutions diluées (environ 5% ou saturées lorsque la solubilité n'était pas suffisamment élevée) dans la diméthyl-acétamide et à l'aide de spectromètres Varian A-60 et Jeolco JNM-4H-100; le tetraméthylsilane a été utilisé comme référence interne.

Appendice

Calcul de l'anisotropie du groupement NO_2 pour le proton H_8

Pour ce calcul nous avons utilisé la méthode proposée par Pople (18) basée sur l'approximation dipolaire. Pour un atome A situé à la distance R du proton étudié, l'anisotropie est donnée par la formule:

$$\sigma^{H-A} = \frac{2}{3NR^3}\left[(\chi^A_P)_{xx} - \tfrac{1}{2}(\chi^A_P)_{yy} - \tfrac{1}{2}(\chi^A_P)_{zz}\right]$$

à condition que l'axe des x soit orienté dans la

direction HA. N est le nombre d'Avogadro; χ_P^A est la susceptibilité paramagnétique de l'atome A. Si χ_P admet une symétrie axiale, la formule précédente se réduit à:

$$\sigma^{H-A} = \frac{1}{3NR^3}(\chi_{\parallel}^A - \chi_{\perp}^A)(1 - 3\cos^2\Theta)$$

où Θ est l'angle formé par l'axe de symétrie et la direction HA. La susceptibilité paramagnétique se calcule à l'aide de la formule proposée par Pople (18).

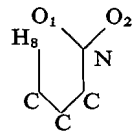
$$\chi_P^A = \frac{Ne^2\hbar^2}{4m^2c^2}\frac{1}{\Delta E}\sum_B Q_{AB}$$

avec

$$Q_{AB} = P_{x_Ax_B}(2\delta_{AB} - P_{y_Ay_B}) + P_{y_Ay_B}(2\delta_{AB} - P_{x_Ax_B}) + 2P_{x_Ay_B}P_{y_Ax_B}$$

Premier cas: *NO_2 est dans le plan des cycles*

On prend l'axe des x dans la direction H_8O_1 et on obtient: $(\chi_P^{O_1})_{xx} = 6.48 \times 10^{-6}$, $(\chi_P^{O_1})_{yy} = 3.30 \times 10^{-6}$, $(\chi_P^{O_1})_{zz} = 4.31 \times 10^{-6}$, d'où $\sigma^{H_8O_1} = -0.59$.



Anisotropie de O_2—On prend maintenant l'axe des x dans la direction H_8O_2, ce qui donne: $(\chi_P^{O_2})_{xx} = 2.76 \times 10^{-6}$, $(\chi_P^{O_2})_{yy} = 7.03 \times 10^{-6}$, $(\chi_P^{O_2})_{zz} = 4.31 \times 10^{-6}$, et $\sigma^{H_8-O_2} = +0.07$.

Anisotropie de N—L'axe des y étant dirigé suivant C—N, on obtient: $(\chi_P^N)_{xx} = 9.91 \times 10^{-6}$, $(\chi_P^N)_{yy} = 9.72 \times 10^{-6}$, $(\chi_P^N)_{zz} = 6.44 \times 10^{-6}$. On voit que χ_P^N est pratiquement symétrique par rapport à l'axe des z. On peut utiliser la deuxième formule, ce qui donne: $\sigma^{H_8N} = -0.13$, d'où finalement $\sigma^{H-NO_2} = -0.65$.

Deuxième cas: *NO_2 perpendiculaire au plan de la molécule*

Dans ce cas le groupement NO_2 n'est plus conjugué avec le reste de la molécule et on doit alors recalculer les indices P_{zz} pour ce groupement. Dans ce but, nous avons utilisé les paramètres suivants: $k_{NO} = 0.70$, $h_N = 1.50$ et $h_O = 1.00$ et on obtient: $P_{z_Nz_N} = 1.245$, $P_{z_Oz_O} = 1.378$ et $P_{z_Nz_O} = 0$.

Pour les deux atomes d'oxygène qui sont maintenant à la même distance de H_8, on prendra l'axe des y parallèle à la liaison C—N et l'axe des x dans le plan de NO_2. On obtient ainsi: $(\chi_P^O)_{xx} = 4.43 \times 10^{-6}$, $(\chi_P^O)_{yy} = 5.24 \times 10^{-6}$, $(\chi_P^O)_{zz} = 4.31 \times 10^{-6}$.

Ici encore on peut admettre qu'il y a symétrie axiale, autour de Oy, d'où: $\sigma^{H_8O} = +0.013$.

Pour l'atome d'azote nous avons pris les mêmes axes que pour l'oxygène et nous avons obtenu les résultats suivants: $(\chi_P^N)_{xx} = (\chi_P^N)_{yy} = 6.46 \times 10^{-6}$, $(\chi_P^N)_{zz} = 5.38 \times 10^{-6}$, d'où $\sigma^{H_8N} = +0.078$ et $\sigma^{H_8NO_2} = +0.10$.

Remerciements

Les auteurs sont reconnaissants à Madame Blain pour sa participation fructueuse à l'élaboration des calculs.

Simone Odiot et François Tonnard remercient l'O.T.A.N. pour sa contribution financière n° 296 qui leur a donné la possibilité de cette collaboration avec Jean Claude Richer, lors de leur séjour à l'Université de Montréal.

Jean Claude Richer remercie vivement le Conseil National de Recherches du Canada pour l'aide financière apportée sous forme de bourse et d'octrois de recherches.

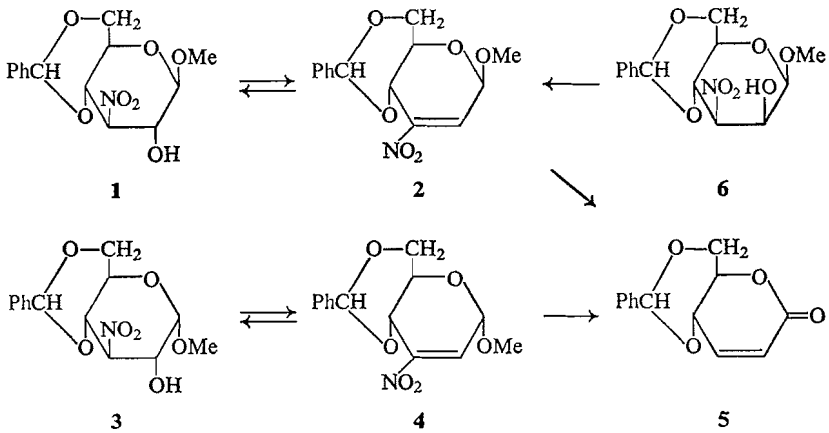
Reactions of nitro sugars. XI. Formation of 2,3-unsaturated hexonolactones by denitration of methyl deoxynitroglycosides[1,2]

HANS H. BAER AND WERNER RANK
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received February 20, 1969

Treatment of methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside (**1**) and its α-anomer (**3**), as well as of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hex-2-enopyranoside (**2**) and its α-anomer (**4**), with basic aluminum oxide in refluxing toluene, leads to loss of the nitro and glycosidic methoxyl groups. As a common product an α,β-unsaturated lactone, 4,6-*O*-benzylidene-2,3-dideoxy-D-*erythro*-hex-2-enono-1,5-lactone (**5**), was isolated in crystalline form. The β-D-*manno* isomer (**6**) of **1** incurs epimerization to **1** and partial conversion to **5**. Methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-galactopyranoside (**7**) and methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*threo*-hex-2-enopyranoside (**8**) similarly yield a crystalline lactone, 4,6-*O*-benzylidene-2,3-dideoxy-D-*threo*-hex-2-enono-1,5-lactone (**9**). The mechanism of this novel reaction is discussed, and certain differences in reactivity in the *gluco* and *galacto* series are pointed out. Base-catalyzed additions of methyl alcohol, ethyl alcohol, and piperidine to **8** afford methyl 4,6-*O*-benzylidene-3-deoxy-2-*O*-methyl-3-nitro-β-D-galactopyranoside (**10**), its 2-*O*-ethyl analogue (**11**), and methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-2-piperidino-β-D-galactopyranoside (**12**), respectively.

Canadian Journal of Chemistry, 47, 2811 (1969)



As has been shown earlier in this series (2), the treatment of methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside (**1**) with basic aluminum oxide in the presence of alcohols or amines leads to an exchange of the C-2 hydroxyl for an alkoxy or amine function. The reaction, which is carried out in refluxing toluene, is considered to be an elimination–addition proceeding via an intermediate nitroalkene, methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hex-2-enopyranoside (**2**). We now wish to report that action of basic aluminum oxide upon **1** as well as **2** in the *absence* of nucleophilic addends furnished a hitherto unknown, unsaturated sugar lactone, namely 4,6-*O*-benzylidene-2,3-dideoxy-D-*erythro*-hex-2-enono-1,5-lactone (**5**). The same lactone (**5**) was also obtained from the α-anomers of **1** and **2** (**3** and **4**).

The structure of **5** followed from elemental analysis which agreed with the formula $C_{13}H_{12}O_4$, and from spectral data. The infrared (i.r.) spectrum exhibited a strong carbonyl band and lacked nitro and hydroxyl absorptions. The nuclear magnetic resonance (n.m.r.) spectrum (Fig. 1) revealed that the product had lost the glycosidic methoxyl but retained the benzylidene group. The latter gave a 5-proton multiplet centered at τ 2.6 and a 1-proton singlet at τ 4.38.

[1]For Part X in this series, see ref. 1.
[2]Presented at the 155th National Meeting of the American Chemical Society, April 1968, San Francisco, California.

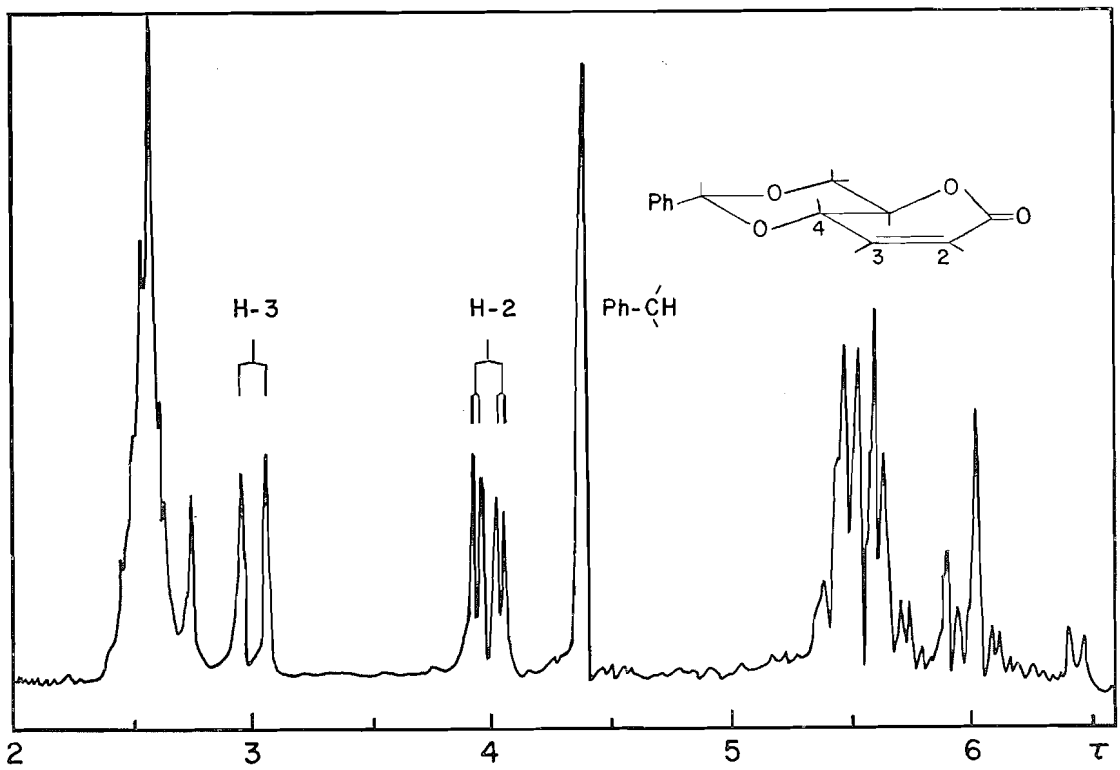


FIG. 1. Nuclear magnetic resonance spectrum (100 MHz) of 4,6-*O*-benzylidene-2,3-dideoxy-D-*erythro*-hex-2-enono-1,5-lactone (**5**).

Two 1-proton signals at τ 3.01 and 4.00 were assigned to the olefinic hydrogens at C-3 and C-2, respectively. The lower-field signal (H-3) appeared as a doublet due to vicinal coupling with H-2 ($J_{2,3}$ = 10 Hz); no vicinal coupling between H-3 and H-4 was observable, and this was not unexpected since, as a Dreiding model shows, the dihedral bond angle is close to 90° and coupling must therefore be at a minimum. The H-2 signal was a quartet exhibiting the 10 Hz vicinal coupling with H-3 and indicating allylic coupling with H-4 ($J_{2,4}$ = 2 Hz). The relatively large allylic coupling seen here is in line with a nearly perpendicular orientation of the bonds (3). Overlapping multiplets with a total intensity corresponding to four protons occurred in the region τ 5.3–6.3 (H-4, H-5, H-6, and H-6′).

With yields in crystalline **5** being about 30% the reactions evidently were incomplete under the conditions investigated. When the hydroxy compounds **1** and **3** were used as starting materials, appreciable proportions of them seemed to remain unaffected. On the other hand, the nitroalkenes **2** and **4** were consumed completely as far as could be judged from thin-layer chromatography (t.l.c.). However, they were in part hydrated to **1** and **3**, respectively, and no increase in yields of **5** resulted. The partial hydration of **2** and **4** was ascertained by the isolation of crystalline **1** and **3** from crude reaction mixtures that contained **5**. The β-D-*gluco* compound (**1**) was also formed, and isolated in 24% yield along with 30% of the lactone (**5**), when methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-mannopyranoside (**6**) was subjected to the reaction. Obviously **6** was dehydrated to give intermediate **2** which was then partly converted into **5** and partly rehydrated, not to **6** but to thermodynamically more stable **1**[3].

[3]It may be recalled that *acetylation* of **6** with hot acetic anhydride and sodium acetate led to the 2-*O*-acetyl derivative of **1** rather than to that of **6** (4). Further studies concerning the base-catalyzed epimerization of **6** to **1** and the hydration of **2** to **1** are reported in Part XII of this series. The fact that conversion of **1** and **3** into **5** was incomplete was due, we believe, to deactivation of the alumina during the reaction.

7 8 9

Analogous experiments were performed with methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-galactopyranoside (**7**) and with the nitroolefin derived from it, namely methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*threo*-hex-2-enopyranoside (**8**). Both compounds furnished the unsaturated lactone, 4,6-*O*-benzylidene-2,3-dideoxy-D-*threo*-hex-2-enono-1,5-lactone (**9**), which was isolated in crystalline form in yields of about 50%.

Elemental analysis of **9** agreed with the formula $C_{13}H_{12}O_4$, and the i.r. spectrum showed a prominent carbonyl peak and indicated the absence of nitro and hydroxyl groups. The n.m.r. spectrum (Fig. 2) exhibited the same general features as that of the D-*erythro* isomer (**5**). A 1-proton quartet attributed to H-3 occurred at τ 3.10 ($J_{2,3}$ = 10 Hz, $J_{3,4}$ = 6 Hz), the vicinal coupling with the quasi-equatorial H-4 being of the expected order. A 1-proton doublet for H-2 was at τ 3.76 (splitting, 10 Hz). In agreement with the bond orientation of H-4, the H-2 signal of **9** showed no allylic coupling (3) and in this respect differed from the analogous signal in isomeric **5**.

The carbonyl frequency in the i.r. spectrum of

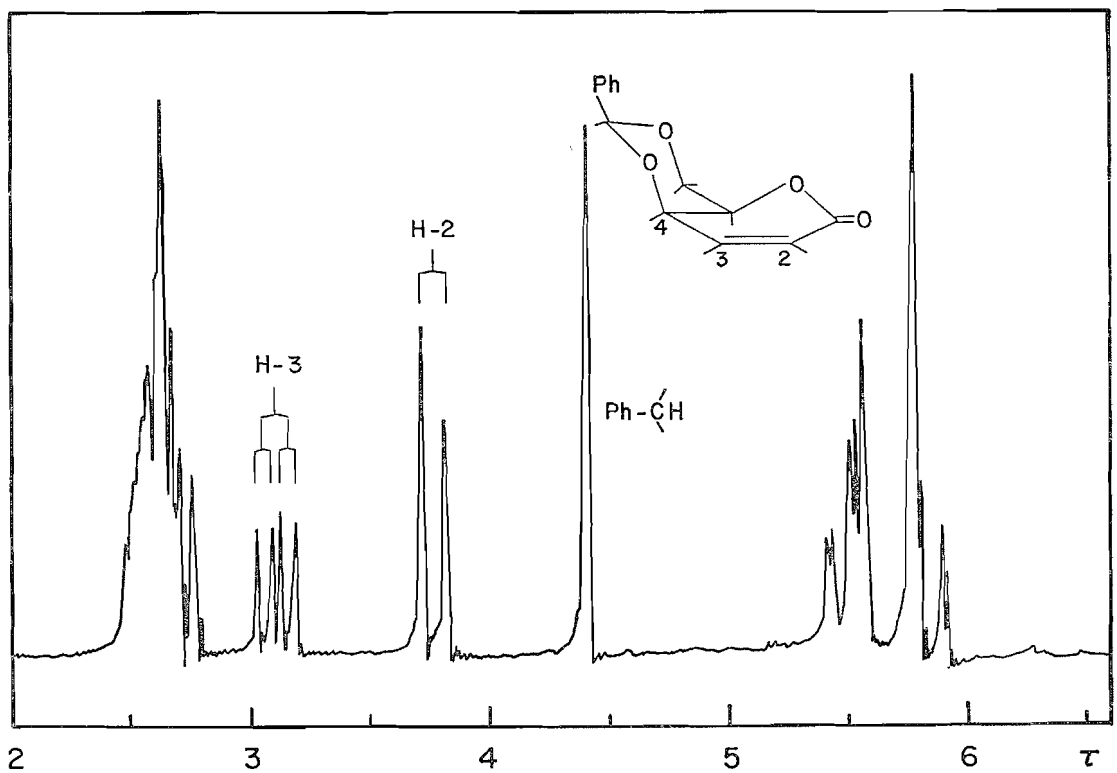

FIG. 2. Nuclear magnetic resonance spectrum (100 MHz) of 4,6-*O*-benzylidene-2,3-dideoxy-D-*threo*-hex-2-enono-1,5-lactone (**9**).

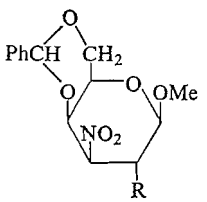
9 was at 1725 cm^{-1} in accord with the α,β-unsaturated, δ-lactone structure. The corresponding peak in stereoisomeric **5** occurred at 1755 cm^{-1}. This surprisingly high value can, we believe, be reconciled with the structure by assuming the presence of some strain in the molecule due to the *trans* junction between the chair and half-chair rings. The assumption received support when hydrolytic removal of the benzylidene group caused the carbonyl frequency to shift to 1725 cm^{-1}.

It could be shown by t.l.c. and other means (see below) that **8** is indeed an intermediate in the conversion of **7** into **9**. In interesting contrast to the behavior of the D-*gluco* compounds described in the preceding section, the D-*galacto* compound (**7**) disappeared entirely from the reaction mixture within 1 h, and when the nitroalkene (**8**) was employed as starting material, no hydration to **7** was observed. This is reminiscent of the behavior of **7** under conditions of sodium acetate - catalyzed acetylation, which resulted (4) in a facile dehydration to **8** rather than production of the 2-acetate[4]. It is considered that transformation of the pyranoside chair conformation of **7** into the half-chair of **8** is attended with relief of strain on account of an outward movement by the axial C-4 oxygen atom; the reverse transformation would involve a corresponding strain increase. This steric factor (6), which is absent in the systems with equatorial C-4 oxygen (**1** ⇄ **2** and **3** ⇄ **4**), is thought to explain the observed differences in reactivity.

However, the steric effect just invoked is obviously not powerful enough to prevent the nitroalkene **8** from adding nucleophiles under more favorable conditions. We have recently reported the preparative addition to **8** of nitroalkanes (7) and of ammonia (8). In the present work, use was made of similar additions to demonstrate the intermediacy of **8** in the reaction **7** → **9**. When the progress of the action of basic aluminum oxide upon **7** was monitored by t.l.c., it was seen that **8** arose as an intermediate showing maximum spot intensity after about 30–40 min; this spot then receded while the lactone (**9**) was slowly engendered, eventually becoming the sole spot (Fig. 3). When the process was interrupted after 40 min by cooling followed by the addition of sodium methoxide, sodium ethoxide, or piperidine, crystalline addition products from intermediate **8** and these nucleophiles could be isolated. They were methyl 4,6-*O*-benzylidene-3-deoxy-2-*O*-methyl-3-nitro-β-D-galactopyranoside (**10**), its 2-*O*-ethyl analogue (**11**), and methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-2-piperidino-β-D-galactopyranoside (**12**). Identical products were obtained from pure **8** directly[5]. The β-D-*galacto* configuration, which on the basis of previous experiences (7, 8) could be predicted as most likely for **10**, **11**, and **12** but required proof nonetheless, was ascertained by n.m.r. spectroscopy. This was possible by analysis of the ring proton signals (see Experimental), and reference is here made to relevant discussions in earlier work (2, 7) on analogous compounds.



10 R = OMe
11 R = OEt
12 R = $N(CH_2)_5$

Concerning the mechanism of formation of the unsaturated lactones we envisage a sequence of acid–base catalyzed reactions as exemplified in Scheme I. The essential steps in that scheme are abstraction of the anomeric (and here, allylic) proton in the starting nitroolefin (**2**), protonation of the resulting nitronate (**13**) followed by hydrolysis of the ketene acetal (**14**), and finally β-elimination of nitrous acid from the nitro lactone (**15**). No intermediates have been isolated so far, but unidentified chromatographic spots, observed in the reactions that furnished **5** from **2** and **4**, are possibly attributable to such intermediates.

The results of the present investigation will remind the reader of two recent studies which

[4]A similar dehydration, leading to the α-anomer of **8**, has been found to take place in the acetylation of the α-D-*talo* isomer of **7** (5).

[5]An attempt to produce **12** from **7** by allowing piperidine to be present from the outset (i.e. during the initial period of heating with aluminum oxide) did not succeed but resulted in decomposition, although an analogous experiment in the D-*gluco* series (2) was successful. It is believed that this failure was caused by the greater sensitivity toward base of the 4,6-*O*-benzylidene blocking group in 3-deoxy-3-nitro-D-galactose derivatives (7, 8).

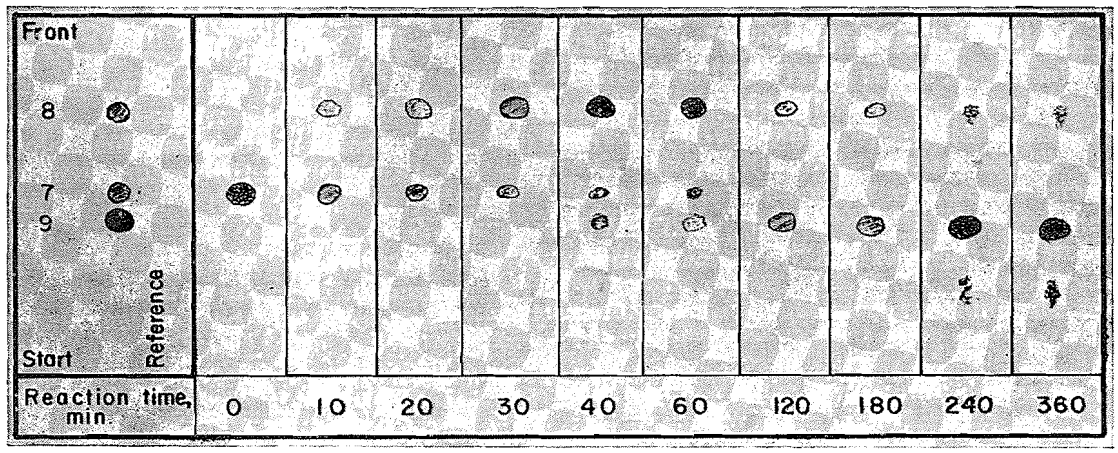


FIG. 3. Thin-layer chromatography of the reaction **7** → **9**.

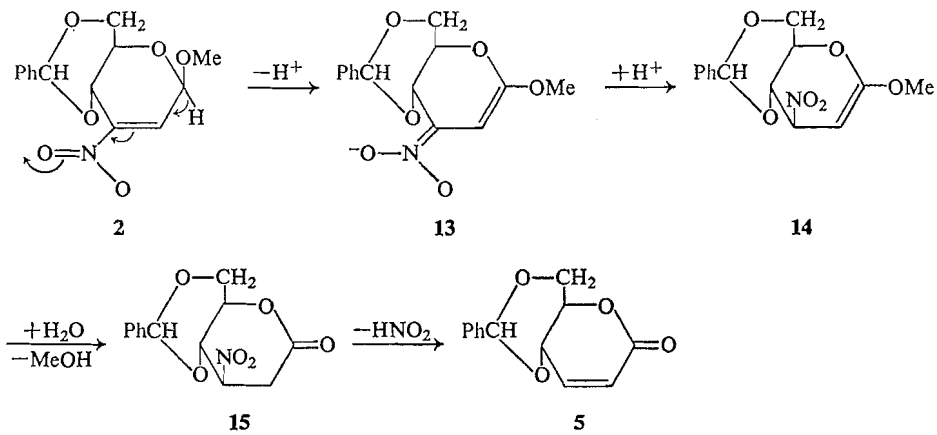
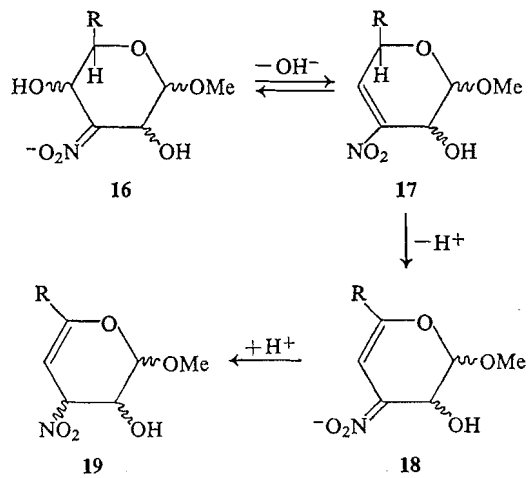


SCHEME I

revealed some related features in other nitro sugar reactions. Firstly, the formation of 4,5-unsaturated glycoside nitronates (9) from glycosides of type **16** in aqueous medium is explained in terms of abstraction of an allylic hydrogen (H-5) in intermediate nitroolefins (**17**); whereas the reaction products proved stable as sodium nitronates (**18**), they rapidly decomposed upon acidification or deionization, evidently as a consequence of hydrolysis of the enol ether linkage in liberated **19** (Scheme II). Although the details of the fate of **19** could not be ascertained, a kinship of the reactions portrayed in Schemes I and II is, nevertheless, quite obvious. Secondly, the facile elimination of the elements of nitrous acid that occurred in a tricyclic Diels–Alder product derived from a nitro



SCHEME II

glycoside (10) constituted a first, if only formally related, example of such an elimination in this field[6].

Experimental

Thin-layer chromatography (t.l.c.) was performed on silica gel G (E. Merck A.G., Darmstadt) with butanone–*n*-heptane (6:4, v/v) as solvent and ceric sulfate–sulfuric acid as spray indicator. Nuclear magnetic resonance (n.m.r.) spectra (100 MHz) were obtained on a Varian HA-100 spectrometer using chloroform-*d* solutions with internal tetramethylsilane standard, unless indicated otherwise. Infrared (i.r.) spectra were taken from Nujol mulls on a Beckman IR-8 instrument. Petroleum ether refers to the fraction with boiling range 30–60°.

*4,6-O-Benzylidene-2,3-dideoxy-*D*-erythro-hex-2-enono-1,5-lactone (5)*

All reactions were performed by heating the nitro glycosides and basic aluminum oxide (hereafter for simplicity referred to as Al_2O_3)[7] under reflux in toluene in the amounts and for the periods of time specified. The toluene had been dried over anhydrous calcium sulfate, and the reflux condenser was equipped with a drying tube. Efficient magnetic stirring was maintained. For work-up the hot mixtures were filtered, the oxide was washed on the filter with benzene, and the filtrates were evaporated after being clarified with activated charcoal if necessary. The crude reaction products so obtained were dry, usually crystalline, and almost colorless substances.

*(a) From Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-*β*-*D*-glucopyranoside (1)*

The reaction of nitro glycoside **1** (12) (300 mg) and Al_2O_3 (1.2 g) in toluene (30 ml) was monitored by t.l.c. Visually estimated ratios of starting material (**1**) to faster moving product (**5**) were approximately 1:1, 1:2, and 1:3 after 2, 4, and 12 h respectively. Work-up after 24 h gave a crude product which still contained some **1**, according to t.l.c. Recrystallization from ethyl acetate – petroleum ether furnished colorless **5** (65 mg, 29%), m.p. 121–123°. Infrared and n.m.r. spectra proved the substance to be virtually the same as the preparations of **5** described below, although the low melting point and a (weak) i.r. peak at 1550 cm^{-1} revealed the presence of a minor impurity.

*(b) From Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-*β*-*D*-erythro-hex-2-enopyranoside (2)*

The nitro glycoside **2** (12) (300 mg) and Al_2O_3 (900 mg) were allowed to react in toluene (30 ml) for 8 h. During this period the appearance on t.l.c. plates of a strong, light-brown spot (**5**) with slightly lower R_f-value than dark-brown **2** was observed. In addition, two blackish brown spots, one faster and the other slower than **5**, were seen. The slower spot corresponded to the hydroxy compound **1**. Work-up gave a crystalline mass (253 mg) which was chromatographed on a column (1.2 × 20 cm) of silica gel G using ethyl acetate–petroleum ether (2:15, v/v) as irrigant. The lactone (**5**), which was eluted first, was once recrystallized from ethyl acetate – petroleum ether and was then pure according to t.l.c. The yield was 79 mg (33%), m.p. 134–135°. A mixture melting point with **5** obtained under (*d*) was undepressed, and i.r. spectra were identical.

Continued elution of the column gave about 85 mg of crystals, m.p. 181–182°, identified with **1** by t.l.c. and i.r. spectrum.

*(c) From Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-*β*-*D*-mannopyranoside (6)*

The nitro glycoside **6** (4) (300 mg) and Al_2O_3 (900 mg) were allowed to react in toluene (30 ml) for 6 h. It was revealed by t.l.c. that after 1 h all the mannoside (**6**) had disappeared and glucoside (**1**) was present along with lactone (**5**) in a ratio of about 3:1. The ratio appeared to be about 3:2 after 3 h and did not seem to change significantly thereafter. Stirring was continued at room temperature overnight, and work-up then yielded a crystalline residue (204 mg) which was subjected to column chromatography as described under (*b*). There was obtained, first, 67 mg (30%) of the lactone (**5**) in colorless crystals that were identified by t.l.c. and an i.r. spectrum. Continued elution gave crystalline **1** (72 mg) which was found to be identical with an authentic sample (12) by t.l.c. and i.r. comparison.

*(d) From Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-*α*-*D*-erythro-hex-2-enopyranoside (4)*

The nitro glycoside **4** (5) (200 mg) and Al_2O_3 (600 mg) were refluxed in toluene (20 ml) for 5 h. Prior pilot experiments using t.l.c. for monitoring the reaction course had indicated the occurrence of three products within 3 min. They were represented by a light-brown spot (**5**) traveling slightly more slowly than the starting glycoside (**4**) which gave a dark-brown spot, and by a black double spot of even lower mobility. The slower (and stronger) portion of the double spot corresponded to the hydroxy compound **3**; the faster portion was unidentified. Inspection of the run in 15-min intervals showed clearly a gradual disappearance of **4** with concomitant increase of spot intensity for the three products until, after 1 h, the growing spot of **5** overlapped what was left of **4**. The three reaction products remained visible without significant changes after 3, 5, and 22 h. An i.r. spectrum taken after 1 h showed a strong carbonyl peak at 1750 cm^{-1} and a strong nitroalkane peak at 1555 cm^{-1} in addition to a weaker nitroalkene peak at 1530 cm^{-1} (of remnant **4**). There also was a broad hydroxyl band (ca. 3400 cm^{-1}). After 3 h the carbonyl peak had grown stronger and the nitroalkene absorption was reduced to a small shoulder to the nitroalkane peak.

Work-up of the preparative run (after 5 h) gave a syrupy residue which was chromatographed on a column as described under (*b*). The first fractions containing solid material were evaporated to give a crystalline product. Recrystallization from acetone–water yielded 45 mg (29%) of the lactone (**5**), m.p. 134–135°, $[\alpha]_D$ +26.5° (*c*, 1 in chloroform). The i.r. spectrum was

[6]During this writing, a communication (11) appeared describing a natural sugar (evernitrose) and its structural elucidation, in the course of which there was effected an elimination quite analogous to that depicted above (**15** → **5**).

[7]"$Al_2O_3 + H_2O$, reagent grade, suitable for chromatographic adsorption, pH (slurry 10:100) 10.0–10.5", manufactured by Shawinigan Chemical Co., and distributed by McArthur Chemical Co. Ltd., Montreal.

For personal use only.

devoid of hydroxyl and nitro absorption but showed a strong carbonyl band at 1755 cm^{-1}. A C=C stretching vibration expected in the 1600 cm^{-1} region was not detectable, possibly owing to ring strain (13). A sample of **5** was debenzylidenated with 90% trifluoroacetic acid (14); it then exhibited hydroxyl absorption in the 3400–3200 cm^{-1} region and ν_{max} 1725 cm^{-1} for the carbonyl band, broadened to smaller frequencies.

Anal. Calcd. for $C_{13}H_{12}O_4$ (232.2): C, 67.20; H, 5.21. Found: C, 67.04; H, 5.34.

Continued elution of the column furnished colorless crystals (38 mg) of the nitro glycoside **3**. Identity with an authentic sample of **3** (4) was established by t.l.c. and by comparison of i.r. spectra.

Another preparative run was worked up without column chromatography. The crude reaction residue was crystallized from cyclohexane–benzene to give fine needles (48 mg, single spot on t.l.c.) of the nitro glycoside **3** melting at 166° and showing $[\alpha]_D$ +85° (*c*, 0.8 in ethanol). (Lit. (4) m.p. 167°, $[\alpha]_D$ +87.2° (*c*, 1 in ethanol)). The mother liquor gave two crops of crystals that were inhomogeneous in t.l.c., both showing the three spots referred to above. The second crop was recrystallized from ethyl acetate – pentane which removed remnant **3** and afforded crystals of m.p. 125–126°. This material consisted largely of the lactone (**5**), but the presence of a by-product (possibly the nitro lactone (**15**)) was indicated by a weak nitro band at 1560 cm^{-1} and by retention of the unidentified (see above) t.l.c. spot. Nearly pure crystals of **5** (m.p. 132°) were obtained by acetamide fusion (10) of the product (5 min on the steam bath), recovery of **5** by trituration with water, and recrystallization from benzene–cyclohexane.

(e) From Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-glucopyranoside (3)

The reaction of nitro glycoside **3** (4) (50 mg) and Al_2O_3 (150 mg) in toluene (10 ml) was monitored by t.l.c. A strong spot of **5** arose within 1 h, and simultaneously the spot that was due to remnant **3** acquired a weak front halo indicating the presence of an intermediate or by-product (**15**?).

4,6-O-Benzylidene-2,3-dideoxy-D-threo-hex-2-enono-1,5-lactone (9)

For the conduct of the reactions that are described hereunder, reference is made to the general remarks preceding the description of **5**.

(a) From Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-β-D-galactopyranoside (7)

The nitro glycoside **7** (4) (300 mg) and Al_2O_3 (900 mg) were refluxed in toluene (50 ml) for 8 h. After that time, t.l.c. revealed the absence of starting material. Filtration and evaporation gave a colorless, crystalline residue (107 mg, 51%) which exhibited a single t.l.c. spot representing the lactone **9** (interestingly, **9** was found to move somewhat *more slowly* than **7**, in contrast to the relative mobilities of **5** and **1**). The product, which was already nearly pure according to its i.r. spectrum, was recrystallized from ethyl acetate–petroleum ether and then melted at 156–157° and showed $[\alpha]_D$ −256° (*c*, 1.1 in chloroform). It lacked hydroxyl and nitro group absorptions in the i.r. and possessed a strong band at 1726 cm^{-1} (C=O) and a weak band at 1633 cm^{-1} (C=C).

Anal. Calcd. for $C_{13}H_{12}O_4$ (232.2): C, 67.20; H, 5.21. Found: C, 67.10; H, 5.16.

Several experiments using varying ratios of **7** and Al_2O_3 were performed. It was found that a reduction in the amount of Al_2O_3 caused a slow reaction whereas an increase in the amount, while accelerating the reaction, was disadvantageous in that it diminished the yield, owing perhaps to more extensive losses by adsorption.

(b) From Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-β-D-threo-hex-2-enopyranoside (8)

Nitro glycoside **8** (4) (100 mg) and Al_2O_3 (300 mg) were refluxed in toluene (10 ml) for 6 h. It was seen by t.l.c. that a large amount of **9** was formed but also, that some starting material (**8**) and an unidentified, slow-moving substance were present, each at an estimated 10%. Work-up gave crystalline **9** which after recrystallization from ethyl acetate – petroleum ether weighed 38 mg (48%) and melted at 157–158°. Its i.r. spectrum was identical with that of **9** obtained under (*a*).

Generation of 8 from 7, and Addition Reactions of 8

(a) General Procedure

Samples of the nitro glycoside **7** (4) (300 mg) and Al_2O_3 (600 mg) were refluxed in toluene (30 ml). Having observed by means of t.l.c. in pilot experiments that **8** was formed and disappeared as depicted in Fig. 3, we arrested the reactions by cooling and filtering the solutions after 40–45 min. In one experiment the solution was evaporated to dryness and the solid residue recrystallized from ethyl acetate – petroleum ether to give impure **8** (205 mg). The i.r. spectrum was very similar to that of authentic **8**, but weak carbonyl and nitroalkane peaks suggested the presence of **9** and **7**, as did a chromatogram. For the addition reactions described subsequently, the filtered toluene solutions were used directly without isolation of **8**.

(b) Methyl 4,6-O-Benzylidene-3-deoxy-2-O-methyl-3-nitro-β-D-galactopyranoside (10)

To the toluene solution (see (*a*), above) was added, at 25°, a solution of sodium (5 mg) in methanol (5 ml). After 30 min, the mixture was deionized and evaporated to furnish a crystalline residue. Recrystallization from methanol–water gave **10** (144 mg, 46%) in 2 crops of m.p. 170–171° and 169–170°; ν_{max} 1555 cm^{-1} (nitroalkane).

Anal. Calcd. for $C_{15}H_{19}NO_7$ (325.3): C, 55.39; H, 5.89; N, 4.31. Found: C, 55.25; H, 5.76; N, 4.29.

Treatment of an authentic sample of **8** (100 mg) in methanol (10 ml) with a few drops of 0.2 *N* sodium methoxide solution for 20 min at 23° followed by deionization, evaporation, and recrystallization gave **10** (98 mg, 88%) as fine needles, m.p. 171°, $[\alpha]_D$ +35.1 (*c*, 1 in dimethylformamide). Infrared and n.m.r. spectra established its identity with the previous product.

Nuclear magnetic resonance data. The substituent signals were τ 2.65 (5H multiplet, $-C_6H_5$); τ 4.52 (1H singlet, benzylidene hydrogen); τ 6.42 and 6.45 (two 3H singlets, $-OCH_3$). The chain hydrogen signals were centered at τ 5.39 (quartet, H-4, with $J_{4,5}$ = 1 Hz and $J_{4,3}$ = 4 Hz); τ 5.51 (quartet, H-3, with $J_{3,4}$ = 4 Hz and $J_{3,2}$ = 9.5 Hz); τ 5.65 (quartet, H-6, with $J_{6,6'}$ = 12.5 Hz and $J_{6,5}$ = 1.5 Hz); τ 5.75 (doublet, H-1, with $J_{1,2}$ = 7.5 Hz); τ 5.98 (two partially overlapping quartets, H-6′ and H-2, with $J_{6,6'}$ = 12.5 Hz, $J_{6',5}$ = 1.5 Hz,

$J_{2,1}$ = 7.5 Hz, and $J_{2,3}$ = 9.5 Hz); τ 6.55 (narrow quartet, H-5, with width at half-height = 4 Hz). In *acetonitrile solution*, the chemical shift difference between H-6 and H-6′ was strongly reduced so that their signals moved together giving a narrow, apparent triplet situated between and not overlapped by the H-1 doublet and the H-2 quartet; the narrow H-4 signal overlapped the upfield portion of the H-3 quartet, and the H-5 signal was displaced slightly downfield of the OCH_3 peaks.

(c) Methyl 4,6-O-Benzylidene-3-deoxy-2-O-ethyl-3-nitro-β-D-galactopyranoside (11)

Starting from the glycoside **7** (as in (*a*), above) and proceeding as in (*b*) except for the use of sodium ethoxide instead of sodium methoxide, we obtained a crude product that was recrystallized from ethanol–water to give colorless needles (168 mg, 53%) of **11** in 2 crops, m.p. 174–176° and 176–178°, which upon further, joint recrystallization melted at 186°; ν_{max}, doublet 1553–1563 cm^{-1} (nitroalkane).

Anal. Calcd. for $C_{16}H_{21}NO_7$ (339.3): C, 56.63; H, 6.24; N, 4.13. Found: C, 56.46; H, 6.09; N, 4.01.

Authentic **8** and sodium ethoxide in ethanol (30 min at 23°) produced **11** in a yield of 95% (crude; 84% after recrystallization). It melted at 186°, showed $[\alpha]_D$ +37.7° (*c*, 0.9 in chloroform), and it was identical with the previous product according to t.l.c., i.r., and n.m.r. spectroscopy.

Nuclear magnetic resonance data. The spectrum showed the same general features as that of **10**, except that there was only one OCH_3 peak (τ 6.45). The OC_2H_5 group gave a 3H triplet centered at τ 8.88 and a 2H quartet at τ 6.23.

(d) Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-2-piperidino-β-D-galactopyranoside (12)

The nitro glycoside **7** was treated as described in (*a*), above. To the filtered solution was then added piperidine (0.5 ml) at room temperature. After 15 min the solvent was removed, and the residue was evaporated twice with ethyl acetate and twice with ethanol and was then recrystallized from ethanol–water. Compound **12** (139 mg, 38%) was obtained in two crops, m.p. 141–142° and 139–141°; ν_{max} 1558 cm^{-1} (nitroalkane).

Anal. Calcd. for $C_{19}H_{26}N_2O_6$ (378.4): C, 60.30; H, 6.93; N, 7.48. Found: C, 60.50; H, 7.08; N, 7.46.

A solution of authentic **8** (100 mg) and piperidine (0.05 ml) in benzene (3 ml) was allowed to stand at 23° for 15 min. The yellow solution was evaporated with several successive additions of benzene, ethyl acetate, and ethanol. The residue was recrystallized from a small amount of cold ethanol by careful addition of water, to give **12** (85 mg, 70%) of m.p. 140° (decomposition). Another recrystallization using warm ethanol but avoiding prolonged heating gave felt-like needles of m.p. 140–141° (decomposition); $[\alpha]_D$ + 72.5° (*c*, 1 in chloroform).

Nuclear magnetic resonance data. The substituent signals were at τ 2.69 (5H multiplet, $-C_6H_5$); τ 4.55 (1H singlet, benzylidene hydrogen); τ 6.51 (3H singlet, $-OCH_3$); τ 7.3 (broad 4H multiplet, α-CH_2 groups of $-NC_5H_{10}$); τ 8.59 (6H singlet, β- and γ-CH_2 groups of $-NC_5H_{10}$). The chain hydrogen signals were centered at τ 5.33 (quartet, H-3, with $J_{3,4}$ = 4 Hz and $J_{3,2}$ = 11.5 Hz); τ 5.48 (quartet, H-4, with $J_{4,3}$ = 4 Hz and $J_{4,5}$ = 1.5 Hz); τ 5.63 (doublet, H-1, with $J_{1,2}$ = 8.5 Hz); τ 5.70 (quartet, H-6, with $J_{6,6'}$ = 12.5 Hz and $J_{6,5}$ = 1.5 Hz); τ 5.94 (quartet, H-6′, with $J_{6',6}$ = 12.5 Hz and $J_{6',5}$ = 1.5 Hz); τ 6.66 (narrow quartet, H-5); H-2 gave a quartet centered at τ 6.53, and although one of the lines was obscured by the OCH_3 peak, the spacings of 8.5 Hz ($J_{1,2}$) and 11.5 Hz ($J_{2,3}$) could still be verified. Assignments were confirmed by deuterium exchange at C-3 which was accomplished by prolonged stirring of a solution of **12** in $CDCl_3$ with two successive portions of D_2O and drying of the organic phase over magnesium sulfate. The H-3 quartet disappeared, the H-4 quartet collapsed to a narrow doublet, and the H-2 signal changed to two lines (spaced by 8.5 Hz) straddling the OCH_3 peak.

Reactions of nitro sugars. XII. A novel type of disaccharide synthesis[1]

HANS H. BAER AND FRANK KIENZLE
Department of Chemistry, University of Ottawa, Ottawa 2, Canada
Received February 20, 1969

Nitro disaccharide methyl glycosides were obtained by base-catalyzed addition of partially blocked sugar derivatives having one free hydroxyl group, across the ethylenic bond in methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hex-2-enopyranoside (**1**) and its α-anomer (**2**). Thus, the addition of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose (**3**) gave blocked derivatives of sophorose, namely methyl 2-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside (**4**) and -α-D-glucopyranoside (**5**). Similarly, the use of methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside (**10**) and its α-anomer (**13**) as addends led to 2 → 2 linked bisglycosidyl ethers; these were the methyl 4,6-*O*-benzylidene-3-deoxy-2-*O*-(methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-D-glucopyranosid-2-yl)-3-nitro-D-glucopyranosides with the anomeric configurations β,β, α,α, and α,β (**11**, **14**, and **15**, respectively). Methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-mannopyranoside (**12**) was found to epimerize to **10** under the reaction conditions; therefore, interaction of **12** and **1** also gave the bis-β-D-glucosidyl ether (**11**). The L-enantiomer of **12** gave with **1** an optically inactive *meso* compound (**16**) possessing a β-L- and a β-D-glucosidyl moiety.

Canadian Journal of Chemistry, 47, 2819 (1969)

Only one disaccharide that contains a nitro sugar has been described in the literature (1): a trehalose-type compound composed of α-D-glucopyranose and 4-deoxy-4-nitro-β-D-*gluco*-heptulopyranose, which was obtained by nitromethane cyclization of the dialdehyde arising in a partial lead tetraacetate oxidation of sucrose. We now wish to report the synthesis of several disaccharide methyl glycosides derived from 3-deoxy-3-nitro-D-glucose. The new compounds were prepared by a method not common in disaccharide synthesis, namely, by nucleophilic addition of one monosaccharide component across an activated double bond in a second component. This article represents a continuation of our recent work on the preparation of nitro sugar ethers (2–4) and branched-chain dinitro sugars (5), in which the same principle of nucleophilic addition was employed.

Methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hex-2-enopyranoside (**1**) as well as its α-anomer (**2**) were allowed to react with 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose (**3**) in refluxing benzene for 3 h. Although the reactions, which were catalyzed by a small amount of solid potassium hydroxide (3), did not go to completion, crystalline disaccharide derivatives (**4** and **5**) could be isolated in yields of 51 and 36%, respectively. They were methyl 2-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside (**4**) and -α-D-glucopyranoside (**5**). Acid debenzylidenation furnished the corresponding, partially acetylated compounds **6** and **7**, and subsequent acetylation gave the hexaacetates **8** and **9**. The disaccharide glycosides may be regarded as derivatives of sophorose (2-*O*-β-D-glucopyranosyl-D-glucose). Proof of configuration will be presented below.

While the synthesis of 1,2-linked disaccharides as just described was a logical extension of our previous work concerning the introduction of various substituents into position-2 of 3-deoxy-3-nitro sugars, there was a second reason that prompted the present investigation. As was reported in 1965, the unsaturated nitro glycoside **1** can be prepared readily by dehydroacetylation of methyl 2-*O*-acetyl-4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside with dry sodium bicarbonate in anhydrous benzene (6); the α-anomer **2** is made analogously (7). We now wish to communicate that, although compound **1** in particular has since been prepared in this laboratory numerous times without difficulty, on some occasions there was encountered an unidentified, high-melting by-product (m.p. 295–299°). Its infrared (i.r.) spectrum suggested a saturated nitro sugar structure devoid of acetyl or hydroxyl functions. The formation of this by-product occurred erratically and seemed to be favored when moisture was not rigorously excluded in the operation. For a working hypothesis it was considered that a small part of **1** may become hydrated to methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside (**10**) which could then react with excess **1** to form the bisglycosidyl ether **11**. The spectral and analytical

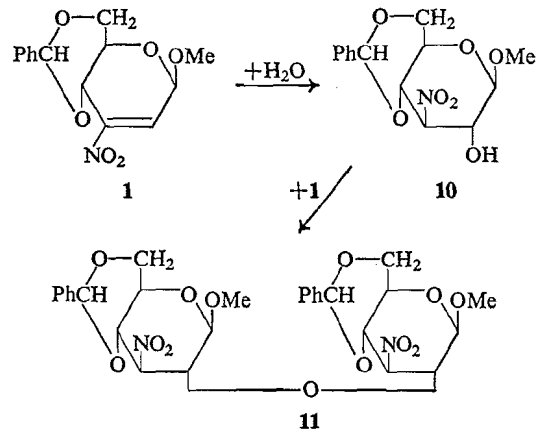
data of the unknown product were in keeping with structure **11**.

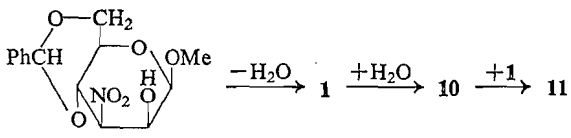
This concept has been substantiated by an experiment showing that water can indeed be added with ease (even without provision of a catalyst) across the double bond of **1** to give **10**. Final proof for the by-product to possess structure **11** was obtained through its synthesis in 65% yield by the interaction of equimolar amounts of **1** and **10**. The compound, whose configurational elucidation will be discussed in a subsequent paragraph, is named methyl 4,6-*O*-benzylidene-3-deoxy-2-*O*-(methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl)-3-nitro-β-D-glucopyranoside. As far as we are aware, **11** is the first example of a derivative of a 2 → 2 linked aldose disaccharide[2].



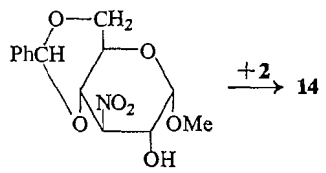
When methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-mannopyranoside (**12**) was substituted for **10** in the above synthesis, the product was the same bis-glucoside **11**, not a stereoisomer thereof. It was verified in a separate experiment that epimerization of **12** to **10** takes place under the reaction conditions. Evidently **10**, with its equatorial hydroxyl group, combines with **1** more readily than does **12** with its axial hydroxyl group. Epimerization in the same sense, undoubtedly proceeding via intermediate **1**, has already been mentioned in the foregoing paper (4) and in earlier work cited there.

A number of stereoisomers of **11** were synthesized as follows. Methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-α-D-glucopyranoside (**13**, the α-anomer of **10**) was added to **2** (the α-anomer of **1**), to produce the bis-α-glycosidyl ether, methyl 4,6-*O*-benzylidene-3-deoxy-2-*O*-(methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-glucopy-

[2]Actually, **11** is a (bis-benzylidenated) intermolecular anhydride of a glycoside. It could be named also as bis(methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl) ether, but such a name ceases to be shorter than one of the type given above when the two moieties are nonidentical, as is the case in some of the analogues to be described. We are obliged to Dr. R. S. Tipson, Washington, D.C., for his kind advice on the nomenclature.



12



13

ranosid-2-yl)-3-nitro-α-D-glucopyranoside (**14**). Combination of the nitroolefin **2** and the nitro alcohol **10** furnished the mixed ether, methyl 4,6-*O*-benzylidene-3-deoxy-2-*O*-(methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl)-3-nitro-α-D-glucopyranoside (**15**)[3]. Finally we synthesized a stereoisomer in which one moiety possesses the β-D-*gluco* configuration and the other, the β-L-*gluco* configuration. This optically inactive *meso* compound, methyl

16

[3]The same ether would be expected to arise from an addition of **13** to **1**. The α and β prefixes in the name of **15** are interchangeable.

[4]A sample of the β-L-mannoside (enantiomer of **12**) happened to be on hand, but the β-L-glucoside (enantiomer of **10**) would have afforded the same product. As shown above for the D-series, *manno* to *gluco* epimerization precedes the disaccharide formation.

4,6-*O*-benzylidene-3-deoxy-2-*O*-(methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl)-3-nitro-β-L-glucopyranoside (**16**), was obtained from **1** and the optical antipode of **12**[4].

Mild acid hydrolysis of the disaccharides **11**, **14**, and **15** gave the corresponding, debenzylidenated compounds **17**, **18**, and **19**, and these were acetylated with acetic anhydride and boron trifluoride to yield the tetraacetates **20**, **21**, and **22**.

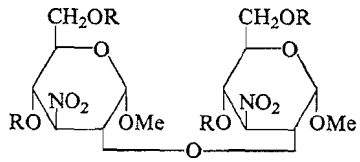
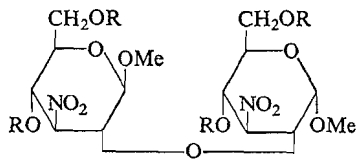
20 R=Ac



18 R=H
21 R=Ac



19 R=H
22 R=Ac

Concerning the stereochemistry of the new disaccharide synthesis it is to be noted that bond formation between the nucleophilic donor and the unsaturated acceptor molecules resulted, in all instances, in 2,3-diequatorial substituent orientation and, therefore, D-*gluco* configuration in the latter component. This was in line with what had been observed earlier in similar addition reactions using various other nucleophiles (2–5). Configurational proof was afforded, as in the previous studies (2, 4, 5), by the character of the nuclear magnetic resonance (n.m.r.) signals from the protons at nitro-substituted C-3. In the acetates **8**, **9**, **20**, **21**, and **22** these signals, which occurred at lowest fields near τ 4.6, were symmetrical triplets with large splittings (10 Hz)

indicating triaxial proton arrangement at C-2, C-3, and C-4. The H-3 triplets of the mononitro compounds **8** and **9** showed the required, one-proton intensity. In the symmetrical dinitro ethers **20** and **21**, all the signals given by one half of the molecule coincided with the corresponding ones of the other half, according to expectation. Thus, the spectra showed one H-3 triplet, one methoxyl singlet, and two separate *O*-acetyl singlets in an intensity ratio 1:3:3:3, although each signal was caused by a double number of protons. By contrast, the molecule halves of the unsymmetrical dinitro ether **22** gave corresponding signals that differed in chemical shift. There were two partially overlapping H-3 triplets, two methoxyl peaks, and four *O*-acetyl peaks (for details see Experimental).

A final point to be considered was the anomeric configuration of the disaccharide linkages in **4** and **5**. It was assumed that no anomerization of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose (**3**) took place during its addition to **1** and **2**, respectively, and consequently, that the linkages were of the β-type. Owing to crowding of the pertinent n.m.r. signals this feature could not be verified unambiguously by means of the spectra. However, the optical rotations of **4** and **5** and their derivatives listed in Table I clearly established the β-disaccharide linkages. The moderate levorotations of the methyl β-glycosides **4**, **6**, and **8**, and the relatively low dextrorotations of the methyl α-glycosides **5**, **7**, and **9**, are comparable in magnitude with the values recorded in the literature for anomeric derivatives of β-D-glucopyranosyl-D-glucoses (sophorose, laminaribiose, cellobiose, gentiobiose), whereas the corresponding derivatives of α-D-glucopyranosyl-D-glucoses (kojibiose, nigerose, maltose, isomaltose) show much higher dextrorotations (8).

Also included in Table I are physical constants of the new 2 → 2 linked disaccharides.

Experimental

The starting compounds **1** (6), **2** (7), **3** (9), **10** (6), **12** (10), the L-enantiomer of **12** (11), and **13** (10) were prepared as previously reported. Melting points were taken in capillaries in an electric aluminium block apparatus. Petroleum ether refers to the fraction of boiling range 30–60°. Thin-layer chromatography (t.l.c.) was performed on silica gel G with ethyl acetate – petroleum ether in the ratio (v/v) 1:1 (solvent *a*) or 1:2 (solvent *b*). Optical rotations (Table I) were determined at about 25° using a Perkin–Elmer 141 photoelectric polarimeter. Infrared spectra were obtained by the Nujol mull technique on a Beckman IR-8 instrument. Nuclear magnetic resonance spectra were taken in chloroform-*d* solution, with internal tetramethylsilane standard, on a 100 MHz Varian spectrometer.

Methyl 2-O-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl)-4,6-O-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside (4)

The nitroolefin **1** (293 mg, 1 mmole) and β-D-glucopyranose 2,3,4,6-tetraacetate (**3**) (348 mg, 1 mmole) were refluxed in dry, reagent grade benzene (50 ml) in the presence of a small chip of potassium hydroxide (ca. 5 mg). Monitoring by t.l.c. (solvent *a*) revealed that the slow-moving (**3**) and fast-moving (**1**) starting materials were gradually replaced by a reaction product (**4**) of inter-

mediate mobility. Refluxing was discontinued after 3 h although residual **1** and **3** were still present. (Prolonged reaction times allowed in preliminary experiments failed to increase the yield). The solution was treated with activated charcoal, filtered, and evaporated to leave a solid residue which after one recrystallization from ethyl acetate – petroleum ether gave colorless **4** (329 mg, 51%) melting at 216°. The m.p. was raised to 218° by another recrystallization from the same solvents and then remained unchanged.

Infrared bands were at 1745 (strong, C=O) and 1555 cm^{-1} (medium strong, NO_2), and at 765 and 705 cm^{-1} (medium strong, C_6H_5); there was no hydroxyl absorption.

Nuclear magnetic resonance data: τ 2.65 (5 H) and 4.51 (1 H), C_6H_5CH; τ 6.42 (3 H), OCH_3; τ 7.92, 7.95, 8.00, 8.03 (12 H), 4 $OCOCH_3$. The 14 sugar chain protons gave complicated signals in the region τ 4.8–6.6.

Anal. Calcd. for $C_{28}H_{35}NO_{16}$ (mol. wt., 641.6): C, 52.42; H, 5.50; N, 2.18. Found: C, 52.64; H, 5.40; N, 2.20.

Methyl 2-O-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl)-3-deoxy-3-nitro-β-D-glucopyranoside (6)

The benzylidene compound **4** (300 mg) and 70% acetic acid (25 ml) were heated on a steam bath for 30 min. Complete conversion of **4** into a non-migrating product was revealed by t.l.c. (solvent *a*). Evaporation of the solution, followed by three co-evaporations with water and two with ethanol, gave a solid which upon recrystallization from aqueous ethanol yielded **6** (163 mg, 63%) of m.p. 159–160°, raised to 164–165° by recrystallization from the same solvents. The i.r. spectrum exhibited broad hydroxyl absorption with ν_{max} 3380 and 3200 cm^{-1}, and bands attributable to C_6H_5 were lacking. A strong ester peak was at 1740 cm^{-1}, and a nitro peak at 1553 cm^{-1}.

Anal. Calcd. for $C_{21}H_{31}NO_{16}$ (mol. wt., 553.5): C, 45.58; H, 5.65; N, 2.53. Found: C, 45.71; H, 5.72; N, 2.36.

Methyl 4,6-Di-O-acetyl-2-O-(2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl)-3-deoxy-3-nitro-β-D-glucopyranoside (8)

Compound **6** (175 mg) was dissolved in acetic anhydride (2 ml), and *one* drop of boron trifluoride etherate was added. The mixture was allowed to stand at ambient temperature for 10 min. Ethanol (5 ml) was then added, and the solution was evaporated to a syrup which was co-evaporated thrice with toluene and twice with ethanol. The residue was dissolved in a small amount of ethyl acetate, petroleum ether was added to incipient cloudiness, and the hexaacetate **8** separated in the course of 2 weeks at 5° as a gel-like material. Filtration, washing with petroleum ether, and drying in a high vacuum gave a white powder (141 mg, 70%) that melted at 97–98°. It showed strong i.r. bands at 1740 (C=O) and 1563 cm^{-1} (NO_2) but lacked hydroxyl absorption.

Nuclear magnetic resonance data: τ 4.64 (triplet, 1 H, J = 9.7 Hz), H-3; τ 4.85–5.95 and ca. 6.3 (compli cated pattern of total intensity 13 H), sugar chain protons; τ 6.44 (singlet, 3 H), OCH_3; τ 7.92, 7.92, 7.96, 7.98, 8.00, 8.03 (singlets, 18 H), 6 $OCOCH_3$.

Anal. Calcd. for $C_{25}H_{35}NO_{18}$ (mol. wt., 637.6): C 47.10; H, 5.53; N, 2.19. Found: C, 47.29; H, 5.48; N, 2.29.

Methyl 2-O-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl)-4,6-O-benzylidene-3-deoxy-3-nitro-α-D-glucopyranoside (5)

The reaction between the nitroolefin **2** and the tetraacetate **3** was carried out precisely as described above for the preparation of **4**, except for a reflux time of 2.5 h. There was obtained, after recrystallization, 232 mg (36%) of **5** as fine, colorless needles with m.p. 267° (unchanged on further recrystallization). Characteristic i.r. bands were at 1745 (with satellite at 1773) (C=O), 1568 (NO_2), and 773 and 705 cm^{-1} (C_6H_5).

Nuclear magnetic resonance data: τ 2.64 (5 H) and 4.50 (1 H), C_6H_5CH; τ 6.55 (3 H), OCH_3; τ 7.91, 7.98, 7.98, 8.02 (12 H), 4 $OCOCH_3$. The 14 sugar chain protons gave complicated signals in the region τ 4.7–6.3.

Anal. Calcd. for $C_{28}H_{35}NO_{16}$ (mol. wt., 641.6): C, 52.42; H, 5.50; N, 2.18. Found: 52.60; H, 5.47; N, 2.30.

Methyl 2-O-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl)-3-deoxy-3-nitro-α-D-glucopyranoside (7)

The debenzylidenation of compound **5** (110 mg), performed as that of **4**, afforded **7** (89 mg, 93%) as beautiful needles, m.p. 197°, from aqueous ethanol. The i.r. spectrum showed broad hydroxyl absorption with ν_{max} 3570, 3510, and 3250 cm^{-1}, as well as strong peaks at 1740 (C=O) and 1553 cm^{-1} (NO_2).

Anal. Calcd. for $C_{21}H_{31}NO_{16}$ (mol. wt., 553.5): C, 45.58; H, 5.65; N, 2.53. Found: C, 45.48; H, 5.56; N, 2.41.

Methyl 4,6-Di-O-acetyl-2-O-(2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl)-3-deoxy-3-nitro-α-D-glucopyranoside (9)

Compound **7** (55 mg) was treated with acetic anhydride (2 ml) and 1 drop of boron trifluoride etherate as described for the acetylation of **6**. The hexaacetate **9** was obtained as needles (44 mg, 69%) from 50% ethanol. It melted at 166° (rapid heating) or at 175–176° (very slow heating). The i.r. spectrum showed strong bands at 1740 (C=O) and 1560 cm^{-1} (NO_2); hydroxyl absorption was absent.

Nuclear magnetic resonance data: τ 4.60 (triplet, 1 H, J = 10 Hz), H-3; τ 4.8 – 5.2 (overlapping signals corresponding to 5 chain protons); τ 5.50 (doublet, 1 H, J = 8 Hz), H-1′; τ 5.65–ca. 6.4 (overlapping signals corresponding to 7 chain protons); τ 6.56 (singlet, 3 H), OCH_3; τ 7.91–8.02 (partially overlapping singlets, 18 H), 6 $OCOCH_3$.

Anal. Calcd. for $C_{25}H_{35}NO_{18}$ (mol. wt., 637.6): C, 47.10; H, 5.53; N, 2.19. Found: C, 47.26; H, 5.42; N, 2.22.

Hydration of Nitroolefin 1

A solution of compound **1** (90 mg) in tetrahydrofuran (10 ml) and water (10 ml) was gently refluxed on a steam bath. Inspection at intervals by t.l.c. (solvent *b*) revealed that the fast-moving **1** was largely converted into a slow-moving product (**10**) within 3.5 h. Removal of the solvents *in vacuo* gave a white solid which upon recrystallization from aqueous ethanol furnished crude **10** (41 mg), m.p. 171–173°. Once more recrystallized from ethyl acetate – petroleum ether, the product (24 mg) melted at 180–181°, showed $[\alpha]_D$ −73.2° (*c*, 0.5 in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ethanol), and gave an i.r. spectrum identical with that of authentic **10**. Reported (6): m.p. 181–182°, $[\alpha]_D$ −72.5° (in ethanol).

Epimerization of the Nitro Mannoside ***12***

Compound **12** (20 mg) was refluxed in dry benzene (10 ml) in the presence of a chip of potassium hydroxide (ca. 5 mg). The conversion into the nitro glucoside **10** was monitored by t.l.c. with solvent *b* (in which **10**, moving somewhat faster, clearly separates from **12**) and was found to be nearly complete after 1 h. Evaporation of the solvent left a solid which was recrystallized from ethyl acetate – petroleum ether to give 14 mg (70%) of chromatographically pure **10**, m.p. 179–180°. A mixture melting point with authentic **10** (6) was undepressed, and the i.r. spectra were identical.

Methyl 4,6-O-Benzylidene-3-deoxy-2-O-(methyl 4,6-O-benzylidene-2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl)-3-nitro-β-D-glucopyranoside ***(11)***

(a) From ***1*** *and* ***10***

The nitroolefin **1** (586 mg, 2 mmole) and nitro glucoside **10** (622 mg, 2 mmole) were refluxed in dry benzene (100 ml) together with a piece (about 20 mg) of solid potassium hydroxide. Thin-layer chromatography with solvent *b* indicated that the starting compounds **1** and **10** (R_f approximately 0.8 and 0.3, respectively) gradually diminished with concurrent formation of a product that did not migrate. (Traces of a very fast by-product were also noticed.) The reaction was stopped after 5 h when it had progressed far, though not quite to completion. The brown solution was decolorized with activated charcoal and evaporated to give a white solid. Recrystallization from ethyl acetate – petroleum ether gave crude **11** (795 mg, 66%) melting at 272–275° decomp. Another recrystallization from the same solvents afforded virtually pure needles (610 mg) of m.p. 295–296° decomp. An analytical sample (twice more recrystallized) had m.p. 299° decomp. The most prominent i.r. bands were at 1555 (nitroalkane), 1105, and 987 cm^{-1} (strong), and at 1168, 1070, 1045, 755, 732, 705, and 665 cm^{-1} (medium strong). Hydroxyl absorption was absent.

Anal. Calcd. for $C_{28}H_{32}N_2O_{13}$ (mol. wt., 604.6): C, 55.62; H, 5.34; N, 4.63. Found: C, 55.73; H, 5.47; N, 4.77.

(b) From ***1*** *and* ***12***

Nitroolefin **1** (50 mg) and nitro mannoside **12** (55 mg) were allowed to react in benzene (25 ml) as described under (*a*) and yielded 28 mg of pure **11**, m.p. 295° decomp. (raised to 299° by further recrystallization). The i.r. spectrum was superimposable with that of **11** as prepared under *(a)* and with that of the high-melting by-product that has occasionally been encountered in the synthesis (6) of **1**.

An experiment in which 1 drop of pyridine was substituted for the potassium hydroxide catalyst failed to produce **11**. According to t.l.c., the starting materials did not seem to change during 24 h of refluxing.

Methyl 3-Deoxy-2-O-(methyl 2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl)-3-nitro-β-D-glucopyranoside ***(17)***

A suspension of **11** (430 mg) in 85% acetic acid (30 ml) was heated on the steam bath until dissolution was complete (4 h). Evaporation *in vacuo*, followed by three evaporations with water and one each with ethanol and ethyl acetate, gave a solid which was dissolved in ethyl acetate (5 ml). Addition of a small amount of petroleum ether and cooling (2 h at 0°) induced crystallization of fine needles (247 mg, 81%) which were isolated and washed with ethyl acetate – petroleum ether (1:2); m.p. 205–206° decomp., unchanged after another recrystallization. (This m.p. was observed when the sample was introduced at 200°; slow temperature raise caused decomposition without melting). Compound **17** showed strong, broad hydroxyl absorption with ν_{max} 3400 and 3200 cm^{-1}.

Anal. Calcd. for $C_{14}H_{24}N_2O_{13}$ (mol. wt., 428.4): C, 39.26; H, 5.65; N, 6.54. Found: C, 39.40; H, 5.72; N, 6.65.

Methyl 4,6-Di-O-acetyl-3-deoxy-2-O-(methyl 4,6-di-O-acetyl-2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl)-3-nitro-β-D-glucopyranoside ***(20)***

The compound **17** (90 mg) was treated with acetic anhydride (2 ml) and boron trifluoride etherate (2 drops) for 10 min at room temperature. Excess anhydride was removed by several co-evaporations with toluene. The crystalline residue was once evaporated with added ethanol and then recrystallized from ethyl acetate – petroleum ether; from these solvents the tetraacetate (**20**) crystallized as big prisms (65 mg) of m.p. 237° decomp. Precipitation by water from solution in DMF or DMSO produced fine needles of the same melting point and with a closely similar i.r. spectrum. There were strong peaks at 1750 and 1737 cm^{-1} (acetate C=O) and at 1555 cm^{-1} (NO_2), and hydroxyl absorption was absent.

In addition to the (constant) specific rotation in *chloroform* (Table I), the rotation in *dimethylformamide* (*c*, 0.85) was taken: $[\alpha]_D$ +24.7° (initial) → +9.9° (5 min) → −23.5° (25 min, constant). The cause of the mutarotation is not clear but could possibly be *aci* – salt formation due to dimethylamine present in the DMF. Compound **20** was recovered unchanged by precipitation with water.

Nuclear magnetic resonance data: τ 4.52 (triplet, J = 10 Hz), H-3; τ 5.39 (triplet, J = 10 Hz), H-4; τ 5.58 (doublet, J = 7.5 Hz), H-1; τ 5.65–6.00 (series of poorly resolved signals due to C-6 methylene and H-2); τ 6.4 (multiplet, extending beneath OCH_3 signal), H-5; τ 6.52 (singlet), OCH_3; τ 7.92 and 7.97 (singlets), $OCOCH_3$.

Anal. Calcd. for $C_{22}H_{32}N_2O_{17}$ (mol. wt., 596.5): C, 44.30; H, 5.41; N, 4.70. Found: C, 44.42; H, 5.34; N, 4.61.

Methyl 4,6-O-Benzylidene-3-deoxy-2-O-(methyl 4,6-O-benzylidene-2,3-dideoxy-3-nitro-α-D-glucopyranosid-2-yl)-3-nitro-α-D-glucopyranoside ***(14)***

Compound **14** was obtained from nitroolefin **2** (425 mg) and nitro glycoside **13** (440 mg) by the procedure (*a*) given for the preparation of **11**. Because of increasing discoloration of the solution, the reaction was stopped after 1.5 h although t.l.c. (solvent *b*) showed considerable spots of **2** and **13** besides a predominant spot of nonmigrating **14** at that stage. The residue of evaporation was dissolved

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in ethyl acetate from which, on addition of petroleum ether and cooling (2 h at 5°), colorless crystals of **14** (210 mg, 24%) separated. They decomposed at about 340°. Recrystallization from benzene – ethyl acetate – petroleum ether (5:1:5) gave fine needles, m.p. 348° decomp. The i.r. spectrum was similar to that of **11**, but was distinguished by a strong band at 1060 cm^{-1}.

Anal. Calcd. for $C_{28}H_{32}N_2O_{13}$ (mol. wt., 604.6): C, 55.62; H, 5.34; N, 4.63. Found: C, 55.49; H, 5.15; N, 4.73.

Methyl 3-Deoxy-2-O-(methyl 2,3-dideoxy-3-nitro-α-D-glucopyranosid-2-yl)-3-nitro-α-D-glucopyranoside (18)

Compound **14** (200 mg) was debenzylidenated with acetic acid as described for **11** → **17**. The crude reaction product was dissolved in ethanol and ethyl acetate (7 ml each), the solution clarified with charcoal, and slow crystallization (3 days at 5°) was induced by adding petroleum ether. The product **18** (57 mg, 40%) melted with decomposition at 248–250°, and at 250–251° after another recrystallization from the same solvents, when introduced at 240°. Slow heating caused decomposition without melting. According to t.l.c. the mother liquor still contained much **18** which did not crystallize. The i.r. spectrum of **18** showed strong, broad hydroxyl adsorption (ν_{max} 3380 cm^{-1}) and no phenyl bands in the 700 cm^{-1} region.

Anal. Calcd. for $C_{14}H_{24}N_2O_{13}$ (mol. wt., 428.4): C, 39.26; H, 5.65; N, 6.54. Found: C, 39.45; H, 5.69; N, 6.40.

Methyl 4,6-Di-O-acetyl-3-deoxy-2-O-(methyl 4,6-di-O-acetyl-2,3-dideoxy-3-nitro-α-D-glucopyranosid-2-yl)-3-nitro-α-D-glucopyranoside (21)

Compound **18** (28 mg) was acetylated as described for the acetylation of **17**. The tetraacetate **21** (30 mg, 77%) crystallized as fine needles, m.p. 202–203°, from 95% ethanol. It exhibited strong i.r. bands at 1735 (ester C=O) and 1550 cm^{-1} (NO_2) and lacked hydroxyl absorption.

Nuclear magnetic resonance data: τ 4.65 (triplet, J = 10 Hz), H-3; τ 5.13 (triplet, J = 10 Hz), H-4; τ 5.22 (doublet, J = 3 Hz), H-1; τ 5.6–6.2 (series of poorly resolved signals due to C-6 methylene, H-2, and H-5); τ 6.62 (singlet), OCH_3; τ 7.91 and 7.96 (singlets), $OCOCH_3$.

Anal. Calcd. for $C_{22}H_{32}N_2O_{17}$ (mol. wt., 596.5): C, 44.30; H, 5.41; N, 4.70. Found: C, 44.56; H, 5.57; N, 4.58.

Methyl 4,6-O-Benzylidene-3-deoxy-2-O-(methyl 4,6-O-benzylidene-2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl)-3-nitro-α-D-glucopyranoside (15)

Compound **15** was obtained from nitroolefin **2** (720 mg) and nitro glycoside **10** (765 mg) by the procedure (*a*) given for the preparation of **11**. The reaction time was 3 h, and 570 mg (38.5%) of **15**, m.p. 315–316° decomp., was obtained. Recrystallization from ethyl acetate–petroleum ether raised the melting point to 325° decomp. The i.r. spectrum was very similar to those of **11** and **14**, with small differences in band positions and intensities.

Anal. Calcd. for $C_{28}H_{32}N_2O_{13}$ (mol. wt., 604.6): C, 55.62; H, 5.34; N, 4.63. Found: C, 55.67; H, 5.20; N, 4.55.

Methyl 3-Deoxy-2-O-(methyl 2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl)-3-nitro-α-D-glucopyranoside (19)

A sample of **15** (100 mg) was debenzylidenated as described for **11** → **17**, except that 70% instead of 85% acetic acid was used; a reaction time of 7 h was required to effect complete dissolution of the sample. Work-up gave 28 mg (39.5%) of crystalline **19**, m.p. 240–241° decomp. (from ethanol – ethyl acetate – petroleum ether).

Another sample of **15** (45 mg) was treated at room temperature with 1 ml of 90% trifluoroacetic acid (12) in which it dissolved within 10 min. After 45 min the solution was concentrated *in vacuo* (bath temperature, 30°) to 0.5 ml. The concentrate was twice evaporated with excess ether whereby **19** crystallized. The crystals were isolated and washed with ether, and melted at 240.5–241.5° decomp. (yield, 18 mg, 57%). They showed strong, broad hydroxyl absorption (ν_{max} 3370 cm^{-1}) and a strong nitro band at 1553 cm^{-1}.

Anal. Calcd. for $C_{14}H_{24}N_2O_{13}$ (mol. wt., 428.4): C, 39.26; H, 5.65; N, 6.54. Found: C, 39.24; H, 5.89; N, 6.38.

Methyl 4,6-Di-O-acetyl-3-deoxy-2-O-(methyl 4,6-di-O-acetyl-2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl)-3-nitro-α-D-glucopyranoside (22)

Compound **19** (17 mg) was treated with acetic anhydride (1 ml) and boron trifluoride etherate (1 drop) for 15 min at room temperature. The mixture was then poured into ice cold methanol and evaporated with several additions of methanol and finally with toluene. The residue was recrystallized from chloroform – petroleum ether to give fine needles (19 mg, 89%) of **22**, m.p. 201–203° decomp. (with sintering from 199°).

Nuclear magnetic resonance data: τ 4.55 and 4.65 (two triplets, J = 10 Hz for each, combined intensity 2 H), H-3β and H-3α; τ 5.0–6.4 (complicated pattern of signals of total intensity 12 H), the remaining sugar chain protons; τ 6.47 (singlet, 3 H), β-OCH_3; τ 6.66 (singlet, 3 H), α-OCH_3; τ 7.91, 7.93, 7.96, 7.97 (singlets, 12 H total), 4 $OCOCH_3$. The substance apparently contained an impurity, as the α-OCH_3 peak was accompanied by a weak, unidentified signal (τ 6.62).

Anal. Calcd. for $C_{22}H_{32}N_2O_{17}$ (mol. wt., 596.6): C, 44.30; H, 5.41. Found: C, 44.47; H, 5.52.

Methyl 4,6-O-Benzylidene-3-deoxy-2-O-(methyl 4,6-O-benzylidene-2,3-dideoxy-3-nitro-β-D-glucopyranosid-2-yl)-3-nitro-β-L-glucopyranoside (16)

The nitroolefin **1** (160 mg) and methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-L-mannopyranoside (170 mg) were refluxed for 3 h in dry benzene (25 ml) in the presence of a chip of potassium hydroxide (ca. 10 mg). The solution was filtered with activated charcoal and evaporated to give a solid which was recrystallized from ethyl acetate – petroleum ether. There was obtained 84 mg of **16** having m.p. 292–293° decomp., raised to 325° decomp. by further recrystallization from the same

solvents. The i.r. spectrum was quite similar to those of the stereoisomeric disaccharides, but the optical rotation was 0.0° (*c*, 0.7 in dimethylformamide).

Anal. Calcd. for $C_{28}H_{32}N_2O_{13}$ (mol. wt., 604.6): C, 55.62; H, 5.34; N, 4.63. Found: C, 55.55; H, 5.21; N, 4.56.

Transannular reactions in the dibenzo[*a*,*d*]cycloheptene series. IV. 10,5 Ketone–amide interactions

M. A. DAVIS, T. A. DOBSON, AND J. M. JORDAN
Ayerst Laboratories, Ayerst, McKenna and Harrison Ltd., Montreal, Quebec

Received January 3, 1969

10-Ketodibenzocycloheptene-5-carboxamides undergo transannular interactions to form carbinolamides. This approach has been used to prepare a number of 11-substituted and -unsubstituted-10,11-dihydro-10,5-(iminomethano)-5*H*-dibenzo[*a*,*d*]cycloheptenes. The ketolactone **3** was a convenient starting material for the substituted compounds. It reacted readily with primary amines to give the carbinolamides **7** or **8**, and underwent equally rapid transformations with secondary amines or alkali to furnish products derived from aerial oxidation, decarboxylation, ring contraction, and/or dimerization. The epoxynitrile **20** was converted by a 5-step sequence to the ketocarboxamide **27** which cyclized at once to the 11-unsubstituted carbinolamide **28**. A modification of this sequence gave the carbinolamine **31**.

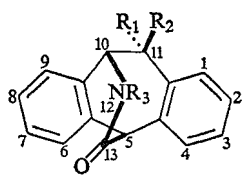
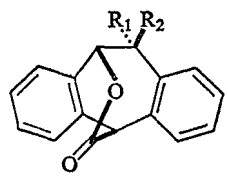
We have previously described methods for the preparation of a number of substituted 10,11-dihydro-10,5-(iminomethano)-5*H*-dibenzo[*a*,*d*]-cycloheptenes (**1**) (1). In principle, these methods utilize the ready transannular reaction of a 10-substituted dibenzocycloheptene-5-carboxamide or -carboxylate derivative. The present paper describes a related preparation of the ring system which relies on a 10,5 ketone–amide interaction to form a carbinolamide. The generality of such interactions in linear (2) and alicyclic amides (3), amino acids and peptides (4), alkaloids (5), and steroids (6) has been discussed. The method has been used for a synthesis of atisine (7) and for an analogue of a degradation product of aconitine (8).



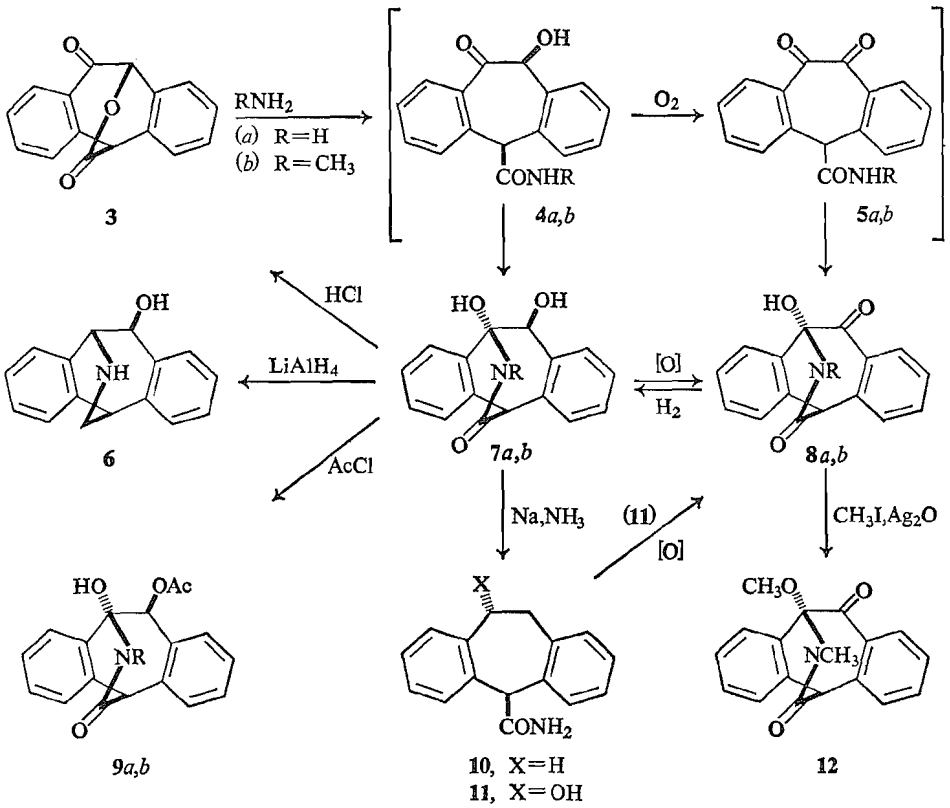
1



2*a*, R_1 = H, R_2 = OH
b, R_1 = OH, R_2 = H
c, $R_1 = R_2$ = H

Chromic acid oxidation of the readily available mixture of hydroxylactones **2***a*,*b* gave the corresponding ketolactone **3** (9). This served as starting material for several of the carbinolamides by way of its varied reactions with nucleophilic reagents. On treatment with ammonia or methylamine in the absence of air it furnished the carbinolamides **7***a*,*b* in which the secondary hydroxyl group was assigned the *syn*-configuration (see below). When the reactions were carried out in the presence of air the corresponding ketocarbinolamides **8***a*,*b* were obtained. The products were obviously formed from the intermediate *o*,*o*′-disubstituted benzoins **4** which could readily be oxidized by air to the corresponding benzils **5** *via* enediol formation (10) (Scheme I). This mechanism was supported by the observation that analytically pure **7***a* underwent aerial oxidation to **8***a* only in the presence of a base, such as ammonium hydroxide.

Several reactions were investigated which supported the structures of the carbinolamides. The action of chromic acid on **7***a* furnished **8***a*. The ketone group of **8***a* was catalytically reduced to the corresponding alcohol **7***a* which in turn was treated with lithium aluminum hydride to give the basic carbinol **6** of known geometry (1). Although **7***a* was unaffected by sodium borohydride, **8***a* gave the *anti*-hydroxylactone **2***b*, presumably by base-promoted ring opening to the 10,11-dione followed by reduction to a *trans*-diol and subsequent lactone formation on acidification. The action of sodium in liquid ammonia removed both hydroxy groups from **7***a* with concomitant ring scission to give the unsubstituted carboxamide **10**. In contrast to this result, ring cleavage did not occur when the 10-desoxy analogue of **7***a* (**1**, $R_1 = R_3 =$ H; $R_2 =$ OH) was treated with sodium in ammonia (1). The action of warm, dilute mineral acid converted **7***a* to the original ketolactone **3**. The tertiary hydroxyl group was unreactive and could not be esterified; acetylation of **7***a*,*b* under various conditions resulted only in acylation of the secondary hydroxyl group to form **9***a*,*b*. The



SCHEME I

hydroxyl group of **8***b* could, however, be etherified: the methyl ether **12** was obtained by the action of methyl iodide and silver oxide. Under similar conditions, the same compound was obtained from **7***b* by simultaneous oxidation of the secondary alcohol. The ketone group of **8***a* was unaffected by treatment with either *p*-toluenesulfonylhydrazine or 1,2-ethanedithiol.

Reactions of the ketolactone **3** with secondary amines were investigated; here carbinolamide formation would not be expected. On treatment with either dry diethylamine or morpholine in the presence of air, the lactone ring was opened and the intermediate 10,11-ketohydroxyamides **13***a,b* were rapidly oxidized to the corresponding 10,11-diones **14***a,b*. Once formed, the latter resisted further attack. When the reactions were carried out in the presence of added water, some hydrolytic opening of the lactone occurred and the resulting carboxylic acid **13***c* was oxidized to the dione **14***c*. This vinylogous β-ketoacid decarboxylated and the product (**15**), under the basic conditions of the reaction, dimerized to give the known compound **16** (11). The yield of this dimer depended on the water content of the reaction medium and became the principal product when the reactions were carried out in 30% aqueous dioxane. Similar paths were followed when the ketolactone was treated with dilute aqueous sodium hydroxide, as shown in Scheme II. Here, the 10,11-dione system could undergo a benzilic acid rearrangement under the influence of the stronger base. In agreement with the results of other workers (12), the intermediate dione **15** formed 9-anthroic acid (**19**) *via* ring contraction and dehydration. In one instance the dione carboxylic acid **14***c* rearranged before decarboxylation could occur and the dicarboxylic acid **18** was isolated. Evidence for enediol formation was obtained by the isolation of the dimeric enediol diacetate **17** on treatment of the ketolactone with sodium hydroxide followed by acetyl

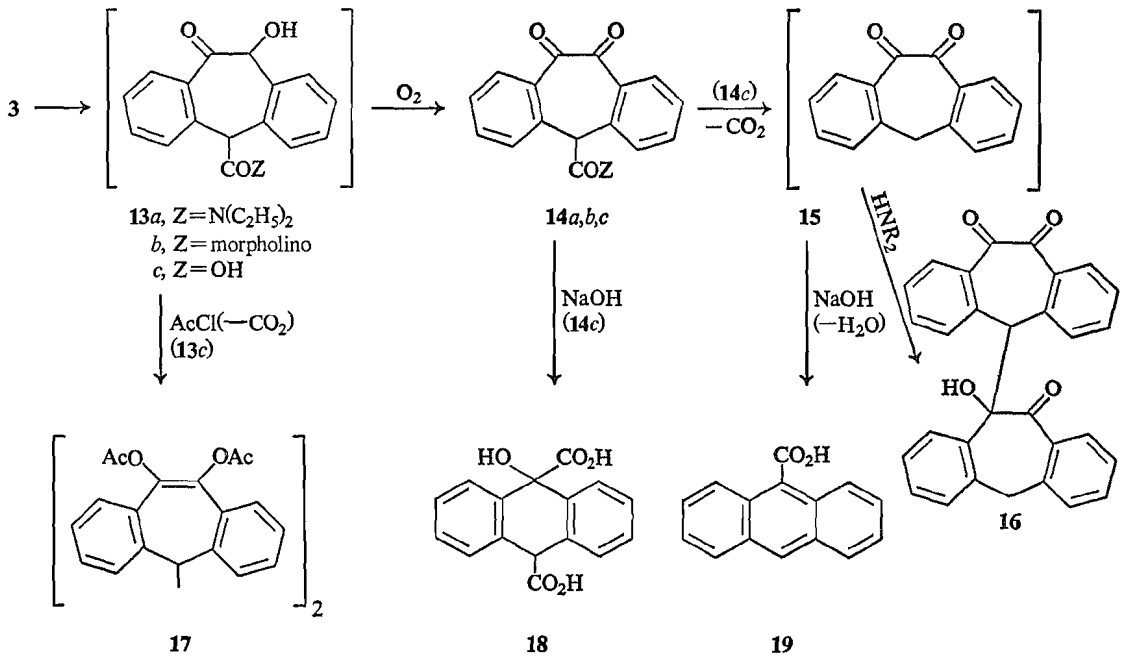

SCHEME II

chloride in the absence of air. Other 5,5′-dimerizations of the dibenzocycloheptene nucleus have been noted (13).

A different route was employed for the preparation of an 11-unsubstituted carbinolamide (Scheme III). Oxidation of 5*H*-dibenzo[*a*,*d*]-cycloheptene-5-carbonitrile with 3-chloroperbenzoic acid gave an apparently homogeneous epoxynitrile **20** of unassigned geometry. Whereas the related 5-keto- (14), 5-hydroxy (15), and 5-unsubstituted epoxides (16) are known to react normally with amines to give the corresponding 10,11-aminoalcohols, the reaction of **20** with diethylamine gave the 9-anthronitrile derivative **23**. This presumably arose by a base-promoted rearrangement of the epoxide (1) to 10-cyano-9,10-dihydro-9-anthraldehyde followed by condensation with the secondary amine and aromatization. Catalytic hydrogenation of the epoxynitrile gave a mixture of epimeric hydroxynitriles **21***a*,*b*, possibly formed by partial epimerization of **20** during the reduction. In one of these epimers, ready interaction of the functional groups occurred. Thus, the iminolactone **22** or its hydrochloride salt were obtained when the *syn*-epimer **21***a* was treated with either aqueous sodium hydroxide or anhydrous hydrogen chloride. Similar behavior has been reported for other hydroxynitriles (6*c*, 17) and the method has been used for a synthesis of aldosterone (18) and steroids bearing an 8β-substituent (19) or a bridged lactone group (20). Chromic acid oxidation of the mixture of alcohols gave the ketonitrile **24**. As with other 10-ketodibenzocycloheptenes (21), the carbonyl group of **24** was markedly enolized and readily formed enol ethers (**25***a*–*c*) rather than ketals on treatment with alcohols in acidic media. Hydration of the nitrile group of **25***a*, using hydrogen peroxide and potassium carbonate (22), gave the corresponding carboxamide **26**. Treatment of this with hydrochloric acid hydrolyzed the enol ether and the resulting 10-ketone **27** cyclized to the desired carbinolamide **28**. A related attempt to obtain **28** by chromic acid oxidation of the *anti*-hydroxyamide **11** gave the ketocarbinolamide **8***a* as the only isolable product.

Since ketone–amide interactions had been shown to proceed with considerable facility, it was of interest to study the behavior of the related ketoamine **30**. Cyclizations of ketoamines are well-known in the alkaloid field (23) and the chemistry of pseudobasic carbinolamines has been reviewed (24). Catalytic hydrogenation of

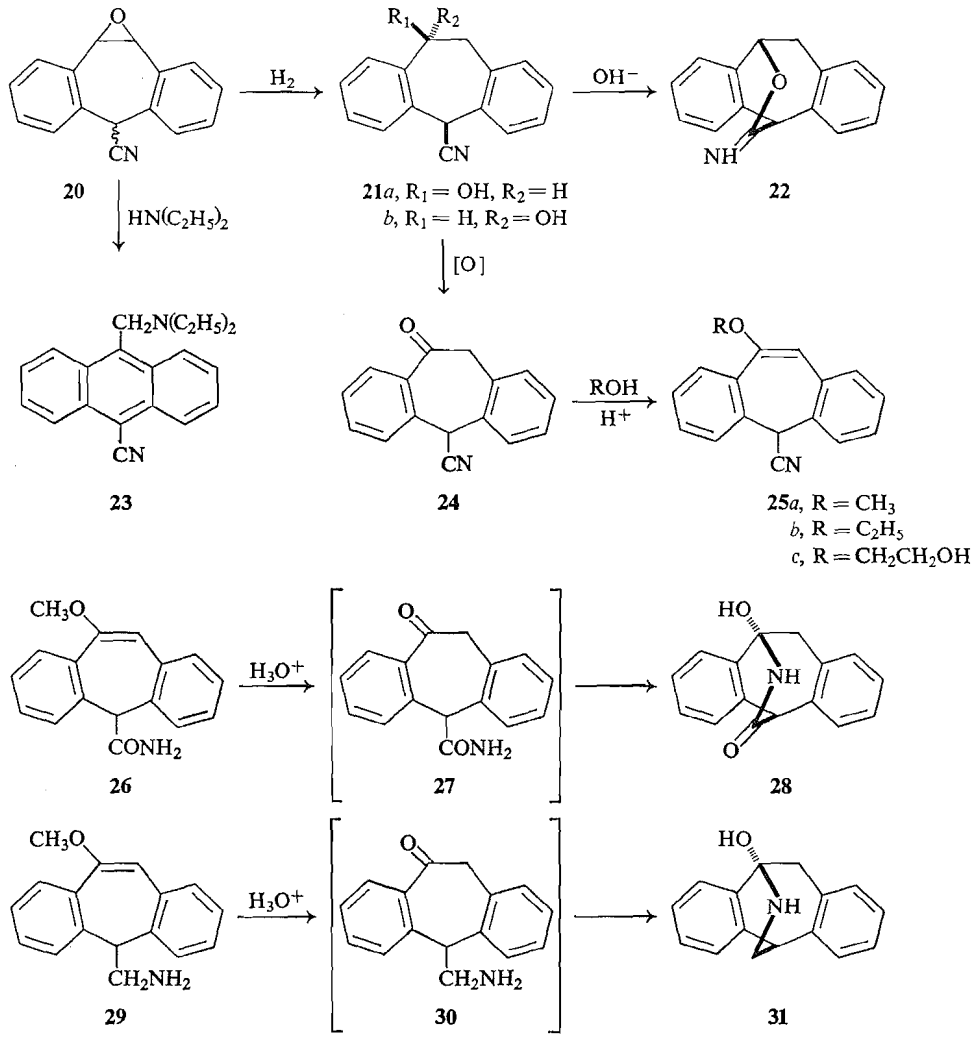

SCHEME III

the nitrile group of **25***a* gave the corresponding 5-aminomethyl compound **29**. The enol ether was hydrolyzed as before to give the 10-ketone **30** which spontaneously formed the carbinolamine **31**. Spectral data indicated that the compound existed as the cyclic form in either neutral or acidic media.

Experimental

Nuclear magnetic resonance (n.m.r.) spectra in the indicated solvents were determined using a Varian A-60A instrument; melting points were recorded on Thomas–Hoover Uni-melt apparatus.

10,11-Dihydro-10,11-dihydroxy-10,5-(iminomethano)-5H-dibenzo[a,d]cyclohepten-13-one (7a)

A solution of ketolactone **3** (8.0 g, 0.03 mole) in dioxane (40 ml) was treated with ammonium hydroxide (*d* 0.88, 250 ml) and the mixture was stirred for 2 h under argon. The precipitated product (4.2 g, 49%) was filtered off and washed with water; m.p. 175–177°, unchanged on recrystallization from chloroform–hexane or from 1,2-dimethoxyethane–ether; ν_{max} (Nujol) 3510, 3430, 3200, 3070 cm^{-1} (NH, OH); 1690 cm^{-1} (lactam); λ_{max} (EtOH) 263 mμ (ε 418); n.m.r. (DMSO), τ: 2.59 (8-H aromatic, m); 5.52 (1-H, s); 5.58 (1-H, s); 6.43 (NH + 2-OH, s).

Anal. Calcd. for $C_{16}H_{13}NO_3$ (267): C, 71.90; H, 4.90; N, 5.24. Found (*m/e* 267): C, 71.53; H, 4.91; N, 5.10.

10,11-Dihydro-10,11-dihydroxy-12-methyl-10,5-(iminomethano)-5H-dibenzo[a,d]cyclohepten-13-one (7b)

A saturated solution of methylamine in anhydrous ether (100 ml) was added to **3** (10.0 g, 0.04 mole) dissolved in dry 1,2-dimethoxyethane (125 ml). The mixture was

For personal use only.

stirred for 1.5 h under argon, diluted with hexane (50 ml), and the precipitate was filtered off. Recrystallization from acetone–hexane or dimethoxyethane gave 4.5 g (40%), m.p. 170–171°.

Anal. Calcd. for $C_{17}H_{15}NO_3$: C, 72.58; H, 5.37; N, 4.98. Found: C, 72.73; H, 5.16; N, 4.95.

From the mother liquors 1.4 g of the corresponding ketone **8***b* was obtained, m.p. 219–224° (see below).

10-Hydroxy-10,5-(iminomethano)-5H-dibenzo[a,d]cycloheptene-11,13(10H)-dione (8a)

a) A solution of **3** (10.0 g) in dioxane (50 ml), ammonium hydroxide (200 ml), and water (100 ml) was stirred and a stream of air was passed through for 3 h. Recrystallization of the precipitated product from dioxane–ether gave 7.4 g (69%) of **8***a*, m.p. 244–245°; ν_{max} (Nujol) 3420 cm^{-1} (OH); 3140, 3050 cm^{-1} (NH); 1695 cm^{-1} (ketone); 1683 cm^{-1} (lactam); λ_{max} (EtOH) 263 mμ (ε 7610); n.m.r. (DMSO), τ: 1.90 (1-H aromatic, m); 2.67 (7-H aromatic, m); 5.15 (1-H at C-5, s); 6.51 (NH + OH, s).

Anal. Calcd. for $C_{16}H_{11}NO_3$ (265): C, 72.44; H, 4.18; N, 5.28. Found (*m/e* 265): C, 72.68; H, 4.34; N, 5.29.

b) Jones' reagent (25)(2 ml) was added dropwise to a stirred solution of 10,11-dihydro-*anti*-11-hydroxy-5*H*-dibenzo[*a,d*]cycloheptene-5-carboxamide (9) (**11**, 200 mg) in acetone (25 ml). The mixture was filtered through Celite, the filtrate diluted with water and extracted with dichloromethane. The organic layer was washed with water and evaporated. Several recrystallizations of the residue from ethanol gave a sample (25 mg) of **8***a*, m.p. 210–216°, whose spectral properties were essentially identical to those of the material obtained above.

10-Hydroxy-12-methyl-10,5-(iminomethano)-5H-dibenzo[a,d]cycloheptene-11,13(10H)-dione (8b)

A saturated solution of methylamine in chloroform (150 ml) was added to **3** (6.0 g, 0.024 mole) dissolved in the same solvent (100 ml) and a stream of air was passed through the mixture for 15 min. It was kept overnight, then evaporated and the residue was recrystallized from ethanol to give 3.5 g (52%) of product, m.p. 225–227°.

Anal. Calcd. for $C_{17}H_{13}NO_3$: C, 73.11; H, 4.69; N, 5.02. Found: C, 73.07; H, 4.84; N, 5.20.

Reactions of Carbinolamides 7

Oxidation

a) A solution of **7***a* (1.0 g) in acetone (25 ml) was treated with Jones' reagent (2.9 ml) and the mixture was processed in the usual manner to give **8***a* (0.1 g), identified by m.p. and mixed m.p.

b) A solution of **7***a* (0.2 g), ammonium hydroxide (5 ml), dioxane (5 ml), and water (10 ml) was kept in an open vessel and the ultraviolet (u.v.) spectrum was taken at intervals. The percentage conversion was 25% (0.5 h), 50% (2 h), 70% (4 h), and 100% (25 h; chromatographically pure **8***a*). A similar reaction with **7***a* (0.1 g), NH_4OH (4 ml), dioxane (1 ml), and water (4 ml) gave 0.03 g of **8***a*, m.p. 233–235°.

Reduction

A suspension of **7***a* (1.0 g, 0.004 mole) and lithium aluminium hydride (0.8 g, 0.004 mole) in dioxane (30 ml) was heated under reflux for 20 h. The complex was hydrolyzed with aqueous sodium hydroxide and the filtered solution was evaporated. The residue was triturated with a little ether and recrystallized from ethanol to give 10,11-dihydro-*syn*-11-hydroxy-10,5-(iminomethano)-5*H*-dibenzo[*a,d*]cycloheptene (1) (**6**, 0.23 g), m.p. and mixed m.p. 190–191°.

Hydrogenolysis

Sodium was added in small portions to a solution of **7***a* (0.5 g, 0.002 mole) in redistilled liquid ammonia (25 ml) until the blue color persisted for 10 min. An excess of ammonium chloride was added and the mixture was allowed to evaporate. The residue was triturated with water and recrystallized from ethanol to give 10,11-dihydro-5*H*-dibenzo[*a,d*]cycloheptene-5-carboxamide (26) (**10**, 0.03 g), m.p. and mixed m.p. 190–192°.

Hydrolysis

A solution of **7***a* (0.5 g) and 1 *N* HCl (20 ml) in dioxane (4 ml) and methanol (5 ml) was heated on the steam bath for 1 h. The cooled mixture was diluted with water and extracted with dichloromethane. Evaporation and recrystallization of the residue from ethanol–hexane gave the ketolactone **3** (0.1 g), m.p. and mixed m.p. 162–163°.

Acetylation

a) A solution of **7***a* (1.0 g, 0.004 mole) and pyridine (7 ml) in dioxane (10 ml) was cooled in an ice bath and treated dropwise with acetyl chloride (3 ml). The solution was kept in the cooling bath for 1 h and then at room temperature for an additional 0.5 h. Water (10 ml) was added and the precipitated product was recrystallized from chloroform–hexane to give 11-acetoxy-10,11-dihydro-10-hydroxy-10,5-(iminomethano)-5*H*-dibenzo-[*a,d*]cyclohepten-13-one (**9***a*; 0.4 g, 36%), m.p. 225–226°; ν_{max} (Nujol) 3230 cm^{-1} (broad, intense; NH + OH); 1730 cm^{-1} (ester); 1663 cm^{-1} (lactam); λ_{max} (EtOH) 256, 262 mμ (596, 596); n.m.r. (DMSO), τ: 1.53 (NH, s); 2.45 (1-H aromatic, m); 2.80 (7-H aromatic, m); 4.12 (1-H at C-11, s); 5.45 (1-H at C-5, s); 6.68 (OH, s); 7.83 (CH_3, s).

Anal. Calcd. for $C_{18}H_{15}NO_4$: C, 69.89; H, 4.89; N, 4.53. Found: C, 69.76; H, 5.18; N, 4.65.

b) A mixture of calcium hydride (2.0 g) and acetic anhydride (27) (20 ml) was heated under reflux for 2 h with stirring. It was cooled to room temperature and a solution of **7***a* (1.0 g) in dry dioxane (20 ml) was added. The mixture was then heated under reflux for 2 h, left overnight and treated successively with ethanol and water. The product was extracted into benzene and the organic layer was extracted with water, dried, and evaporated. Recrystallization gave 0.3 g (27%) of monoacetate **9***a*, m.p. 217–218°.

c) Acetylation of **7***b* (1.0 g, 0.004 mole) with acetyl chloride (5 ml) and pyridine (10 ml) as described above gave 11-acetoxy-10,11-dihydro-10-hydroxy-12-methyl-10,5-(iminomethano)-5*H*-dibenzo[*a,d*]cyclohepten-13-one (**9***b*, 0.06 g), m.p. 200–201° (from ethanol–hexane); n.m.r. (DMSO), τ: 6.95 (NCH_3, s); remainder similar to that of **9***a*.

Anal. Calcd. for $C_{19}H_{17}NO_4$: C, 70.57; H, 5.30; N, 4,33. Found: C, 70.03; H, 5.50; N, 4.32.

Reactions of Carbinolamides 8

Reduction

a) A solution of **8***a* (1.5 g, 0.006 mole) in absolute ethanol (25 ml) and dioxane (15 ml) was hydrogenated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

at 1 atmosphere and 25° for 6.5 h using 10% palladium-on-charcoal (0.2 g). The filtered solution was evaporated and the residue was recrystallized from chloroform to give 7*a* (0.5 g), m.p. and mixed m.p. 173–174°.

b) A solution of 8*a* (0.7 g, 0.003 mole) and sodium borohydride (0.1 g, 0.003 mole) in ethanol (60 ml) was kept at room temperature overnight. The excess of hydride was destroyed by the addition of acetic acid, water was added, and the ethanol was removed *in vacuo*. The product was extracted into chloroform and the solution was dried and evaporated. Recrystallization of the residue from ethanol–hexane gave *anti*-11-hydroxy-10,11-dihydro-10,5-(epoxymethano)-5*H*-dibenzo[*a,d*]-cyclohepten-13-one (9) (2*b*, 0.02 g), m.p. and mixed m.p. 188–190°.

Methylation

Silver oxide (0.3 g) was added to a solution of 8*b* (0.5 g, 0.002 mole) and methyl iodide (5 ml) in acetone (75 ml) and the suspension was stirred for 18 h. The filtered solution was evaporated and the residue was recrystallized from chloroform–hexane to give 10-methoxy-12-methyl-10,5-(iminomethano)-5*H*-dibenzo[*a,d*]cyclo-heptene-11,13(10*H*)-dione (**12**, 0.2 g), m.p. 202–203°; ν_{max} (Nujol) 1695 cm^{-1} (ketone); 1675 cm^{-1} (lactam); 1090 cm^{-1} (ether); λ_{max} (EtOH) 268 mμ (ε 6740); n.m.r. (DMSO), τ: 2.00 (1-H aromatic, m); 2.52 (7-H aromatic, m); 4.97 (1-H at C-5, s); 6.56 and 7.12 (OCH_3 and NCH_3, s).

Anal. Calcd. for $C_{18}H_{15}NO_3$: C, 73.70; H, 5.15; N, 4.78. Found: C, 73.69; H, 5.06; N, 4.67.

Replacing 8*b* by 7*b* also gave the same product, m.p. 195–198°.

N,N-Diethyl-10,11-dioxo-5H-dibenzo[a,d]cycloheptene-5-carboxamide (14a)

Diethylamine (redistilled, 60 ml) was added to the ketolactone **3** (6.0 g, 0.024 mole) dissolved in dry dioxane (60 ml) and the yellow solution was kept for 6 days in an open vessel. The precipitated product was recrystallized from acetonitrile to give 3.2 g (42%) of the amide as yellow crystals, m.p. 271–272°; ν_{max} (Nujol) 1690, 1670 cm^{-1} (ketone); 1613 cm^{-1} (amide); λ_{max} (EtOH) 259 mμ (ε 11 400); $\lambda_{max}(CH_3CN)$ 256 mμ (ε 11 200) (spectra unchanged on addition of HCl).

Anal. Calcd. for $C_{20}H_{19}NO_3$ (321): C, 74.74; H, 5.96; N, 4.36. Found (*m/e* 321): C, 74.91; H, 6.25; N, 4.26.

Keeping a solution of the amide (0.5 g), diethylamine (5 ml), and water (20 ml) in dioxane (75 ml) for 5 days gave unchanged starting material, identified by m.p. and spectral data.

The quinoxaline derivative was prepared by heating the amide with an excess of *O*-phenylenediamine in acetic acid under reflux for 1 h; m.p. 207–208° (from ethanol).

Anal. Calcd. for $C_{26}H_{23}N_3O$: C, 79.36; H, 5.90; N, 10.68. Found: C, 79.41; H, 5.93; N, 10.75.

5-Morpholinocarbonyl-5H-dibenzo[a,d]cycloheptene-10,11-dione (14b)

The interaction of **3** (0.02 mole) and morpholine (undistilled, 20 ml) in dioxane (25 ml) gave the morpholide (1.1 g, 16%), m.p. 288–292° (from acetonitrile); n.m.r. (DMSO), τ: 2.35 (8-H aromatic, m); 4.03 (1-H at C-5, s); 6.08 (2-H, m); 6.53 (6-H, m).

Anal. Calcd. for $C_{20}H_{17}NO_4$: C, 71.63; H, 5.11; N, 4.18. Found: C, 71.74; H, 5.24; N, 4.49.

10′-Hydroxy-{5,10′-bi-5H-dibenzo[a,d]cycloheptene}-10,11,11′-trione (16)

The crude filtrate from the preceding reaction was diluted with water to afford 1.1 g of the dimer. Recrystallization of a portion from acetonitrile gave a sample m.p. 290–295° decomp. (reported (11) m.p. 285° decomp.). As previously observed (11), the compound dissociated to the monomer on heating; the mass spectrum contained a strong peak at *m/e* 222 but on introduction of the sample by direct inlet at temperatures below 150°, a weak peak for the dimer at *m/e* 444 was seen.

Anal. Calcd. for $C_{30}H_{20}O_4$: C, 81.06; H, 4.54. Found: C, 81.41; H, 4.77.

The dimer was formed as the principal product on interaction of the ketolactone with secondary amines in the presence of 30% aqueous dioxane.

The quinoxaline derivative of monomer **15** was prepared from **16** as described (11); m.p. 234–235° (from acetonitrile) (reported m.p. 234°).

Reaction of 3 with sodium hydroxide

a) Finely ground *3* (2.0 g) was added to 1 *N* NaOH (200 ml) and the mixture was stirred overnight in an open vessel. As the reaction proceeded a purple color developed which was quickly discharged on contact with the air. A small quantity of unreacted ketolactone was filtered off and the chilled solution was adjusted to pH 4 with 10% HCl. The precipitated 9-anthroic acid (0.6 g), m.p. 215–217°, was identified by comparison with an authentic specimen.

In a similar experiment, the ketolactone (1.0 g) and 1 *N* NaOH (100 ml) were stirred together for 1 h. The product (0.5 g) was 9,10-dihydro-9-hydroxyanthracene-9,10-dicarboxylic acid (**18**), m.p. 207–209°. Recrystallization from ethanol–ethyl acetate, avoiding undue heating, gave a sample m.p. 217–218°; ν_{max}(Nujol) 3525, 3385, and envelope around 2900 cm^{-1} (OH); 1680 cm^{-1}, broad (carboxyl); λ_{max}(EtOH) 253, 262 mμ (ε 465, 407); n.m.r. (DMSO), τ: 2.33–2.75 (8-H aromatic, m); 4.99 (1-H, s); on the addition of D_2O, 3 exchanged protons were observed.

Anal. Calcd. for $C_{16}H_{12}O_5$: C, 67.59; H, 4.26. Found: C, 67.22; H, 4.26.

b) A solution of **3** (5.0 g, 0.02 mole) in dioxane (75 ml) was kept under purified nitrogen. A 50% NaOH solution which had been freed from air by prior boiling under nitrogen (6.0 ml), was added dropwise. The deeply colored reaction mixture was stirred for 10 min and then treated dropwise with acetyl chloride (4.7 g, 0.06 mole). The gummy precipitate was removed and triturated with a little methanol to afford 2.4 g of material, m.p. > 250°. Recrystallization of a portion from acetonitrile gave a sample of 5,5′bis(5*H*-dibenzo[*a,d*]cycloheptene-10,11-diol)-tetracetate (**17**), m.p. 335–340° (decomp.); ν_{max}(Nujol) 1750 cm^{-1} (enol acetate); 1763, 1205, 1190 cm^{-1} (inflections); $\lambda_{max}(CH_3CN)$ 248 mμ (ε 23 200).

Anal. Calcd. for $C_{38}H_{30}O_8$ (614): C, 74.25; H, 4.92. Found (*m/e* 614, weak; 307, strong): C, 73.77; H, 5.10.

10,11-Dihydro-10,11-epoxy-5H-dibenzo[a,d]cycloheptene-5-carbonitrile (20)

A solution of 5*H*-dibenzo[*a,d*]cycloheptene-5-carbonitrile (26) (100 g, 0.46 mole) and 85% 3-chloroperbenzoic acid (115 g, 0.56 mole) in ethyl acetate (1100 ml) was kept at room temperature for 9 days at which time the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was judged from optical density measurements to be complete. Hexane (800 ml) was added with cooling and the long, needle-like crystals (45.3 g, m.p. 160–161°) were filtered off. An additional amount was obtained by evaporation of the solvent and addition of chloroform to the residue. The insoluble 3-chlorobenzoic acid was removed and the filtrate was extracted successively with aqueous sodium bisulfite and sodium bicarbonate. Evaporation of the solvent and recrystallization from chloroform–hexane gave 26.6 g (total yield 67%), m.p. 157–158°. An analytical sample had m.p. 162–163°; ν_{max}(CHCl$_3$) 2250 cm^{-1} (C≡N); λ_{max}(EtOH) 268 mμ (ε 812); n.m.r. (CDCl$_3$), τ: 2.33 (2-H aromatic, m); 2.70 (6-H aromatic, m); 3.20 (1-H at C-5, s); 5.74 (1-H each at C-10 and C-11, s).

Anal. Calcd. for $C_{16}H_{11}NO$: C, 82.38; H, 4.75; N, 6.01. Found: C, 82.12; H, 4.62; N, 6.05.

10-Diethylaminomethyl-9-anthronitrile (23)

A solution of the epoxynitrile **20** (10.0 g, 0.04 mole) and diethylamine (5.8 g, 0.08 mole) in toluene (100 ml) was heated under reflux for 7 h. The solvent was evaporated and the residue was recrystallized from 2-propanol to give 5.5 g of the anthracene derivative, m.p. 127–128°; ν_{max}(CHCl$_3$) 2215 cm^{-1} (C≡N); λ_{max}(EtOH) 259, 369, 388 mμ (ε 137 000, 7940, 10 140); n.m.r. (CDCl$_3$), τ: 1.50, 2.48 (4-H + 4-H aromatic, m); 5.62 (CH$_2$, s); 7.46 (q) and 8.98 (t; 2-C$_2$H$_5$ groups).

Anal. Calcd. for $C_{20}H_{20}N_2$: C, 83.29; H, 6.99; N, 9.71. Found: C, 83.07; H, 6.81; N, 9.58.

The hydrochloride had m.p. 255–256° (from methanol-2-propanol).

Anal. Calcd. for $C_{20}H_{21}ClN_2$: C, 73.96; H, 6.52; Cl, 10.38; N, 8.62. Found: C, 74.20; H, 6.55; Cl, 10.68; N, 8.73.

10,11-Dihydro-10-hydroxy-5H-dibenzo[a,d]cycloheptene-5-carbonitrile (21)

A solution of **20** (100 g) in absolute ethanol (1000 ml) was hydrogenated over 10% palladium-on-carbon (8 g) at room temperature and atmospheric pressure until the theoretical amount of hydrogen was consumed (2 h). The catalyst was filtered off and the solution was chilled to give 56.0 g of hydroxynitrile, m.p. 150–151°. An additional 21.2 g (m.p. 151–152°) was obtained by evaporation of the solvent, dissolution of the residue in chloroform, and addition of hexane. Further recrystallizations from chloroform afforded a sample of the *syn*-epimer (**21***a*), m.p. 160°; ν_{max}(Nujol) 3500, 3270 cm^{-1} (assoc. OH); 2250, 2240 cm^{-1} (split C≡N); λ_{max}(EtOH) 263 mμ (ε 480); n.m.r. (DMSO), τ: 2.55 (8-H aromatic, m); 3.87 (1-H at C-5, s); 4.31 (OH, d); 4.78 (1-H at C-10, q); 6.65 (CH$_2$, m).

Anal. Calcd. for $C_{16}H_{13}NO$: C, 81.68; H, 5.57; N, 5.95. Found: C, 81.64; H, 5.87; N, 5.92.

The chloroform–hexane filtrate was diluted with a further quantity of hexane to afford an impure sample (4.2 g), m.p. 128–137° of the *anti*-epimer (**21***b*). Recrystallization of material obtained from a similar experiment (m.p. 123–130°) from ether–hexane gave the pure form, m.p. 118–120°; ν_{max}(Nujol) 3510 cm^{-1} (OH): 2225 cm^{-1} (C≡N) (both singlets); λ_{max}(EtOH) 262 mμ (ε 509); n.m.r. (DMSO) τ: 2.55 (8-H aromatic, m); 3.87 (1-H at C-5, s); 4.70 (1-H at C-10, q); 6.72 (CH$_2$, m); 6.68 (OH, s).

Anal. Found: C, 81.51; H, 5.79; N, 5.79.

Carrying out the hydrogenation of **20** (5.0 g) in ethyl acetate (125 ml) under similar conditions (4 h, 0.4 g catalyst) gave mainly **21***b* (3.6 g), m.p. 124–127° after one recrystallization from chloroform–hexane.

10,11-Dihydro-10,5-(epoxymethano)-5H-dibenzo[a,d]cyclohepten-13-imine (22)

A solution of the *syn*-hydroxynitrile **21***a* (11.9 g) in methanol (475 ml) was treated with 10% aqueous NaOH (10 ml) and kept overnight at room temperature. The methanol was removed *in vacuo* and the product was extracted into chloroform. The extracts were washed with water, dried, and evaporated to give the iminolactone (11.6 g, 97%), m.p. 150–152°. An analytical sample had m.p. 153–154° (from chloroform–hexane); ν_{max}(CHCl$_3$) 3280 cm^{-1} (NH); 1660 cm^{-1} (C=N); λ_{max}(EtOH) 265 mμ (ε 574); n.m.r. (DMSO), τ: 2.68 (8-H, aromatic, m); 4.35 (1-H at C-10, q); 5.13 (1-H at C-5, s); 6.65 (CH$_2$, m); 6.67 (NH, s).

Anal. Calcd. for $C_{16}H_{13}NO$: C, 81.68; H, 5.57; N, 5.95. Found: C, 81.58; H, 5.49; N, 5.71.

Treatment of **21***a* (1.0 g) in methanol (40 ml) with 10% NaOH (1 ml) for 45 min furnished 1.0 g of crude iminolactone, m.p. 151–152°. The use of **21***b* under these conditions similarly gave **22** (0.99 g, m.p. 151–153°) although the reaction mixture was discolored by the presence of side-products.

The hydrochloride of **22** was obtained by treating a solution of **21***a* (0.5 g) in anhydrous tetrahydrofuran (25 ml) with ethereal HCl (10 ml). The solution was kept at room temperature for 4 h and the precipitated salt (0.33 g) was filtered off; m.p. 190–191°. Dilution of the filtrate with ether gave an additional 0.11 g (total yield 76%), m.p. 188–190°.

Anal. Calcd. for $C_{16}H_{14}ClNO$: C, 70.71; H, 5.19; Cl, 12.93; N, 5.15. Found: C, 70.62; H, 5.30; Cl, 13.09; N, 5.19.

The *anti*-epimer **21***b* was recovered largely unchanged after similar treatment with HCl.

A solution of the hydrochloride of **22** (0.1 g) in water (20 ml) was kept at 50° for 10 min and the precipitated 10,11-dihydro-10,5-(epoxymethano)-5*H*-dibenzo[*a*,*d*]-cyclohepten-13-one **2***c* (9) (0.07 g) was filtered off; m.p. and mixed m.p. 169–170°.

10-Oxo-5H-dibenzo[a,d]cycloheptene-5(11-H)-carbonitrile (24)

A solution of **21***a*,*b* (32.6 g, 0.14 mole) in acetone (650 ml) was cooled to 0° in an ice–salt bath and Jones' reagent (41.5 ml) was added dropwise with stirring. The precipitate was filtered off (Celite) and the solution was evaporated *in vacuo* to about one-half volume. Water was added and the precipitated product was collected and dissolved in chloroform. The solution was thoroughly extracted with water to remove the last traces of mineral acid. It was dried and evaporated and the residue was recrystallized once from chloroform–hexane to give 26.8 g (83%), m.p. 128–130°; ν_{max}(CHCl$_3$) 2245 cm^{-1} (C≡N); 1672 cm^{-1} (C=O); λ_{max}(CHCl$_3$) 260, 288 mμ (ε 10 550, 1770); λ_{max}(EtOH) 240, 290 mμ (ε 8180, 5200); n.m.r. (CDCl$_3$), τ: 1.95 (1-H aromatic, m); 2.53 (7-H aromatic, m); 4.38 (1-H at C-5, s); 5.75 (CH$_2$, s).

Anal. Calcd. for $C_{16}H_{11}NO$: C, 82.38; H, 4.75; N, 6.01. Found: C, 82.33; H, 4.80; N, 5.78.

Enol Ethers of ***24***

a) The ketonitrile (24.0 g) was added to a saturated solution of HCl in methanol (600 ml) with sufficient warming to effect dissolution. The reaction mixture was kept at room temperature for 1 h and then chilled. The precipitated product was filtered off and washed with ether–hexane to give 10-methoxy-5*H*-dibenzo[*a*,*d*]cycloheptene-5-carbonitrile (***25a***, 21.9 g, 86%), m.p. 145–146°, unchanged on recrystallization from chloroform–hexane or methanol; ν_{max}(Nujol) 2235 cm^{-1} (C≡N); 1562 cm^{-1} (C=C); 1241, 1090 cm^{-1} (C—O); λ_{max}(EtOH) 288 mμ (ε 12 430).

Anal. Calcd. for $C_{17}H_{13}NO$: C, 82.57; H, 5.30; N, 5.66. Found: C, 82.30; H, 5.30; N, 5.92.

A solution of the enol ether (1 g) in dioxane (25 ml) containing concentrated HCl (1 ml) was kept at room temperature for 24 h; regeneration of the ketonitrile (m.p. 116–120°) was almost complete.

b) Absolute ethanol (0.8 ml) was cooled in an ice–salt bath and treated with thionyl chloride (1.0 ml), followed by the ketonitrile (0.5 g) An additional 3 ml of ethanol was added to effect dissolution and the mixture was left at room temperature for 3 days. Recrystallization of the precipitated product (0.35 g) from ethanol gave the ethyl enol ether ***25b***, m.p. 157–158°; ν_{max}(Nujol) 2235 cm^{-1} (C≡N); 1560 cm^{-1} (C=C); 1240, 1135 cm^{-1} (C—O); λ_{max}(EtOH) 287 mμ (ε 12 280).

Anal. Calcd. for $C_{18}H_{15}NO$: C, 82.73; H, 5.79; N, 5.36. Found: C, 83.01; H, 5.77; N, 5.35.

c) A solution of the ketonitrile (0.5 g), ethylene glycol (0.6 g), and *p*-toluenesulfonic acid (0.1 g) in benzene (100 ml) was heated under reflux for 20 h using a Dean–Stark trap to remove the entrained water. The solution was extracted with aqueous sodium bicarbonate and then dried and evaporated. The residue was triturated with a little chloroform–hexane to give 0.3 g of the 2-hydroxyethyl enol ether ***25c***, m.p. 148–150°. An analytical sample had m.p. 152–153° (from ethanol); ν_{max}(Nujol) 3260 cm^{-1} (OH); 2240 cm^{-1} (C≡N); 1563 cm^{-1} (C=C); 1070 cm^{-1} (C—O); λ_{max}(EtOH) 288 mμ (ε 11 460).

Anal. Calcd. for $C_{18}H_{15}NO_2$: C, 77.96; H, 5.45; N, 5.05. Found: C, 78.18; H, 5.29; N, 5.06.

*10-Methoxy-5H-dibenzo[a,d]cycloheptene-5-carboxamide (****26****)*

A solution of the enol ether ***25a*** (31.8 g) in acetone (1350 ml) was chilled in an ice bath and 30% hydrogen peroxide (450 ml) was added, followed by 10% aqueous potassium carbonate (540 ml). The mixture was stirred in the cold for 10 min and then heated to the boiling point during 40 min, at which time an exothermic reaction ensued. The heating mantle was removed, the mixture was left at ambient temperature for 18 h, and the acetone was removed *in vacuo*. The precipitated product was recrystallized from dioxane–ether to give 15.1 g (44%) of the amide, m.p. 224–225°; ν_{max}(Nujol) 3430, 3330 cm^{-1} (NH); 1660 cm^{-1} (amide); 1560 cm^{-1} (C=C); 1250, 1096 (C—O); λ_{max}(EtOH) 286 mμ (ε 12 740).

Anal. Calcd. for $C_{17}H_{15}NO_2$: C, 76.96; H, 5.70; N, 5.28. Found: C, 76.63; H, 6.00; N, 5.42.

*10,11-Dihydro-10-hydroxy-10,5-(iminomethano)-5H-dibenzo[a,d]cyclohepten-13-one (****28****)*

A solution of the preceding amide (6.5 g) in dioxane (200 ml) was treated with concentrated HCl (3 ml) and left at room temperature overnight. It was diluted with water (150 ml) and the dioxane was removed *in vacuo*. The product was extracted into chloroform and this solution was washed with water, dried, and evaporated. Recrystallization of the residue from acetonitrile–ether gave the carbinolamide (3.3 g, 54%), m.p. 213–214° decomp.; ν_{max}(Nujol) 3450, 3200 cm^{-1} (OH, NH); 1662 cm^{-1} (lactam); λ_{max}(EtOH) 260, 272 mμ (ε 886, 698); n.m.r. (DMSO), τ: 1.67 (NH, s); 2.67 (8-H, aromatic, m); 5.50 (1-H at C-5, s); 6.65 (OH, s); 6.70 (CH_2, q).

Anal. Calcd. for $C_{16}H_{13}NO_2$: C, 76.47; H, 5.22; N, 5.57. Found: C, 76.25; H, 5.23; N, 5.72.

*10-Methoxy-5H-dibenzo[a,d]cycloheptene-5-methylamine hydrochloride (****29****)*

a) A solution of ***25a*** (58.0 g) in methanol (600 ml) was saturated with ammonia and hydrogenated over Raney nickel (6 g) at 1100 p.s.i. and 75° for 7 h. The filtered solution was evaporated, taken into ether, and treated with hydrogen chloride. Recrystallization of the precipitate from ethanol–ether gave 39.5 g (58%) of the product, m.p. 241–242°. An analytical sample had m.p. 244–245° (from 2-propanol); ν_{max}(Nujol) 1560 cm^{-1} (C=C); 1210, 1120 cm^{-1} (C—O); λ_{max}(EtOH) 228, 292 mμ (ε 13 100, 12 600); n.m.r. (D_2O), τ: 3.00 (8-H, aromatic, m); 4.10 (1-H at C-11, s); 5.45 (3-H exch, s); 5.96 (1-H at C-5, m); 6.54 (OCH_3, s); 6.96 (CH_2, d).

Anal. Calcd. for $C_{17}H_{18}ClNO$: C, 70.94; H, 6.30; Cl, 12.32; N, 4.87. Found: C, 70.87; H, 6.40; Cl, 12.62; N, 4.97.

From the neutral fraction 21.3 g of unchanged nitrile was obtained, m.p. 142–144°.

b) A solution of ***25a*** (1.0 g) in dry tetrahydrofuran (40 ml) was treated with 1 *M* diborane in tetrahydrofuran (20 ml) and kept overnight. It was then heated under reflux for 1 h to complete the reaction, treated with water, and the solvent removed *in vacuo*. The amine was extracted into chloroform and the solution was washed with water, dried, and evaporated. The crude hydrochloride could not be adequately purified and was reconverted to the free amine. This in turn furnished a hydrochloride, m.p. 244–245° (60 mg).

*10,11-Dihydro-10-hydroxy-10,5-(iminomethano)-5H-dibenzo[a,d]cycloheptene (****31****)*

A solution of the preceding salt (5.0 g) in water (300 ml) and concentrated HCl (6 ml) was kept for 24 h at room temperature. Neutralization with sodium bicarbonate gave a precipitate which was recrystallized from ethanol or nitromethane to furnish 1.8 g (42%), m.p. 180–181°; ν_{max}(Nujol) 3300, 2900 cm^{-1} (NH, OH assoc.); λ_{max}(CH_3CN) 273, 290 mμ (ε 684, 223); λ_{max}(CH_3CN+HCl) 271 (infl.), 293 mμ (ε 828, 773); n.m.r. (DMSO), τ: 2.24 (1-H, aromatic, m); 2.83 (7-H, aromatic, m); 6.00 (1-H at C-5, m); 6.70 (2-CH_2, m).

Anal. Calcd. for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90. Found: C, 80.71; H, 6.36; N, 5.94.

Acknowledgments

We wish to thank Dr. G. S. Myers and his group for furnishing several intermediates in

quantity. Spectral data were recorded by Mrs. J. Jachner and Mr. M. Boulerice, and microanalyses were carried out by Mr. W. J. Turnbull. The mass spectra were determined by Morgan–Schaffer Corp., Montreal.

Cycloalkylation d'aryloléfines par le trifluorure de bore. Synthèse d'hydrocarbures aromatiques polyméthylés[1]

P. CANONNE ET A. REGNAULT[2]
Département de Chimie, Université de Laval, Québec, Québec

Reçu le 23 janvier 1969

L'examen d'ensemble des résultats de nos travaux sur la cyclisation des aryl-4 oléfines nous permet de conclure que le trifluorure de bore est le catalyseur d'élection pour les aryl-4 oléfines ne possédant pas de groupement fonctionnel.

Son utilisation est illustrée par la synthèse du tétraméthyl-1,3,6,8 triphénylène non encore décrit dans la littérature et par une nouvelle méthode rapide de préparation du diméthyl-1,5 naphtalène.

A survey of the results obtained by us in the course of cyclizations of 4-arylolefins indicates that boron trifluoride is the most satisfactory catalyst in the case of otherwise non-functionalized substrates. Its use is illustrated by the synthesis of the heretofore unknown 1,3,6,8-tetramethyltriphenylene and by an improved preparation of 1,5-dimethylnaphthalene.

Canadian Journal of Chemistry, 47, 2837 (1969)

Dans une série de publications (1–4) nous avons développé une nouvelle méthode de synthèse de systèmes polycycliques à partir d'acides aryloléfiniques. L'étude comparative de la cyclisation de diverses aryloléfines possédant des groupements fonctionnels variés ($(COOC_2H_5)_2$, COOH, $COOCH_3$, CH_2OH, CH_3) en β de la double liaison fait l'objet du présent mémoire.

Cyclisation des acides éthyléniques

L'intérêt d'effectuer la cyclisation à cette étape réside dans le fait que seul le carbométhoxy-2 tétrahydro-1,2,3,4 naphtalène peut être aromatisé avec un bon rendement, sans élimination ou transformation du groupement fonctionnel (5). Nous avons ainsi préparé des naphtalènes possédant un groupement réactionnel en position β, lesquels sont difficilement accessibles par d'autres voies (schéma 1). Nous nous sommes aperçus (schéma 1) que les acides benzyl-2 pentène-4 oïques (1) et naphtylméthyl-2 pentène-4 oïques (3) avaient un comportement identique vis à vis des acides protoniques: concurrence entre cyclisation et lactonisation. Afin d'éviter cette dernière réaction parasite (lactonisation) nous nous sommes tournés vers d'autres catalyseurs de cyclisation. Le chlorure d'aluminum nous permet de cycliser quantitativement l'acide **7** lorsque l'on opère à reflux de CS_2, mais si l'on travaille à 0°, on recueille un mélange d'acide cyclisé **8** et de lactone **9** (84:16). Pour expliquer cette différence de comportement suivant la température, nous avons cherché à définir les conditions dans lesquelles la lactone **9** s'isomérisait en acide **8** et nous avons vu que cette transformation s'effectuait totalement dans les conditions employées pour la cyclisation de l'acide éthylénique **7** (schéma 2). Il est bien connu qu'en présence de chlorure d'aluminum les γ-olides se scindent et se conduisent comme des réactifs alkylants.

Cyclisations d'ester éthyléniques

Comme l'on pouvait s'y attendre, la cyclisation du benzyl-2 pentène-4 carboxylate de méthyle (**10**) par les acides protoniques s'accompagne de lactonisation mais par contre le chlorure d'aluminum cyclise cet ester sans lactonisation (schéma 3). Cependant cette réaction n'est pas applicable aux homologues méthylés sur le cycle aromatique ni aux naphtylméthyl-2 pentène-4 oates de méthyle, en raison des inconvénients inhérents à ce catalyseur (transposition intramoléculaire des groupements méthyles du cycle aromatique dans le premier cas, résinification dans le second cas).

Des essais de cyclisation effectués sur l'ester malonique **21**, en présence d'un grand excès de chlorure d'aluminum, n'ont fourni que de faibles rendements en ester cyclisé **22** (schéma 4).

Cyclisation d'alcools éthyléniques

La cyclisation de l'alcool éthylénique **12** est réalisée par chauffage à reflux dans un mélange d'acides sulfurique et acétique (5:95); on

[1]Ce mémoire constitue une partie de la thèse de doctorat de A. Regnault.

recueille l'acétate de l'alcool cyclisé **13** (schéma 5). Effectuer la cyclisation à cette étape permet de conserver le groupement fonctionnel tout en évitant une réaction secondaire (lactonisation des acides éthyléniques). Cependant la cyclisation d'oléfines ne possédant pas de groupement fonctionnel, comme méthode de synthèse de certains hydrocarbures aromatiques polyméthylés, nous a semblé mériter une étude plus détaillée.

Cyclisation d'oléfines

La cyclisation de l'oléfine **14**, préparée à partir de l'acide éthylénique **7**, s'effectue avec un excellent rendement sous l'action de BF_3, en solution benzénique (schéma 6). Pour illustrer cette méthode nous avons mis au point une nouvelle synthèse du diméthyl-1,5 naphtalène (schéma 7). L'oléfine **16** produit de la condensa-

SCHÉMA 6

tion du bromure de crotyle sur le chlorure de (méthyl-2) benzylmagnésium, est cyclisée par BF_3 en diméthyl-1,5 tétrahydro-1,2,3,4 naphtalène (**17**) lequel est aromatisé, en diméthyl-1,5 naphtalène (**18**). Ce naphtalène était auparavant préparé au terme d'une longue synthèse qui impliquait le passage par la méthyl-5 tétralone (6). Les enseignements tirés à l'étude de la cyclisation des bis(pentène-4)yl benzènes (2, 3) ne sont pas applicables aux bis(pentène-4)yl naphtalènes, car le chlorure d'aluminum ne donne pas des résultats satisfaisants dans la cycloalkylation d'aryloléfines contenant un reste naphtalénique. Lors de la cyclisation des acides naphtylméthyl-2 pentène-4 oïques (3), nous avions surmonté cet inconvénient en utilisant les acides protoniques, au prix d'une certaine lactonisation, mais cet artifice ne peut pas être utilisé avec des composés possédant deux chaînes oléfiniques car l'on recueillerait un mélange de diacide, de dilactone, et d'acide–lactone (3). En l'absence de catalyseur capable d'effectuer avec de bons rendements la cyclisation de bis(pentène-4)yl naphtalènes possédant un groupement dicarbéthoxyle ou carboxyle sur la chaîne oléfinique, nous avons réduit ce groupement fonctionnel en méthyle et utilisé le trifluorure de bore à l'étape de cyclisation.

Le tétraméthyl-1,3,6,8 triphénylène est synthétisé par cyclisation de 2 enchaînements oléfiniques portés par un noyau naphtalénique (schéma 8). Le bisbromométhyl-2,3 naphtalène réagit avec 2 molécules d'allylmalonate d'éthyle sodé pour donner le bis(dicarbéthoxy-2,2 pentène-4)yl-2,3 naphtalène (**20**). Le bis(méthyl-2 pentène-4)yl-2,3 naphtalène (**27**) est obtenu par transformation des groupements dicarbéthoxyles en méthyles selon la suite de réactions habituelles.[1] La cyclisation de l'oléfine **27** en tétraméthyl-1,3,6,8 octahydrotriphénylène (**28**) nécessite 2 h de réaction à température ambiante, sous l'action de BF_3 en solution benzénique. L'aromatisation de l'hydrocarbure **28** en présence de Pd/C conduit au tétraméthyl-1,3,6,8 triphénylène

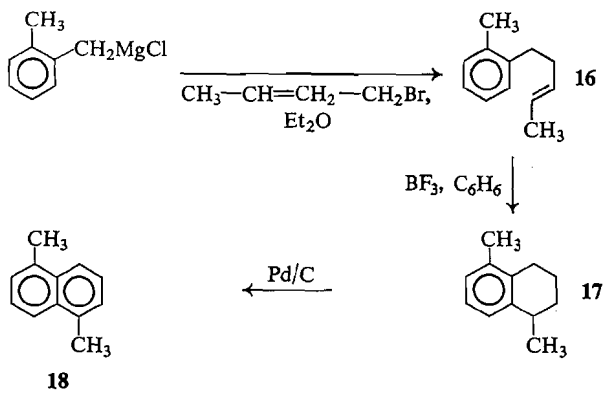

SCHÉMA 7

[1]Une partie de cette synthèse fut réalisée en collaboration avec J. L. Riendeau que nous tenons à remercier.

SCHÉMA 8

(**29**). La synthèse d'hydrocarbures aromatiques polycycliques à partir d'aryloléfines semble générale car nous avons montré que l'utilisation du trifluorure de bore pouvait s'appliquer à tous les cas envisageables (4): simple, double, et triple cyclisation sur un substrat benzénique ou naphtalénique. Les rendements des cyclisations sont toujours supérieurs à 80%.

Partie expérimentale

Les spectres infrarouges (i.r.) ont été pris sur un spectrophotomètre Beckman, modèle IR-4, et les spectres de résonance magnétique nucléaire (r.m.n.) sur un spectromètre Varian, modèle A-60, dans $CDCl_3$, sauf indication contraire. Les points de fusion ont été déterminés dans les tubes capillaires sur un appareil Thomas–Hoover et ne sont pas corrigés. Les analyses élémentaires ont été effectués par Organic Microanalysis (Montréal).

Triméthyl-4,5,8 carbométhoxy-2 naphtalène (3)

L'acide triméthyl-4,5,8 tétrahydro-1,2,3,4 naphtoique-2 (**1**) (p.f. 123–124°) est préparé selon Cannone et Regnault (1). L'ester méthylique **2** correspondant est préparé par action d'une solution éthérée de diazométhane. Dix grammes d'ester **2** et 2.0 g de Pd/C à 5% sont portés pendant 3 h à 320 °C. Après lavage du catalyseur avec 100 ml de méthanol bouillant, on recueille par recristallisation 5.9 g d'ester **3** (p.f. 83–84°).

Spectre i.r.; ν (C=O) 1735 cm^{-1} (CCl_4).

Anal. calc. pour $C_{15}H_{16}O_2$: C, 78.92; H, 7.06; O, 14.02. Trouvé: C, 78.98; H, 7.14.

Acide triméthyl-4,5,8 naphtoique-2 (4)

Obtenu par hydrolyse à la potasse hydroalcoolique de l'ester **3**, p.f. 271–272° (éthanol–benzène).

Anal. calc. pour $C_{14}H_{14}O_2$: C, 78.48; H, 6.59; O, 14.93. Trouvé: C, 78.52; H, 6.51.

Triméthyl-4,5,8 naphtalèneméthanol-2 (5)

La réduction par $LiAlH_4$ de l'ester **3** fournit l'alcool **2**, p.f. 88–89° (éthanol).

Triméthyl-4,5,8 bromométhyl-2 naphtalène (6)

On ajoute à température ambiante une solution de 12.8 g d'alcool **5** dans 100 ml d'acide acétique à 50 ml d'acide acétique saturés en HBr. On laisse réagir 20 min à 50°, et verse sur 200 g de glace pilée. Le bromure **6** précipite, on l'extrait à l'éther, lave les extraits éthérés au bicarbonate et à l'eau, sèche sur $MgSO_4$. On recueille 15.0 g de dérivé bromé **6**, p.f. 70–75° (brut). La réduction d'un échantillon par l'hydrogène en présence de Pd/C et en solution dans l'acétone, fournit le tétraméthyl-1,3,5,8 naphtalène (p.f. 56–57°) identique à celui préparé par aromatisation du tétraméthyl-1,3,5,8 tétrahydro-1,2,3,4 naphtalène (1). Les déplacements chimiques des protons aromatiques et des protons des méthyles sont résumés dans le Tableau I.

Cyclisation de l'α-benzyl-γ-valérolactone (9)

La lactone **9** (p.é. 130–131° sous 0.6 mm Hg, n_D^{25} 15 210) est préparée par lactonisation de l'acide benzyl-2 pentène-4 oïque 7 (1). A une solution de 1.9 g (0.01 mole) de lactone **9** dans 50 ml de CS_2, on ajoute par petites portions 2 g (0.015 mole) de chlorure d'aluminum anhydre. Une fois l'addition de catalyseur terminée, on porte à reflux 1.5 h. On hydrolyse, traite de façon habituelle et recueille 1.75 g d'acide méthyl-4 tétrahydro-1,2,3,4 naphtoique-2 (**8**) (p.f. 115–119°) identique à un échantillon du même acide obtenu par cyclisation de l'acide 7 (spectres i.r. et de r.m.n. superposables). L'acide **8** (p.f. 115–119°) brut, obtenu à partir de l'acide **7** ou de la lactone **9** est un mélange des deux isomères possibles, où le méthyle peut occuper une position quasi axiale (doublet centré à 74 Hz, (J = 7 Hz) ou une position quasi équatoriale (doublet centré à 77.5 Hz, J = 7 Hz). Deux cristallisations dans l'éthanol dilué donnent un isomère pur (p.f. 120–121°); son spectre de r.m.n. ne montre plus qu'un seul doublet à 77.5 Hz.

Anal. calc. pour $C_{14}H_{18}O_2$: C, 77.03; H, 8.31; O, 14.66. Trouvé: C, 77.10; H, 8.38.

Cyclisation du benzyl-2 pentène-4 carboxylate de méthyle (10)

On opère sur 0.01 mole d'ester **10** en suivant le mode opératoire précédent. Après traitement habituel et chromatographie sur alumine (grade 1, éther-éther de pétrole), on recueille 1.80 g de méthyl-4 tétrahydro-1,2,3,4

TABLEAU I

carboxylate de méthyle (**11**) (p.é. 96° sous 0.08 mm Hg). Le méthyle cyclanique apparaît en r.m.n. sous forme de deux doublets d'intensité égale centrés à 73 et 76 Hz (J = 7 Hz).

Anal. calc. pour $C_{15}H_{20}O_2$: C, 77.55; H, 8.68; O, 13.77. Trouvé: C, 77.60; H, 8.62.

*Cyclisation du (méthyl-3)naphtyl-2 méthyl-2 pentène-4 ol-1 (**12**)*

L'alcool **12** provient de la réduction par $LiAlH_4$ de l'acide (méthyl-3)naphtyl-2 méthyl-2 pentène-4 oïque (p.f. 109–111°, préparé selon (3)). On chauffe à reflux pendant 1 h une solution de 1.0 g d'alcool **12** dans 20 ml d'un mélange (5:95) d'acides sulfurique concentre et acétique concentre. Après dilution à l'eau et extraction au benzène, on obtient 0.92 g d'acétate **13** (liquide visqueux incristallisable).

Spectre i.r.; 1230 et 1750 cm^{-1} (acétate).

Spectre de r.m.n. CH_3 cyclanique:76 Hz (d, J = 7 Hz) et 80 Hz (d, J = 7 Hz); CH_3 acétate:122 Hz (s); CH_3 aromatique:140 Hz (s); $—CH_2—O—CO—$:246 Hz (d, J = 6 Hz); H_5, H_6, H_7, H_8:massif complexe (435–485 Hz); H_9:445 Hz (s).

*Cyclisation du benzyl-4 pentène-1 (**14**)*

Cette oléfine est préparée par réduction du groupement carboxyle en méthyle de l'acide 7 (1), p.é. 118–120° sous 20 mm Hg. On fait barboter lentement BF_3 dans une solution de 2.00 g d'oléfine **14** dans 50 ml de benzène jusqu'à apparition d'une couleur rouge-orangée (5–10 min). On abandonne ensuite en flacon bouché pendant 1 h à température ambiante, puis on ajoute 50 ml d'eau et décante la couche benzénique. Après évaporation du solvant, on filtre sur colonne d'alumine et on élue à l'éther de pétrole 1.85 g de diméthyl-1,3 tétrahydro-1,2,3,4 naphtalène (**15**) identique au même hydrocarbure obtenu par réduction du groupement carboxyle en méthyle de l'acide **8** (1).

*Préparation du (méthyl-2) phényl-5 pentène-2 (**16**)*

On prépare, sous atmosphère d'azote, une solution éthérée de chlorure de (méthyl-2) benzylmagnésium à partir de 12 g (0.50 atmospheric g) de magnésium en tournure, 70 g (0.50 mole) de chlorométhyl-1 méthyl-2 benzène (préparée par chloration de l'*O*-xylène au moyen de SO_2Cl_2, selon (7)) et 400 ml d'éther anhydre, en maintenant la température en dessous de −10 °C, ainsi qu'une vigoureuse agitation mécanique. On filtre l'excès de magnésium et ajoute goutte à goutte une solution de 67.5 g (0.50 mole) de bromure de crotyle dans 100 ml d'éther anhydre. On laisse réagir quelques heures à température ambiante, hydrolyse avec une solution aqueuse de chlorure d'ammonium, et on décante la couche éthérée. On évapore le solvant et rectifie l'oléfine **16** sur une colonne de Vigreux: 53.5 g, rdt 67%, p.é. 108–110° sous 20 mm Hg, n_D^{25} 1.5120.

Anal. calc. pour $C_{12}H_{16}$; C, 89.44; H, 10.06. Trouvé: C, 89.99; H, 10.01.

*Cyclisation du (méthyl-2) phényl-5 pentène-2 (**16**)*

L'oléfine **16** est cyclisé par BF_3 en suivant le mode opératoire de la cyclisation de **14** ou **15**, rdt 95%. Spectre r.m.n.: CH_3 cyclanique: 73 Hz (d, J = 7 Hz); CH_3 aromatique: 126 Hz (s), H aromatiques (3): multiplet étroit centré à 418 Hz.

*Diméthyl-1,5 naphtalène (**17**)*

L'aromatisation de 5.0 g de tétraline **16** fournit, après chromatographie sur alumine, 4.2 g de diméthyl-1,5 naphtalène, p.f. 81° (méthanol), (litt. (6) p.f. 81 °C) picrate p.f. 131–132.5°.

Préparation des bis(dicarbéthoxy-2,2 pentène-4)yl naphtalènes

Les bisbromométhyl-2,3 naphtalène (**18**) et bisbromométhyl-2,6 naphtalène **19** sont préparés par bromation des diméthylnaphtalènes correspondants au moyen de deux équivalents de NBS selon Ried et Bodem (8). Dibromure **18**, p.f. 144–145° (litt. (8) p.f. 145°, rdt 66%); dibromure **19**, p.f. 175–180° (litt. (8) p.f. 182°, rdt 72%).

A une solution de 0.30 mole d'allylmalonate d'éthyle sodé dans 300 ml d'éthanol anhydre, on ajoute une solution de 31.4 g de dibromure **18** en solution dans 600 ml de benzène. On laisse réagir une nuit à température ambiante, évapore le maximum de solvants, ajoute 100 ml d'eau, et extrait l'ester malonique à l'éther (4 fois). Le bis(dicarbéthoxy-2,2 pentène-4)-2,3 naphtalène (**20**) est distillé sous pression réduite (206–210° sous 0.08 mm Hg) puis il cristallise lentement (72–73°, méthanol); rdt 74%.

Anal. calc. pour $C_{32}H_{40}O_8$: C, 69.55; H, 7.30; O, 23.16. Trouvé: C, 69.63; H, 7.27.

Après distillation des solvants, le bis(dicarbéthoxy-2,2 pentène-4)-2,6 naphtalène (**21**) se présente sous forme d'une masse pâteuse qui est lavée à l'eau afin d'éliminer le bromure de sodium, puis dissoute dans le méthanol bouillant; l'ester **21** précipite et est recueilli par filtration, p.f. 119–120°, rdt 76%.

Anal. calc. pour $C_{32}H_{40}O_8$: C, 69.55; H, 7.30; O, 23.16. Trouvé: C, 69.64; H, 7.26.

*Cyclisation de l'ester (**21**)*

A une suspension de 11.7 g (0.08 mole) de chlorure d'aluminum anhydre dans 250 ml de CH_2Cl_2, on ajoute lentement une solution de 5.50 g (0.01 mole) d'ester **21** dans 100 ml de CH_2Cl_2. Après 5 h de réaction à température ambiante, on hydrolyse et extrait à l'éther 5.0 g d'une huile brune qui est triturée dans le méthanol. Par filtration on recueille 0.8 g de cristaux fondant à 168–172°. Après plusieurs cristallisations dans un mélange de méthanol–benzène (75:25) le p.f. se stabilise à 179–180°. L'examen du spectre r.m.n. permet d'affirmer que l'on a isolé l'ester **22**. CH_3 (6H): superposition de plusieurs doublets (J = 7 Hz) centrés entre 70 et 82 Hz; H arom: (4H) les protons 6 (et 12) et 5 (et 11) sortent sous forme de deux doublets respectivement centrés à 485 et 488 Hz (J = 6.5 Hz). Les protons allyliques et les protons aromatiques H-1 et H-5 de l'ester **21** ont totalement disparu.

*Préparation des bis(méthyl-2 pentène-4)yl-2,3 naphtalène (**27**)*

L'ester **20** est hydrolysé par la potasse hydroalcoolique en acide malonique **23** (incristallisable), lequel est décarboxylé par reflux dans la pyridine. Les groupements carboxyles du diacide éthylénique **24** (p.f. 129–131°, méthanol sont réduits en méthyles, via dialcool **25** et ditosylate **26** (3)). Le rendement de cette transformation est de 37–39%. L'oléfine **27** est un liquide dont l'examen du spectre de r.m.n. permet de confirmer sa structure; CH_3 (6H):52 Hz (d, J = 6.5 Hz); $=CH_2$ (4H):291 Hz (m) et 304 Hz (m); $—CH=$ (2H):345 Hz (m); H-1 et

H-4:448 Hz (s); H-5, H-6, H-7, H-8:forment un système A_2B_2 centré à 447 Hz. (p.é. 350 °C, 760 mm de Hg).

Tétraméthyl-1,3,6,8 triphénylène (29)

On fait barboter BF_3 pendant 15 min dans une solution de 1.00 g d'oléfine **27** et 25 ml de benzène. Après 3 h de réaction à température ambiante, on hydrolyse, décante la couche benzénique, extrait la couche aqueuse à l'éther de pétrole. On sèche sur $MgSO_4$, évapore les solvants et recueille 0.93 g de tétraméthyl-1,3,6,8 octahydrotriphénylène (**28**). Cet hydrocarbure est aromatisé en présence de 0.50 g de Pd/C à 5%. Après chromatographie, on élue (éther de pétrole–benzène 90:10) 0.81 g de tétraméthyl-1,3,6,8 triphénylène (**29**), p.f. 137–137.5° (éthanol–benzène): *m/e* 284.

Anal. calc. pour $C_{22}H_{20}$: C, 92.91; H, 7.09. Trouvé: C, 92.91; H, 7.13.

Spectre de résonance magnétique nucléaire du triphénylène **29**; méthyles 1 et 8:173 Hz (s); méthyles 3 et 6: 147 Hz (s); protons 2 et 7:433 Hz (large singulet); protons 4 et 5:488 Hz (large singulet); protons 9,10,11,12: forment un système A_2B_2 centré à 474 Hz, dont la partie la plus déblindée (498–512 Hz) est attribuée aux protons 9 et 12 et la partie la plus blindée (440–454 Hz), aux protons 10 et 11. Ces valeurs sont conformes à celles données par Bartle *et al.* (9).

Heterocyclic system containing bridgehead nitrogen atom. Part III. 3-Substituted-, 2,3-disubstituted-5,6-dihydro-4*H*-imidazo[2,1-*b*]thiazoles and 3-substituted-, 2,3-disubstituted-4,5,6,7-tetrahydrothiazolo[3,2-*a*]pyrimidines

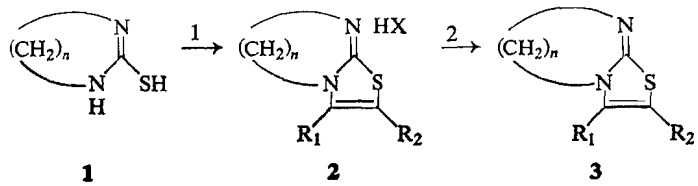
VIJAY K. CHADHA AND H. K. PUJARI
Department of Chemistry, Kurukshetra University, Kurukshetra, India

Received December 17, 1968

The syntheses of 3-substituted-, 2,3-disubstituted-5,6-dihydro-4*H*-imidazo[2,1-*b*]thiazoles and 3-substituted-, 2,3-disubstituted-4,5,6,7-tetrahydrothiazolo[3,2-*a*]pyrimidines have been achieved by reacting ketones with 2-mercaptoimidazoline and 2-mercapto-3,4,5,6-tetrahydropyrimidine respectively in the presence of iodine. The condensation has also been affected by replacing iodine with bromine.

Canadian Journal of Chemistry, 47, 2843 (1969)

In view of the broad spectrum anthelmintic activity of *dl*-6-phenyl-2,3,5,6-tetrahydro-4*H*-imidazo[2,1-*b*]thiazole hydrochloride (tetramisole-HCl) (1–3), it was thought of considerable interest to improve upon the methods of synthesizing condensed thiazoles. The present communication reports the synthesis of two such systems.



1. $R_1COCH_2R_2$, I_2 or Br_2.
2. K_2CO_3 or Et_3N.

Imidazo-thiazoles (**3**, $n = 2$) have been synthesized by condensing 2-mercaptoimidazoline (**1**, $n = 2$) with α-haloketones (4, 5). The observation of King (6) that ketones and halogens can be used in place of α-haloketones in the synthesis of 2-aminothiazoles, has been utilized in the present investigations for the synthesis of imidazo–thiazoles (**3**, $n = 2$) and thiazolo-pyrimidines (**3**, $n = 3$). The method adopted here has a distinct advantage in dispensing with the difficultly available α-haloketones by using ketone and halogens and should also be applicable to the preparation of other condensed thiazoles. Thiazolo-pyrimidines (**3**, $n = 3$) were prepared by three methods. In the first method, 2-mercapto-3,4,5,6-tetrahydropyrimidine (**1**, $n = 3$) was condensed with ketones in the presence of iodine. The resulting hydroiodide salt (**2**, $n = 3$, X = iodine) on treatment with potassium carbonate, yielded the desired base **3**, ($n = 3$). Iodine was replaced by bromine in the second method. The compound **3** ($n = 3$, $R_1 = C_6H_5$, $R_2 = H$) prepared by both of the methods was identical with that obtained by condensing **1** ($n = 3$) with phenacylbromide followed by basification of the hydrobromide (**2**, $n = 3$, X = Br) with potassium carbonate. The structure of **3** ($n = 3$, $R_1 = C_6H_5$, $R_2 = H$; $R_1 = p\text{-}O_2N\text{—}C_6H_4$, $R_2 = H$) was characterized by the infrared (i.r.) spectrum (vide Experimental). Imidazo-thiazoles (**3**, $n = 2$) were also prepared by the above methods.

Fungicidal Tests

For fungicidal assay, the method of Aytoun *et al.* (7) was used. *Aspergillus*, *fusarium*, *penicillium*, and *rhizopus* species were used as test fungi. None of the compounds was found to be active at 1:1000 concentration.

Bactericidal Tests

The Rideal–Walker (8) serial drop dilution method was used for the comparative antibacterial activity. The test organisms were 24 h culture of *Staphylococcus aureus* and *E. coli*.

Among all the compounds tested, compound **3** ($n = 3, R_1 = p\text{-}BrC_6H_4, R_2 = H$) showed maximum activity at 1:4000 concentration.

Experimental[1]

3-Phenyl-4,5,6,7-tetrahydrothiazolo[3,2-a]pyrimidine

(*a*) A mixture of 2-mercapto-3,4,5,6-tetrahydropyrimidine (9) (5 g, 0.431 mole), and phenacylbromide (8.6 g, 0.431 mole) in anhydrous ethanol (50 ml) was heated on a water bath under reflux for 7–8 h. The residue obtained, after distilling off the solvent, was dissolved in boiling water and purified by charcoal treatment. Neutralization of the filtrate with potassium carbonate solution gave an oily substance which solidified on standing. It was filtered, washed with water, and finally recrystallized from aqueous ethanol giving colorless crystals, m.p. 110–111° (7.0 g, 75%); ν_{max} (KBr) 760, 1080, 1135 (monosubstituted benzene ring), 1428 (CH_2 deformation), 1475 (C—N stretching), 1590 (C=N and C=C), 2835, 2910 cm^{-1} (C—H stretching in CH_2). Lack of absorption in the region 1680–1700 cm^{-1} shows the absence of carbonyl group.

Anal. Calcd. for $C_{12}H_{12}N_2S$: S, 14.81; N, 12.07. Found: S, 14.68; N, 11.82.

The picrate had a m.p. 168–169°.

Anal. Calcd. for $C_{18}H_{15}N_5O_7S$: S, 7.19. Found: S, 7.02.

(*b*) A mixture containing 2-mercapto-3,4,5,6-tetrahydropyrimidine (9.3 g, 0.08 mole), acetophenone (4.8 g, 0.04 mole), iodine (10.2 g, 0.04 mole), and anhydrous benzene (30 ml) was heated, under reflux, for 20 h on a water bath and again for 10 h without a condenser. The reaction mixture was kept in contact with ether for 48 h with occasional shaking to remove unchanged ketone. The residual iodine was removed by treatment with sodium thiosulfate solution. The resulting solid was dissolved in boiling water and purified by charcoal treatment. The filtrate on cooling gave hydroiodide salt which was dissolved in water, and basification with potassium carbonate solution yielded the base. Crystallization from aqueous ethanol gave colorless crystals, m.p. 111–112° (6 g, 69%), undepressed with the sample obtained above.

(*c*) Bromine (6.4 g, 0.04 mole) was added dropwise, with constant shaking and cooling under running water, to a mixture of 2-mercapto-3,4,5,6-tetrahydropyrimidine (9.38 g, 0.08 mole) and acetophenone (4.8 g, 0.04 mole) in anhydrous ethanol (30 ml). The reaction mixture was then heated on a water bath for 20 h, under reflux and again for 10 h, after removal of the condenser. The crude product was kept in contact with ether for 24 h with occasional shaking. Last traces of bromine were removed by very dilute thiosulfate solution. The solid thus obtained, was dissolved in water on boiling and purified by charcoal treatment. The filtrate on cooling gave hydrobromide salt which on treatment with potassium carbonate solution yielded the base. (In some cases the salt was obtained on concentration of the filtrate and then on cooling in a fridge.) Crystallization of the base from aqueous ethanol gave colorless crystals, m.p. 110–111° (5 g, 57%), undepressed with the sample obtained above.

3-p-Nitrophenyl-4,5,6,7-tetrahydrothiazolo[3,2-a]-pyrimidine

This compound was prepared by heating 2-mercapto-3,4,5,6-tetrahydropyrimidine with *p*-nitroacetophenone in the presence of iodine, under reflux, on a water bath. The rest of the procedure was followed as in (*b*) above. Crystallization from aqueous ethanol gave yellow crystals, m.p. 168° (43%); ν_{max} (KBr) 850 (1:4-disubstituted benzene ring), 1340 (NO_2), 1430 (CH_2 deformation), 1500 (C—N stretching), 1592 (C=N and C=C), 2840, 2920 cm^{-1} (C—H stretching). The absence of a carbonyl group was indicated by the lack of absorption in the region 1680–1700 cm^{-1}.

Anal. Calcd. for $C_{12}H_{11}N_3O_2S$: S, 12.26; N, 16.09. Found: S, 12.05; N, 15.82.

The picrate had a m.p. 200–201°.

Anal. Calcd. for $C_{18}H_{14}N_6O_9S$: S, 6.53. Found S, 6.38.

The properties and analysis of other thiazolo-pyrimidines prepared by using iodine and bromine are described in Tables I and II respectively.

3-Biphenyl-5,6-dihydro-4H-imidazo[2,1-b]thiazole

(*a*) A mixture of 2-mercaptoimidazoline (9) (2 g, 0.019

mole), *p*-phenylphenacylbromide (10) (5.5 g, 0.019 mole) in anhydrous ethanol (50 ml) was heated under reflux, on water bath for 4½ h. The solvent was then distilled off and the hydrobromide salt (m.p. above 290°) thus obtained, was suspended in ethanol and triethylamine was added dropwise until akaline. The mixture was refluxed for another 10 min and then poured into iced water, yielding cream-colored shiny leaflets. The solid was recrystallized from benzene – petroleum ether (60–80°), m.p. 154–155° (3.3 g, 60%).

Anal. Calcd. for $C_{17}H_{14}N_2S$: S, 11.51; N, 10.07. Found: S, 11.37, N. 9.78.

The picrate had a m.p. 208°.

Anal. Calcd. for $C_{23}H_{17}N_5O_7S$: S, 6.31. Found: S, 6.07.

(*b*) It was prepared by condensation of 2-mercapto-imidazoline (8 g, 0.074 mole) with *p*-phenylacetophenone (10) (7.84 g, 0.037 mole) in the presence of iodine (10.2 g, 0.037 mole). The procedure adopted was the same as in the case of thiazolo-pyrimidine except that triethylamine was used in place of potassium carbonate. It was recrystallized from benzene – petroleum ether (60–80°), m.p. 154–155° (4.54 g, 40%). The mixed m.p. with that obtained by method (*a*) remained undepressed. The picrate had a m.p. 208°, undepressed with the sample obtained above.

(*c*) It was also prepared by condensing 2-mercapto-imidazoline (8 g, 0.074 mole), *p*-phenylacetophenone (7.848 g, 0.037 mole) in presence of bromine (6.4 g, 0.037 mole). The procedure followed was the same as in case of thiazolo-pyrimidine. HBr salt had a m.p. above 290°.

Anal. Calcd. for $C_{17}H_{15}N_2SBr$: S, 8.91. Found: S, 8.62.

The base had a m.p. 155–156° (4 g, 30%), the mixed m.p. remaining undepressed. The picrate had a m.p. 208–209°, undepressed with the sample obtained above.

The properties and analysis of other imidazo-thiazoles prepared by using iodine and bromine are described in Tables III and IV respectively.

Acknowledgments

Structures of bahia-I and bahia-II: two new guaianolides[1]

A. ROMO DE VIVAR AND A. ORTEGA
Instituto de Química de la Universidad Nacional Autónoma de México, México 20, D.F., México

Received November 5, 1968

Two new guaianolides bahia-I and bahia-II were isolated from Bahia pringlei.[2] Their structures are shown to be **1***a* and **1***b*.

Canadian Journal of Chemistry, 47, 2849 (1969)

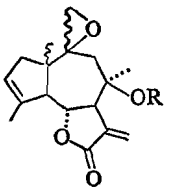
For personal use only.

As part of our search for sesquiterpene lactones we studied *Bahia pringlei,* a small Composita which grows not far from Mexico City. We report herein the isolation of two sesquiterpenes which we propose to name bahia-I and bahia-II.

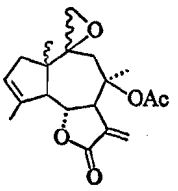
Bahia-I (**1***a*) $C_{15}H_{18}O_4$, m.p. 209–210°, $[\alpha]_D^{28}$ +4° possesses a free hydroxyl group as shown by the infrared (i.r.) band at 3500 cm^{-1} and by the formation of a monoacetate (**2**). It has two double bonds (i.r. bands at 1670 and 1600 cm^{-1}), one of them being an exocyclic double bond conjugated with a γ-lactone (1–3), as indicated by the i.r. band at 1765 cm^{-1}, the ultraviolet (u.v.) absorption (λ_{max} 207 mμ; ε = 10 370), and the characteristic low field doublets in the nuclear magnetic resonance (n.m.r.) spectrum at 6.26 and 5.69 p.p.m. (J = 3.2 c.p.s.). Aluminum amalgam reduction saturated the exocyclic methylene yielding dihydrobahia-I (**6**) whose n.m.r. spectrum showed a new methyl group signal as a doublet at 1.20 p.p.m. (J = 7 c.p.s.). The signals for the exocyclic double bond are not present and the high intensity u.v. absorption has also disappeared.

The second double bond in bahia-I should be trisubstituted since its n.m.r. spectrum showed signals at 5.57 p.p.m. (1H, s) and 1.85 p.p.m. (3H, s) due to the proton at C-3 and to the methyl group at C-4, respectively. The trisubstituted double bond in dihydrobahia-I was further hydrogenated in the presence of platinum oxide, leading to the oily tetrahydrobahia-I (**10**).

Dehydrogenation with palladium on charcoal of the lithium aluminum hydride reduction product of bahia-I afforded chamazulene (**3**),



1*a*, R = H



2

1*b*, R = —O—CO—C(H)=C(HOCH$_2$)(CH$_2$OH)

linderazulene (**4**), and artemazulene (**5**). From these results we can infer that bahia-I is a guaianolide.

The lactone group in bahia-I should be closed to C-6 since the hydrogen on this carbon produces a triplet at 4.42 p.p.m. (1H) (J = 9 c.p.s.), arising from the interaction with the hydrogens at C-7 and C-5.

The methyl present at C-10 in the majority of the guaianolides is absent in bahia-I. However there appeared a singlet at 2.71 p.p.m. (2H) which we attribute to a spiroepoxide. Euparotin (4) containing the same functional group gives a similar signal.

When dihydrobahia-I (**6**) was hydrogenated in acetic acid with Adams' catalyst, the product obtained was the diol (**11**) whose n.m.r. spectrum shows a singlet at 1.30 due to a tertiary methyl group attached to a carbon atom bearing a hydroxyl group; such a grouping must have been formed by hydrogenolysis of the spiroepoxide, since the signal at 2.71 has disappeared.

12 13

Oxidation of the diol (**11**) afforded a ketone (**12**) which still contains the tertiary hydroxyl group (i.r. band at 3550 cm^{-1}). The n.m.r. spectrum of (**12**) shows a singlet at 1.35 p.p.m. due to the tertiary methyl group linked at C-10, the singlet at 2.80 p.p.m. (2H) is attributed to the C-9 hydrogens.

Further evidence for the presence of a spiro-epoxide in bahia-I was obtained by aluminum amalgam reduction of **1***a*. This reaction gave rise to dihydrobahia-I (**6**), together with the product (7) which did not show the epoxide signal in the n.m.r. spectrum. Instead, it showed two singlets at 4.99 and 5.09 p.p.m. with apparent long-range coupling attributed to a new exocyclic methylene group formed by reductive elimination of the spiroepoxide.

Compound (7) was also obtained by $CrCl_2$ treatment of dihydrobahia-I (**6**). This reagent has been reported to produce reductive elimination in other isolated epoxides (5).

Epoxidation of dihydrobahia-I (**6**) afforded the diepoxide (**13**). An attempt to obtain the same product from compound (7) resulted in a di-epoxide with the same gross structure but differing in stereochemistry, probably at C-10.

The secondary alcohol (7) and its oxidation product (**8**) were identified as dihydroligustrin (6) and dihydrodehydroligustrin (6), respectively. This correlation establishes the structure of bahia-I and its stereochemistry at positions C-5, C-6, and C-7 as shown in **1***a*. This correlation also indicates the configuration of the methyl group attached to the lactone ring of dihydro-bahia-I.

The orientation of the secondary hydroxyl group at C-8 was established by the method developed by Horeau (7, 8).

The α-phenylbutyric acid recovered from the esterification of bahia-I with α-phenylbutyric anhydride was dextrorotatory, therefore the C-8 hydroxyl group must have the absolute configuration R (β orientation).

The second and more polar component of *Bahia pringlei*, bahia-II, $C_{20}H_{24}O_7$, m.p. 133–134°, $[\alpha]_D^{28}$ +47.7, contains two hydroxyl groups (i.r. bands at 3620 and 3500 cm^{-1}), and a γ-lactone group conjugated with an exocyclic methylene group as indicated by the i.r. bands at 1765 and 1655 cm^{-1}. The u.v. absorption λ_{max} 212 mμ (ε = 19 500) is the result of the absorption of the conjugated exocyclic methylene group and another chromophore.

Bahia-II is an ester of bahia-I (i.r. band at 1725 cm^{-1}), since reduction of bahia-II with aluminum amalgam followed by hydrolysis produced dihydrobahia-I (**6**) identical in all respects with an authentic sample.

The acid which esterifies bahia-I must be α,β-bis-(hydroxymethyl)-acrylic acid in order to account for the elemental anaylsis of bahia-II, its correlation with bahia-I, and its spectroscopic features. This acid has been found in eupatoriopicrin (9) and cnicin (10). We could not identify the acid chemically. Nevertheless, high resolution n.m.r. (100 M c.p.s.) confirmed the structure **1***b* for bahia-II. It showed a triplet at 6.90 p.p.m. (J = 3 c.p.s.) attributed to the vinylic hydrogen of the α,β-unsaturated ester, a doublet at 4.39 (2H) (J = 3 c.p.s.) is due to a hydroxymethyl group with an allylic double bond. As the coupling constant is similar to that of the vinyl proton in the ester, they should be at vicinal positions (O—CO—C=$CHCH_2$—OH). The second hydroxymethyl group appeared as a singlet at 4.29 p.p.m.

The hydrogen bonded to the carbon bearing the ethereal oxygen of the lactone produces a triplet at 4.68 p.p.m. (J = 4.5 c.p.s.).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The hydrogen at C-8, where the ester is attached is responsible for a multiplet at 5.72 p.p.m.

The structure **1***b* for bahia-II was confirmed by spin decoupling. When bahia-II was irradiated at 6.9 p.p.m., the doublet at 4.39 p.p.m. (—O—CO—C=CH—CH_2—OH) collapsed to a singlet, thus confirming the structure for the ester as shown in (**1***b*).

Irradiation of the triplet at 3.25 p.p.m. (H at C-7) transforms the multiplet at 5.72 p.p.m. into a triplet proving the relative position of the ester and the lactone groups. The chemical shift of the vinylic hydrogen of the ester is characteristic of a tiglate (approximately 6.7 p.p.m.) rather than of an angelate (approximately 6 p.p.m.) (11, 12). Hence, the more probable stereochemistry for the ester should be the *cis*, as depicted in **1***b*.

Experimental

Melting points were carried out in a Koffler apparatus and are uncorrected. Analyses were by Dr. F. Pascher, Bonn, Germany. Infrared spectra were run in chloroform in a Perkin–Elmer double beam spectrophotometer unless otherwise specified. Ultraviolet spectra were run in 95% ethanol and rotation was in chloroform. Nuclear magnetic resonance spectra were run by Mr. Eduardo Díaz on a Varian A-60A n.m.r. spectrometer, in deuterio–chloroform with tetramethylsilane as internal standard unless otherwise specified.

Isolation of bahia-I (1a) and bahia-II (1b)

Bahia pringlei was collected 90 km north of Mexico City along the highway Mexico–Laredo in November, 1966. The whole plant was dried, and ground to a fine powder (3.7 kg), which was extracted with ethanol and worked out in the usual manner, leaving 52 g of a syrup. This was dissolved in benzene and chromatographed on 1 kg of alumina Alcoa F-20, washed previously with ethyl acetate. Benzene ethyl acetate 2:1 eluted 650 mg of bahia-I, m.p. 200°; recrystallization from acetone – isopropyl ether raised the m.p. to 209–210°; ν_{max} 3600, 3500, 1765, 1670, 1600, and 870 cm^{-1}; λ_{max} 207 mμ; $\varepsilon = 10\,370$; $[\alpha]_D^{28}$ +4° (*c* 0.96); n.m.r.: δ 1.85 (3H, s), 2.71 (2H, s), 4.42 (1H, t), (*J* = 9 c.p.s.), 5.57 (1H, s), 5.69 (1H, d), and 6.26 (1H, d) (*J* = 3.2 c.p.s.).

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92; O, 24.40. Found: C, 68.79; H, 6.87; O, 24.38.

Chloroform containing 5% methanol eluted 11.8 g bahia-II, m.p. 126–127°. Further crystallization from ethyl acetate–isopropyl ether raised the m.p. to 134–137°; $[\alpha]_D^{28}$ +47.7° (*c* 1); ν_{max} 3500, 1765, 1725, and 1665 cm^{-1}; λ_{max} 212 mμ; $\varepsilon = 19\,500$; n.m.r. (100 M c.p.s.): δ 1.95 (3H, s), 2.7 (2H, s), 4.29 (2H, s), 4.39 (2H, d) (*J* = 3 c.p.s.), 4.68 (1H, t) (*J* = 4.5 c.p.s.), 5.6 (1H, d) (*J* = 2 c.p.s.), 6.31 (1H, d) (*J* = 2 c.p.s.), 6.90 (1H, t) (*J* = 3 c.p.s.), 5.72 p.p.m. (2H, m).

Anal. Calcd. for $C_{20}H_{24}O_7$: C, 63.82; H, 6.43; O, 29.75. Found: C, 63.93; H, 6.20; O, 29.55.

Dehydrogenation of bahia-I

A solution of crude bahia-I (2.5 g) in anhydrous ethyl ether containing a little THF was added slowly over a slurry of LAH (4 g) in 100 ml of anhydrous ethyl ether and then refluxed for ½ h. The excess of LAH was destroyed with a small amount of water, the mixture filtered, and the filtrate concentrated. The residue (2 g) was treated with 4 g 10% Pd/C in 10 ml of Nujol. The mixture was heated at 300° for 35 min, dissolved in hexane, and chromatographed on 60 g of alumina Alcoa F-20. Hexane eluted, in the first fractions, 45 mg of chamazulene; hexane–benzene 9:1 eluted a little artemazulene and in the last fractions, linderazulene. The 3 aromatization products were identified as the TNB adducts which were compared with authentic samples.

Tetrahydrobahia-I Acetate (9)

Bahia-I (100 mg) was acetylated with acetic anhydride–pyridin in the usual manner, affording 80 mg of an oily product. This was hydrogenated in 15 ml of ethyl acetate with 20 mg 10% $Pd/CaCO_3$, affording 20 mg of tetrahydrobahia-I acetate, m.p. 160–162°. The pure sample was obtained after several recrystallizations from ethyl acetate – isopropyl ether, m.p. 165–167°. The same product was obtained by acetylation of the oily tetrahydrobahia-I (**10**), obtained by hydrogenation of dihydrobahia-I with platinum oxide; n.m.r.: δ 0.95 (3H, d) (*J* = 7 c.p.s.), 1.2 (3H, d) (*J* = 7 c.p.s.), 2.08 (3H, s), 4.75 (1H, t) (*J* = 9.5 c.p.s.), 5.17 (1H, complex signal).

Anal. Calcd. for $C_{17}H_{24}O_5$: C, 66.25; H, 7.85; O, 25.94. Found: C, 66.45; H, 7.76; O, 26.06.

Dihydrobahia-I (6)

A solution of 2 g of bahia-I in 100 ml ethanol was treated with freshly prepared aluminum amalgam (from 5 g Al and 3.5 g Hg_2Cl_2). The reaction mixture was refluxed for 8 h, filtered, and concentrated. Crystallization of the residue afforded 650 mg of a mixture of two substances which were separated by chromatography on silica gel (30 g). The first substance was eluted with a mixture of benzene – ethyl acetate (90:10), yielding 325 mg of product (6), m.p. 144–145°; $[\alpha]_D^{28}$ +62.2°; ν_{max} 3600, 1770, and 1645 cm^{-1}; n.m.r.: δ 1.20 (3H, d) (*J* = 7 c.p.s.), 1.92 (3H, d) (*J* = 1 c.p.s.), 2.69 (2H, s), 4.08 (1H, complex signal), 4.58 (1H, t) (*J* = 9 c.p.s.), 5.5 (1H, s).

Anal. Calcd. for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63; O, 24.21. Found: C, 68.23; H, 7.55; O, 24.10.

The substance (7) was eluted with ethyl acetate (155 mg, m.p. 167–169°). The m.p. of the mixture with dihydrodehydroligustrin (6) showed no depression and the i.r. spectra were superimposable; $[\alpha]_D^{28}$ +92.1°; ν_{max} 3500, 1770, and 1645 cm^{-1}.

Anal. Calcd. for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12; O, 19.33. Found: C, 72.36; H, 8.02; O, 19.55.

Hexahydrobahia-I (11)

A solution of 200 mg of dihydrobahia-I in 15 ml of AcOH was hydrogenated in the presence of 20 mg of PtO_2 until the absorption of hydrogen ceased. The solution was filtered and the solvent evaporated *in vacuo*; the product crystallized on addition of isopropyl ether, yielding 200 mg of hexahydrobahia-I, m.p. 144–146°; ν_{max} 3500 and 1765 cm^{-1}; $[\alpha]_D^{27}$ +5.5° (*c* 1); n.m.r.: δ 0.97 (3H, d) (*J* = 7 c.p.s.), 1.2 (3H, d) (*J* = 7 c.p.s.), 1.30 (3H, s), 4.01 (1H, complex signal), 4.82 (t) (*J* = 10 c.p.s.).

Anal. Calcd. for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02; O, 23.85. Found: C, 67.10; H, 8.98; O, 23.81.

Ketone (8)

A solution of 100 mg of (7) in acetone (3 ml) was oxidized by the Bowers' method (13). Yield: 85 mg, m.p. 108–110°. The analytical sample was obtained by recrystallization from acetone – isopropyl ether; m.p. 114–116°. The m.p. of the mixture with dihydroligustrin (6) was also 114–116° and the i.r. spectra were superimposable; λ_{max} 205 mμ; ε = 10 723.

Anal. Calcd. for $C_{15}H_{18}O_3$: C, 73.14; H, 7.37; O, 19.49. Found: C, 72.93; H, 7.39; O, 20.06.

Oxidation of the Diol (11)

A solution of 50 mg of (**11**) in 3 ml of acetone was oxidized with Jones' reagent (13), and the reaction was completed in 4 min at room temperature. The mixture was diluted with a little water and was cooled; the crystalline product so formed was collected, yielding 50 mg of (**12**), m.p. 174–175°; ν_{max} 1770 and 1725 cm^{-1}; $[\alpha]_D^{28}$ −82.3 (*c* 1.045); n.m.r.: δ 0.95 (3H, d) (*J* = 7 c.p.s.), 1.2 (3H, d) (*J* = 6.5 c.p.s.), 1.35 (3H, s), 2.8 (2H, s), 4.59 (1H, t) (*J* = 8.5 c.p.s.).

Anal. Calcd. for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33; O, 24.03. Found: C, 67.82; H, 8.27; O, 24.07.

Epoxidation of Dihydrobahia-I

A solution of 90 mg of dihydrobahia-I in 25 ml of chloroform was treated with 90 mg of *m*-chloroperbenzoic acid. The mixture was refluxed for 8 h, washed with an $NaHCO_3$ solution and water, dried with anhydrous sodium sulfate, and evaporated to dryness. Yield: 12 mg of 11-dihydro-3-epoxybahia-I (**13**); m.p. 175–178°; a recrystallization from acetone – isopropyl ether raised the m.p. to 178–180°; ν_{max} 3500 and 1780 cm^{-1}; n.m.r.: δ 1.27 (3H, d) (*J* = 7 c.p.s.), 1.64 (3H, s), 4.08 (1H, complex signal), 4.43 (1H, t).

Anal. Calcd. for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19; O, 28.54. Found: C, 64.32; H, 7.12; O, 28.64.

Epoxidation of (7)

A solution of 90 mg of the unsaturated alcohol (7) in 25 ml of chloroform was treated with 90 mg of *m*-chloroperbenzoic acid and worked-up as in the previous case. The substance (**13**) isolated from the oily residue melted at 183–185°; ν_{max} 3500, 1780 cm^{-1}; n.m.r.: δ 1.22 (3H, d) (*J* = 7 c.p.s.), 1.61 (3H, s), 2.65 (s), 4.4 (1H, complex signal), 4.42 (1H, t) (*J* = 9 c.p.s.).

Anal. Calcd. for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19; O, 28.54. Found: C, 64.39; H, 7.09; O, 28.60.

Dihydrobahia-I from Bahia-II

A solution of 1 g of bahia-II in 150 ml of ethanol was treated with 5 g of freshly prepared aluminum amalgam, the reaction mixture refluxed for 8 h, filtered, and taken to dryness. The oily residue (1 g) was dissolved in 30 ml of methanol and treated with 1 g of potassium carbonate in 6 ml of water for 15 h at room temperature. The solution was concentrated at reduced pressure, diluted with water, and extracted with ethyl ether. The organic layer was washed, dried, and evaporated, the residue crystallized from isopropyl ether, affording 300 mg of crude product, m.p. 158–160°. Further recrystallizations from the same solvents raised the m.p. to 169–170°. The product was identified as dihydrobahia-I, as the mixed m.p. showed no depression and the i.r. spectra were identical (superimposable) on a comparison with an authentic sample.

Chromous Chloride Treatment of Compound 6

A solution of 200 mg of dihydrobahia-I in 8 ml of acetone was treated in a CO_2 atmosphere with a solution of chromous chloride in 4 ml of acetic acid. The reaction was completed in 20 min. The mixture was concentrated at reduced pressure and diluted with ethyl acetate.

The organic layer was washed with a sodium bicarbonate solution and with water, dried, and evaporated leaving an oily residue which, after chromatography on alumina, afforded 20 mg of the compound (7) m.p. 167–168°.

Determination of the Configuration at C-8

Esterification of Bahia-I

Racemic α-phenylbutyric anhydride (472.7 mg, 1.287 mmole) and dihydrobahia-I (133 mg, 0.500 mmole) were dissolved in 5 ml pyridine, and the mixture was allowed to stand overnight at room temperature. The reaction mixture was diluted with water and extracted with ethyl acetate. The ethyl acetate extract was washed with water, with a 5% sodium bicarbonate solution, and again with water. The ethyl acetate solution was dried with anhydrous sodium sulfate, and evaporated *in vacuo* to a constant weight of 200.5 mg.

The sodium bicarbonate extract was acidified with HCl and extracted with chloroform. The chloroform was eliminated leaving a residue of 208.5 mg of pure α-phenylbutyric acid. The acid and the ester were identified by n.m.r. spectroscopy. The acid was dissolved in 10 ml of chloroform and the specific rotation was determined: $[\alpha]_D^{25}$ +8.4°.

The optical yield is 36% of dextrorotatory acid.

Etude de la décomposition des diazo-2 dicétones-1,3. II. Cas du diazo-2 diphényl-4,5 cyclohexanedione-1,3

WILLIAM D. BARKER, ROLAND GILBERT, JEAN-PAUL LAPOINTE, HENRI VESCHAMBRE,[1] ET DANIEL VOCELLE[2]

Département de Chimie, Université de Montréal, Montréal, Québec

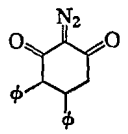
Reçu le 29 octobre, 1968

L'étude des décompositions thermique et photochimique du diazo-2 diphényl-4,5 cyclohexanedione-1,3 dans différents solvants a été réalisée. Les résultats obtenus sont analogues à ceux fournis par le diazo-2 diméthyl-5,5 cyclohexanedione-1,3 dans les mêmes conditions. A savoir: formation de **2***a* au cours de la thermolyse dans le xylène, de **5** dans la photolyse dans le tétrachlorure de carbone, de **6** et **7** dans le méthanol et finalement de **4** dans l'éthanol. Il a été noté que la présence d'un groupement phényle en β du carbène oriente la contraction de cycle.

Canadian Journal of Chemistry, 47, 2853 (1969)

Au cours d'une étude précédente (1) nous avons montré que la décomposition photochimique du diazo-2 diméthyl-5,5 cyclohexanedione-1,3 se faisait selon deux modes principaux de réaction: *1*) par contraction de cycle et *2*) par réduction du carbène.

Dans le but de vérifier la généralité de ces modes réactionnels et en vue de préciser le mécanisme réactionnel de la contraction de cycle, nous avons effectué une étude analogue sur le diazo-2 diphényl-4,5 cyclohexanedione-1,3 (**1**).



1

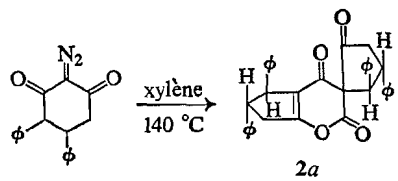
Ce diazo n'avait jamais été préparé jusqu'ici. Nous l'avons obtenu à partir de la diphényl-4,5 cyclohexanedione-1,3 selon une méthode inspirée de celle décrite par Rosenberg *et al.* (2) pour préparer d'autres composés diazoïques.

Afin de pouvoir comparer le comportement du diazo **1** avec celui du diazo-2 diméthyl-5,5 cyclohexanedione-1,3 nous avons refait les mêmes expériences: à savoir décomposition thermique dans le xylène, décompositions photochimiques dans le tétrachlorure de carbone, dans l'alcool méthylique et dans l'alcool éthylique.

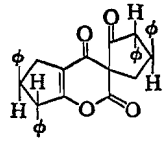
Résultats

(1) Thermolyse

Par décomposition thermique dans le xylène à 140 °C, le diazo-2 diphényl-4,5 cyclohexanedione-1,3 conduit au composé **2***a*.



2*a*



2*b*

Ce composé est du même type que celui obtenu lors de la décomposition thermique du diazo de la dimédone (1). En particulier, les caractéristiques spectrales sont analogues. De plus, l'analyse est en accord avec la formule brute de **2***a* soit $C_{36}H_{28}O_4$. L'ensemble de ces données permet donc d'attribuer à **2***a* la formule du tétraphényl-6,7,4′,5′ trioxo-2,4,2′ hexahydro-2,3,4,5,6,7 spiro (cyclopenta (*b*) pyran-3,1′ cyclopentane).

Ce composé admet plusieurs isomères. Toutefois l'attribution de la structure, telle que décrite ci-dessus, semble raisonnable et repose sur les arguments suivants.

La cyclisation de **3** en présence de base (schéma

SCHÉMA 1

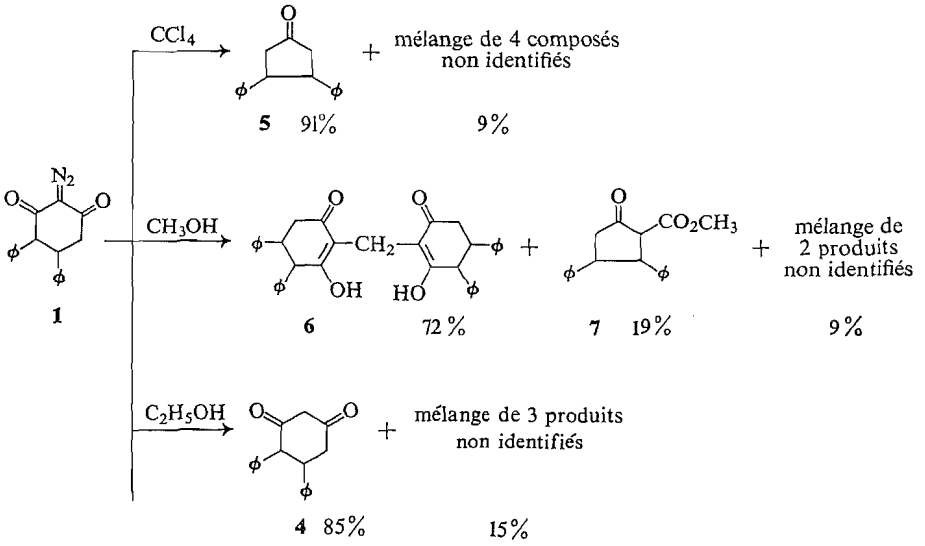

SCHÉMA 2

1) devrait donner la dicétone **4** (phényles *trans* di-équatoriaux) plutôt que l'isomère *cis* (3).

Il sera montré plus loin que le diazo **1**, par décomposition photochimique dans le tétrachlorure de carbone, fournit la *trans*-diphényl-3,4 cyclopentanone. Nonobstant un réarrangement profond de la molécule, la position *trans* des deux groupes phényles dans la cyclopentanone implique un arrangement *trans* dans le diazo **1**.

Finalement un composé isomérique à **2***a* peut être aussi formé. En effet, le composé **2***b* est aussi possible par la réaction de deux molécules de cétène **9**.

Que ce composé ne se forme pas, a été montré par le fait que la thermolyse de **1** dans le xylène et en présence d'une trace de méthanol n'a donné que le céto–ester **7**. Par hydrolyse, ce dernier a donné qu'un seul produit, la *trans*-diphényl-3,4 cyclopentanone.

(2) Photolyse

L'ensemble des résultats, obtenus au cours des décompositions photochimiques du diazo-2 diphényl-4,5 cyclohexanedione-1,3, est rassemblé dans le schéma 2.

Toutes les photolyses ont été réalisées avec une lampe Hanovia de 450 watts sous atmosphère d'azote et pendant 1 h dans presque tous les cas. Après distillation du solvant, le résidu solide a été analysé par chromatographie sur couches minces. Des chromatographies sur colonne ont permis d'isoler purs les principaux produits réactionnels. Les pourcentages paraissant au schéma 2 sont des pourcentages de récupération.

a) Photolyse dans le tétrachlorure de carbone

La photolyse a été effectuée pendant 1 h et 30 min avec un filtre Pyrex.

Le principal produit de la réaction (91%) s'avéra être la *trans*-diphényl-3,4 cyclopentanone (**5**). Elle fut identifiée par comparaison avec un échantillon authentique obtenu selon le mode réactionnel décrit au schéma 3.

Il fut également obtenu, dans un rendement de 9%, un mélange d'au moins quatre produits

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

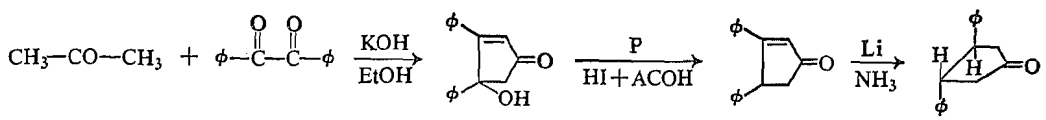

SCHÉMA 3

(chromatographie sur couches minces) qui ne furent pas identifiés.

b) Photolyse dans les alcools méthylique et éthylique

Les photolyses dans les alcools méthylique et éthylique ont été faites pendant 1 h, sans filtre.

Dans le cas du méthanol, la chromatographie sur colonne permit d'isoler un mélange de deux produits qui furent séparés par recristallisation fractionnée dans le méthanol aqueux. Il fut ainsi obtenu 72% de bis (diphényl-4,5 cyclohexèn-1 ol-2 oxo-6 yl) méthane (**6**) et 19% de diphényl-2,3 oxo-5 cyclopentanecarboxylate de méthyle (**7**).

Le composé **6** a été identifié par comparaison avec un échantillon authentique obtenu par réaction de la diphényl-4,5 cyclohexanedione-1,3 sur le formaldéhyde selon la méthode utilisée pour préparer les dérivés dimédoniques des aldéhydes (4).

Le composé **7** a été identifié par ses caractéristiques spectrales:

Infrarouge: bandes à 1755, 1720, et 1600 cm^{-1}.

Résonance magnétique nucléaire: bandes à 2.79 τ (10H, singulet); 6.28 τ (3H, singulet); de 6.1–7.3 τ (5H, multiplet).

Spectre de masse: pic parent à 294 (valeur calculée 294.6) et par son analyse qui est en accord avec la formule brute de **7** soit $C_{19}H_{18}O_3$. En outre, la structure de 7 a été confirmée par une hydrolyse acide; celle-ci conduisit à la *trans*-diphényl-3,4 cyclopentanone (**5**).

Un mélange d'au moins deux produits (chromatographie sur couches minces) fut également obtenu. Ils ne furent pas identifiés.

La photolyse dans l'éthanol a fourni comme principal produit réactionnel la diphényl-4,5 cyclohexanedione-1,3 (**4**) dans un rendement de 85%. Elle fut identifiée par comparaison avec un échantillon authentique. Cette photolyse a également conduit à un mélange d'au moins 3 composés qui ne purent être séparés et qui ne furent pas identifiés.

Discussion

Les résultats des décompositions thermique et photochimiques du diazo-2 diphényl-4,5 cyclohexanedione-1,3 montrent que celui-ci se comporte de la même façon que le diazo-2 diméthyl-5,5 cyclohexanedione-1,3 (1). Les mécanismes permettant d'expliquer la formation des différents composés obtenus sont donc les mêmes. Cependant le diazo-2 diphényl-4,5 cyclohexanedione-1,3 ayant une structure dissymétrique, la contraction de cycle pouvait conduire à deux cétènes différents **8** et **9** selon que la liaison a ou la liaison b se transposait (schéma 4).

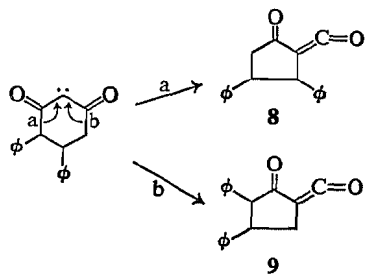

SCHÉMA 4

Les résultats montrent, sans l'ombre d'un doute, que seul la transposition selon a, pour donner **8** intervient. Ce réarrangement unique pourrait s'expliquer par une plus grande stabilité de la charge négative (due à la présence d'un groupement phényle en α) qui doit se développer dans l'état de transition.

Le schéma 5 montre les mécanismes proposés pour expliquer la formation des différents composés obtenus au cours des décompositions thermique et photochimiques du diazo-2 diphényl-4,5 cyclohexanedione-1,3.

Il est à noter que le composé **10** ne se forme pas, au cours de la photolyse du diazo-2 diphényl-4,5 cyclohexanedione-1,3 dans l'alcool éthylique; contrairement à ce qui se passe avec le diazo de la dimédone où un composé similaire est obtenu (1). La réaction entre la dimédone et l'acétaldéhyde selon la méthode de Horning et Horning (4) est très facile et conduit rapidement au composé attendu. Il n'en est pas de même avec la diphényl-4,5 cyclohexanedione-1,3. En

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

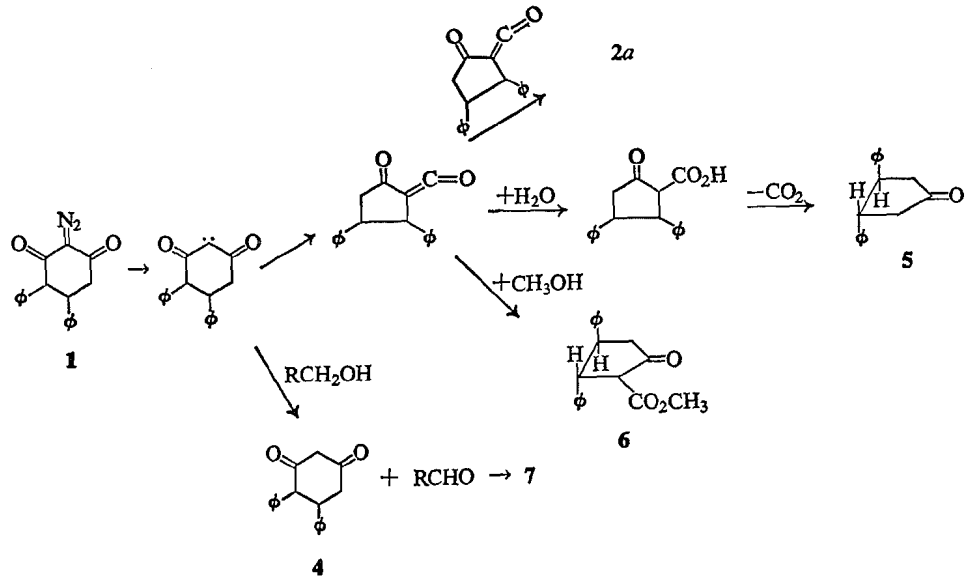

SCHÉMA 5

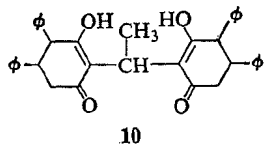

10

effet, celle-ci ne réagit pas avec l'acétaldéhyde dans les conditions décrites par Horning. On la retrouve inchangée à la fin de la réaction.

Cependant la présence de diphényl-4,5 cyclohexanedione-1,3 implique la réduction du carbène et l'oxydation de l'éthanol en acétaldéhyde. La formation de ce dernier, au cours de la photolyse, a d'ailleurs été vérifiée par l'obtention de son dérivé dinitro-2,4 phénylhydrazone (voir Partie expérimentale).

Conclusion

Les résultats obtenus, au cours des décompositions thermique et photochimiques du diazo-2 diphényl-4,5 cyclohexanedione-1,3, montrent que celui-ci se comporte de la même manière que le diazo de la dimédone (1). Les deux modes réactionnels rencontrés au cours de l'étude précédente se retrouvent ici.

De plus, cette étude a permis de montrer que la présence d'un groupement phényle en β du carbène oriente la contraction de cycle. Celle-ci se fait, en effet, uniquement du côté de la molécule contenant le groupement phényle.

Partie expérimentale

Les points de fusion ont été déterminés sur un appareil Büchi Modèle Dr. Tottoli et sont donnés sans correction. Les spectres infrarouges ont été enregistrés sur un spectrophotomètre Beckman IR 8 et les spectres ultraviolets sur un Spectronic 505 de Bausch et Lomb. Les spectres de résonance magnétique nucléaire ont été réalisés sur un appareil Jéol type C60H dans du chloroforme deutérié avec du TMS comme référence interne. Les spectres de masse on été pris sur un appareil Hitachi Perkin–Elmer type RMU-6D. Les microanalyses ont été effectuées par Schwarzkopf Microanalytical Laboratory, Woodside, New York, USA. Les chromatographies sur couches minces ont été faites sur chromagram Eastman–Kodak No 6060 en utilisant le mélange cyclohexane–acétate d'éthyle 75/25 en volume comme éluant.

Synthèse de la diphényl-4,5 cyclohexanedione-1,3 (4)

Elle fut préparée selon la méthode de Zimmerman et Schuster (5) à partir de phénylacétate d'éthyle et de *trans*-phényl-4 buten-3 one-2 p.f. 160–162 °C (litt. p.f. 160–165 °C (5)).

Synthèse du diazo-2 diphényl-4,5 cyclohexanedione-1,3 (1)

Une solution de 21 g (0.08 *M*) de diphényl-4,5 cyclohexanedione-1,3 et de 14 g (0.08 *M*) d'azoture de tosyle dans 1400 ml d'éther anhydre et 25 ml d'alcool éthylique, est refroidie sous agitation. Lorsque la température est inférieure à 5 °C, 10 ml de diéthylamine sont ajoutés rapidement. Le mélange est laissé sous agitation 15 min à froid et 2 h 30 min à température ambiante. La solution éthérée est lavée plusieurs fois avec une solution de soude à 10%, puis à l'eau jusqu'à neutralité. Après séchage sur sulfate de sodium anhydre, le solvant est éliminé et le résidu solide, recristallisé dans l'alcool à 95%. Rendement 45–50%: p.f. 130–132 °C.

Spectre infrarouge: 2165, 2140, et 1645 cm^{-1}.

Spectre ultraviolet (EtOH 95%): λ_{max} = 230 mμ ε_{max} = 15 114; λ_{max} = 259 mμ ε_{max} = 9175.

Spectre de résonance magnétique nucléaire: multiplet centré à 2.85 τ (10H); multiplet entre 6 et 6.6 τ (2H), doublet à 7.15 τ (2H).

Anal. calc. pour $C_{18}H_{14}N_2O_2$ (290.3): C, 74.47; H, 4.86; N, 9.65. Trouvé: C, 74.37; H, 4.97; N, 9.43.

Décomposition thermique du diazo-2 diphényl-4,5 cyclohexanedione-1,3

Trente ml de xylène ont été placés dans un ballon de 100 ml à 2 tubulures muni d'un réfrigérant, d'une ampoule à brome et plongé dans un bain d'huile. Lorsque la température du bain d'huile atteint 140°, une solution de 1 g de diazo-2 diphényl-4,5 cyclohexanedione-1,3 dans 50 ml de *m*-xylène est ajoutée goutte à goutte. Le dégagement gazeux s'arrête 15 min après la fin de l'addition de la solution de diazo. La solution encore chaude est traitée par du charbon actif et filtrée. Le *m*-xylène est éliminé sous pression réduite. Le résidu jaune pâle huileux est repris par une petite quantité d'éther. En chassant rapidement l'éther sous vide, un produit solide est obtenu. Il est purifié par une chromatographie sur colonne de silicagel (éluant cyclohexane–acétate d'éthyle 75/25).

Par comparaison avec le composé obtenu dans le cas du diazo de la dimédone, ce produit fut identifié comme étant le tétraphényl-6,7,4′,5′ trioxo-2,4,2′ hexahydro-2,3,4,5,6,7 spiro (cyclopenta (*b*) pyran-3,1′ cyclopentane) (**2***a*): p.f. 79–80 °C.

Spectre infrarouge: 1780, 1750, 1678, et 1645 cm^{-1}.

Spectre ultraviolet: (EtOH) λ_{max} = 292 mμ ε_{max} = 11 000.

Spectre de masse: pic parent à 524 (valeur calculée 524.6).

Résonance magnétique nucléaire: 2.75 τ (singulet large, 20H) 5.9–7.7 τ (multiplet, 8H).

Anal. calc. pour $C_{36}H_{28}O_4$ (524.6): C, 82.42; H, 5.38. Trouvé: C, 82.06; H, 5.52.

Selon les mêmes conditions, mais en présence d'une trace de méthanol anhydre, le céto–ester **7** a été obtenu. Ce dernier présentait exactement les mêmes caractéristiques que le céto–ester obtenu par photolyse de **1** dans le méthanol: à savoir: p.f. 127–129 °C i.r. et r.m.n. rigoureusement identiques. L'hydrolyse donna une cétone présentant un p.f. 175–177 °C et un dérivé dinitro-2,4 phénylhydrazone p.f. 172–174 °C en plus d'avoir des caractéristiques spectrales rigoureusement identiques à la *trans*-diphényl-3,4 cyclopentanone de synthèse.

Décompositions photochimiques du diazo-2 diphényl-4,5 cyclohexanedione-1,3.

a) Photolyse dans le tétrachlorure de carbone.

1 g de diazo-2 diphényl-4,5 cyclohexanedione-1,3 dissout dans 800 ml de tétrachlorure de carbone (Anachemia reagent) est soumis à la photolyse. Une lampe Hanovia de 450 w avec filtre de Pyrex est utilisée. Après 1 h et 30 min de photolyse sous courant d'azote, le tétrachlorure de carbone est éliminé par distillation. Une chromatographie sur couches minces montra que le résidue contenait au moins 4 produits, dont l'un en très forte majorité. Une chromatographie sur colonne de silicagel (100 g Baker Analyzed, acétate d'éthyle–cyclohexane 25/75) permet d'isoler un composé pur (0.73 g). Celui-ci s'avéra être la *trans*-diphényl-3,4 cyclopentanone (**5**). Elle présente les caractéristiques suivantes: p.f. 175–177 °C (litt. p.f. 177 °C (6)).

Spectre infrarouge: 1740 et 1600 cm^{-1}.

Résonance magnétique nucléaire: singulet très large centré à 2.80 τ (10H); multiplet entre 6.3 et 6.9 τ (2H); multiplet entre 7.1 et 7.7 τ (4H).

Spectre de masse: pic parent à 236 (valeur calculée 236.3). Ces caractéristiques sont rigoureusement identiques à celles obtenues pour un échantillon authentique synthétisé à partir d'acétone et de benzoïne (voir à la fin de la Partie expérimentale). En particulier le point de fusion mixte ne donna lieu à aucune dépression.

Il ne fut pas possible, par chromatographie sur colonne, de séparer les autres constituants du mélange; ils furent toujours obtenus en petites quantités et impurs.

b) Photolyse dans l'alcool méthylique

2.5 g de diazo-2 diphényl-4,5 cyclohexanedione-1,3 sont dissouts dans 500 ml d'alcool méthylique purifié selon la méthode de Lund et Bjerum (7) et soumis à la photolyse. Celle-ci est effectuée pendant 1 h sous courant d'azote et avec une lampe Hanovia 450 W et sans filtre. Le solvant est ensuite éliminé par distillation. Le résidu, analysé par chromatographie sur couches minces contient au moins 4 produits dont 2 sont nettement majoritaires. Une chromatographie sur colonne de silicagel (éluant cyclohexane–acétate d'éthyle 75/25) permet d'isoler le mélange des deux produits majoritaires. Ceux-ci furent séparés par une recristallisation fractionnée dans le méthanol aqueux. Le premier composé qui précipite au cours de cette recristallisation est le bis (diphényl-4,5 cyclohexèn-1 ol-2 oxo-6 yl) méthane (**6**) obtenu dans un rendement de 72%. Ses caractéristiques sont les suivantes: p.f. 114–117 °C.

Infrarouge: 1600 et 1590 cm^{-1}.

Résonance magnétique nucléaire: pic très large entre −2.5 et 1.5 τ (2H); singulet large centré à 2.9 τ (20H); série de bandes entre 6 et 7.3 τ (10H).

Ces caractéristiques sont rigoureusement identiques à celles obtenues pour un échantillon authentique synthétisé à partir de diphényl-4,5 cyclohexanedione-1,3 et de formaldéhyde selon la méthode utilisée pour obtenir les dérivés dimédoniques des aldéhydes (4) (voir à la fin de la Partie expérimentale).

En augmentant la quantité d'eau dans le solvant de recristallisation, 19% de diphényl-2,3 oxo-5 cyclopentane –carboxylate de méthyle (**7**) sont obtenus. Ce composé présente les caractéristiques suivantes: p.f. 127–129 °C.

Infrarouge: 1750, 1725, et 1600 cm^{-1}.

Résonance magnétique nucléaire: singulet large centré à 2.78 τ (10H); singulet à 6.28 τ (3H); multiplet de 6 à 7.3 τ (5H).

Spectre de masse: pic parent à 294 (valeur calculée 294.6).

Anal. calc. pour $C_{19}H_{18}O_3$ (294.6): C, 77.53; H, 6.16. Trouvé: C, 77.93; H, 6.28.

La structure de ce céto–ester a également été confirmée par une hydrolyse acide: 60 mg de **7**, en suspension dans 5 ml d'acide chlorhydrique (1/1), sont chauffés à reflux pendant 2 h. Après refroidissement et dilution de la solution, celle-ci est extraite à l'éther. La solution éthérée est lavée avec de la soude 10%, puis avec de l'eau

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

et séchée par sulfate de sodium anhydre. Après évaporation du solvant, le solide restant est recristallisé dans du méthanol aqueux. Il fut identifié comme étant la *trans*-diphényl-3,4 cyclopentanone (**5**) par comparaison avec un échantillon authentique. Le point de fusion mixte ne donna aucune dépression. Il en fut de même avec les dérivés dinitro-2,4 phénylhydrazones.

Les deux derniers composés (9%) furent obtenus en mélange et ne furent pas identifiés.

c) Photolyse dans l'alcool éthylique.

2.5 g de diazo-2 diphényl-4,5 cyclohexanedione-1,3 sont dissouts dans 500 ml d'alcool éthylique purifié selon la méthode de Lund et Bjerum et soumis à la photolyse pendant une heure, sous courant d'azote. Une lampe Hanovia de 450 w, sans filtre, fut utilisée pour réaliser cette photolyse. Après avoir distillé le solvant, une huile jaune est obtenue, elle cristallise en partie au bout d'un certain temps. La filtration fournit dans un rendement de 85%, la diphényl-4,5 cyclohexanedione-1,3 (**4**). Celle-ci fut caractérisée par comparaison avec un échantillon authentique.

L'huile jaune (15%) obtenue lors de la filtration contient au moins 3 produits. Ceux-ci ne purent pas être séparés par une chromatographie sur colonne et ne furent pas identifiés. La résonance magnétique nucléaire de ce mélange indique qu'il n'y a pas incorporation d'un groupement éthyle.

Nous avons également mis en évidence la formation d'acétaldéhyde au cours de cette photolyse. De la même façon que dans le cas du diazo de la dimédone, l'azote, à la sortie de l'appareil de photolyse a barbotté dans une solution acide de dinitro-2,4 phénylhydrazine. A la fin de la photolyse, un précipité jaune-orangé s'était formé. Il fut identifié comme étant la dinitro-2,4 phénylhydrazone de l'acétaldéhyde par comparaison avec un échantillon authentique.

Synthèse de la trans-diphényl-3,4 cyclopentanone

La diphényl-3,4 cyclopenten-2 ol-4 one fut d'abord préparée par l'action de l'acétone sur la benzoïne en présence de potasse alcoolique selon la méthode de Japp et Knox (8).

Puis la diphényl-3,4 cyclopenten-2 ol-4 one a été traitée par du phosphore rouge en présence d'acide iodhydrique et d'acide acétique selon le procédé de Geissman et Koelsch (9). La diphényl-3,4 cyclopenten-2 one, ainsi obtenue, fut réduite par le lithium dans l'ammoniac pour fournir la *trans*-diphényl-3,4 cyclopentanone: p.f. 175–177 °C (litt. p.f. 177 °C (6)). Dinitro-2,4 phénylhydrazone: p.f. 172–174 °C (litt. p.f. 173 °C (10)).

Infrarouge: 1740 et 1600 cm^{-1}.

Résonance magnétique nucléaire: singulet très large centré à 2.86 τ (1H); multiplet entre 6.3 et 6.7 τ (2H); multiplet entre 7.1 et 7.7 τ (4H).

Synthèse du bis [diphényl-4,5 cyclohexèn-1 ol-2 oxo-6 yl] méthane

700 mg de diphényl-4,5 cyclohexanedione-1,3 sont dissouts dans le minimum d'alcool éthylique 87%. 5 ml d'une solution aqueuse à 37% de formaldéhyde sont ensuite ajoutés. Le mélange est chauffé à reflux pendant 5 min au bain-marie.

Par refroidissement, un abondant précipité se forme, il est filtré et recristallisé dans le méthanol aqueux: p.f. 116–119 °C.

Spectre infrarouge: 1600 et 1590 cm^{-1}.

Résonance magnétique nucléaire: pic très large entre −2.5 et 0.5 τ (2H); singulet large centré à 2.9 τ (20H) série de bandes entre 6 et 7.5 τ (10H).

Anal. calc. pour $C_{37}H_{32}O_4$ (560.7): C, 82.20; H, 5.97. Trouvé: C, 81.92; H, 5.85.

Remerciements

Nous remercions Monsieur le Professeur H. Favre qui a gracieusement mis son laboratoire à notre disposition et sans qui ce travail n'aurait pu avoir lieu. Nos remerciements vont également à Monsieur R. Mayer pour les spectres de résonance magnétique nucléaire et à Monsieur J.C. Regenass pour les spectres de masse. Nous tenons également à remercier le Conseil National de Recherches du Canada pour l'aide financière accordée et pour une bourse de recherches post-doctorale (Subvention A-14).

Diterpene chemistry III. Chemistry of some epoxides derived from methyl pimarate

J. W. ApSimon and H. Krehm
Department of Chemistry, Carleton University, Ottawa, Canada

Received January 13, 1969

Some chemistry of the α- and β-epoxides derived from a methyl pimarate degradation product (vinyl group transformed into a methoxycarbonyl) is described. The α-epoxide was found to be a very reactive species leading, by an intramolecular process, to a hydroxy-γ-lactone even on standing in hexane solution. A possible explanation for the reactivity is given, based on a conformational argument. The β-epoxide undergoes a cleavage reaction with Lewis acid to give a 'backbone' rearrangement product, although a non-rearranged compound was observed in minor yield.

Canadian Journal of Chemistry, 47, 2859 (1969)

In Part II of this series (1) we described the formation of an epoxide **1** during the Lemieux oxidation (2) of methyl pimarate **2**. In this paper we describe some chemistry of the decarbonylated esterified derivative of **1**, i.e. epoxide **3**, and of its α-epoxy isomer ***4a*** synthesized previously (1) in our structural studies. We also present further evidence for the structural assignments for these compounds.

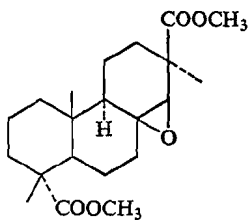
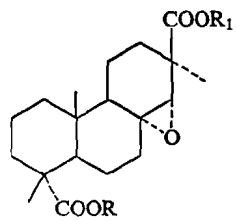
2



3

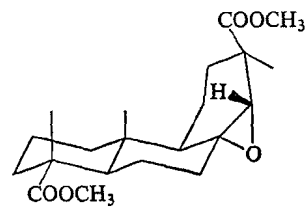


4a R = R_1 = CH_3
b R = CH_3, R_1 = C_2H_5

Some Reactions of α-Epoxide 4a

In our earlier work (1) we proposed the structure of **3** derived from **1** on the basis of a synthesis from a methyl pimarate degradation product and by comparison to the α-epoxide ***4a***. This last compound was obtained by epoxidation of the corresponding olefinic material assuming that the approach of epoxidizing agent was from the least hindered side of the molecule. It is interesting to compare the nuclear magnetic resonance (n.m.r.) spectra of **3** and **4** where the signals for the C-14 protons appear at 2.75 and 3.25 δ respectively. Inspection of models shown here in the perspective drawings **5** and **6** reveal that in the α-oxide **6**≡***4a***, the 14β-proton is always adjacent to the ester group, and would thus be subject to an extra

5



6

deshielding effect by this group, a juxtaposition not possible in **5** (≡**3**).[1]

Epoxide ***4a*** is a very labile compound and rearranges even on warming in hexane to a new material m.p. 215 °C analyzing for $C_{20}H_{30}O_5$.

[1]The conformation **6** representing the α-epoxide is only that which we considered in our early n.m.r. assignments since it seemed the most logical at the time. However, as the chemistry described here has led us to propose that this compound exists as **9** the n.m.r. arguments could be in question. But examination of Dreiding models indicates that, regardless of the conformations taken up by the B and C rings, there still exists a difference in the degree of eclipsing of the C-14 C—H bond and the methoxycarbonyl grouping sufficient to distinguish between the α- and β-epoxides.

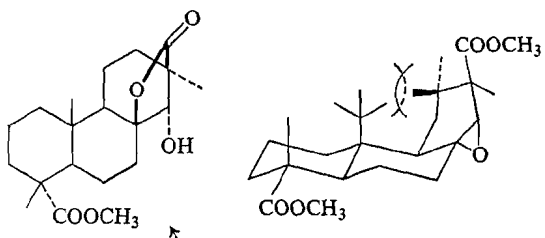
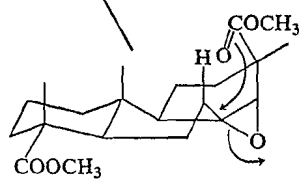
For personal use only.

This compound was best obtained by boiling a hexane solution of **4***a* when direct crystallization from this solvent gave a substantially pure sample. Its infrared (i.r.) spectrum suggested a hydroxy-γ-lactone with $\nu_{max}(CCl_4)$ 3620, 3450 (OH), 1785 (γ-lactone) and 1730 cm^{-1} (ester). The n.m.r. spectrum indicated the loss of one methoxyl group with the appearance of a slightly broadened one proton singlet (half height width = 4 c.p.s.) at 3.5 δ attributable to a single methine proton. This singlet became sharp on addition of D_2O when the loss of a similar singlet at 2.70δ was also noticed. This information suggested structure **7** arising from intramolecular attack on the epoxide by the C-13 ester grouping possibly catalyzed by traces of *m*-chlorobenzoic acid still present in the reaction mixture.[2]



7 **8**

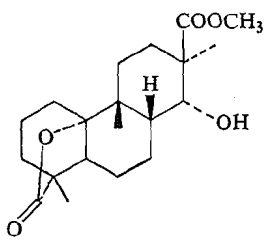


9

An examination of Dreiding models of the α-epoxides in this type of molecule is revealing and possibly gives a clue as to their lability. The B–C *cis* ring fusion, combined with the distorting effect on the epoxide ring, brings the 12β-hydrogen atom very close to the C-10 methyl group leading to a destabilization of conformation **8**. A flip of ring C to relieve this interaction leads to a worse situation between the 13β-methoxycarbonyl group and the C-10 methyl group whilst intermediate conformations of ring C appear equally unfavorable. Thus we suggest that the preferred conformation of epoxide **4** is with ring B in a boat form (3) as shown in **9**. The unfavorable flagpole–flagpole interaction between the C-10 methyl group and H-7 can be relieved somewhat by a flattening of ring B. This, however, is not a perfect situation and the ready rearrangement to **7** is doubtless a reflection of this conformational dilemma, the product being formed as indicated (arrows in **9**).

If **7** does in fact have the structure proposed, then an alternate synthesis of the β-epoxide **3** suggests itself analogous to that already performed (1). Thus the mesylate of **7** was prepared with methane sulfonyl chloride in pyridine which without further purification was dissolved in 50% methanolic potassium hydroxide. After 30 min at room temperature, work-up gave a high yield of **3**. In this manner a ready conversion of the α-epoxide **4***a* to the β-epoxide **3** was accomplished via the route indicated in Scheme 1 and supporting our structural assignments of **3** and **4***a*.

Earlier in our studies on **9** we had some thoughts on structure **10** for this hydroxylactone, although such a structure would have to arise in a stepwise manner by deprotonation–protonation steps (4) to give an 8β—H, and thus account for the low coupling constant with the 14β-proton (5) (n.m.r. shows a singlet). This possibility



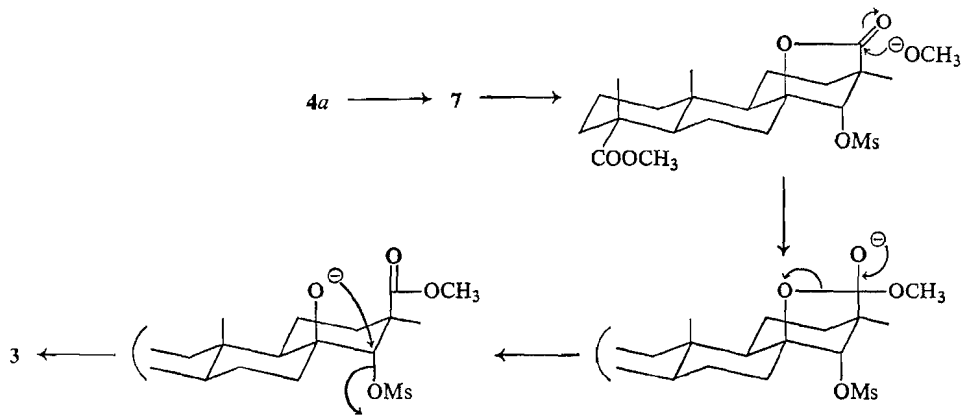
10

was readily eliminated as follows. The ethyl methyl diester epoxide **4***b* was made by esterification of the parent olefinic acid with diazoethane (6). On epoxidation with *m*-chloroperoxybenzoic acid and allowing the product to stand in hexane for several days, the same hydroxylactone **7** was obtained indicating that it is the C-13 ester grouping that is involved in the lactonization, and not that at C-4.

Lewis Acid Cleavage of β-*Epoxide* **3**

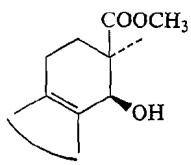
We had hoped to use β-epoxide **3** as a source of

[2]In many epoxidations with *m*-chloroperoxybenzoic acid we have often experienced difficulty in removing all *m*-chlorobenzoic acid even with many bicarbonate washings.

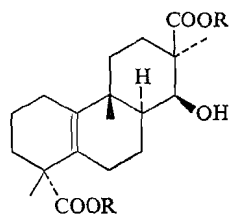


SCHEME 1

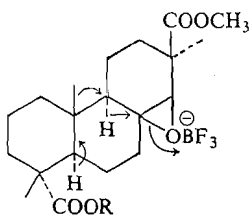
a 14-keto precursor to lead to novel steroids and thus we examined its reaction with Lewis acids (7). Reaction of **3** with either stannic chloride or BF_3–etherate in benzene led to a high yield of an alcohol m.p. 128 °C analyzing for $C_{21}H_{32}O_5$. The i.r. and n.m.r. spectra indicated the presence of both ester groups and probably a secondary alcohol. This last observation was made difficult since the methine proton signal was buried under the methoxyl signals; however, integration of this region indicated 7 protons. A possible formulation for this compound is **11** (partial structure) arising from cleavage of the epoxide followed by deprotonation of the C-8 carbonium ion leading to the tetrasubstituted double bond (no ethylenic signals in n.m.r.). This, however, proved to be



11



12*a* R = CH_3
b R = H



13

incorrect since oxidation of **11** with Jones' reagent (8) gave a saturated ketone and it was inert to manganese dioxide (9), either of which would have been expected to lead to an α,β-unsaturated ketone.

Therefore, it appears that this cleavage product has the 'backbone' rearranged structure **12***a* (4, 10) arising from the concerted anti-peri-planar movement of the migrating groups on cleavage of the β-oxide as shown in **13**. Further support for this structure was obtained by hydrolysis of **12***a* with dilute base to give the diacid **12***b*. The n.m.r. spectrum of this acid revealed the 14α methine proton signal at 4.18 δ as a broadened singlet of half height width 4 c.p.s. This small coupling is indicative of a dihedral angle of about 60° for the vicinal 8 and 14 protons (5) alternate formulations requiring a dihedral angle of 180° or no adjacent protons at all (cf. **11**). Treatment of the diacid **12***b* with concentrated sulfuric acid at 0° afforded a mixture of γ and δ lactones as indicated by i.r. spectroscopy. These lactones could not be successfully separated but their formation is indicative of the β,γ-unsaturated nature of one of the carboxyl groups of **12***b* (4). Having shown that the double bond is tetrasubstituted and is not at the BC ring junction (Δ 8, 9), there only remains the AB junction of a rearranged structure such as proposed[3] in **12***b*.

At one stage in our studies we required a further sample of diester epoxide **3** and therefore

[3]A ring expansion–contraction opening of the oxide would give either a tri-substituted double bond or a ketone neither of which fit the above data.

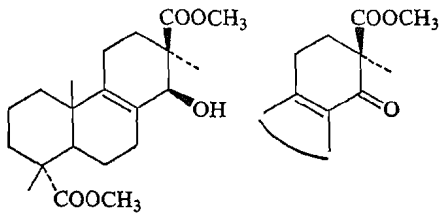
chromatographed some residues from earlier crystallizations which had remained untouched for about 1 year. After elution of **3** on a silica gel column, 50 mg (3% of residues) of another compound were obtained, m.p. 162–164 °C, which analyzed for $C_{21}H_{32}O_5$, whose i.r. spectrum indicated hydroxyl (3500 cm^{-1}) and ester (1725 cm^{-1}) absorption and whose n.m.r. spectrum exhibited an extra proton buried under the methoxyl region (integration). Oxidation with Jones' reagent (7) gave an α,β-unsaturated ketone (λ_{max} 248 nm, ε 9000; ν_{max} 1660, 1620 cm^{-1}). This information leads us to structures **14** and **15** for the alcohol and its oxidation product. Thus **14** represents an intermediate stage in the re-



14 **15**

arrangement pathway of **3** to **12***a*. It is interesting to speculate whether, in fact, **12***a* and **14** represent different reaction pathways (concerted vs stepwise) or whether **14** is merely an intermediate in the rearrangement pathway (11). Lack of starting material terminated our studies at this stage.

Experimental

Infrared spectra were determined on a Perkin–Elmer Infracord 237B spectrophotometer. Nuclear magnetic resonance spectra were determined at 60 MHz on a Jeolco C-60 or a Varian A-60 spectrometer; chemical shifts are given in δ units relative to tetramethylsilane as an internal standard (s is used to signify singlets). Only those signals deemed to be of interest in assigning structures have been quoted. Sample concentrations were approximately 10% (w/v) in deuteriochloroform as solvent. All optical rotations were of 1% solutions in absolute ethanol at room temperatures unless otherwise stated. Ultraviolet spectra were determined in absolute ethanol on a Perkin–Elmer 202 spectrophotometer. Melting points are corrected and were determined on a Köfler hot stage, except for mixed melting points which were done in capillary tubes. Thin-layer chromatography (t.l.c.) was carried out on either silica gel G plates or Eastman Kodak chromatogram sheets. Mass spectra were obtained on the Perkin–Elmer–Hitachi instrument of McMaster University through the kindness of Professors D. B. McLean and R. A. Bell.

Hydroxylactone 7

α-Epoxide **4***a* was very labile, changing even on recrystallization from hexane to another compound m.p. 215 °C; $[\alpha]_D = +7°$ purified by crystallization from hexane and identified as hydroxy-γ-lactone **7**; $\nu_{max}(CCl_4)$, 3620, 3450 (hydroxyl), 1785 (lactone), and 1730 cm^{-1} (ester); n.m.r. signals at 3.70 (3H, s, methyl ester), 3.50 (1H, s, C-14 methine proton), 2.70 (1H, broad s, hydroxyl, D_2O exchange), and 1.30, 1.20, 0.95 δ (3 × 3H, s, angular methyl groups).

Anal. Calcd. for $C_{20}H_{30}O_5$: C, 68.55; H, 8.63. Found: C, 68.46; H, 8.65.

Synthesis of β-Epoxide 3 from Hydroxylactone 7

To a solution of 55 mg (0.151 mmole) of the hydroxy-γ-lactone **7** in 1 ml pyridine was added 0.02 ml of methane sulfonyl chloride; crystals (pyridine·HCl) appeared after several minutes. The mixture was allowed to stand overnight and poured into ice water. Ether extraction followed by drying over magnesium sulfate and evaporation gave 72 mg of an oil, exhibiting little hydroxyl in the i.r. but did show a lactone band (1785 cm^{-1}) and sulfonate bands at 1450 cm^{-1} (film). This compound was dissolved in 2 ml dry methanol and treated with 2 ml of 50% methanolic potassium hydroxide. After 30 min water (5 ml) was added and when the solution was left at room temperature colorless needles separated m.p. 135–137 °C. Recrystallization from methanol gave the epoxy diester **3** identical (melting point, mixture melting point, i.r., and n.m.r. spectra) with that obtained on methylation of the oxidation product of methyl pimarate (1).

Hydroxy-γ-lactone 7 via Ethyl, Methyl Diester Epoxide 4b

The Lemieux oxidation product of methyl pimarate **2**, (carboxyl group for C-13 vinyl) (1) (50 mg) in dry ether was treated with an ethereal solution of diazoethane (5) until a yellow color persisted. After evaporation of the ether, **4***b* was obtained as an oil (52 mg) n.m.r. 5.35 (1H, s, C-14 olefinic proton), 4.12 δ (2H, quartet of ethyl group) and no acid proton signal. This was directly epoxidized with *m*-chloroperoxybenzoic acid in ether (0° for 3 days). The reaction mixture was poured into sodium carbonate solution and extracted with ether, dried, and evaporated to yield an oil (no olefinic protons in n.m.r., signal at 3.2 δ for 14β-proton). This oil was allowed to stand in hexane for several days when, after evaporation of one half of the hexane, crystals of the hydroxy-γ-lactone **7** (20 mg) appeared, identical in all respects to those obtained from **4***a*.

Rearrangement of β-Epoxide 3 to 12a

(a) Boron Trifluoride Etherate Method

To 110 mg (0.32 mmole) of epoxide **3** dissolved in 10 ml dry benzene was added 0.10 ml of freshly distilled boron trifluoride etherate. After 24 h the solution was diluted with 100 ml water and ether extracted. Washing and drying the ethereal extracts in the usual manner yielded 119 mg of a greasy crystalline solid m.p. 115 °C. Repeated crystallization from hexane raised this to 127–128 °C (80 mg) $[\alpha]_D = -30°$; $\nu_{max}(CCl_4)$ 3500 (hydroxyl), 1725 cm^{-1} (diester); n.m.r. signals at 3.74, 3.68 (2 × 3H, s, two methyl esters), 2.65 (1H, s, C-14 hydroxyl, disappearing on D_2O exchange), and 1.25, 1.22, and 1.09 δ (3 × 3H, s, angular methyl groups); ultraviolet (u.v.), λ_{max}208 nm, ε 3480.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Anal. Calcd. for $C_{21}H_{32}O_5$: C, 69.20; H, 8.85. Found (mol. weight: 364 (mass spectral)): C, 69.17; H, 8.58.

(b) Stannic Chloride Method

The above experiment was repeated using 0.2 ml $SnCl_4$ in place of the boron trifluoride etherate. The product obtained was identical with the former (m.p., mixed m.p., t.l.c., and superimposable spectra).

Treatment of an ethanolic solution of alcohol **12***a* with 10% aqueous potassium hydroxide at reflux afforded the diacid **12***b* m.p. 205 °C, ν_{max}(Nujol) 3500 cm^{-1} (hydroxyl), 3300–3050, 1700 cm^{-1} (diacid); n.m.r. signals at 7.0 (3H, broad s, two acids, hydroxyl), 4.18, $J_{1/2}$ band width = 4 c.p.s. (1H, s, methine proton), 1.3, 1.3, and 1.1 δ (3 × 3H, s, angular methyls). The *bis* cyclohexylamine salt of this acid had a melting point of 174–176 °C.

Treatment of 50 mg of this acid in 1 ml chloroform with 1 ml concentrated sulfuric acid at 0 °C gave a mixture of δ- and γ-lactones $\nu_{max}(CCl_4)$ 1780 (γ-lactone), 1750 (δ-lactone) 1700 cm^{-1} (C-13 carboxyl).

Oxidation of **12***a*

(a) With Jones' Reagent (8)

Two drops of Jones' reagent (permanent orange tinge persisted) were added to 40 mg of alcohol **12***a* dissolved in 1 ml acetone. Dilution with water followed by ether extraction gave 30 mg of an oil which appeared to be two compounds by t.l.c. analysis (benzene–trace ether). An i.r. spectrum of this oil (film) showed the absence of hydroxyl absorption, with peaks at 1740, 1730 (diester), and 1720 cm^{-1} (6-membered ketone), *but no bands characteristic of an α,β-unsaturated ketone.* Similarly the u.v. spectrum revealed only the ester absorption λ_{max}218 nm; ε 2900. The oil could not be induced to crystallize from either hexane or aqueous ethanol solution, and was therefore treated with a base in an effort to equilibrate what was presumably a mixture of two ketones. Examination by t.l.c., however, showed the original two spots to be unchanged. The oil was not characterized further.

(b) With Manganese Dioxide (9).

To 60 mg of alcohol **12***a* dissolved in 3 ml chloroform was added an excess of freshly prepared MnO_2 and stirred for 24 h. Thin-layer chromatography analysis (benzene–2% ether) showed only unchanged starting material.

Allylic Alcohol **14** *and α,β-Unsaturated Ketone* **15**

Fifty milligrams (3%) of needles were obtained by column chromatography on silica gel of 1.6 g of diester epoxide, **3**, residues. This material was eluted after the epoxide fraction by 10% ethyl acetate in benzene. Several recrystallizations from hexane raised the m.p. to 162–164 °C, $[\alpha]_D = 107°$; ν_{max} (Nujol) 3500 cm^{-1} (hydroxyl); 1725 cm^{-1} (diester); n.m.r. showed no protons in the olefinic region, and peaks at 3.7, 3.6 (2 × 3H singlets methoxyls); 2.4, 1H broad singlet (angular methyl groups).

Anal. Calcd. for $C_{21}H_{32}O_5$: C, 69.20; H, 8.85. Found (mol. weight 364 (mass spectral)): C, 69.61; H, 8.78.

The above alcohol (10 mg) **16** dissolved in 1 ml acetone was treated with two drops Jones' reagent (8). After 10 min the mixture was diluted with 2 ml water and chilled overnight. Filtration afforded 5 mg of short needles, m.p. 106–108 °C; ν_{max} (KBr), 1740, 1725 cm^{-1} (diester) and 1660 cm^{-1} (α,β-unsaturated ketone); u.v., λ_{max} 248 nm; ε 9900, (endocyclic α,β-unsaturated ketone). A mass spectrum of this compound showed a parent peak *m/e* 362. Insufficient material was available for elemental analysis.

Diterpene chemistry. IV. The oxymercuration–demercuration of methyl pimarate and methyl sandaracopimarate[1]

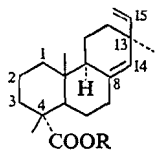
J. W. ApSimon and H. Krehm
Department of Chemistry, Carleton University, Ottawa, Canada

Received January 13, 1969

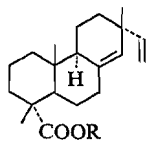
The oxymercuration–demercuration procedure was explored for methyl pimarate and methyl sandaracopimarate. In the first case a dimercurial-monoether was obtained yielding a cyclic ether on demercuration. In the second, a monomercurial was obtained arising from attack on the vinyl group only, and demercuration gave a mixture of alcohols which were oxidized to a methyl ketone, which on hypoiodite degradation yielded a known degradation product of methyl sandaracopimarate. The difference in behavior between the two series is attributed to the proximity of the double bonds in methyl pimarate.

Canadian Journal of Chemistry, 47, 2865 (1969)

As part of our studies on pimaric **1***a* and sandaracopimaric acid **2***a* (1, 2) we were interested in two aspects of their chemistry. Firstly we wished to epoxidize the vinyl groups preferentially in order to study their cleavage in the vicinity of the nuclear double bonds, and secondly we were intrigued by the interaction of the double



1*a* R=H
b R=CH_3



2*a* R=H
b R=CH_3

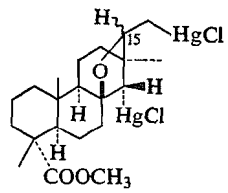
bonds in pimaric acid as compared with sandaracopimaric acid, as evidenced by unusual oxidation products (1).

Normal epoxidation of the parent acids or their methyl esters led exclusively to epoxidation of the nuclear double bond (3, 4), and attempts at bromohydrin formation (5) were inconclusive. Thus we felt that perhaps the oxymercuration procedure (6) would lead to preferential vinyl attack, and this process might also provide us some further information on the spatial interaction of the two double bonds in **1** (7).

Oxymercuration–demercuration of Methyl Pimarate 1b

Reaction of methyl pimarate **1***b* with one equivalent of mercuric nitrate or mercuric acetate in aqueous *t*-butyl alcohol resulted in about 50% conversion to an oxymercurial isolated at its chloroderivative (see Experimental). When two equivalents of mercuric nitrate were used, about 90% conversion was observed.

The crystalline chloromercurial analyzed for $C_{21}H_{32}O_3Hg_2Cl_2$ m.p. 176°, its infrared (i.r.) spectrum indicating no hydroxyl absorption but ester absorption was evident at 1726 cm $^{-1}$. The nuclear magnetic resonance (n.m.r.) spectrum showed no signals for olefinic protons. Assuming Markofinikov-type addition of the mercury salts (6) then these facts are best accommodated by structure **3**. The n.m.r. spectrum of **3** supported the structural assignment as follows.



3

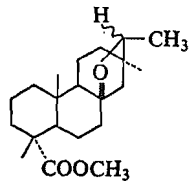
Centered at 3.9 δ was a doublet of doublets characteristic of the X branch of an ABX system with J_{AX} 6 Hz and J_{BX} 11 Hz which we assign to the H-15 proton of **3**. At 3.0 δ there was a weakly coupled singlet (*J* 0.2 Hz) which we assign to H-14β appearing at a lower field than the C-16 protons since it is both tertiary and will be affected somewhat by the proximate ether bridge. The coupling observed is probably due to W-plan coupling (8) with the 12β proton.

The stereochemistry at C-14 is assumed since the intramolecular attack on a mercurinium ion (6, 9) at C-8 and C-14 must come from the opposite face than the mercury (10), and the stereochemistry of pimaric acid fixes the direction of attack from the β face by the two carbon

[1]For Part III see ref. 2.

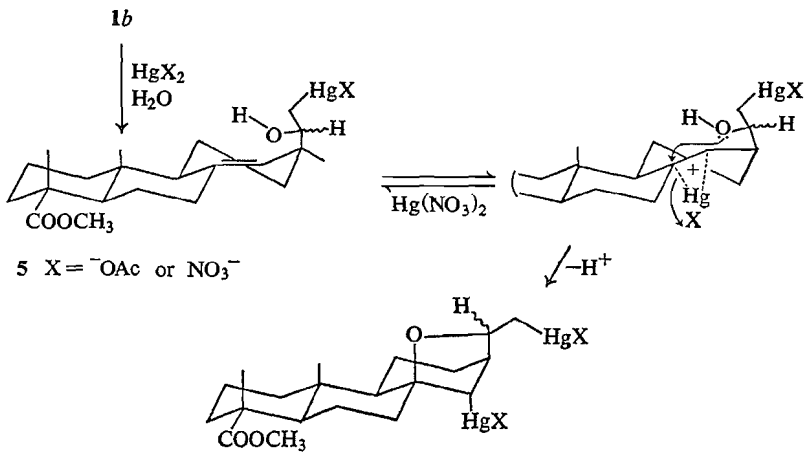
chain of the original vinyl group, thus necessitating an α oriented mercury at C-14 in the final product. There is one position in the product, C-15, where isomers could arise, yet all our evidence points to the formation on only one stereoisomer as inferred from sharp m.p., thin-layer chromatography (t.l.c.) in several solvent systems, and sharp n.m.r. signals.

The stereospecificity of the above process is further supported by the obtention of only one product on reduction of **3** with basic sodium borohydride in tetrahydrofurane or dioxane (7, 11). This product, m.p. 132 °C, analyzed for $C_{21}H_{34}O_3$ and its n.m.r. spectrum exhibited a new methyl group signal as a doublet, 1.2 δ, $J = 8$ Hz, and a one hydrogen quartet centered at 3.76 δ, $J = 8$ Hz. No other low field signals apart from the methoxyl proton signals were evident. On the basis of the structure assigned to **3** and the above data, this reduction product is assigned structure **4**. The stereochemistry at C-15 must remain unassigned at present since, to us at least, conformational arguments appear too tenuous. The mode for formation of **3** is



4

probably as shown in Scheme 1, *via* a very reactive monohydroxymercurial **5**, the intramolecular step being faster than the initial step, otherwise with one equivalent of mercuric salt, the mono-organomercurial **5** might have been



5 X = $^-$OAc or NO_3^-

3 Isolated as X = Cl^-

SCHEME

expected. In none of our experiments were we ever able to detect such an intermediate stage.[2]

Reduction of **3** with borohydride in ethanol/tetrahydrofurane (7, 12) yielded methyl pimarate indicating that no skeletal rearrangements had occurred in the formation of the organomercurial.

[2]Attempts at quenching the reaction after short periods in order to isolate **5** were unsuccessful. This is in agreement with earlier work (13) which indicates a rapid reaction, essentially complete in 30 s.

Oxymercuration–demercuration of Methyl Sandaracopimarate 2b

Oxymercuration of methyl sandaracopimarate, **2***b*, gave a crystalline product, m.p. 164°, analyzing for $C_{21}H_{33}O_3HgCl$, showing hydroxyl absorption at 3420 cm^{-1} in its i.r. spectrum. The n.m.r. spectrum indicated that the vinyl group had reacted, but not the nuclear double bond. The signal for the C-14 olefinic proton was at first puzzling since it appeared as a doublet centered at 5.42 δ; however, it became evident

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

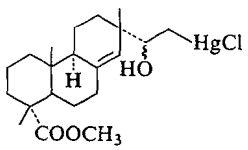
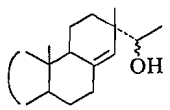
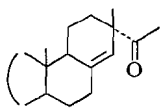
from the demercuration step that a mixture of diastereoisomers at C-15 was present in the product for which we assign structure **6**. This inhomogeneity escaped us at first since the rest of the n.m.r. spectrum showed very sharp signals (e.g. for C-13β methyl group) and the product had a sharp m.p. and showed only one spot on t.l.c. in a number of solvent systems. On basic borohydride reduction (7, 11), a mixture of three compounds was obtained. One was methyl sandaracopimarate, whilst the other two were more polar by t.l.c. and appeared as overlapping spots in a number of solvent systems. It would appear that these reduction products were the epimeric alcohols **7**, although all our attempts at separation failed. Oxidation of this mixture with Jones' reagent (14) gave one compound **8** with a new strong carbonyl absorption of 1710 cm^{-1} in its i.r. spectrum. This ketone was subjected to the iodoform reaction (15), which was



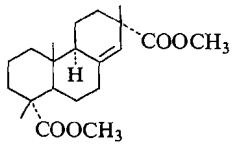
6



7



8



9

positive, and acidification of the reaction mixture followed by extraction and chromatography after methylation with diazomethane gave the dimethyl ester **9**, identical in all respects to an authentic sample previously obtained from our oxidation studies on methyl sandaracopimarate (1). Reduction of the mercurial, **6**, with borohydride in ethanol gave methyl sandaracopimarate. The ease with which methyl sandaracopimarate forms a mono-mercurial[3] and that with which methyl pimarate forms a dimercurial *via* intramolecular attack on the nuclear double bond, again emphasizes the interesting chemistry arising from closely spaced non-conjugated double bonds in a molecule. The results described here reinforce the observation (16) that the oxymercuration–demercuration procedure could be a useful synthetic route to cyclic ethers (17).

[3]Reaction with excess $Hg(OAc)_2$ or $Hg(NO_3)_2$ did not give any evidence of a dimercurial.

Experimental

Infrared spectra were determined on a Perkin-Elmer infracord 237-B spectrophotometer. Nuclear magnetic resonance spectra were determined at 60 MHz on a JEOLCO C-60 or Varian A-60 spectrometer; chemical shifts are given in δ units relative to tetramethylsilane as an internal standard (s is used to signify singlets). Only those signals deemed to be of interest in assigning structures have been quoted. Sample concentrations were approximately 10% in deuteriochloroform as solvent. All optical rotations were of 1% solutions in absolute ethanol at room temperature, unless otherwise stated. Ultraviolet spectra were determined in absolute ethanol on a Perkin-Elmer 202 spectrophotometer. Melting points are corrected and were determined on a Köfler hot stage except for mixed melting points which were done in capillary tubes. Thin-layer chromatography was carried out on either silica gel G plates or Eastman Kodak Chromatogram sheets. Mass spectra were obtained on the Perkin-Elmer-Hitachi instrument of McMaster University through the courtesy of Professors D. B. McLean and R. A. Bell.

Oxymercuration of Methyl Pimarate

(*a*) To 110 mg (0.348 mmole) methyl pimarate in 5 ml *tert*-butyl alcohol, was added a solution of 100 mg (0.312 mmole) mercuric acetate in 6 ml of water. The solution was left for 30 min and at the end of this period gave a negative spot test for mercuric ion with base. The addition of 25 ml of water containing a slight excess of sodium chloride caused the formation of a white precipitate (240 mg, 46%), m.p. 89–100 °C. Several recrystallizations from ethyl acetate – hexane afforded the analytical sample m.p. 176–177 °C; i.r.: $\nu_{max}(CHCl_3)$ 1725 (ester), 1250, 915, and 835 cm^{-1} (ether bands), and no hydroxyl absorption; n.m.r. bands at 3.9 (1H, doublet of doublets, C-15 methine), J = 6 Hz and 0.98 δ (3 × 3H, s, angular methyl groups).

Anal. Calcd. for $C_{21}H_{32}O_3Hg_2Cl_2$: C, 31.30; H, 4.02; Cl, 8.83. Found: C, 31.13; H, 4.02; Cl, 8.97.

The above dimercurial also formed an alcoholate on crystallization from ethyl alcohol, m.p. 100–150 °C, the i.r. spectrum (Nujol) showing strong hydroxyl absorption at 3625 and 3400 cm^{-1}. A satisfactory analysis for this compound was not obtained.

Work-up of the mother liquors by hexane extraction yielded about 40% unchanged starting material (i.r., n.m.r., and t.l.c.).

(b) Two Equivalents of Mercuric Salt

When the above oxymercuration was repeated with two equivalents of mercuric nitrate or acetate, the yield of crude chloromercurial was 90%.

Reduction of Chloromercurial Obtained from Methyl Pimarate

(a) With Sodium Borohydride

To 107 mg (0.133 mmole) of the above mercurial dissolved in absolute ethyl alcohol (5 ml) and tetrahydrofuran (5 ml) at 0 °C was added portionwise sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

borohydride (26 mg) when a vigorous reaction occurred depositing metallic mercury. The solution was left overnight and then filtered and acidified. Extraction with methylene chloride and subsequent work-up yielded 45 mg (90%) of methyl pimarate (i.r., n.m.r., and comparative t.l.c.).

(b) In Basic Dioxane

To a solution of 0.590 g (0.734 mmole) of mercurial dissolved in dioxane (40 ml) and 10% KOH solution (10 ml) was added portionwise solid sodium borohydride (100 mg) at room temperature. After 12 h the mercury was filtered off and the filtrate acidified and extracted with ether. Work-up of the ethereal extracts afforded 232 mg (95%) of a greasy solid. Crystallization from methanol gave colorless needles, m.p. 130–132 °C of ether **4**, $[\alpha]_D$ −18.6°; i.r.: ν_{max}(Nujol) 1723 (ester) 1250, 915, and 835 cm^{-1} (ether) and no hydroxyl absorption; n.m.r.: 3.76, 1H A_3X quartet $J_{AX} = 6$ Hz (C-15 methine) 3.7, s, (methoxyl) and a new methyl doublet centered at 2.2, $J = 6$ Hz in addition to the angular methyls at 1.2, 1.04, and 0.87 δ.

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.41; H, 10.25. Found: C, 75.34; H, 10.00.

Oxymercuration of Methyl Sandaracopimarate 2b

To a solution of 200 mg (0.634 mmole) of methyl sandaracopimarate in 6 ml *tert*-butyl alcohol (peroxide-free) was added a solution of 218 mg (0.637 mmole) mercuric nitrate monohydrate and 1 drop of concentrated nitric acid in 12 ml water. The solution cleared immediately on swirling and after standing for 30 min, the reaction mixture was poured into 75 ml water containing a small excess of sodium chloride. The white precipitate so formed was filtered (391 mg), m.p. 151–159 °C. Recrystallization from methanol raised this to 164–165 °C; i.r.: ν_{max}(Nujol) 3420 broad, (hydroxyl), 1725 cm^{-1} (ester); n.m.r.: 5.5 (1H, s), 5.35 (1H, s, C-14 olefinic protons), 4.0 (1H broadened triplet, C-15 methine), 3.65 (3H, s, methoxyl), 1.2, 1.05, and 0.81 δ (3 × 3H, s, angular methyl groups), but no vinyl protons.

Anal. Calcd. for $C_{21}H_{33}O_3HgCl$: C, 44.29; H, 5.80. Found: C, 44.39; H, 5.88.

Reduction of Chloromercurial 6 Obtained from Methyl Sandaracopimarate

(a) With Sodium Borohydride

To a solution of 159 mg (0.266 mmole) of the above chloromercurial in 10 ml tetrahydrofuran at 0 °C was added portionwise, sodium borohydride (20 mg). The reaction mixture turned gray immediately. After 1 h, more reducing agent was added but no further reaction was observed. The mercury was filtered off and the clear filtrate acidified (2 *N* HCl). Ether extraction and subsequent work-up afforded methyl sandaracopimarate (76 mg, 86%) (i.r., n.m.r., and comparative t.l.c.).

(b) With Sodium Borohydride in Basic Dioxane

To a solution of 650 mg (1.14 mmole) of chloromercurial 6 in 40 ml dioxane and 10 ml 10% sodium hydroxide, were added portionwise ca. 200 mg solid sodium borohydride. The reaction was extremely slow (2–4 days) compared to the non-basic reduction. After filtration of the metallic mercury the filtrate was acidified and ether extracted. Work-up gave 300 mg (79%) of a greasy solid showing three compounds by t.l.c. analysis, two polar spots very close together (diastereomeric alcohols), and some methyl sandaracopimarate, i.r. ($CHCl_3$) 3400 cm^{-1} broad (hydroxyl), and 1725 cm^{-1} (ester). Chromatography on silica gel separated the methyl sandaracopimarate but no separation of the alcohols was obtained. This material crystallized slowly from aqueous methanol to give a low melting solid which was oxidized with Jones' reagent (14). The product (250 mg) **8** after ether extraction showed no hydroxyl in the i.r., (film from ether solution), a new carbonyl peak at 1710 cm^{-1}, and ester absorption at 1725 cm^{-1}. An analytical sample was obtained, by sublimation (90°/10^{-3} mm), m.p. 73–75°, $[\alpha]_D$ −18.4°.

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 75.77; H, 9.62.

An iodoform reaction on 144 mg (15) was positive. This confirmed the presence of an acyl group. Extraction of the acidified reaction mixture after this test gave 80 mg (53%) of an acid: i.r.: ν_{max} (Nujol) 3400 broad, 1700 cm^{-1} (acid), and 1725 cm^{-1} (ester). Treatment of this oil with diazomethane gave diester 9, m.p. 71 °C, a mixture m.p. with the authentic sample (1) was not depressed, i.r., t.l.c. were identical.

Synthesis of 8-deoxy-D-*erythro*-D-*galacto*-octose. Determination of the configuration of two octenoses

D. G. LANCE, W. A. SZAREK, J. K. N. JONES, AND G. B. HOWARTH
Department of Chemistry, Queen's University, Kingston, Ontario

Received March 3, 1969

The preparation of 8-deoxy-1,2:3,4-di-*O*-isopropylidene-D-*erythro*-α-D-*galacto*-octopyranose (**2**) from two octenoses is described. The structure of **2** was established by degradation of its di-*O*-methyl derivative to 1-deoxy-2,3-di-*O*-methyl-L-erythritol. This work permits the assignment of configuration to the octenoses. Acid-catalyzed hydrolysis of **2** gave a new higher-carbon sugar, 8-deoxy-D-*erythro*-D-*galacto*-octose (**4**). The synthesis of 1-deoxy-2,3-di-*O*-methyl-L-threitol and 1-deoxy-2,3-di-*O*-methyl-D-erythritol is reported.

Canadian Journal of Chemistry, 47, 2871 (1969)

Introduction

In a recent publication (1) the preparation of 6,7,8-trideoxy-1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-oct-6-enose (**1**) by the reaction of ethylidenetriphenylphosphorane with 1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose was reported. At that time the configuration of the double bond had not been established. Compound **1** is of particular interest to us since it may be suitable for conversion, by way of a pseudohalogen addition reaction (2), to the carbohydrate moiety in the antibiotic lincomycin (3, 4). In the present paper we describe some experiments which permit the assignment of the *cis* stereochemistry to compound **1**. This work has led also to the synthesis of a new higher-carbon sugar, 8-deoxy-D-*erythro*-D-*galacto*-octose (**4**).

During the course of our synthetic studies related to lincomycin (4), vinylmagnesium bromide was added to 1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose to give a mixture of allylic alcohols. The preponderant epimer was obtained pure in crystalline form. It has now been established that this compound is 7,8-dideoxy-1,2:3,4-di-*O*-isopropylidene-D-*glycero*-α-D-*galacto*-oct-7-enopyranose (**3**).

Results and Discussion

Treatment of the crude Wittig product (1), from the reaction of ethylidenetriphenylphosphorane with 1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose, with aqueous potassium permanganate gave predominantly a crystalline *vic*-diol. The structure of 8-deoxy-1,2:3,4-di-*O*-isopropylidene-D-*erythro*-α-D-*galacto*-octopyranose (**2**) has been assigned to this dihydroxylation product as follows.

Methylation of the crystalline diol gave the di-*O*-methyl derivative, which was obtained as a chromatographically homogeneous and analytically pure syrup. This compound was degraded by removal of the isopropylidene residues with acid, followed by oxidation of the product with sodium metaperiodate. Reduction of the resultant aldehyde with sodium borohydride gave a 1-deoxy-2,3-di-*O*-methyltetritol. The nuclear magnetic resonance (n.m.r.) spectrum of this tetritol was identical with that of authentic 1-deoxy-2,3-di-*O*-methyl-D-erythritol (Fig. 1), and the two compounds were indistinguishable by gas–liquid chromatography (g.l.c.). A comparison of specific rotations (Table I) shows that the two compounds are enantiomers. Thus, the isolation of 1-deoxy-2,3-di-*O*-methyl-L-erythritol establishes the D-*erythro* configuration at C-7 and C-6 in the crystalline diol. Moreover, this work permits the assignment of the *cis* stereochemistry to the predominant octenose (**1**) formed in the Wittig reaction (1), since it is well-known that in the dihydroxylation of alkenes by

permanganate, the mode of addition of the hydroxyl groups is *cis*.

The synthesis of 8-deoxy-1,2:3,4-di-*O*-isopropylidene-D-*erythro*-α-D-*galacto*-octopyranose (**2**) has been achieved also from the preponderant allylic alcohol obtained by the addition of vinylmagnesium bromide to 1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose (4). Compound **2** was obtained by the Markovnikov hydration of the carbon–carbon double bond using the oxymercuration–demercuration procedure of Brown and Geoghegan (5). This result establishes the D-*glycero* configuration at C-6 in the octenose; the compound is, therefore, 7,8-dideoxy-1,2:3,4-di-*O*-isopropylidene-D-*glycero*-α-D-*galacto*-oct-7-enopyranose (**3**).

Acid-catalyzed hydrolysis of compound **2** gave, in crystalline form, a new higher-carbon sugar, 8-deoxy-D-*erythro*-D-*galacto*-octose (**4**), which to our knowledge is the first example of an 8-deoxyoctose.

For the degradative work described above, authentic samples of 1-deoxy-2,3-di-*O*-methylerythritol and -threitol were required. These were readily prepared as follows. 1-Deoxy-2,3-di-*O*-methyl-L-threitol was obtained from 2,3-di-*O*-methyl-D-xylose diethyl dithioacetal (6) by its desulfurization with Raney nickel followed by oxidation of the product with sodium metaperiodate and reduction of the resultant aldehyde with sodium borohydride. A homogeneous liquid was isolated by preparative g.l.c. 1-Deoxy-2,3-di-*O*-methyl-D-erythritol was prepared similarly from 1-deoxy-2,3-di-*O*-methyl-D-ribitol (7). The n.m.r. spectra of the two tetritol derivatives are shown in Fig. 1, and some physical data are given in Table I.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer Model 141 automatic polarimeter at 29°. Thin-layer chromatography (t.l.c.) was performed with Silica Gel G as the adsorbent. The term "petroleum ether" refers to the fraction of b.p. 60–80°. Paper chromatography was carried out by the descending method at room temperature on Whatman No. 1 filter paper in butan-1-ol:ethanol:water, 3:1:1 (v/v). Sugars were detected on paper chromatograms by the *p*-anisidine hydrochloride spray reagent (8); rates of movement of the sugars are given relative to that of glucose (R_{glu}). Gas–liquid chromatography (F and M chromatograph, Model 402) was carried out at a carrier gas (helium) flow rate of ca. 75 ml/min on a column of 20% octylphenoxypoly(oxyethylene)ethanol supported on 100–120 mesh acid washed Chromosorb W at 175°. The chromatograph was adapted for preparative separations as described previously (9), using a column of 1% (w/w) Apiezon L supported on 50–60 mesh DMCS treated Chromosorb W at 120°. Nuclear magnetic resonance spectra were measured on a Varian T-60 spectrometer in chloroform-*d* and tetramethylsilane as internal standard. Infrared (i.r.) spectra were measured on a Beckman-IR5A spectrophotometer.

*8-Deoxy-1,2:3,4-di-O-isopropylidene-*D*-erythro-α-*D*-galacto-octopyranose (2)*

*(a) From 6,7,8-Trideoxy-1,2:3,4-di-O-isopropylidene-α-*D*-galacto-oct-6-enose (1)*

To a solution in ethanol (20 ml) of the crude Wittig product (2.0 g) (1), from the reaction of ethylidenetriphenylphosphorane with 1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose, was added a solution of potassium permanganate (1.5 g) in water (45 ml) dropwise, with stirring, over a period of 30 min. The mixture was then filtered through Celite; the residue was washed with hot ethanol. The colorless filtrate and washings were concentrated to dryness, and the residue was extracted with several portions of hot ethyl acetate. The dried (magnesium sulfate) extracts were concentrated under reduced pressure to a residue, which was crystallized from chloroform – petroleum ether; yield 1.40 g. Compound **2** was obtained pure by sublimation at 130°/0.1 Torr; m.p. 151–152°, $[\alpha]_D$ −57° (*c*, 1.4 in chloroform); λ_{max}(KBr) 2.85 (OH), 7.20, 7.25 μm (CMe_2); n.m.r. data: τ 4.53 (1-proton doublet, $J_{1,2}$ = 5 Hz, H-1), τ 8.50, 8.56, 8.67, 8.72 (3-proton singlets, CMe_2), τ 8.80 (3-proton doublet, J = 6 Hz, C-7 Me).

Anal. Calcd. for $C_{14}H_{24}O_7$: C, 55.2; H, 7.9. Found: C, 55.5; H, 7.8.

Thin-layer chromatographic examination (3:2 ethyl acetate – petroleum ether) of the mother liquors above showed the presence of a component with the same mobility as **2** and material which moved very close to the base line. The faster-moving component was separated by column chromatography on silica gel; it then yielded a small amount of crystalline **2** from chloroform – petroleum ether. Removal of the solvent gave a syrup (0.12 g) which could not be induced to crystallize.

*(b) From 7,8-Dideoxy-1,2:3,4-di-O-isopropylidene-*D*-glycero-α-*D*-galacto-oct-7-enopyranose (3)*

Compound **3** (0.286 g) was added with stirring to a mixture of mercuric acetate (0.319 g) in water (1 ml) and tetrahydrofuran (1 ml). The reaction mixture was stirred for 15 min at room temperature, and then 3 *M* sodium hydroxide (1 ml) followed by a solution of 0.5 *M* sodium borohydride in 3 *M* sodium hydroxide (1 ml) were added. The mercury was allowed to settle, and the supernatant liquid was separated and extracted with chloroform. The extracts were washed with water, dried over magnesium sulfate, and concentrated to a syrup. Thin-layer chromatographic examination (ethyl acetate) showed the presence of two new components, R_f 0.89 and 0.61, and a small amount of starting material, R_f 1.0. The major component (R_f 0.89) was obtained pure by fractional crystallization from ether – petroleum ether as fine needles (0.105 g, 42%), whose physical constants were in agreement with those obtained for compound **2** above.

8-Deoxy-D-erythro-D-galacto-octose (4)

A solution of compound **2** (0.25 g) in 1 *M* sulfuric acid (10 ml) was heated at 100° for 5 h. It was then passed through a column of Duolite A-4 (OH form) anion exchange resin and concentrated to a syrup, which was crystallized from ethanol. Compound 4 was obtained pure on further recrystallization from ethanol; yield 0.126 g, m.p. 118–122°; $[\alpha]_D$ +58.4 ± 0.5° (45 min), +57.4 ± 0.5° (final) (*c*, 2.1 in water); R_{glu} 0.87 (yellow-brown spot with *p*-anisidine hydrochloride spray reagent).

Anal. Calcd. for $C_8H_{16}O_7$: C, 42.9; H, 7.2. Found: C, 42.9; H, 7.3.

8-Deoxy-1,2:3,4-di-O-isopropylidene-6,7-di-O-methyl-D-erythro-α-D-galacto-octopyranose

To solution of compound **2** (0.50 g) in tetrahydrofuran (25 ml) containing powdered sodium hydroxide (5.0 g) was added dimethyl sulfate (5.0 ml) with stirring and over a period of 3 h. More sodium hydroxide (5.0 g) was then added, and the mixture was heated at reflux temperature while dimethyl sulfate (5.0 ml) was added over a period of 1 h. The excess of dimethyl sulfate was destroyed with aqueous ammonia solution, and the product was isolated as a syrup, which was chromatographed on silica gel, with 2:3 ethyl acetate – petroleum ether as eluent. The dimethyl ether was obtained as a syrup (0.40 g), $[\alpha]_D$ −60.5 ± 1° (*c*, 1.0 in ethyl acetate); n.m.r. data: τ 4.53 (1-proton doublet, $J_{1,2}$ = 5 Hz, H-1), τ 6.47, 6.64 (3-proton singlets, OMe), τ 8.50, 8.53, 8.63, 8.69 (3-proton singlets, CMe_2), τ 8.87 (3-proton doublet, J = 7 Hz, C-7 Me).

Anal. Calcd. for $C_{16}H_{28}O_7$: C, 57.8; H, 8.5. Found: C, 57.7; H, 8.7.

Degradation of 8-Deoxy-1,2:3,4-di-O-isopropylidene-6,7-di-O-methyl-D-erythro-α-D-galacto-octopyranose to 1-Deoxy-2,3-di-O-methyl-L-erythritol

A solution of 8-deoxy-1,2:3,4-di-*O*-isopropylidene-6,7-di-*O*-methyl-D-*erythro*-α-D-*galacto*-octopyranose (0.39 g) in methanol (20 ml) containing 2 *M* hydrochloric acid (6 ml) was boiled under reflux for 1.5 h, and then concentrated to dryness under reduced pressure. The syrup (R_{glu} 3.7) was dissolved in 0.1 *M* hydrochloric acid (5 ml) and stirred for 9 h with sodium metaperiodate (1.6 g). The solution was extracted with chloroform (4 × 3 ml), and the combined extracts were stirred vigorously with a solution of sodium borohydride (0.05 g) in water (1 ml) for 15 min. The aqueous phase was extracted with chloroform (2 × 2 ml). Since g.l.c. examination of the combined chloroform solutions showed the presence of only a small amount of a component with *T* 3.5 (Table I), they were then concentrated to a syrup, which was dissolved in 2 *M* hydrochloric acid (5 ml), and heated at 100° for 1 h. The acid was neutralized with an excess of sodium carbonate, and the solution was treated with sodium metaperiodate (0.70 g) for 0.5 h. The solution was extracted with chloroform, and the extracts were treated with sodium borohydride as before. 1-Deoxy-2,3-di-*O*-methyl-L-erythritol was isolated as a homogeneous liquid (25 mg) by preparative g.l.c. Its n.m.r. spectrum was identical with that of 1-deoxy-2,3-di-*O*-methyl-D-erythritol (Fig. 1); specific rotations (±1.3°) (*c*, 1.1 in ethyl acetate) are given in Table I.

1-Deoxy-2,3-di-O-methyl-L-threitol and 1-Deoxy-2,3-di-O-methyl-D-erythritol

A solution of 2,3-di-*O*-methyl-D-xylose diethyl dithioacetal (6) (1.75 g) in ethanol was heated in the presence of freshly prepared Raney nickel (10) (6 g) for 8 h at reflux temperature. The product was treated with sodium metaperiodate and then with sodium borohydride as described above. 1-Deoxy-2,3-di-*O*-methyl-L-threitol was isolated as a homogeneous liquid (45 mg) by preparative g.l.c. 1-Deoxy-2,3-di-*O*-methyl-D-erythritol was prepared similarly from 1-deoxy-2,3-di-*O*-methyl-D-ribitol (7). The n.m.r. spectra of the two tetritol derivatives are shown in Fig. 1, and retention times and specific rotations (±1.0°) (*c*, 1.3 and 1.6 in ethyl acetate, respectively) are given in Table I.

α,β-Epoxy sulfones. The Darzens condensation with α-halosulfones[1]

PETER F. VOGT[2] AND DONALD F. TAVARES
Department of Chemistry, University of Calgary, Calgary, Alberta

Received June 3, 1968

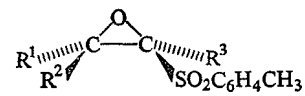
Darzens type condensation of chloromethyl *p*-tolyl sulfone with benzaldehyde, acetaldehyde, acetone, benzophenone, and cyclohexanone, with potassium *tert*-butoxide as base, gave good to excellent yields of the corresponding α,β-epoxy sulfones (**1**). The condensation of α-chloroethyl *p*-tolyl sulfone and bromomethyl *p*-tolyl sulfone with benzaldehyde also gave excellent yields. With the aldehydes only the *trans*-epoxides were formed, which is shown by nuclear magnetic resonance spectroscopy. The mechanism and stereochemistry are discussed.

Canadian Journal of Chemistry, 47, 2875 (1969)

The preparation and reactions of α,β-unsaturated sulfones have commanded much attention in the last 15 years (1). The behavior of saturated sulfones as they compare with ketones has also been investigated and it has been found that the hydrogen adjacent to the sulfonyl group is very acidic (2). This has led to the use of sulfones in many aldol-type condensations.

However, to this date, there have been no reports in the literature on the epoxidation of α,β-unsaturated sulfones, or on other methods for the preparation of α,β-epoxy sulfones, except that of Ballester (3), who mentioned in a review article that he had obtained an α,β-epoxy sulfone by a Darzens type condensation of benzaldehyde with chloromethyl *p*-tolyl sulfone. No further details have ever been published. The only epoxy sulfones described, so far then, are the β,γ-epoxy sulfones (4).

The aim of the present study was the synthesis of α,β-epoxy sulfones of the following type



1

R^1: CH_3, C_6H_5, $-(CH_2)_5-$; R^2: H, CH_3, C_6H_5, $-(CH_2)_5-$; R^3: H, CH_3

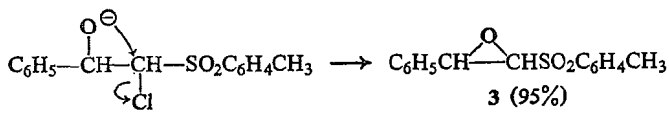
From the great variety of conditions employed in the Darzens condensation, it has been shown that the use of potassium *tert*-butoxide as base resulted in excellent yields (5). In this investigation, therefore, potassium *tert*-butoxide was chosen as the condensing base, in a method similar to that described by Hunt *et al.* (6) and Johnson *et al.* (5).

When a solution of potassium *tert*-butoxide in *tert*-butyl alcohol was added slowly to a solution of chloromethyl *p*-tolyl sulfone (**2**) and benzaldehyde in *tert*-butyl alcohol – ether mixture (2:1, v/v) at 10–15°, the epoxide was formed in 95% yield (eq. [1]).

$$CH_3C_6H_4SO_2CH_2Cl + C_6H_5CHO + t\text{-BuOK} \xrightarrow[10\text{–}15^\circ]{t\text{-BuOH}}$$

2

[1]



3 (95%)

The anhydrous ether in the solvent was used to prevent crystallization of the *tert*-butyl alcohol when the reaction mixture was cooled.

Besides benzaldehyde, acetaldehyde, benzophenone, acetone, and cyclohexanone also gave good to excellent yields of the corresponding epoxide (Table I).

The lower yield using acetaldehyde agrees with the observation of previous workers in the Darzens condensation using aliphatic aldehydes. The obvious explanation is that the aldehyde undergoes aldol condensation more readily than

9	$CH_3C_6H_4SO_2CH_2Br$	C_6H_5CHO	**3**	(91%)	157–159° dec.
10	$CH_3C_6H_4SO_2CH_2Br$	CH_3COCH_3	**5**	(77%)	93.5–94°

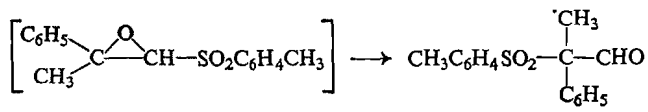
*Using potassium *tert*-butoxide as base.
†Using sodium methoxide as base.

the Darzens condensation reaction, as shown by Field and Carlile (7). The lower yield using benzophenone might be explained by steric hindrance, and therefore a slower reaction.

However, the reaction of acetophenone with **2** resulted only in the isolation of a white crystalline product which was shown to be 2-phenyl-2-(*p*-tolylsulfonyl)propanal (**9**). The formation of this aldehyde is suggested by a rearrangement of the intermediate epoxide[3] (eq. [2])

$$CH_3C_6H_4SO_2CH_2Cl + CH_3COC_6H_5 + t\text{-BuOK} \xrightarrow[10\text{-}15°]{t\text{-BuOH}}$$

[2]



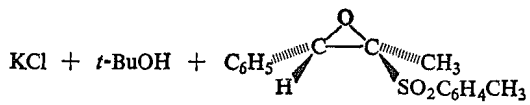
9

Besides chloromethyl *p*-tolyl sulfone, α-chloroethyl *p*-tolyl sulfone (**10**) also gave satisfactory reaction with benzaldehyde, the epoxide **8** being isolated in excellent yield (eq. [3])

$$CH_3C_6H_4SO_2\underset{\displaystyle Cl}{\underset{|}{C}}HCH_3 + C_6H_5CHO + t\text{-BuOK} \xrightarrow[10\text{-}15°]{t\text{-BuOH}}$$

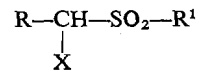
10

[3]



8 (92%)

The Ramberg–Baecklund rearrangement (8), with the formation of an episulfone and subsequent decomposition to the olefin by the action of base, imposes a limitation in the use of other α-chlorosulfones. Therefore, only α-halosulfones of the general formula can be used, where R^1 is bonded to the sulfonyl group with a carbon atom which bears no hydrogen.



R.... H, alkyl, aryl

R^1... phenyl, aryl or *tert*-alkyl

[3]W. E. Truce (private communication) reports the formation of *p*-nitrophenacyl phenyl sulfone by treatment of *p*-nitrobenzaldehyde and chloromethyl phenyl sulfone with sodium ethoxide, also implying the formation of an epoxy sulfone as an intermediate.

An attempt to use sodium methoxide in methanol as the condensing agent in the reaction of **2** and benzaldehyde gave only 20% of epoxide **3**, the halosulfone being recovered in 80% yield.

Although the yields from α-bromocarbonyl compounds are not as high as those from α-chlorocarbonyl compounds in the Darzens condensation, due mostly to the competing alkylation reaction (9), the use of α-bromosulfones such as bromomethyl *p*-tolyl sulfone (**11**), gave in the reaction with benzaldehyde and acetone, the same yields as the corresponding chlorosulfone (Table I).

In contrast to the known retarding effect of an α-sulfonyl group on an intermolecular S_N2 displacement of a halogen atom, the intramolecular S_N2 displacement is facile, and there is no sign of diminished reactivity. This might be explained by the fact that in an intramolecular S_N2 displacement the attacking nucleophile is already close to the reaction center, whereas the nucleophile in the intermolecular attack must overcome the repulsion of the negative charges on the oxygen atoms of the sulfonyl group to get as close. Thus, the difference between bromide and chloride as leaving groups appears to be insignificant.

Mechanism and Stereochemistry

The stereochemistry of the isolated epoxides was established by n.m.r. spectroscopy to be exclusively of the *trans* configuration; no *cis*-epoxide could be detected.

Lyle and Keefer (10) showed, in a series of *cis* and *trans* oxirane compounds, that the coupling constants of the protons for the *cis*-isomers were significantly larger than those of the isomeric *trans*-epoxides. For the coupling constants, they found a range of 2.2–5.2 Hz for the *cis* protons and 1.4–2.6 Hz for the *trans* protons.

Comparing these values for the coupling constants with the coupling constants of 1.5 and 2.0 Hz for epoxides **3** and **4**, respectively (Table II), it seems reasonable to propose that these epoxides are of the *trans* configuration.

A deuterium exchange experiment on **3**, with sodium methoxide in methanol-*d* (eq. [4]), shows that the α-hydrogen has a chemical shift of 5.86 τ while the β-hydrogen is at 5.48 τ, and not the reverse, as was first expected.

No epimerization was observed in this experiment and no other compound was found by either thin-layer chromatography or n.m.r. spectroscopy. Since the β-hydrogen in **12** has the same chemical shift as in **3**, it is in the same environment.

From the position of the epoxymethine protons in **3** it must be inferred that the β-hydrogen is in the paramagnetic region of the β-phenyl ring and therefore the phenyl ring is in a plane perpendicular to the plane of the epoxide ring; this is necessary to obtain any conjugation of the epoxide ring with the phenyl group.

In the case of 2,2-diphenyl-1-(*p*-tolylsulfonyl)-1,2-epoxyethane (**6**), the phenyl groups cannot be

TABLE II

Chemical shifts and coupling constants for the epoxide ring protons in α,β-epoxy sulfones*

	Compound			Chemical shift (τ)†		Coupling constant
	R^1	R^2	R^3	H_α	H_β	$J(H_\alpha, H_\beta)$ in Hz
3	C_6H_5	H	H	5.86	5.48	1.5

Compounds of structure 
[4] 
12

perpendicular to the plane of the epoxide ring, and are probably twisted (steric hindrance) so that the α-hydrogen of the epoxide ring is more in the paramagnetic region of the *cis*-β-phenyl ring. Therefore, the α-hydrogen exhibits a further downfield shift over that observed in epoxide **3** where it is more in the diamagnetic region. Reference (21) gives an interesting discussion concerning the difference in the chemical shift of *cis* and *trans* 1,2-diphenyl compounds.

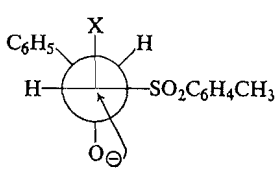
The determination of the β-hydrogen in epoxide **4** was facilitated by its being split into a quartet by the adjacent methyl group.

Thus, the n.m.r. spectra are in good agreement with the proposed structures for the α,β-epoxy sulfones.

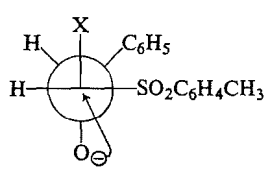
It is not unreasonable to suppose that the mechanism for the formation of α,β-epoxy sulfones might be the same as has been proposed for the general Darzens condensation (3, 11), with some differences caused by the sulfonyl group in the place of the carbonyl group (eqs. [5]–[7]).

[5] 
[6] 
[7] 
The initial nucleophilic attack upon the aldehyde or ketone is probably rapidly reversible, thus leading only to the preferred transition state, as otherwise two isomers should be found.

Since there is little or no angular dependence for effective π-overlap involving 3d orbitals, because of cylindrical symmetry of 3d atomic orbitals, rotation about a 3d–2p π-bond should not then result in diminished overlap (12). Therefore "overlap control," as proposed by Zimmerman and Ahramjian (13) in the Darzens condensation with carbonyl compounds, cannot be considered to have any significant influence on the stereochemistry of the cyclization step. For facile ring closure, however, steric effects are of more importance, and the energy of transition state **B** must be considerably higher than that of **A**.

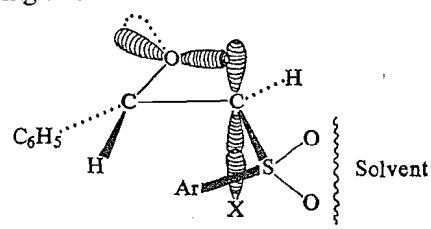


A



B

Also, solvation of the sulfonyl group with its negative charges on oxygen, should be an important factor which holds the oxygen in an outward position, pointing the *p*-tolyl group toward the *cis*-substituent on the other carbon atom. Thus, the preferred transition state would have the following structure



Considering that a wide variety of α-chlorosulfones can be prepared easily by the method of Boehme *et al.* (14), and also the fact that the α-bromosulfones give the same good yields, the Darzens condensation seems an excellent method for the preparation of α,β-epoxy sulfones in large quantities.

Experimental

All melting points were determined on a Kofler hot

stage and are corrected; infrared (i.r.) spectra were determined with a Perkin–Elmer model 337 spectrophotometer by the potassium bromide pellet method, unless otherwise indicated; n.m.r. spectra were measured at 60 MHz in deuteriochloroform (10–20%, by weight), with tetramethylsilane as internal standard ($\tau = 10$); microanalyses, except for sulfur, were performed by S. J. Bagley, University of Calgary; sulfur analyses were performed by C. Daesslé, Montreal.

Reagents

The benzaldehyde used was purified (15) and stored under nitrogen. Reagent-grade benzophenone from Fisher Scientific, m.p. 47.8–48.8°, reagent-grade acetophenone from British Drug Houses, m.p. 18–20°, spectrograde acetone from Matheson, Coleman, and Bell, reagent-grade acetaldehyde from British Drug Houses, and cyclohexanone from Eastman Kodak were used without further purification. Anhydrous ethyl ether was freshly distilled from lithium aluminum hydride.

General Procedure

In a 100 ml 3-necked flask, equipped with thermometer, addition funnel, drying tube (silica gel), and a magnetic stirrer, was placed a solution of 0.016 mole of an α-halosulfone and 0.016 mole of an aldehyde or ketone dissolved in a mixture of 30 ml of *tert*-butyl alcohol (reagent-grade from British Drug Houses, m.p. 24–25.5°) and 15 ml anhydrous ethyl ether. The resulting solution was cooled to 10° in a water bath. Then 1.80 g (0.016 mole) of potassium *tert*-butoxide (from K and K Laboratories), dissolved in 20 ml of *tert*-butyl alcohol, were added slowly so that the temperature did not exceed 15°. After all the base was added, the solution was allowed to warm to room temperature. After being stirred for 3 h, the reaction mixture was poured into 400 ml of water. The solids were separated by filtration and washed with water, and the liquids were extracted with ether. Purification of the crude products by recrystallization gave analytical samples.

Reactions of Chloromethyl p-Tolyl Sulfone (2)

Compound **2** was prepared by a method based on that of Ziegler and Connor (16). Sodium *p*-toluenesulfinate (17) (71.2 g, 0.4 mole) and bromochloromethane (104 g, 0.8 mole; from Eastman Kodak) were heated at reflux in 100 ml of ethanol for 7 days. The sodium bromide which had precipitated out was separated by filtration and the filtrate was evaporated at reduced pressure. Crude **2** was recrystallized from methanol to give 57.3 g (71%) of white crystals, m.p. 81–82° (lit. (18) m.p. 84°).

With Benzaldehyde. trans-2-Phenyl-1-(p-tolylsulfonyl)-1,2-epoxylethane (3)

From benzaldehyde (1.69 g, 0.016 mole) and compound **2** (2.75 g, 0.016 mole). Crude **3** was recrystallized from *n*-hexane – carbon tetrachloride to give 4.1 g (95%) of fine white needles, m.p. 157–159° (with decomposition). The i.r. spectrum showed epoxide ring absorption at 1228, 909, 790, and 828 cm^{-1}, epoxymethine absorption at 3010 cm^{-1}, and sulfonyl absorption at 1315 cm^{-1} (ν_{as}) and 1146 cm^{-1} (ν_s). The n.m.r. spectrum showed three methyl protons at 7.55 τ, one methinyl proton (doublet) at 5.86 τ (α-proton) with $J = 1.5$ Hz, one methinyl proton (doublet) at 5.48 τ (β-proton) with $J = 1.5$ Hz, five phenyl protons at 2.71 τ, and four aromatic protons at 2.52 and 2.16 τ with $J = 8.0$ Hz.

Anal. Calcd. for $C_{15}H_{14}O_3S$: C, 65.69; H, 5.14; S, 11.70. Found: C, 65.54; H, 5.16; S, 11.87.

With Benzaldehyde. Using Sodium Methoxide as Base to form 3

Using sodium methoxide (0.9 g, 0.016 mole) in methanol (20 ml) as the condensing base and methanol (30 ml) as solvent gave, after being stirred for 9 h, only 0.85 g (20%) of **3**, and 2.2 g (80%) of **2** was recovered unchanged.

With Acetaldehyde. trans-1-p-Tolylsulfonyl-1,2-epoxypropane (4)

From acetaldehyde (0.67 g, 0.016 mole) and compound **2** (2.75 g, 0.016 mole). Compound **4** was obtained as a yellow oil, which became solid on standing. Recrystallization from *n*-hexane – carbon tetrachloride gave 1.8 g (53%) of light-yellow crystals, m.p. 60–66°. Three further recrystallizations from *n*-hexane – carbon tetrachloride, using decolorizing charcoal in the last one, gave small white plates, m.p. 83–84°. The i.r. spectrum showed epoxide ring absorptions at 1226, 820, 803, and 828 cm^{-1}, epoxymethine absorption at 3020 cm^{-1}, and sulfonyl absorption at 1318 cm^{-1} (ν_{as}), and 1155 cm^{-1} (ν_s). The n.m.r. spectrum showed three methyl protons at 7.56 τ (CH_3Ar), three methyl protons (doublet) at 8.60 τ with $J = 5.2$ Hz, one methinyl proton (β-proton) at 6.38 τ, consisting of a quartet ($J = 5.2$ Hz) split into doublets ($J = 2.0$ Hz), one methinyl proton (doublet) at 6.14 τ (α-proton) with $J = 2.0$ Hz, and four aromatic protons at 2.65 and 2.33 τ with $J = 8.0$ Hz.

Anal. Calcd. for $C_{10}H_{12}O_3S$: C, 56.58; H, 5.70; S, 15.10. Found: C, 56.35; H, 5.85; S, 15.19.

With Acetone. 2-Methyl-1-(p-tolylsulfonyl)-1,2-epoxypropane (5)

From acetone (0.93 g, 0.016 mole) and **2** (2.75 g, 0.016 mole). Crude **5** was recrystallized from *n*-hexane – carbon tetrachloride to give 2.9 g (80%) of a white crystalline product, m.p. 93.5–94.0°. The i.r. spectrum showed epoxide ring absorptions at 1238, 925, 830, and 749 cm^{-1}, epoxymethine absorption at 3010 cm^{-1}, and sulfonyl absorption at 1316 cm^{-1} (ν_{as}), and 1148 cm^{-1} (ν_s). The n.m.r. spectrum showed three methyl protons at 8.63 τ, three methyl protons at 8.23 τ, three methyl protons (CH_3Ar) at 7.57 τ, one methinyl proton at 6.22 τ, and four aromatic protons at 2.67 and 2.20 τ with $J = 8.0$ Hz.

Anal. Calcd. for $C_{11}H_{14}O_3S$: C, 58.37; H, 6.23; S, 14.19. Found: C, 58.35; H, 6.37; S, 13.99.

With Benzophenone. 1,1-Diphenyl-2-(p-tolylsulfonyl)-1,2-epoxyethane (6)

From benzophenone (2.73 g, 0.016 mole) and **2** (2.75 g, 0.016 mole). Crude **6** was recrystallized from *n*-hexane – carbon tetrachloride to give 3.0 g (57%) of small needles, m.p. 106–107°. The i.r. spectrum showed epoxide ring absorptions at 1250, 945, 795, and 756 cm^{-1}, epoxymethine absorption at 3000 cm^{-1}, and sulfonyl absorption at 1330 cm^{-1} (ν_{as}), and 1150 cm^{-1} (ν_s). The n.m.r. spectrum showed three methyl protons at 7.66 τ, one methinyl proton at 5.60 τ, and fourteen aromatic protons at 2.3–2.8 τ.

Anal. Calcd. for $C_{21}H_{18}O_3S$: C, 71.97; H, 5.18; S, 9.15. Found: C, 71.73; H, 5.27; S, 9.24.

With Cyclohexanone. 1,1-Pentamethylene-2-(p-tolylsulfonyl)-1,2-epoxyethane (7)

From cyclohexanone (1.57 g, 0.016 mole) and **2** (2.75 g, 0.016 mole). Crude **7** was recrystallized from *n*-hexane – carbon tetrachloride to give a fine white powder (3.3 g, 77%), which at first melted at 54–55°, and then formed needles which melted at 69–70°. The i.r. spectrum showed epoxide ring absorptions at 1267, 1210, 940, 849, and 760 cm^{-1}, epoxymethine absorption at 3010 cm^{-1}, and sulfonyl absorption at 1321 cm^{-1} (ν_{as}), and 1149 cm^{-1} (ν_s). The n.m.r. spectrum showed three methyl protons at 7.58 τ, one methinyl proton at 6.45 τ, ten methylene protons (multiplets) at 7.7–8.7 τ, and four aromatic protons at 2.70 and 2.27 τ with $J = 8.0$ Hz.

Anal. Calcd. for $C_{14}H_{18}O_3S$: C, 63.12; H, 6.82; S, 12.04. Found: C, 62.95; H, 6.98; S, 11.94.

With Acetophenone. 2-Phenyl-2-(p-tolylsulfonyl)-propanal (9)

From acetophenone (1.92 g, 0.016 mole) and **2** (2.75 g, 0.016 mole). The product was a yellow oil; this material solidified when left for two days. On recrystallization from carbon tetrachloride compound **9** was obtained as white needles (4.1 g, 89%), m.p. 125–125.5°. The i.r. spectrum showed carbonyl absorption at 1730 cm^{-1}, and sulfonyl absorption at 1310 cm^{-1} (ν_{as}), and 1140 cm^{-1} (ν_s). The n.m.r. spectrum showed three methyl protons at 8.18 τ, three methyl protons (CH_3Ar) at 7.61 τ, five phenyl protons at 2.62 τ, four aromatic protons at 2.83 and 2.60 τ with $J = 8.0$ Hz, and one aldehydic proton at −0.21 τ.

Anal. Calcd. for $C_{16}H_{16}O_3S$: C, 66.66; H, 5.58; S, 11.12. Found: C, 66.81; H, 5.48; S, 10.96.

The 2,4-dinitrophenylhydrazone of compound **9**, prepared in the usual way, melted at 197–198° (with decomposition).

Reactions of α-Chloroethyl p-Tolyl Sulfone (10)

Compound **10** was prepared by a method based on that of Ziegler and Connor (16). A mixture of sodium *p*-toluenesulfinate (17) (36.3 g, 0.204 mole) and chloroiodoethane (19) (38.7 g, 0.204 mole) in 100 ml of ethanol (95%) was heated at reflux for 5 days. Yield, 17.8 g (40%), m.p. 84° (lit. (20) m.p. 84°).

With Benzaldehyde. trans-1-Phenyl-2-(p-tolylsulfonyl)-1,2-epoxypropane (8)

From benzaldehyde (1.69 g, 0.016 mole) and **10** (3.5 g, 0.016 mole). Crude **8** (4.25 g, 92%) was recrystallized from *n*-hexane – carbon tetrachloride to give 3.4 g (78%) of a product with m.p. 113–115° (with decomposition). The i.r. spectrum showed epoxide ring absorption at 1211, 870, and 760 cm^{-1}, epoxymethine absorption at 3020 cm^{-1}, and sulfonyl absorption at 1316 cm^{-1} (ν_{as}), and 1143 cm^{-1} (ν_s). The n.m.r. spectrum showed three methyl protons at 8.65 τ, three methyl protons (CH_3Ar) at 7.53 τ, one methinyl proton at 5.16 τ, five phenyl protons at 2.69 τ, and four aromatic protons at 2.62 and 2.13 τ with $J = 8.0$ Hz.

Anal. Calcd. for $C_{16}H_{16}O_3S$: C, 66.66; H, 5.58; S, 11.12. Found: C, 66.43; H, 5.66; S, 11.00.

Reactions of Bromomethyl p-Tolyl Sulfone (11)

Compound **11** was prepared from sodium *p*-toluenesulfinate (17) and methylene bromide by the method of Ziegler and Connor (16) in 71% yield, m.p. 90–91° (lit. (16) m.p. 89–90°; 90–91°).

With Benzaldehyde to form 3

Benzaldehyde (1.69 g, 0.016 mole) and **11** (4.0 g, 0.016 mole) gave 4.0 g (91%) of **3**, which was identical in every respect with the **3** obtained with **2**.

With Acetone to form 5

Acetone (0.93 g, 0.016 mole) and **11** (4.0 g, 0.016 mole) gave 2.8 g (77%) of **5**, which was identical in every respect with the **5** obtained with chloromethyl *p*-tolyl sulfone.

Deuterium Exchange Experiment. trans-2-Phenyl-1-(p-tolylsulfonyl)-1,2-epoxyethane-1-d (12)

0.1 g (2 mmole) of sodium methoxide was added to a sample of 0.5 g (2 mmole) of **3**, dissolved in 10 ml of methanol-*d* (prepared from sodium methoxide and deuterium oxide) and 10 ml of anhydrous benzene. After standing at room temperature for 36 h, the mixture was diluted with water, the benzene layer was separated, washed with water, dried with anhydrous magnesium sulfate, and the benzene evaporated at reduced pressure. The residue was recrystallized from *n*-hexane – carbon tetrachloride to give 0.45 g (90%) of **12**, m.p. 157–159°; mixed m.p. with **3**, 157–159°. The i.r. spectrum showed epoxide ring absorptions at 1248, 966, 935, and 783 cm^{-1}, epoxymethine absorption at 3010 cm^{-1}, deuterium absorption at 2255 cm^{-1}, and sulfonyl absorption at 1315 cm^{-1} (ν_{as}) and 1146 cm^{-1} (ν_s). The n.m.r. spectrum showed three methyl protons at 7.55 τ, one methinyl proton at 5.48 τ, five phenyl protons at 2.71 τ, and four aromatic protons at 2.52 and 2.16 τ with $J = 8.0$ Hz.

Galactomannan from *Cassia absus* seed. I. Nature of sugars present, methylation, and periodate oxidation studies

V. P. KAPOOR AND S. MUKHERJEE
Department of Organic Chemistry, National Sugar Institute, Kanpur, India

Received March 3, 1969

A galactomannan composed of D-galactose (1 mole) and D-mannose (3 moles) was isolated from the seed of *Cassia absus*. Methylation and hydrolysis of the galactomannan produced 2,3,4,6-tetra-*O*-methyl-D-galactose (2 moles), 2,3,6-tri-*O*-methyl-D-mannose (4.2 moles), 2,3-di-*O*-methyl-D-mannose (1 mole), and 4,6-di-*O*-methyl-D-mannose (1 mole). Periodate consumption was 1.09 moles for each hexose unit with concomitant liberation of 0.26 mole of formic acid. The periodate oxidized and the reduced galactomannan afforded, on hydrolysis, glycerol (1.94 moles), erythritol (5 moles), and D-mannose (1.08 moles).

On the basis of the above findings, a structure for the galactomannan can be proposed in which mannose units form the main chain and the galactose units are present as branches, the former being attached mostly through $1 \rightarrow 4$ (ca. 85%) and the rest which is nearly half the branch points through $1 \rightarrow 3$ or $1 \rightarrow 2$, and branches of single galactose units are attached through $1 \rightarrow 6$ (ca. 50%) and the rest through $1 \rightarrow 2$ or $1 \rightarrow 3$.

Canadian Journal of Chemistry, 47, 2883 (1969)

Cassia absus belongs to the N.O. Leguminosae. The endosperm of leguminous seeds is usually mucilaginous and galactomannan is its main component (1). Many such seeds e.g. guar (2, 3), fenugreek (4), carob (5, 6), lucerne and clover (7), and Kentucky coffee bean (8) have been studied and the structure of galactomannan worked out. It would be interesting to study other seeds of this family and find out the relationship between their polysaccharide material. *Cassia absus* seed, which is medically important (9) and easily available, was taken up for the study. It will be seen that endosperm of this seed, which is about 55% of the total weight, is chiefly a galactomannan.

Isolation of the galactomannan from the seeds was carried out by the usual procedure of extraction with hot water and precipitation with ethanol. This crude polysaccharide formed an insoluble complex when treated with a saturated barium hydroxide solution. The barium complex, containing pure polysaccharide material (10) yielded two fractions, A (soluble) and B (insoluble) when stirred with dilute acetic acid. The two fractions were in the ratio of 3:1. The major fraction A was taken up for the present study. It was taken to be homogeneous since (*i*) almost all of it precipitated from an aqueous solution over a narrow concentration range of ethanol, and (*ii*) the precipitated material displayed the same physical properties as the product regenerated from the acetyl derivative of the original fraction. Complete acid hydrolysis of the purified polysaccharide afforded D-galactose (1 mole), D-mannose (3 moles), and xylose (0.17 mole) (11).

The purified polysaccharide was converted into its fully methylated derivative and fractionated. Hydrolysate of the main fraction showed three spots on paper which were separated on Whatman No. 3 MM sheets. The sugar which moved fastest was 2,3,4,6-tetra-*O*-methyl-D-galactose. It was followed by 2,3,6-tri-*O*-methyl-D-mannose. An unusually elongated spot of the slowest moving component suggested the possibility of its being a mixture of at least two sugars. The common solvent systems failed to resolve this mixture. It could be finally separated with butanone – ethyl acetate – water – ammonia (80:20:8:1 v/v, upper phase), a new solvent composition. These two sugars were 2,3-di-*O*-methyl-D-mannose and 4,6-di-*O*-methyl-D-mannose. The four sugars were in the molar ratio 2:4.2:1:1.

Since 2,3,6-tri-*O*-methyl-D-mannose is the major component, the main chain must be composed of $1 \rightarrow 4$ linkages. The mannose units giving rise to 2,3-di-*O*-methyl-D-mannose would also be $1 \rightarrow 4$ linked, one of the galactose end units being linked to it at C-6. The remaining mannose unit makes its appearance as a 4,6-di-*O*-methyl derivative suggesting linkages through its C-1, C-2, and C-3. Such a combination of linkages is not reported in any of the seed galactomannans. Bishop *et al.* (12) have, however, reported mannose unit similarly linked in a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

dermatophyte (Trichophyton granulosum) galactomannan. This mannose unit may be attached to its adjacent mannose unit through $1 \rightarrow 3$ and to the terminal galactose unit through $1 \rightarrow 2$; the linkages may also be attached otherwise, the proof of which cannot be afforded at this stage. The exact nature of these linkages will be clear only from the isolation of such an oligosaccharide from the galactomannan in which a mannose unit is attached to another mannose unit or a galactose unit is attached to a mannose unit through $1 \rightarrow 2$ or $1 \rightarrow 3$ linkage. Such an attempt will be made in future. The simplest symmetrical structure which can accommodate the above findings is shown in Formula I.

Most of the seed galactomannans have a main chain of $1 \rightarrow 4$ linked mannose units. The side chains are linked at C-6 and are composed of galactose and mannose (8, 13) or only the former (2–7, 14). It will be seen that the *Cassia absus* galactomannan is essentially similar to other seed galactomannans: the major difference being the attachment of half of the galactose side units to C-2 or C-3 of the hexose units in the main chain. In this respect it bears similarity to galactomannans from microorganisms (15–17). In these cases the branches have been shown to be attached at C-2.

The structure shown below would consume 1.125 moles of periodate per hexose unit and would liberate 0.25 mole of formic acid. In actual practice 1.09 moles of periodate were consumed, with the liberation of 0.26 mole formic acid. The periodate-oxidized polysaccharide was reduced with sodium borohydride and hydrolyzed according to the method of Abdel-Akher *et al.* (18). The hydrolysate was resolved on Whatman No. 3 MM sheets using butan-1-ol – ethanol – water (31:11:9 v/v, upper phase) mixture. The components were glycerol (1.94 moles), erythritol (5 moles), D-mannose (1.08 moles), and traces of galactose. The results are in substantial agreement with the expected values, but no satisfactory explanation can yet be given for the detection of traces of galactose.

The infrared (i.r.) spectrum of the galactomannan showed absorption bands at 817 and 874 cm^{-1} thus indicating the presence of α-linked D-galactopyranose units and β-linked D-mannopyranose units respectively (19). The fact that galactomannan has a majority of β-linkages is further confirmed by low positive rotations of the polysaccharide $[\alpha]_D^{20}$ +23.8 (H_2O), its acetate $[\alpha]_D^{24}$ +25.6 (acetone), and its methyl ether $[\alpha]_D^{27}$ +28.3 ($CHCl_3$). Such glycosidic configuration is reported in most seed galactomannans.

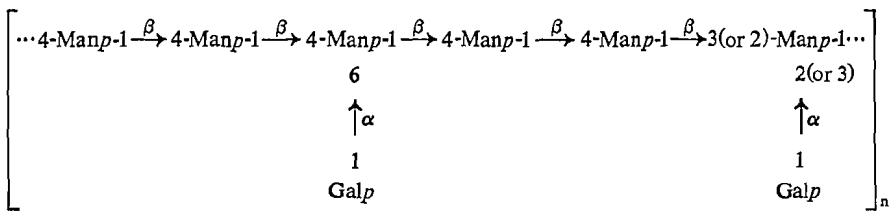
Experimental

Methods

Unless otherwise stated all evaporations were carried out at 40–50° under reduced pressure. All specific rotations are equilibrium values and melting points are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 137-B either in chloroform solutions in sodium chloride cells or in potassium bromide pellets. Paper chromatographic analysis was carried out by descending method on Whatman No. 1 paper using non-aqueous phases of the following solvent systems (by volume): (*a*) butan-1-ol – acetic acid – water (4:1:5); (*b*) benzene – ethanol – water (167:47:15); (*c*) butanone – water azeotrope; (*d*) butanone – ethyl acetate – water – ammonia (80:20:8:1); (*e*) butan-1-ol – ethanol – water (31:11:9). Silver nitrate–sodium hydroxide and *p*-anisidine phosphate were used as spray reagents. Sugar mixtures were separated on Whatman No. 3 MM sheets and columns of Whatman cellulose powder. Deionization was done with Amberlite IR-120 (H^+) and IR-45 (OH^-).

Isolation, Fractionation, and Purification of the Galactomannan

The seeds were cleaved in a low speed grinder when the seedcoat together with the embryo attached to it broke off from the light yellow-colored cotyledons. The cotyledons were separated by winnowing and rejected. The remaining material (100 g) containing the endosperm was soaked in water (3 l) overnight followed by heating at 100° for 4 h. The swollen material was then blended with additional quantities of water. The resulting viscous solution (8 l) was filtered through a muslin cloth and



Formula I. A probable structure of Cassia absus seed galactomannan.
LEGEND: Gal*p*, D-galactopyranose; Man*p*, D-mannopyranose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

centrifuged at 25 000 r.p.m. in a supercentrifuge when most of the suspended matter was removed and an almost clear solution resulted. Addition of ethanol (14 l) to this solution precipitated the polysaccharide in the form of a coarse powder (12.5 g). It was redissolved in water (5 l) with constant mechanical stirring for 5 h. To this solution was added saturated barium hydroxide solution (10 l) when the polysaccharide precipitated out as its barium complex. It was allowed to settle and isolated by decantation followed by filtration. The solid material was stirred with 2 *N* acetic acid (2 l) for 30 h when it partially dissolved. After removal of the insoluble fraction by filtration, the soluble fraction was isolated by precipitation with ethanol (4 l). The two fractions were successively stirred in 2 l each of 50, 80, 90, and 95% ethanol. The washed fractions were free from acetic acid; yield, soluble 7.2 g; insoluble, 2.5 g.

The acetic acid soluble polysaccharide was deionized. The ash-free product (6 g) was stirred for 4 h with water (1 l) and ethanol was added to the solution in stages. After each addition the solution was allowed to stand overnight. Addition of the first 150 ml had no effect but the next 100 ml produced a turbidity which was centrifuged out. Another 75 ml resulted in a slight precipitate (340 mg) which was removed by filtration. Finally, addition of 60 ml more resulted in copious precipitation of the polysaccharide (5.4 g). At this stage alcohol concentration had increased from 19 to 23% (weight of ethanol/weight of solution).

The polysaccharide which was in the form of white amorphous powder had $[\alpha]_D^{20}$ +23.8° (*c*, 1.0 H_2O) and did not reduce Fehling's solution. Nitrogen, sulfur, halogens, methoxyl, and uronic acid were absent. Its preliminary analysis gave sulfated ash (0.12%) and pentosans (6.61%).

Acetylation of the Galactomannan (8)

The polysaccharide (0.8 g) was finely ground and shaken at room temperature with formamide (50 ml) for 24 h. Anhydrous pyridine (12 ml) was added to the above suspension and it was followed by dropwise addition of acetic anhydride (10 ml) during 4 h when a brown viscous solution resulted. It was kept overnight and the acetylated product was precipitated from it as a greyish-white powder by stirring into water. It was washed with water, followed by ethanol, and finally with petroleum ether to dry it. The dried acetyl derivative was dissolved in acetone (50 ml). A small amount of undissolved material was centrifuged out. The pure derivative was then reprecipitated and dried as above; yield, 0.79 g; $[\alpha]_D^{24}$ +25.6 (*c*, 0.5 acetone).

Regeneration of the Galactomannan from its Acetate

The acetate (0.7 g) was dissolved in acetone (25 ml) and refluxed with potassium hydroxide (45%, 25 ml). The lower viscous layer, containing alkali and polysaccharide, was separated and poured into acidified ethanol. A further precipitation in the same manner with neutral ethanol afforded purified galactomannan which was dried by solvent exchange; yield, 0.29 g; $[\alpha]_D^{25}$ +24.7 (*c*, 1.0 H_2O).

Identification and Estimation of Sugars from the Galactomannan

The polysaccharide (1 g) was kept with sulfuric acid (72%, 4 ml) overnight, cooled in a freezing mixture, diluted with water (108 ml), and hydrolyzed at 100°. Hydrolysis was complete after 10 h as shown by iodometric titrations. The resulting solution was neutralized (barium carbonate), deionized, and evaporated to a thin syrup. Paper chromatography in solvent *a* revealed the presence of D-galactose (strong spot), D-mannose (strong spot), and xylose (faint spot). The sugar mixture was resolved on cellulose column using butan-1-ol half saturated with water as eluent. Appropriate fractions of eluate containing single pure sugar were mixed and concentrated. They yielded (*i*) D-galactose, m.p. and mixed m.p. 163–165°; $[\alpha]_D^{34}$ +81.0 (*c*, 0.5 H_2O); *p*-nitro-*N*-phenyl-D-galactosylamine, m.p. and mixed m.p. 216–219°; $[\alpha]_D^{30}$ −247° (*c*, 0.2 pyridine); (*ii*) D-mannose, m.p. and mixed m.p. 132°; $[\alpha]_D^{35}$ +14.2 (*c*, 0.5 H_2O); *p*-nitro-*N*-phenyl-D-mannosylamine, m.p. and mixed m.p. 216–219°; $[\alpha]_D^{32}$ −325° (*c*, 0.5 pyridine).

To estimate the component sugars in the polysaccharide, it (0.2 g) was heated at 100° with 1 *N* sulfuric acid (10 ml) in a sealed tube and finally processed as usual. The sugars were separated on paper. Areas of the paper containing single sugar component were cut out, eluted, and estimated by oxidizing the sugar with periodate (20) and titrating the liberated formic acid with standard alkali. Ratio of galactose, mannose, and xylose was 1:3:0.17.

Methylation of the Galactomannan

The polysaccharide (5 g) was subjected to methylation by Haworth's method by five successive treatments with dimethyl sulfate and sodium hydroxide solution (45%) yielding a light-yellow product (3.95 g). The i.r. spectrum of this polysaccharide in chloroform still had a prominent hydroxyl peak (3400–3600 cm^{-1}).

The partially methylated product was dissolved in dimethyl sulfoxide (150 ml) (21) and to the resulting solution, sodium hydroxide pellets (35 g) and dimethyl sulfate (20 ml) were added during a period of 6 h with constant stirring at 20° under an atmosphere of nitrogen. The reaction mixture was stirred overnight and excess of dimethyl sulfate was decomposed by heating at 95° for 1 h. It was diluted with water to dissolve residual sodium hydroxide, cooled in freezing mixture, and neutralized (sulfuric acid). The solution was dialyzed in running distilled water for 7 days to remove dimethyl sulfoxide and inorganic salts. The solution was concentrated to 100 ml and extracted with chloroform which on evaporation yielded a clear yellow glassy solid (4 g); $[\alpha]_D^{27}$ +28.3 (*c*, 1.5 H_2O). This product showed no hydroxyl absorption in the i.r. spectrum. Further methylations with Purdie reagents did not increase its methoxyl content.

Anal. Found: OCH_3, 43.3.

Fractionation of the Methylated Galactomannan

The methylated polysaccharide (3.8 g) was successively extracted with petroleum ether (40–60°) and chloroform mixture (100 ml) containing increasing proportions of the latter. During every stage the methylated residue was refluxed with solvent mixture for 2 h. Fractions 4, 5, and 6, which were analytically similar and together formed the major component (3.6 g), were combined and further study was carried out only on this material.

Sugars from the Methylated Galactomannan, their Characterization, and Estimation

A solution of methylated polysaccharide (1.5 g) in methanolic hydrogen chloride (4%, 125 ml) was refluxed for 10 h, cooled, neutralized (silver carbonate), filtered, and concentrated. The syrupy residue was then taken up in 1 *N* hydrochloric acid (125 ml) and heated for 8 h at 100°. The cooled solution was neutralized (silver carbonate) and filtered. Silver ions in the filtrate were removed by precipitation with hydrogen sulfide. The filtered solution was deionized and evaporated to a syrup. Paper chromatography in solvent *b* and *c* of this syrup showed three spots. But in the newly devised solvent *d*, the syrup showed four discrete spots which could be separated quantitatively on paper. The additional spot in this case was due to the resolution of the former slowest moving component into two. Table I shows the nature of different sugars.

Fraction I, 2,3,4,6-Tetra-O-methyl-D-galactose

The syrupy product had $[\alpha]_D^{30}$ +110° (*c*, 0.5 H_2O). Its demethylation gave galactose. Treatment of the syrup with aniline in the usual way yielded fine needles of *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-galactosylamine, m.p. and mixed m.p. 194° after recrystallization from ethyl acetate; lit. m.p. 192° (22).

Anal. Calcd. for tetramethyl hexose: OCH_3, 52.5. Found: OCH_3, 52.2.

Fraction II, 2,3,6-Tri-O-methyl-D-mannose

This component had $[\alpha]_D^{26}$ −7.6 (*c*, 1.0 H_2O). On demethylation it gave mannose with traces of galactose. Attempts to separate the two methylated sugars did not succeed. A portion of the syrup was oxidized with bromine water, lactonized in the usual way, and crystallized from acetone – petroleum ether. The resulting crystals of 2,3,6-tri-*O*-methyl-D-mannono-γ-lactone had m.p. 83–85°; lit. m.p. 84–85° (6). *N*-Phenyl-2,3,6-tri-*O*-methyl-D-mannosylamine prepared from another portion of the syrup had m.p. 130°; lit. m.p. 127–128° (23).

Anal. Calcd. for trimethyl hexose: OCH_3, 41.8. Found: OCH_3, 41.5.

Fraction III, 2,3-Di-O-methyl-D-mannose

The syrup had $[\alpha]_D^{25}$ −15.5 (*c*, 0.5 H_2O) and $[\alpha]_D^{25}$ +6.1 (*c*, 0.5 MeOH). Upon demethylation this component gave mannose only. On treatment with *p*-nitrobenzoyl chloride, the sugar yielded 2,3-di-*O*-methyl-D-mannose-1,4,6-tri-*p*-nitrobenzoate m.p. 192–194°; lit. m.p. 192–194° (14).

Anal. Calcd. for dimethyl hexose: OCH_3, 29.8. Found: OCH_3, 29.5.

Fraction IV, 4,6-Di-O-methyl-D-mannose

This component was obtained as glassy solid $[\alpha]_D^{25}$ +23.7 (*c*, 1.0 H_2O) and it gave mannose only on demethylation. It was characterized through its crystalline isopropylidine derivative, m.p. 77°, after recrystallization with petroleum ether; lit. m.p. 76–77° (24).

Anal. Calcd. for dimethyl hexose: OCH_3, 29.8. Found: OCH_3, 29.6.

The mixture of methylated sugars was separated on Whatman No. 1 paper in solvent *d* and the different zones containing methylated sugars were cut out and eluted. The eluted sugars were estimated by hypoiodite titrations (25) and fractions I, II, III, and IV were found to be in the molar ratio of 2:4.2:1:1.

Periodate Oxidation of the Galactomannan

The polysaccharide (141 mg) was dissolved in water (70 ml) and the solution cooled to 0°. A cold solution of 0.12 *M* sodium metaperiodate (30 ml) was added to it and reaction was carried out at 5°. The periodate consumption was determined (26) by treating the solution with excess of potassium iodide after buffering it with borax–boric acid and titrating the liberated iodine equivalent to unreacted periodate with 0.12 *N* sodium arsenite. After destroying the excess of periodate with ethylene glycol, the liberated formic acid was titrated with 0.01 *N* sodium hydroxide solution. The two estimations were done at different time intervals. Titre values became constant after 93 h which corresponded to 1.09 moles of periodate and 0.26 mole of formic acid per hexose unit.

Periodate Degradation of the Galactomannan (18)

The polysaccharide (1.5 g) was oxidized with sodium metaperiodate as mentioned above. The excess periodate was destroyed, solution was dialyzed in running distilled water for 5 days and concentrated to 400 ml. To this solution was added sodium borohydride (1.3 g) to effect reduction of polyaldehyde to corresponding polyalcohol. After standing at room temperature for 20 h, the solution was neutralized (acetic acid), deionized, and evaporated to dryness. After removing boric acid by repeated evaporations with methanol, the residue was hydrolyzed with 1 *N* sulfuric acid (150 ml) for 12 h at 95°. The hydrolysate was neutralized (barium carbonate), filtered, deionized, and evaporated to a syrup. The chromatographic examination in solvent *e* revealed the presence of glycerol, erythritol, D-mannose, and traces of galactose. The alcohols gave very prominent spots if the developed chromatogram passed through silver nitrate and was sprayed with 1% aqueous alcoholic sodium metaperiodate before the final sodium hydroxide spray. The mixture was

TABLE I

Hydrolysis products from methylated galactomannan

Fraction number	Methylated sugar	Yield (mg)	R_G in solvent *b*	R_G in solvent *d*
I	2,3,4,6-tetra-*O*-Methyl-D-galactose	348	0.95	0.92
II	2,3,6-tri-*O*-Methyl-D-mannose	691	0.62	0.67
III	2,3-di-*O*-Methyl-D-mannose	160	0.27	0.34
IV	4,6-di-*O*-Methyl-D-mannose	152	0.27	0.24

R_G values are with reference to 2,3,4,6-tetra-*O*-methyl-D-glucose.

resolved into its components using solvent *e* and Whatman 3 MM papers.

Identification and Estimation of Glycerol, Erythritol, and D-*mannose*

Fraction 1 (140 mg) was glycerol, identified by the preparation of its tri-*p*-nitrobenzoate, m.p. and mixed m.p. 185–186°; lit. m.p. 186–188° (13). Fraction 2 (370 mg) which was erythritol had m.p. and mixed m.p. 121°; lit. m.p. 120–122° (27). It was converted into tetra-*O*-tosyl-erythritol, m.p. and mixed m.p. 164–165°; lit. m.p. 165–166° (27). Fraction 3 (78 mg) on chromatographic examination was found to be D-mannose containing ca. 5–10% galactose. D-mannose was separated on paper in solvent *a* and had $[\alpha]_D^{22}$ +14.1 (*c*, 0.4 H_2O) and was converted into its crystalline *p*-nitroaniline derivative, m.p. and mixed m.p. 217–218°.

The mixture was separated on paper in solvent *e*, the strips corresponding to different components were cut out and eluted. Glycerol and erythritol were estimated by periodate – chromotropic acid method (28) and mannose by phenol–sulfuric acid method (29). The ratio of glycerol, erythritol, and mannose was 1.94:5:1.08.

Acknowledgments

The authors express their sincere thanks to Shri S. C. Gupta, Director, for his kind interest in this investigation. One of the authors (V.P.K.) is also grateful to the Ministry of Education, Government of India, for the award of a senior research scholarship.

NOTES

Some *O*-isopropylidene derivatives of D-ribose diethyl dithioacetal

D. G. LANCE, W. A. SZAREK, AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received December 19, 1968

Acetonation of D-ribose diethyl dithioacetal using anhydrous copper sulfate as catalyst gives predominantly 2,4- and 4,5-*O*-isopropylidene derivatives. The structures of the compounds were established by chemical and nuclear magnetic resonance spectroscopic methods.

L'acétonation du D-ribose diethyl dithioacetal, utilisant le sulfate de cuivre anhydre comme catalyseur, conduit essentiellement aux donnés 2,4- et 4,5-*O*-isopropylideniques. Les structures de ces composés ont été vérifiées par des méthodes chimiques et spectroscopiques (résonance magnétique nucléaire).

Canadian Journal of Chemistry, 47, 2889 (1969)

The acetonation of aldose dithioacetals has been studied by a number of investigators (1, 2). In a previous paper (3) from this laboratory, the formation of 2,3:4,5-di-*O*-isopropylidene-D-xylose diethyl dithioacetal from D-xylose diethyl dithioacetal and acetone was described, with either a strongly acidic ion-exchange resin or anhydrous copper sulfate as catalyst; partial acetonation yields the 4,5-, 3,4-, 2,3-, and 2,4-*O*-isopropylidene derivatives. We report now the preparation of some *O*-isopropylidene derivatives of D-ribose diethyl dithioacetal.

Acetonation of D-ribose diethyl dithioacetal using anhydrous copper sulfate as catalyst gives predominantly two mono-*O*-isopropylidene derivatives. These were isolated by column chromatography, and characterized as 4,5- and 2,4-*O*-isopropylidene-D-ribose diethyl dithioacetals.[1] The evidence for these assignments is given below. Thin-layer chromatographic (t.l.c.) examination of the reaction mixture showed, in addition, the presence of small amounts of two compounds with mobilities expected of di-*O*-isopropylidene derivatives. The structures of these compounds have not been investigated in this work. It has been reported (4), however, that D-ribose diethyl dithioacetal gives the 2,3:4,5-di-*O*-isopropylidene derivative on reaction with acetone in the presence of anhydrous copper sulfate and concentrated sulfuric acid.

[1]The 4,5-*O*-isopropylidene derivative was required for the synthesis of 1-deoxy-2,3-di-*O*-methyl-D-erythritol, a compound which we have used in some structural studies.

4,5-O-Isopropylidene-D-ribose Diethyl Dithioacetal

The 4,5-*O*-isopropylidene derivative was the preponderant product formed in the acetonation reaction; it was obtained as a chromatographically homogeneous and analytically pure syrup (65%). The nuclear magnetic resonance (n.m.r.) spectrum of the compound, measured in methyl sulfoxide-d_6, showed signals of the hydroxyl protons as 1-proton doublets, and hence the two hydroxyl groups are both secondary (5). Methylation of the compound with subsequent desulfurization with Raney nickel and acid-catalyzed hydrolysis gave a 1-deoxy-di-*O*-methyl-D-ribitol. This derivative rapidly consumed periodate, and was shown to possess a primary hydroxyl group by n.m.r. spectroscopy in methyl sulfoxide-d_6. The above observations for a mono-*O*-isopropylidene derivative of D-ribose diethyl dithioacetal are consistent only with the 4,5-isomer; the 1-deoxy-di-*O*-methyl-D-ribitol is, therefore, the 2,3-isomer.

2,4-O-Isopropylidene-D-ribose Diethyl Dithioacetal

The 2,4-*O*-isopropylidene derivative was obtained also as a syrup (12%). Its n.m.r. spectrum, measured in methyl sulfoxide-d_6, showed signals of two hydroxyl protons as a doublet and a triplet, indicating that a secondary and a primary hydroxyl group are present. Reductive desulfurization gave a crystalline 1-deoxy-mono-*O*-isopropylidene-D-ribitol, which was resistant to oxidation with sodium periodate. The crystalline

compound was methylated and then hydrolyzed to give a 1-deoxy-di-*O*-methyl-D-ribitol, which was also resistant to periodate oxidation, and whose n.m.r. spectrum showed the presence of two secondary hydroxyl groups. Thus, the 2,4-*O*-isopropylidene substitution in D-ribose diethyl dithioacetal is established, and the 1-deoxy-di-*O*-methyl-D-ribitol, in this case, is the 3,5-isomer.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer Model 141 automatic polarimeter at 24 ± 2° in ethyl acetate unless otherwise stated. Thin-layer chromatography (t.l.c.) was performed with Silica Gel G as the adsorbent. The developed plates were air-dried, sprayed with 5% ethanolic sulfuric acid, and heated at about 150°. The term "petroleum ether" refers to the fraction of b.p. 60–80°. Nuclear magnetic resonance (n.m.r.) spectra were measured on a Varian T-60 spectrometer in methyl sulfoxide-d_6 and tetramethylsilane as external standard unless otherwise stated; the assignment of peaks to the protons of hydroxyl groups was confirmed by the addition of deuterium oxide. Vacuum distillations were carried out with a Gallenkamp microdistillation apparatus at 70–100°/~ 0.1 Torr.

*2,4- and 4,5-O-Isopropylidene-*D*-ribose Diethyl Dithioacetals*

D-Ribose diethyl dithioacetal (6) (2.0 g) in dry acetone (50 ml) was stirred with anhydrous copper sulfate (5 g) for 3 h at room temperature. The mixture was filtered, and the filtrate was concentrated to dryness. The syrupy residue was dissolved in chloroform, and the solution was washed with water, dried, and concentrated to give an almost colorless syrup. Thin-layer chromatography (2:3 ethyl acetate – petroleum ether) showed the presence of two main components, R_f 0.50 and 0.30, and small amounts of two other components, R_f 0.95 and 0.97. The syrup was chromatographed on silica gel, with the same solvent as eluent. 4,5-*O*-Isopropylidene-D-ribose diethyl dithioacetal was obtained as a syrup (1.52 g, 65%), $[\alpha]_D$ +9.8 ± 0.3° (*c*, 2.8 in chloroform); R_f 0.50 (t.l.c.); n.m.r. data (internal tetramethylsilane standard): τ 4.93, 5.12 (1-proton doublets, J = 6 Hz, secondary OH's), τ 5.5–7.0 (6 protons, sugar-chain H's), τ 7.1–7.5 (4-proton quartet, J = 7 Hz, thioethyl CH_2's), τ 8.6–9.0 (12 protons, CMe_2 and thioethyl Me's).

Anal. Calcd. for $C_{12}H_{24}O_4S_2$: C, 48.6; H, 8.2. Found: C, 48.5; H, 8.4.

2,4-*O*-Isopropylidene-D-ribose diethyl dithioacetal was obtained also as a syrup (0.29 g, 12%), $[\alpha]_D$ −16.7 ± 0.5° (*c*, 1.23); R_f 0.30 (t.l.c.); n.m.r. data: τ 4.80 (1-proton doublet, J = 6 Hz, secondary OH), τ 5.39 (1-proton triplet, J = 5 Hz, primary OH), τ 5.5–6.6 (6 protons, sugar-chain H's), τ 6.9–7.5 (4-proton quartet, J = 7 Hz, thioethyl CH_2's), τ 8.3–8.8 (12 protons, CMe_2 and thioethyl Me's).

Anal. Calcd. for $C_{12}H_{24}O_4S_2$: C, 48.6; H, 8.2. Found: C, 48.3; H, 8.2.

*4,5-O-Isopropylidene-2,3-di-O-methyl-*D*-ribose Diethyl Dithioacetal*

4,5-*O*-Isopropylidene-D-ribose diethyl dithioacetal (1.4 g) was methylated at room temperature by a modification (3) of the method of Falconer and Adams (7). The product was purified by chromatography on silica gel, with 1:4 ethyl acetate – petroleum ether as eluent, to give a mobile oil (1.0 g, 65%), $[\alpha]_D$ +24.0 ± 0.5° (*c*, 1.25); R_f 0.7 (t.l.c.).

Anal. Calcd. for $C_{14}H_{28}O_4S_2$: C, 51.9; H, 8.6. Found: C, 52.2; H, 8.9.

*1-Deoxy-2,3-di-O-methyl-*D*-ribitol*

A solution of 4,5-*O*-isopropylidene-2,3-di-*O*-methyl-D-ribose diethyl dithioacetal (1.0 g) in ethanol (50 ml) was heated in the presence of freshly prepared Raney nickel (8) (~ 6 g) for 8 h at reflux temperature. The product was purified by chromatography on silica gel, with 1:4 ethyl acetate – petroleum ether as eluent, to give an oil (0.30 g, 54%), $[\alpha]_D$ +16.4 ± 0.3° (*c*, 1.65); R_f 0.4 (t.l.c., 1:5 ethyl acetate – petroleum ether). This material (0.28 g) was hydrolyzed overnight at room temperature in methanol (20 ml) and *N* sulfuric acid (5 ml). The product (0.20 g, 92%) was purified by vacuum distillation to give 1-deoxy-2,3-di-*O*-methyl-D-ribitol as a colorless oil, $[\alpha]_D$ +38.6 ± 0.5° (*c*, 1.0); n.m.r. data: τ 5.25 (1-proton, secondary OH), τ 5.48 (1-proton triplet, J = 5.5 Hz, primary OH), τ 6.43, 6.55 (3-proton singlets, OMe's), τ 8.75 (3-proton doublet, J = 6 Hz, CMe). Thin-layer chromatographic analysis revealed only one component, with R_f 0.4 in ethyl acetate; a spot appeared within 1 min with sodium periodate – potassium permanganate spray (9). An aqueous solution of the compound (~ 5 mg) and sodium periodate (~ 25 mg) was left to stand at room temperature. After 30 min, t.l.c. showed that the starting material had all reacted.

*1-Deoxy-2,4-O-isopropylidene-*D*-ribitol*

2,4-*O*-Isopropylidene-D-ribose diethyl dithioacetal (0.23 g) was treated with Raney nickel as described above. The product crystallized from ethyl acetate – petroleum ether. Recrystallization from chloroform – petroleum ether gave the analytically pure desulfurized compound (0.08 g, 58%), m.p. 132.5–133°, $[\alpha]_D$ +12.0 ± 1° (*c*, 0.7); R_f 0.6 (t.l.c., ethyl acetate); n.m.r. data: τ 4.90 (1-proton doublet, J = 6.5 Hz, secondary OH), τ 5.40 (1-proton triplet, J = 5 Hz, primary OH), τ 8.36, 8.50 (3-proton singlets, CMe_2), τ 8.65 (3-proton doublet, J = 6 Hz, CMe). No spot appeared on a thin-layer chromatogram with sodium periodate – potassium permanganate spray, and the compound was unaffected by a sodium periodate solution.

Anal. Calcd. for $C_8H_{16}O_4$: C, 54.6; H, 9.1. Found: C, 54.5; H, 9.2.

*1-Deoxy-3,5-di-O-methyl-*D*-ribitol*

1-Deoxy-2,4-*O*-isopropylidene-D-ribitol (20 mg) was methylated (3), and the product was hydrolyzed by heating a solution in methanol (1 ml) and *N* sulfuric acid (0.25 ml) for 1 h at reflux temperature. The resulting syrup was purified by vacuum distillation to give 1-deoxy-3,5-di-*O*-methyl-D-ribitol as a colorless oil, $[\alpha]_D$ +9.1 ± 1° (*c*, 0.75 in chloroform); R_f 0.5 (t.l.c., ethyl acetate); n.m.r. data: τ 5.24, 5.48 (1-proton doublets, J = 5 Hz, secondary OH's), τ 6.57, 6.65 (3-proton singlets, OMe's), τ 8.89 (3-proton doublet, J = 6 Hz, CMe). No spot appeared

2-*O*-α-D-Glucopyranosyl-D-erythrose condensed with nitromethane in the presence of sodium methoxide to yield a mixture of 1-deoxy-3-*O*-α-D-glucopyranosyl-1-nitro-D-ribitol and 1-deoxy-3-*O*-α-D-glucopyranosyl-1-nitro-D-arabinitol which were converted *via* the Nef reaction to 3-*O*-α-D-glucopyranosyl-D-ribose and 3-*O*-α-D-glucopyranosyl-D-arabinose.

Canadian Journal of Chemistry, 47, 2891 (1969)

Methods for the synthesis of oligosaccharides involving lengthening of the carbon chain at the reducing end-group of known oligosaccharides have usually employed the addition of hydrogen cyanide (1–6) followed by reduction of the resulting acids to their corresponding reducing glycose derivatives. It was considered that the Fischer–Sowden (7) method of chain extension, if experimentally feasible, might provide a more convenient procedure for the synthesis of oligosaccharides which could possibly be extended to the synthesis of derivatives having 2-amino-2-deoxyglycose or 2-deoxyglycose reducing end-groups. This note records the application of the nitromethane method to 2-*O*-α-D-glucopyranosyl-D-erythrose.

2-*O*-α-D-Glucopyranosyl-D-erythrose condensed with nitromethane in the presence of sodium methoxide to yield a mixture of 1-deoxy-3-*O*-α-D-glucopyranosyl-1-nitro-D-ribitol and 1-deoxy-3-*O*-α-D-glucopyranosyl-1-nitro-D-arabinitol which could not be separated by fractional crystallization. The mixture, on treatment with dilute sulfuric acid, gave 3-*O*-α-D-glucopyranosyl-D-ribose and 3-*O*-α-D-glucopyranosyl-D-arabinose which were separated by cellulose column chromatography to yield pure samples of each oligosaccharide in approximately equal amounts and in a 52% overall yield from 2-*O*-α-D-glucopyranosyl-D-erythrose.

The two oligosaccharides were reduced to their corresponding 3-*O*-α-D-glucopyranosyl-pentitol derivatives which when oxidized with periodate

at pH 3 released almost immediately 2 moles of formaldehyde per mole of glycitol, followed by a much slower release of a third mole of formaldehyde. This result is consistent with an oligosaccharide having a 3-*O*-substituted pentitol end-group (8, 9).

Experimental

Paper chromatography was performed by the descending method on Whatman No. 1 filter paper using pyridine – ethyl acetate – water (2:5:5 v/v, top layer) as the mobile phase. Glycose derivatives were detected with alkaline silver nitrate (10) or *p*-anisidine hydrochloride (11) and their rates of movement are quoted relative to D-galactose (R_{gal}).

Melting points were determined on a Fisher–Johns apparatus and are corrected. Optical rotations were determined at room temperature using a Perkin–Elmer 141 polarimeter. Solutions were concentrated under reduced pressure and below 40 °C.

3-O-α-D-Glucopyranosyl-D-ribose and 3-O-α-D-Glucopyranosyl-D-arabinose

To a solution of 2-*O*-α-D-glucopyranosyl-D-erythrose (12) (14 g) in methanol (200 ml) was added nitromethane (55 ml) followed by a solution of sodium (2.5 g) in methanol (100 ml), and the mixture was shaken at room temperature for 18 h. Following the addition of ether (500 ml) the precipitated product was collected, washed with light petroleum (b.p. 30–60 °C), and dried (20.6 g). The mixed 1-deoxy-3-*O*-α-D-glucopyranosyl-1-nitro-D-ribitol and 1-deoxy-3-*O*-α-D-glucopyranosyl-1-nitro-D-arabinitol (19 g) was dissolved in 2 *N* sodium hydroxide (200 ml) and the solution was added dropwise with stirring to 6 *N* sulfuric acid (250 ml) cooled externally in an ice-bath. After 1 h the solution was allowed to stand at 20 °C for 2 h and following neutralization with barium carbonate, the filtered mixture was passed down a column of Rexyn 101(H^+) (250 ml) and Duolite A4(OH^-) (50 ml) ion-exchange resins and the eluate and washings were concentrated to a syrup (13 g).

The syrup was fractionated on a cellulose column (7 × 85 cm) using acetone – water mixture (7:1 v/v) as the mobile phase to yield first 3-*O*-α-D-glucopyranosyl-D-ribose (4.0 g) followed by 3-*O*-α-D-glucopyranosyl-D-arabinose (4.1 g).

3-O-α-D-Glucopyranosyl-D-ribose

The syrup of 3-*O*-α-D-glucopyranosyl-D-ribose gave a single spot on paper chromatography (R_{gal} 1.05), having $[\alpha]_D$ +90.5° (*c*, 3 in water), and on hydrolysis (2 *N* H_2SO_4 for 4 h at 98 °C) it gave D-glucose and D-ribose.

Anal. Calcd. for $C_{11}H_{20}O_{10}$: C, 42.31; H, 6.46. Found: C, 42.22; H, 6.50.

A portion of the oligosaccharide (0.6 g) was acetylated at room temperature with acetic anhydride (15 ml) containing zinc chloride (0.35 g) afforded a hepta-*O*-acetyl derivative as a syrup having $[\alpha]_D$ +77.2° (*c*, 1.2 in chloroform).

Anal. Calcd. for $C_{25}H_{34}O_{17}$: C, 49.50; H, 5.65. Found: C, 48.86; H, 5.64.

3-*O*-α-D-glucopyranosyl-D-ribose (10 mg) in water (10 ml) was reduced for 48 h at room temperature with sodium borohydride (50 mg) and after decationization with Rexyn 101(H^+) ion-exchange resin (15 ml), the concentrated product was evaporated from methanol solution (5 × 30 ml) to remove boric acid. The residue was dissolved in 0.2 *M* acetate buffer pH 3.0 and following the addition of 0.3 *M* sodium metaperiodate (4 ml), the mixture was made up to 50 ml with more acetate buffer. The mixture was analyzed at intervals for formaldehyde using the colorimetric chromotropic acid method (13). 1.98 moles of formaldehyde per mole of oligosaccharide were liberated almost immediately (3 min) followed by a slow release of 0.78 mole of formaldehyde (28 h).

3-O-α-D-Glucopyranosyl-D-arabinose

The syrup of 3-*O*-α-D-glucopyranosyl-D-arabinose gave a single spot on paper chromatography (R_{gal} 0.67), having $[\alpha]_D$ +51.4° → +46° (*c*, 2.7 in water) (lit. (14) $[\alpha]_D$ +57° → +47°) and on hydrolysis (2 *N* H_2SO_4 for 5 h at 98 °C) it gave D-glucose and D-arabinose.

Anal. Calcd. for $C_{11}H_{20}O_{10}$: C, 42.31; H, 6.46. Found: C, 41.80; H, 6.42.

A portion of the disaccharide (0.7 g), acetylated as described above, afforded hepta-*O*-acetyl-3-*O*-α-D-glucopyranosyl-(α-D-arabinose) which after recrystallization from methanol afforded the pure derivative (0.58 g) which had m.p. 192 °C and $[\alpha]_D$ +15.1° (*c*, 1.6 in chloroform). (Nuclear magnetic resonance H-1(arabinose) τ 3.73 spacing 3.7 c.p.s.)

Anal. Calcd. for $C_{25}H_{34}O_{17}$: C, 49.50; H, 5.65. Found: C, 49.42; H, 5.47.

Periodate oxidation of 3-*O*-α-D-glucopyranosyl-D-arabinitol, prepared, and treated as described above, resulted in the rapid release of 1.92 moles of formaldehyde per mole of glycitol (5 min) followed by the slow release of a further 0.69 mole of formaldehyde (22 h).

Synthesis of 3-deoxy-D-*galacto*-octulosonic acid[1]

M. B. PERRY AND ANN C. WEBB
Division of Biochemistry and Molecular Biology, National Research Council of Canada, Ottawa, Canada

Received March 27, 1969

3-Deoxy-D-*galacto*-octulosonic acid was prepared by oxidation of 3-deoxy-D-*glycero*-L-*manno*-octonic acid, and 3-deoxy-D-*glycero*-L-*gluco*-octonic acid made by the action of sodium cyanide on 2-deoxy-D-*galacto*-heptose. Gas–liquid chromatographic procedures for the detection and quantitative analysis of the 3-deoxy-D-*galacto*-octulosonic acid are described.

Canadian Journal of Chemistry, 47, 2893 (1969)

The important role of 3-deoxy-D-*manno*-octulosonic acid as a component of the cell wall lipopolysaccharides of gram negative bacteria is well established (1–5). A recent investigation of the hydrolyzates of several lipopolysaccharide preparations in this laboratory (6) in some cases suggested that an additional 3-deoxyoctulosonic acid was also present, and this prompted us to devise a general synthetic method for the preparation of reference 3-deoxyoctulosonic acids involving the use of 2-deoxyheptoses of known configuration as starting materials.

The chemical synthesis of 3-deoxy-D-*manno*-octulosonic acid has been made by the condensation of D-arabinose with oxalacetic acid (4, 7) or di-*tert*-butyl oxalacetate (8), and Kochetkov *et al.* (9) has described a new synthetic approach in which a monosaccharide is transformed by the Wittig reaction into a 3,4-dideoxyglyculos-3-enoic acid with subsequent lactonization. The present work involving the addition of sodium cyanide to a 2-deoxyheptose to yield epimeric 3-deoxyoctonic acids, which undergo oxidation to yield a 3-deoxyoctulosonic acid derivative having the same configuration of the hydroxyl groups as those present in the starting 2-deoxyheptose, appears to give a general route to the practical synthesis of standard 3-deoxyoctulosonic acids.

On treatment with sodium cyanide, 2-deoxy-D-*galacto*-heptose (10) was converted in almost quantitative yield to a mixture of 3-deoxy-D-*glycero*-L-*manno*-octonic acid and 3-deoxy-D-*glycero*-L-*gluco*-octonic acid, and the mixed acids after conversion to their potassium salts were oxidized with a vanadium chloride – potassium chlorate catalyst, developed by Sprinson *et al.* (11), to yield 3-deoxy-D-*galacto*-octulosonic acid in a 60% overall yield from the 2-deoxy-D-*galacto*-heptose.

The reduction of 3-deoxy-D-*galacto*-octulosonic acid with sodium borohydride gave 3-deoxy - D - *glycero* - L - *manno* - octonic acid and 3-deoxy-D-*glycero*-L-*gluco*-octonic acid, whose lactone derivatives were indistinguishable on paper chromatograms from the lactones of the acids prepared by the addition of cyanide to 2 - deoxy - D - *galacto* - heptose. Similarly the trimethylsilylated 3-deoxyoctonolactones (12, 13) from reduced 3-deoxy-D-*galacto*-octulosonic acid on gas chromatography gave two peaks corresponding in retention times with the trimethylsilyl derivatives of the lactones from the cyanide addition to the 2-deoxy-D-*galacto*-heptose. The 3-deoxy-D-*galacto*-octulosonate after reduction was degraded with ceric sulfate (4, 14) to give 2-deoxy-D-*galacto*-heptose. The above evidence indicates that the catalytic oxidation occurred exclusively at C-2 of the 3-deoxyoctonic acid derivatives, and that the hydroxyl groups of the 3-deoxy-octulosonic acid had the D-*galacto* configuration.

Trimethylsilylation of either free 3-deoxy-D-*galacto*-octulosonic acid or its ammonium salts with bis(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane gave a product, which on gas–liquid chromatography gave a single peak. The procedure could be extended to the quantitative analysis of the acid using D - *glycero* - D - *gulo* - heptono - 1,4 - lactone or α-androstane as an internal standard in the trimethylsilylating mixture. The standards give an equal molar response to the octulosonic acid derivative, thus providing a convenient method for the quantitative analysis of 3-deoxy-D-*galacto*-octulosonic acid. The gas–liquid chromatographic

For personal use only.

method demonstrated that 3-deoxy-D-*galacto*-octulosonate was not a component of any lipopolysaccharide preparation examined so far in this laboratory (6).

Experimental

Paper chromatography was performed by the descending method on Whatman No. 1 filter paper using the solvent systems: (*a*) pyridine – ethyl acetate – water (2:5:5 v/v, top layer) and (*b*) butan-1-ol – pyridine – 0.1 *N* hydrochloric acid (5:3:2 v/v). Compounds were detected on the chromatograms with either (*a*) alkaline silver nitrate (15), or (*b*) periodate – 2-thiobarbiturate (16) spray reagents, and their rates of movement are quoted relative to D-galactose (R_{gal}).

Gas–liquid chromatography was performed using a Hewlett–Packard 402 gas chromatograph with a hydrogen flame detector and fitted with glass U tubes (4 ft × 6 mm × 3 mm internal diameter) packed with either (*a*) 2.5% (w/w) SE-30 on 80–100 mesh acid washed Chromosorb W, (*b*) 10% (w/w) neopentylglycol sebacate polyester on 80–100 mesh acid washed Chromosorb W, or (*c*) a mixture of 1.5% (w/w) neopentylglycol sebacate polyester and 1.5% (w/w) GE–XF 1150 (Applied Science Laboratories Inc., Pa.) on 80–100 mesh acid washed Chromosorb W. Development was made with dry helium at a flow rate of 100 ml per min and samples were injected directly onto the column packing material without the use of the flash heating system. Retention times are quoted relative to penta-*O*-acetyl-L-arabinitol (T_A).

Optical rotations were determined at 20 °C using a Perkin–Elmer 141 polarimeter. Infrared (i.r.) spectra were obtained by the potassium bromide disk technique using a Perkin–Elmer Infracord 237B. Solutions were concentrated under reduced pressure and below 40 °C.

Synthesis of 3-Deoxy-D-galacto-octulosonic Acid

To 2-deoxy-D-*galacto*-heptose (10) (0.3 g) dissolved in water (2.3 ml) and cooled in ice was added a fresh cold solution of sodium cyanide (0.15 g) in water (1.2 ml) and the mixture was left at 0 °C for 4 days. The mixture was aerated and kept at 70 °C for 4 h and the cooled solution was then passed down a column of Rexyn 101(H^+) ion-exchange resin (8 ml). The eluate and washings were concentrated to a syrup (0.36 g) which was shown by paper chromatography to have two components having R_{gal} 1.68 and 1.84 (solvent *a*), R_{gal} 1.13 and 1.26 (solvent *b*). The trimethylsilylated (12, 13) 3-deoxyoctonolactones on gas–liquid chromatography again indicated the presence of two products having retention times expected of 3-deoxy-octono-1,4-lactones T_A 0.74 (33%) and 0.83 (67%) (column *b*, 198 °C), and T_A 0.86 (34%) and 0.97 (66%) (column, *c*, 200 °C). The i.r. spectrum of the mixed lactones showed a strong carbonyl absorption at 1770 cm^{-1} indicative of 1,4-lactone structure.

The mixture of 3-deoxy-D-*glycero*-(L-*manno*- and L-*gluco*)-octono-1,4-lactone (0.32 g) was neutralized with 0.5 *N* potassium hydroxide to the phenolphthalein end-point. A suspension (3.2 ml) of the oxidation catalyst, prepared by dissolving vanadium pentoxide (75 mg) in concentrated hydrochloric acid (4.5 ml) and adding pyridine (4.5 ml) followed by adjustment to pH 3.2 with HCl or pyridine (11), was added, followed by potassium chlorate (0.11 g). The mixture was stirred at room temperature for 8 h and was then neutralized with ammonium hydroxide to the phenolphthalein end-point and the free pyridine was extracted with chloroform. The residual aqueous solution was lyophilized to give a yellow powder (1.4 g) which was subjected to cellulose column chromatography (3.5 × 25 cm) using 75% aqueous acetone as the mobile phase. The portion of the eluant giving a positive reaction with the periodate–thiobarbiturate reagent was collected and concentrated to a small volume. After passage through Rexyn 101 (H^+) ion-exchange resin (5 ml) the eluate was neutralized with ammonium hydroxide and lyophilized to give ammonium 3-deoxy-D-*galacto*-octulosonate (0.25 g), which failed to crystallize from aqueous ethanol and had $[\alpha]_D$ −43° (*c*, 0.3 in water).

Anal. Calcd. for $C_8H_{19}O_9N$: C, 34.78; H, 6.88; N, 5.07. Found: C, 34.5; H, 6.5; N, 4.9.

The i.r. spectrum of ammonium 3-deoxy-D-*galacto*-octulosonate was almost identical with that of lyophilized ammonium 3-deoxy-D-*manno*-octulosonate exhibiting peaks at 3350, 1600 (strong), 1430, 1205, 1143, 1052, 1025, 970, 924, 883, 840, and 775 cm^{-1}.

On paper chromatography the ammonium 3-deoxy-D-*galacto*-octulosonate gave a single spot having R_{gal} 0.27 (solvent *a*) and 0.26 (solvent *b*). The ammonium salt or free 3-deoxyoctulosonic acid after trimethylsilylation in acetonitrile at 80 °C for 2 h with bis(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane (REGISIL™ – TMCS, Regis Chemical Co., Chicago, Ill.) on gas–liquid chromatography gave a single peak T_A 3.50 (column A, 200 °C). It was readily distinguished from the peaks at T_A 2.60 and 3.00 arising for the trimethylsilylated product of 3-deoxy-D-*manno*-octulosonate analyzed under the same conditions.

Synthetic mixtures of ammonium 3-deoxy-D-*galacto*-octulosonate (ca 30–100 μg) and either D-*glycero*-D-*gulo*-heptono-1,4-lactone or α-androstane were trimethylsilylated as described above. On gas–liquid chromatography using column *a* at 200 °C, it was found that the areas of the peaks of the internal standards D-*glycero*-D-*gulo*-heptono-1,4-lactone (T_A 3.30) and α-androstane (T_A 1.57) gave a 1:1 molar response to the 3-deoxy-D-*galacto*-octulosonate peak area. The procedure affords a convenient method of its analysis with an accuracy of ±3%.

Reduction of 3-Deoxy-D-galacto-octulosonic Acid

Ammonium 3-deoxy-D-*galacto*-octulosonate (20 mg) in water (4 ml) was stirred for 1 h with barium carbonate (0.1 g) and, after filtration, the filtrate was treated with sodium borohydride (40 mg) at room temperature for 3 h. Excess borohydride was destroyed by acidification with acetic acid and the mixture, after passage down a column of Rexyn 101 (H^+) ion-exchange resin (5 ml), was concentrated to dryness and the residue was again concentrated from methanol solution (5 × 12 ml) to remove boric acid. The residue when examined on paper chromatography showed two spots having R_{gal} 1.68 and 1.84 (solvent *a*) and R_{gal} 1.13 and 1.26 (solvent *b*) corresponding to the 3-deoxy-octono-1,4-lactones derived from the addition of cyanide to 2-deoxy-D-*galacto*-

heptose. The trimethylsilylated (12, 13) residue on gas chromatography showed only two peaks having T_A 0.74 (56%) and 0.83 (44%) (column *b*, 198 °C) and T_A 0.86 (55%) and 0.97 (45%) (column *c*, 200 °C) corresponding in retention times with the trimethylsilylated 3-deoxy-octono-1,4-lactones obtained directly from 2-deoxy-D-*galacto*-heptose.

*Ceric Sulfate Degradation of 3-Deoxy-*D*-galacto-octulosonic Acid*

Ammonium 3-deoxy-D-*galacto*-octulosonate (40 mg) was reduced with borohydride and the product was oxidized with ceric sulfate as described by Ghalambor *et al.* (4). The product was fractionated on paper chromatograms and the component having R_{gal} 1.40 (solvent *a*) corresponding to 2-deoxy-D-*galacto*-heptose was collected (8 mg). The heptose (8 mg) was reduced with borohydride and was acetylated to yield 1,3,4,5,6,7-hexa-*O*-acetyl-2-deoxy-D-*galacto*-heptitol (5 mg) which had m.p. and mixture m.p. 118 °C and $[\alpha]_D$ +10° (0.05 in methanol) and on gas chromatography it gave a single peak having T_A 4.41 (column *b*, 200 °C) having the same retention time as an authentic specimen.

Nuclear magnetic resonance studies of cyanide ion–2,4,6-trinitroanisole σ-complexes

A. R. NORRIS
Department of Chemistry, Queen's University, Kingston, Ontario

Received February 12, 1969

Nuclear magnetic resonance studies at −30 °C reveal that the cyanide ion reacts with 2,4,6-trinitroanisole to form σ-complexes by attachment of the cyanide ion at both the C-1 and C-3 positions on the ring. In contrast to the methoxide ion adducts of 2,4,6-trinitroanisole, the cyanide ion adduct resulting from attack of the cyanide at the C-3 position is the more stable species.

Canadian Journal of Chemistry, 47, 2895 (1969)

The interactions of neutral or anionic bases with 1-R-2,4,6-trinitrobenzenes (R = CH_3, CHO, Cl, CH_3O, NH_2, CH_3NH) can lead to a variety of products including the σ-complexes **1** and **2** resulting from addition of the base at either the C-1 or the C-3 position (1).

In both chloroform and acetone, the cyanide ion reacts with 2,4,6-trinitrotoluene to form complexes of type **2** (R = CH_3; Y = CN) while with 2,4,6-trinitrobenzaldehyde in the same solvents, complexes of type **1** (R = CHO; Y = CN) are formed (2). In each of these systems, attack of the cyanide ion is either specific at the ring carbon indicated, or the isomeric complex, if formed, rearranges too rapidly to be detected at the temperature of observation (−30 °C).

heptose. The trimethylsilylated (12, 13) residue on gas chromatography showed only two peaks having T_A 0.74 (56%) and 0.83 (44%) (column *b*, 198 °C) and T_A 0.86 (55%) and 0.97 (45%) (column *c*, 200 °C) corresponding in retention times with the trimethylsilylated 3-deoxy-octono-1,4-lactones obtained directly from 2-deoxy-D-*galacto*-heptose.

*Ceric Sulfate Degradation of 3-Deoxy-*D*-galacto-octulosonic Acid*

Ammonium 3-deoxy-D-*galacto*-octulosonate (40 mg) was reduced with borohydride and the product was oxidized with ceric sulfate as described by Ghalambor *et al.* (4). The product was fractionated on paper chromatograms and the component having R_{gal} 1.40 (solvent *a*) corresponding to 2-deoxy-D-*galacto*-heptose was collected (8 mg). The heptose (8 mg) was reduced with borohydride and was acetylated to yield 1,3,4,5,6,7-hexa-*O*-acetyl-2-deoxy-D-*galacto*-heptitol (5 mg) which had m.p. and mixture m.p. 118 °C and $[\alpha]_D$ +10° (0.05 in methanol) and on gas chromatography it gave a single peak having T_A 4.41 (column *b*, 200 °C) having the same retention time as an authentic specimen.

Nuclear magnetic resonance studies of cyanide ion–2,4,6-trinitroanisole σ-complexes

A. R. NORRIS
Department of Chemistry, Queen's University, Kingston, Ontario

Received February 12, 1969

Nuclear magnetic resonance studies at −30 °C reveal that the cyanide ion reacts with 2,4,6-trinitroanisole to form σ-complexes by attachment of the cyanide ion at both the C-1 and C-3 positions on the ring. In contrast to the methoxide ion adducts of 2,4,6-trinitroanisole, the cyanide ion adduct resulting from attack of the cyanide at the C-3 position is the more stable species.

Canadian Journal of Chemistry, 47, 2895 (1969)

The interactions of neutral or anionic bases with 1-R-2,4,6-trinitrobenzenes (R = CH_3, CHO, Cl, CH_3O, NH_2, CH_3NH) can lead to a variety of products including the σ-complexes **1** and **2** resulting from addition of the base at either the C-1 or the C-3 position (1).

In both chloroform and acetone, the cyanide ion reacts with 2,4,6-trinitrotoluene to form complexes of type **2** (R = CH_3; Y = CN) while with 2,4,6-trinitrobenzaldehyde in the same solvents, complexes of type **1** (R = CHO; Y = CN) are formed (2). In each of these systems, attack of the cyanide ion is either specific at the ring carbon indicated, or the isomeric complex, if formed, rearranges too rapidly to be detected at the temperature of observation (−30 °C).

Servis (3) has shown that the reaction of 2,4,6-trinitroanisole with methoxide ion in dimethylsulfoxide – methanol at room temperature yields initially the type **2** complex (R = Y = OCH_3). This complex undergoes a rapid conversion to the thermodynamically more stable **1** product (R = Y = OCH_3), the nuclear magnetic resonance (n.m.r.) characteristics of which are reported by Crampton and Gold (4). With sulfite ion in dimethylsulfoxide – water, 2,4,6-trinitroanisole forms only complex **2** (R = OCH_3; Y = SO_3^-) (5), while with azide ion in acetone-d_6 and acetonitrile-d_3 at −40 °C only σ-complexes of type **1** (R = OCH_3; Y = N_3) have been observed (6).

We wish to report that the cyanide ion also reacts with 2,4,6-trinitroanisole to form two types of σ-complexes. In contrast to the methoxide ion adducts, the cyanide ion σ-complex of type **2** is more stable than the σ-complex of type **1**.

The proton n.m.r. spectrum of 2,4,6-trinitroanisole (TNA) in deuteriochloroform at −30 °C shows resonance absorptions at 9.08 and 4.27 p.p.m. (sharp singlets, relative band areas 2:3)[1]. A deuteriochloroform solution containing 2,4,6-trinitroanisole (0.6 *M*) and tetraphenylarsonium cyanide (0.4 *M*) shows, in addition to the parent TNA peaks now shifted to 9.09 and 4.26 p.p.m. and the multiplet in the 7.8 p.p.m. region due to the tetraphenylarsonium group, new resonances at 8.90 (singlet), 8.64 (doublet), 5.73 (doublet), 3.98 (singlet), and 3.73 (singlet) p.p.m. The absorptions at 8.64, 5.73, and 3.98 p.p.m. have relative areas of 1:1:3 while the absorptions at 8.90 and 3.13 p.p.m. have areas in the ratio of 2:3. The splitting of both the 8.64 and the 5.73 absorption bands is 0.80 c.p.s. The complete spectrum is developed immediately on mixing and both the band positions and the band intensities remain unchanged even after several hours at −30 °C.

The appearance of these new absorptions is consistent with the formation of both σ-complexes **1** and **2** (R = OCH_3; Y = CN). The absorptions at 8.90 and 8.64 p.p.m. are assigned to the H_α hydrogens of **1** and **2** respectively while the absorption at 5.73 is assigned to the H_β hydrogen in complex **2**. The assignments are made on the basis of the chemical shifts observed in the cyanide ion complexes of 1,3,5-trinitrobenzene and 2,4,6-trinitrotoluene (2) and the methoxide ion complexes of 2,4,6-trinitroanisole (3, 4, 7–9). Representative data for these systems are listed in Table I. As in the case of the methoxide ion adducts, the methoxyl group hydrogens in the **1** complex absorb further upfield than the methoxyl group hydrogens in the **2** complex, while the H_α protons in the **1** complex absorb further downfield than the H_α proton in the **2** complex (3).

For the cyanide ion-2,4,6-trinitroanisole system in deuteriochloroform, the integrated areas of the bands due to both the ring and the methyl hydrogens indicate that approximately 70% of the added TNA has been converted to complex under the stated reaction conditions. Of the total complex generated, 80 ± 2% is in the form of complex **2** and 20 ± 2% is in the form of complex **1**. On warming the solution to −6.5 °C, one finds that 60% of the added TNA is now in the form of complex and that of the total complex present, 85 ± 2% is in the form of complex **2** and 15 ± 2% is in the form of complex **1**. The observations suggest that the heat of formation of complex **1** is more negative than the heat of formation of complex **2**.

Irreversible reactions occur when the solutions are warmed to room temperature. Complex **1** disappears rapidly followed by a much slower disappearance of **2**. The solutions which result after several hours possess very complex spectra which suggests that a number of reaction products have been formed. Unlike the spectra obtained in the case of the cyanide–1,3,5-trinitrobenzene and cyanide–2,4,6-trinitrotoluene reactions, the resulting bands in this case are still very sharp.

If deuteriochloroform solutions containing TNA and tetraphenylarsonium cyanide are prepared at room temperature and their spectra recorded as soon as possible after mixing, only the absorption pattern characteristic of complex **2** is observed. This pattern is slowly replaced by that characteristic of the reaction products.

Both types of complex are also formed when 2,4,6-trinitroanisole and tetraphenylarsonium cyanide are allowed to react at −30 °C in

[1]Chemical shifts are quoted relative to a 6% solution of tetramethylsilane in $CHCl_3$ as external standard. Spectra were recorded on Varian A-60 and HA60 instruments.

acetone-d_6. Once again the type **2** complex predominates at −30 °C and is the complex which disappears the least rapidly as the temperature of the solution is raised to room temperature. The chemical shift data (relative to tetramethylsilane internal standard) characteristic of these two cyanide ion complexes of 2,4,6-trinitroanisole in deuterioacetone are given in Table I.

Further studies relating to the effect of solvent on the stabilities and rates of formation and decay of these two types of cyanide ion–2,4,6-trinitroanisole complex are planned.

Acknowledgments

Financial support by the National Research Council of Canada is gratefully acknowledged. The author is indebted to Dr. Art Grey, National Research Council of Canada, Ottawa, for recording a number of the spectra on the Varian HA-60 spectrometer.

Reaction of *m*-methoxyphenol with trichloromethanesulfenyl compounds. A novel route to sulfines

G. DENIS THORN
Research Institute, Canada Department of Agriculture, London, Ontario

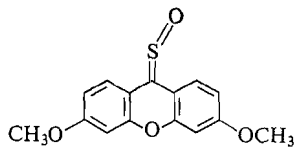
Received March 11, 1969

The reaction of *m*-methoxyphenol with various compounds containing the trichloromethanesulfenyl moiety gives 3,6-dimethoxyxanthione-*S*-oxide.

Canadian Journal of Chemistry, 47, 2898 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The standard method of analysis of captan (*N*-trichloromethanesulfenyl-4-cyclohexene-1,2-dicarboximide) is based on a yellow color produced on heating the test material with resorcinol at 140 °C (1). We have found that *m*-methoxyphenol can be substituted advantageously for resorcinol in the analytical procedure. The structure of the main reaction product on which the analysis is based is proposed to be 3,6-dimethoxyxanthione-*S*-oxide **1**.



1

The assignment of structure **1** is based on elemental analyses and the following considerations. The intense absorption peak at 420 mμ, log ε 4.54 (ethanol) is characteristic of xanthione-*S*-oxides. (Zwanenburg *et al.* (2) give for xanthione-*S*-oxide, λ_{max} 410 mμ, log ε 4.02 (cyclohexane) and for 10-thiaxanthene-9-thione-*S*-oxide, λ_{max} 420 mμ, log ε 3.85.) Characteristic infrared (i.r.) absorptions for the sulfine[1] group (2, 4) are given at 1125 and 1015 cm^{-1} ($CHCl_3$). The proton magnetic resonance spectrum (CF_3COOH) indicates a symmetrical molecule with one *O*-methyl group to three aromatic H showing an ABX pattern almost identical with that given by 3,6-dimethoxyxanthione.

Attempted oxidation with perphthalic acid (2) of 3,6-dimethoxyxanthione to the sulfine yielded in our hands only the corresponding xanthone and unchanged starting material. Spectroscopic monitoring of the reaction, however, indicated transient existence of the sulfine.

[1]Sheppard and Diekmann (3) suggested the name sulfines for thioketone-*S*-oxides.

The same sulfine **1** is obtained by fractionation and methylation (diazomethane) of the reaction product of resorcinol and captan heated at 140 °C, and also, in about the same yield, by reacting *m*-methoxyphenol with various other compounds containing the trichloromethanesulfenyl moiety, including perchloromethylmercaptan, folpet (*N*-trichloromethanesulfenylphthalimide), *N*-trichloromethanesulfenylmorpholine, *N*,*N*-dimethyltrichloromethanesulfenamide, and *N*,*N*-diethyltrichloromethanesulfenamide. The sulfine is not obtained on reaction of thiophosgene and *m*-methoxyphenol under the above conditions.

The low yields obtained are explicable in part by other colored compounds formed in the macro reaction, none of which, however, shows the intense absorption in the 420 mμ region displayed by the isolated sulfine. In the micro, analytical, reaction, the sulfine is formed in yields of 65–85%, depending on the trichloromethanesulfenyl compound involved.

Experimental

Melting points were determined on a Büchi melting point apparatus and are uncorrected. Elemental analyses were performed by C. Daesslé, Montreal. The mass spectrum was determined by the Morgan–Schaffer Corp., Montreal. Infrared spectra were recorded on a Perkin–Elmer 21 spectrophotometer and the nuclear magnetic resonance spectra obtained with the Varian A-60A spectrophotometer.

3,6-Dimethoxyxanthione-S-oxide (*I*)

Captan (1.0 g) was heated in an open test tube with 2.0 ml of *m*-methoxyphenol at 140–145 °C for 20 min. The dark-red product was dissolved in 5 ml of glacial acetic acid and the solution poured into 100 ml of water. The resulting solid was removed by filtration and dried *in vacuo*. The portion soluble in methylene chloride was fractionated by passing through a column of Woelm acid alumina, methylene chloride being used as eluting solvent. The first fraction consisted of brilliant yellow needles, (55 mg) with m.p. 255–256 °C from ethanol – ethyl acetate (1:1).

Anal. Calcd. for $C_{15}H_{12}O_4S$ (mol. wt., 288): C, 62.5;

H, 4.19; S, 11.11; OCH_3, 21.5. Found (M^+, 288): C, 62.7; H, 4.34; S, 11.11; OCH_3, 21.4.

3,6-Dimethoxyxanthone

3,6-Dihydroxyxanthone, prepared according to Grover *et al.* (5), was methylated in methanol – diethyl ether with diazomethane. The product was crystallized from ethanol, m.p. 189.5–190 °C.

Anal. Calcd. for $C_{15}H_{12}O_4$: C, 70.3; H, 4.68. Found: C, 70.1; H, 4.73.

3,6-Dimethoxyxanthione

3,6-Dimethoxyxanthone (1.0 g) and 1.25 g P_2S_5 were intimately mixed and heated in a test tube at 145–150 °C for 1 h. The reaction mixture was extracted with benzene and with ethyl acetate, the solvents removed on a rotary evaporator, and the residue crystallized from ethanol to give 0.40 g of orange product. It was recrystallized from benzene – ethanol to a m.p. of 212.5–213 °C.

Anal. Calcd. for $C_{15}H_{12}O_3S$: C, 66.2; H, 4.42; S, 11.7. Found: C, 66.5; H, 4.32; S, 11.9.

Synthesis of D-chalcose

B. T. Lawton, D. J. Ward, W. A. Szarek, and J. K. N. Jones
Department of Chemistry, Queen's University, Kingston, Ontario

Received January 31, 1969

A facile synthesis of 4,6-dideoxy-3-*O*-methyl-D-*xylo*-hexose (D-chalcose) is described, which involves the preparation of methyl 4,6-dichloro-4,6-dideoxy-3-*O*-methyl-D-galactopyranoside (**2**) by a reaction with sulfuryl chloride, and its reduction to the dideoxy sugar by hydrogenation over Raney nickel.

Canadian Journal of Chemistry, 47, 2899 (1969)

Chalcose (lankavose) is a constituent of the antibiotics chalcomycin (1), lankamycin (2), and neutramycin (3). On the basis of nuclear magnetic resonance (n.m.r.) and chemical evidence (1, 4), the structure of 4,6-dideoxy-3-*O*-methyl-D-*xylo*-hexose (**3**) was assigned to the sugar. The stereochemical assignment has been corroborated by a number of syntheses of chalcose (5–7). In continuation of our syntheses of branched-chain and deoxy sugars, we have now prepared D-chalcose, in high yield, by a route that is considerably more facile than those employed by other workers. Two salient features of this work are the preparation of a methyl 4,6-dichloro-4,6-dideoxy-hexoside by reaction with sulfuryl chloride, and its reduction to the dideoxy sugar by hydrogenation over Raney nickel.

Treatment of 1,2:5,6-di-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose with methanolic hydrogen chloride gave syrupy methyl 3-*O*-methyl-D-glucopyranoside (**1**), presumably as a mixture of α- and β-anomers. Reaction of **1** with sulfuryl chloride, by the general method of Jennings and Jones (8), and dechlorosulfation of the product using sodium iodide afforded methyl 4,6-dichloro-4,6-dideoxy-3-*O*-methyl-D-galactopyranoside (**2**). The stereochemistry at C-4 was assigned on the basis of work with methyl α-D-glucopyranoside (9, 10); C-4 was substituted by a chlorine atom with inversion of configuration.

It is known that the ease of reductive dehalogenation decreases markedly in the order I > Br > Cl > F. Thus, although several examples of the use of bromo- and iodo-deoxy sugars as intermediates in the synthesis of deoxy sugars are known (11), the reduction of chlorodeoxy sugars is rare (12). In the present work, however, we have found that such reductions can be readily achieved by hydrogenation over a W-4 Raney nickel catalyst, prepared by the procedure described by Pavlic and Adkins (13). It is essential that stirring is maintained during this procedure, since catalysts prepared without stirring were not sufficiently active to effect the reduction of chlorodeoxy sugars. Thus, compound **2** was reduced

H, 4.19; S, 11.11; OCH_3, 21.5. Found (M^+, 288): C, 62.7; H, 4.34; S, 11.11; OCH_3, 21.4.

3,6-Dimethoxyxanthone

3,6-Dihydroxyxanthone, prepared according to Grover *et al.* (5), was methylated in methanol – diethyl ether with diazomethane. The product was crystallized from ethanol, m.p. 189.5–190 °C.

Anal. Calcd. for $C_{15}H_{12}O_4$: C, 70.3; H, 4.68. Found: C, 70.1; H, 4.73.

3,6-Dimethoxyxanthione

3,6-Dimethoxyxanthone (1.0 g) and 1.25 g P_2S_5 were intimately mixed and heated in a test tube at 145–150 °C for 1 h. The reaction mixture was extracted with benzene and with ethyl acetate, the solvents removed on a rotary evaporator, and the residue crystallized from ethanol to give 0.40 g of orange product. It was recrystallized from benzene – ethanol to a m.p. of 212.5–213 °C.

Anal. Calcd. for $C_{15}H_{12}O_3S$: C, 66.2; H, 4.42; S, 11.7. Found: C, 66.5; H, 4.32; S, 11.9.

Synthesis of D-chalcose

B. T. Lawton, D. J. Ward, W. A. Szarek, and J. K. N. Jones
Department of Chemistry, Queen's University, Kingston, Ontario

Received January 31, 1969

A facile synthesis of 4,6-dideoxy-3-*O*-methyl-D-*xylo*-hexose (D-chalcose) is described, which involves the preparation of methyl 4,6-dichloro-4,6-dideoxy-3-*O*-methyl-D-galactopyranoside (**2**) by a reaction with sulfuryl chloride, and its reduction to the dideoxy sugar by hydrogenation over Raney nickel.

Canadian Journal of Chemistry, 47, 2899 (1969)

Chalcose (lankavose) is a constituent of the antibiotics chalcomycin (1), lankamycin (2), and neutramycin (3). On the basis of nuclear magnetic resonance (n.m.r.) and chemical evidence (1, 4), the structure of 4,6-dideoxy-3-*O*-methyl-D-*xylo*-hexose (**3**) was assigned to the sugar. The stereochemical assignment has been corroborated by a number of syntheses of chalcose (5–7). In continuation of our syntheses of branched-chain and deoxy sugars, we have now prepared D-chalcose, in high yield, by a route that is considerably more facile than those employed by other workers. Two salient features of this work are the preparation of a methyl 4,6-dichloro-4,6-dideoxy-hexoside by reaction with sulfuryl chloride, and its reduction to the dideoxy sugar by hydrogenation over Raney nickel.

Treatment of 1,2:5,6-di-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose with methanolic hydrogen chloride gave syrupy methyl 3-*O*-methyl-D-glucopyranoside (**1**), presumably as a mixture of α- and β-anomers. Reaction of **1** with sulfuryl chloride, by the general method of Jennings and Jones (8), and dechlorosulfation of the product using sodium iodide afforded methyl 4,6-dichloro-4,6-dideoxy-3-*O*-methyl-D-galactopyranoside (**2**). The stereochemistry at C-4 was assigned on the basis of work with methyl α-D-glucopyranoside (9, 10); C-4 was substituted by a chlorine atom with inversion of configuration.

It is known that the ease of reductive dehalogenation decreases markedly in the order I > Br > Cl > F. Thus, although several examples of the use of bromo- and iodo-deoxy sugars as intermediates in the synthesis of deoxy sugars are known (11), the reduction of chlorodeoxy sugars is rare (12). In the present work, however, we have found that such reductions can be readily achieved by hydrogenation over a W-4 Raney nickel catalyst, prepared by the procedure described by Pavlic and Adkins (13). It is essential that stirring is maintained during this procedure, since catalysts prepared without stirring were not sufficiently active to effect the reduction of chlorodeoxy sugars. Thus, compound **2** was reduced

1 2 3

using the active catalyst and a hydrogen pressure of 45 p.s.i.g. to give a product, which on acid-catalyzed hydrolysis afforded crystalline 4,6-dideoxy-3-*O*-methyl-D-*xylo*-hexose (D-chalcose) (**3**).

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 automatic polarimeter at 23 ± 2°. Thin-layer chromatography (t.l.c.) was performed with Silica Gel G as the adsorbent in the following solvent systems (v/v): (*a*) ethyl acetate – light petroleum (b.p. 60–80°), 2:1; (*b*) chloroform – methanol, 17:3. Sugars were detected by spraying the developed, air-dried plates with 5% ethanolic sulfuric acid, and heating at about 150°.

Methyl 3-O-Methyl-α,β-D-glucopyranoside (1)

1,2:5,6-Di-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose was prepared by treatment of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (1.85 g) with methyl iodide (15 ml) and silver oxide (1 g) at reflux temperature for 16 h. The syrupy product (1.91 g) was heated at reflux temperature in 3% methanolic hydrogen chloride (20 ml) for 4 h to give a chromatographically homogeneous (t.l.c.) syrup (1.46 g). The absence of furanosides was indicated by the fact that no spot was detected when a thin-layer chromatogram was sprayed with sodium periodate – potassium permanganate reagent (14).

Methyl 4,6-Dichloro-4,6-dideoxy-3-O-methyl-α,β-D-galactopyranoside (2)

To a cooled (dry ice – acetone) solution of **1** (1.4 g) in dry pyridine (5.5 ml) and chloroform (14 ml) was added sulfuryl chloride (3.6 ml) dropwise, with stirring. Cooling was continued for an additional 2 h, and then the reaction mixture was stirred at room temperature for a further 6 h. The mixture was diluted with chloroform (25 ml) and washed with 3 *N* hydrochloric acid, sodium hydrogen carbonate solution, and water. Concentration of the dried (Na_2SO_4) chloroform solution gave a syrup, which showed two spots by t.l.c. in solvent *a*. Only the faster-moving component was detected with aniline–pyridine in *n*-butanol (15), a spray reagent for sugars containing a chlorosulfate group.

The syrup was dissolved in methanol (50 ml), and a 10% solution of sodium iodide in 1:1 methanol – water was added dropwise, with stirring, until iodine was no longer observed to be produced. The solution was neutralized with sodium hydrogen carbonate, filtered, and concentrated to a residue, which was partitioned between chloroform and water. The dried (Na_2SO_4) chloroform solution was concentrated to a syrup, which partially crystallized on standing (1.69 g, 99%), $[\alpha]_D$ +128° (*c*, 2.03 in chloroform). Only the slower-moving component observed above, R_f 0.38, was detected by t.l.c. in solvent *a*; no spots were visible with aniline – pyridine spray.

Anal. Calcd. for $C_8H_{14}Cl_2O_4$: C, 39.2; H, 5.8; Cl, 28.9. Found: C, 39.2; H, 6.0; Cl, 29.0.

4,6-Dideoxy-3-O-methyl-D-xylo-hexose (D-Chalcose) (3)

A solution of compound **2** (1.0 g) in absolute ethanol (30 ml) containing potassium hydroxide (0.9 g) and W-4 Raney nickel catalyst (13) (2 g) was subjected to a hydrogen pressure of 45 p.s.i.g. for 4 h. The solution was filtered free of catalyst, and the filtrate was neutralized with *N* hydrochloric acid and concentrated to a residue, which was partitioned between chloroform and water. The dried (Na_2SO_4) chloroform solution was concentrated to a syrup (0.53 g).

A portion of the syrupy product (0.32 g) in water (5 ml) containing Rexyn-101 (H form) resin was heated at reflux temperature for 5 h. Thin-layer chromatography in solvent *b* showed the presence of only one component. The resin was removed and the solution was concentrated to a syrup (0.29 g, 72%), which was distilled at 65–75° (bath)/0.1 Torr; the distillate crystallized on standing. Recrystallization from ether – light petroleum gave D-chalcose (**3**) as needles, m.p. 90–93°, $[\alpha]_D$ +132° (1.5 min) → +76° (final) (*c*, 0.52 in water). The physical constants are in agreement with those published for the sugar by other workers (4–7).

Non-equivalence of *gem*-dimethyl protons in some bi- and tricyclic compounds. Stereochemical assignments in the khusenic, isokhusenic, and chamigrene series

GEORGE A. NEVILLE AND ISHWAR C. NIGAM[1]

Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada

Received September 23, 1968

The non-equivalence of *gem*-dimethyl protons in two novel series of tricyclic sesquiterpenes, khusenic (**1**) and isokhusenic (**2**), is discussed in terms of anisotropy effects and compared with that found in the analogous monoterpenic compounds, fenchone (**8**), pinocamphone (**9**), camphene (**10***a*), methylenenorbornane (**10***b*), camphenilone (**11**), and dimethylnorcampholide (**12**). The stereochemistry of the *gem*-dimethyl groups has been assigned in the above compounds. The chemical shift data and the stereochemistry of the above compounds has been used to make stereochemical assignments in the novel chamigrene series **13**, **15**, **17**, and **19**.

Canadian Journal of Chemistry, 47, 2901 (1969)

In recent years, the isolation and characterization of two novel series of tricyclic sesquiterpenes from Oil of Vetiver, khusenic (**1**) and isokhusenic (**2**), were reported from these laboratories by the late Dr. Nigam[2] and his co-workers (1). About the same time Kido, *et al.* (2) reported similar structural findings for zizanoic acid (= khusenic acid **1***b*) and recorded physicochemical data on the related compounds **1***d*, **3***a*, and **3***b*. Later Kido *et al.* (3) established the stereochemistry of **4** (R = CO_2H) for zizanoic acid which is also applicable to structures **1**, **2**, **3**, and **5**. More recently, our elucidation of long-range couplings in the khusenic (**1**) and isokhusenic (**2**) series (4) has provided additional evidence in support of these tricyclic sesquiterpenic skeletons. We now wish to discuss examples of non-equivalence of *gem*-dimethyl protons found in the khusenic (**1**) and isokhusenic (**2**) series in relation to similar phenomena in the monoterpenic compounds **8**–**12**. The chemical shift data and experience gained from structural analysis of the above compounds proved helpful in assigning the stereochemistry of some recently reported, unique, spiro-bicyclic sesquiterpenes (chamigrene series).

gem-Dimethyl in the Khusenic Series

Non-equivalence of the *gem*-dimethyl protons in the khusenic series (**1**, **5**, and **6**) arises from a combination of anisotropic effects, i.e. from both the carbonyl or olefinic groups and from the proximate C—C and C—H bonds. Undoubtedly, it is the extra anisotropic shielding and deshielding effect on the axial and equatorial methyl substituents respectively, having its origin in the anisotropy of C=C (5) and C=O (6, 7), that accounts for the small, but noticeable non-equivalence of these protons. Dreiding models show **1** and **5** to be rigid molecules in which the cyclohexane ring (stereochemistry of **4**) has the chair configuration. For this configuration, we would assign the low field singlets from **1***a*, **1***b*, **1***c*, **1***d*, **5**, and **6** at 1.05, 1.07, 1.07, 1.06, 1.18, and

1.07 δ, respectively, to the C-7 equatorial methyl protons (cf. **4**). These chemical shift values are in excellent agreement with the chemical shift (1.15 δ) for the C-1 methyl group of fenchone (**8**) whose protons would be exposed to anisotropic deshielding by the vicinal carbonyl group on the basis of the older and commonly accepted anisotropy model (8*a*). In terms of the newly proposed anisotropy model (7) for the carbonyl group, it must be concluded that both the C-1 methyl protons of fenchone (**8**) and the C-7 equatorial methyl protons of **5** are exposed to weak anisotropic shielding from the vicinal carbonyl group while the C-7 axial methyl protons of **5** are exposed to relatively stronger anisotropic shielding.

It is also noteworthy that the frequency of the equatorial *gem*-methyl protons in the cyclohexanone **5** (1.18 δ) and of the C-2 *endo*-methyl protons in pinocamphone (**9**) (1.15 δ, CCl_4) (9) lies within the range (1.15–1.20 δ, CCl_4) reported for the quasi-equatorial, C-2 methyl protons of variously substituted (C-3) cyclobutanones (10). For the khusenic diene methyl ester **6**, the additional unsaturation ($\Delta^{4,5}$) results in no appreciable change in the deshielding of the C-7 equatorial methyl protons from that observed for the methyl ester **1***a* (Table I).

From Table I, it is seen that the C-7 axial methyl protons of the khusenic series (**1**, **5**, and **6**) are shielded relative to the equatorial *gem*-methyl protons and show nearly constant chemical shift. The assignment of the more shielded *gem*-methyl signal to the axial conformation is also in accor-

*The chemical shifts measured in $CDCl_3$ solution (10–15% solute) showed no variation with dilution. Chemical shifts were calibrated by the side-band technique for the 100 MHz spectra and are considered accurate to ± 0.005 p.p.m.; the accuracy for the 60 MHz spectra is considered to be ± 0.02 p.p.m.
†Chemical shifts measured at 100 MHz on the 250 Hz sweep width of a Varian HA-100 spectrometer.
‡Chemical shifts measured at 60 MHz with a Varian A-60A spectrometer.
§Compound not available when 100 MHz spectra were recorded.
‖The 60 MHz spectra of 2*a* and of 2*b* gave unresolved peaks with identical chemical shifts.

dance with the generalization for cyclohexane rings that axial protons absorb at higher field than their equatorial counterparts (8*b*). Constancy of chemical shift for axial methyl protons (1.02–1.05 δ, CCl_4) has also been observed in the cyclobutane ring system (9, 10); however, in contrast to the cyclohexane ring system, axial methyl protons are deshielded relative to equatorial methyl protons in the cyclobutane system. Similarly in the khusenic series (stereochemistry **4**) it appears that the axial methyl protons at C-7 in **1***a*, **1***b*, **1***c*, **1***d*, and **5** (Table I) are also insensitive to changes in anisotropy effects from β-substituents (carbomethoxy, etc.) at C-2. The axial methyl protons of the khusenic diene methyl ester **6**, however, are more deshielded (4–5 Hz) than those in **1***a* due to the additional unsaturation ($\Delta^{4,5}$).

gem-Dimethyl in the Isokhusenic Series

While equivalence of the C-7 *gem*-dimethyl protons might have been expected in the isokhusenic series[3] (**2**) due to the symmetrical arrangement of these methyl groups about the planar olefinic group in the molecule, small non-equivalence has been detected. From inspection of models, it is seen that the *endo*-methyl group in these compounds is much closer to the ethano bridge than the *exo*-methyl group is to the methylene bridge. This factor would, therefore, account for the small non-equivalence found in the *gem*-dimethyl protons of **2***a* by a 100 MHz proton magnetic resonance (p.m.r.) spectrometer. In the isokhusenic series, the *endo*-methyl group at C-7 is assigned to the signal at higher field since these protons are more proximate to the majority of C—C bonds than are the *exo*-methyl protons at C-7. The *endo*-methyl protons should be more shielded also by analogy with the finding that the C-1 proton in camphene[4] (**10***a*) is shielded by 0.41 p.p.m. relative to that in methylenenorbornane (**10***b*) (11).

gem-Dimethyl in Some Bicyclic Monoterpenes

The non-equivalence of the *gem*-dimethyl protons at C-2 in camphene (**10***a*) (1.03 and 1.06 δ, CCl_4) (12) and in camphenilone (**11**) (0.97 and 1.00 δ, CCl_4) appears to arise from the same combination of anisotropy factors operative in the isokhusenic series. Although the *gem*-dimethyl groups of **10** and **11** are symmetrically oriented about the C=C and C=O group respectively, the *endo*-methyl protons are much closer to the ethano bridge than the *exo*-methyl protons are to the methylene bridge; consequently, we would assign the more shielded *gem*-methyl signal in

[3]It would appear from the chemical shift data currently available for other members of the khusenic series (**3** and **7**) (Table I) that *gem*-dimethyl protons are equivalent. It is most likely that small non-equivalence will be detected between these *gem*-dimethyl protons when the above compounds are examined by a high resolution proton magnetic resonance spectrometer.

[4]It also follows from this analogy that the C-1 and C-4 protons of camphenilone (**11**) can be assigned to 2.20 and 2.47 δ (CCl_4) respectively.

each (1.03 and 0.97 δ) to the *endo*-conformation. It is interesting to note, therefore, that introduction of a methyl substituent at C-4 in **11** and introduction of a carboxyl group at C-4 of camphene (**10***a*) results in equivalent *gem*-dimethyl protons for fenchone (**8**) (6H, 1.03 δ, CCl_4) and for the carboxy-derivative of **10** (6H, 1.12 δ, CCl_4) (13) respectively, the *endo*-methyl protons in each derivative being more strongly deshielded than the *exo*-methyl protons relative to the parent molecules.

In dimethylnorcampholide (**12**), the perbenzoic acid oxidation product of **11**, non-equivalence of the *gem*-dimethyl protons (1.35 and 1.30 δ, CCl_4) is also seen. In view of considerable evidence for δ-lactones possessing a planar C—OCO—C group in a half-chair type ring configuration (14), this non-equivalence must arise from the same anisotropy effects as proposed above for camphene (**10***a*) and camphenilone (**11**). Likewise we would assign the *endo*-methyl protons of **12** to the signal at higher field (1.30 δ) and the C-1 and C-5 proton signals to 2.05 and 2.67 δ respectively.

Stereochemical Assignments in the Novel Chamigrene Series

A new, sesquiterpenic hydrocarbon, chamigrene (**13***a*), with a unique spiro-ring system was recently isolated from the leaves of *Chamaecyparis taiwanensis* Masam. and characterized by Itô and his colleagues (15). Tanaka *et al.* (16) have synthesized 5,5,9-trimethyspiro(5,5)undec-8-en-1-one (**15***a*) and derivatives (e.g. **15***b*) as convenient precursors for the synthesis of chamigrene (**13***a*). More recently Ohta and Hirose (17) isolated chamigrene from the oil of the fruits of *Schisandra chinensis* together with two new compounds of the same carbon skeleton, namely, chamigrenal (**13***c*) and α-chamigrene (**19**). In addition, γ-chamigrene (**17**) was obtained by Ohta and Hirose as the minor product from the Wolff–Kishner reduction of the semicarbazone of **13***c*. Since only the gross structure has been reported for the above compounds, it is most appropriate to employ the reported p.m.r. data in conjunction with the deductions made above for the tri- and bi-cyclic terpenic systems, to assign the stereochemistry in these remarkable compounds. This objective appears all the more desirable since the chamigrene system constitutes the first instance of a spiro (5,5)undecane skeleton being found in a sesquiterpenoid (13).

From a study of models, it is seen that chamigrene may have two conformations[5]; "*endo-gem*-dimethyl" (**13***a*), or "*endo*-(*exo*-)methyleno" (**14***a*) by virtue of inversion of the half-chair cyclohexane ring about C-7 and C-11. Conformation **14***a* would appear to be prohibited by a large non-bonded interaction between one of the *exo*-methylene hydrogen atoms and the cyclohexene ring; moreover, the *exo*-cyclic vinylic protons (4.47, 1H, J = 2 Hz; 4.82 δ, 1H, J = 2 and 1 Hz; CCl_4) do not show the shielding which would arise in conformation **14***a* from the double bond of the cyclohexene ring. In addition the *gem*-dimethyl protons appear at much higher field (0.82 and 0.87 δ, CCl_4) than the axial *gem*-methyl protons in the khusenic series (**1**) indicative of conformation **13***a* in which the *gem*-dimethyl protons of chamigrene would be subjected to anisotropic shielding by the double bond of the cyclohexene ring. The same preferred conformation (**13**) must hold for the chamigrene derivatives **13***b* and **13***c* since the *exo*-cyclic vinylic proton signals (4.49, 4.88, and 4.34, 4.84 δ, CCl_4, respectively) appear in the same range as those of **13***a*. The small variation in the chemical shifts for the *gem*-dimethyl protons of **13***b* and **13***c* in the "*endo-gem*-dimethyl" conformation (0.83, 0.88, and 0.87, 0.90 δ, CCl_4, respectively) from those of **13***a* merely reflect the expected change in anisotropy of the cyclohexene ring with variation of the substituent R.

Similarly, for the cyclohexanone analogues (**15**), the preferred conformation is that for the "*endo-gem*-dimethyl" orientation. The fact that the allylic methyl protons of **15***a* (1.58 δ, CCl_4) are not greatly deshielded relative to the allylic methyl protons of **13***a* (1.55 δ, CCl_4), as they would have to be in conformation **16***a*, is evidence for the preferred conformation **15***a*. Moreover, the shielding of the *gem*-dimethyl protons in the "*endo-gem*-dimethyl" conformation **15** is very similar to that found for **13** (Table II), and replacement of R = CH_3 by R = OEt has negligible effect in agreement with conformation **15***b*.

In contrast, γ-chamigrene appears to prefer the conformation **17**. In this compound, the two sets of *exo*-cyclic protons show abnormal chemical shifts (4.46 δ, 2H; and 4.73,5.09 δ, 1H each;

[5]For each stable conformation, a pair of optical antipodes is possible because of the asymmetry about the "spiro" carbon atom.

20

CCl_4), one set at higher field and the other set at lower field than found for those of **13***a*. Since such a mutually shielding and deshielding effect is only possible in conformation **17**, this must be the preferred conformation in which the *exo*-cyclic methylene protons (X) are shielded by the double bond (Y) and the *exo*-cyclic protons (Y) are deshielded by the double bond (X).

Finally, α-chamigrene must prefer the "*endo*-gem-dimethyl" conformation (**19**) since both sets of allylic methyl protons are equivalent (Table II). If α-chamigrene preferred conformation **20**, then the allylic methyl protons would be non-equivalent by virtue of the mutual shielding and deshielding effects of the double bonds in each cyclohexene ring. The *gem*-dimethyl protons of α-chamigrene also show chemical shifts typical for methyl protons shielded by the double bond of the other ring and consistent with conformation **19**.

Concluding Comment

The variety of chemical shift data together with the many stereochemical assignments should prove useful for testing mathematical models designed to predict proton shifts from anisotropy effects. Caution must be exercised not to extrapolate too much from available anisotropy data in treating such compressed ring systems, since poor agreement between calculated and found shifts has been experienced to date in similar bicyclic systems (18). Improved anisotropy data,

phosphatidyl ethanolamines developed in recent years by Baer and co-workers (2) and Daemen and co-workers (3) involved phosphorylation of 1,2-diglycerides and 1,2-diacyl 3-iodopropanediols. The main difficulty in the above syntheses has been the suitable protection of the amino group. The phthaloyl group used for the protection of amino group must be removed by hydrazinolysis, a procedure that attacks the lipid to produce considerable amounts of impurities, extremely difficult to separate from the phosphatides. The first method also suffers from the drawback that poly-unsaturated 1,2-diacyl glycerols cannot be synthesized by the described method, thus limiting its use as a general procedure. In a later synthesis, Daemen and coworkers (4, 10) have used the *t*-butyloxycarbonyl group and Billimoria and Lewis (5) used the trityl group as a protective group for the amino nitrogen. The above two methods involved several step syntheses and the use of silver dibenzyl phosphate as phosphorylating agent.

The present work describes a very convenient method for the preparation of polyunsaturated 1,2-diacyl glycerol.[1] Protection of the amino nitrogen by *t*-butyloxycarbonyl was quite suitable because this group seemed to be rather versatile in the preparation of a wide variety of alkanolamines needed for our future studies.

The removal of the protective group did not offer any difficulty, since the by-products produced could be separated easily from the desired product.

The use of the new protecting group β,β,β-trichloroethoxycarbonyl (6) in lipid chemistry provided a suitable and convenient method for the preparation of optically active 1,2-diacyl-*sn*-glycerol-3-phosphate.[2] The facile removal of the protective group by zinc and acetic acid enabled us to synthesize polyunsaturated, 1,2-diacyl-*sn*-glycerol-3-phosphate that was hitherto unknown.

Reaction of **1** obtained from D-mannitol (7) with β,β,β-trichloroethyl chloroformate (6) gave in almost quantitative yield the corresponding carbonate **2**. When this was passed through a column of Dowex 50 (H^+)ion exchange resin in 90% aqueous methanol, the isopropylidine group was cleaved with the formation of **3** in a very high yield. Subsequently the diol **3** was acylated with 2 moles of the appropriate acylchloride to give the corresponding 1,2-diacyl carbonate **4** that was purified by silica gel chromatography. The trichloroethoxycarbonyl group was removed from **4** very conveniently by treating it with zinc and acetic acid, to give 1,2-diacyl glycerol **5**. Now these diacyl glycerols could be phosphorylated by phosphorous oxychloride to give the 1,2-diacyl-*sn*-3-glycerol phosphate **6** or phosphorylated and coupled with *N*-*t*-butyloxycarbonylethanolamine to give 1,2-diacyl-*sn*-glycerol-3-(*N*-*t*-butyloxycarbonyl-aminoethyl)-phosphate **7**. Alternatively the glycerophosphoric acid **6** could be converted into **7** by treating it in acetonitrile with trichloroacetonitrile and *N*-*t*-butyloxycarbonyl ethanolamine. Phosphorylation of alcohols by treating with phosphoric acid monoester in presence of trichloroacetonitrile is known to proceed in high yield (7).

The protective *t*-butyloxycarbonyl group was removed from **7** by treating it with HCl gas in anhydrous chloroform or ether to give the phosphatidyl ethanolamines **8** (10).

Experimental

The nuclear magnetic resonance (n.m.r.) spectra were taken on a Varian A-60 instrument using trimethylsilane as internal standard. Silica gel G was used as adsorbent for thin-layer chromatography (t.l.c.).

sn-Glycerol 1,2-Isopropylidine-3-(β,β,β-trichloro Ethyl)-carbonate (2)

A solution of 1 g of β,β,β-trichloroethoxy carbonyl chloride (6) in 5 ml of dry ether was added slowly with vigorous stirring to an ice-cooled solution of 500 mg of 1,2-isopropylidine-*sn*-glycerol prepared from D-mannitol (8) and 1 ml of dry pyridine in 5 ml of dry ether. Stirring was continued for 1 h at room temperature, more ether was added, and the precipitated pyridine hydrochloride was filtered off. The ether solution was washed with iced 2 *N* HCl and water and dried over sodium sulfate. Removal of solvent gave 1.125 g of an oil (yield 96%) that showed only one spot on t.l.c. (10% ethyl acetate in benzene). Nuclear magnetic resonance ($CDCl_3$) δ 4.75 (singlet, 2H, CH_2CCl_3) $[\alpha]_D^{25}$ −1.8 (*c*, 1.0 in $CHCl_3$).

Anal. Calcd. for $C_9H_{13}Cl_3O_5$: C, 35.12; H, 4.2; Cl, 34.63. Found: C, 34.98; H, 4.15; Cl, 35.14.

1,2,Dilinolenyl-3-(β,β,β-trichloro Ethoxy)-sn-glycerol (4)

A solution of 1.1 g of **2** in 100 ml of 90% aqueous methanol was percolated through a column (2.5 × 20 cm) containing Dowex 50 resin in H^+ form at the rate of 60 drops per min. The eluate was evaporated to

[1]When the present work was already completed, essentially the same procedure for the preparation of 1,2-diacyl glycerols was disclosed by Pfeiffer *et al.* (12).

[2]Nomenclature conforms to tentative rules proposed by IUPAC-IUB Commission on Biochemical Nomenclature.

dryness under reduced pressure and finally traces of water were removed by azeotropic distillation with benzene. The resulting oil **3** [n.m.r. ($CDCl_3$) δ 4.75 singlet 2H, $CH_2{\cdot}CCl_3$, no CH_3 protons] was used directly for acylation. Linolenyl chloride 2.1 g was added to a solution of 900 mg of **3** in 10 ml of dry DMF and 5 ml of dry pyridine, and the mixture was stored at room temperature for 24 h. The solution was poured into iced 2 *N* HCl and extracted with ether. The ether extract was washed with iced 2 *N* HCl, water, cold $NaHCO_3$ solution and water. It was dried over sodium sulfate. Removal of solvent gave 2.3 g of oil. This was chromatographed over 50 g silica gel. Elution of the column with pure benzene gave 1.2 g of pure oil **4** (yield 48%) showing a single spot on t.l.c. (benzene); n.m.r. ($CDCl_3$) δ 5.35 (4H olefinic), 4.75 (2H singlet $CH_2{\cdot}CCl_3$).

1,2-Dilinoleyl-*sn*-glycerol (oil). $[\alpha]_D$ −2.5° (*c*, 3.0 in $CHCl_3$), (lit. (11) $[\alpha]_D^{20}$ −2.8°).

Anal. Calcd. for $C_{39}H_{72}O_5$: C, 75.43; H, 11.69. Found: C, 75.25; H, 11.58.

1,2-Dilinolenyl-*sn*-glycerol (oil). $[\alpha]_D$ −2.1° (*c*, 4.0 in $CHCl_3$).

Anal. Calcd. for $C_{39}H_{68}O_5$: C, 75.92; H, 11.11. Found: C, 76.10; H, 11.25.

1,2-Dilinolenyl-sn-glycerol-3-phosphate (6)

A solution of 3.00 g of 1,2-dilinolenyl-*sn*-3-glycerol in 15 ml dry benzene containing 0.4 g dry pyridine was added over a period of 10 min to a cooled solution of 0.77 g of distilled phosphorous oxychloride in 20 ml dry benzene. The solution was stirred at room temperature under nitrogen for 2 h, diluted with 100 ml of benzene, and washed with cold water, iced 2 *N* HCl and water, and was dried over sodium sulfate. Removal of solvent gave an oily product that showed essentially one spot on t.l.c. (chloroform, methanol, water; 95:35:6). $[\alpha]_D^{20}$ 3.1° (*c*, 3.5 in $CHCl_3$).

Anal. Calcd. for $C_{39}H_{65}PO_8$: C, 67.62; H, 9.39; P, 4.5. Found: C, 67.85; H, 9.28; P, 4.8.

1,2-Dilinolenyl-sn-glycerol-3-(N-t-butyloxy Carbonyl-aminoethyl)-phosphate (7)

Method A

A solution of 1,2,dilinolenyl-*sn*-glycerol **5** 1.836 g and 0.43 g of dry quinoline in 10 ml dry methylene chloride was added slowly under nitrogen over a period of 30 min to a stirred solution of 0.46 g of freshly distilled phosphorous oxychloride in 10 ml dry methylene chloride cooled to 0°. After this the reaction mixture was kept at room temperature under nitrogen for 2 h. It was recooled to 0° and a solution of 0.483 g of *N-t*-butyloxy carbonyl ethanolamine (4) and 0.8 g pyridine in 10 ml dry methylene chloride was added over a period of 30 min. The reaction mixture was stored at room temperature under nitrogen for 18 h, water (0.05 ml) was added and mixture was stirred for 1 h. It was then diluted with 200 ml of methylene chloride and washed with ice 2 *N* HCl and water. It was dried over sodium sulfate. Removal of solvent gave 2.4 g of an oil. This was chromatographed on silicic acid. Elution with 5% methanol in benzene yielded 2.0 g of the desired product as an oil (yield 80%). This showed only one spot on t.l.c. ($CHCl_3$:MeOH:H_2O ratio is 95:35:6); i.r. ν_{max} ($CHCl_3$) 3400–3500 (broad —OH), 1745 (ester carbonyl) 1690 cm^{-1} (amide).

Anal. Calcd. for $C_{46}H_{86}O_9NP$: C, 66.74; H, 10.39; N, 1.69; P, 3.74. Found: C, 66.85; H, 10.61; N, 1.80; P, 3.40.

Method B

A solution of 1.2 g of *N-t*-butyloxycarbonyl ethanolamine in 3.6 g trichloroacetonitrile and 10 ml of acetonitrile was added to a solution of 1.8 g of 1,2-dilinolenyl-*sn*-glycerol-3-phosphate **6** in 10 ml of dry pyridine, and the mixture was heated in a closed flask under nitrogen at 100° for a period of 4 h. After this, it was cooled and acidified with cold 2 *N* HCl and extracted with ether. Ether solution was washed several times with cold 2 *N* HCl and water, dried over sodium sulfate, and taken to dryness under vacuum. The dark brown oily residue was chromatographed over silicic acid. Elution with 5% methanol in benzene yielded 180 mg of an oily product identical to **7** as obtained by Method A.

1,2-Dilinolenyl-sn-glycerol-3-phosphoryl-ethanolamine (8)

To a solution of 2.1 g of **7** in dry ether, cooled to 0°,

a stream of dry HCl gas was passed for 2 h. The solvent was removed under reduced pressure at 30°. The residue was dissolved in 1 ml of chloroform and chromatographed over 60 g silicic acid. Elution of the column with 5–10% methanol in chloroform yielded 350 mg of the desired product (yield 17.5%); i.r. ν_{max} ($CHCl_3$) 3500–3100 (—OH, phosphate and —NH_2), 1735 (ester carbonyl), 1650 cm^{-1} (—C—NH_2); $[\alpha]_D$ 6.1 (*c*, 2.0 in $CHCl_3$).

Anal. Calcd. for $C_{41}H_{70}O_8NP$: C, 66.93; H, 9.52; N, 1.9; P, 4.21. Found: C, 67.15; H, 9.81; N, 1.69; P, 4.02.

Biological activity

Preliminary studies on various phosphatidyl ethanolamines in an *in vitro* assay of renin inhibition (1) are indicated in Table I. Dilinolenyl phosphatidyl ethanolamine was found to be almost as active as the natural renin inhibitor isolated by Sen *et al.* (1). These observations indicate that for renin-inhibiting action, phosphatidyl ethanolamines should contain fatty acids with more than two double bonds. Other factors, such as positional requirements of the fatty acids are under investigation.

Acknowledgments

The authors wish to acknowledge technical assistance of Mr. A. Malik and thank Dr. G. Schilling and his associates for analytical data. *In vitro* assays were kindly performed by Dr. R. Smeby and his associates of Cleveland Clinic, Cleveland, Ohio. Continuous encouragement by Dr. D.A. Buyske throughout this work is highly appreciated.

COMMUNICATION

The barrier to the conformational interconversion of 1,4-dimethylenecyclohexane and related compounds

MAURICE ST-JACQUES AND MICHEL BERNARD
Department of Chemistry, University of Montreal, Montreal, Quebec

Received May 20, 1969

The proton magnetic resonance spectra of 1,4-cyclohexanedione, 1,4-dimethylenecyclohexane, and 1,4-difluoromethylenecyclohexane have been studied at various temperatures; the spectra of the last two compounds were found to be temperature dependent. ΔF^{+} values of 7.5 and 6.5 kcal/mole, respectively, were estimated from the spectral changes.

Canadian Journal of Chemistry, 47, 2911 (1969)

Recent communications (1, 2) have shown that the replacement of the carbonyl group in cyclohexanone by a methylene group markedly raises the energy barrier to ring inversion. We wish to report that similar chemical transformations of 1,4-cyclohexanedione (**1**) also result in an increased barrier to conformational interconversion.

The proton magnetic resonance (p.m.r.) spectra of **1**, 1,4-dimethylenecyclohexane (**2**), and 1,4-difluoromethylenecyclohexane (**3**) have been investigated at various temperatures. Compound **2** was prepared from **1** by a Wittig reaction using the procedure of Corey and co-workers (3); **3** was also prepared from **1** by the method developed by Fugua and co-workers (4).

The p.m.r. spectrum[1] of **1** consists of a single line at 2.74 p.p.m. from TMS; it showed no peak separation on lowering the temperature to -160 °C. At this temperature, the peak was broader than that of TMS and both were appreciably broad due to an increase in the viscosity of the solution.

The p.m.r. spectrum of **2** has been reported as temperature independent down to -120 °C (5). Our results (Fig. 1) show that a change takes place at lower temperature. At room temperature, the spectrum consists of two singlets centered at

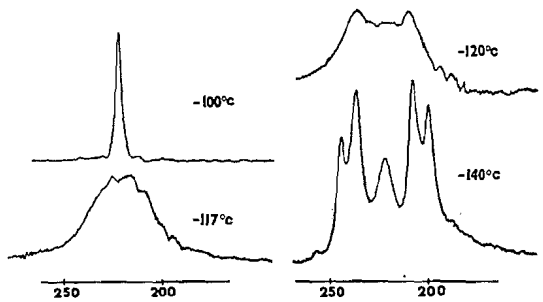

FIG. 1. The ring proton portion of the 100 MHz p.m.r. spectrum of 1,4-dimethylenecyclohexane. The scale is in Hz relative to internal TMS.

4.74 p.p.m. (vinyl protons, relative area 1) and 2.27 p.p.m. (ring protons, relative area 2). As the sample temperature is lowered, the upfield peak broadens and at -118 °C changes into a complex pattern whose symmetric appearance at -140 °C identifies it basically as an AA'BB' (6) for which many lines are not resolved. The quality of the spectra did not improve at lower temperatures. The vinyl proton peak remains a singlet throughout this temperature interval.

A similar change takes place for **3**. At ambient temperature, the ring protons appear as a quintuplet (splitting = 1.3 Hz) at 2.18 p.p.m. owing to coupling with the fluorine atoms. Below -134 °C, a pattern emerges which eventually can be identified basically as an AA'BB' exhibiting overlapping lines and appreciable coupling with the fluorine atoms.

The rate constant, k (in units of s^{-1}), for the conformational interconversions detected were estimated at the coalescence temperature, T_c,

[1]Spectra were recorded with a JEOL JNM-4H-100 spectrometer using a 2% solution of **1** in chlorodifluoromethane and a 7% solution of each **2** and **3** in vinyl chloride containing 10% of chlorodifluoromethane for locking purpose. Temperatures were determined with a thermocouple inside a dummy nuclear magnetic resonance tube.

from the equation (7) $k = \pi(6J_{AB}^2 + \Delta\nu^2)^{1/2}/\sqrt{2}$. This equation is strictly applicable only for an AB spectrum where $\Delta\nu$ is the chemical shift difference (in Hz) between the A and B protons and J_{AB} is the coupling constant. But since the most intense lines of an AA'BB' can be treated as an AB spectrum (6) with an apparent coupling constant equal to N, setting N equal to J_{AB} in the above equation should provide a reasonable approximation for k and subsequently for $\Delta F^{\ddagger}$. Thus from the four most intense lines of the spectrum of **2** (Fig. 1, -140 °C) one obtains $\Delta\nu \approx 35$ Hz and $N \approx 8.5$ Hz; these values give $k = 90\ s^{-1}$ at -118 °C corresponding to a free energy of activation of about 7.5 kcal/mole using a transmission coefficient of 1. Similar calculations for **3** yield $k = 180\ s^{-1}$ and $\Delta F^{\ddagger} = 6.5$ kcal/mole at -134 °C. The uncertainty in $\Delta F^{\ddagger}$ is probably about ± 0.5 kcal/mole. Arguments analogous to Jensen's (1) indicate that $\Delta F^{\ddagger}$ for **1** is probably less than 5 kcal/mole.

It is firmly established that **1** exists as a twist-boat (t.b.) conformation (8) in the solid state (9) and in solution (10), and it has been reported that the coupling constants in the p.m.r. spectrum of **2** at ambient temperature are consistent with that of a twist boat, although a flattened chair conformation could not be excluded (11). The AA'BB' appearance of the low temperature spectra is equally compatible with either the t.b. or the chair (c.) form as the most predominant for **2** and **3**. Only a consideration of the interconversion mechanisms available to both conformations allows a selection to be made.

If it is assumed that the t.b. form is predominant, then two basic modes of interconversion are available, namely, a symmetrical mode and a pseudorotation (12). Both processes have the property of averaging an AA'BB' spectrum into an A_4 singlet as illustrated in Fig. 2, where it is shown that "axial" and "equatorial" protons exchange environments in both interconversion itineraries. Calculations carried out by Allinger and co-workers (13) suggest that the pseudorotation of **2** should have a relatively small energy barrier (about 2.4 kcal/mole); therefore, if **2** existed in the t.b. form, it should still undergo rapid pseudorotation on the nuclear magnetic resonance (n.m.r.) time scale at -140 °C and its p.m.r. spectrum should consist of a singlet instead of a complex pattern. It seems that if the calculations are reasonably accurate, **2** does not exist in the t.b. form.

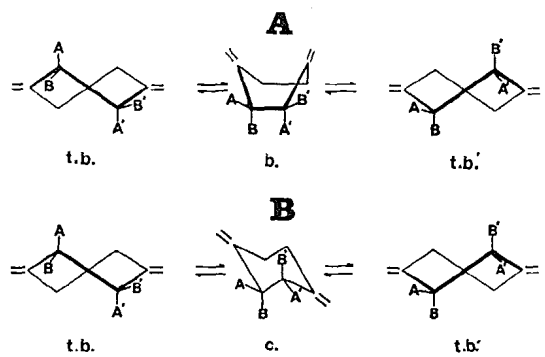

FIG. 2. Interconversion modes for the twist-boat (t.b.) conformation of compounds **1**, **2**, and **3**: (A), pseudorotation; (B), symmetrical mode.

The $\Delta F^{\ddagger}$ determined for **2** is most reconcilable with the chair form as the predominant conformation. The interconversion itinerary is probably analogous to the ring inversion in cyclohexane (12) and involves the symmetrical c. $\rightleftarrows$ t.b. pathway. It is evident from Fig. 2 that this process averages the AA'BB' spectrum expected for c. to a singlet. Calculations have not been carried out for **3** but its behavior appears to be analogous to that of **2**.

The differences in $\Delta F^{\ddagger}$ observed for **1**, **2**, and **3** appear in part to be analogous to the barrier to internal rotation for acetaldehyde (14), propene (14), and 1,1-difluoropropene (15) and the change in nature of the predominant conformation of **1** and **2** reflect in part the greater stability associated with an eclipsed arrangement between α-protons and the exo double bonds of **2**. Studies on other related compounds are planned to define more precisely the factors involved.

Acknowledgments

Infrared spectra, rotational correlation functions, band moments, and intermolecular mean squared torques of methane dissolved in liquid noble gases[1]

A. CABANA, R. BARDOUX, AND A. CHAMBERLAND

Département de Chimie, Université de Sherbrooke, Sherbrooke, Québec

Received January 24, 1969

Extensive measurements of the infrared (i.r.) absorption spectra of liquid methane and of methane dissolved in liquid argon, krypton, and xenon have been carried out. Band profiles for the ν_3 and ν_4 modes of CH_4 and CD_4 are reported. From these profiles the rotational correlation functions have been calculated. Comparison of the experimental functions with the functions calculated for the free rotators at the appropriate temperatures reveals that each molecule rotates freely for only 1.3×10^{-13} s before it undergoes a hard collision; the same result was obtained for all the systems investigated. Difficulties in obtaining accurate values of the band moments are discussed and suggestions for overcoming them are presented. Values ranging from 6.9 to 8.2×10^4 cm^{-2} have been obtained for the mean squared torques acting on methane in the various solutions.

Canadian Journal of Chemistry, 47, 2915 (1969)

Introduction

The vibrational bands of methane in the liquid state have been studied in a number of laboratories (1). However, very little information on the molecular motions in the liquids has been extracted from them because of a lack of a suitable method of interpretation. Until Gordon (2) introduced what he called "the Heisenberg picture of spectroscopy", spectra were analyzed using the conventional method which he referred to as "the Schröedinger approach". In the conventional interpretation of spectroscopic information, knowledge about the molecular motions is obtained from the assignment of various features in the spectrum to the allowed quantum states of the system. In the liquid state, the closely spaced rotational levels blend together to form a continuous band such that no information on molecular rotation can be obtained from such an analysis. However, the Heisenberg picture of spectroscopy makes the interpretation possible by focussing attention on the time development of the system rather than on the energy states. The absorption spectrum may thus be considered as a Fourier transform of an appropriate time correlation function. This paper will discuss the experimental difficulties encountered in the application of this method to the analysis of the i.r. absorption bands of methane both as a pure liquid and in solutions with liquid noble gases. The calculation of the time correlation functions will first be carried out and will yield information on the nature of the motions. It will then be shown that, in order to obtain accurate values of the band moments, unattainable accuracy in the base line position is necessary. In the systems of present interest, it appears that the moments can be calculated to within a factor of about 2 and that reasonable estimates of the intermolecular torques are thus obtained. These torques are a measure of the hindrance to rotation. A similar paper dealing with high pressure gaseous samples has been published recently (3).

Experimental

The vibrational spectra of methane dissolved in liquid noble gases were recorded on a Perkin–Elmer Model 125 prism-grating spectrophotometer calibrated with gaseous methane or hydrogen chloride, using IUPAC tables (4), with a frequency accuracy of ± 0.5 cm^{-1}. Spectral slit widths were of the order of 0.5–1.0 cm^{-1}. The width at half height of the bands investigated was always at least

[1]Work supported, in part, by the Defence Research Board of Canada Grant No. 9511-67.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

an order of magnitude greater. The accuracy of the frequency, limited by the broadness of the observed bands, was ± 2 cm^{-1}.

The cooling was provided by a commercially available cryostat equipped with a variable pressure gas exchanger (obtained from Andonian Associates, Waltham, Mass.) that permits a temperature control; fine control was done by means of electrical heating. The temperatures, readily kept constant to within ± 1 °K, were measured with a copper–constantan thermocouple embedded in the sample cell.

The sample cell, a properly machined copper block, was equipped with either sapphire or irtran-2 windows spaced 2 mm apart. Initially indium wires 0.030 in. diameter, squeezed between the cell body and the windows, were used as seals; it was later found that irtran-2 windows, which were rather fragile, were more easily sealed with wires 0.010 in. diameter.

Research grade noble gases and methane were obtained from Matheson; CD_4 with a stated purity of 99% was purchased from Merck, Sharp and Dohme of Canada, Ltd. In order to ensure complete mixing, the solutions investigated were solidified, evaporated, and heated to 150 °C several times.

In a typical experiment, pure solvent gas was liquefied into the cell, the spectrum recorded, and the gas re-evaporated into the storage bulb. Only then was it mixed with methane in a ratio of at least 500:1 and liquefied again in the sample cell.

In order to minimize absorbance error, the spectra were recorded at a maximum rate of 3 cm^{-1} per min; the slits were kept constant and as wide as consistent with adequate resolution. The gain was set low enough to maintain the noise level within ± 0.2%, yet high enough to ensure proper response.

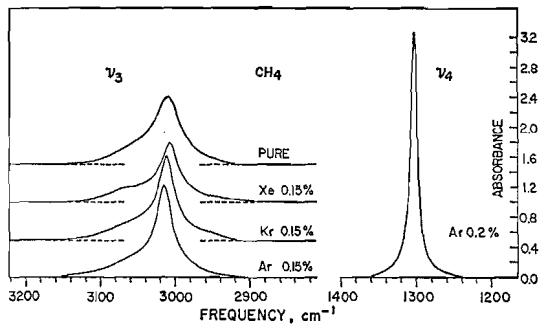

FIG. 1. The ν_3 and ν_4 i.r. absorption bands of CH_4 at various temperatures in various solvents. Pure CH_4, 117 °K; 0.15% CH_4 in xenon, 163 °K; 0.15% CH_4 in krypton, 135 °K; 0.15 and 0.2% CH_4 in argon, 91 °K.

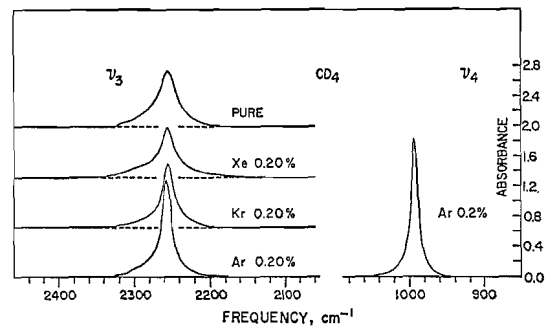

FIG. 2. The ν_3 and ν_4 i.r. absorption bands of CD_4 at various temperatures in various solvents. Pure CD_4, 120 °K; 0.20% CD_4 in xenon, 163 °K; 0.20% CD_4 in krypton, 121 °K; 0.20% CD_4 in argon, 91 °K.

Results and Discussion

Infrared Spectra

An extensive series of i.r. absorption spectra of liquid methane and of methane dissolved in liquid argon, krypton, or xenon has been recorded and analyzed. Representative examples of the profiles of the ν_3 and ν_4 absorption bands of CH_4 are given in Fig. 1 while those of CD_4 are given in Fig. 2. The Coriolis coupling constants for the two CH_4 modes are $\zeta_3 = 0.04$ and $\zeta_4 = 0.46$ (5); the constants for CD_4 are $\zeta_3 = 0.16$ and $\zeta_4 = 0.34$ (6). The effect of a greater constant for the ν_4 modes with respect to the ν_3 modes is clearly seen in both sets of spectra through a narrowing of the bands attributable to the bending modes. The applicability of the Coriolis coupling correction for the liquid state may be questioned since the ζ_i will certainly be affected by the potential fields. The greater moment of inertia for CD_4 with respect to CH_4 is reflected in the spectra by a relative narrowing of the CD_4 bands. For reasons to be discussed later, only the ν_3 bands of CH_4 will be completely analyzed. Remnants of the R branch appear on the high frequency side of every spectrum but more strikingly in the cases of xenon solutions.

Calculation of the Dipole Correlation Functions and Relaxation Rates

An i.r. correlation function is given by $\langle \mu(0)\cdot\mu(t)\rangle$, where $\mu(0)$ and $\mu(t)$ are the appropriate components of the Heisenberg dipole moments at times 0 and t respectively, and the brackets denote the equilibrium ensemble average (2). For convenience $\langle \mu(0)\cdot\mu(t)\rangle$ will be replaced by $C(t)$. The classical theoretical function for a freely rotating top is given by (7)

$$C_{C1}(t) = \frac{1}{3}\left\{1 + 2\left[1 + \left(\frac{kT}{I}\right)i^2\right]\exp\left(-\frac{kT}{2I}\right)t^2\right\}$$

Thus only the temperature and the moment of inertia determine the correlation function of freely rotating molecules. These functions were calculated for CH_4 at 75 and 100 °K and are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

illustrated in Fig. 3. Also shown on the same figure is the theoretical function obtained from a "stick spectrum" calculated at 75 °K; the latter function is then also a function for the free molecules but now quantum effects are somehow taken into account. At short times ($t < 0.3 \times 10^{-12}$ s), both functions are superimposed.

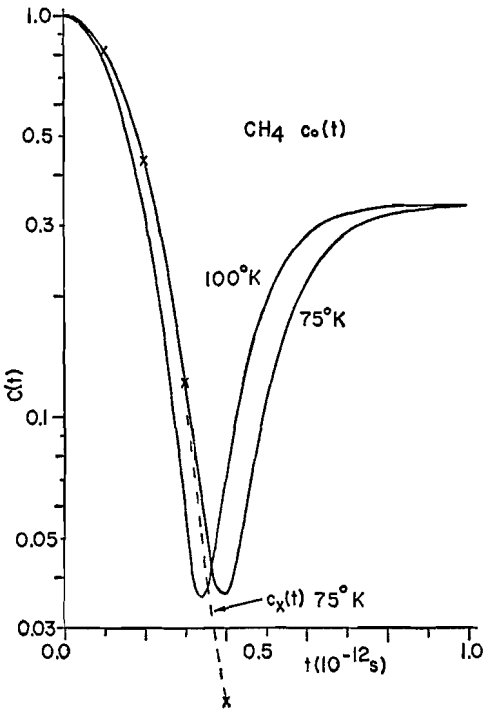

FIG. 3. Theoretical correlation functions for freely rotating methane: full lines, classical functions; dashed line, obtained from a stick spectrum using the method outlined by Gordon. At short times both curves are superimposed.

The experimental dipole correlation functions were calculated (2) from the following expressions

$$C(t) = \int_{\text{band}} \hat{I}(\omega) e^{i\omega t} d\omega$$

In the above relationship the spectrum is normalized to unit area by defining

$$\hat{I}(\omega) = I(\omega) \Big/ \int_{\text{band}} I(\omega) d\omega$$

where ω is the circular frequency measured from the maximum value of $I(\omega)$, $I(\omega)$ is the absorbance, and the summation is carried out over the complete frequency spectrum.

In the actual calculations the following function was evaluated

$$C(t) = \frac{\int_{\text{band}} \log (I_0/I) \cos (\omega t) d\omega}{\int_{\text{band}} \log (I_0/I) d\omega}$$

It may be useful to note that, in a recent paper (8), another form of this relation was given; that relation should be used with caution since a factor of 2 has been omitted from the denominator.

Those vibrational modes which are strongly coupled with the rotational motions cannot be adequately treated using the expressions reproduced above, because for such modes the dipole correlation functions cannot be factorized into vibrational and rotational parts. Both i.r. active vibrations of CD_4 and the ν_4 vibration of CH_4 have large Coriolis coupling constants and consequently the present method is not strictly applicable to them. However, in order to illustrate the influence of the coupling, correlation functions have been obtained for some of those bands and are reproduced in Figs. 4 and 5. Further discussion will be restricted to the ν_3 vibration of CH_4 whose functions are given in

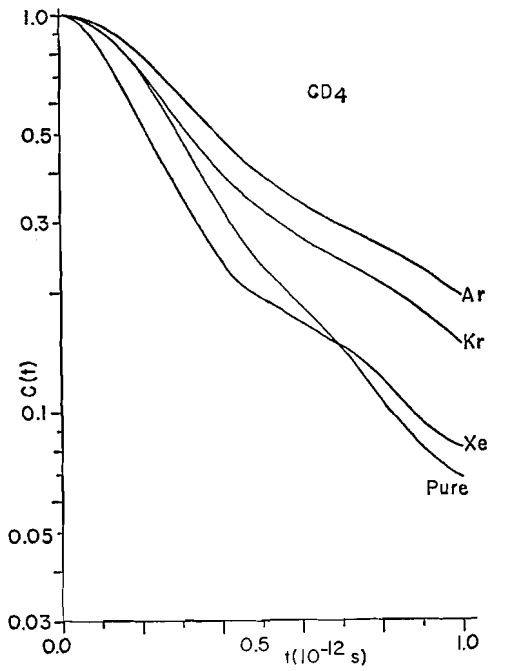

FIG. 4. Rotational correlation functions for CD_4 obtained from the frequency spectra reported in Fig. 2.

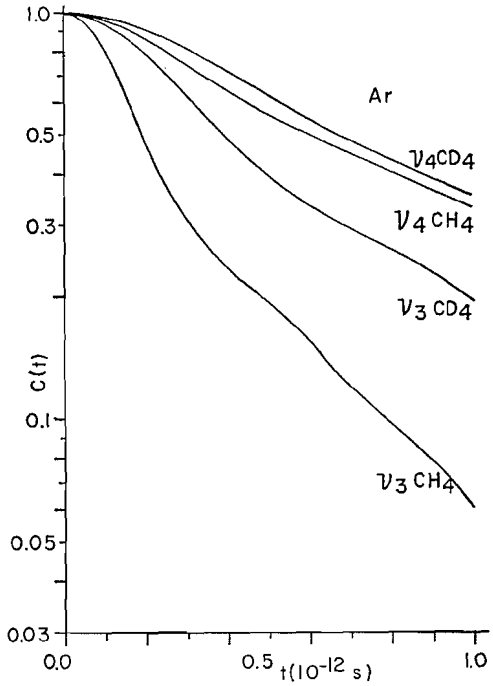

FIG. 5. Rotational correlation functions for CH_4 and CD_4 obtained from frequency spectra shown in Figs. 1 and 2.

Fig. 6. On each absorption spectrum, between 200–300 values of the absorbance were read and carefully subtracted from the corresponding readings of the blank spectrum. The average values of 3 different sets of tracings were used for the calculations. The interval of integration was always chosen to be at least 10 times the width-at-half-height and contained the complete region where measurable absorption occurred. We could not carry out an error calculation because there is no precise way of measuring the uncertainty in absorbance at each wavelength. Moreover, as pointed out by Favelukes and co-workers (9), only an upper limit could be computed. In order to get an estimate of the errors, 3 correlation functions were obtained for 3 different mixtures of the same pair of gases (methane–argon); at short times, the resulting curves were perfectly superimposable but at longer times, when oscillations developed, the dispersion was evident but never large enough to modify the meaning of our results. In some preliminary experiments when the interval of integration was inadvertently truncated or the base line shifted, very large oscillations appeared. There is a simple mathematical reason for these oscillations: when an absorption band is truncated or when the base line is displaced from its exact position, a small rectangle is either added or subtracted from the real band. The Fourier transform of that small rectangle is a function of the form $\sin x/x$ which is either added or subtracted from our real function. Any error in the base line position will thus cause oscillations. It may be possible to avoid such errors by recording an additional spectrum with an increased path length (say 10–20 times) and using this spectrum to obtain more reliable values of the absorbance in the wings. However, in spectra of rather complex molecules, this procedure is in general not applicable since overtones or combination bands overlap the fundamentals. In the ν_3 region of CH_4 for example, $2\nu_2$ or $\nu_2 + \nu_4$ are extremely weak but their presence excludes the possibility of using the method suggested above. Comparison of the experimental curves with those obtained for freely rotating methane (Figs. 6 and 3) reveals that the experimental functions follow the free rotator functions for times shorter than about 1.2×10^{-13} s, and that

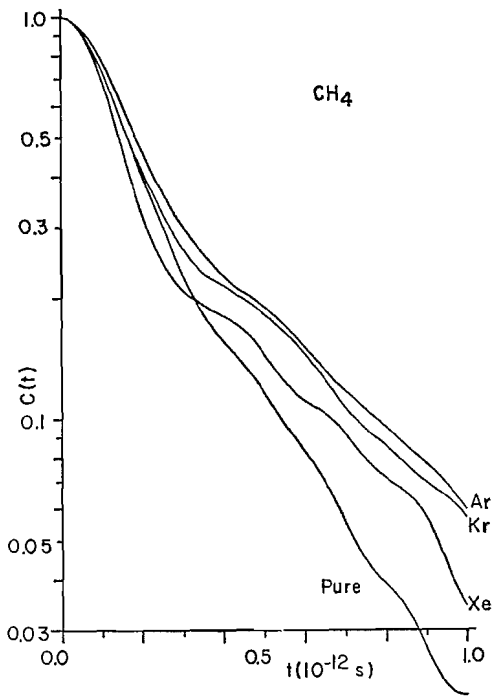

FIG. 6. Rotational correlation functions for CH_4 obtained from frequency spectra shown in Fig. 1.

molecular rotation in pure methane is very similar to molecular rotation of methane in any of the liquid noble gases. At intermediate times, the intermolecular interactions cause the experimental function to decay more slowly than the theoretical function; by that time the molecules will have undergone a hard collision with their neighbors. The semilogarithmic plots illustrate well the exponential decay at long times. The relaxation rates τ_0^{-1} are obtained from the slopes of the straight lines drawn to approximate the long time behavior; Table 1 summarizes the results.

TABLE I

Relaxation rates for CH_4 in various solvents

System	τ_0^{-1} (± 0.2) $\times 10^{12}$ s^{-1}
Pure CH_4	3.5
0.15% CH_4 in Ar	2.4
0.15% CH_4 in Kr	2.5
0.15% CH_4 in Xe	2.4

In the gas phase it has already been shown (3) that the relaxation rate increases with the gas density, and it should be noted that the relaxation rate in a liquid is of the same order of magnitude as that measured in the gas at comparable densities. The relaxation rate of CH_4 in the pure liquid is definitely longer than that of methane mixed with liquid noble gases; the same qualitative behavior is also clearly observed in the CD_4 correlation functions (Fig. 4). The relaxation rates are rather insensitive to base line errors.

Calculation of Band Moments and Torques from Observed Absorption Spectra

The mean squared torque (3) is given by

$$\left[[M(4) - (5/2)M(2)^2]\frac{3}{2}I^2 = \langle\tau^2\rangle\right.$$

In this expression $M(2)$ and $M(4)$ are respectively the 2nd and 4th moments of the i.r. band, I is the moment of inertia, and $\langle\tau\rangle$ is the torque on the radiating molecule; the brackets denote a classical configurational average.

The calculated experimental torques are extremely sensitive to the position of the background level. The background trace was matched to the absorption trace outside the region of measurable absorption. In some experiments, after calculating the moments with the best "visual fit" we searched with the computer to find what shift in the base line would be necessary to obtain a 2nd moment which would have the theoretical classical value. The classical 2nd moment is dependent on the temperature and the moment of inertia but independent of the intermolecular forces. Thus it can be used to augment the accuracy on the fit in the wings. The adjustments necessary to match the experimental 2nd moments to the classical 2nd moments were always small (within the combined errors on both traces) but they had a large effect on the 4th moments and consequently on the mean squared torques. Table II illustrates these effects with a typical example where the base line was deliberately shifted from its real position. We wish to point out that, except for slight modifications of the oscillations observed at long times, these adjustments did not alter the correlation functions; at short times all the curves were superimposable. Table III gives selected values of the 2nd and 4th moments, and of the mean squared torques, for pure methane and methane dissolved in 3 different noble gases. The theoretical classical 2nd moments are also included. The reported moments and torques are the average values obtained from several experiments; sets of band moments where $M(2)$ was too far from the theoretical value were discarded. It was observed that

TABLE II

the experimental torques for methane, in the 4 solutions studied, are all about the same. When great care was exercised in recording and reading the spectra, successive values of the mean squared torques computed from different sets of spectra have shown an uncertainty of $\pm 35\%$; this figure may be considerably larger if insufficient care is taken. It would appear that the uncertainty may be minimized by insisting that the 2nd moments obtained from spectral data have the theoretical classical values. The square root of the mean squared torques should provide a fair idea of the average potential hindering rotation; even if it is not exact, such calculations were carried out and the values obtained were compared to those reported in the literature. For pure methane we have found an average barrier of 2.8×10^2 cm^{-1} and surprisingly enough about the same value was obtained for the noble gases. Values reported in the literature include 63 cm^{-1} for pure liquid methane (1), 165–330 cm^{-1} for pure solid methane (10), and 83 cm^{-1} (11) and 348–533 cm^{-1} (12) for methane dissolved in the solid noble gases. Although these measurements of the average potential hindering rotation were obtained using widely different assumptions, it is interesting to note that they are all within an order of magnitude.

Nuclear charge dispersion in the fission of ^{233}U by protons of medium energy[1]

I. TOMITA[2] AND L. YAFFE

Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Quebec

Received February 11, 1969

Independent yields and excitation functions have been determined for the formation of cesium isotopes with masses $129 \leqslant A \leqslant 138$ in the fission of ^{233}U with protons of energies between 20 and 80 MeV. The energies at which the various excitation functions reach their maxima have been compared with those obtained for the same isotopes from fissioning systems with targets of different neutron-to-proton (N/Z) ratios. The neutron-deficient species have a higher probability of being produced at lower energies from targets with lower N/Z ratios. Charge dispersion curves have been obtained and these show the familiar broadening and displacement of Z_p, the most probable charge, towards stability with increase in bombardment energy. Values of $Z_A - Z_p$ have been compared with those obtained from other fissioning systems, and predictions made for values of Z_p in the fission of systems yet unstudied, e.g. ^{235}U and ^{239}Pu. In addition Z_p values were calculated for ^{233}U fission, assuming compound nucleus formation up to a proton energy of 50 MeV, assuming pre- and post-fission neutron evaporation on the equal charge displacement and unchanged charge division postulates. Experimental values were found to lie between the two predictions.

Canadian Journal of Chemistry, 47, 2921 (1969)

Introduction

Considerable information has been published by workers in this laboratory regarding the charge dispersion of fission products with mass numbers A between 130 and 143, formed in the fission of ^{232}Th (1–3) and ^{238}U (4–6) bombarded by protons of energies 10–85 MeV. Friedlander *et al.* (7) reported a detailed study of excitation functions and nuclear charge dispersion in this fission product mass region in the fission of ^{238}U by protons of energies 0.1–6.2 GeV.

No data for the nuclear charge dispersion in the proton-induced fission of ^{233}U have been published hithertofore. In this paper we report a study of cross sections for the independent and cumulative formation of cesium isotopes (A = 129–128) in the interaction of protons of kinetic energies between 20–85 MeV with ^{233}U. Charge dispersion data are then deduced from these cross sections.

Experimental

1. Targets and Irradiation

The targets were irradiated with protons in the internal beam of the McGill Synchrocyclotron. The target material was finely powdered uranium oxide[3], $^{233}U_3O_8$. The oxide was uniformly mixed with "spec-pure" copper oxide which served as a beam monitor. The mixture (10–15 mg containing about 5 mg uranium oxide) was loaded into a thin (10 mg/cm^2) aluminium tube which had been clamped at one end. The tube was now sealed, flattened by rolling, and clamped to an aluminium holder, which was fastened to a water-cooled probe and positioned in the cyclotron tank at a radius corresponding to the desired proton energy. The time of irradiation varied from 5 to 15 min and the beam intensity was monitored by the reaction $^{65}Cu(p,pn)^{64}Cu$.

2. Chemical Separations

The general procedure for cesium purification was similar to that of Friedlander *et al.* (7). The aluminium tube, containing the uranium and copper oxides, was dissolved in 12 N HCl along with a drop of concentrated nitric acid. Carriers for Cs (20 mg), Ba (50 mg), Rb (5 mg), and La (2 mg) had been added to the centrifuge tube in which the target was dissolved. When it was necessary to separate Ba, barium chloride was precipitated from the concentrated solution by bubbling gaseous hydrogen chloride, and cooling the solution.

The solution containing the cesium was diluted to 6 N HCl, and silicotungstic acid was added to precipitate cesium silicotungstate. The precipitate was centrifuged, washed with 6 N HCl, and dissolved in a minimal volume of sodium hydroxide. The solution was cooled with ice, acetic acid and rubidium hold-back carrier was added, and $Cs_3Bi_2I_9$ was precipitated by the addition of BiI_3–HI reagent. The precipitate was dissolved in concentrated HCl under gentle heat, rubidium hold-back carrier was added, and $Cs_3Bi_2I_9$ was reprecipitated from the cooled solution by further addition of the BiI_3–HI reagent. The final precipitate was washed with 0.1 N HCl, filtered, and mounted for activity measurements. The chemical yield of cesium in this procedure was of the order of 20 to 30%.

The copper was separated from the supernate of the cesium silicotungstate precipitation by anion exchange. The supernate was evaporated to a small volume and made to 10 N in HCl. The solution was adsorbed on a Dowex 1 (x8) anion exchange column. The column was treated successively with 10 and 4 N HCl to remove

TABLE I

Nuclides measured and modes of detection used

Nuclide	Half-life	Mode of decay	Radiation measured	Branch abundance	Instrument used
^{129}Cs	32.0 h	e.c.	X	1.0	NaI spectrometer
^{130}Cs	30 min	β^+, e.c., β^-	β^+	0.46	511–511 coincidence
^{131}Cs	9.7 days	e.c.	X	1.0	NaI spectrometer
^{132}Cs	6.5 days	e.c., (γ)	X 670 keV γ	0.97 0.99	NaI spectrometer
^{134}Cs	2.1 years	β^- (γ)	800 keV γ	0.99	NaI spectrometer
^{134}Cs^m	2.9 h	i.t.	128 keV γ e^-, β^-	0.14 1.0	NaI spectrometer End-window proportional counter
^{136}Cs	12.9 days	β^- (γ)		1.0	End-window proportional counter
^{138}Cs	32.2 min	β^- (γ)		1.0	NaI spectrometer End-window proportional counter

impurities and copper was finally eluted with 2 *N* HCl. The final solution was made up to 2 ml in a standard vial for γ-ray measurements. The chemical yield of copper was determined by titration with the disodium salt of ethylenediamine tetraacetic acid with PAN indicator (8).

In some cases barium was purified (7) and timed extractions of cesium were made.

3. Activity Measurements

The decay characteristics of the radionuclides and their method of assay are given in Table I.

An end-window gas-flow proportional counter was used to measure the counting rates of ^{136}Cs, ^{138}Cs, and in some cases, ^{134}Cs^m. The decay curves were resolved by means of the CLSQ least-square computer program (9). The activities due to ^{138}Cs (32.2 min) and ^{130}Cs (30 min) were initially analyzed as one component. The contribution due to ^{130}Cs was later subtracted when it had been obtained by positron measurements as described later.

In one experiment uranium foil, of normal isotopic composition, was irradiated with 45 MeV protons. Cesium was separated and purified as described, and the radioactivities used to calibrate the end-window counter relative to a $4\pi\beta$-proportional counter. Empirical self-absorption curves for ^{136}Cs and ^{134}Cs^m in $Cs_3Bi_2I_9$ were also constructed.

Gamma rays and K X-rays emitted by the cesium isotopes were measured by a 3 in. × 3 in. NaI(Tl) crystal linked to a 400-channel pulse-height analyzer. Counting efficiencies were determined by the use of radioactive standards whose γ-ray disintegration rates were known. The decay curve from the X-ray data was resolved into half-life components of 32 h (^{129}Cs), 6.5 days (^{132}Cs), 9.7 days (^{131}Cs), 12.9 days (^{136}Cs), and a longer-lived tail. The error in the computer analysis was highest for the 9.7-day component, undoubtedly caused by the presence and interference from the 6.5- and 12.9-day components. Since the 6.5-day ^{132}Cs emits a 670-keV γ-ray, this was also measured and the cross sections calculated in this way compared with those determined from the X-ray data. The agreement was reasonably good. No interference was found from the 660 keV γ-ray from ^{137}Cs (30 years) since its contribution was negligible. A fluorescence yield of 0.87 and an L/K capture ratio (7) were used to convert the measured K X-ray emission rates to K-electron capture disintegration rates.

Positron emission rates of ^{130}Cs (30 min) were determined by means of coincidence measurements of the 511 keV annihilation radiation. The cesium sample was mounted between two copper absorbers 1/16 in. thick. The annihilation radiation was detected by two 1½ in. × 1 in. NaI(Tl) crystals placed at 180° to the source and connected to a single-channel pulse-height analyzer gated to accept the 511 keV photopeak. The contribution to the coincidence rate from nuclear γ-radiation was monitored simultaneously using a third detector placed at 90° to the main assembly. The accidental rate was of the order of 40 and 10% at bombarding energies of 45 and 85 MeV, respectively, during the first hour of measurement, with intermediate values in between. The accidental rate was subtracted from the 180° rate to obtain the true annihilation coincidence rate. The efficiency of the assembly was calibrated by a standard source of ^{22}Na, mounted in a manner similar to that of the ^{130}Cs source.

The ^{64}Cu activity was measured as a liquid source using the γ-ray spectrometer.

Results and Discussion

1. Treatment of Data

The measured counting rates, either at the end of the irradiation, or at time of separation from the parent, were converted to disintegration rates by correcting for counter efficiencies, self-absorption, branching ratio, and chemical yield. The relationships given below to transform these into formation cross sections are essentially those given by Friedlander *et al.* (7) and are summarized and given here for ready reference.

In those experiments which did not require consideration of parent–daughter relationships (e.g. shielded or effectively-shielded nuclides), the cross section, σ, was obtained from the disintegration rate, D^0, at the end of the irradiation by means of the equation

[1] $$\sigma = D^{\infty} \cdot F$$

where

$$F = \frac{W_{Cu}}{W_U} \cdot \frac{A_U}{A_{Cu}} \cdot \frac{\sigma_{Cu}}{D_{Cu}{}^{\infty}}$$

$$D^{\infty} = D^0/[1 - \exp(-\lambda t_0)]$$

and

$$D_{Cu} = D^0{}_{64_{Cu}}/[1 - \exp(-\lambda_{64_{Cu}} t_0)]$$

where λ is the decay constant of the nuclide in question, t_0 is the length of irradiation, W_{Cu} and W_U are the weights of ^{65}Cu and ^{233}U in the target, respectively, A_{Cu} and A_U are the atomic weights of ^{65}Cu and ^{233}U, respectively, and σ_{Cu} is the appropriate formation cross section of ^{64}Cu in copper at various energies. The latter have been interpolated from the excitation functions reported by Meghir (10) and are given in Table II.

TABLE II

Although ^{131}Cs grows from a ^{131}Ba parent with half-life of 12 days, ^{131}Cs was considered to be shielded from β-decay since the separation of cesium from barium was effectively complete within 30 min after irradiation. In the case of ^{129}Cs, the contribution from the parent (2.4 h ^{129}Ba) would be most pronounced at higher energies. A check was made at an irradiation energy of 70 MeV to see how great this contribution was. The cross sections of parent and daughter were determined from a single irradiation followed by 2 successive separations of the daughter product. The daughter activity obtained in the second extraction was used to find the parent cross section in standard fashion, and the daughter cross section was then determined by means of eq. [2] described below from the daughter activity obtained in the first extraction. The result showed that the cross section of ^{129}Cs was about 10 times larger than that of ^{129}Ba at this energy. If the contribution from ^{129}Ba were ignored, and ^{129}Cs treated as a shielded nuclide, the error would be less than 2%, well within experimental error. The independent yield of ^{129}Cs was therefore calculated in terms of eq. [1] in this experiment.

However, for the ^{138}Xe–^{138}Cs pair (half-lives of 14 and 32.2 min, respectively), the contribution from the parent to the yield of the daughter, because of the decay in the period between the end of irradiation and chemical separation, is no longer negligible.

When both members of the pair are produced independently (7) with cross sections σ_p and σ_d, respectively, in an irradiation of duration t_0, the distintegration rate D_d' of the daughter at a time t_1 after the end of irradiation is given by

[2] $$D_d' = (\lambda_d/F)(K_1\sigma_p + K_2\sigma_d)$$

where F is as defined previously, and

$$K_1 = \frac{e^{-\lambda_p t_1}(1 - e^{-\lambda_p t_0}) - (\lambda_p/\lambda_d)e^{-\lambda_d t_1}(1 - e^{-\lambda_d t_0})}{\lambda_d - \lambda_p}$$

$$K_2 = \frac{e^{-\lambda_d t_1}(1 - e^{-\lambda_d t_0})}{\lambda_d}$$

and λ_d and λ_p are the decay constants of the daughter and parent, respectively.

The values of the formation cross sections of ^{138}Xe and ^{138}Cs were determined from two separate irradiations with appropriately chosen times t_0 and t_1, each leading to an equation of the form of eq. [2]. In one irradiation, for example, the target was dissolved as soon as possible after the end of irradiation, and in the second an interval of about 1 h was allowed to elapse before dissolution.

2. Cross Sections and Excitation Functions

The formation cross sections for the nuclides investigated are given in Table III. All results quoted, with the exception of those for ^{138}Xe are independent formation cross sections. The numbers in parentheses following each cross

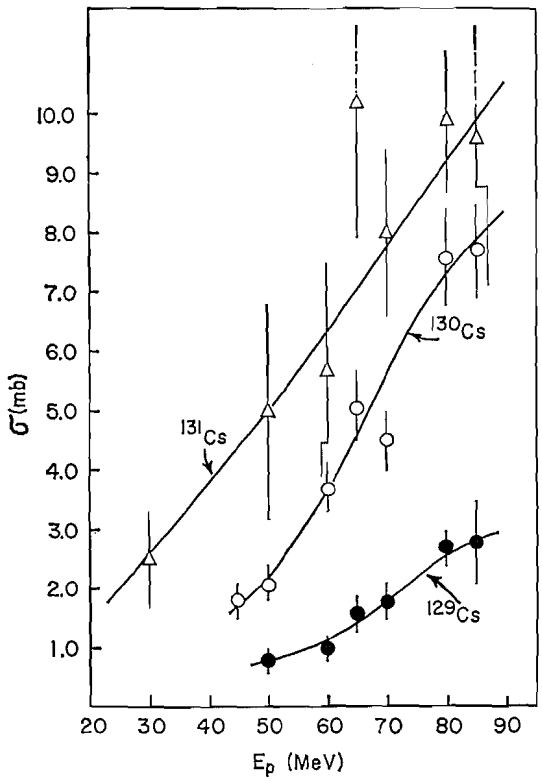

FIG. 1. Excitation functions for the independent yields of ^{129}Cs, ^{130}Cs, and ^{131}Cs.

section value indicate the number of determinations. Errors for individual results were estimated from the uncertainties in decay curve analyses, counting efficiencies, chemical yields, photopeak area estimation (for γ-measurements), and self-absorption (for β-measurements). Where more than one determination was made the average value is given along with the mean deviation.

Excitation functions for the various products are shown in Figs. 1–4. In Table IV the independent formation cross sections of ^{133}Cs, ^{135}Cs, and ^{137}Cs have been interpolated from charge dispersion curves, and these are shown in Fig. 5. The excitation functions of some of the nuclides studied exhibit maxima in this energy region. In Fig. 6, the energy at which the excitation function reaches its maximum is plotted against the neutron-to-proton ratio (N/Z) of the nuclide. The interpolated data have also been included. Corresponding data obtained by others for ^{232}Th (3) and natural uranium (4) targets have also been included for comparison. It has been

TABLE IV

70	20	25	22
80	21	24	19

pointed out previously (3–6) that the energies, at which the excitation functions for the independent formation of various fission products reach their maxima, increase with decreasing neutron-to-proton ratio of the product. That this is also true for ^{233}U is evident from Fig. 6. However, the slope of the curve is a function of the N/Z ratio of the target (1.587, 1.578, and 1.533 for ^{238}U, ^{232}Th, and ^{233}U, respectively).

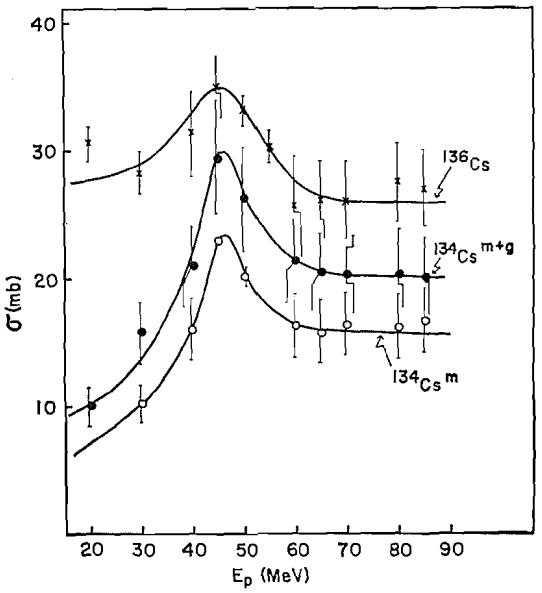

FIG. 3. Excitation functions for the independent yields of $^{134}Cs^{m}$, $^{134}Cs^{m+g}$, and ^{136}Cs.

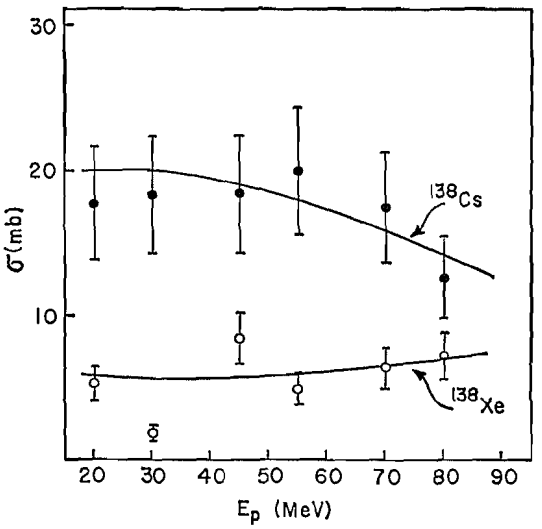

FIG. 4. Excitation functions for the independent yield of ^{138}Cs and the cumulative yield of ^{138}Xe.

More data are needed to give quantitative relations. However, it is obvious that, even though ^{233}U and ^{238}U differ only by 0.054 N/Z units, yet it takes 310 MeV more for ^{132}Cs to be a highly probable fission product in the latter case than the former. Highly neutron-deficient products, normally occurring in relatively high abundance at GeV energies in the case of ^{238}U will be expected at energies that are factors of 10 less in the case of ^{233}U. For example, Friedlander *et al.* (7) found a negligible yield of ^{129}Cs at 100 MeV and only 1.5 mb at 200 MeV bombarding energy in the fission of ^{238}U. The present data for ^{233}U show a yield of 1.5 mb at 65 MeV and the excitation function is rising very steeply. The excitation function would be expected to reach its maximum at about 95 MeV bombardment energy, to be contrasted with the value of 900 MeV, found by Friedlander *et al.* (7) for ^{238}U fission. The role in the fission of the neutron-to-proton ratio of the target is thus quite obvious.

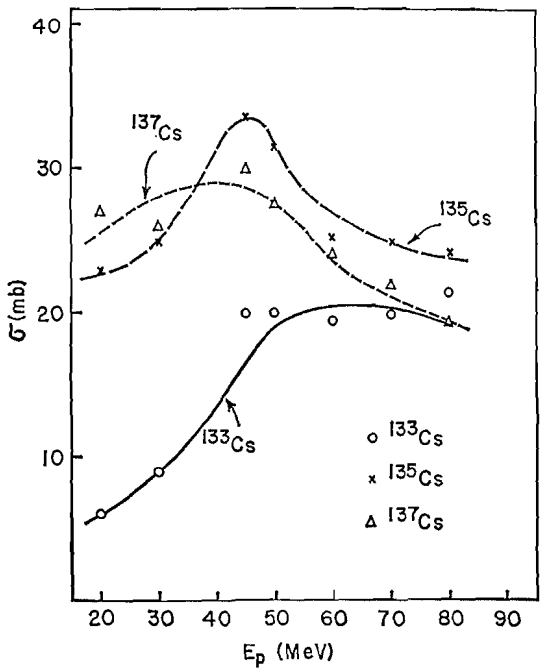

FIG. 5. Excitation functions for the independent yields of ^{133}Cs, ^{135}Cs, and ^{137}Cs, interpolated from charge dispersion curves.

Another feature of the excitation functions is that the independent cross sections for ^{138}Cs do not vary much in the energy region studied, and are relatively small compared to those for ^{136}Cs, the closest shielded isotope. This is not the case for ^{238}U fission (4) and indicates that, in the present case, Z_p, the most probable charge, is considerably displaced relatively towards β-stability. This is also clearly observed in the charge dispersion curves.

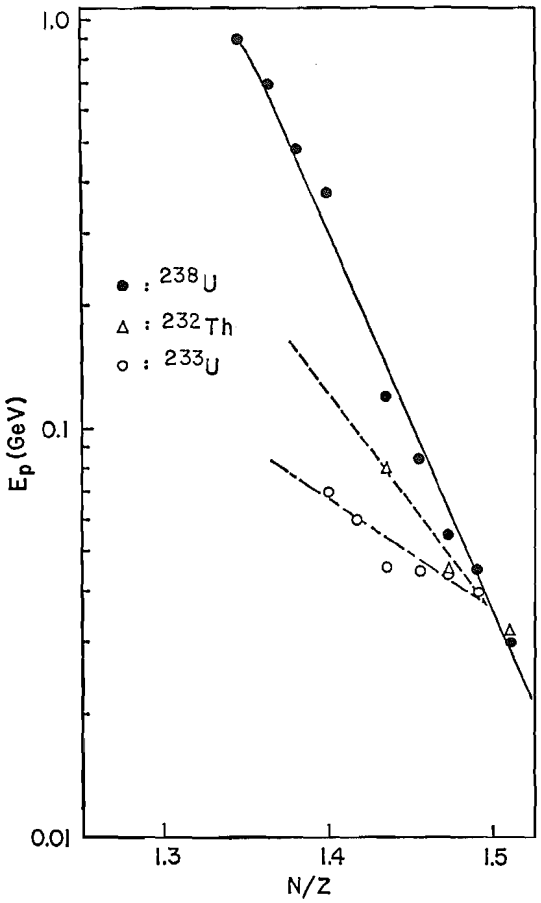

FIG. 6. Energies at which excitation functions reach their maxima.

3. Charge Dispersion

If one assumes that the mass–yield curve is essentially flat in the region $129 \leq A \leq 138$, the cross section data given in Table III can be used to construct charge dispersion curves. These are given in Figs. 7–13 inclusive. The cumulative cross sections of ^{138}Xe were used to define the shape of the neutron-excess sides of the curves where only a few independent yield data were available. The curves, plotted as a function of N/Z, as done by Friedlander *et al.* (7), were drawn in such a fashion that the sum of the interpolated independent yields equalled the experimentally-determined cumulative yields.

As the bombardment energy increases from 20 to 80 MeV the curves become broader, and the peak position, Z_p, moves to smaller N/Z ratios. The relevant parameters of the charge

dispersion curves are given in Table V and the trends are shown graphically in Fig. 14 together with similar data for ^{238}U (4) and ^{232}Th (3). The appropriate values of Z were obtained from the charge dispersion curves in the same way as in ref. 5. The most stable charge for a given A value, Z_A, was taken from Coryell (11). The full-widths at half-maximum seem to be similar for the 3 target nuclei. However, the displacement towards β-stability in the case of ^{233}U relative to both ^{238}U and ^{232}Th is quite apparent. In Fig. 15 the values of $Z_A - Z_p$ at different energies

are plotted against N/Z of the target nuclei. The displacement of the most probable charge from that corresponding to stability for ^{235}U and ^{239}Pu was then read off these curves and the predictions shown in Fig. 14. These target nuclei are now being studied in our laboratory and results should be available shortly.

The total formation cross section for $A = 136$ was estimated as a function of energy from the charge dispersion curves and plotted in Fig. 16 along with data obtained by Davies and Yaffe (4) for ^{238}U. The total isobaric cross section for mass 136 is greater for ^{233}U than for ^{238}U. There is a peak at about 50 MeV in each case, but it is very much more pronounced in ^{233}U.

4. Z_p *Values*

An approximate estimation of Z_p values has been made for bombardment energies up to 50

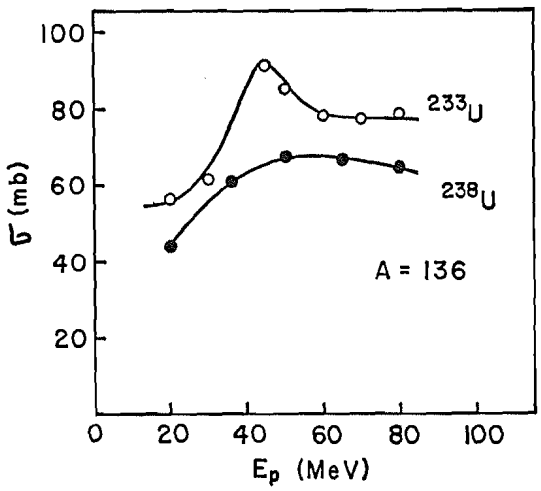

FIG. 16. Total isobaric cross section for $A = 136$.

MeV by means of the postulates of equal charge displacement (e.c.d.) (12) or unchanged charge division (u.c.d.) (13). Compound nucleus formation was assumed in this energy range. The excitation energies given to the compound nucleus were estimated initially as full energy transfer, i.e. 20, 30, and 50 MeV, plus the Q value for the reaction. Then the residual energies were calculated at each stage after neutron emission until the residual excitation energy reached a value below the neutron-binding energy. In each case an average kinetic energy for neutron emission of $2T$ was taken, T being the nuclear temperature. The masses of the fissioning nuclei are shown in Table VI. The

TABLE VI

Estimated fissioning nuclei and initial mass of fission fragment (final $A = 136$) at several bombardment energies

	93	233	138
	93	232	138, 137
30	93	234	139
	93	233	139, 138
	93	232	138
	93	231	137
50	93	234	141, 140
	93	233	140
	93	232	139
	93	231	139, 138
	93	230	138

residual excitation energy of each nucleus was assumed to be divided into two fragments in the ratio of their masses when fissioning. In the next step, several fission processes leading to Cs isotopes were checked for each fissioning nucleus to find out which isotope contributes to the final fission product (^{136}Cs) as a result of post-fission neutron emission.

Z_p values were estimated according to the 2 postulates

$$Z_p = Z_{A_1} - 1/2(Z_{A_1} + Z_{A_2} - Z_f)$$

for e.c.d. where Z_{A_1} and Z_{A_2} are the Z_A values for the complementary fragments of masses A_1 and A_2, and Z_f is the nuclear charge, 93, of the compound nucleus.

Similarly

$$Z_p = (Z_f/A_f)A_1$$

for u.c.d., where A_f is the mass of the fissioning nucleus. Where 2 initial masses for a given fissioning nucleus had to be considered, as shown in Table VI, the average value of separately calculated Z_p values was taken. This is admittedly a crude approximation, but has no appreciable effect on the results.

In order to obtain the actual value of Z_p, to be compared with the experimental value, the formation and fission probabilities for a given fissioning nucleus have to be taken into account. The emission of charged particles can be disregarded in this low-energy region (14).

The probability, G, for the fission of a given nucleus is

$$G = \Gamma_f/(\Gamma_n + \Gamma_f)$$

where Γ_n and Γ_f are neutron evaporation and fission widths, respectively. Values of G were estimated from the data of Vandenbosch and Huizenga (15), assuming that the value of Γ_n/Γ_f is independent of excitation energy (16). The formation probability for the compound nucleus ^{234}Np was assumed to be unity and that for the product resulting from neutron evaporation was the neutron evaporation probability for the precursor.

The Z_p values, calculated on the basis of the e.c.d. and u.c.d. postulates were now weighted by the product of formation and fission probabilities for each fissioning nucleus and the weighted average Z_p value was determined. The calculated and experimental values are given in Table VII.

TABLE VII

Comparison of calculated and experimental Z_p values ($A = 136$)

E_p (MeV)	Z_p e.c.d.	Z_p u.c.d.	Z_p Experimental
20	54.0	55.2	54.8
30	54.0	55.2	54.9
50	54.6	55.8	55.1

The experimental values fall between those predicted by the 2 postulates.

Pappas (17) has suggested that e.c.d. and u.c.d. depict the asymmetric and symmetric modes of fission, respectively. In general, with increasing bombardment energy the yields corresponding to symmetric fission increase rapidly, but the relative yield of very asymmetric fission also increases (18). Thus the two-mode fission hypothesis would predict that the overall fission product distribution be interpreted as the superposition of an asymmetric and symmetric mode. If this is correct, the results given here would indicate that the 2 modes contribute roughly equally to the fission process at these energies.

It has also been shown by others (19, 20) that at low and medium energies, the u.c.d. postulate predicts Z_p values for the heavy mass chains which are higher than those experimentally determined. If one assumes this postulate, lower limits of the average total number of neutrons can be roughly estimated (6). An exact formulation of the u.c.d. postulate should of course involve an exact knowledge of the yields of pre- and post-fission neutrons. Failing that, the simplified expression given below can be used

$$(Z_p)_{fp} = A_{fp}\frac{Z_t + Z_{pr}}{A_t + A_{pr} - \bar{\nu}_T}$$

where fp, t, and pr refer to fission product, target, and projectile, respectively. This simplification makes the gross assumption that all the neutrons emitted are pre-fission neutrons. However, this is equivalent to the assumption that the mass of the fission product is the same as that of the fission fragment (before post-fission neutron emission) and introduces an error of only a few % into the calculations. Average $\bar{\nu}_T$ values estimated on this basis for $A_{fp} = 136$ are 3.2, 3.6, 4.0, and 4.5 neutrons for bombardment energies of 20, 30, 40, and 50 MeV, respectively. Although lower limits, the agreement with values deduced from the data in Table VI is quite good. These data have been extended to 80 MeV, where admittedly the assumption of compound nucleus formation is not so certain, and are compared with data obtained in a similar fashion from the work of Benjamin *et al.* (3) and Davies and Yaffe (4) for ^{232}Th and ^{238}U, respectively. The results are shown in Fig. 17.

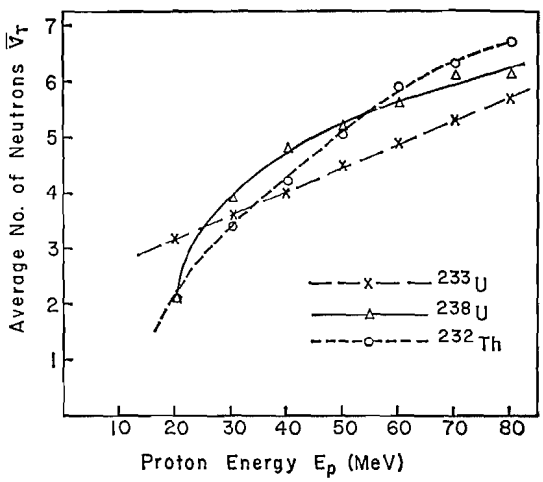

FIG. 17. Average number of neutrons ($\bar{\nu}_T$) as a function of bombardment energy as a lower limit, calculated on the basis of u.c.d.

Acknowledgments

The authors wish to thank Professor R. E. Bell, Director of the Foster Radiation Laboratory, for his ready permission to use the McGill Synchrocyclotron and Mr. R. H. Mills who cheerfully performed the irradiations.

Chemisorption of hydrogen on nickel–magnesia catalysts. Part I. General kinetic characteristics

N. S. VISWANATHAN[1] AND L. M. YEDDANAPALLI
Loyola College, Madras 34, India

Received August 19, 1968

A detailed study of the kinetics of hydrogen chemisorption on 3 different nickel catalysts, supported on magnesia and prepared by coprecipitation, has been made over a wide range of pressures and temperatures. The results have been analyzed in the light of the Elovich equation. Experimental data obtained by variations of pressure and temperature indicate the existence of a number of stages in the chemisorption process and support the multiple kinetic stage hypothesis suggested by Low. The effect of temperature on the parameters has been studied, and relations obtained which have been used to calculate activation energies for each of the stages.

Canadian Journal of Chemistry, 47, 2933 (1969)

The kinetics of chemisorption of gases on solids has been represented by various types of equations. A logarithmic relation, often referred to as the Elovich equation, probably has the widest applicability in accounting for the kinetic data in at least a semiquantitative way, as has been shown by Low (1). It has, however, been criticized quite often as being not much more than an empirical relation. Very recently Allen and Scaife (2) have attempted a modification of the Elovich equation and have indicated its usefulness in explaining commonly encountered experimental observations. They have employed a method based on linear regression analysis and claim a high order of precision in their evaluation of the Elovich parameters (3, 4).

In this paper, we report the experimental results of the chemisorption of hydrogen on nickel–magnesia catalysts, analyzed in the light of the Elovich equation. Not only a more thorough study of the kinetic characteristics of the adsorption than an earlier investigation from this laboratory has been made, but also a detailed study of the temperature effect on the adsorption process has been carried out in view of the conflicting reports on the activation energy of the process.

The Elovich equation is used in the form

$$dq/dt = a \exp(\alpha q)$$

as suggested by Low (1) and in the original paper by Roginskii and Zeldowich (5), a and α being constants.

[1]Present address: Components Division, IBM East Fishkill, Hopewell Junction, New York 12533.

Experimental

The adsorption measurements were made in a constant volume system, provided with a McLeod gauge and accurately calibrated oil and mercury manometers. The dead spaces used in the experiments were 27.97 ml with mercury manometers and 87.97 ml with the Apiezon oil manometers. The adsorption was followed by the decrease in pressure in the constant volume system. In the cases of low initial pressure experiments, limitations were due mainly to noting small changes in pressure of gas remaining in the system after long adsorption times. The oil manometer was of the differential type with Apiezon B oil (ABO) which had been thoroughly degassed and which permitted accurate measurements of low initial pressures (equivalent to 1 mm Hg).

The nickel–magnesia adsorbent was prepared by coprecipitation of the mixed hydroxides from a solution of the 2 nitrates in about 250 ml of distilled water by the addition of 1 *N* sodium hydroxide solution. The precipitates were washed for 48 h with distilled water, dried for 12 h at 110 °C, and finally the dried hydrated oxides were reduced in a stream of purified hydrogen at measured flow rates.

Nickel nitrate, (British Drug Houses) Analar quality was of purity better than 99.94%, magnesium nitrate (Sarabhai Merck) was of guaranteed Reagent quality with purity better than 99.98%, and sodium hydroxide (E. Merck) was of analytical grade.

The amount of nickel in the catalysts was estimated by wet methods. The degree of reduction was estimated by the methods described by Schuit and de Boer (6). The method using HCl was found to give satisfactory results when compared with the sulfur vapor method described by these authors. The data reported in Table I were obtained by the HCl method. The dimethylglyoxime method was crosschecked by an electrochemical method based on the outline by Furman (7). Dead space measurements were made with helium and nitrogen according to the method described by Loebenstein (8). Surface area measurements were made by the Brunauer–Emmett–Teller (B.E.T.) method at −183 °C with nitrogen as the adsorbate. In a few cases krypton was used at −196 °C. There was a variation of 10% in the values of the B.E.T. areas by these gases. All the B.E.T. areas mentioned in

‖Estimate based on hydrogen adsorption at low temperatures.

this paper were made using nitrogen, except in the case of catalyst **1** for which experimental evidence of possible nitrogen chemisorption precluded any B.E.T. measurements with nitrogen as the adsorbate gas.

Hydrogen was purified by passage over platinized asbestos at 450 °C, then through a drying tower, and finally through a cold trap maintained at −183 °C. The flow rates were controlled by Hoke valves and measured by soap bubble flowmeters. Nitrogen was purified by passage over hot copper at 350 °C, dried over drierite, and passed through a dry ice – acetone trap before being allowed into the system. Helium was purified by passing it over reduced copper turnings at 400 °C and then through an activated charcoal trap at −195 °C.

Temperature control better than 1 °C during adsorption experiments was achieved by a Fisher–Serfass relay in conjunction with a Gallenkamp contact thermometer as the sensor in the heating circuit of the furnace. Low temperature measurements were made with appropriate baths, suitably thermostated. For measurements at 100 and 0 °C, boiling water and melting ice were used.

Between adsorption measurements, the adsorbents were degassed for 8 h at 380 ± 4 °C at 10^{-6} mm Hg. This pressure was obtained by a Cenco Megavac and a mercury diffusion pump along with cold traps. Helium flushing was resorted to for a few experiments but this procedure did not seem to lead to any significant improvement over the normal degassing method which was adopted in general. The reproductibility of the surface was checked by making adsorption measurements at standard conditions.

A summary of the properties of the catalysts and some relevant data of interest are given in Table I.

Results and Discussion

For the evaluation of the Elovich parameters, the integrated form of the Elovich equation has been used in the form (9)

$$[1] \qquad q_{nt} - q_{mt} = \frac{2.303}{\alpha} \log n/m$$

where q_{nt} and q_{mt} are the volumes of gas adsorbed at N.T.P. at times nt and mt respectively. In the present study the values of $a\alpha$ were very large and the linearizing constant t_0 for the $q - \log t$ plots was found to be small. Hence the algebraic method suggested by Low and Saramousakis was used entirely for the evaluation of the parameters. α was calculated by eq. [1] and a by using the known values of q according to the relation

$$[2] \qquad q_1 = \frac{2.303}{\alpha_1} \log a_1\alpha_1$$

where q_1 = volume adsorbed at time t = 1 min. This method was found to be superior to using the slopes of Elovich plots.

By an exhaustive study of the adsorption kinetics of a number of gas–solid systems, Low found that the slopes of the Elovich $q - \log t$ plots showed changes both in magnitude and direction. In the case of hydrogen on rhodium and palladium he could detect several kinetic stages (10) in a single adsorption experiment, and on this basis suggested the possibility of multiple kinetic stages in terms of which the experimental data of earlier investigations could be explained. Our own preliminary experiments with catalyst **1** and the earlier work from this laboratory (11) seemed to indicate, in fact, the occurrence of more than one kinetic stage in the same adsorption experiment. Figure 1 represents a typical series of adsorption plots for catalyst **1** at an initial pressure of 60 cm Hg. Curves A and C represent the data for 208 and 30 °C respectively, and show breaks at different times with slopes of different magnitude. In the case of curve A, the slope of the first position is lower than that of the second position whereas the reverse is the case with curve C. Curve B is a straight line; this is being considered for discussion in a later section. In the case of catalyst **3** of a different nickel content, a similar behavior was observed.

*Initial pressure 60.00 ± 1.5 cm Hg.
†Initial pressure 60.00 ± 1.21 cm Hg.

Figure 2 gives the results obtained with catalyst **2** and for initial pressures of hydrogen less than 60 cm ABO, that is, less than 4 cm Hg. Plot *D* represents the data at 30 °C, *F* at 200 °C, and *E* at 84 °C. This last plot is a straight line. A similar type of plot at a constant temperature and varying pressures was obtained, although the data at low pressures were not very quantitative due to difficulty in measuring small volumes of hydrogen.

Having established experimentally that the variation of pressure and temperature bring about variations in the nature of Elovich plots, and knowing that the slope of the plot is equal to $2.303/\alpha$, the quantity of gas adsorbed at time t is given by

$$[3] \qquad q_t = \frac{2.303}{\alpha} \log (1 + a\alpha t)$$

It was of interest to study the effects of temperature and pressure on the Elovich constants which indirectly define the adsorption behavior of the catalyst.

Effect of Temperature

An attempt has been made to examine the Elovich plots at a fixed initial pressure over a range of temperatures on catalysts **1** and **3**. Table II contains the data for these 2 catalysts at the high pressure of 60 cm Hg, and Table III the data for low pressure of 60 cm ABO on catalyst **2**. In both the tables, the values of α_1 and α_2 are for the first and second portions of the plots. Columns 3 and 4 show the values of log $a_1\alpha_1$ and log $a_2\alpha_2$ for the two portions of the curves. It is to be noted that the parameters for the second portion of the curve after the break were evaluated on the assumption that the value of q at the time of the break is equal to q_0 for this portion. q_1 is the q value of the adsorbed gas from the graph at time 1 min plus the time of appearance of the break. Thus, if the break appears at time 20 min, the value of q at time 21 min is taken as the value for the evaluation of a_2. Columns 5 and 6 list the values of a_1 and a_2 evaluated in this manner. The last column shows the time of occurrence of the break in minutes. Table III lists the data obtained similarly on catalyst **2** at low pressures.

Examination of Table II reveals that both α and $a\alpha$ decrease gradually with increasing temperatures. In the case of catalyst **1**, log $a_1\alpha_1$, and a_1 show an increase with temperature but log $a_2\alpha_2$ and hence a_2 show inconsistencies. The data presented for catalyst **3** show that α_1, α_2 log $a_1\alpha_1$, log $a_2\alpha_2$, and a_2 show a decrease with increasing temperature. It is to be noted that an examination of the data available in the literature (1) shows that this is the behavior expected for the hydrogen–nickel system. Catalyst **1** showed some peculiar adsorption data and gave indications of adsorbing nitrogen at low temperatures (12).

Catalyst **2** provides some interesting information as seen from the data in Table III. In the range 200–127 °C, the α values for the first portion of the curve listed in column 2, while decreasing with increasing temperatures, are consistently smaller than the α values for the second portion of the curve. But within the range 70–0 °C the reverse holds true, the α_2 values being smaller than α_1 values. This means that the comparison of the parameters should be made within a restricted range of temperature.

In the range 0–70 °C the values of α_1, α_2, and

0	6.540	5.777	7.516	7.952	5.017×10^{6}	1.550×10^{7}	29

*Initial pressure: 60 ± 1.50 cm ABO.

t_b show the expected decrease with temperature. A similar behavior is seen in the case of the values in the temperature range 127–200 °C. The magnitudes of all the constants change drastically in the region 70–127 °C. The error in the earlier observations reported from this laboratory was due to associating the values of parameters with the kinetic plot itself, assuming that the same kinetic stages were present and could be detected in all the temperature ranges. By this assumption it has not been possible to explain the drastic increase in the α values with an increase in temperature.

In the case of catalyst **1**, in Table II, it is seen that at 100 °C the values of α_1 and α_2 are very close, 3.893 and 3.651 respectively, and these decrease with increasing temperature. Extending this tendency one might say that there should be a temperature at which the values should be equal and the Elovich plot should show no breaks, and be a straight line with $t_b = 0$. By graphical extrapolation of the plot of α values with temperature, the critical temperature was found to be around 96 °C. Runs at 94 ± 4 °C showed that there was no break till 160 min at an initial pressure of 60 cm Hg. This plot is given in Fig. 1 as plot *B*.

It might be of interest to note that from the data in Table III for catalyst **2** it has been possible to estimate the temperature at which the Elovich plot would be a straight line to be 90 °C and the value α to be 3.500. The actual plot obtained at 84 °C with initial pressure of 60 cm ABO is given by *E* in Fig. 2, the experimental α value being 3.519. Utilizing this value the data in Table III can be grouped into those of two temperature ranges, 0–84 °C and 127–200 °C. The results in the latter range show some inconsistency only in the case of a_1 and a_2 values. In the range 84–127 °C, the kinetic data failed to show any regularity. No satisfactory explanation of this is at present available. However, within the temperature ranges mentioned above, the general behavior of adsorption of hydrogen on various catalysts studied seems to be perfectly in line with the results reported by Low (1).

Effect of Pressure

In order to examine the effect of pressure on the adsorption kinetics at constant temperature, catalysts **1** and **3** were used for the high pressure range 10–60 cm Hg and catalyst **2** for the low pressure range 15–60 cm ABO (1–4 cm Hg). Table IV contains the data for catalyst **1** and catalyst **3**. The α values show an increase with decrease in pressure, whereas all other values decrease with decrease in pressure. The decrease in the values of a_1 was found to be quantitative in the case of experiments on catalyst **3** in the sense that a plot of log P_0 (initial pressure) vs. log a_1 gave a straight line. Such a linear relationship has been reported by Kubakowa for hydrogen on chromia gel (13) and by Low (1).

The results on catalyst **1** given in Table V for 30 and 200 °C show that α_1 and α_2 increase with decrease in pressure. The same trend was observed at other temperatures too. However, the changes in the α values at lower pressures are much more marked. Thus, at 200 °C for a variation of pressure from 40 to 30 cm ABO the value changes from 3.650 to 4.461, whereas for a pressure change from 19.96 to 15.05 cm ABO, the α value goes up from 9.001 to 14.040. Experimental limitations prevented accurate measurements at initial pressures less than 10 cm ABO, although these could be of interest.

Figure 3 represents the Elovich plots at 30 °C,

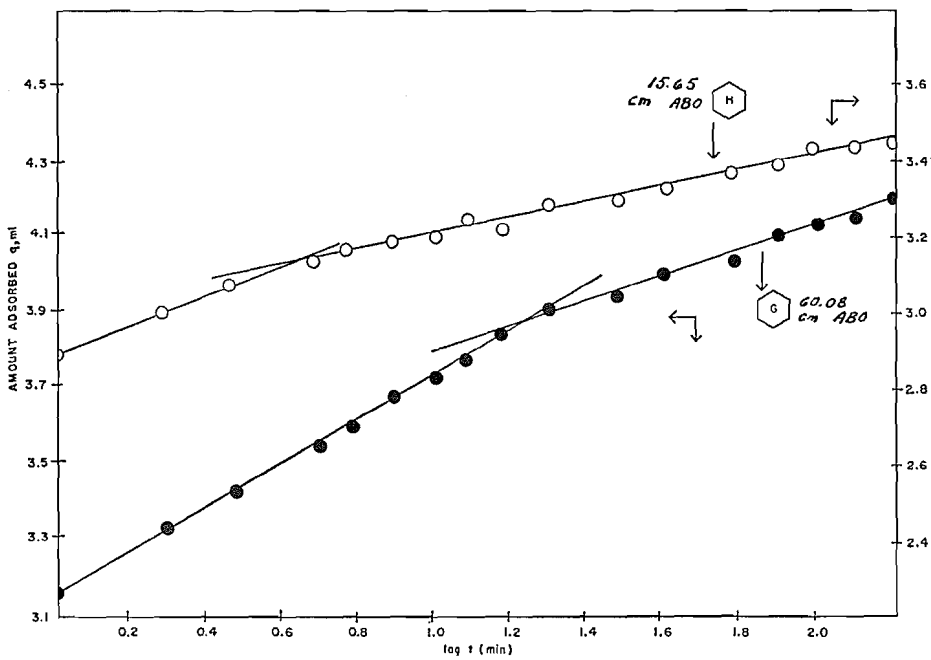

FIG. 3. Effect of pressure on the Elovich plots. Catalyst **2** at 30 °C: *G* at 60.08 cm ABO, ●; *H* at 15.65 cm ABO, ○.

G and *H* being for pressures 60.08 and 15.65 cm ABO respectively. Figure 4 illustrates changes in α values for catalyst **1** at 208 °C for the high pressure region and Fig. 5 for catalyst **2** at 127 °C in the low pressure region. The changes in this last case are drastic, as demonstrated also by Low's data on many systems at low pressure.

From the experimental results presented so far, some general conclusions may be drawn about the nature of the plots. At a constant pressure the break in the $q - \log t$ curve appears earlier with increasing temperature.

At constant temperature, the break appears early with decreasing pressures. Also, the changes in α values seem to depend on the temperature range in question.

Some of our results on catalyst **2** and those of Low on platinum group metals, lend support to his hypothesis of multiple kinetic stages. For instance, α_2 for catalyst **2** in the range 0–70 °C is

less than α_1 of Table III, but in the high temperature range α_1 is less than α_2. In other words, α values show a regular variation only within a definite temperature range. At 84 °C this temperature variation disappears and there is no break in the Elovich plots. Following Low, one might say that the portions of the plots within the temperature range 0–84 °C are analogous to portion *A* of the Low's idealized curve. Our kinetic data above 84 °C represent portion *B*, and the data at higher temperatures, portion *C* of Low's curve. Actually, this last point has not been verified by our results, since due to experimental difficulties, low enough pressures could not be attempted, and at higher temperatures desorption from the metal surface was noticeable. It is as well to note that Low was successful in detecting all these breaks only in a few cases. However, it seems to be reasonable to postulate the occurrence of stepwise adsorption, each step characterized by its own Elovich parameters. In the case of high temperature experiments, our

results would suggest the occurrence of stages II and III, stage I being submerged in the first portion of the plots and experimentally not detectable.

A complete physical explanation of the multiple kinetic stages as mentioned by Low, is not available at present. An excellent parallelism seems to exist between chemisorption stages and the well-established kinetic stages in the oxidation of metals. It may be of interest that our observations made in 1964 (14), were the first to be reported in this connection and that the recent adsorption data reported by Allen and Scaife seem to be in agreement with the multiple stage hypothesis. Our present experiments (15) on variation of support material might throw added light on to this matter.

Energies of Activation

Activation energies have been calculated according to the expression suggested by Leibowitz *et al.* (18)

$$[4] \qquad E = RVq\left(\frac{e^{\alpha q}}{e^{\alpha q} - 1}\right) - RY$$

which, when $e^{\alpha q} \gg 1$ as in the present case, yields $E = RVq - RY$, where R is the gas constant; V and Y are evaluated by the following relationships

$$[5] \qquad \alpha = V/T - U$$

$$[6] \qquad \ln a\alpha = Y/T - X$$

V and Y were evaluated by a least square analysis of experimental data. Substituting these values, we get for stage I, the relationships

$$[7] \qquad \alpha_1 = \frac{3.504 \times 10^3}{T} - 6.290$$

$$[8] \qquad \ln a_1\alpha_1 = \frac{2.450 \times 10^3}{T} - 1.457$$

the expression for E being:

$$[9] \quad E = 1.987\,(3.504 \times q - 2.450 \times 2.303)$$

For this stage at temperatures less than 84 °C, the minimum and maximum values of q are 2.211 and 3.451 ml. On substitution of these values, E is found to be between 4 and 13 kcal.

Stage II, as was suggested earlier, might occur at both temperature ranges below and above 84 °C (as the second portion and the first portion of the Elovich plots) and using q values of 3.452 and 4.972 ml, the value of E is between 7–15 kcal at the low temperature region. In the case of temperatures above 84 °C, the value of E lies between the extremes of 7 to 34 kcal (q being 2.979 to 5.002 ml).

For stage III, calculations show E to have limits of 36 to 60 kcal.

In all the stages considered, E values are positive and seem to fit in the multiple stage hypothesis of Low. The value 4–13 kcal for stage I is well within the range of 7–34 kcal of stage II so that the first portion of the Elovich plot at higher temperatures is in fact a combination of stages I and II. Similarly, the final portions of stage II seem to be in close agreement with the values of E calculated for stage III.

The range of activation energies seems to indicate the actual merger of one stage into the next one. The high values of E for stage II in the final portions and those of stage III from the initial portions are not easy to account for.

The experimental data presented in this paper offer support to the multiple kinetic stage hypothesis suggested by Low. This hypothesis, which is in accordance with his observations on a number of systems, is based on results from our laboratory on the hydrogen–nickel system (10, 15–17) and very recently on the reports of Allen and Scaife (2–4) on a different system. Catalyst **1** used in the present study, however, shows different adsorption behavior than that reported earlier. It has to be stressed here that the catalyst used in the earlier reports had different surface properties (surface area 21.30 m^2 as against 196.8 m^2 in the present case) and the degree of reduction of the surface can be different. The multiple kinetic stages can be caused by the nature of the surface. In their paper, Allen and Scaife offer an explanation based on the interaction of adsorbed particles with the surrounding sites, and use the Elovich equation with an additional term γ. However, the lack of mathematical foundation casts doubt on the universal applicability of this approach to explain the multiple kinetic stages.

The Taylor–Thon model (19) and the Gundry–Tompkins model (20) have enjoyed a wide applicability in the case of a number of gas–solid systems, especially in explaining the effects of temperature on chemisorption kinetics. Special mention should be made of the former model, which is probably the only one which takes the

occurrence of breaks in the Elovich plots into account.

Low, by using the Taylor–Thon model, derives the Elovich equation in the form

$$[10] \qquad \frac{dq}{dt} = K[V_0]\, e^{-(K_d/K)q}$$

giving the values

$$[11] \qquad a = KV_0$$

and

$$[12] \qquad \alpha = \frac{K_d}{K}$$

where K_d is the rate of chain termination (by which free valences terminate on the surface). K is the rate constant for the overall adsorption process, and V_0 is the initial site density. This derivation seems to account for all the relations involving the constants, except in the case of α variations with initial pressure. The following explanation may be considered valid for this phenomenon. α is calculated to be equal to K_d/K. The site destruction process is governed by K, while the formation of sites themselves, as suggested by the Taylor–Thon hypothesis, depends on the adsorbate concentration; this, in a constant volume system, is completely controlled by initial pressure of the gas. This makes K smaller, due to the non-availability of sites making α higher at low pressure regions. It has to be noted that in this treatment, the Elovich constants show the expected variation with the initial pressure. The effect of ambient pressure changes on these is to be reported later.

The model proposed by Allen and Scaife suffers from the drawback that it fails to show any variations of α with pressure and temperature. This is in complete disagreement with all the data available on chemisorption kinetics.

The Gundry–Tompkins model, based on the mobility of adsorbate from sites of strong adsorption to those of weak adsorption, is well supported by the now widely accepted type C adsorption states suggested by Dowden (21), and by a recent tracer experiment by Takeuchi and Miyatani (22). Low temperature experiments should be of real significance in explaining some of the kinetic characteristics.

Chemistry Department, University of New Brunswick, Fredericton, New Brunswick

Received January 29, 1969

The soluble hydrated oxyfluoborates previously reported as "$CuBF_3O \cdot 5H_2O$" and "$ZnBF_3O \cdot 7H_2O$" are now believed to be the fluosilicates $CuSiF_6 \cdot 4H_2O$ and $ZnSiF_6 \cdot 6H_2O$. The insoluble anhydrous oxyfluoborates of Sr, Ba, and Pb could not be prepared.

Introduction

The existence of salts of the oxyfluoborate ion, $[BF_3O]^{2-}$, was first reported in a series of papers by Ray and Mitra (1–6). In these papers, they give the preparation and chemical analysis of the soluble, hydrated oxyfluoborate salts of Cu, Zn, Cd, Co, and Ni; and of the insoluble anhydrous salts of Sr, Ba, and Pb. They also report X-ray powder diffraction patterns for the copper, barium, and lead salts.

Ray and Mitra's claim to have established this new family of salts is supported by two later papers, the preparation and examination of $ZnBF_3O \cdot 7H_2O$ by Long and Bailey (7); and the determination of the structure of $BaBF_3O$ from its X-ray powder diffraction pattern by Chackraburtty (8), using a sample supplied by Mitra.

In this paper, we report that the compounds previously identified as $CuBF_3O \cdot 5H_2O$ and $ZnBF_3O \cdot 7H_2O$ are the fluosilicates: $CuSiF_6 \cdot 4H_2O$ and $ZnSiF_6 \cdot 6H_2O$. We were unable to repeat Ray and Mitra's preparation of the insoluble, anhydrous oxyfluoborate salts of Sr, Ba, and Pb.

Experimental

"$CuBF_3O \cdot 5H_2O$"

This compound was prepared by the reaction of basic copper carbonate, boric acid, hydrofluoric acid, and nitric acid as described by Ray and Mitra. The product was recrystallized from aqueous solution. X-Ray powder diffraction patterns taken before and after recrystallization established that no decomposition had occurred. An identical copper salt was also obtained when the procedure of Ray and Mitra was followed, with the exception that boric acid and nitric acid were not added to the reaction mixture.

"$ZnBF_3O \cdot 7H_2O$"

This salt was prepared by reacting zinc carbonate, boric acid, hydrofluoric acid, and nitric acid as described by Ray and Mitra.

$CuSiF_6 \cdot 4H_2O$

A 25% aqueous solution of HF was allowed to stand over excess silica for several days. The resulting solution was decanted and added to a paste of basic copper carbonate and water. After reaction, the solution was filtered and evaporated to a smaller volume in a hot water bath at 45 °C. The blue crystals obtained were then recrystallized from aqueous solution at the same temperature.

$ZnSiF_6 \cdot 6H_2O$

This compound was prepared by a procedure similar to that for $CuSiF_6 \cdot 4H_2O$.

All compounds were analyzed as follows: copper and zinc gravimetrically by thermal decomposition to the oxides; copper was also determined by electrodeposition; boron by flame spectrophotometer using the emission line at 521 mμ; fluorine by titration with standard base; silicon by using sodium carbonate to precipitate H_2SiO_3 from an aqueous solution of controlled pH and the precipitate analyzed by thermal decomposition to SiO_2.

Table I gives the results of the analyses together with those reported by Ray and Mitra and by Long and Bailey.

Results and Discussion

The analyses and X-ray powder patterns, Tables I, II, and III, establish the identity of both the copper and zinc compounds prepared by us as the fluosilicates $CuSiF_6 \cdot 4H_2O$ and $ZnSiF_6 \cdot 6H_2O$. The powder pattern for "$CuBF_3O \cdot 5H_2O$" published by Ray and Mitra contains relatively few lines. This pattern corresponds, within the limits of probable experimental error, with the strongest lines of $CuSiF_6 \cdot 4H_2O$. The line given at 2.38 Å must be our line at 2.27 Å.

A single crystal examination of both "$CuBF_3O \cdot 5H_2O$" and $CuSiF_6 \cdot 4H_2O$ by oscillation and Weissenberg photography, confirms the powder identification and gives the space group as $P2_1/c$, with cell dimensions $a = 5.36$ Å, $b = 9.64$ Å, $c = 7.22$ Å, $\beta = 105.2°$. These cell dimensions agree with the optical results given by Mellor (9) for $CuSiF_6 \cdot 4H_2O$, ratio $a:b:c = 0.5519:1:0.7604$, $\beta = 105.6°$; and allow the powder patterns to be indexed unambiguously, as shown in Table II.

We have no explanation to offer for the results of the chemical analyses given by Ray and Mitra for both compounds. The analysis of the zinc compound by Long and Bailey does not have a fluorine assay and the boron and zinc content differ from the theoretical values by almost 8%.

The absorption frequencies in the infrared (i.r.) region reported by Long and Bailey can all be accounted for by a mixture of zinc nitrate and zinc tetrafluoborate. The components for these compounds are present in Ray and Mitra's procedure. $ZnSiF_6 \cdot 6H_2O$ shows three absorption frequencies in this i.r. region, none of which coincide with those reported by Long and Bailey, as shown in Table IV.

Neither Ray and Mitra, nor Long and Bailey

examined their preparation for silicon content, as silicon was not intentionally added to the reaction mixture. We believe, however, that silicon enters the reaction mixture at the point in the Ray and Mitra procedure (4) when the mixture is stored in a glass desiccator. We observed that the glass was subject to chemical attack during this storage period and a white deposit was left on the inner surface. This deposit was identified by X-ray analysis as $NaBF_4$. The silicon probably moves into the reaction mixture through the formation of SiF_4 by fluoride attack on the glass. SiF_4 readily reacts with water to form H_2SiF_6.

Attempts to prepare the insoluble oxyfluoborates $BaBF_3O$, $SrBF_3O$, and $PbBF_3O$ by the procedure of Ray and Mitra were unsuccessful. However, we did obtain a small yield of barium salt whose X-ray diffraction pattern is different to that reported for $BaBF_3O$. The powder pattern for this compound identifies it as $BaSiF_6$ (Table V).

Ray and Mitra state that $BaBF_3O$ and $PbBF_3O$ are isomorphous with the corresponding sulfates. Our inability to prepare these compounds, their similarity to the sulfates, and the presence of sulfuric acid as a desiccant in the storage stage of the Ray and Mitra procedure suggest that they may have prepared the sulfates, rather than the oxyfluoborates.

On the characteristic vibrations of the NH_2 group

B. R. CAIN, J. M. FREEMAN, AND T. HENSHALL[1]

Department of Chemistry and Applied Chemistry, University of Salford, Salford M5 4WT, Lancashire, England

Received February 18, 1969

The group frequency factorization procedure developed by King and Crawford (1) for the reduction in size of a vibrational secular determinant, by factorizing from it those frequencies that are characteristic of a constituent group, and subsequently extended by us (2), has now been successfully applied to NH_2 group vibrations.

The method is exemplified by the skeletal vibrations of methylamine, for which satisfactory results are obtained on factorization from the secular determinant of frequencies that are characteristic of both NH_2 and CH_3 groups.

Canadian Journal of Chemistry, 47, 2947 (1969)

The NH_2 group in both primary amines and amides is associated with three characteristic infrared (i.r.) absorption bands. Two, with frequencies around 3500 and 3300 cm^{-1}, are identified respectively with the antisymmetric and symmetric NH stretching vibrations. In the third, in the range 1590–1650 cm^{-1}, the $H\hat{N}H$ bending mode is considered to predominate (3). The NH_2 group can also engage in inter- and intramolecular hydrogen bonds, but no attempt is made to account for these effects in our considerations.

Analysis of the NH_2 group vibrations involves the consideration of a "standard molecule", NH_2—R, with the geometry of Fig. 1, and in

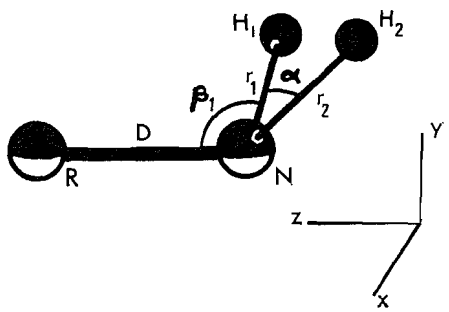

FIG. 1. The "standard molecule" RNH_2: r = 1.014 Å, D = 1.474 Å, α = 106°, β = 112°.

which R is assigned infinite mass (actually 10^6 a.m.u.). This "standard molecule" belongs to the symmetry point group C_s; and the symmetry coordinates chosen for the A′ and A″ vibrational species are given in Table I.

[1]To whom correspondence should be addressed.

TABLE I

Symmetry coordinates in C_s for the "standard molecule"

Species	Coordinate	
A′	$S_1 = (r_1 + r_2)/\sqrt{2}$ $S_2 = \alpha$ $S_3 = D$ $S_4 = (\beta_1 + \beta_2)/\sqrt{2}$	Group coordinates
A″	$S_5 = (r_1 - r_2)/\sqrt{2}$ $S_6 = (\beta_1 - \beta_2)/\sqrt{2}$	Group coordinate

The calculations of the frequencies in NH_2R reported here constitute an extension and improvement of those first reported by King (4) and use the same values for the force constants (Table III), and the valence force field of Table II. In Table III, the constant K_D is representative

TABLE II

Valence force field for NH_2R*

$2V$	r_1	r_2	D	α	β_1	β_2
r_1	K_r	F_r	0	0	0	0
r_2		K_r	0	0	0	0
D			K_D	0	$rF_{D\beta}$	$rF_{D\beta}$
α				r^2H_α	0	0
β_1					r^2H_β	r^2F_β
β_2						r^2H_β

*$r = r(\text{N—H})_{eq}$.

TABLE III

Force constants for "standard molecule" NH_2R (mdyn $Å^{-1}$)

Force constant	Value	Force constant	Value
K_r	6.40	F_r	0.00
K_D	4.80	$F_{D\beta}$	0.14
H_α	0.65	F_β	−0.03
H_β	0.47

For personal use only.

of an N—C bond, with the intention to extend the calculation to organic molecules.

The calculations were performed on an English-Electric KDF-9 computer. The calculated frequencies are listed in Table IV, and the normal coordinate matrices, taken with experimental evidence, indicate that ν_1 and ν_2 in A′, and ν_5 in A″ are group vibrations. The orthogonal transformation matrices **A** relating new displacement coordinates **D** to symmetry coordinates **S** through $\mathbf{D} = \mathbf{A}^*\mathbf{S}$, and which are required in the group factorization procedure (1), are given in Table V. Since the leading elements in the **A** matrices greatly exceed the off-diagonal entries, the success of the NH_2 group frequency factorization procedure was assured, and the submatrix $\bar{\mathbf{H}}_{gf}$ was null as required by the method.

The corrections, $\mathbf{\Phi}_{ff}$, which are to be made to the force field of a framework to which the NH_2 group is attached are given in Table VI; those in the A″ species are so small as to be negligible.

The effective-mass tensor, $(\mathbf{M}^{-1})^+_{NN}$, of the NH_2 group whose elements are the effective inverse masses in $(\text{a.m.u.})^{-1}$ of the nitrogen atom required in the construction of a reduced kinetic matrix $\mathbf{G}^+_{ff}$, is given in Table VII.

TABLE IV

Calculated frequencies of "standard molecule" NH_2R (cm^{-1})

Species	Mode	Frequency	Species	Mode	Frequency
A′	ν_1	3371	A″	ν_5	3432
	ν_2	1630		ν_6	967
	ν_3	688			
	ν_4	786			

TABLE VI

The corrections, Φ_{ff}, to the force constants for framework vibrations (mixed units)

$\Phi_{ff}(A')$	S_3	S_4
S_3	0.0278	−0.0382
S_4	−0.0382	0.0641
$\Phi_{ff}(A'')$	S_6	
S_6	0.0004	

TABLE VII

Effective mass tensor $(M^{-1})^+_{NN}$ for the nitrogen atom in the NH_2 group

$(M^{-1})^+_{NN}$ (a.m.u.$^{-1}$)	X_N	Y_N	Z_N
X_N	0.06529	0	0
Y_N		0.06758	0
Z_N	(symmetrical)		0.06561

The coordinates S_4 and S_6 which describe respectively the symmetric and antisymmetric $\hat{HNR}$ angular deformation frequencies, and which are coupled to the vibrations of the framework to which the NH_2 group is attached, involve the displacements of both N and H atoms. The complete effective mass matrix $(\mathbf{M}^{-1})^+$ which is required for the factorization of the NH_2 group frequencies will hence contain cross-terms involving these atoms. The diagonal elements $(\mathbf{G}^+)_{ii}$ $(i = 4, 6)$, of the reduced kinetic matrix $\mathbf{G}^+_{ff}$ require effective inverse hydrogen masses for their calculation. Following the methods described in (1) with the molecular geometry of Fig. 1, and the assumption that the expressions for μ^+_H are relatively insensitive to

TABLE V

The orthogonal transformation matrix, **A**, for NH_2 group frequency factorization

A (A′)	D_1	D_2	D_3	D_4
S_1	−0.9995	−0.0168	−0.0260	0.0013
S_2	0.0124	−0.9403	0.1464	0.3071
S_3	0.0284	−0.1755	−0.9815	−0.0706
S_4	−0.0005	0.2912	−0.1203	0.9490
A (A″)	D_5	D_6		
S_5	0.9999	−0.0083		
S_6	−0.0083	−0.9999		

changes in geometry, the following results were obtained

$$\mathbf{G}^+_{44} = \mu^+_{H(2)}/r^2(2m^2/\sin^2\beta)(1/D - \cos\beta/r)^2\mu_{Ny} + [2(1 + n\cos\beta)^2/r^2\sin^2\beta]\mu_{Nz} + (2m^2/D^2\sin^2\beta)\mu_R$$

where

$$\mu^+_{H(2)} = 0.4973 + 0.0450a$$

$$\mathbf{G}^+_{66} = \mu^+_{H(1)/r^2} + (2l^2/\sin^2\beta)(\cos\beta/r - 1/D)^2\mu_{Nx} + (2l^2/D^2\sin^2\beta)\mu_R$$

where $\mu^+_{H(1)} = 0.9917 - 0.0015a$, $a = r/D$, and l, m, n are the direction cosines of the N—R bond.

For the off-diagonal elements of $\mathbf{G}^+$ involving the interactions of S_i ($i = 4, 6$), with any framework coordinate S_j, and for which $(\mathbf{G}^+)_{ij} = \boldsymbol{B}_i(\mathbf{M}^{-1})^+\boldsymbol{B}^*_j$, the required row vectors $\boldsymbol{B}_i(\mathbf{M}^{-1})^+$ are given in Table VIII. It is therefore to be noted that when the terms $(1/D - \cos\beta/r)$ and $(1 + n\cos\beta)$ arise in the elements of the $\mathbf{G}$ matrix of the A′ vibrational species of molecules with NH_2 groups, then on taking account in the $\mathbf{G}^+_{ff}$ matrix for vibrational interaction between ν_4 and the group vibrations in such molecules, these terms are to be modified respectively to

$$(1/D - \cos\beta/r + 0.6453/r)$$

and

$$(1 + n\cos\beta - 0.4026 + 0.0319a)$$

Similarly, in considering the vibrations of species A″, when the term $(1/D - \cos\beta/r)$ arises in $\mathbf{G}$, it must be replaced in $\mathbf{G}^+_{ff}$ by $(1/D - \cos\beta/r - 0.0076/r)$ to account for the interaction of ν_6 and the NH_2 group vibrations.

Application of first-order perturbation theory (1) leads to the following approximation equations for the NH_2 group frequencies.

Species A′

$$\lambda_1 = 6.6948 + 1.0434\Delta F_{11} + 0.0147\Delta F_{22} + 0.0016\Delta F_{33} + 0.0006\Delta F_{44} - 0.0020\Delta F_{34}$$

[1] $$\lambda_2 = 1.5648 + 0.0004\Delta F_{11} + 2.0120\Delta F_{22} + 0.0042\Delta F_{33} + 0.4623\Delta F_{44} + 0.0881\Delta F_{34}$$

[2] $$\lambda_5 = 6.9376 + 1.0831\Delta F_{11} + 0.0115\Delta F_{22}$$

$\Delta F_{ij} = F_{ij} - F^0_{ij}$, wherein F^0_{ij} refers to the "standard molecule", and F_{ij} is the corresponding force constant in the molecule bearing the NH_2 group. $\lambda_i = 4\pi^2c^2\nu_i^2/N_0$, where N_0 = Avogadro's number.

When applied to the methylamine molecule (with the notational changes of Tables I and X and with the force constants of Table XII), eqs. [1] and [2] give the encouraging results of Table IX.

It was then decided to attempt the factorization from the vibrational secular equations for methylamine of both the methyl and amino group frequencies. The methylamine molecule has 15 modes of vibration, and in C_s point symmetry, these may be subdivided as in:

characteristic group modes: $6A' + 3A''$

framework modes : $3A' + 3A''$

One of the A″ framework modes involves the relative internal rotation of the NH_2 and CH_3

TABLE VIII

Row vectors, $\boldsymbol{B}_i(\mathbf{M}^{-1})^+$, for the calculation of $\mathbf{G}^+$ involving the interaction of group and framework coordinates*

Vector	N			R		
$\boldsymbol{B}_1(\mathbf{M}^{-1})^+$	x	y	z	x	y	z
$\boldsymbol{B}_4(\mathbf{M}^{-1})^+$	0	b	c	0	$(-\sqrt{2}m/D\sin\beta)\mu_R$	0
$\boldsymbol{B}_6(\mathbf{M}^{-1})^+$	e	0	0	$(\sqrt{2}l/D\sin\beta)\mu_R$	0	0

*Wherein $b = (\sqrt{2}m/\sin\beta)(1/D - \cos\beta/r + 0.6453/r)\mu_{Ny}$
$c = (\sqrt{2}/r\sin\beta)(1 + n\cos\beta - 0.4026 + 0.0319a)\mu_{Nz}$
$e = (-\sqrt{2}l/\sin\beta)(1/D - \cos\beta/r - 0.0764/r)\mu_{Nx}$
l, m, n are direction cosines of the N—R bond, and are respectively $\sin\alpha/2$, $-\cos\beta$, $(\cos^2\alpha/2 - \cos^2\beta)^{\frac{1}{2}}$.

Two linear correlations of pK_a vs. solvent composition

JOAN A. GOWLAND[1] AND GEORGE H. SCHMID
Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received February 18, 1969

The dissociation constants, pK_a, of pyridine, *n*-pentylamine, triethanolamine, and benzylamine were studied in a series of ethanol–water and dimethyl sulfoxide – water solvent systems. Linear correlations were found between the pK_a of these amines and Kosower's Z values and weight % water content of the solvent.

Introduction

Many studies have been carried out to determine the dissociation constants of acids and bases in mixed solvent systems containing water and a miscible organic solvent. Michaelis and Mizutani (1–3), early workers in this field, studied benzoic acids, amines, amino acids, lower weight carboxylic acids, and hydroxycarboxylic acids in ethanol–water and methanol–water solvent systems. Their plots of pK_a vs. % volume alcohol gave non-linear lines of various shapes. Later workers, Hall and Sprinkle, obtained similar results (4).

In time, correlations were attempted which would give linear plots with changing pK_a, and which would lead to some explanation for the change of pK_a with changing solvent composition. One of the first was the correlation between changing pK_a and the inverse of the dielectric constant (5). Again non-linear plots were obtained. Added refinements such as Schwarzenbach's work (6, 7) combining the effects of dielectric constant and changing radius of the species with changing solvent gave only slightly improved results. It was felt (ref. 8, p. 193) that this treatment broke down because the dielectric constant measures a property of the solution in general and takes no account of specific solvent–solute effects.

In light of this, Grunwald and co-workers proposed Y_- and Y_0 activity functions (9–11) for pK_a correlations in the ethanol–water system. Their results were satisfactory for carboxylic acids but less satisfactory for amines, and were limited because the work was confined to the ethanol–water solvent system.

Another recent approach by Glover (12, 13) was to include the molal concentration of the solvent promoting ionization in the K_a equilibrium expression. Difficulties were encountered here in determining the exact structure of the mixed solvent and in deciding which portion of it participated in the ionization process. However, solvation effects do seem to be important in these studies. It was felt that a better understanding of the change in pK_a with changing solvent lay in finding some indication of the nature of the solvent in the immediate vicinity of the molecules involved in the dissociation.

Since none of these correlations gave satisfactory results in all cases, it became of interest to find a linear relation between the changing pK_a of an amine in the mixed solvent systems ethanol–water and dimethyl sulfoxide – water. Since most of the work reported has been concerned with a property of the solvent as a whole, it seemed, then, that some parameter which was a measure of the change of the solvent in the immediate vicinity of the ions might prove a useful correlation.

In 1958, Kosower (14) discovered that the charge transfer band in the ultraviolet (u.v.) spectrum of 1-ethyl-4-carbomethoxypyridinium iodide was very sensitive to solvent changes. The energy calculated from the wavelength of the charge transfer band gave an empirical measure of the ionizing ability of the solvent system and was defined as the Z value of the solvent. It was felt that the solvent environment in this electron transfer might be similar enough to the charge transfer from the protonated base to the free proton, to give a useful correlation. Therefore, in order to test this idea, pK_a values were determined for pyridine, triethanol–amine, benzylamine, and *n*-pentylamine in ethanol–water and dimethyl sulfoxide – water mixtures.

Experimental

A. Preparation and Purification of Materials

All melting points and boiling points are uncorrected. Ultraviolet spectra were taken on a Bausch and Lomb 505 spectrometer equipped with a thermostated cell block with temperature 25.15 ± 0.05°. Refractive indices were measured on a Bausch and Lomb "Abbe" Refractometer.

(a) Solvents

Ethanol. Technical grade absolute ethanol was purified according to a modification of the method of Vogel (15).

Dimethyl Sulfoxide (Fisher Certified Reagent) was distilled with slight modification according to the procedure of Schlafer (16). Because of decomposition at higher temperatures, fractions were collected for use only if the boiling point was less than 55° and the pressure of the system less than 5 mm Hg. The criteria of purity were (*a*) resistance > 9900 Ω, (*b*) freezing point > 18.50°, (*c*) $n_D^{25} = 1.4778$.

Water. Doubly distilled water which was boiled just prior to use, was used to prepare all solutions.

(b) Bases

A value of pK_a in water in good agreement with literature values was considered a good criterion of purity for these bases.

Pyridine (British Drug House Ltd., Analar Grade) was purified by distillation from calcium hydride: b.p. 113.4° (lit. (17) 115.5°); $n_D^{26.5}$, 1.5066 (cf. ref. 18); and $\lambda_{max}^{95\%}$ EtOH, 257 mμ (ε 2862); $\lambda_{max}^{95\%}$ EtOH, 251 mμ (ε 2550, lit. (19)); $\lambda_{max}^{95\%}$ EtOH, 257 mμ (ε 2610); $\lambda_{max}^{95\%}$ EtOH, 251 mμ (ε 2370).

Benzylamine (Eastman Kodak Practical 579). About 25 ml of benzylamine was distilled from calcium hydride through a 20 cm column at reduced pressure, b.p. 83–84° at 23 mm Hg, (lit. (17), b.p. 84° at 24 mm Hg).

n-Pentylamine (Matheson, Coleman and Bell PX 308) was distilled from calcium hydride prior to use, b.p. 104° (lit. (17) b.p. 103°).

Triethanolamine (Fisher Certified Reagent) was distilled under vacuum, b.p. 137° at 150 μ Hg (lit. (17) b.p. 206.2° at 15 mm Hg).

(c) Compounds for Spectroscopy

Pyridine-N-oxide (Eastman Organic Chemicals) was distilled at 1 mm Hg and 75° to give colorless to white crystals.

1-Methyl-4-carbomethoxy-pyridinium-iodine. Isonicotinic methyl ester was prepared from isonicotinic acid (Kodak) according to the method of Levine and Sneed (20). Then, the isonicotinic methyl ester (4 g) and methyl iodide (4 g) were heated together in 6 ml of acetone to give bright orange crystals. The product was recrystallized from methanol, m.p. 174–176° decomp. (lit. (14) m.p. 176–179°).

B. Preparation of Solutions

(a) Ethanol–water solutions were made up by weight % and thus could be duplicated quite precisely. Stock solutions (1000 g) were prepared using absolute ethanol and water as described previously.

(b) Dimethyl sulfoxide – water solutions were prepared just before use with freshly distilled dimethyl sulfoxide (DMSO) in 250 g quantities because solutions did not seem stable over long periods of time. Refractive indices were used to compare different solutions of the same composition.

(c) Hydrochloric acid (approximately 1 *M*) was prepared by diluting C-I-L c.p. reagent concentrated HCl with boiled doubly-distilled water. NaOH, 1.0 *M* (standardized with potassium hydrogen phthalate just prior to use), was used to standardize the acid.

(d) N.B.S. buffers 185*c* (pH = 4.01 at 25.0°), 187*a* (pH = 9.18 at 25.0°), and 186*b* (pH = 6.86 at 25.0°) were prepared according to the instructions of the National Bureau of Standards supplied with the buffers.

C. pK_a Measurements

The general technique used to determine pK_a is that suggested by Albert and Sergeant (21).

(a) Apparatus. A Radiometer Type PHM 4b pH meter was used. It is calibrated to 0.01 pH units and thus pH readings can be made to ±0.002 pH units. Radiometer calomel (K4025) and glass (G2025B) electrodes were used. A Haake Thermostat type "F" bath was used and it maintained the temperature to within ±0.05° of the desired temperature.

The pK_a determinations were made in a jacketed vessel of approximately 125 ml volume. A ground glass top was fitted with ground glass openings for the electrodes, thus insuring the same geometry for the system at all times. An inlet and an outlet for nitrogen were also provided. A Hamilton microliter syringe No. 710 with a Chaney adapter was used to add the HCl. The volume delivered was determined by standardization with distilled water at 25°.

The pH values for triethanolamine and *n*-pentylamine determinations were fairly high and in these cases, the solutions were blanketed with nitrogen during the complete run to prevent contamination by CO_2. Further specific details for each amine are given in the results.

D. Determination of Z Values

Z values were determined according to the method of Kosower (14). In ethanol–water solutions 1-methyl-4-carbomethoxy-pyridinium-iodide was used as the primary standard from 0 to 40% water–ethanol. Because the charge transfer band becomes a poorly defined shoulder at this point, pyridine-N-oxide was used as a secondary standard for the remaining solutions. In a manner similar to Kosower, an equation linearly relating to *Z* values (energy of the charge transfer for the alkyl salt) and the energy, E_t, of the charge transfer for pyridine-N-oxide, $Z = 2.999E_t - 243.67$, was obtained by least squares calculation. In dimethyl sulfoxide – water, *Z* values could only be determined in pure DMSO, 5, 10% DMSO, and pure water (from Kosower's work (14)). These values were used to find the linear correlation between *Z* and E_t of $Z = 2.37E_t - 172.99$.

Results

All pK_a values were obtained by extrapolation to zero ionic strength and are thermodynamic values.

pK_a values for pyridine showed a definite increasing trend with increasing ionic strength as

TABLE I

pK_a of amines in the mixed solvent systems at 25 °C

% Solvent	pK_a

60% H_2O–DMSO	4.733			
50% H_2O–DMSO	4.521			

illustrated in Fig. 1. Therefore, the pK_a values for pyridine have been obtained from least squares calculations of the best line for pK_a vs. the ionic strength. No concentrations greater than 0.007 *M* were used since plots began to curve quite badly at higher ionic strengths. This curvature has been noted by other workers (22).

pK_a values for triethanolamine, benzylamine, and *n*-pentylamine were found to have random deviations smaller than those arising from experimental error and no trends were evident with increasing ionic strength. Therefore, the pK_a values for these three amines are taken to be thermodynamic values. The values obtained at 25° are summarized in Table I.

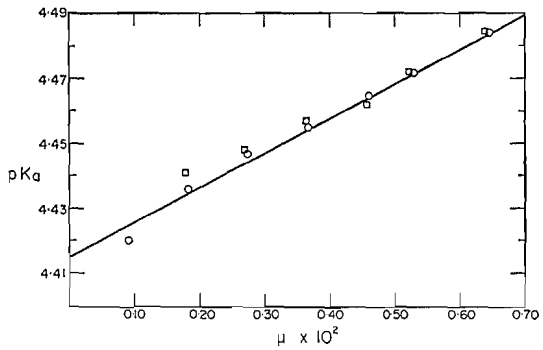

FIG. 1. pK_a of pyridine at different ionic strengths (μ) in 60% H_2O–EtOH at 24.97 °C: ○, no added salt; □, concentration of added LiCl is 0.0883×10^{-2} moles/l.

The validity of pH measurements in aqueous solvent mixtures has been established in other studies (22, 9). Bates (ref. 8, p. 222) has pointed out that many glass electrodes display nearly theoretical response to the hydrogen ion concentration to 10% water concentration.

The *Z* values for water–ethanol solutions are given in Table II and in Table III for water – dimethyl sulfoxide.

In this work, the methyl salt was used instead of the ethyl salt used by Kosower. However, λ_{max} usually differs by 0.5 mμ from the ethyl salt, that is, *Z* for the methyl salt is 0.0 to 0.4 kcal/mole higher than the ethyl salt (14). These differences fall within experimental error and thus the methyl salt energies may be called *Z* values.

To calculate *Z*, where it was not possible to measure λ_{max} for the methyl salt, an equation relating E_t and *Z* in the solutions where λ_{max} for both compounds used could be measured, was obtained by least squares measurements. Then λ_{max} for pyridine-N-oxide was measured, E_t was calculated, and *Z* was determined in the remaining

solutions by substituting E_t into the equation, for both ethanol–water and dimethyl sulfoxide – water. In both cases a *Z* value for water (given as 94.4 kcal/mole by Kosower (28)) was included in the data for find the best straight line.

As can be seen from Tables II and III, the change in the wavelength of λ_{max} for pyridine-N-oxide with changing solvent is quite small. However, measurements made over a period of 2 days on one solvent mixture, and duplicate or more measurements made at the same time on all other solvent mixtures indicate that the peak maximum occurred at a reproducible wavelength in all cases. Thus, the experimental error is estimated to be ± 0.1 mμ for pyridine-N-oxide maxima.

Because the peaks for the methyl salt are not symmetrical, and because there is some change with changing salt concentration in λ_{max}, the error in the wavelength of the maxima is ± 0.5 mμ.

Plots were made of the pK_a of all the amines studied in this work at 25°, vs. *Z* and all were found to be linear. They are shown in Fig. 2.

The data in this figure suggest a good correlation between pK_a and *Z*. However, once the values of pK_a and *Z* had been determined, it was found that plots of *Z* vs. weight % water are also linear from 100 to 40% water by weight for water–ethanol and from 100 to 65% water by weight for water – dimethyl sulfoxide. Although earlier workers suggested that plots against % solvent were not linear, these pK_a values were

plotted against weight % water and found to be linear for all the experimental data obtained, as illustrated in Fig. 3.

The results for plots of pK_a vs. weight % water for the amines studied tend to indicate that this correlation is sufficient and a secondary correlation such as against Z is not necessary.

Since only 4 amines were studied the correlations could not be assumed to hold generally. Therefore, it was of interest to take literature values of pK_a in ethanol–water (since no corresponding work has been reported in dimethyl sulfoxide – water) and see how linear correlations against weight % solvent and against Z would be.

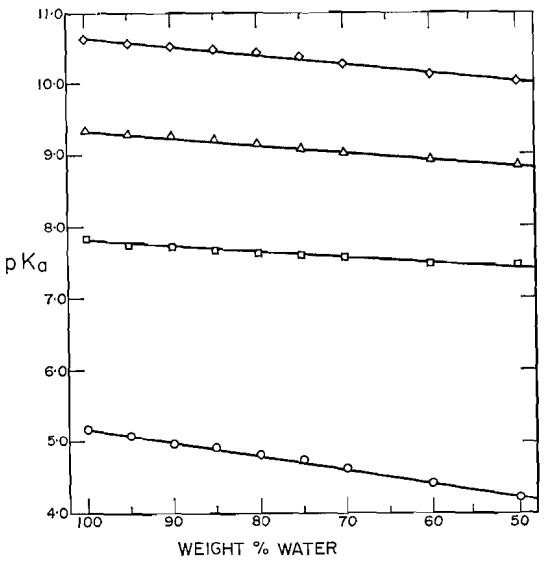

FIG. 3. pK_a of amines at 24.97 °C with changing concentrations of water–ethanol; ○, pyridine; □, triethanolamine; △, benzylamine; ◇, *n*-pentylamine.

Calculations were made on formic, acetic, and benzoic acids (9), *p*-methoxybenzoic acid (23), ϕ-$CH_2CH_2CO_2H$, ϕ-OCH_2CO_2H, and ϕ-SCH_2-CO_2H (24), aniline, methaniline, and dimethylaniline (10). The composition varied from pure water to approximately 20% water. In Table IV, the experimental and calculated pK_a values are given of compounds studied in this work.

As can be seen from Table IV, the results for amines are better than those for acids for the most part. The results from this work are generally in very good agreement (in most cases within experimental error) with the experimental pK_a values. The pK_a results calculated from equations vs. Z are as good as or often better than, results vs. weight % solvent.

The success of the correlation with carboxylic acids seems to depend unfortunately on the nature of the carboxylic acid. In view of the extra work needed to determine the values of Z for the various solvent systems, the correlation of pK_a with weight % water is to be preferred.

Correlation of the experimental data with Grunwald's Y_- (10) values would be of interest. However, only three of the reported Y_- values

are for solvent compositions used in this work. Therefore, it was felt that since other Y_- values were not available, a meaningful correlation with the experimental data was not possible.

Discussion

The plots of pK_a of pyridine vs. weight % water are good straight lines with good correlation coefficients as noted, except in H_2O–DMSO at 25° where the correlation coefficient for the plot against Z is slightly better.

The fact that the slope of the lines for pyridine is smaller in H_2O–DMSO would suggest that this solvent system affects the equilibrium in a different way and certainly to a lesser extent than does water–ethanol.

The two primary amines studied, benzylamine and *n*-pentylamine, both have similar slopes of approximately 0.01 for the plots of pK_a vs. weight % water–ethanol. Thus, they are affected similarly by the changing solvent composition. However, this slope is only about one-half that of pyridine in the same solvent. If the change in solvation of the protonated base affects the equilibrium, then these slopes are strange, for it is generally acknowledged (e.g. ref. 25) that primary amines and ammonium ions are more strongly solvated than tertiary amines. Hence, a greater change in pK_a in mixed solvents would be expected for primary amines than tertiary if the above assumption is correct. Since the opposite result was obtained, it can be suggested that, at least for the amines studied, either changing solvation for the protonated amine does not affect the equilibrium, or, solvation effects are seen only in variations of ΔH^0 and ΔS^0, and because of compensating effects, the variation is not seen in ΔG^0 (and therefore pK_a). For triethanolamine, the lines for pK_a vs. % solvent have slopes which are smaller than those for pyridine, thus indicating again that solvent changes do not affect the triethanolamine equilibrium as greatly.

It is most likely that the changing solvent system is affecting the activity coefficients of the amine, the protonated amine, and the proton. It would seem feasible that the change in the activity coefficients of the amine and protonated amine are either negligible or cancel one another out. Therefore, it is likely that the change in the activity of the proton as another solvent is added to water is affecting the pK_a of the amine. The exact nature of this change is complex and as Franks and Ives point out (26), great difficulty has been encountered in interpreting the data available from studies in alcohol–water systems.

Carbonyl stretching frequencies and force constants in cyclopentadienylmolybdenum tricarbonyl derivatives

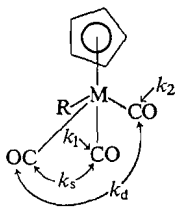
R. B. KING[1] AND L. W. HOUK[2]
Department of Chemistry, University of Georgia, Athens, Georgia

Received January 20, 1969

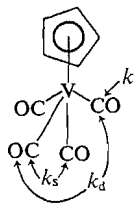
The infrared spectra of compounds of the type $RM(CO)_3C_5H_5$ (M = Mo or W; R = $(CH_3)_3Sn$, σ-alkyl groups, halides, etc.) exhibit the expected three ν(CO) frequencies (2A′ + A″). The relative positions of the A″ and the lower A′ frequencies interchange upon variation of the electronegativity of the R group. Values for the Cotton–Kraihanzel stretching force constants k_1 and k_2 have been calculated from these ν(CO) frequencies assuming the ratio $k_d/k_s = 2$ for the interaction force constants. From these force constants the σ and π parameters of Graham were calculated. The σ and π parameters were found to be very similar for analogous $RM(CO)_3C_5H_5$ and $RMn(CO)_5$ compounds.

Canadian Journal of Chemistry, 47, 2959 (1969)

Recently we have been studying the relationship between the π-cyclopentadienyl proton nuclear magnetic resonance (n.m.r.) chemical shifts and the carbon–oxygen stretching force constants in cyclopentadienylmetal carbonyls in an attempt to investigate the π-cyclopentadienyl n.m.r. chemical shift as a possible indicator of the negative charge on the metal atom (1). Evaluation of the carbon–oxygen stretching force constants in monocarbonyl and dicarbonyl derivatives from the ν(CO) infrared (i.r.) frequencies is a very simple problem. This paper discusses the much more difficult problem of evaluating the carbon–oxygen force constants from the ν(CO) frequencies in compounds of the type $C_5H_5M(CO)_3X$ (**1**: M = Mo or W; R = one-electron donor (2)).



1



2

These $C_5H_5M(CO)_3X$ compounds, **1**, have C_s symmetry. A group theoretical analysis predicts three ν(CO) frequencies (2A′ + A″) which are related to the four force constants (k_1, k_2, k_d, and k_s) by the following secular equations

$$2A': \quad \begin{vmatrix} \mu(k_2 + k_d) - \lambda & \sqrt{2}\mu k_s \\ \sqrt{2}\mu k_s & \mu k_1 - \lambda \end{vmatrix} = 0$$

$$A'': \quad \mu(k_2 - k_d) - \lambda = 0$$

Since there are four force constants but only three ν(CO) frequencies, a solution of the secular equations is only possible if one additional relationship between two of the force constants is used. This additional relationship requires an additional assumption and/or approximation. Since the stretching force constants k_1 and k_2 are both larger and of greater interest than the interaction force constants k_d and k_s, the additional relationship used was an assumption of a constant value for the ratio k_d/k_s.

The constant value of 2 for k_d/k_s was selected for the following reasons: (1) The metal orbitals required for bonding in $C_5H_5MX_4$ were first considered. The five metal orbitals s, p_x, p_y, p_z, and $d_{x^2-y^2}$ are used for the forward σ-bonding of the metal atom to the π-C_5H_5 ligand and the four X groups. The two metal orbitals d_{xz} and d_{yz} are used for the two orthogonal forward π-bonds of the metal atom to the π-C_5H_5 ring. This leaves the two metal orbitals d_{z^2} and d_{xy} available for retrodative bonding. Linear combinations of these two metal orbitals can form the following two hybrid orbitals

$$\psi^+ = 2^{-\frac{1}{2}}[\phi(d_{z^2}) + \phi(d_{xy})]$$

$$\psi^- = 2^{-\frac{1}{2}}[\phi(d_{z^2}) - \phi(d_{xy})]$$

The lobes of one of these hybrid orbitals will be of suitable symmetry to engage in retrodative

π-bonding with two X groups in mutually diagonal[3] positions of the $C_5H_5MX_4$ derivative. Similarly the lobes of the other of these hybrid orbitals can engage in retrodative π-bonding with the two remaining X groups which are also in mutually diagonal positions. However, X groups in lateral[3] positions do not use the same hybrid orbitals for retrodative π-bonding. These theoretical considerations thus suggest that the diagonal interaction force constant (k_d) is appreciably greater than the lateral interaction force constant (k_s) and hence that the ratio k_d/k_s is appreciably greater than 1. Indeed the metal orbitals available for retrodative π-bonding in $C_5H_5MX_4$ derivatives resemble those available for such bonding in the octahedral MX_6 compounds in that X groups in diagonal positions of $C_5H_5MX_4$ derivatives can interact through the same (hybrid) orbital as is the case with the X groups in *trans* positions of the octahedral complexes MX_6, whereas the X groups in lateral positions of $C_5H_5MX_4$ compounds do not interact directly through the same (hybrid) orbital, as is the case with X groups in *cis* positions of the octahedral complex MX_6. The successful approximation $k_t/k_c \approx 2$ for octahedral metal carbonyl complexes (3) suggests a similar approximation $k_d/k_s \approx 2$ for $C_5H_5Mo(CO)_3R$ complexes (2). Empirical evidence has been obtained supporting the approximation $k_d/k_s \approx 2$ for the $C_5H_5M(CO)_3R$ complexes. The related $C_5H_5MX_4$ compound, $C_5H_5V(CO)_4$, **2**, has only three force constants (k, k_d, and k_s) and exhibits the three ν(CO) frequencies A_1 (i.r. and Raman active), B_1 (Raman active), and E (i.r. and Raman active). The ratio k_d/k_s for $C_5H_5V(CO)_4$ can thus be calculated from its ν(CO) frequencies *without any approximations*. Such calculations (4) from Raman data on $C_5H_5V(CO)_4$ for the ratio k_d/k_s gave 1.53 (cyclohexane solution) and 1.73 (solid state). Similarly the ratio k_d/k_s for the acetylcyclopentadienyl derivative $CH_3COC_5H_4V(CO)_4$ was found to be 2.68 for the solid state (4). These experimentally determined values for k_d/k_s in cyclopentadienylvanadium tetracarbonyl derivatives support the assumption, $k_d/k_s \approx 2$, made for the $C_5H_5M(CO)_3R$ derivatives.

Previous studies on the infrared spectra of $C_5H_5M(CO)_3R$ derivatives indicate the observation of the expected three ν(CO) frequencies for some compounds of this type such as organotin derivatives (5) of the type $R_3SnM(CO)_3C_5H_5$ and the halides $C_5H_5M(CO)_3X$ (6). However, in previous work (5, 6) only two ν(CO) bands were observed for the σ-alkyl derivatives $RM(CO)_3C_5H_5$ (e.g. $CH_3Mo(CO)_3C_5H_5$) with metal-carbon bonds to the R group. The lower ν(CO) frequency was considerably more intense than the upper ν(CO) frequency. We have now found that the lower ν(CO) frequency in $RM(CO)_3C_5H_5$ compounds (R = σ-alkyl group) can be split into two closely separated bands by running the spectra under optimum conditions (cyclohexane solution (7) and a grating spectrometer). However, the infrared spectrum of the hydride $C_5H_5W(CO)_3H$ exhibited only two ν(CO) bands even under our optimum conditions.

Having obtained the three ν(CO) frequencies for the compounds of interest, the next problem was the assignment of these frequencies to the two A′ and one A″ modes. Data on related compounds, particularly $M(CO)_3L_2L'$ derivatives (8), indicated the highest and most widely separated ν(CO) frequency to be one of the two A′ modes. The two lowest and relatively close ν(CO) frequencies are then the remaining A′ mode and the A″ mode. Force constant calculations were made using both possible assignments of the two lowest ν(CO) frequencies. Decisions between the two possible assignments were then made using the following criteria:

(1) $k_1 < k_2$

The stretching force constant k_1 represents that of a carbonyl group diagonal to the R group whereas the stretching force constant k_2 represents that of a carbonyl group diagonal to another carbonyl group. Since all of the R groups in the $RM(CO)_3C_5H_5$ compounds investigated are weaker π-acceptors than the carbonyl group (3,

[3]The relative positions of the four X ligands in $C_5H_5MX_4$ complexes are conveniently designated by terms relating to their positions on the square with vertices corresponding to the four atoms of the four X groups which are directly bonded to the metal atom. *Diagonal* positions refer to positions at diagonally opposite corners of this square corresponding to the interaction constants k_d in structures **1** and **2**. Lateral positions refer to positions on one side of this square corresponding to the interaction constants k_s in structures **1** and **2**. Both diagonal and lateral positions are geometrically *cis* positions when considered relative to the metal atom. This paper suggests that diagonal positions in $C_5H_5MX_4$ complexes are electronically similar to *trans* positions in octahedral complexes and lateral positions in $C_5H_5MX_4$ complexes are electronically similar to *cis* positions in octahedral complexes.

7), the bond between the central metal atom and a carbonyl group diagonal to the R group is expected to be stronger than the bond between the central metal atom and a carbonyl group diagonal to another carbonyl group. This weakens the carbon–oxygen bond in carbonyl groups diagonal to the R group relative to that in carbonyl groups diagonal to another carbonyl group. For this reason, a requisite for a satisfactory assignment for the ν(CO) frequencies in the $RM(CO)_3C_5H_5$ compounds was $k_1 < k_2$. Implicit in this reasoning is the assumption of stronger interaction across diagonal positions than across lateral positions in $C_5H_5MX_4$ derivatives; this assumption is supported by both the theoretical considerations and the experimental data on $C_5H_5V(CO)_4$ given above.

(2) Comparison of π and σ parameters calculated for the $RM(CO)_3C_5H_5$ compounds with those previously (9) reported for $RMn(CO)_5$ derivatives with the same R group

In some cases a clear decision between the two possible assignments could be made by calculating the π and σ parameters of Graham (9) from the force constants for both possible assignments and selecting the assignment which gave π and σ parameters closest to those reported (9) for the analogous $RMn(CO)_5$ derivative. This was particularly useful for making the assignments in the cases of the trimethyltin derivatives $(CH_3)_3SnM(CO)_3C_5H_5$ (M = Mo or W) and the halides $C_5H_5M(CO)_3X$.

Table I indicates the assignments for the $RM(CO)_3C_5H_5$ compounds investigated in this work. Of particular interest is the assignment of the lowest ν(CO) frequency in the trimethyltin derivatives $(CH_3)_3SnM(CO)_3C_5H_5$ (M = Mo or W) to the unique A″ mode but the assignment of the middle ν(CO) frequency in the halides $C_5H_5M(CO)_3X$ (M = Mo or W, X = Cl or Br) to the unique A″ mode[4]. The relative positions of the A″ and lower A′ modes thus appear to interchange upon going from the relatively electropositive tin atom to the relatively electronegative halogens in $RM(CO)_3C_5H_5$ compounds. In cases where the $C_5H_5M(CO)_3$ group is bonded to an atom of intermediate electronegativity (carbon or hydrogen) the A″ and lower A′ ν(CO) frequencies are very close together[5]. In the case of the hydride $C_5H_5W(CO)_3H$ the A″ and the lower A′ mode could not be resolved even under our optimum conditions.

Table I also lists the force constants calculated for the $RM(CO)_3C_5H_5$ compounds on the basis $k_d/k_s = 2$. The stretching force constants k_1 and k_2 are all lower for $RM(CO)_3C_5H_5$ compounds than for the analogous $RM(CO)_5$ compounds. This is another example of the lowering of carbon–oxygen stretching force constants in metal carbonyls upon the replacement of carbonyl groups with more weakly retrodative bonding ligands (in this case the π-C_5H_5 ring). The general pattern of changes in k_1 and k_2 with changes in the R group for the $RM(CO)_3C_5H_5$ compounds resembles that previously reported for changes in k_1 and k_2 with changes in the R group for the $RM(CO)_5$ compounds. However, the difference $k_2 - k_1$ is much less with $RM(CO)_3C_5H_5$ compounds than with analogous $RM(CO)_5$ compounds. Changes in the value assumed for k_d/k_s have some effect on the value found for $k_2 - k_1$ with increases in k_d/k_s increasing the difference $k_2 - k_1$. However, even if k_d/k_s is assumed to be 3.33, the values calculated for $k_2 - k_1$ of the $RM(CO)_3C_5H_5$ compounds are still much less than the reported (7, 9) $k_2 - k_1$ values for $RM(CO)_5$ compounds. This means that the effect of a given change in the π-acceptor strength of the R group is less in a formally 7-coordinate $RM(CO)_3C_5H_5$ derivative than in an octahedral $RM(CO)_5$ derivative. This may arise

[4]The opposite assignment for $(CH_3)_3SnMo(CO)_3C_5H_5$ (middle ν(CO) frequency = unique A″ mode) gives the values $\sigma = 0.15$ and $\pi = -0.44$. The opposite assignment for $C_5H_5Mo(CO)_3Cl$ (lowest ν(CO) frequency = unique A″ mode) gives the values $\sigma = 0.10$ and $\pi = 0.29$. In the cases of these compounds as well as their tungsten analogues the σ and π parameters obtained from these "opposite" assignments are radically different from those of the analogous $RMn(CO)_5$ compounds (9).

[5]In the cases of $RM(CO)_3C_5H_5$ derivatives where R is a σ-alkyl group bonded to the metal atom by a metal–carbon bond, the positions of the two lowest ν(CO) frequencies were so close that a reversal in their assignments did not change the force constants enough to permit an unambiguous decision between the two alternatives by the criteria discussed above. In the absence of more definite criteria the assignments of the two lowest ν(CO) frequencies in the $RM(CO)_3C_5H_5$ derivatives with a metal-carbon bond to the R group were taken to be similar to the tin derivatives $(CH_3)_3SnM(CO)_3C_5H_5$ rather than the halides, on the basis of the greater similarity of carbon to tin than to halogen. This made the unique A″ mode the lowest ν(CO) frequency in these $RM(CO)_3C_5H_5$ derivatives with metal-carbon bonds to the R group.

*These frequencies (in cm^{-1}) were obtained from cyclohexane solutions using a Perkin–Elmer Model 621 spectrometer with grating optics. The spectra were calibrated against the 1601.4 cm^{-1} band of polystyrene. The reported frequencies are averages of values obtained from two different spectra.
†These force constants are reported in mdyn/Å. The assumption $k_d/k_s = 2$ was made.
‡These are reported in mdyn/Å and were obtained by the procedure described in ref. 9.
§The methyl derivatives were taken as the zero points.

from the availability of only two metal *d* orbitals for retrodative bonding to π-acceptor ligands in the $RM(CO)_3C_5H_5$ system as contrasted with the availability of three metal *d* orbitals for retrodative bonding to π-acceptor ligands in the $RM(CO)_5$ system.

The σ and π parameters of Graham (9) were also compared for some analogous $RM(CO)_3C_5H_5$ and $RM(CO)_5$ systems (Table II). These parameters were very similar for the same R group in both types of systems indicating the expected independence of σ and π bonding of the ligand on the nature of the metal atom to which the ligand is bonded. In order to test the importance of the assumption $k_d/k_s = 2$, the σ and π parameters found for several complexes were compared as the value of k_d/k_s was varied from 1.54 to 2.00 to 2.70. These calculations were made using the generalized Graham (9) equations $\Delta k_1 = \Delta\sigma + (k_d/k_s)\Delta\pi$ and $\Delta k_2 = \Delta\sigma + \Delta\pi$. The range 1.54 to 2.70 was selected as being the range of k_d/k_s values empirically found from the infrared and Raman studies on $C_5H_5V(CO)_4$ and $CH_3COC_5H_4C(CO)_4$ (4). Varying the k_d/k_s ratio in this manner did not alter significantly the relative σ and π parameters for the different R groups in the $RM(CO)_3C_5H_5$ complexes; instead, varying this ratio merely expanded or contracted the numerical range of the σ and π parameters. For this reason, possible errors

introduced by the assumption $k_d/k_s = 2$ do not affect the assignments and other significant conclusions of this paper.

Experimental

The $RM(CO)_3C_5H_5$ compounds used for this study were samples which had been prepared by published methods[6,7] (10). The infrared spectra in the 2100–1600 cm^{-1} region were run on a Perkin–Elmer Model 621 spectrometer with grating optics. Cyclohexane solutions were used. The spectra were calibrated against the 1601.4 cm^{-1} band of a polystyrene film. The frequencies reported in Table I were the average of frequencies obtained from two different spectra; frequencies observed from the different spectra of the same compound differed by less than 2 cm^{-1}.

The force constants were calculated from the ν(CO) frequencies on the University of Georgia IBM 7094 computer using a previously developed program (11). These calculations were performed for both possible assignments of the two lowest ν(CO) frequencies. In these calculations the *reciprocal* of k_d/k_s was made to vary in the range 0.30 to 0.75 in steps of 0.01. The calculations of force constants for different k_d/k_s ratios (see Table II) indicated that this ratio can deviate appreciably from the assumed value of 2 without having a significant effect on the conclusions of this paper.

Photolysis of thiophene vapor

H. A. WIEBE AND JULIAN HEICKLEN

Department of Chemistry and Center for Air Environment Studies, The Pennsylvania State University, University Park, Pennsylvania 16802

Received February 11, 1969

Thiophene vapor was photoexcited with 2139 and 2288 Å radiation as well as by mercury sensitization at 2537 Å. Experiments were done at 25, 200, and 305 °C at various pressures and light intensities as well as in the presence of CO_2, C_2H_4, butenes, and O_2. In all cases the products were C_2H_2, CH_2CCH_2, CH_3CCH, CS_2, CH_2CHCCH, and polymer. When O_2 was present CO_2, COS, SO_2, and CO were also produced. The product quantum yields dropped as the pressure was raised. A mechanism was deduced and is given by the lettered reactions in the text. The initially formed excited state, Th* (where Th stands for thiophene), as well as the excited intermediate leading to CH_2CCH_2 production, I*, decomposed at a rate dependent only on the total energy content, regardless of whether thermal or photolytic. The efficiencies for energy removal from both Th* and I* decrease along the series: thiophene, C_2H_4, CO_2, O_2. Appropriate rate constant ratios for all the gases were obtained and are listed in Table IX. Experiments in the presence of olefins showed that sulfur atoms were not intermediates. The experiments with O_2 further eliminated a number of possibilities. The hydrocarbons are all produced in primary processes with additional CH_2CHCCH and C_2H_2 coming respectively from the postulated intermediates ·CHCHCHCHS· and C_2H_2S. Along with the C_3 hydrocarbons, excited CS species are produced. They can either react with the above intermediates to produce CS_2 or be deactivated to eventually form polymer (or oxidation products in the presence of O_2).

Introduction

The photochemistry of various arylthiophenes in solution has recently been extensively examined (1, and references therein). A number of 2-arylthiophenes were found to undergo clean, irreversible photoisomerizations to 3-arylthiophenes. While 3-arylthiophenes failed to revert to the 2-substituted isomer upon photolysis, rearrangement of carbon atoms in the thienyl ring was observed.

It was suggested (2) that the photoreorganization proceeds by an excited singlet state intermediate, which may have a valene-type structure (1). Concerted rearrangement of this species would then account for the observed isomerizations. A mechanism involving ring-contracted thioaldehydes or thioketones as intermediates was considered to be unlikely.

On the other hand, furan, the oxygen analogue of thiophene, undergoes decarbonylation as the principal process when photolyzed (3–7). From chemical and kinetic evidence it was inferred that ring-contracted cyclopropene carboxaldehydes were formed as intermediates before loss of carbon monoxide. Photoisomerization of 2-alkylfurans to yield 3-alkylfurans (7) was also postulated to proceed through the ring-contracted intermediate.

Whereas $Hg(^3P_1)$ sensitization of furan gave carbon monoxide and cyclopropene as the principal products, direct photolysis (6) resulted in the formation of CO, allene, and methylacetylene, with cyclopropene present in only trace amounts. A pressure dependence on the quantum yield for CO production was observed in the $Hg(^3P_1)$ sensitized reaction, but was absent in direct photolysis. Since $Hg(^3P_1)$ sensitization should give triplet furan, these results suggested that direct irradiation produces an excited singlet state of furan which does not cross over to the triplet.

The present investigation was carried out to extend the photochemistry of thiophenes to the vapor phase. The effects of temperature, various additives, absorbed intensity, and energy of radiation on the photodecomposition of thiophene were examined. A kinetic analysis of the pressure dependence on the photodecomposition was made to determine if the presence of an intermediate is required to explain the mechanism of the reaction.

Experimental

Thiophene (Sharples Chemical Inc.) was purified by gas chromatography on a 20 ft long column packed with 10% tricresyl phosphate on chromosorb G. The column temperature was 100° with helium as the carrier gas at a flow rate of 60 cc/min. All gases were from the Matheson Co. C.P. grade C_2H_2, iso-C_4H_8, *trans*-2-C_4H_8, and bone dry grade CO_2 were used after degassing at −196°. HBr was distilled in vacuo at −130° after degassing at −196°. Extra dry grade O_2 was introduced into the reaction cell directly.

Cylindrical (50 × 100 mm) quartz reaction cells were used for all irradiations. These were incorporated into a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

grease-free vacuum system which utilized Teflon stopcocks with Viton "O" rings. For the temperature studies a reaction cell was mounted in an aluminium block furnace with quartz windows. The temperature variation during an individual experiment was $\pm 0.5°$.

The radiation sources for direct photolyses were Phillips 25 W cadmium and zinc resonance lamps. The effective emissions of these lamps were the spectral lines at 2139 Å (zinc) and 2288 Å (cadmium). The cadmium lamp also emitted at 2265 Å (about 25% as intense as the 2288 Å line) and at 2144 Å (about 20% as intense as the 2288 Å line). For mercury-photosensitized reactions a Hanovia flat spiral low-pressure mercury-arc in conjunction with a Corning 9-54 filter was used. The filter removed all radiation below 2200 Å. Since the absorption by thiophene vapor is very weak above 2475 Å, direct photolysis by the 2537 Å mercury resonance line was negligible.

After irradiation the products were analyzed by gas chromatography on a 20 ft long column packed with 10% dimethyl sulfolane on chromosorb P and operated at 0 °C with a helium flow rate of 65 cc/min. Samples of the products were obtained from the gas chromatographic effluent and identified on a Nuclide 12-90 mass spectrometer. Further identification came from comparison of the gas chromatographic retention times of the products with authentic commercial samples.

Products from the experiments with added olefin were also analyzed by gas chromatography on a 10 ft long column packed with 10% tricresyl phosphate on chromosorb G operated at room temperature and a helium flow rate of 50 cc/min. No compounds other than those observed with thiophene alone were found.

Since polymer formation was observed during long irradiations (1 h), air was admitted to the cell and heated with an oxygen torch to ca. 500° after each experiment to remove the polymer.

Quantum yields of the gaseous products were measured utilizing HBr as an actinometer at 2288 and 2139 Å (where $\Phi\{H_2\} = 1.00$ for conversions below 1% (8, p. 782)) and N_2O as an actinometer for the mercury-sensitized studies at 2537 Å (where $\Phi\{N_2\} = 1.00$). With 2537 Å radiation, all the light was absorbed and actinometry was straightforward. At the other wavelengths, equal optical densities of reagent and actinometer gases were used to avoid errors due to the uncertain path length of light. Room temperature extinction coefficients (to base 10) at 2139 and 2288 Å were found on a Cary 15 spectrophotometer to be, respectively, 5.40×10^{-3} and 1.17×10^{-3} $Torr^{-1}$ cm^{-1} for HBr and 0.198 and 0.258 $Torr^{-1}$ cm^{-1} for thiophene. The extinction coefficients at elevated temperatures were assumed to be the room temperature values. Thus optical densities are matched at elevated temperatures only if the ratio of extinction coefficients for thiophene and HBr is invariant with temperature. If the ratio is not invariant with temperature, then some error exists in our absolute quantum yields for elevated temperatures at the lower pressures. However, above about 0.8 Torr pressure, absorption is essentially complete, and uncertainties in the extinction coefficients are irrelevant.

Results

Thiophene vapor has a weak absorption band starting at about 2600 Å, but the absorption becomes very strong below 2400 Å (9). We have photodecomposed the vapor with 2139 and 2288 Å radiation as well as by mercury sensitization using 2537 Å radiation. Under all experimental conditions the gas phase products were C_2H_2, $CH_2{=}C{=}CH_2$, $CH_3C{\equiv}CH$, CS_2, and $CH_2{=}CHC{\equiv}CH$ even at elevated temperatures. Also produced was a brown, sulfur-containing polymer. The products were routinely analyzed by gas chromatography. Initially a combination thermal conductivity and hydrogen-flame detector was used; 10% of the sample was passed through the hydrogen flame and 90% was passed through the thermal conductivity cell which was needed for CS_2 analysis. Later a thermistor detector was used to obtain more accurate analyses. The polymer was not identified, but the following inequalities always held

$$[1] \quad \Phi\{CS_2\} \leqslant \Phi\{CH_2CCH_2\} + \Phi\{CH_3CCH\}$$

and

$$\Phi\{CS_2\} \leqslant (1/2)\Phi\{C_2H_2\} + \Phi\{CH_2CHCCH\}$$

The former inequality shows that CS groups were in the polymer, whereas the latter inequality indicated that additional sulfur (i.e., beyond that from CS groups) was also present.

The values reported for I_a are average values assuming uniform absorption in the reaction vessel. Actually the absorption is very nonuniform, and the effective intensity is much higher than the average intensity. All the quantum yields are correct, but relative rate constant ratios of processes first order in intermediates to those second order in intermediates will be lower limits. If the intermediates diffused completely through the cell before reaction then the average intensity goes over to the effective intensity and the computations are correct; otherwise they are not. In this system the intermediates proposed are CS, C_2H_2S, and $\cdot CHCHCHCHS\cdot$, all of which probably are long-lived and diffusion may be complete before reaction. In any case it happens that intensity effects are quite minor. Uncertainties introduced because of the variation in intensity throughout the cell cannot be much greater than the uncertainty due to experimental errors.

The effect of extent of conversion on product yields is shown in Table I for two conditions where it was thought the effect might be greatest.

TABLE I

Effect of extent of conversion on product yields

Irradiation time, min	$\Phi\{C_2H_2\}$	$\Phi\{CH_2CCH_2\}$	$\Phi\{CH_3CCH\}$	$\Phi\{CS_2\}$	$\Phi\{CH_2CHCCH\}$

16.0	0.244	0.071	0.034	0.145	0.113

The ± values reported in the table headings for all the tables do not reflect uncertainties in measurement, but rather variations in the experimental parameters. Product analysis was made utilizing the thermistor detector. For short irradiation times the product yields are all independent of time, but $\Phi\{CH_2CHCCH\}$ falls noticeably as the extent of conversion increases. This falloff is attributed to polymerization of the $CH_2{=}CHC{\equiv}CH$. The other product yields drop slightly as the irradiation time is lengthened at room temperature, but are unaffected at elevated temperatures. The room-temperature drop is an artifact caused by a diminishing intensity as polymer deposits on the windows and absorbs some of the light. This was verified by performing an actinometer run before and after a 30 min irradiation of 10 Torr of thiophene; I_a dropped by 25%. At elevated temperatures, the polymer does not deposit in the cell but rather on the inlet line (which is cold); thus the product yields, except for $CH_2{=}CHC{\equiv}CH$, are independent of extent of conversion. All experiments reported in subsequent tables were for small conversions, and the quantum yields reported are true initial values.

Tables II and III give the results of the photolysis of thiophene at 2139 and 2288 Å, respectively, as a function of pressure and light intensity for various temperatures. At 305 °C, a dark run showed no decomposition. To check that the products were not decomposing, some samples were permitted to remain at this temperature for ½ h after irradiation; the product yields were unaffected. As can be seen from Tables II and III the low pressure limiting value for $\Phi\{C_2H_2\}$ is about 0.31, independent of wavelength or temperature. The quantum yield of each of the products drops measurably as the pressure is enhanced. This effect is shown for C_2H_2 in Fig. 1. In spite of the scatter of the data, the Stern–Volmer plots in Fig. 1 give reasonable straight lines with a common intercept but different slopes for different temperatures and exciting wavelengths.

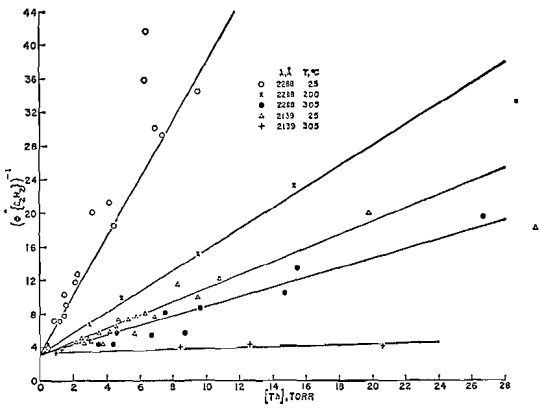

FIG. 1. Plots of the reciprocal acetylene quantum yield vs. thiophene pressure in the photolysis of thiophene vapor.

The quantum yields of the products other than C_2H_2 are presented as ratios, so that less important secondary effects can be discerned more easily. There is no effect of I_a on the hydrocarbon ratios under any conditions even when I_a was altered by a factor of 30. For the CS_2/C_2H_2 ratio there is also little if any dependence on I_a within the scatter of the data except for the room

†Average of runs with more than 2 Torr thiophene.

temperature runs. At room temperature, $\Phi\{CS_2\}/\Phi\{C_2H_2\}$ drops as I_a falls, especially at the higher pressures.

The pressure effects are somewhat more complex. $\Phi\{CH_2CHCCH\}/\Phi\{C_2H_2\}$ initially rises with the pressure and then levels off for all temperatures and incident wavelengths. $\Phi\{CH_3CCH\}/\Phi\{C_2H_2\}$ is invariant with changes in pressure but increases from 0.13 to 0.23 as the energy content is augmented. $\Phi\{CS_2\}/\Phi\{C_2H_2\}$ drops about a factor of 2 as the pressure rises from 0.1 to 40 Torr except for the lowest energy series of runs (i.e. 25 °C, 2288 Å) where the falloff is more pronounced and the highest energy series

of runs (i.e. 305 °C, 2139 Å) where there is no falloff. The ratio $\Phi\{CH_2CCH_2\}/\Phi\{C_2H_2\}$ is invariant to pressure changes at 0.31 ± 0.05 for 2139 Å radiation, but shows a falloff with increasing pressure at 2288 Å. The values range from 0.42 to 0.24 at 25 °C, 0.39 to 0.22 at 200 °C, and 0.38 to 0.30 at 305 °C.

To find out whether the pressure effects involved chemical reactions with the thiophene or whether they were inert gas effects, a number of experiments were done with CO_2. The results are listed in Table IV. For those runs in which CS_2 was not reported, product analysis was by hydrogen flame ionization. For the other runs the thermistor was used. In most respects the variations with CO_2 pressure are similar to but less pronounced than with thiophene, as would be expected for a less efficient inert gas. The quantum yields drop with increasing CO_2 pressure, and almost identical effects to those with thiophene are observed for $\Phi\{CH_2CCH_2\}/\Phi\{C_2H_2\}$, $\Phi\{CH_3CCH\}/\Phi\{C_2H_2\}$, and $\Phi\{CS_2\}/\Phi\{C_2H_2\}$. A minor difference is that $\Phi\{CH_2CCH_2\}/\Phi\{C_2H_2\}$ drops from 0.34 to 0.15 as the CO_2 pressure is raised to 76 Torr at 2139 Å and 25 °C. However, a significant difference occurs in $\Phi\{CH_2CHCCH\}/\Phi\{C_2H_2\}$ in that no enhancement occurs with the addition of

CO_2. Consequently the enhancement caused by increases in thiophene pressure must be a chemical rather than an inert gas effect.

The data in Tables V and VI show the results in the presence of C_2H_4 and O_2, respectively. Those runs of 20 min duration were analyzed by hydrogen flame and thermal conductivity detection, whereas the other runs were analyzed by the thermistor.

Ethylene acts like an inert gas, the effects being similar to those with CO_2. These results surprised us as we expected to trap sulfur atoms and find episulfides and possibly thiols (10). A careful search was made for these compounds but the results were negative. Runs were also done at 2139 Å, 25 °C, and 0.3 Torr of thiophene using 14.5 Torr C_2H_4, 7 Torr iso-C_4H_8, 0.31 Torr *trans*-2-C_4H_8, or 1.67 Torr *trans*-2-C_4H_8. The latter two compounds are respectively, 57 and 22 times more efficient than C_2H_4 in trapping sulfur atoms (10). Yet episulfides and thiols were definitely absent, clearly demonstrating that no free sulfur atoms were in the system.

Oxygen also did not behave much differently than CO_2 or C_2H_4. However, CO_2 and COS were produced, as well as SO_2 and CO. Our analysis procedure did not provide quantum yield information for the latter two products. One result which was different with O_2 was the value for $\Phi\{CH_2CHCCH\}/\Phi\{C_2H_2\}$ which dropped to 0.5 even with only 0.12 Torr of O_2 and remained at that value as $[O_2]$ was raised to 92 Torr.

The results of the Hg sensitized photolyses are in Tables VII and VIII. In Table VII the relative quenching efficiency between thiophene and N_2O was measured from the reduction in $\Phi\{N_2\}$. The C_2H_6 was present to scavenge the oxygen atoms; its cross section for quenching Hg6($^3P_1$) is too small (8, p. 74) to be of consequence. The reactions of pertinence are

[*a*] $\quad Hg^* + N_2O \rightarrow Hg + N_2 + O$

[*b*] $\quad Hg^* + Th \rightarrow$ removal of Hg*

where Hg* is the 6($^3P_1$) state of Hg. The expression for $\Phi\{N_2\}$ is

$$[2] \quad (\Phi\{N_2\})^{-1} = 1 + k_b[Th]/k_a[N_2O]$$

The data give a best estimate of 1.52 for k_b/k_a.

Table VIII lists the results of the Hg sensitized decomposition of thiophene. The gaseous products are the same as for the direct irradiation and even their relative importance is not much different. However the absolute quantum yields are much reduced and there is little, if any, falloff with increasing pressure except for C_2H_2 and CS_2. Extensive amounts of polymer were produced and this interfered with obtaining good

quantitative data. In the presence of O_2, the product quantum yields were not much affected though CO_2 and COS, as well as CO and SO_2, were produced. The CO and SO_2 quantum yields increased with exposure time, and they may be secondary products.

Discussion

The absorption of radiation leads to a π–π^* transition

[c] $\quad Th + h\nu \rightarrow Th^*$

where Th stands for thiophene and Th* is the vibrationally excited, upper singlet state. The Stern–Volmer plots in Fig. 1 show that quenching competes with photodissociation from a state which varies with the energy input to the molecule; this state must be Th*. Furthermore the results in Fig. 1 show that thermal and photolytic energy are equivalent.

Thiophene has 21 oscillators. In the classical limit these would provide 10.3 and 15.7 kcal/mole additional energy at 200 and 305 °C, respectively, over that at 25 °C. However, all the oscillators will not be classical. From Kassel theory computations, the number of effective classical oscillators usually corresponds to 1/2 to 2/3 of the actual number of oscillators. Then the additional thermal energy available at 305 °C would be reduced to 8–11 kcal/mole; at 205 °C, 5–7 kcal/mole. The 2139 Å line is more energetic than the 2288 Å line by 8.7 kcal/mole. Thus if thermal and photolytic energy are equivalent, the room temperature results at 2139 Å should lie between those at 200 and 305 °C at 2288 Å and very near to those at 305 °C and 2288 Å, which indeed they do.

The quenching and decomposition steps are included as follows

[d] $\quad Th^* + M \rightarrow Th + M$

[e] $\quad Th^* \rightarrow I^*$

[f] $\quad \rightarrow Th\ (+h\nu)$

[g] $\quad \rightarrow C_2H_2 + C_2H_2S$

[h] $\quad \rightarrow \cdot CHCHCHCHS\cdot$

[i] $\quad \rightarrow CH_3CCH + CS^*$

Reaction [d] is the normal quenching step, and either reaction [d] or reaction [f] might also lead to triplet thiophene, if that state does not decompose extensively. Reaction [d] could also lead to polymer if the quenching gas is thiophene itself.

The energized intermediate I* is needed as a precursor to $CH_2{=}C{=}CH_2$ formation in order to explain the pressure effect on $\Phi\{CH_2CCH_2\}/\Phi\{C_2H_2\}$. The intermediate I might be the valene intermediate suggested in the studies on arylthiophenes (1). Presumably it is not the triplet state which should be scavenged by O_2, nor the ring-contracted cyclopropene intermediate which should lead to cyclopropene (or propyne if the cyclopropene were formed "hot").

Reactions [f–i] are parallel processes and may proceed through some common precursor, but there is no kinetic need to invoke such a precursor. Steps [g] and [h] are responsible for C_2H_2 and

CH_2CHCCH production, respectively, even though our results with added olefins clearly indicate that sulfur atoms are not produced. The product of reaction [*h*] might be a contracted cyclic compound rather than a biradical, but mechanistic simplicity recommends the latter in the absence of any conclusive evidence. The C_2H_2 cannot come from "hot" CH_2CHCCH, for if it did, then $\Phi\{CH_2CHCCH\}/\Phi\{C_2H_2\}$ would vary with $[CO_2]$ and $[C_2H_4]$ as these quenchers thermalized the "hot" species. The variation of the ratio with [Th] must be interpreted by a chemical reaction rather than an inert gas effect. The subsequent discussion requires that the CS intermediate produced in step [*i*] must be energetic when initially formed and this is designated by the asterisk. Some excitation might also occur by absorption of the radiation by CS, which has a long lifetime and a large extinction coefficient in this region (11).

The intermediate I can either decompose to allene or be deactivated, thus explaining the pressure effect on $\Phi\{CH_2CCH_2\}/\Phi\{C_2H_2\}$.

[*j*] $\quad I^* \rightarrow CH_2CCH_2 + CS^*$

[*k*] $\quad I^* + M \rightarrow Th + M$

Again the CS intermediate is initially energized, the excess energy probably not being the same as from reaction [*i*]. However, for simplicity we shall consider all CS* identical. As before, reaction [*k*] could lead to triplet thiophene or polymer if thiophene is the quenching gas.

CS_2 must come from CS. Since there is an inert gas effect on CS_2 production, presumably the precursor is CS* which can be deactivated and removed as polymer.

[*l*] $\quad CS^* + M \rightarrow CS + M$

[*m*] $\quad nCS \rightarrow (CS)_n$

Reaction [*m*] might occur either in the gas phase or on the wall. The steps leading to CH_2CHCCH production are

[*n*] $\quad CS^* + \cdot CHCHCHCHS\cdot \rightarrow CS_2 + CH_2CHCCH$

[*o*] $\quad 2\cdot CHCHCHCHS\cdot \rightarrow 2CH_2CHCCH + S_2$

[*p*] $\quad Th + \cdot CHCHCHCHS\cdot \rightarrow 2CH_2CHCCH + S_2$

Reaction [*p*] is needed to explain the effect of [Th] on $\Phi\{CH_2CHCCH\}/\Phi\{C_2H_2\}$. These processes require ·CHCHCHCHS· to have a sufficiently long life time for reaction with thiophene. Other sulfur containing biradicals, such as thiodimethylene (12) and thiotetramethylene (13) have long lifetimes as shown by their addition across the double bond of olefins. Hence it is not unreasonable to assume that ·CHCHCHCHS· is also long-lived.

There are two possibilities for the C_2H_2S species. Either it polymerizes all the time or it yields C_2H_2 all the time. The two possibilities are kinetically indistinguishable. We choose the latter by analogy with the ·CHCHCHCHS· species. There is good supporting evidence for this choice. Strausz *et al.* (14) photolyzed $\overline{CH{=}CH{-}N{=}N{-}S}$ and found C_2H_2 and N_2 as the sole gas phase products. The decomposition was shown to proceed through a C_2H_2S intermediate by adding $CF_3C{\equiv}CCF_3$; the C_2H_2 formation was repressed and the adduct of C_2H_2S and $CF_3C{\equiv}CCF_3$ was found. Strausz *et al.* concluded that the structure of C_2H_2S was $\overline{CH{=}CHS}$. The thioketene structure $CH_2{=}C{=}S$ was eliminated since they should have been able to observe it by kinetic absorption spectroscopy in their system, and they did not. (Thioketene is stable as a monomer at -80 °C but polymerizes on warming (15).) The reactions of C_2H_2S become

[*q*] $\quad CS^* + C_2H_2S \rightarrow CS_2 + C_2H_2$

[*r*] $\quad 2C_2H_2S \rightarrow 2C_2H_2 + S_2$

[*s*] $\quad C_2H_2S + \cdot CHCHCHCHS\cdot \rightarrow C_2H_2 + CH_2CHCCH + S_2$

The invariance of $\Phi\{CH_3CCH\}/\Phi\{C_2H_2\}$ with [Th] requires that C_2H_2S does not react with thiophene.

The presence of even small amounts of O_2 drastically reduces CS_2 and CH_2CHCCH. Since this effect cannot possibly be a quenching effect, chemical scavenging of the intermediates must be involved.

[*t*] $\quad O_2 + \cdot CHCHCHCHS\cdot \rightarrow SO_2 + CH_2CHCCH$

[*u*] $\quad O_2 + C_2H_2S \rightarrow SO_2 + C_2H_2$

The COS results from oxidation of CS (16).

[*v*] $\quad CS + O_2 \rightarrow COS + O$

The oxygen atoms may further react to produce CO_2, though this cannot account for all the CO_2. Other photooxidation processes are probably occurring also.

*[Th] = 0.32 Torr.
†[Th] = 0.95 Torr.

The mechanism outlined above leads to numerous quantitative predictions. The C_2H_2 yield should obey the equation

$$[3] \quad (\Phi\{C_2H_2\})^{-1} = k_\phi/2k_g + k_d[M]/2k_g$$

where $k_\phi \equiv k_e + k_f + k_g + k_h + k_i$. Figure 1 shows plots based on eq. [3] when M is thiophene. The intercepts of all 5 plots are essentially the same and give $k_\phi/2k_g = 3.1$. It is only fortuitous that this ratio is independent of conditions since both k_ϕ and k_g should increase with the energy content of Th*. Apparently they increase proportionately. The slopes of the graphs give $k_d/2k_g$ and these are listed in Table IX. Since k_g

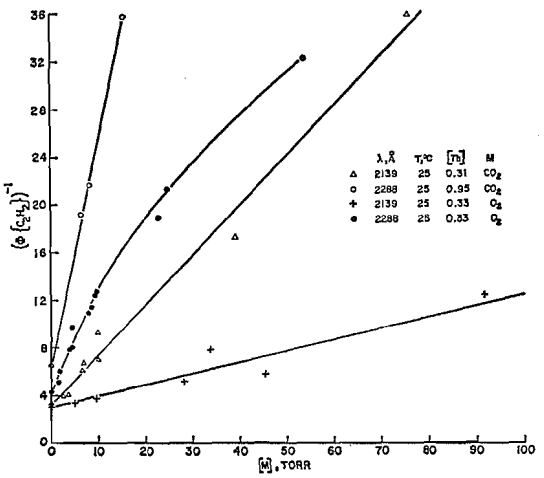

FIG. 2. Plots of the reciprocal acetylene quantum yield vs. the pressure of a foreign gas in the photolysis of thiophene vapor in the presence of foreign gases.

increases with the energy content of Th*, $k_d/2k_g$ drops. Figures 2 and 3 give the Stern–Volmer plots for other chaperone gases. The plots are linear except at low energy content (i.e., 2288 Å and 25 °C) with O_2. Here the falloff in $\Phi\{C_2H_2\}$ is not as rapid as expected at high pressures which suggests that additional oxidation processes are occurring (perhaps of I* or the triplet state) which lead to additional C_2H_2. The low pressure part of the graph is expanded in Fig. 3, and it is linear. The intercepts of each of the plots are different and correspond to the value for the thiophene pressure used at the respective conditions. The slopes give $k_d/2k_g$ and they are also

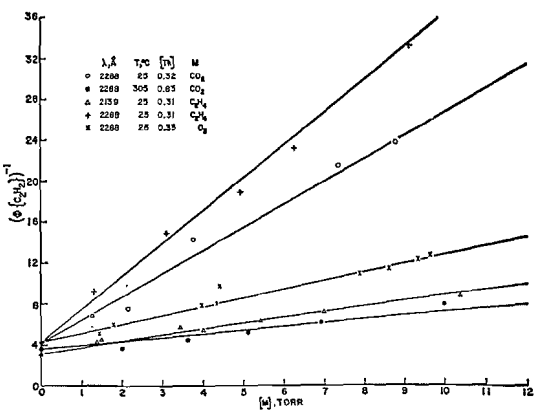

FIG. 3. Plots of the reciprocal acetylene quantum yield vs. the pressure of a foreign gas in the photolysis of thiophene vapor in the presence of foreign gases.

tabulated in Table IX. As with the thiophene, the ratio drops as the energy content of Th* is augmented. The two values for different [Th] at 2288 Å and 25 °C with CO_2 as a chaperone should be the same; within the experimental uncertainty, they are. The relative quenching efficiencies of thiophene, C_2H_4, CO_2, and O_2 are 1.1:1:0.7:0.26 at 25 °C and 2288 Å and 1.5:1:0.9:0.16 at 25 °C and 2139 Å. The quenching efficiencies are in the order expected, i.e. the efficiency increases with the complexity of the quenching molecule. Also it is to be expected that the quenching efficiencies should not be a strong function of the energy content of Th*. Even though $k_d/2k_g$ changes by a factor of 4 to 10 for the two conditions, the relative quenching efficiencies change less than a factor of 2. Finally if quenching occurs with each gas kinetic collision, then the values for $\log k_\phi$ (s^{-1}) vary between about 7 and 8.5, which are reasonable values.

The relative importance of the various decomposition paths [*g*], [*h*], and [*i*] can be obtained directly from the results. The mechanism predicts that

$$[4] \qquad \Phi\{CH_3CCH\}/\Phi\{C_2H_2\} = k_i/2k_g$$

The ratio k_h/k_g can be obtained in two ways. For high values of [Th]

$$[5] \qquad \Phi\{CH_2CHCCH\}/\Phi\{C_2H_2\} \rightarrow k_h/k_g$$

In the presence of O_2, the relationship is

$$[6] \qquad \Phi\{CH_2CHCCH\}/\Phi\{C_2H_2\} = k_h/2k_g$$

The values of $k_i/2k_g$ as obtained from the average value of $\Phi\{CH_3CCH\}/\Phi\{C_2H_2\}$ at each set of conditions are listed in Table IX. The values are independent of the nature of the chaperone gas, as they should be. They increase with the energy content of Th*, indicating that CH_3CCH is energetically more difficult to produce than C_2H_2. This conforms with expectations since CH_3CCH production requires a complex rearrangement of the parent molecule. Table IX also lists the values of k_h/k_g as determined from eqs. [5] and [6] and the data in Tables II–VI. The discrepancy in the values obtained from the two equations is rather large, but probably within the experimental uncertainty. If we accept the values obtained by using eq. [5] then k_h/k_g rises monotonically with the energy content of Th*. This result is somewhat surprising in that it indicates that reaction

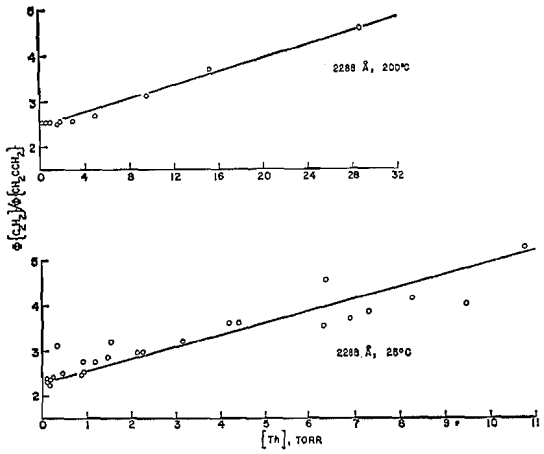

FIG. 4. Plots of the acetylene to allene ratio vs. thiophene pressure in the photolysis of thiophene vapor.

[g] is more favorable, energetically, than reaction [h]; one would have expected the opposite. Incidentally the ratio k_i/k_h rises slightly with energy content of Th*.

Information about the reactions involving the intermediate I* can be obtained from the relationship

$$[7]\quad \Phi\{C_2H_2\}/\Phi\{CH_2CCH_2\} = (2k_g/k_e)(1 + k_k[M]/k_j)$$

Figure 4 is the appropriate plot based on eq. [7] for the two low energy series with no foreign gas. The plots are reasonably linear and the intercepts give $2k_g/k_e$. For the three high-energy series, pressure quenching was too small for plots to be meaningful; however, averages of the low-pressure results for $\Phi\{CH_2CCH_2\}/\Phi\{C_2H_2\}$ give $k_e/2k_g$. The values for $k_e/2k_g$ are listed in Table IX. They diminish as the energy content of I* increases. The fourth entry is about 10% higher than it should be to fit in the progression, but this is probably within the experimental uncertainty. The ratios of slope to intercept for the lines in Fig. 4 give k_k/k_j for the two low-energy series. As expected the value drops from 0.122 $Torr^{-1}$ at 25 °C to 0.030 $Torr^{-1}$ at 200 °C. For higher energy conditions the ratios are so small that accurate values cannot be deduced.

Plots based on eq. [7] are shown in Figs. 5–7, when foreign gases are present. The intercept values do not give $2k_g/k_e$, but rather the value expected for the appropriate pressure of thiophene. The slopes give $(2k_g/k_e)(k_k/k_j)$. With the

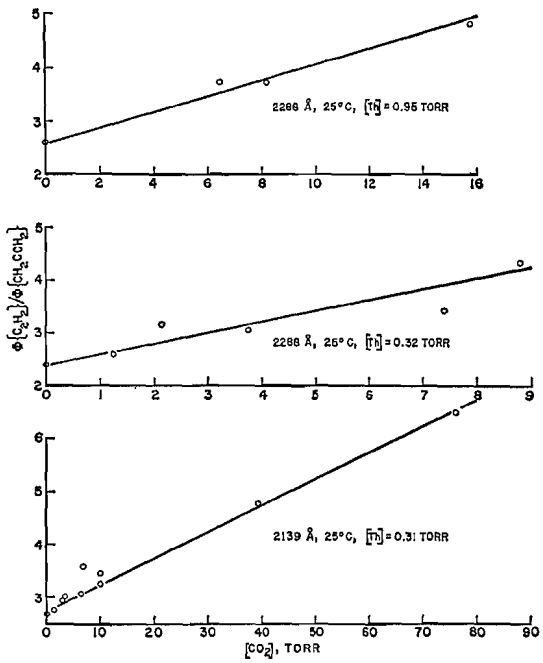

FIG. 5. Plots of the acetylene to allene ratio vs. the pressure of carbon dioxide in the photolysis of thiophene vapor in the presence of carbon dioxide.

values of $2k_g/k_e$ already deduced, values for k_k/k_j can be obtained and they are listed in Table IX. There are abnormalities in the plots for O_2 in Fig. 7. At 25 °C and 2288 Å, the plot deviates from linearity at high pressure though a good straight line prevails at low pressure, as indicated in the expanded plot of the low-pressure portion. The same abnormality was found for quenching

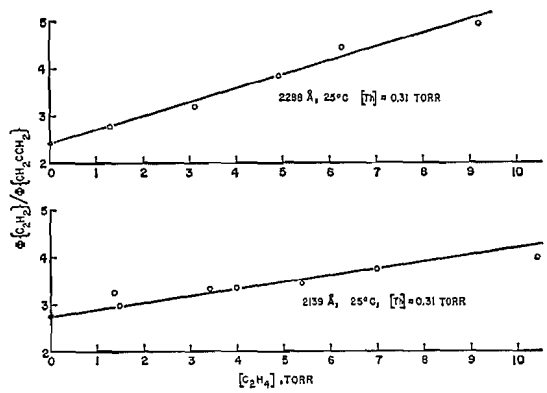

FIG. 6. Plots of the acetylene to allene ratio vs. the pressure of ethylene in the photolysis of thiophene vapor in the presence of ethylene.

For personal use only.

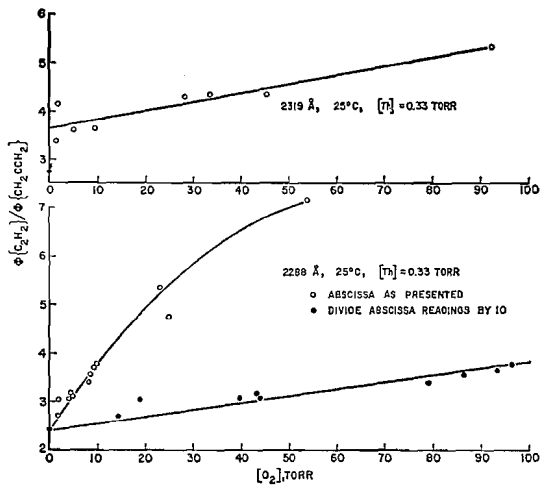

FIG. 7. Plots of the acetylene to allene ratio vs. the pressure of oxygen in the photolysis of thiophene vapor in the presence of oxygen.

of Th* under the same conditions (see Fig. 2); presumably these effects are coupled. An even more serious anomaly exists at 25 °C and 2139 Å. The plot is linear, but the intercept does not correspond to the value in the absence of O_2. Apparently even trace amounts of O_2 inhibit some of the allene production; this must be a scavenging effect rather than a chaperone quenching effect. The proposed mechanism does not explain this scavenging effect. To do so it is necessary to introduce additional steps

$$[w] \qquad I^* \rightarrow B^*$$

$$[x] \qquad B^* \rightarrow CH_2CCH_2 + CS^*$$

$$[y] \qquad B^* + O_2 \rightarrow Th + O_2$$

where B is some other intermediate, perhaps a triplet. Reaction [w] is too slow to be apparent with 2288 Å radiation, but occurs with 2139 Å radiation. From the intercept of Fig. 7, k_w/k_j can be deduced to be 0.33 from the expression

$$[8] \quad k_w/k_j = \Phi_0\{CH_2CCH_2\}/\Phi_0'\{CH_2CCH_2\} - 1$$

where $\Phi_0\{CH_2CCH_2\}$ and $\Phi_0'\{CH_2CCH_2\}$ are $\Phi\{CH_2CCH_2\}$ at zero thiophene pressure in the absence of any foreign gas; $\Phi_0\{CH_2CCH_2\}$, being the true value, and $\Phi_0'\{CH_2CCH_2\}$ being the value obtained from the extrapolation of Fig. 7. In the presence of O_2, these steps lead to the expression

$$[9] \quad \Phi\{C_2H_2\}/\Phi\{CH_2CCH_2\} = (2k_g/k_e)(1 + k_w/k_j + k_k[M]/k_j)$$

The slope of the graph based on eq. [9] multiplied by $k_e/2k_g$ gives k_k/k_j.

The values for k_k/k_j are summarized in Table IX. The two values for CO_2 at 25 °C and 2288 Å should be the same. The discrepancy represents a measure of the experimental uncertainty. As with thiophene, the values for k_k/k_j drop as the energy content rises. As quenchers C_2H_4 and thiophene are equally efficient, CO_2 is less efficient, and O_2 is the least efficient. The relative efficiencies for quenching I* are about the same as for quenching Th*.

The system is too complex to provide a quantitative explanation for CS_2 formation. However since $\Phi\{CS_2\} \leqslant \Phi\{CH_2CCH_2\} + \Phi\{CH_3CCH\}$, all the CS_2 can be explained as coming from CS as a precursor. Nevertheless, at room temperature the equality never holds even at the lowest pressures. Thus all of the CS* cannot have sufficient energy to produce CS_2, even if not deactivated. Presumably the fraction of CS* with sufficient energy should rise with the energy content of Th*, but even this is not so. At 200 °C with 2288 Å radiation $\Phi\{CS_2\}$ at small pressures exceeds that at 25 °C and 2139 Å. Apparently an additional thermal reaction can produce CS_2 at elevated temperatures even from collisionally de-energized CS species or from C_2H_2S (17).

In the presence of O_2, the initial sharp drop in CS_2 formation can be attributed to the scavenging of ·CHCHCHCHS· by O_2. The slower diminution as additional O_2 is added can be caused by deactivation of CS* or scavenging of C_2H_2S or both. However, even at large $[O_2]$, some CS_2 remains; this is difficult to explain.

Some of the CS species react with O_2 to produce COS via reaction [v]. The ratio of COS + CS_2 to CH_2CCH_2 + CH_3CCH is given in Table VI. It never exceeds unity, and is often much less, indicating that other processes may also be occurring, possibly to produce CO_2 or CO.

The results of the mercury sensitized experiments are remarkably similar to those from the direct photolysis. The same products are formed. Also $\Phi\{CS_2\}/\Phi\{C_2H_2\}$ and $\Phi\{CH_2CHCCH\}/\Phi\{C_2H_2\}$ are similar to those values from direct irradiation. Furthermore the addition of O_2 has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the same effect in both cases; COS, SO_2, CO, and CO_2 are produced, but otherwise nothing much happens. The differences are threefold with Hg sensitization: all the quantum yields are much smaller, the pressure quench is much smaller, and $\Phi\{CH_2CCH_2\}/\Phi\{C_2H_2\}$ and $\Phi\{CH_3CCH\}/\Phi\{C_2H_2\}$ rise with pressure. The first difference is consistent with the fact that less energy is put into the thiophene. The second difference can be explained if there is a small residual decomposition from the vibrationally deactivated excited electronic state. This decomposition would be insignificant for the higher energy radiation but would reduce the pressure quench for the low energy input. Finally the third difference can be explained if the vibrationally thermalized excited electronic state decomposes to the C_3 compounds by a unimolecular process in the second order regime.

We conclude that there is every reason to believe that the same excited electronic levels are involved regardless of the method of excitation. The first state, Th*, is presumably the excited singlet state since it is not scavenged by O_2. For the intermediate I we favor the valene intermediate by analogy with the results on substituted thiophenes, and the fact that cyclopropene is not formed. The state B to which I reverts part of the time is presumably a triplet since it is scavenged by O_2. However, whether it is triplet I or triplet Th has not been resolved.

Activity coefficients of aqueous thiocyanic acid solutions from electromotive force, transference number, and freezing-point depression measurements

H. E. BARTLETT, A. JURRIAANSE, AND K. DE HAAS
National Nuclear Research Centre, Pelindaba, Private Bag 256, Pretoria, South Africa

Received February 25, 1969

Accurate values of the activity coefficients of thiocyanic acid in aqueous solution have been obtained for concentrations of up to 0.1 molal at 25 °C by combining results for transference-number experiments with those for cells with transport. The transference-number experiments were done with the moving-boundary method, the transference-number at infinite dilution being calculated from measured conductivities of the thiocyanic acid. For the electromotive force (e.m.f.) measurements, conventional glass electrodes were used in conjunction with a high input-impedance electrometer.

The results obtained electrochemically were checked by determining activity coefficients from freezing-point depression measurements which also extended the range of concentrations to 1 molal.

The results of the two types of measurement are in good agreement.

Canadian Journal of Chemistry, 47, 2981 (1969)

Introduction

In earlier work (1), it was found that there was a need for activity coefficients of aqueous thiocyanic acid to be determined over a wide concentration range. This present work describes the determination of these coefficients by electrochemical and freezing-point depression methods.

For the electrochemical determination, a cell with transport had to be used because the only electrode found to be reproducible in the aqueous thiocyanic acid was a glass electrode. Among other electrodes tried were the standard hydrogen electrode (2) and the silver/silver thiocyanate electrode of Vanderzee and Smith (3), but neither of these was satisfactory because the platinum for the hydrogen electrode was poisoned by the thiocyanic acid and the thiocyanate electrode was not sufficiently reproducible in acid media.

Calculation of activity coefficients from e.m.f. data on cells with transport requires a knowledge of accurate transference-number data and, as none of these were available, the transference-numbers of the hydrogen ion and the conductance of the thiocyanic acid had to be determined.

As a check on the electrochemical method, and to extend the range of concentrations, the activity coefficients were also determined by a freezing-point depression method.

Experimental

Reagents

The methyl isobutyl ketone (MIBK) was of B.D.H. laboratory reagent grade and the sodium thiocyanate was Merck pure grade, while all other reagents were of analytical reagent grade.

Procedure

The water used throughout had been triply distilled through quartz apparatus and had a specific conductivity of less than 0.7×10^{-6} mho cm^{-1}.

Preparation of the Thiocyanic Acid

Thiocyanic acid solutions were prepared by mixing equal volumes of 5 *M* sodium thiocyanate and of 5 *M* sulfuric acid with MIBK which extracted the thiocyanic acid from the aqueous phase (1). After 2 or 3 washings of the MIBK with small volumes of water which, it was found, removed all the sulfate and all but a few p.p.m. of the sodium from the organic phase, the thiocyanic acid was back-extracted from the organic phase into water. Any ketone dissolved in the acid was removed by 3 extractions with small volumes of benzene which, in turn, was removed by filtration and by bubbling oxygen-free nitrogen through the acid.

Finally the concentrated acid was diluted to the concentration required and degassed with oxygen-free nitrogen. The concentrations were determined by titration of the acid with sodium hydroxide solutions, regularly standardized against potassium hydrogen phthalate. At the higher concentrations, bromocresol green indicator was used while, at the lower concentrations, titrations were conducted with a pH meter.

Conversions of the concentrations from molarity to molality were effected using the expression

$$\rho = 0.99707 + 0.017\, m$$

This was based on the densities (ρ) of thiocyanic acid solutions as determined at 25 °C with a pycnometer.

It was found necessary to make a fresh sample of acid daily because hydrogen sulfide could be detected above an aqueous solution of the acid that had been left overnight. During the course of 1 day, however, there was no detectable odor over the acid but, with the transference-number experiments in contrast to the other measurements, the acid could not be kept for more than about 3 h before decomposition became evident from the experimental results.

Transference-Numbers

The transference-numbers were determined by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

moving-boundary method with the sheared rising boundary cell as used by Allgood, Le Roy, and Gordon (4). The tube in which the boundary was formed was about 2.3 mm internal diameter and was marked with a diamond cutter at 1 cm intervals over its entire length of 21 cm.

The tube was calibrated by doing a number of experiments on hydrochloric acid, using KCl solutions as indicators and a silver/silver chloride electrode as described below. The transference-numbers and the data necessary for calculation of the volume correction at the silver/silver chloride cathode were obtained from Longsworth (5).

A number of experiments were also done on hydrochloric acid which had been treated with organic solvents in the same way as the thiocyanic acid had been, but it was found that any solvent that may have remained after degassing with the nitrogen had no measurable effect on the transference-number.

The boundary between the indicator solution (a potassium thiocyanate solution) and the acid was observed by means of the optical system described by Spiro (6), and the cell was immersed in a wide glass tube containing water which was thermostated to 25 °C.

The cathode consisted of a platinum spiral at the end of a ground-glass stopper closing off the one side of the cell. Before the start of an experiment, the platinum spiral was repeatedly dipped into molten silver chloride, thus forming a silver/silver chloride electrode. This electrode was sufficiently deeply immersed in the thiocyanic acid so that no chloride ions reached the boundary between the hydrogen and potassium ions.

The voltage to the cell was supplied either by a d.c. power supply or by a bank of dry batteries. The current was kept only approximately constant and was passed through a standard resistor. The voltage developed across this resistor was converted to a frequency by means of a Dymec Hewlett-Packard voltage-to-frequency converter and the frequency thus generated was integrated on a Hewlett-Packard digital frequency meter. During the experiment, one person observed the motion of the boundary while a second noted down the reading on the digital meter as the boundary passed one of the gradation marks.

By passing a fixed current through a standard resistor for known lengths of time, it was found that this method of current integration described was accurate to within 0.06%.

Before the cell was filled at the start of an experiment, each compartment was rinsed at least 3 times with the acid or the indicator respectively. After being filled, the cell was allowed to stand in the thermostat bath for at least 20 min before the tap shearing the boundary was turned and the potential applied.

Conductivity Measurements

The conductivity of the thiocyanic acid solutions was determined in a Jones' cell, thermostated to 25 °C in an oil bath, using a Wayne Kerr Model B221 impedance bridge which is accurate to 0.1%.

The cell constant was calculated from the measured conductivities of KCl solutions ranging in concentration from 0.2 to 0.01 *M*, using the literature values for the KCl specific conductivities (7).

Electromotive Force Measurements

The electrochemical cell, its method of being filled, and the transferring of the electrodes from one compartment to the other to eliminate the effects of the asymmetry potentials were as described by Covington and Prue (8). However, as electrodes with a resistance sufficiently low to be measured directly with a potentiometer were not available, the potential between two Polymetron type M201 electrodes (resistance about 6 MΩ at 25 °C) was fed into a Keithley Model 610BR electrometer. The scale reading on the electrometer was not sufficiently precise for potential differences greater than 3 mV and so, on the higher ranges, the output from the electrometer recorder points was measured with a Pye Universal Precision potentiometer (Model 7565) which made it possible to attain a higher precision. This output was accurately calibrated against known input potentials from a potentiometer. With this system it was possible to measure any potential up to 30 mV to within a precision of 0.01 mV.

Initially a water-thermostat bath was used but it was found that, on turning the taps isolating the two halves of the transport cell, a leakage path to earth was formed and the measurements of the potentials between the two electrodes were erroneous. This difficulty was obviated by the substitution of a light paraffin for the water.

Freezing-point Measurements

For the freezing-point depression measurements, about 100 ml of the acid in a glass vessel about 5 cm diameter and about 13 cm deep were placed in a Dewar of liquid nitrogen and vigorously stirred so that about 10% of the liquid was frozen into fine ice crystals. The vessel was then transferred to a second Dewar containing a freezing mixture. The top of the vessel was closed with an expanded polystyrene stopper through which passed a Beckmann thermometer and a circular, motor-driven, reciprocating stirrer.

Temperature changes for solutions above 0.1 molal were recorded with a 5 °C Beckmann thermometer graded in 0.01 °C intervals, while for the lower concentrations a 1 °C thermometer graded to 0.002 °C was used. With the 5 °C thermometer, temperatures were estimated to 0.002 °C and with the 1 °C thermometer, to 0.0005 °C.

The temperature was recorded every minute during the course of each experiment, which took between 30 and 50 min, the length of time being controlled by keeping the temperature of the surrounding freezing mixture at 0.1 °C above that of the thiocyanic acid. At the end of the experiment, the differences between the temperatures measured and that of the melting point of pure ice, separately determined with the appropriate thermometer, were plotted as a function of time. The resultant curves were extrapolated according to the method of Sidorova and Baiteryakova (9) to obtain the freezing-point depression at the particular concentration.

Results and Discussion

Transference-Numbers

From the number of coulombs q needed to move the boundary through successive 10 cm lengths, and from the volume V of the tube over

*$m_1 = 0.1006$ moles kg^{-1}, $t_1 = 0.1503$.

the particular length, the transference numbers t^+ were calculated from the equation

$$t^+ = 96\,488 \times c \times \frac{V}{q}$$

where c is the molar concentration of the acid.

Because of the instability of the thiocyanic acid, it was not possible to prepare sufficient acid for a number of determinations at one particular concentration. Hence the acid, after preparation, was diluted to approximately the concentration required, the experiment carried out, and the result tabulated for the nearest round-number concentration. This procedure is justified as the variation of the transference-number with concentration is not rapid.

From weight changes of the cathode it was established that, under the experimental conditions, the electrode functioned as a silver/silver chloride electrode. Hence, the volume corrections for transference-numbers were calculated from the data given by Longsworth (5) for the partial molar volume for hydrochloric acid and for the molar volumes of silver and of silver chloride. However, the calculated corrections were negligible and have not been taken into consideration.

No solvent corrections were made as it was assumed that the conductivity of the water used could be attributed to carbonic acid, the ionization of which would be suppressed by the thiocyanic acid.

The results of the transference-number experiments are presented in Fig. 1 and Table I.

Conductivity Measurements

The results of the conductivity measurements

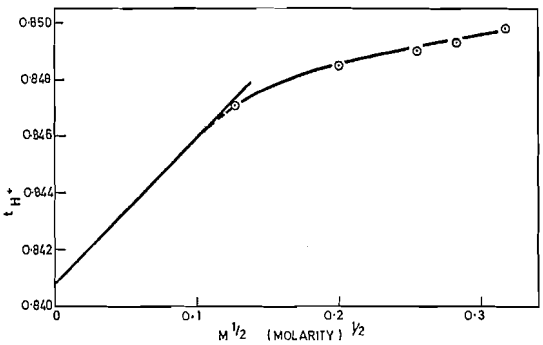

FIG. 1. Variation of the transference-number of the hydrogen ion at 25 °C in an aqueous thiocyanic acid (t_{H^+}) as a function of the square root of the molarity ($M^{\frac{1}{2}}$). The straight line is calculated from the Onsager limiting law.

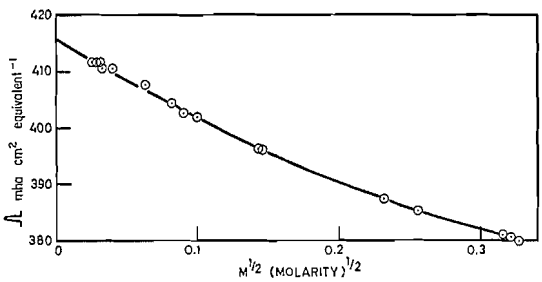

FIG. 2. The equivalent conductance of thiocyanic acid at 25 °C as a function of the square root of the molarity.

are presented graphically in Fig. 2, where the equivalent conductance of the acid is plotted as a function of the square root of the molarity.

The variation in the equivalent conductance Λ as a function of concentration, c, can be expressed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by the relationship proposed by Robinson and Stokes (10)

$$\Lambda = \Lambda^0 - \frac{B_1\Lambda^0 + B_2\sqrt{c}}{1 + Ba\sqrt{c}}$$

where Λ^0 is the equivalent conductance at infinite dilution, B_1, B_2, and B are constants, while a is the mean diameter of the ions in the thiocyanic acid (in Å). Numerical values chosen for the constants at 25 °C are (from Robinson and Stokes (10)): $B_1 = .2300$ mole$^{-\frac{1}{2}}$ $1^{\frac{1}{2}}$; $B_2 =$ 60.65 cm^2 ohm^{-1} equivalent^{-1}(l/mole)$^{\frac{1}{2}}$; $B =$ 0.3291 Å^{-1} mole$^{-\frac{1}{2}}$ $1^{\frac{1}{2}}$. It was found, by an iterative method with an IBM 360 computer, that the values for a and Λ^0 that best fitted the equation were $a = 3.8$ Å and $\Lambda^0 = 416.0 \pm 0.5$ ohm^{-1}cm^2 equivalent^{-1}.

From this value for the equivalent conductance at infinite dilution and from a value of 349.8 ohm^{-1} cm^2 equivalent^{-1} (10) for the limiting equivalent conductance of the hydrogen ion at 25 °C, the value for the limiting transference-number of the hydrogen ion in thiocyanic acid at 25 °C is 0.8409. This value is plotted on Fig. 1 and the line of slope given by the Onsager limiting law (6) is drawn through this point.

Activity Coefficients from E.M.F. Data

After elimination of the effects of the asymmetry potentials of the electrodes, the e.m.f. of the cell

glass electrode |HSCN(m_1)|HSCN(m_2)| glass electrode

is given by the expression

$$E = \frac{2RT}{F}\int_{m_1}^{m_2} t^- \, \mathrm{d} \ln m\gamma$$

where γ is the mean ionic activity coefficient of the thiocyanic acid at molality m and t^- is the value of the transport number of the thiocyanate ion.

Putting $t^- = t_1 + \Delta t$, where t_1 is the transport number of the thiocyanate ion at a fixed molality m_1 (at 25 °C)

$$\log\frac{\gamma_2}{\gamma_1} = \frac{-E}{t_1 \times 0.1183} - \log\frac{m_2}{m_1} - \frac{1}{t_1}\int_{m_1}^{m_2}\Delta t \, \mathrm{d} \log m - \frac{1}{t_1}\int_{\gamma_1}^{\gamma_2}\Delta t \, \mathrm{d} \log \gamma$$

The values of the integrals are obtained by numerical integration, the last term, which is very small, being elucidated by using preliminary values for γ_2 and γ_1 obtained from the expression, with the fourth term eliminated.

Covington and Prue (8) have shown that γ can be given by a Debye-Hückel expression

$$\log\gamma = -\frac{Am^{\frac{1}{2}}}{1 + m^{\frac{1}{2}}} + bm$$

where A is the Debye-Hückel constant taken as having a value of 0.5115 at 25 °C, and b is an empirical constant. Hence

$$\log\frac{\gamma_2}{\gamma_1} = -\frac{Am_2^{\frac{1}{2}}}{1 + m_2^{\frac{1}{2}}} + \frac{Am_1^{\frac{1}{2}}}{1 + m_1^{\frac{1}{2}}} + b(m_2 - m_1)$$

The quantity $-Am_2^{\frac{1}{2}}/(1 + m_2^{\frac{1}{2}}) + Am_1^{\frac{1}{2}}/(1 + m_1^{\frac{1}{2}})$ is defined as $\Delta \log \gamma^{st}$ and therefore

$$\log\frac{\gamma_2}{\gamma_1} - \Delta \log \gamma^{st} = b(m_2 - m_1)$$

In Table I the results of the e.m.f. measurements are given, and in Fig. 3 the values of $\log\gamma_2/\gamma_1 - \Delta \log\gamma^{st}$ against $(m_2 - m_1)$ are plotted. The line in Fig. 3 does not pass through the origin but this is probably due to small errors in the preparation of the solution m_1 of fixed molality.

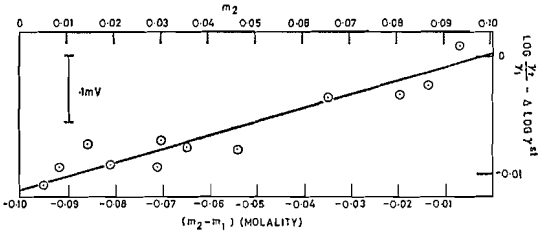

FIG. 3. $\log\gamma_2/\gamma_1 - \Delta \log\gamma^{st}$ as a function of $(m_2 - m_1)$.

From the gradient of the line in Fig. 3, the value of b was determined by least squares analysis as 0.12 ± 0.05. This is the value used in the calculation of the mean activity coefficients at round-number concentrations shown in Table II.

Activity Coefficients from Freezing-point Depression Data

For calculation of γ from the freezing-point depression, θ, for solutions of molality m, the

Randall and Vanselow expression (11)

$$[1] \quad \log \gamma = \int_0^m -j \, \mathrm{d} \log m - \frac{j}{2.303} + \frac{0.00025}{\nu} \int_0^m \frac{\theta}{m} \, \mathrm{d}\theta$$

was used, j being defined by the equation

$$j = 1 - \frac{\theta}{\nu \lambda m}$$

where λ is the molal lowering of the freezing point and has a value of 1.860 and ν is the number of ions into which the molecule ionizes in solution.

The first expression on the right hand side of the eq. [1] is not directly integrable as there is no exact analytical expression for the variation of j with $\log m$. Furthermore, a numerical integration between the limits m and 0 is not possible as $\log m$ is indeterminate at $m = 0$. However, up to a concentration of 0.01 molal, Randall and Vanselow (11) have shown that an equation

$$[2] \quad \log j = \log \beta + \alpha \log m$$

holds for uni-univalent electrolytes with the constant α equal to approximately 0.5.

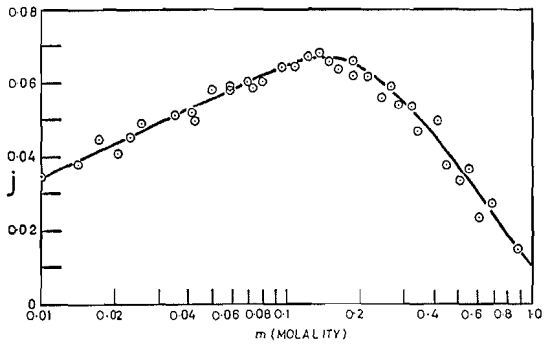

FIG. 4. Values of j plotted as a function of log molality.

Hence, in this work, below a concentration of 0.01 M a straight line with a slope of 0.5 (α) was fitted to a plot of $\log j$ vs. $\log m$ and β obtained as the intercept at $\log m = 0$.

Therefore, elucidation of the integral over the whole concentration range was achieved by use of eq. [2] up to 0.01 molal and numerical integration thereafter.

The value of the third term on the right hand side of eq. [1] was also numerically integrated but it was found that this term only became significant at concentrations above 0.1 molal.

The results are presented in Fig. 4 where the values of j are plotted against $\log m$, and in Table II, the values of the mean activity coefficients are presented at round-number concentrations.

From this Table it can be seen that the results from the freezing-point depression data are marginally higher than those from the e.m.f. measurements. However, it is estimated that the calculated error in b, which is the greatest source of uncertainty in the calculation of the values of the activity coefficients, makes a difference of about 1% to the activity coefficients at 0.1 molal but only about 0.1% at 0.01 molal. These are about the differences between the activity coefficients as determined electrochemically and from the freezing-point depression data. Hence, nothing can be said about the significance of the difference between the data obtained at the two different temperatures.

Reaction of methyl radicals with *cis*-butene-2

NOBUO YOKOYAMA AND R. K. BRINTON[1]
Department of Chemistry, University of California, Davis, California
Received February 3, 1969

Methyl radicals generated by di-*t*-butylperoxide pyrolysis interact at comparable rates with *cis*-butene-2 in the gas phase by both addition and hydrogen atom abstraction. The determination of the rate of these reactions was simplified by the addition of a large concentration of acetaldehyde to the system. The additive, a source of low activation energy abstractable hydrogen atoms, was effective in suppressing polymerization reactions, and in addition, maintained a high steady state methyl radical concentration as a result of the carbonyl radical decomposition. The rate constants, k_5 and k_6 for the reactions [5] and [6], were determined to be $4.5 \times 10^{10} \exp(-7000/RT)$ and $1.8 \times 10^{10} \exp(-7300/RT)$

[5] $CH_3^{\cdot} + \text{C}_4\text{H}_8 \longrightarrow \text{C}_5\text{H}_{11}^{\cdot}$

[6] $\text{C}_5\text{H}_{11}^{\cdot} \longrightarrow CH_4 + \text{C}_4\text{H}_7^{\cdot}$

$cm^3\ mole^{-1}\ s^{-1}$, respectively, over the temperature range 126–163 °C. The butenyl radical formed in reaction [6] isomerizes much faster than its interaction with other species in the system, and the distribution of the various conformations is similar to the equilibrium distribution of the butenes at a similar temperature.

Canadian Journal of Chemistry, 47, 2987 (1969)

Introduction

The study of the vapor phase reaction of methyl radicals with ethylene (1*a*) and propylene (1*b*) is herein extended to the analogous reaction with *cis*-butene-2. Although a number of studies have been made on the reaction between methyl radicals and butenes (2–7), none has dealt in detail with the complicated sequence of radical reactions which occurs in the interaction. In addition, quantitative treatment of the experimental data to obtain kinetic parameters for the methyl radical addition to the butene molecule depends, in all these studies, on various simplifying assumptions as to the relative importance of certain reactions in the total mechanism scheme. The validity of such assumptions cannot, in general, be definitely established experimentally, and the best measure for the significance of the absolute magnitude of the addition parameters evaluated is a correspondence between the values obtained by rather widely different experimental techniques involving dissimilar types of assumptions. For this reason the present study involving a somewhat different technique to that used in previous investigations should offer an important check on the interconsistency of the kinetic data.

The major complication in all studies of the addition of radicals to olefins is produced by the formation of an adduct radical rather than a stable molecule in the primary step. These adduct radicals may add again to the olefin in a chain type polymerization or interact at any stage of the polymerization, in a very complicated fashion, with any of the many types of radicals in the system. In this investigation, a simplification of the reaction mechanism was attained by adding large quantities of acetaldehyde to a di-*t*-butyl peroxide (methyl radical source)/*cis*-butene-2 gaseous system. This technique is similar to the "aldehyde method" used by Trotman-Dickenson and co-workers (8) to study the addition of various alkyl radicals to multiple bonds. Under such conditions, addition polymerization is minimized by the active competition for all radicals in the system by acetaldehyde which furnishes opportunity for a low activation energy hydrogen abstraction of the carbonyl hydrogen. In addition, the methyl radical steady state concentration is maintained at a high level by the decomposition of the acetyl radical formed in the abstraction process, and as a consequence, combination reactions of all radicals with methyl radicals are enhanced. Such combinations lead to easily

[1]Author to whom request for reprints should be addressed.

identified and analyzed products which allow a much easier assessment of the total products resulting from the pentyl radical formed in the primary methyl radical to *cis*-butene-2 addition.

Experimental

The reaction system and procedure for its use were similar to those described earlier (1). The two component system, di-*t*-butyl peroxide (DTBP) + *cis*-C_4H_8-2, or the three component system, DTBP + *cis*-C_4H_8-2 + CH_3CHO, were formed by pressure–volume measurement of the gaseous components followed by thorough mixing in a 2 l glass bulb. Reaction was initiated by expansion of a mixture into a 1 l glass reaction bulb contained in a silicone oil thermostat. Reaction was terminated by a subsequent expansion into a calibrated sample bulb at room temperature.

In many of the early experiments a large amount of the CH_3CHO contained in the three component products was removed by a condensation and polymerization on moist KOH pellets, but this step was eliminated in later work when it was found that on the proper gas chromatographic column, CH_3CHO did not interfere with any step of the analytical procedure. The products were separated by temperature fractionation using a vacuum system with Ward still-traps and a gas buret. These fractions were analyzed, for the most part, using gas chromatographic techniques wherein the evaluation was made from previously prepared standard curves. Details of the analysis of the various fractions follow.

−210 °C

This fraction consisted of CH_4 with CO additionally present when CH_3CHO was added. It was measured by gas buret and analyzed by temperature fractionation after the CO had been converted to CO_2 in a CuO furnace. Analysis was checked on some samples by mass spectrometric methods.

−145 °C

This fraction consisting of C_2 and C_3 hydrocarbons (mainly C_2H_6) was effectively temperature separated from C_4 and higher hydrocarbons as well as from oxygenated products. The fraction was analyzed on an alumina column at 80 °C.

−78 °C

The C_4–C_6 hydrocarbons, CH_3CHO, $(CH_3)_2CO$, and a part of the $CH_3COC_2H_5$, $(CH_3)_3COH$, and a small amount of DTBP were contained in this fraction. Analysis was made by use of an adiponitrile on firebrick column at 0 °C. Oxygen containing compounds, for which no quantitative measure was made, were retained sufficiently to effect the separation of most of the hydrocarbons. In cases where hydrocarbons were not sufficiently separated to allow quantitative estimation, the effluent was condensed at −196 °C and reanalyzed at 25 °C on a dinonylphthalate column which produced separation approximately in order of the boiling points.

Residue

This fraction consisted of DTBP, the remainder of the $(CH_3)_2CO$, $(CH_3)_3COH$, and $CH_3COC_2H_5$ as well as C_8–C_{10} hydrocarbons. Analysis was accomplished at 80 °C on a 0.75 mm inner diameter by 150 m stainless steel capillary column coated with didecylphthalate. Analysis of this fraction was not regularly carried out on the pyrolysis products because of the difficulty of identification and calibration.

The *cis*-butene-2 used in this study was Phillip's research grade of specified 99.87% purity. The impurity, mainly *trans*-C_4H_8-2, was not removed, but proportionate correction was always made for the contamination in the product analyses. Eastman Organic Chemicals' CH_3CHO contained two impurities of the order of 0.01–0.001%, probably polymerization inhibitors, as well as a number of hydrocarbons in very low concentration (3–600 p.p.m.). In initial experiments an attempt was made to correct for those substances in the reaction products. This procedure was unsatisfactory, and CH_3CHO used in the later pyrolyses was purified by gas chromatography on an adiponitrile–firebrick preparative column, a procedure which eliminated all detectable impurities. The CH_3CHO was stored and handled using all due precaution to eliminate formation of paraldehyde as well as the low temperature polymer formed when CH_3CHO is cooled below its freezing point. Di-*t*-butyl peroxide from K and K Laboratories contained trace impurities of CH_3COCH_3, $CH_3COC_2H_5$, and $(CH_3)_3COH$, presumably from gradual decomposition of DTBP. Inasmuch as the rates of formation of these substances were not followed in the present investigation, their presence was considered to have negligible effect, and no serious attempt at their removal was made except a bulb-to-bulb distillation with only center fraction retention. Matheson C. P. grade (99.0% minimum purity) *trans*-C_4H_8-2 and C_4H_8-1 were used as received. Correction for small quantities of isomeric butene impurities was made in the reaction products.

The data for the studies made at 125.8, 136.8, 150.2, and 163.0 °C are shown in Table I. Rates and calculated kinetic data listed are based on average rates ($\Delta C/\Delta t$) and average concentration of a component during the course of the reaction. *cis*-Butene-2 disappearance was always small, ca. 1–3% so the average concentration approximation could cause little error. Decomposition of DTBP (ca. 10–15%) and CH_3CHO reaction (ca. 5–20%) was, however, appreciable. An exact analysis of the errors made in using average rates and concentrations in the treatment of a complicated reaction mechanism is quite difficult. It was concluded, at least in the case of somewhat simplified mechanisms, that concentration changes up to 25–30% caused errors no larger than 2–3% in the values of reaction constants so evaluated. Time of pyrolysis was 320 min at 125.8 °C, 80 min at 136.8 °C, 20 min at 150.2 °C, and 5 min at 163.0 °C except for exp. 331 (25 min), exp. 332 (12.5 min), and exp. 431 (400 min).

Results and Discussion

The pyrolysis of DTBP in the gas phase is described by the following mechanism

[1] $(CH_3)_3COOC(CH_3)_3 \rightarrow 2(CH_3)_3CO^{\bullet}$

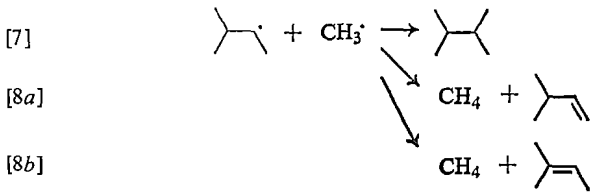
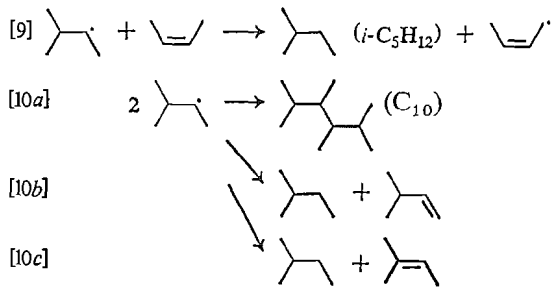
[2] $(CH_3)_3CO^{\cdot} \rightarrow CH_3COCH_3 + CH_3^{\cdot}$

[3] $2CH_3^{\cdot} \rightarrow C_2H_6$

[4] $CH_3^{\cdot} + (CH_3)_3COOC(CH_3)_3 \rightarrow CH_4 + (CH_3)_3COO(CH_3)_2CH_2^{\cdot}$

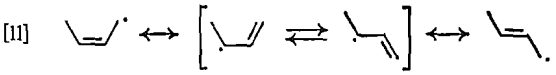
In presence of *cis*-C_4H_8-2, $CH_3^{\cdot}$ reacts at about comparable rates by addition and H atom abstraction



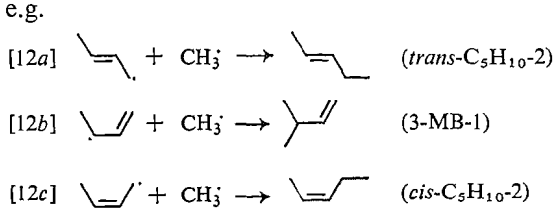


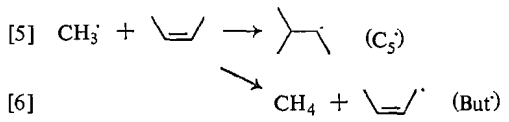
Other minor reactions, some leading to the same products, also occur and discussion concerning such possibilities will be given in later sections of this paper.

The butenyl radical, But$^{\cdot}$, from reactions [6] and [9], is capable of an allylic type resonance and, in addition, rotation may occur about the central bond.



These species may be treated as if three isomeric forms were available for subsequent reaction, and isomeric products result from their interaction with other radicals present in the system, e.g.





An alternate to reaction [6], hydrogen abstraction from the vinyl position, was not observed to any significant extent. The fate of the pentyl radical, $C_5^{\cdot}$, from reaction [5] can be summarized by

and by H atom abstraction

and [13*b*] and [13*c*] analogously.

However, this latter process with *cis*-butene-2 as RH leads to no net change in But$^{\cdot}$ concentration or distribution if the butenyl radical isomerization is much faster than the abstraction process. Combination reactions of butenyl radicals among themselves as well as with the $C_5^{\cdot}$ radical lead to many C_8–C_9 hydrocarbons. Although the $C_5^{\cdot}$ radicals showed a ready ability to disproportionate with loss of an H atom, e.g. reactions [8*a*, *b* – 10*b*, *c*], a careful inspection of the pyrolysis products for butadienes-1,2 and -1,3 indicated that an analogous reaction of But$^{\cdot}$ either did not occur at all, or at most, certainly occurred only to an extent of a few % of the comparable $C_5^{\cdot}$ disproportionation.

The assessment of the rates of reactions [5] and [6], which is necessary for the determination of the activation energies of these two reactions, is possible by determining all products resulting from $C_5^{\cdot}$ and But$^{\cdot}$ interaction with active species in the system. As pointed out above, the many C_8–C_9 hydrocarbon products are not negligible and are, in addition, difficult to analyze. Furthermore, addition of any radical in the system to the *cis*-butene-2 substrate is possible, and the result of such addition reactions is to form products of high molecular weight which further complicate the analytical procedures. As pointed out earlier,

it should be possible to minimize the occurrence of such complicating reactions if large amounts of acetaldehyde, a source of easily abstractable H atom, were added to the system. With this objective in view, a detailed investigation of the effect of acetaldehyde on the *cis*-butene-2/DTBP system was undertaken.

A. The Reactivities of Pentyl and Butenyl Radicals with CH_3CHO

In the two component system the major reaction of both $C_5^{\cdot}$ and But$^{\cdot}$ is combination with $CH_3^{\cdot}$ by reactions [7] and [12], respectively, leading to C_6 and the three corresponding pentenes. In presence of appreciable amounts of CH_3CHO, hydrogen abstraction from the aldehyde

[14]  + $CH_3CHO \rightarrow i\text{-}C_5H_{12} + CH_3CO^{\cdot}$

[15*a*]  + $CH_3CHO \rightarrow trans\text{-}C_4H_8\text{-}2 + CH_3CO$

and [15*b*, *c*] (analogous reactions involving other butenyl radical forms) lead to an increase in $i\text{-}C_5H_{12}$ as well as isomeric butenes and a relative decrease in C_6 and pentenes. However, it is readily seen from the data of Table I that the ratio, $i\text{-}C_5H_{12}/C_6$, increases rapidly with increase in CH_3CHO added, while the increase in *trans*-C_4H_8-2/*trans*-C_5H_{10}-2 is rather insensitive to change in CH_3CHO. This behavior indicates that $C_5^{\cdot}$ and But$^{\cdot}$ abstract H atoms with greatly differing facility. To obtain an estimate of the abstraction rate constants it is to be observed that C_6 is formed by a single process, reaction [7], while $i\text{-}C_5H_{12}$ is formed not only through interaction with CH_3CHO, reaction [14], but also by reaction [9] and other radical–radical interactions. As CH_3CHO concentration is increased, reaction [14] becomes predominant, reaction [7] is still significant because of the high $CH_3^{\cdot}$ concentration from $CH_3CO^{\cdot}$ decomposition, but other reactions contributing to $i\text{-}C_5H_{12}$ formation become relatively unimportant. Thus

$$[16]\quad R_{i\text{-}C_5H_{12}} \approx k_{14}[C_5^{\cdot}][CH_3CHO] + k_9[C_5^{\cdot}][cis\text{-}C_4H_8\text{-}2]$$

$$[17]\quad R_{C_6} = k_7[C_5^{\cdot}][CH_3^{\cdot}]$$

$$[18]\quad R_{C_2H_6} = k_3[CH_3^{\cdot}]^2$$

and

$$[19]\quad \frac{R_{i\text{-}C_5H_{12}}R_{C_2H_6}^{1/2}}{R_{C_6}[cis\text{-}C_4H_8\text{-}2]} \approx \frac{k_{14}k_3^{1/2}[CH_3CHO]}{k_7[cis\text{-}C_4H_8\text{-}2]} + \frac{k_9k_3^{1/2}}{k_7}$$

In this case an average value of $[CH_3CHO]$ is used based on the assumption that all $CH_3CO^{\cdot}$ produced decomposed to $CH_3^{\cdot}$ and CO, an approximation which may be justified in the temperature range above 120 °C by the results of several previous investigations (9). Thus

$$[20]\quad [CH_3CHO]_{ave} = [CH_3CHO]_{initial} - \tfrac{1}{2}R_{CO}\Delta t$$

A similar treatment for the production of *trans*-C_4H_8-2 gives

$$[21]\quad \frac{R_{trans\text{-}C_4H_8\text{-}2}R_{C_2H_6}^{1/2}}{R_{trans\text{-}C_5H_{10}\text{-}2}[cis\text{-}C_4H_8\text{-}2]} \approx \frac{k_{15a}k_3^{1/2}[CH_3CHO]}{k_{12a}[cis\text{-}C_4H_8\text{-}2]} + \frac{k_{13a}k_3^{1/2}}{k_{12a}}$$

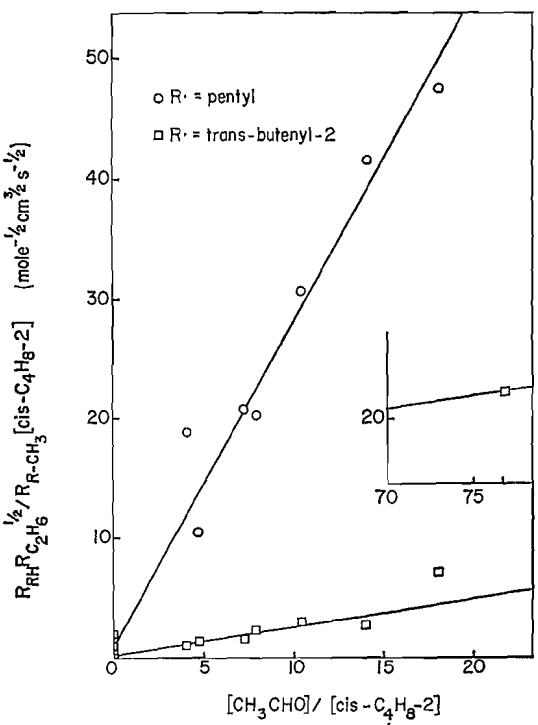

FIG. 1. The reactivities of pentyl and butenyl radicals with CH_3CHO.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In Fig. 1 the quantities on the left of eqs. [19] and [21] are plotted vs. $[CH_3CHO]/[cis\text{-}C_4H_8\text{-}2]$. The slopes $k_{14}k_3^{1/2}/k_7$ and $k_{15a}k_3^{1/2}/k_{12a}$ are found to be 2.7 and 0.22 $(cm^3\ mole^{-1}\ s^{-1})^{1/2}$, respectively, at 150.2 °C. The intercepts on the ordinate would evaluate $k_9k_3^{1/2}/k_7$ and $k_{13a}k_3^{1/2}/k_{12a}$ to be 0.8 and 0.3, but the extrapolation is subject to large errors so that these latter values are of doubtful significance. If it is further assumed that $CH_3^{\cdot}$ combination rates with $C_5^{\cdot}$ and But$^{\cdot}$ are about equal

$$[22] \qquad k_7 \approx k_{12a}$$

then $k_{14}/k_{15a} \approx 12.5$ and, for what it is worth, $k_9/k_{13a} \approx 2.5$. These relationships indicate that H atom abstraction from both CH_3CHO and *cis*-C_4H_8-2 is considerably faster by $C_5^{\cdot}$ than by But$^{\cdot}$. Support for the assumption shown in reaction [22] is indicated by the equivalence of the ratio, C_6/*trans*-C_5H_{10}-2, in the three component system to the ratio of the formation of $C_5^{\cdot}$ to But$^{\cdot}$ in the two component system evaluated in a later section.

B. The Origin of 3-Methylbutene-1

The 3-MB-1 was formed both from $C_5^{\cdot}$ through reaction [8*a*] and other similar disproportionations as well as from But$^{\cdot}$ through reaction [12*b*]. This may be represented as

$$[23] \qquad R_{3\text{-MB-1}} = R_{3\text{-MB-1}[C_5^{\cdot}]} + R_{3\text{-MB-1}[But^{\cdot}]}$$

As seen in the previous discussion, the reactivity of the two radicals with CH_3CHO differs widely. Hence, when the concentration of CH_3CHO is increased sufficiently, the $C_5^{\cdot}$ steady state concentrations could be expected to be reduced to the point where $R_{3\text{-MB-1}[C_5^{\cdot}]}$ becomes negligibly small but $R_{3\text{-MB-1}[But^{\cdot}]}$ is still significant. Thus in the presence of sufficiently large enough amounts of CH_3CHO, But$^{\cdot}$ reactions furnish the only measurable source of 3-MB-1.

$$[24] \qquad R_{3\text{-MB-1}} \approx R_{3\text{-MB-1}[But^{\cdot}]}$$

Inasmuch as the ratio, $R_{3\text{-MB-1}[C_5^{\cdot}]}/R_{2\text{-MB-2}}$, is controlled by k_{8a}/k_{8b} and analogous disproportionation ratios, when $R_{2\text{-MB-2}} = 0$, so should $R_{3\text{-MB-1}[C_5^{\cdot}]}$. In exps. 226, 323, 332, 421, and 531 (Table I), $R_{2\text{-MB-2}}$ was indeed reduced to zero, and eq. [24] should apply. In addition, it is clear according to reactions [11] and [12], that $R_{3\text{-MB-1}[But^{\cdot}]}/R_{trans\text{-}C_5H_{10}\text{-}2}$ should remain constant at a given temperature regardless of the relative concentration of reagents as long as the equilibrium between the various forms of the But$^{\cdot}$ is maintained. Then

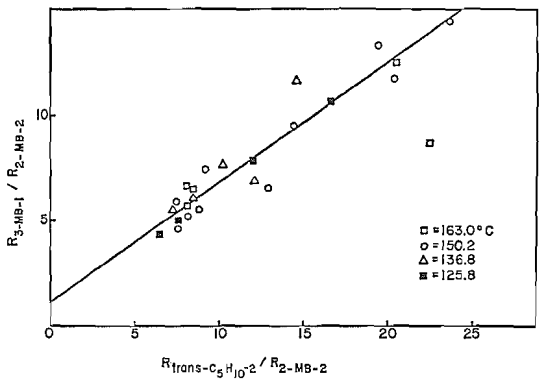

FIG. 2. The origin of 3-methylbutene-1.

$$[25] \qquad \gamma = R_{3\text{-MB-1}[But^{\cdot}]}/R_{trans\text{-}C_5H_{10}\text{-}2}$$

may be obtained when $R_{2\text{-MB-2}} = 0$, and γ thus obtained under these special conditions should apply to all experiments at a similar temperature. By arrangement of eqs. [23] and [25]

$$[26] \qquad \frac{R_{3\text{-MB-1}}}{R_{2\text{-MB-2}}} = \frac{R_{3\text{-MB-1}[C_5^{\cdot}]}}{R_{2\text{-MB-2}}} + \gamma\frac{R_{trans\text{-}C_5H_{10}\text{-}2}}{R_{2\text{-MB-2}}}$$

when $R_{2\text{-MB-2}} \neq 0$. The ratio, $R_{3\text{-MB-1}}/R_{2\text{-MB-2}}$ is plotted vs. $R_{trans\text{-}C_5H_{10}\text{-}2}/R_{2\text{-MB-2}}$ in Fig. 2 for data at various temperatures. The slopes and ordinate intercepts of Fig. 2 obtained by a least squares method are tabulated in Table II. It is seen that the value of γ is essentially independent of temperature, and the variation in the value obtained for the intercept at the various temperatures probably merely indicates the extent of the error in determining this parameter. Nevertheless, the corresponding intercept and γ value were used at each temperature to divide the total

TABLE II

Parameters for the origin of 3-MB-1

For personal use only.

3-MB-1 yield according to eqs. [23] and [25] into amounts attributable to each type of origin. These data are included in Table I. In certain cases involving small overall yields of 3-MB-1 the values of $R_{3\text{-MB-1}[C_5\cdot]}$ calculated from $R_{trans\text{-}C_5H_{10}\text{-}2}$ and a corresponding γ came out with negative values. Such irregularities result from the quantities involved being of the same order as the accuracy of the analytical methods. For these experiments the values of $R_{3\text{-MB-1}[C_5\cdot]}$, certainly small, were assumed to be zero.

C. The Disproportionation Behavior of the $C_5\cdot$ Radical

The data of Table II indicate that the intercepts of Fig. 2, $R_{3\text{-MB-1}[C_5\cdot]}/R_{2\text{-MB-2}}$, do not have a consistent trend with temperature, and as already suggested, could best be interpreted as a single value ca. 0.8 ± 0.3 independent of temperature. It is seen from the possible disproportionation mechanism for the $C_5\cdot$ radical and methyl radical, as in reactions [8*a*, *b*], that $C_5\cdot$ is capable of giving up a hydrogen atom in two different ways. Although other radicals may disproportionate with $C_5\cdot$ in a manner similar to the interaction with $CH_3\cdot$, the transfer of H atom by $C_5\cdot$ in these cases is strictly analogous to the exchange with the $CH_3\cdot$ radical. Thus

$$[27] \qquad R_{3\text{-MB-1}[C_5\cdot]}/R_{2\text{-MB-2}} \approx k_{8a}/k_{8b}$$

There have been many reports on the disproportionation–combination ratio for various pairs of radicals (10, 11) in order to understand the relationship of disproportionation to the bond involved. However, such ratios, because of the wide variation in the absolute value of the combination rate constants (12), may lead to misleading conclusions concerning relative disproportionation tendencies. In the present study the relative split of the $C_5\cdot$ radical between two competing disproportionation mechanisms is unambiguously given by the value of the Fig. 2 intercept, although, to be sure, not with high precision. Calvert and co-workers (13, 14) proposed, from a study of disproportionation between the various butyl radical isomers, that the split would occur in a manner proportional to the number of available H atoms on the carbon atoms adjacent to the radical site. This rule would predict $R_{3\text{-MB-1}[C_5\cdot]}/R_{2\text{-MB-2}} = 3$ for the $C_5\cdot$ disproportionation instead of the 0.8 obtained. Data collected subsequent to Calvert and co-worker's original postulate indicate strongly that the rule is certainly qualitative in nature, and the present test involving a competition for a single tertiary H atom or three primary H atoms indicates a complete lack of conformity.

D. Pentene Formation from Butenyl–Methyl Radical Combination

The combination of $CH_3\cdot$ and $But\cdot$ results in the formation of three pentene isomers as indicated in reactions [12*a*, *b*, *c*]. If the internal rotation of $But\cdot$ about the central bond is much faster than the radical–radical combination, the three pentenes should be produced, at a single temperature, in constant ratio independent of reaction conditions. In addition, if the activation energies of reactions [12*a*, *b*, *c*] are zero or all equal to each other, the constancy of pentene isomer ratio should persist in spite of changes in temperature as well. In the previous analysis of the 3-MB-1 formation, it was shown that $\gamma = R_{12b}/R_{12a} = 0.59$ independent of temperature over the range 126–163 °C. In Fig. 3 is plotted $R_{cis\text{-}C_5H_{10}\text{-}2}$ vs. $R_{trans\text{-}C_5H_{10}\text{-}2}$. Here again the data are consistent with a similar interpretation, and $R_{12c}/R_{12a} = 0.76$ independent of temperature over a similar range. Further support for the rapid rotational equilibrium of the butenyl radical is shown by the results of exp. 233 which involves the reaction of *trans*-C_4H_8-2 and DTBP. The ratio, $R_{cis\text{-}C_5H_{10}\text{-}2}/R_{trans\text{-}C_5H_{10}\text{-}2}$ has the same value, 0.78, even though the original butenyl radical was of opposite steric configuration. Con-

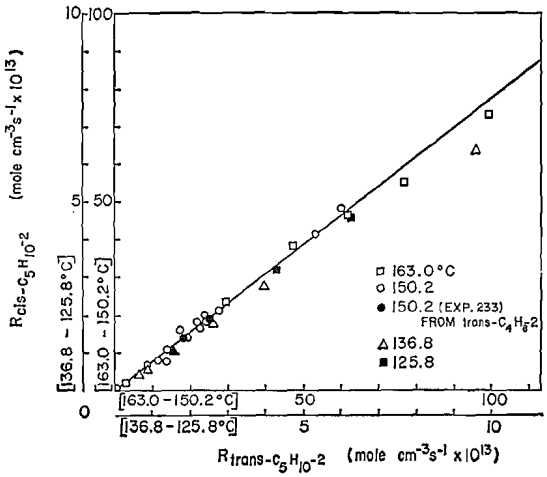

FIG. 3. The formation of *cis*- and *trans*-pentene-2.

trary evidence concerning butenyl radical isomerization was obtained by Walling and Thaler (15) who reported complete retention of the *cis–trans* configuration of But· in the liquid phase at 40 °C. Holroyd and Klein (16) reported a similar result at −88 °C. It seems probable within the range 40–125 °C that a region exists wherein the rotation rate may be effectively measured by a kinetic study.

E. Combination of Butenyl and Pentyl Radicals

Combination of C_5· and the three isomeric But· radicals should form a decane, three nonenes, and six octadienes. Search was made for these products in exps. 213, 213′, and 213″. Three of the octadiene isomers were positively identified and the presence of the other seven products was tentatively established by the retention times. In view of the difficulty entailed in carrying out such analyses on a quantitative basis, it was decided to calculate the rates of formation of these products for their use in calculations to be made in the next section. These evaluations are based on the premise that the cross combination ratio (12), $R_{ab}/R_{aa}^{1/2}R_{bb}^{1/2} = k_{ab}/k_{aa}^{1/2}k_{bb}^{1/2} = 2$, a result justified by fairly extensive experimental evidence, but not easily predicted quantitatively by a priori theory. Although no direct confirmation is available that this relationship is valid for the radicals under consideration, the results of the calculations do agree quite well with the limited experimental data of exps. 213, 213′, and 213″. By use of the rates of formation of C_2H_6, C_6, *cis*- and *trans*-C_5H_{10}-2, and 3-MB-1 [But·], the quantity of C_5· and But· radicals which disappeared by formation of these C_8–C_{10} hydrocarbons could be estimated.

$$[28] \quad \text{High } C_5\cdot = \sum_{C_9C_{10}} C_5\cdot = 2C_{10} + \sum \text{nonenes}$$

$$[29] \quad \text{High But}\cdot = \sum_{C_8C_9} \text{But}\cdot = \sum \text{nonenes} + 2\sum \text{octadienes}$$

Results of these calculations are also included in Table I.

F. The Rates of the Primary Reactions

Maintenance of a steady state concentration of C_5· in the system allows the rate of C_5· formation to be evaluated in terms of its product formation rates,

$$[30] \quad R_{C_5\cdot} = k_5[CH_3][cis\text{-}C_4H_8\text{-}2] = R_{C_6} + R_{i\text{-}C_5H_{12}} + R_{2\text{-MB-2}} + R_{3\text{-MB-1}[C_5\cdot]} + R_{\text{High } C_5\cdot}$$

The values of $R_{C_5\cdot}$, calculated from the individual terms of eq. [30] given in Table I, are plotted vs. $R_{C_2H_6}{}^{1/2}[cis\text{-}C_4H_8\text{-}2]$ in Figs. 4 and 5. In order to make it clear that the last term of eq. [30] is merely calculated according to the postulate of the preceding section, this portion of the rate is indicated by a vertical line for the 150.2 °C data displayed in Fig. 4. In the reactions containing no CH_3CHO, this portion amounts to as much as 25% of the total (exp. 217). The corrections for those experiments which contain added CH_3CHO are in almost all cases very minor. The corrected values, both with and without CH_3CHO, lie to within the limits of experimental error on a single line, an indication that the correction procedure is valid.

Ignored in the above expression is the second step addition of C_5· to the *cis*-C_4H_8-2 substrate to yield a nonyl radical (C_9·). This radical could in turn combine and disproportionate with CH_3·

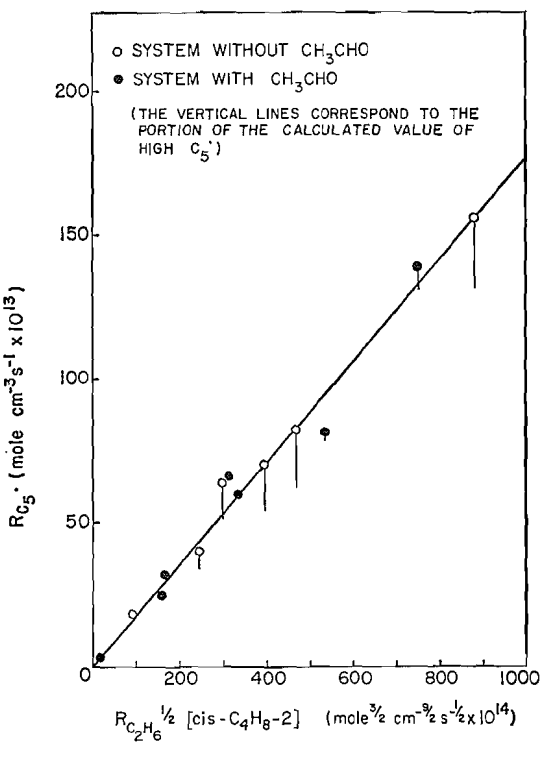

FIG. 4. Pentyl radical formation at 150.2 °C.

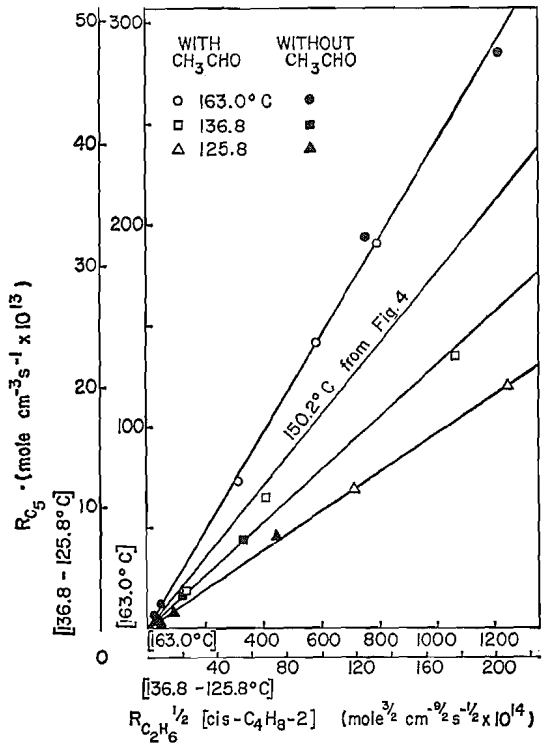

FIG. 5. Pentyl radical formation at other temperatures.

and other radicals in the system. The relative rates of formation of pentyl and nonyl radical, $R_{C_5\cdot}/R_{C_9\cdot}$ may be shown to be approximately equal to $R_{C_2H_6}/R_{C_6}$ if the rates of addition of the two radicals to *cis*-C_4H_8-2 are equal. Furthermore, this result would represent a minimum value of this rate, since it is to be predicted that $C_5\cdot$ would add more slowly than $CH_3\cdot$. Calculation of the values of $R_{C_2H_6}/R_{C_6}$ from the data of Table I shows the very strong influence of added CH_3CHO in minimizing the second stage addition to *cis*-C_4H_8-2. In general, experiments without CH_3CHO showed calculated $C_5\cdot$ addition to be of significant magnitude, ~15–40% as great as the comparable $CH_3\cdot$ addition. Experiments conducted with added CH_3CHO had almost negligible $C_5\cdot$ addition, ~0–3%. Conditions most favorable for minimizing second step addition are low concentrations of DTBP and *cis*-C_4H_8-2, and high CH_3CHO concentration. Inspection of the curves of Figs. 4 and 5 does not indicate the kind of difference between the two and three component systems that is predicted in the above argument. It must be concluded that $C_5\cdot$ radicals are much less active than $CH_3\cdot$ in adding to *cis*-C_4H_8-2.

The rate of But· formation may be formulated analogously as

$$[31]\quad R_{But\cdot} = R_{trans\text{-}C_5H_{10}\text{-}2} + R_{cis\text{-}C_5H_{10}\text{-}2} + R_{3\text{-}MB\text{-}1[But\cdot]} + R_{Butenes} + R_{High\ But\cdot}$$

$R_{Butenes}$ represents the formation of three butene isomers by H atom abstraction reactions of But· reactions [13*a*, *b*, *c*], from molecules such as *cis*-C_4H_8-2 and CH_3CHO as well as disproportionation reactions between But· and other radicals, mainly $C_5\cdot$. Of these three isomers *trans*-C_4H_8-2 was regularly measured; C_4H_8-1 was partially separated and identified, but could not be quantitatively determined by gas chromatography because of its small magnitude and incomplete separation from *i*-C_5H_{12}. It was possible to identify *cis*-C_4H_8-2 in the products from exps. 232 and 233, reactions conducted with C_4H_8-1 and *trans*-C_4H_8-2, but again quantitative estimation was unsuccessful. Consequently the distribution of butenes was calculated from the amount of *trans*-C_4H_8-2 experimentally determined combined with the corresponding thermodynamic equilibrium distribution data for the butenes recently reported by Golden, Egger, and Benson (17).

$$[32]\quad R_{Butenes} = \alpha R_{trans\text{-}C_4H_8\text{-}2}$$

α = 1.63(163.0 °C), 1.60(150.2 °C), 1.58(136.8 °C), 1.56(125.8 °C)

Although such an approximation probably leads to small errors in the amounts of the butene isomers so calculated, their total amount is generally not appreciable and no great differences result in the overall But· formation rate.

Unlike the expression developed for $R_{C_5\cdot}$, eq. [30], the above expression for $R_{But\cdot}$, eq. [31], does not directly apply to a single process for the formation of But·, $R_6 = k_6[CH_3][cis\text{-}C_4H_8\text{-}2]$, but also includes But· generated by H atom abstraction by other radicals, mainly $C_5\cdot$ and But·, from *cis*-C_4H_8-2. Thus $R_{But\cdot}$ represents a maximum value possible for R_6. In addition, the effect of a second step addition of But· to *cis*-C_4H_8-2 is again ignored. An argument similar to the one used for the second step $C_5\cdot$ addition would apply here also, and in this case the addition would produce an octenyl radical (Oct·). The minimum value of the ratio of rates of formation

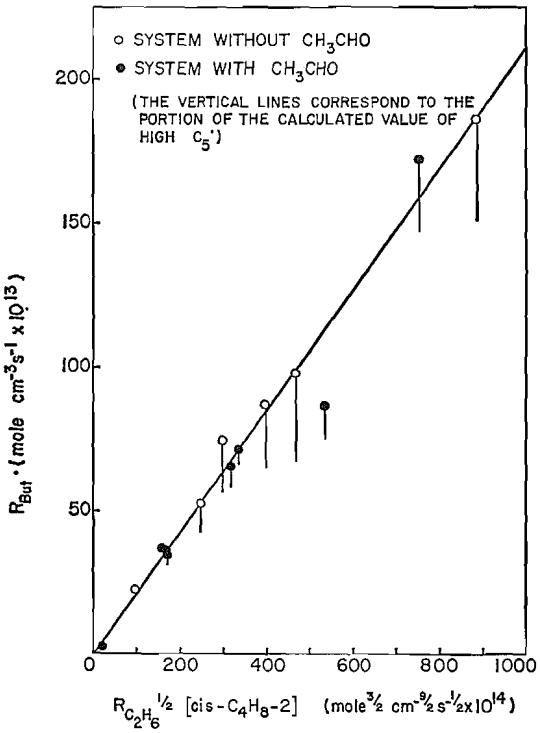

FIG. 6. Butenyl radical formation at 150.2 °C.

of But· and Oct·, $R_{But\cdot}/R_{Oct\cdot} \approx R_{C_2H_6}/R_{C_5H_{10}}[But\cdot]$. Although the addition of CH_3CHO also minimizes the second step addition of But·, the effect is not as pronounced as with the C_5· radical because of the inability of But· to react rapidly with CH_3CHO by H atom abstraction. However, reasonably high concentrations of CH_3CHO do cause the formation of Oct· to be almost negligible.

The data for $R_{But\cdot}$ is shown in Figs. 6 and 7. In spite of the prediction that the corrected value of $R_{But\cdot}$ determined in the absence of CH_3CHO might differ appreciably from its value in the experiments with CH_3CHO, it is seen that no significant deviation is apparent. This may be due to counteracting errors, those tending toward high $R_{But\cdot}$ because of But· formed by processes other than reaction [6] and those leading to low $R_{But\cdot}$ because of the neglect of products of the second step But· addition. In any event the results of the experiments with CH_3CHO may be expected to give valid results due to the high CH_3· steady state concentration which minimizes the complicating factors of the R_6 determination. The Arrhenius plot of the data contained in Figs. 4, 5, 6, and 7 is given in Fig. 8. Rate constants evaluated from the best lines are

$$k_5/k_3^{1/2} = 9.5 \times 10^3 \exp(-7000/RT) \quad (\text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1})^{1/2}$$

$$k_6/k_3^{1/2} = 3.9 \times 10^3 \exp(-7300/RT) \quad (\text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1})^{1/2}$$

or if the value of Shepp (18) is used for $k_3 = 2.2 \times 10^{13}$ cm^3 mole^{-1} s^{-1}, $k_5 = 4.5 \times 10^{10} \exp(-7000/RT)$, and $k_6 = 1.8 \times 10^{10} \exp(-7300/RT)$ cm^3 mole^{-1} s^{-1}. These values compare favorably with the corresponding k_5 and k_6 determined by Cvetanović and Irvin (6) of $9.0 \times 10^{10} \exp(-7500/RT)$ and $1.3 \times 10^{11} \exp(-7600/RT)$, respectively.

G. CH_4 Formation

In the absence of CH_3CHO, CH_4 is formed by abstraction from DTBP, reaction [4], and *cis*-butene-2, reaction [6], as well as by CH_3· disproportionation with other radicals present, a source for the most part represented by reactions

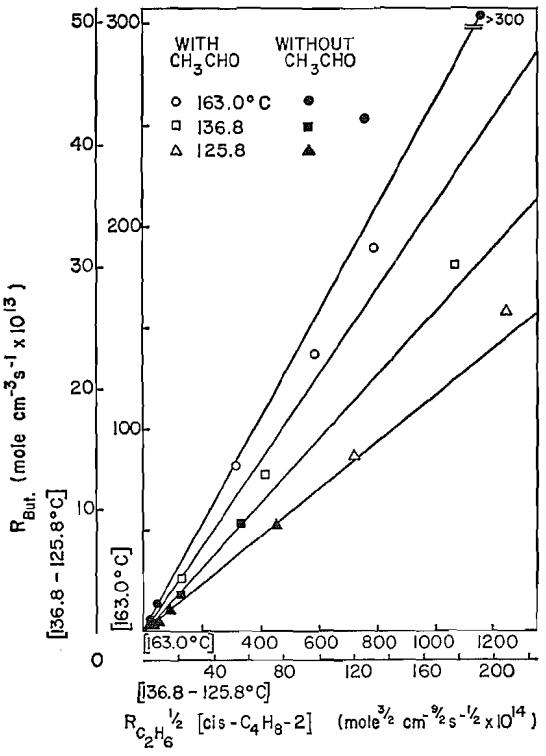

FIG. 7. Butenyl radical formation at other temperatures.

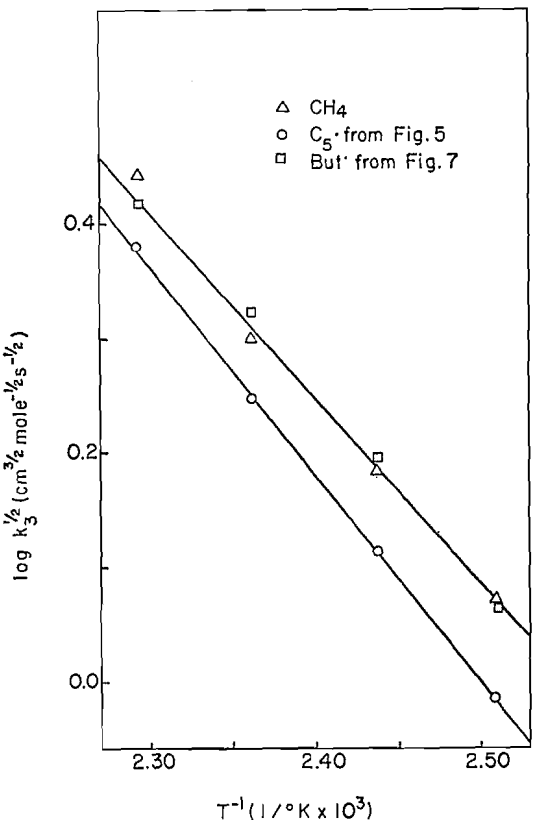

FIG. 8. The formation of methane, pentyl and butenyl radicals as a function of temperatures.

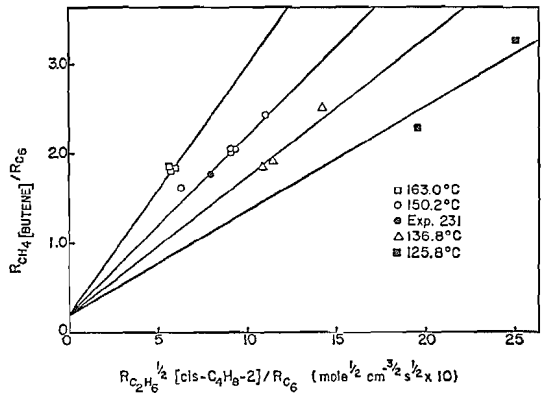

FIG. 9. The formation of methane from *cis*-butene-2.

[8*a*, *b*]. The portion attributable to reaction [4] may be estimated similarly to the method used by Miyoshi and Brinton (1*b*). Split of the CH_4 between reactions [6] and [8*a*, *b*] may be evaluated by plotting of the easily derived function

$$[33]\quad \frac{R_{CH_4[Butene]}}{R_{C_6}} = \frac{k_6 R_{C_2H_6}{}^{1/2}}{k_3{}^{1/2} R_{C_6}}[cis\text{-}C_4H_8\text{-}2] + \frac{k_{8a} + k_{8b}}{k_7}$$

where $R_{CH_4[Butene]}$ represents the CH_4 arising solely through butene interaction, i.e. R_{CH_4} corrected for $R_{CH_4[DTBP]}$. The plot shown in Fig. 9 is not a critical test of eq. [33] because the spread of the variables is limited in extent at most temperatures. The intercept, $k_{8a} + k_{8b}/k_7$, ≈ 0.2 is a very rough evaluation of the disproportionation–combination ratio of the CH_3–$C_5{}^{\cdot}$ interaction. However, the 0.2 intercept is not inconsistent with any of the curves, and the slopes, $k_6/k_3{}^{1/2}$, which are much more accurately given from the curves than the intercepts, are included in Fig. 8. It is seen that points evaluating $k_6/k_3{}^{1/2}$ from quite different procedures, CH_4 formation as contrasted to But$^{\cdot}$ radical formation, are quite consistent and a single line may be drawn through the two sets of data. This correspondence gives confidence that the value of $k_6/k_3{}^{1/2}$ given earlier is a reasonable one. However, the check of the But$^{\cdot}$ formation data may well be fortuitous as discussed previously.

In presence of CH_3CHO large quantities of CH_4 and CO are formed by the following chain mechanism

$$[34]\quad CH_3{}^{\cdot} + CH_3CHO \rightarrow CH_4 + CH_3CO^{\cdot}$$

or more generally

$$[35]\quad R^{\cdot} + CH_3CHO \rightarrow CH_4 + CH_3CO^{\cdot}$$

and

$$[36]\quad CH_3CO^{\cdot} \rightarrow CH_3{}^{\cdot} + CO$$

The % of the total CH_4 formed by reactions associated with *cis*-C_4H_8-2 and $CH_3{}^{\cdot}$ interaction was quite small in all cases when appreciable CH_3CHO was present. Plots of $R_{CH_4[CH_3CHO]}$ vs. $R_{C_2H_6}{}^{1/2}[CH_3CHO]$ gave good lines at single temperatures. An Arrhenius plot of these data evaluated $k_{34}/k_3{}^{1/2} = 8.5 \times 10^4 \exp(-7200/RT)$ (cm^3 mole^{-1} s^{-1})$^{1/2}$. Volman and Brinton (19) reported $E_{34} = 7500 \pm 300$ cal mole^{-1} for the system containing only DTBP and CH_3CHO. Kerr and Calvert (20), from a composite Arrhenius plot of the data of a number of studies involving quite different systems, determined E_{34} as 6800 cal mole^{-1}.

Preparation and properties of σ-bonded picryl platinum compounds

A. R. Norris and M. C. Baird
Department of Chemistry, Queen's University, Kingston, Ontario

Received March 4, 1969

The compounds *cis*-PtCl(pic)(EPh_3)$_2$ (pic = 2,4,6-trinitrophenyl; E = P, As) have been prepared by the oxidative addition of picryl chloride to the zero valent platinum compounds, $Pt(PPh_3)_3$ and $Pt(AsPh_3)_4$. Both new compounds react with cyanide ion to give intensely colored red complexes.

Canadian Journal of Chemistry, 47, 3003 (1969)

Introduction

In recent years a number of σ-bonded organoplatinum compounds have been prepared by the oxidative addition of active halides such as methyl iodide, allylchloride, and acyl and sulfonyl halides to the zero valent platinum compounds $Pt(PPh_3)_{3,4}$ (1). The method has proven to be extremely useful in preparing compounds of the general formula $PtRCl(PPh_3)_2$, where R is an organic moiety for which the Grignard or lithium derivative cannot be prepared.

We have now found that picrylchloride (1-Cl-2,4,6-trinitrobenzene) readily adds to both $Pt(PPh_3)_3$ and $Pt(AsPh_3)_4$ to form the stable new compounds PtCl(pic)(EPh_3)$_2$ (E = P, As; pic = 2,4,6-trinitrophenyl). The infrared and proton nuclear magnetic resonance (n.m.r.) spectra of these compounds and their interactions with cyanide ion are described.

Observations

A solution of $Pt(PPh_3)_3$ (2) in benzene treated with an excess of picryl chloride rapidly turns deep red-brown. By refluxing for 15 min, concentrating, adding ethanol, and cooling, a virtually quantitative yield of pale orange-yellow crystals of Pt(pic)Cl(PPh_3)$_2$ was obtained. The yellow triphenylarsine analogue PtCl(pic)($AsPh_3$)$_2$ was similarly obtained by treating $Pt(AsPh_3)_4$ (2) with excess picryl chloride. Both compounds are very stable, soluble in chloroform (0.10 *M*) and benzene, and virtually insoluble in alcohols, ether, and acetone.

In addition to bands which can be assigned to the triphenylphosphine or arsine, the infrared (i.r.) spectra (Nujol mull, KBr disk) of both compounds contain bands assignable to the picryl group at 1590 (strong, C—C stretch), 1515 (strong, ν_{asym}-NO_2), 1330 (strong, ν_{sym}-NO_2) and 730 cm^{-1} (medium, in-plane deformation, NO_2). The frequencies of the first three bands are significantly lower than the average values of these same vibrations in 17 picryl compounds, in which R is the more conventional substituent (Cl, Br, I, CH_3, etc.) (3). In both compounds the band at 755 cm^{-1}, characteristic of the C—Cl stretch in picryl chloride, is absent. The phosphine compound has a band at 306 cm^{-1} which can be assigned to the platinum–chlorine stretching mode. This region is obscured in the i.r. spectrum of the arsine complex by a triphenylarsine band and ν_{Pt-Cl} cannot be assigned in this case.

The proton n.m.r. spectrum ($CDCl_3$, 37 °C) of PtCl(pic)(PPh_3)$_2$ contains a number of intense bands at about 2.6τ (relative intensity 30) which may be assigned to triphenylphosphine resonances and a triplet of doublets centered at 1.43τ (relative intensity 2) which may be assigned to the two picryl protons. This spectrum is compatible only with *cis* square planar coordination about the platinum, the triplet structure being due to coupling with ^{195}Pt ($J = \frac{1}{2}$, 34% abundance, J_{Pt-H} = 9.6 c.p.s.) and the doublets being due to coupling with one of the phosphorus atoms (J_{P-H} = 1.6 c.p.s.). Only a single sharp line at 1.52τ can be assigned to the picryl protons in the n.m.r. spectrum of the arsine derivative; no satellites due to coupling with the platinum could be observed. In both the triphenylarsine and triphenylphosphine complexes the resonance absorptions of the picryl hydrogens are considerably upfield compared to the resonance absorbances of the ring hydrogens in 1,3,5-trinitrobenzene (0.67τ) and 1-R-2,4,6-trinitrobenzenes, where R = CH_3 (1.00τ), OCH_3 (0.95τ) and COH (~0τ) (4).

Attempts to replace the chlorine in PtCl(pic)-(PPh_3)$_2$ by refluxing with excess tetraethylammonium bromide in acetonitrile for ½ h were unsuccessful, the chloro complex being reisolated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in good yield. The absence of substitution in this reaction is in direct contrast with the ease of similar metathetical reactions in other arylplatinum compounds (5, 6).

Reactions of $Pt(PPh_3)_3$ with 1,3,5-trinitrobenzene (TNB), *m*-dinitrobenzene, 2,4,6-trinitrotoluene, and 1-chloro-2,4-dinitrobenzene all gave deeply colored solutions. However, only the first reaction appeared promising, yielding a black crystalline compound which analyzed as $Pt(TNB)(PPh_3)_2$ and which has been reported separately (7).

Both $PtCl(pic)(PPh_3)_2$ and $PtCl(pic)(AsPh_3)_2$ interact with cyanide ion (introduced as the tetraphenylarsonium salt) in a wide range of protic and dipolar aprotic solvents to yield intensely colored red solutions which possess two absorption maxima in the range 350 to 850 mμ. The shorter wavelength absorption is always the more intense by a factor of 1.1 to 1.3. The positions of maximum absorption vary to a slight extent in different solvents but the general form of the visible absorption bands is the same in all the solvents investigated. A similar behavior has been noted for the σ-complex formed between cyanide ion and 1,3,5-trinitrobenzene (8).

The molar extinction coefficients (ε) of the colored species at the wavelength of maximum absorption and the equilibrium constants (K) associated with their formation were evaluated in several solvents from absorbance studies of a series of solutions in which the $PtCl(pic)(PPh_3)_2$ concentration was held constant (usually near 1.0×10^{-4} M) and the concentration of tetraphenylarsonium cyanide varied over the range 1.0×10^{-4} to 5.0×10^{-3} M. The results indicate that complexes of 1:1 stoichiometry are formed in acetone (λ_{max}, 458 mμ), chloroform (461 mμ), dichloromethane (459 mμ) and acetonitrile (455 mμ) with, in all cases, a molar extinction coefficient of $1.9 \pm 0.5 \times 10^4$ l mole^{-1} cm^{-1} at the absorption maximum. The equilibrium constant for complex formation is strongly solvent dependent, being $3.0 \pm 0.5 \times 10^2$ in chloroform and $1.5 \pm 0.5 \times 10^4$ in acetone.

Very little could be learned about the structure of the cyanide complex from the n.m.r. spectrum of the red solution in $CDCl_3$. As the ratio CN^-:Pt was increased, the absorptions at 1.43τ (in the case of the phosphine complex) remained at the same position but decreased in intensity. However, no new resonance absorptions could be detected in the range 10 to 0τ. Since the addition of cyanide ion to a C-3 position on the picryl group would be expected to lead to resonance absorptions of equal intensity at ca. 2.4 and 4τ (4), the absence of the latter absorption strongly suggests that cyanide adds at the C-1 position. In this case the resonance absorptions of the two picryl protons in the complex would be buried under the very intense phenyl resonances of the tetraphenylarsonium ion (4). The infrared spectra of the products obtained after long standing of the solutions used in the n.m.r. studies indicate that cyanide eventually replaces the picryl group in the inner coordination sphere of the platinum.

Experimental

Infrared spectra were run on a Beckman IR-10 spectrophotometer, n.m.r. spectra on a Varian T-60 using internal TMS as a standard and visible spectra on Unicam SP800 and Cary 14 spectrophotometers. Determinations of K and ε were carried out using spectro-grade solvents, matched silica cells of 1.0 cm path length and with the cell compartments of the spectrophotometers maintained at 25.0 ± 0.1 °C. Molecular weights were determined using a Mechrolab vapor pressure osmometer. Melting points (uncorrected) were obtained using a Gallenkamp melting point apparatus. Analyses were carried out by A. Bernhardt, Max Planck Institut, Mulheim, Ruhr, West Germany.

Chloropicrylbistriphenylphosphineplatinum(II)

Treatment of 1.805 g $Pt(PPh_3)_3$ with 1.38 g picryl chloride in 40 ml benzene solution under nitrogen at room temperature gave a dark-colored solution. On refluxing for 15 min, the color of the solution turned lighter, and on concentrating, adding excess ethanol, and cooling, 1.73 g (92% yield) of the crude *complex* precipitated. Recrystallization from benzene–ethanol gave pale orange-yellow crystals, m.p. 264–265 °C (decomp.).

Anal. Calcd. for $C_{42}H_{32}ClN_3O_6P_2Pt$: C, 52.15; H, 3.34; Cl, 3.67; N, 4.34; M, 967. Found: C, 51.17; H, 3.25; Cl, 3.33; N, 4.30; M, 1200 (chloroform).

Chloropicrylbistriphenylarsineplatinum(II)

The compound was prepared from $Pt(AsPh_3)_4$ and picryl chloride by a method similar to that used for the phosphine analogue. Recrystallized from benzene–ethanol, the compound formed pale yellow crystals, m.p. 238–239 °C.

Anal. Calcd. for $C_{42}H_{32}As_2ClN_3O_6Pt$: C, 47.81; H, 3.06; M, 1055. Found: C, 48.21; H, 3.26; M, 1340 (chloroform).

Discussion

Oxidative addition reactions of active halocarbons to $Pt(PPh_3)_3$ are well-known, platinum compounds containing methyl (6), acetyl (9), and benzoyl (10) groups having been reported previously. Although addition of an alkyl or aryl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

halide to a metal atom presumably yields a *cis*-adduct initially, isomerization to the more stable *trans*-isomer usually occurs very readily, especially in the presence of free phosphine (6). On this basis the stable *cis*-configuration of PtCl(pic)-$(PPh_3)_2$, as shown unequivocally by the n.m.r. spectrum, seems surprising. However, *cis-trans* isomerization would undoubtedly occur via attack on the platinum atom by free phosphine, a process which would be sterically hindered by the ortho nitro groups of the picryl ring. The failure to substitute the chloride by bromide, a reaction which normally proceeds rapidly, is also presumably hindered by steric interactions.

The position of ν_{Pt-Cl} (306 cm^{-1}) of PtCl(pic)-$(PPh_3)_2$ lies within the range normally found for chloride *trans* to tertiary phosphines in platinum compounds (11). X-Ray powder diffraction patterns of the two picryl compounds reported here indicate that the compounds are not isomorphous, and thus nothing can be said about the structure of the arsine compound.

Aside from determining the stereochemistry, the n.m.r. spectrum of $PtCl(pic)(PPh_3)_2$ is of great interest because of the large long-range interactions which are observed. The platinum–hydrogen coupling constant (9.6 c.p.s.) is much greater than coupling constants through four bonds in several other organometallic compounds (12), while the phosphorus–hydrogen coupling constant (1.6 c.p.s.) extends through five bonds involving four different elements. It is generally agreed (12) that *trans* couplings in square complexes are larger than *cis* couplings, and therefore it is likely that the coupling observed here is with the *trans* phosphine. The fact that such long-range coupling is observed suggests that π-electron delocalization via platinum–carbon d_π–p_π bonding and platinum–phosphorus d_π–d_π bonding must be important. Parshall has demonstrated extensive back-donation from platinum(II) to fluorophenyl groups (13); it is to be expected that the highly electronegative nitro-groups would also facilitate such back-donation.

In this respect, it is interesting to note, as mentioned above, that the NO stretching modes in the i.r. spectrum of the platinum compounds are lower than normal, suggesting that a platinum atom donates greater electron density to an aromatic ring than do ordinary organic functional groups. Similarly the resonances of the protons on the picryl group appear at much higher fields in the n.m.r. spectra of the platinum compounds than is found for other picryl compounds. Indeed, the positions of resonance are approximately the same as for the cyanide adducts of other picryl compounds (4). Again extensive delocalization of electron density from the metal atom into the ring is implied.

Primary yields and mechanism in the radiolysis of gaseous ammonia[1]

C. WILLIS, A. W. BOYD, AND O. A. MILLER

Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received March 10, 1969

Ammonia vapor has been irradiated with single pulses of electrons at a very high dose rate (10^{27} eV g^{-1} s^{-1}) with a Febetron 705. At this dose rate radical–product reactions are not significant. In pure ammonia, hydrogen, nitrogen, and hydrazine are produced and the yields[2] found at 10^{27} eV g^{-1} s^{-1} are: $G(H_2) = 3.58 \pm 0.08$; $G(N_2) = 1.00 \pm 0.05$; $G(N_2H_4) = 0.58 \pm 0.05$. The yields are independent of pressure from 1 to 5 atm and of temperature between 20 and 200 °C. Above 250 °C the yields of all three products increase significantly and this is due to reaction [1] competing with radical–radical reactions.

[1] $$H + NH_3 \rightarrow H_2 + NH_2$$

A rate constant for this reaction has been determined,

$$k_1 = 4 \pm 2 \times 10^9 \exp(-10\,000 \pm 1\,500/RT) \quad 1\ \text{mole}^{-1}\ \text{s}^{-1}$$

Product yields have been measured for ammonia–propene mixtures. These yields have allowed determination of the primary radiation yields $G_{NH} = 0.74$; $G_{H_2} = 0.74$; $G_{NH_2} = 4.8$; $G_H = 4.8$; and $G(-NH_3) = 5.4$.

Canadian Journal of Chemistry, 47, 3007 (1969)

Introduction

It has long been known (1) that the products of ammonia radiolysis are hydrogen, nitrogen, and hydrazine and that under static conditions only hydrogen and nitrogen are found. It is clear that hydrogen atoms and NH_2 radicals are formed and product yields depend upon the reaction of these radicals with each other and with hydrazine. Only recently have radical yields been measured and primary mechanisms proposed.

A non-scavengeable or direct yield of hydrogen has been determined to be $G(H_2) = 0.74 - 0.75$ by the addition of ethylene (2–4). There is considerable disagreement in the value for the yield of hydrogen atoms. Jones and Sworski (2) obtained $G_H = 12.5$ from the formation of HD in D_2–ammonia mixtures and from the formation of hydrogen in hydrazine–ammonia mixtures. Johnson and Simic (3) found $G_H = 7.2$ from the addition of propane. Nishikawa *et al.* (4) also used propane but found $G_H = 5.1$ by extrapolating to zero concentration of propane.

At low dose rates, 10^{16}–10^{20} eV g^{-1} s^{-1}, the yield of hydrogen in pure ammonia ranges from $G(H_2) \sim 5$ at room temperature to $G(H_2) \sim 15$ above 200 °C. This temperature dependence has been accounted for by reaction [1] becoming increasingly important with temperature (2).

[1] $$H + NH_3 \rightarrow H_2 + NH_2$$

Johnson and Simic (3) rejected this because of the low apparent activation energy (~2 kcal $mole^{-1}$) for the increase in yields and suggested competition between reactions [2] and [3]

[2] $$H + NH_2 + M \rightarrow NH_3 + M$$

[3] $$H + N_2H_4 \rightarrow H_2 + N_2H_3$$

Anderson and Winter (5) proposed that the increase is due to changes in the clustering of ions with temperature, resulting in different yields of hydrogen atoms on neutralization.

Because of the disagreement in radical yields and the proposed mechanisms a further investigation of ammonia radiolysis seemed worthwhile. In previous papers (6, 7) we have reported on results obtained at very high dose rates (10^{27} eV g^{-1} s^{-1}) from a Febetron pulsed electron accelerator and have done liquid (8) and gas (9–11) phase dosimetry for these dose rates. At very high dose rates radical–radical reactions become dominant and it is possible to measure yields with no interference from radical–product reactions.

We have irradiated ammonia and ammonia mixed with propene at temperatures from 20–450 °C with single electron pulses from the Febetron. From the effects of propene and the variation of yields with temperature we have

[1]Issued as A.E.C.L. No. 3325

[2]G_x is the primary yield of species x, $G(x)$ is the observed yield of species x.

derived values for the yields of primary species and have proposed a mechanism for the radiolysis of ammonia under "zero dose" conditions.

Experimental

Pulsed Electron Accelerator and Dosimetry

The pulsed electron accelerator[3] was a Febetron 705 which gives ~100 ns pulses of 1.0–1.7 MeV electrons with a maximum current of ~5000 A. Details have been given previously (6–9).

The dosimetry was based on a nitrogen yield of $G(N_2) = 12.4 \pm 0.2$ for the radiolysis of nitrous oxide at 1 atm. This value was obtained by comparing the yields from nitrous oxide with the dose per pulse measured by adiabatic calorimetry (9). This yield is independent of temperature from 20–200 °C (10). The dosimetry at low pressures, below 600 Torr, is very uncertain. The yield of nitrogen from nitrous oxide increases by a factor of 2 between 600 and 15 Torr. This increase, which is thought to be due to transient electric fields, is discussed elsewhere (12). The dose absorbed in the ammonia was calculated from the measured dose in nitrous oxide using standard electron stopping parameters (9).

Gas samples were contained in quartz cells with ~0.5 mm quartz electron windows. The actual pulse shape and duration in these cells are uncertain. The voltage range of the transmitted pulse is estimated to be 0.4–1.1 MeV and its duration to be 30–50 ns. We have no detailed knowledge of the homogeneity of the irradiation field over the cell volume, however, variations should be less than a factor of 3.

Irradiation Cells

The irradiation cells and the furnace are shown in Fig. 1. The cells are quartz with a Pyrex break seal (C). The electron window (A) was made by pulling down quartz tubing to make a thin membrane ~0.5 mm thick. The windows were not uniform in thickness. Variations of dose from cell to cell were kept to ±10%. The dose in each cell was determined several times with nitrous oxide. Typically a cell could withstand 2.5 atm pressure.

For irradiations at elevated temperatures the cells were placed in the annular furnace shown in Fig. 1. This gave good temperature uniformity over the cell volume. The cells were placed in the preheated furnace for 15 min before irradiation (with the removable transite cover (E) in place) to allow temperature to be attained. Above 250 °C some pyrolysis of samples occurred. The irradiation yields reported are corrected for the contribution of pyrolysis. The corrections were generally small but above 450 °C could be as much as 10%. No results are given for experiments conducted above this temperature.

Each sample was quenched in liquid nitrogen within 20 s of irradiation. Unquenched samples gave low hydrazine yields and high nitrogen and hydrogen yields. This was almost certainly due to pyrolysis of the hydrazine formed by radiolysis. However, even at 400 °C, provided quenching was performed within 60 s after irradiation, reproducible results were obtained.

Sample Preparation and Gas Analysis

The ammonia used was Matheson anhydrous grade. The propene was Phillip's research grade hydrocarbon. All gases were used directly from the cylinder and subjected to several freeze–pump–thaw cycles to remove non-condensible impurities. Samples were frozen into the cell and the cell was closed by collapsing the Pyrex break seal under vacuum.

Analysis of the gaseous products was achieved by immersing the irradiated cell in liquid nitrogen and pumping off the non-condensible product gases into a McLeod gauge. After the volume of the gas had been measured its composition was determined by mass spectrometry.

Early experiments involved distillation of the residual ammonia and hydrazine into a cold trap followed by flaming of the cell to ensure no errors due to adsorbed products. Flaming did contribute about 20% more gas, but this arose from a non-radiation process. Some ammonia seemed to have been irreversibly adsorbed on to the quartz walls and, when the cell was flamed, pyrolyzed to give nitrogen and hydrogen. Identical

"flaming" yields were obtained from irradiated and unirradiated samples. The yields reported in this paper are those obtained without flaming.

Hydrazine Analysis

The hydrazine yield was measured using the spectrophotometric method of Watt and Crisp (13). The method is based on the yellow color developed upon the addition of *p*-dimethylaminobenzaldehyde to hydrazine in dilute hydrochloric acid solution. The irradiated ammonia sample was frozen in the cell and after the break seal was opened, dilute hydrochloric acid was added to neutralize the ammonia and to dissolve the hydrazine. The solution was then mixed with *p*-dimethylaminobenzaldehyde reagent solution and left at least 15 min for the color to develop. The % transmittancy of the solution was read at 455 nm and the hydrazine concentration read from calibration curves. Normally duplicate ammonia samples were irradiated; one being used to measure the gas yield and the other to measure the hydrazine yield.

Results

(a) Pure Ammonia

The amounts of nitrogen, hydrogen, and hydrazine produced at 24 °C as a function of absorbed dose are shown in Fig. 2. These were obtained by pulsing the same sample with more than one electron pulse. The amounts of all three products are linear with absorbed dose up to at least six pulses.

The effect of pressure on product yields is shown in Fig. 3. The yields are constant from 1–2.25 atm. Irradiations in stainless steel cells (9) showed the independence of yields on pressure up to 5 atm. Below 700 Torr the yields increase with decreasing pressure.

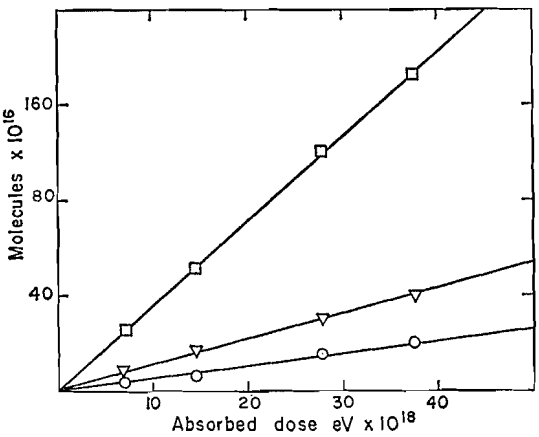

FIG. 2. Product yields as a function of dose; □, hydrogen yield; ▽, nitrogen yield; and ○, hydrazine yield.

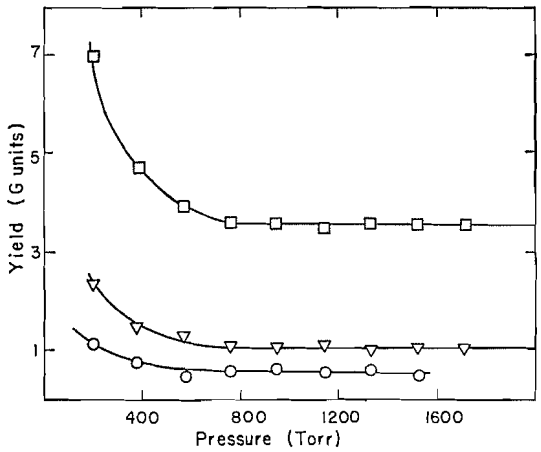

FIG. 3. Product yields as a function of pressure; □, hydrogen; ▽, nitrogen; and ○, hydrazine.

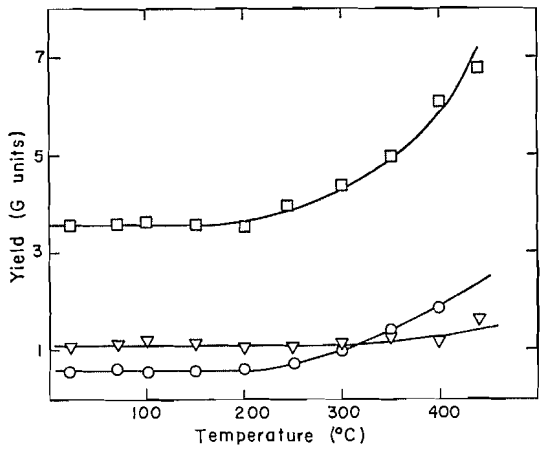

FIG. 4. Product yields as a function of temperature; □, hydrogen; ▽, nitrogen; and ○, hydrazine. Yields are corrected for pyrolysis.

The effect of temperature on the product yields is shown in Fig. 4. The results are for a dose of 1.7 Mrads (1 pulse) for pure ammonia at 760 Torr.

(b) Ammonia–Propene Mixtures

The product yields from ammonia–propene mixtures are shown in Figs. 5 and 6. The yields are calculated using the dose absorbed in the ammonia. Initially the hydrogen yield rapidly decreases and then decreases more slowly as more propene is added. The nitrogen yield decreases slowly with increasing propene. The hydrazine yield rapidly increases to a maximum and then decreases as more propene is added.

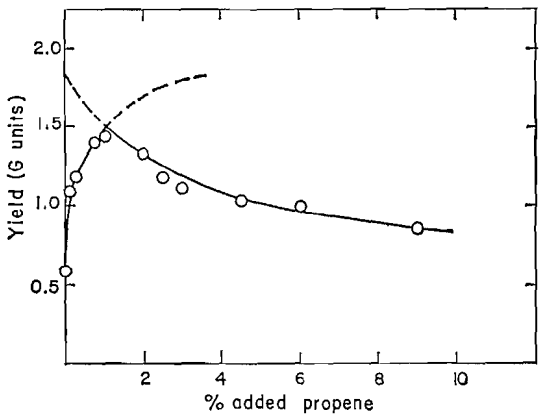

FIG. 6. Hydrazine yield in presence of added propene.

Discussion

(a) Pure Ammonia

At the dose rates used in the present experiments the product yields in the radiolysis of ammonia are: $G(H_2) = 3.58 \pm 0.08$; $G(N_2) = 1.00 \pm 0.05$; and $G(N_2H_4) = 0.58 \pm 0.05$. These yields are independent of dose over at least a factor of 5; of temperature from 20–200 °C; and of pressure from 1–5 atm.

At lower dose rates, up to 10^{19} eV g^{-1} s^{-1}, no hydrazine is found in static systems, and the yields of hydrogen and nitrogen are markedly temperature dependent in the range 0–200 °C (2, 3, 5).

At Febetron dose rates of 10^{27} eV g^{-1} s^{-1}, primary ion–molecule reactions[4]–[6] should not be affected.

[4] $NH_3 \rightarrow NH_3^+ + e$

[5] $NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2$

[6] $NH_4^+ + e \rightarrow NH_3 + H$

At very high dose rates, it is possible that the NH_3^+ ion may be neutralized as in reaction [7] before it undergoes reaction [5].

[7] $NH_3^+ + e \rightarrow NH_3^*$

However, this can be eliminated for the dose rates of the present experiments. Although the rate constant[4] for reaction [7] is 10^3 that of reaction [5], the maximum concentration of NH_3^+ ions that can be obtained during the pulse is less than 10^{-5} of the ammonia concentration.

The reactions of radicals, however, will change at 10^{27} eV g^{-1} s^{-1}. At this dose rate radical–radical reactions can compete with radical–hydrazine reactions. For example, reaction [2]

[2] $NH_2 + H + M \rightarrow NH_3 + M$

at 1 atm pressure is $\sim 10^4$ times faster than reaction [3].

[3] $H + N_2H_4 \rightarrow H_2 + N_2H_3$

The total hydrazine concentration even after several pulses (e.g. 10 Mrads total dose and assuming $G(N_2H_4) \sim 3$) is 2×10^{19} molecules g^{-1} whereas the total NH_2 radical concentration immediately after a single 1 Mrad pulse is 2×10^{18} molecules g^{-1}, giving

$$k_3[N_2H_4]/k_2[NH_2] = 10^{-3}$$

The linearity of the amount of hydrazine produced with absorbed dose (Fig. 2) confirms that reaction [3] does not compete with reaction [2] and further, it demonstrates that no radical–hydrazine reactions occur.

The radiolysis yields, therefore, can largely be considered to be a result of competition between the following radical–radical reactions

[8] $NH_2 + NH_2 + M \rightarrow N_2H_4 + M$

[9] $NH_2 + NH_2 (+ M) \rightarrow \cdots \rightarrow N_2 + 2H_2 + M$

[10] $NH_2 + NH_2 \rightarrow NH + NH_3$

[2] $NH_2 + H + M \rightarrow NH_3 + M$

[11] $NH_2 + H (+ M) \rightarrow \cdots \rightarrow \frac{1}{2}N_2 + \frac{3}{2}H_2$

[12] $H + H + M \rightarrow H_2 + M$

Above 200 °C, it is suggested that the increase in

[4]All rate constants and their references are collected in Table IV and generally will not be referred to in the text.

yields of hydrogen, nitrogen, and hydrazine is due to reaction [1] and that below this temperature it does not occur for the present conditions.

[1] $$NH_3 + H \rightarrow NH_2 + H_2$$

Reaction [9], the bimolecular disproportionation of NH_2 radicals to give nitrogen and hydrogen, may occur as written. A similar reaction has been observed in the photochemistry of hydrazine (14). However, this may involve an electronically

[13] $$N_2H_4 + h\nu \rightarrow N_2H_2 + H_2 \rightarrow N_2 + 2H_2$$

excited hydrazine molecule which is different from the transition state for reaction [9]. Thus reaction [9] should only be taken as a formalism for the overall reaction of hydrogen and nitrogen production, initiated by a bimolecular reaction between NH_2 radicals. Similarly, reaction [11] is a formalism for gas production from reaction of a hydrogen atom with an NH_2 radical. This may involve an NH radical intermediate but no definite evidence can be presented at present.

Reaction [2] shows a three body pressure dependence between 10–1000 Torr (15). As the pressure is reduced in this range, recombination of hydrogen atoms and NH_2 radicals is decreased, resulting in a net increase in yields. As can be seen in Fig. 3 the yields of all products do increase with decreasing pressure. The increase is far too large to be quantitatively explained by changes in reaction [2]. The reasons for increases of yields of this type for intense electron beam radiolysis are discussed elsewhere (12).

(b) Ammonia–Propene Mixtures

At low dose rates, the addition of olefins removes both H atoms and NH_2 radicals from the system. The effects of propene addition at 10^{27} eV g^{-1} s^{-1} are shown in Figs. 5 and 6. These are most simply explained by reactions [14] and [15]

[14] $$H + C_3H_6 \rightarrow C_3H_7$$

[15] $$NH_2 + C_3H_6 \rightarrow \text{Products}$$

Reaction [14] accounts for the initial increase in $G(N_2H_4)$ and decrease in $G(H_2)$ at low olefin concentrations. Initially reaction [14] competes with reaction [12] and then with reactions [2] and [11] so as to allow the NH_2 radicals to take part in reactions [8], [9], and [10]. The more gradual decrease in yields at higher propene concentrations can be due both to reaction [15] withdrawing NH_2 radicals from the system and to reaction [16] withdrawing NH radicals from the system.

[16] $$NH + C_3H_6 \rightarrow \text{Products}$$

Using the known rate constants for reactions [14], [2], [11], and [12], it is possible to extrapolate the yields in the presence of propene to eliminate scavenging of the NH_2 and NH radicals and to maximize the H atom scavenging as shown in Figs. 5 and 6. The extrapolated yields for this low propene condition are: $G(N_2H_4) = 1.8_2$, $G(N_2) = 0.9_5$, and $G(H_2) = 2.3_0$.

These yields result only from NH_2 radicals reacting either by reactions [8] or [9] plus the direct yields. The hydrazine yield directly gives the contribution of reaction [8]. The contribution of reaction [9] is estimated from the measured nitrogen yield less the direct yield. Therefore, the total yield of NH_2 radicals is $G_{NH_2} = 2 \times G(N_2H_4) + 2\{G(N_2) - G_{N_2}\text{ (direct)}\}$. The "direct" yield of nitrogen included in this expression is more properly the yield of nitrogen from processes not involving NH_2 radicals. A "direct" yield usually refers to the direct elimination of a stable product from a substrate molecule. Obviously this cannot be the case for nitrogen from ammonia and this direct yield should perhaps be called the "pseudo-direct" yield. It will be referred to as such.

At low dose rates, in the presence of olefin, a "molecular" yield of hydrogen has been determined (2–4) to be $G(H_2\text{ molecular}) = 0.74$. This yield has been demonstrated to have no ionic precursor (16), eliminating reactions of the type

[17] $$NH_4^+ + e \rightarrow NH_2 + H_2$$

The most obvious origin of this direct hydrogen yield is dissociation of an excited ammonia molecule as suggested by Okabe and co-workers (17, 18).

[18] $$NH_3^* \rightarrow NH + H_2$$

In the presence of olefin at low dose rates the NH radical will be scavenged, leaving only the direct yield of hydrogen. It is evident, therefore, that $G_{NH} = G_{H_2} = 0.74$.

Now for conditions where the NH radical is not scavenged by some additive (as is the case for the present high dose rate studies) it can react to give nitrogen and hydrogen by reaction either

TABLE I

The mechanism of high dose rate radiolysis: contributions of reactions in pure ammonia

	Reaction	Radicals used G_H	Radicals used G_{NH_2}	Yields $G(H_2)$	Yields $G(N_2)$	Yields $G(N_2H_4)$
	Pseudo-direct			1.11	0.37	
[8]	$NH_2 + NH_2 \rightarrow N_2H_4$	—	1.16	—	—	0.58
[9]	$NH_2 + NH_2 \rightarrow N_2 + 2H_2$	—	0.37	0.37	0.19	—
[11]	$NH_2 + H \rightarrow \frac{1}{2}N_2 + \frac{3}{2}H_2$	0.88	0.88	1.32	0.44	—
[2]	$NH_2 + H \rightarrow NH_3$	2.39	2.39	—	—	—
[12]	$H + H \rightarrow H_2$	1.53	—	0.77	—	—
	Totals	4.80	4.80	3.57	1.00	0.58

with itself as in reaction [19], or with NH_2 radicals, or with hydrogen atoms. Because we do

[19] $NH + NH \rightarrow N_2H_2 \rightarrow N_2 + H_2$

not have a detailed knowledge of the reactions of the NH radical, it will be assumed that all NH radicals react via reaction [19]. Although this is an approximation if the NH yield is 0.74 G units then it will not seriously affect the calculation of yields of the other radicals. The yields of nitrogen and hydrogen by reaction [19] will be $G(N_2) = G(H_2) = \frac{1}{2}G_{NH} = 0.37$. The total values for the pseudo-direct yields that should be used for conditions where the NH radical is not scavenged then, are $G(H_2) = 0.74 + 0.37 = 1.11$ and $G(N_2) = 0.37$. Such will be the case for extrapolation to low propene addition with Febetron irradiations.

Therefore, $G_{NH_2} = 2 \times 1.8_2 + 2(0.95 - 0.37) = 4.8$. The above values can be used to give the ratio of reaction [8] to reaction [9] of $k_8/k_9 = 1.8_2/0.5_8 = 3.1$.

Considering the results for pure ammonia at room temperature the contributions to the yields of reactions [2], [11], and [12] can be obtained. The total nitrogen yield from pure ammonia with the Febetron is $G(N_2) = 1.0$. This is the pseudo-direct yield ($G(N_2) = 0.37$) plus contributions from reactions [9] and [11]. The contribution of reaction [9] is that of reaction [8] times k_9/k_8. The contribution of reaction [8] is given directly by the hydrazine yield, $G(N_2H_4) = 0.58$. Therefore the contribution of reaction [9] to the nitrogen yield is equal to $1.00 - 0.37 - 0.58 \times (1/3.1) = 0.44$. This neglects the contribution of reaction [10]. The significance of reaction [10] will be discussed later.

In the same way the contributions of reactions [2] and [12] can be assessed and the contributions of all the reactions are summarized in Table I. The contribution of reaction [12] uses the value of $G_H = 4.8$, which is implicit in the mass balance.

The ratio of reactions [2] to [11] is determined to be $k_2/k_{11} = 2.71$.

Assuming initially equal concentrations of H atoms and NH_2 radicals, the ratio of total rate constants for the disappearance of NH_2 radicals by reaction with H atoms to disappearance by reaction with itself, i.e. $(k_2 + k_{11})/2(k_8 + k_9)$ is 4.4.

The yields extrapolated to low propene concentration are consistent with the above values. The net yields of hydrogen and nitrogen, $G(H_2) = 2.30 - 1.11 = 1.19$ and $G(N_2) = 0.95 - 0.37 = 0.58$, are very close to a ratio of 2:1. This implies that these yields originate from NH_2 radicals rather than NH radicals and that reaction [10] is not significant.

In the foregoing we have neglected reaction of propyl radicals with NH_2 radicals

[20] $C_3H_7 + NH_2 \rightarrow C_3H_7NH_2$ and/or $C_3H_6 + NH_3$

This has been suggested to occur in the photochemistry of ammonia in the presence of propane by Groth *et al.* (19). This would leave our yield of $G_{NH_2} = 4.8$ as a minimum. The importance of reaction [20] cannot be assessed at the present time due to the lack of rate data. Considering the rate of disappearance of propyl radicals by dimerization (20), it is perhaps not significant.

[21] $C_3H_7 + C_3H_7 \rightarrow C_6H_{14}$ and $C_3H_6 + C_3H_8$

Also the agreement of the present work with both other yield data and kinetic data suggests that the effect of propyl radical reaction with NH_2 radicals is not important.

440	2.33	6.79	1.49	1.53

*$G(N_2) \equiv [G(H_2) - G(N_2H_4)]/3$.

(c) Effect of Temperature

At low temperatures in pure ammonia we have proposed that reactions [2], [12], [8], [9], and [11] (plus the pseudo-direct contributions) account for the hydrogen, nitrogen, and hydrazine yields at 10^{27} eV g^{-1} s^{-1}. As the temperature increases above 200 °C, the hydrogen, nitrogen, and hydrazine yields increase.

This increase in yields with temperature is most simply explained by reaction [1]

[1] $$H + NH_3 \rightarrow NH_2 + H_2$$

If all of the H atoms react with ammonia in this way the limiting yields of the products would be $G(H_2) = 8.30$; $G(N_2) = 1.55$; and $G(N_2H_4) = 3.60$.

It is apparent from Fig. 4 that the limiting conditions have not been reached at 400–450 °C, but the observed product yields are not inconsistent with the above values. Table II shows the mass balance calculations for the results obtained as a function of temperature. Calculated nitrogen yields may be compared to the measured values. Good agreement is found at all temperatures.

In order to calculate an activation energy for reaction [1] it is necessary to relate the increase in reaction [1] with absolute temperature. Now although the increase in the hydrogen and hydrazine yields are related to an increase in reaction [1], since there is no linear correlation between these, it is not useful to plot either ln $\Delta G(H_2)$ or ln $\Delta G(N_2H_4)$ against the reciprocal temperature. The quantity which does directly correlate is the increase in NH_2 yield with temperature. Using the ratios of reactions obtained above and the G values given in Table II, $\Delta G(NH_2)$ has been calculated at various temperatures and is given in Table III. The Arrhenius plot of these values is given in Fig. 7. The slope of the line gives E_a/RT where E_a is the activation energy of reaction [1]. The value obtained is $E_a = 10.0 \pm 1.5$ kcal $mole^{-1}$.

TABLE III

Total yield of NH_2 as a function of temperature

Temperature, °C	$G(NH_2)$	$\Delta G(NH_2)$
24	4.80	—
250	5.30	0.50
300	5.70	0.90
350	6.64	1.84
400	7.70	2.90
440	9.10	4.30

When $\Delta G(NH_2) = \frac{1}{2}G_H = 2.4$, reaction [1] will account for half of the H atoms in the system. This occurs at ~380 °C (see Fig. 7). If we assume that the other H atoms react with NH_2 radicals by reactions [2] and [11], as is suggested by the mechanism, then

$$\frac{k_1[NH_3]}{(k_2 + k_{11})[NH_2]} = 1$$

Now for a pulse of 1.7 Mrads, assuming no decay of NH_2 radicals during the pulse, the NH_2 radical concentration is $\sim 5.5 \times 10^{18}$ molecules g^{-1}. Using the value of 1.1×10^{10} l $mole^{-1}$ s^{-1} for $(k_2 + k_{11})$ (see Table IV), k_1 at 380 °C = 1.7×10^6 l $mole^{-1}$ s^{-1}

$$\therefore \quad k_1 = 4 \pm 2 \times 10^9 \exp\left(-\frac{10\,000 \pm 1\,500}{RT}\right) \text{ l mole}^{-1}\ \text{s}^{-1}$$

(d) Comparison with Previous Work

Some reactions and rate constants that might be important in irradiated ammonia are given in Table IV.

TABLE IV

Reactions and rate constants for possible processes in irradiated ammonia*

	Reaction	Rate constant 1 mole^{-1} s^{-1}	Reference
[1]	$NH_3 + H \rightarrow NH_2 + H_2$	Estimated 10^4 at 150 °C	21
[2]	$NH_2 + H + M \rightarrow NH_3 + M$	$(k_2 + k_{11}) = 1.1 \pm 0.1 \times 10^{10}$	15
[3]	$H + N_2H_4 \rightarrow H_2 + N_2H_3$	$3.5 \times 10^8 \exp(-2000/RT)$	22
[4]	$NH_3 \rightarrow NH_3^+ + e$	—	—
[5]	$NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2$	$5 \pm 2 \times 10^{11}$	23,24
[6]	$NH_4^+ + e \rightarrow NH_3 + H$	$> 5 \times 10^{13}$	Estimated
[7]	$NH_3^+ + e \rightarrow NH_3^*$	$> 5 \times 10^{13}$	Estimated
[8]	$NH_2 + NH_2 + M \rightarrow N_2H_4 + M$	$(k_8 + k_9) = 2.3 \times 10^9$	15
[9]	$NH_2 + NH_2 + M \rightarrow N_2 + 2H_2 + M$	See [8]	—
[10]	$NH_2 + NH_2 \rightarrow NH + NH_3$	$\sim 4 \times 10^8$	15,25–27
[11]	$NH_2 + H (+ M) \rightarrow \frac{1}{2}N_2 + \frac{3}{2}H_2$	See [2]	—
[12]	$H + H + M \rightarrow H_2 + M$	1.6×10^8	28
[14]	$H + C_3H_6 \rightarrow C_3H_7$	1.6×10^8	22,29
[15]	$NH_2 + C_3H_6 \rightarrow$ Products	—	—
[16]	$NH + C_3H_6 \rightarrow$ Products	—	30,31
[17]	$NH_4^+ + e \rightarrow NH_2 + H_2$	see [6]	5
[18]	$NH_3^* \rightarrow NH + H_2$	—	17,18
[19]	$NH + NH \rightarrow N_2H_2 \rightarrow N_2 + H_2$	$< 10^{11}$	25,26,31
[20]	$NH_2 + C_3H_7 \rightarrow C_3H_7NH_2$	—	19
[21]	$C_3H_7 + C_3H_7 \rightarrow C_6H_{14}$	$\sim 1.8 \times 10^{10}$	20
[22]	$NH_2^+ + NH_3 \rightarrow NH_3^+ + NH_2$	1×10^{12}	24
[23]	$NH_2^+ + NH_3 \rightarrow NH_4^+ + NH$	—	32
[24]	$N_2H_3 + N_2H_3 \rightarrow N_2 + 2NH_3$	3×10^9	33

*The rate constants for reactions [8] + [9] and [2] + [11] are for the high pressure two body limit. This occurs ~ 1.0 Torr for reactions [8] + [9] and at ~ 1000 Torr for reactions [2] + [11] (15). Other three body reactions are calculated out for 1 atm.

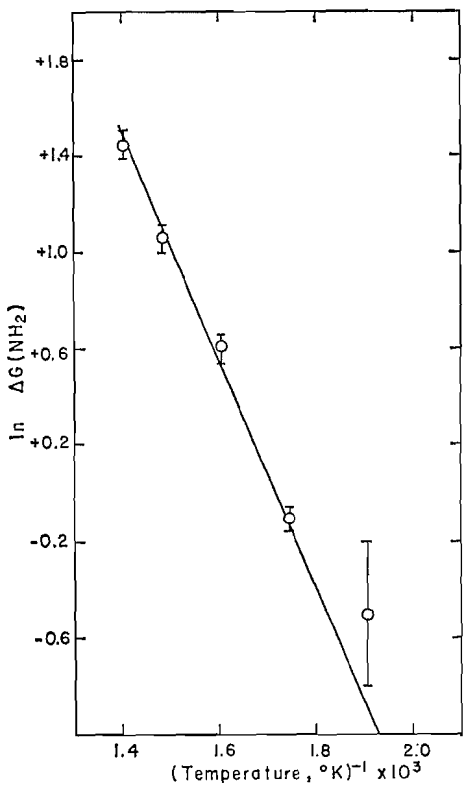

FIG. 7. Arrhenius plot of $\Delta G(NH_2)$.

The rate of disappearance of NH_2 radicals by reaction with H atoms compared to the rate of reaction with themselves, $[k_2 + k_{11}]/[k_8 + k_9 (+ k_{10})]$ is given by Hanes and Bair (15) to be $1.1 \times 10^{10}/2.3 \times 10^9 = 4.8$ at 1000 Torr pressure. This compares very well to the value calculated by us to be 4.4 (equals $(k_2 + k_{11})/2(k_8 + k_9)$).

The value of k_1 estimated by Schiavello and Volpi (21) to be 10^4 l mole^{-1} s^{-1} at 150 °C from mass spectrometric evidence is in good agreement with a value of 2.4×10^4 l mole^{-1} s^{-1} at 150 °C, obtained by using the rate constant determined from the temperature effect. The value for k_1 compares to known H atom transfer rate constants (22).

The only work directly comparable to the present work is that of Meaburn and Gordon (31). These workers irradiated ammonia vapor with a Febetron type device. They stressed the importance of the NH radical in the radiation chemistry of gaseous ammonia. Qualitatively their observations agree with the general mechanism we have proposed. The yields measured by these workers do not agree with the present work, however; their data are rather sparse and their experimental conditions are not well defined. They estimate $G(NH) \simeq 0.53$, which is comparable with the direct yield expected to be $G_{NH} = 0.74$.

Our value of $G_{NH_2} = G_H = 4.8$ is in very good agreement with the work of Nishikawa *et al.* (4). These workers report $G_H = 5.1$. The validity of this low value compared to the higher values of Jones and Sworski (2) and Johnson and Simic (3) has already been adequately discussed (4).

It seems very unlikely that the temperature effect observed by other workers at low dose rates (3) is due to competition between reaction [2] and reaction [3]

[2] $$NH_2 + H + M \rightarrow NH_3 + M$$

[3] $$N_2H_4 + H \rightarrow H_2 + N_2H_3$$

This conflicts with the rate data given in Table IV. The coincidence of activation energies for the increase of hydrogen yields with temperature with that of reaction [3] is meaningless without a clear knowledge of the mechanism involved. There are a large number of possibilities for reaction of N_2H_3 type radicals that might show a temperature dependence to give the hydrogen yield increases observed. It is also possible that there is indeed a competition between reaction [1] and reaction [3] as the temperature increases, as has been tentatively suggested (2).

Anderson and Winter have suggested that clustering of the NH_4^+ ion is important in the radiation chemistry of ammonia (5), and that neutralization of an unclustered NH_4^+ ion could yield two H atoms, whereas neutralization of a clustered ion is thermodynamically capable of producing only one H atom.

Clustering of NH_4^+ ions has been demonstrated by Hogg and Kebarle (34) and Searles and Kebarle (35). They found that there can be up to 20 ammonia molecules around the ion with 4 molecules in the inner shell, and an energy of about 80 kcal $mole^{-1}$ associated with the clustering. However, Johnson and Simic (3) have shown that the neutralization yield of H atoms is $\sim$ 3.9 G units and is independent of temperature. The W value of ammonia is $\sim$ 26 eV/ion pair (36), G(ion pair) $\simeq$ 3.8. This suggests that only one H atom is produced on neutralization and that any change in clustering with temperature is not significant in the radiation chemistry of ammonia. Some confirmation of the yield of one H atom per neutralization of NH_4^+ is a total G_H value of 5.1 given by Nishikawa *et al.* (4)

The equivalence of this low yield (4) for low dose rates with our high dose rate value implies either that significant clustering is complete before neutralization at 10^{27} eV g^{-1} s^{-1} or that clustering does not significantly affect the radiation chemistry yields. The lifetime of NH_4^+ ions with respect to neutralization at these dose rates is $\sim 2 \times 10^{-9}$ s (11). Kinetic data on the rate of clustering is not presently available but Dugan and Magee (37) have calculated some cross-sections for clustering. From their calculations it is unlikely that ions would neutralize before being clustered, even at our dose rates.

Conclusions

We have defined a possible primary mechanism for the radiolysis of gaseous ammonia. It is consistent with the initial primary yields being $G_{H_2} = 0.74$; $G_{NH} = 0.74$; $G_H = 4.8$; and $G_{NH_2} = 4.8$. If the W value for ammonia (36) is a reliable measure of G(ion pair) and if all ion pairs eventually lead to one H atom and one NH_2 radical, as has been suggested, then G(ionization) = 3.8; G(excitation) = 1.6; and $G(-NH_3) = 5.4$; where G(excitation) refers to dissociative excitation. This implies that H atoms and NH_2 radicals arise predominantly by ion–molecule reactions rather than by excited state dissociation. This conclusion is supported by the observations of Marx and Mauclaire (38). These authors have bombarded ammonia vapor with electrons of well defined energies and observed the generation of NH_2 radicals as a function of electron energy. The large proportion of radicals are produced by electrons with 8–11 eV, very close to the first ionization potential of ammonia at 10.4 eV (39). This should be compared with the energy loss impact spectrum (40).

The mechanism defined for the radiolysis of ammonia from the present study is only applicable to lower dose rates for very low absorbed doses (i.e. "zero dose" condition). As soon as the concentration of hydrazine becomes sufficient to compete with the radicals the mechanism will change.

The rate constant for the reaction of hydrogen atoms with ammonia has been estimated to be

$$k_1 = 4 \pm 2 \times 10^9 \exp\left(-\frac{10\,000 \pm 1\,500}{RT}\right) \text{ l mole}^{-1}\ \text{s}^{-1}$$

this indicates that reaction [1] is important in the room temperature radiolysis of ammonia vapor at low dose rates.

We have omitted detailed discussion of the reaction of NH radicals and of propyl radicals in

the ammonia propene mixture. It is possible that reactions of these radicals could change the estimated yields given. Such changes would probably not be significant for the reasons already given.

The effect of both of these omissions could be corrected by a measurement of the yields from pure ammonia in the high temperature plateau region, where all H atoms react with ammonia molecules. In order to carry out these measurements at temperatures where pyrolysis is not a problem a slightly lower dose rate must be used (about 1/20th of the present value to give the plateau at ~ 200 °C). We are presently attempting to make these measurements.

Acknowledgments

We would like to thank Mr. D. R. Leeder and Mr. R. Cyr for some of the preliminary experimental work. We should also like to thank Dr. R. S. Dixon of WNRE and Drs. D. R. Smith and W. A. Seddon of CRNL for their critical reading of the manuscript and their useful comments.

Absolute rate constants for hydrocarbon autoxidation. XIII. Aldehydes: photo-oxidation, co-oxidation, and inhibition[1]

G. E. ZAIKOV[2], J. A. HOWARD, AND K. U. INGOLD
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received March 24, 1969

The oxidations of acetaldehyde, heptanal, octanal, cyclohexanecarboxaldehyde, pivaldehyde, and benzaldehyde in chlorobenzene at 0 °C have been studied. These aldehydes oxidize at similar rates under similar conditions because there are compensating changes in the rate constants for chain propagation (k_p) and chain termination ($2k_t$). The termination rate constants increase from $\sim 7 \times 10^6\ M^{-1}\ s^{-1}$ for pivaldehyde and cyclohexanecarboxaldehyde to $\sim 2 \times 10^9\ M^{-1}\ s^{-1}$ for benzaldehyde. The propagation rate constants increase from $\sim 1 \times 10^3\ M^{-1}\ s^{-1}$ for pivaldehyde to $\sim 1 \times 10^4\ M^{-1}\ s^{-1}$ for benzaldehyde.

The rate of oxidation of the aldehydes was decreased by the addition of 1,4-cyclohexadiene, tetralin, tetralin hydroperoxide, cumene, cumene hydroperoxide, *t*-butyl hydroperoxide, and 2,6-di-*t*-butyl-4-methylphenol. As a result of product analysis and absolute rate constant measurements, it is concluded that the peroxy radicals derived from aldehydes are considerably more reactive in hydrogen atom abstraction from hydrocarbons than are the peroxy radicals derived from the hydrocarbons. In the abstraction from cyclohexadiene, the acylperoxy radicals appear to be from 15 to 70 times as reactive, and the benzoylperoxy radicals about 800–900 times as reactive, as the hydroperoxy radical. The differences in reactivity are very much less pronounced in the abstraction from 2,6-di-*t*-butyl-4-methylphenol.

The great ease of oxidation of all aldehydes, and particularly benzaldehyde, is due at least in part to the high reactivity of the peroxy radicals formed in these reactions.

Canadian Journal of Chemistry, 47, 3017 (1969)

Introduction

The thermal or photochemically initiated autoxidation of aldehydes in the liquid phase was shown by Bäckström (1) to be a chain reaction yielding, as the initial product, a peracid. At the oxygen pressures normally used in the kinetic studies of aldehyde oxidation (0.2–1.0 atm) the following mechanism is generally accepted

Initiation

[1] $\mathrm{RCHO} \rightarrow \mathrm{R\dot{C}{=}O}$

Propagation

[2] $\mathrm{R\dot{C}{=}O + O_2 \rightarrow RC(=O)OO\cdot}$

[3] $\mathrm{RC(=O)OO\cdot + H\text{-}C(=O)R \xrightarrow{k_p} RC(=O)OOH + R\dot{C}{=}O}$

Termination

[4] $\mathrm{RC(=O)OO\cdot + RC(=O)OO\cdot \xrightarrow{2k_t}}$ Inactive products

A subsequent polar reaction between the peracid and aldehyde forms the final product of autoxidation, the carboxylic acid

[5] $\mathrm{RC(=O)OOH + H\text{-}C(=O)R \rightarrow RC(=O)OH + RC(=O)OH}$

In the 1950's a number of workers provided information about many details of aldehyde oxidations (see e.g. refs. 2–11). By carrying out competitive oxidations of ring-substituted benzaldehydes, Walling and McElhill (2) were able to compare the relative reactivities of the different aldehydes towards a particular peroxy radical. They found that electron supplying groups on the ring facilitated, and electron withdrawing groups retarded the attack by the peroxy radical on the aldehyde. Furthermore, *n*-butyraldehyde was found to be twice as reactive towards *p*-chlorobenzoylperoxy radicals as benzaldehyde, which suggests that polar effects rather than C—H bond strengths are of primary importance in determining the rate of reaction [3]. A more direct approach to the determination of aldehyde reactivities was the measurements by Melville and co-workers of the absolute rate constants for propagation (reaction [3]) and termination (reaction [4]) in the oxidation of *n*-decanal (4), benzaldehyde (6), and mixtures of the two aldehydes (5).

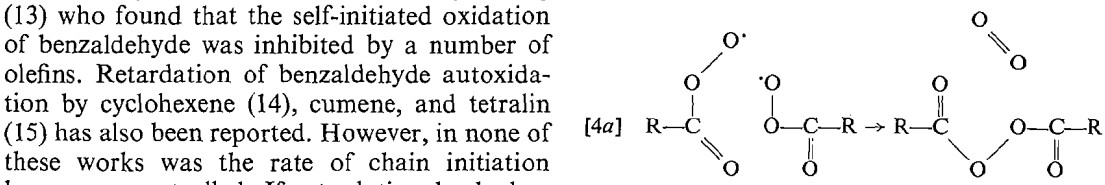
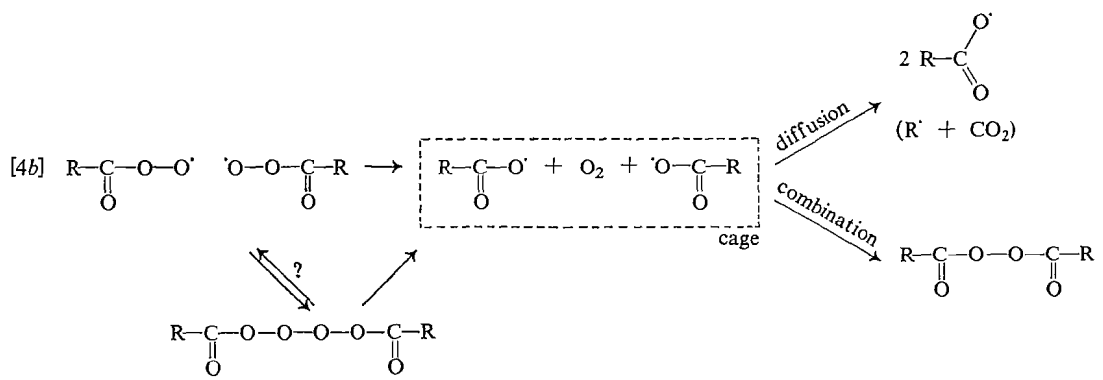
The work of Walling and of Melville leaves two major questions unanswered, viz. (*a*) do acylperoxy, aroylperoxy, and alkylperoxy radicals have similar reactivities (towards hydrogen atom abstraction)? and (*b*) are the termination rate constants reported by Melville typical for aldehyde autoxidations?

With regard to the first question, Bateman and Morris (12) have pointed out that aldehydes are produced as scission products of olefin autoxidations and are found as such in significant yield, despite their oxidizability separately being so much greater than the olefin. They suggest that this is due to the greater reactivity of acylperoxy radicals relative to alkenylperoxy radicals. That is, both types of peroxy radicals attack the olefin more readily than they attack the aldehyde, so that the olefin is oxidized preferentially. A similar suggestion was made earlier by Wittig (13) who found that the self-initiated oxidation of benzaldehyde was inhibited by a number of olefins. Retardation of benzaldehyde autoxidation by cyclohexene (14), cumene, and tetralin (15) has also been reported. However, in none of these works was the rate of chain initiation known or controlled. If retardation by hydrocarbons is due to their effect on the propagation step rather than the initiation or termination step, it would certainly suggest that the perbenzoate radical has an unusually high reactivity.

With regard to the second question, Melville reported termination rate constants of $7.5 \times 10^6\ M^{-1}\ s^{-1}$ for *n*-decanal, 3.4×10^7 for *n*-decanal in *n*-decane, and 2.1×10^8 for benzaldehyde in *n*-decane. These values appear high in relation to the values found for tertiary peroxy radicals[3] (10^3–$10^6\ M^{-1}\ s^{-1}$ (16, 17)). High termination constants have also been reported for the gas phase oxidation of acetaldehyde and propionaldehyde (8.9×10^{10} and $2.7 \times 10^{10}\ M^{-1}\ s^{-1}$, respectively (21)). In the gas phase, it has been shown by means of $^{18}O_2$ labeling of peroxyacetyl radicals that the molecular oxygen evolved in termination comes from both radicals (22). Even if the same holds true for the liquid phase, it does not allow a distinction to be made between a concerted process analogous to the Russell mechanism for secondary peroxy radicals (19), i.e.



and a process (possibly involving the reversible formation of a tetroxide intermediate) analogous to that for tertiary peroxy radicals (see e.g. ref. 23), i.e.

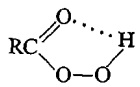


According to the second mechanism, a significant fraction of peroxy radical interactions may be non-terminating because of the diffusion of acyloxy (and, presumably, alkyl radicals) from the cage. Such a process has been demonstrated for some *t*-alkylperoxy radicals by showing that the corresponding *t*-alkyl hydroperoxides can undergo a radical induced chain decomposition (24). Our attempts to induce similar decomposi-

[3]Rate constants for the self-reactions of primary and secondary alkylperoxy radicals are generally higher than those of tertiary peroxy radicals (16, 18), apparently because of the availability for transfer between the reactants of a hydrogen atom on the α-carbon (19, 20).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

tions of perbenzoic acid, *m*-chloroperbenzoic acid, and per-octanoic acid with azo-bis-isobutyronitrile and *t*-butyl hyponitrite (TBH) in carbon tetrachloride at 30 °C were unsuccessful. That is, the rate of loss of peroxide, as measured by iodometric titration, was essentially unaffected by the addition of the initiators. It is possible that the per-acids are relatively unreactive towards free radicals because the acidic hydrogen is intramolecularly bonded, i.e.



Intermolecular hydrogen bonds have been shown to have a very large retarding effect on the analogous transfer reaction between a peroxy radical and a hydroperoxide (25)

[6] $$ROO^{\cdot} + R'OOH \rightleftarrows ROOH + R'OO^{\cdot}$$

We have utilized reaction [6] to determine the absolute reactivities of different alkylperoxy radicals towards the same substrate by oxidizing the substrate in the presence of the different hydroperoxides. This technique cannot be applied to acylperoxy radicals because the transfer between alkylperoxy radicals and per-acids is too slow. The potential alternative procedure involving the addition of alkyl hydroperoxides to aldehydes did not look particularly promising because of the well known equilibrium

[7] 
The present paper describes our preliminary attempt to answer the questions posed above. Propagation and termination rate constants have been measured for the oxidation of six aldehydes in chlorobenzene at 0 °C. The question of acylperoxy radical reactivity has been approached in two ways. Firstly, by the co-oxidation composition procedure in which the aldehydes were oxidized in the presence of a very reactive hydrocarbon (1,4-cyclohexadiene) and the relative consumptions of the two reactants were determined (see ref. 26 for a critical discussion of this method). Secondly, by the co-oxidation kinetic procedure in which the rates and some of the rate constants were measured for the co-oxidation of the aldehydes with one or two representative hydrocarbons. The aldehydes were also oxidized in the presence of the hindered phenol 2,6-di-*t*-butyl-4-methylphenol, "Ionol", (InH). Under ideal conditions, chain termination then occurs (27) by the reactions

[8] 
[9] 
The ratio of the rate constants for propagation and hydrogen abstraction from the phenol, i.e., k_p/k_{inh} can be determined from the inhibited rates of oxidation.

Experimental

Preliminary experiments at our usual temperature of 30 °C confirmed the observation of Cooper and Melville (3) that thermally initiated oxidations are important even with carefully purified aldehydes. We followed their general procedure for decreasing the importance of the thermal reaction relative to the photochemical reaction by working with dilute aldehyde solutions at 0 °C. Chlorobenzene was used as the inert diluent rather than *n*-decane (3) because it has been the principal solvent in our work with hydrocarbons. The thermal reaction was always less than 10% of the photo reaction.

Our general procedure for determining absolute rate constants for autoxidations has been described in previous papers in this series (18, 28). In each oxidation experiment the absolute rate constants were determined from averages of at least 4 and generally 6–10 consecutive measurements of the ratio of the rate under steady illumination to the rate with the optimum frequency of intermittent light. The rate constants showed no systematic variation with aldehyde concentration nor with the extent of aldehyde consumption (between 2 and 20%).

Oxidation rates were measured with a Dynisco pressure transducer (DPT 85-2). Rates could be measured with greater accuracy on smaller samples and at lower extent of oxidation than was possible in Melville and Cooper's experiments. In the kinetic work, the aldehyde was rarely oxidized beyond 5–10%. Under these conditions the yield of per-acid, as determined by iodometric titration, was 98–100% based on the absorbed oxygen provided the titration was performed without delay. That is, reaction [5] is of little importance under our experimental conditions.

The photochemical oxidation of the aldehydes does not require the addition of an azo photo-initiator. The rates of chain initiation were determined by the inhibitor method using hydroquinone (4) and, less satisfactorily, 2,6-di-*t*-butyl-4-methoxyphenol. The efficiency of photoinitiation at full light intensity for each aldehyde is reasonably constant at different aldehyde concentrations (i.e. R_i/[aldehyde] ≈ constant, see Table I). There is, however, a pronounced increase in efficiency along the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

series, octanal ~ heptanal < cyclohexanecarboxaldehyde < pivaldehyde ≪ benzaldehyde. The greater photoinitiating efficiency of benzaldehyde relative to *n*-decanal has been noted previously (6) and has been attributed to its stronger absorption of the incident light. Cyclohexanecarboxaldehyde also appears to absorb slightly more strongly than *n*-alkanals at the initiating wavelengths (3500–3800 Å).

In the co-oxidation experiments the analyses were performed by vapor phase chromatography (v.p.c.) on a silicone rubber column using a saturated hydrocarbon as the internal standard. All analytical results are averages of at least 3 separate measurements.

Cyclohexanecarboxaldehyde, *n*-octanal, and pivaldehyde were obtained from the J. T. Baker Chemical Co., benzaldehyde from Anachemia Chemicals Ltd., and acetaldehyde and *n*-heptanal from Eastman Organic Chemicals. They were dried and purified by distillation on a vacuum line. Samples only came in contact with the air immediately before an oxidation.

All the work described in this paper was done at 0 °C.

Results

Absolute Rate Constants

Under 1 atm of oxygen the overall rates of oxidation of the six aldehydes are given by[4]

$$-\frac{d[O_2]}{dt} = R_s = \frac{k_p[RCHO]R_i^{1/2}}{(2k_t)^{1/2}}$$

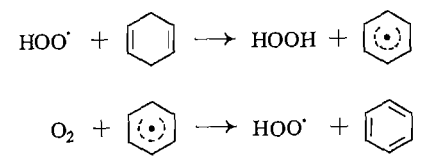
and the absolute rate constants for their oxidation are given in Table I. The values of $k_p/(2k_t)^{1/2}$ are quite similar for the different aldehydes (0.3–1.0 $M^{-1/2}$ $s^{-1/2}$) but there is a wide variation in the absolute values of k_p (1–12 × 10^3 M^{-1} s^{-1}) and $2k_t$ (7–1800 × 10^6 M^{-1} s^{-1}).

The propagation and termination rate constants for heptanal and octanal are in reasonably good agreement with Melville's values of 2.7 × 10^3 and 3.4 × 10^7 M^{-1} s^{-1} for a 30% solution of decanal in decane at 5 °C (4). The present termination constant for benzaldehyde (~ 2 × 10^9 M^{-1} s^{-1}) is an order of magnitude greater than that reported by Ingles and Melville (6). We believe that our value is more likely to be correct because of the more accurate method used to measure the rates (see above) and the ratios of rates (28). Incidentally, there was a small contribution to termination from a kinetically first order process in all but one of the benzaldehyde oxidations. The effect of the first order process was allowed for in the usual way (28). If the first order process was ignored the calculated values of $2k_t$ would have been about 10^{10} M^{-1} s^{-1}.

Propagation and termination rate constants for the oxidation of 1,4-cyclohexadiene and tetralin at 0 °C are also included in Table I. The values obtained for tetralin are in good agreement with those estimated from our previous measurements in the temperature range 13–50 °C (29).

Composition Co-oxidations

A primary purpose of this work was to determine whether the peroxy radicals derived from aldehydes have similar reactivities to the peroxy radicals involved in hydrocarbon oxidations. The aldehydes (except acetaldehyde) were co-oxidized with 1,4-cyclohexadiene which was chosen because of its high propagation rate constant and because its oxidation product, benzene, could be analyzed easily. This diene suffers the minor disadvantage that the oxidation chain is carried by a hydroperoxy radical rather than by an alkylperoxy radical (30), i.e.



However, it seems likely that the reactivities of HOO· and ROO· radicals will be rather similar.

There was a slow reaction between cyclohexadiene and the per-acids in the dark at 0 °C, amounting to about 1% conversion of diene to benzene per hour under typical experimental conditions. For this reason the products were analyzed immediately after oxidation. The results given in Table II show that only with very extensive oxidation is the absorbed oxygen not equal to the yield of titratable peroxide. This implies that for low extents of oxidation, the aldehyde and diene are consumed in the primary chain process, i.e., by reaction with peroxy radicals. The benzene yield is generally in good agreement with the amount of diene consumed.

[4]In the range of oxygen pressures from 200–760 mm only pivaldehyde showed any dependence of the rate on the oxygen pressure. Over this 3–4 fold change in pressure the rate of oxidation of pivaldehyde decreased by about 20%. Decreasing the oxygen pressure to 80 mm decreased the rate by about 50%. These results indicate that termination processes involving $(CH_3)_3CCO$ (or $(CH_3)_3C^{\cdot}$) radicals play a role in the reaction at low oxygen pressures. However, the effect of these processes on the overall reaction under 1 atm of oxygen is small enough to be ignored for the purpose of the present work.

TABLE III
Rate constant ratios for co-oxidations

AH	BH	r_a	r_b	$r_a r_b$
Heptanal	Cyclohexadiene	0.64	1.65	1.06
Octanal	Cyclohexadiene	0.64	1.65	1.06
Cyclohexanecarboxaldehyde	Cyclohexadiene	0.95	0.44	0.42
Pivaldehyde	Cyclohexadiene	2.15	0.36	0.77
Benzaldehyde	Cyclohexadiene	0.17	4.75	0.81
Heptanal	Benzaldehyde	~10	~0.1	~1.0

The propagation reactions for the co-oxidation of an aldehyde, AH, and cyclohexadiene, BH, can be represented by

$$A^{\cdot} + O_2 \longrightarrow AOO^{\cdot}$$

$$B^{\cdot} + O_2 \longrightarrow HOO^{\cdot} + C_6H_6$$

$$\left.\begin{aligned} AOO^{\cdot} + AH &\xrightarrow{k_p^{aa}} AOOH + A^{\cdot} \\ AOO^{\cdot} + BH &\xrightarrow{k_p^{ab}} AOOH + B^{\cdot} \end{aligned}\right\} r_a = k_p^{aa}/k_p^{ab}$$

$$\left.\begin{aligned} HOO^{\cdot} + BH &\xrightarrow{k_p^{hb}} HOOH + B^{\cdot} \\ HOO^{\cdot} + AH &\xrightarrow{k_p^{ha}} HOOH + A^{\cdot} \end{aligned}\right\} r_b = k_p^{hb}/k_p^{ha}$$

At long chain lengths and relatively low conversions r_a and r_b can be obtained by applying the copolymer composition equation (31) to these co-oxidations. That is

$$\rho = \frac{\Delta[AH]}{\Delta[BH]} = \frac{r_a[AH]/[BH] + 1}{r_b[BH]/[AH] + 1}$$

where $\Delta[AH]$ and $\Delta[BH]$ are the amounts of AH and BH consumed. In the present work, the r values were determined by the method of Fineman and Ross (32). That is, if $(\rho - 1)/R$ is plotted against ρ/R^2, a straight line should be obtained with intercept r_a and slope $-r_b$, the quantity R being the average value of [AH]/[BH] during the reaction. The data from Table II are plotted in this way in Fig. 1, rather good straight lines are obtained in all cases. The values of r_a and r_b are given in Table III. If the relative reactivity of AH and BH towards $AOO^{\cdot}$ is the same as towards $HOO^{\cdot}$, then $r_a = 1/r_b$ and $r_a r_b = 1$. Values of $r_a r_b$ less than 1.0 may be due to polar or to steric factors (26). However, Mayo *et al.* (26) have pointed out that in co-oxidations, all $r_a r_b$ products less than 0.5 or greater than 1.0 should be considered suspect unless unusual care has been taken to confirm them. The $r_a r_b$ products obtained with aldehydes and cyclohexadiene in the present work are reasonably satisfactory according to this criterion.

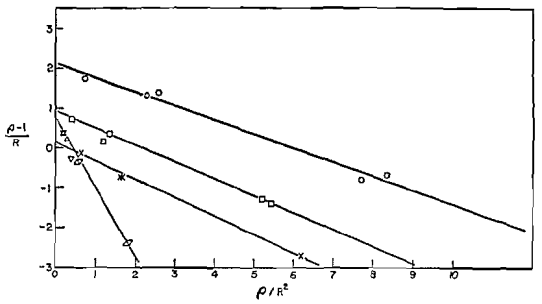

FIG. 1. Fineman–Ross plot of the co-oxidation of 1,4-cyclohexadiene with pivaldehyde, ○; cyclohexanecarboxaldehyde, □; octanal, △; heptanal, ▽; and benzaldehyde, ×. (The abscissa for the cyclohexadiene-benzaldehyde co-oxidation is 1/10 of that shown.) Data are from Table II.

The r_a and r_b values in Table III imply that saturated aldehydes and cyclohexadiene have rather similar reactivities towards acylperoxy and hydroperoxy radicals. However, benzaldehyde would appear to be quite a bit less reactive than the diene. This was not entirely unexpected in view of previous work on benzaldehyde co-oxidations (2, 5). The low reactivity of benzaldehyde was confirmed by its co-oxidation with *n*-heptanal. In these reactions so little benzaldehyde was consumed that errors in the analyses made it impossible to determine r_a and r_b with much accuracy even after repeated experiments. The estimated values of r_a (~ 10) and r_b (~ 0.1) given in Table III are subject to considerable error. They are, however, in reasonable agreement with the values reported for the butanal, *p*-chlorobenzaldehyde co-oxidation ($r_a = 10.7$, $r_b = 0.28$ (2)) and for the decanal, benzaldehyde co-oxidation ($r_a = 8.6$, $r_b = 0.2$ (5)).

Co-oxidation Kinetics

A comparison of the oxidation rates listed in Tables I and II show that the aldehydes oxidize

much more rapidly in the absence of cyclohexadiene. In quantitative terms, the values of $R_s/[RCHO]R_i^{1/2}$ for the aldehydes and for their 1.0:0.97 M mixtures with cyclohexadiene are 0.39 and 0.02 for heptanal, 0.47 and 0.018 for octanal, 0.44 and 0.027 for cyclohexanecarboxaldehyde, 0.96 and 0.018 for pivaldehyde, and 0.31 and 0.03 for benzaldehyde. In principle, this inhibition might be due solely to the fact that chain terminations involving HOO· radicals occur very rapidly. However, the absolute rate constants found for benzaldehyde, heptanal, and octanal relative to cyclohexadiene (Table I) rule out this explanation.

The photochemically initiated oxidation of benzaldehyde (0.5 M) is also retarded by the addition of other fairly readily oxidized hydrocarbons and by the addition of hydroperoxides. Thus tetralin, tetralin hydroperoxide, *t*-butyl hydroperoxide, and cumene hydroperoxide reduce the rate of oxidation of benzaldehyde by a factor of 10–50 and cumene reduces the rate by a factor of 5 (see Table IV and Fig. 2). The hydroperoxide concentrations in Table IV and Fig. 2 represent, of course, the amount of hydroperoxide added. It is not clear what role, if any, the hydroperoxide–aldehyde addition product (reaction [7]) plays in retarding the oxidation.

*$R_i = 3.4 \times 10^{-7}\ M\ s^{-1}$

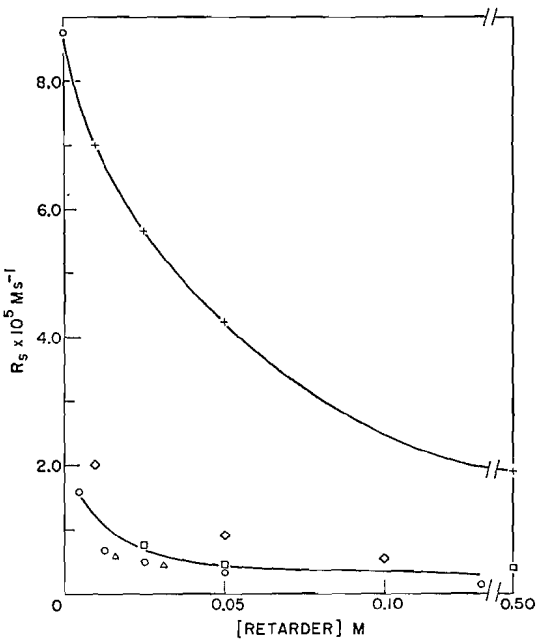

FIG. 2. The oxidation of benzaldehyde (0.5 M) in the presence of tetralin, □; tetralin hydroperoxide, ○; cumene, ×; cumene hydroperoxide, ◇; and *t*-butyl hydroperoxide, △. Data are from Table IV.

The rate constants for the oxidation of benzaldehyde (0.5 M) in the presence of tetralin (0.5 M) are $k_p/(2k_t)^{1/2} = 0.011\ M^{-1/2}\ s^{-1/2}$, $k_p = 23\ M^{-1}\ s^{-1}$, and $2k_t = 4.5 \times 10^6\ M^{-1}\ s^{-1}$, and in the presence of tetralin hydroperoxide (0.13 M) $k_p/(2k_t)^{1/2} = 0.0053\ M^{-1/2}\ s^{-1/2}$, $k_p = 13\ M^{-1}\ s^{-1}$, and $2k_t = 6.0 \times 10^6\ M^{-1}\ s^{-1}$. These termination rate constants are about 1/400 of the value found for pure benzaldehyde in chlorobenzene. They are, in fact, similar to the value for pure tetralin which suggests that tetralylperoxy radicals are by far the most abundant peroxy radical species present in these reactions. Tetralin and tetralin hydroperoxide reduce the rate of oxidation of benzaldehyde in spite of the fact that they reduce the termination rate constant. The propagation rate constant is, therefore, much lower in the oxidation of the mixtures than in the oxidation of pure benzaldehyde. The retarding effect that hydrocarbons and their hydroperoxides have on the oxidation of benzaldehyde must be due to the participation of alkylperoxy radicals in the oxidation chain. Alkylperoxy radicals must therefore be considerably less reactive than the benzoylperoxy radical.

TABLE V

Thermal oxidation of aldehydes and their co-oxidation with tetralin and cumene*

Aldehyde	Concentration, M	$R_s \times 10^5\ M\ s^{-1}$	Tetralin (0.5 M) $R_s \times 10^5\ M\ s^{-1}$	Cumene (0.5 M) $R_s \times 10^5\ M\ s^{-1}$

Cyclohexanecarboxaldehyde	0.45	1.13	0.44	1.12
Pivaldehyde	0.5	2.0	0.47	1.61
Benzaldehyde	0.5	0.51	0.024	0.11

*[TBH] = 0.2 M; $R_i = 2.6 \times 10^{-9}\ M\ s^{-1}$.

Tetralin and cumene also retard the oxidations of heptanal, cyclohexanecarboxaldehyde, and pivaldehyde (Table V). Tetralin reduces the rate of oxidation of these three aldehydes by a factor of 3–4 which is considerably less than its retarding effect on benzaldehyde ($\sim$ 20). Cumene is a rather weak retarder for the oxidation of these aliphatic aldehydes. Its effect on them is much less than its effect on benzaldehyde. The rate constants for the co-oxidation of heptanal (0.5 M) – tetralin (0.5 M) are $k_p/(2k_t)^{1/2} = 0.07\ M^{-1/2}\ s^{-1/2}$, $k_p = 700\ M^{-1}\ s^{-1}$, and $2k_t = 1 \times 10^8\ M^{-1}\ s^{-1}$. The termination rate constant is reasonably close to the value for pure heptanal. The retarding effect of tetralin on the oxidation of heptanal is, therefore, due to a decrease in the rate constant for the propagation of the chain. The chain is probably carried by both acylperoxy radicals and tetralylperoxy radicals, with the former predominating.

The TBH thermally initiated aldehyde oxidations were also inhibited with 2,6-di-*t*-butyl-4-methylphenol (Ionol). The rates were inversely proportional to the Ionol concentration and the kinetics are similar to those of hydrocarbon oxidations inhibited with this phenol (27). The rate controlling step for chain termination involves abstraction of the phenolic hydrogen by a peroxy radical (reaction [8]). The inhibited rate is given by

$$R_{inh} = \frac{k_p[\mathrm{RCHO}]R_i}{2k_{inh}[\mathrm{InH}]}$$

The values of k_p/k_{inh} and k_{inh} are given in Table VI. This table also summarizes the absolute rate constants determined from the photo-initiated reactions and the values of $k_p/(2k_t)^{1/2}$ obtained from the TBH thermally initiated oxidations (Table V, column 2).

Discussion

Termination

The aldehydes studied in the present work oxidize at similar rates under similar experimental conditions. That is, the values of $k_p/(2k_t)^{1/2}$ only differ slightly from one aldehyde to another. The absolute rate constants summarized in Table VI show that this is due to compensating changes in k_p and $2k_t$. The termination rate constants increase from $\sim 7 \times 10^6$ for pivaldehyde and cyclohexanecarboxaldehyde, to $\sim 6 \times 10^7$ for heptanal and octanal, $\sim 1 \times 10^8$ for acetaldehyde, and to $\sim 2 \times 10^9$ for benzaldehyde. The propagation rate constants increase from $\sim 1 \times 10^3$ for pivaldehyde to $\sim 1 \times 10^4$ for benzaldehyde.

The termination rate constant for benzaldehyde is close to the diffusion controlled limit for a bimolecular reaction. This implies that the aroyl tetroxide, $PhC(O)O_4C(O)Ph$ (whether a true intermediate or merely a transition state), is not formed reversibly. Moreover, if this tetroxide decomposes to give benzoyloxy radicals (reaction [4*b*]), the majority of these radicals must combine in the cage.

The lower termination constants for the alkanals may arise partly from the rapid decarboxylation of the acyloxy radicals formed in the tetroxide homolysis. That is, the radical centers will be separated by a greater distance if CO_2 loss occurs concurrently with, or immediately after, oxygen loss, e.g.

[4*c*] $Me_3CCOOOOCCMe_3 \rightarrow$ (O, O) $Me_3C^{\cdot} + CO_2 + O_2 + CO_2 + {}^{\cdot}CMe_3$

Carbon dioxide is, in fact, formed in these oxidations. Under the usual experimental conditions, acetaldehyde and pivaldehyde gave one

molecule of carbon dioxide per chain initiated, but benzaldehyde gave only 0.1. Although Kiefer and Traylor (33) have shown that the presence of one or two small molecules (O_2, N_2, CO_2) in the cage separating a *t*-butoxy radical pair has only a relatively small effect on the percentage of geminate combination in the cage, it is possible that three molecules would have a significant effect on this percentage.

A possible additional reason for the slower termination of acylperoxy radicals compared with benzoylperoxy radicals is that the acyltetroxides are formed reversibly and decompose more slowly than the aroyltetroxide. A parallel may perhaps be drawn with the tertiary peroxy radicals for which it has been found that *t*-alkylperoxy radicals terminate oxidation chains more slowly than *t*-aralkylperoxy radicals, apparently because the *t*-alkyltetroxides are more stable than the *t*-aralkyltetroxides (34).

A contributing factor to the low termination rate constants of the alkanals may be the presence of alkylperoxy radicals in the reaction. Since these radicals have a much lower reactivity in propagation than acylperoxy radicals, their steady-state concentration might rise to the point where they contributed significantly to termination even though they do not themselves terminate chains particularly rapidly[5]. If alkylperoxy radicals do play a role in the reaction, the alkyl radicals may be formed by the non-terminating interactions of acylperoxy radicals (reactions [4*b*] and [4*c*]) or, with the linear alkanals, by intramolecular hydrogen abstraction by the acylperoxy radical. Alkylperoxy radicals are not formed by decarbonylation of the acyl radical (35) at 0 °C since carbon monoxide is virtually absent in the gaseous products of the oxidation of 0.2 *M* pivaldehyde to 20% conversion. The fact that alkylperoxy radicals cannot be present in large amounts in this pivaldehyde oxidation was confirmed by the fact that *t*-butanol was not detected when the peroxidic products of the reaction were reduced with triphenylphosphine.

Propagation

The propagation rate constants for aldehyde oxidation can best be understood in terms of the variations in the reactivity of the aldehyde and the variations in the reactivity of the attacking peroxy radical. The reactivities of the aldehydes towards a single peroxy radical (HOO·) are given by the k_p^{ha} values in Table VI. These rate constants decrease by an order of magnitude along the series pivaldehyde > cyclohexanecarboxaldehyde > heptanal[6] ~ octanal > benzaldehyde[6]. While not too much reliance should be put on the absolute values of k_p^{ha}, this order can best be understood in terms of the inductive effect of the group R attached to the CHO group, increased electron donation increasing the rate of hydrogen abstraction by a peroxy radical (cf. 2, 36, 37). It is perhaps worth noting that alkyl radicals also abstract hydrogen more rapidly from alkanals than from benzaldehyde (35).

The variation in the reactivity of the various acylperoxy radicals is clearly demonstrated by the absolute rate constants for their attack on cyclohexadiene, i.e., k_p^{ab} (Table VI, last column). The peroxy radicals from pivaldehyde and cyclohexanecarboxaldehyde are about 15 times as reactive as the hydroperoxy radical, those from heptanal and octanal are about 70 times as reactive, and the benzoylperoxy radicals about 860 times as reactive as HOO·. The high reactivity of benzoylperoxy radicals relative to arylperoxy radicals is also indicated by the greater sensitivity to inhibition by hydrocarbons of the oxidation of benzaldehyde compared with the other aldehydes. Moreover, if tetralylperoxy radicals are in fact dominant in the benzaldehyde–tetralin co-oxidation and the benzaldehyde–tetralin hydroperoxide oxidation, as is suggested by the termination rate constants, then the propagation rate constant for these reactions (~ 13–23 M^{-1} s^{-1}) represents the rate constant for attack of tetralylperoxy radicals on benzaldehyde. Since benzoylperoxy radicals attack benzaldehyde with a rate constant of 12 000 M^{-1} s^{-1}, the benzoylperoxy radical is 12 000/23 to 12 000/13 ≈ 520–920 times as reactive as tetralylperoxy in abstraction from benzaldehyde.

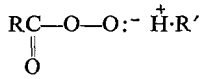
The differences in reactivity between the various acylperoxy radicals are probably due mainly to polar effects. Acylperoxy radicals must be considerably more electrophilic species than

[5]The rate constants for the self reactions of *t*-butylperoxy and cyclohexylperoxy radicals at 30 °C are 1.3×10^3 and 2.0×10^6 M^{-1} s^{-1} (17, 18, 20).

[6]The co-oxidation of heptanal and benzaldehyde (Table III) indicates that the former is about ten times as reactive as the latter towards the two corresponding acylperoxy radicals.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

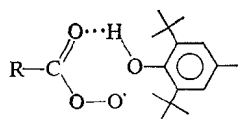
alkylperoxy radicals[7] and polar effects must play an important role in their reactions. Electron releasing groups will decrease the electrophilicity of the radical and hence decrease the importance of polar contributions of the following type to the transition state



Electron releasing groups will therefore decrease the reactivity of an acylperoxy radical and electron attracting groups will increase its reactivity, and hence the radical reactivity increases along the aldehyde series from pivaldehyde to benzaldehyde. Since this polar effect works in the opposite direction from that influencing the intrinsic reactivity of the aldehyde, the two effects tend to cancel each other out in determining the reactivity of the aldehyde towards its own peroxy radical (i.e. the k_p values).

The Ionol Inhibited Reaction

The rate constants for attack on Ionol by the acylperoxy and benzoylperoxy radicals (k_{inh}, Table VI) are roughly equal to the values found for their attack on cyclohexadiene (k_p^{ab}). In contrast, the hydroperoxy radical attacks Ionol about 30 times as fast as it attacks cyclohexadiene, the rate constant for the Ionol reaction (and for the tetralylperoxy–Ionol reaction) being similar to the values for the acylperoxy–Ionol reaction. Only the benzoylperoxy radicals are noticeably more reactive towards Ionol than the other radicals. The reason for (what appears to be) an unexpectedly low reactivity of Ionol towards acylperoxy and benzoylperoxy is not at all obvious. Conceivably, the rate of hydrogen atom transfer from the phenol might be reduced by the bonding of the phenolic hydrogen to the carbonyl oxygen of the acylperoxy radical, i.e.



Conclusion

Although excessive reliance on any of the individual rate constants or rate constant ratios obtained in this work is unjustified, the overall picture leaves little doubt that acylperoxy radicals are considerably more reactive in hydrogen atom abstraction than alkylperoxy radicals. The main reason for this must be that acylperoxy radicals form stronger bonds to hydrogen than alkylperoxy radicals, i.e. $D(RC(O)OO—H) > D(ROO—H)$[8]. A greater O—H bond strength in the per-acid is to be expected both because of strong polar contributions to the bond[9] and because of the intramolecular hydrogen bond to the carbonyl oxygen. Perbenzoic acid is a slightly stronger acid than alkyl per-acids which could mean that its O—H bond strength is also greater, thus accounting for the higher reactivity of benzoylperoxy radicals relative to acylperoxy radicals.

The enhanced reactivity of acylperoxy and benzoylperoxy radicals provides a ready explanation for the inhibition of aldehyde oxidations by hydrocarbons (see Tables IV and V and ref. 39). That is, by its attack on the hydrocarbon the acylperoxy radical is converted to an alkyl peroxy radical of much lower reactivity. The overall propagation rate constant is therefore decreased. This was confirmed by the actual measurement of the propagation rate constants in the benzaldehyde–tetralin and heptanal–tetralin mixtures.

Thermal decomposition of barium perchlorate

R. J. Acheson and P. W. M. Jacobs
Department of Chemistry, University of Western Ontario, London, Ontario

Received February 20, 1969

The thermal decomposition of anhydrous barium perchlorate to barium chloride and oxygen has been studied by pressure measurements, or by weight loss, in vacuo, under the accumulated gaseous products (0–3 Torr oxygen), under dry air or nitrogen, and mixed with added barium chloride. The plots of fractional decomposition (α) against time (t) are complex, as would be expected for a reaction proceeding via unstable intermediates. The most pronounced features of the $\alpha(t)$ curves are an initial acceleratory period, which is succeeded by an approximately linear period and then, after a sharp break (reduction in rate), by a deceleratory period which conforms to the contracting-volume kinetic law. The latter stage is associated with the decomposition of barium chlorate and has an activation energy of 59 kcal/mole. The first two stages comprise the decomposition of perchlorate to chlorate with the approximate stoichiometry $3ClO_4^- \rightleftharpoons 2ClO_3^- + Cl^- + 3O_2$. A chain reaction sequence, which involves O atoms as chain carriers, is proposed for these stages. The effect of the removal of products, of increasing the ambient pressure of inert gas, and of the addition of barium chloride, can all be explained on this model.

Canadian Journal of Chemistry, 47, 3031 (1969)

The thermal decomposition of barium perchlorate (BP) yields barium chloride and oxygen (1). Barium perchlorate trihydrate may be dehydrated, without decomposition *in vacuo*, but in air, hydrolysis of the perchlorate accompanies dehydration. Dehydration to the monohydrate occurs on pumping at room temperature and subsequent dehydration occurs at temperatures well below that of the thermal decomposition of the anhydrous salt (435–495 °C).

Barium perchlorate is known to undergo two crystalline phase transitions (2). The transition from α-BP to β-BP occurs at 284 °C and that from β-BP to γ-BP at 360 °C. At the time this work was performed no complete study of the thermal decomposition of BP had been reported although one incomplete study (3) had yielded an activation energy of 61.6 kcal/mole. When this paper had been written in manuscript form, a series of papers (4–8) by Solymosi and his collaborators, which overlaps our work, appeared. Our manuscript has therefore been rewritten to take account of these new data. The principal experimental differences are that Solymosi (8) used only pressure measurements to investigate the thermal decomposition of BP, whereas we used thermogravimetric measurements as well, but he also studied the decomposition of $Ba(ClO_2)_2$ (4) and $Ba(ClO_3)_2$ (5). There are also considerable differences in the kinetic analyses and in the interpretation of the results.

Thermal Decomposition of Anhydrous Barium Perchlorate

The thermal decomposition of anhydrous BP *in vacuo* was studied by measurement, with McLeod gauges, of the pressure increase as a function of time in a constant volume system. The isothermal decomposition of single crystals, pellets, and crushed reactant was followed in this way. Weight loss measurements in a dynamic vacuum were also made. The percentage residue obtained from 4 determinations was $62.75 \pm 1.05\%$ which may be compared with a theoretical value 61.76% for complete decomposition to $BaCl_2$. Thus decomposition of BP to $BaCl_2$ under our experimental conditions is $97.4 \pm 1.5\%$ complete to $BaCl_2$, in substantial agreement with the results from ref. 1, thus vindicating the use of pressure–time measurements to follow the kinetics.

Plots were made of the fractional decomposition (α) against time. In all runs the general form of $\alpha(t)$ was acceleratory up to $\alpha = 0.52 \pm 0.02$ (but see later for more specific comments). The rate of this reaction was independent of the mechanical pre-treatment of the reactant, or of the ambient gas atmosphere. The kinetics of thermal decomposition ($\alpha \lesssim 0.52$) of crystals, pellets, or powder samples, in a dynamic vacuum, in the accumulated reaction products (volatile at −195 °C), or in 160 Torr dry air, were identical within experimental error.

Representative $\alpha(t)$ plots are shown in Fig. 1. At $\alpha = 0.52 \pm 0.02$ a distinct break occurred and thereafter the reaction was slower by a factor of ~ 10. This break occurred when the decomposition was carried out in N_2, in air, or in the gaseous reaction products, though not when BP was decomposed in a dynamic vacuum. Above $\alpha = 0.52 \pm 0.02$ the reaction was always deceleratory throughout. As the ambient pressure was

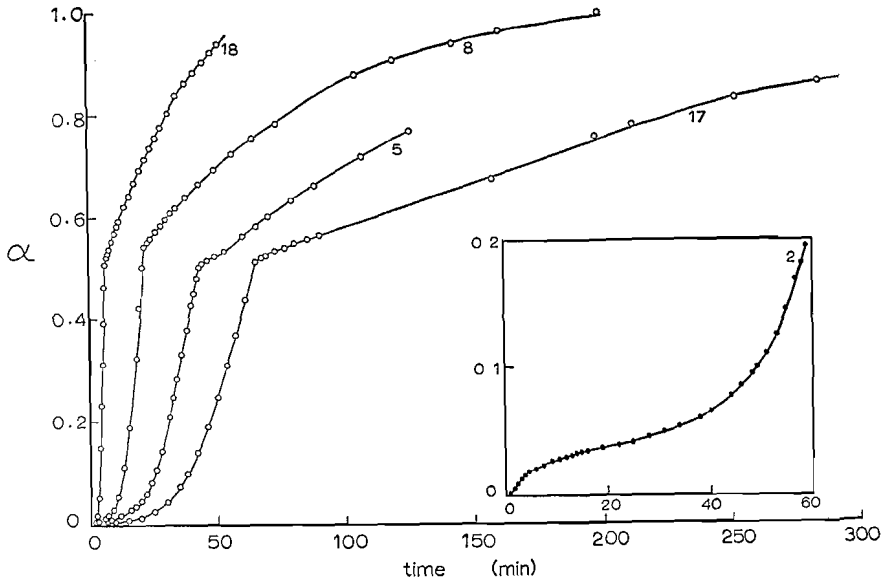

FIG. 1. Plots of fractional decomposition α against time for the thermal decomposition of anhydrous BP in vacuo. Run 18, 487 °C; run 8, 467.5 °C; run 5, 459.6 °C; run 17, 451.6 °C.

decreased, the rate of the reaction for $\alpha \gtrsim 0.52$ increased markedly and in a vacuum of better than 10^{-3} Torr no distinct change was seen in the $\alpha(t)$ plot and the reaction continued without a break. This effect is displayed in Fig. 2 where curve *a* shows "normal" behavior when BP decomposes under its own reaction products (i.e. oxygen, which reaches a pressure of $\sim$ 1–3 Torr at the break), curve *b* shows the effect of reduced pressure, and curve *c* shows an $\alpha(t)$ plot in a dynamic vacuum of $\sim 10^{-3}$ Torr, with the break just distinguishable.

Solymosi (8) followed the reaction only by measuring the pressure of the accumulated products and his results (see Fig. 1 of ref. 8) are similar to ours under these conditions. Reaction of those samples of crystals or pelleted reactant which contained a small percentage of water, due to incomplete dehydration prior to heating to the reaction temperature, was initially deceleratory, but following the completion ($\alpha < 0.05$) of this reaction, decomposition continued in a manner identical to that of the anhydrous reactant. This effect is illustrated in the inset diagram in Fig. 1.

Four preparations of BP were used in this investigation. These were (*a*) Analytical Grade barium perchlorate from Alfa Inorganics Inc., (*b*) anhydrous barium perchlorate, (*c*) once recrystallized BP, and (*d*) twice recrystallized BP. No differences in the behavior or kinetics of decomposition of the 4 samples were observed. The hydrated salts were dehydrated, normally *in situ*, at $\sim$ 250 °C prior to reaction (except for commercial "anhydrous" BP, which nevertheless contained a substantial amount of water). Melting did not appear to occur since the shape of the original sample, whether pellet or single crystal, was usually retained throughout the experiment (corresponding differential thermal analysis results presented later). One experiment was interrupted at $\alpha = 0.4$, the reactant was cooled to room temperature, exposed to air, re-evacuated, reheated to the original reaction temperature, and decomposition continued. This procedure resulted in no significant deviation of the kinetics of the subsequent reaction ($0.4 < \alpha < 0.96$) from those expected for an uninterrupted experiment.

Kinetics of Thermal Decomposition for $0 < \alpha < 0.5$

No significant differences were detected between the thermal decomposition of BP, in the temperature range 435–495 °C, when this was followed by (*a*) pressure measurements, or (*b*) weight-loss measurements. The reaction was

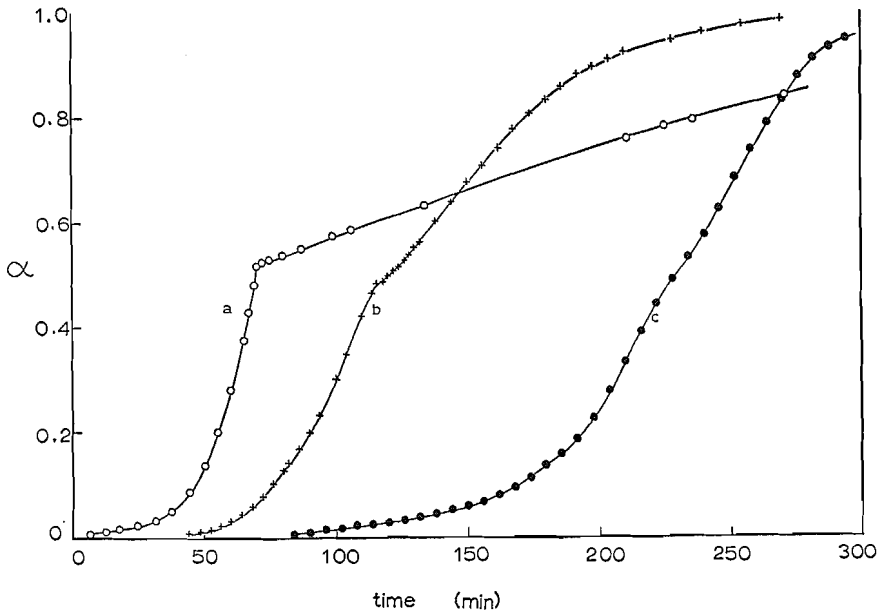

FIG. 2. Effect of pressure on the kinetics of the reaction for $\alpha > 0.52$. (*a*) ○, Decomposition at 446.6 °C under accumulated reaction products volatile at −195 °C (i.e. oxygen); (*b*) +, decomposition at 441.1 °C under reduced pressure; (*c*) ●, decomposition at 437.5 °C at $P < 10^{-3}$ Torr.

acceleratory $0 < \alpha < 0.25$. For $0.25 < \alpha < 0.5$, the reaction generally continued at an approximately linear rate, although in a significant number of experiments the reaction either became somewhat decelerating or continued in a slightly acceleratory fashion. Clearly, therefore, the kinetics cannot obey a single rate equation, even over the range $0 < \alpha < 0.5$.

It is evident from Fig. 1 that $t_{0.1}$, the time taken to reach $\alpha = 0.1$, is a measure of the induction period for the reaction. Accordingly $\log (t_{0.1} - \tau)$ where τ is the heat-up time ($\tau = 1$ min for pressure measurements, 4 min for weight-loss measurements) was plotted against T^{-1} whence the parameters $E = 83.5$ kcal/mole, $\log (A/s^{-1}) = 21.72$ were derived by least mean squares (l.m.s.) fit to the Arrhenius equation. The rate during the roughly linear portion of the $\alpha(t)$ curve was obtained by calculating the slopes, $S(0.25)$, of the $\alpha(t)$ plots at $\alpha = 0.25$. This method was adopted in order to include those runs which displayed an acceleratory or deceleratory character. The least squares values for the Arrhenius parameters derived from $S(0.25)$ were $E = 80.0$ kcal/mole, $\log (A/s^{-1}) = 20.52$.

Because of the predominantly acceleratory kinetics at small α, extensive use was made initially of the Avrami–Erofeev equation

$$[1] \qquad [-\ln (1 - \alpha)]^{\frac{1}{n}} = k_1 t$$

However, both the range of α over which this relationship was obeyed and the value of n varied significantly for different experiments, the full range of n being $2 \leq n \leq 5$. Rate-constants k_1 were therefore extracted from the relationship

$$[1'] \quad \log [-\ln (1 - \alpha)] = n \log k_1 + n \log t$$

and a least squares fit to the Arrhenius equation for k_1 yielded values for the activation energy and pre-exponential factor of $E = 76.7$ kcal/mole and $\log (A/s^{-1}) = 19.54$, respectively. However, because of the large variations in n, this analysis was not considered satisfactory, although the value of the activation energy $E = 76.7$ kcal/mole for $0.05 < \alpha < 0.36$ may be of some significance (see later).

Despite the unsatisfactory representation of the data by eq. [1'], a simple power law

$$[2] \qquad \alpha^{\frac{1}{2}} = k_2(t - t_0)$$

fitted the kinetics quite well. Plots of $\alpha^{\frac{1}{2}}$ against t

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

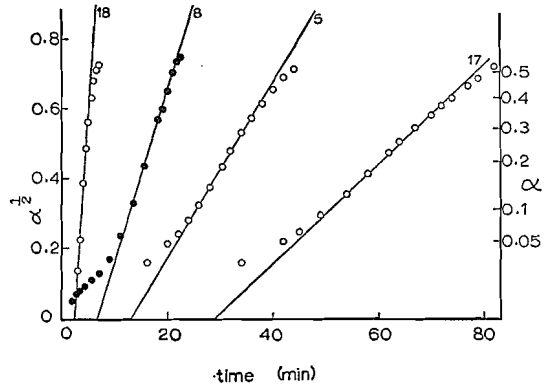

FIG. 3. Plots of $\alpha^{\frac{1}{2}}$ against t for the data shown in Fig. 1.

for the runs depicted in Fig. 1 are given in Fig. 3. The fit seems to improve somewhat with temperature but covers the range $0.06 < \alpha < 0.4$–0.5, in general. The least mean squares Arrhenius parameters for k_2 were $E = 80.9$ kcal/mole and $\log (A/s^{-1}) = 20.72$. The values of t_0, which represent the induction period before eq. [2] is obeyed, were also fitted to the Arrhenius equation and yielded the l.m.s. parameter-values $E = 69.7$ kcal/mole, $\log (A/s^{-1}) = 17.91$.

Effect of Additives

(a) Ammonium Perchlorate (AP)

The thermal decomposition of an intimately crushed mixture of BP with 3.86% AP showed an initial deceleratory reaction for $0 < \alpha < 0.03$. A first order rate plot using $\alpha' = \alpha/0.03$ was linear and the rate constant obtained (0.382 min^{-1} at 450 °C) was in close agreement with that found for the thermal decomposition of pure AP at this temperature (9). For $\alpha > 0.03$ the reaction was acceleratory, the rate being a factor of ~ 1.7 faster than that for pure BP at this temperature. Apparently AP and BP decompose essentially independently at this temperature with only a marginal change in the rate of decomposition of the BP. This might easily arise from the changes in porosity, etc., brought about by the distillation of the products from the AP decomposition of the reactant matrix.

(b) Barium Chloride

The thermal decomposition of an intimate mixture of anhydrous BP and excess anhydrous barium chloride is shown in Fig. 4. If the gaseous products are allowed to accumulate in the reaction zone, the decomposition is deceleratory throughout. (The kinetics of this reaction are described later, along with those for $\alpha > 0.52$, which they

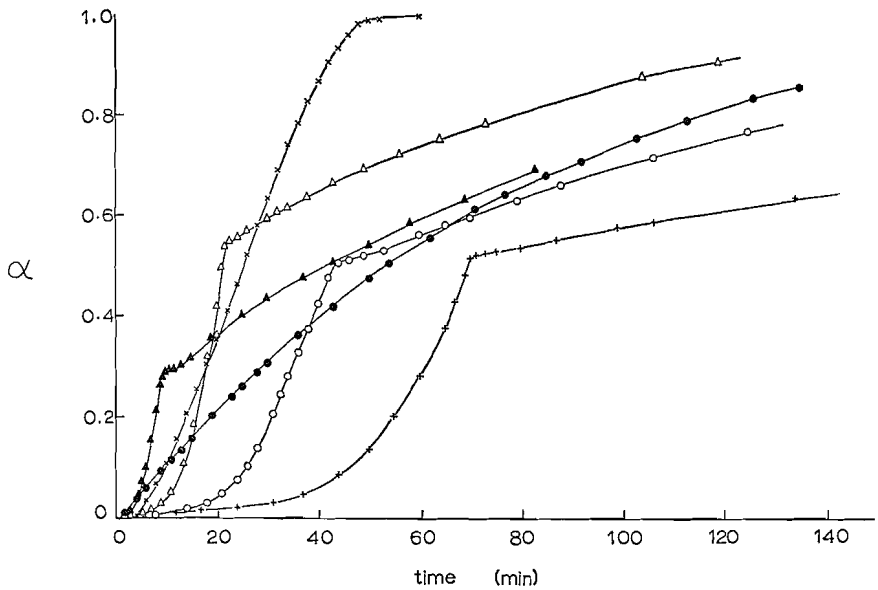

FIG. 4. Effect of $BaCl_2$ on the decomposition of BP. ○, Normal reactant at 459.6 °C; ●, BP with excess $BaCl_2$ at 459.4 °C; △, normal reactant at 467,5 °C; ▲, BP plus 31 mole % $BaCl_2$ at 466.0 °C; +, normal reactant at 446.6 °C; ×, BP with excess $BaCl_2$ at 445 °C in a vacuum of $< 10^{-3}$ Torr.

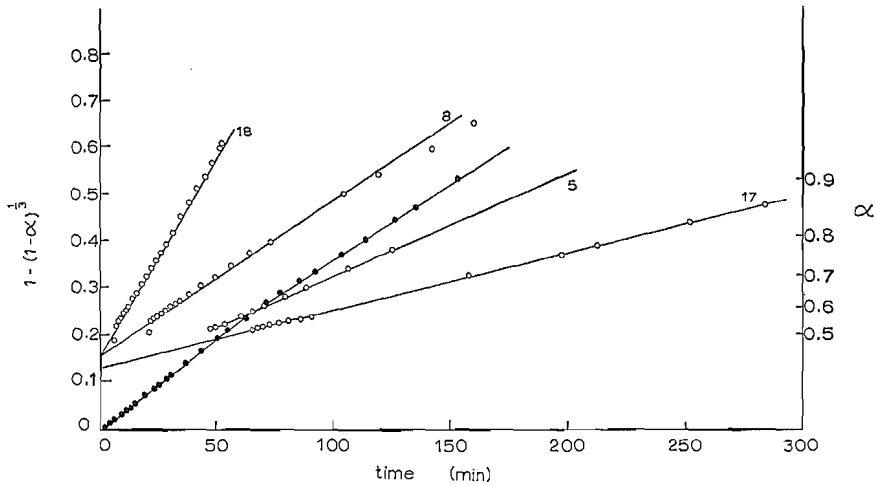

FIG. 5. Plots of the function $1 - (1 - \alpha)^{\frac{1}{3}}$ against t to test eq. [3]. ○, Normal reactant, run numbers as in Fig. 1; ●, BP with excess $BaCl_2$, 459.4 °C.

resemble.) In a dynamic vacuum, however, an acceleratory period was noted. The thermal decomposition of an intimate mixture of 0.69 mole fraction BP with 0.31 mole fraction $BaCl_2$ was acceleratory in the range $0 < \alpha < 0.29$ even though gaseous products were allowed to accumulate. It is apparent from these experiments that the sharp change to deceleratory kinetics (Figs. 1 and 4) is associated with a composition equivalent to equimolar proportions of BP and $BaCl_2$. For the decomposition of pure BP this occurs at $\alpha = 0.52$. The addition of excess $BaCl_2$ is therefore expected to suppress the acceleratory reaction, as is indeed observed. Further, a reaction mixture containing initially 0.31 mole fraction of $BaCl_2$ is predicted to show the discontinuity at $\alpha = 0.29$, exactly as observed. The acceleratory portion of the reaction of BP, containing excess $BaCl_2$, *in vacuo* obeyed the power law, eq. [2], in the range $0.01 < \alpha < 0.50$ but the rate constant was 3.8 times faster than that of pure BP.

(c) Thermal Decomposition of BP in Air or Nitrogen

The plot of α against t for a single experiment in which BP was decomposed under a pressure of 160 Torr of dry air was identical in form to that for reaction under the accumulated gaseous products, but started *in vacuo*, with the discontinuity occurring at $\alpha = 0.52$, as usual. For decomposition under 250 Torr dry nitrogen, the $\alpha(t)$ curve was again similar to that under 160 Torr dry air.

Kinetics of Thermal Decomposition for $\alpha > 0.52$

The thermal decomposition of BP for $0.54 < \alpha < 0.90$ obeys the contracting volume formula

$$[3] \qquad R_3(\alpha) \equiv 1 - (1 - \alpha)^{\frac{1}{3}} = k_3 t$$

as found previously (3), when the reaction occurs (*i*) in air, (*ii*) in nitrogen and, (*iii*) in the accumulated product gases. Representative plots of $R_3(\alpha)$ against t are shown in Fig. 5. The least squares values of the Arrhenius parameters corresponding to k_3, measured for decomposition under product gases, are $E = 59.1$ kcal/mole, $\log (A/s^{-1}) = 13.16$. Reaction under air or nitrogen was a factor of 1.4 times slower. Reaction in a dynamic vacuum was much faster than (*iii*). For example, at a steady state pressure of 10^{-3} Torr the reaction was ~ 12 times faster than under the accumulated reaction products. These facts are illustrated in Fig. 6.

Effect of Added Barium Chloride

It will be recalled that the kinetics of the thermal decomposition of BP in the presence of excess $BaCl_2$ are deceleratory throughout when reaction occurs under the accumulated product gases. Under these conditions $\alpha(t)$ obeys the contracting volume equation throughout the range $0 < \alpha < 0.9$, Fig. 5. The rate constants determined under these conditions are plotted in Fig. 6, where the least mean squares line shown was calculated for k_3 determined for the decomposition of BP,

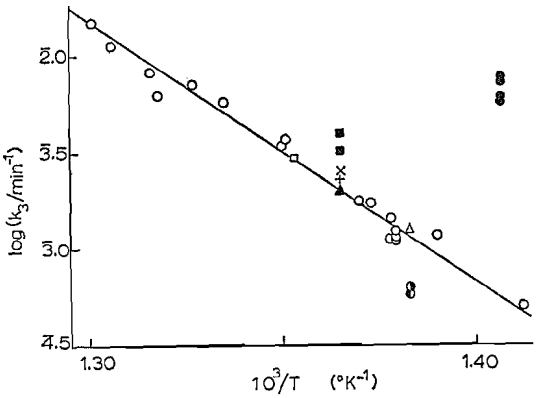

FIG. 6. Arrhenius plot for the rate constant k_3 obtained by fitting the data to eq. [3]. ○, BP decomposed under the accumulated gaseous products; △, BP containing 3.86 mole % AP; ◐, BP under 250 Torr N_2; ◑, BP under 160 Torr air; ●, $P < 10^{-3}$ Torr; □, BP plus 31 mole % $BaCl_2$; ■, BP plus excess $BaCl_2$; ▲, $P = 0.25$ Torr; + , $P = 0.048$ Torr; × , $P = 0.025$ Torr.

without added $BaCl_2$, under the accumulated product gases in the range $0.54 < \alpha < 0.90$. The rate constant in the range $0 < \alpha < 0.5$ with $BaCl_2$ is somewhat greater than, but clearly similar to, the rate constant in the range $0.54 < \alpha < 0.90$ without added $BaCl_2$. The variation (decrease) in k_3 during the course of the decomposition is perhaps explained in part by the dependence of the reaction kinetics on the ambient pressure (Figs. 2 and 6) which is, of course, "zero" at the start of the reaction and increases with α. This pressure-dependence of the kinetics is illustrated by (see Fig. 6) the variation of k_3 for pure BP with product-gas pressure in the range 0.25–0.025 Torr at 459.5 °C ($10^3/T = 1.365$), by the increase in k_3 by a factor of around 12 when the ambient pressure is decreased to $< 10^{-3}$ Torr (4 points at 437.5 °C, or $10^3/T = 1.407$), and by the decrease in k_3 when the ambient pressure is increased (160 Torr air or 250 Torr nitrogen, 449.9 °C or $10^3/T = 1.383$). The fact that adding $BaCl_2$ alters the range of the last part of the reaction, which usually begins at $\alpha > 0.52$ in pure BP (Figs. 1 and 5), but not the mechanism or rate constant, is emphasized by the point in Fig. 6 which corresponds to a mixture of BP containing 0.31 mole fraction $BaCl_2$ and which lies right on the least squares line (from data for pure BP) even though the break occurs at $\alpha = 0.29$ and eq. [3] holds from $\alpha > 0.36$ (466.0 °C or $10^3/T = 1.353$). The least mean squares line in Fig. 6 was calculated for data from "normal" runs in which the pressure of the accumulated products lay in the range 1–2.5 Torr at $\alpha = 0.52$.

Differential Thermal Analysis

A differential thermal analysis (d.t.a.) trace for crushed barium perchlorate is shown in Fig. 7. The first endotherm commencing at around 60 °C represents loss of water and corresponds to dehydration from $3H_2O$ to $1H_2O$, the two stages not being clearly separated. The second broad endotherm in the range 150–220 °C corresponds to loss of the final 1 mole of water. This is preceded by a peak with a sharp leading edge which probably represents a phase change in the monohydrate. The next two endotherms commencing at 282 and 358 °C correspond to the $\alpha \rightarrow \beta$ and $\beta \rightarrow \gamma$ phase transitions of anhydrous BP (2). The single exotherm with its first major peak at 486 °C corresponds to thermal decomposition of anhydrous BP. There is no evidence of melting, in agreement with our visual observations.

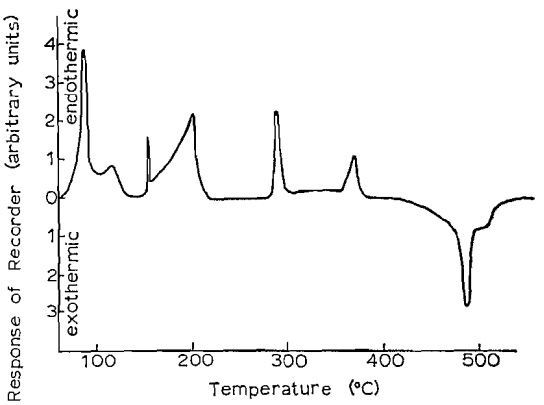

FIG. 7. Differential thermal analysis trace for crushed barium perchlorate showing dehydration and phase transition endotherms and the decomposition exotherm.

Discussion

The Gibb's free energy of formation of $BaCl_2$(c) is more negative than that of BaO(c) by −31.8 kcal/mole at 427 °C (10). Thus decomposition of BP to $BaCl_2$ rather than to the oxide is predicted and this is confirmed both by previous work and by the present study. Decomposition of BP to the chloride appears to be 97.5 ± 1.5% complete. The $\alpha(t)$ plots (Fig. 1) are complicated, indicating at least 2, and probably 3, stages to the reaction. Of many possible intermediates the likely ones,

on the basis of the limited thermodynamic data available, are $Ba(ClO_3)_2$ and $Ba(ClO_2)_2$. Since oxygen is the only gaseous product, the break which occurs at $\alpha \simeq 0.52$ corresponds stoichiometrically to formation of $Ba(ClO_2)_2$. However, Solymosi and Bánsági (4) have shown that $Ba(ClO_2)_2$, in the presence of equimolar amounts of Al_2O_3, NiO, $Ba(ClO_3)_2$, or $BaCl_2$, is transformed completely into $Ba(ClO_3)_2$ and $BaCl_2$.

[4] $$3ClO_2^- \leftrightharpoons 2ClO_3^- + Cl^-$$

We conclude, therefore, that the break corresponds to the complete decomposition of $Ba(ClO_4)_2$ into $Ba(ClO_3)_2$ and $BaCl_2$ in the mole ratio of 2:1 and that, because of the precise and reproducible value of α at which this occurs, the reaction involves $Ba(ClO_2)_2$ as an unstable intermediate. The first half of the reaction therefore corresponds to

[5] $$3ClO_4^- \rightarrow 2ClO_3^- + Cl^- + 3O_2$$

with little decomposition ($\sim$ 4%) of ClO_3^- having occurred prior to this point. The second half of the reaction then corresponds to the decomposition of barium chlorate into barium chloride and oxygen.

Mechanism of Decomposition for $\alpha > 0.52$

According to our model the reaction after the break corresponds to the decomposition of ClO_3^-. The kinetics fit eq. [3] so that a contracting interface is indicated. The activation energy (Table I) is 59.1 kcal/mole and this is reasonably close to, although lower than, that expected for the splitting of a single Cl—O bond, D(Cl—O) = 64.2 kcal/mole (11). We conclude, therefore, that the first step is

[6] $$ClO_3^- \rightarrow ClO_2^- + O$$

Since the transition state involves the loss of one vibrational degree of freedom only, the pre-exponential factor is expected to be "normal", i.e. about 10^{13} s^{-1}. The experimental value is 1.5×10^{13} s^{-1}. One knows from the work of Solymosi and Bánsági (4, 5) that ClO_2^- and ClO^- are less stable than ClO_3^-, and that ClO_2^- disproportionates into $ClO_3^- + Cl^-$, eq. [4]. Thus we propose the mechanism

[6] $$ClO_3^- \rightleftharpoons ClO_2^- + O$$

[7] $$ClO_2^- \rightleftharpoons ClO^- + O$$

[8] $$ClO^- \rightleftharpoons Cl^- + O$$

[9] $$O + O + M \rightarrow O_2$$

The effect of the pressure and nature of the ambient gas are only explicable if the combination of O atoms (reaction [9]) is relatively inefficient so that O atoms produced in reactions [6] – [8] have the choice of either diffusing away through the gas phase or of reacting with $Cl^- \rightarrow ClO^-$, or with $ClO^- \rightarrow ClO_2^-$, or with ClO_2^-. Although data for ΔG_f^0 for $Ba(ClO)_2$ and $Ba(ClO_2)_2$ are not available, there is no evidence that we know of that O_2 reacts with Cl^-. The most direct evidence for reaction of ClO_2^- with O *atoms* is that the rate of decomposition of ClO_3^- increases about 12 times in a pumping vacuum. If the retardation observed under 1–3 Torr of oxygen were due to a back-reaction with O_2 molecules

[10] $$ClO_2^- + O_2 \rightarrow ClO_3^- + O$$

this would have to mean that $k_{10} \gg k_6$ and so complete decomposition under oxygen would never be observed. Furthermore, air and nitrogen are equally effective in retarding the reaction, thus proving that the retardation is competitive with diffusion. Thus reaction [6] has to be reversible. Evidence for reactions [7] and [8] being reversible comes from the effect of $BaCl_2$ on the reaction, to be discussed in the next section. Reactions [6]–[8] are consistent with Solymosi and Bánsági's findings on the disproportionation of $Ba(ClO_2)_2$ into $Ba(ClO_3)_2$ and $BaCl_2$. An approximate order of rate constants is: $k_{\bar{8}} > k_8 > k_{\bar{6}} > k_{\bar{7}} > k_7 > k_6$.

TABLE I

Activation parameters for the thermal decomposition of barium perchlorate

Equation [1′]	0.05–0.36	76.7	19.54
Equation [2], k_2	0.06–0.45	80.9	20.72
Equation [3]	$\alpha > 0.52$	59.1	13.16

Mechanism of Decomposition for $\alpha < 0.52$

The decomposition of Na, K, Rb, and Cs perchlorates has recently been studied at low fractional decompositions ($\alpha < 0.035$) by Cordes and Smith (12) using a mass spectrometric method. Their data thus refer to the reaction

[11] $$2ClO_4^- \rightarrow 2ClO_3^- + O_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

without complications arising from secondary reactions. The activation energies found, 44.6 kcal/mole for $CsClO_4$, 46.0 kcal/mole for $RbClO_4$, and 50.2 kcal/mole for $KClO_4$, are similar, indicating little dependence of the anion decomposition (reaction [11]) on the cation, and being all markedly less than D(Cl—O). A bimolecular reaction, with the transition state O_3Cl^-—O---O—ClO_3^-, is therefore indicated (12) and this is confirmed by the low value of the pre-exponential factor $\sim 10^8$ s^{-1}, since the reactants will be freely rotating but the complex will have restricted rotation about the O---O bond because of the value of the Cl—O---O dihedral angle (cf. H_2O_2).

The kinetic analysis of the BP decomposition for $\alpha < 0.52$ is complicated by the fact that a number of reactions are going on simultaneously. That which has been achieved is recognizably empirical; nevertheless the activation energies (Table I) will be at least qualitatively meaningful. That referring to the lowest extent of decomposition is the value from t_0, the induction period before the empirical square law, eq. [2], starts to describe the data. This value is 69.7 kcal/mole which is not much greater than D(Cl—O); in fact one anticipates a high value because all the E values referring to higher values of α are much higher than 64 kcal/mole, so that any admixture of secondary reactions with the primary process

[12] $$ClO_4^- \rightarrow ClO_3^- + O$$

will tend to raise E. The pre-exponential factor is high, almost 10^{18} s^{-1}, but not much outside the range, $10^{18} - 10^{17}$ s^{-1}, which is considered appropriate for unimolecular solid state reactions (13, 14). The remaining 4 activation energies determined in different ways at higher α are all around 80 kcal/mole and so are either composite or refer to a different process than reaction [12].

The effect of $BaCl_2$ provides a clue to the other reactions occurring. The break in the $\alpha(t)$ curves is a linear function of the initial $BaCl_2$:BP ratio, r. Furthermore, the effect of $BaCl_2$ when $r < 1$ is to shorten the induction period, but leave the subsequent linear rate unchanged. When $r > 1$, the induction period, as well as the approximately linear portion of the reaction, are removed completely and the decomposition of BP is decelerator throughout (Fig. 4) under the accumulated product gases. The reaction rate for $\alpha > 0.3$ with 0.29 mole fraction $BaCl_2$ is identical with that for $\alpha > 0.52$ with no added $BaCl_2$ (both under product oxygen). This shows that the added $BaCl_2$ is converted to $Ba(ClO)_2$, and thence to $Ba(ClO_3)_2$ + $BaCl_2$, by reacting with the oxygen atoms produced in reaction [12] with great efficiency. As the $BaCl_2$ and BP are particulate, and not a solid solution, diffusion of O atoms is prerequisite.

In the absence of $BaCl_2$ the initial reaction is much slower than with $BaCl_2$ present ($r < 1$, or $r > 1$ in a pumping vacuum). This shows that when the O atoms are not trapped by Cl^- (and ClO^-) they react partly with ClO_3^- to reform ClO_4^- thus slowing down the production of O_2. Finally, the fact the reaction is acceleratory means that autocatalysis must be involved. We thus arrive at the following reaction scheme

[13]	$ClO_4^- \rightarrow ClO_3^- + O$	initiation
[14]	$O + ClO_4^- \rightarrow ClO_3^- + O_2$	propagation
[6]	$ClO_3^- \rightarrow ClO_2^- + O$	
[4]	$3ClO_2^- \rightarrow 2ClO_3^- + Cl^-$	
[9]	$O + O + M \rightarrow O_2 + M$	termination
[13]	$O + ClO_3^- \rightarrow ClO_4^-$	

For $\alpha < 0.52$, ClO_2^- is the *effective* end of the chain because of the ease with which it undergoes the disproportionation reaction [4], the mechanism of which involves reactions [7], [8], and [$\bar{6}$]. The induction period is explained by the importance of reaction [13], and the apparent stability of ClO_3^-, while any ClO_4^- remains, is due to the fact that its production from reactions [13], [14], [$\bar{6}$], and [4] just balances its loss by reaction [6] and [$\bar{13}$].

This scheme is consistent with all the experimental facts. Being a chain reaction it is acceleratory at first. The acceleratory period is removed practically completely (Fig. 4) by adding Cl^- since these react with O atoms with high efficiency, thus reducing the importance of the back reaction [$\bar{13}$] and also reaction [14]. In the presence of excess Cl^- the following (fast) reactions occur

[13]	$ClO_4^- \rightarrow ClO_3^- + O$
[6]	$ClO_3^- \rightarrow ClO_2^- + O$
[$\bar{8}$]	$O + Cl^- \rightarrow ClO^-$
[$\bar{7}$]	$O + ClO^- \rightarrow ClO_2^-$
[4]	$3ClO_2^- \rightarrow 2ClO_3^- + Cl^-$

so that the whole reaction appears as the decomposition of ClO_3^- (equal in amount to $1\frac{1}{3}$ times

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the number of moles of BP initially present, if $r > 1$), Fig. 4. For $r = 0.31$, the induction period is reduced because the trapping of O atoms by the added Cl^- (reactions [8] and [7]) competes successfully with reaction [13], but the amount of Cl^- added is insufficient to provide for complete rapid conversion of ClO_4^- to ClO_3^-. Thus the remaining 0.38 mole fraction of ClO_4^- (equivalent to $\alpha = 0.29$) decomposes to ClO_3^- by the usual route.

As explained above, the preservation of $\frac{2}{3}$ mole of ClO_3^- in the reaction without added Cl^- is a classic example of a steady-state situation and this explains the almost linear kinetics in the range $0.2 < \alpha < 0.52$. There is evidently a delicate balance between the various contributing processes, since both acceleratory and decelera-tory rates are sometimes observed.

The activation energy for $0.05 < \alpha < 0.45$ has not been determined very accurately but is evidently about 80 ± 4 kcal/mole, with a corresponding pre-exponential factor of $\sim 3 \times 10^{20}$ s^{-1}. These parameters do not refer to a single rate constant but rather to the temperature-dependence of a complex expression involving many rate constants. While this reaction scheme is certainly capable of explaining the experimental results in a qualitative fashion, it is too complicated for the time-dependent problem to be readily solved in a general way.

One of the simplest representations of chain kinetics is the Prout–Tompkins (P–T) equation (15). It is based on assumptions (16) that are hardly likely to apply in this complicated situation but nevertheless, containing as it does the essential features of branching and termination, it might be expected to represent the kinetics of BP decomposition tolerably well. In fact, the P–T equation describes the course of the decomposition at least as well as the other equations tried (eq. [2], eq. [3]) and the activation energies deduced $E = 58.4$ kcal/mole, for $\alpha > 0.52$ and $E = 86.4$ kcal/mole, for $0.02 < \alpha < 0.40$, are consistent with those found by the other methods. Solymosi (8) used only the P–T equation and the first order law to analyze his kinetic results. The activation energies he reports are $E = 60.2$ kcal/mole ($\alpha < 0.52$) and $E = 52.2$ kcal/mole ($\alpha > 0.52$) from the P–T equation and $E = 46.7$ kcal/mole from the first order law, which can clearly only apply after the break. He states that the contracting volume eq. [3] also fits the decay period ($0.45 < \alpha < 0.9$) but no examples of this were shown, nor was an activation energy quoted.

Raman spectra of liquid and crystalline HCN and DCN

M. PÉZOLET AND R. SAVOIE
Chemistry Department, Laval University, Quebec, Quebec

Received March 27, 1969

Raman spectra of liquid and crystalline HCN and DCN have been recorded at various temperatures down to 77 °K. The spectra of the liquids are characteristic of hydrogen-bonded compounds. The two solid phases have very similar spectra, in which each fundamental is complicated by an anomalous shoulder on the high-frequency side. Possible explanations for these are given.

Les spectres Raman de HCN et DCN liquides et solides ont été enregistrés à diverses températures entre 77 et 290 °K. Les spectres des liquides mettent en évidence les effets dus aux liaisons hydrogène. Les deux phases solides présentent dans chaque cas des spectres à peu près identiques, où chacune des fondamentales est compliquée par un épaulement du côté des hautes fréquences. On suggère quelques explications pour ces anomalies.

Canadian Journal of Chemistry, 47, 3041 (1969)

Introduction

The structure of the free HCN molecule has been accurately determined from its microwave (1) and vibration–rotation (2) spectra. Hydrogen cyanide forms unexpectedly strong hydrogen bonds, given the C—H donor group and the N acceptor. This results in some association in the vapor phase (3) and in the exceptionally high dielectric constant of the liquid, which has been explained by the formation of polymeric linear chains (4, 5).

Specific-heat measurements (3) on solid HCN (m.p. 259.86 °K) have indicated a phase transition at 170.37 °K. The very small entropy change (0.022 e.u.) associated with this process was interpreted in terms of a rearrangement involving large groups of hydrogen cyanide molecular units. This was later confirmed by an X-ray diffraction study (6) which showed that both crystalline phases are composed of infinite linear chains with all the molecules and the chains oriented in the same direction. The high-temperature modification, described by the space group $C_{4v}{}^{9}$-*I*4*mm*, is tetragonal with unit-cell dimensions: $a = 4.63$, $c = 4.34$ Å. In the orthorhombic low-temperature phase ($C_{2v}{}^{20}$-*Imm*), the *a* and *b* dimensions of the unit-cell are slightly different ($a = 4.13$ and $b = 4.85$ Å).

The mid-infrared spectrum of solid HCN has been obtained by Hornig and co-workers (7, 8) and the measurements were recently extended to the far-infrared (9). An infrared study of HCN and DCN isolated in various solid matrices has also been published (10). Our main purpose in undertaking the present study was to determine whether the Raman spectra of HCN in its two solid phases were consistent with the reported crystal structures. The liquid also seemed worth studying in view of its unusual properties. Finally, it was hoped that the Raman bands of crystalline HCN and DCN would help to explain the marked asymmetry of the Raman components of the H—X stretching doublets of HCl and HBr in their low-temperature modification (11).

Experimental

The hydrogen cyanide used in our experiments was obtained by the method of Ziegler (12), slightly modified in that the evolved gas was transferred under reduced pressure (1/2 atm) rather than by a flow of dry nitrogen gas. Diluted aqueous H_2SO_4 (1:1 per volume) was slowly added to a solution containing 200 g NaCN in 500 ml water. The evolved HCN was then passed through drying columns (P_2O_5 and $CaCl_2$) and condensed in a trap at liquid-nitrogen temperature. The ~ 75 ml of sample thus collected was then distilled several times, the middle portion only being retained at each distillation. A mass spectrum of the final product indicated traces of water present as an impurity (0.1%). The deuterated acid was obtained in a similar manner by reacting a 1:1 D_2SO_4/D_2O solution with 30 g NaCN in 50 g D_2O. The D_2SO_4 was produced by distilling SO_3 from 30% fuming sulfuric acid into D_2O (99.7% isotopic purity, Merk Sharpe Dohme of Canada, Ltd.). In order to prevent any undue isotopic contamination, the DCN sample was purified by passing it through thoroughly dried $CaCl_2$ only. The percentage of deuteration of the sample was estimated at 85%, from the relative intensity of an HCN impurity band in the Raman spectrum.

The 10–15 ml samples were studied in 19 mm diameter cylindrical Pyrex cells. The solids were obtained by slowly (usually over a 12 h period) lowering the cell into a constant-temperature bath maintained at approximately −20 °C. The polycrystalline solids thus obtained were not completely transparent and cracked upon cooling.

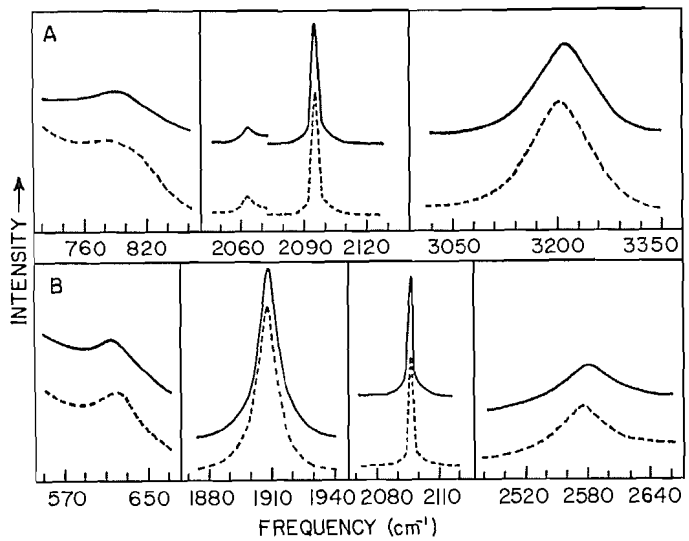

FIG. 1. Raman spectra of liquid (A) HCN and (B) DCN at 19 (—) and −12 °C (· · · · ·).

TABLE I

Observed frequencies in gaseous and liquid HCN and DCN

Frequencies (cm^{-1})						
HCN			DCN			
Gas (i.r.) Reference 2	Liquid (Raman) 19 °C	Liquid (Raman) −12 °C	Gas (i.r.) Reference 2	Liquid (Raman) 19 °C	Liquid (Raman) −12 °C	Assignment
3311.4	3215	3207 (95)*	2630.3	2581	2575 (50)*	ν_3
3295	—	—	2589	—	—	ν_3 ($H^{13}CN$)
2096.7	2096	2097 (3)	1928.0	1909	1908 (11)	ν_1
	2097	2097 (2.5)				ν_1 HCN in DCN
712.1	~794	~798 (~55)	569.1	~615	~622 (~30)	ν_2

*Numbers in parentheses refer to band width at half-intensity.

The low-temperature spectra were recorded with the sample cell placed inside a Pyrex Dewar and cooled by a flow of cold nitrogen gas, as previously described (13).

The spectra were obtained on a Cary 81 Raman spectrometer equipped with a Toronto-arc source. The instrument was calibrated with various discharge lamps (Ne, Na, and Hg) and the frequencies cited later are believed to be accurate to ± 1 cm^{-1} for sharp peaks. The spectral slit width was adjusted between 0.5 to 5 cm^{-1}, so as to obtain reasonable intensity in each region of the spectra. A background run in the low-frequency region indicated ghost bands at ca. 90, 145, and 175 cm^{-1}, that at 145 cm^{-1} being the sharpest and the most intense.

Results and Discussion

(A) Raman Spectra of Liquid HCN and DCN

The Raman spectra of liquid HCN and DCN at −12 and 19 °C are reproduced in Fig. 1. Observed frequencies are collected in Table I, which also includes the width at half intensity and the infrared frequencies in the gas phase. Since the ν_3 (C—H or C—D stretch) and ν_2 (H—C—N or D—C—N bend) bands of liquid HCN and DCN are very weak, large slit widths (~ 5 cm^{-1}) had to be used to obtain reasonable intensity. However, in the ν_1 (C—N stretch) region, a slit width of ~ 1 cm^{-1} was usually sufficient.

On the whole, the spectra of liquid HCN and DCN are those which might be expected for hydrogen-bonded compounds. The ν_3 band appears at a frequency lower than that in the gas, in both HCN and DCN, while the bending vibration is shifted to higher frequency. The C—N

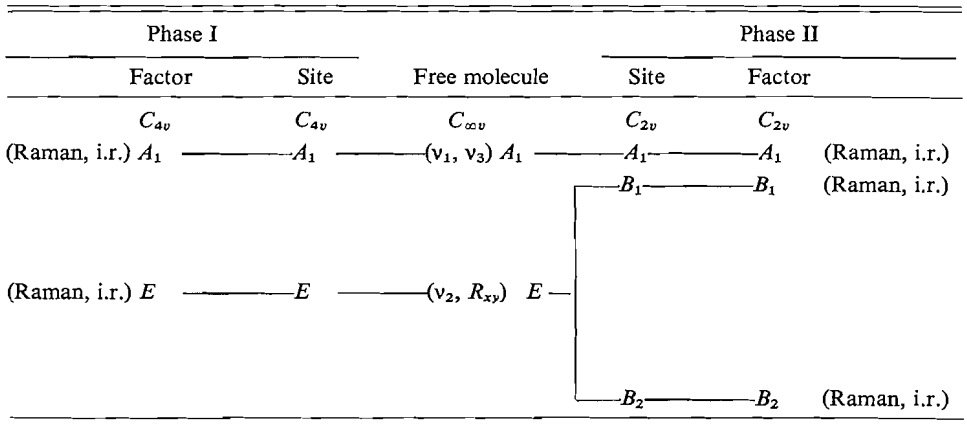
Symmetry correlation diagrams for crystalline HCN and DCN



stretching mode on the other hand is only slightly shifted, indicating that the strong C—N bond is weakly perturbed by molecular interactions. Band widths in both spectra are proportional to gas–liquid frequency shifts.

The appreciable blue shift of the bending mode of hydrogen cyanide upon condensation is unique in that it is almost as large as that of the ν_3 mode. This is probably because the atomic masses in HCN are such that a bending of the molecule involves mostly a displacement of the hydrogen atom, which is most influenced by hydrogen-bonding. The fact that the ν_1 band of DCN is almost 4 times as broad as the corresponding band of HCN is also peculiar. This does not imply that hydrogen bonds are stronger in DCN, since the gas–liquid frequency shifts of ν_3 in HCN and DCN are comparable. Rather, it is likely that the breadth of ν_3 (in both HCN and DCN) is partly transmitted to ν_1 through intramolecular coupling. Since the ν_3–ν_1 frequency difference is greater in HCN than in DCN, we can expect the coupling to be less in the first case. This would therefore explain why the ν_1 band of HCN is sharper than that of DCN, even when HCN is present as an impurity in liquid DCN.

The temperature effects on the Raman spectra of liquid HCN and DCN are small, as can be seen by comparing the spectra at −12 and 19 °C. (The normal boiling point of HCN is 25.7 °C.) Small frequency shifts occur for those bands which are more sensitive to hydrogen-bond formation, but these variations are not accompanied by any significant changes in band widths. Furthermore, all the bands have symmetrical shapes suggesting that the polymeric units in the liquid are rather long. Were monomers and dimers present in appreciable concentrations, a high-frequency tail should be observed alongside ν_3, contrary to our findings.

(B) Raman Spectra and Crystal Structures of the Solids

Hydrogen cyanide has very simple crystal structures in both its solid phases (6). Since there is only one molecule per primitive cell in each case (although there are two per crystallographic unit-cell), no translational lattice mode should be observed in the vibrational spectra of the pure solid. This is because acoustic modes have vanishing frequency at the center of the Brillouin zone ($\boldsymbol{k} = 0$), where optical transitions occur. The site and coupling effects in the crystal are easily taken into account by the use of a correlation diagram (Table II) which is straightforwardly obtained from standard group-theoretical procedures (14, 15). It is thus seen that the two stretching modes (ν_1 and ν_3) should not be split in either solid phase. The bending (ν_2) and librational modes, however, although they should appear as singlets in phase I, are predicted to yield two components (B_1 and B_2) in phase II. Physically, this comes about because of the anisotropy of the static crystalline field (in the x and y directions) in the low-temperature modification of the crystal. This results in different

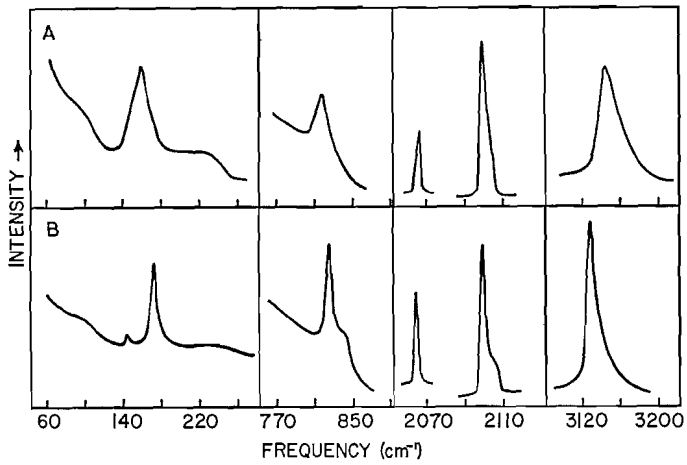

FIG. 2. Raman spectra of HCN in (A) phase I at −90 °C and (B) phase II at −195 °C.

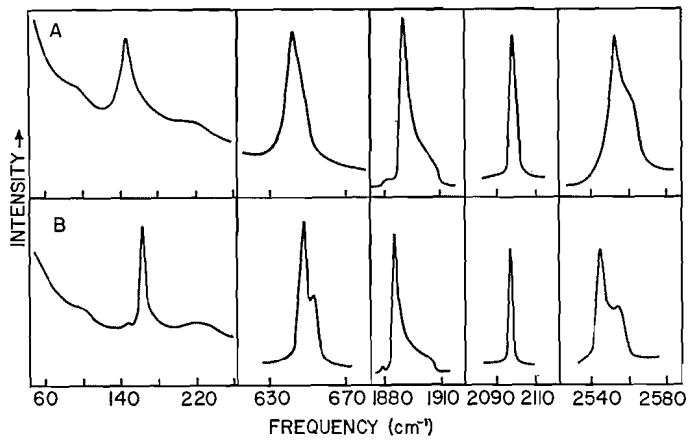

FIG. 3. Raman spectra of DCN in (A) phase I at −90 °C and (B) phase II at −195 °C.

frequencies for the two perpendicular motions involved in the otherwise doubly degenerate E modes.

The Raman spectra of crystalline HCN and DCN in their two solid phases are reproduced in Figs. 2 and 3. Observed frequencies are given in Table III. The spectra differ appreciably from those predicted above on the basis of the accepted crystal structures. In particular, the C—N and C—H (C—D) stretching vibrations (ν_1 and ν_3) are complicated by high-frequency shoulders, whereas the bending mode yields an asymmetric peak, even in the high-temperature phase. In the lattice region, the only predicted active mode is most probably responsible for the sharp peak at 161 cm^{-1} in the spectrum of HCN at −90 °C. The corresponding band appears at 149 cm^{-1} in DCN, with an appropriate (0.93) isotopic frequency shift. The predicted site splitting of this band in the low-temperature phase is not observed, which raises the question as to whether the two components in the ν_2 region arise from a site splitting. The broad band in the Raman spectra of both HCN and DCN at $\sim$ 220 cm^{-1} cannot be assigned to a component of the librational mode arising from a site splitting, since it is also present in phase I spectra. We do not believe that the present results are in contradiction with the crystal structures obtained from X-ray diffraction. Rather, it seems that all fundamentals (including the librational mode) are complicated by anomalous high-frequency shoulders, which may appear as separate components at low temperature because of band sharpening. Possible

†The far- (ref. 9) and mid-infrared (ref. 7) data were obtained at approximately −180 °C.

explanations for these anomalies will be given below (see section *D*). The similarity of the crystal structures of the two solid phases is such that very little change is seen in the spectra at the phase transition. However, temperature dependence studies have shown that some frequency shifts occur at the transition temperature.

(C) Force-constant Calculations

A puzzling characteristic of the high-frequency shoulders observed alongside the fundamentals of crystalline hydrogen cyanide is their anomalous shapes, which suggest a whole frequency distribution rather than a separate component with a normal band shape. This is especially noticeable in the shape of the shoulder alongside the band at 1885 cm^{-1} in the spectrum of DCN at −195 °C (Fig. 3). We first thought that transitions at $\boldsymbol{k} \neq 0$, possibly induced by crystalline disorder, could be responsible for the above anomalies. This prompted us to calculate the force constants and obtain the frequency dispersion curves for the vibrations taking place along the chains in crystalline HCN and DCN.

In order to simplify the problem, the approximation of a linear triatomic chain of infinite length was used. This is particularly well justified in this case because molecular interactions within a chain are much greater than those between adjacent chains. The calculations of the fundamental frequencies, in the harmonic oscillator approximation, are quite simple for the $\boldsymbol{k} = 0$ case. The procedure described by Shimanouchi *et al.* (16) was followed and four force constants were used: f_0, f_1, and f_2 were related to the variations of the N · · · H, H—C, and C—N distances, respectively, whereas f_{12} took into account the coupling of the C—H and C—N stretching motions. The normal frequencies were obtained from the secular equation

$$\begin{vmatrix} f_0(\mu_1 + \mu_3) - \omega^2 & -f_1\mu_1 - f_{12}\mu_3 & -f_{12}\mu_1 - f_2\mu_3 \\ -f_0\mu_1 & f_1(\mu_1 + \mu_2) - f_{12}\mu_2 - \omega^2 & f_{12}(\mu_1 + \mu_2) - f_2\mu_2 \\ -f_0\mu_3 & -f_1\mu_2 + f_{12}(\mu_2 + \mu_3) & -f_{12}\mu_2 + f_2(\mu_2 + \mu_3) - \omega^2 \end{vmatrix} = 0$$

where ω is the angular frequency ($\omega = 2\pi\nu$ c.p.s.) and μ_1, μ_2, and μ_3 are the inverses of the H, C, and N atomic masses. Expansion of the determinant yields the following equation

$$\omega^6 - \omega^4[\mu_1 X + \mu_2(X + Y - 2Z) + \mu_3 Y] + \omega^2[(\mu_1\mu_2 + \mu_1\mu_3 + \mu_2\mu_3)(XY - Z^2)] = 0$$

where
$$X = f_0 + f_1$$
$$Y = f_0 + f_2$$
$$Z = f_0 + f_{12}$$

One possible solution of this equation is $\omega = 0$. This is expected since the acoustic branch has zero frequency at $\boldsymbol{k} = 0$, in which case the motion corresponds to a displacement of the whole chain. It is also seen from the above equation that the force constants cannot be individually calculated, although the three parameters X, Y, and Z can be obtained for both HCN and DCN from three observed frequencies (C—H, C—N, and ^{13}C—N stretching). This procedure applied separately to HCN and DCN yields two sets of values which differ appreciably because of anharmonicity. However, it was found that the following set of force constants can reproduce the observed stretching frequencies of both HCN and DCN to better than 2% (at −195 °C)

$$f_0 + f_1 = 4.95$$
$$f_0 + f_2 = 19.28$$
$$f_0 + f_{12} = -0.37 \text{ mdyn/Å}$$

These values, when compared to the corresponding force constants of the free molecule ($f_1 = 5.62, f_2 = 18.85$, and $f_{12} = -0.44$ mdyn/Å (8)), points to the weakening of the C—H bond in the solid and allows f_0 to be estimated at ~ 0.3 mdyn/Å. This intermolecular force constant could be obtained directly from the frequency of the H bond stretching of a HCN dimer isolated in a solid matrix. Such a dimer should also yield two doubly degenerate libration-like modes. In the far-infrared spectrum of HCN isolated in a solid N_2 matrix, King and Nixon (10) have observed three bands at 96, 137, and 144 cm^{-1}. If the dimer is regarded as a diatomic oscillator, the lowest of these frequencies yields a force constant of 0.074 mdyn/Å, which is rather low. If on the other hand, the stretching motion is taken to have a frequency of 144 cm^{-1}, a more reasonable value of 0.19 mdyn/Å is obtained.

The calculations involved in obtaining the frequency dispersion curves for a linear triatomic chain will not be given here, since it is only an extension of the well-known case of the diatomic linear chain, which is treated by the Born–von Kármán approach in most textbooks on solid state physics (see, for example, refs. 17–19). The acoustic and optical frequencies were obtained as a function of the wave vector $\boldsymbol{k}$ from the equation

$$\omega^6 - \omega^4[\mu_1(f_0 + f_1) + \mu_2(f_2 + f_1 - 2f_{12}) + \mu_3(f_0 + f_2)] + \omega^2[(\mu_1\mu_2 + \mu_2\mu_3)(f_0f_1 + f_0f_2 + f_1f_2 - 2f_0f_{12} - f_{12}^2) + (\mu_1\mu_3)(f_0f_1 + f_0f_2 + f_1f_2 - 2f_0f_{12}\cos \boldsymbol{k}d - f_{12}^2)] + 2(f_0f_1f_2 - f_0f_{12}^2)(\cos \boldsymbol{k}d - 1)(\mu_1\mu_2\mu_3) = 0$$

where d is the primitive unit-cell dimension along the chain axis. The frequency dispersion curves obtained from this equation, with f_0 arbitrarily fixed at 0.2 mdyn/Å, are given in Fig. 4.

(D) Anomalies in Raman Spectra

The possible causes for the anomalous shoulders observed on the high-frequency side of the fundamentals in the Raman spectra of crystalline HCN and DCN are numerous and only the more plausible ones will be discussed.

(a) Incorrect Crystal Structure

The X-ray study on crystalline HCN (6) has unambiguously established the parallel-linear-chain structure of this solid. However, given the

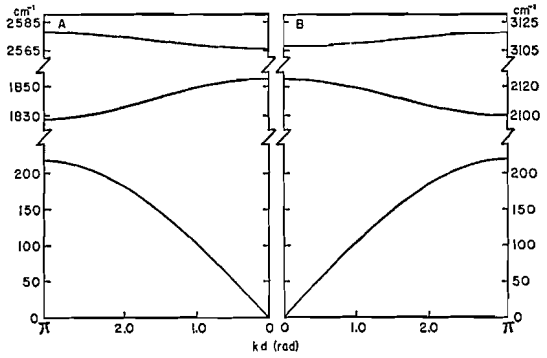

FIG. 4. Dispersion curves for motions along linear chains of (*A*) DCN and (*B*) HCN molecules.

For personal use only.

cylindrical shape of the HCN molecule and the small scattering cross section of the hydrogen atom, it could be argued that the X-ray study has failed to recognize the exact molecular orientation in the solid. The strongest point against this hypothesis is the pyroelectric nature of the crystal in phase II, which is only possible if the crystal is non centro-symmetric. Furthermore, because of the low heat of transition between the two solid phases (3) and their similar Raman spectra, it is most likely that phase I is also non centro-symmetric. The coincidence of Raman and infrared (7) frequencies of the internal modes at low temperature and the simplicity of the Raman spectra in the lattice region are in agreement with this conclusion. It should also be pointed out that a centro-symmetric structure would not lead to a splitting of the ν_1 and ν_3 bands in the crystal, and cannot therefore explain the observed anomalies.

(b) Disorder

Although crystalline HCN should have a well-ordered structure, positional and orientational disorder could be introduced in the crystal through bad crystallization. This could possibly explain the large number of bands in the far-infrared spectrum of crystalline HCN and DCN (9). In these experiments, the samples had to be deposited from the vapor onto a cold window maintained at approximately -100 °C, because of the high vapor pressure of the solid. Subsequent annealing of the sample was not possible for the same reason. It is clear that such a drastic process is not the ideal way to obtain a good crystal. If the weaker peaks in the far-infrared spectra of HCN and DCN are ascribed to disorder, one is left with a very intense band complicated by a high-frequency shoulder, which is exactly what we observe in the Raman spectra. The frequencies differ somewhat in the two types of spectra contrary to what can be predicted on the basis of a non centro-symmetric crystal structure, but this can be explained by the strong overlapping of the infrared bands.

There is both experimental and theoretical evidence that the anomalies observed in the Raman spectra are not caused by the above type of disorder. In particular, improving the quality of the solid samples, by extending the time of crystallization to one week, failed to produce any significant change in the Raman band shapes. Also, attempts to induce disorder by rapid crystallization (1/2 h) or by filling the sample cell with capillary tubes led to the same results. Theoretically, disorder should broaden the vibrational bands by allowing the observation of part of the exciton spectrum. Consequently, the frequency spread of the anomalous shoulders alongside the stretching bands in the Raman spectra would be expected to bear a rough proportionality to the variation in frequency of the optical vibrations between the center and the edge of the Brillouin zone. This is not the case, as can be seen from the dispersion curves (Fig. 4). Furthermore, there is no reason for disorder to cause a broadening of the bands on the high-frequency side only.

(c) Piezoelectric-crystal Anomalies

We have pointed out in a recent note (20) that the type of anomaly discussed here could well be related to the piezoelectric nature of the crystals studied. Frequencies of Raman bands of piezoelectric uniaxial (or biaxial) crystals should vary with the angle of incidence of the exciting light with respect to the optic axis of the crystal (21, 22). Theoretically, the frequency spread for a given band should be approximately limited by the transverse (ν_t) and longitudinal (ν_l) frequencies. Furthermore, it has been shown (22) that

$$\nu_l^2 - \nu_t^2 \propto \left(\frac{\partial \mu}{\partial Q}\right)^2 \propto I$$

where I is the intensity of the corresponding infrared absorption band. Although this relation is open to some theoretical question (23), it should hold approximately in the case of HCN and the hydrogen halides, the spectra of which contain but a small number of relatively well separated bands.

Assuming that ν_t corresponds to the band maximum and that ν_l is given by the high-frequency cutoff of the anomalous shoulder, for any particular band in a Raman spectrum, it should be possible to calculate the relative intensity of the infrared bands from Raman data alone. The above relation applied to the ν_3 and ν_1 bands of crystalline HCN yields $I(\nu_3)/I(\nu_1) = 7.2$, which agrees reasonably well with the value of 5.7 measured experimentally (7). If the high-frequency shoulder alongside ν_2 is used to calculate $I(\nu_2)$, one obtains $I(\nu_2)/I(\nu_1) = 1.2$, which is quite close to the experimental value of 1.4. This suggests that the asymmetric shape of ν_2 does not arise from a site splitting, and is more

consistent with the absence of splitting of the librational mode (in phase II). Calculations based on our Raman results for DCN indicate that ν_1 and ν_3 should have equal infrared intensities, the ν_2 band being about 6 times weaker. We intend to do complementary infrared studies on HCN and DCN and check if this prediction is verified. Also planned is a study of the reflection spectra of these compounds. If the interpretation given above is correct, reflection bands should be seen in the infrared where anomalous shoulders appear in Raman spectra.

As further evidence for the correctness of our assignment of the high-frequency tails in the Raman spectra of HCN and DCN, we turn to the case of HCl and HBr where such shoulders were first observed (11). The H—X stretching region of the Raman spectra of HCl and HBr in their low-temperature modification consists of two sharp peaks, each complicated by a high-frequency tail. These shoulders were first interpreted as arising from a factor-group splitting, and a model with four molecules per primitive cell was proposed for these crystals. However, a recent neutron-diffraction study (24) has shown that orthorhombic crystalline HCl consists of zigzag planar chains, with two molecules per cell, in which case we predict only a doublet in the H—X stretching region. If the shoulders are taken to be analogous to those observed in HCN, we can use the same procedure as above to calculate the infrared intensity ratio of the two components of the doublets. The calculated values (1.55 for HCl and 1.16 for HBr) are almost identical to those measured experimentally (ref. 25, 1.54 for HCl and 1.14 for HBr). Such a close agreement is probably accidental, given the somewhat uncertain choice of ν_1 and the approximate nature of the formula used. Nevertheless, it is a good indication that our interpretation of the anomalous Raman shoulders is correct.

Anomalous shoulders have also been observed in Raman spectra of SO_2 (26) and ICN (27). The fact that these crystals are piezoelectric adds some support to our conclusions, since $\nu_1 \neq \nu_t$ only if $\partial\mu/\partial Q \neq 0$, which is only possible for non centro-symmetric (piezoelectric) crystals. It is expected that anomalies such as those discussed here should be observable in Raman spectra of many piezoelectric molecular crystals. It is therefore advisable in these cases to check the intensity of the corresponding infrared bands, in order to properly assign these "anomalous" features.

Acknowledgments

We gratefully acknowledge financial support of this work by the National Research Council of Canada. We also wish to thank Professor J. R. Durig, Dr. F. G. Baglin, and Mr. G. L. Coulter (Department of Chemistry, University of South Carolina) for communication of their unpublished far-infrared results. Stimulating discussions with Professor W. B. Person and Professor G. Andermann were much appreciated. Finally, one of us (M.P.) is indebted to the National Research Council of Canada for a Graduate Studentship.

Solubility of some iodides in non-polar solvents

S. K. SURI AND V. RAMAKRISHNA[1]

Department of Chemistry, Indian Institute of Technology, New Delhi-29, India

Received February 20, 1969

The solubilities of SnI_4, AsI_3, SbI_3, and BiI_3 in carbon tetrachloride, cyclohexane, benzene, and dioxane have been determined at different temperatures (30–55 °C). The entropy of solution of these iodides at 25 °C has been calculated from the data, and compared with the calculated entropy of fusion. The solubility parameters of these iodides have been computed and their spectral behavior in the solvents studied in the near ultraviolet region. On the basis of these data, the nature of the solutions of the iodides in the non-polar solvents has been compared.

Canadian Journal of Chemistry, 47, 3049 (1969)

In the course of their investigations on the solubility of non-electrolytes, Hildebrand and Scott (1); and Smith and Walkley (2) determined the solubility of several solutes, including I_2 and SnI_4, in a large number of solvents. They showed that the entropy of dissolution of the solutes could be predicted in those solvents where complexing tendency did not exist, on the basis of the "regular solution theory". The fundamental assumptions of the theory are: (*i*) a random distribution of molecules in solutions of non-polar liquids, leading to an entropy of mixing term from liquid state, of value $-R\ln X_i$; and (*ii*) a geometric mean for the cohesive energy density i.e. $C_{12} = (C_{11}C_{22})^{\frac{1}{2}}$, where $C_{ii} = \Delta E_i^{vap}/V_i$ and ΔE_i^{vap} = energy of vaporization and V_i = molar volume of the liquid. Given these assumptions, the regular solution theory can predict thermodynamic properties of solutions within 10–20% of those calculated from thermal data. Hildebrand and Scott (1) and Smith and Walkley (2) demonstrated the remarkable usefulness of this approach in dealing with a variety of solutions of non-electrolytes, in comparison to the more limited applicability of the other elaborate theoretical treatments.

While the solubility of SnI_4 has been studied to some extent (1), other covalently bonded iodides have received considerably less attention. It would be interesting to compare the solutions of other covalently bonded iodides, particularly those of Group V elements, for which thermochemical properties have become available in recent years (3, 4). Also, the solvent properties of dioxane have not been studied in this manner previously. With this in view, we have studied the solubilities of the iodides of As, Sb, Bi, and Sn, in four solvents; viz. carbon tetrachloride, cyclohexane, benzene, and dioxane, and also determined their spectroscopic behavior in the near ultraviolet (u.v.) region.

Experimental Procedure

The solvents used were purified according to standard procedures (5). Some of the physical properties determined showed good agreement with literature values (6).

Stannic iodide was prepared in lots of 40–50 g by the method described by Dorfmann and Hildebrand (7). Arsenic, antimony, and bismuth tri-iodides were prepared and purified according to methods described by Cubicciotti and Eding (3, 4) in lots of $\sim$ 30 g.

The technique we used for the determination of solubilities was similar to that of Glew and Hildebrand (8). In the place of a teflon bearing for the stirring shaft, we used the conventional mercury seal. We did not observe any chemical action on mercury during these experiments with the iodides. The temperature of the circulating water was controlled to ± 0.01 °C and the difference between inlet and outlet temperature was not greater than 0.02 °C at the highest temperature of determination. The solubility was measured by taking out a known weight (approximately 15 ml) of the solution into a tared dish, then carefully evaporating the solution under slightly reduced pressure and finally under a good vacuum. Constancy of weight fraction of iodides over three successive determinations at a temperature was taken as indicative of the final equilibrium value. These results were also checked by the chemical analysis of the residue left. SnI_4 gave a precipitate in concentrated solutions of dioxane. BiI_3 was found to be sparingly soluble in carbon tetrachloride, cyclohexane, and benzene. Hence, no solubility data could be obtained for these systems.

Spectroscopic measurements were carried out using a Unicam SP-500 manually operated spectrophotometer with 1 cm quartz cells. The concentrations of the solutes in these measurements were kept at $\sim 5 \times 10^{-5}$ *M*.

composition of the iodides have been recorded in Table I and the solubilities over the temperature range 30–55 °C in Table II. The results are shown as log X_2 (subscript 2 denoting the solute) vs. log T plots in Fig. 1. Our values for the solubility of SnI_4 in benzene and CCl_4 extrapolated to 25 °C are in good agreement with those reported by Smith and Walkley (2) and Dorfmann and Hildebrand (7). The solubility plots given in Fig. 1 yield good straight lines in all cases, similar to the results of previous workers (1, 2), and permitting accurate determination of entropy (1). Further, it is seen that the solubility of all the iodides, determined in the present investigations, increases in the order: cyclohexane, carbon tetrachloride, benzene, and dioxane. In the first three solvents, the same order has been observed for the solubility of other solutes in earlier investigations (vide 1, 2). The solubility of the iodides in dioxane is much larger than in other conventional solvents.

In Table III, the known thermochemical properties for the iodides (1, 3, 4) are recorded. Other values presented in Table III, have been estimated as follows.

Since $\Delta C_p(= C_p(\mathrm{l}) - C_p(\mathrm{s}))$, is known for these iodides (vide column 4, Table III), and is not close to zero, the following equation has

been used for estimating log a_2, a_2 being the activity of the iodides

$$[1] \quad \log a_2 = -\frac{\Delta H_f}{2{\cdot}303R}\left[\frac{T_f - T}{T T_f}\right] + \frac{\Delta C_p}{2{\cdot}303R}\left[\frac{T_f - T}{T}\right] - \frac{\Delta C_p}{R}\log\frac{T_f}{T}$$

In the above equation ΔH_f = heat of fusion and T_f = temperature of fusion of the iodides, and the other symbols have their usual significance.

The entropy of fusion of the iodides at 25 °C has been obtained by extrapolation from their melting points by the aid of ΔH_f and ΔC_p data given in Table III. It is estimated that the error in log a_2 values so obtained would be of the order of 3–5%. The molar volumes in the liquid state for these iodides (except for SnI_4), as far as we know, are not available in literature. We have proceeded, therefore, to estimate them by comparing with the corresponding bromides, for which the requisite data are available (9). The assumption we have made in this estimation is that the % volume expansion upon change of state from solid to liquid for the iodides and bromides of the same elements are equal. In the case of SnI_4, for which molar volume data are available, the error caused by our estimation procedure is observed to be ~ 2%. With the data thus estimated, it has been possible to calculate the Hildebrand solubility parameters of the iodides (1) from the following equation

$$[2] \quad \log a_2 = \log X_2 + \frac{V_2\phi_1^2(\delta_2 - \delta_1)^2}{2{\cdot}303RT}$$

where ϕ_1 = volume fraction of solvent, δ_i = solubility parameter = $(C_{ii})^{\frac{1}{2}} = (\Delta E_i^{vap}/V_i)^{\frac{1}{2}}$. The δ's so calculated are tabulated in Table VII, along with the values obtained from $[(\Delta H^{vap} - RT)/V]^{\frac{1}{2}}$. The value of ΔH^{vap} used here involves extrapolation over a fairly wide range of temperature, from the melting point of the solids to 25 °C. The data reported in Table VII are probably in error to the extent of 5–10%.

From the slope of the straight lines of Fig. 1, the term, $R(\partial \ln X_2/\partial \ln T)_{sat}$ has been calculated and recorded in Table IV, together with the corresponding $(-R \ln X_2)$ values at 25 °C, at which temperature most of the earlier solubility

TABLE IV

Estimated entropy of solution and solubility of the iodides in four solvents at 25 °C

Solute	Solvent	$\Delta\bar{S}_2$ (cal/deg mole)	$-R \ln X_2$
AsI_3	CCl_4	26.37	13.79
	c-C_6H_{12}	27.70	14.70
	C_6H_6	24.24	11.77
	Dioxane	23.74	10.79
SbI_3	CCl_4	34.10	17.95
	c-C_6H_{12}	33.78	19.22
	C_6H_6	18.41	12.55
	Dioxane	20.47	10.96
BiI_3	Dioxane	18.88	14.80
SnI_4	CCl_4	19.61	8.42
	c-C_6H_{12}	20.47	8.50
	C_6H_6	19.45	7.55

data have been reported (1). The entropy of solution at saturation is related to the term $R(\partial \ln X_2/\partial \ln T)_{sat}$ by means of the following equation

$$[3] \quad \Delta\bar{S}_2 = \bar{S}_2 - S_2^S = R(\partial \ln X_2/\partial \ln T)_{sat,P} \times (\partial \ln a_2/\partial \ln X_2)_{P,T}$$

The factor $(\partial \ln a_2/\partial \ln X_2)_T$ in eq. [3], which is the "Henry's Law" factor, is not far from unity when X_2 is small. Hence the values recorded in Table IV can be taken to represent $(\bar{S}_2 - S_2^S)$, the entropy of solution of the iodides in the solvents.

Discussion

The first point to observe is that the values recorded for SnI_4 solutions in benzene and carbon tetrachloride agree very well with those of Smith and Walkley (2), and serve as a check on our determinations. The $\Delta\bar{S}_2$ value for SnI_4 solution in cyclohexane recorded in Table IV is higher than in other solvents. Cyclohexane has given similar higher values for other solutes studied by earlier workers (vide 1). According to the regular solution theory, the entropy of dissolution of a solid, $(\bar{S}_2 - S_2^S)$, obeys the linear relationship: $(\bar{S}_2 - S_2^S) = -R \ln X_2 + \Delta S$(fusion). That is, a plot of entropy of dissolution vs. $-R \ln X_2$ is expected to have a slope of unity and an intercept of ΔS (fusion). When the entropy measurements are made at constant pressure, as in our systems, the slope of the above line would be expected to be higher than unity, depending on the term $(\partial P/\partial T)_{v,1} \cdot \bar{V}_2^E$. The slopes obtained by us for various solutions

TABLE V

Slope of the lines joining ΔS (fusion) of iodides with $\Delta\bar{S}_2$ in various solvents

	Slopes			
Iodides	CCl_4	c-C_6H_{12}	C_6H_6	Dioxane
AsI_3	1.08	1.11	1.09	1.14
SbI_3	1.37	1.26	0.71	1.00
BiI_3	—	—	—	0.82
SnI_4	1.25	1.34	1.37	—

are given in Table V. It will be observed that for SnI_4 solutions in all the solvents studied, and for SbI_3 in CCl_4 and c-C_6H_{12} the slopes are 25–37% larger than unity. This is to be expected when the large value of $\bar{V}_2^E$ for the solutes is taken into consideration, anticipated on the basis of the value for SnI_4 (vide 1). However, all other values in Table V are smaller than expected, particularly for solutions of SbI_3 and BiI_3 in benzene and dioxane, indicating the possibility of complexing in solution, which reduces the number of independent molecules. In the case of I_2 and SnI_4 solutions, Hildebrand and Scott (1) and Smith and Walkley (2) found that the degree of complexing could be related to the departure of solubility from what it would be if the solution were regular. Applying this concept to our data (Table V), it would appear that the solutions of

SnI_4	11.50	11.12	11.82	—	11.70

*δ, values obtained from ΔH^{vap} of solvent (1).

SbI_3 in benzene and dioxane and of BiI_3 in dioxane have undergone considerable complexing, while the solutions of AsI_3 show this tendency to a smaller extent. This also explains the greater solvation of BiI_3 in dioxane, while it is only sparingly soluble in the other three solvents.

In this context, it is of interest to examine the electronic spectra of these systems. There are generally two characteristic absorption maxima, for which the separation has been calculated in wave numbers (Table VI). For these iodides in CCl_4 and c-C_6H_{12} solutions, the higher frequency absorption peak occurs at 282–285 mμ, while the other falls in a wider range from 345–384 mμ, depending on the solute. We will use the first two solvents as a reference for comparison. For SnI_4 in benzene and dioxane, the lower frequency peak is more or less unchanged, while the other is shifted to 292 mμ, in agreement with earlier observations (1). For AsI_3, there is no change in the absorption maxima in benzene. In the case of SbI_3 only one peak at 280 mμ is observed in benzene compared to 288 mμ in CCl_4, the lower frequency peak being absent from both solutions. A similar observation has recently been made by Mishra and Ramakrishna (14) in our laboratories in chloroform and t-BuOH solutions, contrary to reports available in literature (10, 11). On this aspect, further investigations are underway. However, it will be noted in Table VI that both the absorption peaks for AsI_3, SbI_3 (except 345 mμ), and BiI_3 in dioxane solutions shift to a higher frequency. The electronic spectra of these iodides therefore generally support complexation in dioxane solutions.

Finally, attention is drawn to the solubility parameters for the solutes (Table VII), which have been calculated from the solutions on the basis of eq. [2]. The values thus obtained are in strikingly good agreement with those calculated from the enthalpy of vaporization given in the last column. The value of δ_2 obtained for SbI_3 in benzene and dioxane is much lower than the corresponding values for AsI_3; and the value for BiI_3 is exceptionally low, corroborating again that in these solutions specific solute–solvent interactions occur.

Electrochemistry of copper, silver, gold, gallium, indium, and thallium in fused $AlCl_3$–NaCl–KCl eutectic[1]

UDO ANDERS AND JAMES A. PLAMBECK
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 3, 1969

The electrochemistry of copper, silver, gold, gallium, indium, thallium, and their ions, and of chlorine and bromine in fused $AlCl_3$–NaCl–KCl was investigated by electromotive force (e.m.f.) and voltammetric techniques. Univalent oxidation states were observed for all the metals. In addition, copper was further oxidized to the divalent species while gallium and indium were oxidized to trivalent species. The standard potentials for the above couples were established in the $AlCl_3$–NaCl–KCl eutectic at 135 °C.

Canadian Journal of Chemistry, **47**, 3055 (1969)

Introduction

It has been shown by electrochemical and spectroscopic methods (1–3) that molten salt systems containing $AlCl_3$ have a tendency to stabilize low valence states of metal ions. The presence of Bi(I) has been established in $NaAlCl_4$ (3), as has that of Cd(I) (4). A recent electrochemical study (2) of the Group IIB elements has demonstrated the enhanced stability of lower valence states in the fused ternary $AlCl_3$–NaCl–KCl (66:20:14 mole %, respectively) eutectic. The present paper extends that study to the Group IB and IIIA elements.

Some of these metals have been investigated by Yntema and co-workers (6–9) in this solvent. The primary objective of these studies was deposition of the metals from their solutions in the eutectic, and little attention was paid to other effects. Thus when Ga(III) was added to the melt and gallium electrodeposited at the cathode, the presence of Ga(I) was not recognized although the polarization curve displayed one additional break. Indium was not investigated. No electrochemical activity was found when TlCl was added to the melt, and it was concluded that thallous chloride was therefore insoluble. The present study shows, however, that the oxidation and reduction potentials of Tl(I) are beyond the melt range and so no electrochemical activity should be observed. Yntema reported his studies of gallium 25 years ago when the chemistry of gallium was not well understood. It is now known that gallium metal reacts with gallium trichloride to form $Ga(GaCl_4)$, a complex containing equal amounts of Ga(I) and Ga(III). Excess gallium metal does not undergo further reaction with this complex unless aluminum trichloride is added (5); under these circumstances the $GaCl_4^-$ ion reacts until all Ga(III) is reduced to Ga(I). The resulting complex has the formula $Ga(AlCl_4)$.

Experimental

The electronic instrumentation and electrochemical cell used have been described previously (2). The metals for the electrodes were obtained in wire form from A.D. MacKay (New York) and were of 99.99% purity. Anhydrous $GaCl_3$ and $InCl_3$ were produced from the pure metals and chlorine gas (10). Anhydrous InCl was purchased from Alfa Inorganics (Beverly, Mass.). Reagent grade $AlCl_3$, NaCl, and KCl (Fisher Scientific Co.) were used. The purification procedure used for the aluminum chloride in this investigation was less cumbersome than that previously reported (2) and allowed the preparation of a new melt for each experiment. In this procedure, 250 g of aluminum chloride were placed in a closed-end Pyrex tube 40 cm long and 5 cm in diameter, which was fitted with a 6 cm O-ring joint. The aluminum chloride was covered with a 1 cm thick layer of granular aluminum metal (reagent grade 30 mesh, Fisher Scientific Co.). The tube was flushed with nitrogen and closed with a Pyrex cap which had a 4 mm stopcock on top; this was open to a mercury pressure relief valve during the sublimation. The vertical tube was heated by an external heating mantle and heating tape which extended to the height of the aluminum layer. A tubular ring with pin holes pointing inwards fitted loosely over the sublimation tube. Compressed air was blown through it to cool the tube and prevent condensation of subliming aluminum chloride in the upper half of the tube. It was positioned approximately 10 cm down from the glass joint. The aluminum chloride condensed over a length of 7–10 cm as a colorless, crystalline solid. After nearly complete sublimation, the closed tube was cooled and transferred into a glove box filled with dry nitrogen. The glass tube

[1]Taken from the Thesis of U. Anders submitted to the Faculty of Graduate Studies, University of Alberta, Edmonton, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

For personal use only.

was then broken to obtain the solid aluminum chloride. The lower part of the crystallized aluminum chloride cylinder was generally discarded due to baked-in granular aluminum.

The aluminum chloride obtained by the above procedure was a crystalline material, pure white in color. It was ground, transferred into a tightly stoppered flask, removed from the glove box, weighed, and returned to the glove box in which all further work was done. After addition of the appropriate amounts of sodium chloride and potassium chloride, the mixture was melted in a round bottomed flask and transferred into the electrochemical cell previously described (2). It was observed that the color of the melt varied with the temperature employed during this initial melting process, from a faint yellow to light-brown. The cause of the coloration is unknown. It has been suggested that it is due to carbon from organic material (11, 12) or dissolved silicon compounds (13). An aluminum wire spiral was added to the melt for 1 h in order to reduce any metal ion impurities.

Reference Electrode

All potentials were measured with respect to an aluminum wire inserted into the melt. The use and nonpolarizability of this reference electrode have been described (2). All measurements were made at 135 ± 1 °C rather than at 150 °C (2), to keep evaporation of the aluminum chloride to a minimum during the experiments.

Metal–Metal Ion Electrodes

The compartments consisted of 10C sealing tubes (Ace Glass Inc., Vineland, N.J.) which were inserted into the melt and allowed to fill to the melt level. The metals were inserted as wires except in the case of gallium which is a liquid at this temperature. Here a spoon-like Pyrex cup attached to the end of a glass tube was used. A platinum wire which did not come in contact with the melt led to the bottom of the cup, which was filled with liquid gallium metal and then inserted into the compartment.

Gas Electrodes

The chlorine electrode employed a compartment consisting of a 10D sealing tube extended to 20 cm and closed on top. A tungsten wire was sealed through the top and reached to the frit, parallel to a glass tube, 5 mm outer diameter, which served as a feed-in tube for chlorine gas and which also entered the compartment near the top. A second tube on top of this half cell was used as a gas outlet. The chlorine gas was dried over phosphorus pentoxide before being fed through Teflon tubing to the electrode.

Chlorine gas was first bubbled through the melt rapidly to saturate the melt and displace the nitrogen above it. Then time was allowed for the melt to reach thermal equilibrium, until the potential became stable within 1 mV. It was ascertained by several more small additions of chlorine and successive equilibrations that the melt was truly saturated with chlorine gas.

The bromine cell differed from the above by an additional 10/35 standard taper joint on top, into which a small dropping funnel containing liquid bromine was fitted. At first a total of 5 ml of bromine was added in small portions to saturate the melt with bromine, as well as to replace the nitrogen above it by bromine vapor. Bromide ion was produced by coulometric reduction of bromine in the compartment at a tungsten electrode operated at low current densities. The melt was occasionally checked for bromine saturation by addition of small amounts of bromine as described above for the chlorine electrode.

Results and Discussion

The standard states used in this work are those defined previously (2, 14). The reference electrode used for all standard or measured potentials is Al(III)/Al(0), for which the standard and measured potentials are the same. The standard potentials calculated for all couples are given in Table I.

Chlorine

To establish the potential span of the melt in terms of standard potentials, the e.m.f. of the Cl_2/Cl^- couple was measured precisely. Wade *et al.* (6) reported a value of 2.09 ± 0.04 V for this couple at 156 °C. Treadwell and Terebesi (15) found 2.062 V at 721 mm Hg and 135 °C in a slightly different ternary system (62 mole % $AlCl_3$, 26 mole % NaCl, and 12 mole % KCl). The temperature dependence at a platinum electrode, as measured against an Al(III)/Al(0) reference electrode, was − 0.72 mV/°C.

The present study reports a standard potential of 2.064 ± 0.002 V at 135 °C and 1 atm, the standard and measured potentials for this couple being the same. The temperature dependence of the electrode from 120 to 180 °C was −0.65 ± 0.03 mV/°C. No hysteresis was observed.

Identical potentials were obtained for chlorine in the $AlCl_3$–NaCl–KCl melt with carbon and tungsten electrodes. It must be noted that the carbon electrodes disintegrated slowly upon contact with the melt to give carbon powder. This, however, did not give rise to an observable change in potential. Apparently this disintegration, which also occurs in the melt in the absence of chlorine, is due to the high content of aluminum trichloride since carbon electrodes have been used successfully in the $NaAlCl_4$ melt (1).

Bromine

The molal standard potential of the Br_2/Br^- couple was found to be 1.785 ± 0.002 V at 135 °C and 1 atm. The temperature dependence of this couple was measured as −0.16 ± 0.03 mV/°C from 120 to 170 °C.

Gallium

Gallium metal was anodized at low current densities to form Ga(I) (Fig. 1). The Nernst plot indicated a slope of 81 mV/log unit for this process, corresponding to 1.0 ± 0.1 electrons. The molal standard potential was 0.222 ± 0.002 V. Voltammetry with an inert tungsten electrode indicated the presence of an anodic wave corresponding to the oxidation of Ga(I). Quantitative coulometric oxidation at a platinum electrode at 5 mA/cm^2 showed this to be a two-electron process. The plot of log (Ga(I)/Ga(III)) vs. e.m.f. (Fig. 2) resulted in a straight line whose slope corresponded to 2.2 ± 0.1 electrons. A

standard potential of 0.766 ± 0.002 V was measured at equal concentrations of Ga(I) and Ga(III). The voltammetric value of 0.77 ± 0.02 V is in good agreement (Fig. 3).

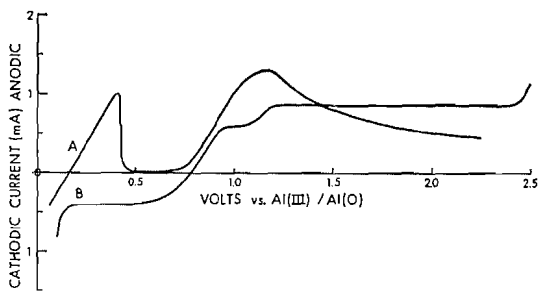

FIG. 3. Voltammetry of gallium ions. A, 0.1 molal Ga(I), 0.04 V/s; B, 0.05 molal Ga(I), 0.05 molal Ga(III), 0.02 V/s. Tungsten microelectrodes, scan direction toward the positive potential.

With these data it is possible to calculate the equilibrium constant. If the equilibrium reaction is defined as 1/2Ga(III) + Ga(0) ⇄ 3/2Ga(I), which involves a change of one electron, $K = 5.0 \times 10^{6}$ (Table II). The equilibrium constant is in molal units and is given by $K = [Ga(I)]^{3/2}/[Ga(III)]^{1/2}$.

Figure 3 shows two voltammetric curves of gallium solutions which were obtained with a tungsten microelectrode. Curve A represents the result of a scan of a solution approximately 0.1 molal in Ga(I) while curve B was obtained at equal concentrations of Ga(I) and Ga(III), about 0.05 molal. The peak of curve A is slightly broader than is usual in fused salts (16); this is due to the high IR drop across the cell resistance (250 Ω, primarily in the frit of the compartment). Curve B shows waves rather than peaks. The first anodic wave in curve B is followed by a second, suggesting further oxidation of Ga(III). However, a voltammetric scan of a solution of pure $GaCl_3$ shows no such second anodic wave, and the cathodic wave observed on attempted reduction of Ga(III) to Ga(I) appears at the expected potential. The shapes of the second anodic wave (curve B) and the cathodic reduction wave are not simple; the significance of this is not clearly understood and may be due to slow kinetic steps in the oxidations and reductions involved.

Indium

Indium metal in contact with the melt reacts with it completely to give aluminum metal. From the amount of indium metal put into the melt and, in the case of a complete reaction, of aluminum metal obtained, it was ascertained that In(I) was formed in solution by the reaction Al(III) + 3In(0) → Al(0) + 3In(I). The In(I)/In(0) couple must therefore be more negative in potential than the Al(III)/Al(0) couple. Monovalent indium can be further oxidized within the melt range; a voltammetric scan indicates oxidation at 1.2 ± 0.1 V. Likewise, the addition of $InCl_3$ and subsequent scanning results in a cathodic wave at 1.1 ± 0.1 V. More precise potentiometric measurements could not be made because $InCl_3$ scarcely dissolves into the melt even if the temperature is raised to 220 °C, while In(I) could not be quantitatively oxidized at higher In(I) concentrations. The waves seen in voltammetry must, however, correspond to the oxidation of In(I) to In(III) and the reduction from In(III) to In(I).

The data obtained allow estimation of the lower limit of K for the reaction 1/2In(III) + In(0) $\rightleftarrows$ 3/2In(I) as 4×10^{13}.

Thallium

Thallium metal also reacts with the melt with production of aluminum. It was shown, by the method described above for indium, that thallium exists as Tl(I) in the melt. It is, however, not possible to further oxidize Tl(I) to Tl(III) inside the melt range. The lower limit of the equilibrium constant for 1/2Tl(III) + Tl(0) $\rightleftarrows$ 3/2Tl(I) can then be estimated as 4×10^{25}.

Copper

Wade *et al.* (6) measured the decomposition potential of Cu(I) from which a value of $E^0 = 0.81 \pm 0.03$ V was calculated (14) on the mole fraction scale. He made no attempt to oxidize Cu(I) to Cu(II). In the present study, potentials of both the Cu(I)/Cu(0) and Cu(II)/Cu(I) couples were measured accurately, which allowed the determination of their standard potentials and equilibrium constants. A value of 0.710 ± 0.002 V was obtained for the molal standard potential of the Cu(I)/Cu(0) couple. Cu(I) was then oxidized coulometrically at inert electrodes in the same manner as Ga(I).

Plotting the coulometric data as log [Cu(I)]/[Cu(II)] vs. e.m.f. resulted in a straight line with a slope corresponding to 1.0 ± 0.1 electrons. The standard potential was measured at equal concentrations of Cu(I) and Cu(II) as 1.866 ± 0.001 V. The solution of Cu(II) in this melt shows the well-known green color of chloride-solvated Cu(II) while the solution of Cu(I) is colorless. The equilibrium value for the reaction Cu(II) + Cu(0) $\rightleftarrows$ 2Cu(I), with K defined using molal concentrations, is $K = 2.1 \times 10^{14}$ which is much larger than the aqueous value of 5.9×10^{-7} (18); the equilibrium in acetonitrile, however, is favored by an even larger constant of 2.5×10^{25} (19).

Silver

The couple Ag(I)/Ag(0) has been measured previously (2) at 150 °C and a value of 0.795 ± 0.001 V was reported. In the present study the molal standard potential obtained was 0.719 ± 0.001 V at 135° with a temperature dependence of -0.44 ± 0.03 mV/°C from 120 to 170 °C. The temperature vs. e.m.f. plot did not show any hysteresis. The Nernst slope corresponded to 1.0 ± 0.1 electrons. Anodizing silver in another experiment at 150 °C resulted in a value of 0.729 V for the standard potential with $n = 1.1$. The experimental conditions such as concentration and current densities during anodization were identical to the ones of the previous runs at 135 °C. However, weighing the silver wire before and after the experiment disclosed that more silver metal was lost than corresponded to the faradaic process. Reducing the amount of melt inside the compartments in another run resulted in a molal standard potential of 0.736 V with $n = 0.97$. The amount of silver lost was always significantly larger than corresponded to the faradaic process. This, together with the consistent value of one electron, seems to suggest a complex silver species, e.g. Ag_q^{p+} with q and p depending on the experimental conditions. Although complex silver ions have not thus far been observed in fused salts, species like Bi_5^{3+} are known (20) in chloroaluminate melts. It should therefore not be assumed that the potential measured for this couple corresponds to the simple reaction $Ag^+ + e^- \rightleftarrows Ag$. The matter is discussed in more detail in the Thesis of the junior author.

Gold

Gold was anodized into solution at low current densities with a slope corresponding to 1.1 ± 0.1 electrons. Several of the earlier anodization runs were unsuccessful in that no stable potentials could be obtained. Inspection of the gold wire after these experiments showed that anodization had occurred only in a few spots where it had resulted in the formation of deep pin holes. The holes showed the crystalline structure of the metal wire. It was found that remelting the wire before use tended to prevent deep holes although dissolution was still not uniform. Stable potentials were thus obtained, however, and a molar standard potential of 2.046 ± 0.002 V was calculated for the Au(I)/Au(0) couple. This value is much higher than those for Cu(I)/Cu(0) and Ag(I)/Ag(0). The solution containing Au(I) is orange in color while those of Cu(I) and Ag(I) are colorless, which may indicate that the solvation of Au(I) is different from that of the other two ions.

Conclusion

As Table II clearly shows, chloroaluminate melts favor the existence of lower-valence ionic species more strongly than water or chloride melts. This appears to be a general phenomenon

in which the chlorides, strongly polarized by aluminum, are unable to donate as much electron density toward stabilization of the higher valence state, rather than a specific characteristic of the elements studied. The nature of the actual chloroaluminate species and its effect on other metal ions are being investigated.

Relaxations of molecular charge distributions and the vibrational force constants in diatomic hydrides

R. F. W. BADER AND J. L. GINSBURG
Department of Chemistry, McMaster University, Hamilton, Ontario
Received February 24, 1969

The force constants for LiH, HF, NaH, and HCl are calculated from Hartree–Fock wavefunctions by a polynomial fit of the forces exerted on the nuclei as a function of the internuclear separation. The magnitude of the force constant is interpreted in terms of the relaxation of the molecular charge distribution induced by the nuclear displacement. In LiH or NaH, for which the molecular charge distribution exhibits the characteristics of ionic binding, two distinct relaxations are evident: a relaxation in the region of the cationic core and a relaxation of the density localized on the proton. The relaxation of the charge density in the vicinity of the Li^+ or Na^+ core opposes the motion of either nucleus while the relaxation of the density localized on the proton facilitates the displacement of the nuclei. In HF or HCl the relaxation of the molecular charge distribution is dominated by one continuous region of charge increase (for bond contraction) or decrease (for bond extension) over the whole of the binding region, a relaxation which facilitates the motion of the nuclei. Thus the relaxation of a molecular charge distribution and its effect in determining the magnitude of the force constant is dominated by the same features of the static charge distribution which serve to distinguish ionic from covalent binding.

Canadian Journal of Chemistry, 47, 3061 (1969)

I. Introduction

In a previous paper (1) we presented an interpretation of the vibrational force constant in terms of the relaxation of the molecular charge distribution. The study was concerned with the origin and variation in the magnitude of the force constants through the two series of molecules N_2, CO, BF and BeO, LiF. The present paper extends this study to the diatomic hydrides, specifically to the molecules LiH, HF, NaH, and HCl. The force constants for hydride molecules have been the subject of numerous theoretical investigations, most of them based on assumed models of the charge distribution and employing simplifying assumptions regarding the manner in which the charge density changes during a vibrational motion (2–5). In this work the force constants are calculated from and interpreted in terms of charge distributions obtained from Hartree–Fock (H.F.) wavefunctions, functions which are known to give the charge density and its dependent properties correct to second-order (6).

Previous publications have presented an interpretation of chemical binding in terms of the molecular charge distribution, the density difference distribution $\Delta\rho_{SA}(r)$, and the forces which the charge distribution exerts on the nuclei (7–10). The $\Delta\rho_{SA}(r)$ distribution is obtained by subtracting from the molecular charge distribution the distribution obtained from the overlap of the component atomic densities with the nuclei situated at the same internuclear separation as found in the molecule. These studies provide detailed knowledge of the spatial distribution and polarizations (relative to the atomic densities via the $\Delta\rho_{SA}(r)$ distributions) of molecular charge densities covering the spectrum of possible bond types from the covalent to the ionic extremes. A knowledge of the properties of the equilibrium charge distributions is a necessary prerequisite for the understanding of the force constant since the dominant characteristic of the relaxation of a charge distribution caused by a nuclear motion, whether it opposes or facilitates the motion of the nuclei, is directly determined by the polarizations present in the static charge distribution of the undistorted molecule (1). The initial study determined the nature of the relaxation of the molecular charge distribution associated with the motions of nuclei of first-row atoms in the two extremes of binding, ionic and covalent. The terms ionic and covalent as used here are defined in terms of the properties of the molecular charge distribution (7–10). In the present work the dominant characteristics of the relaxation of the charge distribution accompanying the motion of a proton in the two binding situations are to be determined. The four hydride molecules considered will make possible both intra- and inter-row comparisons of the relaxation characteristics.

†$K_3{}^e$ denotes the electronic contribution to the cubic potential constant.
‡A negative force implies a force of attraction.

II. Calculation of the Force Constants

In what follows we give a brief summary of the methods used in the calculation and interpretation of the force constant (1). The force on nucleus A in a diatomic molecule AH is given by (11)

$$[1] \quad F_A = \frac{-dE}{dR} = \frac{\partial E}{\partial X_A} = \frac{Z_A Z_H}{R^2} - Z_A \int \rho(r) \frac{\cos\theta_A}{r_A{}^2} dr$$

where $\rho(r)$ is the molecular charge distribution expressed in terms of space-fixed coordinates r, and r_A and θ_A are polar coordinates centered on nucleus A. A change in the nuclear positions causes a change in the charge distribution and hence a change in the forces acting on the nuclei. Thus the electrostatic interpretation of binding in terms of the forces exerted on the nuclei afforded by eq. [1] may be extended to the interpretation of the vibrational potential constants as well. In particular, the second-order potential constant is given by

$$[2] \quad K_{2A} = K_A = \left(\frac{d^2E}{dR^2}\right)_{R_e} = \left(\frac{\partial^2 E}{\partial X_A{}^2}\right)_{R_e} = \frac{2Z_A Z_H}{R_e{}^3} - Z_A \frac{\partial}{\partial X_A} \int \rho(r) \frac{\cos\theta_A}{r_A{}^2} dr$$

A corresponding equation may be written for K_H.

The wavefunctions employed in this investigation were obtained by Cade and Huo (12) and are claimed to be close to the Hartree–Fock limit. From these functions, the forces on each nucleus were calculated at seven values of R. The points other than R_e (the Hartree–Fock value) were regularly situated with respect to R_e. The potential constants were then determined from a Dunham expansion of the force curve. The coefficients of the expansion were obtained by a five-term Tchebycheff polynomial best fit, which was at all times checked against a least-squares fit of the same degree in order to ensure consistency of the method. In Table I, we present the harmonic force constants and the cubic constants K_3 obtained from a fitting of the force curves for the A and H nuclei in the four hydride molecules. These results are compared with the experimental values and with the values of K_2 obtained by Cade and Huo (12) by a Dunham analysis of the potential energy curve.

The values of K_2 calculated from the force curves for the proton K_H are in fair agreement with experiment, the values for the hydrides LiH and NaH being in error by 4 and 6%, while the values for HF and HCl are in error by 18 and 17%, respectively. The values of K_H are in agreement with the values of K_2 calculated from the curvature of the potential energy curves. The agreement with experiment of the K_2 values determined by the force curves for the A nuclei

is less satisfactory[1]. Kern and Karplus (6) have shown that it is a requirement of the true Hartree–Fock wavefunction that $F_A = F_H$ for all values of R. From this it follows that $K_A = K_H$, the equality of the force constants providing an even more stringent test of how closely a given wavefunction approaches the Hartree–Fock limit. The value of K_2 as determined by an energy fit should also equal the value determined by a fitting of the force curve for an exact Hartree–Fock result. Table I shows that the condition $F_A = F_H$ (= 0 at R_e(H.F.)) is most closely met for the first-row hydrides. There is a larger discrepancy between F_A and F_H for the second-row results, including a difference in sign. The calculated values of F_A and hence K_A are expected to deteriorate as Z_A increases. It should be pointed out that the force and force constant criteria given above for the true Hartree–Fock limit are very stringent and perhaps impossible to attain from any analytical expansion of the wavefunction with the coefficients of the basis orbitals given to only five or six significant figures.

The values of K_A and K_H are accurate enough to warrant the interpretive analysis which follows. The important quantities for this analysis are the polarizations present in the charge distributions, and comparison of the Hartree–Fock results with more accurate functions (13, 14) indicates that the Hartree–Fock functions provide excellent representations of the overall distribution of the charge densities.

III. Interpretation of the Force Constant

Schwendeman (15) has shown that when the charge distribution is expanded in terms of a coordinate system which is centered on A and which *translates with center A*, denoted by $\rho(\alpha,r_A)$, the entire electronic contribution to K_A may be expressed as

$$[3] \quad \frac{\partial}{\partial X_A}\int \rho(\alpha,r_A)\frac{\cos\theta_A}{r_A^2}\,d\tau = \int \frac{\partial\rho(\alpha,r_A)}{\partial X'_A}\frac{\cos\theta_A}{r_A^2}\,d\tau_A = K_A^e$$

The prime on the X-coordinate of nucleus A in the differentiation implies that the derivative of $\rho(\alpha,r_A)$ is to be taken only through the parameters α in $\rho(\alpha,r_A)$ which change as the internuclear distance is changed.

$$\frac{\partial\rho(\alpha,r_A)}{\partial X'_A} = \sum_\alpha \frac{\partial\alpha}{\partial X_A}\frac{\partial\rho(\alpha,r_A)}{\partial\alpha}$$

In the present expressions for $\rho(\alpha,r_A)$, the parameters α refer to orbital coefficients and exponents, which because of the fixed nucleus approximation, depend parametrically on the internuclear separation. Equation [3] states that any portion of the charge density which moves rigidly with nucleus A does not contribute to the force constant; only a change in the charge distribution, a polarization or a change in polarization, i.e., a "relaxation" of the charge density can contribute to the force constant governing the motion of nucleus A. The "relaxation" of a molecular charge distribution for the motion of nucleus A as defined by $\partial\rho(\alpha,r_A)/\partial X'_A \neq 0$ may be presented pictorially by subtracting the charge distribution for $R = R_e$ from that obtained for $R \neq R_e$, and at the same time holding the position of nucleus A fixed in space. Since

$$\partial\rho(\alpha,r_A)/\partial X'_A = -\partial\rho(\alpha,r_A)/\partial X_B$$

and

$$\partial r_A/\partial X_B = 0$$

the only contributions to a density difference map obtained by holding A fixed and moving B will arise from those parts of the charge density which do not remain rigidly attached to nucleus A. Such a map thus exhibits the relaxation of the charge density with respect to the motion of nucleus A and represents the entire electronic contribution to the force constant. For interpretive purposes, however, a breakdown of the total relaxation effect is necessary and is indeed suggested by the following analysis. When the charge density is expanded about and tied to center A, any density which remains rigidly

[1]In the previous paper dealing with the force constants in N_2, CO, BF, BeO, and LiF, substantially better agreement was obtained between the calculated and theoretical values of the force constants when the forces were expanded about R_e (exp.) rather than about R_e (H.F.). A rationalization of this observation was given based on the fact that for all the above molecules R_e (H.F.) < R_e(exp.) as is indeed expected. This latter inequality is true for HF and HCl as well and the errors in the value of K_H using R_e(exp.) for these two molecules are reduced to 1 and 11%, respectively. However, for some reason, R_e(H.F.) > R_e(exp.) for LiH and NaH. Not surprisingly, the error in K_H is increased for these molecules (to 8 and 14%, respectively) if R_e(exp.) is employed rather than R_e(H.F.) in the expansion of the forces.

bound to the second nucleus, inner shell density, for example, will appear to relax with respect to a motion of the A nucleus, since it remains fixed to B as A is displaced. If we wish to reserve the term relaxation for changes in the density distribution which do not include rigid following of either nucleus, then the contribution to K_A^e from density which remains rigidly attached to B as A is moved should be treated separately. We have, in fact, previously shown that there is no real distinction between a relaxation with respect to A and a static field gradient contribution from density rigidly fixed to B (1). That is,

$$[4] \quad -\int \frac{\partial \rho_B(\alpha, r_A)}{\partial X_A} \frac{\cos\theta_A}{r_A^2} \, dr_A = (4\pi/3)\rho_B(A) - \int \rho_B(\beta, r_B) \frac{3\cos^2\theta_A - 1}{r_A^3} \, dr$$

Equation [4] states that the contribution to the relaxation integral from density bound rigidly to B, but expanded from center A, is equal to $(4\pi/3)$ times the amount of charge density which ρ_B places at the position of the A nucleus $\rho_B(A)$, plus the electronic field gradient which ρ_B exerts at A. The former term is small relative to the latter and actual calculations show that the difference between the electronic force constant contribution from ρ_B and its static field gradient is very small, of the order of a few %.

The approach outlined above requires a partitioning of the total charge density into atomic components on B, ρ_B, and on A, ρ_A, leaving a delocalized component, ρ_{AB}. While there is no unique way in which such a partitioning may be carried out, the identification of ρ_A, ρ_B, and ρ_{AB} with the usual atomic and overlap populations obtained from the wavefunctions used in this study does, in general, yield physically meaningful results. The molecular Hartree–Fock wavefunctions used in the present study were obtained by starting with a consistent set of accurate atomic basis sets sufficient in size to yield Hartree–Fock solutions for the atoms, to which are added the minimum number of orbitals with higher l values required to adequately describe the polarizations and distortions encountered in forming the molecule from atoms (12). All orbital exponents were then reoptimized. In this way the best orbital description of the atoms is built into the molecular basis set with a minimum of alterations. Since this procedure is followed consistently for all the hydrides, comparisons between molecules of quantities based on the derived populations should be meaningful.

The total electronic contribution to the force constant is partitioned into a contribution K_A^{AA} from the atomic density ρ_A, K_A^{AB} from the delocalized or overlap density ρ_{AB}, and K_A^{BB} from the atomic density ρ_B. Each of these quantities has in turn been multiplied by $R_e^3/2$, a factor which converts their values into an equivalent number of charges. These contributions were determined by separate polynomial fits of the corresponding atomic and overlap contributions to the forces on the A or H nuclei.

The final working expression for the force constant for the displacement of the A nucleus with the proton held fixed in space is

$$[5] \quad K_A = \frac{2Z_A}{R_e^3}[(Z_H - K_A^{HH}) - K_A^R]$$

where $K_A^R = (K_A^{AA} + K_A^{AH})$ represents the total relaxation contribution. The first term in brackets $(Z_H - K_A^{HH})$ is the *net* unshielded nuclear charge on the proton. As discussed above, the contribution to K_A from the atomic charge density on the proton may be interpreted as a field gradient effect and $(Z_H - K_A^{HH})$, when multiplied by $2/R_e^3$, is the static field gradient contribution to K_A from the proton and its associated charge density. Its value may be less than or greater than zero depending on whether charge density is transferred to or removed from the proton in the formation of the molecule. The relaxation contribution K_A^R is different from zero only if ρ_A and ρ_{AH} do not rigidly follow the displacement of the A nucleus. For example, if the relaxation of the charge density corresponds to a polarization or transfer of charge density in the direction of motion of nucleus A, thereby facilitating the nuclear motion, $-K_A^R$ is negative in sign and hence, by eq. [5], will decrease the force constant. If, on the other hand, the relaxation corresponds to a transfer of charge density in a direction counter to the motion of nucleus A, the effect of the relaxation will be to oppose the motion of the nucleus. The value of $-K_A^R$ will be greater than zero and the magnitude of the force constant will be increased. An equation corresponding to [5] may be written for K_H expressed in terms of K_H^R and $(Z_A - K_H^{AA})$.

The contributions to the force constants for a displacement of the A nuclei are given in Table

TABLE II

Contributions to the force constants K_A

AH	$-K_A^R$	$-K_A^{HH}$	$Z_H - K_A^{HH}$
LiH	0.219	−0.885	0.115
NaH	0.497	−1.397	−0.397
FH	−0.711	−0.075	0.925
ClH	−0.344	−0.583	0.417

II, and Fig. 1 gives a pictorial representation of the accompanying relaxations when the displacement corresponds to a bond extension. These contour maps were constructed in the manner outlined in Section II. They do not, however, include the atomic density on the proton since its contribution to the force constant is primarily that of a static field gradient.

The contour maps of the total charge distribution of LiH and NaH show the charge density in each case to be almost totally localized in near spherical contours centered on the Li or Na and hydrogen nuclei (8, 10). The amount of charge in these localized components and their radii are consistent with those expected for Li^+, Na^+, and H^- ions. These properties of the charge distributions and an analysis of the forces which they exert on the nuclei indicate that the binding in LiH and NaH is ionic. The relaxation maps for the LiH and NaH molecules in Fig. 1 reflect this localization of the total charge densities. Both maps exhibit two distinct relaxations: a relaxation in the regions of the Li^+ and Na^+ ion cores[2] and a relaxation of the density localized on the proton.

It is clear from the presence of the term $\cos\theta_A$ in the relaxation integral, eq. [3], that only the dipolar component of the charge relaxation contributes to K_2. Both relaxations indicated in the contour maps for LiH and NaH exhibit large dipolar characteristics, but the relaxation in the regions of the cationic cores will, in each case, dominate the relaxation because of the $1/r_A^2$ dependence of the relaxation integral. The core relaxations in both LiH and NaH correspond to a flow of charge in a direction counter to the direction of the displacement of the cationic nucleus, therefore opposing nuclear displacement. The relaxation of the density around the proton is in the same direction as that in the regions of the cores, resulting in a transfer of charge density from the binding to the antibinding region of the proton and thereby facilitating displacement of the Li or Na nucleus. The total relaxation effect is, however, dominated by the relaxation in the region of the Li^+ and Na^+ cores and the net effect of the relaxation in both molecules is to impede the motion of the displaced nucleus. As seen from Table II, $-K_A^R$ is positive for both LiH and NaH in accordance with the above conclusions. A positive contribution to K_2 from the relaxation of the charge density was also found for a displacement of the Li nucleus in LiF and the Be nucleus in BeO, and is a characteristic feature of ionic binding (1).

The molecular charge distributions of HF and HCl exhibit contours of high value which encompass both nuclei and large, continuous concentrations of charge density in the region between the nuclei. Unlike the LiH and NaH molecules in which both nuclei are bound by the charge density transferred to and localized on the proton, the nuclei in HF and HCl are bound by the density which is accumulated and shared in the region between the two nuclei. The binding is covalent (8, 10). The differences in the disposition of the total charge density between the hydrides from the two extremes of the periodic table are reflected in their respective relaxation densities. Thus the relaxation of the charge densities in HF and HCl for a displacement of the heavy nucleus is characterized by one continuous region of charge depletion between the nuclei[3]. Charge density is removed from the antibinding regions of the F and Cl nuclei as well but not to as great an extent as from the binding region. The charge increase at the F and Cl nuclei is restricted to a belt-like region perpendicular to the bond axis at the positions of these nuclei. Since the relaxations result in a more extensive loss of charge density from the binding regions than from the antibinding regions of the F and Cl nuclei, the relaxation facilitates outward displacements of these

[2]The relaxation of the Na^+ "KL core" actually exhibits three polarizations, a reflection of the more complex static polarizations of the core density found in the second-row molecules compared to that found in the first-row. This feature will be discussed more fully below. The outermost and dominant polarization induced in the region of the Na^+ core is, however, in the same direction as that found for the Li^+ core and the initial discussion will be concerned with this particular polarization.

[3]The "KL" core of Cl exhibits a polarization as well, but the relaxation of the valence density is similar in form to that observed for HF.

nuclei. Thus, as seen from Table II, the values of $-K_A{}^R$ for the covalently bound hydrides HF and HCl are large and negative and the relaxations decrease the force constants. A relaxation which facilitates the motions of the nuclei is characteristic of covalent binding (1). The magnitude of $K_F{}^R$ is greater than that of $K_{Cl}{}^R$ since the principal relaxation, that of the valence density, is excluded from the immediate region of the Cl nucleus by the presence of the large "KL" core density on this nucleus. The relaxation of the core itself results in a more symmetrical redistribution of the charge as can be seen most clearly from the profile of the relaxation diagram. Consequently its contribution to $-K_{Cl}{}^R$ is relatively small.

In summary, the relaxation of the charge distribution of a diatomic hydride is such as to oppose the displacement of the heavy nucleus when the binding is ionic and to facilitate the motion when the binding is covalent. In spite of the relaxation contributions favoring a larger force constant for the ionic molecules, the force constants for the covalently bound molecules are greater than those for molecules with ionic binding. The reason for this is to be found in the much larger positive field gradient contributions to K_A (or K_H) in the covalent as opposed to the ionic cases. It is characteristic of covalent binding that the charge density in the regions of *both* nuclei are considerably decreased (7) thereby giving rise to large unshielded nuclear charges and hence to large net field gradient contributions $2(Z_H - K_A{}^{HH})/R_e{}^3$ and $2(Z_A - K_H{}^{AA})/R_e{}^3$. In ionic binding, the shielding of one nucleus is increased and the other decreased by the transfer of charge density from one center to the other in the formation of the molecule. However, as shown below, the deshielding of the Li or Na nucleus in the ionic hydrides does not approach in magnitude the deshielding of the F or Cl nuclei in the covalent hydrides.

The values of $K_A{}^{HH}$ in Table II may be interpreted as the number of electronic charges which when placed at the position of the proton exert the same field gradient at the A nuclei as do the atomic charge populations on the protons in these molecules. As expected, this number is least for HF, where the charge equivalent of the field gradient exerted at F by the atomic charge density on the proton is only -0.075, and the charge equivalent of the net positive field gradient exerted at F, $+0.925$, is close to that exerted by a bare proton. The deshielding of the proton in HCl is much less severe and the net field gradient at Cl corresponds to approximately 2/5 of the protonic charge. The strength of the "A nucleus + core" electric field is reduced in the second-row hydrides because of the increased size of the KL-shell core relative to that of the K-shell core. In fact, the reduction in the effective field which the A nuclei of the second-row exert on the valence density is largely responsible for the differences between the binding of the proton in the first- and second-row hydrides (10). A direct consequence of the reduced field exerted by the Cl nucleus + core compared to that exerted by the F nucleus + core is the reduction in the extent to which the proton is deshielded in HCl compared to HF. The quantity $Z_H - F_A{}^{HH}$ is the charge equivalent of the net *field* exerted at the A nucleus by the proton and its associated charge density at R_e. In HCl this field is equivalent to $+0.463$ charges while in HF its value is $+0.876$. It is the *gradient* of this repulsive field which determines the value of the field gradient contribution $Z_H - K_A{}^{HH}$ to the force constant. If the atomic density on the proton, which is approximately spherical in its distribution, remained completely rigid during a displacement of the A nucleus, the *charge equivalents* for the field and field gradients at A would be identical. The two values differ by only 5% of a unit charge for both HF and HCl.

In NaH the net field gradient at the Na nucleus is *negative* because of the transfer of charge density to the proton. Surprisingly, the net field gradient contribution at Li in LiH is slightly positive[4]. This is, however, simply a case where the population analysis does not yield a valid description of the charge distribution. The ρ and $\Delta\rho$ maps (and separate maps for the individual populations) indicate that the overlap population in this molecule is, in fact, almost totally localized on the proton. The atomic nature of the overlap population is reflected in the relaxation map for LiH as well. If the positive and negative contours of the relaxation in the vicinity of the proton, a

[4]The almost complete rigidity of the atomic densities on the protons in LiH and NaH is evidenced by the near equality of the charge equivalents of the net fields and field gradients which they exert at the A nuclei. The charge equivalent of the field $Z_H - F_A{}^{HH}$, is $+0.110$ in LiH and -0.354 in NaH.

relaxation which arises from the overlap population, were exact mirror images of one another, the relaxation would correspond to the density remaining rigidly bound to the proton. Figure 1 shows that this is nearly the case in LiH, and to a lesser extent in NaH. In both cases the extent of charge removal exceeds slightly the charge increase in the region of the proton. An examination of the separate relaxation maps for the overlap populations indicates that the charge density lost from the region of the proton is transferred back to the cation. Thus, a small amount of valence charge density is transferred from H to Li or Na as the bond is extended. In LiH the transferred charge is placed in a tight, near spherical distribution centered on Li with an essentially zero dipolar component. In NaH on the other hand, the valence density transferred to Na is primarily responsible for the large diffuse charge accumulation on the bonded side in the region of the Na core. Thus in LiH the major contribution from the overlap density is a static field gradient effect and is, therefore, more suitably included with contribution from the atomic population or the proton. The addition of $-K_{Li}^{LiH}$ to $-K_{Li}^{HH}$ yields a net static field gradient of -0.341, and a relaxation contribution (which then equals $-K_{Li}^{LiLi}$) of $+0.675$.

Regardless of the imperfect nature of the breakdown of the contributions to the force constant, the following clear distinctions may be made between the ionic and covalent cases. The net field gradients exerted at the Li and Na nuclei arising from the proton and the charge density which moves rigidly with it, are negative. Thus the whole of the *positive* restoring force acting on the Li and Na nuclei when they are displaced from their equilibrium positions originates in a relaxation of the charge density in the core regions, a relaxation which results in a transfer of charge density in a direction opposite to the direction of the displacement. In contrast, the relaxation of the charge density in HF and HCl is such as to facilitate the motion of the nuclei as charge density is shifted in the same direction as that of the nuclear displacement. The large force constants for the covalently bound hydrides (relative to the ionic cases) are a result of the large gradient of the repulsive field exerted by the unshielded proton.

The fundamental difference which exists between the relaxation of an ionic and a covalent charge distribution is very clearly illustrated in Fig. 2. This figure illustrates the relaxation of the *total* charge densities for a displacement of Li and F nuclei in LiH and HF, as described[5] in Section II. In LiH the density on the proton follows its motion with almost complete rigidity as can be judged from the essentially complete antisymmetry of the relaxation with respect to a plane through the proton (see, in particular, the profile map for LiH). This justifies our ascribing the major contribution from the density localized on the proton in LiH to a field gradient effect. In HF the area of charge depletion extends over the whole of the binding region. The relaxation with respect to the proton is particularly unsymmetrical, with an obvious net loss of charge density. In this case the major contribution to the total relaxation integral arises from a non-rigid relaxation of the charge density. The opposite effects which the relaxations in the vicinities of Li and F have on the motions of these nuclei is clearly evident in these diagrams. Note that the spike-like charge increase at F also facilitates the outward motion of the F nucleus.

The forms of the relaxations are readily understood in terms of the static polarizations present in the equilibrium charge densities. The $\Delta\rho_{SA}(r)$ maps for LiH and NaH show that the densities localized on A and H are polarized in a direction *counter* to the direction of charge transfer from A to H (8, 10). These polarizations[6] are a necessary requirement for the attainment of electrostatic equilibrium in the face of an almost complete transfer of one electronic charge from Li to H or Na to H. Thus the relaxation of the charge density in LiH for bond extension represents a simple reversal of the static polarizations present in the equilibrium charge distribution. Since bond extension is the reverse of bond formation, the relaxation map should exhibit a reversal of (i.e., a decrease in) the polarizations present in the $\Delta\rho_{SA}(r)$ map, as this

[5]Such maps are meaningful only when the position of a proton is not held fixed in their construction. In any other case, the amount of charge density shifted with the nucleus displaced in the construction of the diagram is so great that it dominates the entire map.

[6]The transfer of valence density results in a net negative field and an attractive force on the Li or Na nucleus, and in a net positive field and a force of repulsion on the proton. These forces are balanced by the core densities of Li or Na being polarized away from the proton and the density localized on the proton being polarized towards the Li or Na.

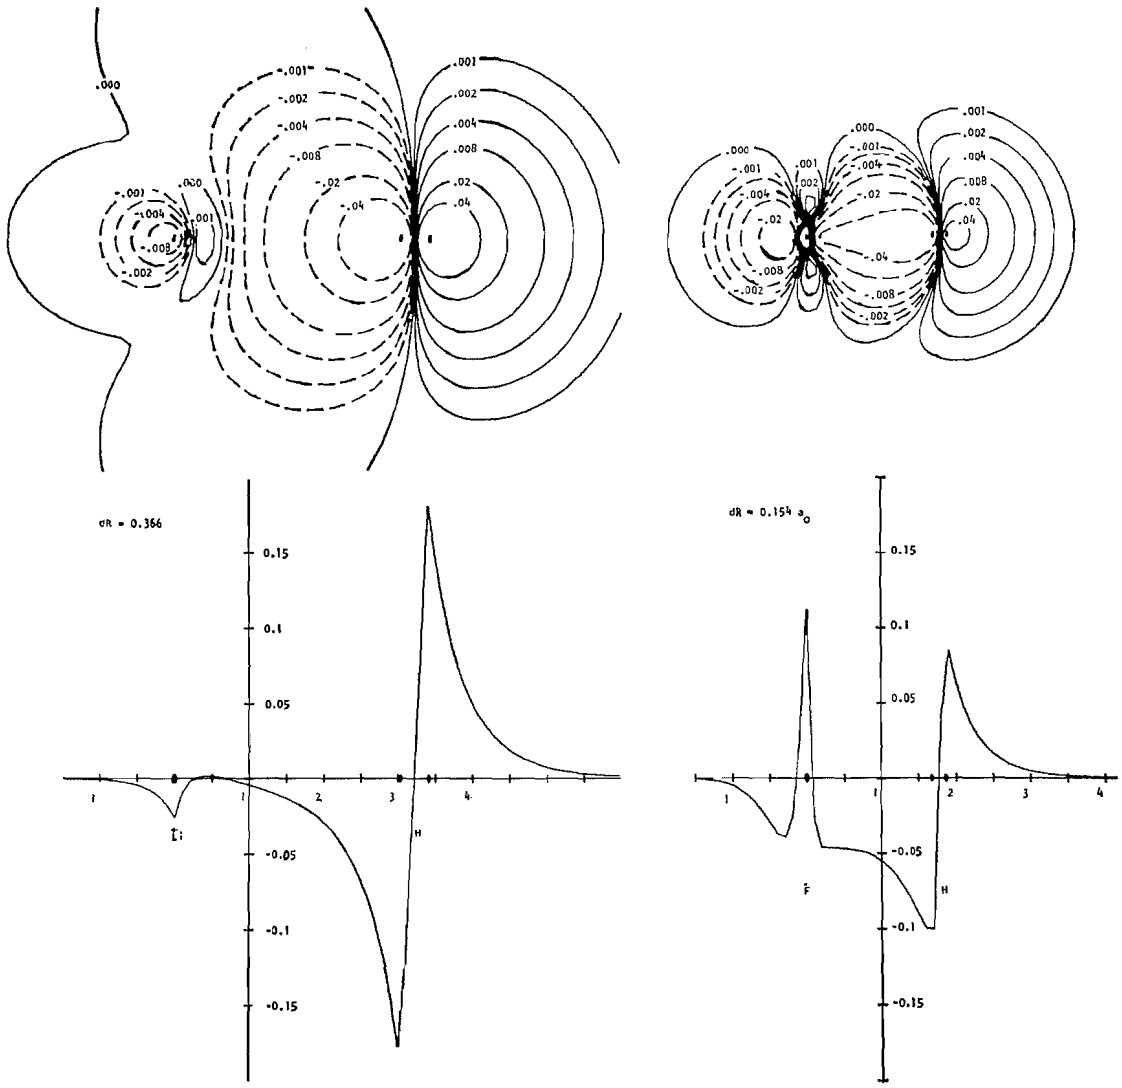

FIG. 2. Contour maps and profiles of the *total* electronic relaxations as seen from the A nuclei in LiH and HF for a bond extension.

latter map represents the total change in density on forming the bond from the separated atoms. A relaxation diagram for bond contraction would be of the same form as shown in Fig. 1, but with all signs reversed. A bond contraction thus *enhances* the polarizations depicted in the $\Delta\rho_{SA}(r)$ map, a bond extension *diminishes* them. The $\Delta\rho_{SA}(r)$ maps for HF and HCl exhibit large accumulations of charge density in the internuclear region. In addition, the density remaining on the A and H nuclei (as opposed to the molecules with ionic binding) is strongly polarized in the direction of charge transfer from H → A. The charge removal in the vicinity of either the F or Cl is restricted to a belt-like region perpendicular to the bond axis at the position of the A nucleus. Thus the dominant polarization induced in the valence densities of F and Cl by bond formation is quadrupolar, an increase in charge density along the bond axis on both the bonded and nonbonded sides of the A nucleus and a decrease from a torus-like region

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

perpendicular to the axis (16). The relaxation maps for a bond extension in HF and HCl represent a simple reversal of the polarizations present in the $\Delta\rho_{SA}(r)$ maps, including a reversal of the quadrupolar polarization in the regions of the F and Cl nuclei. Note that the polarizations of the charge densities in the vicinities of the H, Li, and Na nuclei are predominantly dipolar in character in both their $\Delta\rho_{SA}(r)$ and relaxation maps, a characteristic of atoms which employ principally s-type orbitals in forming chemical bonds (16).

Just as the dipolar components of the charge relaxation determines K_2, so the cubic constant K_3 is determined by the quadrupolar component (15). The much larger values of K_3 and their electronic contributions listed in Table I for HF and HCl compared to those for LiH and NaH are thus readily explained in terms of the polarizations evident in the relaxation maps (or the $\Delta\rho_{SA}(r)$ maps). In HF and HCl the binding is primarily the result of the participation of p-type orbitals and only in these two molecules is there a large quadrupole component in the charge reorganization accompanying a displacement of the nuclei.

The "KL" cores of Na and Cl require special comment (10). The transfer of valence density from around the Na^+ core to around the proton on bond formation induces an opposing polarization in the $2\sigma^2 \sim 2s^2$ and $1\pi^4 \sim 2p\pi^2$ densities in the direction ($\bar{A}$—H), which in turn is countered to a slight extent by a deeper axial attractive polarization of the $3\sigma^2 \sim 2p\sigma^2$ density (A—H), which is opposed by a back-polarization of the $1\sigma^2 \sim 1s^2$ density ($\bar{A}$—H) in the immediate vicinity of the Na nucleus. Unlike LiH, the residual "tail" of valence density in the region of Na is polarized in the direction ($\vec{A}$—H) in opposition to the back-polarized core (10). However, the net polarization of the atomic density on sodium is still the direction ($\bar{A}$—H).

As determined from both the separate relaxation maps for ρ_{Na} and from the negative sign of $-K_{Na}^{NaNa}$, the net relaxation of ρ_{Na} is not dominated by a reversal of the statically dominant core polarization which would oppose nuclear motion but by a relaxation of the valence "tail" which facilitates nuclear displacement. The total relaxation contribution, $-K_{Na}^{R}$, is positive because, as mentioned previously, the density transferred back from H^- to Na^+ builds up in front of and strongly opposes displacement of the Na nucleus. This rather more complex relaxation, compared to LiH, is mirrored in Fig. 1 and is especially clear in the profile. The sharp deficit at the nucleus (and unsymmetrically placed with respect to it) and the increase immediately adjacent to the nucleus represent a reversal of the $1s^2$ polarization. This is bounded by an increase of charge density on the nonbonded side and a decrease on the bonded side. This mostly represents a reversal of the residual $4\sigma^2$ polarization. Finally, the outermost deficit in density (so shallow that it is difficult to illustrate on the profile) is a reversal of the polarization of the $2s^2$ (and $2p\pi^4$ off the axis) density while the outermost increase on the bonded side of the Na nucleus is both a reversal of the $2s^2$ polarization and, more important, a result of charge transfer from H^- back to Na^+. Thus we see that the subtle dynamic interplay between core and valence densities complicates the simple connection between the static and dynamic picture which exists for LiH.

As the direction and extent of charge transfer changes in the formation of HA from HNa → HCl, the response of the core density changes. Thus in HCl, the outermost core polarization is now directed *towards* the proton in response to the transfer of valence density from H to Cl, the axial polarization is directed away from H and the inner $1\sigma^2$ ($\sim 1s^2$) polarization is directed towards H. The reversal of these polarizations and hence of their corresponding relaxations and their more evenly balanced nature compared to those of the Na core are evident in the profile diagram in Fig. 1. Note that the core, as well as the valence density of Cl, exhibits a quadrupolar-type relaxation.

Figure 3 illustrates the relaxation encountered in the four molecules for a displacement of the proton and the contributions K_H^R and K_H^{AA} are given in Table III. In both LiH and NaH there is a loss of charge from the vicinity of the proton[7]. The loss of charge is unsymmetrically placed

[7]These relaxation maps and those for the displacement of the A nuclei are self-consistent even though the maps in Fig. 1 indicate a charge increase in the antibinding region of the proton. Figure 1 depicts the change in density observed from an A nucleus as it recedes from a proton; Fig. 3 depicts the change in density as viewed from a proton as it recedes from an A nucleus. Any overlap density rigidly tied to the proton appears in Fig. 1 but not in Fig. 3. The striking extent to which the relaxation maps represent a reversal of the static polarizations in the $\Delta\rho_{SA}(r)$ maps can be seen by comparing the two distributions for LiH. (See ref. (8) for the $\Delta\rho_{SA}(r)$ plot for LiH.)

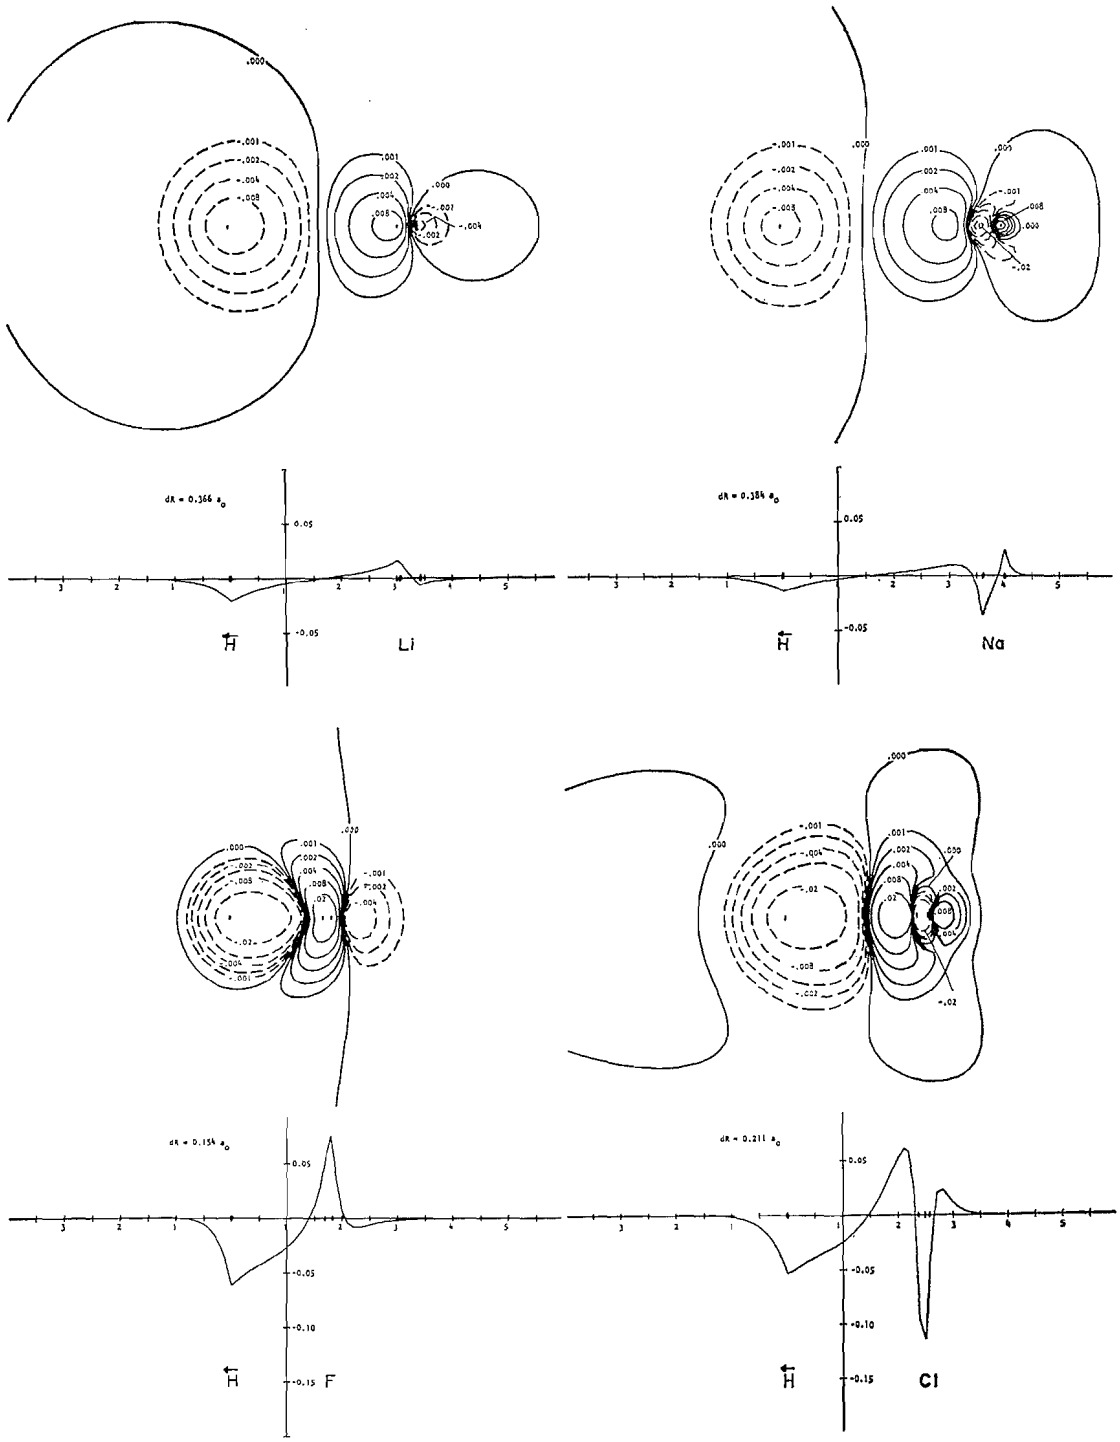

FIG. 3. Contour maps and profiles of the relaxation of the molecular charge distribution for an outward displacement of the proton.

TABLE III

Contributions to the force constants K_H

HA	$-K_H^R$	$-K_H^{AA}$	$Z_A - K_H^{AA}$
HLi	−0.121	−1.923	1.077
HNa	0.148	−9.893	1.107
HF	−0.850	−6.366	2.634
HCl	−1.667	−12.702	4.298

with respect to the proton such that less charge is removed from the region into which the proton moves than from the region it moves from. This relaxation thus facilitates the displacement of the proton in both LiH and NaH. Countering this, however, is the dipolar relaxation of the densities in the vicinities of the Li and Na nuclei, relaxations which concentrate charge density on the bonded side of the proton and oppose its outward displacement. (Note that both relaxations in LiH or NaH are in the same direction for a displacement of A or H. The relaxation in the vicinity of the Li or Na nuclei opposes the motion of either A or H, while that on the proton facilitates either motion.) The two opposing relaxations are more evenly balanced for a displacement of the proton than they are for a motion of the A nuclei and the magnitude of the relaxation contribution to K_H is small in both LiH and NaH. In LiH the net effect is to facilitate the displacement of the proton, while in NaH it opposes the motion. Figure 3 clearly indicates that the charge removal from the proton in NaH is much more symmetrically placed with respect to the proton than in LiH and hence it has a smaller dipolar component, while the induced polarization in the region of the Na core is greater than that in the region of the Li core.

The static field gradient contributions to K_H in LiH and NaH, $Z_A - K_H^{AA}$, are both nearly equivalent to a charge of +1.00 situated at the Li or Na nuclei, values corresponding to the presence of Li^+ or Na^+ ions. Because of the near cancellation of the opposing relaxations generated by a motion of the proton, the force constants in LiH and NaH are both approximately equal to the nuclear charge of the proton multiplied by the field gradient obtained from a *single positive charge* located a distance R_e away; $K_H \sim Z_H \times 2/R_e^3 = 2/R_e^3$. The present results regarding the differing behavior of the relaxations in the two molecules predict that for LiH, $K_2 < 2/R_e^3$ while in NaH, $K_2 > 2/R_e^3$. These are indeed the experimental results as the values of K_2 for LiH and NaH in units of $2/R_e^3$ are 0.896 and 1.41, respectively. The relationship $K_2 \sim 2/R_e^3$ for the ionic hydrides was first noticed by Bratož *et al.* (5). Salem (4) has shown how the result can be rationalized in terms of a simple charge model corresponding to A^+H^- with *rigid*, spherical, nonoverlapping charge distributions on both A^+ and H^-. With no relaxation effects whatsoever, it is clear from the present formulation of K_2 as well, that a simple ionic charge distribution will yield $K_2 = 2/R_e$. In actual fact, the relationship is not that closely obeyed and the relaxations in the vicinities of A^+ and H^- are important. It is interesting to note that of all the alkali metal diatomic hydrides, only for LiH is $K_2 < 2/R_e^3$. For the remaining members NaH to CsH, $K_2 > 2/R_e^3$ (4). Thus the relaxation of the charge density in the vicinity of the cationic core must be the dominant one in KH → CsH as in NaH. That the relaxation of the charge distribution is essential to the understanding of the force constants in the ionic hydrides is further illustrated by the fact that Salem's rigid ionic model predicts a *negative* force constant for a displacement of the cation, equal to $-2/R_e^3$. Furthermore, as shown above, the relaxation of the charge distribution provides the whole of the restoring force when the force constant of an ionic molecule is viewed from a displacement of the cationic nucleus.

It is interesting to note that in ionic fluorides and oxides, the contribution from the relaxation of the charge density localized on the anionic nucleus is considerably greater in magnitude than that of the H^--like distribution in the ionic hydrides and is always dominant (1). Thus the force constants in the ionic fluorides and oxides are all substantially less than the values anticipated on the basis of static field gradients of $2/R_e^3$ (for the fluorides) and $4/R_e^3$ (for the oxides). The relaxation in the fluorides, $-K_F^R$, reduces the unit positive charge contribution from the cation by approximately 2/3 in LiF → CsF and similarly in the oxides, $-K_O^R$, has the almost constant value of −1.35, more than halving the nuclear charge equivalent of +2.00 on the cation in BeO → BaO.

The relaxation contribution for a displacement of the proton in HF or HCl is large in magnitude and negative in value. The relaxation is very

unsymmetrical with respect to the proton in both cases with a much larger removal of charge density from the binding region than from the antibinding region of this nucleus. In HF the principal charge increase occurs in a belt-like region perpendicular to the bond at the position of the F nucleus. In HCl this same charge increase is shifted towards the proton. There is an additional counter polarization induced in the Cl core density. The relaxations in the regions of F and Cl mimic the reverse of the quadrupolar polarizations shown in the respective $\Delta\rho_{SA}(r)$ maps.

The $\Delta\rho_{SA}(r)$ maps for HF and HCl indicate that relative to the separated atom densities, a considerable amount of charge is removed from the antibinding region of the proton and transferred primarily to the binding region. One might anticipate that an outward displacement of the proton would result in a return of charge density to the proton and thus to a region of positive contours on the side of the proton in the direction of the displacement. Instead the relaxation maps indicate that the charge density in the vicinity of the proton is decreased in both the binding and antibinding regions and the dipolar nature of the polarization is reflected only in the unsymmetrical removal from the two sides of the proton. In fact, there is less charge density in the vicinity of the proton for values of R slightly larger than R_e than when $R = R_e$, as an examination of the molecular charge density as a function of R shows. For example, the $\Delta\rho_{SA}(r)$ map for HF at $R = 2.00$ a.u. ($> R_e$) indicates a loss of charge from the general region of the proton, from both the bonded and nonbonded sides. The charge lost by the proton is transferred to the F and accumulated along the bond axis in both its binding and antibinding regions with the typical quadrupolar-type polarization. As R is further decreased to R_e the proton *penetrates* the charge build-up in the binding region of F and the area of charge deficit remaining in the antibinding region of the proton is decreased in magnitude and extent. Thus the outward displacement of the proton from its equilibrium position does not result in a transfer of charge density from F $\rightarrow$ H, a phenomenon which does occur at larger R values, but instead in a reorganization of charge density in the vicinity of the F via a reduction in its quadrupole polarization. The relaxation map for HF in Fig. 3 clearly illustrates the removal of charge from the binding and antibinding regions of the F and its accumulation in a torus-like region at the F nucleus perpendicular to the bond. The equilibrium charge distribution in HF and its relaxation are both dominated by the field of the F nucleus.

The considerable penetration of the charge density localized on the F and Cl nuclei by the proton in HF and HCl is reflected in the large positive field gradients exerted at the proton by these nuclei and their associated atomic densities. The field gradients are equivalent to 2.6 and 4.3 nuclear charges at the positions of the F and Cl nuclei, respectively, and thus far exceed the corresponding values of approximately unity observed in LiH and NaH, values which correspond to the stripping of the valence density from Li and Na, leaving the cores intact. Thus when viewed from either a displacement of the proton or the A nuclei, the large force constants in HF and HCl compared to those in the ionic hydrides are a result of the large positive gradients of the repulsive forces, which result from the deshielding of both the A and H nuclei in formation of a covalently bound hydride. The relaxation of the charge density in such a situation always facilitates the motion of the nuclei as it is dominated by the accumulation (for a bond contraction) or removal (for a bond extension) of charge density from the binding region between the nuclei.

The simplest model for predicting K_2 of polar (in the sense $A^{\delta-}H^{\delta+}$) diatomic hydrides is that of Platt (2). In Platt's model the charge distribution in the hydride is taken as that of the corresponding united atom with $Z_A + 1$ electrons. The proton is assumed to penetrate the spherical charge distribution on A up to a separation R_e such that the sphere of volume $(4/3)\pi R_e^3$ contains Z_A electrons. This results in a zero force on the proton (but not on A). A simple electrostatic calculation then shows that if the charge distribution is assumed to remain rigidly bound to A as H is displaced, the force constant is equal to $4\pi\rho(H)$. The quantity $\rho(H)$ is the density at the position of the proton predicted by the united atom density distribution. The model thus predicts both R_e and K_2 and successfully mimics the variations in K_2 across the rows in the periodic table. Platt's result is easily derived in the present formulation. *Assuming a rigid spherical charge distribution* which remains tied

For personal use only.

to the A nucleus as the proton is displaced, and applying to this distribution the theorem previously proved (1) and expressed in eq. [4], we find

$$K_H = Z_H\left(\frac{2Z_A}{R_e^3} - \int \rho_A \frac{3\cos^2\theta_H - 1}{r_H^3}\,d\tau + \tfrac{4}{3}\pi\rho(H)\right)$$

However, the static field gradient at H of a spherical charge distribution centered on A and containing Z_A electronic charges in the sphere defined by R_e is given by

$$-\int \rho_A \frac{3\cos^2\theta_H - 1}{r_H^3}\,d\tau = -\frac{2Z_A}{R_e^3} + \tfrac{8}{3}\pi\rho(H)$$

Thus the nuclear field gradient is cancelled and the result for K_H is that obtained by Platt.

In actual fact the charge density of HA is not well approximated by the united atom density. We have previously presented diagrams of the density difference distribution

$$\Delta\rho_{UA}(r) = \rho_{HA}(r) - \rho_{UA}(r)$$

for the first- and second-row hydrides (8, 10) where $\rho_{HA}(r)$ and $\rho_{UA}(r)$ are the Hartree–Fock density distributions for HA and the corresponding united atom, respectively. The $\Delta\rho_{UA}(r)$ maps indicate that the density in the region of the proton is greatly underestimated by $\rho_{UA}(r)$ and in particular the value of $\rho(H)$, the important quantity in Platt's model, is in error by approximately 90%. The assumption regarding the rigidity of the charge distribution during displacement of the proton is, of course, also incorrect. However, the two assumptions lead to a cancellation of errors.

Following Clinton (17) we may investigate Platt's model in more detail by expressing the exact density distribution of the hydride as

$$\rho_{HA}(r_H) = \rho_{UA}(r_H) + \Delta\rho_{UA}(r_H)$$

Platt's result that $K_H = 4\pi\rho_{UA}(H)$ will be obtained (not necessarily at the correct value of R_e) if

$$\int \frac{\partial\Delta\rho_{UA}(r_H)}{\partial X'_H}\frac{\cos\theta_H}{r_H^2}\,dr_H = 0$$

that is, if the relaxation of the density difference distribution $\Delta\rho_{UA}(r_H)$ exhibits no dipolar component with respect to the proton. We have investigated the relaxation of $\Delta\rho_{UA}(r)$ for HF using a Hartree–Fock wavefunction for Ne. Platt's model, in this case[8], yields $R_e = 1.52$ and $K_H = 0.98$ a.u. A contour map of the relaxation of $\Delta\rho_{UA}(r)$ for HF indicates that its contribution might be expected to be small. The proton is encompassed by an unsymmetrical region of charge removal, one which facilitates the motion of the proton. Immediately adjacent to this region on the bonded side of the proton, however, is an even larger increase in charge density, an increase which opposes the motion of the proton. The net contribution from the relaxation of $\Delta\rho_{UA}(r)$ should be small. Thus Platt's model yields values for K_H of the right order of magnitude *not* because ρ_{HA} resembles or behaves as does a rigid ρ_{UA} but rather because $\rho(H)$ is greatly underestimated by ρ_{UA} and the relaxation contribution from the error in the density $\Delta\rho_{UA}(r)$ is small.

[8]It should be pointed out that when a Hartree–Fock wavefunction is used in Platt's model for the united atom the results obtained are not as satisfactory as those obtained originally by Platt who used Hartree (self-consistent field without exchange) or simple Slater functions.

Received January 16, 1969

The complexes PdL_2X_2 (L = p-nitrosodimethylaniline, p-nitrosodiethylaniline; X = Cl, Br, I) have been prepared. The principal absorption band in the visible spectra of the complexes has been identified as a π–π^* transition centered primarily on the ligands on the basis of its high oscillator strength, the similarity of the latter to that of the free organic ligand, and the insensitivity of the band position to the nature of the halide. Infrared data indicate that palladium is bonded through the NO group.

Canadian Journal of Chemistry, 47, 3075 (1969)

p-Nitrosodialkylanilines have been used for the colorimetric determination of palladium and platinum for many years (1–3). Solid products were isolated from the reaction mixtures and formulated as PdL_2Cl_2 (L = p-$NOC_6H_4NH_2$, p-$NOC_6H_4N(Me)_2$, p-$NOC_6H_4NEt_2$) (1) and $Pt(p\text{-}NOC_6H_4NMe_2)_4Cl_2$ (2).

In this paper we report the isolation, ultraviolet–visible spectra, and infrared spectra of the complexes PdL_2X_2 (L = p-$NOC_6H_4NMe_2$, p-$NOC_6H_4NEt_2$; X = Cl, Br, I) and conclude that Pd is bonded to the NO group.

Experimental

Starting Materials

p-Nitrosodimethylaniline and p-nitrosodiethylaniline, obtained from Hopkin and Williams, Ltd., were twice recrystallized from diethyl ether. $PdCl_2$ and K_2PdBr_4 were obtained from Johnson Matthey, Ltd. K_2PdCl_4 was made as described in the literature (4).

Preparation of Complexes

The procedure of Overholser and Yoe (2) gave poor results and was modified to remove the traces of unreacted ligand believed to be contaminating the product. For PdL_2Cl_2 (L = nitrosodimethylaniline) the recommendation is: dilute 20 ml of palladium(II) chloride solution containing 20 mg of palladium to 500 ml with water. Add 40 ml of a filtered alcoholic solution containing 100 mg of p-nitrosodimethylaniline. Allow the bright red suspension to stand for several hours and then filter through a G4 sintered-glass crucible. Wash the precipitate with three 5 ml portions of water and then three 5 ml portions of diethyl ether. Dry at 110 °C for 3 h and then under vacuum over anhydrous calcium chloride for several days.

The procedures for the other complexes are the same except that the iodide complexes should not be heated. The microanalytical figures obtained appear in Table I. Decomposition temperatures were determined with a simple electric melting point apparatus.

The complexes were only readily soluble in chloroform, tetrachloroethane, tetrahydrofuran, and acetone. The solutions in chloroform were stable (for several weeks) and the original compounds were recoverable from them.

Spectral Measurements

Ultraviolet–visible spectra were recorded on a Beckman DK2A spectrophotometer using 1 cm quartz cells.

Infrared (i.r.) spectra were recorded by means of a Hilger H900 Infrascan spectrometer over the region 4000–700 cm^{-1} and a Hilger H800 spectrometer equipped with cesium iodide optics over the region 1000–280 cm^{-1}. The latter instrument was thermostated at 25 °C and flushed with dry dust-free air during operations below 400 cm^{-1}. The H900 was calibrated by the polystyrene film method and the H800 against polythene film and water vapor. The i.r. spectral bands of the complexes and organic ligands were recorded on mulls in Nujol and hexachlorobutadiene.

Results and Discussion

The electronic spectra of p-$NOC_6H_4NEt_2$ and the complex $Pd(p\text{-}NOC_6H_4NEt_2)_2Cl_2$, both in chloroform solution, appear in Fig. 1. Changing

the halogen in the complex did not change the band positions but with bromide and, to a greater extent iodide, the high energy band became more, and the low energy bands less, intense. Complexes with p-$NOC_6H_4NMe_2$ gave essentially the same spectra as those with p-$NOC_6H_4NEt_2$.

The electronic transition of the *C*-nitrosodialkylanilines responsible for their green color has been assigned as a π–π^* transition (5). Its oscillator strength[2], defined as $4.32 \times 10^{-9} \int \varepsilon dv$, was found to be 0.485 in the case of L′ = p-$NOC_6H_4NEt_2$. The spectrum of the complex, $PdCl_2L'_2$, although showing some overlap with that of the ligand L′, is primarily shifted to lower energy and split into at least 2 components. The total oscillator strength of the bands of the complex[2] is 0.48. This intensity is about 100 times too large for d–d transitions of Pd(II) and the frequency (ν_{max} = 19 000 cm^{-1}) too low for Pd^{2+}–Cl^- charge transfer transitions (6). The constancy of oscillator strength and the insensitivity of band position and shape to the change from Cl to Br to I, suggest that we are still seeing the π–π^* transition of the ligand but lowered in energy and split through complexing. Reference to the molecular orbital scheme of Ballhausen and Gray (6) for square planar complexes of metals with π-bonding ligands—those with relatively low π^* levels—indicates the likelihood of the energy shift and, if we note that the scheme is for D_{4h} symmetry, the splitting of the degenerate π^* levels in $PdCl_2L'_2$ is not unreasonable. (We are dealing with Pd(II) and L′ orbitals, not Cl orbitals.)

It is usual for complexes PdX_2Y_2 to have a *trans* structure unless there is considerable Pd—Y π-bonding. The arguments above then, raise the possibility of a *cis* structure for $PdCl_2L'_2$.

The i.r. spectra of the free ligands are in accord with previous studies (7–9). Bands in the region 1500–1550 cm^{-1}, attributed to the N—O stretching vibration are altered in the complexes. Further, new bands appear on complexing in the 780 cm^{-1} region. This would be consistent with bonding from palladium to the N—O group and activation of a N—O deformation mode at 780 cm^{-1}. The 510 cm^{-1} band of L and the 505 cm^{-1} band of L′ drop by 15 cm^{-1} in the chloride and bromide complexes and are not discernible in the iodide complexes. This is the expected region of Pd—O and Pd—N stretching vibrations (10) and one might tentatively assign them at $\sim$ 490 cm^{-1} but the evidence is not conclusive. Finally, both chloride complexes show an intense band at 340 cm^{-1} with shoulders on the low frequency side. This

[2]The spectral limits for L′ were $\nu_1 = 2.0 \times 10^4$ and $\nu_2 = 2.7 \times 10^4$ cm^{-1}, and for PdL_2Cl_2, $\nu_1 = 1.7 \times 10^4$ and $\nu_2 = 2.5 \times 10^4$ cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

is clearly the Pd—Cl stretching vibration (11). For *trans*-PdX_2Y_2 only one Pd—X band is expected and this at 353–359 cm^{-1}, but for *cis*-PdX_2Y_2 2 bands, separated by 10–30 cm^{-1}, are expected in the 270–335 cm^{-1} region. For the complexes in question one cannot be too definite; although the band structure is complex and occurs below 350 cm^{-1}, a ligand vibration also occurs in this region as shown in the spectra of bromide and iodides. The general impression is of one very strong and one moderate band in line with a *cis* structure.

Since palladium has a greater affinity for nitrogen than for oxygen we would expect the bonding sequence Pd—N—R but the data do

not preclude Pd—O—N—R. If bonding to palladium were through the amino-nitrogen then the N—O vibration and the π–π^* transition, which is primarily concerned with the N—O group, should not be noticeably affected.

Radiation induced dimerization of 2- and 3-methyl-2-pentenes

J. L. Brash and M. A. Golub[1]
Stanford Research Institute, Menlo Park, California 94025

Received March 12, 1969

The dimers formed in the electron irradiation of 2- and 3-methyl-2-pentenes were found to have average unsaturations of 1.53 and 1.35 double bonds per dimer molecule, respectively, and were formed with *G* values of 2.6 and 1.8, respectively. The dimers were considered to form by both ion-molecule and radical mechanisms.

Canadian Journal of Chemistry, **47**, 3077 (1969)

Introduction

The radiation induced dimerization of terminal olefins is known to proceed largely through a mechanism involving rapid condensation of an electron-deficient molecule with a neighboring olefin molecule, followed by intramolecular hydride transfer and electron recombination (1–5). The dimers resulting from this ion–molecule mechanism are exclusively mono-olefinic. To account for the formation of other dimer structures from terminal olefins, a second ionic mechanism is invoked which involves hydrogen transfer from the parent olefin to the molecule-ion, leading to a carbonium ion and an alkenyl radical, followed by ion–molecule condensation as well as radical coupling. The latter mechanism yields mixtures of saturated, mono-olefinic and diolefinic dimers but with an *average* unsaturation of just one double bond per dimer molecule. This, in combination with the former mechanism, is compatible with the observed overall mono-olefinic character of the total dimeric product obtained from a terminal olefin. Both of these ionic mechanisms, designated [I*a*] and [I*b*], respectively (6), or just [I*b*] itself, have been considered to account for part of the radiation induced dimerization of several non-terminal olefins (4, 6), the remaining part being

attributed to a radical process [R] which yields additional diolefinic dimers (7).

As an extension of our earlier work on the radiolysis of hexene-1, -2, and -3 (6), the present note reports results on the radiation induced dimerization of 2-methyl-2-pentene and 3-methyl-2-pentene.

Experimental

3-Methyl-2-pentene (3MP2) was prepared by dehydration of 3-methylpentanol-3 with *p*-toluenesulfonic acid, and purified by bulb-to-bulb distillation on the vacuum line. The resulting product was a mixture of the geometric isomers, 29.2% *cis*; 70.8% *trans*. 2-Methyl-2-pentene (2MP2) (Phillips technical grade) was purified by bulb-to-bulb distillation.

Irradiations were carried out *in vacuo* at ~20 °C using 1 MeV electrons as described previously (6).

The yield of dimer was obtained from gas–liquid chromatography (g.l.c.) measurements using a 3 ft silicone column (G.E. SF-96) at 155 °C. Partial resolution of dimer components from the irradiated methylpentenes was carried out with the same column at 100 °C. The dimers, and various dimer components, were collected as they emerged from the g.l.c. and characterized by nuclear magnetic resonance (n.m.r.) and infrared spectroscopy, as before (6).

Results and Discussion

Dimerization of Methylpentenes

The *G*(dimer) values obtained in this work for 2MP2 and 3MP2 (2.6 and 1.8, respectively) are comparable to the values obtained (2.4–2.6) for the structurally related compound, dihydromyrcene (8), but considerably lower than those obtained for the nonterminal *n*-hexenes (4.6 and 4.1 for hexene-2 and -3, respectively (6)). Evidently, the trisubstituted double bond is less prone to take part in ion–molecule condensation than is the disubstituted double bond; on the other hand, the trisubstituted double bond apparently favors a relatively larger contribution from the radical mechanism [R]. Thus, the total dimeric products obtained from 2MP2 and 3MP2 had average unsaturations of 1.53 and 1.35 double bonds per dimer molecule, respectively, whereas the total dimers from hexene-2 and -3 both had average unsaturations of 1.2 double bonds per dimer molecule. The dimer yield reported here for 3MP2 (at 20 °C) is very similar to the *G*(dimer) values of 1.7 and 2.2 obtained by Wagner (9) for *cis*- and *trans*-3MP2, respectively (at −196 °C).

(a) 2-Methyl-2-pentene

The silicone chromatogram for 2MP2 dimer showed three peaks which could not be fully resolved and which, following collection, yielded very similar infrared and n.m.r. spectra. Accordingly, the observations on the 2MP2 dimer were based on a careful analysis of the spectra of the total dimeric product, including a thorough quantitative reconcilement of all the n.m.r. spectral features with one another and with the proposed assortment of dimeric structures.

The infrared spectrum of the whole dimer revealed the presence of the following unsaturation: trisubstituted, or isoprenic, double bonds (at 11.9 μ), *trans*-vinylene (at 10.4 μ), vinylidene (at 11.3 μ), probable *cis*-vinylene (at ~13.6 μ), and negligible vinyl (at 11.0 μ). The isoprenic/vinylidene ratio was ~4.8:1, and the *trans*-vinylene/vinylidene ratio was 1.23:1. The n.m.r. spectrum showed the presence of 43.9% of the protons as $CH_3-\overset{|}{C}-$, 24.4% as $CH_3-\overset{|}{C}=$, 3.1% as $-CH=CH-$ (*cis* and *trans*), 4.1% as $-\overset{|}{C}=CH-$, 2.0% as $CH_2=\overset{|}{C}-$, 10.5% as $-CH_2-\overset{|}{C}=$, and 12.0% as $-CH_2-\overset{|}{C}-$. From these spectroscopic data, it was deduced that the 2MP2 dimer had an *average* unsaturation of 1.53 double bonds per dimer molecule, consisting of 0.95 isoprenic, 0.35 vinylene, and 0.23 vinylidene units.

Since the overall unsaturation is well below 2.0 double bonds per molecule, the dimerization cannot proceed exclusively by the radical mechanism [R] but must also involve an important contribution from some ionic process. In terms of an effective 1,5 hydride transfer (5), mechanism [I*a*] could account for some of the vinylene and vinylidene units formed, while mechanism [I*b*], to the extent that various isomers of the 2MP2 allylic radical are formed, could give rise to dimers having these same double bonds and isoprenic units as well.

(b) 3-Methyl-2-pentene

As with 2MP2, the chromatogram of the 3MP2 dimer showed three peaks which could not be adequately separated, and so the spectroscopic analysis was again based on the whole dimeric product.

The infrared spectrum showed the presence of isoprenic double bonds (at 12.15 μ), and vinylidene and vinyl double bonds in the ratio of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$\sim$1.6:1, but no vinylene units. The n.m.r. spectrum showed the following distribution of protons: 42.4% as $CH_3-\overset{|}{C}-$, 23.4% as $CH_3C=$, 1.9% as $CH_2=\overset{|}{C}-$, 5.9% as olefinic protons in $-CH=CH-$ and $CH_2=CH-$, 15.1% as $-CH_2C=$, and 11.3% as $-CH_2-\overset{|}{C}-$. From these spectroscopic results, it was deduced that the 3MP2 dimer had an *average* unsaturation of 1.35 double bonds per dimer molecule, consisting of 0.99 isoprenic, 0.22 vinylidene, and 0.14 vinyl units.

Once again, both ionic and radical processes must be invoked to account for the radiation induced dimerization of 3MP2. Mechanism [I*a*] would be compatible with the formation of isoprenic and vinyl units, while [I*b*] could yield these double bonds and vinylidene units as well.

On the absence of triplet ketene in ketene excited in the region 2800–3660 Å

M. Grossman, G. P. Semeluk, and I. Unger

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received March 12, 1969

The sensitized biacetyl emission technique was used in an attempt to detect triplet ketene molecules, which might be formed when ketene is excited by light ranging in wavelength from 2800 to 3600 Å. No sensitized emission was observed in this exciting wavelength region thus confirming the recent results of Voisey (1) which also show that triplet ketene is not produced when ketene is excited by light between 2800 and 3200 Å, and that the triplet CH_2 found in such systems must arise from some source other than triplet ketene.

Canadian Journal of Chemistry, **47**, 3079 (1969)

Introduction

The photolysis of ketene was first examined by Norrish and co-workers (2) in 1933. Since then, this molecule has received much attention (3–6, and for a recent review see ref. 7). In 1964, Simons and Rabinovitch (8) showed that both singlet and triplet CH_2 are produced when ketene is excited by radiation of 3130 Å. It has been shown by several authors (9, 10) that the ratio of singlet to triplet CH_2 produced in the photolysis of ketene is wavelength dependent. The ratio of triplet CH_2 increases with increasing wavelength. It has been suggested (11) that the precursor of triplet CH_2 is triplet ketene.

Recently, Voisey (1) examined the photolysis of ketene and diazomethane in the presence of ethyl methyl ether and concluded that triplet CH_2 was formed from singlet CH_2 by collisional processes, although he did acknowledge the possibility of triplet ketene formation at the irradiating wavelengths greater than 3200 Å.

We have attempted to detect triplet ketene, using the sensitized biacetyl emission technique (12), in ketene–biacetyl mixtures irradiated by wavelengths ranging from 2800 to 3660 Å.

Experimental

The ketene was prepared, according to a method described by Ho and Noyes (11), in a mercury free vacuum system equipped mostly with teflon stop-cocks, and stored at -196 °C until needed.

The biacetyl was obtained from the Aldrich Chemical Company and was used without further purification. Research grade *cis*-butene-2 was obtained from the Phillips Petroleum Company. Vapor phase chromatography shows this material to be essentially pure.

The emission data were obtained on a modified Aminco–Bowman spectrophoto-fluorometer (s.p.f.) which

has been described previously (13). A mercury and grease free high vacuum system, equipped with Hoke Packless Diaphragm (stainless steel) metal valves was used to handle the compounds.

Mixing was accomplished by means of flash vaporization and by circulating the vapors through the s.p.f. cell by means of an all glass circulating pump constructed at the National Research Council of Canada in Ottawa.

All experiments were carried out at room temperature ($\sim$ 27 °C).

Results and Discussion

Two types of experiments were performed. Mixtures of ketene and biacetyl were irradiated and the intensity of the biacetyl emission (as an area under a curve) was noted. Then, similar mixtures were prepared containing *cis*-butene-2 instead of ketene, irradiated at the same wavelength, and the intensity of the biacetyl emission was again noted. The *cis*-butene-2 experiments were performed as a control, since biacetyl absorbs in the spectral region used in this study and exhibits a weak emission which can be enhanced by the addition of vibrational quenchers (14). Thus, the amount of light absorbed by the biacetyl was approximately the same for each comparison pair of mixtures. The results of these experiments are given in Table I. The major requirement for the successful use of the biacetyl sensitized emission technique is that the triplet of the donor be higher in energy than the triplet of biacetyl (15). The triplet of ketene has been given as 61 kcal (16), while the triplet of biacetyl has been given as 55 kcal (17). Thus, if ketene triplets are produced in the presence of biacetyl, one would expect to observe an enhanced emission from biacetyl due to the reaction

$$^3K + BiA \rightarrow {}^3BiA + K$$

Our data indicate that biacetyl emission is reduced in the presence of ketene. One is thus forced to the conclusion that either (*a*) ketene

For personal use only.

reacts chemically with excited biacetyl, or (*b*) that triplet ketene is not produced in this irradiation wavelength region. Voisey's work, the relatively small energy separation between triplet and singlet methylene (18), and the evidence of Ring and Rabinovitch (19) which disputes the reliability of the conventional method of diagnosing singlet and triplet methylene, leads us to suggest the latter conclusion to be the more likely.

Effect of chain length on storage stability and hydrolytic reversion of sodium polyphosphate glasses

Robert J. Fuchs and Charles W. Lutz

Inorganic Research and Development Department, FMC Corporation, Carteret, New Jersey 07008

Received February 14, 1969

At low concentrations in hard water, the polyphosphates revert to orthophosphate at rates which are not predictable from data obtained at higher concentrations. A reversal in the effect of pH on reversion rate at lower concentrations appears to be due to complex formation between the polyphosphate and the hard water metal ions. A minimum in the rate of reversion of polyphosphate glasses to orthophosphate occurs at an average chain length between about 13 and 40 under the low concentration hard water conditions. Phosphate glasses having an average chain length below 30 show good storage stability but longer-chain glasses undergo a decrease in chain length under normal "dry" storage conditions, with the rate of degradation increasing with increasing chain length.

Canadian Journal of Chemistry, **47**, 3081 (1969)

Most of the published work on hydrolytic degradation, or reversion, of polyphosphates (1) has overlooked the effect of phosphate concentration or has treated it over a very limited range. Bell (2) studied the reversion of commercially available phosphates at concentrations of 1 and 10% and showed a relatively small effect of concentration. However, at the low (p.p.m.) phosphate concentration levels used in such applications as industrial water treatment, the published reversion data for higher concentrations are of little value. At these low concentrations the effects of water hardness and other materials dissolved in the water become highly significant. In the presence of microorganisms, enzyme catalysis can increase the rate of reversion of the polyphosphates by a factor of 10^5–10^6 (3) but these enzymes are deactivated or destroyed in high temperature systems or by the use of biocides. Green (4) studied the reversion

*Synthetic hard water = 40 p.p.m. Ca (as $CaCO_3$), 20 p.p.m. Mg (as $CaCO_3$), and 12 p.p.m. Cl.
†TSPP = tetrasodium pyrophosphate, STPP = sodium tripolyphosphate, glasses are designated by their number average chain length.

of some commercially-available sodium polyphosphates at phosphate concentrations of 5 and 50 p.p.m., under typical water-treatment conditions. The work described in this paper is intended to supplement his work and give more insight into the effects of chain length on reversion, both in dilute aqueous systems and under "dry" storage conditions. Like Green we used the ultimate hydrolyzed-phosphate species, orthophosphate, as our measure of reversion in aqueous systems.

In the use of polyphosphates for inhibition of corrosion or scale formation, all of the chain polyphosphate species are effective and the rate of formation of orthophosphate is usually the determining factor in selecting a polyphosphate for a specific use. The formation of ring phosphates, such as sodium trimetaphosphate, during hydrolysis of long-chain phosphates (5, 6) is also important, since these species are not effective in water treatment, but they are subsequently hydrolyzed to useful chain phosphates.

Experimental

Five sodium polyphosphate glasses of varying average chain length, from 6–400, were tested for reversion in aqueous systems and several additional glasses of intermediate chain length were evaluated for dry storage stability. For comparison, two crystalline polyphosphates, tetrasodium pyrophosphate (TSPP) and sodium tripolyphosphate (STPP), were tested. All samples were well below 1% in orthophosphate content. Tests were run in distilled water and in a "synthetic hard water" which contained a calcium hardness of 40 p.p.m. $CaCO_3$, a magnesium hardness of 20 p.p.m. $CaCO_3$, and 12 p.p.m. chloride.

In the 100 °C tests, the samples were added to boiling water and the pH adjusted immediately and periodically as required. Initially, samples were analyzed by paper chromatography (7, 8) to determine the change in composition with time. In subsequent tests samples were analyzed for orthophosphate using the Martin and Doty method (9).

In the 63 °C tests, the pH was checked and adjusted twice daily. The validity of this procedure was established using a pH-stat (Stat Model B-1, JKM Instrument Co.) in which the sample was kept at a constant pH by automatic introduction of acid or base when the pH changed slightly.

Average chain lengths ($\bar{n}$) were determined using the method of Van Wazer *et al.* (10).

Results and Discussion

The 100 °C reversion test was used to determine the effects of chain length, concentration, pH, and the presence of multivalent cations under conditions in which there would be no contribution from enzymes or microorganisms.

†TSPP = tetrasodium pyrophosphate, STPP = sodium tripolyphosphate, glasses are designated by their number average chain length.

In the initial tests, the change in composition with time was followed by paper chromatography. Figure 1 shows a typical distribution curve for a glass of average chain length 13. No attempt was made to separate the species longer than chain length 3. A 21 chain length glass gave a distribution curve that was almost identical to Fig. 1 in all species except orthophosphate, which increased to only 38% in 3 h instead of 55%, and in the content of chains longer than 3, which was higher by the corresponding amount.

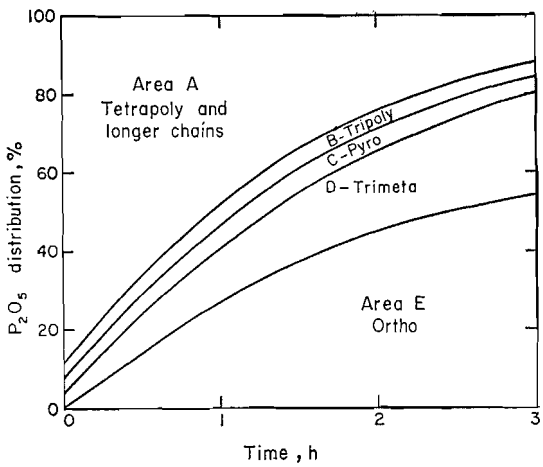

FIG. 1. Change in distribution of phosphate species with time for sodium polyphosphate glass of average chain length 13 in 1% solution at pH 6 at 100 °C.

Results at 100 p.p.m. concentration were very similar to those at 1%.

On the basis of these initial results, it was decided to standardize on a 1.5 h test, since the increase in orthophosphate and decrease in chain phosphate content are close to linear up to this point. Similar tests at 63 °C gave about the same change in composition in 5 days as the 100 °C tests did in 1.5 h, so this time interval was selected as a standard.

Results of the 100 °C tests in Table I show very little change in reversion rate with concentration, over the range of 1% to 40 p.p.m., in distilled water. However, in synthetic hard water there was a significant shift in behavior, with the effect of pH in the 40 p.p.m. tests being reversed from that at 1%. All of the glasses as well as TSPP and STPP showed greater reversion at pH 9 than at pH 6 or 7 in the 40 p.p.m. tests in synthetic hard water. The cross-over point (between increasing and decreasing reversion with increased pH) for the 13 and 21 chain length glasses appears to occur at about 500 p.p.m. concentration under these test conditions. At this concentration a substantial portion (of the order of one-half) of the polyphosphate should be present as a complex with the calcium and magnesium ions of the standard hard water.

Table II shows results of tests at 63 °C, a temperature more typical of industrial water treatment applications. Results show a similar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

pattern to those at 100 °C, indicating that enzymatic hydrolysis did not contribute significantly to reversion at the low concentrations. A sodium polyphosphate glass having an average chain length of about 400 was tested at 12 p.p.m. concentration under the conditions shown in Table II and gave exactly the same amount of reversion to orthophosphate as that of the 40 chain length glass in each test.

The combined data from the distilled water tests show a general trend towards reduced reversion with increase in average chain length which is in qualitative agreement with the combined data of Griffith and Buxton (11) and of Wieker (12) who found an increase in reversion rate with increasing chain length up to 8 and a decreasing rate with increasing chain length above 24. Our data indicate that the maximum reversion rate must lie between 8 and 13, probably close to chain length 8. However, our data show that at low concentrations of phosphate in hard water there is a minimum in rate of reversion between a chain length of about 13 and 40.

In the course of this work, some of the "dry" phosphate glass samples which were stored in the laboratory in screw capped jars were reanalyzed after a period of several months and found to have decreased in average chain length. All of the stored glass samples were reanalyzed and it was found that none of the samples having an average chain length of less than 30 had changed significantly on storage while all samples above 30 had degraded. Both groups contained samples which had been stored for periods ranging from 3 to 12 months. Storage conditions were not closely controlled (heated laboratory in winter, air-conditioned in summer) but all samples were stored in the same manner.

Figure 2 shows the rate of decrease in average chain length for the various stored samples. Glasses having an average chain length between 30 and 90 show a linear increase in rate of degradation with increasing chain length. Because of the wide range of storage times and storage conditions represented by the data, only qualitative conclusions can be drawn, but the excellent fit of the experimental data to a straight line graph attests to its reliability.

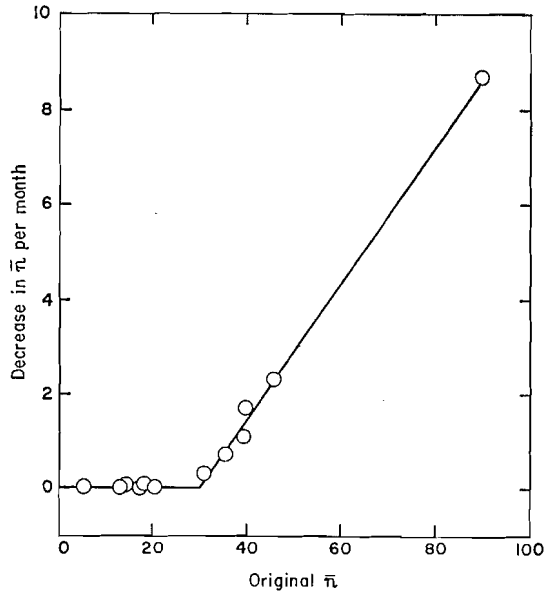

FIG. 2. Rate of reduction in average chain length of sodium polyphosphate glasses under "dry" storage conditions as a function of initial average chain length.

Studies in ferrocene derivatives. VII[1]. The synthesis of ferrocenyl ethylenes via an abnormal Grignard reaction[2]

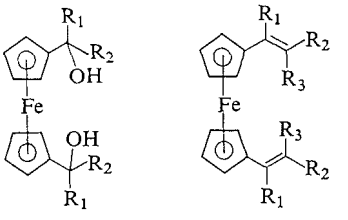
Received February 27, 1969

RMgBr reacts normally with acylferrocenes to give the corresponding alcohols. RMgI gives good yields of the most highly substituted ferrocenyl ethylene. In solutions of moderate acid strength, α-ferrocenyl carbonium ions lose a proton to form the substituted alkene rather than undergo nucleophilic attack by water to give the corresponding alcohol. Since the alcohols are more basic than the alkenes, it is possible to devise a general synthesis of ferrocenyl ethylenes by the reaction of any Grignard reagent with an acylferrocene.

Canadian Journal of Chemistry, 47, 3085 (1969)

Ferrocenyl ethylenes have been synthesized previously by the facile dehydration of ferrocenyl alcohols (3–6), the reaction of acyl ferrocenes with alkyl lithium reagents (5), and, more recently, by the Wittig reaction (7, 8). In connection with other work on ferrocenophanes (9), we required several ferrocenyl-1,1′-diols of the general structure **1**. These compounds had been prepared previously by reaction of the 1,1′-diacyl ferrocene with the appropriate Grignard reagent followed by conventional work-up. The synthesis of **1**; $R_1 = R_2 = CH_3$) was accomplished as described in the literature (10). Preliminary examination of the crude product showed that there were two major products and chromatographic work-up gave the diol (**1**; $R_1 = R_2 = CH_3$) in a 56% yield and the bis alkene (**2**; $R_1 = CH_3$, $R_2 = R_3 = H$) in 32% yield. This constitutes a useful synthesis of 1,1′-bis isopropenyl ferrocene since alternative syntheses involve the prior formation of 6,6-dimethyl fulvene (11) or methylene triphenyl phosphorane (7, 8).

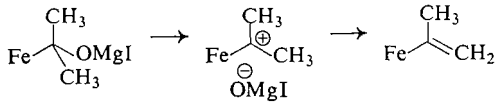


1 **2**

Examination of the literature (10, 12), showed that in many cases where alkyl magnesium iodides had been used in the synthesis of ferrocenyl alcohols, the yields were somewhat lower than would be expected in a Grignard reaction; the yields obtained from alkyl magnesium bromides were usually much higher. Accordingly, we examined the reaction of several acyl ferrocenes with RMgI and RMgBr. The former gave good yields of alkenes whereas the latter usually gave high yields of the corresponding alcohol. Since the work-up conditions were identical for both iodides and bromides it appears likely that

[1]See ref. 1 for Part VI of this series.
[2]See ref. 2.
[3]The author to whom correspondence may be addressed.

the elimination occurs during the reaction, and not during the work-up procedure. The elimination of HOMgI is not without precedent (13) in Grignard reactions, but the conditions employed are usually severe, involving the use of acids and/or refluxing solvents. It appears likely that this reaction involves the ionization of the magnesium alcoholate to give an intermediate α-ferrocenyl carbonium ion which then loses a proton to form the ferrocenyl ethylene (eq. [1]).



Eq. [1]

Support for this hypothesis comes from the reaction of 2-ferrocenyl-propan-2-ol (**4**) with an excess of methyl magnesium iodide in refluxing benzene – ether overnight. Chromatography of the crude product gave 2-ferrocenyl propene in 44% conversion with 36% of the alcohol being recovered. Although the work-up conditions used in these reactions were identical for the Grignard reagents derived from alkyl iodides and alkyl bromides, it was necessary to prove convincingly that the alkenes were present in the RMgI reactions before hydrolysis. This was normally done by thin-layer chromatographic (t.l.c.) examination of the crude reaction mixture. In the case of the reaction between acetylferrocene and methyl magnesium iodide, the reaction mixture was chromatographed without the hydrolysis step. The alkene (**5**) was obtained in yields of greater than 80% whether the alumina was used as received or after drying to Brockman Activity I. This constitutes strong support for the mechanism outlined in eq. [1]. Our results, together with these in the literature, are summarized in Table I.

Acyl ferrocenes which yield secondary alcohols react normally with alkyl magnesium iodides, whereas the formation of tertiary magnesium alcoholates gives rise to substantial quantities of alkene. The greater the degree of substitution of the double bond, the more likely is alkene formation. Branching of the carbon chain of the acyl ferrocene e.g. pivaloyl ferrocene decreases the amount of alkene formed. In fact no ferrocenyl ethylene was found in the reaction between pivaloyl ferrocene and methyl magnesium iodide, the only product isolated being the endo

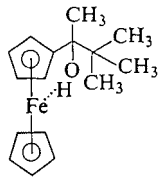
alcohol (**3**) where the hydroxyl group is strongly hydrogen bonded to the iron atom, as shown by the sharp OH stretch at 3560 cm^{-1} (14) and the fact that it sublimes readily. It showed the chromatographic behavior normally associated with a ferrocenyl ethylene. It would appear, therefore, that where possible ferrocenyl alcohols should be synthesized either by reaction with alkyl magnesium bromides or the corresponding lithium reagent, to avoid the dehydration problems encountered with the corresponding iodides. In many cases, reaction with alkyl magnesium iodides leads to synthetically useful yields of the most highly substituted alkene.



3

It would be useful if the abnormal Grignard reaction could be modified to give the alkene as the sole product. In connection with our work on α-ferrocenyl carbonium ions (15), we have compared the basicity of 2-ferrocenyl propan-2-ol (**4**) and 2-ferrocenyl propene (**5**), both compounds forming the dimethyl ferrocenyl carbonium ion (**6**) (eq. [2]). The alcohol is 1/2 protonated in 37%

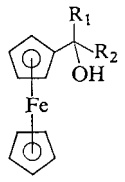
EQ. [2]

sulfuric acid and the alkene in 44% sulfuric acid. The carbonium ion formed deprotonates to give the alkene much faster than it undergoes solvolytic attack to form the alcohol. Accordingly by working-up the Grignard reaction mixture by treatment with dilute acid ca. 20% H_2SO_4 in a two-phase system, the alkene formed is removed into the organic layer. A two-phase system of carbon tetrachloride – 20% H_2SO_4 gave a 95% conversion of (**4**) to (**5**).

We have discussed the nuclear magnetic resonance (n.m.r.) spectra of ferrocenyl ethylenes previously (8) in some detail. Most of the alcohols described in this work have all been prepared previously without mention of their n.m.r. spectra. These are unexceptional and the observed spectra are recorded in Table II.

The mass spectra of the alcohols have been recorded and in most instances the molecular ion is not observed in the mass spectrometer, the major peak being attributable to the corresponding alkene. The same is also true of vapor phase chromatography (v.p.c.) of the alcohols where injection of the alcohol leads to formation of the olefin.



7

Experimental

The acyl ferrocenes used were synthesized by standard methods (12*b*). Nuclear magnetic resonance spectra were recorded on a Perkin–Elmer R10 (60 Mc.p.s.) spectrometer or a Varian A60 spectrometer in CCl_4 solution. Mass spectra were recorded on an M.S. 12 instrument.

Pivaloyl ferrocene was prepared essentially as described by Leigh (16). The crude product had to be chromatographed several times on alumina (Fisher A540) to remove several other products e.g. 1-*t*-butyl-1′-pivaloyl ferrocene which were formed during the Friedel-Crafts reaction.

1-Ferrocenyl-3,3-dimethyl Butan-2-ol (3)

Pivaloyl ferrocene (2.7 g; 10 mmole) in dry benzene (15 ml) was added to a refluxing solution CH_3MgI (from Mg (0.72g)) and CH_3I (1.8 ml) in anhydrous ether (25 ml). The mauve solution was refluxed for 3½ h and the reaction terminated by pouring the cooled solution into water (200 ml). The precipitated magnesium salts were dissolved using 20% H_2SO_4. The organic layer was separated and the ether washings of the aqueous layer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

added. The combined extracts were washed (water) till neutral and dried (Na_2SO_4). Removal of solvent (rotary evaporator) gave a yellow crystalline solid, m.p. 70–80°. Chromatography on alumina (Fisher 540H) using skellysolve F:benzene (1:1) gave **3** as yellow plates m.p. 85–87° (2.1 g, 73.4%). An analytical sample was obtained by sublimation at 100 °C/2 mm as golden-yellow plates, m.p. 91–92°.

Anal. Calcd. for $C_{16}H_{22}FeO$ (mol. wt. (mass spectra) 286): C, 67.20; H, 7.70. Found: C, 67.17; H, 7.8.

Synthesis of Ferrocenyl Ethylenes

(i) 2-Ferrocenyl Prop-2-ene

Acetyl ferrocene (10 mmole) in benzene (10 ml) was added over 30 min to a refluxing solution of methyl magnesium iodide (100 mmole) in ether (15 ml). The reaction mixture was refluxed for 20 min, cooled, and quenched in ice water (100 ml). The organic phase was separated, washed with water, dried (Na_2SO_4), and solvent removed. The semi-crystalline residue was chromatographed on alumina (Fisher 540A) and the olefin eluted with skellysolve F. The yield of olefin varied from 62–75%. Further elution with benzene – ether (1:4) gave 2-ferrocenyl propan-2-ol in ca. 15% yield.

(ii) 2-Ferrocenyl But-2-ene

Acetyl ferrocene (20 mmole) in benzene (25 ml) was added to a stirred solution of ethyl magnesium iodide (30 mmole) over 30 min and the mixture stirred overnight. The reaction mixture was worked-up in the usual manner and the crude product chromatographed on alumina (Spence, H). Elution with petrol gave the ferrocenyl ethylene as a red oil in a 68.4% yield.

Synthesis of Ferrocenyl Alcohols

(iii) Bis-1,1'-(2-hydroxy-1-methyl propyl) Ferrocene (***1***; $R_1 = CH_3$, $R_2 = C_2H_5$)

1,1'-Diacetyl ferrocene (25 mmole) in benzene (40 ml) was added to a stirred solution of ethyl magnesium bromide (100 mmole) in ether (100 ml) and the reaction mixture stirred overnight. Conventional work-up gave the product as an oil which was chromatographed on alumina. Elution with benzene – ether (1:4) gave the diol as yellow plates, m.p. 100–101° (10) in an 88% yield.

Dehydration of Ferrocenyl Alcohols Using a Two-Phase System of 20% H_2SO_4–CCl_4

2-Ferrocenyl-2-propanol (1 g) was dissolved in carbon tetrachloride (20 ml) and 20% H_2SO_4 (20 ml) added. The two-phase system was shaken mechanically for 3½ h and the reaction followed by t.l.c. The CCl_4 layer was separated, washed with water till neutral, dried (Na_2SO_4), and solvent removed. The residue was pure (by v.p.c.) 2-ferrocenyl prop-2-ene (0.89 g, 95%) m.p. 61–62°.

Nuclear magnetic resonance studies. XVI.[1] Oxygen-17 shieldings of some substituted acetophenones

D. J. SARDELLA[2] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ontario
Received February 25, 1969

The ^{17}O spectra of some *ortho*- and *para*-substituted acetophenones were determined to examine the effect of substituent polarity and steric hindrance on the acetyl oxygen shieldings. The results are compatible with proposals previously advanced on the basis of the ^{13}C shielding data for these compounds.

Introduction

An examination of the ^{13}C magnetic resonance (c.m.r.) spectra of an extensive series of substituted acetophenones (1) and alkyl phenyl ketones (2) revealed that the shielding of the carbonyl carbon is insensitive to substituent polarity for a wide range of *meta*- and *para*-substituted compounds. Although there is ample evidence from reactivity studies (3) and infrared spectra (4) to show that the carbonyl bond is perturbed by polar substituents, the ^{13}C results indicate that the electron density about the carbonyl carbon is not significantly altered even with the change, *p*-NMe_2 → *p*-NO_2. This behavior is in direct contrast with that exhibited by the fluorine nucleus in *p*-substituted fluorobenzenes for which the ^{19}F shieldings vary by ca. 28 p.p.m. for the same change in substituent. An interpretation of the ^{13}C results was advanced (1) in terms of the resonance forms contributing to the structures of these compounds in which it was suggested that the location of a nucleus within the aryl system could be an important factor governing substituent effects on its shielding. In the fluorobenzenes the fluorine nucleus is at the end of the resonance system while the carbonyl carbon in the aryl ketones is one atom from the end. Polarization of the π-cloud governed by the electronic character of a substituent could, it was suggested, be expected to cause appreciable changes in the electron density at the end of the system but these would be much less pronounced at nuclei within the system, e.g. the carbonyl carbon. Some support for this proposal was subsequently obtained from the c.m.r. spectra of a series of substituted styrenes (5). The vinyl carbon shieldings in these materials were measured and found to differ in their response to a variety of polar substituents. The absorption of the β-carbon of the vinyl groups shifts to lower field with electron-withdrawing substituents. A total change of −10 p.p.m. was found for the change, *p*-NMe_2 → *p*-NO_2. On the other hand, the α-carbon shieldings for the same series appear over a total range of only 1.6 p.p.m. Although this variation is just greater than the experimental uncertainty, the trend, if any, is in the opposite direction to that exhibited by the β-carbons. Although it was gratifying to find that the styrene results offered some confirmation of our proposal regarding polar effects on side-chain carbons of substituted aromatics, the vinyl group differs substantially from a carbonyl group and further evidence to support our interpretation is desirable. To this end we have measured the ^{17}O shieldings of the carbonyl oxygen in some of the acetophenones for which we have the ^{13}C data and these results are presented in this paper. For this work, the compounds chosen were enriched with ^{17}O to aid the determination of their shieldings.

Experimental

Spectra

The ^{17}O spectra were obtained at 8.13 MHz with a Varian DP-60 spectrometer using a V-4210A variable frequency oscillator. The audio side-band technique was employed to calibrate the spectra and chemical shifts were measured relative to external ^{17}O-enriched water. The audio and radio frequencies were measured with an HP-5245L counter. The samples were examined in a concentric cell arrangment having an outer spherical cavity containing ca. 1 ml of the sample and an inner sphere ca. 0.2 ml in volume containing enriched water. Acetone solutions of the labelled acetophenones were employed in concentrations of ca. 1:3 (v/v). A more dilute solution (1:6) of acetophenone in acetone was

examined to check for the absence of an appreciable solvent effect.

Proton and infrared spectra of all samples of the ^{17}O-enriched acetophenones were obtained to ensure the absence of impurities. Ultraviolet spectra of these acetophenones were recorded on a Cary 14 spectrophotometer to measure the position of the $n \rightarrow \pi^*$ transitions in n-hexane solutions. The infrared spectra, (i.r.), provided a measure of the ^{18}O content, after exchange, from which the ^{17}O enrichment was determined. To test the reliability of the infrared analysis, the ^{18}O content of 4-bromoacetophenone was also determined by mass spectrometry.[3] Comparison of the intensities of peaks, m/e = 202 and 198 for $^{81}Br^{18}O^{12}C_8H_7$ and $^{79}Br^{18}O^{12}C_8H_7$, respectively, gave, after correction for the background due to mercury isotopes and the $^{79}Br/^{81}Br$ ratio (1.021), the ^{18}O enrichment. The results of the isotopic analyses are included in Table I. The $^{18}O/^{17}O$ ratio for the water used to enrich the ketones was provided by the supplier, Yeda Research and Development Co.

†Estimated from ^{18}O content measured by i.r. absorption.
‡By mass spectrometry, 1.5% ^{17}O.

Materials

The ^{17}O-labelled acetophenones were prepared following either of two routes: (*a*) by hydrolysis of the corresponding anil or (*b*) by acid-catalyzed exchange with ^{17}O-enriched water (6). The general procedures are described and the specific method employed for each case is indicated in Table I.

Method (a)

A solution of the ketone (0.02 mole) in aniline (15 ml) was placed in a Dean–Stark apparatus and 0.05 g of an aniline – zinc chloride complex was added. The mixture was heated under reflux for 4 h.

The catalyst was obtained by mixing aniline (50 ml) with anhydrous zinc chloride (3.5 g) in a flask protected from atmospheric moisture by a drying tube. After the initial reaction subsided the flask was shaken and left to stand with occasional shaking. The resulting suspension was filtered and the filtrant washed thoroughly with dry ether to remove all traces of aniline. After storage overnight under vacuum the complex was ready for use.

After cooling, the reaction mixture was distilled to remove the excess aniline, the residue was shown to be mainly the desired anil (ca. 80%) containing some of the original ketone (ca. 20%). Since the i.r. and ^1H spectra showed the absence of impurities this mixture was used directly in the next step.

The crude anil was dissolved in CCl_4 (ca. 1 ml) and ^{17}O-enriched water (0.12 g) added. Hydrogen chloride was bubbled through the mixture for a few minutes and then the mixture was shaken. This was repeated until no further reaction was evident. After the addition of more solvent, the solids were removed by filtration and the solution dried over magnesium sulfate. Removal of the solvent yielded a product shown to be essentially pure ketone by i.r. and nuclear magnetic resonance (n.m.r.) spectroscopy with the presence of an additional carbonyl band in the former.

Method (b)

To a solution of the ketone (0.04 mole) in dioxane (12 ml) containing ^{17}O-enriched water (0.3 ml) was added two drops of concentrated HCl and the solution heated under reflux overnight. After cooling, the water was removed with 4A molecular sieves and the solvent removed by distillation under vacuum. The residue was examined by i.r. and ^1H spectroscopy to ensure the absence of impurities.

Results and Discussion

Five members of the *para*-substituted series were examined and the data are listed in Table II. The total range of these ^{17}O shieldings was found to be 19 p.p.m. for the substituent change *para*-methoxyl to *para*-nitro. We have found acetophenone itself to absorb at −555 p.p.m. (from external water) in these acetone solutions and, furthermore, the shielding was unchanged at the two dilutions examined, 33 and 15% (v/v). Earlier, Christ and Diehl (7) reported that neat acetophenone absorbs at −546 p.p.m. This difference is larger than the combined experimental uncertainty and may be due, in part, to a medium effect. We feel, however, that the present set of data is internally consistent. The trend exhibited by the *para*-substituted derivatives is in agreement with expectations since a progressive increase in electron-withdrawing power tends to shift the ^{17}O absorption to lower field, a paramagnetic shift. This trend was found earlier (7) in a comparison of the ^{17}O shieldings of *p*-anisaldehyde and benzaldehyde which differ by 24 p.p.m. with *p*-anisaldehyde at the higher field.

It has been established that the paramagnetic contribution, σ_p, to the total screening constant, σ, dominates ^{17}O nuclear shieldings (7, 8) and

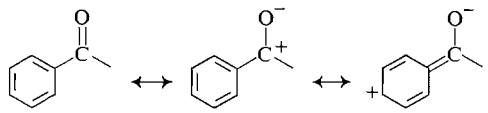
2,6-Me_2	-608 ± 5	~310
2,4,6-Me_3	-593 ± 15	~313

the present results may be considered qualitatively in terms of this contribution which has the form

$$\sigma_p \alpha - \frac{1}{\Delta E}\langle r^{-3}\rangle_{2p}$$

where ΔE represents the excitation energy to the low lying excited state, and $\langle r^{-3}\rangle_{2p}$, is the mean inverse cube radius for the 2p orbitals. The latter term accounts for the charge density effect in the paramagnetic term since increasing charge density leads to an expansion of the orbitals and thereby a reduction in σ_p. Comparing a carbonyl oxygen in a saturated ketone with one in a conjugated system would lead to the prediction that σ_p should be less for the latter *if the* $\langle r^{-3}\rangle_{2p}$ *term dominates* since there is a greater contribution from the polarized forms such as **2** and **3** in conjugated systems.



1 **2** **3**

It has been shown by Figgis *et al.* (8) that organic carbonyl oxygen shieldings correlate approximately with $\lambda_{max}^{n\rightarrow\pi^*}$ values (i.e. the inverse of the excitation energy for the lowest electronic transition), if the series including several different types of carbonyl compound is considered. Within specific families, such as the aliphatic ketones, however, the correlation does not hold. For the *para*-substituted derivatives in the present study, a correlation of the δ_0 with λ_{max} may exist but the interdependence between these two parameters is quite different from that of Figgis *et al.* in which a shielding change of ca. -3 p.p.m./mμ was found while our series shows a change of only ca. -0.6 p.p.m./mμ. Furthermore, the δ_0 values for the *ortho*-substituted cases (see Table II) exhibit the opposite trend with the $\lambda_{max}^{n\rightarrow\pi^*}$ data. Clearly a consistent explanation of the present results in terms of a dominant $1/\Delta E$ contribution does not exist. A reason for this may be the fact that the ΔE term represents a summation extending over all ground to excited state transitions and the exclusion of all but the n $\rightarrow \pi^*$ transition is too drastic an approximation for aryl ketones since the $\pi \rightarrow \pi^*$ transitions are relatively close. An indication that this is the case is provided by the observation that the shielding difference between acetone and acetophenone of -17 p.p.m. bears no relation to the value of ca. -120 p.p.m. predicted by the original δ_0 vs. $\lambda_{max}^{n\rightarrow\pi^*}$ correlation. It is interesting, however, that the solvent dependence of the oxygen shielding for acetone correlates rather nicely with $1/\Delta E$ for the n $\rightarrow \pi^*$ transition energies as shown in Fig. 1, in which the shielding data reported by Christ and Diehl (7) are plotted vs. $\lambda_{max}^{n\rightarrow\pi^*}$ for five solvents (9). In fact the slope, δ_0/λ_{max}, is essentially the same as that found by Figgis *et al.* (8).

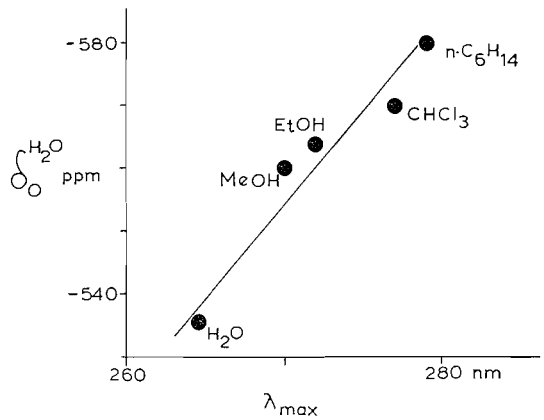


FIG. 1. A plot of acetone oxygen shieldings (7) vs. $\lambda_{max}^{n\rightarrow\pi^*}$ (9) in the indicated solvents.

In terms of the relative contribution of forms akin to **2** and **3** to the electronic distribution about the carbonyl oxygen nuclei, however, a certain consistency appears to hold throughout the present series. The polarized form will be more important in those cases in which an electron-releasing substituent is present at the *para* position and less important for electron-withdrawing substituents. In other words the $\langle r^{-3}\rangle_{2p}$ term will increase along the series *p*-MeO

$\rightarrow p$-NO_2 and, consequently, σ_p will increase. Thus δ_0 will be expected to decrease, i.e. a shift to lower field, since σ_p is negative. Another mechanism by which the polarization of the carbonyl bond may be decreased is through steric inhibition of resonance. Thus, substitution of the *ortho* protons with methyl groups should result in a shift of δ_0 to lower field if the $\langle r^{-3} \rangle$ term dominates. This is the observed trend. The fact that the ^{17}O nucleus in the *ortho*-substituted cases absorbs at even lower field than that in aliphatic systems suggests the presence of an additional perturbation. This may be a contribution due to a dispersion or van der Waals effect owing to the close approach of the methyl protons of the *ortho*-groups. In any event, it appears that the ^{17}O shieldings in these aryl ketones can be satisfactorily interpreted in terms of a charge transfer effect which is manifested in the $\langle r^{-3} \rangle_{2p}$ term of the paramagnetic term, σ_p. This trend is in general agreement with that found earlier in these laboratories from the c.m.r. spectra of substituted styrenes (5) in which the variation of the β-vinyl carbon shieldings exhibit similar variations. The previous c.m.r. and the present ^{17}O magnetic resonance data are plotted in Fig. 2 to illustrate the similarities.

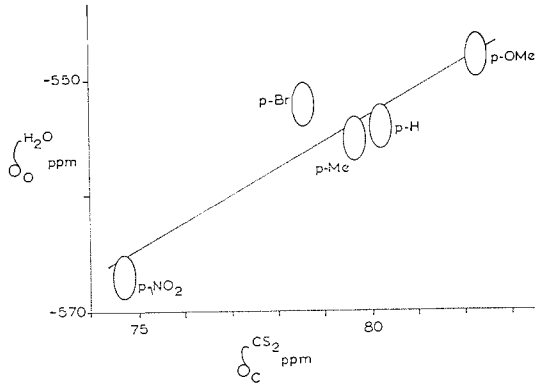

FIG. 2. A plot of the ^{17}O shieldings of some substituted acetophenones vs. the β-vinyl ^{13}C shieldings of the corresponding styrenes.

Stereochemistry of some olefins $R_fCH{=}CHI$ and the preparation of some new cyclopropenes

W. R. CULLEN AND M. C. WALDMAN
Chemistry Department, University of British Columbia, Vancouver, British Columbia

Received April 9, 1969

The light induced additions of CF_3I and C_2F_5I to acetylene yield the *trans* 1:1 adducts predominantly [$CF_3CH{=}CHI$ (*trans*:*cis* = 6.7:1) and $C_2F_5CH{=}CHI$ (*trans*:*cis* = 9:1)]. The addition of *i*-C_3F_7I to acetylene gives a 1:1 adduct consisting of a higher proportion of the *cis* isomer (*trans*:*cis* = 1.78:1). The *i*-C_3F_7I-acetylene adduct can be dehydrohalogenated to produce *i*-$C_3F_7C{\equiv}CH$. Difluorocarbene (from $(CH_3)_3SnCF_3$) does not add to the olefinic 1:1 adducts but does add to the polyfluoroalkyl acetylenes $R_fC{\equiv}CH$ to produce the cyclopropenes $R_fC{=}CHCF_2$ (R_f = CF_3, C_2F_5, *i*-C_3F_7).

Canadian Journal of Chemistry, 47, 3093 (1969)

Introduction

The light induced free radical addition of perfluoroalkyl iodides to acetylenes has been reported by several authors.

[1] $RC{\equiv}CH + R_fI \rightarrow RCI{=}CHR_f$
R = H, R_f = CF_3 (1), C_2F_5 (2); R = CH_3, R_f = CF_3 (3, 4);
R = CF_3, R_f = CF_3, C_2F_5, *n*-C_3F_7 (3);
R = C_6H_5, R_f = CF_3 (5);
R = CD_3, R_f = CF_3 (6).

Trifluoroiodomethane also adds to hexafluorobut-2-yne and *N*,*N*-bis(trifluoromethyl)amine under the influence of heat, probably by a radical mechanism (7, 8).

[2] $CF_3I + CF_3C{\equiv}CCF_3 \rightarrow (CF_3)_2C{=}CICF_3$

[3] $CF_3I + (CF_3)_2NC{\equiv}CH \rightarrow (CF_3)_2NCI{=}CHCF_3$

Stereochemical information about the vinyl iodide products is limited. The zinc – hydrochloric acid reduction of 1,1,1,4,4,4-hexafluoro-2-iodobut-2-ene produced a 70% yield of *trans*-1,1,1,4,4,4-hexafluorobut-2-ene; and a similar reduction using magnesium gave a 78% yield of the same butene (3). The *trans* nature of the iodobutene (implying *cis* addition) was inferred from these results. The product of eq. [3] was found by vapor phase chromatography (v.p.c.) to be a 1:1 mixture of isomers (8).

In the course of preparing 3,3,4,4,4-pentafluorobutyne and 3,4,4,4-tetrafluoro-3-(trifluoromethyl)butyne for our studies on sigma bonded fluorocarbon alkynyl derivatives of metals (9–11), we have isolated and studied the stereochemistry of the intermediate vinyl iodides produced by the radical addition of R_fI to acetylene (eq. [1]: R = H; R_f = CF_3, C_2F_5, and *i*-C_3F_7).

In keeping with our interest in difluorocarbene additions to unsaturated systems (9–11) we have reacted the olefins $R_fCH{=}CHI$ and the acetylenes $R_fC{\equiv}CH$ (R_f = CF_3, C_2F_5, and *i*-C_3F_7) with the carbene source, $(CH_3)_3SnCF_3$, in the gas phase.

Experimental

Volatile reactants and products were manipulated in a vacuum system. All reactions were carried out in sealed Pyrex tubes. Infrared (i.r.) spectra were recorded using Perkin–Elmer models 21 and 457 instruments and nuclear magnetic resonance (n.m.r.) spectra were run using Varian A-60 and HA-100 spectrometers. Chemical shifts are given in p.p.m. with respect to external tetramethylsilane (^1H spectra) and either internal or external $CFCl_3$ (^{19}F spectra), negative values being to low field. Analytical and spectroscopic data are listed in Tables I–IV and in diagrams **4–15**. Microanalyses were done by Mr. Peter Borda of this Department.

The perfluoroalkyl iodides were obtained from Peninsular ChemResearch Inc. and $CF_3CCl{=}CCl_2$ from Columbia Organic Chemicals. Acetylene was purchased from Matheson of Canada Ltd. and the acetone solvent was removed by trap-to-trap distillation. 3,3,3-Trifluoropropyne was prepared from $CF_3CCl{=}CCl_2$ by the method of Finnigan and Norris (12) with two slight modifications. The amount of fused zinc chloride was increased from 0.025 to 0.3 moles and the reaction temperature was maintained at 140–150° instead of 100° during the addition of the propene. Using these modifications a 77% yield of the propyne was obtained. 3,3,4,4,4-Pentafluorobutyne was prepared in 51.2% yield as described by Haszeldine and Leedham (2).

Preparation of 3,3,3-Trifluoro-1-iodopropene

3,3,3-Trifluoro-1-iodopropene (**1**) was prepared from acetylene and trifluoroiodomethane as described by Haszeldine (1). The reactants were irradiated for 14 days (100 W lamp).[1] The product **1** (69% yield) was purified by distillation at atmospheric pressure, b.p. 70.5°–73.0°

[1]A Hanovia lamp, 608A-36 or 679A-36 (100 or 450 W), was placed 10 cm from the reaction tube.

(lit. value 70.2° (1)) and was further identified by microanalysis (Table I). The ^1H n.m.r. spectrum of **1** was unaltered after distillation. The isomer ratio *trans*:*cis* = 6.7:1 was determined from the ^{19}F n.m.r. spectrum. The i.r. spectrum of a very small, higher boiling fraction (< 1 g) showed double bonds at 1662 and 1630 cm^{-1}. It was presumably the known diene $CF_3CH{=}CH{-}CH{=}CHI$ (1) and was not further studied.

Preparation of 3,3,4,4,4-Pentafluoro-1-iodobutene

3,3,4,4,4-Pentafluoro-1-iodobutene (**2**) was also prepared as previously described (2). In two separate experiments the reactants were irradiated with 100 and 450 W lamps for 14 days each. The former produced an 87% yield of **2**, the latter, a 78% yield, b.p. 89° (lit. value 84.4° (2)). The ^{19}F n.m.r. spectrum of **2** produced by irradiation under the 450 W lamp showed an isomer ratio of *trans*:*cis* = 9:1. A higher boiling fraction (0.35 g, b.p. 97° (48 mm)) analyzed (Table I) for the known 5,5,6,6,6-pentafluoro-1-iodohexa-1,3-diene (b.p. lit. value 104° (46 mm) (2)). The i.r. spectrum showed absorptions at 1642 and 1573 cm^{-1}.

Preparation of 3,4,4,4-Tetrafluoro-3-(trifluoromethyl)-1-iodobutene (3)

1,1,1,2,3,3,3-Heptafluoro-2-iodopropane (122.67 g) and acetylene (13.06 g) in six Carius tubes, were irradiated for 14 days (100 W lamp). A small amount (0.4 g) of unreacted acetylene was isolated. The major distillation fraction, b.p. 92°–120°, was found by v.p.c. (Kel-F grease at 70°) to be a mixture of isomers of 3,4,4,4-tetrafluoro-3-(trifluoromethyl)-1-iodobutene (**3**) (85% yield), (*trans*:*cis* = 1.78:1) (b.p. *trans*, 97.8°, b.p. *cis*, 109.7° (micro boiling points)). Two small, higher boiling fractions, 110°–114° (285 mm) and 113°–114.5° (151 mm) were obtained which had the same i.r. spectrum with double bond absorptions at 1648 and 1578 cm^{-1}.

Ultraviolet Irradiation of cis- and trans-3,4,4,4-Tetrafluoro-3-(trifluoromethyl)-1-iodobutene

In two separate experiments pure samples of the *cis* and *trans* **3** were irradiated for 15 days under a 450 W lamp. A v.p.c. examination of the material in both tubes after irradiation showed that the same ratio of isomers, *trans*:*cis* = 1.49:1, had been established.

Preparation of 3,4,4,4-Tetrafluoro-3-(trifluoromethyl)-butyne

The butyne was prepared using Haszeldine's method for the preparation of 3,3,4,4,4-pentafluorobutyne (1).

In two separate experiments **3** was added to a large excess of finely powdered KOH and heated under reflux (1 h). The resultant acetylene (26.2 g, 42%) was purified by trap-to-trap distillation and dried for one day over KOH.

The extrapolated vapor pressure curve gave a boiling point of 23.0° (ΔH_{vap} = 6.28 kcal/mole; Trouton's constant = 21.2 cal/mole deg).

Addition of Difluorocarbene to the Olefins and Acetylenes

Trimethyl(trifluoromethyl)tin did not react with the olefins **1**, **2**, and **3** in the gas phase at 150° (24 h) to produce cyclopropanes.

The gas phase reaction of trimethyl(trifluoromethyl)tin with each of the acetylenes $R_fC{\equiv}CH$ ($R_f = CF_3$, C_2F_5, and *i*-C_3F_7) at 150° (24 h) did produce the expected cyclopropene $R_fC{=}CHCF_2$ (Table IV). The cyclopropenes were condensed in a trap cooled to −78° and characterized by their ^1H, ^{19}F, and i.r. spectra.

Results and Discussion

Stereochemistry of the Addition Reactions

3,3,3-Trifluoro-1-iodopropene (**1**) and 3,3,4,4,4-pentafluoro-1-iodobutene (**2**) were prepared

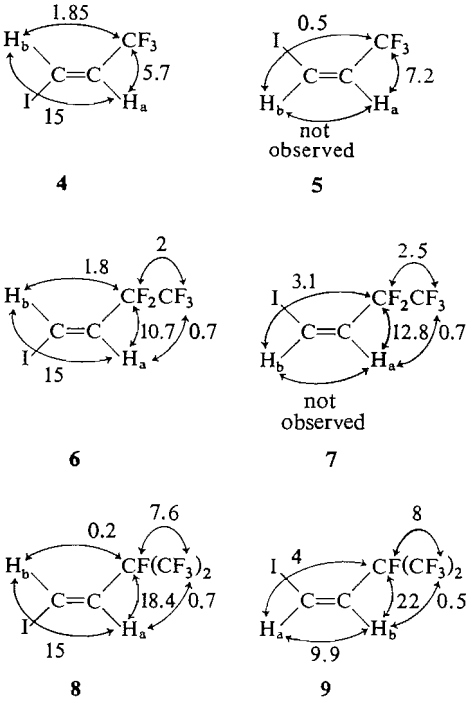
in good yield by the known ultraviolet (u.v.) induced (presumably free radical) reactions of trifluoroiodomethane and pentafluoroiodoethane with acetylene (1, 2). The ^1H n.m.r. spectrum of **1**, because of peak overlap, shows the presence of the *trans* adduct only (Table III, (**4**)); however, the ^{19}F n.m.r. spectrum does show both isomers **5**. The assignments are based on the now well-established results for substituted trifluoromethyl compounds: $J_{CF_3-H(trans)}$ ~0, $J_{CF_3-H(cis)}$ ~2, and $J_{CF_3-H(gem)}$ ~8 (13–15). The integrated ^{19}F n.m.r. spectrum gives the ratio *trans*:*cis* = 6.7:1.

First-order analysis of the ^1H and ^{19}F n.m.r. spectra of **2** gives the couplings shown in **6** and **7**. The *cis* isomer is again seen only in the ^{19}F n.m.r. spectrum due to overlapping peaks in the ^1H spectrum. Because the H—H couplings could not be established, the assignments are based on the finding that $J_{F-H(gem)}$ in the *cis* isomer > $J_{F-H(gem)}$ in the *trans* isomer (13); this is also seen in **4** and **5**. This assignment gives consistent values for the other couplings, especially the $J_{H-H(trans)}$ of 15 c.p.s. which is the same as in **4**. Confirmation of the predominantly *trans* structure comes from the i.r. spectrum which shows the characteristic band at 942 cm^{-1} (16). The isomer distribution, *trans*:*cis* = 9:1, was determined from the integrated ^{19}F n.m.r. spectrum.

3,4,4,4-Tetrafluoro-3-(trifluoromethyl)-1-iodobutene (**3**) can be prepared by reacting heptafluoroisopropyl iodide with acetylene under u.v. light. The reaction gives an 85% yield of a mixture of the *trans* and *cis* isomers of **3** which



4 **5** **6** **7** **8** **9**

can be separated by v.p.c. Two smaller higher boiling fractions are also obtained which have almost identical i.r. spectra with double bond absorptions at 1648 and 1578 cm^{-1}. These are, presumably, mixtures of isomers of the diadduct, *i*-$C_3F_7CH{=}CH{-}CH{=}CHI$ (1, 2). The assignments for the two isomers of **3** (Table III, (**8**) and (**9**)) are based on the now generally accepted rule that for olefins $J_{H-H(trans)} > J_{H-H(cis)}$. The assigned coupling constants are of the same

TABLE IV

Difluorocarbene reactions with polyfluoroacetylenes

Reactants	Conditions	Products identified	Yield (%)
$CF_3C{\equiv}CH$ (1.119 g, 11.9 mmole) $(CH_3)_3SnCF_3$ (2.634 g, 11.3 mmole)	150° (24 h)		15.2
$C_2F_5C{\equiv}CH$ (0.830 g, 5.75 mmole) $(CH_3)_3SnCF_3$ (1.985 g, 8.52 mmole)	150° (24 h)		23.6
$(CF_3)_2CFC{\equiv}CH$ (0.683 g, 3.52 mmole) $(CH_3)_3SnCF_3$ (1.142 g, 4.91 mmole)	150° (24 h)		8.25

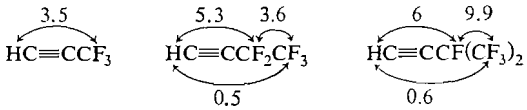
order of magnitude as those found for *trans* and *cis* i-$C_3F_7CH{=}CHF$ (17). The isomer distribution, *trans*:*cis* = 1.78:1, was determined by v.p.c.

Interconversion of **8** and **9** occurs readily under u.v. irradiation to give an equilibrium mixture of **8** to **9** equal to 1.49:1. The ratio present in the product mixture (**3**) is greater than this, namely, 1.78:1 indicating that the *trans* isomer (**8**) is formed preferentially by *trans* addition as it is in the reactions giving **1** and **2**. As mentioned in the Introduction *cis* addition of trifluoroiodomethane to 3,3,3-trifluoropropyne seems to take place (3).

Although, with respect to the double bond, $J_{F-H(cis)}$ (**4**) > $J_{F-H(trans)}$ (**5**), the reverse is true for the same couplings shown in **6** and **7** and in **8** and **9**. Bothner-By and co-workers (15) found that as fluorine atoms are substituted by hydrogen, $J_{F-H(trans)}$ decreases from +0.03 to −0.89 c.p.s. and $J_{F-H(cis)}$ decreases from −2.22 to −4.32 c.p.s. in going from 3,3,3-trifluoropropene to 3-fluoropropene. It is possible that our results have a similar explanation. However, a complete explanation lies in a determination of the relative populations of the most preferred rotamers and the relative signs and contributions of the couplings of each rotamer to the observed averaged coupling constant. This, however, is beyond the scope of the present investigation.

The dehydrohalogenation of **3** produced a 42% yield of the isopropyl acetylene i-$C_3F_7C{\equiv}CH$ (**12**). The new acetylene has the expected ^1H n.m.r., ^{19}F n.m.r., and i.r. spectra (Tables I–III, (**12**)) and the formula is confirmed by analysis (Table I). The i.r. spectrum shows the strong C≡C stretching frequency at 2155 cm^{-1}.

The spectra of 3,3,4,4,4-pentafluorobutyne have also been recorded for the first time (Tables II and III and Diagrams (**10**–**12**)).



10 **11** **12**

The coupling constant J_{F-H} for 3,3,3-trifluoropropyne is 3.5 c.p.s. (**10**). This same coupling constant increases as the fluorine atoms are replaced by the less electronegative trifluoromethyl groups in **11** and **12**. Similar electronegative effects have been found by Abraham and Cavalli (18).

Difluorocarbene Additions

Difluorocarbene from trimethyl(trifluoromethyl)tin (19) does not add in the gas phase at 150° to any of the olefins **1**, **2**, or **3**. This carbene does add, under the same conditions, to 2-dimethylarsino-1,1,1,4,4,4-hexafluorobutene to give the expected cyclopropane (9) although it does not add to the analogous trimethylsilyl compound. Seyferth and co-workers (20) have added difluorocarbene to a number of olefins using the same tin compound as the carbene source. These reactions, however, were done in solution.

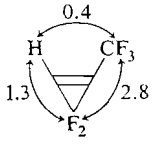
Difluorocarbene from various sources has been added to several acetylenes to produce

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

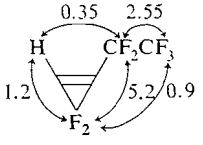
cyclopropenes (9–11, 21, 22). We have added difluorocarbene (from $(CH_3)_3SnCF_3$) in the gas phase at 150° to the acetylenes $R_fC{\equiv}CH$ (R_f = CF_3, C_2F_5, and *i*-C_3F_7) to produce the cyclopropenes $R_fC{=}CHCF_2$ in low yield. Be-

[4] $R_fC{\equiv}CH + (CH_3)_3SnCF_3 \rightarrow$  $+ (CH_3)_3SnF$

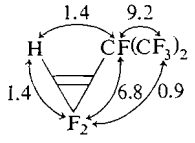
cause of difficulties in separating these novel compounds from trace impurities, the cyclopropenes have been characterized on the basis of their spectroscopic properties. The i.r. spectra of



13



14



15

all three compounds show the characteristic high frequency double bond absorption, and the spectrum of the trifluoromethyl compound in the CF stretching region is very similar to those of related and fully characterized compounds (9, 11). The best confirmation of their structure comes from their n.m.r. spectra (Table III); the structures **13**, **14** and **15** which can be assigned on a first-order basis, give couplings which are again consistent with those of known cyclopropenes (9–11).

Some reactions of 2,4-dimethoxytetrahydropyrans[1]

M. J. BALDWIN[2] AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received January 13, 1969

Acid-catalyzed elimination of methanol from 2,4-dimethoxytetrahydropyran (**1**) produces 2-methoxy-5,6-dihydro-2*H*-pyran (**3**) rather than the expected olefin 4-methoxy-3,4-dihydro-2*H*-pyran (**2**).

The reaction of 1,3-dibromo-5,5-dimethylhydantoin with **3** in ether – methanol gives a 2:1 mixture of the isomers 3β-bromo-2α,4α-dimethoxytetrahydropyran (**5***a*) and 3α-bromo-2α,4β-dimethoxytetrahydropyran (**5***b*) respectively. A rationale is given to explain the preponderance of **5***a* over **5***b* and the highly selective attack of the bromine of the hydantoin and the methanol on C-3 and C-4 respectively of the double bond of **3**. Reduction of **5***ab* with zinc in ethanol provides only compound **3**.

The room temperature reaction of **1** in a mixture of water and 1,2-dimethoxyethane containing Amberlite IR-120, produces 2-hydroxy-4-methoxytetrahydropyran (**6**) as an equilibrium mixture of *cis* and *trans* isomers in the ratio 1:1. This gave a value of 0.9 kcal/mole for the anomeric effect in **6**. Pyrolysis of the derivative, 2-acetoxy-4-methoxytetrahydropyran failed to produce the olefin **2** and resulted only in extensive decomposition.

Introduction

A recent communication from this laboratory described the preparation of *cis*- and *trans*-2,4-dimethoxytetrahydropyran (1). Since then, we have explored the utility of these isomers as intermediates for the preparation of 3-alkyl (or aryl) thio-2,4-dimethoxytetrahydropyrans. Although in our hands the 2,4-dimethoxytetrahydropyrans could not be converted to 3-alkyl (or aryl) thio-2,4-dimethoxytetrahydropyrans, a number of interesting reactions and properties of the dimethoxy compounds was discovered. This paper describes the results of these findings.

Results and Discussion

Since it has been shown that 3,4-dihydro-2*H*-pyran reacts with ethanesulfenyl chloride and then with methanol to produce 3-ethylthio-2-methoxytetrahydropyran (2, 3), it is quite possible that 4-methoxy-3,4-dihydro-2*H*-pyran (**2**, Scheme 1) might react in the same manner to provide the 3 - alkylthio - 2,4 - dimethoxytetrahydropyran. Accordingly, attempts were made to convert 2,4-dimethoxytetrahydropyran, (**1**), into **2**. This appeared to be feasible since both 2-*n*-butoxy-4-methyltetrahydropyran (4) and the 2-ethoxy homologue (5) have been successfully converted to 4-methyl-3,4-dihydro-2*H*-pyran by treatment with phosphorus pentoxide and *p*-toluenesulfonic acid respectively.

A *cis–trans* mixture of 2,4-dimethoxytetrahydropyran (**1**) (1) was heated at 180° with a catalytic amount of phosphorus pentoxide (4). Only extensive decomposition occurred. At a lower temperature (130° for 1.5 h), only unchanged **1** was obtained in an 88% yield (by distillation). When **1** was heated at 150° with a catalytic amount of *p*-toluenesulfonic acid (5), only 2-methoxy-5,6-dihydro-2*H*-pyran (**3**, Scheme 1) was obtained in an 86% yield. This product was identical in all respects with an authentic sample (6).

The formation of **3** is somewhat surprising since of the two methoxy groups in **1**, that at the anomeric carbon (C-2) is undoubtedly the more readily removed by acid catalysts because it is part of an acetal structure. It is quite likely that compound **3** was formed by a route such as the reverse of eq. *a*, Scheme 2 in the previous report (1).

A second route to 4-methoxy-3,4-dihydro-2*H*-pyran (**2**) was attempted, based upon the knowledge that reductive removal of halogen and an alkoxy group from a β-haloether leads to the formation of an olefin (7). The necessary intermediate, 3 - bromo - 2,4 - dimethoxytetrahydropyran was prepared by the reaction of 1,3-dibromo-5,5-dimethylhydantoin with 2-methoxy-5,6-dihydro-2*H*-pyran (**3**) in the solvent ether – methanol, a technique for bromomethoxylation of olefins employed by van de Sande and Kopecky (8). This route provided in a

(p-TSOH = p-$CH_3C_6H_4SO_3H$)

SCHEME 1

72% yield an isomeric mixture which was composed essentially of the two compounds, 3β-bromo - 2α,4α - dimethoxytetrahydropyran (**5***a* in Scheme 2) and 3α-bromo-2α,4β-dimethoxytetrahydropyran (**5***b*), in the proportion 2:1 respectively.

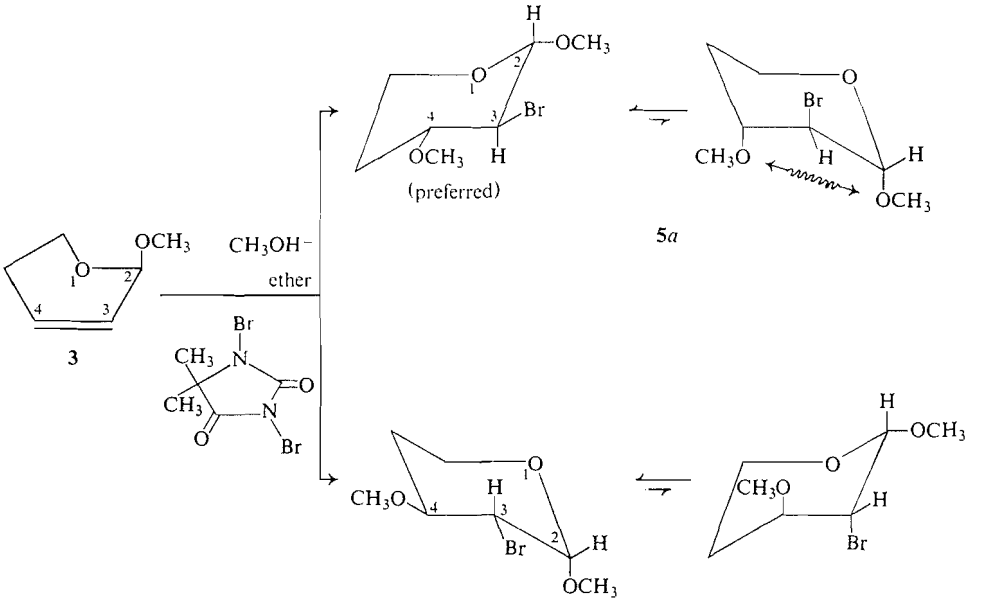
That the 2:1 mixture of **5***a* and **5***b* did not arise from an equilibration process stemming from acid catalyzed isomerization of the acetal linkage during the bromomethoxylation reaction, is strongly supported by the finding (9) that 2α-ethoxy - 3α,4β - dibromotetrahydropyran and 2α - ethoxy - 3β,4α - dibromotetrahydropyran, heated separately for 12 h in refluxing absolute ethanol containing some p-toluenesulfonic acid, failed to show evidence of isomerization. It is well-known that electron-withdrawing groups attached to the carbon adjacent to the anomeric center of an acetal, strongly retard hydrolysis of the acetal. Since both **5***a* and **5***b* are closely similar to the 2-ethoxy-3,4-dibromotetrahydropyrans both in structure and nature of the substituents, it can be concluded that under the low temperature conditions of bromomethoxylation (−50°), and during the short time required for the reaction, no significant isomerization would have occurred.

The structures and preferred conformations of the isomers **5***a* and **5***b* were determined by the following methods. Catalytic hydrogenation of this mixture, with palladium, gave a 2:1 mixture of *cis*- and *trans*-2,4-dimethoxytetrahydropyran whose nuclear magnetic resonance (n.m.r.) spectrum, refractive index, and infrared (i.r.) spectrum were identical to those of an authentic 2:1 mixture of these compounds (1). Thus, bromomethoxylation of **3** has occurred with highly selective attack of the methanol and bromine on C-4 and C-3 respectively of the double bond in **3**. The 100 MHz n.m.r. spectrum of the isomeric mixture (**5***a* and **5***b*) in $CDCl_3$ showed two doublets in the anomeric proton region, at τ 5.21 ($J_{2,3}$ = 2.6 Hz) and at τ 5.62 $J_{2,3}$ = 7.5 Hz). The magnitudes of the couplings permit the assignment of the former signal (τ 5.21) to the C-2 proton in a structure in which the C-3 bromine and C-2 methoxy groups are either *cis* to each other (axial–equatorial) or *trans* diaxial, while the latter signal (at τ 5.62) can be assigned to the C-2 proton of a structure in which these two groups are *trans* diequatorial (10).

Experience has shown that bromomethoxylation of olefins occurs such that the bromine and methoxy groups attack the double bond *trans* to each other (11). As well, in the absence of strong 1,3-diaxial interaction, the anomeric effect (12) favors that conformer in the 2-alkoxytetrahydropyrans in which the alkoxy group is axial. On the basis of these two observations and the information given above, a definite structural and preferred conformational assignment of **5***a* and **5***b* can be made. These are shown in Scheme 2.

The following rationale is given to explain both the 2:1 predominance of isomer **5***a* in which the C-3 bromine and C-2 methoxy groups are *trans* to each other, and the highly selective attack of the bromine atom on C-3 of compound **3**. Because of the anomeric effect (12), the preferred conformation of compound **3** is no doubt that in which the anomeric methoxy group is *quasi* axial (9). Accordingly, attack by the bulky

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.



SCHEME 2

1,3-dibromo-5,5-dimethylhydantoin then must be preferably by a route *trans* to the C-2 methoxy group of **3** to avoid its bulk steric opposition (route (*a*), Scheme 3). However, the formation of a substantial amount of isomer **5***b* in which the C-3 bromine is *cis* to the C-2 methoxy group, clearly shows that the double bond is reasonably accessible from the side on which the C-2 methoxy group is located. This could occur by way of the alternative conformer of **3** in which the C-2 methoxy group is *quasi* equatorial (route (*b*), Scheme 3), since in such a position it would offer less steric resistance. However, previous work (9) has indicated that compound **3** exists to the extent of 80% in the conformation in which the anomeric methoxy group is *quasi* axial. In view of this, and the fact that there is no hindrance to approach by the brominating agent via route (*a*) *trans* to the anomeric methoxy group, one should expect an even greater proportion of **5***a* to **5***b* than 2:1. It appears then that there is some other factor which promotes attack by the *N*-bromohydantoin from the same side as the *quasi* axial anomeric methoxy group. Our recent work (9), concerning the preferred attack of bromine on the C-3 position of compound **3** and also *cis* to the C-2 methoxy group, has suggested the possibility that the brominating agent could transfer the species $Br^{\oplus}$ to the double bond by association of the bromine with the anomeric methoxy group's oxygen atom. In the present case, the extent to which such association (route (*c*), Scheme 3) is involved in the bromination reaction would depend upon the ability of the oxygen atom to compete for the $Br^{\oplus}$ with the resonance stabilized hydantoin anion which liberates the $Br^{\oplus}$. Such a directive effect of the anomeric methoxy group, possibly assisted to some extent by a similar association with the ring oxygen when the *quasi* equatorial conformer is attacked, might well play a part in this reaction and thus account at least in part for the 33% proportion of isomer **5***b*.

Both the above mentioned directions of attack on the double bond of **3** by the brominating agent would lead to the transient formation of the 3-membered ring bromonium ion (Scheme 3), which is then attacked by the methanol from the side *trans* to the bromine atom (13, 14). The factors which determine the direction of opening of such 3-membered halonium rings have been discussed previously (13, 14). It is clear that the reaction of the *trans* bromonium ion (obtained by route (*a*)) with methanol should (*and does*)

occur preferentially at C-4, since by this path, the bulk steric and the polar repulsion of the C-2 methoxy group is minimal. As well, C-4 — Br bond breaking to form an incipient carbonium ion at C-4 is less inhibited by the electron-withdrawing effect of the geminal dioxy group on C-2, than is carbonium ion formation at C-3 (9, 15). Attack at C-4 would also permit the opening of the 3-membered ring so that the substituents at C-3 and C-4 are *trans* diaxial, with the tetrahydropyran ring in the favored chair form (16). For this same type of favored ring opening to occur by attack of methanol at C-3, a conformational change in the bromonium ion structure must occur in opposition to the anomeric effect.

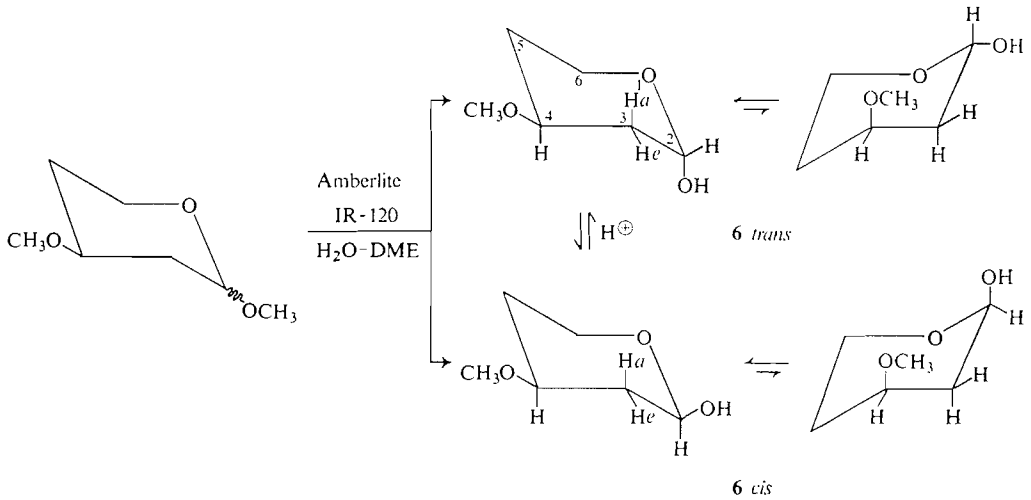
With respect to the *cis* bromonium ion obtainable via route (*b*) and/or (*c*) (Scheme 3), the experimental evidence shows that attack by methanol is essentially at C-4. For this to occur in agreement with the view that preference is given to the pathway in which the entering and "leaving" groups of the 3-membered ring are *trans* diaxial and the 6-membered ring is in the chair form (16), a conformational change must also take place in the bromonium ion structure so that the C-2 methoxy group is *quasi* equatorial. This must occur in opposition to the anomeric effect and hence such a reaction should be retarded. It is not sufficient to say that a reaction involving the less favored conformation would occur because the alternative route (attack of methanol at C-3, with attendant *trans* diaxial opening and maintenance of chair form) would have all three substituents axially disposed, hence resulting in sufficient 1,3-diaxial repulsion to prevent this alternative route, since similar 1,3-diaxial repulsion of all three substituents was not prohibitive in route (*a*). A factor which may be very important in promoting C-4 — Br bond breaking and successful attack by the methanol at C-4 is the electronic effect of the C-2 geminal dioxy group, which would retard incipient carbonium ion formation less at C-4 than at C-3. This factor is present in both the *trans* (route (*a*)) and the *cis* (route (*b*), (*c*)) species and hence may be the dominant factor which determines that **5***a* and **5***b* be formed.

Separation of the isomers **5***a* and **5***b* was not attempted. When this 2:1 mixture was treated with zinc in refluxing ethanol according to Boord's method (7), there was obtained only unchanged starting material (~50%) and 2-methoxy-5,6-dihydro-2*H*-pyran, (**3**) (in a 44% yield). None of the expected olefin, **2**, was detected.

A final attempt to synthesize 4-methoxy-3,4-dihydro-2*H*-pyran (**2**) was made using the method of ester pyrolysis to produce olefins. The advantage of such a method is that it provides a product free from isomers (17). The pyrolysis of carbonate esters (18) has the added advantage that they decompose at lower temperatures than do the acetate esters, and produce the innocuous products carbon dioxide and an alcohol rather than acetic acid.

For the preparation of such esters, the compound 2 - hydroxy - 4 - methoxytetrahydropyran (**6**) was required. This was readily made in a 74% yield by treatment of a solution of 2,4-dimethoxytetrahydropyran (**1**) in the mixed solvent, water, and 1,2-dimethoxyethane (DME), with Amberlite IR-120 (Scheme 4). This distillable material was found to be a 1:1 equilibrium mixture of the *cis* and *trans* isomers as shown by the 100 MHz n.m.r. spectrum in D_2O. The signals for the anomeric protons were at τ 4.80 (triplet, $J_{2,3a} = J_{2,3e} = 3.7$ Hz) and at τ 5.28 (quartet, $J_{2,3a} = 7.5$ Hz, $J_{2,3e} = 2.0$ Hz).

It has been shown that in the compounds *cis*- and *trans*-2,4-dimethoxytetrahydropyran, the C-4 methoxy group prefers to adopt the equatorial position (1). Accordingly, the *cis*- and *trans*-2-hydroxy - 4 - methoxytetrahydropyrans most likely exhibit the same preference in conformation. On this basis, the magnitudes of the couplings stated above permit the indentification of the *cis* and *trans* isomers. These isomers, **6**, and their preferred conformations are shown in Scheme 4. From the integrated area of the anomeric proton signals we know that the ratio of *cis*:*trans* is 1:1, and since this is an acid catalyzed equilibrium mixture, it is clear that in D_2O the free energy difference between the two isomers is ~0 kcal/mole. Inspection of the preferred conformers of *cis*- and *trans*-2-hydroxy-4-methoxytetrahydropyran (Scheme 4) suggests that the *cis* isomer, possessing an equatorial hydroxyl group at C-2, should be preferred over the *trans* isomer with the axial hydroxyl group at C-2 by ~0.9 kcal/mole as a result of the interaction of the axial hydroxyl group in the latter isomer with the two *syn*- axial hydrogen atoms at C-4 and C-6 (19). The equilibrium composition of 1:1 for



SCHEME 4

the two isomers shows that the magnitude of the anomeric effect present in 2-hydroxy-4-methoxytetrahydropyran in D_2O must then be ~0.9 kcal/mole. The anomeric effect for the compounds *cis*- and *trans* - 2,4 - dimethoxytetrahydropyran, on the basis of their spectra in $CDCl_3$, has been calculated to be ~1.4 kcal/mole (1). The smaller value (0.9 kcal/mole) observed for 2 - hydroxy - 4 - methoxytetrahydropyran is not surprising since it is known that the anomeric effect decreases as the solvent becomes more polar (19, 20).

Treatment of the isomeric mixture of **6** with acetic anhydride in pyridine provided a 61% yield of a mixture of *cis*- and *trans*-2-acetoxy-4-methoxytetrahydropyran in the expected 1:1 ratio, as shown by the 60 MHz n.m.r. spectrum in $CDCl_3$. The magnitude of the couplings agrees with the preferred conformation in which the C-4 methoxy group is equatorial. The signals at τ 3.88 (triplet, $J_{2,3a} = J_{2,3e} = 3.0$ Hz) and at τ 4.34 (quartet, $J_{2,3a} = 7.5$ Hz, $J_{2,3e} = 3.0$ Hz were assigned to the anomeric protons of the *trans* and *cis* isomers respectively.

Room temperature treatment of the 1:1 mixture of 2-acetoxy-4-methoxytetrahydropyran in glacial acetic acid, with a catalytic amount of *p*-toluenesulfonic acid, in an attempt to achieve equilibrium, as had been done by Anderson and Sepp (21) with 2-acetoxy-4-methyltetrahydropyran, in order to determine the influence of the acetoxy group in determining the magnitude of the anomeric effect, was unsuccessful. Within 1 h the solution had darkened, and an n.m.r. analysis of the crude reaction product in $CDCl_3$ showed complete absence of the signals at τ 3.88 and τ 4.34 due to the anomeric protons of the two isomers. Apparently, a simple anomerization had not occurred. The nature of this change was not investigated further.

Pyrolysis of 2-acetoxy-4-methoxytetrahydropyran at either 180° or 290° gave only extensive decomposition. No evidence was found for the formation of either 4-methoxy-3,4-dihydro-2*H*-pyran (**2**) or its isomer 2-methoxy-5,6-dihydro-2*H*-pyran (**3**).

Attempts to prepare the carbonate ester of **6** by treatment with methyl chloroformate in pyridine (18) gave only unchanged **6** in high yield.

Experimental

All boiling points and melting points are uncorrected.

Infrared spectra were recorded on Perkin–Elmer instruments, models 21 and 421.

The n.m.r. spectra were obtained with a Varian Associates model A-60 (60 MHz) spectrometer or a Varian Associates HA-100 (100 MHz) spectrometer. Unless otherwise stated, the n.m.r. spectra were obtained from samples dissolved in $CDCl_3$. Tetramethylsilane was used as internal reference.

Solvents were removed by a rotary evaporator under reduced pressure unless otherwise stated.

Elemental analyses and molecular weight determinations were carried out by Mrs. Darlene Mahlow of the Chemistry Department of the University of Alberta, Edmonton, Alberta.

2-Methoxy-5,6-dihydro-2H-pyran (3)

It was prepared by a modification of the procedure of Woods and Sanders (6). To a stirred solution of sodium methoxide (29.7 g, 0.55 mole) in 300 ml of anhydrous dimethylsulfoxide was added dropwise 97 g (0.5 mole) of 3-bromo-2-methoxytetrahydropyran (15). An exothermic reaction ensued and the rate of addition was controlled so that the reaction temperature did not exceed 60°. When the addition was completed, the mixture was stirred for a further 15 min, and then subjected to fractional distillation under reduced pressure. All material in the boiling range 62° at 700 mm to 90° at 23 mm was collected in a dry ice–acetone cooled receiver. This material was redistilled under reduced pressure in a Nestor–Faust spinning band column and afforded 44 g (77%) of 2-methoxy-5,6-dihydro-2*H*-pyran, b.p. 66° at 67 mm, n_D^{23} 1.4430 (lit. b.p., 136–138° at 700 mm, n_D^{25} 1.4425 (6)).

2,4-Dimethoxytetrahydropyran (1)

It was prepared according to published directions (1).

Attempted Acid Catalyzed Removal of Methanol from 1 to Produce 4-Methoxy-3,4-dihydro-2H-pyran (2)

The published procedure (5) provided no detailed directions. Accordingly, those employed here are described below. A solution of 100 mg of *p*-toluenesulfonic acid in 20 g (0.137 mole) of 2,4-dimethoxytetrahydropyran (1) was heated to 150° for 2 h. Distillation of the reaction mixture under reduced pressure afforded 13.5 g (86%) of 2-methoxy-5,6-dihydro-2*H*-pyran, boiling at 69° at 70 mm. This was identical to authentic material (6) as shown by its i.r. and n.m.r. spectra.

3-Bromo-2,4-dimethoxytetrahydropyran (5)

1,3-Dibromo-5,5-dimethylhydantoin (7.0 g, 0.025 mole) (Matheson, Coleman and Bell) was added in small portions to a cold (−50°) stirred solution of 2-methoxy-5,6-dihydro-2*H*-pyran (5.7 g, 0.05 mole) in a mixture of 10 ml of dry ether and 10 ml of dry methanol. When the addition was completed, the reaction mixture was allowed to warm to room temperature and then poured into ice-cold, saturated sodium bicarbonate solution. The resulting mixture was extracted with ether, and the ether extract washed with saturated aqueous sodium bisulfite solution and then with saturated aqueous sodium bicarbonate solution. The dried ($MgSO_4$) ether solution was separated from the drying agent and freed from ether. The residual oil was distilled under vacuum and provided 8.0 g (72%) of 3-bromo-2,4-dimethoxytetrahydropyran, b.p., 63° at 0.05 mm, n_D^{22} 1.4832.

Anal. Calcd. for $C_7H_{13}BrO_3$ (mol. wt. 225): C, 37.36; H, 5.82; Br, 35.50. Found (mol. wt. (mass spectrum) 225): C, 37.35; H, 5.77; Br, 35.78.

The n.m.r. spectrum was consistent with the structure. The significant details of the n.m.r. spectrum are given in the Discussion.

To 3-bromo-2,4-dimethoxytetrahydropyran (5.2 g, 0.023 mole) in 50 ml of anhydrous methanol containing 1.7 g (0.03 mole) of sodium methoxide, was added 500 mg of 5% palladium on charcoal. The resulting mixture was shaken for 24 h with hydrogen at 55 p.s.i. in a Parr hydrogenator. The solids were then separated by filtration and the solvent removed from the filtrate. An ether solution of the residual paste was washed with water, dried ($MgSO_4$), and freed from solvent by fractional distillation. The product (2.2 g, 67%) was 2,4-dimethoxytetrahydropyran whose refractive index, n.m.r., and i.r. spectra were identical with those of an authentic sample (1). The n.m.r. spectrum showed it to be a mixture of *cis* and *trans* isomers in the ratio 2:1 (integrated areas of the anomeric proton signals).

2-Hydroxy-4-methoxytetrahydropyran (6)

A solution of 2,4-dimethoxytetrahydropyran (1) (7 g, 0.454 mole) in 75 ml of water containing 25 ml of DME and 1.5 g of Amberlite IR-120 ion exchange resin, was stirred at room temperature for 24 h. The solution was then filtered and the filtrate freed from solvents. Toluene (10 ml) was added towards the end of the solvent removal to effect complete elimination of water by azeotropic distillation. Fractional distillation of the residual oil under reduced pressure gave 4.7 g (74%) of 2-hydroxy-4-methoxytetrahydropyran as a (1:1) mixture of *cis* and *trans* isomers, b.p., 65° at 0.1 mm; n_D^{23} 1.4573.

Anal. Calcd. for $C_6H_{12}O_3$: C, 54.53; H, 9.15. Found: C, 54.61; H, 9.37.

The i.r. absorption spectrum in CCl_4 showed a broad absorption band at 3400 cm^{-1} (OH). The n.m.r. spectrum was consistent with the assigned structure and the analysis of its significant features is described in the Discussion.

2-Acetoxy-4-methoxytetrahydropyran

A solution of 2-hydroxy-4-methoxytetrahydropyran (8 g, 0.06 mole) and acetic anhydride (10.2 g, 0.1 mole) in 50 ml of dried (KOH) pyridine was heated under reflux for 15 min. The cooled reaction mixture was diluted with 125 ml of water and then treated with solid sodium bicarbonate until evolution of carbon dioxide ceased. An ether extract (3X) was washed successively with ice-cold 10% hydrochloric acid, with saturated aqueous sodium bicarbonate, and then with water. The dried ($MgSO_4$) ether solution was freed from solvent and the residue distilled under reduced pressure to give 6.4 g (61%) of 2-acetoxy-4-methoxytetrahydropyran. This was a 1:1 mixture of *cis* and *trans* isomers as shown by integration of the anomeric proton signal areas of the n.m.r. spectrum. The salient features of the n.m.r. spectrum are presented in the Discussion. It had b.p., 67° at 0.05 mm; n_D^{22} 1.4447.

Anal. Calcd. for $C_8H_{14}O_4$: C, 55.16; H, 8.10. Found: C, 55.07; H, 7.91.

Mechanism of formation of trimethylisoxazole and intermediates upon alkaline hydrolysis of nitroethane

R. W. LOCKHART, K. W. NG, P. E. NOTT, AND A. M. UNRAU
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received March 6, 1969

Nitroethane and higher homologous primary nitroalkanes undergo a base-catalyzed condensation yielding the corresponding 2,3,4-trialkyisoxazoles. Basic hydrolysis of nitroethane to acetaldehyde is the key initial step followed by a series of condensation and elimination reactions. Through the use of appropriately ^{14}C-labelled intermediates and acetaldehyde-d_4, a relatively simple mechanism is indicated which will satisfactorily account for all observed intermediates indicated in a summary of the reaction sequence.

1) nitroethane → acetaldehyde + nitrite

2) acetaldehyde + nitroethane → nitroalcohol → nitroolefin

3) nitroolefin + nitroethane → 2,4-dinitro-3-methylpentane → 3-methylpentan-2,4-dioxime → 3,4,5-trimethylisoxazole

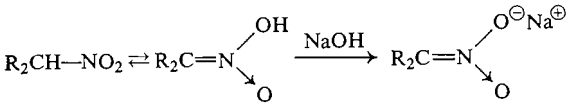
Discussion

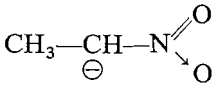
Primary and secondary nitroparaffins usually dissolve in aqueous or aqueous alcoholic solutions of strong alkali due to the formation of the corresponding salt of the aci-form, e.g.



Other reactions of such nitroparaffins with alkali and/or other reagents have been reported (1–6) and most have been considered to involve the aci-forms. One particularly common product of prolonged action of alkali on nitroethane is trimethylisoxazole. By treating nitroethane with a concentrated solution of potassium carbonate, Dunstan *et al.* (2, 3) identified acetonitrile, trimethylisoxazole, and nitrite ions. An aldehyde was also found in the reaction mixture of alcoholic KOH and nitroethane. Nitropropane gave under similar conditions propionitrile, triethylisoxazole, and nitrite ion (2).

In considerably more recent work, Lippincott (1) has shown that using an organic base such as propylamine in aqueous solution in conjunction with nitroethane, facilitates the isolation of crystalline 3-methyl-2,4-pentanedionedioxime, which upon subsequent heating in aqueous medium gives trimethylisoxazole. The 1,3-dioximes have long been known as suitable precursors in the preparation of isoxazoles (7). In the mechanism proposed by Lippincott (1), the aci-nitroethane was considered as the key starting compound.

It has been found that 2-methyl-2-nitro-1,3-propanediol decomposes in alkali to give nitrite in variable yields (8), with the reverse aldol reaction becoming increasingly important as the alkali concentration is increased. Even in the absence of a base, 2-methyl-2-nitro-1,3-propanediol and 2-ethyl-2-nitro-1,3-propanediol were found to generate formaldehyde when heated under reflux in water (ca. 30%). The resulting solution became acidic, whereupon no further formation of formaldehyde and only a trace of nitrite (0.5 %) could be detected in the decomposition mixture. In the absence of a base, the decomposition does not go to completion due to the acidity of the resulting solution, since the nitroparaffin may behave as a pseudo acid,



Treatment of nitroethane with saturated potassium carbonate resulted in the formation of a red-colored oil, which accumulated on the surface of the mixture on warming or upon storage at room temperature for several days. It was shown by gas chromatography to be composed of acetonitrile, acetaldoxime, and trimethylisoxazole (Fig. 1). The nitrite ion, up to 35% based on the nitroethane, could be detected in the aqueous solution. When a mixture of

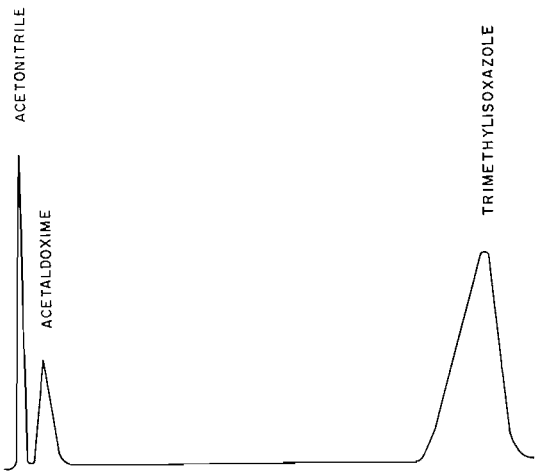


FIG. 1. Gas chromatography of product from nitroethane in potassium carbonate solution, silicone gum rubber column at 100 °C helium flow 30 ml/min.

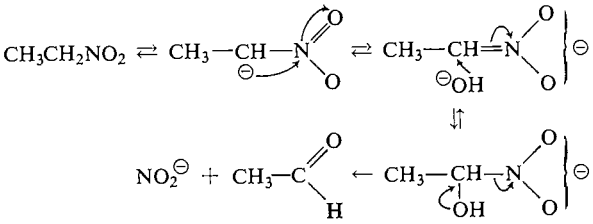
nitroethane in carbonate solution was distilled prior to the appearance of the red oil, the distillate was shown to contain acetaldehyde which was identified as its 2,4-dinitrophenylhydrazone.

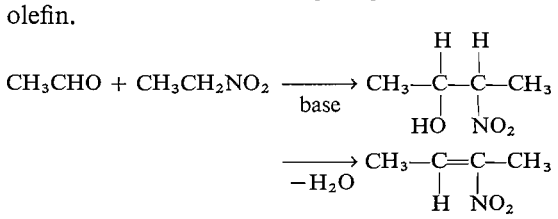
The conversion of primary and secondary nitroparaffins to aldehydes and ketones, respectively, by acidifying the aci-salts was discovered by Nef and has been extensively investigated (9). Oxidation of some nitroparaffins in basic media to the corresponding carbonyl compounds has also been reported (4, 10, 11). However, the isolation of acetaldehyde from a mixture of nitroethane in aqueous potassium carbonate solution has apparently not been reported before. To explain the formation of these reaction products, we formulate the reaction as follows (cf. 12).

(1) Conversion of nitroethane to acetaldehyde and nitrite ion in the following sequence



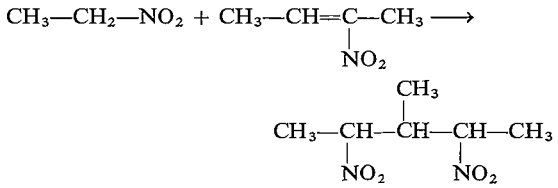
It has been suggested (4, 10) that an oxidative process involving free radical intermediates may be involved in this conversion. We have found little or no change in the rate of formation of the nitrite ion under nitrogen, and hence the hydrolytic mechanism involving the initial carbanion formation is favored.

(2) A condensation of acetaldehyde and nitroethane in the presence of a base, followed by facile elimination of water giving rise to a nitro-olefin.



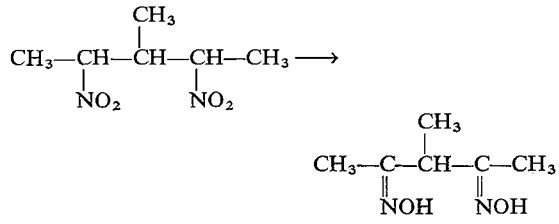
The formation of a nitro-olefin from the corresponding nitro-alcohol is not uncommon. For example, Reasenberg and Smith (13) have isolated 2-nitro-2-butene from a mixture of acetaldehyde and nitroethane in alcoholic solution with a trace of sodium hydroxide. With high base concentrations such as in our experiment, the elimination reaction would be very much enhanced.

(3) Condensation of nitroethane with 2-nitro-2-butene gives rise to 2,4-dinitro-3-methylpentane. Analogous reactions between primary or secondary aliphatic nitro compounds with



α-nitro-olefins have been described (14, 15) and this forms the basis of the preparation of 1,3-dinitroparaffins, although yields are reported to be variable.

(4) The γ-dinitroparaffin is converted to the corresponding dioxime. Lippincott (1) has shown that the dioxime is an isolable intermediate in the reaction of nitroethane with an



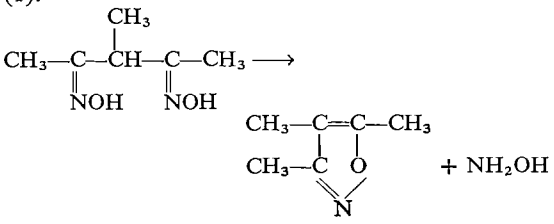
organic base. The exact mechanism of the conversion of the dinitro compound to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

dioxime is as yet not clear. The possibility exists that acetaldehyde may serve as a reducing agent since some ^{14}C-labelled acetate was found when acetaldehyde-1-^{14}C was used. More likely, acetate is formed in the competitive alkaline oxidation of the corresponding aldehyde or via oxidation by the nitrite. Alternatively, the dinitroparaffin may be converted to the dioxime via a hydrolytic process either involving the carbanion or hydration of the nitro form. Detailed experimentation would be necessary to illucidate the exact mechanism involved in this particular step.

(5) The 2,4-dioxime, on hydrolysis with or without an acid or base, will give the expected trimethylisoxazole together with hydroxylamine (1).



(6) The formation of acetaldoxime and acetonitrile as by-products can be accounted for by the reaction between an aldehyde and hydroxylamine while acetonitrile results from

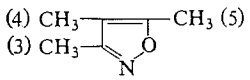
$$CH_3CHO + NH_2OH \longrightarrow$$

$$CH_3{-}CH{=}NOH \xrightarrow{-H_2O} CH_3CN$$

a dehydration of the oxime. In the preparation of heptaldoxime in the presence of a strong sodium carbonate solution, the corresponding nitrile has been identified (16).

The isolation of the intermediates indicated above has been accomplished either in our laboratory or reported by others and particularly, we have now isolated for the first time the intermediate 1,3-dioxime in the aqueous, basic reaction medium. The identity of the dioxime (3-methyl-acetylacetone-2,4-dioxime) was provided by nuclear magnetic resonance (n.m.r.) and by comparison of physical properties (melting point) with those of the corresponding dioxime provided by direct synthesis. Further proof of identity of the dioxime was its facile transformation in slightly basic aqueous media to form the expected 3,4,5-trimethylisoxazole.

We have obtained supporting evidence for the above mechanism by the reaction of nitroethane with formaldehyde, acetaldehyde-1-^{14}C, formaldehyde-^{14}C, and deuterated (d_4) acetaldehyde. When the reaction was carried out in the presence of formaldehyde, the products were 3,4,5-trimethylisoxazole and 3,5-dimethylisoxazole as predicted from the mechanism. Reactions carried out in the presence of acetaldehyde-1-^{14}C and formaldehyde-^{14}C resulted in radioactivity incorporation of a high percentage into the respective isoxazole. Decomposition of the labelled isoxazole and positive positioning of the radioactive carbon gave further proof for the suggested mechanism. Finally, deuterated (d_4) acetaldehyde was also incorporated in the predicted fashion as shown by n.m.r. The n.m.r. spectrum of 3,4,5-trimethylisoxazole consists of three singlet peaks with τ values of 8.2, 7.95, and 7.8. These peaks have been ascribed to the methyl groups on the 4, 3, and 5 positions, respectively.



The singlet at τ 7.95 has a maximum intensity while the other two have equivalent intensities but the intensity of each individually is about two-thirds of that at 7.95. Deuterated acetaldehyde was incorporated into trimethyl isoxazole with the D_3C-group appearing in the predicted 4 position since the intensity of the peak at τ 8.2 was reduced to about two-thirds its usual intensity, while the intensity ratio of the other peaks did not change.

Experimental

Analytical Methods

(1) Estimation of Nitrite Ions

The standard colorimetric method of determination of nitrite ion by diazotizing sulfanilic acid followed by coupling with α-naphthylamine was employed (17).

(2) Estimation of Formaldehyde

The colorimetric determination by complex formation with chromotropic acid was employed (18).

(3) Identification of Products by Gas Chromatography

Reaction products were separated by gas chromatography, on a column (5 ft long, 0.25 in. diameter) packed with 60–80 Chromosorb W containing 20% silicone gum rubber SE-30 as liquid phase. The helium flow rate was 30 ml/min. and the temperature adjusted to 100 °C. Each component in a mixture was identified by comparing its retention time with that of a known compound from other sources except for trimethylisoxazole. Trimethylisoxazole was separated from the rest of the product mixture by treating the mixture with a saturated aqueous solution of mercuric chloride. The grayish precipitate was collected,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

washed with cold water, and dried between filter papers. This double salt of trimethylisoxazole was suspended in water and distilled. The distillate was extracted with petroleum ether (30–60°) and the extract dried with sodium sulfate. The residue of the extract, after evaporating off the solvent, was an oil of pyridine-like odor. This oil was shown to be the component having the longest retention time on gas chromatography and gave the expected n.m.r. spectrum with singlets of τ 8.2, 7.95, and 7.8.

Preparative Experiments

(1) Synthesis of 3,4,5-Trimethylisoxazole

To a saturated aqueous solution (100 ml) of potassium carbonate was added with thorough mixing, 3-methylpentane-2,4-dione (12 g) and hydroxylamine hydrochloride (16 g) and the mixture heated at 60–70° for 4 h. The reddish oil that formed was separated and excess saturated aqueous mercuric chloride added to yield the water insoluble mercury complex. The gray precipitate was suspended in water and the mixture distilled. The distillate was extracted with chloroform, the extract dried with sodium carbonate, and evaporation of the solvent left a pale yellow oil. Distillation under reduced pressure gave a clear oil the n.m.r. of which showed the three expected methyl singlets at τ 8.2 (C-4), 7.95 (C-5), and 7.8 (C-3).

Anal. Calcd. for C_6H_9NO: C, 64.86; H, 8.18; N, 12.61. Found: C, 64.86; H, 8.21; N, 12.75.

(2) Synthesis of 3,5-Dimethylisoxazole

This isoxazole was synthesized as described above from pentane-2,4-dione (11 g) and hydroxylamine hydrochloride (16 g) as described for 3,4,5-trimethylisoxazole. The n.m.r. spectrum showed the two expected methyl singlets with τ 7.82 (C-5) and 7.68 (C-3) with a vinylic proton singlet (C-4) at τ 4.15.

Anal. Calcd. for C_5H_7NO: C, 61.84; H, 7.21; N, 14.43. Found: C, 61.83; H, 7.29; N, 14.52.

(3) Synthesis of 3,4,5-Trimethylisoxazole from Nitroethane

Nitroethane (15 ml, 0.2 mole) was introduced to a saturated aqueous solution of potassium carbonate (138 g, 1 mole) and thoroughly mixed. The mixture was either heated gently to about 60–70 °C or left at room temperature for several days until a red oil (ca. 5 ml) separated at the surface. The oil was separated, followed by drying with potassium carbonate and by gas chromatography (Fig. 1). Alternatively, the cooled two phase mixture was extracted with chloroform and the chloroform extract was washed with water and evaporated under vacuum. Addition of an excess of a saturated aqueous solution of mercuric chloride to the residue gave a gray-brown precipitate which was filtered off and washed with cold water. The precipitate was suspended in water (300 ml) and the mixture distilled. The distillate was extracted with chloroform and the chloroform extract was evaporated to leave a pale yellow oil. Distillation of the oil under reduced pressure gave trimethylisoxazole with physical characteristics identical to trimethylisoxazole prepared from 3-methylpentane-2,4-dione.

(4) Isolation of 3-Methylpentane-2,4-dione Dioxime from Nitroethane – K_2CO_3 Reaction Mixtures

Reaction mixtures of nitroethane (15 ml) in saturated aqueous potassium carbonate solution (100 ml) were stored at room temperature for extended time periods (4–7 days). A white, crystalline solid that slowly collected at the interface of the reddish oil (trimethylisoxazole) and the aqueous phase, was collected, washed with ether, and recrystallized from acetone – ether, m.p. 130–131 °C, undepressed upon admixture with dioxime obtained from 3-methylpentane-2,4-dione. The n.m.r. spectrum was also identical to that of the dioxime synthesized from the dione (C-1 and C-5 methyl singlet, τ 8.25, C-3 proton quartet, τ 7.3, 3-methyl doublet, τ 8.9, and the N—O—H proton singlet downfield, τ −0.8 to −1.0).

Anal. Calcd. for $C_6H_{12}N_2O_2$: C, 50.00; H, 8.33; N, 19.44. Found: C, 50.09; H, 8.27; N, 19.32.

(5) Synthesis of Dioxime of 3-Methylpentane-2,4-dione

To an ethanolic solution (20 ml) of the dione (5.0 g) was added a neutral alcoholic solution (20 ml) containing a 2.2 molar equivalent of hydroxylamine. The mixture was gently heated (50–60°) for 30 min after which the volume of the solution was reduced and upon storage at 5 °C, a white, crystalline solid separated. Upon recrystallization from acetone – ether, it had m.p. 131–132 °C. The n.m.r. spectrum showed the expected singlet for the C-1 and C-5 methyl protons, τ 8.2, C-3 proton quartet, τ 7.3, 3-methyl doublet, τ 8.9, and the N—O—H proton singlet downfield, τ −0.7 to −1.0.

Anal. Calcd. for $C_6H_{12}N_2O_2$: C, 50.00; H, 8.33; N, 19.44. Found: C, 50.05; H, 8.30; N, 19.51.

(6) Incorporation of ^{14}C-Formaldehyde

To a solution (200 ml) of potassium carbonate (138 g) was added nitroethane (15 ml) and ^{14}C-formaldehyde (5 ml aqueous solution containing 5.25×10^6 d.p.m.) and the mixture refluxed for 4 h. Steam distillation followed by extraction of the distillate with chloroform, and evaporation, yielded a light yellow oil which upon gas chromatographic analysis showed the presence of trimethylisoxazole (main component) and 3,5-dimethylisoxazole. Collection of the components in the scintillator liquid showed no radioactivity in the trimethylisoxazole while 3,5-dimethylisoxazole was highly active (see Table I). Total activity (5.094×10^6 d.p.m.) in the mixture showed only a 3% loss of added ^{14}C-formaldehyde. Authentic 3,5-dimethylisoxazole was added to the reaction product and the mixture separated on a preparative vapor phase chromatographic (v.p.c.) column (XF-1150 liquid phase, 6 ft × 1/2 in., operating temperature 120 °C). The specific activity of 3,5-dimethylisoxazole was 73.6×10^6 d.p.m./mole.

(7) Degradation of Radioactive 3,5-Dimethylisoxazole

Label positioning was accomplished as follows: aliquots of dimethylisoxazole (DMI) in dry ethylacetate were subjected to ozone treatment. The ozonide was decomposed with water (10 ml) containing 6 *N* H_2SO_4 (3 ml). Nitrogen was passed through the reaction mixture for 20 min after which $KMnO_4$ solution (15 ml, 2 mmoles) was added. The CO_2 evolved was trapped in either barium hydroxide solution or ethanolamine (5 ml). Control experiments with pyruvic acid indicated about 80% decarboxylation under these conditions. Addition of acetate-1-^{14}C showed insignificant degradation (1–3%). The recoveries of $^{14}CO_2$ from C-1 of pyruvate (corresponding to the 4 position of 3,5-dimethylisoxazole) are summarized below in Table I.

TABLE I

Label positioning of radioactive 3,5-dimethylisoxazole

	d.p.m. of DMI	d.p.m. in CO_2	% recovery
1.	80 300	60 700	75
2.	4 620	3 690	80
3.	8 160	7 150	88
4.	6 010	5 520	91

(8) Incorporation of Acetaldehyde-1-^{14}C into 3,4,5-trimethylisoxazole

To a solution (200 ml) of potassium carbonate (45 g) and nitroethane (15 ml) was added aqueous (5 ml) acetaldehyde-1-^{14}C (11.1×10^6 d.p.m.) and the solution heated (70–80 °C) for 5 h, after which the reaction mixture was stored at room temperature overnight. A v.p.c. analysis of the red oil appearing at the surface indicated, as before, the presence of acetonitrile, acetaldoxime (both minor peaks appearing in that order), and trimethylisoxazole (major peak). Trapping of these components in the scintillator liquid showed minor radioactivity in acetonitrile and acetaldoxime while trimethylisoxazole was highly radioactive. Separate collections of acetonitrile and acetaldoxime were diluted with the cold compound followed by alkaline oxidation to acetate. The resulting acetate was degraded to CO_2 and the methylamine by the Schmidt procedure (19) (see Table II).

TABLE II

Label positioning of radioactive acetonitrile and acetaldoxime

d.p.m. in:	d.p.m. in CO_2	% recovery
Acetonitrile		
1. 75	73	97
2. 85	81	95
3. 105	101	97
Acetaldoxime		
1. 175	170	97
2. 140	135	96
3. 210	190	91

The alkaline reaction was exhaustively extracted with chloroform and the extract evaporated to yield a reddish oil, which upon v.p.c. analysis indicated almost pure 3,4,5-trimethylisoxazole (3.2 g, 9.1×10^6 d.p.m.). Total recovery of radioactivity in trimethylisoxazole was about 90%. The aqueous alkaline solution was acidified with sulfuric acid (8 *N*) and the acid solution extracted exhaustively with ether. Evaporation to a small volume (3 ml) and v.p.c. analysis indicated the presence of acetic acid containing some radioactivity. Glacial acetic acid (1.0 ml) was added and the solution neutralized with sodium carbonate followed by evaporation to dryness. The sodium salt was consequently degraded (in triplicate) to CO_2 and methylamine by the Schmidt procedure (19) (see Table III).

(9) Degradation of Radioactive Trimethylisoxazole

To aliquots of radioactive 3,4,5-trimethylisoxazole dissolved in water saturated ether was added metallic sodium. A typical run would involve about 100 mg of isoxazole (2845 d.p.m.) in 200 ml water saturated ether. Upon completion of refluxing (2 h), 2-butanone (5 ml) was added and the butanone fraction (4.5 ml) recovered by fractional distillation. The total radioactivity recovered was between 200 and 300 d.p.m. The butanone fraction was treated with alkaline hypoiodite, the iodoform which formed being collected and found to be inactive while the sodium propionate contained all the radioactivity. Propionate was decarboxylated to acetate via a Hoffman reaction (ethylamine being oxidized to acetate with permanganate) in the usual manner. All radioactivity remained in acetate. Acetate was degraded by the Schmidt procedure (see Table IV).

TABLE III

Label positioning in radioactive acetate

	d.p.m. in acetate	d.p.m. in CO_2	% recovery
1.	275	260	95
2.	350	340	97
3.	310	195	93

TABLE IV

Label positioning in methylethylketone from trimethylisoxazole

	d.p.m. in original MEK sample	d.p.m. in CO_2 from acetate	% recovery
1.	215	185	86
2.	275	255	93

(10) Incorporation of Acetaldehyde-d_4

To a solution (100 ml) of nitroethane (15 ml) and potassium carbonate (30 g) was added acetaldehyde-d_4 (5 ml) and the solution heated (80 °C) for 4 h followed by storage at room temperature for a further 16 h. The reaction mixture was worked up as described above and the 3,4,5-trimethylisoxazole formed analyzed by n.m.r. spectroscopy. A reduction (ca. 40%) in the intensity of the C-4 methyl singlet (τ, 8.2) was noted.

^{13}C Nuclear magnetic resonance studies. XII. Conformational effects on ^{13}C shieldings in alicyclic oxygenated compounds[1,2]

G. W. BUCHANAN,[3] J. B. STOTHERS, AND SIU-TZYY WU
Department of Chemistry, University of Western Ontario, London, Ontario

Received February 25, 1969

The ^{13}C shieldings of the primary carbinyl carbons in cyclohexylmethanol, its acetate and methyl ether as well as those for the corresponding carbon in their 4-*t*-butyl derivatives have been measured at 15.1 MHz using the 'proton-decoupling' method. Similar data for the 1-methyl-4-*t*-butylcyclohexylcarbinols and their acetates were obtained to examine the influence of the additional methyl substituent. Possible origins of the observed conformational effects on ^{13}C nuclear shieldings are considered. The ^{1}H results for the methylene protons in these carbinyl groups are also presented and discussed. These results, which permit estimations of the conformational free energies ($-\Delta G°$) of the $—CH_2OR$ groupings (R = H, Ac, Me), are presented to illustrate the ^{13}C approach to conformational analysis.

Canadian Journal of Chemistry, 47, 3113 (1969)

Introduction

From the results now available, it is clear that ^{13}C nuclear shieldings are affected by molecular conformation (1–4) and, therefore, these parameters should yield information regarding conformational preferences for a variety of functional groups in a manner similar to that exhibited by the nuclear magnetic resonance data for several other nuclei. This has been demonstrated for the hydroxyl, methoxyl, and acetoxyl groups in cyclohexanes (3) and the fact that axial and equatorial carbon atoms on cyclohexane ring systems experience different shielding influences has been confirmed in the case of the methylcyclohexanes (4). To examine these differences for carbons bearing oxygenated functional groups we have prepared as model compounds, the *cis*- and *trans*-4-*t*-butyl derivatives of cyclohexylmethanol (**1**), its acetate (**2**) and ether (**3**) and of (1-methylcyclohexyl)-methanol (**4**) and the corresponding acetate (**5**) and determined the ^{13}C shielding of the carbinyl carbon ($—CH_2OR$) nucleus in each of these as well as in those of the parent compounds. The shieldings for the methylene protons of these carbinyl groups were also measured. In this paper we present these results and examine their utility for the determination of the conformational free energies of the $—CH_2OR$ groups (R=H, Me, Ac). A preliminary report of this work has already appeared (6).

[1]For Pt. XI see reference 6; for Pt. X see reference 20.
[2]These results were presented in part at the 2nd International nuclear magnetic resonance Symposium, Sao Paulo, Brazil, July, 1968.
[3]Holder of NRCC Studentships 1966–1968. Present address: Dept. of Chemistry, UCLA, Los Angeles, California.

Experimental

Spectra

The natural abundance ^{13}C spectra were obtained at 15.1 MHz on a dual-purpose Varian spectrometer utilizing a NMR Specialties SD-60 spin-decoupler operating at a nominal frequency of 60 MHz. The irradiating frequencies were monitored directly with a Hewlett-Packard 5245L counter. The 'proton-decoupling' technique developed by Paul and Grant (5) was employed for the ^{13}C shielding measurements and the results are reported relative to CS_2.

The proton spectra were recorded with a Varian A60 spectrometer using the usual audio side-band technique to measure the position of the proton absorptions relative to internal TMS to better than 0.5 Hz.

The alcohols were examined in carbon disulfide solution (5 *M*) while the esters and ethers were studied as neat liquids.

Materials

Cyclohexylmethanol, its acetate and methyl ether were prepared by standard methods and their physical constants agreed well with the published data (7). Reduction with lithium aluminum hydride was employed to prepare 1-methylcyclohexylcarbinol from 1-methylcyclohexane carboxylic acid, which was obtained by the reaction of 2-methylcyclohexanol with formic acid (8).

cis- and trans-4-t-Butyl Cyclohexylmethanols (1)

Hydrogenation of *p-t*-butylbenzoic acid to yield a mixture of the isomeric 4-*t*-butylcyclohexane carboxylic acids was done according to the published method (9) except that less catalyst was found necessary (1 g PtO_2 for 37 g acid). After separation by fractional crystallization, each of the acids gave the desired carbinol in 98% yield upon reduction with lithium aluminum hydride.

cis- and trans-4-t-Butylcyclohexylmethyl Acetates (2)

These materials were prepared from the corresponding alcohols by heating with acetic anhydride and sodium

acetate for 1 h at 120 °C. After dilution with water the acetate was extracted with ether and isolated by distillation.

cis-Acetate: b.p. 94–95/1.5 mm; n_D^{25} 1.4565.

Anal. Calcd. for $C_{13}H_{24}O_2$: C, 73.54; H, 11.39. Found: C, 73.55; H, 11.16.

trans-Acetate: b.p. 79–80/0.2 mm; n_D^{25} 1.4520.

Anal. Calcd. for $C_{13}H_{24}O_2$: C, 73.54; H, 11.39. Found: C, 73.53; H, 11.16.

cis- and trans-4-t-Butylcyclohexylmethyl Methyl Ethers (3)

The cyclohexylmethanols were allowed to react with sodium in ether until hydrogen evolution ceased. Excess methyl iodide was slowly added and the mixture refluxed gently for 2 h. The product was isolated by distillation.

cis-Ether: b.p. 104.6/16 mm., n_D^{25} 1.4520.

Anal. Calcd. for $C_{12}H_{24}O$: C, 78.19; H, 13.13. Found: C, 78.06; H, 13.07.

trans-Ether: b.p. 102.3/16 mm. n_D^{25} 1.4508.

Anal. Calcd. for $C_{12}H_{24}O$: C, 78.19; H, 13.13. Found: C, 77.92; H, 12.89.

cis- and trans-1-Methyl-4-t-butylcyclohexyl Carbinols (4)

The mixture of the isomeric 1-methyl-4-*t*-butylcyclohexanols obtained by the reaction of 4-*t*-butylcyclohexanone with methyl magnesium iodide was treated with zinc chloride and hydrochloric acid to give a mixture of the corresponding cycloalkyl chlorides. Reaction of these chlorides in ether solution with magnesium, followed by carbonation of the resulting Grignard reagent, afforded a mixture of the 1-methyl-4-*t*-butylcyclohexane carboxylic acids in 30% yield. This mixture was reduced with lithium aluminum hydride. The alcohol product was separated by chromatography on alumina to yield a first fraction of *cis*-1-methyl-4-*t*-butylcyclohexyl carbinol, m.p. 76–78°, while later fractions gave the *trans*-isomer, m.p. 73.5–75°.

Anal. Calcd. for $C_{12}H_{24}O$: C, 78.19; H, 13.13.

cis-Isomer; Found: C, 78.10; H, 12.99.

trans-Isomer: Found: C, 78.09; H, 13.20.

cis- and trans-(1-Methyl-4-t-butylcyclohexyl) Methyl Acetates (5)

These materials were prepared on a small scale by reaction of the carbinols with acetic anhydride and sodium acetate in the usual fashion. Their structures were confirmed by infrared and proton spectra. The *cis*-isomer has n_D^{28} = 1.4519, while n_D^{28} = 1.4527 for the *trans*-isomer.

Results and Discussion

The ^{13}C and ^{1}H shielding values for the carbinyl carbons and the protons bonded thereto are collected in Tables I–III. The results for the compounds having essentially fixed conformations because of the 4-*t*-butyl substituent are listed in Table I, the results for the *trans*-isomers, **1–3**, are compared with those for isobutyl alcohol, isobutyl acetate and isobutyl methyl ether in Table II while the data for the conformationally mobile systems appear in Table III. As noted above, the ^{13}C results were obtained by the 'proton-decoupling' method (5) wherein the proton frequency required to obtain an optimum ^{13}C signal is determined as carefully as possible and the ratio of this frequency to that employed to irradiate the ^{13}C nucleus, Γ_i, measured. Having a reference Γ_0 value for a standard substance, the ^{13}C shielding value, δ_c,

TABLE II

^{13}C and ^{1}H Shieldings for $—CH_2OR$ groups in iso-butyl alcohol, *trans*-4-*t*-butylcyclohexylmethanol and their derivatives

Compound	Shielding results	
	^{13}C(p.p.m. from CS_2)	^{1}H(p.p.m. from TMS)
iso-Butyl alcohol	123.4	3.30
trans-**1**	123.7	3.33
iso-Butyl methyl ether	112.7	3.07
trans-**3**	113.0	3.09
iso-Butyl acetate	122.4	3.81
trans-**2**	123.3	3.81
neo-Pentyl alcohol	119.5	3.14
trans-**4**	118.3	3.15
neo-Pentyl acetate	118.9	3.73
trans-**5**	117.5	3.72

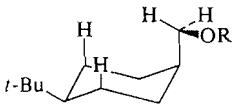
is computed using the expression (5):

$$\delta_c = 1 - \frac{\Gamma_0}{\Gamma_i}(1 + \delta_H)$$

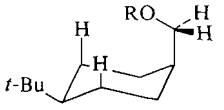
where δ_H is the shielding difference between the protons of the standard and those of the compound measured on the δ-scale (TMS = 0 p.p.m.). In this case we have used methyl iodide as our standard, $\Gamma_0 = 3.97702300$, and converted the data to the CS_2 scale using the value 213.10 p.p.m. as the shift difference between methyl iodide and CS_2 (10).

From Table I it is clear that the axial carbinyl carbons are significantly shielded relative to the corresponding equatorial nuclei for each pair of *cis–trans* isomers, **1–5**. The differences appear to fall into two groups, 4.8 ± 0.2 p.p.m. for **1–3** and 7.0 ± 0.3 p.p.m. for **4** and **5**, which may be contrasted to the difference of −0.21 ± 0.02 p.p.m. found for the methylene protons bonded to these carbinyl carbons. It is especially interesting that the shifts for the methylene protons in the two orientations change in the direction opposite to that exhibited by the ^{13}C nuclei in that the protons on axial carbinyl carbons are deshielded relative to their equatorial counterparts. Furthermore, the difference in magnitude of the ^{1}H and ^{13}C shifts by a factor of ca. 25 is remarkably similar to the difference in their sensitivities to electron density changes (11, 12). These trends suggest that polarization effects may be principally responsible for the observed changes.

Of the two stable rotamers, **11** and **12**, available to the *cis*-isomers, **1–5**, the former will be much more highly populated because of the destabilizing interaction in **12** between the oxygen atom and the axial ring protons on C-3 and C-5. In **11**, however, one of the methylene



11



12

protons is within ca. 2 Å of these axial protons and a relatively strong repulsive force will act between these nuclei. The net result will be a perturbation of the local electron clouds which can be expected to reduce their shielding

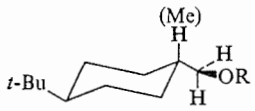
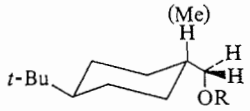
relative to that of a proton in a similar chemical environment but lacking this steric perturbation, as in the corresponding *trans*-isomers having equatorial carbinyl groups. It seems reasonable to assume that this dispersion effect at the carbinyl proton will tend to polarize the electrons of the C—H bond such that the electron density at the carbinyl carbon is increased. Consequently this carbon will be shielded relative to that in the *trans*-isomer. Dalling and Grant (4) have presented their measurements of the ^{13}C shieldings in several methylated cyclohexanes and have discussed the observed trends on the basis of steric perturbation of the electron distributions. Grant and Cheney (13) have described a theoretical approach for the estimation of this effect which attributes the changes entirely to polarization. The difference of 3.9 p.p.m. found for the shieldings of isolated axial and equatorial methyl carbons is comparable to the differences observed in the present series. It is interesting that the corresponding change for the methyl protons is ca. 0.1 p.p.m. which is approximately 50% of that found in the present series (Table I) and is consistent with the assumption that rotamer **11** will be more highly populated than **12**. It seems unlikely that the introduction of the 1-methyl group in *cis*-**4** and *cis*-**5** will alter the situation as far as rotamer populations are concerned.

In the *trans*-series, there are two different rotamers, **13** and **14** available to the equatorial carbinyl groups of which **13** should be favored,



13



14

both statistically and energetically. In the 1-methyl substituted cases, however, **13** will be destabilized to some degree due to methyl H---O non-bonded interactions. It follows, therefore, that the rotamer populations for the equatorial cases may be different for the two types, **1–3** and **4–5**. Perhaps this is the reason that the ^{13}C shielding difference between the *cis*-pairs **1**, **4** and **2**, **5** is 3.3 ± 0.1 p.p.m. while that between the *trans*-pairs **1**, **4** and **2**, **5** is 5.5 ± 0.2 p.p.m. For alkyl groups it is well established (1, 4, 12) that replacement of a proton with a methyl group tends to deshield the β-carbon by several p.p.m.

i.e. 
In hydrocarbons with X=C or H this change is ca. 9 p.p.m. Clearly the effect is markedly attenuated with X=O, a trend that was reported previously in the case of carbonyl compounds (14). A recent theoretical interpretation of alkyl substituent effects on ^{13}C shieldings in hydrocarbons failed to predict the β-effect (15) and its origin remains obscure.

Since the distances of closest approach between non-bonded atoms are all appreciably larger in the series of *trans*-isomers, **1–5**, it seems reasonable to propose that the major factor contributing to the shielding differences between axial and equatorial carbinyl nuclei in these systems is a steric perturbation of the local electron distributions in the axial orientation. Support for this conclusion is provided by ^{1}H and ^{13}C shielding data for the carbinyl nuclei in *iso*-butyl alcohol, its acetate and methyl ether and in *neo*-pentyl alcohol and acetate. These results are listed in Table II together with those for the *trans*-isomers, **1–5**. Presumably, rotamer populations will be similar in the acyclic and cyclic systems and it is clear that the shieldings are remarkably similar for each pair of compounds. It follows, therefore, that the different shieldings observed for the *cis*-isomers, **1–5**, are primarily due to steric effects acting on the axial carbinyl groups.

The fact that the shielding differences for the carbinyl carbons in the alcohols are comparable to those exhibited by the ethers and acetates indicates that hydrogen-bonding is not a major factor. Dalling and Grant (4) have already suggested that a basic difference in the electronic structure of axial and equatorial methyls probably exists which precludes precise characterization of the steric effects on their shieldings by direct comparison of the observed values. If this be the case, the same difficulty arises in the present cases. In any event, the effect of medium on ^{13}C shieldings has not been adequately investigated, although there are indications that these can be significant (14, 16). Because of the polar nature of the compounds examined in this study, it appears necessary to investigate medium effects in detail before attempting even a semi-

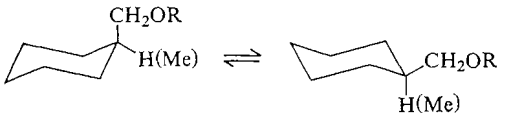
quantitative interpretation of the observed trends.

Although a detailed analysis of the trends exhibited by these *cis–trans* isomers cannot be offered, the use of these compounds as model systems to estimate conformational preferences of the —CH_2OR groups merits consideration. For this purpose, we have determined the shieldings of the protons and carbons in the carbinyl groups of these systems in the "mobile" forms (i.e. lacking the 4-*t*-butyl group). These data, listed in Table III, permit one to estimate K_e for the conformational equilibrium, **15** ⇄ **16**, assuming that the data for the *cis*-isomers, **1–5**, are characteristic of the axial forms, **15**,



15 **16**

and those for the *trans*-series, **1–5**, for the equatorial conformation, **16**, for the compounds, **6–10** respectively.

Using the expressions

$$K_e = (\delta_{cis} - \delta)/(\delta - \delta_{trans})$$

where δ is the observed shielding for the mobile systems, **6–10**, and $-\Delta G^0 = RT\ln K_e$, values for $-\Delta G^0$, the conformational free energy, for the —CH_2OR groups (R = H, Me, Ac) have been estimated. Both ^{1}H and ^{13}C data were employed to obtain independent assessments. The results are collected in Table IV and the estimated precision of the individual values is indicated. There are rather large discrepancies apparent between the $-\Delta G^0$ values obtained from each set of shielding results, but there is an indication that $-\Delta G^0_{CH_2OAc} > -\Delta G^0_{CH_2OMe} \approx -\Delta G^0_{-CH_2OH}$. In fact, the close agreement between the latter values indicates that hydrogen bonding is a minor factor contributing to these equilibria.

TABLE IV

Conformational free energies ($-\Delta G^0_x$) of —CH_2OR groups (in kcal/mole)

X	Method of estimation	
	^{13}C	^{1}H
—CH_2OH	1.42±0.30*	1.77±0.15*
—CH_2OMe	1.40±0.24	1.65±0.15
—CH_2OAc	1.87±0.35	1.94±0.15
—CH_2OH—Me	0.37±0.07*	0.29±0.10*
—CH_2OAc—Me	0.28±0.05	0.18±0.10

*5 *M* in CS_2.

Perhaps the more reliable data, however, are those obtained for the 1-methyl substituted cases because the shieldings observed for **9** and **10** are mid-way between the absorption positions of the "fixed" systems, **4** and **5**. The experimental error is therefore reduced as indicated in Table IV. In the simpler systems, **6–8**, the —CH_2OR group heavily biases the equilibrium toward the equatorial forms, **16**, and the differences between their shielding values and those for the *trans*-isomers, **1–3**, are small, leading to a proportionately larger error in $-\Delta G^0$. Assuming that the better data are those for the methyl substituted systems, it would appear that the CH_2OH and CH_2OAc groups have comparable $-\Delta G^0$ values. In combination with the value $-\Delta G^0_{Me}$ = 1.56 kcal/mole (17), the present results indicate that $-\Delta G^0_{CH_2OH}$ and $-\Delta G^0_{CH_2OAc}$ are 1.90 and 1.79 kcal/mole, respectively.

Eliel, Nielsen and Gilbert (18) have recently reported results of measurements of $-\Delta G^0$ for the hydroxymethyl group by the equilibration method. Their determinations lead to the values 1.65 and 2.06 kcal/mole in the solvents, cyclohexane and isopropyl alcohol, respectively, at 80° using Raney nickel as the catalyst. These results serve to support our conclusion that ^{13}C nuclear magnetic resonance offers an alternative approach to conformational analysis, at least in a semi-quantitative fashion. The pronounced sensitivity of ^{13}C shieldings to steric perturbations is apparent and it is conceivable that these parameters may offer a more reliable approach for stereochemical studies than proton data, since the contribution of other factors may be much less significant. Jensen (19) has clearly demonstrated the error associated with estimations of $-\Delta G^0$ values from proton results employing the 4-*t*-butyl derivatives as models for the axial and equatorial forms. In view of his findings, it is highly probable that the results obtained from the proton parameters are, at best, a first approximation. The reliability of the ^{13}C results herein remains to be demonstrated. To this end, we are in the course of investigating the ^{13}C spectra of the series, **1–3**, which have been enriched in ^{13}C at the carbinyl carbon. With these models, the study can be extended to include the effect of medium at low concentration and the effect of temperature.

Acknowledgments

Support of this investigation from the Petroleum Research Fund, administered by the American Chemical Society and from the National Research Council of Canada is gratefully acknowledged. We thank Dr. D. J. Sardella for recording some of the proton spectra.

Composition of the leaf wax of Little Club wheat[1]

A. P. TULLOCH AND R. O. WEENINK[2]
Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received January 27, 1969

Leaf wax of Little Club wheat is composed of: hydrocarbons (8–15%); esters (20–26%); alcohols (25–42%); acids (2%); β-diketone (6–10%); hydroxy β-diketones (9–16%); and unidentified material (9–12%). The esters are mainly octacosanol esters of C_{14} to C_{32} fatty acids but lesser amounts of esters of *trans* 2-tetracosenoic and *trans* 2-docosenoic acids also occur. The free alcohols are almost entirely octacosanol. The β-diketone is hentriacontane-14,16-dione and the hydroxy-β-diketones are a 1:1 mixture of 8- and 9-hydroxyhentriacontane-14,16-diones.

During investigations of the spores of wheat stem rust, spores were collected by washing infected wheat plants with light petroleum (1). It was then found that a good yield of wheat leaf wax could be recovered from the petroleum washings. This extraction procedure was applied to a number of wheat varieties and the yield of wax varied from 0.2 to 0.45% of the dry weight depending on the variety and maturity of the plants.

Apparently only one previous investigation of wheat leaf wax has been made. Pollard *et al.* (2) extracted an unspecified variety of wheat and reported that the principal component of saponified wax was octacosanol. Since large amounts of straw are potentially available in Western Canada, it seemed worthwhile to determine the composition of the wax and to find out whether or not it contained any useful components.

Horn and Lamberton (3) showed that β-diketones are major components of a number of plant waxes and that they can be detected and estimated by infrared (i.r.) and ultraviolet (u.v.) spectroscopy. We have found that they can also be readily detected by thin-layer chromatography (t.l.c.) since they rapidly give yellow spots on exposure to iodine vapor. Hydrocarbons, esters, free alcohols, and other hydroxy compounds can also be detected by t.l.c.

Waxes from 6 varieties of wheat were examined spectroscopically and by t.l.c., and that of Little Club (*Triticum compactum* Host.) contained the most even distribution of the different components. Though Little Club is not a commercial wheat variety it was convenient to examine wax from it, since most of the components could be isolated in reasonable yield, rather than waxes from some other varieties which contained major proportions of just one or two components.

The approximate composition of Little Club wax collected in 1964 and 1965 is shown in Table I along with the yields and u.v. absorption characteristics. The 1965 wax, though harvested at approximately the same stage of growth, contained more alcohols and less β-diketones than the 1964 wax. It has been suggested recently (4) that some varieties of wheat produce wax containing alcohols in place of β-diketones, but growing conditions and maturity apparently must also be taken into account.

Separation of Components

β-Diketones were removed from the wax (1965) as copper complexes (3, 5) but part of the alcohols crystallized at the same time. The resulting mixture of β-diketones, alcohols, and hydroxy-β-diketones was separated chromatographically. Free acids were lost, presumably as copper salts. However, they were isolated in earlier experiments with 1964 wax (6).

Wax remaining after the above removal of β-diketones and part of the alcohols was separated into 20 fractions by a combination of column chromatography and crystallization as shown in Fig. 1. Similar fractions were combined and examined by gas–liquid chromatography (g.l.c.). The composition of the hydrocarbons (fraction 1) is shown in Table II; the principal components were saturated C_{27}–C_{33} hydrocarbons with an odd number of carbon atoms.

*Number in parentheses refers to number of components.

nuclear magnetic resonance (n.m.r.) signals at 5.7 and 6.8 p.p.m., characteristic of acids with *trans* 2,3-unsaturation (7, 8), and the fact that oxidation with the permanganate–periodate reagent (9) yielded saturated C_{20} and C_{22} acids. *trans* 2-Tetracosenoic and docosenoic acids do not seem to have been isolated from natural sources before though a number of *trans* αβ-unsaturated C_{10} acids have been isolated from bees (7, 10).

Fractions 12, 19, and 20, which were eluted just after the monoesters or along with the alcohols (Fig. 1), appeared from t.l.c. to be mixtures of several components. The hydrolysis products are listed in Table III. Difunctional components such as diols or hydroxy acids, the presence of which could account for the low yields of alcohols, were not detected. The structures of the parent compounds could not be completely elucidated, but part probably consists of esters of *trans* 2-tetracosenoic and docosenoic acids with C_{20}–C_{28} alcohols.

It is of interest that the *trans* αβ-unsaturated acids are found only as C_{22} and C_{24} compounds whereas the acids of the other ester fractions range from C_{14} to C_{32}. When all ester fractions are considered together, the approximate % of esters containing *trans* 2-docosenoic acid is 5% and of esters containing *trans* 2-tetracosenoic acid is 10%.

The free fatty acids in Table II are similar to those of the esters except that palmitic acid is the major component. These acids were isolated from wax collected in 1964 whereas the other analyses were made on material collected in 1965. However, hydrolysis of the total ester fraction of the 1964 wax gave acids with the composition: C_{14} 2.4; C_{16} 9.8; C_{18} 4.5; C_{20} 9.9; C_{22} 20.1; *trans* $C_{22:1}$ 10.2; C_{24} 8.4; *trans* $C_{24:1}$ 15.5; C_{26} 3.1; C_{28} 8.4; C_{30} 4.5; C_{32} 2.8; C_{34} 0.4%, which is not very different from that of the 1965 esters.

The composition of the free alcohols is similar to that of the alcohols of the esters but an even higher proportion of octacosanol is present (Table II).

β-*Diketone*

Only one β-diketone, hentriacontane-14,16-dione, was present. The chain length was established by reduction to hentriacontane (3). Alkaline hydrolysis gave equal amounts of pentadecan-2-one and heptadecan-2-one and of myristic and palmitic acids. This diketone has not previously been isolated in the pure state though it occurs as a minor component of the mixed β-diketones of leaf wax of two species of

Eucalyptus (5). Wax of the grass *Festuca glauca* contained mainly tritriacontane-12,14-dione (5).

Hydroxy-β-diketones

These components also gave only hentriacontane on reduction. The n.m.r. spectrum showed that a secondary hydroxyl group was present which was at least 4 methylene groups removed from the diketone group (11). The neutral fraction obtained by alkaline hydrolysis was a mixture of heptadecan-2-one and hydroxypentadecan-2-ones, which were separated on a silicic acid column. The acidic fraction was shown by g.l.c. to be a mixture of palmitic and hydroxymyristic acids, which as methyl esters, were also separated chromatographically.

Oxidation of the hydroxy esters with chromium trioxide at 25° (12) gave an oxomyristate which appeared to be a mixture of 6- and 7-oxomyristates (g.l.c. using QF-1 column (13)). Oxidation with chromium trioxide at 100° (12), when cleavage occurs on both sides of the oxygenated carbon atom, gave the monocarboxylic acids heptanoic, octanoic, and nonanoic approximately in the ratio 1:2:1, and the dicarboxylic acids glutaric, adipic, and pimelic also in the ratio 1:2:1, showing that an approximately equimolar mixture of 6- and 7-hydroxymyristates had been oxidized.

The n.m.r. spectrum of the hydroxymyristates in quinoline was indistinguishable from that of a 1:1 mixture of synthetic 6- and 7-hydroxymyristates. It was shown previously (11) that, using quinoline as solvent, the center of the α-CH_2 signal of 6-hydroxystearate appears at ca. 0.1 p.p.m. downfield from the corresponding signal of 7-hydroxystearate. The hydroxymyristates showed signals at both positions and the rest of the spectrum also agreed with the proposed structure. This was confirmed by the mass spectrum of the hydroxymyristates which showed peaks at *m/e* 145 (also shown by methyl 6-hydroxymyristate) and at *m/e* 159 (also shown by methyl 7-hydroxymyristate). Mass spectra of the corresponding hydroxystearates (14) show that the peak at *m/e* 145 is due to the ion $^{+}CHOH(CH_2)_4CO_2CH_3$ and at *m/e* 159 is due to the ion $^{+}CHOH(CH_2)_5CO_2CH_3$. The hydroxymyristates have a positive rotation suggesting the L-configuration (15, 16).

We conclude that the hydroxy-β-diketone fraction of Little Club wax consists of an approximately 1:1 mixture of 8- and 9-hydroxyhentriacontane-14,16-diones.

Hydrolysis of the most polar wax fraction (5, Fig. 1) gave palmitic acid as 15% of the fraction and a brown gum from which no definite compounds could be isolated. No diols or hydroxy acids could be detected. The unidentified portion of the wax consists of material of indefinite composition from fraction 5 above and of materials not recovered from the chromatographic columns.

The compositions of the wax components have certain features of interest. The hydrocarbons are composed mainly of 4 chain lengths C_{27}–C_{33}, whereas the other components with an odd number of carbon atoms, the β-diketones, have a chain length of 31 carbons only. The lack of relation between chain length of hydrocarbons and β-diketones was also observed with waxes of *Eucalyptus* species (5). The compositions of the free acids and free alcohols are fairly similar to those of the acids and alcohols of the esters. In many studies of waxes these pairs of components have not been examined separately. However, the acids contain a wide variety of chain lengths but the alcohols are composed largely of octacosanol. These differences and also the finding of unsaturated C_{22} and C_{24} acids, suggest the operation of several different biosynthetic pathways. Diols and hydroxy acids, which are frequently isolated from plant waxes (17) are apparently absent. Hydroxy-β-diketones have not previously been found in waxes, though hydroxy-ketones are present in cabbage wax (18).

Experimental

Silicic acid (Bio-Sil A from Bio-Rad Laboratories) was used for column chromatography, after activation at 120° for 18 h, and silica gel G for t.l.c. Typical *R* values found by t.l.c. of representative compounds in benzene and chloroform respectively were: triacontane 0.86, 0.74; octadecanol octadecanoate 0.68, 0.70; methyl octacosanoate 0.40, 0.49; β-diketone 0.38, 0.45; octacosanol 0.07, 0.15; hydroxy-β-diketones 0.02, 0.06; octacosanoic acid 0.00, 0.00. Chloroform was the most satisfactory solvent for t.l.c. although it sometimes did not separate hydrocarbons and wax esters. Iodine vapor was used to detect β-diketones, which rapidly gave dark orange spots, and the other components were detected by spraying with 50% sulfuric acid and heating.

Nuclear magnetic resonance spectra were measured at 100 Mc.p.s. using a Varian HA-100 spectrometer. Chemical shifts are in parts per million (p.p.m.) from tetramethylsilane (internal standard). Carbon tetrachloride was used as solvent except where otherwise

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

stated. Specific rotations were measured at 25° using a Perkin Elmer model 141 polarimeter. Infrared spectra were recorded in carbon tetrachloride (5% solution) in a 0.1 mm cell. Mass spectra were determined by the Morgan–Schaffer Corporation, Montreal.

Gas–Liquid Chromatography

Gas–liquid chromatography (g.l.c.) was carried out using: (*A*) an F and M model 402 gas chromatograph with flame ionization detectors fitted with 3 ft × 1/4 in. glass columns packed with 20–30 mesh glass beads coated with 0.3% silicone SE 30 and having a flow rate of 45 ml of helium/min, with the temperature programmed at 2°/min from various temperatures between 100 and 200° to 325° depending on the samples being analyzed; (*B*) an F and M model 5750 gas chromatograph with a flame ionization detector fitted with an 8 ft × 1/4 in. stainless steel column packed with 5% w/w 1,3-propanediol succinate (prepared by Dr. B. M. Craig) on 60–80 mesh acid washed chromosorb W operated isothermally at 215° with a flow rate of 40 ml/min; and (*C*) a unit of conventional design with thermal conductivity detectors and a 3 ft × 1/4 in. copper column packed with 5% silicone SE 30 on 60–80 mesh acid washed celite.

When synthetic, even numbered long chain alcohol esters of long chain acids were analyzed by unit (*A*) and the temperature programmed from 200–325°, a plot of retention temperature against carbon number (19) was almost a straight line making possible the measurement of the carbon numbers of the wax esters. The results were confirmed by re-analysis after addition of synthetic esters of various chain lengths to the mixture. Also, analysis of mixtures of synthetic esters showed that correction factors were not required to calculate composition. Unit (*A*) programmed from 100 to 275° was used to analyze hydrocarbons, alcohols, and methyl esters. Hydrocarbons and methyl esters were also analyzed using units (*B*) and (*C*); alcohols and their acetates were also analyzed on unit (*C*); carbon numbers were determined from isothermal analyses.

Synthesis of Octacosanol and Other Model Compounds

13-Oxooctacosanoic acid (19.8 g) was synthesized from 1-morpholino-1-cyclododecene (20) (17.5 g) and hexadecanoyl chloride (13.7 g) by the method previously used to prepare 13-oxodocosanoic acid (21). After crystallization from ethyl acetate, the m.p. was 100.5–101.5 (lit. (22), 99.5°). Wolf–Kishner reduction of the oxo acid (18 g) and crystallization of the product from chloroform gave octacosanoic acid (10 g), m.p. 89.5–90.5 (lit. (22), 90.2°). Reduction of octacosanoic acid with lithium aluminum hydride in tetrahydrofuran gave octacosanol in high yield. The alcohol was crystallized from chloroform, m.p. 82.5–83.5 (lit. (22), 82.5°); the acetate had a m.p. 64°.

Other long chain alcohols were prepared by reduction of the corresponding acids which were commercial products. Even-numbered hydrocarbons with 26 and 34 carbons were prepared by the method previously used to prepare tetracosane (23). The synthesis and properties of long chain wax-like esters will be described elsewhere.

Isolation and Properties of the Wax

Plants of *Triticum compactum* Host. var. Little Club were grown outdoors and collected 4–6 weeks before maturity (generally just before the heads appeared and when green leaf formation was greatest). One sample was also collected from mature straw. The plants were swirled in light petroleum b.p. 40–60° for about 10 s (cf. 1) and the extract filtered and evaporated to dryness.

Further washings generally yielded only a small amount of wax with a composition similar to that of the first extract, though sometimes later extracts seemed to contain higher proportions of polar, pigmented material. Purdy and Truter (24) found that repeated extraction of cabbage leaves with different solvents gave wax samples which all had similar compositions. Some wax components, as pure compounds, were poorly soluble in light petroleum but, as mixtures in the wax, were quite soluble.

The melting point of the wax was 42–62°. The i.r. spectra had a broad peak at ca. 1600 cm^{-1} (β-diketone), a small shoulder at 1655 cm^{-1} (double bond of αβ-unsaturated ester), broad carbonyl absorption at 1705–1730 cm^{-1}, and a small OH peak at 3670 cm^{-1}; the peak at 1655 cm^{-1} was most pronounced in the spectrum of wax from mature straw. Thin layer chromatography indicated the presence of hydrocarbons, esters, β-diketone, alcohols, hydroxy β-diketones, and a trace of free acids.

Separation of Components

β-Diketones were separated from the wax (14.2 g, collected 6-7-65) as copper complexes, as described by Horn *et al.* (5), but some alcohols also crystallized with the complex. The mixture (4.6 g) obtained after decomposition of the complex was chromatographed on silicic acid giving β-diketone (0.73 g) (elution with hexane – chloroform 3:1), alcohols (1.61 g), and a mixture of alcohols and hydroxy-β-diketones (2.0 g) (elution with hexane – chloroform 1:1). The mixed fraction gave alcohols (0.3 g) on crystallization from chloroform and the mother liquors, after two further chromatographic separations, gave alcohols (0.64 g) and hydroxy-β-diketones (0.98 g).

When wax collected on 20-7-64 was separated on a column without removing diketones first (6), free acids were found in the alcohol fraction. Treatment with diazomethane and rechromatography on silicic acid (elution with hexane – chloroform 3:1) gave methyl esters of the free acids (0.044 g from 5.7 g wax).

Determination of Structure of Components of Wax

Hydrocarbons

Analysis of fraction 1 (Fig. 1) by g.l.c. and examination by n.m.r. spectroscopy showed that the principal components were saturated, straight chain compounds (25). Chromatography on a silver nitrate – silicic acid column (26) gave only a small fraction (4% of total hydrocarbons) which appeared (by n.m.r.) to be partly unsaturated hydrocarbons.

Saturated esters

Fractions 6, 13, and 18 (Fig. 1) were combined and analyzed by g.l.c. using unit (*A*) and programming from 250–325°. By adding eicosanol eicosanoate as internal standard (27), components found by g.l.c. were shown to compose 91% of the combined fractions. Esters (1.746 g) were refluxed for 22 h with ethanol (125 ml) containing 5% hydrogen chloride; the mixture was then poured into water, extracted with chloroform and dried over sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sulfate. The product (1.852 g) was examined by t.l.c. and showed only traces of unhydrolyzed material; there were no spots corresponding to diols or hydroxy esters.

The product was chromatographed on silicic acid (200 g) and elution with hexane – 10% chloroform gave hydrocarbons (0.057 g) and unhydrolyzed esters (0.068 g). Elution with hexane – 25% chloroform gave ethyl esters (0.685 g) and with hexane – 50% chloroform, first an unidentified component (0.065 g) with R_f 0.3 (chloroform) and then alcohols (0.956 g). Ethyl esters were converted to methyl esters by refluxing with methanolic hydrogen chloride (6%) for 20 h. Methyl esters and alcohols were analyzed by g.l.c. giving the results shown in Table II. A portion of the alcohols was acetylated and the relative intensities of the n.m.r. signals (in chloroform, with chloroform proton as lock signal) confirmed that they were straight chain, saturated, primary alcohols.

Fraction 5 was hydrolyzed, after ethanolysis, and gave acids (0.104 g) consisting mainly of palmitic acid but no other definite compounds were isolated.

αβ-Unsaturated esters

Fraction 12

Analysis by t.l.c. showed a major spot with R_f 0.18 (benzene) and 0.55 (chloroform) and a minor spot in the free alcohol region. Analysis by g.l.c. showed small C_{22} to C_{28} alcohol peaks and a single very broad peak in the C_{52} to C_{62} ester region. The n.m.r. spectrum showed signals for free primary alcohols (triplet 3.5 p.p.m., *c* 1 proton), acylated primary alcohols (triplet 4.00 p.p.m., *c* 2 protons), and for 2 protons of a *trans* double bond αβ to an ester group (H-2, doublet, 5.70 p.p.m.; $J = 16$ c.p.s.; H-3, 2 triplets, 6.82 p.p.m., $J = 16$ c.p.s.).

Fraction 19

Analysis by t.l.c. (benzene) showed a major spot at R_f 0.65 and a minor spot at 0.40; in chloroform there were spots at R_f 0.70 and 0.50. Analysis by g.l.c. showed peaks with retention times of C_{42}, C_{44}, and C_{46} esters. The n.m.r. spectrum was similar to that of fraction 12 except that the free alcohol —CH_2OH signal was missing and the other signals were weaker and less well-defined.

Fraction 20

Analysis by t.l.c. (chloroform) showed 6 ill-defined spots, 4 of which had R_f's intermediate between those of wax ester and of alcohol and the other two were slower. No peak was obtained by g.l.c. using unit (*A*) at 350°. The n.m.r. spectrum was similar to that of fraction 19.

On ethanolysis, as above, fraction 12 (0.280 g) gave esters (0.130 g) and alcohols (0.104). The i.r. spectrum of the methyl esters was very similar to that of methyl *trans* 2-octadecenoate. The carbon numbers of the two principal components of the methyl esters were 22.4 and 24.4 (silicone column) and 23.35 and 25.4 (polyester column). Methyl *trans* 2-octadecenoate had carbon numbers 18.4 and 19.35 using the same two columns.

Oxidation of the methyl esters of fraction 12 with the permanganate–periodate reagent (9, 28) gave a mixture of monocarboxylic acids with the composition C_{20}, 39.3%; C_{22}, 56.7%; and C_{24}, 4.0% (g.l.c. analysis as methyl esters using two different columns).

On ethanolysis, fraction 19 (0.250 g) gave esters (0.117 g) and alcohols (0.037 g) and an unidentified product (0.042 g) (R_f 0.3 ($CHCl_3$)). Ethanolysis of fraction 20 (0.510 g) gave esters (0.300) and alcohols (0.060 g) and unidentified gum (0.104 g). The compositions of methyl ester and alcohol fractions are given in Table III.

β-Diketone

The β-diketone was crystallized from ethyl acetate and had m.p. 58–59° and u.v. absorption maximum at 273 mμ (ε 12 125). The i.r. spectrum had a strong band at 1605 cm^{-1}. Nuclear magnetic resonance: terminal CH_3 0.87 (6 protons); methylene groups, 1.25; α-CH_2 (triplet, 2.19 (4 protons)); CH of enolic form (singlet, 5.31 (0.9 protons)).

Anal. Calcd. for $C_{31}H_{60}O_2$: C, 80.10; H, 13.01. Found: C, 79.92; H, 12.80.

β-Diketone (1.0 g) was refluxed with 4% ethanolic potassium hydroxide for 18 h when water was added; extraction with hexane gave neutral product (0.53 g). The aqueous layer was then acidified and the acidic product (0.52 g) extracted with ether. Analysis by g.l.c. (unit (*C*)) showed that the neutral product consisted of equal amounts of pentadecan-2-one and heptadecan-2-one and the acidic product of equal amounts of myristic and palmitic acids.

The ketones were separated in batches by g.l.c. (unit (*C*) at 180°) and gave equal weights of pentadecan-2-one, m.p. 37.5–38.5°, the mixed m.p. with synthetic ketone (m.p. 37.5–38.5, lit. (29) gives 39°) was 38.0–38.5°, and heptadecan-2-one, m.p. 47.5–48.5°, the mixed m.p. with synthetic ketone (m.p. 48–48.5°, lit. (29) gives 48°) was 47.5–48.5°. Authentic methyl ketones were synthesized by alkaline hydrolysis of methyl 3-oxohexadecanoate and 3-oxooctadecanoate (30, 31). The acids were converted to methyl esters and separated in the same way giving equal weights of methyl myristate and methyl palmitate. Hydrolysis yielded myristic acid, m.p. and mixed m.p. 51.5–53°, and palmitic acid, m.p. and mixed m.p. 62–63°.

Reduction of the β-diketone (3, 32) gave only hentriacontane (g.l.c. using unit (*C*) at 250°).

Free Alcohols

Fractions 8, 11, and 17 (Fig. 1) were combined with alcohols separated from the β-diketone fraction and analyzed by g.l.c.; a portion was also acetylated and reanalyzed. Crystallization from chloroform gave almost pure octacosanol (99% by g.l.c.), the m.p. was 81.5–82.5° and mixed m.p. with synthetic octacosanol (m.p. 82.5–83.5°) was 82–83°.

Hydroxy-β-diketones

Hydroxy-β-diketones were crystallized from ethyl acetate and had m.p. 70–72° and $[\alpha]_D$ +0.99°, $[\alpha]_{546}$ +1.19, $[\alpha]_{436}$ +1.94, $[\alpha]_{365}$ +2.91 (*c*, 9.3 in chloroform). The u.v. absorption maximum was at 273 mμ (ε 12 410) and the i.r. spectrum had bands at 1602 (s) and 3660 (w) cm^{-1}. Nuclear magnetic resonance: CH of CHOH (multiplet) 3.43, CH of enolic form (singlet) 5.30 and one hydroxylic proton removed by D_2O.

Anal. Calcd. for $C_{31}H_{60}O_3$: C, 77.44; H, 12.58. Found: C, 77.39; H, 12.47.

On hydrolysis as before, hydroxy-β-diketones (0.76) gave acidic (0.39 g) and neutral (0.40) fractions. After conversion of acids to methyl esters, g.l.c. analysis (unit (*C*), 220°) showed only one peak for each fraction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

but after acetylation both fractions showed 2 approximately equal peaks differing by 2 carbon numbers (cf. 12 and 13).

The acidic fraction, as methyl esters, was chromatographed on a silic acid column. Elution with hexane – 4% ether gave methyl palmitate (0.19 g) which on hydrolysis gave palmitic acid, m.p. and mixed m.p. with authentic acid 61–62°. Elution with hexane – 5% acetone yielded methyl hydroxymyristates. After crystallization from hexane these esters had m.p. 31–33° and $[\alpha]_D$ +1.33, $[\alpha]_{546}$ +1.51, $[\alpha]_{436}$ +2.54 and $[\alpha]_{365}$ +3.86 (*c*, 7.4 in chloroform). Nuclear magnetic resonance (quinoline): the signal in the α CH_2 region contained peaks at 2.38 and 2.30 corresponding to the central portion of the α CH_2 signal in spectra of 6- and 7-hydroxymyristates respectively. The rest of the spectrum was indistinguishable from that of a 1:1 mixture of synthetic methyl 6- and 7-hydroxymyristates (13).

Anal. Calcd. for $C_{15}H_{30}O_3$: C, 69.72; H, 11.70. Found: C, 69.39; H, 11.47.

Hydrolysis gave hydroxymyristic acids which, after crystallization from hexane had m.p. 61.5–62.5 (neutralization equiv. 247; calcd. for $C_{14}H_{28}O_3$, 244).

Chromic acid oxidation at 25° (12) gave oxo acids with m.p. 53–53.5° which was unchanged by repeated crystallization from hexane (6-oxotetradecanoic acid has m.p. 70.5–71.5 and 7-oxotetradecanoic acid has m.p. 67.5–68° (13)). When analyzed by g.l.c. using a QF-1 column (conditions used with methyl oxooctadecanoates (13)), two partly resolved peaks of equal size with retention times of 21.4 and 22.3 min were obtained (methyl 6-oxo and 7-oxotetradecanoates had retention times of 21.5 and 22.3 min respectively).

The mixed oxo esters were oxidized with chromic oxide at 100° (12) and the product converted to methyl esters. Analysis by g.l.c. (QF-1 column) showed the presence of C_7, C_8, and C_9 monocarboxylic esters (retention times 1.65, 2.4, and 3.3 min) and C_5, C_6, and C_7-dicarboxylic esters (retention times 4.8, 7.0, and 9.9 min). The molar percentages were C_7 26.7; C_8 46.7; C_9 26.6 and C_5 25.0; C_6 50.6; C_7 24.4. When the oxidation product was saponified, steam distilled, and mono- and dicarboxylic acids analyzed separately, the same acids were found as before showing that decanoic and succinic acids, which have retention times (as methyl esters), close to those of glutaric and nonanoic acids respectively, were absent.

The neutral fraction isolated on hydrolysis of the hydroxy β-diketones was separated into two approximately equal fractions as above. The first, heptadecan-2-one, was crystallized from methanol and had m.p. and mixed m.p. 47–48°. The second, 7- and 8-hydroxypentadecan-2-ones, had m.p. 39–53°, and $[\alpha]_D$ +1.06°, $[\alpha]_{546}$ +1.22°, $[\alpha]_{436}$ +2.10°, $[\alpha]_{365}$ +3.12° (*c*, 7.5 in chloroform).

Anal. Calcd. for $C_{15}H_{30}O_2$: C, 74.32; H, 12.48. Found: C, 74.56; H, 12.45.

Reduction of the hydroxy-β-diketones as before gave only hentriacontane.

Acknowledgments

A new direct synthesis of equilin from equilenin. Potassium–ammonia reduction of some non-conjugated double bonds[1]

DAVID J. MARSHALL AND ROMANO DEGHENGHI
Ayerst Research Laboratories, Montreal, Quebec

Received March 18, 1969

It is shown that the reduction of equilenin ethylene ketal with alkali metals in ammonia can be controlled to yield equilin ketal as the major product. With potassium at −33°, equilenin and equilin ketals are readily reduced to afford 8α-estrone ketals in good yield. Analogous reactions were observed with 2-naphthol.

Canadian Journal of Chemistry, 47, 3127 (1969)

Only one of the known syntheses of equilin (1–4), uses equilenin as starting material. Equilenin methyl ether and derivatives (**1**) on prolonged reduction with lithium and *t*-butanol in ammonia afforded tetrahydro compounds (**2**) which underwent bromination–dehydrobromination in ring A to give estra-1,3,5(10),7-tetraenes (**3**, R = H or Me) in rather low overall yields (4).

The work to be described here started with the assumption that a naphthol-type molecule such as equilenin in the presence of alkali metal in liquid ammonia would rapidly form a naphthoxide anion. If the oxygen at C-17 was protected so that no other negative charge could develop, the addition of electrons which is necessary for reduction should take place most readily (at least from an electrostatic point of view) in ring B, which could lead to a direct synthesis of equilin.

Experiments in which equilenin ethylene ketal (**4**) was allowed to react with alkali metals in ammonia without an added proton source and preferably at −70° showed that equilin (**5**) could indeed be obtained as the major product (except with potassium at −33°; see below), after hydrolysis of the intermediate ketal. Slightly better yields were obtained if the naphthoxide anion was formed by reaction of the ketal with sodium hydride in tetrahydrofuran before addition to a solution of the metal in ammonia. Analysis by gas–liquid chromatography (g.l.c.) of the total crude product of a reaction carried out in this way with lithium as the metal showed the presence of 76% of equilin. Purification by crystallization afforded a 55% yield of equilin, identified by melting point and mixture melting point with an authentic sample.

Analysis by g.l.c. of crude reaction products showed that the major by-products were a pair of closely related compounds, one of which was identical (by g.l.c. and thin-layer chromatography (t.l.c.)) with 3β-hydroxyestra-5,7,9-trien-17-one (5). The other member of the pair was presumably the 3-epimer. Infrared (i.r.) spectra indicated the presence of the 3-ketone (**6**) (band at 1715 cm^{-1}) in the product of some runs.[2]

At −70°, the yield of equilin as determined by g.l.c. was affected only to a minor extent on changing the metal from lithium to sodium to potassium. With calcium, however, the major product was the mixture of ring A-reduced alcohols **7**. If the oxygen at C-17 was in the form of a free hydroxyl or carbonyl group, and hence not protected against reaction with the metal, lower yields of estra-1,3,5(10),7-tetraenes resulted. When the starting material was a 3-methyl or 3-tetrahydropyranyl ether, complex mixtures of products were obtained.

At −33°, the major product of reduction of equilenin ethylene ketal with sodium and lithium followed by acid hydrolysis was equilin, but the

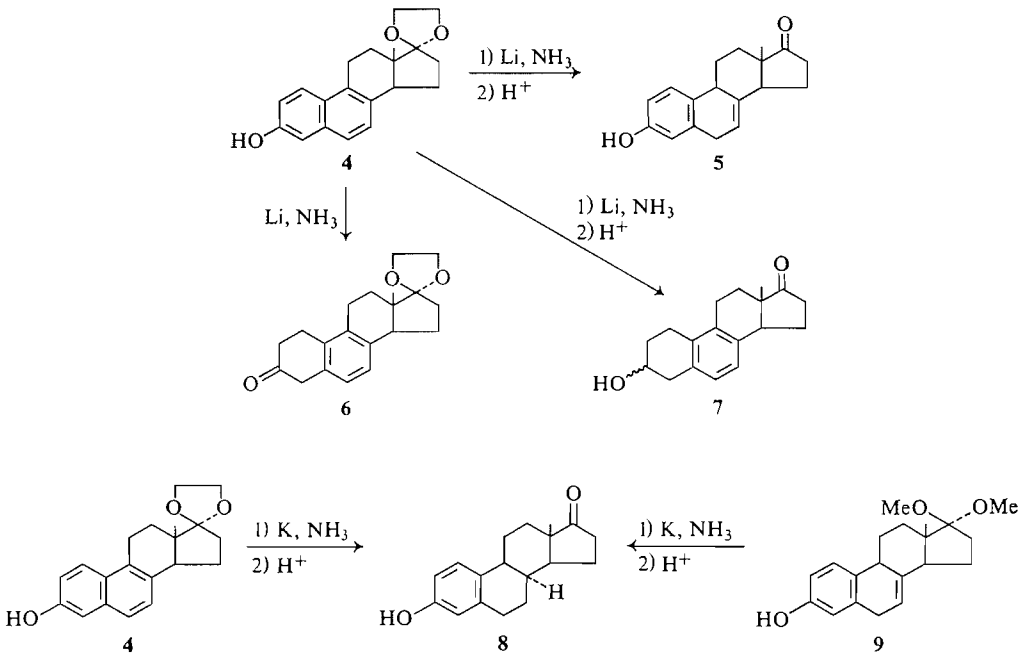
[1]This work was presented at the 51st Annual Conference of the Chemical Institute of Canada, Vancouver, British Columbia, June 3, 1968.

[2]The formation of the pair of ring A-reduced compounds **7** may be analogous to the formation of estr-5(10)-ene-3α,17β-diol by Birch reduction of estrone (6).



4 5 6 7 4 8 9

yield was inferior to that obtained at −70°. On the other hand, with potassium at −33°, no equilin at all was obtained. Instead a tetrahydro derivative of equilenin formed which was shown to be 8α-estrone (**8**). The same product could be obtained in high yield on reduction of equilin (as the dimethyl ketal **9**) with potassium at −33°. The structure was established by comparison of physical constants with those recorded (7,8) for 8α-estrone and by conversion to the methyl ether which was identical spectroscopically with a sample of totally synthetic *dl*-8α-estrone methyl ether (9).

The reduction of the double bond of equilin with potassium in ammonia was quite unexpected. Isolated non-terminal double bonds are not normally reduced by this method unless the intermediate radical–anion can be stabilized by the presence of a suitably situated double bond, as in the case of norbornadiene, which is reduced to norbornene by sodium or lithium in ammonia (10).

It could be shown that the formation of 8α-estrone under our conditions was not the result of amide-catalyzed rearrangement to the conjugated 8-dehydro isomer. Equilin dimethyl ketal, on contact with potassium amide in ammonia for 2 h, underwent rearrangement to the 8-dehydro isomer to the extent of only about 30%. In addition, 8-dehydroestrone ketal gave no 8α-estrone on reduction with potassium in ammonia. The reduction of equilin methyl ether dimethyl ketal with potassium at −33° afforded a mixture consisting of 55% starting material, 45% 8β-estrone methyl ether and, at most, traces of 8α-estrone methyl ether.[3]

Since the behavior of these related compounds towards potassium in ammonia is different from that of equilin ketal, we appear to be dealing with a direct reduction of the 7,8-double bond in the case of the latter compound. The fact that a 3-methyl ether does not undergo the same reaction shows that the negative charge of the anion formed on contact of the phenol with the metal must be participating in the reduction, perhaps by resonance stabilization of the radical anion **10**: The addition of the second electron and proton (e.g., **11** → **12**) might well be a fast, kinetically-controlled process taking place from the less hindered α-side of the molecule, resulting in the formation of the *cis*-fused 8α,9α-system.

[3]The 8β-estrone methyl ether probably was formed via the conjugated 8-dehydroestrone derivative, since metal–ammonia reduction of 8-dehydroestrone methyl ether is known to result in the formation of the *trans*-8β,9α-system (9).

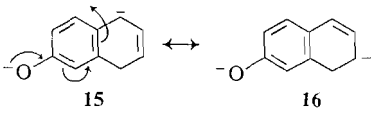
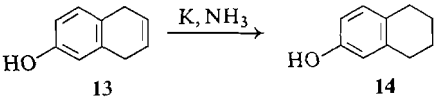
The nature of the oxygen–metal bond may account for the unique effectiveness of potassium in this reaction. This metal would be expected to form a more ionic bond to oxygen than would sodium or lithium. The negative charge on oxygen might, therefore, be more "available" for stabilization of the radical anion **10** in the presence of potassium than it would be in the presence of the more covalently bound sodium or lithium.

Since Birch (11) has shown that 2-naphthol is reduced to 2-tetralone by sodium and *t*-amyl alcohol in refluxing ammonia, it was of interest to determine how this simple analogue of the steroid system would behave under our reducing conditions. It was found that with sodium at −70° and in the absence of alcohol, 2-naphthol gave a 56% yield of a 3:2 mixture (as determined by g.l.c.) of 5,8-dihydro-2-naphthol (**13**) and 5,6,7,8-tetrahydro-2-naphthol (**14**). The dihydro compound **13** could not be obtained completely free of tetrahydro compound **14**, but its structure was evident from its ultraviolet (u.v.) spectrum (λ_{max} 282 mμ, ε 2220) and its nuclear magnetic resonance (n.m.r.) spectrum which showed multiplets centered at δ 3.40 (C-5, C-8 protons) and δ 5.93 p.p.m. (C-6, C-7 olefinic protons). Catalytic reduction of the impure **13** with palladium-on-charcoal gave a mixture consisting of 86% **14** and 13% 2-naphthol, as determined by g.l.c. The ratio of **13** to **14** obtained in the sodium–ammonia reduction of 2-naphthol was not a function of the length of time the reaction was allowed to proceed; hence, it is unlikely that **14** arises by rearrangement of **13** to a styrenoid isomer followed by reduction.

The formation of the tetrahydro derivative **14** under these conditions, in contrast to the case of naphthalene which affords only the1,4-dihydro derivative with sodium at −70° (12,13), perhaps reflects a destabilization of the resonance structure **15** relative to **16** due to the influence of the



negatively charged oxygen-bearing ring (cf. **15**, arrows). However, the same effect is not seen in the steroid series, since very little, if any, tetrahydro derivative is formed (as judged by g.l.c.) in the reduction of equilenin ethylene ketal at −70°.



The dihydronaphthol **13** was rapidly reduced to the tetrahydro derivative **14** by potassium in ammonia at −33° but not by sodium. As in the case of the analogous reaction in the steroid series, it appeared that this reduction was not taking place via conjugation of the double bond, since, on contact with potassium amide under the same conditions, **13** underwent rearrangement to the extent of only 20%. Thus, here again, reduction of the double bond apparently occurs with the participation of the oxygen-bearing ring with its associated negative charge.

Experimental

Melting points were determined on a Thomas Hoover apparatus and are uncorrected. Nuclear magnetic resonance spectra were taken on a Varian A-60A instrument with tetramethylsilane as internal standard. Microanalyses were performed by W. J. Turnbull and associates. Gas–liquid chromatography was carried out on trimethylsilyl ethers of steroids on an F and M model 402 instrument on 6 ft columns of 3.75% DEGS on Gaschrom Q, 80–100 mesh, at 200°. In the case of naphthols, analyses by g.l.c. were done on a Perkin-Elmer model 800 instrument on 6 ft columns of 15% QF-1 on Gaschrom Q at 150°. Liquid ammonia was distilled from a commercial cylinder into reaction flasks fitted with dry ice condensers. Except where otherwise indicated, "usual work-up" of a reaction in liquid ammonia means that excess ammonium chloride was added, the ammonia was allowed to evaporate, usually under a stream of nitrogen, ether and water were added, and the product was extracted with ether. The ether extracts were washed several times with water, dried, and the solvent was removed under reduced pressure.

Equilin (8)

A mixture of 8.7 g of equilenin, 0.70 g of *p*-toluenesulfonic acid, and 70 ml of ethylene glycol in 600 ml of benzene was stirred and heated under reflux using a water separator for 7 h. The cooled benzene solution was washed with $NaHCO_3$ solution and water and, after removal of solvent, crystallization from methylene chloride–hexane yielded 7.2 g of equilenin ethylene ketal, m.p. 161–163°.

Sodium hydride (1.54 g of a 50% dispersion in mineral oil) was washed three times by decantation with petroleum ether. The adhering solvent was blown off by a stream of nitrogen, 25 ml of tetrahydrofuran (THF) was added, and a solution of 7.00 g of equilenin ethylene ketal in 75 ml of THF was added dropwise with stirring under nitrogen. The solution was stirred for 1 h at room temperature and was then transferred to a dropping funnel attached to a 3-necked flask containing a solution of 2.65 g of lithium in 250 ml of ammonia (previously prepared by stirring at the b.p. of ammonia for 1 h). The lithium solution was cooled to −70° with a dry ice–acetone bath and the steroid solution was added dropwise with stirring over a period of 30 min. Stirring was continued at −70° for 2 h. A small sample of the crude ketal obtained after the usual work-up was hydrolyzed with dilute HCl and the product was found to contain 76% equilin by g.l.c. analysis. The remainder of the crude ketal was dissolved in 75 ml of methanol and 5 ml of 10% HCl were added. After 2 h at room temperature, the mixture, containing precipitated product, was cooled and filtered, and the solid was washed with cold 1:1 methanol–water. The product (3.6 g, m.p. 229–233°) was crystallized once from isopropanol to yield 3.28 g of equilin, m.p. 234–237°, undepressed on admixture with an authentic sample.

8α-Estrone (8)

a) From Equilenin

To a solution of 10.2 g of potassium in 250 ml of ammonia under reflux was added dropwise a solution of 1.00 g of equilenin ethylene ketal in 20 ml of THF. After stirring for 3 h, ethanol was added to decolorize the solution, the ammonia was allowed to evaporate, and the product was extracted with ether. A solution of the crude product in 10 ml of acetone and 1 ml of 10% HCl was kept at 40–50° for 1 h, concentrated, and extracted with ethyl acetate. The product (545 mg) was chromatographed on 40 g of deactivated silica gel. Elution with ether–benzene 5:95 gave 436 mg of 8α-estrone which, after crystallization from methanol, had m.p. 246–247° (decomp.), λ_{max} 278.5 mμ (ε 2340). This product was identical (by mixture melting point) with the 8α-estrone prepared from equilin (see below).

b) From Equilin

To a stirred suspension of 5.00 g of equilin in 25 ml of methanol and 25 ml of trimethyl orthoformate were added 2.5 ml of a solution of 0.2 ml of concentrated H_2SO_4 in 4 ml of trimethyl orthoformate. The steroid rapidly dissolved and the product precipitated slowly. After 2 h, the mixture was neutralized with a few drops of pyridine, cooled, and filtered to yield 4.63 g of equilin dimethyl ketal, m.p. 199–200°. The i.r. spectrum showed the absence of carbonyl absorption and the presence of ether bands at 1105–1110 cm^{-1}. The compound decomposed on prolonged standing and on attempted crystallization.

To a solution of 20.4 g of potassium in 300 ml of refluxing ammonia was added dropwise a solution of 2.00 g of equilin dimethyl ketal in 20 ml of THF. After stirring for 3 h, the reaction mixture was worked up as usual. A solution of the crude product in 20 ml of acetone was treated with 0.5 ml of 10% HCl and kept for 1 h at room temperature. Dilution with 25 ml of water and filtration yielded 1.7 g of 8α-estrone, m.p. 242–244° (decomp.). Recrystallization from methanol and then from ethyl acetate gave an analytical sample, m.p. 247–249° (decomp.), $[\alpha]_D$ +101° (dioxane) (lit. (7) m.p. 242–244°, $[\alpha]_D$ +105° (EtOH)).

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20. Found: C, 79.97; H, 8.10.

Methylation with dimethyl sulfate and aqueous KOH in ethanol gave 8α-estrone methyl ether, m.p. 92.5–95.5° (from hexane) (lit. (7) m.p. 93–94°).

Anal. Calcd. for $C_{19}H_{24}O_2$: C, 80.24; H, 8.51. Found: C, 80.50; H, 8.60.

This compound was identical spectroscopically (by i.r., n.m.r.) and by g.l.c. with *dl*-8α-estrone methyl ether (8).

Reaction of Equilin Dimethyl Ketal with Potassium Amide

To a suspension of potassium amide made from 440 mg of potassium and a trace of ferric chloride hydrate in 50 ml of ammonia under reflux was added dropwise a solution of 500 mg of equilin dimethyl ketal in 10 ml of THF. The resulting orange suspension was stirred for 2 h. After the usual work-up and hydrolysis of the ketal grouping with dilute HCl in methanol at room temperature, a solid (375 mg) was obtained with λ_{max} 275–281 mμ (ε 5460). Analysis by g.l.c. and n.m.r. showed this product to consist essentially of a 2:1 mixture of equilin and 8-dehydroestrone.

Reduction of 8-Dehydroestrone Ethylene Ketal

A mixture of 480 mg of *dl*-8-dehydroestrone (8), 35 mg of *p*-toluenesulfonic acid, and 3 ml of ethylene glycol in 35 ml of benzene was stirred and heated under reflux for 8 h using a water separator. After washing with $NaHCO_3$

For personal use only.

solution and water followed by drying and removal of solvent, a pale-yellow foam was obtained whose i.r. spectrum showed no carbonyl absorption.

A solution of 490 mg of this material in 8 ml of THF was added to a solution of 3.4 g of potassium in 50 ml of ammonia under reflux. After stirring for 4 h, the usual work-up gave a yellow foam with λ_{max} 271 mμ (ε 12 100). Analysis by n.m.r. and g.l.c. (after hydrolysis of the ketal group with dilute HCl in methanol) showed the product to be a mixture of 27% 8-dehydroestrone, 34% estrone, and 19% 9(11)-dehydroestrone.[4]

Reduction of Equilin Methyl Ether Dimethyl Ketal

To a suspension of 1.00 g of equilin methyl ether in 3 ml of methanol and 3 ml of trimethyl orthoformate was added 0.3 ml of a solution of 0.1 ml of concentrated H_2SO_4 in 2 ml of trimethyl orthoformate. The ketal began to precipitate after 10 min. After stirring for 3 h, a few drops of pyridine and 3 ml of water were added and the product was filtered and washed with cold methanol. The yield of dimethyl ketal was 1.10 g, m.p. 106–109°, showing no carbonyl absorption in its i.r. spectrum.

A solution of 570 mg of this ketal in 5 ml of THF was added to a refluxing solution of 3.4 g of potassium in 50 ml of ammonia. After a reaction time of 2 h followed by the usual work-up and hydrolysis of the ketal with dilute HCl in methanol, 365 mg of a crystalline solid was obtained, m.p. 152–158°. Analysis by n.m.r. spectrum and g.l.c. (the latter performed on the 17-alcohol formed by reduction with $NaBH_4$ in methanol) showed the product to consist essentially of a 55:45 mixture of starting material and 8β-estrone methyl ether possibly containing a very small amount of 8α-estrone methyl ether.

Reduction of 2-Naphthol

A solution of 2.77 g of sodium in 80 ml of ammonia was cooled to −70° and a solution of 5.00 g of 2-naphthol in 20 ml of ether was added dropwise over a period of 10 min. After stirring for 1 h at −70°, ammonium chloride was added and the ammonia was allowed to evaporate under a stream of nitrogen. Ether and dilute HCl were added, and an ether extract of the crude product was extracted six times with cold 5% NaOH solution. Acidification of the alkaline extracts with dilute HCl followed by ether extraction gave 3.9 g of a dark brown oil. Shortpath distillation at 0.1 mm yielded 2.8 g of a colorless solid with m.p. 71–73°. Analysis by g.l.c. and n.m.r. spectrum showed this to be a 3:2 mixture of 5,8-dihydro-2-naphthol (**13**) and 5,6,7,8-tetrahydro-2-naphthol (**14**). Repeated recrystallization from ether–petroleum ether gave **13** with m.p. 78–79° which still contained 7% of tetrahydro compound; λ_{max} 282 mμ (ε 2220); n.m.r. ($CDCl_3$) δ 1.76, 2.72 (multiplets, tetrahydro compound impurity), 3.40 (multiplet, C-5, C-8 H), 5.10 (singlet, O—H), 5.93 (multiplet, C-6, C-7 H), and 6.60–7.18 p.p.m. (multiplet, aromatic H).

Anal. Calcd. for $C_{10}H_{10}O$: C, 82.16; H, 6.89. Found: C, 82.06; H, 6.88.

A solution of 1.51 g of **13** which contained 21% of **14** in 30 ml of benzene was shaken with hydrogen in the presence of 300 mg of 5% palladium-on-charcoal. When hydrogen absorption ceased after 1.5 h, the mixture was filtered and the solvent was evaporated to give a colorless oil. Analysis by g.l.c. showed this product to be a mixture containing 86% **14**, 13% 2-naphthol, and 0.5% **13**.

Reduction of 5,8-Dihydro-2-naphthol (13) with Potassium in Ammonia

To a stirred refluxing solution of 4.4 g of potassium in 50 ml of ammonia was added dropwise over a period of 2 min a solution of 500 mg of a 65:35 mixture of **13** and **14** in 5 ml THF. After stirring for 15 min, the reaction mixture was worked up in the usual way to give an oil which solidified. Analysis by g.l.c. showed this product to be pure tetrahydro compound **14**. Crystallization from hexane gave **14** with m.p. 59–60° (lit. m.p. 58–59° (14)).

With sodium, under the same conditions, no reduction of **13** took place. A sample of **13** which was allowed to react with potassium amide in ammonia for 15 min was found by g.l.c. to have undergone rearrangement to the extent of about 20%.

[4]The 9(11)-dehydroestrone was probably formed by isomerization during the ketal formation (cf. (8)) and the estrone could have arisen from either the 8- or 9(11)-dehydroestrone.

Acknowledgments

We are indebted to Dr. G. Schilling and associates for n.m.r. data and for numerous g.l.c. analyses. We are extremely grateful to J. Schmid for enthusiastic and skilled technical assistance.

Fragmentation reactions promoted by cyanogen bromide

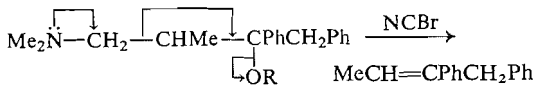
A. F. Casy, M. M. A. Hassan, and A. P. Parulkar
Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alberta

Received December 23, 1968

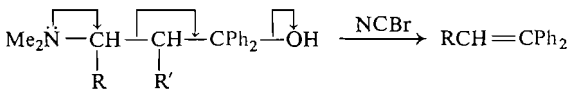
The fragmentation of α-4-dimethylamino-3-methyl-1,2-diphenylbutan-2-ol to *cis* H/Ph 3-methyl-1,2-diphenylprop-2-ene, normally induced by treating the corresponding 2-chloro derivative with a base, also results when the alcohol itself is treated with cyanogen bromide; related γ-hydroxy acyclic tertiary amines similarly undergo fragmentation in this reaction. In contrast, cyclic analogues such as β-1,3-dimethyl-4-phenyl-4-piperidinol are not cleaved by cyanogen bromide (corresponding *N*-cyano derivatives are formed in low yield) even though β-4-chloro-1,3-dimethyl-4-phenylpiperidine is fragmented by potassium cyanide to *trans* H/Ph 5(*N*-cyanomethyl-*N*-methylamino)-3-phenylpent-2-ene.

Canadian Journal of Chemistry, 47, 3133 (1969)

As part of a study of the von Braun *N*-demethylation procedure (1), the aminoalcohols **1***a*, **2***a*, and **2***b* were treated with cyanogen bromide. These compounds were chosen as reaction substrates because of the previous finding (1) that bases with oxygen functions delta to a dimethylamino group (e.g. methadone) are converted to cyclic products by cyanogen bromide (NCBr) instead of to *N*-cyano-*N*-methyl derivatives, the normal products of the von Braun reaction. An abnormal reaction course was also seen in the present experiments, the alcohols **1***a*, **2***a*, and **2***b* (OH γ- to NMe_2) being fragmented by NCBr at room temperature. Products isolated from the α-(±)-diastereoisomer of **1***a*, of known configuration (2), were *cis* H/Ph 3-methyl-1,2-diphenylprop-2-ene **3** (3) [ultraviolet (u.v.) and proton

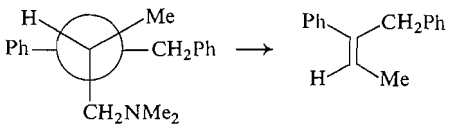


1 *a*) R = H; *b*) R = OCOMe — **3**



2 *a*) R = H, R′ = Me; *b*) R = Me, R′ = H — **4** *a*) R = Me; *b*) R = H

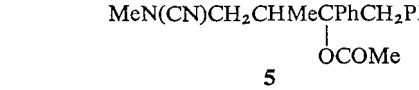
magnetic resonance (p.m.r.) spectra were identical with those of an authentic sample obtained from the 2-chloro analogue of **1***a* and sodium methoxide or pyridine] and α-**1***a* hydrobromide. No attempt was made to isolate the fragment complementary to the propene **3**. The diphenylpropan-1-ols **2***a* and **2***b* gave 1,1-diphenylprop-1-ene **4***a* and 1,1-diphenylethylene **4***b* respectively together with the corresponding substrate hydrobromides. No *N*-cyano derivatives were detected in any of the reaction products. The α-acetate **1***b* was also fragmented by NCBr giving *cis* **3**, but in this case the non-basic fraction contained the *N*-cyano-*N*-methyl acetate **5** in comparable amount (proton magnetic resonance evidence). Reaction between NCBr and the β-(±) diastereoisomer of **1***a* again gave the *cis* propene **3** as the major non-basic product. Hence, reaction of both α- and β-**1***a* appears to proceed through a common intermediate. This is probably a carbonium ion since if NCBr is regarded as analogous to an acyl halide, its reaction upon the tertiary benzylic alcohols **1** and **2** would be expected to give a reaction species of this nature.[1] The intermediate is represented in **6** by a conformer which satisfies the stereoelectronic requirements of fragmentation (4) and accounts for the exclusive or preponderant formation of the *cis* H/Ph



6

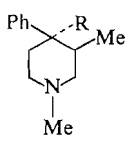
alkene **3**. Recovery of the α- rather than the β-**1***a* hydrobromide when β-**1***a* is treated with NCBr further supports the above interpretation of the reaction course. The β-ester **1***b* with NCBr gave a solid *N*-cyano-*N*-methyl ester **5** as the sole non-basic reaction product.

Some related reactions of the cyclic γ-hydroxy-tertiary amine **7** (β-prodinol, *cis* 3-Me/4-Ph) were next investigated. The 4-chloro analogue **7***b*, obtained by treating **7***a* with thionyl chloride (5), has



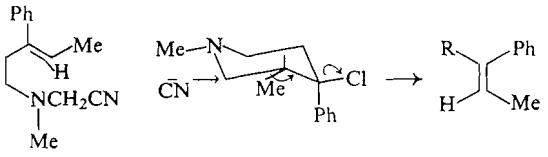
5

[1]Thanks to a referee for this suggestion.



7 *a*) R = OH,
b) R = Cl

the same configuration as the parent alcohol since its 3-methyl p.m.r. signal suffers a pronounced downfield shift (base, 52 Hz; HCl, 68 Hz from TMS in $CDCl_3$ at 60 MHz) when the basic center is protonated [the 3-methyl chemical shifts of α-isomers (*trans* 3-Me/4-Ph) of this type are little changed after *N*-protonation] (6). When **7***b* was treated with potassium cyanide in ethanol–water at the reflux temperature, a fragmentation reaction[2] occurred (cf. reaction between 3-β-chlorotropane and potassium cyanide) (7), the major product being 5-(*N*-methyl-*N*-cyanomethylamino)-3-phenylpent-2-ene **8**; this structure is substantiated by spectroscopic evidence (see Ex-

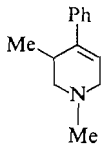


8 **9**

perimental). The predicted stereochemistry of **8**, based on reaction proceeding via the intermediate **9**, consistent with the stereoelectronic requirements of fragmentation (4) and the *cis* 3-Me/4-Ph configuration of **7***b*, is *trans* H/Ph. Support for this assignment is provided by the higher field chemical shift of the vinylic proton of **8** (336 Hz from TMS, base in $CDCl_3$) compared with that of the *cis* analogue **3** (365 Hz from TMS in $CDCl_3$) and comparative u.v. characteristics (**8** λ_{max} 231 mμ, ε 7600; **3** λ_{max} 245 mμ, ε 10 850 both in ethanol); these differences are consistent with a reduced degree of aromatic ring double bond coplanarity in the *trans* H/Ph derivative. β-Prodinol **7***a* and the tetrahydropyridine **10** were minor products of this reaction.

In view of the proneness of **7***b* to fragmentation, it was felt that NCBr should induce the cleavage of the precursor alcohol itself (**7***a*) by analogy with experiments upon the acyclic amino–alcohol

[2]The two fragments are, of necessity, linked together because of the ring system and no loss of carbon occurs.



10

$Me_2NCH_2CMe{=}CPh_2$ **11**

$BrCH_2CMe{=}CPh_2$ **12**

1*a* and its chloro derivative. When β-prodinol was treated with NCBr in chloroform or benzene, however, the alcohol was recovered in high yield as the hydrobromide salt together with a small amount of the *N*-cyano-4-piperidinol (**7***a*, N—Me replaced by N—CN). The absence of a vinylic signal in the p.m.r. spectrum of the total hydrobromide showed that no fragmentation product formed. A similar result was obtained when 1-methyl-4-phenyl-4-piperidinol was used in this reaction, except that a small yield of the dehydrated alcohol also resulted. The process by which hydrogen bromide is generated in these reactions is not clear. The relative inertness of β-prodinol **7***a* (and the 3-desmethyl analogue) towards NCBr is possibly due to the highly hindered nature of its hydroxyl function (axial in preferred conformation and geminal to phenyl) (6).

Reaction of NCBr with the aminoalkene **11** gave 3-bromo-2-methyl-1,1-diphenylprop-1-ene **12**. This appears to be a normal tertiary-amino NCBr reaction in that one of the groups attached to nitrogen is cleaved, but is unusual in that the largest rather than the smallest *N*-substituent is lost.

Experimental

The p.m.r. spectra were recorded on a Varian A-60 spectrometer using $CDCl_3$ or DMSO-d_6 as solvent. Chemical shifts are expressed in τ units with TMS as standard. Infrared (i.r.) spectra of salts were recorded as Nujol mulls. The previously described (1) method for the reaction of tertiary amino substrates with NCBr was used. In the following specific cases, weight of substrate, reaction period, and temperature are given in parentheses after each example. Salts were crystallized from ethanol–ether.

(*a*) The α-butan-2-ol **1***a* (2) (11.2 g, 2 h, room) and NCBr (4.2 g) in $CHCl_3$ (40 ml) gave α-**1***a* hydrobromide (6.5 g), m.p. 235–237°, lit. (8) 235–236°, and 3-methyl-1,2-diphenylprop-2-ene (3.4 g) b.p. 104°/0.05 mm. Characteristics of the latter's u.v. and p.m.r. spectra were the same as those of the authentic *cis* H/Ph propene **3** (3).

(*b*) The α-acetate **1***b* (2) (14.6 g, 3 h, room) and NCBr (4.8 g) in $CHCl_3$ (40 ml) gave α-**1***b* hydrobromide, (7.5 g), ν_{max} 2650 ($\overset{+}{N}H$), 1735 (C=O) and 3350 cm^{-1} (H_2O), and the *cis* H/Ph propene **3** (4 g) b.p. 104°/0.05 mm.

Anal. Calcd. for $C_{21}H_{28}BrNO_2 \cdot H_2O$: C, 59.4; H, 7.1. Found: C, 60.0; H, 7.05.

The p.m.r. spectrum of the total non-basic fraction in $CDCl_3$ displayed signals due to the *N*-cyanomethyl derivative of **1***b* [singlets 7.33 (NMe) and 8.1 (OCOMe) and doublet 8.95 τ, *J* 6.5 Hz (3-Me)] as well as those due to the *cis* propene **3**.

(*c*) The β-butan-2-ol **1***a* (2) (3 g, 12 h, room) and NCBr (1 g) in $CHCl_3$ (20 ml) have **1***a* hydrobromide (2 g), m.p. 234–236° established as the α-diastereoisomer since its i.r. spectrum showed bands at 3080 and 3240 cm^{-1}, typical of the α-form and absence of β-bands (9). The major component of the non-basic product (0.5 g) was the *cis* propene **3** (p.m.r. comparisons).

(*d*) The β-acetate **1***b* (2) (1.5 g, 2 h, room) and NCBr (0.5 g) in $CHCl_3$ (20 ml) gave 2-acetoxy-4-*N*-cyano-*N*-methylamino-3-methyl-1,2-diphenylbutane (0.4 g), m.p. 131–132° from ether, ν_{max} 2195 (NCN) and 1730 cm^{-1} (C=O); p.m.r. characteristics in $CDCl_3$: singlets 7.23 (NMe) and 7.97 (COMe), doublet 8.95 τ, *J* 6.5 Hz (3-Me).

Anal. Calcd. for $C_{21}H_{24}N_2O_2$: C, 75.0; H, 7.2; N, 8.3. Found: C, 75.2; H, 7.3; N, 8.3.

(*e*) β-Prodinol **6***a* (10) (10.2 g, 2 h, room) and NCBr (5.3 g) in $CHCl_3$ (50 ml) or benzene (50 ml) gave **6***a* hydrobromide (6.5 g), m.p. 203–205°.

Anal. Calcd. for $C_{13}H_{20}BrNO$: C, 52.9; H, 7.1. Found: C, 52.5; H, 7.1.

1-Cyano-3-methyl-4-phenyl-4-piperidinol (0.18 g), m.p. 106–108° from hexane–methanol, was also isolated.

Anal. Calcd. for $C_{13}H_{16}N_2O$: C, 72.1; H, 7.45; N, 13.9. Found: C, 72.2; H, 7.6; N, 13.85.

The total hydrobromide had a p.m.r. spectrum in DMSO-d_6 very similar to that of β-**6***a* hydrochloride and lacked signals in the vinylic region.

The same treatment of 1-methyl-4-phenyl-4-piperidinol (1.6 g) gave 1-cyano-4-phenyl-4-piperidinol (40 mg), m.p. 138–140° from hexane–methanol.

Anal. Calcd. for $C_{12}H_{14}N_2O$: C, 71.2; H, 7.0; N, 14.85. Found: C, 71.0; H, 7.0; N, 14.7.

The piperidinol hydrobromide (0.5 g) and 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine, isolated as a hydrochloride m.p. 252–253°, lit. (11) 251–253°, were also obtained.

(*f*) The amino-propanol **2***a* (10.8 g, 2 h, room) and NCBr (4.2 g) in $CHCl_3$ (40 ml) gave **2***a* hydrobromide (6.5 g), m.p. 228–230°, ν_{max} 2650 cm^{-1} ($\overset{+}{N}$—H).

Anal. Calcd. for $C_{18}H_{24}BrNO$: C, 61.7; H, 6.9. Found: C, 61.4; H, 6.9.

The non-basic product of this reaction, 1,1-diphenylprop-1-ene (2 g), m.p. 46–48° from ethanol, lit. (12) b.p. 143–145°/11 mm, had u.v. and p.m.r. characteristics similar to those reported (12).

Anal. Calcd. for $C_{15}H_{14}$: C, 92.7; H, 7.3. Found: C, 92.85; H, 7.3.

(*g*) The amino-propanol **2***b* (10.8 g, 3 h, room) and NCBr (4.3 g) in $CHCl_3$ (40 ml) gave **2***b* hydrobromide (7 g), m.p. 229–231°. Anal. Found: C, 61.6; H, 6.7.

The non-basic product of this reaction, 1,1-diphenylethylene (2.2 g), b.p. 102°/0.5 mm, lit (12) b.p. 128°/10 mm, had u.v. and p.m.r. characteristics similar to those reported (12).

(*h*) The amino-alkene **10** (obtained by dehydrating the propanol **2***a* with HCl–acetic acid) (4 g, 3 h, room) and NCBr (1.7 g) in $CHCl_3$ (20 ml) gave 3-bromo-2-methyl-1,1-diphenylprop-1-ene (3.5 g), b.p. 118°/0.05 mm, m.p. 45–47°, λ_{max} 252 mμ, ε 13 200 in ethanol; p.m.r. characteristics in $CDCl_3$: multiplet 2.8 (10 aryl protons), singlets 5.97 (2-methylene protons) and 8.08 τ (*t*-methyl).

Anal. Calcd. for $C_{16}H_{15}Br$: C, 66.9; H, 5.3; Br, 28.5. Found: C, 66.9; H, 5.1; Br, 28.55.

Reaction of β-4-chloro-1-methyl-4-phenylpiperidine with KCN.

A mixture of the 4-chloropiperidine (6), (1.8 g), freshly liberated from the hydrochloride salt, KCN (0.6 g), ethanol (15 ml), and water (2.8 ml) was heated under reflux for 11 h. The product was concentrated, diluted with water, and extracted with ether. The ether (dried, Na_2SO_4) was evaporated and the residue (1.7 g) acidified with ethanol–HCl when the cyanomethylamino-alkene **7** hydrochloride (0.6 g) m.p. 125.5–126.5° after recrystallization, separated; ν_{max} 2245 cm^{-1} (CN, base, band obscured in the salt), λ_{max} 231 mμ, ε 7600 in ethanol; p.m.r. characteristics in $CDCl_3$; quartet 4.2 *J* 7 Hz (base 4.4, vinylic proton), broad singlet 4.72 (base 6.62, NCH_2CN), singlet 7.08 (base 7.78, NMe), and doublet 8.4 *J* 7 (base 8.45, τ MeCH=).

Anal. Calcd. for $C_{14}H_{19}ClN_2$: C, 67.1; H, 7.6; N, 11.2. Found: C, 67.6; H, 7.6; N, 11.6.

β-Prodinol hydrochloride (0.2 g), m.p. 214–214.5°, was isolated from the mother liquors.

Anal. Calcd. for $C_{13}H_{20}ClNO$: C, 64.5; H, 8.3; N, 5.8. Found: C, 64.3; H, 8.25; N, 6.1. The p.m.r. spectrum of the total reaction product (base in $CDCl_3$) had signals characteristic of β-prodinol (3-Me doublet at 9.23) (7) and the tetrahydropyridine **9** (vinylic band at 4.17 and Me doublet at 9.02 τ) (13).

Acknowledgments

The authors thank Dr. J. Lee of Roche (Nutley, N.J.) for a sample of β-prodinol, and the Medical Research Council of Canada for financial support.

Conformation and configuration of some α,β-unsaturated carbonyl compounds from their nuclear magnetic resonance spectra

W. M. PHILLIPS AND D. J. CURRIE
Chemistry Section, Defence Research Establishment, Suffield, Ralston, Alberta

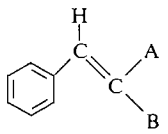
Received February 21, 1969

Nuclear magnetic resonance spectra were recorded for 95 styrenes with two functional groups (A and B) on the β-carbon atom where A, B are $COCH_3$, $COCH_3$; $COCH_3$, $CO_2C_2H_5$; $CO_2C_2H_5$, $COCH_3$; $CO_2C_2H_5$, $CO_2C_2H_5$; $CO_2C_2H_5$, CN; and $CO_2C_2H_5$, H. The chemical shifts of the ethylenic hydrogen and the hydrogens of the functional A and B groups were examined in detail to determine the effects of ring substituents. The configuration of the unsymmetrical styrenes and the conformation of the A and B groups as deduced from the spectra are discussed.

Canadian Journal of Chemistry, 47, 3137 (1969)

Introduction

Nuclear magnetic resonance (n.m.r.) spectra have been used by Timmons (1) to assign *S-cis* or *S-trans* conformations to α,β-unsaturated ketones and by Hayashi (2) to deduce the configuration of β-alkyl-α-cyanocinnamic esters. In this work the n.m.r. spectra of a number of ethyl α-cyanocinnamates or ethyl benzalcyanoacetates, **1**(A = $CO_2C_2H_5$, B = CN), ethyl benzalacetoacetates,



1

1(A = $COCH_3$, B = $CO_2C_2H_5$ or A = $CO_2C_2H_5$, B = $COCH_3$), diethyl benzalmalonates, **1**(A = B = $CO_2C_2H_5$), and 3-benzal-2,4-pentanediones, **1**(A = B = $COCH_3$), were used to assign configuration to the compounds with different A and B groups and to deduce the conformation of the A and B groups. The electronic environment of the ethylenic hydrogen and the hydrogens of the functional ester and ketone groups were monitored and changes in the conformation of these functional groups with substitution on the phenyl ring were examined.

Experimental

The preparation, properties, and analyses of the compounds used in this work have been described by Silver *et al.* (3). Solutions of the compounds, 10–20% w/v in $CDCl_3$ containing tetramethylsilane as the internal reference were used to record the spectra on a Varian A-60 spectrometer.

Results

Nuclear magnetic resonance spectral evidence indicates that all the compounds examined are geometrically homogeneous except the 2-methyl-, 3-methyl-, 3-fluoro-, 2-chloro-, 3-chloro-, 2-methoxy-, 4-methoxy-, 3,*n*-propoxy-, 2,6-dichloro-, 2,3-dimethoxy-, 2,4-dimethoxy-, and 3,4-methylenedioxy- derivatives of ethyl benzalacetoacetate, **1**(A or B = $COCH_3$ or $CO_2C_2H_5$). The τ values for the ethylenic proton and for those of the ketone and ester groups are tabulated in Tables I–VI. Displacements for similarly located protons in analogous members of different series

*Compounds of structure  .

†These compounds were initially geometrically non-homogeneous.

relative to the unsubstituted parent compounds are virtually identical except when substitution occurs at C-2 and C-6 of the phenyl group. These average displacements appear in Table VII.

Substituted ethyl cinnamates[1], **1**(A = $CO_2C_2H_5$, B = H), (5, 6) (Table VI) were used as reference for assigning configuration to the unsymmetrical difunctional styrenes, **1**. The chemical shifts of the methyl triplet and the methylene quartet in these compounds are virtually independent of the position and nature of the substituent on the phenyl group. For the substituted diethyl benzalmalonates, **1**(A = B = $CO_2C_2H_5$), (Table IV) the chemical shifts of one of the two sets of methyl and of the methylene protons[2] likewise are virtually independent of the substituent on the phenyl group and therefore were assigned to the A position. The alternative set of absorptions which exhibit marked dependence upon substitution in the benzene ring were associated with the ester in the B position.

Chemical shifts for the ester group of the geometrically homogeneous ethyl benzalacetoacetates (Table II) are dependent upon phenyl substituents so the ester must be in the B position of **1**(A = $COCH_3$, B = $CO_2C_2H_5$). These compounds are unstable in solution and isomerize to approximately equimolar mixtures of the two geometric isomers. The chemical shifts for the ester protons of the new geometric isomers, **1**(A = $CO_2C_2H_5$, B = $COCH_3$), like those for the ethyl cinnamates, were independent of ring substituents (Table III). For those ethyl benzalacetoacetates that were mixtures of geometric isomers prior to recording the spectra (Tables II and III), it was possible to assign the two sets of absorption bands to the respective A and B ester groups by comparing the chemical shifts with those of the analogous diethyl benzalmalonates. Where overlap of the two sets of absorption bands occurred, the relative intensities of the methylene and methyl absorption peaks materi-

[1]The coupling constant for the ethylenic hydrogens of ethyl cinnamate is 16.3 ± 0.2 c.p.s. For the methyl and methylene protons in all ethyl ester derivatives of **1**, the coupling constant is 7.1 ± 0.2 c.p.s.

[2]For diethyl dihydrobenzalmalonate, only single absorptions (τ (CH_3) 8.84, τ (CH_2) 5.89) were observed.

†These compounds were formed by isomerization in $CDCl_3$.

ally assisted in associating the bands with each of two geometrically positioned ester groups. Characterization of the A and B carbethoxyl groups of the isomeric ethyl benzalacetoacetates permitted the assignment of τ values to the A and B methyl ketone singlets. Assignment of the twin singlets for the A and B methyl ketones of the 3-benzal-2,4-pentanediones, **1**(A = B = $COCH_3$), followed (Table I). The positions of the methyl absorption for the A ketone of the 3-benzal-2,4-pentanediones and the ethyl benzalacetoacetates, like those of A ester groups, were independent of ring substituents while the positions of bands for the methyl protons of the B ketone groups were quite variable. If this approach to configuration is valid the methyl ketone protons of benzalacetone, **1**(A = $COCH_3$, B = H), should absorb at ~ 7.60 τ. The observed absorption was at 7.58 τ.

Similar arguments lead to the conclusion that the ester group in the ethyl benzalcyanoacetates, **1**(A = $CO_2C_2H_5$, B = CN), (Table V) is in the A position and that these compounds are not susceptible to isomerization in solution.

The positions of the methyl singlets in the phenyl substituted methyl and methoxyl derivatives of these styrenes are listed in Table VIII.

Discussion

The probable conformation of the difunctional conjugated heteroenoid compound is revealed in the relative positions of the various absorption bands of the C-2 -substituted derivatives. The aplanarity of the styrene moiety in C-2 -substituted ethyl cinnamates, **1**(A = $CO_2C_2H_5$, B = H), due to interference of the substituent with the B hydrogen atom[3] is reflected in a large downfield shift of the ethylenic hydrogen vicinal to the benzene ring, relative to that for the analogous hydrogen atom of the parent unsubstituted ethyl cinnamate. The orientation of this hydrogen in the deshielding field of the benzene ring, by itself, is not sufficient to account for the magnitude of

[3]Any discussion of the variation in the displacements of B hydrogen atoms with substitution on the phenyl group must await further data from similar systems.

†Phenyl absorptions occur in this region.

the shift (4) and moreover, the hydrogen probably moves along an isoshielding line (5) as the phenyl group is rotated. Resonance will be damped as soon as the styrene moiety is forced into an aplanar conformation, and the carbon atom attached to the benzene ring thereby acquires a more positive character resulting in less shielding of the attached hydrogen atom. The magnitude of the downfield displacement for this hydrogen in C-2 -substituted derivatives relative to that in ethyl cinnamate is therefore a function of the size of the C-2 -substituent; the bulkier the substituent the less the overlap of π orbitals between the benzene ring and those of the styrenic double bond. Displacements of the bands for this hydrogen in the C-2 -substituted 3-benzal-2,4-pentanediones, **1**(A = B = $COCH_3$), the ethyl benzalacetoacetates, **1**(A or B = $COCH_3$ or $CO_2C_2H_5$), and the diethyl benzalmalonates, **1**(A = B = $CO_2C_2H_5$), are similar to those for similarly substituted ethyl cinnamates. Enhanced displacements are observed for these members of the ethyl benzalcyanoacetates, **1**(A = $CO_2C_2H_5$, B = CN),

and benzalcyanoacetamides[4], **1**(A = $CONH_2$, B = CN), and are similar to those already reported for the benzalmalononitriles, **1**(A = B = CN), (4). While the conjugative effect of the A group governs the extent of the chemical shift, the conformation of the B group appears to be a decisive factor as well.

Substituents on the phenyl group, especially at C-2, cause a marked variation in the chemical shift of the methyl of a B ketone and the methyl and methylene of similarly located ester groups, while the effect on the corresponding protons of A groups is small. Since the functional group at A is undoubtedly involved in conjugation, stabilization of the molecule would dictate planarity of this group over that of an angular B group (6). Moreover, repulsion between the phenyl group and the negative charge on the polarized B carbonyl group would favor a predominantly *S-trans* configuration[5] for this carbonyl group. This being the case, the methyl group of the ketone at B and the ethyl group of the ester at B will be in the field of the phenyl ring (5) (see Figs. 1, 2). The small displacements of τ (CH_3) (ketone or ester) and τ (CH_2) (ester) upon introduction of substituents at C-3 or C-4 (Table VII) arise then from small changes in the anisotropy of the ring due to the electronic effects of the substituent. The marked effect of C-2 -substituents, on the other hand, supports the *S-trans* configuration for the B functional group and the orientation of the phenyl ring (2) must outweigh the electronic effects of the substituent in positioning the proton bands of the neighboring ester or ketone. In accord with this, the downfield shifts of these protons increase with increasing dimensions of the C-2 -substituent in the order CH_3O < Cl < CH_3 < NO_2.

The τ value for the ethylenic hydrogen vicinal to the benzene ring in 2-benzal-1,3-indanedione, **1**(A, B = —CO—C_6H_4—CO—), supports the premise that the conformation of the B functional group governs in part, the chemical shift for this proton. For 3-benzal-2,4-pentanedione, with the B carbonyl in an *S-trans* configuration, τ(CH=C) is 2.51 while for 2-benzal-1,3-indanedione which has a B carbonyl with an unambiguous *S-cis* configuration, τ is 1.93. The linear B cyano group of ethyl benzalcyanoacetate, benzalcyanoacetamide,

and benzalmalononitrile apparently functions similarly to a B ketone group with an *S-cis* configuration since the ethylenic hydrogen is downfield compared to that in related *S-trans* ketone compounds. The effect of steric arrangement of these groups is also manifest in increased reactivity of *S-cis* B carbonyl compounds and B cyano compounds with thiols (7, 8).

In contrast to the chemical shifts for the methyl protons of the A ester of the diethyl benzalmalonates and ethyl benzalacetoacetates, those for the methylene protons are displaced downfield compared to those for the analogous ethyl cinnamates. For the compounds to which an *S-trans* configuration has been assigned to the B carbonyl group, an *S-cis* configuration for the A ester would place the methylene protons in the field of the B carbonyl group. In accord with the *S-cis* character of the cyano group in the ethyl benzalcyanoacetates, both the methyl and methylene protons, as expected, are deshielded (see Fig. 3).

Unusual chemical shifts were observed for 2,6-disubstituted conjugated heteroenoid compounds. With chlorine atoms in these positions

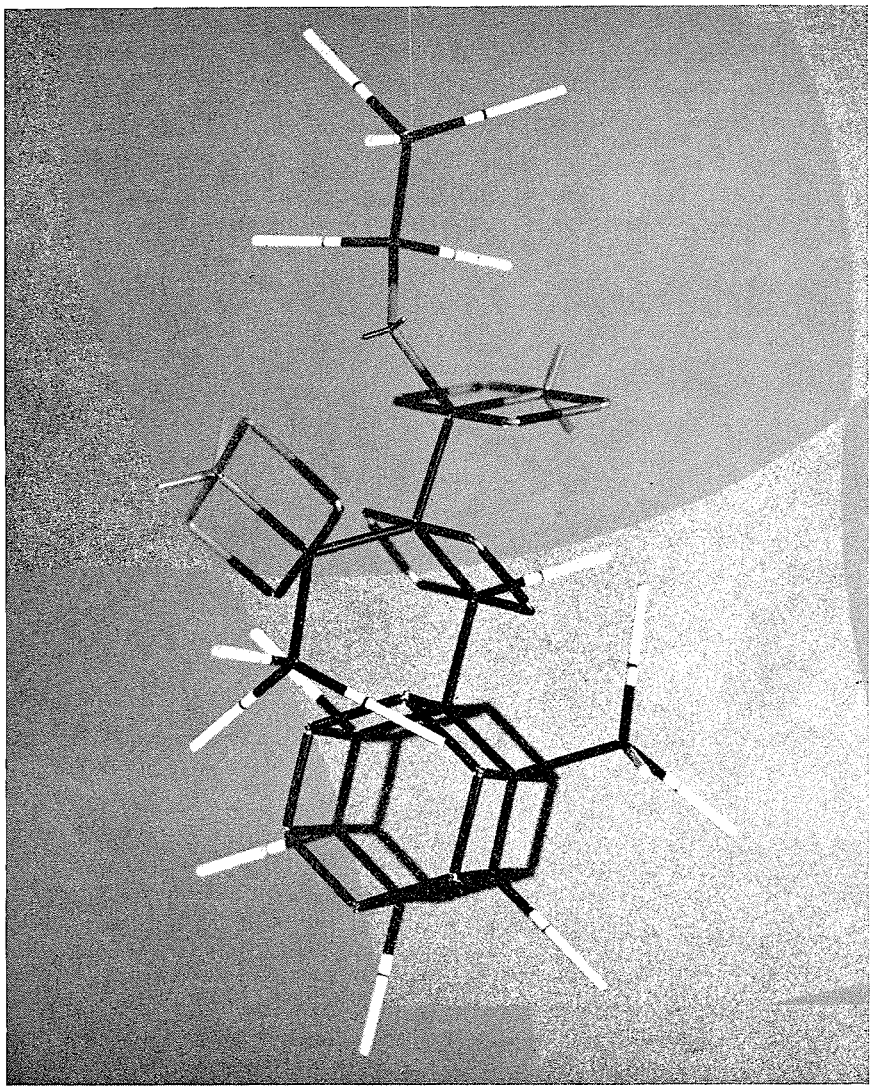

FIG. 2. The Prentice–Hall framework molecular model of ethyl 2-methylbenzalacetaocetate, **1**(A = $CO_2C_2H_5$, B = $COCH_3$).

the absorption of the ethylenic proton is variable and displaced slightly upfield relative to the parent compound and dramatically upfield from that of the 2-chloro derivative. However, with methyl groups in the same positions the ethylenic proton is downfield relative to the parent compound. Lapine's Stewart–Briegleb models indicate that the ethylenic hydrogen is locked in a position intermediate between the C-2 - and C-6 -substituents. The ethylenic bond, then, is virtually at right angles to the plane of the phenyl group and a maximal downfield displacement for this hydrogen would be anticipated. In the case of the 2,6-dichloro-derivatives, the field effects of these chlorines counteract the deshielding influence of the ring.

The positions of the B ketone–methyl absorption bands in the 2,6-dichloro-derivatives are only slightly upfield relative to those in 3-benzal-2,4-pentanedione and ethyl benzalacetoacetate, while the positions of the B methyl ester in the 2,6-dichloro-derivatives exhibit the expected signif-

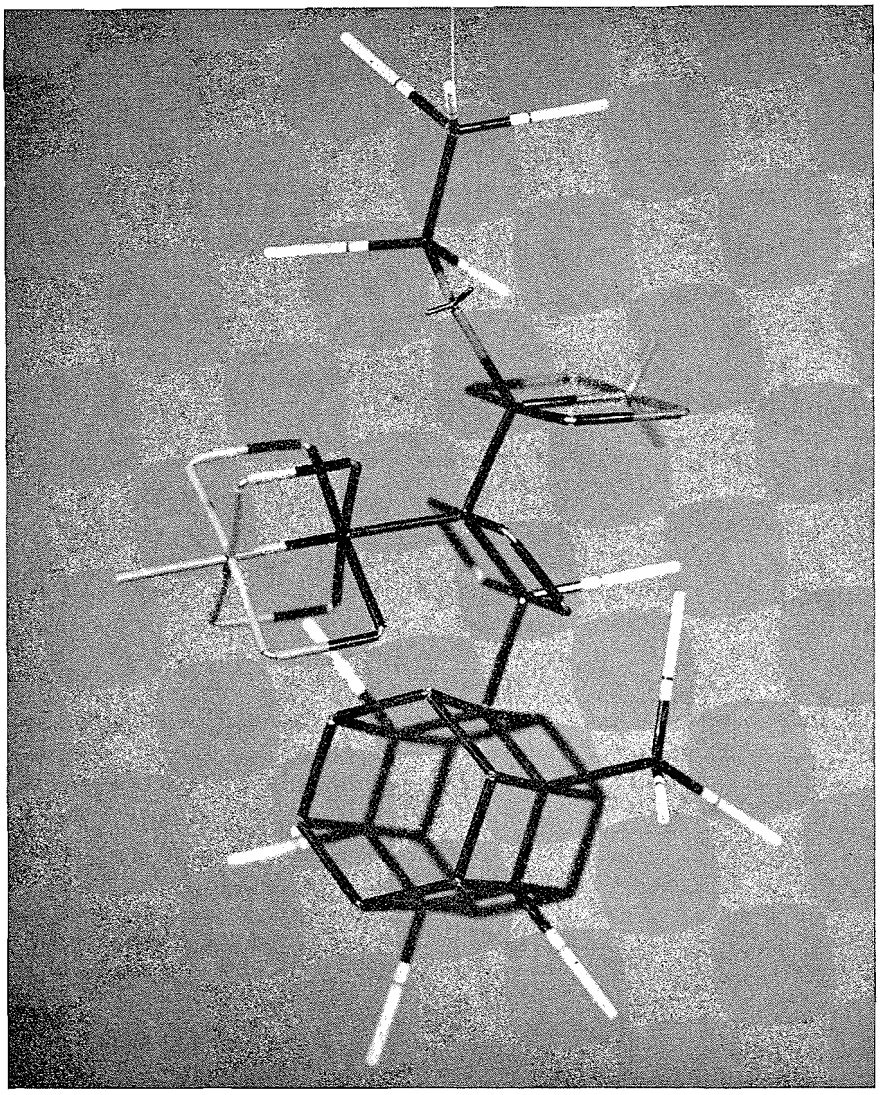

FIG. 3. The Prentice–Hall framework molecular model of ethyl 2-methylbenzalcyanoacetate, **1**(A = $CO_2C_2H_5$, B = CN).

icant displacements compared with those of ethyl benzalacetoacetate and diethyl benzalmalonate. The smaller bulk of the ethoxy–oxygen of the ester relative to that of the methyl group of the methyl ketone permits a normal *S-trans* conformation for the B ester function but requires an abnormal *S-cis* conformation for the analogous methyl ketone function. In this way the methyl protons of the methyl ketone are outside the field of the benzene ring. Downfield shifts for the protons of the A ketone in 2′,6′-dichloro-3-benzal-2,4-pentanedione and the A ester in ethyl 2,6-dichlorobenzalacetoacetate suggest a similar reversal to the *S-trans* conformation for these functional groups. The chemical shift for the B methyl ketone protons in 2′,4′,6′-trimethyl-3-benzal-2,4-pentanedione indicates that the normal *S-trans* configuration obtains for this functional group. Electronic repulsion of the B carbonyl group by the trimethylphenyl group may account

for this. The upfield shifts of the ring-methyl protons in this trimethylphenyl derivative relative to those of an analogous C-2 or C-4 monomethylphenyl derivative attest to the highly negative character of this ring.

The conformations assigned to the A and B functional groups in these compounds accord with those deduced from infrared spectral data (10). A study of n.m.r. solvent shifts should provide additional evidence for *S-trans* and *S-cis* conformations (9).

Acknowledgments

The authors thank Dr. H. L. Holmes for supplying samples of the compounds used in this study, members of the Chemistry Section for helpful discussions, and Mr. J. B. Richardson, Mr. H. S. Johnson, and Mr. C. E. Lough for technical assistance.

Effect of functional group conformation on the infrared spectra of some gem difunctional phenylethylene derivatives

D. J. Currie, C. E. Lough, F. K. McClusky, and H. L. Holmes
Chemistry Section, Defence Research Establishment Suffield, Ralston, Alberta

Received February 21, 1969

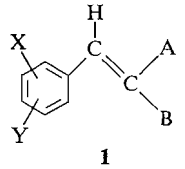
Except for the benzalmalononitriles, two functional group stretching vibrations occur in the infrared (i.r.) spectra of the β,β-difunctional-styrenes with similar functional groups. For geometrically homogeneous compounds with dissimilar functional groups only one absorption band occurs for each functional group. The two bands for similar functional groups have been ascribed to *S-cis*- and *S-trans*-conformations of the carbonyl groups with respect to the ethylene and variation in the frequencies of each of these oriented carbonyls to rotation of the functional group or groups out of the plane of the ethylene by steric factors.

Frequencies for ethylenic C—H out of plane deformation bands for β-monofunctional styrenes accorded with those already assigned to this vibration. A similar assignment could not be made for the difunctional analogues.

Canadian Journal of Chemistry, 47, 3147 (1969)

Introduction

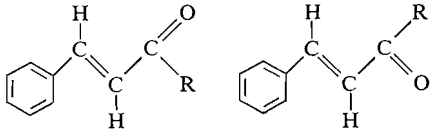
Demonstration of a relationship of stimulatory activity on the hind legs of pithed frogs (1) and bacterial growth inhibitory activity (2) of conjugated heteroenoid compounds, **1**, with rates of reaction with nucleophiles and the



1

dependence of these rates upon the functional groups, A and B,[1] has necessitated an extensive study of the conformations of A and B in these compounds. An insight has been gained from nuclear magnetic resonance (n.m.r.) spectral work into the orientation of the B group (3) while a parallel i.r. study has now shed light upon the conformation (*S-cis* or *S-trans* to the ethylene (4)) of the A group.

Models of **1** where A and B are angular groups ($COCH_3$, $CO_2C_2H_5$, $CONH_2$, CONHR, $CONR_2$, etc.) indicate the presence of considerable steric restraint due to spatial congestion between A, B, and the phenyl group, and Shubert and Sweeney (5) have shown that inhibition of molecular planarity in the armethylacetophenones has a pronounced influence upon their i.r. spectra. The spectra of compounds with structure **1** have been similarly ascribed by Zabicky (6) to aplanarity of the molecule. Hayes and Timmons have demonstrated recently that, depending upon the bulk of the alkyl group of the alkylstyryeketone, the conformation of the planar conjugated system in solution may be either *S-cis*, **2**, or *S-trans*, **3**, while in potassium bromide disc spectra, one conformation may be favored to the exclusion of the other (4). The



2 **3**

large number of compounds, **1**, that were prepared for the biological program and which have *S-cis* and *S-trans* arrangements of the —CH=C(B) moiety of the molecule[2] have been examined spectrally in the i.r. region, and an interpretation is advanced for the observed frequencies in the ethylenic and functional group stretching regions.

Experimental

The preparation of the compounds used in this work, and their purity are described in Silver *et al.* (7). The

[1]The A and B groups will always refer respectively to the functional groups *trans* and *cis* to the phenyl group.

[2]See the previous paper (3) for nuclear magnetic resonance evidence.

spectra[3] were recorded on a model 621 Perkin–Elmer spectrophotometer using potassium bromide pellets for solids and contact films for liquids. The spectra of chloroform solutions of a number of these compounds were also recorded.

Results

A number of absorption bands occur in the region of the spectra between 2500 and 1380 cm^{-1} and their positions are summarized in Table I. At least two, and in most cases, three bands appear in the carbonyl region of the spectra of the 3-benzal-2,4-pentanediones, **1**(A = B = $COCH_3$) and of the benzalmalonamides, **1**(A = B = $CONH_2$). The band with the lowest frequency, however, falls in the ethylenic stretching vibration region (8). A similar multiplicity of bands is also observed in the carbonyl region of the diphenyl benzalmalonates, **1**(A = B = $CO_2C_6H_5$). In the analogous spectra of the diethyl benzalmalonates, **1**(A = B = $CO_2C_2H_5$), the contiguous carbonyl bands are fused into one broad band.

In contrast to the carbonyl stretching region only a single band appears in the cyano stretching region, irrespective of whether A or B = CN, and its position is relatively insensitive to structural changes. The limited steric restraint of the cyano group (9) affords the greatest opportunity for a planar molecule in these gem-difunctional compounds. When the conjugative effect (9) of the A group differs but slightly, e.g., $CO_2C_2H_5$, from that of the cyano group in the B position, then electromeric shifts in the *cis*–cinnamonitrile moiety should contribute materially to the resonance stabilization of the molecule as a whole. When the conjugative effect of the A group, e.g. COC_6H_5 in α-cyano-*trans*-benzalacetophenone, markedly exceeds that of the cyano group at B, then the cyano group might be expected to function more like a non-conjugated cyano group to i.r. light than that in ethyl benzalcyanoacetate. For equimolar solutions of these two compounds in chloroform, the absorbance of the former was somewhat greater than in the latter but the area under the two peaks was about the same.

Analysis of the 1670–1550 cm^{-1} spectral region proved difficult because the diagnosis of these bands as either ethylenic stretch vibrations or skeletal aromatic ring vibrations could not be made with certainty especially in the vicinity of 1600 cm^{-1}. Two bands at 1500 and 1440 cm^{-1} which are common to most of the spectra are undoubtedly due to skeletal aromatic ring vibrations and, in most cases, were accompanied by other bands. While some consider absorption at ~ 1600 cm^{-1} to be aromatic in origin Hayes and Timmons (4) have assigned bands between 1616 and 1604 cm^{-1} in alkylstyrylketones, **1**(A = COR, B = H) to cisoid ethylenic stretch vibrations.

Discussion

Functional Group Stretching Vibrations

The multiplicity of bands appearing in the 1750–1500 cm^{-1} region of the spectra of conjugated heteroenoid compounds with *gem* difunctional groups, **1**, might be ascribed, on steric grounds, to conjugated A and non-conjugated B groups as was done in the derivation of numerical values for the steric, conjugative, and inductive effects for the groups around the ethylene in these compounds and which provides long wavelength ultraviolet (u.v.) absorption maxima in accord with those observed (9). This band multiplicity could equally well arise from the presence of *S-trans* and *S-cis* conformations of the A- and B-carbonyl groups resulting from steric restraints imposed by the A, B, and phenyl groups. This tacitly implies that the molecules of these compounds are planar or nearly so. A combination of these two hypotheses appears to more adequately accommodate the facts.

The two carbonyl absorptions (1669 and 1691 cm^{-1}) in the spectrum of benzalacetone, **1**(A = $COCH_3$, B = H), have been ascribed (4) to the existence of *S-trans* and *S-cis* carbonyl groups in this compound while steric factors have favored the existence of only an *S-cis* carbonyl group (1678 cm^{-1}) in 4,4-dimethyl-1-phenyl-1-pentene-3-one, **2**(R = $(CH_3)_3C$) (4). There are then four possible combinations for the conformation of the A(*S-cis* or *S-trans*) and B(*S-cis* and *S-trans*) groups in 3-benzal-2,4-pentanedione, **1**(A = B = $COCH_3$). Only two of the four requisite bands are apparent and have frequencies of 1691 and 1711 cm^{-1}. Two of the possible conformations either do not occur or their absorption bands are superimposed upon the two already described. If each of these bands

[3]Photocopies of the pellet or liquid contact spectra of some 300 compounds recorded on a model 21 Perkin–Elmer spectrophotometer may be obtained, upon request, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada.

For personal use only.

represents single absorptions then from n.m.r. data (3) the first one must be associated with the *S-trans* B-carbonyl group and the remaining *S-cis* carbonyl absorption band must arise from the carbonyl group of the A-acetyl group. The hypsochromic shifts of $\sim 20\ cm^{-1}$ from the position of the analogous bands in benzalacetone must then be ascribed to rotation of the A- and B-acetyl groups out of the plane of the ethylene.

The spectrum of ethyl cinnamate, **1**(A = $CO_2C_2H_5$, B = H), has one band at 1715 cm^{-1} in the carbonyl region while that of diethyl benzalmalonate, **1**(A = B = $CO_2C_2H_5$), has a broad band[4] at 1727 cm^{-1}. Nuclear magnetic resonance evidence (3) associates an *S-trans* conformation with the B-ester carbonyl of diethyl benzalmalonate. If, as above, the distortion from planarity accounts for the frequency shift in the bands of diethyl benzalmalonate relative to ethyl cinnamate, then the broad band at 1727 cm^{-1} must be associated with both the *S-trans* B group and the *S-cis* A group. The smaller deviation ($\sim 12\ cm^{-1}$) between the frequencies for the *S-trans* carbonyl group in ethyl cinnamate and diethyl benzalmalonate, compared to that for their ketone analogues ($\sim 20\ cm^{-1}$), probably stems from less steric interference by the ethoxyl in the ester group compared to that of the methyl in the acetyl group.

The hypothesis ascribing the magnitude of the hypsochromic shifts, observed above, to the extent of steric restraint finds added support in the spectra of phenyl cinnamate, **1**(A = $CO_2C_6H_5$, B = H) and diphenyl benzalmalonate, **1**(A = B = $CO_2C_6H_5$). Bands at 1728 and 1690 cm^{-1} in the spectrum indicate the presence of both *S-cis* and *S-trans* conformers in phenyl cinnamate. The corresponding bands in the spectrum of diphenyl benzalmalonate are at 1756 and 1735 cm^{-1}. The larger shifts in going from the monoester to the diester (28 and 45 cm^{-1}) are in the direction expected for the greater steric effects of the phenoxy group in these esters.

The carbonyl group of cinnamamide, **1**(A = $CONH_2$, B = H) absorbs at 1661 cm^{-1} while those of benzalmalonamide, **1**(A = B = $CONH_2$) absorb at 1660 and 1690 cm^{-1}. The carbonyl group in benzalmalonamide associated with the 1660 cm^{-1} band probably has the same conformation as that in cinnamamide and in analogy with the previous cases, it is surmised that this is the B-carboxyamide group.[5] In any event the two carboxyamides have opposite conformations. If the conformation of the carbonyl of cinnamamide is the same as that of ethyl cinnamate and benzalacetone then the picture is consistent throughout.

Using a similar approach, the 1660 cm^{-1} band has been assigned to the *S-trans* carbonyl group of cinnamanilide, **1**(A = $CONHC_6H_5$, B = H), and benzalmalonanilide, **1**(A = B = $CONHC_6H_5$) and the 1678 cm^{-1} band to the *S-cis* carbonyl of both compounds. The carbonyl absorption in benzalcyanoacetanilide at 1680 cm^{-1} is at the same frequency as the *S-cis* carbonyl groups in the above mono- and diamides. By similar reasoning the absorption for *S-trans* carbonyl of *N*-alkylcarboxyamides occurs at 1656 cm^{-1} while that for the *S-cis* carbonyl occurs at 1675 cm^{-1}. The absence of steric influences upon the position of carbonyl absorption of carboxyamides and their *N*-alkyl derivatives demonstrates that hydrogen bonding can exert a pronounced influence upon the planarity of the conjugated system.

Steric factors and the absence of hydrogen bonding alter the conformation of the *N,N*-dialkylbenzalcyanoacetamides, as it did in 4,4-dimethyl-1-phenyl-1-pentene-3-one. The carbonyl group in *N,N*-dimethylbenzalcyanoacetamide, **1**(A = $CON(CH_3)_2$, B = CN) appears to be restricted to the *S-trans* (1645 cm^{-1})[6] conformation since it absorbs at a frequency similar to that (1648 cm^{-1}) for that in *N,N*-dimethylcinnamamide, **1**(A = $CON(CH_3)_2$, B = H).

The linear cyano group, by its very nature, minimizes steric effects (9) and favors a coplanar molecule with the result that only a single

[4]A small shoulder, present at $\sim 1705\ cm^{-1}$, which was present in the parent compound was absent in about one third of the substituted derivatives.

[5]Limited solubility in $CDCl_3$ precluded the n.m.r. conformational analysis of the B-carbonyl group in the benzalmalonamides. The conformations assigned throughout to the amide carbonyl group are, however, in accord with their observed rates of reaction with *n*-butanethiol.

[6]A less likely explanation for the 1645 cm^{-1} band for the *N,N*-dialkylbenzalcyanoacetamides is that the *N*-methyl groups rotate the *S-cis* A-carboxyamide group out of the plane of the molecule. With properties more like that of a non-conjugated amide group the carbonyl absorption would be shifted to a lower frequency (10). The assignment for compound **1** (A = B = $CON(CH_3)_2$) is tentative.

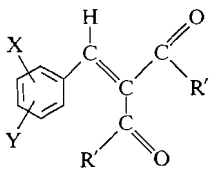
For personal use only.

absorption is observed for this functional group whether located at A and/or B.

Combinations of different functional groups in the same molecule present no spectral complications, however, the ethyl benzalacetoacetates, **1**(A = $COCH_3$, B = $CO_2C_2H_5$) geometrically isomerize slowly in chloroform solution. The initial conformation of the carbonyl group of the B-ester, on n.m.r. spectral evidence[7] has been diagnosed as *S-trans*. Using the same inductive argument as above the conformation of the A-ketone carbonyl would be expected to be *S-cis*. The observed absorption bands at 1696 and 1729 cm^{-1} are in accord with this concept. The decreased spatial congestion between A($COCH_3$) and B = $CO_2C_2H_5$ relative to that when B = $COCH_3$ (9) accounts for the bathochromic shift (15 cm^{-1}) for the *S-cis* A-ketone carbonyl of ethyl benzalacetoacetate compared with that in 3-benzal-2,4-pentanedione. The *S-trans* B-ester carbonyl group of ethyl benzalacetoacetate absorbs at 1729 cm^{-1} as does the B-ester carbonyl of diethyl benzalmalonate.

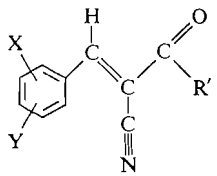
Absorption at 1731 cm^{-1} in the spectra of the ethyl benzalcyanoacetates, **1**(A = $CO_2C_2H_5$, B = CN), is ascribed to the carbonyl with an *S-cis* conformation which then must be the counterpart of the 1692 cm^{-1} band in benzalcyanoacetamide, **1**(A = $CONH_2$, B = CN).

Based upon the above arguments the conformations of all these gem difunctional compounds are given by **4** and **5**.



R′ = CH_3, OC_2H_5, OC_6H_5, NH_2, NHC_6H_5

4



R′ = OC_2H_5, NH_2, NHR

5

Ethylenic Stretching Vibrations

Hayes and Timmons (4) have shown that the position of the ethylenic stretching vibration in the spectra of the ac-alkylbenzalacetones is intimately associated with the conformation of the ketone carbonyl group. The ethylenic stretch vibration associated with an *S-cis* ketone carbonyl has intense absorption between 1616 and 1604 cm^{-1} while the absorption of that associated with an *S-trans* ketone carbonyl is less intense and occurs from 1630 to 1620 cm^{-1}. In gem difunctional compounds, **1**, with similar angular functional groups the ethylene is cisoid with respect to the A-carbonyl but transoid to the B-carbonyl. A band appearing between 1660 and 1620 cm^{-1} in the spectra of these compounds has been diagnosed as an ethylenic stretching vibration and if a second band is present it is masked by the phenyl doublet at about 1600 cm^{-1}. The frequency of the clearly defined ethylenic stretching vibration is intimately associated with degree of substitution around the ethylene and the nature of the substituents. This is not the only factor influencing the frequency of this vibration since attempts to account for their position on steric grounds alone have been only partially successful. The position of this band is summarized in Table I.

The ethylene (1628 cm^{-1}) of benzalacetone, **1**(A = $COCH_3$, B = H) absorbs at a much lower frequency than that (1658 cm^{-1}) of the more hindered 3-benzal-2,4-pentanedione, **1**(A = B = $COCH_3$). Similarly the analogous band for cinnamamide, **1**(A = $CONH_2$, B = H), is at a lower wavenumber (1632 cm^{-1}) than it is in benzalmalonamide (1642 cm^{-1}). The same is true for the *N*-phenylated derivatives, cinnamanilide (1625 cm^{-1}) and benzalmalonanilide (1645 cm^{-1}) as would be expected on steric grounds.[8] On the other hand, the ethylene of ethyl cinnamate and of phenyl cinnamate absorb at frequencies 10–15 cm^{-1} greater than those of the analogous gem difunctional compounds. Furthermore the frequency of the absorption band for this group in ethyl benzalacetoacetate, **1**(A = $COCH_3$, B = $CO_2C_2H_5$) is at a very high frequency (1660 cm^{-1}) although the hinderance to coplanarity should be intermediate between that of 3-benzal-2,4-pentanedione and of diethyl benzalmalonate.

[7]See previous paper. Only 2,6-dichloro-3′-benzal-2′4′-pentanedione and one isomer of ethyl 2,6-dichlorobenzalacetoacetate, **1**(A = $CO_2C_2H_5$, B = $COCH_3$) had *S-cis* B-carbonyl groups.

[8]On the same grounds the ethylenic stretch vibration for β-nitrostyrene, **1**(A = NO_2, B = H) should, and does, absorb (1634 cm^{-1}) at a lower frequency than that of β-nitropropenylbenzene, **1**(A = NO_2, B = CH_3) (1659 cm^{-1}) or of β-nitrobutenylbenzene (1650 cm^{-1}).

In general, when only *S-cis* carbonyl groups are possible, as in 2-benzal-1,3-indanedione, or when B is a cyano group the ethylenic stretch vibration is either absent or is masked by phenyl absorptions at $\sim$ 1600 cm^{-1}.

The 975 cm^{-1} region of the spectra has been examined for evidence for an ethylenic C—H out of plane deformation band for the monofunctional compounds, **1**(B = H), and the 850–790 cm^{-1} region (11) scanned for a similar band in the difunctional compounds, **1**. The former diagnosis is confirmed by this work but such is not the case for the latter.

The dramatic differences in rates of reaction of thiols with difunctional compounds of type **1** and the extent to which they proceed may be intimately associated with the conformation of the A and/or B groups. If this is the case, then the evidence presented herein suggests that the *S-cis* B-ketone carbonyl of the 2-benzal-1,3-indanediones is involved in the rapid attainment of equilibrium in the *n*-butanethiol addition reaction (12). All evidence points to the conclusion that the B-cyano group of the cyano-containing compounds, **1**, (B = CN), fulfills the same role.

Free radical hydrobromination of propargyl bromide and bromoallene[1]

KARL R. KOPECKY AND SHIMA GROVER[2]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received November 22, 1968

Rearrangement is observed in the free-radical hydrobromination of propargyl bromide. Between −20 and +30 °C in *n*-pentane or ether solution, 1,2-dibromopropene is the major product. A detailed stereochemical and kinetic study of the reaction indicates that the 1,2-dibromopropene is formed via bromoallene which results from the loss of a bromine atom from the first formed 1,3-dibromo-2-propenyl radical. Only 1/3 to 1/2 of the bromoallene diffuses away from its bromine atom partner. The remainder of the bromoallene recombines within the solvent cage with its bromine atom partner at a rate which is competitive with its rate of rotation with respect to the bromine atom. When the free radical hydrobromination of propargyl bromide is carried out at −78° in liquid hydrogen bromide, the 1,3-dibromo-2-propenyl radical can be trapped to a large extent by the hydrogen bromide to form *cis*-1,3-dibromopropene. The stereochemistry of this addition reaction > 99% *trans*. A small amount of 1,2-dibromopropene which is 77% *trans* is also formed. Under the same conditions a 3:1 mixture of 1,2- and 1,3-dibromopropenes is produced from bromoallene. The 1,3-dibromopropene produced from bromoallene is > 95% *cis*, while the 1,2-dibromopropene consists of a 49:51 *cis*:*trans* mixture of isomers.

In connection with another problem in these laboratories a large amount of 1,3-dibromopropene was required. The free radical hydrobromination of propargyl bromide appeared to be a more convenient route to this compound than

[1] $HC{\equiv}CCH_2Br + HBr \rightarrow CHBr{=}CHCH_2Br$

those already available (1–3). Free radical hydrobromination of terminal acetylenes has been shown to give anti-Markovnikov products (4–6). However, when hydrogen bromide was bubbled through propargyl bromide containing benzoyl peroxide at 0 °C, only ca. 15% of 1,3-dibromopropene was formed. The major product was 1,2-dibromopropene which was isolated in 54% yield. A rearrangement, presumably migration of a bromine atom, has clearly occurred in this transformation. In view of the interest in bromine migrations (7, 8) and the mechanism of free radical addition of hydrogen bromide to unsaturated systems (7–16), the course of this reaction was examined in detail.

Products and Nature of Reaction

It was found that up to 7 compounds can be present in reaction mixtures from the hydrobromination of propargyl bromide. These are *cis*- and *trans*-1,2-dibromopropene, *cis*- and *trans*-1,3-dibromopropene, 2-3-dibromopropene, bromoallene, and propargyl bromide. Clean separation by gas–liquid chromatography of all these compounds could be achieved using a 9.5 ft × 1/4 in. column of 10% UCON 50HB5100 on Chromosorb W. All analyses reported were obtained by gas–liquid chromatography using this column. The identification of these compounds is described in the Experimental.

Some preliminary experiments were carried out in order to confirm that the formation of 1,2-dibromopropene from the hydrobromination of propargyl bromide was the result of a free radical process. These are summarized in Table I.

High yields of 1,2-dibromopropene were obtained only in the presence of benzoyl peroxide or under illumination. Addition of the free radical inhibitors hydroquinone and ferrous chloride to the reaction mixtures resulted in the formation of considerable amounts of 1,3- and 2,3-dibromopropenes, presumably by an ionic process or processes. Reaction in the dark is very slow in the absence of initiators. This evidence confirms that hydrobromination of propargyl bromide under free radical conditions results in almost exclusive formation of a product of a rearrangement, 1,2-dibromopropene, at 0 °C.

No evidence was found for the formation of any 3,3-dibromopropene by either the free radical or ionic addition of hydrogen bromide to

propargyl bromide. Product balances of 95–100% were obtained indicating that little, if any, polymer or tribromide was formed in either the ionic or free radical reactions and that these reactions stopped cleanly at the dibromide stage.

The 1,2- and 1,3-dibromopropenes produced in these reactions are mixtures of *cis* and *trans* isomers. It was shown that these mixtures are equilibrium mixtures. The equilibrium compositions of the 1,2- and 1,3-dibromopropenes were determined by irradiating with a sun lamp, the pure geometric isomers in pentane solution saturated with hydrogen bromide until no further change in isomer composition was observed. These results are shown in Table II.

TABLE II

Equilibration of isomers of 1,2- and 1,3-dibromopropene at 0 °C.

Starting compound	Equilibrium composition
cis-1,2-Dibromopropene	76.8% *trans*
trans-1,2-Dibromopropene	77.1% *trans*
cis-1,3-Dibromopropene	84.5% *cis*
trans-1,3-Dibromopropene	83.1% *cis*

Bromoallene was detected in reactions which were interrupted before completion. Continuous monitoring of several hydrobromination reactions in pentane containing benzoyl peroxide as initiator revealed that the concentration of bromoallene always increases to a maximum of about 10% of the initial propargyl bromide concentration at about 20 to 40% reaction, and then slowly decreases as the reaction progresses further. The amount of propargyl bromide smoothly decreases and that of 1,2-dibromopropene smoothly increases as the reaction progresses. This behavior is independent of the rate of hydrogen bromide addition and of the initial propargyl bromide and benzoyl peroxide concentrations. The propargyl bromide initially contained less than 0.5% bromoallene. These observations, coupled with the observation that no bromoallene is produced in the dark in the absence of benzoyl peroxide under otherwise identical conditions (run 6, Table I), show that formation of bromoallene from propargyl bromide also is a free radical process under these conditions.

When pure bromoallene is hydrobrominated at 0° in pentane solution in the presence of benzoyl peroxide, a mixture of 95% 1,2-dibromopropene and 5% 1,3-dibromopropene is formed. This product composition is essentially identical to that obtained from propargyl bromide under these conditions (run 3, Table I). Only trace amounts of propargyl bromide are formed during the hydrobromination of bromoallene under these conditions.

Attempts to Trap Radical Intermediate

It seemed possible that all the dibromide produced from the free radical hydrobromination of propargyl bromide is formed from bromoallene after a prior isomerization of the propargyl bromide to bromoallene under the reaction conditions, eqs. [2]–[5]. The bromoallene could be formed from propargyl bromide by addition of a bromine atom to the terminal carbon atom of the acetylene, followed by loss of the bromine atom originally present, see

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

[2] 
[3] 
[4] 
[5] 
reactions [2] and [3]. In the free radical hydrobromination of propyne to form *cis*-1-bromopropene (6) the bromine atom adds to the terminal carbon atom, and it has been shown that a bromine atom is readily lost from a carbon atom adjacent to a radical center (17). Addition of a bromine atom to the center carbon atom of bromoallene would give a long-lived allylic radical, reaction [4], which would react with hydrogen bromide to form 1,2-dibromopropene.

Several attempts were made to trap the postulated intermediate *cis*-1,3-dibromo-2-propenyl radical with hydrogen bromide at 25° in solution, reaction [6*a*]. Increasing the rate of introduction of hydrogen bromide into hydrobromination reactions of propargyl bromide in pentane solution did not result in any change in product composition. The maximum concentration of hydrogen bromide in pentane which could have been attained under these conditions is ca. 0.6 *M* (18). More concentrated hydrogen bromide solutions can be prepared in ether. A hydrobromination under illumination by a sun lamp of propargyl bromide in ether saturated with hydrogen bromide (ca. 40% HBr) did result in formation of significant amounts of 1,3-dibromopropene. The distribution of dibromides formed was 1,2-dibromopropene (11%), 2,3-dibromopropene (19%), and 1,3-dibromopropene (70%). The presence of a considerable quantity of 2,3-dibromopropene in the product mixture indicates that a significant amount of ionic reaction had occurred. This makes uncertain what amount of 1,3-dibromopropene was formed by trapping of any intermediate radical. A hydrobromination under illumination of propargyl bromide in ether solution 1.3 *M* in hydrogen bromide resulted in the formation of a 90:10 mixture of 1,2-:1,3-dibromopropene and only traces of 2,3-dibromopropene. This product composition is not significantly different from those of numerous runs carried out in ether solution 0.32 *M* in hydrogen bromide at 25° (see below) or in one run at −20°. Hydrobromination under illumination of propargyl bromide in ether solution more concentrated than about 1.3 *M* in hydrogen bromide always resulted in formation of significant amounts of 2,3-dibromopropene. The intermediate radical cannot be trapped to any significant extent by hydrogen bromide at hydrogen bromide concentrations of up to 1.3 *M* at 25°. Above this concentration ionic reactions begin to interfere.

An earlier attempt to carry out free radical addition of hydrogen bromide to unsaturated systems in ether solution failed (10). In the present study free radical hydrobrominations in ether solution occurred only if ether was carefully treated prior to reaction (see Experimental).

The intermediate 1,3-dibromo-2-propenyl radical would be expected to have a longer life at lower temperatures and experiments designed to trap it at −78° were carried out.

Attempts to carry out free radical hydrobromination of propargyl bromide in ether or pentane solution at low temperature were

frustrated by the formation of solid phases. When a 0.32 *M* solution of hydrogen bromide in ether was cooled to −78° a large amount of white precipitate formed. A pentane solution 0.32 *M* in hydrogen bromide was homogeneous at −78°. However, introduction of even small amounts of propargyl bromide resulted in immediate formation of a precipitate.

Both bromoallene and propargyl bromide form homogeneous solutions with hydrogen bromide at −78°. A number of free radical hydrobrominations of bromoallene and propargyl bromide were carried out in degassed liquid hydrogen bromide solution at this temperature. Reactions were initiated by illumination from a sun lamp. Similar conditions have previously been used for the free radical hydrobromination of propyne (6). No addition or isomerization occurred in the absence of illumination. No reaction products with molecular weight higher than that of dibromopropene were detected. Results from a number of experiments are summarized in Table III. Propargyl bromide and bromoallene gave different product distributions under these conditions and product distributions from both were different from those observed in reactions at room temperature in solution. The ratio 1,2-:1,3-dibromopropene formed in the radical hydrobromination of either bromoallene or propargyl bromide in solution at room temperature is always in the range 10:1 to 30:1. In reactions at −78° the 1,2-:1,3-dibromopropene ratio obtained from propargyl bromide was ca. 1:12 and that obtained from bromoallene was ca. 3:1. Radical hydrobromination of propargyl bromide can yield either 1,2-dibromopropene almost exclusively or 1,3-dibromopropene almost exclusively depending upon reaction conditions. The very predominant formation of 1,3-dibromopropene at low temperature shows that the bromine atom adds at the terminal acetylenic carbon atom of propargyl bromide. That only small amounts of bromoallene and 1,2-dibromopropene are formed from propargyl bromide in these reactions can be explained by postulating that in liquid hydrogen bromide at −78° (*a*) the intermediate *cis*-1,3-dibromo-2-propenyl radical, if formed, abstracts a hydrogen atom from hydrogen bromide much more rapidly than it loses a bromine atom to form bromoallene, or (*b*) the bromine atom reacts with a propargyl bromide–hydrogen bromide complex and hydrogen atom transfer is rapid (10).

Stereochemistry of Hydrogen Bromide Addition at −78°

The proportion of the *cis*-isomer in the 1,3-dibromopropene mixture decreases somewhat as the reaction proceeds. This appears to be due to a slow isomerization catalyzed by hydrogen bromide. Extrapolation of a plot of % *cis*-1,3-dibromopropene vs. % conversion to 0% conversion gives an intercept of 99.2% *cis*. This value is significantly different from the equilibrium value which is calculated to be ca. 90% *cis* at −78°. The radical hydrobromination of propargyl bromide under these conditions is a stereospecific *trans* addition reaction. The hydrobromination of propyne has also been shown to be a stereospecific *trans* addition reaction under the same conditions (6).

Unexpectedly, the 1,3-dibromopropene formed from bromoallene under these conditions is also

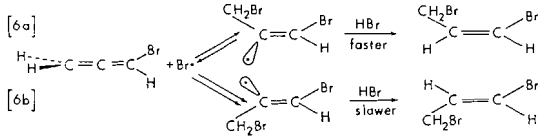
mainly the *cis*-isomer. Extrapolation to 0% conversion indicates that the proportion of *cis*-isomer formed initially in this reaction is > 96%.

The radical addition of hydrogen bromide to olefins at low temperature has been shown to be a stereospecific *trans*-process (11, 12, 19) and there is no obvious reason why addition of a bromine atom could not occur equally well at either side of the bromoallene molecule to give a mixture of *cis*- and *trans*-1,3-dibromo-2-propenyl radicals, at least in incipient form, reactions [6*a*] and [6*b*]. Perhaps hydrogen transfer



from hydrogen bromide to the *trans*-radical is sterically hindered. Inspection of Fisher–Hirschfelder–Taylor molecular models indicates that there may be some interference by the vinyl bromine atom to approach of hydrogen bromide to the adjacent vinylic radical center in the *trans* radical. In the case of the reaction involving a hydrogen bromide–allene complex, the hydrogen bromide would have to shift from a symmetrical position between the terminal and central carbon atoms toward the central carbon atom before hydrogen atom transfer could occur, and this shift would also be more difficult in the process leading to the *trans*-dibromide.

The 1,2-dibromopropene produced from bromoallene has a different isomer composition from that produced from propargyl bromide. At −78° the equilibrium mixture is calculated to contain ca. 82% of the *trans*-isomer. In neither reaction is the equilibrium mixture formed. The isomer ratio of 1,2-dibromopropene remains essentially constant during both reactions, so that 1,2-dibromopropene is isomerized much more slowly than 1,3-dibromopropene under these reaction conditions.

Kinetic Evidence for Radical Intermediate in Solution

The results of the low temperature hydrobrominations of propargyl bromide show that the initial point of attack of the bromine atom is at the terminal carbon atom of the acetylernic group. This would indicate that in ether and pentane solution bromoallene is formed by way of the *cis*-1,3-dibromo-2-propenyl radical, reactions [2] and [3]. In order to obtain kinetic evidence for the formation of this intermediate, several runs were made in ether with known concentrations of reactants and were continuously monitored.

Oxygen-free solutions of propargyl bromide and hydrogen bromide in ether were irradiated at room temperature. These reactions were homogeneous. As was observed in the more qualitative runs carried out in pentane, the bromoallene concentration increased to ca. 10–12% of the initial propargyl bromide concentration and then decreased as the reaction progressed further. No variation in behavior was observed when the initial hydrogen bromide concentrations were varied from 0.32 to 1.3 *M*. Results from two runs at the extremes of hydrogen bromide concentration used are shown in Fig. 1. No reaction was observed in the absence of illumination.

Although the 1,2-dibromopropenes formed in hydrobromination reactions carried out in pentane solution were always equilibrated, this was not the case when the reactions were carried out in ether solution. Here the isomer ratio varied during the course of a reaction and always contained less than the equilibrium amount of the *trans*-isomer.

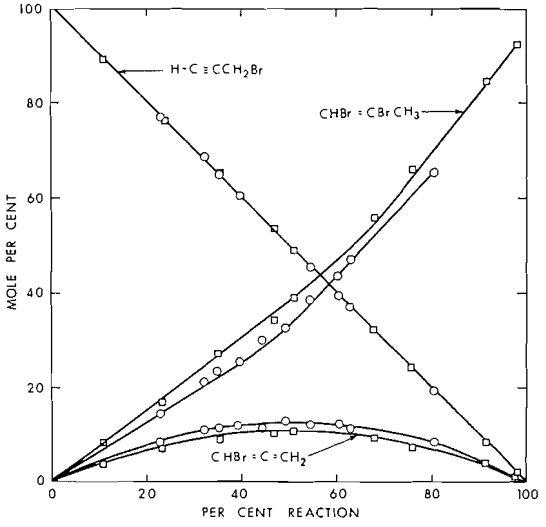


FIG. 1. Disappearance of starting material and formation of products in radical hydrobromination of propargyl bromide in ether at 25°. □, run 8, $[HBr]_0$ = 1.32 *M*, $[PB]_0$ = 0.032 *M*, 6% 1,3-dibromopropene present at 80% reaction; ○, run 10, $[HBr]_0$ = 0.32 *M*, $[PB]_0$ = 0.032 *M*, 5% 1,3-dibromopropene present at the end of the reaction.

The equilibrium ratio was determined in ether by irradiating a solution of pure *trans*-1,2-dibromopropene and hydrogen bromide in this solvent. Equilibration proceeded much more slowly than did the equilibration in pentane, but afforded essentially the same isomer composition as formed in pentane: 77.8% *trans*- and 22.2% *cis*-1,2-dibromopropene.

It appeared at first that the 1,2-dibromopropene formed initially contained more of the *cis*-isomer than the equilibrium mixture and that equilibration occurred slowly as the reaction progressed. However, when the isomer composition was monitored early in the reaction, it was found that the reaction was more complex. The upper curve of Fig. 2 shows the variation of the % of *trans*-isomer in the 1,2-dibromopropenes formed from propargyl bromide during ca. the first 30% of reaction. Extrapolation of the curve to 0% reaction gives an intercept of ca. 74% *trans*-1,2-dibromopropene. The % of *trans*-isomer present actually decreases from near the equilibrium % early in the reaction, to 67%, and only later beings to increase again.

The lower curve of Fig. 2 shows the variation during approximately the first 30% of reaction of the % of the *trans*-isomer of the 1,2-dibromopropenes formed in hydrobromination of bromoallene under illumination in ether. The results are entirely different from those obtained with propargyl bromide. Initially, nearly equal amounts of *cis*- and *trans*-isomers are present. As the reaction progresses the proportion of *trans*-isomer increases slowly.

It is clear that mechanism of formation of 1,2-dibromopropene in the radical hydrobromination of propargyl bromide is more complex than is indicated by reactions [2]–[5]. In ether solution at 25° a significant portion of the product must arise by a process not involving free bromoallene.

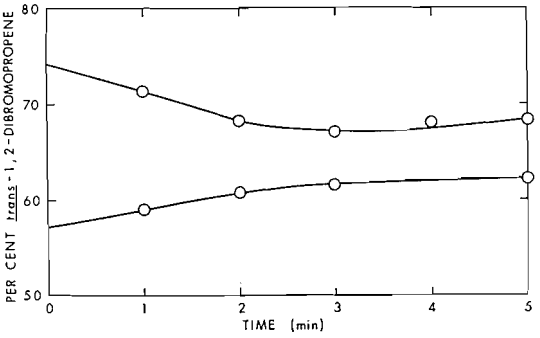

FIG. 2. Variation of isomer composition of 1,2-dibromopropene with time in radical hydrobromination of propargyl bromide (upper curve) and bromoallene (lower curve) in ether at 25°.

Further support for this conclusion is obtained from the kinetic analysis of the reaction. If all the product were formed via free bromoallene then the reactions may be formulated as in reactions [2]–[5]. Since the loss of a bromine atom from the 1,3-dibromo-2-propenyl radical is fast and the amount of bromoallene present in the reactions is independent of hydrogen bromide concentration, Fig. 1, rate-determining steps may be represented as

$$[7] \qquad PB + Br\cdot \xrightarrow{k_1} BA + Br\cdot$$

$$[8] \qquad BA + Br\cdot \xrightarrow{k_2} DB$$

where PB = propargyl bromide, BA = bromoallene, and DB = 1,2-dibromopropene. The following expressions may now be written

$$[9] \qquad \frac{-d[PB]}{dt} = k_1[PB][Br\cdot]$$

$$[10] \qquad \frac{-d[BA]}{dt} = k_2[BA][Br\cdot] - k_1[PB][Br\cdot]$$

$$[11] \qquad \frac{d[BA]}{d[PB]} = \frac{k_2[BA] - k_1[PB]}{k_1[PB]}$$

$$[12] \qquad \frac{d[BA]}{d[PB]} - \frac{k_2[BA]}{k_1[PB]} = -1$$

This expression may be integrated (20) using $[PB_0]$ and [0] as the initial limits, and [PB] and [BA] as the final limits of the variables to give

$$[13] \qquad [BA] = \frac{[PB]}{1 - k_2/k_1}\left[\left(\frac{[PB]}{[PB_0]}\right)^{k_2/k_1 - 1} - 1\right]$$

This result is identical to that obtained by McMillan (21) using a somewhat different method. The ratio k_2/k_1 may be determined from the maximum concentration of bromoallene.

$$[14] \qquad \frac{-d[BA]}{dt} = 0 = k_2[BA][Br\cdot] - k_1[PB][Br\cdot]$$

$$[15] \qquad k_2/k_1 = [PB]/[BA] \text{ at maximum BA}$$

Unfortunately the concentration of bromoallene passes through a broad maximum and the concentration of propargyl bromide varies considerably, while the concentration of bromoallene varies but little. In each of a number of runs the ratio k_2/k_1 calculated in this manner varied from about 5 at the beginning of the broad maximum to about 3.5 at the end of the broad maximum. The ratios used for calculations were taken from concentrations at the estimated midpoint of the broad maximum and were 4.0 for three runs and 4.7 for one run. Using eq. [13] the upper curve of Fig. 3 was calculated for the concentration of bromoallene during run 10. This curve is clearly different from the experimental curve. Bromoallene is neither being formed as rapidly nor consumed as rapidly as required were all the intermediate *cis*-1,3-dibromo-2-propenyl radicals converted to free bromoallene. It appears that only a portion of the intermediate radicals formed yields free bromoallene.

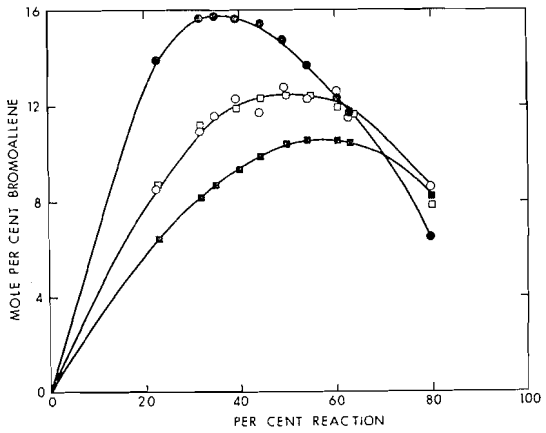

FIG. 3. Variation of bromoallene concentration with time in hydrobromination of propargyl bromide in ether at 25° in run 10. ○, Observed; ●, calculated using eq. [13]; □, calculated using eq. [16] with $F = 1/2$; ■, calculated using eq. [16] with $F = 1/3$. The middle curve is drawn through the experimental points.

If only a fraction, F, of the intermediate *cis*-1,3-dibromo-2-propenyl radicals formed is diverted to free bromoallene, the following equation may be derived to represent the concentration of bromoallene during the course of the reaction

$$[16] \quad [BA] = \frac{F[PB]}{1 - k_2/k_1}\left[\left(\frac{[PB]}{[PB_0]}\right)^{k_2/k_1 - 1} - 1\right]$$

A series of curves was calculated for each run using various values of F. The ratio k_2/k_1 in these cases is given by

$$[17] \quad k_2/k_1 = F\,[PB]/[BA] \text{ at maximum BA}$$

Figure 3 shows curves obtained using eq. [16] for run 10 using different values of F. The curve calculated using $F = 1/2$ gives a very close fit to the experimental curve. For four runs very close agreement between the calculated and experimental curves was obtained, with the values of F and k_2/k_1 shown in Table IV. These results indicate that about 50% of the reaction proceeds by a process not involving free bromoallene.

TABLE IV

10	0.032	1.30	1/2	2.0

*Propargyl bromide contained less than 0.5% bromoallene initially.

Reactions of the Radical Intermediate

There appear to be two possible processes which could account for that part of the reaction which does not form free bromoallene. One process involves an intramolecular bromine atom migration, Fig. 4, to form the allylic 1,2-dibromopropenyl radical. The other process could be a

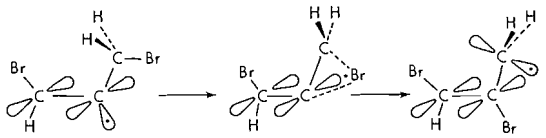

FIG. 4. Stereochemistry of bromine atom migration.

cage reaction between bromoallene and its bromine atom partner which results from loss of a bromine atom from the 1,3-dibromo-2-propenyl radical, Fig. 5. A choice can be made between these two processes by considering the stereochemistry of the reaction in ether solution at short reaction times, Fig. 2, and the geometric requirements of the two processes.

As Fig. 4 shows, bromine atom migration must produce the 1,2-dibromopropenyl radical with the bromine atoms *trans*. This would also

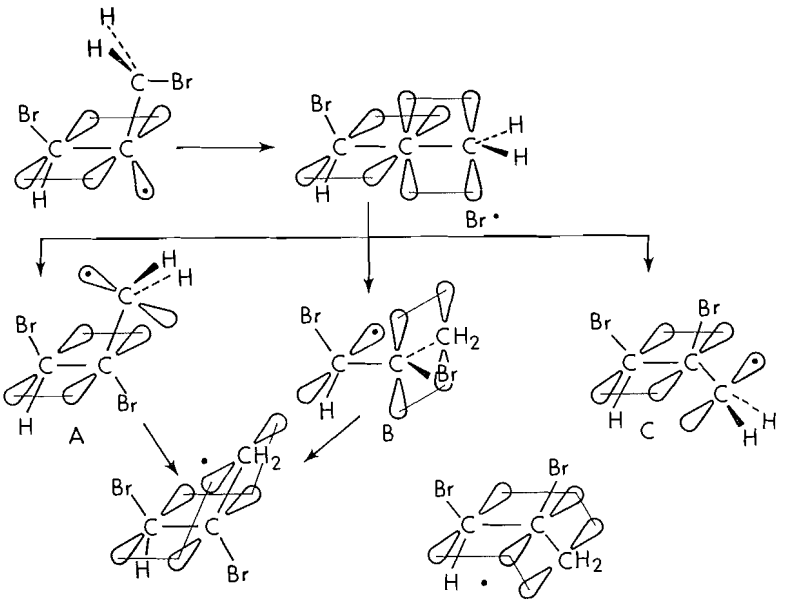

FIG. 5. Stereochemistry of bromine atom elimination followed by recombination.

be so if the initial radical were a bridged radical instead of a vinyl radical as depicted. However, it is difficult to account for the formation of bromoallene from a bridged radical without first opening it to *cis*-1,3-dibromo-2-propenyl radical, and it is not required to account for any of the results. From the stereochemical results illustrated in Fig. 2, it can be concluded that the 1,2-dibromopropenyl radicals must maintain their geometry under these reaction conditions. It has already been shown that other types of allylic radicals are geometrically stable (22). Thus, any 1,2-dibromopropene formed via bromine atom migration must be completely *trans*. The stereochemistry of the first formed 1,2-dibromopropene can be determined by reference to Fig. 2. The intercept at 0% reaction of the upper curve gives the stereochemistry of the initial product before isomerization and before any reaction of bromoallene. The result is 74% *trans*. It can be shown in another way from the data illustrated in Fig. 2 that the initial stereochemistry cannot be 100% *trans*. The lower curve in Fig. 2 shows that isomerization of the products (to 78% *trans*) is very slow under these conditions and that at reaction times of 2–5 min the stereochemistry of the 1,2-dibromopropenes formed from bromoallene is about 60% *trans*. Assuming that 50% of the 1,2-dibromopropenes produced in the hydrobromination of propargyl bromide under these conditions arises via free bromoallene (a maximum amount based on the kinetic results) and the other 50% arises via a process giving 74% *trans*, then the net isomer distribution during this time should be about 67% *trans*. This agrees well with the value of 68–69% *trans* shown by the upper curve of Fig. 2. Were the other 50% to arise via a process giving 100% *trans* rather than 74% *trans*, then the net isomer distribution would be about 80% *trans* during the first 2–5 min of reaction. This is not observed. Clearly the stereochemistry of the first formed 1,2-dibromopropenes must be quite different from 100% *trans* which indicates that a bromine atom migration cannot be involved. This is not unexpected as the initial radical formed upon bromine atom migration would not be the stabilized allyl radical but one in which the odd electron is localized in an atomic p orbital which is perpendicular to the plane of the adjacent π-orbital. There is no driving force for the migration as the primary radical formed would not be expected to show stability over the initial vinyl radical.

This leaves the cage reaction as the only alternative for the ca. 50% of the reaction which does not proceed via bromoallene. The cage

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reaction must be stereoselective since the initial stereochemistry of the 1,2-dibromopropene formed from bromoallene is different from that of the 1,2-dibromopropene formed from propargyl bromide. Loss of a bromine atom from the 1,3-dibromo-2-propenyl radical must occur from a conformation in which the carbon–bromine bond that is breaking is parallel to the orbital containing the odd electron. The conformation of lower energy is shown in Fig. 5. The other conformation in which the bromomethyl group has rotated by 180° with respect to the conformation shown is seen by inspection of Fisher–Hirschfelder–Taylor models to be severely strained due to steric interference between the bromine atoms. In fact, that conformation cannot be made with the models. When initially formed the bromoallene molecule and the bromine atom have the steric relationship shown in Fig. 5 in which the bromine atom is on the opposite side of the molecule from the bromine atom in the molecule and in the plane defined by the bromomethylene group. Radical A, formed by recombination of the bromine atom with the p orbital in the plane of the bromomethylene group on the side opposite to the bound bromine, will give the *trans*-1,2-dibromopropenyl radical upon rotation of the methylene group and will finally give *trans*-1,2-dibromopropene. Reaction at the same orbital at the side *cis* to the bound bromine will give radical C which will then give the *cis*-1,2-dibromopropenyl radical and thus *cis*-1,2-dibromopropene. Reaction with the other p orbital will give radical B. Rotation of the bromomethylene group in either direction will give a stable allylic radical so that one would expect radical B to give approximately equal amounts of *cis*- and *trans*-1,2-dibromopropenyl radicals, and hence equal amounts of *cis*- and *trans*-1,2-dibromopropene. Since the cage recombination gives more *trans*-1,2-dibromopropene than does recombination outside the cage, the cage recombination to give radical A must compete with rotation of the bromoallene molecule with respect to its bromine atom partner. This is, then, an example of a stereoselective atom–molecule cage recombination reaction.

Relaxation times for molecular rotation of a number of small molecules in the liquid phase are near 10^{-11} s (23–25). This corresponds to the time that two particles will be confined to a solvent cage (26). It is thus reasonable that a reaction which can compete with diffusion can also compete with molecular rotation. Cage recombination of radicals derived from optically active azo compounds is a stereoselective process (27).

The addition of a bromine atom to bromoallene must have a very low activation energy if it is to compete with diffusion and molecular rotation. It has been suggested that the addition of a bromine atom to allene requires little or no activation energy (28). The energetic requirements for the bromine atom – bromoallene addition reaction are expected to be very similar. An atom–molecule cage recombination appears to occur in the radical chlorination of *t*-butyl bromide by *t*-butyl hypochlorite (29).

In an excellent study of the radical hydrobromination of allene it was shown that bromine atoms add to the terminal and central carbon atoms of allene at equal rates, and that the radical resulting from addition to the central carbon has a longer lifetime with respect to loss of the bromine atom than the radical resulting from terminal addition (28). As a result only products resulting from an initial addition of a bromine atom at the central carbon of allene are isolated when the concentration of hydrogen bromide is low or at high temperatures (30–32), while products resulting from initial addition at the terminal carbon are observed only at high hydrogen bromide concentrations and lower temperatures. It was suggested that a bromine-bridged radical was not required to account for these results (28). The results of the present study are in complete agreement with these conclusions, and provide stereochemical evidence against the intervention of bromine-bridged radicals in allenic systems.

The significance of the results obtained in the present study with respect to other systems in which bromine-bridged radicals or bromine atom migrations have been postulated (6–8, 33–35) is unclear. As was pointed out above there appears to be little, if any, driving force for bromine atom migration in the 1,3-dibromo-2-propenyl radical. In most of the other systems migration would lead directly to a more stable radical. Also, in the present system the orbital bearing the odd electron is directed more away from the adjacent carbon–bromine bond than is the case in a saturated system, Fig. 6. Both factors would make either bridging or migration in the 1,3-dibromo-2-propenyl radical less favorable than in the saturated systems. Thus, although the present

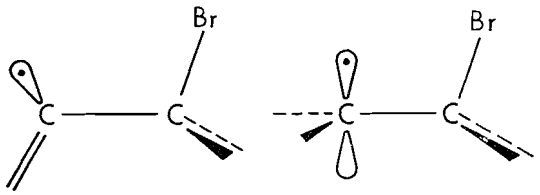

FIG. 6. Geometry of the 3-bromo-2-propenyl and the 1-bromo-2-propyl radicals.

study provides additional evidence that the loss of a bromine atom adjacent to a radical center is very rapid (17, 29) and that recombination at a different carbon atom is very rapid, the present system does not serve as a good model for an analogous process in the saturated systems.

The ratio of terminal to center addition of a bromine atom to bromoallene observed in liquid hydrogen bromide in this study, 1:3, differs from the ratio of 1:1 to be expected from the limiting ratio found in the case of allene (28). It is difficult to tell if the difference is significant as no effort was made in the present study to determine whether the ratio found was the limiting ratio.

Gas Phase Reactions

The gas phase hydrobromination of propargyl bromide was also briefly studied in an attempt to confirm that a considerable amount of the bromoallene formed in solution from propargyl bromide is consumed by a cage recombination reaction. There can be no cage reaction in the gas phase and in the absence of bromine atom migration; all the 1,2-dibromopropene formed should result from free bromoallene. If bromine atom migration is occurring in solution it should also occur in the gas phase, and there would be, as in solution, two routes to 1,2-dibromopropene. Reactions were carried out in an oxygen-free system at room temperature under illumination. All the reactions had an inhibition period of ca. 5 min. No reaction was observed in the dark. In contrast to the reactions in solution, bromoallene was always formed much more rapidly than was 1,2-dibromopropene. The isomer composition of the 1,2-dibromopropene formed initially is ca. 54% *trans*, Fig. 7. Isomerization is rapid and the equilibrated mixture was present after only 2.6% 1,2-dibromopropene had been formed. About 35% bromoallene was present by this time. No structurally isomeric dibromopropenes were detected at these amounts of conversions. At higher conversions a thin film

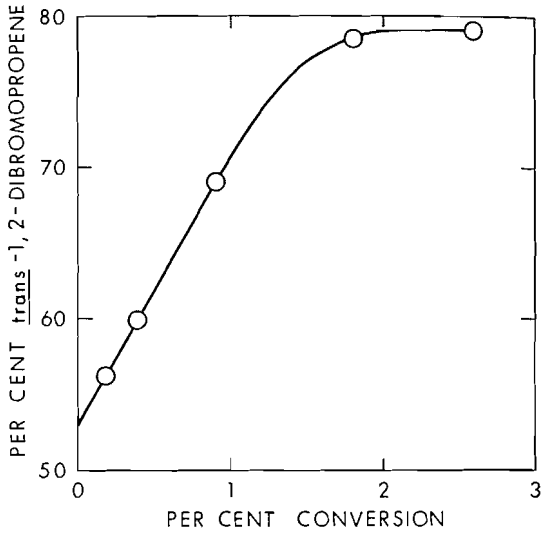

FIG. 7. Variation of isomer composition of 1,2-dibromopropene with conversion in the gas phase hydrobromination of propargyl bromide at 25°.

deposited on the walls of the reaction vessel so the reaction was not investigated at higher conversions. The stereochemistry of the 1,2-dibromopropenes formed is quite similar to that found from hydrobromination of bromoallene in solution. This indicates that in the gas phase the 1,2-dibromopropenes are formed entirely from free bromoallene and that bromine atom migration is unimportant.

A recent report describes the equilibration of propargyl bromide and bromoallene catalyzed by hydrogen bromide under illumination at 135–200° (36). Equilibrium could be reached starting with either component and propargyl bromide was found to be more stable than bromoallene by 0.83 kcal at 400 °K. No more than traces of propargyl bromide were observed in any of the radical hydrobrominations of bromoallene in solution in the present study, even though at 25° the equilibrium mixture should consist of about 80% propargyl bromide. The route to propargyl bromide from bromoallene would be the reverse of reaction [3] followed by the reverse of reaction [2]. That this process does not occur at 25° indicates that the activation energy for the loss of the vinyl bromine atom from the 1,3-dibromo-2-propenyl radical to give propargyl bromide, reaction [2], is significantly greater than is that for loss of the allylic bromine atom to give bromoallene, reaction [3]. This is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[18–19] $$H{-}C{\equiv}C{-}CH_2Br + Br\cdot \rightleftarrows HBr + \left[\begin{array}{c} H{-}C{\equiv}C\dot{C}HBr \\ \updownarrow \\ HC{=}C{=}CHBr \end{array}\right] \rightleftarrows Br\cdot + H_2C{=}C{=}CHBr$$

to be expected as aryl bromides, and, therefore, quite probably, vinyl bromides, have much stronger carbon bromine bonds than do allylic bromides (37).

The mechanism proposed for the propargyl bromide–bromoallene equilibration (36) consists of reversible hydrogen atom abstractions by bromine atoms, reactions [18–19]. From the results of the present study it is clear that propargyl bromide can be converted to bromoallene simply by addition and subsequent elimination of bromine atoms, reactions [2] and [3]. These steps should be reversible at the temperatures used in the equilibration studies (36) and such a reversible addition–elimination sequence surely contributes significantly to the equilibration process and may well account for almost all the equilibration.

Hydrogen chloride was also reported to catalyze the equilibration and a reversible hydrogen abstraction reaction by chlorine atoms was invoked to account for it. However, an addition–elimination sequence probably contributes in this case also. Such a sequence would initially produce chloroallene and bromine atoms, reactions [20] and [21]. After only a few per cent conversion to chloroallene there would be enough bromine atoms produced, so that they would then become the exclusive chain carriers.

Experimental

Boiling points are uncorrected values. Infrared (i.r.) spectra were recorded on a Perkin–Elmer recording infrared spectrophotometer, model 421, equipped with sodium chloride optics. Nuclear magnetic resonance (n.m.r.) spectra were recorded on a Varian analytical spectrophotometer, Model A-60. Tetramethylsilane was used as internal standard.

Analytical gas–liquid chromatography (g.l.c.) was carried out with an Aerograph 202 fractometer using a 9.5 ft × 1/4 in. stainless steel column packed with 10% Ucon-50-HB5100 (Polyglycol) on Chromosorb W. For preparative g.l.c. an Aerograph Autoprep equipped with a 20 ft × 3/8 in. stainless steel column packed with 10% Ucon-50-HB280X (Polyglycol) on Diaport W.A.W. was used. The order of elution was the same on both columns and was bromoallene, propargyl bromide, *trans*-1,2-dibromopropene, *cis*-1,2-dibromopropene, 2,3-dibromopropene, *cis*-1,3-dibromopropene, and *trans*-1,3-dibromopropene. Heptane was used as internal standard. Areas were measured by peak height × width at half-peak height. Controls using authentic mixtures showed that the thermal response factors of all the above materials were within 2% of the internal standard and no corrections were applied.

Reactions carried out under irradiation were irradiated with a General Electric sun lamp. Solutions were dried with anhydrous magnesium sulfate. Matheson 99.8% hydrogen bromide was used without further purification.

Pentane was purified by shaking 500 ml technical grade material with 50 ml portions of concentrated sulfuric acid until the sulfuric acid layer remained colorless. The pentane was then shaken several times with water, dried, and distilled through a 40 cm vigreaux column. Heptane was purified in the same manner.

Diethyl ether used as solvent for photoinitiated hydrobrominations was purified in the following way. Mallinckrodt absolute reagent grade material was distilled, anhydrous hydrogen bromide added to the distillate, and the resulting solution irradiated for 1 h. The ether was then washed with saturated salt solution until the aqueous layer was neutral, dried, distilled, and stored over sodium. Photoinitiated hydrobrominations in ether which was not purified in this manner had very long induction periods and produced impurities which interfered with product analysis by g.l.c.

Propargyl bromide was prepared according to the method of Jacobs and Brill (38), b.p. 79° (695 mm), n_D^{25} 1.4906; reported b.p. 81.8° (750 mm), n_D^{20} 1.4929 (38). This material always contained less than 0.5% bromoallene according to g.l.c. analysis.

Bromoallene was prepared according to a modification of the method of Jacobs and Brill (38). The crude product

[20] $$Cl\cdot + H{-}C{\equiv}C{-}CH_2Br \rightarrow \begin{array}{l} Cl \\ \quad\diagdown \\ \quad\quad C{=}\dot{C} \\ \quad\diagup \\ \quad H \end{array} \quad \begin{array}{l} \\ \diagup CH_2Br \\ \\ \\ \end{array}$$

[21] $$\begin{array}{l} Cl \\ \quad\diagdown \\ \quad\quad C{=}\dot{C} \\ \quad\diagup \\ \quad H \end{array} \quad \begin{array}{l} \\ \diagup CH_2Br \\ \\ \\ \end{array} \rightarrow \begin{array}{l} Cl \\ \quad\diagdown \\ \quad\quad C{=}C{=}CH_2 \\ \quad\diagup \\ \quad H \end{array} + Br\cdot$$

was purified by preparative g.l.c. to give material containing less than 0.5% propargyl bromide, n_D^{25} 1.5182, reported n_D^{20} 1.5200 (38).

Hydrobromination Reactions at Room Temperature

Reactions in pentane were carried out by bubbling hydrogen bromide through a stirred solution of 5 g propargyl bromide or bromoallene and 5 g heptane in 20 ml pentane in a 3-necked round bottomed flask fitted with a dry ice condenser. Peroxide-initiated runs were carried out using 0.5 g benzoyl peroxide as additive. Dark reactions were carried out in a darkened hood in apparatus wrapped with aluminium foil. Before g.l.c. analysis the reaction mixtures were poured into ice water. The organic layer was washed twice more with ice water, once with sodium bicarbonate solution, and dried. Results are summarized in Table I.

Ionic reactions in ether were carried out in the dark by adding 0.6 g propargyl bromide or bromoallene to 10 ml of an ether solution saturated with hydrogen bromide and containing 0.5 g of hydroquinone and/or 0.5 g ferrous chloride. Before analysis, solutions were freed from hydrogen bromide as described for the reactions in pentane.

Free radical reactions in ether were carried out in a 3-necked flask attached to a vacuum line using as solvent ether purified as described above. The system was purged with nitrogen by several cycles of evacuating and filling with purified nitrogen before each run. Ether and hydrogen bromide which had been stored under nitrogen were distilled into the flask. Propargyl bromide or bromoallene were introduced through a serum cap with a hypodermic syringe and the solution was irradiated. The reactions had induction periods of 1–2 min and were complete in about 1 h. Samples were withdrawn through the serum cap periodically, freed of hydrogen bromide as described above, and analyzed.

One run was carried out in ether solution at −20° with propargyl bromide. The product distribution was the same as in the runs carried out at room temperature. Homogeneous hydrobrominations of propargyl bromide at −78° in pentane and ether solution could not be carried out. When propargyl bromide was added to a solution of hydrogen bromide in pentane at −78° a white precipitate formed immediately. This presumably was a complex of hydrogen bromide and propargyl bromide (39). A 1 *M* solution of hydrogen bromide in ether formed white crystals on cooling to −40°.

Hydrobromination Reactions in Liquid Hydrogen Bromide

A 10 ml pear-shaped flask was charged with 0.83 g (0.01 *M*) hydrogen bromide and 1.25 g (0.01 *M*) propargyl bromide. A homogeneous solution formed. The solution was degassed with two freeze–thaw cycles, −195° to −78°, before irradiation. The flask was then irradiated from 20 cm while immersed in a bath at −78°. After irradiation the flask was evacuated and the contents distilled twice from flask to flask under 2 mm pressure before analysis. Extensive *cis–trans* isomerization occurred when analyses were performed without prior distillation of the reaction mixture.

Gas Phase Hydrobromination of Propargyl Bromide

Hydrogen bromide and propargyl bromide were introduced into a 200 ml evacuated flask to partial pressures of 34 and 49 mm respectively. The contents were stirred for 5 min with a magnetic stirrer. The flask and its contents were irradiated after which a 5 ml portion of anhydrous ether was injected into the flask. The ether solution was freed of hydrogen bromide as described previously, before analysis. All the reactions had an inhibition period of ca. 5 min and formed a thin film on the wall of the flask after ca. 7 min of irradiation. Irradiations were not carried on beyond this point.

Product Identification

The products of the hydrobromination reactions were identified by comparison of their retention times on the g.l.c. column used and by comparison of n.m.r and i.r. spectra of samples collected from the effluent of the g.l.c. with those of authentic samples, with the exception of 2,3-dibromopropene.

trans-1,2-Dibromopropene was prepared by the slow addition of bromine to a solution of propyne in methylene chloride at −78°. The product was 99% *trans*-1,2-dibromopropene, b.p. 124–125° (688 mm), n_D^{25} 1.5323; reported b.p. 125.9°, $n_D^{17.4}$ 1.5369 (40). The n.m.r. spectrum (neat) showed absorption at τ 3.58 (multiplet) and τ 7.67 (doublet, J = 1.1 c.p.s.) with relative areas 1.0:3.0.

cis-1,2-Dibromopropene was prepared by isomerization of the *trans*-compound. *trans*-1,2-Dibromopropene was dissolved in pentane containing some hydrogen bromide and the solution was irradiated for 1 h. The solution was then washed several times with ice water, dried, and distilled. The fraction boiling at 45° at 18.5 mm was collected and contained 77% *trans*- and 23% *cis*-1,2-dibromopropene. A sample of the *cis*-isomer was collected by preparative g.l.c., b.p. 133–134° (688 mm), n_D^{25} 1.5290; reported b.p. 135.2°, $n_D^{17.4}$ 1.5337 (40). The n.m.r. spectrum (neat) showed absorption τ 3.91 (multiplet) and τ 7.66 (doublet, J = 1.1 c.p.s.) with relative areas of 1.0:3.0.

A mixture of *cis*- and *trans*-1,3-dibromopropene prepared by the method of Hatch (1) was separated into the two components by g.l.c. The n.m.r. spectrum (neat) of the *cis*-isomer, n_D^{25} 1.5519, reported n_D^{25} 1.5516 (41), liquid at −78°, showed absorption at τ 3.6 (multiplet) and τ 5.95 (multiplet) with relative areas 1.0:1.0. The n.m.r. spectrum of the *trans*-isomer, n_D^{25} 1.5572, reported n_D^{25} 1.5570 (41), solid at −78°, showed absorption at τ 3.6 (multiplet) and τ 6.15 (multiplet) with relative areas of 1.0:1.1. Hatch reports that *cis*-1,3-dibromopropene is a liquid at −78° while *trans*-1,3-dibromopropene is a solid at −78° (1).

The material with retention time between those of *cis*-1,2-dibromopropene and *trans*-1,3-dibromopropene was identified only on the basis of its n.m.r. spectrum (neat) which showed absorption at τ 3.91 (multiplet), τ 4.32 (doublet, J = 2.2 c.p.s.), and τ 5.75 (doublet, J = 1.0 c.p.s.) with relative areas 1.0:1.0:2.0. The data are in agreement with those reported for 2,3-dibromopropene (42).

No evidence was obtained in any of the reactions for the formation of 3,3-dibromopropene.

Determination of cis–trans Equilibria

A stirred solution of 0.29 g of a pure isomer of dibromopropene in 125 ml pentane was irradiated while a very slow stream of hydrogen bromide was slowly

bubbled into the solution. Aliquots were withdrawn periodically and analyzed directly by g.l.c. Irradiation was continued until there was no further change in isomer composition.

Magnetic nonequivalence in asymmetric phosphorus compounds

L. FRANKEL, J. CARGIOLI, H. KLAPPER, AND R. DANIELSON
Physical Chemistry Department, Chemical Research Laboratory, Edgewood Arsenal, Maryland, 21010

Received April 17, 1969

The nuclear magnetic resonance (n.m.r.) spectra of seven compounds of the type $(CH_3)P(O)(SCH_2SR)(OR')$ have been examined as a function of solvent. The resonance pattern of the methylene protons, SCH_2S, is strongly solvent dependent. In solvents of low dielectric constant, the methylene protons are magnetically nonequivalent and are observed as the AB part of an ABX spin system, where X is the phosphorus atom. In high dielectric constant medium (DMSO d_6) only a well-resolved doublet is obtained indicating magnetic equivalence. When $R' = CH(CH_3)_2$, nonequivalent methyl groups which show analogous solvent effects are observed.

Eight compounds of the type $(CH_3)P(O)(OCH(CH_3)_2)(X)$ have been studied. The chemical shift between the magnetically nonequivalent isopropyl methyl groups does not correlate with any simple property of X.

Introduction

Several n.m.r. studies have been reported on the effect of asymmetric carbon atoms in causing magnetic nonequivalence (1). An asymmetric phosphorus atom may also cause magnetic nonequivalence in nearby methylene protons (2, 3) and methyl groups (4–6). The origin of the magnetic nonequivalence is strictly due to symmetry effects (7) which may be further augmented by the effect of conformational preference. For all previously reported systems rapid intramolecular rotation occurs. The experimental parameters observed are averages over all conformers (7).

$$[1] \qquad \delta = \sum_i X_i(\nu_{A,i} - \nu_{B,i})$$

$$J_K = \sum_i X_i J_{K,i}$$

where X_i is the mole fraction of a particular conformer and the sum is over all conformers. $J_{K,i}$ and $\nu_{X,i}$ are the coupling constants and frequencies of a particular conformer. It has been previously pointed out that chemical shift differences are usually of questionable use for investigating conformer preference, because individual conformer frequencies are generally expected to be both temperature and solvent dependent to a much greater degree than $J_{K,i}$ coupling constants (8).

We wish to report our findings on the organophosphorus compounds in Tables I and V. Comparisons are made with the factors (solvent, temperature, and substituent effects) that influence the spectra of asymmetric carbon atoms.

TABLE I

Compounds of the type $(CH_3)P(O)(SCH_2SR)(OR')$ have been investigated

No.	R	R′
1	CH_3	Cyclopentyl
2	CH_3	$CH(CH_3)_2$
3	$(CH_2)_2CH_3$	$CH(CH_3)_2$
4	$(CH_2)_3CH_3$	$CH(CH_3)_2$
5	$(CH_2)_4CH_3$	$CH(CH_3)_2$
6	$CH(CH_3)_2$	Cyclopentyl
7	$CH(CH_3)_2$	$CH(CH_3)_2$

Experimental

Spectra were obtained on a Varian HA-100 spectrometer. When required, supplementary spectra were obtained on a Varian A-60 spectrometer. All the compounds reported are liquids. Their spectra were obtained in a 10% by volume solution which contained less than 5% by volume of TMS.

The compounds in Tables I and V were supplied by Mr. Ray Irino (Organic Chemistry Department of this laboratory) or obtained from commercial sources. General characterizations of those compounds not commercially available will be reported at a later date. The n.m.r. spectra were in consonance with the proposed structures.

Results and Discussion

The SCH_2S methylene protons of the compounds in Table I form the AB part of an ABX spin system where X is the phosphorus atom. A typical spectrum is shown in Fig. 1 (the second peak from the right contains two overlapping peaks). The spectra were analyzed as previously described (3). The coupling constants J_{AX} and J_{BX} may be of like or unlike sign. A comparison of the 100 and 60 Mc.p.s. spectra definitively shows that the coupling constants have the same relative sign (3). The magnitude of the coupling constants

NOTE: The following parameters show only a ±0.2 c.p.s. variation with solvent $J_{PCH_3} = 15.9$ c.p.s., $J_{AB} = 13.2$ c.p.s., $J_{CH_{3(A)},H} = J_{CH_{3(B)},H} = 6.3$ c.p.s.

*Dielectric constant of protonated solvents.
†The chemical shift between nonequivalent methylene protons.
‡The chemical shift between nonequivalent methyl groups.
§Assumed to be twice J_{AX}.

J_{HX} (Tables II and III), $9 < J_{HX} < 14$ c.p.s., is within the expected range (3, 9). Assignment of different signs would lead to one unusually large value for J_{HX}. Since the errors in J_{AX} and J_{BX} can be large while the errors in their sum is small, only the latter quantity is considered.

From a detailed analysis of the AB part of the ABX spectrum, one obtains three manifestations of the nonequivalence of the methylene protons. These parameters are listed in Tables II and IV. They are: (*1*) proton coupling between nonequivalent methylene protons, J_{AB}; (*2*) a chemical shift difference between nonequivalent methylene protons, δ_{CH_2}; (*3*) heteronuclear proton phosphorus coupling which in general is different for different protons, $J_{H(A),X} \neq J_{H(B),X}$.

*See Table I for identification of compounds.
†The spectrum is not sufficiently resolved to permit calculations.
‡The methylene protons are equivalent in DMSO.
§Assumed to be twice J_{AX}.

The n.m.r. data for the SCH_2S methylene protons of compound **2** (Table I) as a function of solvent are summarized in Table II. Figure 2 clearly shows that $\lvert J_{AX} + J_{BX}\rvert$ and δ_{CH_2} depend on common factors. In DMSO d_6 the methylene protons appear as a well-resolved doublet with a line width at half height which is identical to that of the PCH_3 methyl group (0.5 c.p.s.). Previously it had been suggested that a primary prerequisite for magnetic nonequivalence to be observable in an asymmetric phosphorus compound was that one of the substituents be a benzene ring (4). Our data as well as that of Rowsell (5) clearly show this need not be the case.

The R′ group of compound **2** also contains a magnetically nonequivalent set of methyl groups. The spectrum of these methyl groups is two doublets separated by an internal chemical shift δ_{CH_3}. The data for the methyl groups are included in Table II.

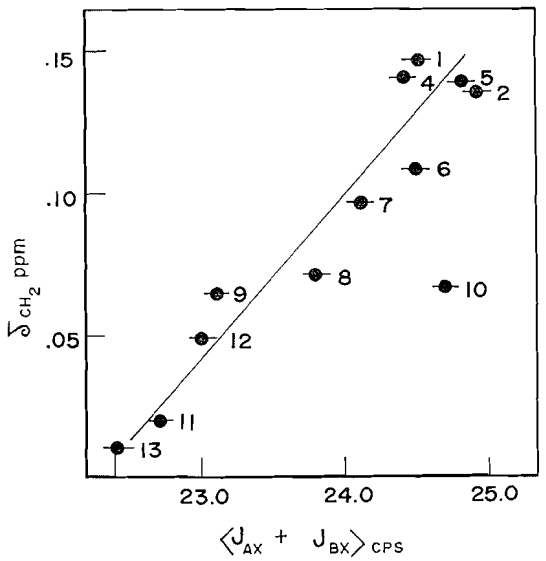

FIG. 2. A plot of δ_{CH_2} vs. $|J_{AX} + J_{BX}|$ of the SCH_2S methylene protons of $(CH_3)P(O)(SCH_2SCH_3)(OCH(CH_3)_2)$ in various solvents. The experimental points are numbered by solvents according to Table II.

Assuming $J_{K,i}$ is constant for the same compound in different solvents, the extent of conformer preference of the SCH_2S protons may be examined. The small variation of J_{PCH_3} with solvent supports this assumption.

As the temperature is increased the degree of conformer preference, determined by the relative values of X_i (eq. [1]), decreases. The results of a variable temperature study summarized in Table III suggest that the smaller values of $|J_{AX} + J_{BX}|$ are associated with reduced conformer preference. Intervening groups between the asymmetric phosphorus atom and the nonequivalent protons do not allow a simple representation of the conformers. The solvents in Table II are arranged with regard to increasing dielectric constant. $|J_{AX} + J_{BX}|$ shows decreasing conformer preference with increasing dielectric constant. Similar solvent effects have been observed in symmetry restricted phosphorus (3) and carbon analogues (10–12). The degree of conformer preference follows an inverse dependence with the dielectric constant of the solvent in agreement with the predictions of an electrostatic model (12).

Previous explanations of similar results have generally considered two major factors, (*1*) solvent dielectric constant effects and (*2*) solvent anisotropy effects. The latter can be included within (*1*) by taking a more cognizant picture of the microscopic dielectric medium which may be primarily governed by solvent anisotropy. While it is not readily possible to separate micro–macro dielectric effects, attention is called to the fact that the above views are not necessarily divergent (12, 13).

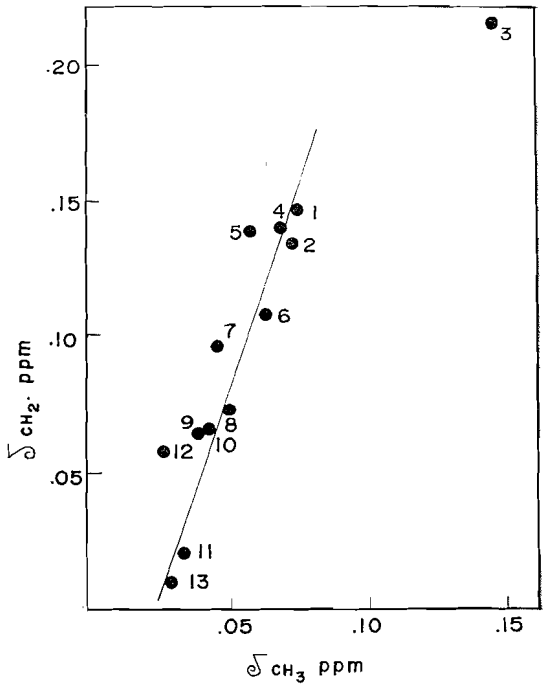

FIG. 3. The chemical shift of the methylene protons SCH_2S vs. the chemical shift of the isopropyl methyl groups of $(CH_3)P(O)(SCH_2SCH_3)(OCH(CH_3)_2)$ in various solvents. The experimental points are numbered by solvent according to Table II.

The spectra of the isopropyl methyl groups are relatively insensitive to temperature (Table III). Figure 3 shows that the degree of magnetic nonequivalence of δ_{CH_2} and δ_{CH_3} are related. Apparently the medium dielectric constant is a primary factor in determining the magnitude of the magnetic nonequivalence.

Some exceptions to the trends discussed are noted. Both δ_{CH_3} and δ_{CH_2} are unusually large in benzene as is typical of aromatic solvents (11, 12). In Fig. 2, the values for methanol clearly deviate from the general trend. A reasonable explanation for this is that hydrogen bonding between the phosphoryl group and/or the lone pair sulfur electrons and methanol is responsible.

An interesting feature of the data in Table II is that in solvents of low dielectric constant $\delta_{CH_2} > \delta_{CH_3}$ while in high dielectric media, the reverse may hold.

The results for the other compounds in Table I, summarized in Table IV, show similar solvent effects.

In benzene the methyl protons on R of compounds **6** and **7** (Table I) are observed as a sharp doublet due to coupling with the methine proton. No evidence for long range magnetic nonequivalence is observed. Roberts *et al.* (1) have reported nonequivalent methyl groups seven bonds removed from an asymmetric carbon atom.

An attempt was made to see if the degree of magnetic nonequivalence of the isopropyl methyl groups could be correlated to the nature of one of the substituents at the asymmetric center (11).

TABLE V

A comparison of the degree of magnetic nonequivalence of the isopropyl methyl groups of $(CH_3)P(O)(OCH(CH_3)_2)(X)$ in benzene

X	δ_{CH_3} p.p.m.
SCH_2S	0.166–0.128*
S-phenyl	0.125
H	0.108
SH	0.080
$OCH(CH_3)_2$	0.010
F	<0.010†
OH	<0.010‡
OCH_3	<0.010‡

*Range of results reported in Tables II and IV.
†For X = F, δ_{CH_3} is too small to be measured accurately.
‡No evidence of magnetic nonequivalence is observed for X = OH or OCH_3.

Compounds of the following type were examined, $(CH_3)P(O)(OCH(CH_3)_2)(X)$, in benzene and the results summarized in Table V. Although δ_{CH_3} shows large variations as X is varied, there is no obvious effect such as steric hindrance or electronegativity that can account for the observed variation of δ_{CH_3}.

The pseudo asymmetric compound listed in Table V, $(CH_3)P(O)(OCH(CH_3)_2)_2$, is the methyl analogue of a compound reported by Finegold (14) which has been discussed by Waugh and Cotton (15). The compounds $(H)P(O)(OCH(CH_3)_2)_2$ ($\delta_{CH_3} = 0.029$ p.p.m.) and $(phenyl)P(O)(OCH(CH_3)_2)_2$ ($\delta_{CH_3} = 0.107$ p.p.m.) also show magnetic nonequivalent methyl groups.

π-Electronic structure and reactivity of phenoxazine (1), phenothiazine (2), and phenoxthiin (3)

H. H. MANTSCH[1]
Institute of Chemistry, Cluj, Rumania

AND

J. DEHLER
Study Group of Structural Chemistry, Technische Hochschule, Munich, Germany

Received March 7, 1969

The ultraviolet, fluorescence, and phosphorescence spectra as well as the corresponding polarized excitation spectra were recorded for phenoxazine, phenothiazine, and phenoxthiin at 80 °K and discussed in terms of a number of theoretical transitions, calculated by a configuration interaction π-electron approximation.

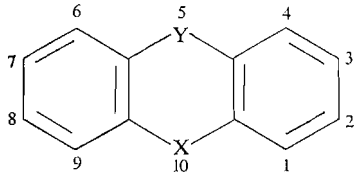
The computed transition energies and the reactivity indices (π-electronic charge, mobile bond order, free-valence index, superdelocalizability index, and localization energy) are in good agreement with experimental data and chemical evidence.

Canadian Journal of Chemistry, 47, 3173 (1969)

Introduction

In connection with current investigations on the π-electronic structure and reactivity of heterocyclic systems (1, 2), we have examined the three heterocycles mentioned in the title which are of both theoretical and practical interest, since many of their derivatives are pharmacologically highly important substances (e.g. phenothiazine drugs). As it has been pointed out elsewhere, a better knowledge of their physical properties might be important for understanding the way these systems interact with living organisms.

The reactivity indices calculated in this paper are within the limits of the accuracy which can be achieved by considering the π-electrons only, yet with all the known limitations in mind, they still should be successful in covering the order of reactivity of individual positions mainly for electrophilic substitutions.



1, X = NH; Y = O
2, X = NH; Y = S
3, X = S; Y = O

Parameterization

The present calculations were performed by a self-consistent field (s.c.f.) method within the Pariser–Parr–Pople (PPP) approximation (zero differential-overlap), and the semi-empirical parameters U_μ, $\gamma_{\mu\mu}$, and $\beta_{\mu\nu}$ have been compiled by testing s.c.f. calculations on monosubstituted benzene derivatives containing the heteroatoms oxygen, sulfur, and nitrogen, to achieve optimum fit to the electronic spectra. The transfer ability of the established parameters to greater molecules like those investigated in this paper was assured by calculating the energy, the intensity pattern, and the direction of polarization for the corresponding $\pi^* \leftarrow \pi$-transitions up to 50 000 cm^{-1} which are compared with the experimental ultraviolet and polarized excitation spectra in Figs. 1–3 (*vide infra*).

The one-center repulsion integrals $\gamma_{\mu\mu}$ and the U_μ integrals for heteroatoms were evaluated as follows: $\gamma_{CC} = 11$ eV; $\gamma_{SS} = 11$ eV; $\gamma_{NN} = 13$ eV and $\gamma_{OO} = 15$ eV; $U_S - U_C = -9$ eV; $U_N - U_C = -11$ eV and $U_O - U_C = -16$ eV, while the two-center repulsion integrals $\gamma_{\mu\nu}$ ($\mu \neq \nu$) have been approximated by the already classical method of Nishimoto and Mataga (3). All resonance integrals $\beta_{\mu\nu}$ are taken to be -2.3 eV, except for the CS bond which should be lowered slightly i.e. $\beta_{CS} = 0.6\beta_{CC}$.

The π-electronic system of these molecules consists of a number of 16 π-electrons on 14

centers and although they are not rigorously planar, (roughly speaking they are slightly folded along their short axis) the calculations we carried out assumed a common "aromatic" length of 1.4 Å and an angle of 120° throughout for the initial guessed input values, which later are refined by an iterative process. By considering a few folded structures for input values, we actually found that the geometry is not too critical as far as the reproduction of the electronic transitions is concerned.

An initial set of orthogonalized eigenvectors obtained from a Hückel approximation was used to construct the starting molecular orbitals, while the molecular orbitals obtained from Pople's s.c.f. procedure were then used as the basis for a configuration interaction treatment which included all possible configurations arising from single electron excitations between the 5 highest occupied and the 4 lowest empty orbitals.

From the various proposed bond order (p_{rs}), bond length (r_{rs}) relationships for CC bonds, we have used the linear one of Coulson and Golebiewski (4) which is particularly suitable for benzenoid bonds. The CN and CO bond lengths have been evaluated by two similar relations compiled by Nishimoto and Forster (5), assuming that the differences between a double bond and the hypothetical single bond with sp^2-hybridization distances are all 0.180 Å. As a similar relation was lacking for carbon–sulfur bonds, we have compiled it in a similar manner by using the values of 1.61 Å for a CS double bond and 1.82 Å for a corresponding single bond (6), i.e. 1.79 Å after correcting it for sp^2-hybridization.

$$r_{CC} = 1.517 - 0.180p_{CC}\ (Å)$$

$$r_{CN} = 1.451 - 0.180p_{CN}\ (Å)$$

$$r_{CO} = 1.410 - 0.180p_{CO}\ (Å)$$

$$r_{CS} = 1.790 - 0.180p_{CS}\ (Å)$$

The actual computations were carried out on a Telefunken TR-4 computer with a closed shell s.c.f.-CI computer program written in Algol.

Experimental

The $\pi^* \leftarrow \pi$-transitions calculated by this procedure are shown as vertical lines under the experimental absorption spectra (curves A) in Figs. 1–3 while their height is chosen as $\log f + 4$ (where f represents the oscillator strength calculated from the dipole strength of the transition). This allows for a better comparison between calculated and experimental intensities.

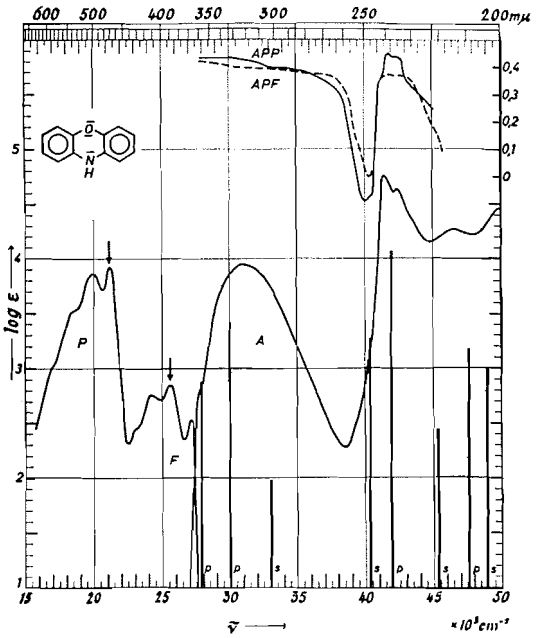

FIG. 1. Phenoxazine in ethanol at 80 °K. A, Absorption spectrum; F, fluorescence spectrum; P, phosphorescence spectrum; APF, polarized excitation spectrum based on the fluorescence; APP, polarized excitation spectrum based on the phosphorescence; vertical lines, calculated $\pi^* \leftarrow \pi$-transitions (p, parallel, s, perpendicularly polarized).

Besides these two parameters i.e. energy and intensity, an additional quite valuable criteria for testing theoretical calculations is provided by the direction of polarization of the $\pi^* \leftarrow \pi$-transitions. Therefore we have measured the polarized excitation spectra either based on the fluorescence spectrum (F), or based on the phosphorescence spectrum (P) and they are shown in the upper part of Figs. 1–3 as APF and APP spectra; the polarizations have been measured relative to the most intense vibronic band, marked by an arrow. The experimental technique for recording polarized excitation spectra has been described extensively by Dörr (7). In the line diagrams, the calculated direction of polarization is marked as p for parallel and s for perpendicular orientation of the transition moments in relation to the long axis of the molecular framework.

By considering these calculations, the electronic spectra of **1**, **2**, and **3** may now be discussed briefly as follows. The broad absorption band at the longest wavelength consists of three closely situated $\pi^* \leftarrow \pi$-transitions, with two strong parallel polarized transitions which yield high positive APF and APP values for the corresponding polarized excitation spectra in this region. The most intense transition at about 41 500 cm^{-1} (**1** and **3**) and 39 000 cm^{-1} (**2**) is also parallel polarized in agreement with the strong maximum in the polarized excitation

For personal use only.

spectra; this strong transition is preceded by a perpendicular polarized transition about ten fold less intense and which is marked by the strong minimum (especially for **1** and **3**) at about 40 000 cm^{-1} in the APF and APP spectra. The PPP calculations in agreement with the decrease of the APF and APP curves, predict another perpendicularly polarized transition between 43 000–45 000 cm^{-1} where the experimental limit of APF and APP spectra is reached.

Results and Discussion

As shown in the previous section, the assumed model on which the PPP calculations are resting is successful, within the expected limits, in reproducing the experimental transition energies, intensities, and polarization, and hence it should allow for at least qualitative reactivity calculations.

The reactivity indices i.e. the π-electronic charge (q_r), the mobile bond order (p_{rs}), and the free-valence index (F_r), as well as the superdelocalizability index (S_r) and the localization energy (L_r), were obtained on expanding the corresponding coefficients and orbital energies (8) and are shown in Figs. 4–6.

The chemical reactivity of these three molecules, governed primarily by their excellent electron-donor properties, is evidenced by the particularly easy formation of charge-transfer

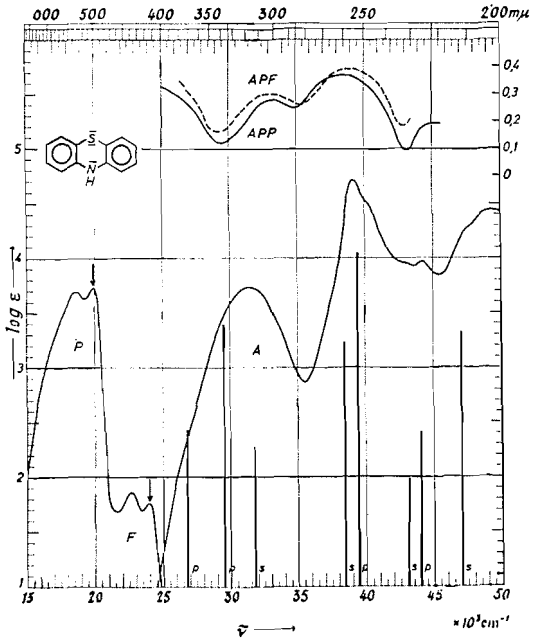

FIG. 2. Phenothiazine in ethanol at 80 °K. For notation see Fig. 1.

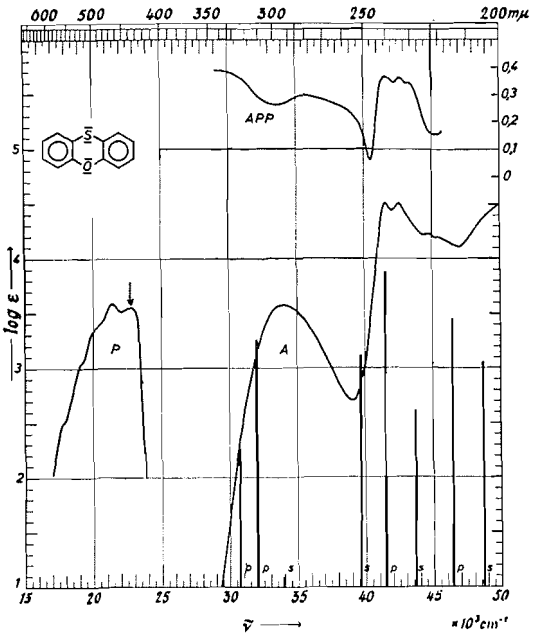

FIG. 3. Phenoxthiin in ethanol at 80 °K. For notation see Fig. 1.

complexes and by their enhanced reactivity towards electrophilic reagents. Indeed, the following molecular diagrams show that there is an excess of charge at all carbon atoms in the ground state configuration (see Fig. 4).

In discussing the chemical reactivity, the peculiarities of their ring structure should be considered first. These heterocyclic systems, which are not strictly heteroaromatic, consist of two benzenoid rings linked together by two *ortho* located bridges. The two groups which constitute these bridges (i.e. imino, sulfide or oxide) may slightly interact with each other through the two rings, yet the main influence exerted by these heteroatoms is directed towards the π-electronic distribution and hence to the reactivity within the carbocyclic rings.

Insofar as the chemical reactivity of phenoxazine and phenothiazine is concerned, it appears that the nitrogen plays the key role, in only a very few cases is the directing influence of the oxygen or sulfur important. The highest π-electron density, excepting the S or O atoms, is located at the nitrogen atom where some electrophilic reagents attack the heterocyclic ring, whereas with **2** and **3**, sulfoxides are formed quite easily by an electrophilic attack of the oxidant at the sulfur atom.

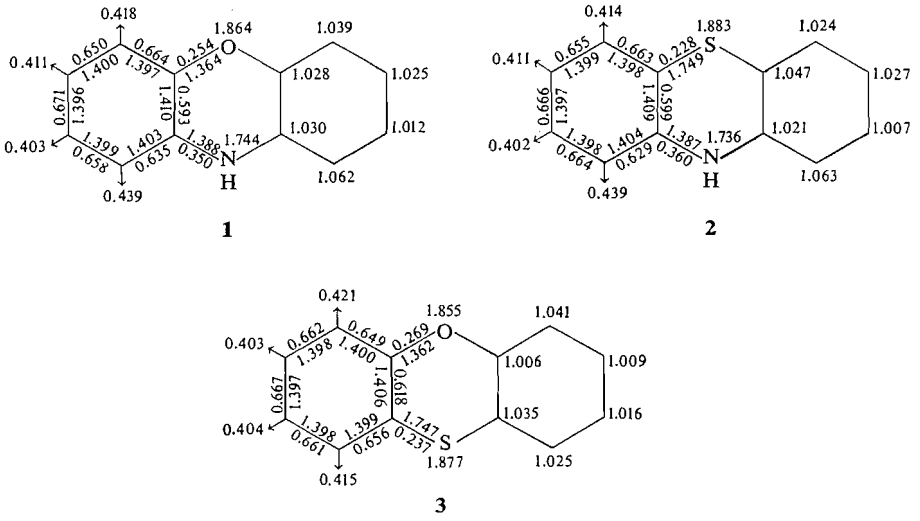

FIG. 4. Molecular diagrams for phenoxazine (**1**), phenothiazine (**2**), and phenoxthiin (**3**). π-Electronic charge (q_r), at the atomic centers; bond orders (p_{rs}), on the corresponding bonds (outside); bond lengths in Å (r_{rs}), on the corresponding bonds (inside); free-valence index (F_r), at the arrows.

Nevertheless the most important electrophilic reactions are associated with C-substitution. Indeed with phenoxazine (9) and phenothiazine (10), positions 3 and 7 are preferentially attacked by electrophilic reagents; reactions such as nitration, halogenation, Friedel–Crafts acylation, Vilsmeier formylation, sulfonation, or thiocyanation yield firstly 3 or 7-mono, or 3,7-disubstituted products and under more rigorous conditions, the 1,3,7,9-tetrasubstituted derivatives.

These experimental results are in good agreement with the calculated S_r and L_r values of these two compounds (see Figs. 5 and 6) which show that all positions in the carbocyclic rings are suitable for electrophilic substitution ($L_r < 1$ eV) and that positions 3 and 1 (or 7 and 9) are favored strongly over positions 2 and 4 (or 8 and 6), supporting the conclusions drawn in ref. 9, p. 101 and ref. 10, p. 431, that the reactivity of the carbon atoms of the phenoxazine and phenothiazine ring systems during electrophilic substitution decreases in the following order: $3 \geq 1 \gg 2 \geq 4$. This confirms that mainly the nitrogen is determining the reactivity of these two compounds, whereas the influence of the oxygen or sulfur is relatively small.

A different situation is encountered with the phenoxthiin ring system (**3**) which possesses two similar activating and competing heteroatoms to direct the substitution. According to the S_r and L_r values, there is no strongly favored position for electrophilic substitution and the L_r values are relatively high compared with positions 3 and 1 in **1** and **2**. Yet the experimental results (the chemistry of this heterocyclic system has been reviewed by Maior (11)) showed that a number of electrophilic substitutions like bromination, formylation, or chloromethylation actually occur at position 2 or 8 i.e. *para* to the oxygen. Now it has been proved that the bromination for instance occurs via an isolable phenoxthiin–dibromide complex, but no definite structure has been assigned to it (σ- or π-complexes). If one admits that the electrophilic substitution of **3** is preceded by the formation of a more or less stable complex with the electrophile, one could possibly understand the directing influence of the oxygen atom because the sulfur is more involved in the complex formation and should be deactivated slightly.

The nucleophilic substitution of these three ring systems should be very difficult as indicated by the high localization energy values (Fig. 6), yet unfortunately there are no reliable experimental results concerning nucleophilic substitutions of the unsubstituted ring systems **1**, **2**, and **3**. However it is interesting to mention that the metalation of these ring systems (9, 10) with butyllithium (observed experimentally), follows the order of the free-valence index i.e. availability of π-electrons for radical substitution, whereas

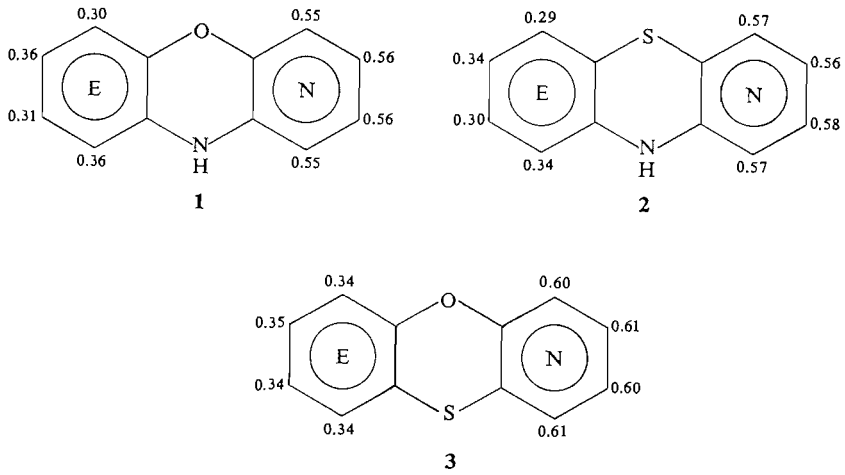

FIG. 5. The calculated superdelocalizability index (S_r) for phenoxazine (**1**), phenothiazine (**2**), and phenoxthiin (**3**) shown on the left side rings (E) for electrophilic and on the right side rings (N) for nucleophilic substitution. The larger the magnitude of S_r, the easier the reaction, considered separately for electrophilic and nucleophilic substitutions.

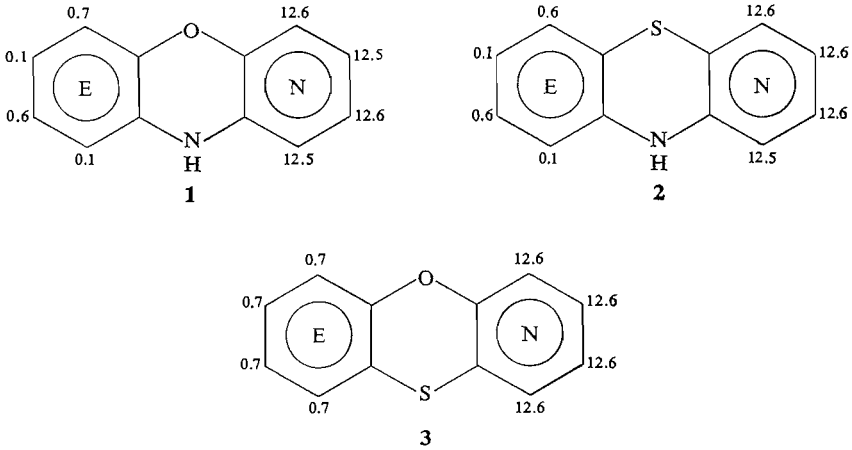

FIG. 6. Calculated localization energies (L_r) in eV, shown for electrophilic substitutions on the left side rings (E) and for nucleophilic substitutions on the right side rings (N). The smaller the magnitude of L_r, the easier the reaction.

the calculated reactivity indices S_r for nucleophilic substitution do not greatly favor any particular position.

The computed interatomic distances shown in Fig. 4 indicate a rather small interaction of the two carbocyclic rings through the central heteroring, which itself shows little aromatic character; indeed the carbocyclic rings do not show the strong bond order alternation which is found for instance with the carbocyclic rings in acridine (1). As indicated by these calculations, the two carbocyclic rings within the three compounds investigated are quite independent and the chemical behavior of the molecule resembles the chemistry of the corresponding *ortho*-disubstituted benzene derivatives; perhaps to explain other peculiarities of these ring systems one has also to invoke steric considerations, imposed by the two fixed heteroatom bridges.

Réactions des acides aminés avec l'épithiocyclohexane

KRZYSZTOF JANKOWSKI, ROGER GAUTHIER, ET CASIMIR BERSE
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 16 septembre 1968

L'ouverture de l'épithiocyclohexane (**1**) a été effectuée avec le glycinate d'éthyle et le sarcosinate d'éthyle. Les produits d'ouverture simple ont été isolés dans les deux cas. De plus, des produits de "disubstitution" (attaque du produit formé sur une deuxième molécule de l'épithiocyclohexane) ont été observés. Les structures des mercaptoesters formés sont discutées. Leur fragmentation en spectroscopie de masse a été étudiée et comparée avec celle des produits modèles.

Canadian Journal of Chemistry, 47, 3179 (1969)

L'ouverture des époxydes par les acides aminés à déjà été étudiée (1–4). Il nous a semblé intéressant d'observer le comportement des épisulfures face aux mêmes réactifs, de façon à établir les différences de réactivité entre les deux cycles. De plus les ouvertures des épisulfures ont été très peu étudiées (5) comparativement aux époxydes, ce qui présente un intérêt supplémentaire.

Il a été impossible d'utiliser les acides aminés libres ou les sels sodés des acides aminés comme réactifs; en effet, les acides aminés libres ne donnent pas de produits d'ouverture, ce qui est en accord avec les résultats obtenus avec les époxydes (2). Quant aux sels sodés, ils conduisent, avec de très bas rendements, à des mélanges de produits difficilement séparables et identifiables. Nous avons donc utilisé les esters éthyliques de la glycine et de la sarcosine comme réactifs.

Les produits obtenus sont des mercaptoesters, qui sont plus stables que leurs analogues hydroxylés obtenus par ouverture des époxydes. En effet, dans le cas des époxydes alicycliques, les produits primaires d'ouverture sont instables et se réarrangent en dicéto-2,5 pipérazines ou morpholones substituées, ce qui n'arrive pas avec les épisulfures. La réaction du glycinate d'éthyle sur **1** mène à deux produits d'ouverture, que l'on peut appeler monosubstitué et disubstitué: le *N*-(mercapto-2 cyclohexyl) glycinate d'éthyle (**2**) et le *N*-[(mercapto-2′ cyclohexylthio)-2 cyclohexyl] glycinate d'éthyle (**3**).

L'influence du solvant sur la réaction a été étudiée, ainsi que celle de la concentration. Comme on voit par le tableau I, la réaction sans solvant est de loin celle qui donne le meilleur rendement, et ce pour les deux produits obtenus. Toutes les valeurs sont données pour 2 h de chauffage à reflux. Les rendements ont été déterminés par chromatographie préparative sur couche mince.

TABLEAU I

Influence du solvant sur le rendement des produits **2** et **3**

Solvant	Rapport épithiocyclohexane acide aminé	Rendement de **2** (%)	Rendement de **3** (%)
—	1:1	16	2
	2:1	7	11
Benzène*	1:1	4	—
	2:1	3	2
Chloroforme*	1:1	8	Trace
	2:1	3	4

*Concentration ~ 10%.

Les produits **2** et **3** peuvent être séparés soit par distillation sous pression réduite, soit par chromatographie sur colonne. Les structures des deux produits ont été déterminées à l'aide des spectres et par synthèse. Pour le produit **2**, le spectra infrarouge indique la présence des groupements NH, SH et C=O (ester); les spectres de r.m.n. et de masse concordent aussi parfaitement avec la structure proposée (la fragmentation en spectrométrie de masse est donnée à la fin pour tous les produits d'ouverture).

Le produit **2** a aussi été synthétisé à partir de l'amino-2 cyclohexanethiol (**4**) (voir le Schéma 1). La réaction de ce dernier produit—connu dans la littérature (6) mais obtenu cette fois par l'action de l'ammoniaque sur l'épithiocyclohexane (**1**)—avec le chloroacétate d'éthyle a donné le chlorhydrate de *N*-(mercapto-2 cyclohexyl) glycinate d'éthyle (**5**). Le même produit a été obtenu par saturation avec HCl *gazeux* du composé **2**. Les deux produits ont des spectres i.r. et r.m.n. identiques et présentent de plus le même R_f en chromatographie sur couche mince.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

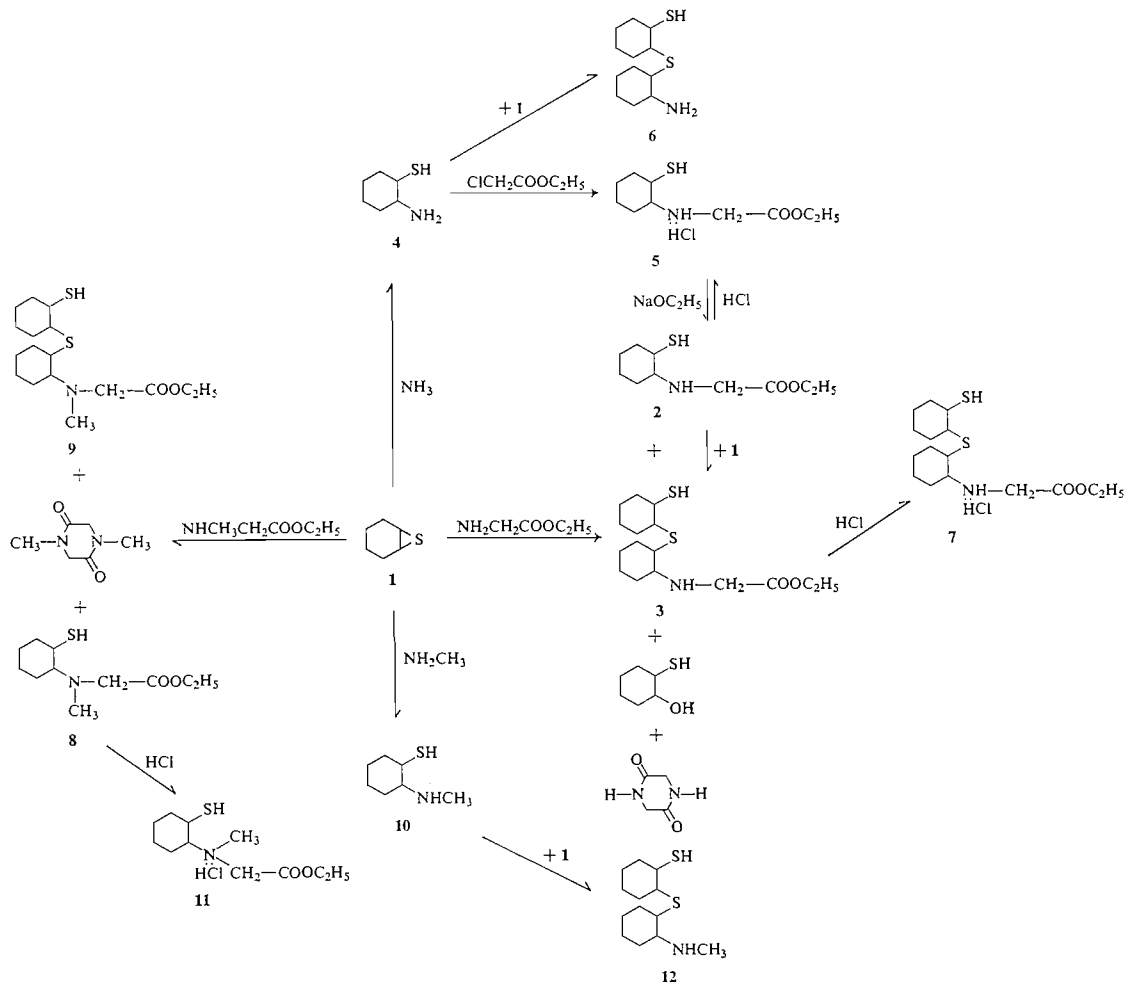

SCHÉMA 1

Le produit **5** synthétique a été libéré de son chlorhydrate avec l'éthanolate de sodium en donnant le produit **2** avec un bon rendement. L'identité de ce produit avec le produit d'ouverture **2**, a été prouvée par les spectres r.m.n. et i.r. ainsi que par un test chimique démontrant la présence de —SH.

Pour le deuxième produit d'ouverture deux structures peuvent être proposées: *N*-[(mercapto-2′ cyclohexylthio)-2 cyclohexyl] glycinate d'éthyle (**3**) ou *N*,*N*-bis (mercapto-2 cyclohexyl) glycinate d'éthyle (**3***a*).

L'examen des différentes données spectrales montre toutefois que seule la structure **3** est possible; le spectre infrarouge présente les bandes NH et SH et dans le spectre de r.m.n., il y a échange de NH avec D_2O. De plus la structure **3** a été vérifiée par comparaison avec le produit

8	H	CH_3

SCHÉMA 2

modèle: la (mercapto-2′ cyclohexylthio)-2 cyclohexylamine (**6**) a été obtenue par l'action de **4** sur l'épithiocyclohexane (**1**). Le chlorhydrate du *N*-[(mercapto-2′ cyclohexylthio)-2 cyclohexyl] glycinate d'éthyle (**7**) a été obtenu par saturation avec HCl de l'ester libre **3.**

Les arguments justifiant la structure du produit **6** sont les suivants: échange de deux hydrogènes dans le spectre de r.m.n. avec D_2O (présence de NH_2) et discussion du spectre de masse.

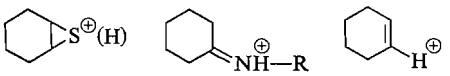
De plus, le produit **3** a été obtenu directement par réaction de l'épithiocyclohexane (**1**) sur l'ester libre **2** obtenu du produit **5**, ce qui justifie indirectement la structure du produit **6.**

Avec le sarcosinate d'éthyle, deux produits ont été obtenus, correspondant au *N*-(mercapto-2 cyclohexyl) sarcosinate d'éthyle (**8**) et *N*-[(mercapto-2′ cyclohexylthio)-2 cyclohexyl] sarcosinate d'éthyle (**9**) (Schéma 1). La structure du produit **8** a été établie à l'aide des spectres et des produits modèles. L'épithiocyclohexane (**1**) avec la méthylamine produit soit le méthylamino-2 cyclohexanethiol (**10**) soit, si on travaille avec un excès de **1**, la *N*-[(mercapto-2′ cyclohexylthio)-2 cyclohexyl] méthylamine (**12**). Le chlorhydrate du *N*-(mercapto-2 cyclohexyl) sarcosinate d'éthyle (**11**) a été obtenu par saturation de l'ester **8** avec le HCl *gazeux*.

La structure du produit **9** n'ext basée que sur les spectres infrarouge et de r.m.n. ainsi que les données analytiques, à cause de la très faible quantité de produit obtenu.

La fragmentation en spectrométrie de masse des produits **2**, **3**, **6**, **8** et **12** a été étudiée. Les esters **2**, **3** et **8** (voir Fig. 1, 2, et 3) se fragmentent par perte de $—COOC_2H_5$ suivie de la perte de H_2 pour donner l'ion le plus intense—l'ion cyclohexyl-[*b*]-dihydro-4,5 thiazolonium tel qu'indiqué dans le Schéma 2.

De plus on peut observer la présence des pics très intenses *m/e* 115 (114), 98 (112) et 81 correspondant aux structures suivantes:



2 R = H
8 R = CH_3

Les deux dernières structures peuvent être obtenues à partir d'une deuxième route de

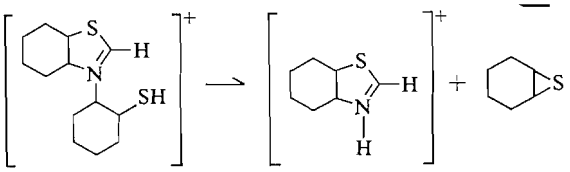
fragmentation possible commençant par la perte de SH. D'ailleurs, le spectre de masse pris à 70° met en évidence ce processus de fragmentation. Cependant, vu la faible intensité du fragment *m/e* 184 pour le produit **2**, cette deuxième route est beaucoup moins importante.

La présence des pics 142 et 98 dans le spectre du produit **3** est un argument supplémentaire en faveur de la structure proposée pour ce produit. En effet, il est difficile d'obtenir ces 2 pics à partir de la structure **3***a*. Si le produit **3** avant la structure **3***a*, on devrait très probablement trouver un pic assez intense à *m/e* 256:



m/e 256 *m/e* 142

L'absence de ce pic dans le spectre de masse de **3** constitue un argument supplémentaire pour le rejet de la structure **3***a*.

Les spectres des deux produits modèles **6** et **12** (voir Fig. 4 et 5) ont également été étudiés pour vérifier la présence éventuelle d'un ion bicyclohexylthio ou mercapto-2 bicyclohexylthio. L'absence de ces deux fragments à la fois dans les spectres des produits **3**, **6** et **12** supporte l'exactitude du mécanisme proposé ainsi que la structure du produit **3**.

Dans les deux cas la réaction a donné aussi les dérivés de la dicéto-2,5 pipérazine et l'hydroxy-2 cyclohexanethiol.

Partie expérimentale

Les spectres infrarouges ont été pris sur un spectrophotomètre Beckman IR-8 à double réseau. Les spectres de résonance magnétique nucléaire ont été pris à l'aide d'un spectrophotomètre modèle A-60 de la compagnie Varian. Les déplacements chimiques δ sont exprimés en p.p.m. et le tétraméthylsilane est utilisé comme référence interne. Les spectres de masse ont été enregistrés sur un appareil Hitachi RMU-6D (température de 25 °C et 70 °C, 70 eV).

Les points de fusion et d'ébullition ne sont pas corrigés.

Les analyses élémentaires ont été faites par C. Daesslé, Organic Microanalysis à Montréal, et par nous-même (micro Kjeldahl).

L'épithiocyclohexane (**1**) a été obtenu d'après la méthode de E. van Tamelen (7).

Les esters éthyliques de la glycine et de la sarcosine ont été obtenus selon la méthode de Fischer (8).

L'amino-2 cyclohexanethiol (**4**), p.é. 115–117°/40 mm Hg a été obtenu par l'ouverture du produit **1** avec un excès d'ammoniaque concentré dans l'éthanol avec un rendement de 40%. Le méthylamino-2 cyclohexanethiol (**10**) p.é. 97°/1 mm Hg (9) a été obtenu par l'action de la méthylamine sur le produit **1** avec un rendement de 25–27%. (Les deux composés ont été obtenus par l'ouverture de **1** pour la première fois.)

Ouverture de l'épithiocyclohexane (1) par le glycinate d'éthyle

Un mélange de l'épithiocyclohexane (**1**) et du glycinate d'éthyle[1] a été porté à reflux pendant 2 h. La chromatographie du mélange sur silice a donné les quatre produits suivants: (*a*) dicéto-2,5 pipérazine, p.f. 260°, identifié par comparaison des spectres i.r., et point de fusion mixte (10). Rendement ~40%. (*b*) mercapto-2 cyclohexanol, p.éb. 137°/45 mm identifié par les spectres i.r. et r.m.n. (11), et comparé avec le produit d'ouverture de **1** avec H_2O. Rendement ~10%.

Anal. Calc. pour $C_6H_{12}OS$ (132.2): C, 54.53; H, 9.15. Trouvé: C, 54.60; H, 8.60. (*c*) *N*-(mercapto-2 cyclohexyl) glycinate d'éthyle (**2**) (voir tableau II). (*d*) *N*-[(mercapto-2 cyclohexylthio)-2 cyclohexyl] glycinate d'éthyle (**3**) (voir tableau II).

Ouverture de l'épithiocyclohexane (1) par le sarcosinate d'éthyle

Un mélange de quantités équimoléculaires l'épithiocyclohexane (1) avec le sarcosinate d'éthyle a été porté à reflux pendant 2 h. Les trois produits formés ont été séparés par chromatographie sur silice: (*a*) diméthyl-1,4 dicéto-2,5 pipérazine, p.f. 144–146° (12) identifiée par comparaison des spectres i.r. et r.m.n. Rendement ~20%. (*b*) *N*-(mercapto-2 cyclohexyl) sarcosinate d'éthyle (**8**). (Voir tableau II), rendement: 13%. (*c*) *N*-[(mercapto-2' cyclohexylthio)-2 cyclohexyl] sarcosinate d'éthyle (**9**). (Voir tableau II), rendement: ~20%.

Préparation des produits 6 et 12

Une solution éthanolique des produits **4** ou **10** (~10%) a été portée à reflux pendant 2 h avec 60% d'une quantité équimoléculaire d'épithiocyclohexane. La solution a été évaporée sous vide, le résidu dissous dans l'éthanol absolu et le 40% restant d'épithiocyclohexane a été ajouté; le mélange a été porté à reflux pendant 2 h. Le solvant a été évaporé sous vide et distillé sous pression réduite. Le rendement brut est de 60%. Les rendements après distillation pour les produits **6** et **12** sont de 23% et 31% respectivement (tableau II).

N-[(*Mercapto-2' cyclohexylthio*)-*2 cyclohexyl glycinate d'éthyle (3)*

Une solution du *N*-(mercapto-2 cyclohexyl) glycinate d'éthyle (**2**) (50 mg, 0.25 mmole) dans l'éthanol absolu (5 ml) a été chauffé à reflux avec l'épithiocyclohexane (25 mg, ~0.25 mmole) pendant 2 h. Le solvant a été évaporé *in vacuo* et le produit a été dissous dans l'éther anhydre et la solution éthérée a été décantée, séchée sur carbonate de potassium anhydre. Le solvant a été évaporé *in vacuo*. Le produit formé a été identifié au produit **3** obtenu précédemment, à l'aide des spectres de

Chlorhydrates des esters

Méthode a (par saturation)

On a fait barbotter HCl gazeux dans une solution éthanolique de l'ester (environ 20%) jusqu'à saturation. La solution a été évaporée *in vacuo* et le résidu a été redissous dans l'éthanol absolu et saturé à nouveau avec HCl. L'évaporation du solvant a donné un résidu huileux, qui a été dissous dans l'éther anhydre. La solution éthérée contenant l'ester libre a été décantée et le résidu séché sous vide. Il a été impossible d'obtenir les produits sous forme cristalline à cause de leur caractère hygroscopique. Les chlorhydrates **5**, **7** et **11** ont été obtenus par cette méthode (tableau III).

Méthode b (synthèse)

Une solution éthanolique (~10%) de l'aminothiol **4**, (500 mg) a été portée à reflux avec une quantité équimoléculaire de chloroacétate d'éthyle pendant 5 h. Le solvant a été évaporé sous vide, puis le résidu a été dissous dans l'éther anhydre (50 ml) et agité pendant 30 min. La solution éthérée a été décantée, et le résidu séché *in vacuo*. Le produit huileux a été comparé avec celui obtenu précédemment.

Trois produits ont été indentifiés: les deux produits de départ, et le chlorhydrate de l'ester **5**. De plus, la présence d'un quatrième produit a été décelée par migration sur couche mince, mais il n'a pas été identifié.

Libération du chlorhydrate 5

Une solution du chlorhydrate de *N*-(mercapto-2 cyclohexyl) glycinate d'éthyle **5** (50 mg, 0.2 mmole) dans l'éthanol absolu a été traitée avec quelques gouttes d'éthanolate de sodium 10%, et le mélange a été chauffé pendant 20 min au bain-marie. Après refroidissement, le NaCl a été filtré. La solution éthanolique a été évaporée *in vacuo* et le résidu distillé (70–74%/0.4 mm Hg); rendement 42%. Le produit obtenu **2** est identique avec celui obtenu par l'ouverture du produit **1** avec le glycinate d'éthyle (spectre de r.m.n. et i.r.).

Liquid-phase oxidation of 2-butene in the presence of benzaldehyde

FUJIO TSUCHIYA AND TSUNEO IKAWA
Tokyo Institute of Technology, O-Okayama, Meguro-ku, Tokyo, Japan
Received February 7, 1969

The co-oxidation of *cis*- and *trans*-2-butene and benzaldehyde at 110 °C has been carried out in benzene and the mechanism of epoxide formation has been investigated by examining the ratio of *cis*- to *trans*-epoxides. The results indicate that epoxides were formed by two mechanisms, one involving the benzoylperoxy radical to give about half *cis* and half *trans* epoxides and the other by stereospecific epoxidation with perbenzoic acid. Experimental results show that the stereospecific character of epoxidation increases with the reaction time and the concentration of benzaldehyde, but does not depend on the concentration of 2-butene.

Introduction

It has been reported that various olefins trap acylperoxy radicals which are formed from aldehydes in the liquid-phase oxidation of aldehydes at room temperature, and react as a retarder (1, 2), and also that much epoxide was formed in the co-oxidation of cyclohexene with benzaldehyde at 70 and 110 °C. Two major processes of epoxidation have been proposed by the study of products (1), the first being the reaction of the benzoylperoxy radical, formed from benzaldehyde with cyclohexene, the second being the reaction of perbenzoic acid, formed from benzaldehyde with cyclohexene.

It has been shown that the stereochemistry is preserved during the epoxidation of olefins by per-acids (3). In this paper we will examine the mechanism of epoxidation in the co-oxidation of olefins with aldehydes by means of the stereochemical character of epoxides, using *cis*- and *trans*-2-butene as olefins and benzaldehyde.

Experimental

The reactions were conducted in a 200 cc autoclave, equipped with a reservoir and a magnetic stirrer. The volume of the reaction solution was kept constant at 100 cc, the total pressure 15 kg/cm^2, the partial pressure of oxygen 3 kg/cm^2, and the reaction temperature 110 °C. Benzene was used as solvent. The reaction time and concentration of the 2-butenes and benzaldehyde were changed. Oxygen was supplied from an oxygen accumulator to maintain a constant pressure during the course of the reaction.

The epoxidation of *cis*-2-butene by perbenzoic acid was performed, using authentic perbenzoic acid prepared from benzoyl chloride by the method of Moyer and Manley (4).

Benzene and acetonitrile were purified as usual, and benzaldehyde was distilled under a reduced nitrogen pressure in the dark. *cis*-2-Butene and *trans*-2-butene were 99.0% pure grade. Oxygen and nitrogen were 99.8% pure.

Gas chromatography was used to analyze the reacted and unreacted substances: *cis*- and *trans*-2,3-butyleneoxides, methylvinylcarbinol, crotonaldehyde, and acetaldehyde by a 2 m column of polyethyleneglycol-(PEG) 20 *M* at 60 °C, and unreacted benzaldehyde by the same column at 150 °C, *cis*- and *trans*-butenes by a 1 m column of DMF and 6 m of benzyl cyanide at room temperature, with a hydrogen flow rate of 40 cc/min. The total acids were measured by a titration with alcoholic potassium hydroxide, and most of the acid was found to be benzoic acid (m.p. 121 °C) by an elemental analysis after distillation of the products. Peroxide was measured by iodometry. *cis*- and *trans*-2,3-Butyleneoxides were isolated by the gas chromatography, and identified by infrared absorption spectra at 777 cm^{-1} (*cis*) and 812 cm^{-1} (*trans*), which are assigned to the epoxide rings (5).

Results

A series of runs with 1.6 moles/l of *cis*- and *trans*-2-butene and 2.3 moles/l of benzaldehyde was carried out in benzene at 110 °C with reaction times varying from 4 to 80 min. The results are summarized in Table I. Moreover the results of co-oxidation of 1.6 moles/l of *cis*-2-butene and 2.7 moles/l of benzaldehyde are tabulated in Table I. Table I shows that there is no difference between the rate of co-oxidation for the 2-butene isomers and also that the selectivity of epoxide, which is defined as the mole percent of epoxide based on consumed 2-butene, increases in accordance with the increase in the conversion of 2-butene. In these experiments 2,3-butyleneoxide was the main product. Other products were acetaldehyde and carbon dioxide. Oily products, having high boiling points higher than 180 °C at 60 mm Hg, were found but not analyzed. The absolute amount of benzoic acid was equal to that of butyleneoxide. Methylvinylcarbinol and

crotonaldehyde, which are the primary products after the abstraction of hydrogen from 2-butene were not observed. Traces of methylformate and acetic acid were found on gas chromatograms.

The molar ratios of *cis*-epoxide to *trans*-epoxide against 2-butene conversion are plotted in Fig. 1. These show that the stereospecific character increases with the increase in conversion. Figure 1 also shows that the concentration of benzaldehyde affects the stereochemical character of the formed epoxide.

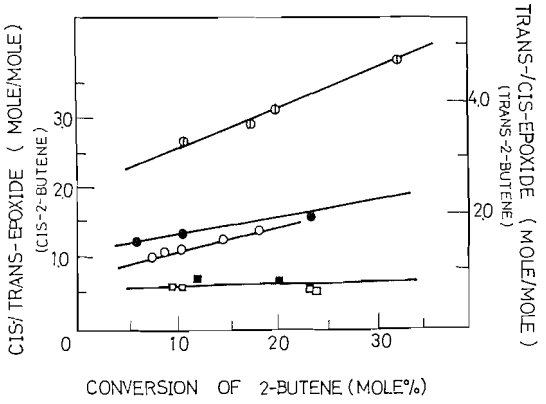

FIG. 1. Molar ratio of stereoisomers of epoxide versus conversion of 2-butene. *cis*-2-Butene, 1.6 moles/l: ○ benzaldehyde, 2.3 moles/l; ● benzaldehyde, 2.7 moles/l; □ benzaldehyde, 2.3 moles/l, $Co(OCOCH_3)_2$, 0.2 g; ■ benzaldehyde, 2.3 moles/l in acetonitrile. *trans*-2-Butene, 1.6 moles/l: ⓘ benzaldehyde, 2.3 moles/l.

A series of runs with 1.6 moles/l of *cis*- and *trans*-2-butenes was carried out in benzene at 110 °C for 20 min during which time the concentration of benzaldehyde was varied from 0 to 3.1 mole/l. The results are summarized in Table II. Molar ratios of *cis*- to *trans*-epoxide are plotted against the concentration of benzaldehyde in Fig. 2. It is apparent that the stereospecific character increases with an increase in concentration of aldehyde. The same result was obtained using *trans*-2-butene, as shown in Fig. 2.

The concentration of *cis*-2-butene was varied while the concentration of benzaldehyde and the reaction time were kept constant at 2.3 moles/l and 20 min, respectively. The results are tabulated in Table III.

With the increase in the concentration of butene, the amount of the reacted butene decreased and also the amount of absorbed oxygen decreased, as shown in Table III. These

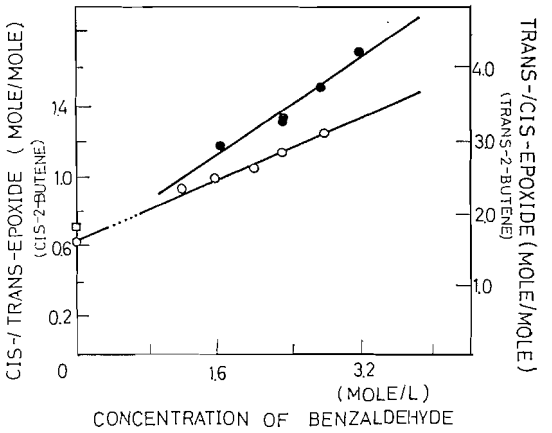

FIG. 2. Molar ratio of stereoisomers of epoxide versus concentration of benzaldehyde. ○ *cis*-2-Butene, 1.6 moles/l; □ Brill's result; ● *trans*-2-butene, 1.6 moles/l.

facts indicate that *cis*-2-butene reacts as a retarder of the reaction. The variation in the concentration of *cis*-2-butene caused a very large change in the conversion in the same reaction time. Therefore, the molar ratios of *cis*- to *trans*-epoxide formed in various concentrations of butene were plotted against the conversion of benzaldehyde, and found to be on the same line, as shown in Fig. 3. This means that the molar ratio of the stereoisomer does not depend on the concentration of *cis*-2-butene.

REACTION SCHEME 1.

The epoxide formed from the reaction of *cis*-2-butene and perbenzoic acid was only *cis*-2,3-butyleneoxide.

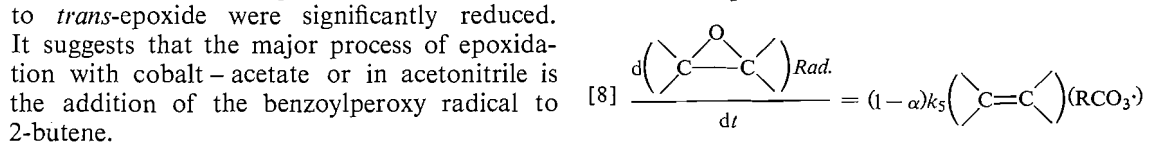
It is known that the decomposition of perbenzoic acid by cobalt – acetate is faster than the epoxidation of olefin (1), and also that acetonitrile forms a complex with per-acid to prevent the epoxidation by per-acid (7). Thus, if cobalt – acetate is added under the reaction conditions to the reaction mixture of 1.6 moles/l of *cis*-2-butene and 2.3 moles/l of benzaldehyde at 110 °C, or if acetonitrile instead of benzene is used as a solvent under the same reaction conditions, the epoxidation by per-acid will be prevented and the stereospecificity will be reduced. The results are summarized in Table IV. The behaviors of the molar ratios of the stereoisomer are shown in Fig. 1. Molar ratios of *cis*- to *trans*-epoxide were significantly reduced. It suggests that the major process of epoxidation with cobalt – acetate or in acetonitrile is the addition of the benzoylperoxy radical to 2-butene.

Discussion

The authors have proposed the reaction scheme for the co-oxidation of benzaldehyde and olefins (1, 2). In the case of this experiment, the hydrogen abstraction from 2-butene by radicals may be neglected, since only traces of methylvinylcarbinol and crotonaldehyde have been found. The decomposition of per-acid will be small (8) in comparison with the epoxidation by per-acid (9). The rate of the epoxidation is larger than the Baeyer-Villiger reaction by per-acid (10). Consequently, epoxides seem to be formed by reactions [5″] and [7], as shown in Reaction scheme 1.

In this experiment, the conversions of 2-butene were fairly large, and the concentrations of 2-butene and aldehyde varied during the course of reaction. However, applying the stationary state method to the elementary radical reactions, we kinetically speculate the epoxidation mechanism, comparing with the experimental results.

The consideration of the factors that affect the molar ratio of *cis*- to *trans*-epoxide is as follows. The rate of epoxide formation by reaction [5″] is



The rate of epoxide formation by reaction [7] is

The concentration of per-acid will be calculated by the rate of per-acid formation as follows

$$[10] \qquad \frac{d(RCO_3H)}{dt} = k_3(RCO_3\cdot)(RCHO)$$

Moreover, we may write the next approximation assuming the steady state of radicals and the low conversion of reactants

$$[11] \qquad (RCO_3H) \doteqdot k_3(RCO_3\cdot)(RCHO)t$$

where t is the reaction time.

It is reasonable to consider that the epoxidation [5″] does not preserve a stereochemical character of the reactant olefin and the epoxides formed are a mixture of *cis*- and *trans*-epoxides, while the epoxide formed by reaction [7] preserves a stereochemical character of the reactant olefin. Then, the following relation can be obtained by the integration of eqs. [8], [9], and [11], assuming the steady state of radicals and the low conversion of reactants

$$[12] \qquad \frac{cis\text{-epoxide}}{trans\text{-epoxide}} = \beta + \frac{1}{2}\frac{1+\beta}{1-\alpha}\frac{k_3}{k_5} \times k_7(RCHO)t$$

where, β is the molar ratio of *cis*- to *trans*-epoxide formed by radical attack, that is, eq. [8], and the value of β seems to be a constant, about 0.6. We shall discuss this in more detail in the following section.

This equation indicates that the molar ratio of stereoisomers depends on the concentration of aldehyde and the reaction time, i.e., conversion of the reactants, but does not depend on the concentration of olefin.

These results derived kinetically are consistent qualitatively with the trend of the experimental results, shown in Figs. 1–3.

It is shown in Table I that the distribution of *trans*-epoxide formed from *cis*-2-butene has not changed, while *cis*-epoxide has increased with conversion. This fact indicates that the reaction [7] of *cis*-epoxide formation is the successive reaction. The same behavior has been observed in the case of *trans*-2-butene.

It is clear in Table III that olefin reacts as a scavenger of peroxy radical, i.e., as in reaction [5], and gives a mixture of epoxides, or reacts further with 2-butene to form inert products such as polymers or esters. These will correspond to the brownish oily products having high boiling points. Adding cobalt – acetate, which decomposes per-acid, or using acetonitrile as a solvent instead of benzene (which makes a complex to prevent the epoxidation by reaction [7]), the amount of *cis*-epoxide formed from *cis*-2-butene has been decreased. These experimental results, shown in Fig. 1, indicate epoxidation by per-acid and peroxyradical. The value of the molar ratio of *cis*- to *trans*-epoxide formed from *cis*-2-butene is about 0.6, when the epoxidation by per-acid is completely prevented, and this value agrees with that when only *cis*-2-butene has been oxidized without aldehyde, the value by Brill and Baronr (6), and also the value extrapolated to zero concentration of aldehyde, as shown in Fig. 2. These facts mean that the value of the molar ratio (β) of *cis*- to *trans*-epoxide formed from *cis*-2-butene by radical attack is about 0.6.

From the above discussion on the value of the molar ratio of stereoisomers by a radical process, and the epoxidation by per-acid being a successive reaction, the increase in the molar ratio with the concentration of benzaldehyde (Fig. 2) and with the conversion of benzaldehyde (Fig. 3) is thought to be due to the contribution of epoxidation by per-acid. The amount of *cis*-epoxide in excess of 0.6 of the *trans*-epoxide results from the epoxidation by per-acid in the experiment using *cis*-2-butene. Therefore, the relative proportion of non-radical epoxidation to radical epoxidation is $(N - 0.6)/0.6$, where N is the molar ratio of *cis*- to *trans*-epoxide in the products.

Permanganate oxidation of aromatic alcohols in acid solution[1]

FARIZA BANOO[2] AND ROSS STEWART
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received March 13, 1969

The mechanism of the permanganate oxidation of di- and tri-arylcarbinols has been studied in aqueous sulfuric acid. With both kinds of alcohols the rate-controlling step in solutions more acidic than H_0 −0.50 was found to be the ionization of the carbinol to give the carbonium ion followed, it is believed, by rapid reaction with permanganate ion to form the ester which decomposes rapidly to products. In the case of the tertiary alcohols the decomposition probably proceeds via a 1,2-aryl shift. The effect of substituents is correlated with σ^+ in both cases, ρ^+ being −1.02 and −1.39 for the secondary and tertiary series. The acidity function which governs both reactions is H_0. Tri(*p*-tolyl)carbinol is exceptional in that its oxidation in solutions more acidic than H_R −2.6 is second-order and is governed by the H_R acidity function.

Canadian Journal of Chemistry, 47, 3199 (1969)

Introduction

The permanganate oxidation of primary and secondary alcohols has previously been studied in basic and weakly acidic solution (1–4). The reaction is strongly accelerated by base and this has been shown to be due to the ready transfer of hydrogen (either as a hydride ion or as a hydrogen atom) from the alkoxide ion to the permanganate ion.

$$R_2CHOH + OH^- \rightleftarrows R_2CHO^- + H_2O$$

$$R_2CHO^- + MnO_4^- \rightarrow \begin{cases} R_2C{=}O + Mn(V) \xrightarrow{Mn(VII)} \\ R_2\dot{C}{-}O^- + Mn(VI) \xrightarrow{Mn(VII)} \end{cases} R_2C{=}O + Mn(VI)$$

Little is known about the way in which strongly acidic permanganate reacts with alcohols, although it has been shown that aldehyde hydrates (which are gem diols) undergo much more rapid oxidation in acidic than in neutral solution, because of the increased reactivity of the permanganate acid formed in this region (5). Furthermore, virtually nothing is known about the way tertiary alcohols are oxidized by permanganate. These compounds lack a hydrogen atom on the alcoholic carbon and any oxidation must produce carbon–carbon bond cleavage, possibly via aryl migration. It seemed worthwhile to study these reactions and accordingly, a series of diarylcarbinols and triarylcarbinols were prepared and subjected to permanganate oxidation over a wide acidity range. The results have been analyzed in terms of mechanism.

[1]Part IX of the series, Mechanisms of Permanganate Oxidation. Taken in part from the Ph.D. Thesis of Fariza Banoo, University of British Columbia, 1968.

Experimental

Materials

The substituted benzhydrols were prepared by standard methods usually involving the reduction of the corresponding ketone (1). The triarylcarbinols were, with one exception (4-nitrotriphenylcarbinol (6)) prepared by the Grignard procedure. The physical properties of those compounds that have previously been prepared agreed in all cases with the literature values. The following two compounds have not been previously reported.

(1) 3-Trifluoromethyl-4′-methyltriphenylcarbinol: from 4-methylbenzophenone and 3-trifluoromethylphenylmagnesiumbromide. Yield 41%, b.p. 184°/0.8 mm.

Anal. Calcd. C, 73.7; H, 4.97; F, 16.7. Found: C, 73.5; H, 5.11; F, 16.9.

(2) 3-Trifluoromethyltriphenylcarbinol: from benzophenone and 3-trifluoromethylphenylmagnesiumbromide. (We thank Mr. I. Beheshti for the preparation of this compound.) Yield, 61%, b.p. 120°/0.2 mm.

Anal. Calcd. C, 73.17; H, 4.57; F, 17.37. Found: C, 73,14; H, 4.87; F, 17.14.

Reaction Products

The following benzhydrols were oxidized (listed in the order in which they appear in Fig. 8, left to right: 4,4′-dimethoxy, 2,4,6,2′,4′,6′-hexamethyl (σ^+ value calculated from pK_{R+} of the diarylcarbinol (9), 4-methoxyl 4,4′-dimethyl, 4-methyl, unsubstituted, 4-chloro, 4,4′-dichloro, 4-carboxy. Isolation experiments

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

were performed in the cases of benzhydrol and 4-methoxybenzhydrol. The former gave a 99.2% yield of benzophenone, m.p. 49°, 2,4-dinitrophenylhydrazone, m.p. 238°. The latter gave a 98.1% yield of crystalline 4-methoxybenzophenone, m.p. 62°. The reaction products of all the other alcohols contained strong carbonyl peaks in their infrared spectra.

The following triphenylcarbinols were oxidized (listed in the order which they appear in Fig. 9, left to right): 3,3′,3″-trichloro, 4,4′,4″-trichloro, 4,4′-dichloro, 3-trifluoromethyl-4′-methyl, 4-chloro, unsubstituted, 4-fluoro, 4-methyl, 4,4′-dimethyl, 4,4′,4″-trimethyl. The ketonic products have been identified in the case of triphenylcarbinol and two of its derivatives (Table II). Triphenylcarbinol was shown to produce benzophenone and carbon dioxide when an excess of permanganate was employed. The carbon dioxide was swept out of the reaction mixture and trapped in barium hydroxide solution. The increase in weight of this system corresponded to the production of 6 moles of carbon dioxide. We conclude that phenol is the other product of reaction and that it has been completely degraded by the acidic permanganate, the known fate of phenol under these conditions (4).

Kinetics

The kinetics of the reaction were followed by two procedures; titration of unreacted permanganate and observation of the disappearance of the 526 mμ permanganate peak in the visible spectrum, essentially as previously described (1, 5, 7).

A spectrophotometric method was used to follow the rate of ionization of 4-methoxybenzhydrol by observing the increase in absorption of the corresponding carbonium ion at 466 mμ. Because of the low solubility of the carbinol in water, 70% methanol (by volume) in water was taken as the reaction medium. In a typical experiment 2 ml of 18.0 *M* sulfuric acid was taken in a 10 ml volumetric flask and made up to the mark with the aqueous methanol; 2.5 ml of this solution was taken in a cell and placed in the thermostatted cell compartment of a Cary 16 spectrophotometer. Next 50 μl of a 2.5 *M* solution of 4-methoxybenzhydrol were injected to the cell from a syringe. The increase in optical density at 466 mμ showed the extent of ionization. The values for the acidity functions, H_0 and H_R, for the solutions were determined by the standard Hammett indicator technique (8). The results are given in Table I.

TABLE I

H_0 and H_R values for 70 vol% aqueous methanol

M(H_2SO_4)	H_0*	H_R†	(H_R)‡
1.80	−0.15 (−0.14)	−0.58	−0.63
2.16	−0.38	−0.98	−0.89

2.88	−0.64	−1.65	−1.78
3.60	−0.82	−1.94	−2.01

*4-Chloro-2-nitroaniline was used as indicator except for the value in parentheses which was obtained using 2-nitroaniline (8).
†4,4′-Dimethoxytriphenylchloromethane was used as indicator (9).
‡Calculated from the final absorbance of the 4-methoxybenzhydryl cation (9).

Results and Discussion

The stoichiometry of both reactions, the oxidation to the ketone in the case of the secondary alcohols, and the oxidative cleavage in the case of the tertiary alcohols, requires a 3:2 molar ratio of alcohol to permanganate

$$3Ar_2CHOH + 2MnO_4^- + 2H^+ \rightarrow 3Ar_2C{=}O + 2MnO_2 + 4H_2O$$

$$3Ar_3COH + 2MnO_4^- + 2H^+ \rightarrow 3Ar_2C{=}O + 3ArOH + 2MnO_2 + H_2O$$

Although the permanganate–alcohol reaction in basic and in mildly acidic solution is cleanly second-order (1), the reaction that becomes dominant as more acidic conditions are reached ($H_0 < -0.50$) is first-order in alcohol and zero-order in permanganate. Figure 1 shows a typical first-order plot for the oxidation of benzhydrol. Doubling the permanganate concentration has no effect on the rate at which it is consumed.

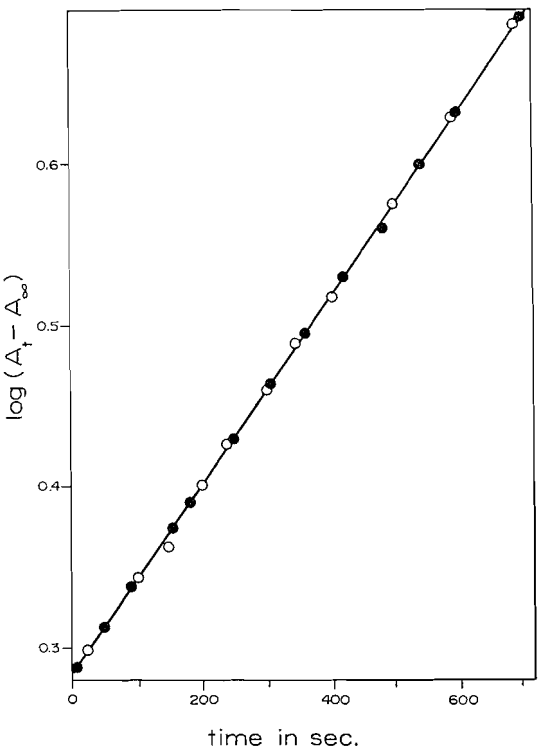

FIG. 1. First-order rate plots of the permanganate oxidation of benzhydrol, $H_0 = -0.69$, $T = 25°$, [benzhydrol] = 3.65×10^{-4}; [MnO_4^-] = 4.87×10^{-4} (open circles), [MnO_4^-] = 2.43×10^{-4} (closed circles); $k_1 = 2.00 \times 10^{-3}$ s^{-1}.

‡The conjugate acid of 4-chlorobenzophenone absorbs at 300 and 367 mμ (13).

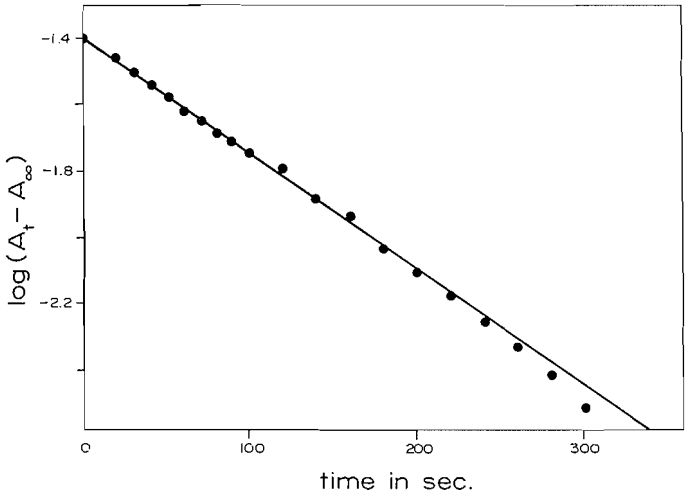

FIG. 2. First-order rate plot of the permanganate oxidation of triphenylcarbinol, $H_0 = -1.50$, $T = 25°$, $k_1 = 1.14 \times 10^{-2}\ s^{-1}$.

Most of the tertiary alcohols also gave good first-order plots up to about 50–60% reaction, after which serious deviations began to appear, presumably because of degradation of the phenolic products (Fig. 2). In the case of tri(*p*-tolyl)carbinol a second-order reaction reappeared at higher acidities ($H_R < -2.6$).

The effect of acidity on the rate of the permanganate oxidation of benzhydrol and triphenylcarbinol is shown in Figs. 3 and 4. In both cases, reasonably linear plots are obtained when the logarithm of the first-order rate constant is plotted against H_0 (8) and the slopes are found to be close to unity. When the acidity function H_R is used (9), somewhat less linear plots are obtained and, more significantly, the slopes are found to deviate greatly from unity (0.58 for benzhydrol and 0.45 for triphenylcarbinol). Only for tri(*p*-tolyl)carbinol did H_R appear to govern the rate of the oxidation reaction. Between H_R values of -2.5 and -3.6, a straight line of unit slope was obtained when the logarithm of the second-order rate constant for the oxidation of this alcohol is plotted against H_R (Fig. 5).

Rate-controlling Step

The first-order dependence of the rate on the concentration of alcohol, the zero-order dependence on permanganate, and the first-order dependence on the acidity means that the rate can be expressed by the equation

$$\text{rate} = k[\text{alcohol}]h_0 \quad \text{where } h_0 = -\text{antilog } H_0$$

This suggests that the rate-controlling step is the ionization of the alcohol to give the carbonium ion

$$ROH + H^+ \rightleftarrows ROH_2^+ \quad \text{fast}$$
$$ROH_2^+ \rightarrow R^+ + H_2O \quad \text{slow}$$
$$R^+ + MnO_4^- \rightarrow \text{products} \quad \text{fast}$$

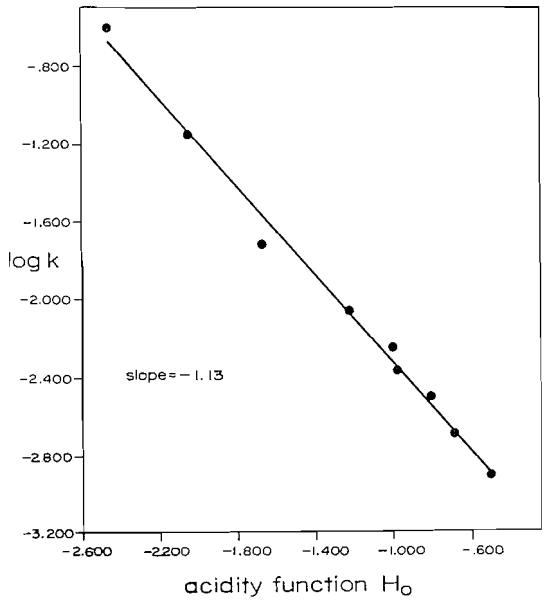

FIG. 3. Variation of the rate of permanganate oxidation of benzhydrol as a function of H_0; correlation coefficient, 0.996.

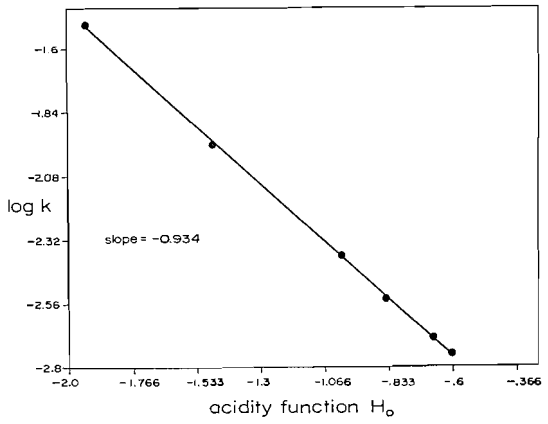

FIG. 4. Variation of the rate of permanganate oxidation of triphenylcarbinol as a function of H_0; correlation coefficient, 0.999.

Although the rate-controlling step above involves the formation of a carbonium ion, it is not surprising that the operative acidity function is H_0 rather than H_R. The latter governs the *equilibrium* of the alcohol–carbonium ion reaction and differs in form from H_0 by containing a water activity term. It seems unlikely that the activity of water in the medium will alter the *rate* at which a water molecule is expelled

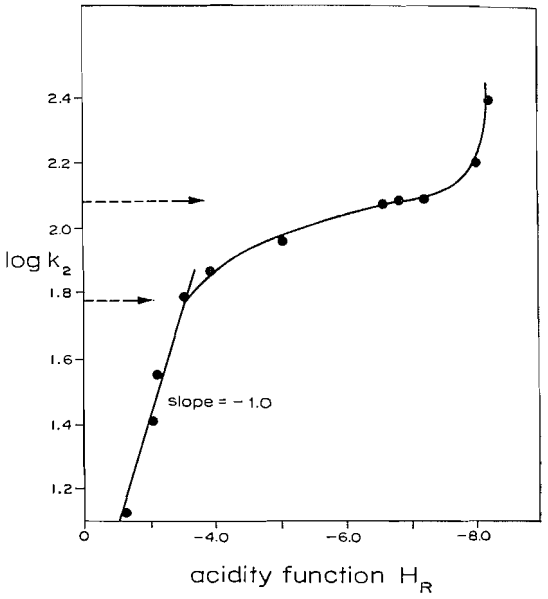

FIG. 5. Variation of the rate of permanganate oxidation of tri(*p*-tolyl) carbinol with H_R.

although it will clearly affect the equilibrium position of the system. In this connection Rocek (10) has shown that the rate of carbonium ion formation from 1-methylcyclohexanol is governed by H_0. Further information on this point was obtained by measuring the rate of ionization of *p*-methoxybenzhydrol under conditions that were as close as possible to those used for the oxidation process. Unfortunately the high concentration of alcohol required to measure the rate and degree of ionization of this alcohol at acidities so far from its pK_{R+} value, precluded the use of a purely aqueous system. The rates of ionization of 4-methoxybenzhydrol were accordingly determined in 70 vol% aqueous methanol containing sulfuric acid ranging from 1.8 to 3.6 *M*. The reaction was found to be of first-order in carbinol concentration. The following first-order rate expression was used to obtain the rate constants

$$kt = 2.303 \log \frac{A_\infty}{A_\infty - A_t}$$

where A_∞ = absorbance at infinite time, and A_t = absorbance at time t, at the wavelength maximum for the carbonium ion, 466 mμ. Log $(A_\infty - A_t)$ was plotted against time and the rate constants calculated from the slopes of the lines. A typical rate plot is shown in Fig. 6.

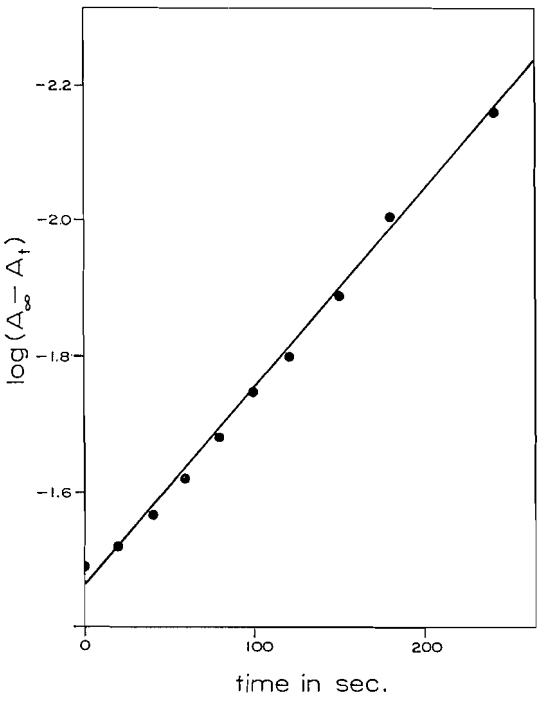

FIG. 6. Rate of ionization of *p*-methoxybenzhydrol in 70 vol% aqueous methanol containing sulfuric acid, 25°. $H_0 = -0.38$, $[H_2SO_4] = 2.16$, [*p*-methoxybenzhydrol] = 6.0. $k_1 = 5.99 \times 10^{-3}\ s^{-1}$.

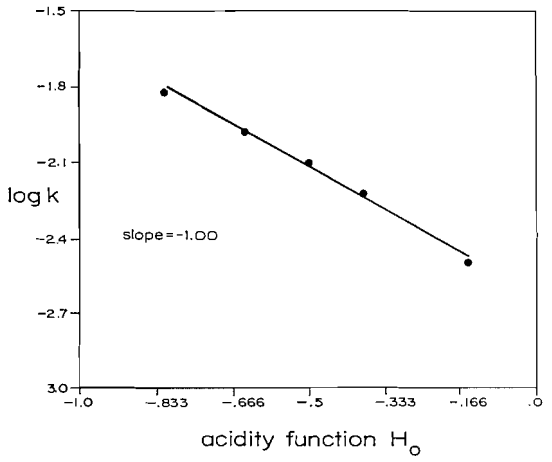

FIG. 7. The variation of the rate of ionization of *p*-methoxybenzhydrol with H_0; correlation coefficient, 0.998.

In Fig. 7 the logarithm of the ionization rate for *p*-methoxybenzhydrol in 70 vol% aqueous methanol is plotted against the acidity function H_0. A straight line of slope −1.00 with a correlation coefficient of 0.998 is obtained by this means whereas the use of the function H_R gives a considerably less satisfactory relation (slope = −0.48, correlation coefficient 0.990). The rate of ionization of 4-methoxybenzhydrol is close to this compound's rate of oxidation by permanganate when these measurements are made in solutions of the same acidity. For an H_0 of −0.81 the two rates are $1.55 \times 10^{-2}\ s^{-1}$ for the ionization (in 70 vol% aqueous methanol) and $1.79 \times 10^{-2}\ s^{-1}$ for the oxidation (in water).

The isotope effect for the permanganate oxidation of $(C_6H_5)_2CDOH$ at 25° is 7.3 at pH 7.00 (where the reaction is second-order) (1), but is only 1.08 in the region between $H_0 = -0.50$ and −1.22 (where the reaction is first-order). This, too, is consistent with the ionization reaction being the rate-controlling step of the oxidation.

Overall Reaction Path

The following path accounts for the oxidation of secondary aromatic alcohols by permanganate in aqueous sulfuric acid

$$Ar_2CHOH + H^+ \rightarrow Ar_2CH^+ + H_2O \quad \text{slow}$$

$$Ar_2CH^+ + MnO_4^- \rightarrow \text{products} \quad \text{fast}$$

A permanganate ester, $Ar_2CH—O—MnO_3$, is likely the first intermediate formed in the fast steps that lead to product.

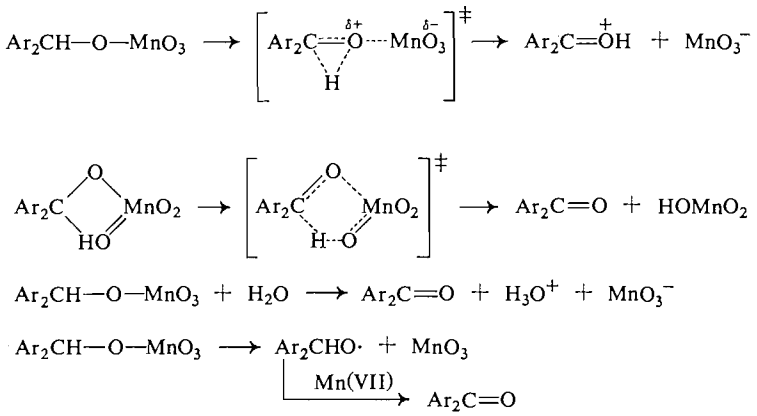
The tertiary alcohols follow a similar course with the decomposition of the permanganate ester probably involving rearrangement of an aryl group, followed by hydrolysis

$$Ar_3C—O—MnO_3 \longrightarrow \left[Ar_2C{=}\overset{\diagdown\ \diagup}{O}{\cdots}MnO_3\right]^{\ddagger} \longrightarrow Ar_2C{=}\overset{+}{O}—Ar + MnO_3^-$$

$$Ar_2C{=}\overset{+}{O}—Ar \xrightarrow{H_2O} Ar_2\overset{OH}{\overset{|}{C}}—OAr \longrightarrow Ar_2C{=}O + ArOH$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

It is conceivable that the permanganate esters of secondary aromatic alcohols also decompose by a 1,2-rearrangement step in which hydride ion is transferred from carbon to oxygen or in which hydrogen is transferred to the oxygen of the ester via a cyclic 5-membered transition state. Alternatively, the decomposition may proceed by proton loss to a water molecule and expulsion of MnO_3^-. This general question is discussed in greater detail in the accompanying paper on chromium(VI) oxidations. A 1-equivalent step has been considered distinctly possible in the base-promoted permanganate oxidation of alcohols (3, 4) and for the secondary alcohols, at least, it cannot be ruled out for the acid-promoted reaction. Four possibilities, three 2-equivalent and one 1-equivalent routes, are given below. (Since this step follows the rate-controlling step it is difficult to distinguish between these possibilities.)



Effect of Substituents

The effect of substituents on the oxidation of the secondary alcohols is shown by the plot in Fig. 8 in which σ^+ substituent constants are used (11). The Hammett rho value of -1.02 and the excellent correlation with σ^+ support the idea that the rate-controlling step is ionization of the carbinol.

The effect of substituents on the rate of oxidation of the tertiary aromatic alcohols is shown in Fig. 9. As in the case of the secondary alcohols an excellent correlation is obtained when σ^+ is used. The rho value of -1.39 is also consistent with an ionization process, the larger value probably reflecting a higher degree of bond-breaking in the transition state.

In the case of tri(*p*-tolyl)carbinol the ionization step at intermediate acidities is faster than the decomposition of the ester as shown by the observations that the reaction is first-order in both alcohol and permanganate and is governed by the H_R acidity function (Fig. 5). The pK_{R+} of this alcohol is -3.56 (9) and the levelling-off of the rate above $H_R = -4$ doubtless reflects the fact that the ionization equilibrium has moved towards completion, although the curve shown in Fig. 5 does not duplicate exactly the ionization curve expected for this alcohol. The sharp rise in rate beyond an H_R of -7.2 (52% sulfuric acid) is

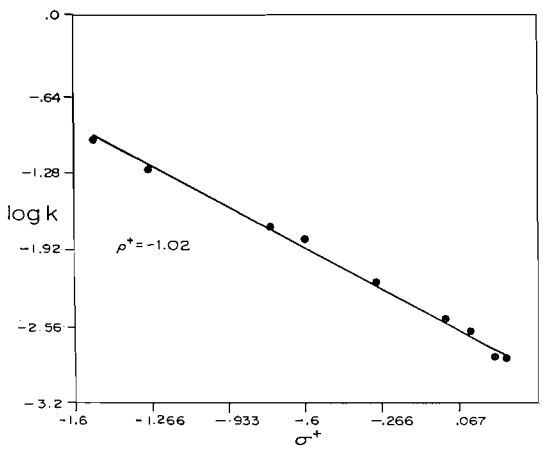


FIG. 8. The effect of substituents on the rate of the permanganate oxidation of diarylcarbinols, $H_0 = -0.81$; correlation coefficient, 0.998.

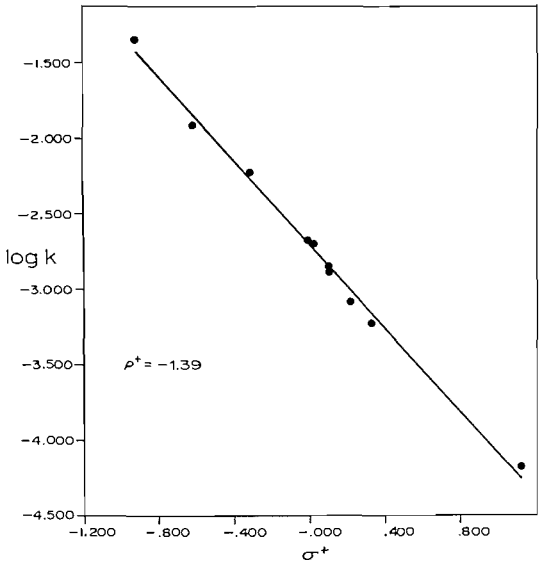

FIG. 9. The effect of substituents on the rate of the permanganate oxidation of triarylcarbinols, $H_0 = -0.65$; correlation coefficient, 0.998.

probably caused by formation of the powerful oxidant, permanganic acid, which is half-ionized in 61% sulfuric acid (5).

In the case of triphenylcarbinol the activation parameters for the oxidation at an H_0 of -1.00 are $\Delta H\dagger = 17.2$ kcal/mole and $\Delta S\dagger = 11.7$ e.u. The temperature range over which these measurements were conducted was 15–40°.

Chromic acid oxidation of aromatic alcohols[1]

ROSS STEWART AND FARIZA BANOO[2]
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

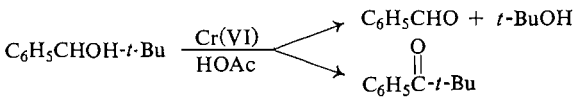
Received March 13, 1969

The mechanism of the chromic acid oxidation of di- and tri-aryl carbinols has been studied in 80 wt% acetic acid containing sulfuric acid. The reactions are cleanly second-order and give benzophenones in the case of the secondary alcohols and benzophenones plus phenols in the case of the tertiary alcohols. Electron-donating substituents in the tertiary alcohol appear predominantly in the phenol component and the rate-controlling step is believed to be a 1,2-aryl shift. The reaction constant for the migration is $\rho^+ = -1.44$ and that for the overall reaction is $\rho^+ = -0.879$. The presence of manganous ions does not alter these values although it lowers the overall rate of reaction. Although an analogous 1,2-hydride shift mechanism can be written for the oxidation of the secondary alcohols, there are enough points of difference between the oxidations of the secondary and tertiary systems to make this appear unlikely.

Canadian Journal of Chemistry, 47, 3207 (1969)

Introduction

The chromic acid oxidation of primary and secondary alcohols has been very extensively studied and is believed by most workers in the field to proceed via a chromate ester whose decomposition may proceed either by proton loss to the solvent or by an internal hydrogen shift (1–4). Tertiary alcohols which can be dehydrated to alkenes often suffer oxidation via the alkenes. Those which cannot be dehydrated undergo oxidative cleavage, triphenylcarbinol producing benzophenone. Bartlett and Cotman (5) showed that *p*-nitrotriphenylcarbinol gives *p*-nitrobenzophenone and they considered the reaction pathway to involve rearrangement of a phenyl group to electron deficient oxygen. Cleavage products also appear in the case of the secondary alcohol, phenyl *t*-butyl carbinol (6, 7) which gives a 60–70% yield of benzaldehyde and *t*-butyl alcohol, phenyl *t*-butyl ketone being the minor product.



The cleavage reaction can be virtually eliminated, however, by the addition of manganous or cerous ions to the system. These ions scavenge chromium(IV) and chromium(V) intermediates (1, 6–8) and it is clear that the cleavage is not caused by chromium(VI).

In order to learn more about the mode of the chromic acid cleavage of tertiary aromatic alcohols we have examined the reaction kinetics, the effect of substituents, and the product distribution in a series of triarylcarbinols. A similar study of an analogous series of diarylcarbinols was made for the purposes of comparison.

Experimental

The preparation of the alcohols is described elsewhere (9*a*). The reaction rates were followed spectrophotometrically, essentially as previouly described (9*b*). A 3:2 ratio of alcohol to Cr(VI) was used for the secondary alcohols. Because of the lower acidities used with the tertiary alcohols and because of the production of phenol, which is subject to some degradation, a considerable excess of tertiary alcohol was used and the second-order rate constants obtained by correction. The extinction coefficient of Cr(VI) at 350 mμ is 3.33×10^3 whereas that of $(C_6H_5)_3C^+$ at the same wavelength is 1.03×10^2; hence the change of concentration of $(C_6H_5)_3C^+$ (and the other triaryl cations) will have only a small effect on the decrease in absorbance at 350 mμ. In a typical run, 10 μl of 0.14 *M* potassium dichromate was added by syringe to 2 ml of a solution made by mixing 80 wt% acetic acid and the required quantity of 99.9% sulfuric acid and containing 2.3×10^{-3} *M* benzhydrol.

Product Analysis

The secondary alcohols gave nearly quantitative yields of ketones. In the case of 4-methylbenzhydrol a yield of 96.4% of ketone was obtained and the small amount of oily residue showed no absorption bands characteristic of benzaldehyde, the product that would be formed if aryl migration occurred instead of hydrogen loss.

With the tertiary alcohols a weighed quantity (0.001 mole) of the carbinol under investigation was dissolved in 85 ml of 80 wt% aqueous acetic acid and 15 ml of 99.9% sulfuric acid was added slowly and with stirring. This gave a solution containing approximately 23% sulfuric acid. Next, 0.10 g potassium dichromate (a slight excess) dissolved in 3 ml of 80 wt% acetic acid in water

containing 0.5 ml of 99.9% sulfuric acid was added. After standing for several days the mixture was diluted with water and extracted several times with ligroin. The extract was treated with dilute sodium bicarbonate solution to remove acid and then with 10% sodium hydroxide solution to remove the phenols. The ligroin extract was evaporated to dryness and the infrared (i.r.) spectrum of the residue was taken. The residue was then dissolved in a measured quantity of ether and the ether solution was analyzed by vapor-phase chromatography (v.p.c.). The exact quantities of each component of the products were determined by measuring the areas of the peaks and comparing them with those obtained from known quantities of the corresponding compounds.

The alkali washings of the ligroin extract were acidified with dilute hydrochloric acid and extracted with ether. The ether extract was analyzed for phenols by preparing the corresponding bromo-derivatives.

Acidity Functions

The solvent used for the oxidations and for the acidity function determinations was made by adding a known weight of 80 wt% aqueous acetic acid (80 g acetic acid and 20 g water) to a given weight of 99.99% sulfuric acid. The concentrations are expressed as wt% sulfuric acid and refer to that % of the solution weight that is contributed by the sulfuric acid. (A consequence of this procedure is that the % of acetic acid in the system varies somewhat as the sulfuric acid concentration changes.)

The H_0 and H_R values were determined by standard techniques using previously established values of pK_{BH}^+ and pK_R^+ of the indicators (10, 11). The results are given in Table II.

Results and Discussion

Acidity Dependence

As with other alcohol–chromic acid systems that have been examined the kinetics are cleanly second-order, first-order in each of the alcohol and oxidant. (In the case of the tertiary alcohols deviations were apparent beyond 60% reaction; this is presumably due to some degradation of the phenol produced in the reaction.) The acid-catalysis of the oxidation of benzhydrol was similar to that found previously with isopropyl alcohol (9) i.e. a linear relation of unit slope between log k and H_0 up to an H_0 of approximately −1, fol-

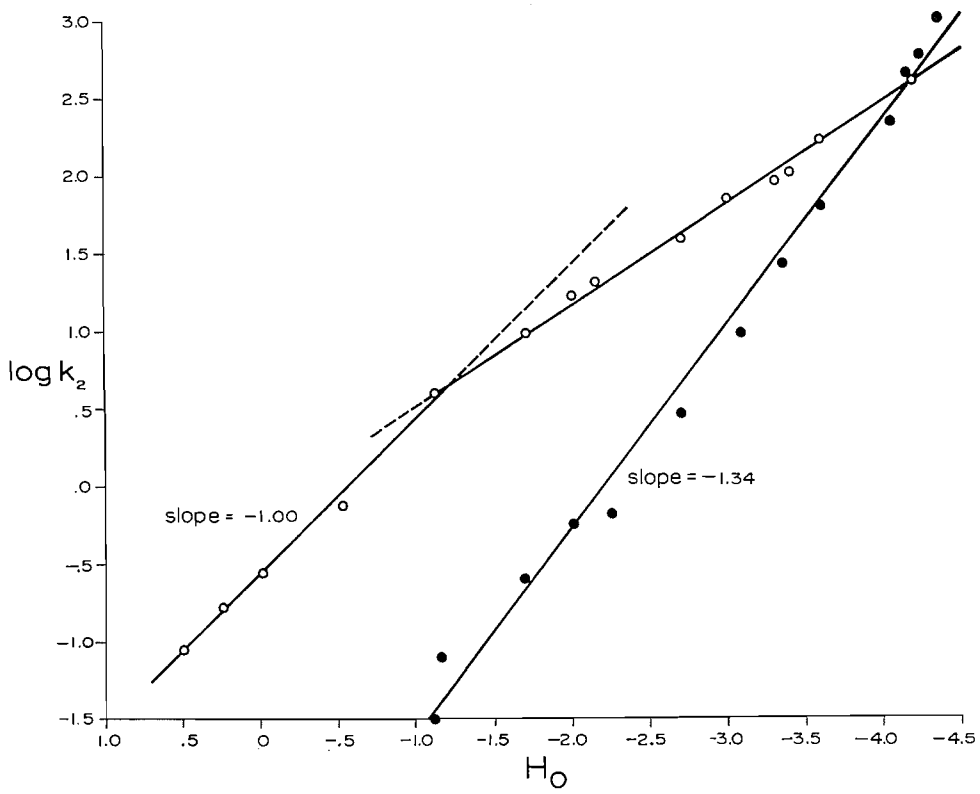

FIG. 1. Effect of acidity on the rate of the chromic acid oxidation of diphenylcarbinol (open circles) and triphenylcarbinol (closed circles).

lowed by a more gradual increase in rate as the acidity of the solution was increased (Fig. 1). The source of this effect, which is believed to be connected with ligand substitution on chromium, has been discussed previously (9). Curiously enough this effect is not present in the case of the tertiary alcohol, triphenylcarbinol. Indeed, the greater dependence of rate on acidity in this case causes the tertiary alcohol to be oxidized faster than the secondary alcohol at high acidities. (When H_R is used instead of H_0 a somewhat better straight line of slope -0.92 is obtained for triphenyl carbinol.)

Substituent Effects

Analysis of products showed that both the secondary and tertiary alcohols produced high yields of ketones, with phenols also being formed in the latter case. The cleavage which occurs with the tertiary alcohols produces mixtures of products when substituted triarylcarbinols are used and Table I gives the distribution of these products with various substituents. The tendency for electron-withdrawing substituents to be retained in the ketone, which is clearly apparent from the results in the table, suggests that a 1,2-shift to an electron-deficient atom is occurring in agreement with the early suggestion of Bartlett and Cotman (5). (In contrast, homolytic rearrangements of these systems have quite different migration aptitudes (5, 12).) On this basis the migration aptitudes for the various rings were calculated, with appropriate statistical corrections being made, and the results are given in Table III and plotted against σ^+ (13) in Fig. 2. The ρ^+ value for migration is -1.44 and this was not affected appreciably by the addition of manganous ions.

The effect of substituents on the overall rate of oxidation of diarylcarbinols is similar to that found with other secondary alcohols except that the reaction constant is lower, being -0.54 (Fig. 3). In the case of the tertiary alcohols the effect of substituents was best correlated with σ^+ (Fig. 4). The reaction constant for the oxidation, ρ^+, was found to be -0.879. In the presence of added

†Compound F gave a value of 0.34.

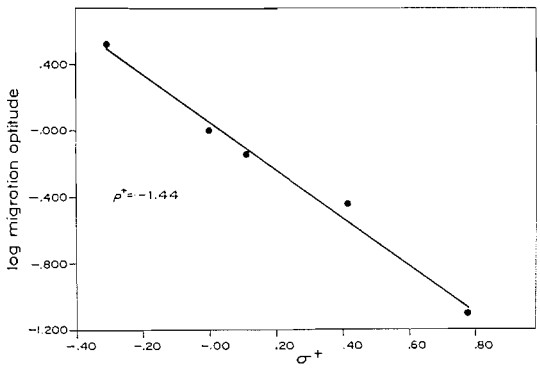

FIG. 2. Effect of substituents on the migration aptitude of aryl rings in the chromic acid oxidation of triarylcarbinols.

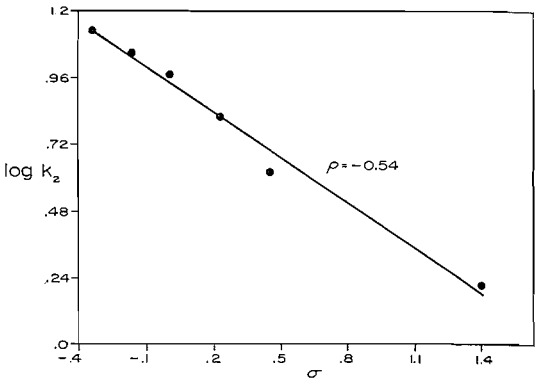

FIG. 3. Effect of substituents on the rate of the chromic acid oxidation of diarylcarbinols in 80 wt% aqueous acetic acid at 25°, $H_0 = -1.70$, correlation coefficient, 0.993. Substituents are from upper left to lower right: 4,4′-dimethyl, 4-methyl, none, 4-chloro, 4,4′-dichloro, 2,4,6,2′,4′,6′-hexamethyl. The latter's σ was calculated using the pK_{HA} of mesitoic acid.

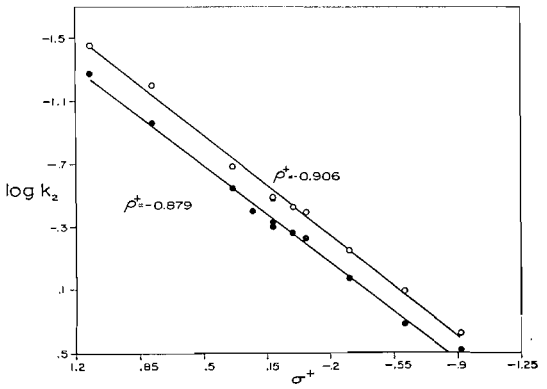

FIG. 4. Effect of substituents on the rate of the chromic acid oxidation of triarylcarbinols. Open circles, manganous ion present; closed circles, manganous ion absent.

manganous ions, an almost uniform reduction in rate was observed for all the tertiary alcohols (Table IV), the ρ^+ value, −0.906, being almost identical with that found in the absence of manganous ions. The cleavage reaction, which evidently occurs via a 1,2-shift of an aryl group, thus takes place in the same way whether chromium(VI) or chromium ions of intermediate valence are the active oxidants.

Mechanism

The mechanism of the chromium(VI) oxidation of triarylcarbinols to substituted benzophenones and phenols can be written as follows

$$Ar_3COH + H_2CrO_4 + H^+ \rightleftarrows Ar_3C{-}O{-}CrO_3H_2^+ + H_2O$$

$$Ar_3C{-}O{-}CrO_3H_2^+ \rightarrow \left[Ar_2C\overset{\delta+}{\underset{Ar}{\cdots}}O\cdots CrO_3H_2^{\delta+}\right] \rightarrow Ar_2C{=}\overset{+}{O}{-}Ar + H_2CrO_3$$

transition state

$$Ar_2C{=}\overset{+}{O}{-}Ar + H_2O \rightarrow Ar_2C{=}O + ArOH + H^+$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The effects of substituents and acidity on the rate of the oxidation are in agreement with the above path. Preferential migration of rings containing electron-donating substituents is expected and is found, although the influence of substituents on migration aptitude[3] is somewhat smaller than that found in the analogous acid-catalyzed rearrangement of triarylmethyl hydroperoxides (14)

$$Ar_3C{-}O{-}OH + H^+ \rightleftarrows Ar_3C{-}O{-}\overset{+}{O}H_2 \rightarrow$$
$$Ar_2C{=}\overset{+}{O}Ar + H_2O \rightarrow Ar_2C{=}O + ArOH + H^+$$

The possibility that secondary and primary alcohols are oxidized by a similar mechanism, i.e. a 1,2-hydride shift to give the conjugate acid of benzophenone, should be considered. Such shifts occur with ease in many other systems (15).

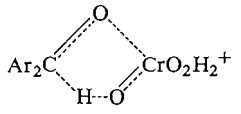
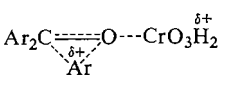
Over most of the acidity range examined, benzhydrol is oxidized considerably faster than triphenylcarbinol and if the two pre-equilibrium steps are comparable, this would require a hydride shift to be faster than a phenyl shift. There is evidence that this order prevails in some, though not all, 1,2-shifts (15). On the whole, however, the weight of evidence is against a 1,2-hydride shift mechanism. First, a careful examination of the products of the oxidation of 4-methylbenzhydrol revealed no trace of 4-methylphenol. It seems unlikely that a hydride shift would be that much more facile than a 4-methylphenyl shift. (It was not possible to study alkoxybenzhydrols under the same conditions as were used for the other carbinols because complex formation between the alkoxy group and chromium(VI) occurs.) Second, the dependence of the oxidation rate on acidity is sufficiently different for secondary and tertiary aromatic alcohols (Fig. 1) as to suggest different reaction paths. (The effect of substituents also shows an important difference—the secondary alcohols follow ρ and the tertiary alcohols follow ρ^+—but this may simply be due to the participation of the substituent in the migrating ring in the latter case.) Third, the activation parameters are rather different for the chromic acid oxidation of the two kinds of alcohol. At an H_R of -3.95, the activation parameters for the oxidation of triphenylcarbinol are $\Delta H\dagger = 11.8$ kcal mole^{-1} and $\Delta S\dagger = -25.1$ e.u., whereas for benzhydrol at $H_R = -2.62$ the values are $\Delta H\dagger = 5.9$ kcal mole^{-1} and $\Delta S\dagger = -37.1$ e.u. (The weight to be attached to this factor is uncertain since significant variations in these quantities can occur even with secondary alcohols (16).)

We conclude that tertiary aromatic alcohols are oxidized by means of a 1,2-aryl shift (5) but that primary and secondary alcohols undergo some other form of carbon–hydrogen bond rupture involving, we would suggest, the 5-membered transition state that has been previously favored (2, 3, 17). The two transition states are shown below



2° alcohol



3° alcohol

[3]A referee has made the interesting suggestion that the higher ρ^+ for migration than for reaction may be due to partial equilibration of bridged ions after the rate-controlling step.

Large heterocyclic rings from carbohydrate precursors

J. F. STODDART, W. A. SZAREK, AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received April 2, 1969

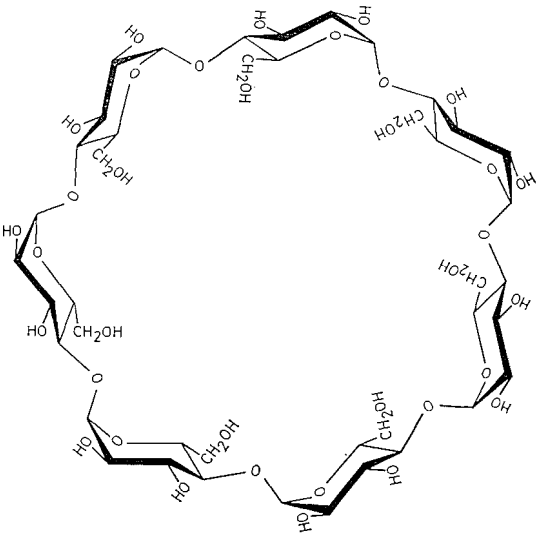
Periodate oxidation of cycloheptaamylose and cyclohexaamylose, followed by borohydride reduction and acetylation, yields 2*s*,4*S*,5*R*,7*s*,9*S*,10*R*,12*s*,14*S*,15*R*,17*s*,19*S*,20*R*,22*s*,24*S*,25*R*,27*s*,29*S*,30*R*,32*s*,34*S*,-35*R*-heneicosaacetoxymethyl-1,3,6,8,11,13,16,18,21,23,26,28,31,33-tetradecaoxacyclopentatriacontane (**2**) and 2*s*,4*S*,5*R*,7*s*,9*S*,10*R*,12*s*,14*S*,15*R*,17*s*,19*S*,20*R*,22*s*,24*S*,25*R*,27*s*,29*S*,30*R*-octadecaacetoxymethyl-1,3,6,8,11,13,16,18,21,23,26,28-dodecaoxacyclotriacontane (**5**), respectively. Both molecules are achiral.

L'oxydation périodique du cycloheptaamylose et du cyclohexaamylose, suivie de réduction au borohydrure, puis d'acétylation, conduit respectivement au 2*s*,4*S*,5*R*,7*s*,9*S*,10*R*,12*s*,14*S*,15*R*,17*s*,19*S*,20*R*,-22*s*,24*S*,25*R*,27*s*,29*S*,30*R*,32*s*,34*S*,35*R*-heneicosaacetoxymethyl-1,3,6,8,11,13,16,18,21,23,26,28,31,33-tetradecaoxacyclopentatriacontane (**2**) et au 2*s*,4*S*,5*R*,7*s*,9*S*,10*R*,12*s*,14*S*,15*R*,17*s*,19*S*,20*R*,22*s*,24*S*,25*R*,-27*s*,29*S*,30*R*-octadecaacetoxymethyl-1,3,6,8,11,13,16,18,21,23,26,28-dodecaoxacyclotriacontane (**5**). Ces deux molécules sont achirales.

Canadian Journal of Chemistry, 47, 3213 (1969)

Recently, it has been shown (1) that periodate oxidation of di-β-D-ribofuranose 1,5′:1′,5-dianhydride (1–5), followed by borohydride reduction and acetylation yields 2*R*,4*S*,7*R*,9*S*-tetraacetoxymethyl-1,3,6,8-tetraoxacyclodecane. During this investigation, it was appreciated that the same sequence of reactions employed on the Schardinger dextrins (6)[1] would provide a route to the synthesis of large heterocyclic rings.

When cycloheptaamylose (**1**) was subjected to periodate oxidation (7), followed by borohydride reduction and acetylation (1, 8), a crystalline compound was obtained in 11% yield. The expected product from this reaction sequence is a cyclic acetal (**2**) with 14 oxygen atoms and 21 carbon atoms in a 35-membered ring. Examination of the symmetry properties of **2** shows that it has seven σ planes which intersect at a C_7 axis. Thus, the molecule belongs to point group $\mathbf{C}_{7v}$ and is achiral. The observation that the crystalline compound is optically inactive suggests that it is indeed 2*s*,4*S*,5*R*,7*s*,9*S*,-10*R*,12*s*,14*S*,15*R*,17*s*,19*S*,20*R*,22*s*,24*S*,25*R*,27*s*,-29*S*,30*R*,32*s*,34*S*,35*R*-heneicosaacetoxymethyl-1,3,6,8,11,13,16,18,21,23,26,28,31,33-tetradecaoxacyclopentatriacontane (**2**). In addition, elemental analysis, acetyl content, molecular weight, and infrared (i.r.) and proton magnetic resonance (p.m.r.) spectral data are all consistent



1

with this structural formulation. A low field 7-proton triplet in the p.m.r. spectrum between τ 4.63–5.04 (*J* 4.0 Hz) was assigned to the equivalent acetal protons at C-2,7,12,17,22,27, and 32. De-*O*-acetylation of **2** yielded 2*s*,4*S*,5*R*,7*s*,9*S*,-10*R*,12*s*,14*S*,15*R*,17*s*,19*S*,20*R*,22*s*,24*S*,25*R*,27*s*,-29*S*,30*R*,32*s*,34*S*,35*R*-heneicosahydroxymethyl-1,3,6,8,11,13,16,18,21,23,26,28,31,33-tetradecaoxacyclopentatriacontane (**3**), which was also optically inactive and gave a satisfactory elemental analysis. Mild acid hydrolysis of **3**, followed by

[1]The Schardinger dextrins provide additional examples (11) of molecules having $\mathbf{C}_n$ symmetry of an order higher than two. For example, cyclohexaamylose and cycloheptaamylose belong to point groups $\mathbf{C}_6$ and $\mathbf{C}_7$, respectively.

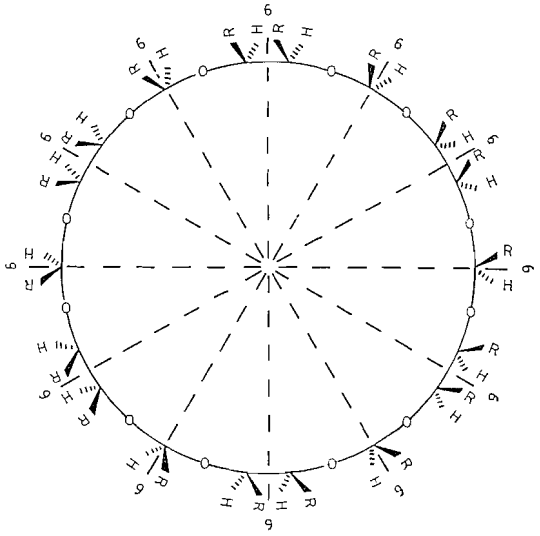
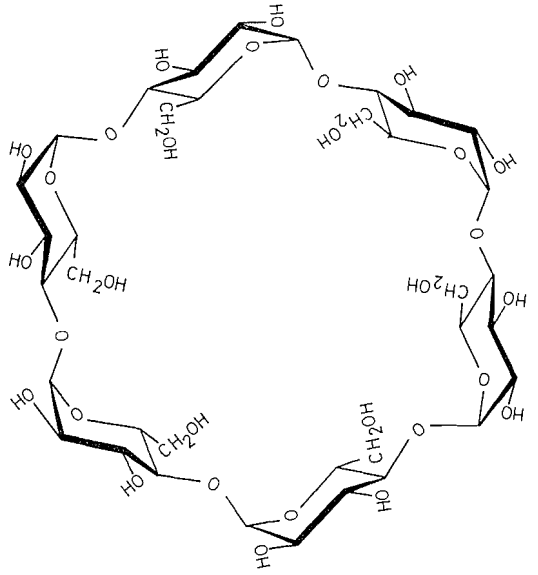
3 R = CH_2OH



5 R = CH_2OAc



4

borohydride reduction of the products gave erythritol and ethylene glycol.

Examination of the symmetry properties of the cyclic acetal (**5**) with 12 oxygen atoms and 18 carbon atoms in a 30-membered ring, obtained after borohydride reduction and acetylation of periodate-oxidized (7) cyclohexaamylose (**4**), shows that it has six σ planes which intersect at a C_6 axis (point group $\mathbf{C}_{6v}$) and is therefore achiral. Indeed, the crystalline product (**5**) is optically inactive. All other physical and analytical data are consistent with the formulation of the structure as 2*s*,4*S*,5*R*,7*s*,9*S*,10*R*,12*s*,14*S*,15*R*,17*s*, 19*S*, 20*R*, 22*s*, 24*S*, 25*R*, 27*s*, 29*S*, 30*R*-octadecaacetoxymethyl-1,3,6,8,11,13,16,18,21,23,26,28-dodecaoxacyclotriacontane (**5**).

Experimental

Melting points are uncorrected and were determined with a Fisher–Johns apparatus. Optical rotations were measured using a Perkin–Elmer model 141 automatic polarimeter at 23 ± 2°. Molecular weights were determined in chloroform using a Mechrolab vapor pressure osmometer model 301A. Solvent calibration (9) was achieved using tetra-*O*-acetyl-β-D-ribofuranose 1,5′:1′,5-dianhydride (mol. wt. 432) (1–5) and tetra-*O*-benzoyl-β-D-ribofuranose 1,5′:1′,5-dianhydride (mol. wt. 681).[2] Paper chromatography was carried out on Whatman No. 1 paper using the following solvent systems (v/v):

[2]The tetrabenzoate was prepared[3] from di-β-D-ribofuranose 1,5′:1′,5-dianhydride in the usual manner. Recrystallization from ethanol yielded needle-shaped crystals, m.p. 219–220°, $[\alpha]_D$ +12.0° (*c*, 1.12 in chloroform). Elemental analysis and i.r. and p.m.r. spectroscopic data were consistent with the compound being tetra-*O*-benzoyl-β-D-ribofuranose 1,5′:1′,5-dianhydride.

(*a*) benzene – butan-1-ol–pyridine–water (1:5:3:3, upper layer); (*b*) butan-1-ol–ethanol – water (4:1:5, upper layer). Sugars were detected with the periodate–permanganate spray reagent (10). Thin-layer chromatography (t.l.c.) was carried out on glass microplates (40 × 90 mm) coated with silica gel (Camag) using the following solvent systems (v/v): (*c*) chloroform – methanol (19:1); (*d*) ethyl acetate – petroleum ether (b.p. 60–80°) (1:1). The developed plates were air-dried and heated at about 150°. Infrared spectra were recorded on a Beckman-IR5A spectrophotometer. Proton magnetic resonance spectra were measured at 60 MHz in chloroform-*d* with tetramethylsilane (τ 10.00) as internal standard.

2s,4S,5R,7s,9S,10R,12s,14S,15R,17s,19S,20R,22s,24S,-25R,27s,29S,30R,32s,34S,35R-Heneicosaacetoxymethyl-1,3,6,8,11,13,16,18,21,23,26,28,31,33-tetradecaoxacyclopentatriacontane (2)

Cycloheptaamylose (**1**) (4 g) was dissolved in water (125 ml) and a solution of sodium metaperiodate (5.8 g) in water (125 ml) was added. The reaction mixture was allowed to stand at 26° for 60 h. After excess of periodate and iodate had been precipitated by addition of a 10% aqueous barium chloride solution, sodium borohydride (2 g) was added to the filtered solution and the reaction mixture was allowed to stand at 26°. After 48 h, excess of borohydride was destroyed by addition of dry ice and the solution was concentrated to dryness. The residue was extracted twice (200 ml and then 100 ml) with boiling ethanol and the combined extracts were concentrated to a syrup, which was acetylated in the usual manner with acetic anhydride (60 ml) and pyridine (60 ml). After 18 h, the acetylation mixture was poured into ice water (1000 ml) and allowed to stand for 1 h before being extracted several times with chloroform. The chloroform extracts were combined, washed with water, dried over anhydrous sodium sulfate, filtered, and the filtrate concentrated to a syrup, which migrated as one spot on t.l.c. in solvents (*c*) and (*d*). On addition of ethanol, the syrup crystallized. Recrystallization from the same solvent yielded needle-shaped crystals of the title compound (**2**) (813 mg, 11%), m.p. 106–109°, $[\alpha]_D$ 0 ± 1° (*c*, 2.0 in chloroform); λ_{max} (Nujol) 5.75 μm (OAc), no absorption attributable to OH; p.m.r. data: τ 4.63–5.04 (7-proton triplet, *J* 4.0 Hz, H-2,7,12,17,22,27,32), τ 7.64–8.04 (63-proton multiplet, OAc groups on C-2,4,5,7,9,-10,12,14,15,17,19,20,22,24,25,27,29,30,32,34,35).

Anal. Calcd. for $C_{84}H_{126}O_{56}$ (mol. wt. 2032): C, 49.65; H, 6.25; CH_3CO, 43.2. Found (mol. wt. 2000 ± 50): C, 49.37; H, 6.19; CH_3CO, 42.6.

2s,4S,5R,7s,9S,10R,12s,14S,15R,17s,19S,20R,22s,24S,-25R,27s,29S,30R,32s,34S,35R-Heneicosahydroxymethyl-1,3,6,8,11,13,16,18,21,23,26,28,31,33-tetradecaoxacyclopentatriacontane (3)

The heneicosaacetate (**2**) (500 mg) was dissolved in chloroform (25 ml) and methanol (25 ml), and 2 drops of a 7% solution of sodium methoxide were added. The de-*O*-acetylation was followed by t.l.c. in solvent (*c*) and was complete after 3 h. Dry ice was added to the reaction mixture, the solution was filtered, and the filtrate was concentrated to a crystalline product. Recrystallization from ethanol yielded the title compound (**3**) (230 mg, 81%), m.p. 125–132°, $[\alpha]_D$ 0 ± 1° (**c**, 2.0 in water); λ_{max} (Nujol) 2.75–4.25 μm (OH), no absorption attributable to OAc.

Anal. Calcd. for $C_{42}H_{84}O_{35}$: C, 43.9; H, 7.37. Found: C, 43.5; H, 7.24.

The heneicosaalcohol (**3**) (50 mg) was hydrolyzed with 0.1 *N* sulfuric acid (20 ml) on a steam bath for 6 h. The cooled solution was neutralized with barium carbonate, filtered, and allowed to stand for 36 h after addition of sodium borohydride (50 mg). Excess of borohydride was destroyed by treatment with Amberlite IR-120 (H form) resin, followed by filtration, and concentration of the filtrate to a syrup after removal of borate ions as methyl borate. Paper chromatographic examination of the syrup in solvents (*a*) and (*b*) indicated the presence of erythritol and ethylene glycol. No glucose was detected.

2s,4S,5R,7s,9S,10R,12s,14S,15R,17s,19S,20R,22s,24S,-25R,27s,29S,30R-Octadecaacetoxymethyl-1,3,6,8,-11,13,16,18,21,23,26,28-dodecaoxacyclotriacontane (5)

Cyclohexaamylose (**4**) (2.84 g) was subjected to the same sequence of reactions as described for cycloheptaamylose (**1**) to yield the title compound (**5**) (35 mg, 0.6%), m.p. 162–164°, $[\alpha]_D$ 0 ± 1° (*c*, 2.0 in chloroform); λ_{max} (Nujol) 5.75 μm (OAc), no absorption attributable to OH; p.m.r. data: τ 4.65–5.03 (6-proton triplet, *J* 4.5 Hz, H-2,7,12,17,22,27), τ 7.70–8.06 (54-proton multiplet, OAc groups on C-2,4,5,7,9,10,12,14,15,17,19,20,22,24,-25,27,29,30).

Anal. Calcd. for $C_{72}H_{108}O_{48}$ (mol. wt. 1742): C, 49.65; H, 6.25; CH_3CO, 43.2. Found (mol. wt. 1760 ± 40): C, 49.26; H, 6.22; CH_3CO, 43.2.

Acknowledgments

These investigations were supported by grants from the National Research Council of Canada. The authors wish to express their thanks to Dr. D. French of Iowa State University for providing a sample of cycloheptaamylose and to Dr. A. G. Harrison of the University of Toronto for his attempts to obtain mass spectrometric data for **2**.

Study of the exchange rates of ethanol and water on ferriprotoporphyrin IX by n.m.r. line broadening

N. S. ANGERMAN, B. B. HASINOFF, H. B. DUNFORD, AND R. B. JORDAN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received January 6, 1969

The nuclear magnetic resonance (n.m.r.) line broadening technique has been used to determine the rate of solvent exchange from the first coordination sphere of ferriprotoporphyrin IX (hemin) in aqueous ethanol. The line broadenings of the methyl and methylene protons of ethanol and the water protons have been studied as a function of solvent composition at 35° and of temperature in 48.8 mole % ethanol.

The average values of the kinetic parameters for ethanol molecule exchange, taken from the CH_3 and CH_2 proton broadening are $\Delta H^{\ddagger} = 6.2 \pm 1.0$ kcal mole^{-1} and $\Delta S^{\ddagger} = -9.1 \pm 4.4$ cal mole^{-1} deg^{-1}. Both proton transfer and water molecule exchange contribute to the water proton line broadening with a net value of $\Delta H^{\ddagger} = 6.3 \pm 0.5$ kcal mole^{-1} and $\Delta S^{\ddagger} = -3.8 \pm 2.0$ cal mole^{-1} deg^{-1}.

From the n.m.r. study at varying solvent composition, it is concluded that monomeric and dimeric hemin undergo solvent exchange at the same rate. The equilibrium constant for formation of the mono-ethanol solvated hemin from hydroxyhemin is determined as 8.7 at 35° from this study.

A comparison of the rate of ethanol exchange (1.8×10^6 s^{-1} at 25°) and the rate of imidazole binding to hemin (from a separate temperature jump study) indicates that the imidazole substitution occurs through an S_N1 ion pair mechanism.

Canadian Journal of Chemistry, 47, 3217 (1969)

Introduction

Ferriprotoporphyrin IX (Fig. 1) is the prosthetic group of a number of heme proteins including hemoglobin, myoglobin, horseradish peroxidase and catalase. We shall henceforth use the simpler name hemin for ferriprotoporphyrin IX. Four of the coordination positions of iron(III) in hemin are occupied by the dianionic porphyrin ring so that there is a formal charge of +1 on the ferric ion. Because of the two propionate side chains the net charge on the molecule is −1. The remaining fifth and sixth coordination positions, which are *trans* to each other above and below the plane of the porphyrin ring, are occupied by solvent molecules. It should be noted that X-ray crystallographic studies (1) have shown that the iron atom (high spin) in porphyrins is above the plane of the four nitrogen atoms and is five coordinate. However the fact that dimidazole (2) and dipyridine (3, 4) complexes are formed by hemin indicates that in solution, the iron atom in hemin is best considered as six coordinate.

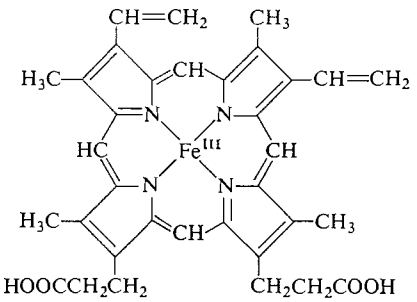

FIG. 1. Ferriprotoporphyrin IX or hemin.

It has been shown previously by Maehly and Akeson (5) that hemin exists as a dimer in aqueous solution. The same authors found that addition of ethanol causes the dimer to dissociate and that the complex is almost completely monomeric in 50 volume % ethanol. These observations have been confirmed by the polarographic study of Davis and Martin (4). Thus complications due to dimer formation may be avoided by working in ethanol – water solutions.

In connection with a recent temperature jump study (2) of the exchange rate of imidazole on hemin, it became of interest to study the linewidths of the solvent n.m.r. resonances as a function of solvent composition and temperature. The n.m.r. results may be used to characterize the solvated species and to determine the exchange rate of the solvent molecules from the paramagnetic iron center in hemin.

The ethanol – water solvent system has been used in this and the temperature jump work (2). The n.m.r. line broadenings of water and the methyl and methylene proton resonances of ethanol have been studied. The linewidths were observed as a function of solvent composition at 35° and the temperature dependence of the

line broadening was measured in 48.8 mole % ethanol between −40° and 70°. The results indicate that the monomer and dimer are kinetically indistinguishable, and the solvent exchange rates have been determined.

Experimental

In order to dissolve ferriprotoporphyrin IX (Eastman Organic Chemicals) it was necessary to wet the complex first with concentrated sodium hydroxide and then dilute the solution to the required volume and pH*[1]. The n.m.r. spectra were run on 5 samples in the concentration range $1.2_5 \times 10^{-3}$ to $5.0_0 \times 10^{-3}$ *M*. The line broadenings were found to vary linearly with the concentration of hemin. Shifts were measured from internal sodium 3-(trimethylsilyl)-1-propanesulfonate, (Eastman Organic Chemicals) which was dissolved at the minimum concentration for detection of the methyl resonance signal. The data were obtained at pH* 11, but it was found that the linewidths were independent of hydroxide ion concentration over the range 10^{-6} to 0.1 *M*.

The n.m.r. spectra were run on a Varian model A-56/60 spectrometer equipped with a standard variable temperature probe and temperature controller. All full linewidths at half height and chemical shifts were reproducible to ±2 Hz. A DuPont 310 curve resolver was used to separate the contribution of the water and ethanol to the hydroxy proton resonance.

Spectrophotometric measurements were made on a Cary Model 14 spectrophotometer equipped with variable temperature cell holders. The temperature was controlled to ±1° by rapidly flowing water from an external temperature bath.

Results

A spectrophotometric study was carried out to determine the monomer–dimer equilibrium constant. The extinction coefficients for the dimer and monomer were determined in a 1.0×10^{-5} *M* solution of hemin at 400 mμ at 5 and 64.8 mole % ethanol. The equilibrium constant K_1 for dimerization was then calculated from the spectrum in a 48.8 mole % ethanol solution (the solvent for the n.m.r. temperature study) containing 5×10^{-3} *M* hemin

$$[1] \qquad 2M \rightleftharpoons D$$

where M represents monomer and D represents dimer and $K_1 = [D]/[M]^2$. The values for K_1 at 25.0° and 34.8° are 25 and 34 M^{-1}. Therefore there is about 10% of the dimer present in the 48.8 mole % solution used in the n.m.r. temperature study. For the more dilute solutions used in the accompanying kinetic study, the dimer concentration is insignificant (2).

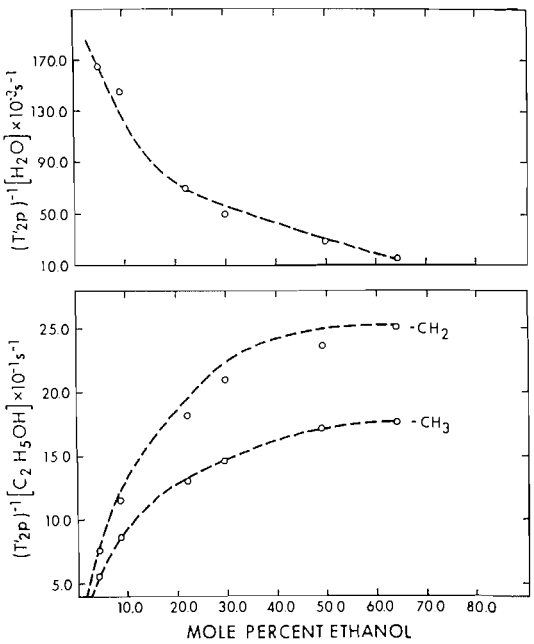

FIG. 2. Variation of solvent proton $(T_{2p'})^{-1}$ with solvent composition at 35°.

The results of a study of the n.m.r. linewidths at various ethanol concentrations at 35 °C are shown in Fig. 2. The full linewidths at half height of the line in the presence of hemin ($\Delta\nu_{obs}$) and in the pure solvent ($\Delta\nu_s$) are related to the transverse relaxation time, T_{2p} by

$$[2] \qquad (T_{2p'})^{-1} = \frac{(T_{2p})^{-1}}{[M]_T} = \frac{\pi(\Delta\nu_{obs} - \Delta\nu_s)}{[M]_T}$$

where $[M]_T$ is the total hemin concentration.

The full width at half height of the methyl proton resonance was determined from the center peak of the triplet, and that of the methylene protons from the average width of the two center peaks of the quartet. It is somewhat more difficult to analyze the hydroxy proton resonance because it consists of contributions from the water protons and the hydroxy proton of ethanol. To separate these two contributions, it was assumed that the peak due to the hydroxy proton on ethanol has an area corresponding to one proton and that it has the same width as the methylene proton resonance. The latter assumption is not necessarily valid but has little effect on the results,

[1]We use the term pH* as defined by Bates *et al.* (15) for a mixed solvent system.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

because of the small contribution of the hydroxy proton to the total signal.

In order to discuss the results in Fig. 2, it is necessary to anticipate the conclusions of the temperature study. From the latter study it is concluded that at 35° the relaxation time is given by limiting conditions [10*b*] and [10*d*] of Swift and Connick (6). Then

$$[3] \quad (T_{2p})^{-1} = P_m\{(T_{2m})^{-1} + \tau_m\Delta\omega_m{}^2\}$$

where P_m is the ratio of solvent bound to the metal ion to the free solvent concentration, τ_m is the lifetime of the solvent molecule in the first coordination sphere of the metal ion, T_{2m} is the transverse relaxation time of the protons in the first coordination sphere of the paramagnetic ion, and $\Delta\omega_m$ is the chemical shift of the same protons from their position in the bulk solvent. At 35° the $T_{2m}{}^{-1}$ term constitutes about 50 and 30% of $(T_{2p'})^{-1}$ for the methyl and methylene protons and about 30% of $(T_{2p'})^{-1}$ for the water protons. Therefore, the results in Fig. 2 might be interpreted qualitatively as being due to the change from dimer to monomer with a longer T_{2m} for ethanol protons in the dimer. However, the T_{2m} relaxation mechanism should be the same for both the water and alcohol protons and, therefore, a parallel change in T_{2mw} and T_{2ma} would be expected on going from monomer to dimer. The subscripts "w" and "a" refer to water and alcohol. Aside from these qualitative arguments, the monomer–dimer equilibrium constant K_1 may be calculated at 48.8 mole % ethanol using limiting values at 0 and 64 mole % ethanol. The values obtained are 2.12×10^{-2}, 3.90×10^{-2}, and 1.46 M^{-1} from the methyl, methylene, and water protons. These values for K_1 do not agree with the value of 34 M^{-1} obtained by the spectrophotometric method, nor with each other. Therefore, it is concluded that the dimer–monomer equilibrium is not the process causing the variation in linewidth shown in Fig. 2.

The curves in Fig. 2 may be explained by the replacement of water or hydroxide by ethanol or ethoxide in the first coordination sphere of the iron, as represented by eqs. [4] and [4*a*].

$$[4] \quad HOFe(OH_2) + C_2H_5OH \overset{K_4}{\rightleftharpoons} HOFe(C_2H_5OH) + H_2O$$

$$[4a] \quad HOFe(OH) + C_2H_5OH \rightleftharpoons HOFe(OC_2H_5) + H_2O$$

The subsequent treatment assumes that the monomer and dimer give the same n.m.r. line broadening per iron atom, at 35°. This assumption is consistent with the fact that the line broadening was directly dependent on the hemin concentration and gives internal consistency between the two studies in which solvent composition and temperature were varied. Therefore there is no justification for making further complicating assumptions. The apparent similarity in line broadening properties of monomer and dimer are most easily rationalized if dimerization involves hydrophobic bonding between the hemin ring systems or its substituents as proposed by Gallagher and Elliott (7). However it is not necessarily inconsistent with an oxide ion bridged dimer. In the latter case the above assumption requires that the electron spin relaxation times of the Fe and the solvent exchange rate are unaffected by changing the hydroxide ion ligand in $(HO)Fe(OH_2)$ for an $(H_2O)FeO$ ligand in the dimer $(H_2O)Fe—O—Fe(OH_2)$.

Consideration of the equilibrium properties of the system represented by eq. [4] or [4*a*] and [3] shows that

$$[5] \quad (T_{2p'})_a{}^{-1}[C_2H_5OH] = \frac{K_4[C_2H_5OH]}{[H_2O] + K_4[C_2H_5OH]} \times \{T_{2ma}{}^{-1} + \tau_{ma}\Delta\omega_{ma}{}^2\}$$

$$[6] \quad (T_{2p'})_w{}^{-1}[H_2O] = \frac{[H_2O]}{[H_2O] + K_4[C_2H_5OH]} \times \{T_{2mw}{}^{-1} + \tau_{mw}\Delta\omega_{mw}{}^2\}$$

Initially the $—CH_2—$ and CH_3 proton data in Fig. 2 will be considered. The value of τ_{ma} may or may not depend on the water and ethanol concentrations. If the latter condition holds then consideration of eq. [5] shows that a plot of $(T_{2p'})_a[C_2H_5OH]^{-1}$ vs. $[H_2O]/[C_2H_5OH]$ should be linear with an intercept of $(T_{2ma}{}^{-1} + \tau_{ma}\Delta\omega_{ma}{}^2)^{-1}$ and a slope of $[K_4(T_{2ma}{}^{-1} + \tau_{ma}\Delta\omega_{ma}{}^2)]^{-1}$. The value of $[T_{2ma}{}^{-1} + \tau_{ma}\Delta\omega_{ma}{}^2]$ can be determined from the temperature study in 48.8 mole % ethanol for comparison to the intercepts on Fig. 3. Also the values of K_4 obtained from the $—CH_2—$ protons should be

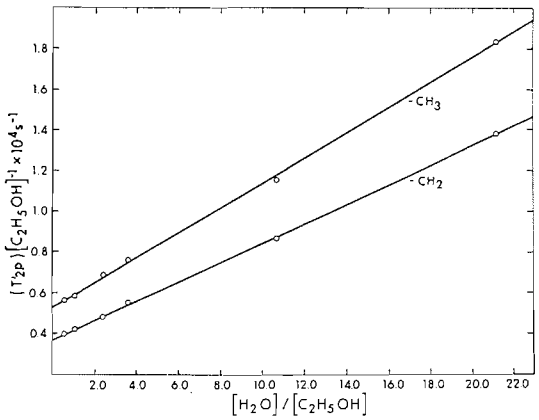

FIG. 3. Dependence of the transverse relaxation time of the methyl (—CH_3) and methylene (—CH_2—) ethanol protons on solvent composition; temperature 35°.

equal. Although these ideals are not completely achieved, the agreement is good. For the CH_3 protons the values of $[T_{2ma}^{-1} + \tau_{ma}\Delta\omega_{ma}^2]$ from the intercept of Fig. 3 and from the temperature study are 1.89×10^4 and 1.75×10^4 s^{-1}. The value of K_4 from Fig. 3 is 8.7_5. The analogous values for the —CH_2— protons are 2.7×10^4, 2.4×10^4 s^{-1}, and 7.7_9 respectively[2]. It should be pointed out that for the methyl protons $\tau_{ma}\Delta\omega_{ma}^2$ is 6.40×10^3 s^{-1} compared to T_{2ma}^{-1} of 11.1×10^3 s^{-1}. Therefore the $\tau_{ma}\Delta\omega_{ma}^2$ term is contributing significantly to the sum. The observed discrepancies between the temperature study and solvent variation study are within the errors of the temperature study values (see Table II). It is concluded that τ_{ma} is zero-order in ethanol and water concentrations.

A similar analysis may be made of the water proton data in Fig. 2. Equation [6] indicates that a plot of $(T_{2p'})_w[H_2O]^{-1}$ vs. $[C_2H_5OH]/[H_2O]$ should be linear with the intercept and slope yielding values analogous to those for the ethanol protons. However, in this case the plot is not linear. This result might be expected from examination of Fig. 2 because the water line broadening does not decrease to zero as predicted if τ_{mw} is independent of water concentration, but rather seems to level off at the high ethanol concentrations. It is found empirically that the water broadening data may be represented by

$$[7] \quad (T_{2p'})_w^{-1}[H_2O] = \frac{[H_2O]}{[H_2O] + K_4[C_2H_5OH]} \times \left\{T_{2mw}^{-1} + \frac{1.50 \times 10^{-6}}{13.5 + [H_2O]}\Delta\omega_{mw}^2\right\}$$

using the values for T_{2mw}^{-1} and $\Delta\omega_{mw}$ of 1.90×10^5 s^{-1} and 1.34×10^6 radians s^{-1}, as obtained from the temperature study in 48.8 mole % ethanol. The observed and calculated results are compared in Table I. It should be noted that a considerable range of values around 13.5 in eq. [7] would still give a reasonable fit to the experimental data.

TABLE I

Water proton relaxation time as a function of solvent composition at 35°

4.5	1.65	1.65
8.6	1.47	1.30
21.8	0.70	0.68
29.5	0.50	0.56
48.8	0.29	0.31
64.0	0.15	0.15

*Calculated from eq. [7] using K_4, 8.7; $(T_{2mw})^{-1}$, 1.90×10^5 s^{-1}; $\Delta\omega_{mw}$, 1.34×10^6 radians s^{-1}.

†The molar ethanol concentrations for the solvent compositions listed in the order shown in the table are 2.28; 4.03; 8.22; 9.93; 13.1, and 14.7. The corresponding water molarities are 48.3; 42.8; 29.4; 23.7; 13.9, and 8.3.

The variation of $(T_{2p'})^{-1}$ with temperature for the water and ethanol protons is shown in Figs. 4 and 5, respectively. The kinetic parameters for this system were determined by fitting the data in Figs. 4 and 5 to the general eq. [8] developed by Swift and Connick (6), using a non-linear least squares computer program (IBM SHARE Library, 1964 Program SDA 3094).

$$[8] \quad (T_{2p})^{-1} = \frac{P_m}{\tau_m}\left\{\frac{(T_{2m}\tau_m)^{-1} + T_{2m}^{-2} + \Delta\omega_m^2}{[T_{2m}^{-1} + \tau_m^{-1}]^2 + \Delta\omega_m^2}\right\}$$

In treating the temperature dependence of $(T_{2p})^{-1}$ it was assumed that τ_m^{-1} was represented by the usual transition state theory expression. The temperature dependence of $\Delta\omega_m$ and its

[2]In the subsequent analysis a somewhat arbitrary value of 8.7 has been used for K_4, giving more weight to the methyl proton value since these data seem in better agreement with the temperature study.

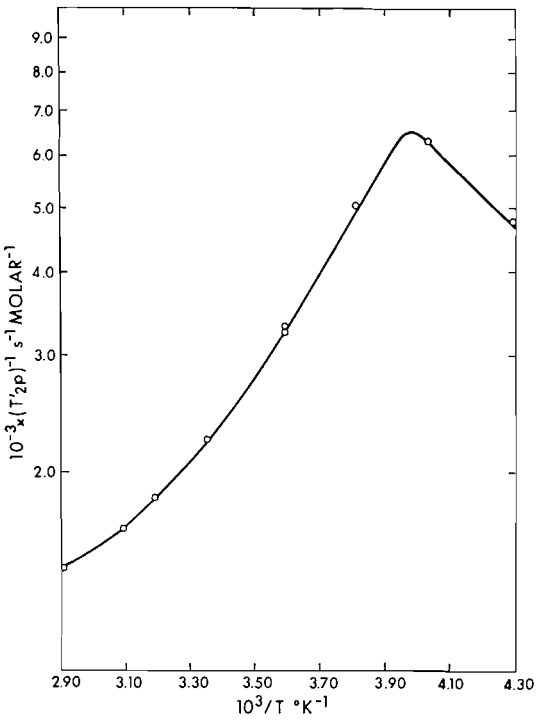

FIG. 4. Dependence of $-\log (P_m T_{2p'})$ for water protons on the reciprocal of the absolute temperature for solutions of hemin in 48.8 mole % ethanol.

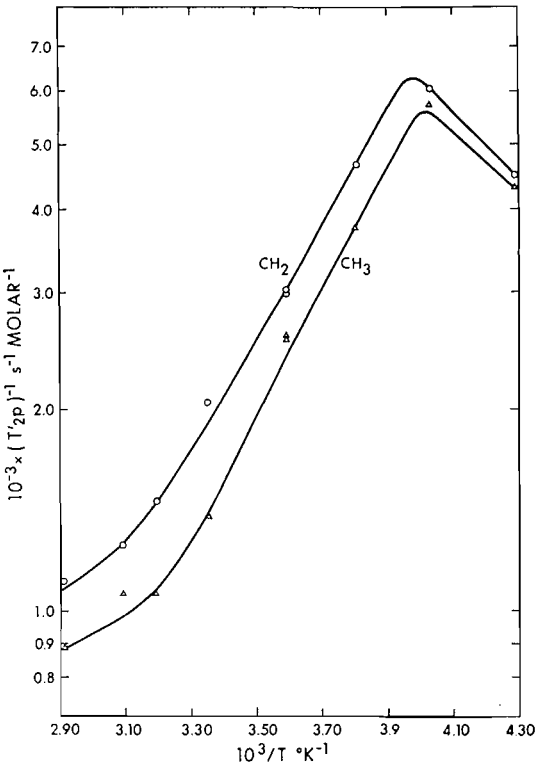

FIG. 5. Dependence of $-\log (P_m T_{2p'})$ on the reciprocal of the absolute temperature for the methyl and methylene protons of solvent ethanol in solutions of hemin in 48.8 mole % ethanol.

relationship to the hyperfine coupling constant are given by eq. [9].

$$[9] \qquad \Delta\omega_m = \frac{\omega_o(S)(S+1)(A/h)h\gamma_e}{3kT\gamma_I}$$

where ω_o is the operating frequency, h is Planck's constant, k is Boltzman's constant, γ_e and γ_I are the magnetogyric ratios of the electron and proton, respectively, S is the spin quantum number for the paramagnetic ion, and (A/h) is the electron–nuclear hyperfine coupling constant (8). In eq. [9] the spin only magnetic moment for the paramagnetic ion is assumed.

Preliminary calculations indicated that T_{2m} was controlled by the electron–nuclear hyperfine interaction, rather than the dipole–dipole interaction, and that the condition $\omega_s^2\tau^2 \gg 1$ would apply, where τ is the correlation time for the interaction and ω_s is the resonance frequency of the free electron. The expression for (T_{2m}^{-1}) under these conditions is (9)

$$[10] \qquad (T_{2m})^{-1} = \frac{1}{3}(S)(S+1)\left(\frac{A}{\hbar}\right)^2\tau_e$$

In the subsequent treatment the temperature dependence of the correlation time is assumed to have the form

$$[11] \qquad \tau_e = \tau_o \exp(E_a/RT)$$

In the non-linear least squares program the values of $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, A/h, τ_o and E_a were used as adjustable parameters. The initial estimates of these parameters, necessary for the computation, were obtained by the usual graphical procedure using the limiting conditions [10a], [10b], and [10d] of Swift and Connick (6). The resulting least squares parameters for the water and ethanol protons are given in Table II, along with their standard errors determined from the computer best fit to the data. The results in Table II show that the values of $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, τ_o, and E_a for the methyl and methylene protons are the same within their standard errors from the fit, as is necessary for whole ethanol molecule exchange.

TABLE II

Best fit parameters for n.m.r. line broadening

Parameters	Ethanol		Water
	CH_3	CH_2	
$\Delta H^{\ddagger}$ kcal mole^{-1}	6.3 ± 0.9	6.1 ± 1.0	6.3 ±0.5

$\tau_0 \times 10^{-12}$ s	44 ±86	99 ±16	1.77±1.1
E_a kcal mole^{-1}	0.12± 1.3	1.0 ± 0.5	0.73±0.43
$A/h \times 10^{-6}$ Hz	1.16± 0.06	1.22± 0.05	11.9 ±0.03

The values in Table II are calculated assuming that K_4 is temperature independent. In 48.8 mole % ethanol the water or hydroxide solvated species makes up 10.8% of the total hemin concentration. Therefore, if K_4 were not essentially temperature independent, the concentration of ($HOFeOH_2$) or ($HOFeOH^-$) would change considerably over the wide temperature range of the study, and some rather unusual effects would be noted in the plot of $(T_{2p'})_w^{-1}$ [H_2O] vs. $(T)^{-1}$ °K^{-1}. Since this is not the case the results are consistent with the assumed temperature independence of K_4. This assumption is also consistent with the studies of Kemp and King (10) on the solvated chromium ion in ethanol – water solutions.

The hyperfine coupling constants in Table II may be used to calculate the chemical shift which should be observed in the solutions. Although the coupling constants are large, the small concentration of hemin ($< 5 \times 10^{-3}$ *M*) results in a calculated shift of less than 5 Hz in all cases. A downfield shift was observed generally but its magnitude was too small and the error in the measurement too large to permit any quantitative analysis. The downfield direction of the shift indicates a positive value for the coupling constants.

It has also been observed that the solvent n.m.r. resonances have their natural linewidths when imidazole is added to the hemin solution in a mole ratio of 100:1. This result confirms that imidazole binds to the paramagnetic center and displaces solvent molecules from the coordination sphere of the metal ion.

A study was also made of the effect of hydroxide ion on the linewidths in 48.8 mole % ethanol at 35°. No change in the linewidths was observed between 10^{-6} and 0.1 *M* hydroxide ion.

Discussion

In the previous analysis to obtain the results, the exact nature of the solvated species causing the n.m.r. line broadening was not specified. The results are consistent with the assumption that the dimeric and monomeric forms of hemin have the same kinetic properties. The study of the linewidth dependence on ethanol and water concentration has shown that in the mixed ethanol – water solvent there is an equilibrium between water or hydroxide and ethanol or ethoxide solvated hemin. These species may be represented by the formulae [H_2OFeOH], [$HOFeOH]^-$, [$C_2H_5OHFeOH$], and [$C_2H_5OFeOH]^-$ where the porphyrin ring structure is omitted.

Hasinoff *et al.* (2) have measured an acid dissociation constant for hemin of 1.4×10^{-7} *M*. This equilibrium might be represented by eqs. [12*a*] or [12*b*]

[12*a*] $$H_2OFeOH_2 \rightleftharpoons H_2OFeOH + H^+$$

or

[12*b*] $$HOFeOH_2 \rightleftharpoons HOFeOH + H^+$$

Then at pH* 11 the water solvated species may be either (H_2OFeOH) or $(HOFeOH)^-$. A reexamination by Phillips (3) of the data of Schack and Clark (11) gives a pK_a of 7.3 for proton dissociation from the dimeric diaquo species, $(H_2OFeOH_2)_2^{2+}$, to give the hydroxy–aquo dimer, $(H_2OFeOH)_2$, in water. This pK is reasonably close to the value of 6.8_5 obtained by Hasinoff *et al.* (2) for the monomer in ethanol – water solution, indicating that the same process [12*a*] is being observed in both studies. This is also consistent with the potentiometric work of Davis and Martin (4) in ethanol – water mixtures. It is therefore, assumed in the subsequent discussion that the solvated species are (H_2OFeOH) and ($C_2H_5OHFeOH$).

In interpreting the water proton exchange rates there is a further difficulty because the water protons may exchange with the whole water molecule or by proton transfer. Since the activa-

tion parameters for water and ethanol exchange are the same, within their error limits, it is tempting to propose that entire water molecules are exchanging. However, the term directly dependent on water concentration in the rate law for water proton exchange indicates that these protons may be exchanging by a different process from the ethanol molecule exchange.

A possible pathway for water proton transfer is represented by

$$[13]\quad (H_2OFeOH) + H_2O \underset{k_{-13}}{\overset{k_{13}}{\rightleftharpoons}} (H_2OFeOH_2)^+ + OH^-$$

$$\frac{1}{\tau_m} = k_{13}[H_2O] = \frac{[H_2O]}{1.5 \times 10^{-6}}$$

The value for τ_m is given in eq. [7]. It can be shown by using the value of 1.4×10^{-7} determined in ref. (3) for the dissociation constant of $[H_2OFeOH_2]^+$, that

$$[14]\qquad \frac{k_{13}}{k_{-13}} = \frac{K_w}{1.4 \times 10^{-7}}$$

Therefore, $k_{-13} = 0.93 \times 10^{13}$. This value of k_{-13} is several orders of magnitude larger than the usually accepted diffusion controlled limit. Therefore, proton transfer cannot be occurring by reaction [13].

A similar analysis shows that the reaction

$$[15]\quad (HOFeOH_2) + H_2O \rightleftharpoons (HOFeOH)^- + H_3O^+$$

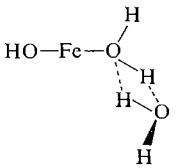
cannot be contributing to proton exchange unless the coordinated water is a moderately weak acid, a conclusion which is inconsistent with the pH titrations and the analysis of Phillips (3).

A reaction such as

$$[16]\quad (HOFeOH_2) + OH^- \rightleftharpoons (HOFeOH)^- + H_2O$$

cannot be contributing to proton exchange because the exchange lifetime, τ_m^{-1}, is independent of hydroxide ion.

One transition state for proton transfer might be pictured as



where the dotted lines represent hydrogen bonds between the free and coordinated solvent. Proton transfer might take place by a concerted interchange of the hydrogen-bonded hydrogens. It is difficult to judge the likelihood of such a mechanism. There appears to be no evidence for this type of transfer in the studies of proton exchange in simple hydrated metal cations. However, in these systems the hydrated ion is a weak acid and exchange by a process analogous to reaction [15] usually predominates. It is also unlikely that these cations will be solvated with the hydrogen end of the solvent water molecule. The mechanism pictured for the proton transfer is similar in some ways to that proposed for proton exchange in methanolic solutions of benzoic acids (12, 13) and for proton exchange between trimethylamine and the trimethylammonium ion in aqueous solution (14). It should be noted that this mechanism for water proton exchange has been proposed because other seemingly reasonable possibilities are not consistent with the acid–base properties of the hemin.

The results on the ethanol proton line broadening are free from the ambiguities of the water protons because there is no possibility for the methyl or methylene protons to exchange independently. Therefore, the values for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ given in Table II are for the exchange of a whole ethanol molecule from the coordination sphere of iron (III) in hemin. If average parameters, from the $-CH_2-$ and $-CH_3-$ protons, of 6.2_0 kcal mole^{-1} for $\Delta H^{\ddagger}$ and -9.1_0 cal mole^{-1} deg^{-1} for $\Delta S^{\ddagger}$ are used, then the average rate constant for ethanol exchange is 1.8×10^6 s^{-1} at 25°.

The solvent-independent term in the water exchange rate is presumably due to whole water molecule exchange. The rate constant for water exchange is 9×10^5 s^{-1} at 35°, and if an activation energy of 6.2 kcal mole^{-1} is assumed, based on the ethanol value, then the exchange rate is 6×10^5 s^{-1} at 25°. If a limiting S_N1 mechanism is assumed for the solvent exchange, then the mechanism may be represented by the following equation

$$(HOFeOH_2) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \{HOFe\} + \underset{H_2O}{C_2H_5OH} \underset{k_2}{\overset{k_{-2}}{\rightleftharpoons}} (HOFeC_2H_5OH)$$

Therefore

$$\frac{k_1 k_{-2}}{k_2 k_{-1}} = K_4 = 8.7$$

The values of k_1 and k_2 are 6×10^5 and 1.8×10^6 s^{-1}; therefore $k_{-2}/k_{-1} \approx 25$. This value indicates that ethanol is 25 times more nucleophilic than water, a result which is not consistent with the expected nucleophilic order of water and ethanol. The high ratio of k_{-2}/k_{-1} may be due to preferential solvation by ethanol in the second coordination sphere of the hemin and also to the neglect of the solvent activity ratios in calculating K_4 (5).

The relative rates of solvent exchange and imidazole substitution (2) on hemin seem most consistent with an ion pair substitution mechanism. The imidazole study was carried out under conditions where the hemin is about 70% in the ethanol form, therefore the rather uncertain value for the water exchange rate does not affect these conclusions. If protonated imidazole (HIm^+) and imidazole (Im) are the binding species then the binding rate constants are 4×10^6 and 3×10^4 $M^{-1}s^{-1}$ respectively. The larger rate constant for HIm^+ substitution may be accounted for by an ion pair formation constant of about 3 for HIm^+ and 0.02 for Im. This and other mechanisms are discussed more fully by Hasinoff *et al.* (2).

Temperature jump kinetics of the binding of imidazole to ferriprotoporphyrin IX

BRIAN B. HASINOFF, H. BRIAN DUNFORD, AND DALE G. HORNE
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received January 6, 1969

The kinetics of binding of imidazole to ferriprotoporphyrin IX (hemin) in aqueous ethanol has been studied at 25° using the temperature jump technique. The reaction was studied quantitatively as a function of acid concentration using the pH scale developed by Bates *et al.* for mixed solvent systems. The results can be explained by a mechanism in which the imidazolium ion binds to hemin with a specific rate constant of $(4 \pm 2) \times 10^6\ M^{-1}\ s^{-1}$ and imidazole binds with a rate constant of $(3 \pm 0.3) \times 10^4\ M^{-1}\ s^{-1}$. The dissociation constant for the imidazolium ion was determined by acid–base titration to be $1.8 \times 10^{-7}\ M$, and a dissociation constant for the hemin of $2.3 \times 10^{-7}\ M$ was determined by spectrophotometric titration in a solvent containing 44.5 weight % of ethanol. The latter dissociation involves the proton on a solvent ligand.

Introduction

Some equilibrium studies have been carried out on the coordination of various ligands to ferriprotoporphyrin IX (hemin) in a variety of solvents (1, 2). Neutral or acidic aqueous solutions of hemin are prone to precipitation. At high pH in aqueous solution, hemin tends to dimerize or polymerize (3). Maehly and Akeson have shown that a solvent composed of about 50 volume % ethanol stabilizes a dilute solution of monomeric hemin (4). For this reason the present study of the kinetics of imidazole binding was conducted in 44.5 weight % ethanol.

Experimental

The kinetic measurements were conducted on a temperature jump apparatus constructed in this laboratory and based on the concepts put forth by Eigen (5, 6). The detection circuit, monochromator, light source, and light power supply were identical to those described elsewhere (7). The temperature jump was obtained by triggering the discharge of a high voltage capacitor (Plastic Capacitors, Inc. LK500-104ZND, 0.1 μF, 50 kV) through a spark gap in series with the temperature jump cell. The trigger module (TM-11) was obtained from EG and G Inc. The voltage for charging the capacitor was supplied by a Spellman high voltage power supply Model 2040. The cell, constructed of Plexiglass with cylindrical quartz lenses, was designed so that approximately 1 ml of the solution was heated. It was possible to perform experiments on a minimum of 5 ml of solution. The cell fitted snugly into a brass thermostatting jacket enclosed in a light-tight canister. The heating time constant of the cell and the response time constant of the photomultiplier circuit were negligibly small compared to the measured chemical relaxations.

Association constants of the imidazole–hemin complex were determined by measuring absorbances with a Beckman DU spectrophotometer with a cell compartment thermostatted at 25.0°. Imidazole and hemin of White Label grade were obtained from Eastman Organic Chemicals and were used without further purification. The solvent, 44.5 weight % ethanol, was prepared from distilled, filtered, deionized water and reagent grade 95% ethanol. A stock hemin solution was prepared by dissolving hemin in 0.1 *M* NaOH and diluting until the stock was $1.0 \times 10^{-3}\ M$ in hemin and $1.0 \times 10^{-2}\ M$ in NaOH. This stock was stored in a refrigerator and from it freshly diluted solutions, $4.00 \times 10^{-5}\ M$ in hemin, were prepared for each day's experiments. Kinetic and equilibrium measurements were conducted on $4.00 \times 10^{-6}\ M$ hemin solutions within minutes of their preparation. For all experiments the imidazole concentrations were at least 50 times larger than the hemin concentrations.

An operational pH scale was established using the method described by Bates *et al.* (8). We shall follow their nomenclature in which the term pH* is used for pH in a mixed aqueous solvent. An accurate measure of pH* can be obtained with an aqueous glass electrode in a mixed aqueous solvent. The glass electrode (a Beckman long thin probe combination 38183) was stored in a solution of composition, pH*, and ionic strength similar to that used in the experiments, and was standardized with a triethanolammonium chloride – triethanolamine buffer of pH* 7.05 (8). This electrode was used in combination with a Beckman expanded scale pH meter. All solutions contained a buffer contributing 0.01 to the total ionic strength of 0.11 with the remainder contributed by KNO_3. In the pH* range 4.5–6.0 acetate buffer was used, 6.2–7.5 maleate buffer, 6.3–8.3 phosphate buffer, and 8.8–10.3 borate buffer.

The temperature jump cell was thermostatted at 19.0° and a voltage of 20.5 kV was applied which was sufficient to give a 6° rise in temperature. A monochromator setting of 413 mμ was employed which corresponded to the maximum of the difference spectrum of the two absorbing species in solution. Changes in absorbance caused by the temperature perturbation were observed by monitoring the output voltage of a photomultiplier on an oscilloscope with a differential high gain d.c. amplifier. The relaxation curve was photographed and the single observed relaxation time, τ, was determined by use of a photographic enlarger to match the negative of the oscilloscope trace with one of a series of exponential curves specially

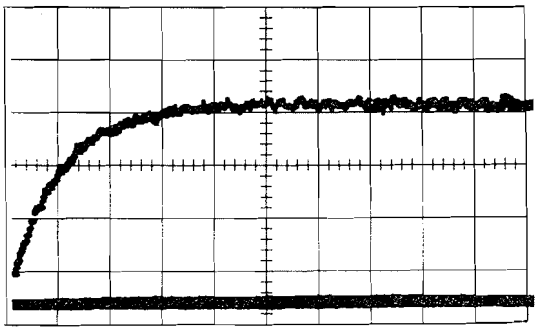

FIG. 1. Oscilloscope trace of voltage *vs.* time. Concentration of hemin was 4.0×10^{-6} *M* and of imidazole 1.2×10^{-3} *M*. The pH* was 7.5 and ionic strength 0.11 with 0.01 contributed by maleate buffer. The horizontal scale is 1 ms/cm and the vertical scale 100 mV/cm. Monochromator setting was 413 mμ.

constructed for this purpose. A typical trace is shown in Fig. 1.

Results

At a constant pH* the hemin solutions were found to obey Beer's law for a single absorbing species over an appreciable range of hemin concentrations, indicating that the hemin species did not change as a function of concentration. From the studies of Maehly and Akeson this species is known to be monomeric hemin (4).

Studies were made of spectral changes as a function of pH*. Hemin solutions with pH* ranging from 8 to 3.6 *M* with respect to NaOH showed no significant spectral changes. From pH* 8 to 5.5 significant spectral changes were observed at 400 mμ, where the maximum absorption in the Soret region occurs. Upon standing 24 h or more, solutions of hemin at pH* less than 5.8 were observed to precipitate. Hence it was difficult to obtain accurate absorbance readings corresponding to complete conversion to the acid form of the hemin. Nevertheless, using the absorbance of the alkaline solutions as reference, it was possible using the method of Coward and Kiser (9) to show that the absorbance changes corresponded to a single proton dissociation with a p*K* of 6.6_3. The titration results, shown as the fraction of protonated species, α, *vs.* pH*, are shown in Fig. 2. No attempt was made to measure possible p*K*'s which might be observed in more acid solutions and kinetic experiments were not conducted below pH* 6.0.

The acid dissociation constant of imidazolium ion in 44.5 weight % ethanol was measured at a constant ionic strength of 0.11 and a temperature of 25.0°, by titrating a solution of 0.1 *M* imidazole with concentrated HNO_3 so that the volume change over the course of the titration was negligibly small. The inflection point of the sigmoid titration curve (plot of pH* *vs.* volume of HNO_3 added) indicated the acid dissociation constant of imidazolium ion, K_{ImH}, to be 1.8×10^{-7} *M*.

When imidazole is added to a solution of hemin, large changes in the spectrum occur as shown in Fig. 3. There are 4 well-defined isosbestic points indicating the presence of two absorbing species in solution which, as discussed below,

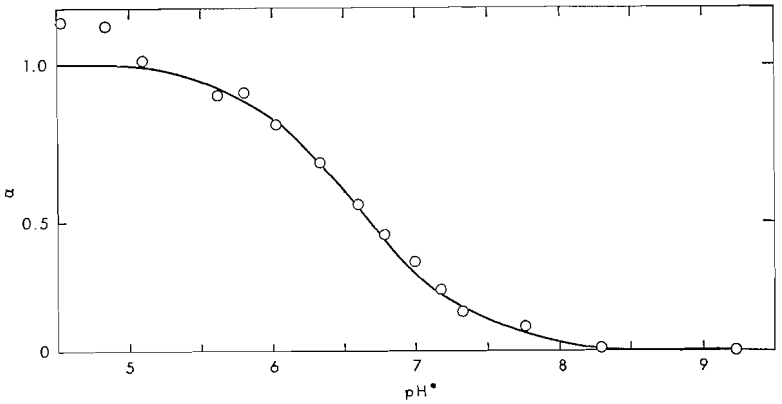

FIG. 2. Plot of α, the fraction of hemin present, *vs.* pH*. The solid line is a theoretical sigmoid curve for the dissociation of a single proton from an acid group with a p*K* of 6.63 and the circles represent experimental points.

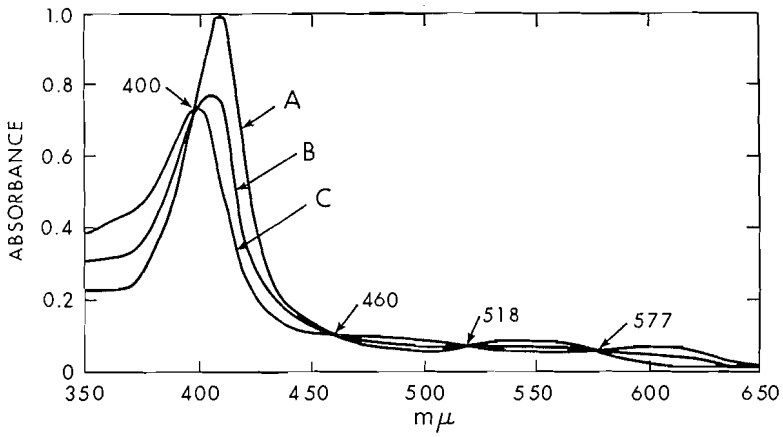

FIG. 3. Plot of absorbance *vs.* wavelength in mμ. Concentration of hemin was 8.0×10^{-6} *M* and concentrations of imidazole for curves A, B, and C were 1×10^{-2}, 1×10^{-3}, and 0 *M*. The pH* was 7.6 and the ionic strength 0.11. Curve A is the spectrum of fully complexed diimidazole hemin.

appear to be hemin and diimidazole hemin. No spectral evidence could be obtained for the existence of an intermediate species. If the state of ionization of the various species is neglected, the association of imidazole and hemin may be represented as[1]

[1] $$M + 2Im \rightleftarrows MIm_2$$

The corresponding apparent association constant is

[2] $$K_{app} = \frac{[\overline{MIm_2}]}{[\overline{M}][\overline{Im}]^2}$$

The slope of a plot of log $[(A_r - A_s)/(A_s - A_\infty)]$ *vs.* log $[\overline{Im}]$, shown in Fig. 4, indicates the number of molecules of imidazole that are binding to a molecule of hemin (2). The slope of our plot is 1.9 which, within experimental error, confirms the validity of eqs. [1] and [2]. From eq. [2], it can be shown that a plot of $\Delta A/[\overline{Im}]^2$ *vs.* ΔA should be linear with the absolute value of the slope equal to the association constant, K_{app} (9). Linear plots were obtained over the entire pH* range; a typical example is shown in Fig. 5. This type of plot is particularly useful when a large excess of ligand is required for complete formation of the complex. The K_{app} data as a function of pH* are listed in column 3 of Table I and are plotted in Fig. 6.

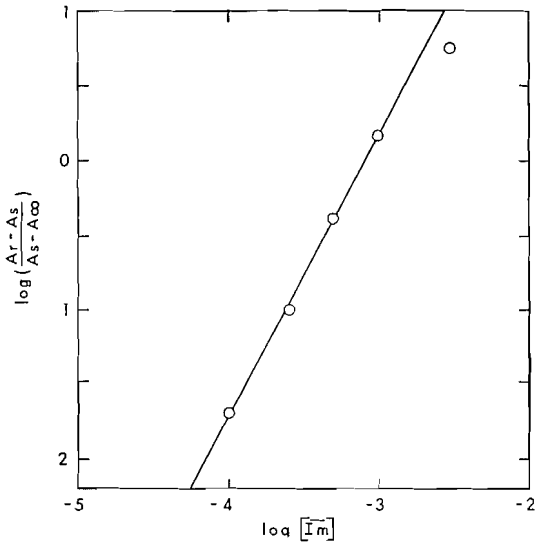

FIG. 4. Plot of log $[(A_r - A_s)/(A_s - A_\infty)]$ *vs.* log $[\overline{Im}]$. The concentration of hemin was 4.0×10^{-6} *M*. The pH* was 7.5. The slope of 1.9 indicates that 2 molecules of imidazole coordinate per molecule of hemin.

[1]Abbreviations used: M or $M(H_2O)$ is the metalloporphyrin ferriprotoporphyrin IX or hemin; M(OH), hydroxyhemin or hematin; MIm, monoimidazole hemin; MIm_2, diimidazole hemin; Im, imidazole; ImH, imidazolium ion. The bracketed quantities which have bars or subscript zero represent equilibrium concentrations or total initial concentrations. The absorbances of hemin solutions in a 1 cm cuvette with no added imidazole (reference), a known amount of imidazole added (sample), and an excess of imidazole added such that the diimidazole hemin complex is completely formed, are designated A_r, A_s, and A_∞; ΔA is $A_s - A_r$; α is the fraction of the hemin present as $M(H_2O)$.

The overall reaction represented in eq. [1] can be written in two steps

$$\mathrm{M} + \mathrm{Im} \underset{k_{-1\mathrm{app}}}{\overset{k_{1\mathrm{app}}}{\rightleftharpoons}} \mathrm{MIm} \qquad [3]$$

$$\mathrm{MIm} + \mathrm{Im} \underset{k_{-2\mathrm{app}}}{\overset{k_{2\mathrm{app}}}{\rightleftharpoons}} \mathrm{MIm_2}$$

The relation between the association constant, K_{app}, and the apparent rate constants is

$$K_{app} = \frac{k_{1\,app}k_{2\,app}}{k_{-1\,app}k_{-2\,app}} \qquad [4]$$

In all temperature jump experiments only one relaxation time, τ, was observed. The values of τ, which are dependent upon the concentration of added imidazole, ranged from about 0.1 to 2 ms. The single relaxation time and lack of any spectroscopically observable intermediate provides evidence that the steady state approximation

$$\frac{d[\mathrm{MIm}]}{dt} = 0 \qquad [5]$$

is valid. Without the steady state condition two relaxation times would be expected (10). The reciprocal of the relaxation time, based on eqs. [3]–[5] is given by

$$\frac{1}{\tau} = \frac{k_{-2\,app}(1 + K_{app}[\overline{\mathrm{Im}}]^2)}{1 + \frac{k_{2\,app}}{k_{-1\,app}}[\overline{\mathrm{Im}}]} \qquad [6]$$

where $[\overline{\mathrm{Im}}] = [\mathrm{Im}]_0 \gg [\mathrm{M}]_0$. It is possible to show that for large $[\overline{\mathrm{Im}}]$, eq. [6] is reduced to $1/\tau = k_{1app}[\overline{\mathrm{Im}}]$ and for small $[\overline{\mathrm{Im}}]$, it becomes $1/\tau = k_{-2app}$. Therefore from plots of $1/\tau$ *vs.* $[\overline{\mathrm{Im}}]$, the limiting slopes at large $[\overline{\mathrm{Im}}]$ yield k_{1app} data. A typical limiting slope plot is shown in Fig. 7. Values of k_{1app} as a function of pH*, obtained by the limiting slope method, are listed in column 2 of Table I and are plotted in Fig. 8. Values of k_{-2app} and k_{2app}/k_{-1app} were computed from eq. [6] using K_{app}, from the spectrophotometric titrations, and τ and $[\overline{\mathrm{Im}}]$ values as input data for a non-linear least squares program (11). They are listed in columns 4 and 5 of Table I. Finally, in order to obtain values of K_{app}, solely from kinetic data, as a check on the spectrophotometric titration results, all three quantities K_{app}, k_{-2app}, and k_{2app}/k_{-1app} were treated as unknowns and best-fit values were obtained from eq. [6] using the same computer program (11). The results for K_{app} are listed in column 6 of Table I.

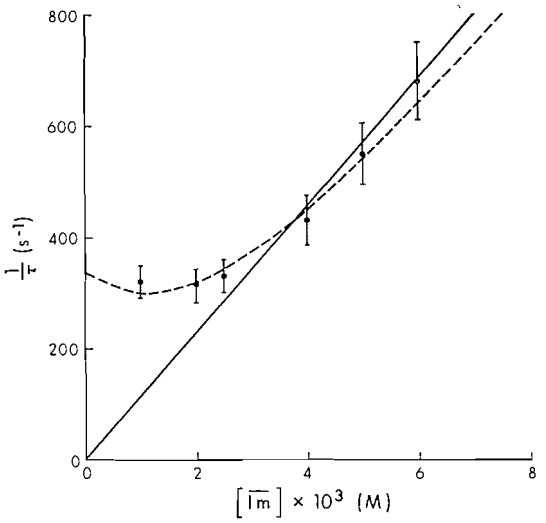

FIG. 7. Plot of $1/\tau$ *vs.* $[\overline{\mathrm{Im}}]$ for imidazole binding to hemin at pH* 8.82. The solid line is an estimated limiting slope and the dashed line was computed from eq. [6] using K_{app} determined spectrophotometrically and best-fit values for k_{-2app} and k_{2app}/k_{-1app}.

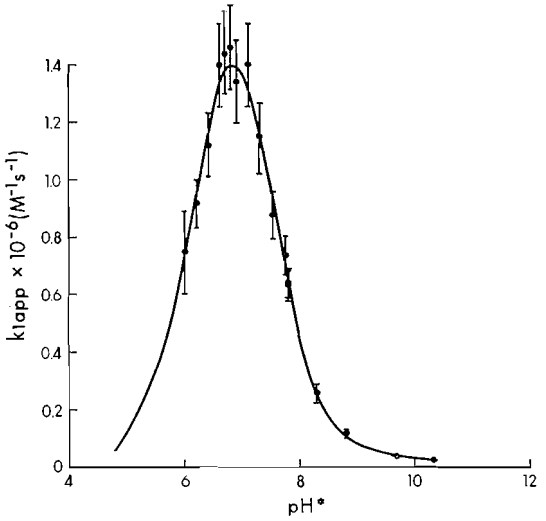

FIG. 8. Plot of k_{1app} *vs.* pH*. The solid line is that predicted using the best four-parameter fit to eq. [10]. The circles are experimental points and error limits are estimated.

Discussion

There are two kinetically indistinguishable mechanisms which can explain the pH* dependence of the k_{1app} data. In one, imidazole is

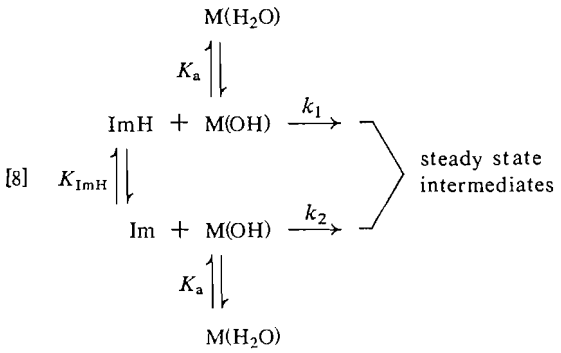
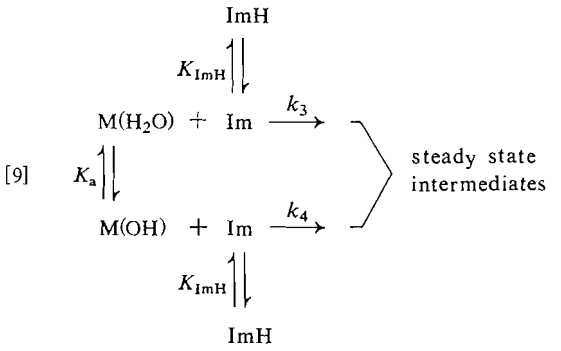
postulated to bind to two forms of hemin differing by a single ionizable proton



where K_a and K_{ImH} are the acid dissociation constants of hemin and imidazolium ion. The vertical arrows indicate fast proton transfer reactions in buffered solutions and the horizontal arrows slower bimolecular association reactions. The other mechanism is



According to eq. [8] the apparent forward rate constant, k_{1app} is given by

$$[10]\quad k_{1app} = \left[\frac{k_1}{1 + K_{ImH}/[H^+]} + \frac{k_2}{1 + [H^+]/K_{ImH}}\right] \times \left[\frac{1}{1 + [H^+]/K_a}\right]$$

and from eq. [9] one obtains

$$[11]\quad k_{1app} = \left[\frac{k_3}{1 + K_a/[H^+]} + \frac{k_4}{1 + [H^+]/K_a}\right] \times \left[\frac{1}{1 + [H^+]/K_{ImH}}\right]$$

It can be shown that $k_3 = k_1K_a/K_{ImH}$ whereas $k_2 = k_4$. Equations [10] and [11] are readily tested using a non-linear least squares program (11). The program was modified to minimize the sum of the squares of the relative residuals rather than the sum of the squares of the absolute residuals. The results of two different approaches are summarized in Table II. In the first approach, 4 parameters from eq. [10], k_1, k_2, K_{ImH}, and K_a and 4 from eq. [11], k_3, k_4, K_{ImH}, and K_a, were regarded as unknowns and best-fit values were obtained. In the second approach, the values of K_{ImH} and K_a, 1.8×10^{-7} and 2.3×10^{-7} M, obtained independently by titration, were treated as constants and the best-fit values of the other two parameters to each of eqs. [10] and [11] were obtained. The agreement between the four- and two-adjustable-parameter fits is somewhat better for eq. [10] than for eq. [11]. This does not provide sufficient evidence to exclude the mechanism represented in eqs. [9] and [11] however.

From an examination of the equilibrium data one can write two pairs of equations

$$[12]\quad M(OH) + ImH + Im \overset{K'}{\rightleftarrows} M(Im)_2 + H_2O$$

$$[13]\quad K_{app} = K'\left[\frac{K_a}{K_a + [H^+]}\right]\left[\frac{K_{ImH}}{K_{ImH} + [H^+]}\right] \times \left[\frac{[H^+]}{K_{ImH} + [H^+]}\right]$$

as well as

$$[14]\quad M(H_2O) + 2Im \overset{K''}{\leftrightarrows} M(Im)_2 + H_2O$$

$$[15]\quad K_{app} = K''\left[\frac{K_{ImH}}{K_{ImH} + [H^+]}\right]^2\left[\frac{[H^+]}{K_a + [H^+]}\right]$$

Both pairs of equations provide equally reasonable approximations to the observed equilibrium data, and therefore offer no clue as to a preferred mechanism.

From independent evidence, reviewed in the accompanying nuclear magnetic resonance (n.m.r.) study of solvent exchange of hemin (12), it appears likely that the $M(H_2O)$ is an equilibrium mixture of diaquohemin and aquoethanol hemin, whereas M(OH) is an equilibrium mixture of hydroxyaquo hemin and hydroxyethanol hemin. From the n.m.r. data, the rate constant for the dissociation of ethanol from hydroxyethanol hemin was determined to be 2×10^6 s^{-1}, whereas for the water from hydroxyaquo hemin it was 6×10^5 s^{-1} at 25° (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

From simple electrostatic consideration, the OH^- ligand should labilize other ligands. Thus the water exchange rate on $Fe(OH_2)_5OH^{2+}$ is faster than on $Fe(OH_2)_6{}^{3+}$ (13). On this basis the reaction scheme outlined in eq. [8] appears more plausible. From the results of Table II, the value of k_1 is $(4 \pm 2) \times 10^6\ M^{-1}\ s^{-1}$ and for k_2 $(3.0 \pm 0.2) \times 10^4\ M^{-1}\ s^{-1}$.

If an S_N1 limiting mechanism is considered (14), then the first reaction in eq. [8] becomes

$$[16]\qquad M(C_2H_5OH)^{2-} \underset{k_b}{\overset{k_a}{\rightleftarrows}} M'^{2-} + C_2H_5OH$$

$$M'^{2-} + ImH^+ \underset{k_d}{\overset{k_c}{\rightleftarrows}} MIm^{2-} + H^+$$

where M'^{2-} represents a pentacoordinated hemin intermediate and $M(C_2H_5OH)^{2-}$ is hydroxyethanol hemin with only its most labile ligand shown. For eqs. [16] and [17] total charges on the ionic species are shown. Since no inhibition at large [Im] is observed, $k_1 = k_a k_c / k_b$[EtOH] (15). The value of k_a is $2 \times 10^6\ s^{-1}$ from the n.m.r. results (12), and $k_1 = 4 \times 10^6/0.7 = 6 \times 10^6\ M^{-1}\ s^{-1}$. The correction is applied to k_1 since the n.m.r. results indicate that the hemin is about 70% in its ethanol form. The concentration of EtOH is about 8.2 M so that $k_c/k_b \approx 25$, or in words, the imidazolium ion is predicted to be 25 times better as a nucleophile than ethanol. Furthermore since $k_1 \gg k_2$, the imidazolium ion is predicted to be a better nucleophile than imidazole. Both of these predictions appear highly questionable.

On the other hand, if an ion pair mechanism is considered, the first reaction in eq. [8] becomes

$$[17]\qquad M(C_2H_5OH)^{2-} + ImH^+ \overset{K}{\rightleftarrows} M(C_2H_5OH)(ImH)^-$$

$$M(C_2H_5OH)(ImH)^- \overset{k_e}{\rightleftarrows} MIm^{2-} + H^+ + C_2H_5OH$$

It would appear plausible that the imidazolium ligand transfers its acid proton to the solvent molecule which it replaces. From the comparison of eqs. [8] and [17], $k_1 = Kk_e$, where K is the ion pair formation constant (15). If the rate of solvent exchange is not affected by ion pair formation, then $k_e = 2 \times 10^6\ s^{-1}$ and since $k_1 = 6 \times 10^6\ M^{-1}\ s^{-1}$, then $K = 3\ M^{-1}$ which appears quite reasonable. If the ion pair accelerates solvent removal then this value of K represents an upper limit. On a similar basis the "ion pair" constant for Im is about $0.02\ M^{-1}$ and a decrease in K is expected when a cation is replaced by a neutral ligand.

Fleischer *et al.* have studied ligand binding to cobalt(III) and iron(III) hematoporphyrin IX presumably in monomeric form in aqueous solution (16). Hematoporphyrin IX has two $CH_3CH(OH)$— substituents in place of the two vinyl groups in protoporphyrin IX. It can be shown that their measured specific rate constant for the overall pseudo first-order binding reaction is identical to our $1/\tau$, so that when their k_{obs} is plotted *vs.* ligand concentration, the behavior exhibited in Fig. 8 might be expected. However, they operated with a much larger excess of ligand than in our temperature jump experiments, so that detection of a finite intercept in the plot is more difficult. With the large excess of ligand they were able to obtain evidence for an S_N1 ligand substitution mechanism for the cobalt system but not for the iron system.

Les acétates énoliques des *tert*-butyl-6α et 7α décalones-2 *cis*[1]

H. Favre et A. J. Liston[2]
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 2 avril 1969

Les *tert*-butyl-6α et 7α décalones-2 *cis*, respectivement *cis a* et *cis e*, ont été préparées. A l'équilibre, les acétates énoliques Δ^1, Δ^2 en série *cis a* sont dans le rapport 35–65; en série *cis e*, un seul acétate énolique est présent, l'isomère Δ^1. Ces faits invalident la règle de l'énolisation préférentielle des décalones-2 *cis* vers la position 1. Une comparaison de ces résultats avec ceux obtenus à partir des décalones-2 *cis* diméthylées en 6,6 et 7,7 permet de dégager quelques conclusions au sujet des interactions non liées qui représentent un facteur important dans la direction de l'énolisation.

Canadian Journal of Chemistry, 47, 3233 (1969)

Les acétates énoliques sont particulièrement appropriés pour apporter des éclaircissements sur la direction de l'énolisation de cétones cyclohexaniques (1), polycyclohexaniques (2,3) et stéroïdiques, (4,5). Il nous a paru intéressant d'étendre notre étude préliminaire dans la série décalinique *cis*. Il conviendrait d'avoir en mains plusieurs cas types, de manière à mieux asseoir les faits sur lesquels se fondent les études, qui, par calcul, déterminent les énergies conformationnelles (6,7) et qui, en dernier ressort apporteront les précisions indispensables à notre compréhension de la direction de l'énolisation.

Ce travail rapporte l'étude des acétates énoliques de la *tert*-butyl-6α décalone-2 *cis* (**1**) et de la *tert*-butyl-7α décalones-2 *cis* (**2**). Elles présentent l'avantage sur les décalone-2 diméthylées en 6,6 et 7,7 d'avoir une bonne stabilité conformationnelle stéroïde et non stéroïde respectivement, et de ne posséder aucun substituant axial, source d'interactions entre atomes non liés. Les décalones-2 *cis tert*-butylées peuvent ainsi être considérées comme les véritables représentants des deux systèmes fondamentaux, les décalones-2 *cis a* et *cis e* (nomenclature de Klyne (8)).

La conformation double chaise des décalones-2 *cis* est ajourd'hui bien établie (9,10).

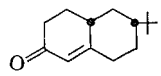
[1]Ce mémoire est tiré de la thèse de doctorat de A. J. Liston.

[2]Adresse actuelle: Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada.

Synthèse de la tert-butyl-6α décalone-2 cis (1)

La *tert*-butyl-4 cyclohexanone est le composé de départ. Une annellation à la manière de Stork (11) par l'intermédiaire de l'ènepyrrolidine correspondante, conduit à un mélange brut contenant entre autres, les octalones **3** et **4** (bandes infrarouges (i.r.) à 1675 cm^{-1} et 1710 cm^{-1}). Par distillation, on obtient un mélange des octalones **3** et **4**, les proportions étant 60–40 environ par dosage par résonance magnétique nucléaire (r.m.n.). Ce mélange 60–40 traité, par l'acide *p*-toluènesulfonique dans le benzène, s'isomérise en un mélange formé de 83% de l'octalone **3** et de 17% de l'isomère **4**; une distillation dans une colonne munie d'une bande tournante permet d'obtenir l'octalone pure **3**.



3

1

D'une manière générale, les $\Delta^{1(9)}$-octalones-2 se réduisent par le lithium dans l'ammoniac en décalone-2 *trans* (12,13) et catalytiquement en décalone *cis*. Traitée par le lithium et l'ammoniac, l'octalone **3** conduit à une décalone de point de fusion 55.5°. Réduite catalytiquement (palladium sur charbon) en solution alcoolique contenant de l'acide chlorhydrique (14), l'octalone **3** conduit à une décalone liquide homogène en chromatographie en phase gazeuse (c.p.g.) différente de celle obtenue par la réduction par le lithium et l'ammoniac. Il est raisonnable de conclure que la réduction chimique conduit à l'isomère *trans* **5** tandis que la réduction catalytique conduit à

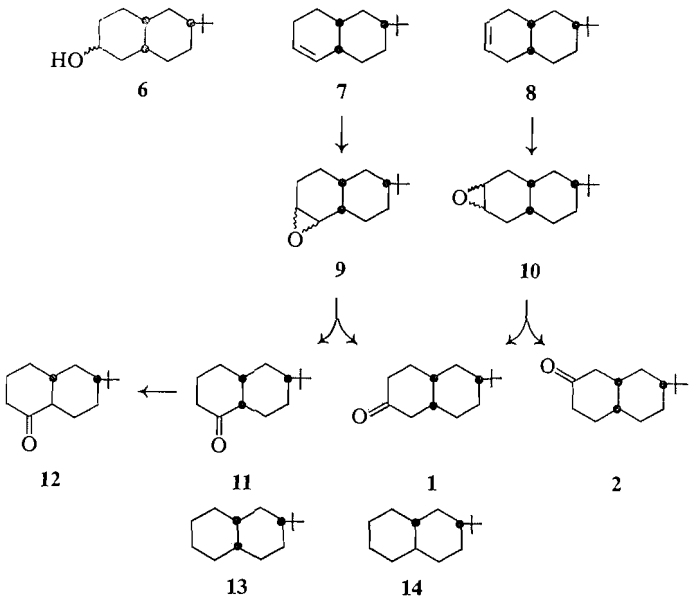

SCHÉMA 1. Synthèse de la décalone **2**.

l'isomère *cis a* (**1**). L'isomérisation que subit le mélange des octalones **3** et **4** en milieu acide donne certainement la configuration **3**, configuration *cis* pour le groupe *tert*-butyle (équatorial) et la liaison 4 (10) (équatoriale). Voir (11) pour les résultats de l'annellation de la décalone-2 *trans*. Cette octalone se réduit catalytiquement en engendrant une liaison 1 (9) axiale, comme c'est le cas pour la nor-19 testostérone qui donne un composé 5β, 10β (15). Nous apportons plus loin une autre preuve de la configuration *cis a*.[3]

Synthèse de la tert-butyl-7 décalone-2 cis (2)

La synthèse de la décalone **2** se fait à partir de la décalone **1** par une méthode qui s'inspire du travail de Church, Ireland, et Shridhar (16).

La décalone **1** réduite catalytiquement sur nickel de Raney, engendre un mélange des deux alcools, dont les configurations n'ont été déterminées, est de **3** à **2** comme le montre une analyse par c.p.g.[4] Le mélange des deux alcools est déshydraté pour donner un mélange des deux octalines **7** et **8**: la méthode de Chugaev conduit à un rapport **7**–**8** de 1–1 tandis que le rapport est de 61–39 lorsque l'agent de déshydratation est le bisulfate de potassium. La structure octalinique découle du fait que la méthode de Chugaev ne s'accompagne d'aucune transposition (17). Les deux octalines se séparent aisément en c.p.g. préparative et s'obtiennent pures. Leur preuve de structure, qui constitue en même temps la synthèse de la décalone **2** est la suivante.

Chacune des oléfines **7** et **8** est traitée par l'acide perbenzoïque, les époxydes sont réduits par l'hydrure de lithium et d'aluminium et les alcools oxydés par l'anhydride chromique.

De cette manière, l'une des octalines conduit à 90% environ de décalone **1** connue et à 10% environ de deux décalones auxquelles nous attribuons les formules **11** et **12**: en effet, le mélange brut s'isomérise en présence d'hydroxyde de potassium en un mélange qui ne contient plus que deux décalones, **1** et **12**; une réduction de Clemmensen confirme la présence de la décalone-2 *trans* (**12**) dans le mélange, en conduisant à un mélange des décalines **13** et **14** dans le rapport de 86 à 14; ces décalines s'obtiennent pures à partir des décalones-2 *cis* et *trans* **1** et **5**. L'autre octaline conduit à 60% de décalone **1** connue et à 40% de la décalone désirée **2** que l'on retire du mélange

[3]Maes, Ottinger, Reisse, et Chiurdoglu (29) ont préparé la cétone **1** par réduction catalytique de la cétone **3**. Ils lui attribuent la conformation *cis a* à la suite d'une étude en r.m.n.

[4]Selon la théorie générale (30), l'alcool prépondérant sera axial.
