However, none of these experiments establishes pelletierine as an obligatory intermediate.

We now present evidence which confirms that pelletierine is indeed an obligatory intermediate in the biosynthesis of lycopodine.

In earlier papers (4, 9, 17) we described tracer experiments which supported the view that the $C_{16}N_2$ and the $C_{16}N$ Lycopodium alkaloids, and lycopodine in particular, are modified dimers of a C_8N precursor. Radioactivity from each of six different ^{14}C-labelled substrates entered lycopodine in such a manner that the two C_8 units, C-1 to -8 and C-9 to -16, which constitute the two "halves" of the lycopodine skeleton, each contained one half of the activity of the intact alkaloid. Such a distribution of label is obligatory in a biosynthetic product derived from a dimeric intermediate, *i.e.*, one which originates by combination of two identical monomer units. Since the compounds which exhibited this mode of incorporation into lycopodine had been shown to be specific precursors of the pelletierine skeleton (*vide supra*) or were closely related to these precursors (lysine, cadaverine, Δ^1-piperideine, acetate, acetoacetate, β-hydroxybutyrate) we suggested that pelletierine was the monomeric C_8N precursor which was implicated in lycopodine biosynthesis (4, 17).

This hypothesis did not stand up to direct experimental test (9). Pelletierine was indeed found to enter lycopodine, but only one intact

pelletierine unit was incorporated, serving as the specific precursor of the C_8 unit, C-9 to -16. The C_8 unit, C-1 to -8, of lycopodine did not originate from pelletierine. Evidently lycopodine was not a modified dimer of pelletierine.

One of two conclusions became unavoidable:

Either (*a*) pelletierine was an obligatory precursor of lycopodine, in which case the alkaloid cannot be derived from a dimeric intermediate. This inference was difficult to reconcile with the finding that the two "halves" of lycopodine were equally labelled in 11 separate experiments with six different substrates. A model consistent with this alternative (ref. 9, Scheme 8) involved intermediacy of 4-(2-piperidyl)acetoacetate (**14**), which not only served as the precursor of the C_8 unit, C-1 to -8, of lycopodine, but which, by irreversible decarboxylation, gave rise to pelletierine, the precursor of the other C_8 unit, C-9 to -16.

Or (*b*) lycopodine was indeed generated from a dimeric intermediate such as (**10**), in which case pelletierine could not be a normal precursor. This conclusion raised the question of the identity of the C_8N monomer, and gave rise to the apparent paradox that pelletierine replaced one but not the other of two identical monomer units. A model capable of rationalizing this alternative (ref. 9, Scheme 9) involved 2-allylpiperidine (3-(2-piperidyl)-prop-1-ene) as the monomeric C_8N unit. This model demands that activity from ^{14}C-labelled 2-allylpiperidine should enter equally into the two "halves" of lycopodine, C-1 to -8, and C-9 to -16. Thus [2-^{14}C]-2-allylpiperidine should yield lycopodine labelled exclusively and equally at C-5 and C-13.

One of the experiments here reported was designed to test this model. The result which was obtained eliminates the allylpiperidine hypothesis from contention. *Lycopodium tristachyum* was kept in contact with a sample of [2-^{14}C]-2-allylpiperidine, prepared by reaction of [2-^{14}C]-Δ^1-piperideine with allyl magnesium chloride (19). The radioactive lycopodine which was isolated from these plants (Table 1, experiment 15) was converted into the phenyldihydro-derivative, which on oxidation yielded benzoic acid (4). Since the benzoic acid, representing C-5 of the allylpiperidine-derived lycopodine, was essentially free of radioactivity (Table 2), allylpiperidine had not served as a specific precursor of the C_8 unit, C-1 to -8, of lycopodine, and cannot be the C_8N monomer unit demanded by model (*b*). The allylpiperidine hypothesis is thus clearly untenable, regardless of whether a 2-allylpiperidine unit is incorporated intact into lycopodine or not,[3] since

[3]The degradation result does not distinguish between these alternatives. It is shown merely that activity from [2-^{14}C]-2-allylpiperidine enters lycopodine non-randomly, since little of this activity was present at C-5 of the alkaloid.

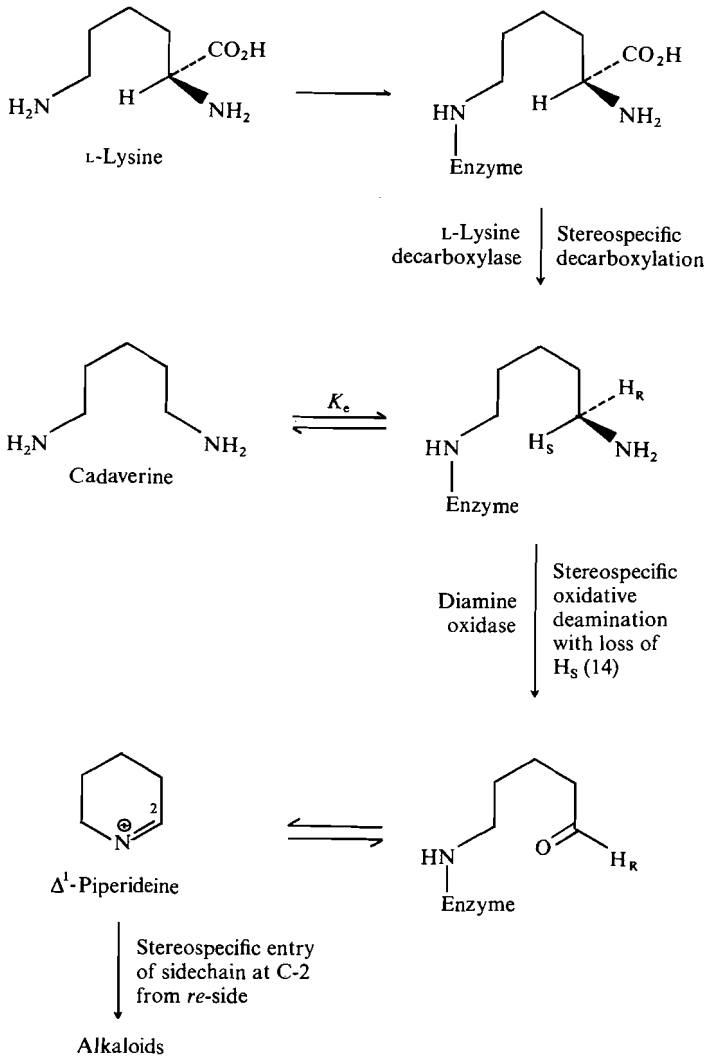

SCHEME 5. The biosynthesis of the lysine-derived piperidine alkaloids (14). If $K_e \leqslant 1$, incorporation of label from [2-^{14}C]- or [6-^{14}C]-lysine into the alkaloids is symmetrical. If $K_e \gg 1$, incorporation of label from [2-^{14}C]- or [6-^{14}C]-lysine into the alkaloids is nonsymmetrical.

even if intact incorporation of such a unit had occurred, it could have served only as the precursor of the C_8 moiety, C-9 to -16, *i.e.*, the same C_8 moiety which is derived from pelletierine, and not of both C_8 moieties. Further examination of the distribution of activity within the sample of lycopodine derived from [2-^{14}C]-2-allylpiperidine was thus unnecessary and was not pursued.

Instead, we directed our attention towards the experimental examination of model (*a*). Since the key intermediate envisaged by this model, 4-(2-piperidyl)-acetoacetate (**14**), has not been described, and since our attempts to prepare this compound have so far been unsuccessful, we focussed our efforts on marshalling evidence that pelletierine is an obligatory intermediate in the biosynthesis of lycopodine, as required by the model.

Absolute proof of an obligatory precursor–product relationship cannot be obtained from experiments with intact organisms. Even in

fragmented systems the experimental difficulties of obtaining conclusive evidence are, for all practical purposes, regarded as insuperable (20). Two criteria which are conditions for a precursor–product relationship, but do not prove the obligatory nature of the relationship between substrate and product, are (*i*) the entry of tracer from specifically labelled samples of substrate into predictable sites within the product, and (*ii*) the formation of the substrate within the system in which the product is formed. Reliable kinetic data which might show the flow of tracer from precursor via intermediates to product in a sequence of successive steps are not readily obtained from experiments with labelled multicarbon substrates in intact plant systems (*e.g.*, 21). Other parameters, *e.g.*, efficiency of incorporation of label from substrate into product, and the sparing of incorporation of label from a general carbon source by the substrate (isotope dilution) are unsatisfactory as criteria for a precursor–product relationship in intact systems (*e.g.*, 22), since they may be controlled by extraneous factors such as permeability and are subject to the variability of the biological material.

One of the essential conditions for a precursor–product relationship of pelletierine to lycopodine, specific incorporation of substrate, ((*i*) above), has already been fully documented (9). We now present evidence for the other ((*ii*), above), formation of pelletierine in *Lycopodium tristachyum* at a time when lycopodine is being formed.

Radioactive pelletierine hydrochloride was isolated from *Lycopodium* plants which had been kept in contact with [2-^{14}C]-Δ^1-piperideine (experiment 16) and with [1,5-^{14}C]-cadaverine (experiment 17) (Table 1) by "metabolite swamping" (*i.e.*, by administration of an inactive sample of pelletierine in admixture with the labelled substrate). Non-random incorporation of precursor into the pelletierine isolated in the latter experiment was demonstrated by partial degradation (Table 3). All activity was present in the degradation fragment containing the piperidine nucleus, none in the terminal carbons of the sidechain.

Thus, not only is pelletierine shown to be incorporated into lycopodine in *L. tristachyum* (9), but it is now also shown to be present in the plant, formed from compounds which are known to serve as precursors of lycopodine.

These findings show that a precursor–product relationship exists between pelletierine and lycopodine but they cannot serve as evidence that this relationship represents a normal, obligatory biosynthetic sequence and not merely a minor pathway. Under normal circumstances no further conclusions could have been drawn.

The present instance represents an exceptional case, however.

If pelletierine served as an obligatory intermediate between cadaverine or Δ^1-piperideine and lycopodine, then, in short term experiments under ideal conditions, the efficiency of incorporation of tracer from [^{14}C]-cadaverine and from [^{14}C]-Δ^1-piperideine into lycopodine must be lower in experiments in which inactive pelletierine is administered along with the tracer than in experiments in which tracer alone is fed to the plant. Such ideal conditions obtain only if, in the two experiments which are to be compared, all other variables can be controlled.

Such control cannot be achieved in experiments with intact plants. Thus, since only a small number of plants is used in each of the experiments, it is not possible to eliminate the possible effect of individual biological variation. This factor can be eliminated only by using a very large population of individuals (such as is found in a microbiological culture). Nor is it possible to ensure that the rate of uptake of pelletierine into the cells where biosynthesis occurs is at least as high as the rate of uptake of labelled substrate.

TABLE 3. Distribution of label within pelletierine isolated from *L. tristachyum* grown in contact with [1,5-^{14}C]-cadaverine (experiment 17)

	SA (counts min^{-1} mmol^{-1}) $\times 10^{-4}$	RSA (%)
Pelletierine	0.82 ± 0.02	100 ± 3
Pipecolic acid by oxidation of pelletierine	0.82 ± 0.02	100 ± 4

Thus the apparent lowering of the efficiency of incorporation of [^{14}C] from [^{14}C]-cadaverine and [^{14}C]-Δ^1-piperideine into lycopodine in the presence of added pelletierine (Tables 4 and 5) is, at best, no more than indicative, unless some additional parameter can be used as an independent internal standard, and as a basis for the comparison.

Such an internal standard is not normally available in experiments with intact plants. In the present instance, however, an important additional criterion exists.

It is established that activity from each of [^{14}C]-cadaverine and [^{14}C]-Δ^1-piperideine enters both C_8 units, C-1 to -8 and C-9 to -16, of lycopodine with equal efficiency, whereas pelletierine serves as a precursor of the C_8 unit, C-9 to -16, but not of the C_8 unit, C-1 to -8 (4, 9). Pelletierine cannot therefore lie on the pathway between cadaverine or Δ^1-piperideine and the C_8 unit, C-1 to -8, of lycopodine, but it could be (but need not be) an obligatory intermediate on the route from cadaverine and Δ^1-piperideine into the C_8 unit, C-9 to -16, of lycopodine.

If pelletierine were not an obligatory intermediate, addition of unlabelled pelletierine would not affect the entry of ^{14}C from cadaverine or from Δ^1-piperideine into either of the two C_8 units of lycopodine. Each of these two units would thus contain one half of the label of the intact lycopodine derived from [^{14}C]-

cadaverine or [^{14}C]-Δ^1-piperideine, regardless of whether inactive pelletierine were added to the system or not.

If pelletierine were a normal intermediate on the route from cadaverine and Δ^1-piperideine into the C_8 unit, C-9 to -16, of lycopodine, addition of inactive pelletierine to the system would suppress entry of label from [^{14}C]-cadaverine or from [^{14}C]-Δ^1-piperideine into the C_8 unit, C-8 to -16, but not into the C_8 unit, C-1 to -8, of lycopodine. It follows that under these conditions, the two C_8 units of lycopodine derived from [^{14}C]-cadaverine or [^{14}C]-Δ^1-piperideine would no longer be equally labelled. The C_8 unit, C-9 to -16, should contain less activity than the C_8 unit, C-1 to -8. In the limit, suppression of incorporation of label into the C_8 unit, C-9 to -16, by carrier pelletierine would be complete, so that all activity from [^{14}C]-cadaverine or [^{14}C]-Δ^1-piperideine would enter the C_8 unit, C-1 to -8. Since only one carbon, C-5, within this unit is labelled when [2-^{14}C]-Δ^1-piperideine serves as the substrate, all, or most of the activity from this precursor should be located at this carbon atom of the lycopodine obtained when [2-^{14}C]-Δ^1-piperideine is administered in the presence of inactive pelletierine (experiment 16), if pelletierine were an obligatory intermediate, whereas if it were not, only one half of the activity of the intact lycopodine would be located at this site, as found in the absence of added pelletierine (experiment 13, ref. 9). In fact about 90% of the total activity of the lycopodine from experiment 16 was found at C-5 (benzoic acid) (Table 2) (Scheme 6).

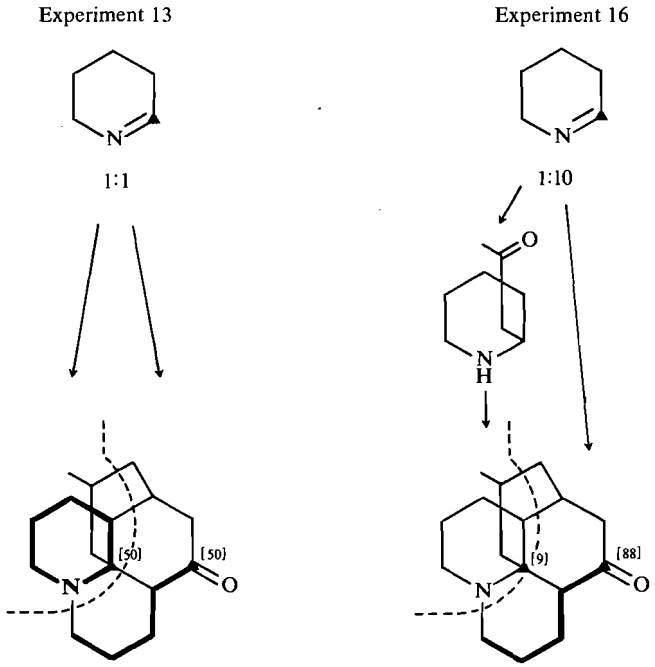

SCHEME 6. The mode of incorporation of activity from [2-^{14}C]-Δ^1-piperideine into lycopodine in the absence (experiment 13) and in the presence (experiment 16) of added inactive pelletierine. (Numbers in square brackets are percent of total specific activity of lycopodine, located at the indicated carbon atom.)

Similarly, two carbon atoms, C-5 and C-1, within the C_8 unit, C-1 to -8, become labelled when [1,5-^{14}C]-cadaverine serves as the substrate. In the presence of inactive pelletierine (experiment 17), all or most of the activity of lycopodine derived from this substrate should be divided equally among these two carbon atoms, so that C-5 should contain 50% of the activity of this lycopodine sample, if pelletierine were an obligatory intermediate between cadaverine and lycopodine and suppression of incorporation of the earlier percursor were complete. If pelletierine were not an obligatory intermediate only one quarter of the activity of the intact lycopodine would reside at this site, a distribution identical with that found in the absence of added pelletierine (experiment 11, ref. 4). In fact 44% of the total activity of the lycopodine from experiment 17 was recovered from C-5 (benzoic acid) (Table 2) (Scheme 7).

Thus, pelletierine is indeed an obligatory intermediate on the route from cadaverine and Δ^1-piperideine into the C_8 unit, C-9 to -16, of lycopodine. Therefore lycopodine cannot be derived from a true dimer. A hypothetical model which reconciles this inference with the observation that activity from six different substrates enters the two halves of lycopodine with equal efficiency is shown in Scheme 8. Provided the steady state concentration of pelletierine (**2**) is small compared to that of its postulated precursor, the coenzyme A derivative of 4-(2-piperidyl)acetoacetic acid (**13**), and the conversion of (**13**) into pelletierine is irreversible, all observations are accounted for. A novel route to **13** and **14**, via the coenzyme A derivative of piperidyl-2-acetic acid (**12**), is now suggested. This route is consistent with the observation that acetoacetate and β-hydroxybutyrate are not incorporated intact into lycopodine (4) or into *N*-methylpelletierine (11). Further experimental support for this hypothesis is being sought.

Experimental

Labelled Compounds

[2-^{14}C]-Δ^1-Piperideine (9) (experiment 16) and [2-^{14}C]-2-allylpiperidine (19) (experiment 15) were prepared from [2-^{14}C]-DL-lysine monohydrochloride (New England Nuclear). [1,5-^{14}C]-Cadaverine hydrochloride (experiment 17) was a commercial sample (New England Nuclear).

Tracer Experiments

In each of the three experiments, excised shoots of *Lycopodium tristachyum* Pursh were packed, cut surfaces

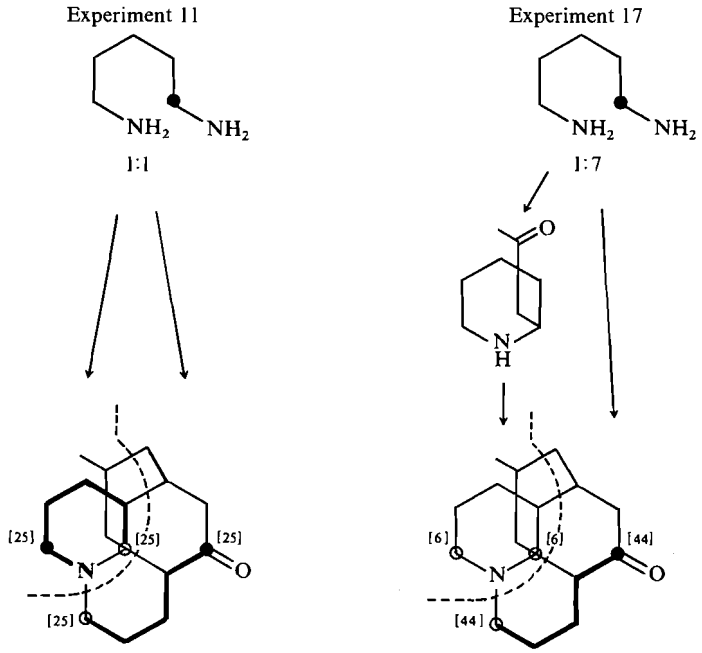

SCHEME 7. The mode of incorporation of activity from [1,5-^{14}C]-cadaverine into lycopodine in the absence (experiment 11) and in the presence (experiment 17) of added inactive pelletierine. (Numbers in square brackets are percent of total specific activity of lycopodine, demonstrated (full circles) or inferred (hollow circles) to reside at the indicated carbon atoms.)

downward, into two 100 ml beakers. The feeding solution was divided among the beakers.

In experiments 16 and 17, unlabelled pelletierine hydrochloride (23) (200 and 400 mg, respectively, in 10 ml glass-distilled water) was administered. When most of this solution had been absorbed by the cuttings, a solution of [2-^{14}C]-Δ^1-piperideine (nominal specific activity, 1.0 mCi per mmol, nominal total activity, 0.1 mCi) (experiment 16) or a solution of [1,5-^{14}C]-cadaverine hydrochloride (nominal specific activity, 3.2 mCi per mmol, nominal total activity, 0.1 mCi) (experiment 17), respectively, in 10 ml glass-distilled water, was added. In experiment 15, [2-^{14}C]-2-allylpiperidine (nominal specific activity, 0.5 mCi per mmol, nominal total activity, 0.04 mCi) in 10 ml glass-distilled water, was administered. In each experiment the cuttings were kept in contact with the tracer solution for 48 h.

Isolation of Lycopodine and of Pelletierine Hydrochloride

Radioactive lycopodine was isolated from each of the three feeding experiments. The method of isolation described in an earlier paper (4) was employed in experiment 15. In experiments 16 and 17, radioactive pelletierine hydrochloride as well as lycopodine was isolated.

The method for the isolation of lycopodine and pelletierine from experiment 16 gave a very poor yield of pelletierine and needs to be recorded in outline only: lycopodine (58 mg) was isolated by fractional crystallization from a hexane solution of the basic fraction of the plant extract, and was further purified by crystallization from hexane, followed by sublimation at 80–100° and 3×10^{-3} mm. Inactive lycopodine (100 mg) was then added to the hexane mother liquor and reisolated, to remove residual activity associated with this alkaloid. The hexane mother liquor was then evaporated, the residue dissolved in dry methanol (0.5 ml), the solution saturated with hydrogen chloride, solvent evaporated, and the residue applied to a plate of silica gel which was developed with chloroform/methanol (9:1). The zone corresponding in R_f value to that of an authentic sample of pelletierine hydrochloride was eluted with chloroform/methanol (1:1), and the product (5 mg) isolated by column chromatography on alumina, followed by sublimation in high vacuum.

An improved procedure was used to isolate the products from experiment 17.

The shoots of *L. tristachyum* were dried and ground to a fine powder in a blender (Osterizer Galaxie 10). The powder was continuously extracted with methanol for 24 h. The extract was evaporated *in vacuo* and the solid residue was repeatedly extracted with hydrochloric acid (5%, 3×100 ml). The mixture was filtered through Celite, and the filtrate was basified with ammonia and extracted with chloroform (3×150 ml). The chloroform extract was dried and evaporated, and the oily residue applied to a column of basic alumina. Elution with benzene afforded lycopodine which was further purified by crystallization from hexane, followed by sublimation at 5×10^{-3} mm. Elution with chloroform gave pelletierine: the chloroform was evaporated at room temperature and the residue dissolved in dry ether. When dry hydrogen chloride was passed through the ether solution pelletierine hydrochloride crystallized (300 mg). Paper chromatography (Whatman No. 1,

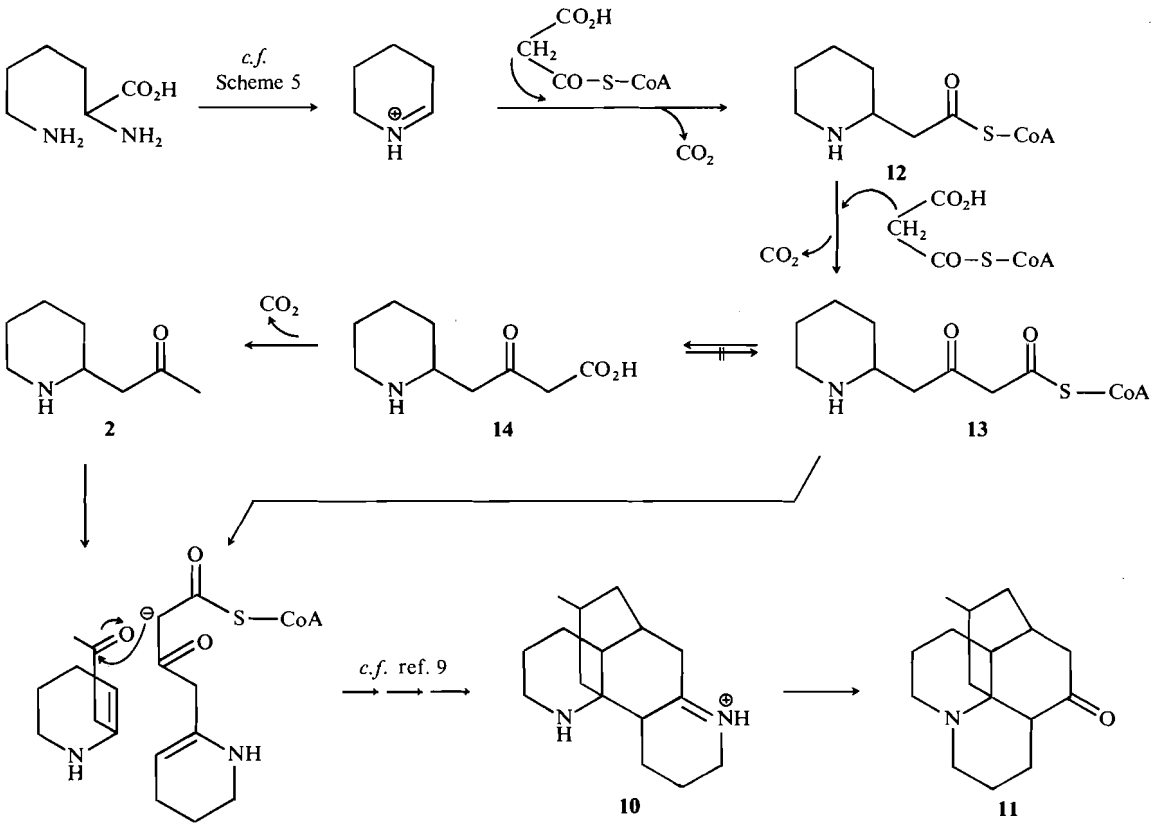

SCHEME 8. The biosynthesis of lycopodine. A hypothetical pathway consistent with the experimental evidence.

n-butanol/acetic acid/water, 2:1:1) of a sample of the crude product from this experiment with [1,5-^{14}C]-cadaverine (experiment 17) revealed the presence of a highly radioactive contaminant whose R_f value was identical with that of cadaverine hydrochloride. A portion of the crude pelletierine hydrochloride (10 mg) was therefore purified by paper chromatography on a preparative scale, using the same solvent system. The pelletierine zone was eluted with methanol, and the product purified to constant radioactivity by recrystallization from ethanol/ether, followed by high vacuum sublimation at 110–120° and 3×10^{-3} mm.

Degradation of Labelled Samples

The labelled samples of lycopodine and of pelletierine were partially degraded. Carbon-5 of lycopodine was separated as benzoic acid (4), and carbons-7 to -16 were recovered as 7-methyl-5,6,7,8-tetrahydroquinoline (4). The labelled pelletierine hydrochloride was oxidized to pipecolic acid (9) which was purified by paper chromatography (*n*-butanol/acetic acid/water, 2:1:1), followed by sublimation at 5×10^{-3} mm.

Determination of Radioactivity

Radioactivity was assayed on samples of finite thickness on aluminum planchettes with a gas-flow system (Model 4342 Nuclear Chicago). The usual corrections for background and self-absorption were applied. For plating, a 1% solution of collodion in dimethylformamide was used as the solvent. In the case of benzoic acid, a drop of a 1% solution of sodium hydroxide in 50% aqueous methanol was added to prevent loss by evaporation.

Confidence limits given in the tables are standard deviation of the mean.

Infrared and Electronic Spectral Studies of Cobalt(II) and Nickel(II) Complexes of *N*-Allyl Urea and *N*-Allyl Thiourea

P. P. SINGH AND I. M. PANDE

Chemistry Department, M.L.K. College, Balrampur, U.P., India

Received December 23, 1971

Complexes of *N*-allyl urea (NAU) and *N*-allyl thiourea (NATU) with cobalt(II) and nickel(II) halides and perchlorates have been prepared and characterized by electrical conductance, magnetic susceptibility, infrared and electronic spectra. Infrared spectra suggest coordination in NAU through oxygen and in NATU through nitrogen. The electronic spectra and magnetic susceptibility data indicate tetrahedral and octahedral stereochemistry for cobalt(II) and nickel(II) halide complexes, respectively. The various ligand field parameters Dq, B', and β calculated for these complexes show about 25 and 11% covalency for Co(II) and Ni(II), respectively, and suggest a weak ligand field.

Les complexes de la *N*-allylurée (NAU) et *N*-allyl thiourée (NATU) avec les halogénures et perchlorates de cobalt(II) et nickel(II), ont été préparés et caractérisés par conductance électrique, susceptibilité magnétique, spectres infrarouge et électronique. Les spectres infrarouge suggèrent une coordination dans la NAU à travers l'oxygène et dans la NATU, à travers l'azote. Les spectres électroniques et les données sur la susceptibilité magnétique, indiquent une stéréochimie tétraédrale et octaédrale respectivement pour les complexes avec les halogénures de cobalt(II) et nickel(II). Les divers paramètres du champ de ligand Dq, B', et β, calculés pour ces complexes, donnent environ 25 et 11% de covalence pour le Co(II) et Ni(II) respectivement et laisse penser à un champ de ligand faible.

Canadian Journal of Chemistry, **50**, 2603 (1972)

Introduction

In view of the great variations in structure (1–13) of cobalt(II) and nickel(II) complexes, we have prepared a series of complexes of these ions with *N*-allyl urea and *N*-allyl thiourea, and have carried out conductance, magnetic, infrared and electronic spectral measurements to characterize them. Also we have tried from Dq and B' values to draw some conclusions regarding the site of bonding in ligands and to correlate these with the infrared spectral results.

Experimental

Materials

Reagent grade cobalt(II) and nickel(II) halides and perchlorate (Alfa Inorganics) were used without further purification. *N*-Allyl urea (NAU) and *N*-allyl thiourea (NATU) were of reagent grade and were used as such. Solvents were dried before use, and the water sensitive compounds were handled in dry box flushed with nitrogen.

Physical Measurements

The electrolytic conductance measurements were carried out at 25 °C in nitromethane with a Philips Conductivity measuring bridge Model PR 9500/90 and Conductivity cell Model PV 9055. Magnetic measurements were carried out at room temperature by the Gouy method (14) and the diamagnetic corrections were estimated by the procedure of Figgis and Lewis (15). Infrared spectra of the complexes were obtained on a Perkin–Elmer Model 7I, using KBr pellets. Electronic spectra were obtained using Cary 14 spectrophotometer in nitromethane and a single band for the broad or scattered peaks, was selected by the method of Cotton *et al.* (16). The various spectral parameters Dq, B', and β were calculated by using the secular equation of Tanabe and Sugano (17).

Preparation of the Complexes

Complexes were prepared by refluxing and stirring the anhydrous metal salt and ligand, in suitable molar ratios, in $CHCl_3$ for 24 h. The perchlorate complexes were, however, prepared by first stirring the salts with 6 ml of 2,2-dimethoxypropane before adding a chloroform solution of the ligand (1:4 or 1:6 ratio) and continuing the stirring for 24 h. In each case, except for NATU complexes, insoluble precipitates were obtained which were filtered, washed with the solvent, dried in vacuum, and recrystallized either from ethanol or *n*-butanol.

In the case of NATU complexes, the precipitates frequently appeared as an oil, whose consistency was increased by repeatedly shaking with ether. The viscous mass thus obtained was spread in a thin layer on the surface of a porcelain dish and kept for several weeks over P_4O_{10}; a solid mass was then obtained.

Analysis of the Complexes

Cobalt(II) and nickel(II) complexes were analyzed for halogen and nitrogen as described earlier (18). Cobalt and nickel were determined gravimetrically as anthranilate and dimethylglyoximate, respectively. The analytical results are presented in Table 1.

Results and Discussion

Electrolytic Conductance and Magnetic Study

Reference to Table 1 shows that all the complexes are non-electrolytes except the perchlo-

rates which have the high conductance values expected of 1:2 electrolytes (5). The magnetic susceptibility data are in the expected range of tetrahedral and octahedral complexes of cobalt(II) and nickel(II), respectively. The observed regular increase in moments on proceeding from chloro to iodo complexes is in accord with ligand field theory (19, 20).

Electronic Absorption Spectral Study

Cobalt(II) Halide Complexes

The electronic spectral data and the values chosen for the energies ν_2 and ν_3 together with the values of spectral parameters Dq, B', and β derived therefrom are given in Table 2. The ε_{max} values, color of the complexes, and the magnetic susceptibility data indicate that the complexes have tetrahedral configuration (5, 16). So we have made our assignments and calculations on this basis.

The complexes show the characteristic absorption (ν_3), in the 18 000 – 13 500 cm^{-1} range, assigned to $^4A_{2g} \rightarrow {}^4T_{1g}(P)$ transition; this absorption moves towards lower energy from chloro to iodo complexes. They also exhibit the multicomponent absorption in the 6500–5500 cm^{-1} range assigned to $^4A_{2g} \rightarrow {}^4T_{1g}(F)$ transition. The splittings of the components of ν_2 and ν_3 frequencies are presumably due to distortion from tetrahedral symmetry. The values of the spectral parameters Dq, B', and β are in the expected range for tetrahedral cobalt(II) complexes.

The Dq and B' values of ethylene urea and ethylene thiourea complexes can be compared with the previously known tetrahedral complexes of cobalt(II) from Table 3 and the position of the ligand in the spectrochemical and nephelauxetic series can be suggested.

It is interesting to note that the Dq and B' values of NAU and NATU are similar, suggesting that both have similar donor atoms. Thus the donor site in NAU and NATU may be nitrogen, or in the case of NAU it could be oxygen, because there is very little difference (0.5 unit) in the electronegativity of nitrogen (3.0) and oxygen (3.5) and in their π-bonding character. There are no chances of bonding through sulfur in NATU, as it would have caused considerable difference in the values of Dq and B' because it has the possibility of extensive π-bonding through the vacant d-orbital.

Nickel(II) Halide Complexes

The electronic spectral data and crystal field parameters Dq, B', and β calculated from the positions of ν_1 and ν_3 bands, are shown in Table 4. These assignments are well supported by the excellent agreement between the calculated and experimental values of the ν_2 band, obtained for the transition $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ and also by the constancy of the ratio (3.0) of the values of ν_3 and ν_1. In all our nickel(II) complexes, the band assigned to ν_2 around 14 000 cm^{-1} has a double peak, characteristic of weak field complexes (21–25).

The spectrochemical and nephelauxetic series for the nickel(II) complexes can be represented by a reference to Table 3. The energy of $^3T_{1g}(P)$, as calculated from the positions of the bands for different complexes comes to 14 000 – 15 600 cm^{-1}, whereas the gaseous ion energy of $^3T_{1g}(P)$ for nickel(II) complexes is 15 840 cm^{-1}. From these two values, the nephelauxetic parameter β is calculated and found to be of the same order as other oxygen donors (26, 27).

Nickel(II) Perchlorate Complexes

The electronic spectra of the $[Ni(NAU)_4](ClO_4)_2$ complex (Table 4) exhibits an intense band ν_3 at 24 700 cm^{-1} ($\varepsilon_{max} \approx 7.0$), and a much weaker band of ν_2 at 14 200 cm^{-1} ($\varepsilon_{max} \approx 2.5$) and ν_1 at 8600 cm^{-1} ($\varepsilon_{max} \approx 2.0$). Such a spectrum is indicative of a square-planar complex (9). Thus, the complex possibly has D_{4h} symmetry. Donoghue and Drago (12) have suggested a T_d symmetry for the $[Ni(HMPA)_4](ClO_4)_2$ complex on the basis of its great similarity with the spectrum of $[NiCl_4]^{2-}$. As our spectrum of $[Ni(NAU)_4](ClO_4)_2$ is very much different from the spectrum of $[NiCl_4]^{2-}$, we conclude that tetrahedral symmetry in our case is not likely. This further supports D_{4h} symmetry for the complex.

The perchlorate also forms $[Ni(NAU)_6](ClO_4)_2$ which gives a typical spectrum of octahedral nickel(II) complex (10, 26). Thus, NAU, like ethylene thiourea (13), forms two types of perchlorate complex, one having D_{4h} symmetry, the other O_h.

Spin–Orbit Coupling Constants

An important correlation between spectral and magnetic studies has been obtained by calculating the effective values of the spin–orbit coupling constants (λ') for the cobalt(II) and

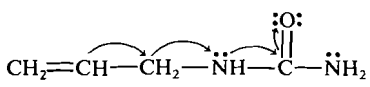
nickel(II) complexes (10, 12). As shown in Tables 2 and 4, the λ' values for Co(II) complexes are about 70–80% of the free ion value (178 cm^{-1}) and Ni(II) complexes about 70–90% of the free ion value (315 cm^{-1}). The λ' values in complexes appear generally lower than the λ values in the free ions. It is due to orbital overlap, resulting in delocalization of the d-electrons. The position of NAU in the nephelauxetic series also suggests a reasonable degree of delocalization.

Infrared Spectral Study

N-Allyl Urea Complexes

The assignments of various bands of NAU and its complexes are presented in Table 5. Considerable difference in the positions of N—H and C=O stretching frequencies in the solid and solution phase of the spectrum of NAU indicates the presence of intermolecular hydrogen bonding (28). We have, therefore, chosen the spectrum of the ligand in solution for the comparison purpose.

A negative shift of the order of 48 and 20 cm^{-1} in amide I (ν(C=O)) and amide II ($\delta(NH_2)$) bands, respectively, and a positive shift of 15 cm^{-1} in amide III (ν(C—N)) band, suggest that carbonyl oxygen is the donor site, but a negative shift of the order of 165 cm^{-1} in the N—H stretching frequency supports linkage through nitrogen. Similar observations by previous workers in many amine (29) and amide (8) complexes have been interpreted as due to hydrogen bonding between N—H and halogen (29, 30) and not to coordination. A small negative shift of the order of 10 cm^{-1} in the double bond on coordination is probably due to drain of electrons towards oxygen.



(*N*-allyl urea)

The magnitude of the shift in carbonyl stretching frequency on complex formation is consistent with the order Cl > Br > I for acceptor strength. The magnitude of the shift is higher with Ni(II) complexes, suggesting that the metal–ligand bonding is stronger than that of the Co(II) complexes.

N-Allyl Thiourea Complexes

Comparison of the various assignments of the ligand with those of the complexes (Table 5) shows negative shift of the order of 200 cm^{-1} in N—H stretching frequency, indicating either coordination through nitrogen (3) or hydrogen bonding between the hydrogen of the N—H and halogen of the metal halide (29, 30). However, the bands assigned to thioamide I [ν(C=S) + ν(C—N)] and thioamide II [δ(CH) + δ(NH) + ν(CN)] at 1442 cm^{-1}, respectively, show a positive shift, suggesting coordination through nitrogen. Also, the positive shifts observed in thioamide III [ν(CS) + ν(C'N)] and [ν(C=S) + δ(NCS)] indirectly support our assumption of linkage through nitrogen. This had been well supported from electronic spectral study as well.

The authors wish to express their sincere thanks to the C.S.I.R., New Delhi, for providing financial assistance and to the College authorities for providing research facilities.

Examination of Two Theories for Absorption of Microwave and Far Infrared Radiation by Polar Liquids

M. BENSON, G. D. MARTIN, S. WALKER, J. WARREN, AND R. WILSON

Department of Chemistry and Department of Physics, Lakehead University, Thunder Bay, Ontario

Received September 1, 1971

The far infrared spectra of twenty polar organic liquids have been obtained using a cube interferometer spectrometer. Some new liquids have been examined and some of the previously studied liquids have been re-examined over a wider frequency range and the integrated absorption of the broad band with its peak absorption frequency below about 100 cm^{-1} evaluated, while any contribution from any overlapping higher frequency band has been subtracted. In general, this has not been taken into account in previous such work. Two approaches which have been previously examined to account for the far infrared absorption of such liquids have been tested for a wider variety of liquids and neither mechanism appears to explain quantitatively the observed absorption intensities. Thus the absorption cannot be accounted for by a simple rotational type of mechanism based on Gordon's equation, plus a contribution similar to that which is found in a non polar liquid as has been suggested earlier. In addition, the parameters of the continuous distribution function approach do not match up to those determined experimentally.

Nous avons obtenu le spectre infrarouge lointain de vingt liquides organiques polaires en utilisant un spectromètre à interféromètre cubique. Nous avons examiné quelques nouveaux liquides et quelques liquides déjà étudiés ont été réexaminés sur un plus grand domaine de fréquence; nous avons évalué l'absorption intégrée de la bande large avec la fréquence de son pic d'absorption au-dessous de 100 cm^{-1}, tout en soustrayant la contribution de la bande de fréquence supérieure qui pourrait chevaucher la bande qui nous intéresse. En général, on ne tenait pas compte d'une telle opération dans des travaux précédents. Deux approches qui ont été préalablement étudiées pour tenir compte de l'absorption dans l'infrarouge lointain de tels liquides ont été essayées pour une plus grande variété de liquides et aucun mécanisme ne semble expliquer quantitativement les intensités d'absorption observées. On ne peut donc pas tenir compte de l'absorption par un type simple de mécanisme rotationnel basé sur l'équation de Gordon, plus une contribution semblable à celle qu'on trouve dans un liquide non-polaire, tel qu'il avait été suggéré précédemment. De plus, les paramètres de l'approche à la fonction de distribution continue ne s'accordent pas avec ceux déterminés expérimentalement.

Canadian Journal of Chemistry, **50**, 2610 (1972)

Introduction

Each polar liquid whose far infrared spectrum is reported in the literature has exhibited a band with a maximum somewhere in the 10–100 cm^{-1} region. This type of band which is broad and has a half band width ranging between about 45–90 cm^{-1}, a typical value being about 75 cm^{-1}, has met various interpretations. Some workers have sought to explain it in terms of rotation-like transitions (1, 2), whereas other workers have felt that this absorption may have a translational component (3, 4). A process which involves a collision-induced dipole moment (5) has been identified for non polar liquids which leads to a generally weaker absorption. Hill has examined a model to explain the absorption based on a continuous distribution of resonance frequencies (6); this approach has, however, been tested by only three polar liquids. Rocard (7), Powles (8), and Leroy *et al.* (9) have taken into account the contribution of the inertial term to the Debye absorption. In order to evaluate the full Debye absorption dielectric data are required (*e.g.* see Table 1).

An integrated absorption approach studied by Kroon and van der Elsken (4) and by Davies *et al.* (14) has been tested by only a limited number of polar liquids. Our major aim was to re-examine their approaches (which appeared adequate for their data) with a wider number of polar liquids. Other interesting approaches such as that by Rothschild (15) based on large-size rotational and translational diffusion steps of the polar molecule will not be examined here.

In the approach of Davies *et al.* (14) and also that of Mansingh (16) a band area has been employed to assess a particular theory. We also sought to obtain more accurate band areas and, consequently, where appropriate, corrections have been made for a contribution from an overlapping band due to an intramolecular vibration. In several cases we have re-examined

CH_3CCl_3 (12)	5.8	7.11	2.06	345
$(CH_3)_3CBr$ (13)	6.3	10.41	2.21	412
$(CH_3)_3CCl$ (13)	5.6	10.45	1.95	279
1-$ClC_{10}H_7$ (12)	52.4	5.30	2.67	956

systems reported in the literature where such band overlap occurs where this had not been taken into account in the reported values. Further, the highest frequency employed in the study of Davies *et al.* (14) was 120 cm^{-1}, and since there is often the tail-end of the broad band in this region we have extended the high frequency side to greater than 200 cm^{-1}.

Experimental

The interferograms were recorded on an NPL modular cube interferometer manufactured by Grubb–Parsons. The detector was a Golay pneumatic cell with diamond windows which allow the spectral region from 10–450 cm^{-1} to be investigated. The radiation source was a mercury lamp. Melinex beam-splitters of 25 μ thickness and 6.25 μ thickness provided transparent regions of 10–130 and 130–450 cm^{-1}, respectively. An optical path difference of ±2 mm for both the background and sample interferograms gave a resolution of 5 cm^{-1}. An increased resolution was not deemed necessary because of the broad nature of the absorption. The analog interferograms were converted to digital ones in the form of punched tapes. The spectra were then constructed from the digital interferograms utilizing an IBM 360/50 computer.

All compounds were studied at room temperature (~22 °C) in a variable path cell. The cell windows were polyethylene with a Teflon spacer. A continuously variable path cell with polyethylene windows was used to check the effects of reflections. Quartz windows were used in yet another liquid cell to detect any absorption of the liquid into the polyethylene.

The absorption coefficient (α) was obtained from the intensity against wave number graphs for the background and sample spectra, where α is defined by the equation:

$$[1] \qquad \alpha = \frac{1}{l} \ln \frac{I_0}{I_s}$$

where l is the path length in cm, and I_0 and I_s are the intensities at the particular wave number for the background and sample, respectively.

TABLE 2. The peak absorption (α_{max}), the center (ν_0) and the half width ($\Delta\nu_{1/2}$) of the broad band absorption of the polar liquids at ~22 °C

Molecule	α_{max} (nepers cm^{-1})	ν_0 (cm^{-1})	$\Delta\nu_{1/2}$ (cm^{-1})
C_6H_5F	24	35	80
C_6H_5Cl	17	43	78
C_6H_5Br	13	35	65
C_6H_5I	12	33	64
$C_6H_5NO_2$	77	43	84
C_6H_5CN	93	57	85
$C_6H_5CH_3$	5.6	76	99
o-FC_6H_4F	47	33	72
o-ClC_6H_4Cl	21	45	71
o-BrC_6H_4Br	15	44	56
m-FC_6H_4F	21	51	89
m-ClC_6H_4Cl	12	60	74
CH_3I	101	62	88
$CHCl_3$	18	32	66
$CHBr_3$	8	37	49
CH_3CCl_3	31	27	55
$(CH_3)_3CBr$	48	23	45
$(CH_3)_3CCl$	60	23	45
1-$ClC_{10}H_7$	8.5	50	75

In Table 2 the peak absorption (α_{max} in neper cm^{-1}), the center (ν_0 in cm^{-1}), and half-width ($\Delta\nu_{1/2}$ in cm^{-1}) are listed for the broad band absorption of the polar liquids where any contribution from an intramolecular band has been first subtracted.

For fluoro-, chloro-, and bromobenzene and 1-chloronaphthalene we also measured the absorption at 4.6 cm^{-1} and for chlorobenzene at 2.3 cm^{-1} as well. At both these frequencies a Michelson interferometer technique was employed (17, 18).

The compounds were commercially available and the reagent grade liquids were dried before use.

The moments of inertia for the symmetric top molecules were obtained from microwave spectra. The remaining moments were calculated using appropriate interatomic distances taken mainly from the data compiled by Sutton (19).

Discussion

Two examples of the far infrared spectra of the pure liquids are illustrated in Figs. 1 and 2. The chlorobenzene, as other halobenzenes, has an intramolecular band in the 200 cm^{-1} region.

The integrated absorption (A) was determined for all of the pure liquids by integration of the absorption coefficient (α). The experimental area is given by

$$[2] \qquad A = \frac{1}{N} \int_0^\infty \alpha \, d\nu$$

where N is the number of molecules per cc. The reproducibility of α is about ±5%. In line with

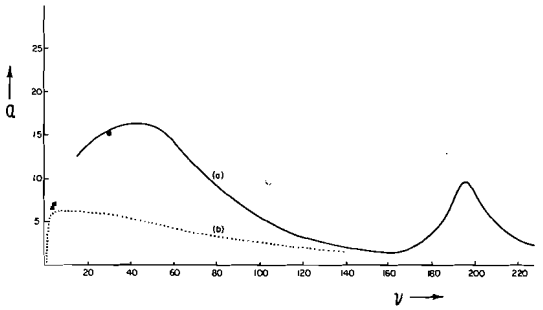

FIG. 1. Far infrared spectrum of chlorobenzene at room temperature (~22 °C): (*a*) observed curve; (*b*) Powles curve: ●, maser point (21) at 29.6 cm^{-1}, ■, microwave points at 2.3 and 4.6 cm^{-1}.

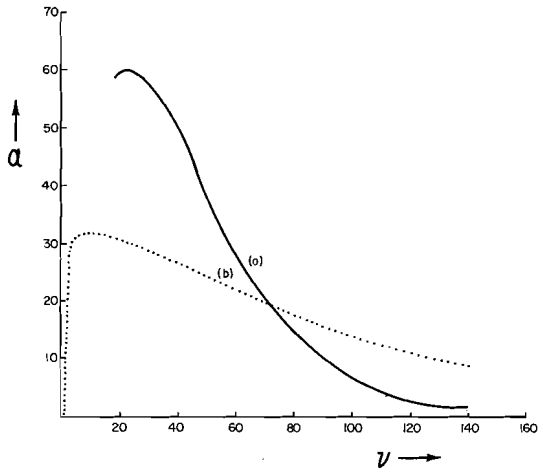

FIG. 2. Far infrared spectrum of *t*-butylchloride at room temperature (~22 °C); (*a*) observed curve, (*b*) Powles curve.

previous workers (10, 14) we have extrapolated α to zero at the low frequency end of the absorption band.

The correction for an overlapping band contribution was obtained by fitting to this band a Lorentz type of function of the form (20):

$$[3] \qquad \ln\left[\frac{I_0}{I_s}\right]_\nu = \frac{a}{(\nu - \nu_{max})^2 + b^2}$$

where

$$\ln\left[\frac{I_0}{I_s}\right]_{\nu_{max}} = \frac{a}{b^2}$$

when

$$[4] \qquad \nu = \nu_{max}$$

and half-band-width $= \Delta\nu_{1/2} = 2b$.

Thus, if we divide eq. 3 by *l*, the cell path length, we obtain from these equations and eq. 1

$$[6] \qquad \alpha = \frac{\alpha_{max}(\Delta\nu_{1/2}/2)^2}{(\nu - \nu_{max})^2 + (\Delta\nu_{1/2}/2)^2}$$

This gave α values for the various ν of the overlapping band. The absorption contribution of this band was then subtracted from the low frequency band, and the remaining area under the lower frequency band was then termed A_{obs} in Table 3.

Of the A_{obs} values in Table 3 seven have been reported also by Mansingh (16), and, on the whole, the agreement between the two sets of values (see Table 3) is reasonable. In the case of toluene Davies *et al.* (14) obtained an A_{obs} of 9.6×10^{-20} cm as opposed to our value of 7×10^{-20} cm. The difference between the two values may be explained by a small contribution from the tail end of an overlapping band, which was not taken account of in their investigation, and of which the highest wave number examined was 120 cm^{-1}. However, in general, comparison of our band data, for cases where there was no appreciable band overlap, yielded similar data (10). Our band center, peak absorption, and half-band-width data are listed in Table 2.

In order to determine how nearly the Debye approach could explain the A_{obs} values for a variety of compounds the *A* values (A_p) have been evaluated from this theory where the contribution to the absorption from the inertial term has been included.

The Rocard and also the Powles treatment, which take this term into account, enable the corresponding Debye type of absorption to be calculated for the far infrared region and lead to an expression from which the loss factor (ε″) may be obtained as a function of frequency. Davies *et al.* (10) showed that for benzonitrile the Rocard and also the Powles treatment led to an almost identical absorption contribution.

The appropriate Powles equation is

$$[7] \qquad \varepsilon'' = \frac{(\varepsilon_0 - \varepsilon_\infty)\omega\tau}{[1 - x(\omega\tau)^2]^2 + (\omega\tau)^2}$$

with

$$[8] \qquad x = \frac{I}{2kT\tau^2}$$

where ε_0, ε_∞ are the static and very high frequency dielectric constants, ω the angular frequency, τ the observed relaxation time, and *I*

*A_{obs} is the experimental value, A_g is the calculated value for the gas phase based on Gordon's equation while A_l' and A_l'' are the values for the corresponding liquid based on the Polo–Wilson and Mecke treatments, respectively. $\Delta A_{PW} = A_{obs} - A_l'$ and $\Delta A_0 = A_{obs} - A_l''$. All the values have been multiplied by 10^{20} and are in cm units.

†Reference 16.

the moment of inertia. From the following equation

$$[9] \qquad \alpha = 2\pi\varepsilon''\nu/n$$

where the corresponding Powles absorption coefficient (termed α_p) may be calculated either by measuring the real part of the refractive index (n) at the wave number (ν) or by assuming it to be 1.6. Davies *et al.* (10) have indicated that n will normally change only some few % between 10 and 100 cm^{-1}. With the exception of the data used for chlorobenzene in Fig. 1 (where the n against frequency data (10) were available), the conversion of ε'' to α values was carried out using a constant value of 1.6 for n. For chlorobenzene the maser point (21) at 29.7 cm^{-1} lies on the experimental curve (Fig. 1) whereas for fluoro- and bromobenzene the maser point (21) lies slightly below. For the maser point to lie on the α against frequency curve for the fluoro- and bromobenzene compounds, the n values would have to be 1.43 and 1.50, respectively. The microwave points at 4.6 cm^{-1} for fluoro-, chloro-, bromo-, and 1-chloronaphthalene appear to lie on the extrapolated far infrared low frequency spectrum and lie either on or very close to the Powles curve which itself passes through the origin. This is illustrated in Fig. 1 for the case of chlorobenzene and the 2.3 cm^{-1} result is also plotted and bears this out.

The data employed in the Powles calculations are given in Table 1. In Figs. 1 and 2 plots of α against frequency (in cm^{-1}) are given for the experimental results and also for the Powles treatment.

For the small fairly spherical molecules with a low moment of inertia such as t-butylchloride (see Fig. 2), the Powles contribution at the very high frequency end of the spectrum lies above the experimental curve and clearly indicates the inadequacy of this treatment for such molecules. The molecules examined here which fall into this category are 1,1,1-trichloroethane, t-butylchloride and bromide.

The approach by Leroy *et al.* (9) using autocorrelation functions leads to similar absorption curves to those by the Powles treatment, the two treatments, of course, being merely different mathematical procedures to calculate the same classical dynamic problem.

It is readily apparent from Figs. 1 and 2 that the Powles treatment cannot account for the total absorption by the liquids at these far infrared frequencies, and as the moment of inertia increases (see Table 1), the discrepancy

For personal use only.

between the A_{obs} and the A_p values (see Table 3) becomes, in general, more appreciable. In fact, when the compounds are arranged in the sequence of increasing moment of inertia, the ratio of A_{obs}/A_p tends to increase, being 1.8 for *t*-butylchloride and 6.3 for iodobenzene. Benzonitrile and toluene are noticeable exceptions to this sequence, and both have high A_{obs}/A_p ratios for their particular moment of inertia values. Clearly, the Powles type of treatment could in no way account for the A_{obs} values.

Hill (6) and also Davies *et al.* (14) have recently examined two different models by which to interpret the absorption intensity of the broad band. Davies *et al.* (14) and Kroon and van der Elsken (4) have employed integrated absorption approaches to determine the mechanism of the broad band absorption. They treated the molecules in the liquid phase as capable of undergoing rotation and proceeded to compare the integrated absorption with that estimated from Gordon's equation (22) which gives the integrated absorption (A_g) for a molecule undergoing pure rotation in the gaseous phase. This value is then converted into A_l, the corresponding absorption for the liquid phase. For a molecule where the molecular dipole moment (μ_z) lies along a principal axis Gordon's appropriate equation is

$$[10] \quad A_g = \frac{1}{N}\int_0^\infty \alpha \, dv = \frac{\pi}{3c^2}\mu_z^2\left[\frac{1}{I_x}+\frac{1}{I_y}\right]$$

where I_x, I_y are the moments of inertia along the x and y axes which are perpendicular to the z-axis.

Before comparing this calculated value with the observed intensity, one must correct the calculated area for the change in field intensity brought about by the dielectric environment in changing from the gaseous to the liquid state. Three equations have been evolved which enable the calculation of A_l from A_g

$$[11] \quad \frac{A_l'}{A_g} = \frac{1}{n}\left(\frac{n^2+2}{3}\right)^2$$

$$[12] \quad \frac{A_l''}{A_g} = \frac{1}{n}\left(\frac{3n^2}{2n^2+1}\right)^2$$

$$[13] \quad \frac{A_l'''}{A_g} = \frac{(n^2+2)^2(2\varepsilon+1)^2}{9(2\varepsilon+n^2)^2}$$

where n is the refractive index of the liquid and ε its static dielectric constant.

Equation 11 was derived by Polo and Wilson (23) and is the one which, so far, has found the most frequent use in determining A_l. Some workers have felt that it is more generally consistent with experimental observations, and also that the assumptions upon which it is based are more clearly recognized (24). Equation 12 was derived by Mecke (25) and is based upon Onsager's theory. Equation 13 was derived by Hirota (26) and seems to give nearly the same A_l value as the Polo–Wilson equation.

In Table 3 the A_l values are given as calculated from the Polo–Wilson and Mecke equations. The value used for n was n_D where n_D is the refractive index for the sodium-D lines. The n_D values for the organic liquids examined here lie in the 1.4 to 1.6 range, and this is of the same order as the refractive index (n) of the infrared region.

Davies *et al.* (14) examined ΔA values for the broad band absorption of the type

$$[14] \quad \Delta A = A_{obs} - A_l$$

where A_l becomes the A_l' for the Polo–Wilson and A_l'' for the Mecke values respectively. When ΔA is derived from A_l' it will be designated ΔA_{PW} while for the A_l'' case ΔA_0. Davies *et al.* (14) indicated that this absorption can be mainly accounted for by means of the A_l' derived from the value of A_g as deduced from eq. 11 and that the excess absorption ΔA_{PW} for polar liquids is of the same order as the non polar liquid benzene which has a value of 6×10^{-20} cm. This was based on results for only five polar liquids, and of these two had higher ΔA_{PW} values than this. It was suggested that the higher ΔA_{PW} values than that for benzene could be accounted for by a dipole – polarizable molecule interaction. However, the ΔA_{PW} values for fluoro-, chloro-, bromo-, and iodobenzene clearly indicate that a polar effect alone could not explain their values of 17, 8, 8, and 13×10^{-20} cm, respectively, since their dipole moments (27) are all of the same magnitude (1.5 ± 0.1 D) and the polarizability of the fluorobenzene would be least and the iodobenzene the greatest. In fact, of the compounds listed in Table 3 about half of them have ΔA_{PW} values of $\geqslant 11 \times 10^{20}$ cm; that is nearly double or greater than the value of the nonpolar benzene.

The Onsager theory leads to much greater ΔA values. They follow much the same order as

TABLE 4

ΔA_{PW} but are larger in some cases by a factor of about 1.5. The A''_1/A_g ratio is approximately one for the Mecke equation. Perhaps the main factor from our point of view is that these ΔA_0 values do not offer any more obvious pattern for interpretation than do the ΔA_{PW}.

It is quite apparent from both the ΔA_{PW} and ΔA_0 values in Table 3 that broad band absorption cannot, in general, be accounted for in terms of a simple rotational type of mechanism based on the Gordon equation plus an additional contribution of the type exhibited by nonpolar liquids.

Hill has made a few approaches to account for the far infrared absorption of polar liquids (6, 28, 29). In a recent approach she chose a model based on a continuous distribution of resonance absorptions (6). Two types of distribution functions were examined, a Debye and a Gaussian distribution. The Debye had one adjustable parameter, g (a damping constant), while the Gaussian distribution had two adjustable parameters, g and the width parameter (W). She evaluated integrals involving the two distribution functions for different values of g and W and found that the two types of distributions lead to essentially similar absorption curves. She concluded that the damping parameter of the individual resonances was of the order of unity and characterized her theoretical curves by the following parameters: x_{max} is the frequency at which the absorption is a maximum, x_+ the frequency at which the absorption falls to half its maximum value on the high frequency side and x_- the corresponding frequency on the low frequency side. Further parameters were defined as $r_+ = x_+/x_{max}$, $r_- = x_-/x_{max}$ and the relative frequency of the refractive index minimum $r_{min} = x_{min}/x_{max}$. She then calculated these parameters for the two distribution functions mentioned and compared them with the r_+, r_-, and r_{min} values from the experimental data of the observed minus Powles absorption curves for three polar and two non-polar liquids. The success of the model was assessed in matching up a particular set of the theoretical and experimental values. Unfortunately, we were not in a position to determine r_{min} values.

Our r_+ and r_- values obtained from the observed minus Powles absorption curve are listed in Table 4 as are also the corresponding r'_+ and r'_-, the analogous values which were obtained from the experimental curve itself, since the most recent work of Hill (30) indicates that "no advantage is to be gained by subtracting a Debye tail from the experimentally observed absorption".

We found good agreement for our values of r_+ and r_- with those quoted by Hill for chlorobenzene (1.75 and 0.25) and moderate agreement with her values for toluene (1.5 and 0.42) and 1,1,1-trichloroethane (1.8 and 0.44).

In the Gaussian distribution for $g = 1.0$ and varying value of W, it can be seen that with increases in the latter r_+ increases while r_- decreases. The width parameter then affects the distribution curve so as to widen it on both sides as W increases in value. What the present data appear to indicate is that the values of "r_+" and "r_-" from the observed spectra vary independently of one another. For example, the experimentally obtained r_+ values of *t*-butylbromide, 1,1,1-trichlorethane, bromobenzene, and nitrobenzene are identical whereas the corresponding r_- values are 0.48, 0.38, 0.31, and 0.38, respectively. The r'_+ values for these compounds are 2.3 ± 0.3 while the r'_- values range between 0.44 and 0.22. For chlorobenzene, benzonitrile, and 1-chloronaphthalene in particular, it appears that the experimentally determined "r" values do not come close to matching up with the theoretical "r" values of either the Debye or Gaussian type of distribution.

It would seem that neither of these two distribution functions can satisfactorily account for the broad band absorption.

High Stereoselectivity in the Deuteration of a Primary Carbon L-Threose-4-*d* (4*S*)

A. MARADUFU,[1] D. M. MACKIE,[2] AND A. S. PERLIN
Department of Chemistry, McGill University, Montreal, Quebec

Received March 20, 1972

Chemical synthesis of a deuterated primary carbinol, L-threose-4-*d* (4*S*), has been effected with virtually complete stereoselectivity. It involves deuteride reduction of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide, conversion of the resulting 1,5-anhydride-1-*d* into the corresponding 4-deoxy-6-*aldehydo*-hex-4-ene derivative, and then ozonolysis, without deuterium scrambling. In this way, C-4 and stereoselectively-deuterated C-1 of the hexose have been interconverted to become, respectively, C-1 and stereoselectively-deuterated C-4 of the L-threose molecule. This study also furnishes support for previous evidence that D-galactose oxidase catalyzes removal of the *pro-S* 6-hydrogen atom of D-galactose.

La synthèse chimique du carbinol deutérié primaire L-thréose-4-*d* (4*S*), a été réalisée avec une stéréosélectivité pratiquement totale. Cette synthèse comprend: la réduction par le deutérure du bromure de tétra-*O*-acétyl-2,3,4,6-α-D-glucopyranosyle, la conversion de l'anhydride-1,5-1-*d* résultant en dérivé déoxy-4 *aldéhydo*-6 hexène-4 correspondant et enfin l'ozonolyse sans modification sur le deutérium. Ainsi, le C-4 et le C-1, deutérié de façon stéréosélective de l'hexose, ont été interconvertis pour donner respectivement C-1 et C-4 deutérié sélectivement, dans la molécule de L-thréose. Cette étude vient à l'appui de la preuve précédente pour laquelle le D-galactose oxydase catalyse l'enlèvement de l'atome d'hydrogène-6 *pro-S* du D-galactose.

Canadian Journal of Chemistry, **50**, 2617 (1972)

Deuterated (or tritiated) compounds are used widely for the investigation of biological reaction mechanisms (1–6). Usually, highly stereoselective[3] deuteration may be achieved at a secondary position by the use of well-established chemical procedures (5, 6). At a primary position, however, the degree of selectivity is invariably much lower (5, 6), although the enzymatic reduction of aldehydes has been utilized for the preparation of a number of specifically[3] deuterated carbinols (8). The current paper reports *chemical* synthesis of a deuterated primary carbinol of virtually complete optical purity. This compound is L-threose-4-*d* (4*S*) (**1**), its synthesis having been carried out as part of a recent study (9) on the stereochemistry of H-6 abstraction from the homomorphous D-hexose, D-galactose, by D-galactose oxidase.

Scheme 1 shows the reaction sequence utilized in the synthesis of **1**. In the first step, 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide was reduced (10) with lithium aluminum deuteride with concomitant de-*O*-acylation to 1,5-anhydro-D-glucitol-1-*d* (**2**). In accord with the known characteristics of nucleophilic displacement reactions at C-1 of glycosyl halides (*e.g.* refs. 11–13), as well as of the deuteride reduction of 1,2-*cis*-tri-*O*-acetyl-pentopyranosyl bromides (14), it was to be expected that the deuterium atom would be incorporated with inversion,[4] *i.e.*, equatorially in this instance. The stereochemistry of the reaction was confirmed by the fact that **2** produced only one H-1 resonance signal (Fig. 1; **2** tetraacetate) and that this signal appeared as a doublet of 9.8 Hz consistent with the axial coplanar disposition of H-1 with respect to axial H-2 (16).

Compound **2** was converted into the 6-*O*-trityl ether, then acetylated and de-tritylated, affording triacetate **3** in which the primary carbinol group is unsubstituted. As shown previously (17, 18), **3** should undergo oxidation and elimination when treated with methyl sulfoxide in the presence of triethylamine and sulfur trioxide (19). Accordingly in the current instance it gave the deuterated α,β-unsaturated aldehyde **4**. Ozonolysis of **4** then effected ring cleavage and led to generation of the desired tetrose-4-*d* (**1**), which was converted into its crystalline α-triacetate (**6**).

Although ozonolysis was expected to yield an *O*-glyoxalyl ester (**5**) as an intermediate, the

[1]C. B. Purves Scholarship Holder, 1970–1972.

[2]NRCC Scholarship Holder, 1969–1971.

[3]The terms "stereoselective" and "stereospecific" are used here in the sense defined by Mislow (7).

[4]Stereoselective deuteration in this manner by reduction of alkyl halides is well known (5, 6, 15).

SCHEME 1

only product isolated was **1** itself, *i.e.*, complete de-esterification took place. *O*-Acetyl groups are stable towards ozone (see *e.g.* ref. 20), but it is possible that the *O*-glyoxalate moiety suffered oxidation, because the reaction mixture invariably became strongly acidic; presumably, this acidity accounted for hydrolysis of the ester groups during subsequent work-up. It may be noted also that attempts to obtain **1** via cleavage of the double bond of **4** with osmate–periodate (21) were unsuccessful.

A comparison of the p.m.r. spectrum of 1,2,3-tri-*O*-acetyl-α-L-threofuranose-4-*d* (4*S*) (**6**) with that of the unlabelled compound shows that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

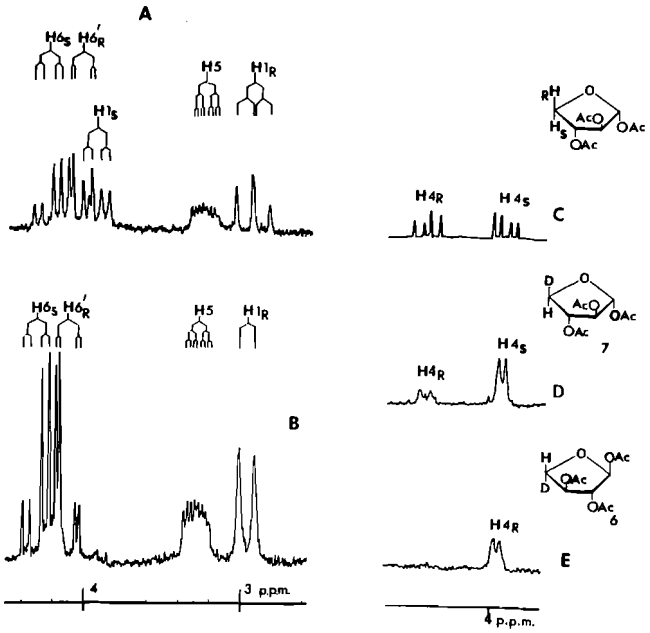

FIG. 1. Partial p.m.r. spectra of (A) 2,3,4,6-tetra-*O*-acetyl-1,5-anhydro-D-glucitol (24) and (B) 2,3,4,6-tetra-*O*-acetyl-1,5-anhydro-D-glucitol-1-*d* (1*S*) (**8**) in benzene-d_6; (C) 1,2,3-tri-*O*-acetyl-α-D-threose, (D) 1,2,3-tri-*O*-acetyl-α-D-threose-4-*d* (4*R*, 4*S*), and 1,2,3-tri-*O*-acetyl-α-L-threose-4-*d* (4*S*), in chloroform-*d*.

one of the H-4 signals is completely (within the limits of detection) eliminated by deuteration (Fig. 1). Accordingly the H-4 signal at 4.0 p.p.m. appears in the spectrum of **6** as a doublet slightly broadened by deuterium coupling. This shows that the high degree of stereoselectivity effected in the initial, deuteride reduction step, is retained during the succeeding transformations. Furthermore, the assignment of an *S*-configuration at C-4 is in harmony with the stereochemistry of 1,2,3-tri-*O*-acetyl-α-D-threofuranose-4-*d* synthesized previously as unequal mixtures of 4 *R* and 4 *S* isomers (9). That is, the p.m.r. spectrum (Fig. 1) of the predominantly *R* isomer (**7**) much more closely resembles that of **6**, with which it should be enantiomeric, than does the spectrum of the predominantly *S* isomer (9). Hence the synthesis of **6**, by providing an independent proof of the configuration at C-4 of **7**, also serves to support previous conclusions about the stereochemistry of the dehydrogenation of D-galactose by D-galactose oxidase.

Experimental

P.m.r. spectra were recorded with a Varian HA-100 spectrometer, using tetramethylsilane as an internal reference. T.l.c. was carried out with silica gel (Macherey Nagel) as adsorbent and with the solvents indicated below. Solvents were dried over sodium. Melting points are uncorrected.

*1,5-Anhydro-*D*-glucitol-1-d (1S) (***2***)*

The procedure of Ness *et al.* (10) was used. 2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosyl bromide (34.0 g) in benzene (5 ml) and ether (400 ml) was added to a stirred suspension of lithium aluminum deuteride (10 g; 99% deuterium) in ether (100 ml) maintained under gentle reflux. When the reaction had been completed (t.l.c., benzene : ether (1 : 1)), the excess deuteride was decomposed with ethyl acetate, followed by water, and then more water (300 ml) was added. The ether layer was decanted off, and the aqueous layer was clarified by centrifugation, de-ionized with Amberlite-IR-120 (H^+) and Dowex-(HCO_3^-) exchange resins, and concentrated. A thick syrup was obtained; when dried through azeotrope-formation with benzene : ethanol, it solidified (yield, 11.2 g); after recrystallization from methanol : ether, m.p. 145–147°, $[\alpha]_D$ +43° (*c*, 2 water), (lit. (10), non-deuterated, m.p. 141–142°, $[\alpha]_D$ +42.5°).

*2,3,4-Tri-O-acetyl-6-O-trityl-1,5-anhydro-*D*-glucitol-1-d (1S)*

To a solution of the deuterated anhydride (2) (7.0 g) in pyridine (25 ml), triphenylchloromethane (13.0 g) was added and the solution was heated with stirring at 45–50° for 12 h (reaction complete according to t.l.c.; *n*-propanol : ethyl acetate : water (3 : 2 : 1)). Pyridine (20 ml) and acetic anhydride (30 ml) were introduced to the cooled solution, and after 48 h at room temperature the solution was poured onto ice, diluted with chloroform, and the chloroform layer washed successively with 2 *N* hydrochloric acid, saturated sodium bicarbonate, and water. The dried chloroform extract afforded a syrup which was purified by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

chromatography on a column of silica gel (benzene:ether: petroleum ether 65–110° (1:3:5) as eluent), and crystallized from ethanol; m.p. 93–95 °C, $[\alpha]_D$ +69° (*c*, 3 chloroform) (lit. (18), non-deuterated, m.p. 92–93°, $[\alpha]_D$ +82° (*c*, 3 pyridine).

*2,3,4-Tri-O-acetyl-1,5-anhydro-*D*-glucitol-1-d (1S) (**3**)*

De-*O*-tritylation of the preceding compound (7.0 g) was effected by brief treatment with cold hydrobromic acid (32% in acetic acid), which yielded **3** (3.2 g), m.p. 113–114 °C, $[\alpha]_D$ +37° (*c*, 4 chloroform), (lit. (18), non-deuterated, m.p. 111–113°, $[\alpha]_D$ 49° (*c*, 3 chloroform).

*4,5-di-O-acetyl-2,6-anhydro-3-deoxy-aldehydo-*L*-threo-hex-2-enose-6-d (**4**)*

The triacetate (**3**) (0.6 g) was dissolved in methyl sulfoxide (8 ml), triethylamine (2.6 ml) was added followed by a solution of sulfur trioxide–pyridine (2.6 g) in methyl sulfoxide (8 ml). The mixture was shaken for 10 min, cooled in an acetone–CO_2 bath, diluted with chloroform, and the chloroform solution was washed successively with cold 2 *N* hydrochloric acid, saturated sodium bicarbonate, and water. Evaporation of the solvent afforded an oil (0.30 g) which was purified by chromatography on silica gel (eluent, benzene:ether (9:1); $[\alpha]_D$ +189° (*c*, 0.4 chloroform); 2,4-dinitrophenylhydrazone, m.p. 177–179°, undepressed by admixture with a non-deuterated specimen (18). (A higher melting form (m.p. 185–186°) of the hydrazone has also been prepared in this laboratory (18), and it is indistinguishable from the lower melting material by i.r. and p.m.r. spectroscopy.)

*Ozonolysis of **4**. Preparation of **6***

Ozone (Welsback generator) was bubbled into a solution of **4** (0.13 g) in cold (acetone–CO_2) ethyl acetate at an oxygen rate of 0.5 l/min for 15–20 min (t.l.c., benzene:ether (1:1)) at which time **4** was absent. Evaporation of the solvent left an acidic syrup (0.15 g) (sparingly soluble in chloroform) which was triturated in water (2 ml) and then left with stirring for 10 h. After neutralization with Dowex-1 (HCO_3^-) ion exchange resin, the solution was shown chromatographically to contain a major product, travelling at the rate of D-threose (solvent, *n*-propanol:ethyl acetate: water (3:2:1)); minor components, presumably partially acetylated derivatives of threose, were also detected. The solution was lyophilized, benzoyl chloride and pyridine at 0° were added to the residue, and the benzoylation product was purified by chromatography on silica gel (eluent, benzene:ether (9:1)),(yield, 30 mg) and then by crystallization from ethanol; m.p. 175–178°; (1,2,3-tri-*O*-benzoyl-α-D-threofuranose has m.p. 178–180°, $[\alpha]_D$ 0° (*c*, 5 chloroform)).

In another ozonolysis experiment, carried out for 10 min, a lower proportion of free tetrose was obtained (yield 48 mg from 150 mg of **4**). The crude product was acetylated with acetic anhydride/sodium acetate affording, after purification by chromatography on silica gel as above and crystallization from ethanol, 1,2,3-tri-*O*-acetyl-α-L-threofuranose-4-*d* (**6**) m.p. 121–122°, $[\alpha]_D$ −26° (*c*, 0.4 chloroform); (1,2,3-tri-*O*-acetyl-α-D-threofuranose has m.p. 120–122°, $[\alpha]_D$ +34° (22)). Benzoylation of the crude ozonolysis product afforded material which, according to p.m.r. spectroscopy, appeared to be mono-*O*-benzoyl-di-*O*-acetyl-α,β-L-threose.

*Oxidation of **4** with Osmium Tetroxide–Periodate*

Attempts were made to obtain **6** via cleavage of the double bond of **4** with osmium tetroxide–sodium periodate (21). Two sets of conditions were examined: *i.e.*, according to ref. 21 using ether as the solvent, and to ref. 23 using dioxane:*t*-butanol:water as solvent. In each instance, the reaction was very slow (48–72 h, as shown by t.l.c. examination) and a dark syrupy product, possibly containing osmate ester, was isolated. The p.m.r. spectrum of the product was poorly resolved and suggestive of a mixture of components.

*2,3,4,6-Tetra-O-acetyl-1,5-anhydro-*D*-glucitol-1-d (1S) (**8**)*

Compound 2 was acetylated in acetic anhydride–pyridine. Evaporation of excess acetic anhydride and pyridine gave a syrup which crystallized in ether–petroleum ether (b.p. 30–60°). Recrystallization in the same solvent afforded crystals m.p. 73–75°, $[\alpha]_D$ +40.2° (*c*, 2 chloroform), (lit. (25), non-deuterated), m.p. 73–74° $[\alpha]_D$ +38.9° (c, 2 chloroform).

The authors express their gratitude to the Pulp and Paper Research Institute of Canada and to the National Research Council of Canada for generous support. Sincere thanks are due also to Dr. H. J. Koch and R. Simoneau for recording the p.m.r. spectra, and to G. Suranyi for kindly providing facilities for the generation of ozone.

Coordination Compounds of Indium. Part XV.[1] The Stability Constants of some Trifluoromethyl-β-diketonate Complexes of Indium (III)

KEITH BOWDEN,[2] (MRS.) G. M. TANNER, AND D. G. TUCK
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received March 7, 1972

The stability constants K_1 and K_2 have been measured for the interaction of indium(III) with the ligands $R{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}CF_3$ (R = 2-furyl, 2-thienyl, phenyl, 2-naphthyl, *i*-butyl, and *t*-butyl). The pK_a values for these compounds, and for R = 3-pyridyl and methyl, are also reported. A conventional potentiometric technique was used; the results refer to 46% aqueous acetone, at an ionic strength of approximately 0.1 *M*. The results are compared with published values for complexes of these ligands with divalent cations in other solvent systems.

Les constantes de stabilité K_1 et K_2 ont été mesurées pour l'interaction de l'indium(III) avec les ligands $R{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}CF_3$ (R = furyl-2, thienyl-2, phenyl, naphthyl-2, isobutyl, et *t*-butyl). Les valeurs des pK_a de ces composés et pour R = pyridyl-3 et méthyle, ont été rapportées. La technique potentiométrique courante a été utilisée, les résultats ayant pour référence l'acétone aqueuse à 46%, à une force ionique de 0.1 *M* approximativement. Les résultats sont comparés aux valeurs publiées pour les complexes de ces ligands avec des cations divalents dans d'autres systèmes de solvants.

Canadian Journal of Chemistry, **50**, 2622 (1972)

The mechanism of the ligand exchange reaction

$$[1] \qquad In(L^-)_3 + L \rightarrow In(L^-)_3 + L$$

in a series of organic solvents has recently been investigated in this laboratory by n.m.r. techniques (1), using a number of 1,1,1-trifluoromethyl-β-diketonate ligands, **1**, $(CF_3{\cdot}CO{\cdot}CH{\cdot}CO{\cdot}R)^-$. The free energy of activation for the exchange, and hence the rate of exchange, depends both on the particular solvent chosen and on the nature of the terminal group R (= methyl, *i*-butyl, phenyl, 2-naphthyl, 2-furyl, or 2-thienyl).

One possible mechanism for the exchange process [1] would involve dissociation of the complex into free ligand (or ligand anion) and a residue of lower coordination number. In order to investigate the significance of such processes, we have now measured the stability constants of a series of these chelate complexes. Results have been obtained for the pK_a of the diketones themselves, and for the first and second stability constants using a simple potentiometric titration method; it proved impossible to obtain reproducible values for K_3 due to the chemical instability of the parent diketones in strongly alkaline solution (see below). Measurements have been carried out for the ligands listed above, and for R = 3-pyridyl and *t*-butyl. A number of solvents and solvent mixtures were examined in preliminary experiments, with approximately 50% aqueous acetone proving the most satisfactory in terms of solubility for both ligands and indium complexes.

There are relatively few references in the literature to stability constant measurements with these ligands, and none referring to complexes of Group IIIA cations. The ligand most widely studied has been 1,1,1-trifluoro-4(2-thienyl)-2,4-butanedione (TTA; **1**, R = 2-thienyl), presumably because of the well established use of this compound in solvent extraction. Of special interest, however, are the studies of Van Uitert *et al.* (2) on the stability constants for the reaction of Ba^{2+}, Cu^{2+}, and Ni^{2+} with four of the ligands studied by us (**1**; R = methyl, naphthyl, thienyl, and furyl). Their results show many of the same general features found in the present work.

Experimental

Materials

All the trifluoromethyl-β-diketonates were obtained from Eastman Organic Chemicals and were used as supplied. Acetone was Analytical Grade material.

Tetraethylammonium perchlorate was prepared by mixing hot aqueous solutions of tetraethylammonium bromide and sodium perchlorate, and recrystallized from water.

A weighed amount of indium metal (~1 mmol) was dissolved in concentrated aqueous hydrochloric acid, and the resultant solution evaporated to yield $InCl_3 \cdot \sim 3H_2O$. This material was dissolved in 10 ml of 0.1 *M* perchloric acid in the preparation of the titration solution.

Apparatus and Procedures

For measurements of pK_a, pH changes were recorded with a Corning Model 10 pH meter and a glass electrode, calibrated for work in aqueous acetone. Solutions were thermostated to 25 ± 0.2°. The results so obtained (Table 1) refer to ~0.1 *M* ionic strength tetraethylammonium perchlorate in 46% aqueous acetone (by volume) at a diketone concentration of 0.02 *M*.

The bulk phase in the stability constant measurements was 90 ml acetone, 100 ml aqueous (0.2 *M*) tetraethylammonium perchlorate solution, and 10 ml 0.1 *M* aqueous perchloric acid containing 1 mmol In(III) as the hydrated chloride. This mixture was titrated with an acetone solution of the ligand, previously neutralized with concentrated aqueous tetraethylammonium hydroxide solution and made up to 10 ml with acetone. The mid-point of the titration curve therefore refers to a solution of approximately 0.1 *M* total ionic strength, in 46% aqueous acetone (by volume).

Van Uitert *et al.* (2) have commented on the low chemical stability of 1,1,1-trifluoromethyl-β-diketones, and the experimental problems resulting from this instability, which they ascribe to hydrolysis. While this fission reaction is likely to be of general importance for the diketones, we observed that in the case of the methyl compound, the addition of excess tetraethylammonium hydroxide to an acetone solution of the diketone produced a red oil, and we were therefore unable to carry out any stability constant measurements with this ligand. This red product probably arises from an intermolecular base-catalyzed condensation between the acidic methyl group and the highly electrophilic carbonyl group α to the trifluoromethyl group. Following Van Uitert *et al.*, all measurements were carried out as rapidly as possible but despite this, results at high pH were irreproducible and no K_3 values could be obtained in highly alkaline solution.

Calculation of Results

In the first series of experiments, pK_a values were obtained graphically; duplicate experiments agreed to ±0.02 pK units.

The potentiometric results in the stability constant experiments were treated by a least-squares computer program (IBM 360/50) to give values of $\bar{n}$, the average ligand number, and hence β_1 and β_2. No significant changes were found when values of β_1 and β_2 were computed after removing those experimental values, showing high deviations in the least-squares analysis. The values in Table 2 are the mean of at least two determinations, and are assigned a probable error of ±0.05 units.

TABLE 2. Stability constants for indium(III) complexes of some 1,1,1-trifluoromethyl-β-diketonates

R	log K_1	log K_2
2-Furyl	5.93	5.45

Results and Discussion

pK_a Measurements

The pK_a values for the trifluoromethyl diketones studied are given in the Table 1, together with earlier results in the literature, and relevant data for other acidic compounds containing the same substituent groups.

We note first that the pK_a values of β-diketones are strongly dependent on the solvent involved; Van Uitert *et al.* (10) have published graphs showing the changes in the measured pK_a with composition in water:dioxane mixtures. In view of this, a detailed comparison of our results with those of other workers is not productive, but we note that the order of pK_a values is the same in both columns 2 and 3 of Table 1, with the sole exception of the methyl/furyl pair. The differences here are however small, and this apparent anomaly may well arise from errors in the measurements for $CF_3 \cdot CO \cdot CH_2 \cdot CO \cdot CH_3$ due to the instability of this compound in alkaline solution (see Experimental section). Similar comments apply to the comparison of the present pK_a results with the values for the $CH_3 \cdot CO \cdot CH_2 \cdot CO \cdot R$ diketones (column 4, Table 1).

Table 1 also shows that the various substituent groups investigated have substantially parallel effects on the pK_a's of $CF_3 \cdot CO \cdot CH_2 \cdot CO \cdot R$, $CH_3 \cdot CO \cdot CH_2 \cdot CO \cdot R$, and $R \cdot COOH$ over the relatively small range of values involved. Such linear correlations are to be expected, provided that there are no other compensating effects. The results in Table 1 refer to a range of aliphatic, aromatic, and heterocyclic substituents, so that a strictly linear relationship between the present results and the values in columns 5 and 6 of Table 1 would be unlikely. It is, however, of interest to note that the pK_a values of the $CF_3 \cdot CO \cdot CH_2 \cdot CO \cdot R$ compounds do in fact depend significantly on the nature of R. This suggests that the structure of the anion involves considerable distribution of the negative charge onto all three possible sites (*i.e.*, the central carbon atom and both oxygens), despite the presence of the very strongly electron-withdrawing trifluoromethyl group, which might have been expected to localize the anionic charge on sites proximate to this group.

Stability Constant Measurements

The stability constants K_1 and K_2 obtained in the present experiments are shown in Table 2. It is clear that all the complexes are thermodynamically very stable; the log β_2 values are in the range 11–13, from which one may reasonably deduce that log $\beta_3 > 15$. The implications of this finding for the kinetic studies are discussed elsewhere (1). As in other studies with these trifluoromethyl-β-diketones (2), the K_2 values are only slightly smaller than those for K_1. The experimental errors for K_2 are greater than for K_1, since the former arise from experimental results in alkaline conditions, where ligand decomposition is an important consideration. For the phenyl compound, we find K_2 slightly larger than K_1; this is almost certainly an artefact arising from the reasons just outlined.

It is instructive to compare the results in Table 2 with those reported for the interaction of some of these ligands with Ba^{2+}, Ni^{2+}, and Cu^{2+} (2) (see Table 2). A dependence of, for example, pK_1 on pK_a is generally found in such studies; in particular, the stability constants of β-diketonate complexes show a monotonic increase with pK_a for a variety of alkyl and aromatic terminal groups, over a pK_a range of 6–14 (and a corresponding pK_1 range, for Ni^{2+}, of 4–12). Within this wide range however some non-linear relationships appear, and it is interesting to note that this is the case for complexes of certain of the present ligands with the three M^{2+} ions studied by Van Uitert *et al.* (2). A graph of the pK_a values against pK_1 (Tables 1 and 2) demonstrates that there are also significant deviations from a linear relationship for the indium(III) complexes. The results may of course have been affected by the instability of the ligands in alkaline solution. Alternatively, this non-linearity may be evidence of some unusual thermodynamic factors in these systems; in particular, steric interactions between CF_3 and R groups in a constrained conformation around the metal could lead to destabilization relative to the free ligand anion.

We note finally that the failure in earlier work (1) to obtain the $In(py \cdot CO \cdot CH \cdot CO \cdot CF_3)_3$ complex was presumably due to the choice of inappropriate experimental conditions; the extrapolated values for pK_1, etc.,

which can be obtained from a comparison of Tables 1 and 2 show that this compound should be thermodynamically stable.

This work was supported in part by an Operating Grant (to D.G.T.) from the National Research Council of Canada. We wish to thank Mr. R. C. Ferguson for advice on computer programs.

INDO–MO Calculations and Proton Isotropic Shifts of Methyl-Substituted Pyridine Ligands in Ni(II) Complexes

M. S. SUN, F. GREIN, AND D. G. BREWER

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received March 7, 1972

Relative p.m.r. isotropic shifts for the ligands in the complexes $NiL_4(NO_3)_2$ (L = 4-picoline and 3,5-lutidine), $NiL_3(NO_3)_2$ (L = 3-picoline and 3,4-lutidine), and $NiL_2(NO_3)_2$ (L = 2-picoline, 2,3-lutidine, 2,4-lutidine, and 2,5-lutidine) were determined in $CDCl_3$. Proton hyperfine coupling constants for corresponding pyridine cations and analogous phenyl radicals were calculated by the INDO–MO method. Analysis of the p.m.r. shifts and subsequent correlation with the INDO data revealed that the spin transfer process between metal and ligand was dominated by a σ-mechanism, as indicated by ring protons at the α- and β-positions. The γ-ring proton and methyl protons at all positions indicated a π-mechanism was also operative through σ–π spin polarization at the nitrogen atom. The INDO calculations based on spin densities of the hydrogen 1s orbitals, however, predicted that all ring protons would be dominated by a σ-mechanism, and that methyl protons at the α- and γ-positions should manifest a π-mechanism. Both mechanisms should be operative for the β-CH_3 protons, with 50–60% σ-contribution in the pyridine cations and 30–50% σ-contribution in the phenyl radicals. The pattern of spin polarization (*i.e.*, negative at α-C and γ-C, positive at β-C) is not altered by a small excess of α or β spin in the π-system. However, the π-spin density ratios, especially at the α- and γ-positions, are affected, as is the magnitude of the π-spin densities on each carbon. A comparison of the observed isotropic shifts for the methyl protons and for the γ-ring proton with the INDO calculated π-spin densities allows a determination of the spin delocalization in the ligand π-system.

Les déplacements isotropiques relatifs p.m.r. pour les ligands dans les complexes $NiL_4(NO_3)_2$ (L = picoline-4 et lutidine-3,5), $NiL_3(NO_3)_2$ (L = picoline-3 et lutidine-3,4), et $NiL_2(NO_3)_2$ (L = picoline-2, lutidine-2,3, lutidine-2,4 et lutidine-2,5), ont été déterminés dans le $CDCl_3$. Les constantes de couplage hyperfin du proton pour les cations pyridine correspondants et les radicaux analogues du phényle, ont été calculées par la méthode INDO–MO. L'analyse des déplacements p.m.r. et la corrélation subséquente avec les données INDO, révèlent que le processus de transfert de spin entre le métal et le ligand est surtout un mécanisme-σ, comme le montrent les protons du cycle en position α et β. Le proton γ du cycle et les protons du méthyle dans toutes les positions indiquent qu'un mécanisme-π est aussi effectif, par l'intermédiaire d'une polarisation de spin σ–π sur l'atome d'azote. Les calculs INDO, fondés sur les densités de spin dans les orbitales ls de l'hydrogène, laissent prévoir cependant que tous les protons du cycle seraient dominés par un mécanisme-σ et que les protons du méthyle sur les positions α et γ manifesteraient un mécanisme de type π. Ces deux mécanismes seraient effectifs pour les protons du CH_3-β, avec une contribution σ de 50–60% dans les cations pyridine et 30–50% dans les radicaux phényles. Le modèle de la polarisation de spin (c'est-à-dire négative sur C-α et C-γ, positive sur C-β) n'est pas effecté par un léger excès de spin en α ou β dans le système π. Cependant, les rapports de densité de spin π, surtout en position α et γ, sont modifiés de même que l'amplitude des densités de spin π sur chaque carbone. En comparant les déplacements isotropiques observés pour les protons du méthyle et pour le proton en γ du cycle, avec les densités de spin π calculées par la méthode INDO, il a été possible de déterminer la délocalisation de spin dans le système π du ligand.

Canadian Journal of Chemistry, **50**, 2626 (1972)

Introduction

Nuclear magnetic resonance isotropic shifts arising from electron–nuclear hyperfine contact interactions have been employed to study paramagnetic Ni(II) complexes with considerable success in recent years (1–6). A typical example is the spin delocalization in the π-electron system of Ni(II) complexes with aminotroponeimines (1–3), where the observations agreed very well with valence bond (VB) calculations. Other examples, such as the Ni(II)–pyrromethene (4) and the Ni(II)–salicylaldimine (6) systems gave results which correlated well with molecular orbital (MO) calculations. Thus, spin delocalization in a π-fragment of an aromatic molecule is predicted to exhibit shifts alternating in sign at adjacent positions, and substitution of a methyl group for a proton should give a shift opposite in sign to that of the replaced proton (7). In 1963, Happe and Ward (8) first reported the isotropic shifts of pyridine type ligands coordinated to Ni(II) acetylacetonate. They concluded that spin delocalization in pyridines was dominated

by a σ-mechanism, as the ring protons demonstrated decreasing downfield shifts (*viz.* $\alpha:\beta:\gamma = 1.00:0.294:0.077$ for pyridine) in contrast to the alternating sign characteristic of a π-mechanism. They also indicated that a small π-mechanism might be operative because of upfield shifts of the methyl protons at the α- and γ-positions.

Molecular orbital calculations appear to be essential in interpreting observed shifts in terms of some spin transfer mechanism. MO calculations involving only π-electrons[1] cannot account for the proton shifts, including methyl protons, of a pyridine type molecule. Although the extended Hückel theory (E.H.T.) is applicable to large molecules involving all valence electrons (10), calculations on pyridine carried out by Holm *et al.* (11) correlated poorly with the experimental data, particularly for the γ-proton where too large a contact shift ($\alpha:\beta:\gamma = 1.00:0.291:1.97$) was predicted. Cramer and Drago (12) did more refined E.H.T. calculations on pyridine and some methyl-substituted pyridines. They claimed that the β-spin was also delocalized in the Ni(II)–pyridine π-system via a $d-p_\pi$ or $d-p_{\pi^*}$ interaction. In their calculations (*viz.* $\alpha:\beta:\gamma = 1.00:0.382:1.01$ for pyridine), little improvement was obtained for the γ-proton. Furthermore, the E.H.T. was unable to handle negative spin densities.

Very recently, a more sophisticated "approximate molecular orbital theory" has been developed by Pople *et al.* (13) to handle large molecules. Scarlett *et al.* (14) have used the "intermediate neglect of differential overlap" (INDO) method to perform open-shell calculations on pyridine and some monosubstituted pyridine cations. Their results correlated fairly well with the p.m.r. data. Substantial improvement was obtained for the γ-proton ($\alpha:\beta:\gamma = 1.00:0.28:0.58$ for the pyridine cation) though it was still too large in comparison with the experimental data. Signs of the methyl proton shifts at different positions were correctly predicted by the INDO method. Horrocks and Johnston (15) performed similar calculations on analogous monomethyl phenyl radicals isoelectronic with the corresponding pyridine cations. The results ($\alpha:\beta:\gamma = 1.00:0.326:0.208$ for the phenyl radical) compared even better with p.m.r. data of the Ni(II)–pyridine complexes and they concluded that the observed isotropic shifts, including those of the methyl protons, in Ni(II)–pyridine complexes can be attributed to a σ-mechanism only.

In this paper, p.m.r. data are presented for some dimethyl pyridines coordinated to Ni(II) nitrate. INDO open-shell calculations are carried out on dimethyl pyridine cations and their analogous isoelectronic radicals. Two CH_3 groups on each ring, in the case of dimethyl pyridines, provide a better basis for the study of CH_3 proton shifts. An analysis of the CH_3 proton data should show if there is any correlation between the CH_3 proton shifts and a purely π-spin delocalization in pyridine ligands. Furthermore, in view of the good agreement between the calculated hyperfine coupling constants for the phenyl radical and its e.s.r. data (*viz.* $\alpha:\beta:\gamma = 1.00:0.34:0.11$ observed) (16), the INDO method should do equally well with the pyridine cation radical.

Experimental

Complex compounds $NiL_4(NO_3)_2$ (where L = 4-picoline and 3,5-lutidine), $NiL_3(NO_3)_2$ (where L = 3-picoline and 3,4-lutidine), and $NiL_2(NO_3)_2$ (where L = 2-picoline, 2,3-lutidine, 2,4-lutidine, and 2,5-lutidine) were prepared according to published procedures (17–19).[2] Compounds were checked via electronic spectroscopy confirming an octahedral configuration in chloroform solutions in agreement with those reported in the literature (17–19).

P.m.r. spectra of the complexes were obtained in $CDCl_3$ with TMS as internal standard at 29 ± 1 °C. A Varian 4300B high resolution n.m.r. spectrometer of 56.4 Mc/s was used for the measurement. The isotropic shifts were determined by subtracting the diamagnetic ligand shifts from the paramagnetic complexed ligand shifts. All complexes were very soluble in chloroform. The solutions of the complexes with 2,3-lutidine and 2,4-lutidine were clouded, and yellowish green precipitates settled upon standing. This was probably caused by moisture from both solvent and air. Fortunately however, p.m.r. spectra were not appreciably affected by such precipitation. The concentration of the samples was about 50 mg/ml or less giving sufficiently strong peaks of good resolution. The assignment of peaks was based on an analysis of the intensity ratios and line widths. The line widths should be greatest for protons closest to the paramagnetic ion (20, 21). However, the peaks of non-equivalent β-protons in 2-picoline and 2,4-lutidine

[1]Recent detailed treatment on pyridine π-electrons is given by Zeiss (9).

[2]We obtained, however, $NiL_3(NO_3)_2$ instead of $NiL_4(NO_3)_2$ with L = 3,4-lutidine.

Anal. Calcd. for $NiL_3(NO_3)_2$: C, 50.02; H, 5.40; O, 19.04; N, 13.89; Ni, 11.64. Found: C, 49.98; H, 5.45; O, 18.95; N, 14.09; Ni, 11.76.

could not be distinguished (J–J coupling was not observed) on such a basis. They were assigned from the results of MO calculations. There is fast ligand exchange in solution with excess ligand. No attempt was made to obtain the "absolute shifts".

INDO open-shell calculations were performed on an IBM System/360 Model 50I computer using CNINDO program written by P. A. Dobosh, obtained from the Quantum Chemistry Program Exchange at Indiana University. Geometrical parameters for the pyridine molecule were chosen according to the summary by Wong and Brewer (22). Additional bond lengths and bond angles for the methyl group were taken as follows: C—H 1.09 Å; C—CH_3 1.53 Å; ⟨HCH and ⟨HCC 109.467°. Of the three methyl protons, one was placed above the plane of the ring and the other two symmetrically below. The methyl proton hyperfine coupling constants were obtained by averaging over the three individual values assuming free rotation of the methyl group. The standard geometry of benzene was used for the phenyl radicals (C—H 1.08 Å; C—C 1.40 Å; ⟨CCC and ⟨HCC 120°).

Results and Discussion

Isotropic shifts may arise from either a hyperfine contact interaction between the unpaired electrons and the nucleus or a pseudo-contact (dipolar) interaction owing to electronic g-factor anisotropy of the transition metal (23). The latter is absent in the case of purely octahedral Ni(II) complexes because of magnetical isotropy of the $^3A_{2g}$ ground state.

The isotropic hyperfine coupling constant A_n (G) is related to the contact shift $\Delta\nu_n$ (c.p.s.) according to the equation

$$[1] \qquad A_n = -\left(\frac{3kT}{g\beta S(S+1)H}\cdot\frac{\gamma_n}{\gamma_e}\right)\Delta\nu_n$$

where g is the electronic g factor; β is the Bohr magneton; γ_e and γ_n are the gyromagnetic ratios for electron and nucleus, respectively; H is the probe frequency and S is the total spin (23). For a particular system involving similar nuclei, the quantity in brackets is a constant and A_n is directly proportional to $\Delta\nu_n$. Theoretically, A_n is directly related to the spin density at the magnetic nucleus n by the equation

$$[2] \qquad A_n = K\langle\psi|\rho(\hat{r}_n)|\psi\rangle$$

where $K = (4\pi/3)\, g\beta\gamma_n\hbar\langle S_z\rangle^{-1}$; $\rho(\hat{r}_n)$ is the spin density operator at the nucleus n; ψ is the electronic molecular wavefunction, and $\langle S_z\rangle$ is the average spin (13). If ψ is a MO wavefunction containing only valence orbitals (as in the INDO method) and if contributions to the spin density at the nucleus n from neighboring atomic orbitals are neglected, eq. 2 reduces to

$$[3] \qquad A_n = [K|\phi_{sn}(\hat{r}_n)|^2]\rho_{sn}$$

where ρ_{sn} is the spin density of the valence s orbital ϕ_{sn} of atom n, and $|\phi_{sn}(\hat{r}_n)|^2$ is the density at the nucleus n. For a particular atom, the quantity in brackets is constant and can be evaluated by a least-squares fit between the observed A_n and the calculated ρ_{sn}. In the case of hydrogen atoms, this quantity was found to be 539.86 G (13).

Relative hyperfine coupling constants from p.m.r. data for pyridine ligands in Ni(II) complexes and those obtained from INDO calculations according to eq. 3 for pyridine cations and analogous phenyl radicals are listed in Table 1. The results of our calculations on the pyridine and the picolines are almost identical to those reported by Scarlett *et al.* (14). The INDO data for the monomethylphenyl radicals were taken from ref. 15. More elaborate calculations based on eq. 2, taking account of neighboring atomic orbitals, show only slight improvement as far as the γ-H is concerned (*e.g.*, for pyridine cation, $\alpha:\beta:\gamma = 19.47:5.96:10.07 = 1.00:0.306:0.517$). The assumptions of eq. 3 are apparently justified in this case.

P.m.r. data for pyridine ligands in various types of Ni(II) complexes obtained by different investigators are listed for comparison. The results are very similar, indicating that the relative isotropic shifts are independent of the geometry of the complex. This means that the dipolar shift which depends on geometry and magnetic anisotropy of the molecule is not important in these complexes, and the isotropic shift is dominated by the contact term. It has been found, however, that some magnetic anisotropy does exist in pseudo-tetrahedral Ni(II) complexes (24, 25). In Table 1, the p.m.r. data of NiL_2I_2 which is pseudo-tetrahedral show no appreciable difference from the corresponding distorted octahedral case, in which the magnetic anisotropy was estimated to be less than 5% (26); apparently the dipolar shift in NiL_2I_2 is also very small. The relative shifts of β- and γ-protons in the octahedral $NiL_6(ClO_4)_2$ are substantially larger than those in the complexes of other geometries. This should not be considered as the result of complete removal of

γ-CH_3	0.98	0.84

the dipolar contribution in $NiL_6(ClO_4)_2$. According to the geometrical positions suggested by Happe and Ward (8) for the ligand protons in $NiL_2(aa)_2$, it is impossible to obtain a pure contact case similar to that of $NiL_6(ClO_4)_2$ by subtracting any reasonable amount of dipolar contribution from the data of $NiL_2(aa)_2$. Therefore, the discrepancies among p.m.r. data for the complexes of different geometries listed in Table 1 may be attributed to different experimental conditions (27)[3] and to experimental errors. Our experience indicates that the accuracy of locating very broad peaks is questionable and that the nonlinear sweeping of the magnetic field over a large range of chemical shifts may be the greatest source of error, and could have been ignored by some investigators.

INDO calculations on the corresponding radicals (pyridine cations and phenyls) assumed to be in doublet states show that the unpaired electron is delocalized in the highest bonding MO of σ-symmetry (σ_b). The average ratios of calculated A_H to experimental $-\Delta\nu_H$ (both normalized) are summarized in Table 2. The ratio should be equal to 1.0 if experiment and calculations agree perfectly. The data of the distorted octahedral nitrato complexes, $NiL_4(NO_3)_2$, $NiL_3(NO_3)_2$, and $NiL_2(NO_3)_2$, were used for such comparisons. The results in Table 2 indicate that our p.m.r. data compare favorably with the INDO calculations for the pyridine cations at the positions α-H, β-H, α-CH_3, and γ-CH_3, but poorly at the γ-H and β-CH_3 positions. The calculations for phenyl radicals, on the other hand, show substantial improvement at the γ-H and β-CH_3 positions, but the agreement is still far from satisfactory. Furthermore, the discrepancy for the β-H is large. Overall, the phenyl radical model cannot be judged superior to the pyridine cation model.

[3]Some of the results in ref. 27 are quite different from those in ref. 8.

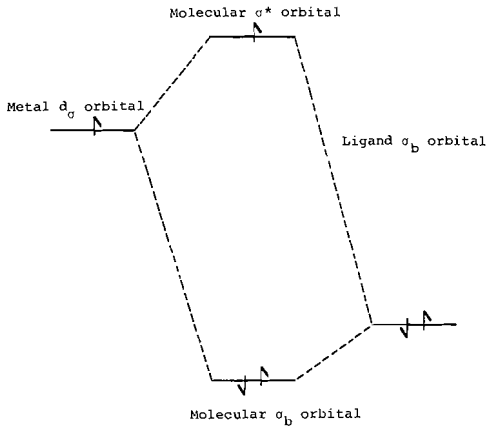

FIG. 1. Spin delocalization in molecular σ* orbital of metal–ligand system.

Spin delocalization in the σ-system of Ni(II)–pyridine complexes can be explained as being due to the interaction between the ligand σ_b (bonding) orbital containing the lone pair and the metal d_σ orbital containing the unpaired electron; this would place some α-spin in the pyridine ring. The discrepancies, especially at γ-H, between observation and theory might be the result of neglecting the metal–ligand interactions in the INDO calculations. Such weak interactions, of course, would not appreciably affect the parameters for the nitrogen atom, but would place the unpaired electron in a σ*-orbital (anti-bonding) of the metal–ligand system, contrary to the case of pyridine cations where the unpaired electron is placed in a σ_b orbital. This is illustrated in Fig. 1. Since only a small fraction of spin is transferred from metal to ligand, the σ* orbital would be mainly localized on the metal, and the σ_b orbital, on the other hand, would be filled and mainly localized on the ligand. The pattern of spin distribution, as far as the pyridine ring is concerned, in a σ* orbital of the complexes may be very different from that in a σ_b orbital of the cations.

Since the CNINDO program is, however, not capable of handling the transition metals, we have performed calculations where the hydrogen atom and selected first row atoms take the place of the Ni metal atom. Some of the

F–Pyr$^+$ triplet	1.60	1.00	0.41	0.35

*Spin densities multiplied by −1.

results are summarized in Table 3. All these models, at the X–N distances indicated, demonstrate spin delocalization in the σ^* orbitals. The X–N distances were adjusted so that the interactions were sufficiently weak and the energy levels of the σ^* orbitals were below the π^* orbitals. A strong X–L interaction would bring the unpaired electron into a π^* orbital. These calculations show that the coefficients of the σ^* orbital depend heavily on the nature of the elements perturbing the lone pair. None of the results agree with the p.m.r. data. The closest is the F–Pyr$^+$ triplet case; however, more than 80% of an unpaired electron is delocalized in the ligand in this case.

The p.m.r. data for the methyl protons exhibit alternation of signs at different positions, in agreement with the INDO prediction. This may be an indication of spin delocalization in the π-system. However, the relative magnitudes of shifts do not agree with the relative spin densities predicted for any π-type orbitals of the pyridine molecule. Happe and Ward (8) and other investigators (21, 28) have already proposed that such a phenomenon was probably due to σ–π spin polarization mechanisms induced by the excessive α-spin in the lone pair of a σ-type orbital. The pattern of such spin polarization in a pyridine framework could never be checked by theory until the INDO method became available. The INDO spin densities in the π-system resulting from σ–π spin polarization mechanism for the pyridine cations are listed in Table 4. The total spin density, ρ_π^t, for the non-substituted pyridine cation is zero, as no spin transfer takes place from any source. In the case of methyl substituted pyridine cations, some spins could be delocalized in the π-systems via a hyperconjugation mechanism with the methyl protons. The data in Table 4 indicate that α-spins are delocalized in the π-systems of α- and γ-substituted cations whereas β-spins are found in the β-substituted cases. Note that there is no appreciable change in the pattern of spin polarization with a small amount of excessive spin in the π-system. There is, however, a trend which indicates that the ratio $\rho_\pi^\gamma/\rho_\pi^\alpha$ is dependent upon ρ_π^t. Thus, the ratio tends to go down when ρ_π^t is positive such as in the case of 2,4-lutidine; and to go up if ρ_π^t is negative, such as in the case of 3,5-lutidine. In the case of phenyl radicals, however, no such trend is found.

The total spin density ρ_π^t should equal in magnitude the spin density (opposite in sign) in the methyl protons, ρ_s', assuming a complete hyperconjugation mechanism. Hence, ρ_s' can be recalculated based on a hyperconjugation model, and then both p.m.r. and INDO data can be checked. For the picolines, ρ_s' is readily obtained from Table 4 by reversing the sign of ρ_π^t. As to the lutidines, a set of simultaneous equations has to be solved in order to obtain the values for each methyl group. According to Levy's equation (29),

$$[4] \qquad A_H = Q'_{CH_3}(\rho_s' + \rho_\pi' + \rho_\pi)$$

where ρ_π' is the π-spin density on the methyl carbon and ρ_π on the ring carbon next to the methyl group. Since $A_H = (539.86/3)\rho_s'$, the unknowns Q'_{CH_3}, ρ'_{sx}, and ρ'_{sy} can be obtained by solving

$$(\rho'_{sx} + \rho'_{\pi x} + \rho_{\pi x})Q'_{CH_3} = 180\rho'_{sx}$$

$$(\rho'_{sy} + \rho'_{\pi y} + \rho_{\pi y})Q'_{CH_3} = 180\rho'_{sy}$$

$$\rho'_{sx} + \rho'_{sy} = -\rho_\pi^t$$

The recalculated spin densities for the methyl protons are summarized in Table 5. The average value of Q'_{CH_3} is 27.6 G comparing favorably with 25.7 G reported by Talcott and Myers (30) on methyl substituted pyridine anions. Almost identical spin densities were obtained using McLachlan's relation (7), $A_H = Q_{CH_3}\rho_\pi$. The average Q_{CH_3} value is 30.7 G.

The INDO predicted spin densities ρ_s for α-CH_3 and γ-CH_3 agree well with the recalculated values. However, the INDO ρ_s for β-CH_3 is about 100–200% greater than the ρ_s'. We may conclude that the INDO predicted hyperfine coupling constants for the methyl groups in pyridine cations are dominated by a π-mechanism at the α- and γ-positions, resulting

†Based on the average value of β-CH_3.

from σ–π spin polarization, whereas both σ- and π-mechanisms are operative at the β-position with 50–60% σ-participation. A similar conclusion can be drawn from the data for the phenyl radicals with 30–50% σ-mechanism at the β-position. Good agreement between p.m.r. data and the recalculated values taking the ratio of the relative contact shift of the methyl proton to that of the α-CH_3 proton (with the value of α-CH_3 normalized to -1.00) is illustrated in Table 6. Thus, another conclusion is that the p.m.r. isotropic shifts of the methyl protons at all positions of the pyridine type ligands coordinated to Ni(II) are caused by a π-mechanism through hyperconjugation with the ρ_π electrons whose spins are polarized by the unpaired electron in a σ-type metal–ligand bond.

As far as the pyridine ligands are concerned, the σ-contributions to β-CH_3 and γ-H are overemphasized by the INDO theory. In view of the observed small shifts of γ-H in the ligands, we may assume that the σ-mechanism is also absent at this position and the shift is dominated by a π-mechanism. Then with spin densities presented in Table 4 and a Q_H value of 24.5 G reported by Talcott and Myers (30), A_H for γ-H can be recalculated using McConnell's relation (31), $A_H = Q_H\rho_\pi$. An overall comparison between p.m.r. and the recalculated data is presented in Table 7. The data in Table 7 reveal that the recalculated values for methyl groups and γ-H are lower than those from p.m.r. data. This is expected since the spin polarization in a π-system is not linearly correlated to the amount of spin density in the σ-system of a pyridine framework and the σ-spin in a pyridine ligand is far less than that in a pyridine cation. This is clearly illustrated in Table 8. Assuming that, in Table 8, ρ^t_σ is linearly related to the spin density in α-H, the ratio ρ_π/ρ^t_σ should be a measure of the relative A_H (or $-\Delta\nu_H$) for the methyl protons and γ-H, as A_H is almost directly proportional to $\rho\pi$. It is clear that ρ_π/ρ^t_σ increases readily with decreasing ρ^t_σ. In a pyridine ligand coordinated to Ni(II), ρ^t_σ should be far less than unity and, therefore, a larger relative $-\Delta\nu_H$ for protons dominated by a π-mechanism would be expected. It can be concluded that the relative proton hyperfine coupling constants at γ-H, α-CH_3, β-CH_3, and γ-CH_3 positions dominated

by a π-mechanism are influenced by the amount of σ-spins delocalized in the pyridine molecules. Comparing the recalculated data of pyridine cations, the larger relative values at those positions in the pyridine ligands may be attributed to the smaller amounts of σ-spins delocalized in the ligands.

As discussed before, some excessive spin in the π-system would affect the ratio $\rho_\pi^\gamma/\rho_\pi^\alpha$. This is better demonstrated in Table 9. It shows that 2.93% of an α-spin in the π-system brings the ratio down to 0.64, whereas the ratio is 1.00 with 1.79% of a β-spin delocalization, and 0.93 with little or no spin delocalization. Thus in Table 6, the shift ratio of methyl protons, $\Delta\nu_H^\gamma/\Delta\nu_H^\alpha = 0.77$, smaller than the cation case, 0.89, may be an indication of α-spin delocalization in the ligand π-system, though this is not favored by the symmetry of the distorted octahedral Ni(II) complexes. Both Tables 4 and 9 reveal that the excess α-spin in the π-system tends to depress spin polarization; *i.e.*, reduce ρ_π at each ring atom, while the β-spin tends to enhance it. Hence the magnitude of ρ_π/ρ_σ^l is influenced by both ρ_σ^l and ρ_π^l. According to the results in Table 7, one may infer that the trend shown by ρ_π/ρ_σ^l is dominated by ρ_σ^l in the complexed ligands but its magnitude has been reduced by the influence of ρ_π^l (α-spin). Nevertheless, in view of the smaller relative shifts of γ-H, β-CH_3, and γ-CH_3 in NiL_2I_2 complexes (Table 1), more α-spin may have been delocalized in the π-system of the ligands, and this is allowed by symmetry.

From the results and discussions presented above, the importance of σ–π spin polarization in pyridine complex systems is obvious. Neglect of this has led to incorrect conclusions by some investigators (12, 15). The simultaneous equations set up by Cramer and Drago (12) in an attempt to separate σ and π contributions to the observed contact shifts indicate that no π-shifts should be observed for the methyl proton if the *net* spin density in the π-system is zero. This is not correct when σ–π spin polarization arises. In fact, σ–π spin polarization in the pyridine framework would have overrun any spin polarization pattern characteristic of a particular π-orbital, if there is any spin in that orbital. Therefore, it is inadequate to compare the observed π-shifts with the spin densities in a particular π-orbital of the pyridine ligands.

The conclusion drawn by Horrocks and Johnston (15) on the methyl proton shifts implies that the unpaired electrons in the methyl hydrogen atoms giving rise to contact shifts have been directly transferred from a σ-network. Our results show that these spins resulted from hyperconjugation between the methyl hydrogen 1s orbitals and the filled π-orbitals of the pyridine ring, and the unpaired electrons in the π-system are generated via σ–π spin polarization mechanism.

Conclusions

(*1*) The spin transfer process between Ni(II) and pyridine type ligands is dominated by a σ-mechanism. However, only ring protons at α- and β-positions manifested such a mechanism via proton isotropic shifts.

(*2*) The unpaired electron is delocalized in a σ^* orbital of the metal–ligand system while for the corresponding cation radicals spin delocalization takes place in a bonding σ orbital. Such a difference may be the cause of discrepancies between observation and theory.

(*3*) The σ–π spin polarization mechanism is very important in the metal–ligand system. The isotropic shifts of all methyl protons and γ-H are dominated by this mechanism which becomes more significant as the amount of σ-spin decreases (*i.e.*, ρ_π/ρ_σ^l increases). Thus zero spin density in the π-system, $\rho_\pi^l = 0$, would not zero the π-contact shifts of these protons.

(*4*) The spin density ratio $\rho_\pi^\gamma/\rho_\pi^\alpha$ will remain constant if the net spin in the π-system, $\rho_\pi^l = 0$. However, the ratio will increase if $\rho_\pi^l < 0$ and decrease if $\rho_\pi^l > 0$. The ratio is manifested by the isotropic shifts of the methyl protons at α- and γ-positions.

(*5*) The magnitudes of π-spin densities on the ring carbons are affected by ρ_π^l. They will decrease if $\rho_\pi^l > 0$, and increase if $\rho_\pi^l < 0$. The magnitudes are manifested by the isotropic shifts of methyl protons and γ-H.

Determination of $D[(CH_3)_3Pb—CH_3]$ by the Toluene Carrier Method

K. M. GILROY, S. J. PRICE, AND N. J. WEBSTER
Chemistry Department, University of Windsor, Windsor 11, Ontario

Received March 10, 1972

The pyrolysis of tetramethyl lead has been studied in a toluene carrier flow system over the temperature range 671–753 °K (contact times 0.72–1.67 s, 3–77% decomposition). The reaction was followed by measuring the amount of methane, ethane, and ethylbenzene formed. Comparison of the extent of reaction based on product analysis and on alkyl recovery indicates that approximately four methyl radicals are released for each molecule undergoing reaction 1.

[1] $$Pb(CH_3)_4 \rightarrow Pb(CH_3)_3 + CH_3$$

The method of least squares gives $k_1 = 5.0 \times 10^{14} \exp(-49\,400/RT)\ sB^1$ with an estimated uncertainty of $\pm$ 1 000 cal mol^{-1} in E_1. Under the conditions used E_1 should be a reasonable measure of $D[(CH_3)_3Pb—CH_3]$.

La pyrolyse du Plomb tétraméthyle a été étudiée dans un système continu avec le toluène pour gaz vecteur, dans l'intervalle de température 671–753 °K (durées de contact 0.72–1.67 sec, décomposition 3–77%). La réaction a été suivie en mesurant la quantité de méthane, d'éthane et d'éthylbenzène formée. La comparaison de l'étendue de la réaction fondée sur l'analyse du produit et l'alkyle retrouvé, indique que quatre radicaux méthyles approximativement sont libérés par chaque molécule subissant la réaction (1)

[1] $$Pb(CH_3)_4 \rightarrow Pb(CH_3)_3 + CH_3$$

La méthode des moindres carrés permet d'avoir $k_1 = 5.0 \times 10^{14} \exp(-49400/RT)\ s^{-1}$ avec une incertitude sur E_1 estimée à $\pm$ 1 000 cal mol^{-1}. Dans les conditions utilisées E_1 serait une mesure raisonnable de $D[(CH_3)_3Pb—CH_3]$.

Canadian Journal of Chemistry, **50**, 2639 (1972)

Introduction

The kinetics of the pyrolysis of $Pb(CH_3)_4$ has been previously studied by Eltenton (1). With a very dilute stream of $Pb(CH_3)_4$ in He at a total pressure of 0.4 mm he obtained $k_1 = 1.5 \times 10^{10} \exp(-28\,200/RT)\ s^{-1}$ (400–700 °C, decomposition essentially complete above 600 °C).

[1] $$Pb(CH_3)_4 \rightleftharpoons Pb(CH_3)_3 + CH_3$$

Both the A factor and activation energy are unreasonably low. A recent investigation (2) combined mass spectrometric data (A.P. and I.P.) with pertinent thermochemistry to give $D[(CH_3)_3Pb—CH_3] = 48.8$ kcal mol^{-1}, based on $\Delta H^0_{f0}(CH_3,g) = 34.8$ kcal mol^{-1} (3). The present work was designed to obtain a revaluation of both A_1 and D_1

Experimental

Materials

(*a*) Toluene from sulfonic acid (Eastman organic X 325) was refluxed over sodium under vacuum and then degassed by bulb-to-bulb distillation.

(*b*) Tetramethyl lead was obtained from the Ethyl Corporation as a blend containing 68% $Pb(CH_3)_4$ and 32% toluene. The $Pb(CH_3)_4$ was separated by a series of four successive fractional crystallizations in each stage of which approximately 50% of the solution was allowed to solidify and the remaining liquid was discarded. The resulting product had a refractive index of 1.5120 at 20 °C in agreement with the literature value (4). A small quantity of residual toluene (approx. 0.3%) was found by gas chromatographic analysis. Apart from necessitating a small correction in the weight of alkyl used in a run, the residual toluene was of no significance as all experiments were carried out in a toluene carrier system.

Apparatus and Procedure

Except for the substitution of an electron capture detector for the hydrogen flame detector when tests were made for possible lead containing products, all apparatus and procedures were identical to those used previously for $Sn(CH_3)_4$ (5).

Results and Discussion

Selected experimental results are given in Tables 1–4. They may be discussed in terms of the following mechanism

[1] $$Pb(CH_3)_4 \rightleftharpoons Pb(CH_3)_3 + CH_3$$

[2] $$Pb(CH_3)_3 \rightleftharpoons Pb(CH_3)_2 + CH_3$$

[3] $$Pb(CH_3)_2 \rightleftharpoons PbCH_3 + CH_3$$

[4] $$PbCH_3 \rightleftharpoons Pb + CH_3$$

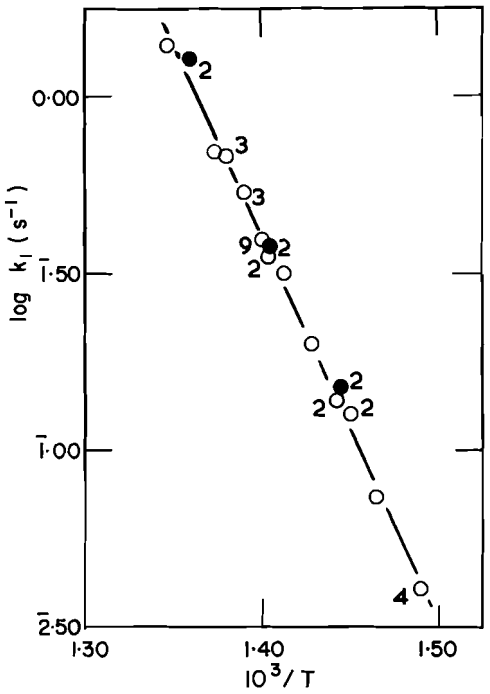

FIG. 1. Arrhenius plot of k_1. Full circles, runs in packed reaction vessel. Numbers indicate number of runs averaged to obtain the given point.

The agreement between these methods shows that essentially four methyl radicals are released for each molecule undergoing reaction 1 and indicates that no undetected major products were produced. Acid digestion of the deposit formed outside the reactor did indicate the formation of about 0.1% $(Pb—CH_3)_n$ or some similar compound. Early results also seemed to indicate the formation of a very small amount of a volatile lead containing product but this could not be confirmed.

The values of k_1 shown in Tables 1, 3, and 4 and used to obtain the Arrhenius plot shown in Fig. 1 have all been calculated from the usual first order equation,

$$k_1 = \frac{2.3}{t_c} \log \frac{100}{100 - x}$$

where x, the percent decomposed, has been calculated from eq. 8. The results in Table 3 support the assumption of first order behavior and Table 4 shows that as expected no significant unimolecular pressure effects are observed.

Least-squares analysis of the points in Fig. 1 gives $k_1 = 5.0 \times 10^{14} \exp(-49\,400/RT)$ s^{-1} with an estimated uncertainty of $\pm 1\,000$ cal mol^{-1} in E_1. This result has been obtained at the high pressure limit and using flow conditions selected to minimize errors due to thermal equilibrium or diffusion problems (6, 7). The observed activation energy should therefore be a reasonable measure of $D[(CH_3)_3Pb—CH_3]$. Comparison with the value of Lappert *et al.* (2), 48.8 kcal mol^{-1} indicates good agreement.

With $\Delta H^0_{f298}(CH_3,g) = 33.2$ kcal mol^{-1} (8), $\Delta H^0_{f298}(Pb,g) = 46.6$ kcal mol^{-1} (8), and $\Delta H^0_{f298}(Pb(CH_3)_4,g) = 32.5$ kcal mol^{-1} (8), $(D_1 + D_2 + D_3 + D_4)$ 298 °K = 146.9 kcal mol^{-1} or at 0 °K approx. 142.9 kcal mol^{-1}. This leads to an average bond dissociation energy for the four Pb—CH_3 bonds of $\bar{D} = 35.7$ kcal mol^{-1} compared to the value of 38.4 kcal mol^{-1} used by Lappert *et al.* (2). 0.8 kcal mol^{-1} of the difference is due to different values accepted for $\Delta H^0_{f0}(CH_3,g)$, 34.0 kcal mol^{-1} in the present work (8) and 34.8 by Lappert (3). The bulk of the remaining 1.9 kcal mol^{-1} difference is due to an error in Lappert's work caused by using $\Delta H^0_{f0}(CH_3,g)$, and $\Delta H^0_{f0}(Pb,g)$ in conjunction with $\Delta H^0_{f298}(Pb(CH_3)_4,g)$. Therefore accepting E_1 as a reasonable measure of D_1 gives $D_2 + D_3 + D_7 = 93.5$–96.7 kcal mol^{-1} (depending on the value chosen for $\Delta H^0_{f0}(CH_3,g)$). An estimated correction for the effect of pressure thus gives $E_2 + E_3 + E_4 =$ approximately 85–88 kcal mol^{-1}. With any reasonable choice of A_2, A_3, and A_4 (5) it is obvious that values of E_2, E_3, and E_4 can be assigned which satisfy the relationship $k_1 \gg k_2, k_3, k_4$. Decomposition by reactions 1–4 with reaction 1 rate controlling is therefore plausible.

Photoelectron Spectra of Some Bromoethylenes and 2-Bromopropene

D. CHADWICK,[1] D. C. FROST, A. KATRIB, C. A. MCDOWELL AND R. A. N. MCLEAN[2]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received April 10, 1972

The photoelectron spectra of vinyl bromide, *cis*- and *trans*-1,2-dibromoethylene and 2-bromopropene have been obtained. Interaction of the bromine "lone pair" electrons with those in the C=C π bond is discussed. The assignments are considered in relation to the chloroethylenes. The spectra provide experimental evidence for a proposal by Klasson and Manne that previous studies have reported too many I.P.'s for some of the chloroethylenes.

Les spectres photoélectroniques du bromure de vinyle, du dibromo-1,2 éthylène *cis* et *trans* et du bromo-2 propène ont été obtenus. L'interaction du doublet électronique libre du Brome avec les électrons de la liaison π est discutée. Les attributions ont été faites en relation avec les chloroéthylènes. Les spectres apportent une preuve expérimentale à la suggestion de Klasson et Manne selon laquelle les études précédentes avaient exagéré le rôle des doublets libres dans certains chloroéthylènes.

Canadian Journal of Chemistry, **50**, 2642 (1972)

Introduction

The electronic structure of ethylene and its derivatives is a problem of great chemical interest (1). Photoelectron spectroscopy (p.e.s.) offers the possibility of evaluating the orbital structures of these molecules, and ethylene itself has been the subject of several investigations (2–5). In the case of the haloethylenes one can use p.e.s. to study the inductive and resonance effects (6). More specifically, the latter effect is the interaction between the halogen "lone pair" electrons and those in the C=C π bond. Evidence for this may be obtained from many physical and chemical properties, but not all of these clearly distinguish between the two effects. For example, the C—Cl bond length in vinyl chloride (1.726 Å) (7) is much shorter than the C—Cl bond length (8) in ethyl chloride (1.788 Å), but this cannot be attributed wholly to π-bonding because of the different carbon hybridization in the two molecules. On the other hand, chlorine nuclear quadrupole coupling constants measured for several chloroethylenes (7, 9, 10) do indicate directly that the C—Cl bonds have considerable "π character". Any "π" interaction, by its very nature, must be reflected in the molecular energy levels and thus in the photoelectron spectrum. Since only one of the possible "lone pair" orbitals in each haloethylene has the correct symmetry to interact with the C=C π orbital, the resonance effect is to be observed as a stabilization of one "lone pair" orbital relative to the other(s).

In view of the recent work on the p.e. spectra of chloro- (6, 11) and fluoroethylenes (6, 12) it is of interest to examine the "π" interaction in some bromoethylenes. In this paper, we present the HeI photoelectron spectra of vinyl bromide, *cis*- and *trans*-1,2-dibromoethylene and 2-bromopropene.

There remains considerable uncertainty over the correct assignment of the p.e. spectra of the chloroethylenes with the exception of the first i.p.'s. On the basis of a comparison with Cl K_β X-ray emission spectra, extended Hückel calculations, and a consideration of the total number of states which should be observed up to 21.2 eV, Klasson and Manne (13) have suggested that too many i.p.'s have been reported by previous workers (6, 11) in some cases. The p.e. spectra of the bromoethylenes, reported here, are found to provide experimental support for this proposal of Klasson and Manne.

Experimental

The p.e. spectra were obtained using the 584 Å HeI resonance line excited by a 2450 MHz microwave discharge. The spectrometer employs a hemispherical electrostatic analyzer with a 4 in. radius. The resolution (f.w.h.m.) of the instrument as measured by the argon doublet was 15 mV. The spectra were calibrated by flowing a small amount of argon through the spectrometer simultaneously with the sample gas.

The samples of bromoethylenes and 2-bromopropene were obtained from commercial sources. The *cis* and *trans* isomers of 1,2-dibromoethylene were separated using preparative vapor phase chromatography.

Results and Discussion

The photoelectron spectra of the four molecules studied are reproduced in Figs. 1–4. Measured ionization potentials are given in Table 1. For each molecule, many of the observed p.e. bands exhibit resolvable fine structure due to vibrational excitation of the corresponding ion. The measured vibrational spacings are given in Table 1 where appropriate. These vibrational frequencies of the ions may

be compared with the known frequencies of the ground state molecule. Such a comparison often indicates the bonding characteristics of the molecular orbital associated with a particular i.p.

It is worthwhile to consider briefly the features which can be expected to occur in the p.e. spectra of these four molecules. Ionizations arising from the C=C π orbital should all lie in the lower binding energy region of the spectra. In each molecule, one of the possible "lone pair" orbitals has the correct symmetry to interact with the π orbital. In the monobromo species this will simply be the out-of-plane "lone pair", while in *cis*- and *trans*-1,2-dibromoethylene it will be the b_1 and a_u combinations,

respectively. A value of 10.5 eV for the unperturbed π orbital in these molecules can be taken from ethylene itself (3). Comparison with bromine (14) and the bromomethanes (15) places the binding energies of the bromine "lone pair" orbitals in the range 10.5–13 eV. Hence, any "π" interaction must result in a destabilization of the C=C π orbital and a stabilization of the appropriate "lone pair" orbital. In this event, the perturbed C=C π orbital would possess C—Br antibonding character. The inductive effect of bromine should stabilize the π orbital. Thus, with respect to the C=C π orbital, the inductive and resonance effects work in opposite directions. In the fluoroethylenes they apparently balance, resulting in the π orbital binding energies remaining unmodified relative to ethylene (6, 12). This has been established for other fluorinated planar molecules which contain π orbitals (12). In the chloroethylenes (6, 11) the resonance effect dominates, resulting in an overall destabilization of the C=C π orbital relative to ethylene. We would expect this to be true also for the bromoethylenes. For 2-bromopropene we must consider the addition effect of the methyl group.

Vinyl Bromide

At least seven bands can be seen in the p.e. spectrum of vinyl bromide (Fig. 1*a*). A low resolution p.e. spectrum of this molecule, reported previously by Turner *et al.* (16), did not reveal any vibrational structure. The low symmetry of CH_2=CHBr (C_s) gives rise to two irreducible representations, a' and a''. Only two valence molecular orbitals possess a'' symmetry, the C=C π orbital and the out-of-plane bromine "lone pair".

The first band, shown in Fig. 1*b*, exhibits extensive vibrational structure. This is interpreted in terms of the excitation of three ionic vibrational modes at 1340, 740, and 290 cm^{-1}. The adiabatic i.p. of 9.80 eV is in good agreement with the previously reported photoionization value (17). In view of the above discussion, this first band can be assigned with certainty to the removal of an electron from the C=C π orbital (a''). It may be noted that in the first bands of ethylene (3) and vinyl bromide the 0–0 component is the strongest. The 1340 cm^{-1} vibration is assigned to the C=C stretching frequency which occurs at 1595 cm^{-1} in the ground state of the neutral molecule (18, 19). The reduction in frequency upon ionization (255 cm^{-1}) is similar to that observed in ethylene (273 cm^{-1}) (3) and vinyl chloride (208 cm^{-1}) (6) and is strong evidence for the assignment. At the same time this substantiates our original assignment of the observed vibrational frequency for the ethylene ion and refutes the recent contrary, and in our view, erroneous contentions made by Brundle and Brown (5). The 740 cm^{-1} vibration corresponds to the C—Br stretch which is slightly increased in frequency from its ground state value of 598 cm^{-1}. The same effect is observed in vinyl fluoride and chloride (6). The 290 cm^{-1} vibration is assigned to the in-plane C—C—Br bending mode which occurs at 345 cm^{-1} in the neutral molecule (18). This vibrational mode was excited also in the first band of vinyl chloride. The observed increase in the C—Br

stretching mode on ionization may be taken as an indication of the C—Br antibonding character of the C=C π orbital and, hence, some degree of "π" interaction with the bromine a'' "lone pair". Since the binding energy of the C=C π orbital is lower than that of the corresponding orbital in ethylene, we conclude that the resonance effect dominates over the inductive effect by approximately 0.7 eV. This will be discussed further below.

The second p.e. band has an adiabatic i.p. of 10.90 eV and is shown in Fig. 1*c*. The observed structure corresponds to two ionic vibrational modes at 1200 and 460 cm^{-1}. It may be concluded from the strength of the 0–0 component that the parent orbital for this ionization is relatively non-bonding. Since the resonance effect is significantly larger than the inductive effect (*vide supra*), we expect the bromine a'' "lone pair" to be stabilized relative to the a'. Also, any interaction of the a' "lone pair" with higher σ bonding orbitals would enhance this effect. On this basis we assign this second band to the in-plane (a') "lone pair". From the p.e. spectrum of vinyl chloride, Lake and Thompson (6) conclude that the two chlorine "lone pair" orbitals are almost degenerate at 11.72 and 11.87 eV. Klasson and Manne (13) and Turner *et al.* (16) do not agree with this interpretation on the grounds that one of the chlorine "lone pair" orbitals is demonstrably interacting with the C=C π orbital, because of the observed destabilization of the latter orbital relative to ethylene. Extended Hückel calculations on the chloroethylenes (13) predict strong mixing of the a'' orbitals. Similar large mixing of π orbitals has been concluded for $Cl_2C{=}O$ and $Cl_2C{=}S$ (20). Klasson and Manne (13) have suggested that there is only one i.p. at 11.72 eV in $CH_2{=}CHCl$ and that the 11.87 eV peak is due to vibrational structure. Returning to the second band of $CH_2{=}CHBr$, it can be inferred that there is no coincidence of ionization potentials at 10.90 eV. The C=C π orbital binding energies do not vary greatly over the four molecules studied here (*vide infra*). Thus, if the two bromine "lone pair" orbitals in vinyl bromide are degenerate, a similar situation must exist in the remaining three molecules in order to explain the p.e. spectra in the range 10.5–12.0 eV. This is very unlikely and no evidence in favor of it was obtained from any of the spectra (Figs. 1–4). The 460 cm^{-1} vibration probably corresponds to the C—Br stretch compared to 598 cm^{-1} in the neutral molecule, which would indicate some C—Br bonding character. The 1200 cm^{-1} vibration may be the CH_2 deformation which occurs at 1260 cm^{-1} in the molecular ground state (18). It is interesting to note that the difference between the 11.72 and 11.87 eV peaks in the spectrum of vinyl chloride is 1200 cm^{-1}.

The third and fourth bands occur at vertical i.p.'s of 12.28 and 12.94 eV, respectively. Both bands are broad which indicates the bonding nature of the molecular orbitals involved. In view of the above assignments, one of these i.p.'s must correspond to the second a'' orbital. The remaining i.p. must arise from a σ bonding orbital (a') which may be essentially either C—H or C—Br bonding. Ionization from the $1b_{3g}$ C—H bonding orbital in ethylene occurs at a vertical i.p. of 12.85 eV (12). It is expected that this orbital will be stabilized to some extent in the vinyl halides with the highest binding energy occurring in vinyl fluoride. The corresponding i.p. in $CH_2{=}CHF$ is at 13.79 eV and 13.14 or 13.6 eV in $CH_2{=}CHCl$ (6). Ionization from an essentially C—Br orbital occurs at 13.49 eV in methyl bromide (15) and should shift to higher binding energy in vinyl bromide due to the increased carbon s orbital participation. Thus, we can confidently assign the fourth band in $CH_2{=}CHBr$ at 12.94 eV as arising from an a' orbital which correlates with the $1b_{3g}$ orbital in ethylene. Therefore, the third band at 12.28 eV must correspond to the second a'' orbital. If we take the separation of the bromine "lone pair" orbitals as an approximate measure of the extent of the "π" interaction, then we obtain values of 1.4 and 0.7 eV for the resonance and inductive effects, respectively.

The broad fifth and sixth bands at 15.02 and 16.21 eV, respectively, must arise from σ bonding orbitals (a'). A recently reported p.e. spectrum of Br_2CO (21) shows that the highest energy σ orbitals are overlapping in the range 15.5–16.5 eV. A σ orbital with significant C—Br character should occur at lower binding energy in $CH_2{=}CHBr$, but higher than in CH_3Br (*vide supra*). On this basis, we assign the fifth band in vinyl bromide as corresponding to an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

essentially C—Br σ bonding orbital and the sixth band to a C—C and C—H bonding orbital, as far as such divisions are possible.

Summarizing, the orbital structure of vinyl bromide is concluded to be $....(a')^2(a'')^2(a')^2(a'')^2$. These assignments are shown in Fig. 1*a*.

2-Bromopropene

In 2-bromopropene we have the additional complication of a methyl group. It has been assumed in the following discussion that $CH_2{=}CBr.CH_3$ possesses C_s symmetry, so that $a'(\sigma)$ and $a''(\pi)$ are still valid orbital descriptions. The p.e. spectra of the methyl halides (15), methyl cyanide, and methyl acetylene (22) indicate that the methyl group in 2-bromopropene should provide two i.p.'s in the 14–16 eV region, arising from a' and a'' orbitals. Thus, the spectrum below 14 eV should be similar to that of vinyl bromide.

The p.e. spectrum of 2-bromopropene, shown in Fig. 2*a*, reveals at least eight bands below 21.2 eV and, indeed, the region below 14 eV is almost identical in appearance to $CH_2{=}CHBr$. The apparent effect of the methyl group has been to destabilize the four highest energy orbitals relative to vinyl bromide and it is tempting to assign the p.e. bands by a straightforward comparison of the two spectra. The vibrational structure of the first band at 9.58 eV (Fig. 2*b*) is complex and appears to contain two ionic modes at 1200 and 290 cm^{-1}. The former may be assigned to the C=C stretch reduced in frequency from the neutral molecule (1636 cm^{-1}) (18), or a CH_2 or CH_3 deformation. The 290 cm^{-1} vibration must correspond to the C—C—Br bending mode, which was also excited in the first band of vinyl bromide. There can be no doubt that this first band in 2-bromopropene arises from the C=C π orbital (a''). As in vinyl bromide, this orbital has been destabilized relative to ethylene. If we assume a similar interaction with the a'' bromine "lone pair", then the overall effect of the methyl group has been to destabilize the C=C π orbital by *ca.* 0.2 eV.

The second band has an adiabatic i.p. at 10.51 eV and is rather sharp (Fig. 2*c*) indicating that the parent orbital is relatively non-bonding. There is also an indication of vibrational structure of *ca.* 350 cm^{-1} which would probably correspond to the in-plane C—C—Br bending mode (345 cm^{-1} in the ground state of vinyl bromide). We assign this band to the bromine a' "lone pair", for reasons discussed previously in relation to the second band of vinyl bromide.

Direct comparison with the p.e. spectrum of vinyl bromide would lead us to assign the third band in 2-bromopropene at 11.62 eV to the a'' bromine "lone pair", and the fourth at 12.40 eV to an a' orbital. However, it is possible that introduction of the methyl group would reverse this ordering. The third i.p. of vinyl bromide is 12.28 eV which is slightly lower than the fourth i.p. of 2-bromopropene. Were we to assign this latter i.p. as arising from the a'' bromine orbital, the apparent stabilization relative to the corresponding orbital in $CH_2{=}CHBr$ may be attributed to a slight increase in the mixing with the C=C π orbital (*cf.* the 0.2 eV destabilization of this orbital with respect to $CH_2{=}CHBr$), or to the presence of the methyl group. This assignment would imply, therefore, that the methyl group leads to a destabilization of the lower binding energy a' orbitals only. This is unlikely, since the methyl group introduces both a' and a'' orbitals in the 15 eV region, and so we prefer to assign the third and fourth bands in $CH_2{=}CBr{-}CH_3$ to a'' and a' orbitals, respectively, as is the case for vinyl bromide. The order of the outer orbitals in 2-bromopropene is therefore $.....(a')^2(a'')^2(a')^2(a'')^2$.

Definite assignment of the higher i.p.'s, which must arise from σ bonding orbitals, is difficult, because of the low molecular symmetry. The broad band between 14–17 eV is, however, similar in appearance to ionizations from the methyl group orbitals in other low symmetry compounds such as CH_3SH (23).

cis-1,2-Dibromoethylene

The p.e. spectrum of *cis*-1,2-dibromoethylene shows eight distinct bands below 21.2 eV (Fig. 3). The first band has an adiabatic i.p. of 9.32 eV and two vibrational modes of the ion are observed at 1280 and 650 cm^{-1}. The vertical i.p. of 9.44 eV is in good agreement with the photoionization value of 9.45 eV (17). By analogy with the p.e. spectra of the dichloroethylenes (6, 11), vinyl bromide, and 2-bromopropene (*vide supra*), we attribute this first band to ionization from the C=C π orbital (b_1). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1280 cm^{-1} vibration is assigned to the C=C stretching mode which is reduced from the molecular ground state value of 1584 cm^{-1}. The 650 cm^{-1} vibration corresponds to the C—Br stretching mode, showing a slight increase over the 580 cm^{-1} for the neutral molecule (18). This indicates that the C=C π orbital possesses some C—Br antibonding character and, therefore, that some mixing with the b_1 bromine "lone pair" orbital has occurred. A similar conclusion was reached for vinyl bromide (*vide supra*). The same vibrational modes were observed in the first band of *cis*-1,2-dichloroethylene (6). The binding energy of the C=C π orbital is less than the corresponding orbital in ethylene, and even in vinyl bromide. Again, we interpret this in terms of the resonance effect being larger than the inductive effect by approximately 1.07 eV.

The 10–12 eV region contains three bands at vertical i.p.'s of 10.74, 11.24, and 11.56 eV (Fig. 3). No vibrational structure was resolved on any of these bands which may indicate the short lifetime of the ion in the corresponding states. The sharpness of the 11.24 and 11.56 eV bands compared to the remainder of the spectrum clearly suggests that they arise from bromine "non-bonding" orbitals. In *cis*-1,2-dibromoethylene there will be four orbitals derived from the 4p "lone pair" atomic orbitals of the bromine atoms namely, b_2, b_1, a_2, and a_1. The order is that expected on the basis of bromine–bromine overlap only, with the a_1 combination occurring at the highest binding energy. The importance of the interaction of these "lone pair" orbitals with other molecular orbitals in modifying the above ordering has been pointed out for dichloro- and dibromomethane (24), dichlorosilane (25), and other dichloro compounds (20, 26). The a_2 orbital is symmetry determined and cannot interact with any other valence molecular orbital. Therefore, one might expect ionization from this orbital to result in a narrow p.e. band. We anticipate ionizations from bromine non-bonding orbitals to occur in the 10.5–13 eV region. Since we have demonstrated that the resonance effect is at least 1.07 eV, the b_1 bromine orbital must be at higher binding energy than the b_2, a_2, and a_1 non-bonding combinations. As there is no b_2 orbital at lower binding energy than the bromine "lone pair" orbitals, the order b_2 lower than a_2 should remain unaltered. Therefore, we assign the 10.74, 11.24, and 11.56 eV bands as arising from the b_2, a_2, and a_1 bromine orbitals, respectively. The fact that the 11.24 eV band is the sharpest of these three is consistent with its assignment to the a_2 orbital.

The fifth band contains two i.p.'s at 12.85 and 13.27 eV. One of these must arise from the inner b_1 orbital and comparison with the third (a'') and fourth (a') bands in the p.e. spectrum of vinyl bromide suggests that the other may be due to a C—H σ bonding orbital of b_2 symmetry. b_2 and a_1 C—Br σ bonding orbitals in CH_2Br_2 (15) give rise to ionizations in the 14–15 eV range. It is expected that these orbitals will be more stable in dibromoethylene. Therefore, it is the essentially C—H σ bonding orbital (b_2) which is responsible for either the 12.85 or the 13.27 eV i.p. Both i.p.'s are lower than those corresponding to the highest energy σ bonding orbitals in *cis*-1,2-difluoroethylene (12) and *cis*-1,2-dichloroethylene (6, 11), and are greater or equal to the $1b_{3g}$ ionization in ethylene (3) so that no assignment is forthcoming from such a comparison. Since the two b_2 orbitals are at similar energies the higher energy b_2 may be above the inner b_1 orbital. However, comparison with CH_2=CHBr indicates the reverse, namely b_1 above b_2. The problem may be resolved in the following way. If we assume that the unperturbed b_1 bromine "lone pair" ionization would occur between the assigned a_2 and a_1 bands at $\sim$11.4 eV, then assignment of the 12.85 eV ionization to the inner b_1 orbital leads to a resonance stabilization of 1.45 eV. Furthermore, the inductive effect of the two bromines on the C=C π orbital would be $1.45 - 1.07 \approx 0.4$ eV, whereas in vinyl bromide it is 0.7 eV. That is, this assignment would imply that the inductive effect of two bromines is less than one. Alternatively, if the 13.27 eV band is the b_1, then the resonance effect becomes *ca.* 1.9 eV and the inductive effect *ca.* 0.8 eV. Although the reliability of such calculations is probably limited, we prefer this latter interpretation.

In the light of the above discussion the seventh and eighth i.p.'s at 14.80 and 16.49 eV are assigned to ionization from b_2 and a_1 orbitals, respectively, which are essentially C—Br in character, the former being the anti-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

bonding combination. The orbital structure of *cis*-1,2-dibromoethylene is concluded to be

$$\ldots.(a_1)^2(b_2)^2(b_1)^2(b_2)^2(a_1)^2(a_2)^2(b_2)^2(b_1)^2$$

These assignments are shown in Fig. 3.

trans-1,2-dibromoethylene

Only six distinct bands are observed in the p.e. spectrum of *trans*-1,2-dibromoethylene (Fig. 4*a*). Clearly, some overlapping of bands has occurred. A straightforward comparison of the spectra of *cis*- and *trans*-dibromoethylene suggests that the second (11.05 eV), fourth (*ca.* 13 eV), and fifth (15.9 eV) bands each contain two i.p.'s.

The first p.e. band, shown in Fig. 4*b*, has an adiabatic i.p. of 9.30 eV and a vertical i.p. of 9.44 eV which agrees well with the photoionization value of 9.46 eV (27). There is an indication of a vibrational spacing of 1315 cm^{-1}, which is assigned to the C=C stretching frequency, reduced from its value of 1578 cm^{-1} in the neutral molecule (18). The broad nature of the peaks may be due to the short lifetime of the ion in this state or to the presence of a low frequency ionic vibrational mode which is unresolved. The band is assigned to ionization from the C=C π orbital which in *trans*-CHBr=CHBr possesses a_u symmetry. The vertical i.p. is identical to that of *cis*-1,2-dibromoethylene and so we again conclude that the resonance effect dominates over the inductive effect by *ca.* 1.07 eV.

Figure 4*c* shows the 11–12 eV region, which appears to contain only two p.e. bands, at high resolution. The cross-section of the band with adiabatic i.p. at 11.05 eV is twice that of the band at 11.60 eV, indicating that two i.p.'s may be superimposed in the former. Clearly, there can be no more than three i.p.'s in this range, which supports the assignment of only one i.p. at 10.90 eV in vinyl bromide and three i.p.'s in the range 10–12 eV in *cis*-1,2-dibromoethylene (*vide supra*). One component of the second band must have a vertical i.p. at 11.05 eV. However, it is difficult to assess the true adiabatic or vertical i.p. of the second component. It may be at 11.05 eV also, or at 11.13 eV (the second peak). Neither is an interpretation of the vibrational structure any easier since the spacing is not quite regular and more than one vibrational mode may be involved. The 680 cm^{-1} spacing observed on the third band probably corresponds to the C—Br stretching frequency which is only slightly reduced from its ground-state value of 748 cm^{-1} (18). All three ionizations are sharp and there can be no doubt that they arise from bromine "lone pair" orbitals. The b_2, a_2, b_1, and a_1 combinations in *cis*-CHBr=CHBr become a_g, b_g, a_u, and b_u, respectively, in the *trans* isomer. The a_u ionization must be at higher binding energy than the other three due to the conjugative interaction with the a_u C=C π orbital (*vide supra*). The strong peak at 11.05 eV must correspond to the b_g "pure" bromine orbital. Since the a_g orbital should be at higher energy than the b_g, we assign both to be degenerate at 11.05 eV. Thus, the 11.60 eV band is due to ionization from the b_u orbital. As the two bromine atoms are further apart in the *trans* compound than in the *cis*, their mutual interaction is smaller, resulting in the "lone pair" orbitals being more nearly degenerate.

The fourth and fifth bands at 13 and 15.9 eV, respectively, are both the result of two ionizations. We assign a_g and a_u ionizations to the 13 eV band and a_g and b_u ionizations to the 15.9 eV band by direct comparison with our assignments for the p.e. spectrum of *cis*-CHBr=CHBr. It may be noted that this coalescence of higher i.p.'s in the *trans* isomer is also observed in *trans*-1,2-dichloroethylene (6). The orbital structure of *trans*-CHBr=CHBr is therefore

$$\ldots\ldots.(b_u)^2(a_g)^2(a_u)^2(a_g)^2(b_u)^2(b_g)^2(a_g)^2(a_u)^2$$

where the ordering of the seemingly degenerate orbitals has been made with reference to *cis*-1,2-dibromoethylene.

General Comments

The results derived from the p.e. spectra of the bromoethylenes, 2-bromopropene, chloroethylenes, and ethylene are reproduced in the form of an orbital correlation diagram, Fig. 5. The i.p.'s of the chloroethylenes were taken from ref. 6 and those of ethylene from ref. 12. The assignments of the chloroethylenes below 15 eV are those suggested by Klasson and Manne (13).

It is important to consider the number of states which should be observed below 21.2 eV

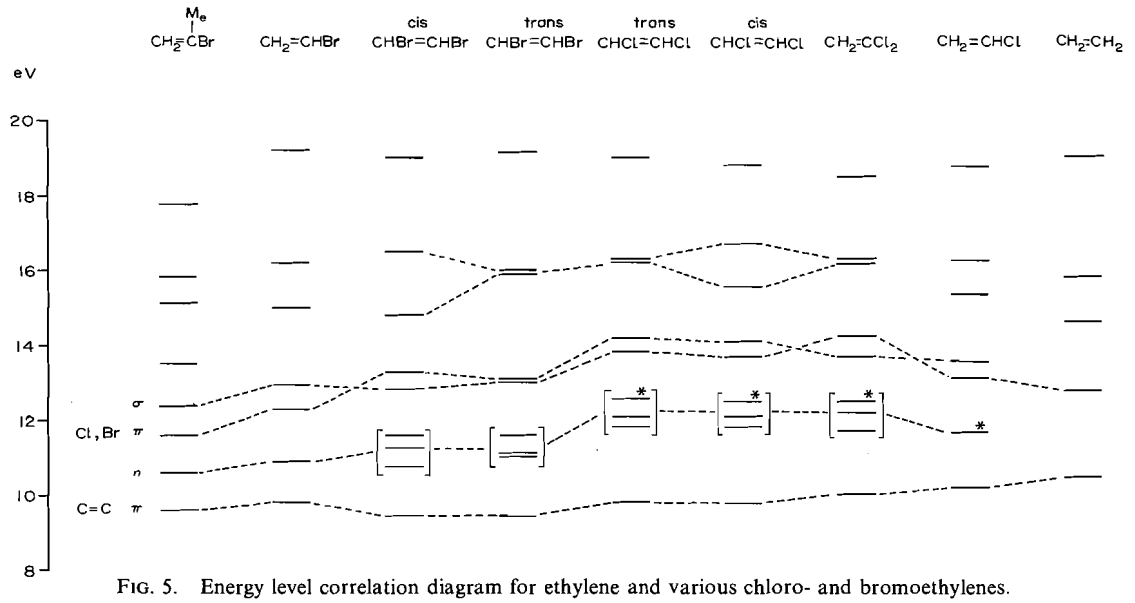

FIG. 5. Energy level correlation diagram for ethylene and various chloro- and bromoethylenes.

in the chloro- and bromoethylenes. Klasson and Manne have pointed out that one i.p. for each chlorine atom and one i.p. for the two carbon atoms should be above 21.2 eV in the chloroethylenes (13). We can expect the same in the bromoethylenes, although these high i.p.'s may be lower than in the chloroethylenes, and and it is possible that one may fall at or just below 21.2 eV. With this provision, we should observe seven states in the HeI p.e. spectra of vinyl bromide and chloride, and nine states for the dichloro- and dibromoethylenes. Reference to Fig. 5 shows that the correct number of states has been observed in the bromoethylenes, though there is some overlapping in *trans*-CHBr=CHBr. However, on the basis of the above argument, Klasson and Manne (13) suggested that previous workers reported too many states for *cis*-1,2-dichloroethylene and too few for 1,1-dichloroethylene (6, 11). We consider first the region above 15 eV. Three states are observed between 15 and 20 eV for the bromoethylenes, so that the same should be true of corresponding chloroethylenes. Simple comparison assigns two states to the 16.2 eV bands in *trans*-CHCl=CHCl and CH_2=CCl_2. This conclusion was reached also by Klasson and Manne (13). Although there are apparent accidental degeneracies in these molecules, the actual p.e. bands involved are very broad and the true vertical i.p.'s may be 0.5–1.0 eV apart.

In each chloroethylene there are indisputably two states between 13–15 eV (6, 11) which are consistent with the two states in the 12–14 eV range in the bromoethylenes. Thus, adjustment to the correct number of states in the chloroethylenes must be made in the 11–13 eV region which contains the ionizations from chlorine "lone pair" orbitals. Klasson and Manne (13) suggested that one too many i.p.'s were reported in this region for *cis*- and *trans*-dichloroethylene and vinyl chloride. A comparison with the corresponding bromoethylenes supports this interpretation and in Fig. 5 we have eliminated one i.p. for each of these three molecules.

Let us consider the alternative. If the number of i.p.'s reported (6, 11) for vinyl chloride and the dichloroethylenes in the 11–13 eV range is correct then the chlorine "lone pair" orbitals which are interacting with the C=C π orbital are assigned (6) to the levels marked with asterisks in Fig. 5. In this event there will be two bands at *ca.* 11.7 eV in vinyl chloride. Comparing these assignments to our interpretation of the p.e. spectra of the bromoethylenes, we would conclude that (*i*) the resonance effects are smaller in the chloroethylenes than in the bromoethylenes, (*ii*) the

inductive effect of chlorine on the C=C π orbital is less than bromine, and (*iii*) the mutual overlap of chlorine 3p orbitals in the dichloroethylenes is less than that of the bromine 4p orbitals in the corresponding bromo compounds. None of these three items is likely. However, for the chloroethylene assignments shown in Fig. 5, irrespective of the order of the states in the 13–15 eV range, we conclude that (*i*) the resonance effects in the bromo- and chloroethylenes are approximately the same, (*ii*) the inductive effect of chlorine on the C=C π orbital is greater than that of bromine, and (*iii*) the mutual overlap of the chlorine 3p orbitals and the bromine 4p orbitals in these molecules is approximately the same. These conclusions are more reasonable and argue strongly for the interpretation presented in Fig. 5.

Klasson and Manne assign the two bands in the 13–15 eV region in the chloroethylenes by reference to extended Hückel calculations (13), with the exception of $CH_2{=}CCl_2$ which they assign on the basis of the observed excitation of a C—H vibration on the higher of the two i.p.'s (6). Recently reported HeII spectra of vinyl chloride and C_2Cl_4 (12) may be important in this respect. The reduced cross-section for HeII compared to HeI of all the bands in the 11–14 eV region in C_2Cl_4 demonstrates that they arise from chlorine 3p orbitals. Of the two bands at 15 eV, the lower binding energy component has a much lower cross-section for HeII, but the higher component does not. It would appear that the lower component is a chlorine 3p ionization, whereas the higher i.p. probably arises from a σ orbital. The results for vinyl chloride are less clear, although the 11.72 eV band is shown to be a chlorine "lone pair" ionization by its reduced cross-section for HeII. If anything, the HeII spectra of $CH_2{=}$CHCl indicates that it is the 13.6 eV band which is the other chlorine 3p ionization rather than the one at 13.1 eV, which agrees with the assignment of Klasson and Manne (13).

Received April 5, 1972

Details of our synthesis of 5-aminomethyl-4,3′-dicarboxymethyl-3,4′-di-(2-carboxyethyl)-dipyrrylmethane (**1***b*), as a stable potassium salt are now reported. This synthetic product had been shown to be an intermediate in the biosynthesis of uroporphinogen 1. The analogous tripyrrane, **15**, should be available from the lactam of 2-(2-methoxycarbonylethyl)-3-methoxycarbonylmethyl-4,6-di-(2-ethoxycarbonylethyl)-5-ethoxycarbonylmethyl-7-carboxymethyl-8-aminomethyl-tripyrrane (**22**) which has also been synthesized.

5-Formyl-4,3′-di-ethoxycarbonylmethyl-3,4′-di-(2-ethoxycarbonylethyl)-5′-benzyloxycarbonyldipyrrylmethane (**24**), was obtained through the condensation of the bromomethyl pyrrole **2***b* with the hydrazone, **23**, from a 2-formyl-5-free pyrrole and Girard's "T" reagent. This depends on the supression of the deactivating effect of the aldehyde group in a hydrazone from which the aldehyde is easily regenerated.

Notre synthèse de l'aminométhyl-5 dicarboxyméthyl-4,3′ di(carboxy-2 éthyl)-3,4′ dipyrrylméthane (**1***b*), comme sel de potassium stable est maintenant rapportée de façon détaillée. On a montré que ce produit synthétique est un intermédiaire dans la biosynthèse de l'uroporphinogène 1. L'analogue tripyrrane **15** pourrait être disponible à partir de la lactame de la (méthoxycarbonyl-2 éthyl)-2 méthoxycarbonyl méthyl-3 di(éthoxycarbonyl-2 éthyl)-4,6 éthoxy carbonylméthyl-5 carboxyméthyl-7 aminométhyl-8 tripyrrane (**22**), qui a été également synthétisée. Le formyl-5 diéthoxycarbonylméthyl-4,3′ di(éthoxycarbonyl-2 éthyl)-3,4′ benzyloxycarbonyl-5′ dipyrridylméthane (**24**), a été obtenu par condensation du bromométhylpyrrole **2***b* avec l'hydrazone **23** du formyl-2 pyrrole libre en -5 et le réactif "T" de Girard. Cela dépend de la suppression de l'effet désactivant du groupe aldéhyde dans une hydrazone à partir de laquelle l'aldéhyde est facile à regénérer.

Canadian Journal of Chemistry, **50**, 2652 (1972)

Introduction

Some time ago we undertook the synthesis of compounds which might be intermediates between porphobilinogen and the uroporphinogens in the biosynthesis of the porphyrins. Although there was no evidence at the time that such intermediates existed, they would be identified if the synthetic materials were substrates for the enzymes involved. Another incentive arose because the value of labelling is minimized when four identical units of porphobilinogen condense to the uroporhinogen; a second substrate, not equivalent to porphobilinogen, would provide one solution to this difficulty.

After it was shown (1) that neither opsopyrrole-dicarboxylic acid (2) nor *iso*-porphobilinogen (3) were intermediates, we turned to dipyrrylmethanes. Neither **1***a* nor its symmetrical isomers were intermediates (1, 4). However, their synthesis (5, 6) showed that unsymmetrical 5,5′-dicarbethoxydipyrrylmethanes, free of symmetrical isomers, could be obtained by condensing 2-free and 2-bromomethyl pyrroles[9] in hot AcOH–NaOAc. More important, unstabilized dipyrrylmethanes such as **1***a* were easily obtained from their carboxylated derivatives, and their quite unexpected stability (*cf.* 7, 8) was a prerequisite for further work in this direction.

Attention was then directed to aminomethyl dipyrrylmethanes, first to methylene-bis-porphobilinogen (3) which was not an intermediate (1, 4), and then to **1***b*. A synthesis of **1***b* based on that of **1***a* would involve the condensation of **2***b*, presumably available by known general methods, with a 5-free pyrrole bearing a potential 2-aminomethyl group. Such groups, like

CN, frequently deactivate the 5-position, but a suitable component was found in the ethyl ester of porphobilinogen lactam, **3**, which condensed with **2***a* to **4***a* (3).

We have indicated the later steps in the synthesis of **1***b* (9), and the product, used as its potassium salt, was shown to be an intermediate in the biosynthesis of uroporphyrin 1, into which up to *ca.* 50% of **1***b* was incorporated by the enzyme system (22, 10). We have been reluctant to publish the synthetic work in detail because the product **1***b* has not been characterized in a way which would distinguish it from its isomers, and because it contained about 10% of an impurity. This limits the usefulness of **1***b*: its 10% incorporation would be ambiguous, and a natural intermediate could not be positively identified merely by comparison with it. In its critical steps, our synthesis does not differ in principle from those that have been described (11) or outlined (12).

In order to obtain the bromomethylpyrrole **2***b*, we first converted **5** to **8** by methods which were also applicable to the conversion of **9** into **12**; the latter would be required for isomers of **1***b*. We failed to obtain **8** from the diethyl ester

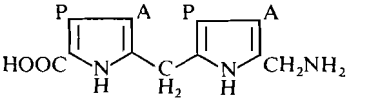
of hemopyrrole-dicarboxylic acid with phosgene, dimethylaniline, and benzyl alcohol, *cf.* (13). Although this method converted the diethyl ester of cryptopyrrole-dicarboxylic acid, **13**, into **12**, the overall yield from **9** was only 15%. Another general method involving successive transesterifications, *cf.* (14), also failed, but a modification in its first step was useful. When **5** or **9** were heated with sodium benzylate in benzyl alcohol, the tribenzyl esters **6** and **10** first formed were converted to **7** and **11**. These conversions occurred directly rather than during the work-up, *cf.* (14), and the formation of acids here was not unprecedented (15). Under modified conditions, **7** and **11** became the chief products, and these were esterified to **8** and **12**. The hydrogenation of **6**, **7**, or **8** removed the benzyl groups to yield the expected acids. Neither the partial hydrolysis of **6** to **7** nor the partial transesterification of **10** to **12** was promising.

The 2-methylpyrroles **6** and **8** were brominated to the corresponding 2-bromomethylpyrroles one of which, **2***b* from **8**, was condensed with **3** to **4***b*, *cf.* (3). The latter was hydrogenated to **4***c* which gave **4***d* with iodine in bicarbonate, and thence **4***e* by hydrogenation. It was later found that this last could be obtained by decarboxylating **4***c* directly in water at 100°, but the product then contained impurities which were only evident through t.l.c. and were difficult to remove.

It was essential to obtain the dipyrrylmethane **1***b*, an acid-labile acid, in a stable form. Further, a product containing excess salts could not be subjected to thin-layer electrophoresis. Many pyrrole-polycarboxylic acids are precipitated as their potassium salts when the corresponding esters are heated in ethanolic KOH, and **4***e* was thus converted into the tetrapotassium salt of **1***b*. Sodium and barium salts were obtained likewise but to no advantage.

The potassium salt was stable when dry and, in the absence of porphobilinogen, gave no uroporphinogen under the conditions of incubation (10), *cf.* however (11). The analysis of the first specimen obtained was satisfactory, but those of later specimens were less so, and their n.m.r. spectra showed that ethoxy was present. This was not due to ester groups for, after the products had been dissolved in water and freeze-dried, ethoxy was absent and the analyses were satisfactory. It was also evident that the lactam ring, in which the CH_2CO protons are easily exchanged, was not present in the product, *cf.* (9). Thus, when **4***e* was hydrolyzed in NaOH–EtOH or in NaOD–EtOD, the sodium salt isolated showed *ca.* 4 or 2 protons respectively at τ 6.7, before or after subsequent treatment with $NaOD–D_2O$ or $NaOH–H_2O$. Evidently the hydrolyses were complete and ethoxy in the products was due to ethanol. Thin-layer electrophoresis of the potassium salt revealed the more troublesome faster running impurity mentioned above; subject to the uncertainty of the Ehrlich color, the amount of this was roughly 10%.[10]

When **4***a* was heated in ethanolic KOH a potassium salt again separated. The free acid, **14**, obtained from it, analyzed badly and



14

attempts to decarboxylate it were, as expected, unpromising.

When **1***b* proved to be an intermediate in the biosynthesis of uroporphyrin 1, we undertook the synthesis of the corresponding tripyrrane **15**. This has been carried to the lactam ester **22** analogous to **4***e*. However, in view of the impurity found in **1***b*, the hydrolysis of **22** as well as the biochemical work on the product, are being studied in cooperation with Bogorad, so the hydrolysis of **22** can be monitored by thin-layer electrophoresis.

The synthesis of **22** by a repetition of the reactions which had converted **3** into **4***e* would probably involve more labile intermediates. In particular, the tripyrrane from **2***b* and **4***e* might not be stable in the acid medium in which it was formed, and some preliminary experiments were unpromising. We turned to the condensation of 2-formylpyrroles with **4***e* because the resulting tripyrrenes should be more stable than tripyrranes in acid, and because pyrrole-2-aldehydes, unlike 2-bromomethylpyrroles, could be obtained without blocking groups (benzyloxycarbonyl) in the 5-position. In preliminary experiments, the aldehydes **16***a* and *b* were condensed with **4***e* to give **17***a* and *b*; the latter was hydrogenated to **18**. When the aldehydes **19***a* or *b* were used, the products were not

crystalline; the aldehyde **16***c*, which we have not obtained pure, also failed to give a crystalline product. However, **20** condensed with **4***e* to give the beautifully crystalline tripyrrene **21**, and this was hydrogenated with **22**.

We had explored other approaches to aminomethyl derivatives of dipyrrylmethanes, tripyrranes, and tetrapyrranes. One such, which we have not followed up, might depend on the interconversion (19) of 5-chloro- and 5-hydroxydipyrrylmethenes, and the latter (unlike the former) undergoing typical pyrrole reactions. Another might have been based on the conversion of 5-methyl- to 5-formyl-dipyrrylmethenes (20) had this been sufficiently general. A third approach, now attractive in connection with tetrapyrranes, was to condense **2***b* with pyrroles other than **3**, avoiding the limitations imposed by the use of the latter. 2-Formyl pyrroles, and to a lesser extent their condensation products with malondinitrile, etc., are strongly deactivated at the 5-position. The corresponding oximes, however, condensed with bromomethyl pyrroles to oximes of 5-formyl-dipyrrylmethanes. These condensations are not reported here because the results were erratic, but they did suggest the use of **23**, for Girard hydrazones are stable in AcOH but are easily split by dilute HCl. The condensation of **2***b* with **23** in hot AcOH–NaOAc gave the water-soluble hydrazone from which the aldehyde **24** was obtained with dilute HCl. Other 5-formyl-5′-benzyloxy-

carbonyl-dipyrrylmethanes, with difierent β-substituents, have been obtained from the corresponding 5-*t*-butoxycarbonyl-dipyrrylmethanes (21), a route which would involve more intermediates in the present case. The benzyl ester **24** was hydrogenated to the corresponding acid, to which we referred some time ago (20); but we have recently had difficulty in repeating this hydrogenation.

Experimental

2-Methyl-3-carboxymethyl-4-β-carboxyethyl-5-benzyloxycarbonylpyrrole (7), and 2-Methyl-3-benzyloxycarbonylmethyl-4-β-benzyloxycarbonylethyl-5-benzyloxycarbonylpyrrole (6)

2-Methyl-3-ethoxycarbonylmethyl-4-β-ethoxycarbonylethyl-5-carbethoxypyrrole (**5** (16), 10.8 g) was added to a warm solution of 2.2 g of sodium in 260 ml of pure benzyl alcohol. The mixture was heated for 1 h on the steam bath with frequent swirling while a gel formed, then for 3 h under water-pump vacuum. Benzyl alcohol was then removed (rotary, 0.05 mm, bath 100°). The solution of the residue in 150 ml of water was extracted with ether (2 × 100 ml), then slowly acidified to congo red with 10% HCl. The precipitate was recrystallized from acetone (thimble) as colorless needles of the monobenzyl ester (7.2 g, 65%), m.p. 244°. Ehrlich's reaction, weakly positive on warming.

Anal. Calcd. for $C_{18}H_{19}O_6N$: C, 62.60; H, 5.55; N, 4.06; OEt, 0.00. Found: C, 62.81; H, 5.82; N, 3.47; OEt, 0.00.

Ether and benzyl alcohol were removed from the ether washings, finally at 100° and 0.1 mm, and the residue was crystallized from hexane (thimble) as colorless hairs of the tribenzyl ester (0.4 g), m.p. 108°. The yield of this is increased by using less sodium.

Anal. Calcd. for $C_{32}H_{31}O_6N$: C, 73.12; H, 5.95; N, 2.67. Found: C, 72.91; H, 5.91; N, 3.08.

Both the monobenzyl ester and the tribenzyl ester were converted into the corresponding tricarboxylic acid, m.p. 151–152° dec. (lit. (16), 155–156° dec.), by hydrogenation in ethanol over palladium black.

When the tribenzyl ester (400 mg) was refluxed for 1.5 h in 65 ml of tetrahydrofuran and 15 ml of *N*/10 NaOH, the unchanged tribenzyl ester (147 mg) and the monobenzyl ester (76 mg) were recovered.

2-Methyl-3-ethoxycarbonylmethyl-4-β-ethoxycarbonylethyl-5-benzyloxycarbonylpyrrole (8)

The monobenzyl ester (**7**, 2.8 g) was left in the dark overnight in 80 ml of 5% absolute ethanolic HCl at 20°. Ethanol was evaporated at $<50°$, more ethanol was added and evaporated, and the residue was recrystallized from hexane (thimble) as colorless needles (2.6 g, 79%), m.p. 97–98°.

Anal. Calcd. for $C_{22}H_{27}NO_6$: C, 65.82; H, 6.78; N, 3.49. Found: C, 65.89; H, 6.83; N, 3.67.

2-Methyl-3-ethoxycarbonylmethyl-4-β-ethoxycarbonylethyl-5-carboxypyrrole

The corresponding 5-carbobenzoxypyrrole, **8**, was hydrogenated in ethanol over palladium black. The catalyst and solvent were removed, and the residue was crystallized from cold acetone–hexane as colorless plates, m.p. 126–127°, Ehrlich's reaction, strongly positive cold.

Anal. Calcd. for $C_{15}H_{21}O_6N$: C, 57.85; H, 6.80; N, 4.50. Found: C, 58.01; H, 6.84; N, 4.63.

2-Bromomethyl-3-ethoxycarbonylmethyl-4-β-ethoxycarbonylethyl-5-benzyloxycarbonylpyrrole (2b)

Method a; Using Bromine

The corresponding 2-methylpyrrole (**8**, 204 mg) in 5 ml of carbon tetrachloride, was treated with a solution of bromine (0.025 ml) in carbon tetrachloride (2 ml), and the solution was irradiated for 20 min under a u.v. lamp. The solvent was removed *in vacuo* at 20°, more was added and removed in the same way, and the residue was crystallized from *n*-hexane (thimble) as colorless needles (45–55%), m.p. 119–120°.

Anal. Calcd. for $C_{22}H_{26}NO_6Br$: C, 55.00; H, 5.46; N, 2.92; Br, 16.64. Found: C, 54.78; H, 5.39; N, 3.04; Br, 16.49.

To scale up this preparation, the crude products from small runs were crystallized together.

Method b; Using N-Bromosuccinimide

The 2-methylpyrrole (**8**, 4 g) in 105 ml of CCl_4 under dry N_2 was heated (bath 89–90°) and stirred for 20 min under reflux with 1.78 g of NBS and a trace of benzoylperoxide. The filtrate and washings from the cooled mixture were evaporated and the crystalline residue was crystallized from 45 ml of benzene–*n*-hexane (1:2) using Darco, then recrystallized twice from the same solvents; yield 40–50%.

2-Acetoxymethyl-3-ethoxycarbonylmethyl-4-β-ethoxycarbonylethyl-5-benzyloxycarbonylpyrrole

The bromomethylpyrrole **2***b* (500 mg) in 15 ml of acetic acid containing 50 mg of anhydrous sodium acetate, was warmed for 10 min at 70°. Water was then added and the turbid solution was left at 10°. The colorless product was separated and recrystallized from aqueous ethanol as needles, m.p. 105–106°.

Anal. Calcd. for $C_{24}H_{29}NO_8$: C, 62.73; H, 6.36; N, 3.05. Found: C, 62.55; H, 6.51; N, 2.89.

2-Bromomethyl-3-benzyloxycarbonylmethyl-4-β-benzyloxycarbonylethyl-5-benzyloxycarbonylpyrrole

The corresponding 2-methyl pyrrole (**6**, 988 mg) was dissolved in 10 ml CCl_4, 0.1 ml of bromine was added, and the solution was irradiated by a u.v. lamp for 20 min. The solution, from which some of the product had precipitated, was evaporated below 50°; more solvent was added and removed in the same way. The residue was crystallized from ether–hexane (thimble), dissolved in ether, and the ether solution was filtered through Darco. When the solution was concentrated, the product separated. It was recrystallized twice from ether–hexane as colorless hairs, m.p. 140–141°.

Anal. Calcd. for $C_{32}H_{30}NO_6Br$: C, 63.57; H, 5.01; N, 2.32; Br, 13.23. Found: C, 63.43; H, 5.00; N, 2.40; Br, 13.02.

2-Methyl-3-β-carboxyethyl-4-carboxymethyl-5-benzyloxycarbonyl-pyrrole (11)

Sodium (0.52 g) was warmed to solution in 35 ml of pure benzyl alcohol and 2-methyl-3-β-ethoxycarbonylethyl-4-ethoxycarbonylmethyl-5-carbethoxypyrrole (**9** (17), 2.59 g) in 40 ml of benzyl alcohol was added. The solution was heated on the steam bath for 5 1/4 h, cooled, poured into 400 ml of ether, and the whole was extracted with water.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The product (68%), m.p. 211–215°, was precipitated when the aqueous layer was acidified. It was recrystallized from acetone–hexane then from acetone as colorless prisms, m.p. 217–218°.

Anal. Calcd. for $C_{18}H_{19}NO_6$: C, 62.60; H, 5.55; N, 4.06. Found: C, 63.20; H, 5.87; N, 3.86.

The ether layer was evaporated and the residue was crystallized from hexane to give the tribenzyl ester (see below) as colorless needles (67 mg), m.p. 89–92°.

*2-Methyl-3-β-benzyloxycarbonylethyl-4-benzyloxycarbonylmethyl-5-benzyloxycarbonylpyrrole (**10**)*

2-Methyl-3-β-ethoxycarbonylethyl-4-ethoxycarbonylmethyl-5-carbethoxypyrrole (**9**, 4.99 g) was dissolved in 25 ml of pure benzyl alcohol, 0.105 g of sodium were added, and the mixture was heated in the steam bath first for 1 h excluding moisture, then for 2 h at 12 mm. The solvent was removed *in vacuo* at 100°, water was added to the residue, and the mixture was extracted with ether. The product which crystallized from the ether at 0° was recrystallized from *n*-hexane as colorless needles (31%), m.p. 92–93°.

Anal. Calcd. for $C_{32}H_{31}NO_6$: C, 73.12; H, 5.95; N, 2.67. Found: C, 72.84; H, 5.88; N, 2.96.

When the tribenzyl ester was refluxed with sodium (1.5 atoms) in ethanol for 20 min, it was reconverted into the triethyl ester (50%), m.p. and mixed m.p. 63°.

*2-Methyl-3-β-ethoxycarbonylethyl-4-ethoxycarbonylmethyl-5-benzyloxycarbonylpyrrole (**12**)*

2-Methyl-3-β-carboxyethyl-4-carboxymethyl-5-benzyloxycarbonylpyrrole, **11**, was left overnight in 30 parts of 5% ethanolic HCl in the dark. The solvent was removed at 50°, more ethanol was added and removed in the same way, and the residue (98%) was recrystallized from *n*-pentane as colorless needles, m.p. 88–89°.

Anal. Calcd. for $C_{22}H_{27}NO_6$: C, 65.82; H, 6.78; N, 3.49. Found: C, 65.74; H, 6.72; N, 3.46.

*Lactam of 5-Aminomethyl-4-carboxymethyl-3,4′-di-(β-ethoxycarbonylethyl)-3′-ethoxycarbonylmethyl-5′-benzyloxycarbonyldipyrrylmethane (**4b**)*

The ethyl ester of porphobilinogen lactam (**3** (3), 118 mg) and the 2-bromomethylpyrrole (**2***b*, 240 mg) in 5 ml of acetic acid containing 50 mg of anhydrous sodium acetate were heated for 40 min on the steam bath. Water (9 ml) was then slowly added, and the mixture was heated until clear. When crystals appeared in the cooled solution, 50 ml of hot water were added, and the mixture was allowed to cool, finally at 10°. The product was separated and recrystallized from 35% ethanol (60 ml) as pale yellow micro-crystals (55–75%), m.p. 142–142.5°; other forms melting up to 180° may appear directly or from the melt. T.l.c.[11] in $CHCl_3$–MeOH (9:1): R_f 0.60 and usually a small spot on the start line. Larger runs are equally satisfactory. The analogous trimethyl-benzyl ester has been described (11).

Anal. Calcd. for $C_{34}H_{41}N_3O_9$: C, 64.24; H, 6.50; N, 6.62. Found: C, 64.11; H, 6.60; N, 6.49.

*Lactam of 5-Aminomethyl-4-carboxymethyl-3,4′-di-(β-ethoxycarbonylethyl)-3′-ethoxycarbonylmethyl-5′-carboxydipyrrylmethane (**4c**)*

The corresponding 5′-carbobenzoxydipyrrylmethane (**4***b*, 1.91 g) in 1 l of 95% ethanol was shaken with 400 mg of palladium black for 24 h under hydrogen. The mixture was then warmed to dissolve the product and filtered. The filtrate was concentrated and then cooled. The product which separated was recrystallized from 250 ml of 95% ethanol as a gray micro-crystalline powder (60–75%), m.p. 192.5–193.5 (dec.). T.l.c. in $CHCl_3$–MeOH (1:1): R_f 0.6 only.

Anal. Calcd. for $C_{27}H_{35}N_3O_7$: C, 59.43; H, 6.46; N, 7.70. Found: C, 59.29; H, 6.39; N, 7.66.

*Lactam of 5-Aminomethyl-4-carboxymethyl-3,4′-di-(β-ethoxycarbonylethyl)-3′-ethoxycarbonylmethyl-5′-iododipyrrylmethane (**4d**)*

The corresponding 5′-carboxy-dipyrrylmethane (**4***c*, 347 mg) was warmed to solution in 17.5 ml of 95% ethanol and 7 ml of water containing 165 mg of sodium bicarbonate. Iodine (164 mg) in ethanol (7 ml) was added to the cooled solution, which was heated briefly then refrigerated overnight. The product (55–70%) was washed with water then with ethanol. For analysis, it was recrystallized from ethanol–acetone (1:2) as small light yellow crystals, m.p. 149–150° (dec.). T.l.c. in $CHCl_3$–MeOH (1:1): R_f 0.8 only.

Anal. Calcd. for $C_{26}H_{34}N_3O_7I$: C, 49.76; H, 5.57; N, 6.70; I, 20.23. Found: C, 49.98; H, 5.50; N, 6.81; I. 19.99.

*Lactam of 5-Aminomethyl-4-carboxymethyl-3,4′-di-(β-ethoxycarbonylethyl)-3′-ethoxycarbonylmethyldipyrrylmethane (**4e**) (J. M. Osgerby)*

A suspension of the 5′-iodo-dipyrrylmethane (**4***d*, 232 mg) in 500 ml of ethanol, to which had been added 35 mg of anhydrous sodium acetate in 3 ml of water, was shaken in the dark overnight with palladium black under hydrogen. The colorless solution was filtered and the solvent removed below 50°. The residue was recrystallized from aqueous ethanol as small grey prismatic rods (70–80%), m.p. 180°; Ehrlich's reaction, strongly positive cold. For analysis, it was recrystallized from ether (thimble). N.m.r. ($CDCl_3$) τ 8.78 (m, 9.4, OCH_2CH_3), 7.38 (sym. m, 7.9, CH_2CH_2CO), 6.68, 6.50, 6.21, 5.92, and 5.66 (poorly resolved t, J = 2.5–3.0 Hz, s, s, m, broad s, 13.6, CH_2CONH, CH_2COO, bridge CH_2, OCH_2CH_3, CH_2NHCO), 3.58 and 3.19 (d, J = 2.5 Hz, broad s, 2.4, pyrrole C*H*, CON*H*), 0.94 and 0.64 (poorly resolved d, J = 2.0–2.5 Hz, s, 1.7, two pyrrole N*H*). T.l.c. ($CHCl_3$–MeOH, 4:1): R_f 0.74 only. The analogous trimethyl ester has been described (11).

Anal. Calcd. for $C_{26}H_{35}N_3O_7$: C, 62.26; H, 7.04; N, 8.38. Found: C, 62.20; H, 7.07; N, 8.44.

*Tetrapotassium Salt of 5-Aminomethyl-4,3′-di-carboxymethyl-3,4′-di-β-carboxyethyldipyrrylmethane (**1b**), cf. (11) (J. Pluscec)*

The lactam ester (**4***e*, 113 mg) in 5 ml of absolute ethanol containing 560 mg of KOH was refluxed on the steam bath for 80 min; the product began to separate after 5 min. The product was washed by decantation with absolute ethanol, with ether, then with acetone. It was transferred to a tube using acetone, then dried for 15 h in the dark (1×10^{-4} mm, 20°). The product was a light brown powder (75%), very hygroscopic before it was dried; Ehrlich's reaction, strongly positive cold. For the second analysis and for the n.m.r. spectrum, a specimen was dissolved in water and then freeze-dried; n.m.r. (D_2O) τ 7.48 (m, 8, CH_2CH_2CO), 6.68 (s, 3.9, CH_2COO), 6.27 (s, 1.9, bridge CH_2), 5.92 (s, 1.7, CH_2NH_2), 3.50 (s, 0.8, pyrrole C*H*); u.v. no strong absorption 650–300 mμ.

[11]All t.l.c. on silica gel H coated plates.

Anal. Calcd. for $C_{20}H_{21}N_3O_8K_4$: C, 40.87; H, 3.60; N, 7.15; K, 26.61. Found: C, 40.52, 40.48; H, 3.97, 3.97; N, 7.32, 6.92; K, 26.23, 26.39.

A sample was heated for 20 min at 100° in 0.5 *N* HCl. The product was a mixture of isomeric uroporphyrins (40%), methyl ester m.p. 250°.

*5-Aminomethyl-4,3′-di-carboxymethyl-3,4′-di-(β-carboxyethyl)-5′-carboxydipyrrylmethane (**14**), cf. (11)*

The tetra-ethyl ester of the corresponding lactam (**4***a* (3), 460 mg) was refluxed for 1 3/4 h in 22 ml of absolute ethanol containing 2.25 g of KOH. The light-brown precipitate was washed by decantation, first with ethanol then with ether. It was dissolved in 4 ml of water and the product (90%) was precipitated by dilute HCl. It was obtained as a pinkish amorphous powder, m.p. 193–195° (reddening at 125°) by precipitating three times from 0.5 *N* ammonia with *N*-acetic acid, using de-aerated water; Ehrlich's reaction, positive after standing in the cold.

Anal. Calcd. for $C_{21}H_{25}N_3O_{10}$: C, 52.61; H, 5.26; N, 8.77. Found: C, 52.64; H, 6.51; N, 9.72.

In an attempt to decarboxylate the product, it was heated with water for 2 h at 100° in a tube which had been sealed under vacuum. From the dark red product, only uroporphyrin (2%) was isolated. This contained some uroporphyrin 2 for the m.p. of its methyl ester was raised from 265–275° to 295–305° by recrystallizing it from chloroform–acetone, *cf.* (18).

*2-Formyl-3-ethoxycarbonylmethyl-4-β-ethoxycarbonylethyl-5-benzyloxycarbonylpyrrole (**16***b*)

Sulfuryl chloride (0.43 ml) was slowly added to a stirred solution of the 2-methyl pyrrole (**8**, 1g) in 15 ml of absolute ether at 0–4°. After 5 min, the ice bath was removed and stirring was continued for 30 min. The ether was removed *in vacuo* below 20°, and 3 × 10 ml of ether were added and removed in the same way. The oily residue was boiled for 3 min with 40 ml of water containing 2.5 g of sodium acetate. The mixture was quickly cooled to 0°. The product which separated was crystallized from 40 ml of ethanol and 190 ml of water, then recrystallized from hexane (thimble) as colorless needles (80%), m.p. 89–91°. For analysis it was twice recrystallized from hexane, m.p. then 90–92°.

Anal. Calcd. for $C_{22}H_{25}NO_7$: C, 63.60; H, 6.07; N, 3.37. Found: C, 63.38; H, 6.24; N, 3.56.

2-Formyl-3-β-ethoxycarbonylethyl-4-ethoxycarbonylmethyl-5-benzyloxycarbonylpyrrole

The preparation of this from the 2-methyl pyrrole **12** and sulfuryl chloride followed that of its isomer with the 3- and 4-substituents interchanged. The colorless needles of the product (80%), m.p. 98–100°, were recrystallized twice from hexane for analysis, m.p. then 99–101°.

Anal. Calcd. for $C_{22}H_{25}NO_7$: C, 63.60; H, 6.07; N, 3.37. Found: C, 63.43; H, 6.00; N, 3.51.

*Lactam of 1-Ethoxycarbonyl-2,4,6-tri-β-ethoxycarbonylethyl-3,5-di-ethoxycarbonylmethyl-7-carboxymethyl-8-aminomethyltripyrrene-12-hydrobromide (**17***a*)

The 5-carbethoxypyrrole aldehyde (**16***a* (2), 35 mg) and the dipyrrylmethane (**4***e*, 50 mg, prepared by decarboxylating its 5′-carboxylic acid directly in water at 100°) in 5 ml of ethanol were treated with 2 drops of 48% HBr, cooling, and scratching. After the product began to separate, the mixture stood at 10° overnight. The solvent was evaporated and the crystalline residue was washed with ethanol then recrystallized from the same solvent (3 ml) as small red crystals (31%), m.p. 130–132°. For analysis, it was recrystallized again as small red rods, m.p. unchanged; t.l.c. in $CHCl_3$–MeOH (9:1): R_f 0.74 only; u.v. in ethanol λ_{max} (ε): 493 (32 000), 277 mμ (17 400).

Anal. Calcd. for $C_{43}H_{57}N_4O_{13}Br$: C, 56.27; H, 6.21; N, 6.11; Br, 8.72. Found: C, 55.99; H, 6.17; N, 6.21; Br, 8.79.

*Lactam of 1-Benzyloxycarbonyl-2,4,6-tri-β-ethoxycarbonylethyl-3,5-di-ethoxycarbonylmethyl-7-carboxymethyl-8-aminomethyltripyrrene-12-hydrobromide (**17***b*)

This was obtained like the 1-ethoxycarbonyl derivative as small red rods (45%), m.p. 137–139° (dec.), from the 5-benzyloxycarbonylpyrrole aldehyde **16***b* and the dipyrrylmethane **4***e*. Here the mixture was not left overnight, nor was the residue washed before being recrystallized. U.v. in ethanol λ_{max}(ε): 493 (29 800), 277 mμ (17 300).

Anal. Calcd. for $C_{48}H_{59}N_4O_{13}Br$: C, 58.90; H, 6.03; N, 5.72; Br, 8.18. Found: C, 58.76; H, 6.13; N, 5.67; Br, 8.24.

*Lactam of 1-Carboxy-2,4,6-tri-β-ethoxycarbonylethyl-3,5-di-ethoxycarbonylmethyl-7-carboxymethyl-8-aminomethyltripyrrane (**18**) (F. Boyer)*

The 1-benzyloxycarbonyl derivative (**17***b*, 100 mg) in 40 ml of absolute ethanol was converted into the yellow base with ammonia vapor then shaken with 100 mg of palladium black under hydrogen. The absorption was theoretical in about 1 h. The catalyst was separated and the solvent was removed. The residue was crystallized from 10 ml of ethanol as tiny colorless crystals (48 mg), m.p. 194–196° (dec.), unchanged on recrystallization.

Anal. Calcd. for $C_{41}H_{54}N_4O_{13}$: C, 60.74; H, 6.66; N, 6.91. Found: C, 60.58; H, 6.70; N, 6.85.

Lactam of 2-β-Carboxyethyl-3,7-di-carboxymethyl-4,6-di-β-ethoxycarbonylethyl-5-ethoxycarbonylmethyl-8-aminomethyltripyrrene-12-hydrobromide

3-Carboxymethyl-4-β-carboxyethylpyrrole-2-aldehyde (**19***a*) (3) and the dipyrrylmethane **4***e* were condensed as above. After the solvent was removed, ethanol was twice added to the residue and evaporated. The residue was dissolved in hot absolute ethanol, the solution was cooled and dry ether was added to turbidity. The dark red partially crystalline product, m.p. 140° (dec.), was re-precipitated for analysis.

Anal. Calcd. for $C_{36}H_{45}N_4O_{11}Br$: C, 54.76; H, 5.73; N, 7.10; Br, 10.26. Found: C, 54.71; H, 5.64; N, 7.19; Br, 10.30.

*2-Formyl-3-methoxycarbonylmethyl-4-β-methoxycarbonylethylpyrrole (**20**), cf. (11)*

To the corresponding pure decarboxylic acid (**19***a* (3), 128 mg) in 2 ml of absolute ethanol and 5 ml of dry ether, ethereal diazomethane (from 3 g of nitrosomethylurea) was slowly added. When the solvent was evaporated below 20°, the residue crystallized at once. It was recrystallized from 85% ethanol as flattened rods (70%), m.p. 99–100°; t.l.c. in chloroform–methanol (9:1): R_f 0.70 only (iodine or Ehrlich's). This had not been obtained crystalline (11).

Anal. Calcd. for $C_{12}H_{15}NO_5$: C, 56.91; H, 5.97; N, 5.53. Found: C, 56.81; H, 6.10; N, 5.69.

*Lactam of 2-β-Methoxycarbonylethyl-3-methoxycarbonylmethyl-4,6-di-(β-ethoxycarbonylethyl)-5-ethoxycarbonylmethyl-7-carboxymethyl-8-aminomethyltripyrrene-12-hydrobromide (**21**)*

The aldehyde **20** (32 mg) and the dipyrrylmethane **4e** (55 mg, obtained from its 5′-iodo derivative) were gently warmed to solution in 3 ml of absolute ethanol. To the cooled solution, two drops of 48% HBr were added, and crystallization was induced in the deep red solution by scratching, first in the ice-bath then at room temperature (*ca.* 1/2 h). After the mixture had stood 2 h in the cold, the product was separated on a sintered glass funnel and washed with 2 ml of ether. It formed small red rods (64%), m.p. 117–119°. For analysis, it was recrystallized from ethanol as red rods, m.p. 119–120°, t.l.c. in acetone–methanol (2:1): R_f 0.70 only, a yellow spot turned brown by iodine, or light grey with Ehrlich's reagent and HCl vapor; u.v. in ethanol λ_{max} 482 mμ (26 400).

Anal. Calcd. for $C_{38}H_{49}N_4O_{11}Br$: C, 55.81; H, 6.04; N, 6.85; Br, 9.77. Found: C, 55.83; H, 6.19; N, 6.80; Br, 9.59.

*Lactam of 2-β-Methoxycarbonylethyl-3-methoxycarbonylmethyl-4,6-di-(β-ethoxycarbonylethyl)-5-ethoxycarbonylmethyl-7-carboxymethyl-8-aminomethyltripyrrane (**22**) (N. Stojanac)*

The tripyrrene hydrobromide **21** (126 mg) was dissolved in 100 ml of 95% ethanol and converted to the yellow base by adding 3 drops of NH_4OH. Palladium black (80 mg) was added, and the solution was shaken for 2 h under hydrogen (1 atm, 21°); the uptake ceased at the theoretical amount in 15 min. The catalyst was separated and washed with hot ethanol. Ethanol was evaporated (rotary, bath 35°) and the residue was crystallized from 12 ml of ethanol as a grey micro-crystalline powder (68%), m.p. 169–171° (dec.); Beilstein test for halogen negative, Ehrlich's reaction, positive cold. For analysis, it was recrystallized from ether (thimble, 7 h) as a light grey powder, m.p. 171–173° (dec.); t.l.c. (crude product or pure) in acetone–methanol (2:1): R_f 0.69 only; n.m.r. ($CDCl_3$, TMS) τ 8.83 (m, 13.1, OCH_2CH_3), 7.40 (sym. m, 12.3 CH_2CH_2CO), 6.66 and 6.57 (singlets, 5.2, CH_2CONH and CH_2COOR), 6.35 and 6.27 (singlets, 8.4, OCH_3 and bridge CH_2), 5.94 (m, 4.7, OCH_2CH_3), 5.65 (broad s, 1.2, CH_2NH), 3.73 and 3.61 (singlets, 2.7, pyrrole CH and CH_2NH), 1.40 (s, 0.9, pyrrole NH), 0.83 (s, 1.40, pyrrole NH).

Anal. Calcd. for $C_{38}H_{50}N_4O_{11}$: C, 61.75; H, 6.82; N, 7.58. Found: C, 61.81; H, 6.67; N, 7.40.

*Hydrazone (**23**) from 2-Formyl-3-ethoxycarbonylmethyl-4-(2-ethoxycarbonylethyl)-pyrrole and Girard's "T" Reagent*

A solution of the aldehyde (**16c**, 0.8 g) and Girard's "T" reagent (0.55 g) in 10 ml of 95% ethanol and 0.9 ml of AcOH was refluxed on the steam-bath for 30 min. The solvents were removed from the cooled solution (rotary, finally at 0.1 mm). The residue was dissolved in *n*-propanol, ether was added to turbidity, and some Girard's reagent which separated at once was removed. When more ether was added to the solution, the product crystallized. It was recrystallized until t.l.c. showed it to be pure (about four times) by dissolving it in a little *n*-propanol, filtering from some undissolved Girard's reagent, and adding ether to turbidity. It formed colorless plates (50%), m.p. 212–214°; t.l.c. (ethanol–ammonia–water, 7:1:2) R_f 0.3 only.

Anal. Calcd. for $C_{19}H_{31}N_4O_5Cl$: C, 52.95; H, 7.25; N, 13.00; Cl, 8.23. Found: C, 52.81; H, 7.08; N, 13.09; Cl, 8.14.

*5-Formyl-4,3′-di-ethoxycarbonylmethyl-3,4′-di-(2-ethoxycarbonylethyl)-5′-benzyloxycarbonyl-dipyrrylmethane (**24**)*

A solution of **2b** (165 mg), **23** (150 mg), and anhydrous NaOAc (34 mg) in 3.4 ml of acetic acid was heated 30 min on the steam-bath. The solvent was then removed, finally at 1×10^{-4} mm. The residual hydrazone was dissolved in 7.5 ml of water by gentle warming and concentrated HCl (1.6 ml) was added to the filtered solution. After 10 min, the precipitated oily aldehyde was washed with water by decantation until it was neutral. Its dried (Na_2SO_4) solution in benzene was poured onto a column of alumina (grade 3, made up in benzene), from which the product was eluted with ether. The eluate was evaporated and the residue was crystallized from aqueous ethanol to give the product (35%), m.p. 94–97°. For analysis it was recrystallized twice as colorless needles, m.p. 102.5–104°; Ehrlich's reaction, negative cold; t.l.c. (chloroform–ether, 3:1) R_f 0.2 only; n.m.r. ($CDCl_3$) 8.82 (m, 11, OCH_2CH_3), 7.32 (m, 7.1, CH_2CH_2COO), 6.52 and 6.38 (singlets, 3.7, CH_2COO), 6.06 and 5.96 (m and s, 9, bridge CH_2 and OCH_2CH_3), 4.86 (s, 1.7, Ph CH_2), 2.86 (s, 4.5, C_6H_5), 0.64 (s, 0.9, CHO), 0.06 (broad s, 0.7, NH), −0.4 (broad s, 0.8, NH).

Anal. Calcd. for $C_{36}H_{44}N_2O_{11}$ (mol. wt. 680.7): C, 63.53; H, 6.52; N, 4.12. Found (681 (mass spectrum)): C, 63.35; H, 6.64; N, 4.30.

2-Formyl-4,3′-di-ethoxycarbonylmethyl-3,4′-di-(2-ethoxycarbonylethyl)-5′-carboxydipyrrylmethane (J. Pluscec)

The corresponding 5′-benzyloxycarbonyl derivative (**24**, 485 mg) was hydrogenated in 10 ml of 95% ethanol over palladium black (150 mg). After the theoretical uptake of hydrogen, the catalyst was separated and the solution was concentrated to 2 ml. The product (56%), m.p. 154–156° (dec.) separated at 10°.

For analysis, it was recrystallized twice as colorless prisms turning red in air, m.p. 156–158° (dec.), Ehrlich's reaction, positive cold.

Anal. Calcd. for $C_{29}H_{38}N_2O_{11}$ (neut. equiv. 591): C, 58.96; H, 6.49; N, 4.74. Found (589): C, 59.13; H, 6.66; N, 4.88.

Hydrazine Derivatives. I. Transcarbamylation Reaction

JACQUES A. LENOIR AND (in part) LAWRENCE D. COLEBROOK AND DONALD F. WILLIAMS
Department of Chemistry, Sir George Williams University, Montreal 107, Quebec

Received April 4, 1972

Improvements in the synthesis of urazoles via a proposed transcarbamylation reaction are reported. Some experimental evidence for a transcarbamylation mechanism as indicated by the formation of identified intermediate products is shown. ^{13}C n.m.r. studies on 1-phenyl-4-anilinourazole have settled the controversy on the structure of Pinner's compounds by establishing that they are 1,2,4-triazoles rather than *sym*-tetrazines.

Amélioration des synthèses des urazoles au moyen de conditions favorables aux réactions de transcarbamylation. L'identification de quelques produits intermédiaires favorise le postulat d'un mécanisme de transcarbamylation. La controverse sur la structure des tétrazines symmétriques et triazoles-1,2,4 est définitivement réglée. Les études de r.m.n. basées sur le C^{13} établissent clairement la nature des produits de Pinner.

Canadian Journal of Chemistry, **50**, 2661 (1972)

It has long been known that upon prolonged boiling, aqueous solutions of semicarbazide give rise to biurea and hydrazine (1). Scheme 1 can be postulated.

From a comprehensive study of the work of Thiele and Stange (1) and of Pellizzari and Roncagliolo (2) it may be concluded that, in reactions of this type carried out under similar conditions, a transcarbamylation mechanism is predominant (3). In 1864, von Baeyer (4) recognized the nature of the reaction and proposed that it involved a *Umamidierung* between urea and primary amines at temperatures between 150 and 170° (molten state). A study of the literature on reactions of this type suggested a few innovations capable of providing further information on the nature and utility of such transcarbamylation reactions and resulting in improved methods of synthesis. Some of these reactions are summarized below.

The results in Table 1 indicate that the transcarbamylation reaction in the hydrazine series occurs within the temperature range 160–210 °C with a reaction time never less than 3–4 h. The synthesis of 4-aminourazole is the most convenient until now (experiments nos. 3 and 4, Table 1). The reaction pattern is in accord with the fact that the cyclization of carbohydrazide-*N*-carboxamide gives rise to 4-aminourazole by heating with hydrochloric acid (5) (see Scheme 2).

Further, for an efficient transcarbamylation reaction to take place the amine function of the reagent must be present specifically as the hydrochloride salt as shown in Table 2. Contrary to some opinions, carbanilide is a superior transcarbamylation reagent as compared to biurea. Also, Table 2 shows the best and most convenient methods for the preparation of 4-phenylurazole, 4-aminourazole, and guanazoguanazole.

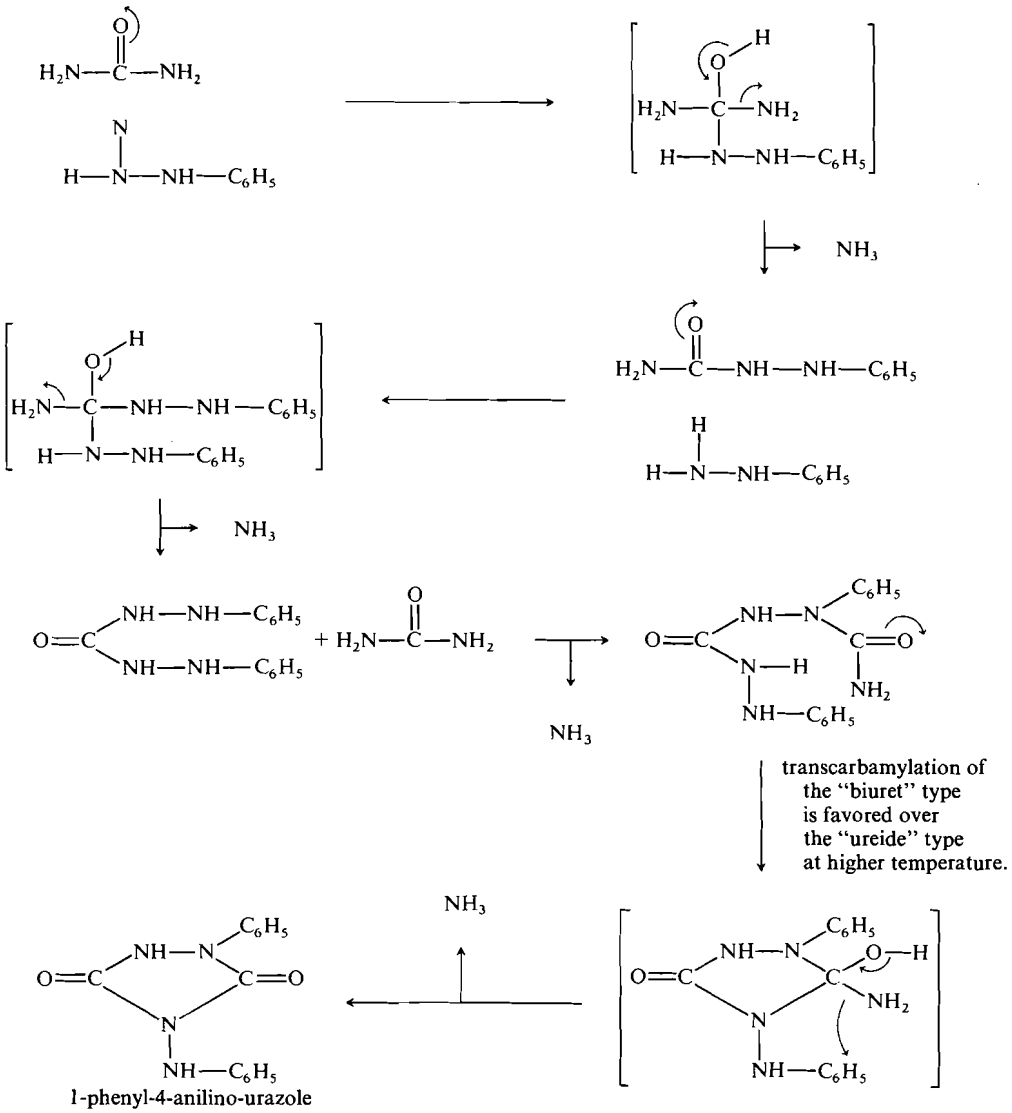

SCHEME 3

According to Pinner (6), Skinner and Ruhemann (7) phenylhydrazine hydrochloride and urea (or biuret) (1:4) give 1-phenylurazole. This conclusion is based on erroneous analysis. Later, Pinner (8) proposed the structure of a tetrazine for his diphenylurazine favoring the formula 1,2-diphenyl-tetrahydro-1,2,3,5-tetrazine-4,6-dione over that of a 1,4-diphenyl-tetrahydro-1,2,4,5-tetrazine-3,6-dione by reasoning from the structure of his 1-phenylurazole. Also, Pinner (8) as well as many other authors retained the 1-phenylurazole structure for the product formed from 1-phenylsemicarbazide and urea. The 1-phenylsemicarbazide was obtained from the reaction between phenylhydrazine hydrochloride and urea (1:1). Various authors (9) accepted Pinner's views although these were challenged by Busch (10). The latter's argument was not rigorous enough to solve the problem of Pinner's "phenylurazole" structure. There is also some doubt about the structure of the "phenylurazole" of Dains and coworkers

TABLE 2. Influence of hydrochloride salt, time, and temperature

Experiment no.	Starting material	Medium	Temperature (°C)	Period (h)	Products (yield, %)
1	Biurea	*n*-Octanol	195–197	4	Biurea (100)
2	Biurea:aniline (1:1)	*n*-Octanol	195–197	4	*n*-Octyl *N*-phenylcarbamate (26)
3	Carbanilide	*n*-Octanol	195–197	4	*n*-Octyl *N*-phenylcarbamate (40)
4	Biurea	Kerosene	211	18	Biurea (98), urazole (2)
5	Biurea:aniline (1:3)	Kerosene	211	12	Biurea (almost 100% recovery)
6	Biurea:NH_4Cl (1:1)	Kerosene	211	11	Urazole (only)
7	"	Petroleum	157–160	11	Biurea (90) and a very small amount of impure cyanuric acid
8	Biurea:aniline·HCl (1:1)	Kerosene	211	1	1-Phenylbiurea (almost 100%)
9	"	Kerosene	211	7	1-Phenylbiurea (10), 4-Phenylurazole (62)
10	Biurea:hydrazine dihydrochloride (1:1)	Kerosene	211	4	4-Aminourazole (65)
11	Hydrazine·2HCl: cyanoguanidine (1:2)	Petroleum	157–160	2–3	Guanazoguanazole (83)

(11). The controversy on whether Pinner's "phenylurazole" and "diphenylurazine" are *sym*-tetrazines or 1,2,4-triazoles has now been settled in this laboratory by ^{13}C n.m.r. The product formed by the action of phenylhydrazine hydrochloride and urea (1:4) using the procedure described by Pinner (6, 8) is identical with the product obtained by the method described in this paper (see Scheme 3).

The reactants were heated in petroleum ether (b.p. 155–160°) for 5 h under reflux to give 1-phenyl-4-anilino-urazole in almost quantitative yield. The products of both of these reactions have identical melting points and i.r. spectra. Numerous 4-alkylurazoles were prepared and compared with those reported by Tsuji (12). His results and other inherent difficulties and contradictions are too involved to be published at this time (3).

Discussion

The proton n.m.r. spectrum does not provide information useful in enabling a distinction to be made between the two possible structures, **1** and **2**, because of the very broad nature of the N—H signals (DMSO-d_6 solution). A distinction between these structures may be made on the basis of the number of lines appearing in the ^{13}C n.m.r. spectrum.

In the noise decoupled spectra of **1** and **2**, all magnetically distinct carbon atoms must give rise to individual single lines. However, in the coupled spectra only the carbonyl and the aryl carbon atoms at the point of attachment should give rise to single lines, the other aryl carbon lines being split by coupling to hydrogen to give doublets with separation J, considering only single bond ^{13}C–H coupling. In the case of off-resonance decoupling this separation will be reduced to J_r, but can be used to identify carbons directly bound to hydrogen (13). Under the conditions of partial decoupling employed, only the direct ^{13}C–H couplings are detectable, so that the smaller couplings involving more than one bond do not complicate the spectra.

In structure **1**, both carbonyl groups and both aryl groups are equivalent since the molecule has a center of symmetry. Providing that accidental overlap is absent, five lines (one carbonyl and four aryl) are predicted in the noise decoupled ^{13}C spectrum. Two of these should remain unsplit in the off-resonance decoupled spectrum, for which eight lines are predicted.

Ten lines are predicted for the noise decoupled spectrum of the less symmetrical structure, **2**. Of these, four should remain unsplit in the off-resonance decoupled spectrum, for which a maximum of 16 lines is predicted. The experimental data are summarized in Table 3. Seven lines are observed in the noise decoupled spectrum. Of these, four remain unsplit in the off-resonance decoupled spectrum, which shows ten resolved lines. These data are consistent only with structure **2**. Fewer lines are observed

TABLE 3. Carbon[13] chemical shifts*

Peak	Noise decoupling	Off-resonance decoupling
1	153.5	153.7
2	150.9	150.9
3	149.2	149.4
4	136.4	136.5
5	128.3	128.5†, $J_r = 47$ Hz
6	124.1	124.2†, $J_r = 46$ Hz
7	117.9	117.8†, $J_r = 49$ Hz

*p.p.m. downfield from TMS.
†Center of doublet.

than are predicted for this structure because of overlap between lines from corresponding carbons of the non-equivalent aryl groups, only the carbon atoms at the points of attachment being fully resolved. Incomplete resolution of the other aryl carbons is evident from their line widths. Structure **1** must be excluded because both the fully decoupled spectrum and the off-resonance decoupled spectrum show more than the predicted maximum numbers of lines. The chemical shifts in Table 3 agree well with those of some 3-aryl substituted hydantoins and arylureas under investigation in this laboratory.

Conclusion

Of the two possible structures, **1** is quite inconsistent whereas the five-membered ring structure **2** is fully consistent with the experimental spectra.

Experimental

Melting points were taken on a Mettler melting point apparatus.

The ^{13}C n.m.r. spectra were obtained from a 32% solution of 1-phenyl-4-anilinourazole in DMSO in an 8 mm spinning sample tube. Spectra were recorded in the frequency sweep mode using a Varian HA-100 spectrometer operating at 25.15 MHz and equipped with a V-3530 wide sweep accessory and a V-4335-1 probe. A V-3512-1 heteronuclear decoupler provided irradiation centered on the DMSO protons, with a noise bandwidth of 1.8 kHz for complete proton decoupling, and in the coherent mode for single frequency off-resonance decoupling. One hundred scans of 1.2 kHz width were accumulated in a C-1024 time averaging computer, using scan times of 50 s. The instrument was locked to the natural abundance ^{13}C signal of the proton decoupled solvent, which was also used as the internal reference. The chemical shifts relative to TMS were calculated by taking the chemical shift of DMSO to be 39.9 p.p.m. downfield from TMS, and are estimated to be internally accurate to ± 0.2 p.p.m.

Authentic samples of the following compounds were prepared: urazole (Moeller) (14), also purchased from the Aldrich Chemical Company: 4-aminourazole (*p*-urazine) (Bailar) (5); 4-phenylurazole (Zinner and Deucker) (15); *n*-octyl *N*-phenylcarbamate (Cheronis and Entrikin) (16); guanazoguanazole (Kaiser, Peters and Wystrach) (17); 1-phenyl-4-anilinourazole (Pinner) (6, 8) and (Skinner and Ruhemann) (7); biurea, very conveniently, according to Müller (18) (from hydrazine sulfate and urea), to Thiele (19) (from hydrazine sulfate and potassium cyanate), and to Leboucq (20) (from semicarbazide hydrochloride and potassium cyanate). All the above compounds gave identical i.r. with the compounds prepared as described in this paper.

General Procedure

As a typical example, the preparation of 1-phenyl-4-anilinourazole is given.

A suspension of 14.5 g (0.1 mol) of phenylhydrazine hydrochloride and 24–25 g (0.4 mol) of urea was heated under reflux in 100 ml of petroleum ether (b.p. 155–160°) with magnetic stirring. Within 15 min the solid mixture melted and shortly after copious fumes of ammonia were evolved. After 5 h the reaction mixture was cooled with the stirring maintained. The crude product was filtered off and washed with petroleum ether (b.p. 35–60°). After having been dried the product was extracted with water to remove water soluble impurities and was purified by recrystallization from aqueous ethanol. The yield of 1-phenyl-4-anilinourazole, m.p. 264.2°, (lit. 262–263 (6); 260 (7); 264° (8)) was almost quantitative. This product was subjected to ^{13}C n.m.r. studies.

4-Aminourazole (p-Urazine)

The synthesis of this compound did not follow the general procedure as described above. The method used is much more accessible, the yields are higher, and the procedure is very simple compared to previously described methods (5).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

A suspension of 11.2 g (0.1 mol) of semicarbazide hydrochloride and 10 ml (0.2 mol) of hydrazine hydrate (99–100%) was heated under reflux in 50 ml of 95% ethanol for 3 h. Vacuum distillation of the reaction mixture yielded a thick syrup.

A thermometer was arranged to dip into the syrup in such a way that its tip did not come in contact with a teflon coated magnetic stirring bar. After the addition of 12 ml of concentrated hydrochloric acid heat was slowly applied. Foaming occurred but later subsided. The temperature was controlled between 210–215°, the total heating time being about 2 h. When the material had cooled, 50 ml of water was added, and the mixture heated to 90° in order to dissolve the solid. After a few hours in a refrigerator at -5°C the solution deposited crystals of 4-aminourazole. These were filtered off, washed with a little ice cold water, then ice cold 95% ethanol, and finally with diethyl ether. This sequence quickly yielded a dry product. The yield of 4-aminourazole, m.p. 276 °C (dec.) (lit. 276° (5)) was 3.8 g (65%). The product was characterized as its benzaldehyde derivative, m.p. 254 °C (lit. 253 °C (5)). Both 4-aminourazole and its benzal derivative gave i.r. spectra identical with those of control preparations as given in ref. 5.

Mobilities and Ranges of Electrons in Liquids: Effect of Molecular Structure in C_5–C_{12} Alkanes

JEAN-POL DODELET AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton 7, Alberta

Received January 26, 1972

X-radiolysis free ion yields and electron mobilities were measured in a series of branched chain hydrocarbons at several temperatures. The numbers listed after the following compounds are the temperature (K), G_{fi}, most probable penetration range of the secondary electrons (Å) and thermal electron mobility ($cm^2/V\ s$): 2,2-dimethylpropane (neopentane), 294, 1.09, 213, 50; 2,2,3,3-tetramethylbutane, 379, 0.80, 130, –; 2,2,4,4-tetramethylpentane, 295, 0.83, 158, 24; 2,2,5,5-tetramethylhexane, 293, 0.67, 138, 12; 2,2,6,6-tetramethylheptane, 293, 0.47, 113, —; 2,2,7,7-tetramethyloctane, 383, 0.58, 100, —; 2,2,3,3-tetramethylpentane, 295, 0.42, 102, 5.2; cyclohexane, 294, 0.16, 67, 0.45. The difference between the activation energies of the reactions

[14] $$[M^+ + e^-] \rightarrow \text{geminate neutralization}$$

and

[15] $$[M^+ + e^-] \rightarrow \text{free ions}$$

is $(E_{15} - E_{14}) \approx (2 \text{ to } 3)RT$ for twenty two different hydrocarbons, including olefins and benzene. The rate of energy loss by epithermal electrons in liquid hydrocarbons increases with increasing anisotropy of polarizability of the molecules or groups; the range of the electron interaction in a given molecule appears to be about two C—C bonds in series (groups up to neopentyl in size). There is a correlation between the mobilities of thermal electrons in liquids and the penetration ranges of the secondary electrons in the liquids. The electron mobility in a liquid alkane appears to be limited by inelastic scattering. The inelastic scattering cross sections for both thermal (<0.1 eV) and epithermal (~1 eV) electrons in liquid alkanes are affected in similar ways by the anisotropy of polarizability of the molecules. In both instances the scattering apparently involves rotational (librational) excitation of the medium.

Les rendements en ions libres et les mobilités électroniques ont été mesurés, sous irradiation X, à plusieurs températures, pour un certain nombre d'hydrocarbures à chaîne ramifiée. En utilisant le symbolisme suivant: liquide, température (K), rendement en ions libres, valeur la plus probable de pénétration pour les électrons secondaires (Å) et mobilité de l'électron thermique ($cm^2/V\ s$), il est possible de donner une idée rapide des résultats obtenus: 2,2-diméthylpropane (néopentane), 294, 1.09, 213, 50; 2,2,3,3-tétraméthylbutane, 379, 0.80, 130, —; 2,2,4,4-tétraméthylpentane, 295, 0.83, 158, 24; 2,2,5,5-tétraméthylhexane, 293, 0.67, 138, 12; 2,2,6,6-tétraméthylheptane, 293, 0.47, 113, —; 2,2,7,7-tétraméthyloctane, 383, 0.58, 100, —; 2,2,3,3-tétraméthylpentane, 295, 0.42, 102, 5.2; cyclohexane, 294, 0.16, 67, 0.45. La différence entre les énergies d'activation des réactions

[14] $$[M^+ + e^-] \rightarrow \text{neutralisation dans les grappes}$$

et

[15] $$[M^+ + e^-] \rightarrow \text{ions libres}$$

est $(E_{15} - E_{14}) \approx (2 \text{ à } 3)RT$; cette valeur est obtenue pour vingt-deux hydrocarbures y compris des oléfines et le benzène. Les électrons épithermiques perdent d'autant plus rapidement leur énergie, dans les hydrocarbures liquides, que l'anisotropie de polarisabilité de ces molécules (ou groupements) est importante; il semble qu'un électron puisse perturber une molécule donnée sur une distance équivalant à 2 liens C—C consécutifs, c'est à dire, un domaine couvrant l'ensemble d'un groupement néopentyle. Il y a, en phase liquide, une corrélation entre les mobilités des électrons thermiques et les distances de pénétration des électrons secondaires produits lors de l'irradiation. Les mobilités électroniques, dans un alcane liquide, semblent être limitées par la diffusion inélastique dont les sections efficaces, pour les électrons épithermiques (~1 eV) et thermiques (<0.1 eV), sont influencées d'une manière similaire par l'anisotropie de polarisabilité des molécules. Dans les deux cas, la diffusion impliquerait l'excitation de la rotation (libration) dans le milieu.

Introduction

The radiolytic free ion yields G_{fi} (1–6) and the mobilities of electrons u_e (6–11) in liquid alkanes increase with increasing sphericity of the hydrocarbon molecules (1, 3, 6). The values of G_{fi} and u_e do not correlate with the dipole moments of the molecules, all of which are $\mu \leqslant 0.1$ D (12). The significant property of the molecules studied thus far seems to be the degree of anisotropy of polarizability (1, 6). The anisotropy of polarizability varies inversely with the degree of sphericity of the molecules.

It had previously been noted that *t*-butyl groups augment the radiation induced electrical conductance C of hydrocarbons (13). This is consistent with the above correlation because *t*-butyl groups are globular and

$$[1] \qquad C = \mathrm{fn}(G_{fi}, u_e, u_p)$$

where u_p is the mobility of the positive ions. In an attempt to learn more about the electron molecule interactions in hydrocarbon liquids the free ion yields and electron mobilities have been measured in a series of compounds $(CH_3)_3C(CH_2)_nC(CH_3)_3$ with $n = 0$, 1, 2, 3, and 4. By progressively separating the *t*-butyl groups from each other it has been possible to estimate the effective range of the electron–molecule interaction.

Experimental

Materials

The cyclohexane and neopentane were Phillips Research Grade. The 2,2,3,3-tetramethylbutane (2233TMB), 2,2,4,4-tetramethylpentane (2244TMP), 2,2,3,3-tetramethylpentane (2233TMP), 2,2,5,5-tetramethylhexane (2255TMH), 2,2,6,6-tetramethylheptane (2266TMHp), and 2,2,7,7-tetramethyloctane (2277TMO) were obtained from Chemical Samples Co. All these compounds were $\geqslant 99\%$ pure. The 2233TMB (m.p. 374 K) and 2277TMO (m.p. 315 K) are solid at room temperature, while the other compounds are liquid.

The liquids were purified by shaking with concentrated sulfuric acid to remove olefins. They were then washed several times with a dilute solution of sodium carbonate, then repeatedly with triply distilled water, then dried over lithium aluminum hydride. They were then distilled under vacuum onto sodium mirrors to remove the last traces of water and to react with traces of halides that might be present.

The 2233TMB and 2277TMO were purified by degassing above the melting point and treatment of the melt for at least 10 h with a sodium mirror.

All the compounds were thoroughly degassed before being sealed into the conductance cell under a remaining pressure of $< 7 \times 10^{-4}$ N/m^2 (5×10^{-6} Torr). The final criterion of purity was the observation of an electron conductance transient (ECT). In most of the liquids at 293 K the ECT had a half-life of 2–3 μs after a 1 μs pulse of X-rays. In order to achieve the maximum half-life and intensity of the ECT it was usually necessary to irradiate the filled conductance cell with γ rays to a dose of 10^{18}–10^{19} eV/g. Irradiation converted the remaining traces of oxygen and carbon dioxide into less efficient electron scavengers.

Although an ECT was obtained in each of the liquids studied, those observed in 2233TMB, 2266TMH$_p$, and 2277TMO had decay times equal to that of the measuring circuit, $t_{1/2} = 0.5$ μs. These liquids apparently contained small amounts of electron scavengers that were not removed by the purification treatment. However, the fact that an ECT was observed indicates that the scavenger concentration was low enough that the free ion yield would be decreased only slightly.

Equipment and Technique

(a) Conductance Cell

The plain, parallel, stainless steel electrodes were 30 mm in diameter and 3 mm apart, sealed in a 32 mm i.d. Pyrex envelope. The liquid entered the cell from side-arms joined to the flat ends, so that the cylindrical space between the electrodes was completely confined by a proximate glass wall. The cell constant (L/A cm^{-1}) was measured conductiometrically using standard KCl solutions.

The high voltage and charge-collection leads were shielded from the cooling or heating bath by glass tubes sealed to the cell and emerging out of the bath.

(b) Constant-Temperature Baths

Solid-liquid slushes of the following compounds were used to obtain refrigerant baths: chloroform (212 K), chlorobenzene (229 K), bromobenzene (254 K), water (273 K). A thermostated silicone oil bath was used for temperatures 293–473 K.

(c) Determination of the Free Ion Yields

The charge clearing technique (2, 3) was used. The irradiation dose per pulse (1 μs, 1.7 MeV X-rays) was 2–3 $\times 10^{10}$ eV/cm^3. The electric field (0.5–15 kV/cm) was applied across the cell throughout each experiment. The charge collected after a radiation pulse was fed into a low drift, high sensitivity integrator for 0.5–5 s to allow maximal collection of the ions; the signal was then put into half of the memory of a Fabritek 1062 Signal Averager. After each signal a blank (no pulse from the van de Graaff) was measured by the integrator for 0.5–5 s and put into the other half of the 1062 memory. In a typical run four alternate signals and blanks were fed into the 1062; the signals and blanks were then averaged separately and subtracted. The net signal was displayed on an oscilloscope. Larger numbers of signals and blanks were used for smaller collected charges. The signals and blanks were also monitored with a Tektronix 549B oscilloscope with a type 1A7 plug-in.

The circuit used was similar to that reported elsewhere (5), with a sensitivity up to 2 pcoul/cm.

(d) Measurement of the Electron Conductance Transient (ECT)

The circuit used is shown in Fig. 1. The greatest useful current sensitivity was 20 nA/cm. The response time of earlier circuits (6) increased with increasing capacitance of the conductance cell. The present circuit decay half-time is

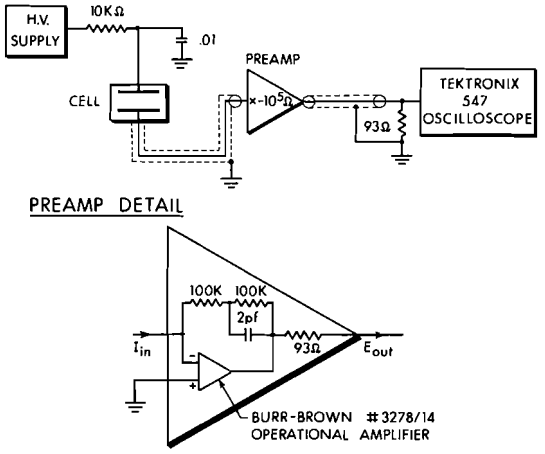

FIG. 1. Circuit for measuring the electron conductance transient.

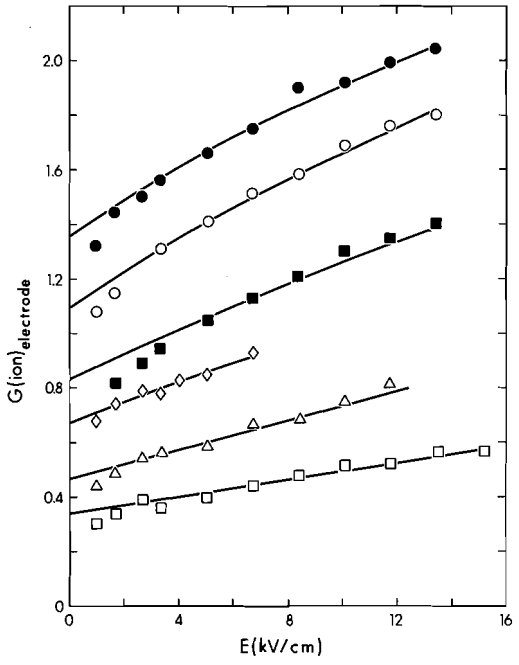

FIG. 2. Yield of ions collected at each electrode as a function of applied field strength E. Neopentane 293 K ○; 333 K ●; 2244TMP, 295 K ■; 2255TMH, 293 K ◇; 2266TMHp, 293 K △; 2277TMO, 316 K □. The curves were calculated by the method in refs. 17 and 18.

0.5 μs, independent of the cell capacitance; the noise level rather than the response time increases with increasing capacitance.

The 1 μs irradiation pulse dose used was $3–6 \times 10^{10}$ eV/cm^3.

(e) Dosimetry

The method used was the same as that described elsewhere (5, 6).

(f) Physical Properties of the Liquids

The densities d (14, 15) and dielectric constants ε (15) of the compounds were obtained by extrapolation or calculation from data in the references indicated. When necessary the value of the dielectric constant at one temperature was obtained from the relation $\varepsilon = n_D^2$, and values at other temperatures were calculated from the Clausius Mosotti equation (16); n_D is the refractive index. By comparison with values for other hydrocarbons (12), the dipole moments of all of the present alkanes are probably $\leqslant 0.1$ D and would contribute $<1\%$ to the dielectric constant of the liquid.

Results

Free Ion Yields and Secondary Electron Ranges

The free ion yields increase with increasing applied electric field strength and with increasing temperature. Typical results are shown in Fig. 2. For a given temperature the 100 eV yields of free ions at field strengths E, G_{fi}^E, were extrapolated to the value at zero field strength, G_{fi}^0, using eq. 2 (17, 18).

$$[2]\quad G_{fi}^E/G_{fi}^0 = 1 + \frac{9.69E}{\varepsilon T^2} + \frac{35.2E^2}{\varepsilon^2 T^4} - \frac{4.21 \times 10^4 E^2}{\varepsilon T^3} \frac{\int_0^\infty F(y)\, e^{-r/y} y\, dy}{\int_0^\infty F(y)\, e^{-r/y}\, dy} + \ldots$$

where ε is the dielectric constant of the liquid, T is the absolute temperature, $F(y)$ is the fraction of electron–ion pairs that have an initial separation distance y between the thermalized electron and its parent ion, $r = \xi^2/\varepsilon kT$, ξ is the electronic charge and k is Boltzmann's constant. Furthermore,

$$G_{fi}^0 = G_{tot} \int_0^\infty F(y)\, e^{-r/y}\, dy$$

where G_{tot} is the total ionization yield.

It was assumed that $F(y)$ had a Gaussian form

$$[3]\quad F(y) = (4y^2/\pi^{1/2}b^3) \exp(-y^2/b^2)$$

where b is the dispersion parameter; b is also the most probable value of y. The use of Gaussian distributions for liquids that give $G_{fi}^0 > 0.2$ was justified earlier (18). It was also assumed that in all of the liquids $G_{tot} = 4.3$, which equals the gas phase ionization yield in many alkanes (19, 20).

	395	0.37	1.86	79	53	

The yields of ions collected at the electrodes with a field strength of 1 kV/cm were slightly below the calculated $G_{fi}^{1\ kV}$ values because some of the ions and electrons were lost by mutual neutralization before they could be collected at this field strength.

The values of G_{fi}^0 and b for all the compounds at the various temperatures are listed in Table 1.

Thermal Electron Mobilities

The mobility of thermal electrons in a liquid was calculated from C_0, which was obtained from the initial magnitude of the ECT (6, 8).

$$[4] \qquad C_0 = \frac{6.24 \times 10^{20}\ i_0}{\text{dose}\ AE} = G_{fi}^E u$$

where i_0 is the peak current (A), the pulse dose

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

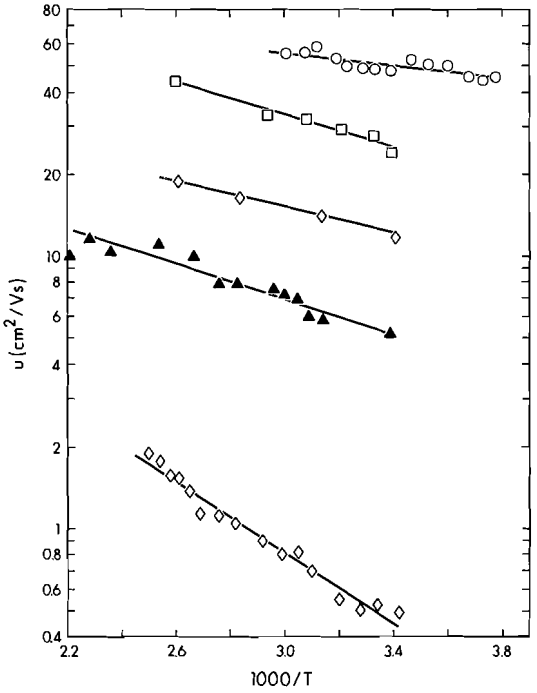

FIG. 3. Arrhenius plots of electron mobilities in liquid hydrocarbons. The electric field strengths used in the various hydrocarbons are listed in Table 2. ○, neopentane; ■, 2244TMP; ◇, 2255TMH; ▲, 2233TMP; ◆, cyclohexane. Many of the points are averages of two sets of values.

is expressed in eV/cm^3, A is the area of the collecting electrode (cm^2), E is the applied field strength (V/cm), G_{fi}^E is the free ion yield at field strength E, and u is the electron mobility. It was assumed that the positive ion mobility was negligible, which would be true in the absence of an electronic mechanism for positive hole migration in these liquids.

To obtain the value of C_0 the observed ECT was corrected for decay that occurred during the measurement. This was necessary because neither the pulse duration ($t_p = 1.0$ μs) nor the circuit response time ($t_{cr} = 0.5$ μs) was negligible by comparison with the ECT decay half-life (1–2 μs). The ECT decay was first order. To minimize the error in C_0 the magnitude of the ECT was read at a time $t \geqslant (t_p + 2t_{cr})$, measured from the beginning of the radiation pulse as $t = 0$. For an ECT with a first order decay half-life $t_{1/2}$ and a magnitude C_t at $t \geqslant (t_p + 2t_{cr})$, the value of C_0 for use in eq. 4 is given by eq. 5.

$$[5]\quad C_0 = C_t\left\{\frac{t_{1/2}}{0.69t_p}[1 - \exp(-0.69t_p/t_{1/2})] \times \exp(-0.69[t - t_p]/t_{1/2})\right\}^{-1}$$

Representative values of u and G_{fi}^E are given in Table 2. More complete mobility data are shown in Fig. 3. Values of the activation energies E_u for the electron mobilities were derived from Fig. 3 and are listed in Table 2.

Values of C_0 and hence of u could not be determined in 2233TMB, 2266TMHp, or 2277-TMO because the observed ECT decay times in these liquids equaled that of the measuring circuit.

Discussion

Free Ion Yields and Secondary Electron Ranges

The relationship between the radiolytic free ion yields and the secondary electron ranges has been extensively discussed (1–4, 17, 18, 21, 22) and does not require repetition here.

In each of the liquids the range b increases somewhat with increasing temperature (Table 1). However, the product of b and the liquid density d is constant for a given compound; the small increases or decreases in bd with increasing temperature recorded for some of the compounds in Table 1 do not seem to form a pattern and may be within the experimental error.

It was noted earlier that the electron ranges (1) and values of bd (2, 4) increase with increasing degree of sphericity of small molecules (3, 5). The values of bd in Table 1 indicate that for larger molecules the situation is more complex. The molecules of 2244TMP are much less sphere-like than are those of neopentane, yet the values of bd for the two liquids are similar, being 117 and 127, respectively (10^{-8} g/cm^2).

Consider for a moment the results of Schmidt and Allen (4) listed in Table 3. Methyl substitution on either n-butane or n-pentane has little effect on the value of bd as long as no carbon becomes completely substituted. However, formation of a t-butyl group (complete substitution of a carbon) on either butane or pentane increases the value of bd by about 30%. The last compound in the first column of Table 3 is denoted by A and that in the second column by B. Addition of one methyl group to A, to

*For neopentane the value $bd = 105 \times 10^{-8}$ g/cm^2 was reported (4).

complete a second *t*-butyl group in the molecule, increased *bd* by 35% from 63 to 85 units (see 2233TMB in Table 1). Addition of one methyl group to B, to complete a second *t*-butyl group in the molecule, increased *bd* by 80% from 65 to 117 units (see 2244TMP in Table 1); *bd* is 38% larger in 2244TMP than in 2233TMB. A 2244TMP molecule is comprised of two neopentyl groups overlapping at the central CH_2. Neopentyl groups are more sphere-like than are the two *t*-butyl groups that comprise 2233-TMB. It appears that a large molecule that is not sphere-like but that contains sphere-like groups is characterized by a large value of *bd*. The value of *bd* in 2244TMP is only slightly smaller than that in neopentane (Table 1).

Increasing the length of the central—$(CH_2)_n$—chain, where $n = 1, 2, \ldots$, between the globular end groups progressively decreases the value of *bd* (see 2244TMP to 2277TMO in Table 1). Straight chain hydrocarbons have $bd \approx 48 \times 10^{-8}$ g/cm^2 (Table 1 and ref. 4), so this value would presumably be asymptotically approached with increasing n if the present series were extended.

It now remains to discuss possible reasons for the effect of hydrocarbon molecular structure on the ranges of the secondary electrons in the liquids.

Correlation Between Electron Energy Loss Efficiency and Taft's σ^*

The Taft coefficient σ^* (23) indicates the relative inductive effect of a functional group. The electron-accepting powers of three hydrocarbon groups of interest here decrease in the order $CH{=}CH_2 > C_2H_5 > C(CH_3)_3$ ($\sigma^* = +0.7, -0.1$, and -0.3, respectively).

The value of the density-normalized range of the secondary electrons *bd* is inversely related to the efficiency of the electron energy loss processes. From the relative values of *bd* (1, 4, 5) one may conclude that the efficiencies of the electron energy loss processes in the liquids also decrease in the order $RCH{=}CH_2 > RC_2H_5 > RC(CH_3)_3$, where R is an alkyl group ($bd = 35$, 45, and 60, respectively, when R is C_2H_5 or n-C_4H_9 (4)). Thus there is a correlation between the electron accepting power of the groups and the efficiency of the electron energy loss interactions with the molecules.

Although the correlation is only crude it might indicate that one of the electron energy loss processes involves the approach to a transient negative ion state of the molecules (24), resulting in vibrational excitations of the molecule.

Inductive effects have short ranges, being negligible after two consecutive C—C bonds

*α_1, α_2, and α_3 are the principal components of the molecular polarizability. The mean value is $\bar{\alpha} = (1/3)(\alpha_1 + \alpha_2 + \alpha_3)$ and the anisotropy α^a is given by $(\alpha^a)^2 = (1/2)[(\alpha_1 - \alpha_2)^2 + (\alpha_2 - \alpha_3)^2 + (\alpha_3 - \alpha_1)^2]$. The values were calculated from information in ref. 27. The values of α_1, α_2, and α_3 reported for ethane and propane in ref. 43 lead to $\alpha^a = 1.5$ Å^3 for ethane and 1.9 Å^3 for propane. They should be rejected because they were taken from data (44) that indicate $\alpha^a = 0.9$ Å^3 for methane. Landolt–Börnstein report $\alpha^a = 0.0$ Å^3 for methane, on the basis of symmetry. If one subtracts the methane error of 0.9 from the ethane and propane values one obtains 0.6 and 1.0 Å^3, respectively, in reasonable agreement with the values in the above table. The Le Fèvre work (27) is also preferred because it is two decades more recent than that of Stuart. The depolarization of 90° scattered light is nearly an order of magnitude greater from a liquid compound than from its vapor (45), but the trends are similar from compound to compound. The phase effect is discussed by Bhagavantam in ref. 46.

†Reference 5.

‡Present work.

§Reference 4. These values should be increased somewhat for comparison with the present work because our value of *bd* in neopentane is 21% greater than that reported in ref. 4.

‖Using the CH_2—CH_3, CH_2—CH_2, or CH=CH_2 axis as the direction of α_1.

(25). Thus larger molecules would be sensed by the electrons as collections of groups rather than as whole molecules.

Taft reactivity coefficients are determined empirically. They are rationalized in terms of group electronegativities, but are not basically understood (23). The correlation between the Taft coefficients and the epithermal electron energy loss efficiencies might have an indirect cause. Fundamental interpretations of the effects of molecular structure on these phenomena are needed.

Correlation Between Electron Energy Loss Efficiency and Anisotropy of Polarizability of the Molecules

From studies of C_1–C_6 hydrocarbons it has been found that there is a qualitative correlation between the degree of sphericity of the molecules and the value of *bd* for the secondary electrons in the liquid (1, 5, 6). This has been attributed to a correlation, not yet understood, between the anisotropy of polarizability of the molecules and the efficiency of the electron energy loss (and perhaps localization) processes in the liquid (1, 5, 6).

The polarizability α of a molecule can be divided into three principal components α_1, α_2, and α_3 at right angles to each other (26, 27). The mean value $\bar{\alpha}$ is given by eq. 6 and the magnitude of the anisotropy of the polarizability of α^a is governed by eq. 7.

$$[6] \qquad \bar{\alpha} = 1/3(\alpha_1 + \alpha_2 + \alpha_3)$$

$$[7] \qquad (\alpha^a)^2 = 1/2[(\alpha_1 - \alpha_2)^2 + (\alpha_2 - \alpha_3)^2 + (\alpha_3 - \alpha_1)^2]$$

Values of α_1, α_2, α_3, $\bar{\alpha}$, and α^a have been calculated for a number of hydrocarbon molecules from information in ref. 27. It was assumed that the molecules were rigid, *i.e.*, not vibrating. The results are listed along with the values of *bd* in Table 4.

Consider first the series of isotropically polarizable molecules ($\alpha^a = 0.0$). The value of *bd* decreases with increasing molecular complexity (Table 4). The decrease in *bd* might be partly

For personal use only.

due to anisotropy introduced by antisymmetric vibrations in the molecule, and partly due to the short range of the electron induced-dipole interaction. The net coulombic interaction energy between a particle of charge ξ and a nonpolar molecule at distance r from it in a medium of dielectric constant ε is given approximately by eq. 8.

$$[8] \qquad E_{coul} = \frac{-\xi^2\alpha}{\varepsilon^2 r^4}$$

In the simplest case r is large compared with the molecular diameter and ε is a constant. However, the coulombic interaction between an electron and a nearest neighbor molecule in a liquid varies across the molecule, mainly due to variation in r^{-4} but partly also due to the change in ε^{-2}. The variation is greater the larger the molecule. Thus a methane molecule, with its isotropically polarizable C—H bonds (27), will appear more isotropic to a colliding electron than will a neopentane molecule with its outer C—H bonds and anisotropically polarizable inner C—C bonds (27). For electron approach to most of the surface of Me_3CCH_2-CMe_3 the molecule will interact like neopentane (CMe_4), but for approach to the CH_2 group the interaction will be more like that with propane, which has an anisotropic polarizability.

Now consider the series of molecules with $\alpha^a = 0.7$ (Table 4). The value of *bd* is much smaller in ethane than it is in methane, but increases with increasing molecular complexity in the $\alpha^a = 0.7$ series. This can also be attributed to the short range of the electron–molecule interactions. The anisotropy of $Me_3CCH_2CH_2$-CMe_3 is due to the central —CH_2CH_2— group, but the two ends of the molecule are neopentane-like. Thus the average appearance of the large molecule to the myopic electron is more like neopentane than ethane.

The value of α^a is greater in ethylene than in ethane, and the value of *bd* is smaller in the former than in the latter. This confirms the inverse correlation between *bd* and α^a and supports the suggestion that there is a connection between the value of α^a and the efficiency of electron energy loss processes in the liquid. The fact that *bd* is greater in $Me_3CCH{=}CH_2$ than in C_2H_4 also supports the suggestion that the effective interactions are short range; an electron directly approaching the Me_3 end is largely shielded from the double bond. From space-filling molecular models one can determine that about 20% of the surface of $Me_3CCH{=}CH_2$ would look like that of neopentane to a myopic electron, while the olefin group would dominate the interaction for approach to the other 80% of the surface. Thus the value of *bd* in $Me_3CCH{=}CH_2$ is much closer to that in C_2H_4 than to that in neopentane.

Having demonstrated the correlation between the anisotropy of polarizability of the molecules and the electron energy loss efficiencies in the liquids, one still has not arrived at an explanation. It should be stated, however, that the short range of the energy loss interactions is not compatible with any previous concept that used the de Broglie wavelength for the interaction distance; $\lambda = 12$ Å for a 1.0 eV electron.

The anisotropies of the molecules reflect the anisotropic fields encountered by the electrons in the liquids.

Raman-Type Rotational Excitation

The only well known type of molecular excitation process that depends upon the anisotropy of polarizability is Raman rotational excitation (refs. 26, 28; in particular chapter 6 of ref. 28).

Raman excitational processes require a periodic variation in polarizability,

$$[9] \qquad \frac{d\alpha}{dt} = f(\omega t)$$

where $\omega/2\pi$ is the periodic frequency and t is the time. When the polarizability changes with internuclear distance R, *i.e.* for $d\alpha/dR \neq 0$, the molecule is susceptible to Raman vibrational excitation because for a vibration $dR/dt = f'(\omega t)$. Hence,

$$[10] \qquad \frac{d\alpha}{dR}\cdot\frac{dR}{dt} = f_v(\omega t)$$

When the polarizability in a given direction changes during the rotation of a molecule, *i.e.* $d\alpha/d\theta \neq 0$, the molecule is susceptible to Raman rotational excitation because for a rotation

$d\theta/dt = f''(\omega t)$ and so

$$[11] \qquad \frac{d\alpha}{d\theta}\cdot\frac{d\theta}{dt} = f_r(\omega t)$$

The condition $d\alpha/d\theta \neq 0$ is fulfilled when $\alpha^a \neq 0$.

In normal Raman spectroscopy the symmetric stretching vibrations of a molecule often have the largest values of $d\alpha/dR$ and hence the largest Raman intensities. This is true, for example, in methane (ref. 26, p. 306). If Raman-type intramolecular vibrational excitation were the main energy sink for the epithermal electrons, *bd* should have been nearly the same in methane and in ethane, because $d\alpha/dR = 1.0 \times 10^{-16}$ cm^2 for both C—H and C—C bonds (29). The present results (Table 5) imply that for molecules with $\alpha^a \neq 0$ Raman-type vibrational excitation is not the predominant process by which the electrons lose their energy. Raman-type rotational excitation would be consistent with the observations; rotational motion is greatly hindered in the liquid, but excitation of the hindred rotations (librations) would also fulfill the present requirements.

Normal Raman processes involve interactions between molecules and photons that have energies less than the lowest electronic excitation energy of the molecules (ref. 26, p. 261). In the present discussion the major concern is with interactions between molecules and electrons that have energies less than the lowest electronic excitation energy of the molecules ($T_{e^-} \approx 10^{0\pm1}$ eV).

An energetic electron passing near to a molecule is felt by the molecule as an impulsive electric field. The force exerted on the molecule varies in direction with time, but can be resolved into two normal components, one parallel to the electron path (longitudinal component) and the other perpendicular to it (transverse component) (30). Each component of the impulsive electric field can be decomposed by Fourier transformation into a series of waves of different frequencies ν_i. Thus the effect on a molecule of an electron passing close to or colliding with it is analogous to that of a beam of photons with frequencies ν_i traversing it. The transverse component is much more intense than is the longitudinal component (30). The energies $h\nu_i$ of the virtual photons vary from that of the electron down to zero, and the effective number of photons at each frequency increases approximately as ν_i^{-1} (30). Perhaps the relatively large number of low energy virtual photons associated with the subelectronic-excitation-energy electrons explains why it is the rotational modes rather than the vibrational modes of the molecules that serve as the principal energy sink in liquid hydrocarbons. The energy spacings of C—H stretching vibrations are 0.4 eV (ref. 26, p. 306), while those of intermolecular motions such as librations are ~0.01 eV in many liquids (31, 32).

The electric field at a distance of 3 Å from an electron is 10^8 V/cm, and it varies as $1/r^2$. At such high field strengths the induced dipole moment μ_{ind} does not vary linearly with electric field strength (33), but is given by

$$[12] \qquad \mu_{ind} = \alpha E + \tfrac{1}{2}\beta E^2 + \tfrac{1}{6}\gamma E^3 + \ldots$$

where β and γ are the first and second hyperpolarizabilities, respectively. The hyperpolarizabilities do not have the same symmetry properties as does α, and β is often negative whereas α is always positive (33). An electron is always surrounded by its intense, inhomogeneous field, so the hyperpolarizabilities might influence the electron energy loss processes.

Molecules with isotropic polarizabilities are less efficient in taking energy from the electrons,

so the density normalized electron penetration distances *bd* are greater in such liquids (Table 4). If Raman-type processes are important in liquid hydrocarbons, direct excitations of librations should be important in liquids that contain permanent dipoles. Interactions between ions and permanent dipoles are usually stronger than those between ions and induced dipoles. Thus the value of *bd* should be smaller in polar liquids than in *n*-hexane or cyclohexane. This will be shown to be true in a subsequent publication (34).

Temperature Dependence of G^0_{fi}

The variation of the free ion yields with temperature in the present liquids is adequately described by eq. 3. The behavior is not of the simple Arrhenius type because the exponential factor $\exp(-\xi^2/\varepsilon kTy)$ must be integrated over the distribution $F(y)$. Furthermore, ε decreases and y increases with increasing temperature. The net effect is found empirically to be a tendency for the temperature coefficient to increase with increasing temperature.

Plots of $\ln G_{fi}$ against T^{-1} were made to obtain estimates of the exponential temperature coefficient $E_{G_{fi}}$. Values of $E_{G_{fi}}$ averaged over the temperature range studied are listed in Table 5; they are in the region of 1–2 kcal/mol.

From the point of view of competition between reactions 14 and 15

[13] $\quad M \rightsquigarrow [M^+ + e^-]$

[14] $\quad [M^+ + e^-] \rightarrow$ geminate neutralization

[15] $\quad [M^+ + e^-] \rightarrow M^+ + e^-$ (free ions)

one may write

$$[16] \quad E_{esc} = E_{15} - E_{14} = -R[\partial \ln (G_{fi}/G_{gn})/\partial T]$$

where G_{gn} is the geminate neutralization yield, taken as $(4.3 - G_{fi})$ in the present liquids. The rates of both reactions 14 and 15 increase with temperature through the increases in the diffusion coefficients of M^+ and e^-. The net exponential temperature coefficient of escape from geminate neutralization is E_{esc}.

It was reported earlier (5) that the value of E_{esc} was 2–3 times the mean value of RT in the low temperature studies of C_2 and C_3 hydrocarbons. The same is true in the present high temperature studies (Table 5). Analysis of the data from earlier temperature studies of free ion yields in hydrocarbons (2, 4–6, 35) shows that in every case, including olefins and benzene, $E_{esc}/RT_m = 2$–3, where T_m is the mean temperature. The average of the twenty two values obtained to date is 2.4 ± 0.3. In terms of the present model, the temperature sensitivity of the free ion yields in hydrocarbons arises mainly from the pairs that have y values between about 80 and 300 Å.

Thermal Electron Mobilities

The mobility of thermal electrons in a liquid hydrocarbon is affected by the structure of the molecules (Table 2 and refs. 3, 6, 9–11). The activation energy of the electron mobilities tends to be smaller in the alkanes in which the mobilities are larger (Table 2 and refs. 6, 9); extrapolation to "infinite temperature" gives $u_\infty \approx 10^2$ cm^2/V s in each alkane, which is the normally accepted region of mobilities of quasi-free electrons (36). The enormous range of mobilities observed in liquid hydrocarbons indicates that a continuous variation in the "degree of freeness" of electrons is possible. It is not sufficient to distinguish simply between quasifree and localized states of electrons in these liquids. The degree of freeness is characterized by the mobility.

There is no correlation between the electron mobility and the viscosity of the liquid, nor between the activation energy of electron mobility and that of the liquid viscosity (Table 2). The electron mobility is governed by the electron scattering property of the liquid. The electron scattering property and the viscosity both depend upon the molecular properties and the liquid density, but in different ways.

There is, however, a correlation between the mobilities of thermal electrons in liquids and the penetration ranges b of the secondary electrons in the irradiated liquids. Values of u from Table 2 are plotted against those of b from Table 1, along with other data from the literature (4–6, 8–10, 34, 37–39) in Fig. 4. Although most of the compounds in Fig. 4 are alkanes, tetramethylsilane (4, 9), argon (6, 38), water (34, 37), and two alcohols (34) are included.[1] The correlaton is striking.

The continuous nature of the degree of freeness of electrons in liquids is evident from Fig. 4. The mobility of electrons in liquid argon may be

[1]Values of u_{e^-} in methanol and ethanol were calculated from data of ref. 39*a*, using u_{H^+} and u_{RO^-} from ref. 39*b*.

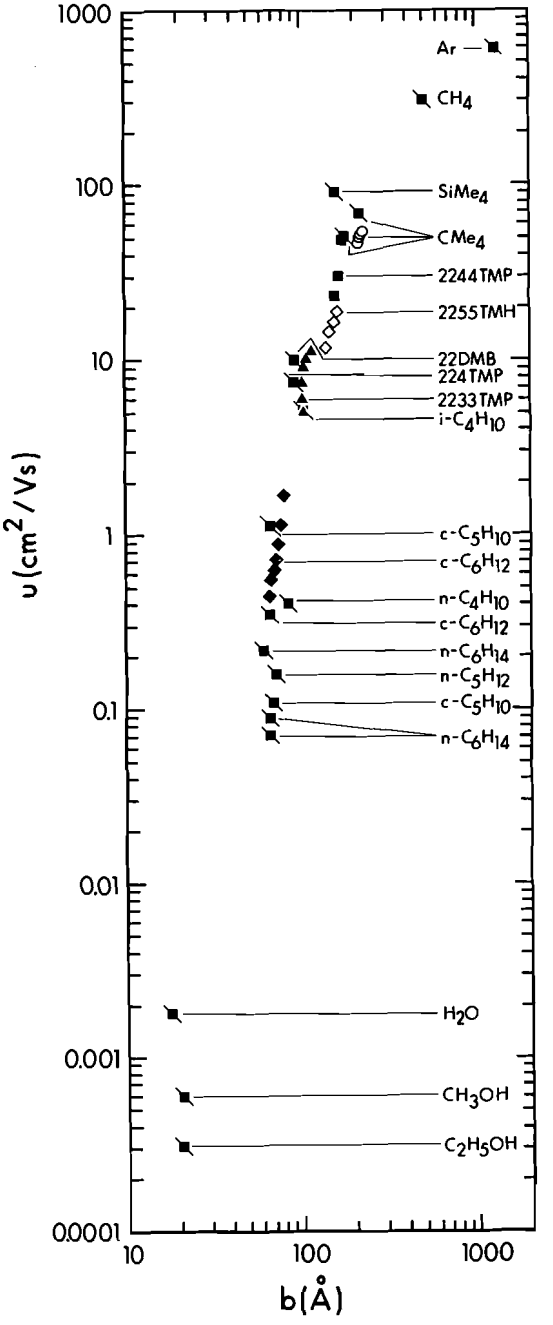

FIG. 4. Correlation between thermal electron mobility (u) and the most probable range (b) of the secondary electrons in irradiated liquid saturated compounds. The symbols ○, ◇, △, ◆, ▲, ■ represent the present results. Each type of symbol represents the compound indicated. The values from the literature (4–6, 8–10, 34, 37, 38) are designated by the symbol ■ and each point is labelled.

explained by assuming that an electron is scattered by only one atom at a time (single-body scattering approximation), because the electron scattering cross section of argon is small (40, 41). As one considers molecules that have larger and larger electron scattering cross sections it becomes necessary to consider interactions of the electron with more than one molecule at a time in the liquids (multi-body scattering). Electron localization may be considered as an extreme case of multi-body scattering, including both elastic and inelastic modes. Relaxation of the initial localized state to the solvated state involves inelastic scattering and solvent rearrangement; maintenance of the localized state, including the solvated state, involves elastic scattering. The short range interactions that must be considered in theoretical treatments of the solvated state may be considered to be scattering interactions.

It appears that the inelastic (incoherent) scattering cross sections of alkanes for thermal electrons are affected by the same things as are those for epithermal electrons. The dominant molecular property in alkanes appears to be the anisotropy of polarizability of groups containing up to two C—C bonds in series (up to neopentyl in size). In polar liquids the permanent dipole moment probably predominates.

The density of the liquid is important in the above processes because it affects the mean free path of the electrons.

We are grateful to the staff of the Radiation Research Center for help with the electronics. The financial support of the National Research Council of Canada is much appreciated.

Potentiometric Titration of Fulvic Acid: Equivalence Point Calculations and Acidic Functional Groups[1]

DONALD S. GAMBLE

Soil Research Institute, Canada Department of Agriculture, Ottawa, Canada K1A 0C6

Received February 25, 1972

Gran's functions corrected for buffering and H_2O dissociation have been incorporated into the iterative calculation for the two equivalence points and the acid dissociation equilibria. The experimental and mathematical conditions required for accurate, dependable operation of the method have been examined. The resulting equivalence point calculations are based directly on a chemical interpretation of the system, without approximations. The first equivalence point is higher than previously reported, and is displaced upward by KCl. Detailed chemical information has been obtained for some of the acidic functional groups, from plots of $K_A = (m_H \delta m_A / \delta m_{AH})$ *vs.* mequiv./g. Carboxyl groups at the chelating sites are essentially all ionized for H^+ concentrations less than 1×10^{-5} *m*.

Les fonctions de Gran corrigées pour le tampon et la dissociation de H_2O ont été introduites dans le calcul itératif des deux points d'équivalence et d'équilibre de dissociation acide. Les conditions expérimentales et mathématiques requises pour une opération sûre et précise de la méthode ont été examinées. Les calculs du point d'équivalence qui en résultent, sont fondés directement sur une interprétation chimique du système sans approximations. Le premier point d'équivalence est plus élevé que celui précedemment rapporté et se trouve déplacé par KCl. Une information chimique détaillée a été obtenue pour certains des groupes fonctionnels acides, à partir des courbes de $K_A = m_H \delta m_A / \delta m_{AH}$ en mequiv./g. Les groupes carboxyles sur les sites de chélation sont essentiellement et entièrement ionisés pour des concentrations en H^+ inférieures à 1×10^{-5} *m*.

Canadian Journal of Chemistry, 50, 2680 (1972)

Introduction

The characterization of fulvic acid is prerequisite to studies of such phenomena as its metal ion chelation and sorption by clays. The complex nature of fulvic acid requires that it be characterized by a number of experimental techniques. Potentiometric titration with standard base is one of the more important of these methods. It requires, however, some adaptation to this kind of polyelectrolyte system. The two particular problems that must be solved for this purpose are the evaluation of titration equivalence points, and the calculation of acid dissociation equilibrium functions as functions of their corresponding degrees of ionization.

Even for monomeric, monobasic weak acids, Meites and Goldman (1) found that the first of the two inflection points generally differs from 1/2 the equivalence point except for the special case in which $K_a = \sqrt{K_w}$. The second one occurs before the equivalence point, although the discrepancy is small for $K_a \geqslant 10^{-8}$. These effects increase with increasing dilution. Polyelectrolytes are rather less tractable, and van Dijk (2) and Posner (3) have both pointed out the difficulty of determining equivalence points from potentiometric titrations of humic materials. A number of authors have simply chosen arbitrary pH values as the "end points" for such titrations (4–6). Speiser *et al.* (7) assumed the inflection point at p$H = 7.5$ to be the equivalence point for pectin titrations.

Pommer and Breger took a more promising direction (8) by applying Gran's calculation method (9, 10) to humic acid titration curves for which they had observed only one equivalence point. They assumed the equivalence point to be at the point of intersection of a pair of Gran's functions uncorrected for buffering and H_2O dissociation. Because their Gran's functions were linear and because they obtained agreement between two calculation methods, they believed their equivalence point values to be correct. In a similar way, uncorrected Gran's functions were used in the previously reported part of this work (11) for the two fulvic acid equivalence points. Like those of Pommer and Breger, these Gran's functions did not vanish

[1]Presented in preliminary form at the 54th Annual Conference of the Chemical Institute of Canada, Halifax, May 30 – June 2, 1971. Contribution No. 409.

at the points of intersection, which were taken to be the equivalence points. Unlike those of Pommer and Breger, however, the Gran's functions of this fulvic acid were not linear. Because the Gran's functions were non-ideal in these two respects, conductivity titrations were used as an independent experimental check on the equivalence point values. The two methods were apparently in agreement for that particular case. This implied that the calculation errors caused by the neglect of buffering and H_2O dissociation were either small, largely cancelled, or both. Subsequent examination has not only revealed that correction terms for buffering and H_2O dissociation can be comparable in size to Gran's original functions, but also has indicated that the first equivalence point values could be low. Another difficulty is the doubtful chemical authenticity of equivalence points calculated directly from voltage readings as Gran originally recommended.

The determination of potentiometric titration equivalence points for fulvic acid therefore required re-examination. In addition to the buffering effects which Rossotti and Rossotti (12) have shown to be the causes of non-linear, non-vanishing Gran's functions for monomeric weak acids, the previously reported dependence of $\bar{K}$ on the degree of ionization of fulvic acid (11) contributes further to such non-ideal behavior. Liteanu and Cőrmős (13) have investigated potentiometric titrations for which the Gran's functions are linear but do not vanish at the equivalence point. They first fitted each of the pair of Gran's functions to a straight line by the method of least squares. The solution to this pair of simultaneous equations was not generally at the equivalence point. They then calculated the equivalence point by applying an algebraic correction for the asymmetry of the titration curve. Apart from its not being applicable to non-linear fulvic acid results, the Liteanu–Cőrmős calculation techniques has two possible disadvantages. Firstly, the correction calculation is based on a symmetry argument rather than on direct chemical reasoning. Secondly, Gran's functions that do not vanish at the equivalence point lack the insensitivity to experimental and calculation errors which Lanza and Mazzei (14) have demonstrated for those that do vanish.

The first objectives of this work are to obtain characteristic, reproducible equivalence point values, and to establish that they correspond to chemical reality rather than being merely mathematical or experimental artifacts. Another objective is to characterize the Type I carboxyl groups, that is, those ortho to phenolic-OH groups (11). The best experimental method for this purpose is to "map out" detailed H^+ concentrations *vs.* mls titration curves with large numbers of H^+ concentration standards. This may be done by adapting the previously reported procedure (11) for extension into the basic region of the titration curve. Other authors have fully discussed the reasons for doing this rather than using the more usual pH measurements (15–18). The method adopted here for basing the equivalence point calculations directly on chemical reasoning is to use Gran's functions corrected for buffering, H_2O dissociation, and the dependence of the two $\bar{K}$ functions on their respective degrees of ionization. Such corrected Gran's functions will vanish at the equivalence points. Each of the two equivalence points may therefore be calculated with just one corrected Gran's function. Those used are the one before the first equivalence point and the one after the second equivalence point.

Theory

(a) Weak Acid Properties

The concepts developed in the previously reported part of the work (11) must now be adapted to cases for which the first titration equivalence point extends beyond the Type I carboxyl groups, which are defined as those on aromatic rings ortho to phenolic OH groups. Let C be the total molality of acidic functional groups, both ionized and unionized, accumulated in the order of decreasing acid strengths up to some point in the titration. If Type A functional groups are all of those up to the first equivalence point, then for Type I and Type A functional groups respectively, C becomes

$$C_L = m_L + m_{LH} \quad [1]$$

$$C_A = m_A + m_{AH} \quad [2]$$

Ionized and unionized functional groups are indicated by the subscripts. Generally, $C_L \leqslant C_A$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Accordingly for Type B acidic functional groups between the two equivalence points,

$$[3] \qquad C_B = m_B + m_{BH} = C_{MAX} - C_A$$

In terms of the A and B types of acidic functional groups, the total titratable acid remaining at any point in the titration becomes

$$[4] \quad C_H = \frac{C_A}{\left(\frac{\bar{K}_A}{m_H} + 1\right)} + \frac{C_B}{\left(\frac{\bar{K}_B}{m_H} + 1\right)} + m_H - \frac{K_w}{m_H}$$

$\bar{K}_A$ and $\bar{K}_B$ are the previously defined type of weighted average H^+ dissociation equilibrium function (11), and m_H is the H^+ molality.

The Type A functional groups are of the greatest chemical interest because they are strongly acidic, and because they include the Type I carboxyl groups located at bidentate chelating sites (19, 20). Detailed chemical information about these functional groups is not provided by $\bar{K}_A = \bar{f}_A(\alpha_A)$, since it is an average. Such information should be available, however, from K_A which has been defined according to eq. 5 for an infinitesimal increment of functional groups.

$$[5] \quad K_A = \frac{m_H \delta m_A}{\delta m_{AH}} = K_A^0 \Gamma_A \, e^{-\Delta G_A^e/RT} = f_A(\alpha_A)$$

Γ_A is a ratio of activity coefficient products, and ΔG_A^e is the electrostatic free energy. The K_A calculation described earlier is simplified by means of the familiar relationship $\bar{K}_A = \alpha_A m_H/(1 - \alpha_A)$. The result is eq. 6.

$$[6] \qquad K_A = -\frac{d(\alpha_A m_H)}{d\alpha_A}$$

For cases in which $C_L < C_A$, the degree of ionization of the Type I carboxyl groups, α_1, is not identical to α_A. The method of calculating α_1 is developed from eq. 7, the material balance equation for ionized Type A functional groups.

$$[7] \qquad m_A = \sum_{i=0}^{k} m_{A_i}$$

The index "i" denotes the ith small increment of Type A functional groups, $c_i = m_{A_i} + m_{A_iH}$. The degree of ionization of this ith increment is

$$[8] \qquad \beta_i = \frac{m_{A_i}}{c_i}$$

With substitution into eq. 7 from eq. 8 and division by C_A, α_A is found to be a weighted average of the β_i values.

$$[9] \qquad \alpha_A = \frac{1}{C_A} \sum_{i=0}^{k} \beta_i c_i$$

Assume that the increments become very small, so that

$$\lim_{c_i \to 0} c_i = \delta C = (\delta m_A + \delta m_{AH})$$

The β_i values may then be replaced by a continuous function,

$$[10] \quad \beta_A = \frac{\delta m_A}{\delta C} = \frac{K_A}{K_A + m_H} = \beta_A(C, m_H)$$

β_A is a function of two variables, since its value depends not only on the H^+ molality, but also on the particular infinitesimal increment of Type A functional groups being considered. This is characterized by C, its position in the "inventory" of acidic functional groups accumulated in the order of decreasing acid strength. Therefore, the summation of eq. 9 may be replaced by an integration at a constant H^+ molality.

$$[11] \quad \alpha_A = \frac{1}{C_A} \int_0^{C_A} \beta_A \, dC = \alpha_A(m_H) = \alpha(C_A, m_H)$$

Differentiating eq. 11 at this same H^+ molality gives

$$\left(\frac{\partial \alpha_A}{\partial C}\right)_{m_H} = \frac{\beta_A}{C_A}$$

$$\partial m_A = \beta_A(C, m_H) \partial C$$

For the carboxyl groups in the region $C \leqslant C_L$, that is, the Type I carboxyl groups,

$$\partial m_A = \partial m_L = C_L \partial \alpha_1$$

$$[12] \qquad \left(\frac{\partial \alpha_1}{\partial C}\right)_{m_H} = \frac{\beta_A}{C_L}$$

The degree of ionization of the Type I carboxyl groups as a function of H^+ molality is therefore calculated by integrating between the limits 0 and C_L.

$$[13] \quad \alpha_1 = \frac{1}{C_L} \int_0^{C_L} \beta_A(C, m_H) dC = \alpha_1(m_H)$$
$$= \alpha(C_L, m_H)$$

This calculation requires an experimental measurement of C_L, the total molality of Type I carboxyl groups.

(b) Corrected Gran's Functions

The molality of total base added by titration is given by eq. 14:

$$[14] \qquad C_{OH} = m_{OH} + m_A + m_B - m_H = \left(\frac{N_B}{W_0 + R_w R_v V}\right) V$$

N_B is the normality of standard base used for the titration, W_0 is the initial weight of water in the sample solution, V is the volume of standard base added by titration, and R_w and R_v are constants for converting volume of standard base to weight of water. This and similar equations for C_B and C_H are combined with the expression for $\bar{K}_A$ to give the First Gran's Function, eq. 15.

$$[15] \qquad Y_1 \equiv (Vm_H - Q_1) = \bar{K}_A(V_{e1} - V)$$
$$Q_1 = \left(\frac{W_0 + R_w R_v V}{N_B}\right)\left(m_B - m_H + \frac{K_w}{m_H}\right) \times (\bar{K}_A + m_H)$$

This is applicable before the first equivalence point, V_{e1}. In a similar way, eq. 14 and the equations for C_A, C_B, and K_w are used to derive Y_4, the Fourth Gran's Function. It is applicable after V_{e2}, the second equivalence point.

$$[16] \qquad Y_4 \equiv \left(\frac{W_0 + R_w R_v V}{m_H} - Q_4\right) = \frac{N_B}{K_w}(V - V_{e2})$$
$$Q_4 = \left(\frac{W_0 + R_w R_v V}{K_W}\right)(m_{AH} + m_{BH} + m_H)$$

Equations 15 and 16 are simple extensions of Gran's original work, and differ from his equations essentially only by the inclusion of the correction terms Q_1 and Q_4.

The numerical values of Q_1 and Q_4 depend quite directly on the current values of V_{e1} and V_{e2}, while Gran's original terms are independent of them. The ease with which iterative calculations using Y_1 and Y_4 converge should therefore depend on the sizes of the ratios $|Q_1/Y_1|$ and $|Q_4/Y_4|$. The effects on Y_1 and Y_4 of errors in $\bar{K}_A$ and $\bar{K}_B$ should likewise depend on the sizes of these ratios.

Calculation Techniques for V_{e1}, $\bar{K}_A$, V_{e2}, and $\bar{K}_B$

The evaluation of Q_1 and Q_4 requires estimates of the functions

$$\bar{K}_A \equiv \bar{f}_A(\alpha_A)$$
$$\bar{K}_B \equiv \bar{f}_B(\alpha_B)$$

The corrected Gran's functions have therefore been incorporated into the iterative calculation for V_{e1}, $\bar{K}_A$, V_{e2}, and $\bar{K}_B$. The steps for each iteration are as follows:

1. $\bar{K}_A$ is calculated for each titration data point from eq. 4, over the range $0.000 \leqslant V < V_{e1}$. The current values of V_{e1}, V_{e2}, $\bar{K}_B$, and K_w are used, with K_w being evaluated from the KCl solution data of Harned and Hamer (21). For the first iteration, $\bar{K}_B = 0$ is used. Beyond the V range used, $\bar{K}_A$ is set equal to the average of the last six values.

2. $\bar{K}_B$ is calculated in a similar way from eq. 4, over the range $V_{e1} \leqslant V \leqslant V_{e2}$. Before and after this range $\bar{K}_B$ is set equal respectively to the average of the first six and to the average of the last six $\bar{K}_B$ values.

3. α_A and α_B are calculated for each titration data point.

4. Y_1 is calculated for each titration data point from the start of the titration up to the point at which negative Y_1 values occur. Y_1 calculation then ceases, and values for which $|Q_1/Y_1| > 0.500$ are discarded.

5. The remaining Y_1 values are fitted to a polynomial by the method of least squares, and V_{e1} is calculated by the Newton–Raphson method (22) at the point $Y_1(V_{e1}) = 0$.

6. Y_4 is calculated for each titration data point from $V > V_{e1}$ to the end of the titration. Values for which $|Q_4/Y_4| > 0.500$ are rejected.

7. Except that a linear least squares fit is used, V_{e2} is calculated as is V_{e1}.

The mathematical requirements for proper convergence of this calculation are:

1. The least squares fitting requires a sufficient density of titration data points without excessive scatter.

2. $\bar{K}$ values strongly affected by experimental errors in the high error regions where α approaches 0 or 1 must be rejected.

3. Data points for which the ratios $|Q_1/Y_1|$ and $|Q_4/Y_4|$ are too high must be rejected from the sets of Gran's function values.

4. The zero order approximations for V_{e1} and V_{e2} must be within certain limits of the final values. For V_{e2} this might typically be $\pm 10\%$, but V_{e1} usually has wider limits.

5. The Y_1 *vs.* V curve must not approach the $Y_1 = 0$ line at too small an angle.

6. All negative values of $\bar{K}_A$, $\bar{K}_B$, α_A, α_B, Y_1, and Y_4 must be rejected from the calculation.

These calculations were programmed in Fortran V for the Univac 1108.

Experimental

(a) Chemicals

Fulvic Acid Batch FA1 was prepared essentially as previously described, from a soil sample collected at the same geographical location (23, 24). Freeze drying was substituted for flash evaporation in the last step, to minimize exposure to higher temperatures. The ash content was 1.1%. Analysis by atomic absorption spectrophotometry indicated less than 0.1 p.p.m. each, of Ca^{2+}, K^+, Na^+, Fe^{3+}, Cu^{2+}, Al^{3+}, Zn^{2+}, and Mg^{2+}. Final drying to constant weight before use was as previously reported (11).

H_2O, redistilled under N_2.

KCl, Anachemia A.C.S. Reagent grade crystals. Lot No. 86B920. Dried to constant weight at 110 °C.

HCl Standard (0.1 *N*), Fisher reagent, Lot No. 784176.

KOH Standard (0.1 *N* at 25.0 °C), Lot No. 782654.

KOH Standard (0.01 *N* at 25.0 °C); prepared gravimetrically from 0.1 *N* standard KOH.

(b) Apparatus

The potentiometric titration apparatus was the same as previously described (11).

(c) H^+ Molality Standards

These were all prepared under N_2 with redistilled H_2O. For the acid range of the titration, 23 to 29 H^+ standards were prepared gravimetrically over the range 3×10^{-3} to 1×10^{-6} *m* H^+. Their KCl concentrations were adjusted to compensate for KCl dilution during titration. The base range of the titration was covered by 38 to 43 standards from about 10^{-8} *m* to 1×10^{-11} *m* H^+. These were prepared by titrating 100 g of solvent with either 0.01 or 0.1 *N* standard KOH. Literature activity coefficient data (21) were used in correcting the H^+ concentrations for H_2O dissociation.

(d) Potentiometric Titration Procedure

Sample preparations and potentiometric measurements were done under N_2. The measurements were carried out at 25.00 ± 0.05 °C in a room maintained at 23.2 ± 2 °C.

Sample solutions were prepared gravimetrically with either 0.01 or 0.1 g of fulvic acid per 100 g of solution, and with various KCl concentrations from 0 to 0.2 *m*. Some were prepared directly from solvent and fulvic acid powder. Dry fulvic acid powder rapidly takes up electrostatic charge and atmospheric moisture. To avoid consequent weighing errors in the samples used for measuring the milliequivalents of acidic groups per g of dry fulvic acid, they were prepared with particular care from gravimetric stock solutions.

Each sample solution and its acid range standards were thermostated overnight at 25.00 ± 0.05 °C. Voltage readings were first taken for the acid range standards, and then the titration was carried out. The base range standard H^+ measurements were finally done by titration of solvent. Each set of measurements always proceeded in the direction of decreasing H^+ concentrations. Stirring was required for proper electrode response and steady readings with H^+ concentrations less than 1×10^{-5} *m*, but had no effect above that. Gregor and Frederick for example (28) have also noted the importance of proper stirring procedures. Voltage readings were more difficult to obtain in the absence of background KCl.

When not in use the combination microelectrode was stored in saturated KCl solution, and during an experiment it was kept in dilute KCl between sets of readings. The electrode system including cables was found to be free from field effects. The p*H* meter was kept carefully grounded.

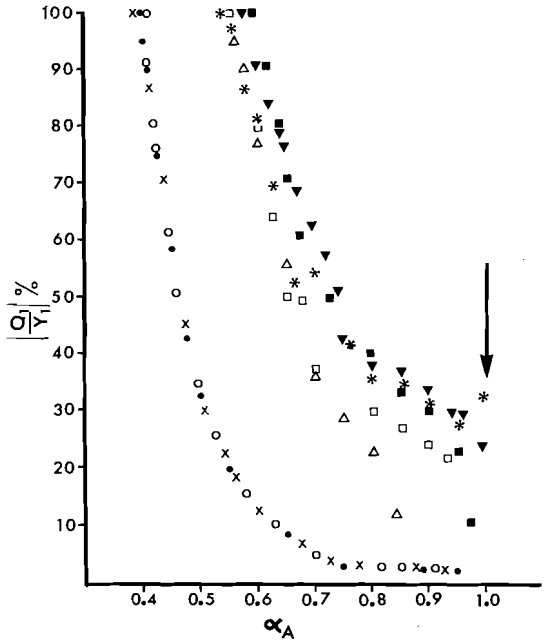

FIG. 1. First equivalence point in 0.1 *M* KCl. $|Q_1/Y_1|$, the relative size of the correction term, as a function of α_A. Each symbol represents a separate titration, and the arrow gives the equivalence point location. Upper set of curves, 0.01 g fulvic acid/100 g of solution. Lower set of curves, 0.1 g fulvic acid/100 g of solution.

Results

Both the natures of the correction terms and the effects of concentrations on them are observed in Figs. 1 and 2. The points to note are:

1. The relative size of Q_1, $|Q_1/Y_1|$, decreases as the equivalence point is approached. In contrast, $|Q_4/Y_4|$ increases as the equivalence point is approached.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

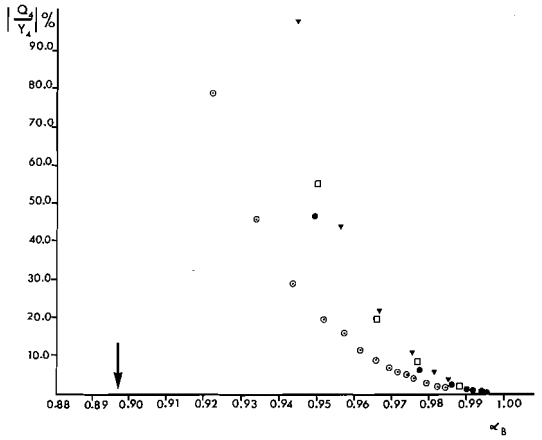

FIG. 2. Second equivalence point in 0.1 *m* KCl. Relative size of the correction term, as a function of α_B. Each symbol represents a different titration with (0.1 g fulvic acid/100 g of solution). The arrow shows the equivalence point location.

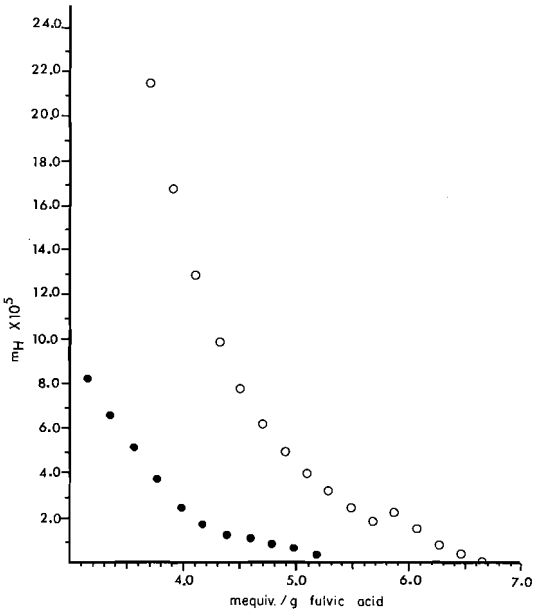

FIG. 3. Effect of KCl on fulvic acid titration at 25.0 °C. m_H as a function of the amount of standard base added. Typical examples with (0.1 g fulvic acid/100 g of solution): ○, 0.1 *m* KCl. ●, no KCl.

2. For titrations of 0.1 g of fulvic acid per 100 g of solution, $|Q_1 Y_1|$ falls sharply with little scatter in the data. The results for 0.01 g of fulvic acid per 100 g solution are somewhat less favorable to the iterative calculations.

3. Experimental error has a much more serious effect on $|Q_4/Y_4|$ than on $|Q_1/Y_1|$, even at the higher concentration of fulvic acid.

4. A curve not shown in Fig. 1 indicates that at 0.1 g fulvic acid per 100 g of solution, KCl has little effect if any on these curves. The V_{e1} calculation is consequently expected to converge well and give reproducible values, for the higher fulvic acid concentration. Poorer calculation results are expected for V_{e2}, and for V_{e1} with titrations of 0.01 g fulvic acid per 100 g of solution.

An approximately thousand-fold drop in H^+ molality occurs at the first equivalence point, when 0.1 g of fulvic acid in 100 g of sample solution is titrated. The anticipated release of H^+ by KCl added to the sample solution is so great that the location of this thousand-fold drop, and therefore the first equivalence point, is shifted to a higher titration value. The points at which typical curves drop off, and the effect of KCl are illustrated in Fig. 3.

As is illustrated in Fig. 3, KCl increases the angle of approach of the m_H curve to the $m_H = 0$ line. These curves reflect the shapes of the corresponding Gran's functions, especially near the equivalence point. Since the V_{e1} calculation consists of solving the simultaneous equations

$$Y_1 = Y_1(V)$$

$$Y_1 = 0$$

KCl is therefore expected to improve the performance of the Newton–Raphson calculation.

The data presented in Tables 1 and 2 verify these predictions about the effects of fulvic acid and KCl concentrations on the calculations.

Another conclusion drawn from Table 2 is

TABLE 1. Effect of sample solution composition on the iterative Gran's calculation

*Average of all 9 values for the second equivalence point is 7.71 ± 0.25.

that KCl had no effect on the second equivalence point that is observable outside the experimental errors.

$\bar{K}_A$ as a function of α_A is given in Table 3. The two 0.1 *m* KCl equations covering the ranges $0.38 \leqslant \alpha_A < 0.50$ and $0.50 \leqslant \alpha_A < 0.70$ were obtained directly by least squares fitting of the computer printout. The 0.1 *m* KCl result for the range $0.70 \leqslant \alpha_A \leqslant 0.90$ was produced by recalculating $\bar{K}_A$ with the average V_{e1} value of 6.54 (mequiv./g) from Table 2, and then averaging the computer output. For comparison, the 0.1 *m* KCl titration curves with 0.1 g fulvic acid/100 g of solution gave $\bar{K}_A = 0.15 \times 10^{-3}$ with $\sigma = \pm 0.03 \times 10^{-3}$ over this same α_A range. The two cases without KCl were obtained by recalculation with the V_{e1} average of 4.99 (mequiv./g) and least squares fitting. These $\bar{K}_A$ *vs.* α_A curves show a distinct and reproducible change of slope in the region $0.5 < \alpha_A < 0.6$.

The $\bar{K}_B$ calculations summarized in Table 4 show no dependance on α_B outisde the experimental errors. It should be noted that the 0.0 *m* KCl value belongs to acid functional groups including the 1.5 mequiv./g of functional groups strongly affected by KCl, while the 0.1 *m* KCl value does not (see Fig. 3 and Table 2). Considering the sizes of the experimental errors, these two $\bar{K}_B$ values cannot be assumed to be different.

K_A, calculated according to eq. 6 and plotted in Fig. 4, gives a useful picture of the acidic functional groups up to the first equivalence point. The 0.1 and 0 *m* KCl curves in Fig. 4 were calculated with data from six and five titration curves, respectively. In the former curve, the horizontal region above 5 mequiv./g is equal to $\bar{K}_A = (0.170 \pm 0.006) \times 10^{-3}$, since for the constant $\bar{K}_A$,

$$K_A = -\frac{d[(1-\alpha_A)\bar{K}_A]}{d\alpha_A} = \bar{K}_A$$

The very distinct break at 3 ± 0.1 mequiv./g corresponds to the above mentioned sudden

slope change of the $\bar{K}_A$ *vs.* α_A equations in Table 3. These first 3 mequiv./g of acidic functional groups are evidently the Type 1 carboxyl groups originally identified by Schnitzer and co-workers (11, 23–27). There are two other distinct types of functional groups, occupying the regions $3 \leqslant$ mequiv./g $\lesssim 5$ and $5 \leqslant$ mequiv./g $\lesssim 6.54$, respectively. Not only do they respond very differently to the presence of KCl, but also one is a constant at constant KCl concentration while the other is a decreasing function of α_A.

The degree of ionization of Type I carboxyl groups, α_1, has been calculated according to eqs. 10 and 13 for fulvic acid solutions both with and without KCl. These are given in Tables 5 and 6, together with corresponding α_A values for comparison.

Experimental Errors

As in the previous work (11), the most important source of experimental error was the potentiometric measurements. In addition to the experimental scatter expected from the earlier work, the H^+ molality *vs.* mls titrations were found to have biases of comparable sizes, as shown in Fig. 5. This curve shows the anticipated rapid rise near neutrality. Examination of sets of titrations, however, indicates that these biases occur randomly. Because K_A is calculated by differentiation, it is especially sensitive to errors in the shape of the titration curve. It is therefore necessary to average out the random errors of a number of titration curves, in order to obtain chemical information from K_A. The standard errors indicated in Fig. 4 for the K_A curves were conservatively estimated from the number of biased titration curves used for each, rather than from the total numbers of titration data points used.

$\bar{K}_B$ is necessarily measured in the high error

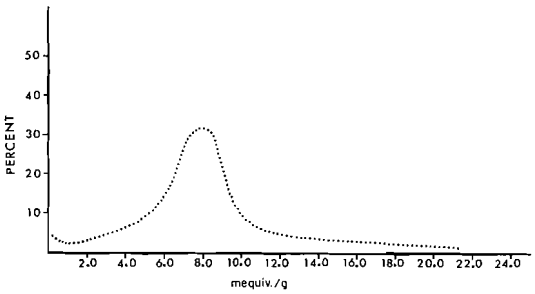

FIG. 5. Average H^+ molality error for titration curves at 25.0 °C, 0.1 *m* KCl, 0.1 g fulvic acid/100 g of solution.

region of Fig. 5. This requires that a large number of values be averaged, and limits the chemical conclusions that may be drawn about the acidic functional groups in this region. $\bar{K}_B$ values outside the approximate range 5.4 to 7.6 mequiv./g must be discarded because of the exaggeration of experimental errors at high and low α_B values.

Discussion

(a) Analytical Chemistry Aspects

Ratios such as $Z_1 = |Q_1/Y_1|$ and $Z_4 = |Q_4/Y_4|$ prove useful in various ways.

1. They measure the applicability and inherent limitations of corrected Gran's functions for particular equivalence points.

2. They facilitate judgements about the effects of experimental error on the equivalence point calculations.

3. Optimum experimental conditions for equivalence point determinations may be found using them.

4. These ratios are essential for establishing the ranges of Gran's function values for which the iterative calculation will converge.

Because Z_1, for example, is found to decrease as the equivalence point is approached, the First Corrected Gran's Function is an excellent technique for the first equivalence point. In contrast to this, the use of the Second and Third Corrected Gran's Functions was found from Fig. 5 and their correction terms to be unwise.

The first equivalence point could be estimated directly from the sudden drop in H^+ concentration in the region $6.5 <$ mequiv./g < 6.8. An important virtue of Gran's method, however, is that it employs data from a relatively extensive section of the titration curve rather than poorer quality data just at the equivalence point.

(b) Fulvic Acid Chemistry

The differences between the two curves of Fig. 4 are in the direction expected for the effect of salt, and above 3 mequiv./g are well outside the estimated standard errors. Below this point the difference is probably also real, but should be checked by further experiment. The existence of the 3 mequiv./g break in Fig. 4 is further verified by the shape of the $\bar{K}_A$ *vs.* α_A curves found in Table 3, since the decisive slope change of the $\bar{K}_A$ curves occurs in the neighborhood of this 3 mequiv./g break.

The acidic functional groups in the $3 \leqslant$ mequiv./g $\lesssim 5$ region of Fig. 4 are likely carboxyl groups. The relatively small effect of KCl on their acid strength suggests that some or all of them might represent monomeric acids. Schnitzer and co-workers (29, 30) have separated and identified a number of monomeric acids from fulvic acid, by methylating the sample. The amounts of these which they report indicate an upper limit of 0.07 mequiv./g for monomeric acids in fulvic acid. Monomeric acids therefore cannot account for any sizeable portion of the carboxyl groups in this region of Fig. 4. Because of the strong effect of KCl on their acid strength, the functional groups in the region $5 \lesssim$ mequiv./g $\leqslant 6.54$ of Fig. 4 must certainly represent polymeric functions of the fulvic acid. What is not clear, however, is whether all or only some of these acidic groups are carboxyl groups. The differences in chemical structure between these two types of functional groups beyond 3 mequiv./g are also unknown. The benzene carboxylic acids whose structures and acid constants were discussed by Maxwell and Partington (31) may serve as useful models, since some of them were among the monomeric acids isolated from fulvic acid by Schnitzer and co-workers.

The H^+ displacement effects of salt reported by Posner (3) for humic acids may be the same phenomena that are described here. In addition to the expected increase in acid strength, he found a slight increase in the "exchange capacities of the acid region", with increasing KCl concentration.

Posner (3) has also recognized that $\bar{K}$ is an average, by postulating a Gaussian distribution of acid strengths for humic acids. If this postulate is valid for fulvic acid, then it applies to $\mathscr{K}_A^0 = K_A^0 \gamma_H^0 \gamma_A^0 / \gamma_{AH}^0$ rather than to K_A, in eq. 5.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

A direct, rigorous test of Posner's postulate would require that the electrostatic and activity coefficient terms of eq. 5 be evaluated. This would need to be done separately for each of the three types of functional groups shown in Fig. 4.

Soil solutions and surface waters are typically found with pH values of 5 to 6. Tables 5 and 6 indicate that at such pH's the Type I carboxyl groups are essentially all ionized, and the Type A functional groups are more than 80% ionized. This must favor metal ion chelation under natural conditions. It also implies that fulvic acid and similar humic materials sorbed onto or into clay particles must exist as metal complexes or chelates. The chelation or complexing of divalent and trivalent metal ions may sorb fulvic acid onto undissolved humic materials, by bridging between polymer molecules. The carboxyl groups remaining free on such sorbed fulvic acid would then become ion exchange sites. In addition to these reactions, fulvic acid in a soil system might decompose clay crystals through a combination of acid attack and chelation of cations from the crystal lattice. The elucidation of such soil chemistry will require equilibrium measurements of the chelation and electrostatic binding of cations by fulvic acid. The degrees of ionization of acidic functional groups as a function of H^+ concentration or activity, as presented in Tables 5 and 6, are prerequisite to the calculation of such equilibria. The application of weighted average and differential functions comparable to the $\bar{K}_A$ and K_A already described (11, 20) will be useful and perhaps necessary for dealing with such fulvic acid problems in soils.

Mr. D. A. Hindle and Mr. H. T. Lie carried out the careful experimental work, including a large number of very exacting measurements.

The Infrared and Raman Spectra of Dimethyliodoarsine

H. F. SHURVELL, M. R. GOLD, AND A. R. NORRIS
Department of Chemistry, Queen's University, Kingston, Ontario

Received February 22, 1972

The infrared and laser–Raman spectra of liquid dimethyliodoarsine, $(CH_3)_2AsI$, have been recorded. Assignments of the observed frequencies have been made to the 24 normal modes of vibration of the molecule. A normal coordinate calculation has been carried out in support of the assignment.

Les spectres infrarouge et Raman laser de la diméthyliodoarsine liquide $(CH_3)_2$ AsI ont été enregistrés. Les attributions des fréquences observées ont été faites pour les 24 modes de vibration normaux de la molécule. Le calcul dans les coordonnées normales a été effectué pour appuyer cette assignation.

Introduction

The compound $(CH_3)_2AsI$ is an important reagent in the synthesis of a number of organo–arsenic compounds, including *cis*- and *trans*-1,2-bis(dimethylarsino)ethylene (**1** and **2**) and 1,2-bis(dimethylarsine)acetylene (**3**), which serve as very powerful ligands. As part of a general study of the complexes of **1**, **2**, and **3** with Pt(II), Pd(II), Au(III), and Au(I), we require detailed i.r. and Raman spectra of the ligands and in order to interpret the spectra of **1**, **2**, and **3**, it is essential to have the complete i.r. and Raman spectra of $(CH_3)_2AsI$, together with a reliable assignment of the fundamentals.

Some information is available in the literature on the vibrational spectra of organoarsenic halides. The methylhaloarsines were examined by Raman spectroscopy using mercury arc excitation (1). More recently, i.r. and Raman spectra and tentative assignments have been published for $(CH_3)_2AsCl$ and CH_3AsCl_2 (2). Infrared and Raman spectra of CH_3AsCl_2, $(CH_3)_2AsCl$ and $(CH_3)_2AsCl_3$ and some phenylarsenic halides have been reported (3), and very recently, spectra of CH_3AsCl_2, CH_3AsBr_2, CH_3AsI_2, and CD_3AsI_2 have been studied in another laboratory (4).

It appears that the only spectroscopic datum available for $(CH_3)_2AsI$ is the partial Raman spectrum published by Van der Kelen and Herman in 1956 (1). We have therefore recorded i.r. and laser Raman spectra for this molecule and attempted to make assignments of the observed frequencies to the 24 normal modes. Since 24 separate i.r. bands or Raman lines were not observed, it was decided to carry out a normal coordinate calculation to predict the frequencies of the fundamentals. For the skeletal vibrations of the C_2AsI group and the vibrations involving bending of the As—C—H angles, the calculation proved to be useful in deciding among possible assignments. A band contour resolution technique was applied to two of the bands as a further aid in assigning frequencies to the fundamentals.

Experimental

Dimethyliodoarsine was prepared by the method described by Burrows and Turner (5). The oily layer containing $(CH_3)_2AsI$ was dried over molecular sieves, then distilled under nitrogen at 1 atm pressure (b.p. 157 °C; lit. 154–157 °C (5)). The proton magnetic resonance spectrum of the sample in CCl_4 solution showed a single peak at 2.04 p.p.m. (TMS, internal standard). The mass spectrum of the compound was recorded on a JEOL model JMS 01SC mass spectrometer. The main peak at mass 232 and all other strong peaks due to fragmentation were consistent with the compound $(CH_3)_2AsI$.

Infrared survey spectra were recorded on a Beckman IR 10 spectrometer. High resolution spectra were recorded using Perkin–Elmer Ebert single beam and Perkin–Elmer model 180 instruments. The Raman spectrum was recorded on a Perkin–Elmer LR 1 laser Raman spectrometer, using He/Ne laser excitation. A 2.5 ml multiple reflection cell was used and the laser power at the sample was about 25 mW. The Raman instrument was calibrated using known frequencies of $CHCl_3$, benzene, etc., and neon emission lines. The Raman frequencies are only accurate to ± 5 cm^{-1}, whereas the infrared frequencies are believed to be correct to within ± 1 cm^{-1}. This may explain some apparent differences between our reported i.r. and Raman frequencies.

Normal Coordinate and Band Contour Calculations

A calculation of vibrational frequencies and force constants for the skeletal modes of $(CH_3)_2AsCl$ and $(CH_3)_2AsBr$ has been reported previously (6). Trimethylarsine has also been the subject of similar calculations (7, 8), so that initial values for the force constants of the C_2AsI skeleton are

available. Cossee and Schachtschneider (9) performed a vibrational analysis for acetone, from which force constants for the methyl groups can be taken. Force constant calculations for AsI_3 (10, 11) provided a starting value for the As—I stretching constant.

The Wilson **FG** matrix method (12) was used for the normal coordinate calculations which were carried out using a computer program originally written by Schachtschneider (13) and modified by Brooks (14) for the IBM 360/50 computer. It is assumed that the molecule has a plane of symmetry containing the As and I atoms. Bond lengths and angles used in the calculation were (15): As—C = 1.98 Å; As—I = 2.52 Å; C—H = 1.09 Å; ∠CAsC = 96°; ∠CAsI = 98°; ∠HCH and ∠AsCH = 109.5°. It is assumed that the methyl groups are tetrahedral. Internal coordinates were chosen as changes in bond lengths and angles and the two torsions about the As—C bonds. A detailed list of internal coordinates is given in Table A1 of the Appendix, which is available from the Depository of Unpublished Data.[1] A valence force field containing 8 diagonal and 22 interaction constants was used. Descriptions of these 30 force constants are given in Table A2 of the Appendix. A set of symmetry coordinates was chosen to factor the **F** and **G** matrices into A' and A'' blocks. Details of these symmetry coordinates are given in Table A3 of the Appendix.

[1]Complete set of tables in Appendix is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada, K1A 0S2.

All interactions were initially set equal to zero and the initial set of diagonal force constants was varied, with the addition of interactions, until a satisfactory fit was obtained between observed and calculated frequencies. Several assignments of the low frequency vibrations were tried. The results of these calculations will be introduced where pertinent in the discussion part of this paper.

For cases where overlapping infrared or Raman bands cannot be resolved, a method of band resolution by the computer has been devised by Jones and co-workers (16). The method involves digitizing the spectrum. This can be done mechanically, producing a punched paper tape, or manually from a band that has been spread out by an abscissa expansion device. Manual digitization may be accomplished fairly quickly with the aid of a computer program devised by Bulmer and Shurvell (17), which minimizes the actual labor involved. The digitized spectrum is fitted by a synthetic spectrum containing two or more bands calculated by the computer. A Gaussian–Lorentzian product function was used to study two bands in the present work and the results will be used later in the discussion.

Results and Discussion

The observed i.r. and Raman frequencies are listed in Table 1. The Raman spectrum is shown in Fig. 1 and an i.r. spectrum in Fig. 2. In Fig. 3 one of the far i.r. bands is shown under high resolution, together with the computed

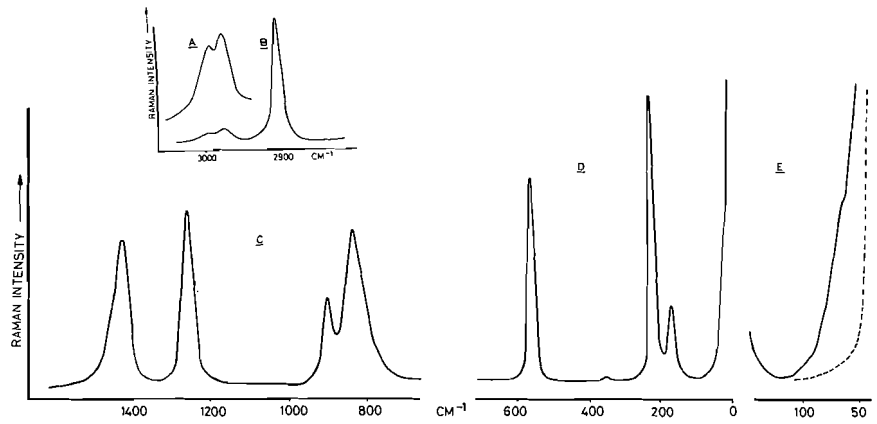

FIG. 1. The Raman spectrum of dimethyliodoarsine from a 2.5 ml multiple reflection cell. Spectral slit widths for spectra *A*, *B*, *C*, *D*, and *E* were: 12, 8, 5, 7, and 20 cm^{-1}, respectively. A higher amplifier gain was used for *A* than for *B*. High gain was also used for regions *C* and *E*. Medium and low gains were used for regions *B* and *D*, respectively. The dashed line in region *E* was obtained with pure CCl_4 in the cell under similar instrumental conditions.

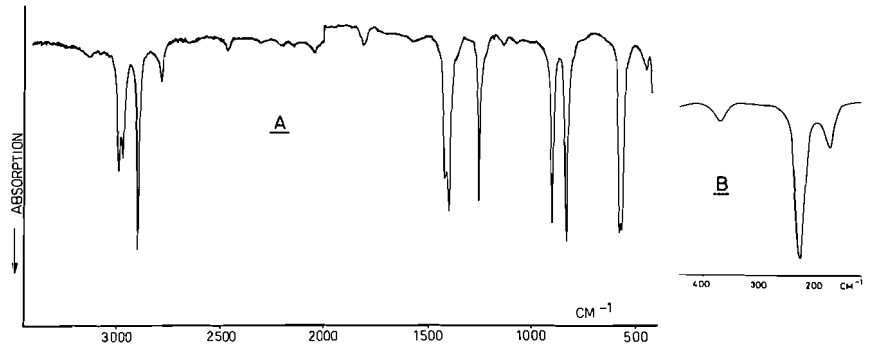

FIG. 2. The i.r. spectrum of dimethyliodoarsine. For region *A*, a liquid film between two KBr plates was used. For region *B*, a disposable polyethylene cell of path length 0.5 mm was used.

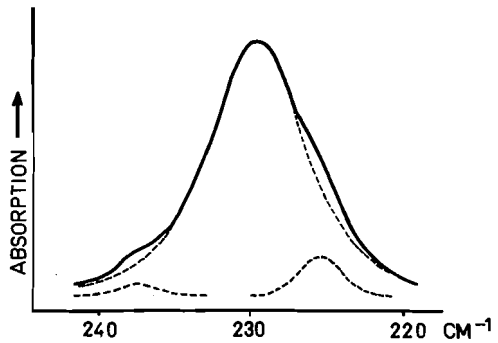

FIG. 3. The components of the 230 cm^{-1} infrared band of $(CH_3)_2AsI$ resolved by computer. The solid line is the observed band and the dotted curves are the computed components.

components from the band resolution program mentioned earlier.

Relatively simple i.r. and Raman spectra are expected for $(CH_3)_2AsI$. The spectra should consist basically of four main features due to methyl group stretching and bending modes plus the vibrations of the C_2AsI skeleton. All combinations and overtones are allowed, so that some additional weak bands are also expected. However, only a few overtones and combinations were observed and these have been included in Table 1.

Assignments

CH Stretching

A high resolution i.r. spectrum of the CH stretching region shows a doublet at 2998 and 2976 cm^{-1}. This is assigned to the in-phase (*A'*) and out-of-phase (A'') components of the antisymmetric CH_3 stretching mode. The assignment is confirmed by the Raman spectrum in which these lines are weak and depolar-

For personal use only.

ized. It is assumed that the local C_{3v} symmetry determines the depolarization, so that, while the in-phase combination is A' with respect to the C_s symmetry of the molecule, the actual vibrations are of E species with respect to the C_{3v} symmetry of the methyl groups and are therefore depolarized. The 2910 cm^{-1} band on the other hand is strong and polarized in the Raman spectrum, as expected for the symmetric CH_3 stretching mode.

CH_3 Deformation

Again, the antisymmetric mode is split into a doublet in the i.r. spectrum at 1415 and 1430 cm^{-1}. A line with a shoulder is observed in the Raman spectrum and this was depolarized, consistent with the assigment to the antisymmetric CH_3 deformation.

The symmetric CH_3 deformations were observed as a single peak in both i.r. and Raman. The Raman line was polarized, although not as strongly as the line due to the symmetric stretching vibration.

C—As Stretching

It is generally agreed that compounds containing C—As bonds give rise to i.r. absorption bands and Raman lines in the range 560–590 cm^{-1} (3, 4, 6, 7). In $(CH_3)_2AsI$, there should be two features attributable to C—As stretching. A very strong polarized Raman line at 564 cm^{-1} corresponds with the lower frequency component of a strong doublet in the i.r. at 567/576 cm^{-1}. These two frequencies are assigned to the symmetric and antisymmetric C—As stretching modes, respectively.

As-I Stretching

The very strong polarized Raman line at 228 cm^{-1} and the corresponding very strong i.r. band centered at 230 cm^{-1} are assigned to the As—I stretching mode in agreement with frequencies reported for CH_3AsI_2 (4) and AsI_3 (11).

As—C—H Deformations (CH_3 Rocking)

For the dimethylhaloarsines there should be four normal modes involving As—C—H deformations. Normal coordinate calculations indicate that all four vibrations have frequencies in the 900–800 cm^{-1} region. Frequencies near 830 cm^{-1} were reported for the three methyldihaloarsines, CH_3AsX_2 (X = Cl, Br, and I) (4). We assume that the 900 and 830 cm^{-1} bands in the i.r. and Raman spectra of dimethyliodoarsine are both due to two fundamentals and in fact resolution of the 830 cm^{-1} band was achieved using the contour resolution program.

CH_3 Torsions

Torsional vibrations of methyl groups have been observed over a wide range of frequencies (270 to 100 cm^{-1}) in a variety of compounds (18, 19). For the CH_3AsX_2 molecules (4) it was concluded that the torsions should lie in the range 185–135 cm^{-1}, but a definite assignment was only made in one case, namely 134 cm^{-1} for CH_3AsBr_2.

In the present work, the normal coordinate calculation predicts two almost degenerate frequencies for the torsions, but the calculated values can vary over a wide range depending on the choice of torsional force constant. For example, using a force constant of 0.05 mdyn Å/sq. radian, the calculated frequencies are 168 cm^{-1} for the A' mode and 170 cm^{-1} for the A'' vibration. These are close to observed i.r. and Raman frequencies, but alternative assignments are preferable and will be discussed below. Torsional force constants of 0.007 and 0.009 mdyn Å/sq. radian were used for acetone (9). A value near 0.01 mdyn Å/sq. radian would seem to be reasonable for $(CH_3)_2AsI$ and this leads to calculated frequencies of 70 and 71 cm^{-1}.

Methyl torsions are often very weak in both i.r. and Raman spectra and it is possible that in the present case they lie near 70 cm^{-1}, where a weak shoulder is observed in the Raman spectrum.

Other Skeletal Vibrations

Three skeletal vibrations remain to be assigned: the C—As—C deformation and two C—As—I deformation modes. In related molecules, C—As—C deformation modes were assigned to frequencies in the 240–220 cm^{-1} region (7, 8). The possibility of finding more than one component in the 230 cm^{-1} band previously assigned to the As—I stretch leads us to carry out a contour resolution calculation, with the result shown in Fig. 3. The observed band is composed of two weak absorptions at 225 and 237 cm^{-1}, in addition to the strong peak at 229.5 cm^{-1}. The 237 cm^{-1} band can be explained as a combination of the 177 cm^{-1} fundamental with the lowest frequency fundamental believed to be observed as a

shoulder on the Rayleigh line in the Raman spectrum. The 225 cm^{-1} feature could be assigned as the C—As—C deformation. In this case, the 177 cm^{-1} frequency would be assigned as the A'' C—As—C deformation, and the shoulder near 95 cm^{-1} in the Raman spectrum as the A' mode. This assignment follows that of Van der Kelen and Herman (1), but there is a serious objection to it, since a large difference in frequency (80 cm^{-1}) between A' and A'' C—As—I deformation modes is unlikely. It is possible of course that the 177 cm^{-1} frequency is due to both A' and A'' modes, but this is definitely not in agreement with the normal coordinate calculation.

We believe that the following assignment of the low frequency modes is the correct one. The 177 cm^{-1} frequency is the C—As—C bending mode and the shoulder near 95 cm^{-1} in the Raman spectrum is due to both C—As—I deformations. The 225 cm^{-1} component of the band centered at 230 cm^{-1} is most likely a hot band, $(\nu_{As-I} + \nu_i - \nu_i)$, where ν_i is one of the lowest frequency fundamentals. The normal coordinate calculation definitely supports this assignment, since in each of the A' and A'' blocks, a frequency is predicted near 100 cm^{-1}. The potential energy distribution indicates that these modes are between 80–90% CAsI deformations. Only for the A' block is there a calculated frequency near 177 cm^{-1}. The P.E.D. for this frequency indicates nearly 100% C—As—C deformation.

The calculated force constants seem to be very reasonable for this assignment and only a few small interactions are necessary to produce a satisfactory fit between observed and calculated frequencies. The results of the calculation including the major contributions to the P.E.D.'s are listed in Table 2. The P.E.D.'s are in complete agreement with the descriptions given in Table 1. The 1255 cm^{-1} frequency is correctly assigned to HCH bending, but because in this mode the AsCH angles bend simultaneously, the AsCH and HCH bending force constants contribute almost equally to the P.E.D. The CAsI bends are coupled to a small extent to the torsions and as discussed above, a change in the torsional force constant can change the assignment of the low frequency modes. However, it is felt that the present assignment is the correct one.

Conclusions

The i.r. and Raman spectra of dimethyliodoarsine have been interpreted in terms of methyl group vibrations and vibrations of the C_2AsI skeleton. Band contour resolution techniques and normal coordinate calculations have been useful in locating some of the fundamentals and making assignments.

The present assignment should prove to be useful in future studies on dimethylarsine-containing ligands and their complexes.

The authors are grateful to Dr. W. V. F. Brooks of the University of New Brunswick for the use of his programs for the normal coordinate calculations and to Dr. R. N. Jones of the National Research Council of Canada, Ottawa, for the band contour resolution programs. The financial assistance of the National Research Council of Canada is also gratefully acknowledged.

Comparison between Molecular Structure Effects in Triplet Positronium Annihilation Rates and Radiolysis Free Ion Yields in Liquid Hydrocarbons

G. R. FREEMAN AND J.-P. DODELET
Chemistry Department, University of Alberta, Edmonton, Alberta T6G 2G2

Received January 26, 1972

Two seemingly unrelated phenomena in liquid hydrocarbons have similar trends in their dependences upon the molecular structure of the hydrocarbon. The phenomena are the annihilation half-life of triplet positronium and the radiolysis free ion yield. In *n*-alkanes the effect of increasing the molecular chain length, upon both phenomena, appears to be simply to increase the density of interacting sites. Branching the alkane chain decreases the strength of molecular interaction with both electrons and positronium, although the relative decrease is much greater for the former than for the latter. The effects of double bonds on the phenomena, after separating out the density effect, are different from each other.

Le rendement en ions libres obtenus dans les hydrocarbures liquides sous radiolyse gamma et le temps de demi vie, lors de l'annihilation du positronium à l'état triplet dans ces liquides, sont deux phénomènes en apparence indépendants. Toutefois il semble que leur dépendance vis-à-vis de la structure moléculaire des hydrocarbures soit semblable: dans les alcanes normaux l'alongement de la chaîne carbonée agirait en changeant la densité des sites d'interaction; les alcanes à chaîne ramifiée seraient responsables d'une diminution de l'interaction de la molécule avec l'électron ou le positronium. Cet effet est cependant beaucoup plus marqué pour les électrons. D'autre part, après avoir tenu compte de l'effet dû à la densité, il semble que les deux phénomènes soient différents pour les molécules contenant des double liaisons.

Canadian Journal of Chemistry, **50**, 2697 (1972)

The annihilation half-life τ_2 of triplet positronium in a liquid hydrocarbon is influenced by the molecular structure of the hydrocarbon (1, 2). The yield of free ions generated during the radiolysis of a liquid hydrocarbon is also affected by molecular structure (3–6). The trends in the two phenomena are similar and it is informative to compare them.

Values of τ_2 and G_{fi} (number of pairs of free ions formed per 100 eV of energy absorbed) for a number of liquids are listed in Table 1. Both τ_2 and G_{fi} decrease with increasing chain length in the *n*-alkanes.

The effect of chain length on G_{fi} in the *n*-alkanes is due simply to the change in liquid density (5). The free ion yield is related exponentially to the penetration range b of the secondary electrons in the liquid (7, 8).

$$[1] \qquad G_{fi} \propto \exp(-1/b)$$

The value of b decreases with increasing density d of the liquid (9). The product bd has a constant value for all *n*-alkanes from *n*-butane to *n*-tetradecane (5); examples are given in Table 1. This means that the density-normalized rate of energy loss of the electrons, which is proportional to $(bd)^{-1}$, is constant. The electron–molecule energy transfer interactions are short range (6), so changing the *n*-alkane chain length from C_4 to C_{14} does not increase the strength of the interactions but merely decreases the electron mean free path by increasing the density of scattering centers.

The product of τ_2 and the liquid density is also constant for the *n*-alkanes (Table 1); $\tau_2 d$ is inversely proportional to the density-normalized rate of annihilation. The annihilation rate has been empirically related to the molar polarization of the liquids (1), but the correlation is not exact and is not fundamentally understood (2). In *n*-alkanes the effect of chain length is probably simply to increase the density of interacting sites.

Branching the alkane chain increases both bd and $\tau_2 d$, but the effect is greater on the former than on the latter (Table 1). The polarizability of neopentane is nearly isotropic, which greatly reduces the inelastic scattering

*At 299 K, ref. 1.
†At 296 K, ref. 5: b is the most probable penetration range of the secondary electrons and d is the liquid density.
‡At 294 K, ref. 6.

cross section of the molecules for epithermal electrons (6). Anisotropy of polarizability appears to be less important in the positronium annihilation process. Although the structure effect on τ_2 is small, it is believed to be real (1, 2). The smaller effect on τ_2 might be related to the fact that positronium is neutral, whereas the electron is not.

The value of bd in a straight chain olefin is smaller than that in an n-alkane, whereas the value of $\tau_2 d$ is the same in the two types of liquid (Table 1). In benzene bd is smaller than in n-hexane, whereas the $\tau_2 d$ is larger in benzene than in hexane. The double bond effects are different in the two processes.

The structure effects on bd were greatest in the series of simple molecules CH_4, C_2H_6, and C_2H_4, with $bd = 210$, 81, and 54×10^{-8} g/cm^2, respectively (10). It would be useful to determine $\tau_2 d$ in these liquids to confirm the partial annihilation rates that have been assigned to bonds (1, 2). The partial rate assigned to a given type of bond depends on the position of the bond in the molecule (1, 2), which makes it doubtful that the effect can accurately be attributed to individual bonds.

We are grateful to the National Research Council of Canada for financial assistance.

Optical and Thermal Bleaching of Trapped Electrons in Aliphatic Amine Glasses

SHOJI NODA, KENJI FUEKI, AND ZEN-ICHIRO KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan

Received April 4, 1972

An optical bleaching study has been made of trapped electrons in γ-irradiated aliphatic amines at -196 °C. The results indicate that the optical absorption of the trapped electrons in the amines is attributed to optical transitions to both bound excited states and a continuum state. The thermal decay of the trapped electrons has been studied by the e.s.r. technique at temperatures above -196 °C. It has been found that the line width of the e.s.r. spectra of the trapped electrons in some of the amines changes on warming.

Nous avons effectué une étude thermique de décoloration d'électrons piégés dans des amines irradiées par des rayons-γ à -196 °C. Les résultats indiquent que l'absorption optique des électrons jugés dans les amines est attribuable à des transitions optiques entre les deux niveaux liants excités et un niveau continu. Nous avons aussi étudié par r.p.c. la désintégration thermique à des températures au-dessus de -196 °C. Nous trouvons que la largeur des raies du spectre r.p.c. des électrons piégés dans quelques amines change au cours du chauffage.

Canadian Journal of Chemistry, **50**, 2699 (1972)

Introduction

In the previous communication (1) we have reported optical and e.s.r. observations on trapped electrons produced in γ-irradiated aliphatic amine glasses at -196 °C, giving the optical and e.s.r. parameters as well as yields of the trapped electrons.

In this work, we have made an optical bleaching study of the trapped electrons in aliphatic amine glasses at -196 °C to get a better understanding of the nature of the excited states to which optical transitions occur. Using the e.s.r. technique we have also made a thermal bleaching study of the trapped electrons at temperatures above -196 °C to demonstrate the temperature at which the trapped electrons decay rapidly in these matrices and to obtain some information about the effect of matrix relaxation on the e.s.r. spectra of the trapped electrons.

Experimental

Aliphatic amines (*s*-butylamine, diisopropylamine, triethylamine, 2-methyl-*n*-amylamine, *N*-methyl-*n*-butylamine, and 3-methylpiperidine) were purified by refluxing over potassium hydroxide pellets followed by repeated middle-cut distillation under nitrogen atmosphere. The middle portion from distillation was treated with sodium blocks and distilled under vacuum on a freshly prepared sodium mirror. The purified amines were transferred to e.s.r. tubes or optical absorption cells and were sealed under vacuum.

Samples were irradiated by ^{60}Co γ-rays at -196 °C in the dark. The dose rate was 1.2×10^{18} eV min^{-1} g^{-1} and the total dose was 3.6×10^{19} eV g^{-1}. Optical bleaching experiments were performed with a monochromatic light which was obtained from a 45-W tungsten (quartz–iodine) lamp combined with a high intensity Shimazu–Bausch and Lomb monochromator. The full width at half height of the light band emitted from the monochromator was 38 nm when entrance and exit widths of the monochromator were 3.0 and 1.5 mm, respectively.

E.s.r. measurements were carried out with a conventional X-band spectrometer using 100 kc.p.s. magnetic field modulation. Optical absorption spectra were taken on a Hitachi EPU-2A spectrophotometer. Both the e.s.r. and optical absorption measurements were carried out at -196 °C. A variable-temperature e.s.r. Dewar was employed for annealing the samples at temperatures above -196 °C. Any desired temperature was obtained by controlling the flow rate of cold nitrogen gas and the temperature of the samples was measured with a copper–constantan thermocouple.

Results and Discussion

Optical Bleaching

Relative quantum efficiencies for photobleaching were obtained for trapped electrons produced in γ-irradiated *s*-butylamine, diisopropylamine, and triethylamine at -196 °C, which are the primary, the secondary, and the tertiary amine, respectively. In Figs. 1–3 are shown the initial relative quantum efficiencies for photobleaching *vs.* the energy of photon used for the photobleaching together with their optical absorption spectra. It can be seen in Figs. 1–3 that the threshold energies for photobleaching are around the energies at which the optical absorption maxima are located, *i.e.*, 1.1 eV (1170 nm) for the *s*-butylamine, 0.87 eV

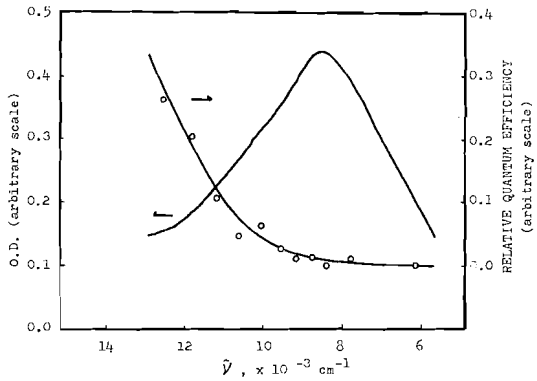

FIG. 1. Relative quantum efficiency for photobleaching of the trapped electrons in *s*-butylamine at −196 °C versus the wavenumber of the bleaching light. The optical absorption spectrum of the trapped electrons is shown on the same wavenumber scale.

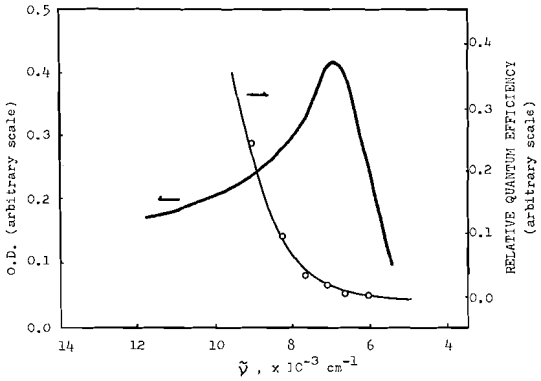

FIG. 2. Relative quantum efficiency for photobleaching of the trapped electrons in diisopropylamine at −196 °C *vs.* the wavenumber of the bleaching light. The optical absorption spectrum of the trapped electrons is shown on the same wavenumber scale.

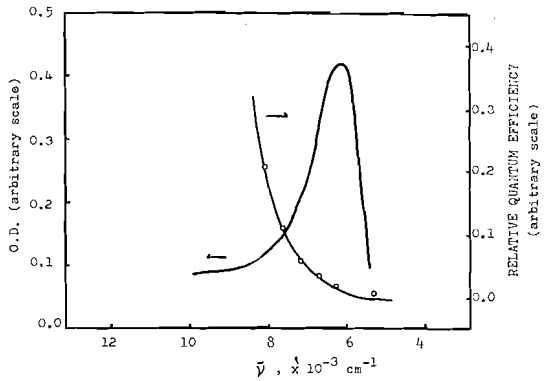

FIG. 3. Relative quantum efficiency for photobleaching of the trapped electrons in triethylamine at −196 °C *vs.* the wavenumber of the bleaching light. The optical absorption spectrum of the trapped electrons is shown on the same wavenumber scale.

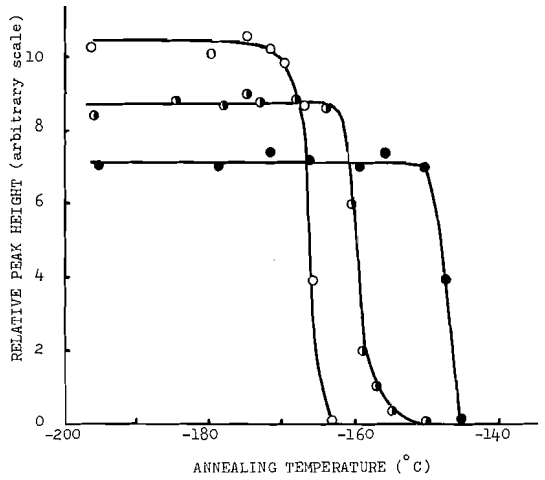

FIG. 4. The effect of thermal annealing at temperatures above −196 °C on the concentration of the trapped electrons in aliphatic amines: ○, *s*-butylamine; ◑, diisopropylamine; ●, 2-methyl-*n*-amylamine.

(1430 nm) for the diisopropylamine, and 0.75 eV (1650 nm) for the triethylamine.

These results indicate that the optical absorption of the trapped electrons in aliphatic amine glasses corresponds to optical transitions to both bound excited states and a continuum state, and the probabilities of these transitions depend on the photon energy. Similar observations on photobleaching behavior were previously reported on trapped electrons in glassy methyltetrahydrofuran (2, 3) and alcohols (4, 5), and in the single crystal of ice doped with impurities (6) at −196 °C. It is noted here that alkaline ice (7, 8) is one exception, where no bound excited state exists for trapped electrons in this matrix.

Thermal Bleaching

Thermal decay experiments were carried out to demonstrate the temperature at which the trapped electrons disappeared rapidly. Small temperature increments were used and in each run the sample was kept for about 5 min at each temperature.

Figure 4 shows plots of the intensity of the singlet e.s.r. spectra of the trapped electrons against the temperature for γ-irradiated *s*-butylamine, diisopropylamine, and 2-methyl-*n*-amylamine. As can be seen in Fig. 4, the trapped electrons decayed rapidly in a temperature region of −170 to −163 °C for the *s*-butyla-

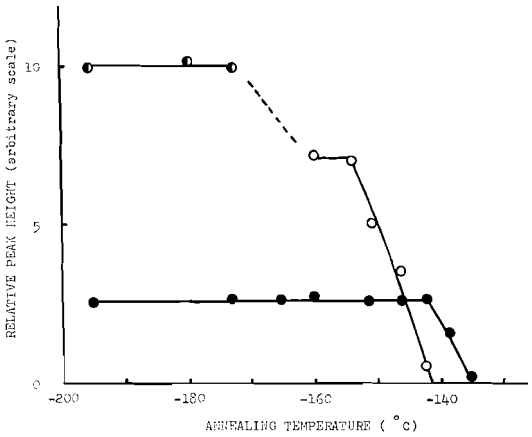

FIG. 5. The effect of thermal annealing at temperatures above −196 °C on the concentrations of the trapped electrons and radicals in *N*-methyl-*n*-butylamine: ◐, trapped electrons; ○, trapped electrons in the sample annealed at −161 °C for 2 h after γ-irradiation at −196 °C; ●, trapped radicals responsible for the underlying spectrum.

mine, −164 to −155 °C for the diisopropylamine, and −153 to −148 °C for the 2-methyl-*n*-amylamine.

A thermal annealing profile for trapped electrons in *N*-methyl-*n*-butylamine is displayed in Fig. 5. It is noted that when the temperature of the sample was kept at −161 °C for 2 h after γ-irradiation at −196 °C, the line width between derivative maxima, ΔH_{ms}, increased from 12 to 17 G accompanied by a decrease in the peak height. Both ΔH_{ms} and the peak height remained constant from −161 to −154 °C. A broad underlying e.s.r. spectrum decayed at a temperature higher than the temperature at which the trapped electron spectrum decayed. Since our primary interest was in the trapped electron, we did not try to identify the trapped radicals responsible for the underlying spectrum. An e.s.r. study of the trapped radicals in γ-irradiated aliphatic amines at −196 °C was recently made by Wardman and Smith (9). In the e.s.r. spectrum of trapped electrons in 3-methylpiperidine an increase in ΔH_{ms} from 14 to 17 G was observed when the sample was annealed in a temperature region of −173 to −148 °C.

Such a change in the e.s.r. spectra of the trapped electrons at an annealing temperature higher than −196 °C may be attributed to relaxation of electron trapping sites which is presumably due to re-orientation of the solvent dipoles around the trapped electrons. Similar phenomena were previously observed for trapped electrons in glassy ethanol and methyltetrahydrofuran upon warming from 4 to 77 °K after γ-irradiation at 4 °K (10, 11). Optical studies of trapped electrons in alcohol glasses also revealed the effect of such matrix relaxation on the optical absorption spectra of the trapped electrons (12–14).

Reactivity of Organic Halides toward the Mobile Electron in Methyltetrahydrofuran Glass

NORIYUKI KATO, KENJI FUEKI, AND ZEN-ICHIRO KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan

Received March 28, 1972

The relative reactivity of a number of organic halides with the mobile electron produced in γ-irradiated methyltetrahydrofuran glass at 77 °K has been studied by a scavenger competition kinetics. It has been found that for the organic halides there exists a correlation between the relative electron capture cross section in the glassy matrix and the heat of reaction for dissociative electron capture estimated from gas phase data.

Nous avons étudié la réactivité relative de certains halogénures organiques vis-à-vis l'électron mobile produit en irradiant par des rayons-γ le méthyltétrahydrofuranne vitreux à 77 °K, au moyen d'une cinétique de compétition de piège. Nous avons trouvé qu'il existe, pour les halogénures organiques, une corrélation entre la surface relative de capture d'électron dans la matrice vitreuse et la chaleur de réaction dans le cas de la capture dissociative d'électron, estimée à partir des résultats en phase gazeuse.

The effect of a number of different electron scavengers have been studied on both the optical and e.s.r. absorption of trapped electrons in polar glasses, such as alkaline ice (1–3), alcohols (4–12), water–alcohol mixtures (13–15), and methyltetrahydrofuran (16–25). One objective of scavenger studies has been to produce new anions from the reaction of the mobile electron with the scavenger molecule. The second objective has been to study the relative reactivity of the radiation produced mobile electron with various scavenger solutes.

In this note we report the relative cross sections of various organic halides for capturing mobile electrons (e_m^-) produced in γ-irradiated methyltetrahydrofuran (MTHF) glass at 77 °K. We also show that for the organic halides there exists a correlation between the electron capture cross section in the glassy matrix and the heat of reaction for dissociative electron capture estimated from gas phase data.

MTHF was purified by passage through a column of activated alumina, and was degassed by the freeze–pump–thaw technique and dried over calcium hydride under vacuum. MTHF was further dried with a sodium mirror prior to use. Biphenyl was purified by recrystallization from *n*-hexane. Organic halides as solutes were the purest grade commercially available. They were alkyl iodides (CH_3I, C_2H_5I, *n*-C_3H_7I, *i*-C_3H_7I, *n*-C_4H_9I), alkyl bromides (C_2H_5Br, *i*-C_3H_7Br, *n*-C_4H_9Br, *t*-C_4H_9Br), alkyl chlorides (*n*-C_3H_7Cl, *i*-C_3H_7Cl, *n*-C_4H_9Cl, *i*-C_4H_9Cl, *t*-C_4H_9Cl), and benzyl bromide and chloride.

γ-Irradiations of samples containing 0.13 mol% biphenyl and the halides at various concentrations were carried out at 77 °K in the dark to a dose of 1.04×10^4 rad. The optical absorption band of biphenyl anion with a peak at 408 nm was measured on the γ-irradiated samples at 77 °K in the dark.

The efficiencies of electron capture by the halides were determined by making use of competitive reactions between biphenyl (ϕ_2) as the reference substance and the halides (RX) as second solutes (reactions 1 and 2).

$$[1] \qquad \phi_2 + e_m^- \rightarrow \phi_2^-$$

$$[2] \qquad RX + e_m^- \rightarrow R + X^-$$

A simple competition kinetics based on reactions 1 and 2 leads to eq. 3 (16):

$$[3] \qquad \frac{1}{G_{\phi_2^-}} = \frac{1}{G^0_{\phi_2^-}} + \frac{1}{G^0_{\phi_2^-}} \frac{\sigma_{RX}[RX]}{\sigma_{\phi_2}[\phi_2]}$$

where $G_{\phi_2^-}$ and $G^0_{\phi_2^-}$ are the G-values of biphenyl anion in the presence and absence of a halide, [RX] and $[\phi_2]$ are the concentrations of the halide and the biphenyl, respectively, and σ_{RX} and σ_{ϕ_2} are the cross sections for electron capture by the halide and the biphenyl respectively. Equation 3 indicates that $1/G_{\phi_2^-}$ be linear to [RX]. It was found that several data points for each halide fit a straight line as expected from eq. 3. Figure 1 illustrates such plots for the iodides. The relative electron capture cross section, σ_{RX}, was determined from the slope of the straight line, and $G^0_{\phi_2^-}$ was obtained from

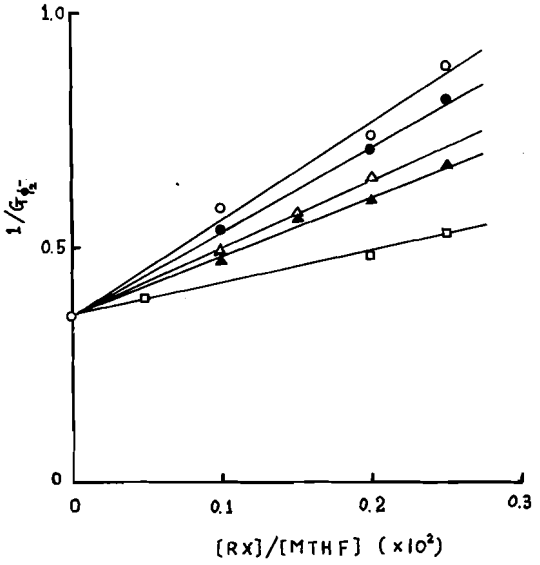

FIG. 1. Plot of $1/G_{\phi_2^-}$ *vs.* [RX]/[MTHF]: ○, *i*-C_3H_7I; ●, *n*-C_4H_9I; △, C_2H_5I; ▲, *n*-C_3H_7I; □, CH_3I. Concentration of biphenyl = 0.13 mol %.

the intercept on the ordinate by extrapolating the straight line to [RX] = 0. $G^0_{\phi_2^-}$ was 2.8 assuming that the extinction coefficient of biphenyl anion at 408 nm is 3.7×10^4 mol^{-1} cm^{-1} (17). It should be noted here that the relative electron capture cross sections of the halides are independent of the absolute *G*-value of biphenyl anion.

The values of σ_{RX} are listed in Table 1, where σ_{RX} of benzyl bromide is taken to be 1.0. In Table 1, the heats of reaction, ΔH, for dissociative electron capture by the halides in the gas phase are also given, and the rate constants for reaction of the halides with the hydrated electron (e^-_{aq}) are shown for comparison.

It can be seen in Table 1 that σ_{RX} is in decreasing order for the iodide, the bromide, and the chloride when the same type of RX is compared. A similar trend is seen for the hydrated electron rate constants, although the difference in rate constant between the iodide and the bromide is rather small and the rate constants for the chlorides are much smaller than those of the iodides and the bromides. However, within each series of the iodides, the bromides, and the chlorides, the individual values of σ_{RX} do not correspond to those of $k(e^-_{aq} + RX)$. It appears that the smaller halides have the higher rate constants for reaction with the hydrated electron. For the reaction of the halides with mobile electrons in MTHF glass, there exists a

Hypersonic Velocities in Molten Salts by Brillouin Spectroscopy

V. C. REINSBOROUGH[1] AND J. P. VALLEAU
Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario

Received April 17, 1972

Hypersonic velocities in three molten nitrates have been obtained by Brillouin spectroscopy. Velocity dispersions in molten $AgNO_3$ and $Ca(NO_3)_2 \cdot 4H_2O$ suggest that these two melts are more complex structurally than molten $NaNO_3$.

Les vitesses supersoniques dans trois nitrates fondus ont été obtenues par la spectroscopie Brillouin. Les vitesses de dispersion dans $AgNO_3$ fondu et $Ca(NO_3)_2 \cdot 4H_2O$ laissent penser que ces deux masses fondues sont plus complexes dans leurs structures que $NaNO_3$ fondu.

Canadian Journal of Chemistry, **50**, 2704 (1972)

Introduction

Frequency dispersion in sound velocity occurs in liquids when structural relaxations or other rapid processes are encountered in the frequency range under investigation. This note reports on velocity dispersion in three molten nitrates as revealed by the hypersonic velocities in these melts measured through Brillouin spectroscopy. This technique has not, as far as is known, been applied previously to molten salts.

The three melts were chosen because they are generally assumed to exhibit a wide range of structural complexity and yet do not show velocity dispersion in the ultrasonic range. Sodium nitrate is a simple ionic liquid. Physicochemical measurements in molten silver nitrate differ in many respects from such simple melts. This has been explained in terms of covalent bonding in molten silver nitrate (1–3). Molten calcium nitrate tetrahydrate is a viscous glass-former that is more complex than both of the two anhydrous nitrates.

Experimental

The Brillouin spectrometer was modelled on that of Chiao and Stoicheff (4) with modifications to be described elsewhere.[2] In short, the spectra were detected photo-

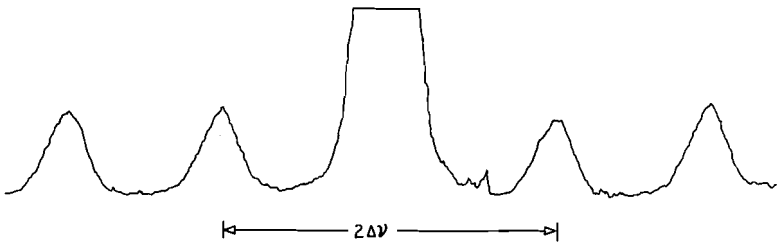

FIG. 1. Brillouin spectrum for molten $AgNO_3$ at 260° showing the truncated Rayleigh peak with its two Brillouin peaks separated by a distance $2\Delta\nu$. The Brillouin peaks of the preceding and following interferometric orders are included as well.

electrically with a high resolution Fabray–Perot interferometer that pressure-scanned light scattered from the 6328 Å laser beam as it was transmitted through the molten salt.

A thermally insulated optical cell contained the molten salt at the high temperatures employed. It consisted of a vertically mounted Pyrex cylinder 22 mm in diameter with two diametrically opposed side-arms, one serving as the light inlet and the other as a back-reflection trap (Wood's horn). Four heater coils encircled the horizontal and vertical sections of the cell. Scattered light in the range 45° to 135° could be observed by means of a horizontal viewing slit in the furnace. Temperature was noted to the nearest degree by an iron–constantan thermocouple situated in the melt, just above the slit.

Analytical grade reagents were used without purification. Considerable care was taken in filtering the melts prior to use, to minimize "dust" scattering. Calcium nitrate tetrahydrate was melted slowly in a sealed Seitz filtration vessel and then filtered by positive pressure through a 0.1 μ asbestos filter. Molten $AgNO_3$ and $NaNO_3$ were filtered by vacuum at 50° above their melting points through an ultrafine fritted disc (porosity 1 μ).

Results

The scattering consists of a triplet of a central line at the same frequency as the incident light (the Rayleigh peak) and two symmetrically located lines of changed frequency (the Brillouin peaks). Figure 1 depicts the Rayleigh and Brillouin spectra for molten $AgNO_3$ at 260°. The frequency separation of the Brillouin lines from the Rayleigh component is

$$\Delta\nu = \pm 2\nu_0\eta(V/c)\sin(\theta/2)$$

where ν_0 is the frequency of the incident light travelling at velocity c, θ is the scattering angle, and V is the hypersonic velocity in the medium of refractive index η. Precise measurements of V are made simply by measuring $\Delta\nu$ from spectra such as Fig. 1.

The scattering angle was chosen so that the Brillouin lines were midway between the Rayleigh line and the Brillouin line of the next interferometric order. This minimizes the "shrinkage effect" caused by the pulling of the spectral components towards one another (5).

Table 1 lists the hypersonic velocities and the frequency at which they were determined for molten $NaNO_3$ (395–400°), $AgNO_3$ (240–325°), and $Ca(NO_3)_2.4H_2O$ (25–80°). Literature values of the ultrasonic velocity are included for comparison. The refractive indices required in the calculations were taken from Rao and Angell,[3] Bloom and Rhodes (6) and Janz (7). The scattering angles were 60° for the molten hydrate and 75° for the anhydrous melts. Each

velocity in Table 1 was obtained by averaging the Brillouin shifts of at least five interferometric orders. The random error was $\pm 0.5\%$ with the absolute error estimated at $\pm 1\%$ in the hypersonic velocities for the first two melts. With molten $NaNO_3$, the error was more likely $\pm 2\%$ because of the higher temperature and the more pronounced "dust" scattering. Exact centering of the cell was crucial for a 1% difference in the velocity was registered when the sample vessel was shifted a few mm off-center.

Discussion

The velocity in both the ultrasonic and hypersonic regions was the same within experimental error for molten sodium nitrate. On the other hand, for molten silver nitrate melts the hypersonic velocities were consistently 10% greater than the ultrasonic velocities from the literature. This means that a relaxation process occurs in the range 100 MHz to 5 GHz for molten silver nitrate. This difference in behavior presumably results from the occurrence of covalent bonding in the silver nitrate case. This relaxation could result from the formation of complexes, for example; or could, on the other hand, be structural relaxation due to the formation of covalent networks in the melt. The present results do not allow one to specify the details of the mechanism.

The velocity dispersion was much more temperature dependent in molten $Ca(NO_3)_2 \cdot 4H_2O$ (m.p. 42°). At 29°, the dispersion was 30% while at 70° it was only 5%. These large dispersions with large negative temperature variations are of the type observed in other highly viscous liquids such as glycerol (5). From their work with molten $Ca(NO_3)_2 \cdot 3.2H_2O$, Darbari and co-workers (11) have predicted a viscoelastic relaxation for the molten tetrahydrate in the several hundred MHz region for low temperatures where the high viscosity causes an increase in the relaxation time. Presumably, the marked velocity dispersion in the GHz region at low temperatures reflects this relaxation.

Mass Spectra of β-Keto Esters

LARRY WEILER
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received April 6, 1972

The mass spectra of several γ-substituted β-keto esters have been recorded and interpreted. The fragmentation patterns are compared to those of α-substituted β-keto esters and are found to be very useful in differentiating the α- and γ-substituted isomers. The mass spectral fragmentation schemes are dominated by cleavages α to the carbonyl groups and by McLafferty rearrangements.

Les spectres de masse de plusieurs β-cétoesters γ-substitués ont été enregistrés et interprétés. La comparaison des spectres de fragmentation avec ceux des β-cétoesters α-substitués a été très utile pour différencier les isomères α et γ. Les schémas de fragmentation sont dominés par les clivages en α des groupes carbonyles et par les réarrangements de McLafferty.

Recently we developed a useful synthetic route to a variety of γ-substituted β-keto esters (**1**). In the course of this study it was imperative to demonstrate that we had obtained the γ-substituted isomer (**1**) and not the α-substituted isomer (**2**). We have found that mass spectrometry can be very useful in distinguishing the two isomers. A comparison of the mass spectra of **1** (R = R′ = Me) and **2** (R = R′ = Me) reveals that there are gross differences in the two spectra which should aid the structural assignments. Bowie *et al.* (2) measured the mass spectra of a small number of α-substituted β-keto esters **2** (R = alkyl, R′ = Et). They found that the major fragmentation pathways follow two different McLafferty rearrangements and simple α-cleavage to give a base peak at *m/e* 43 (CH_3CO). Later Reed and Takhistov extended this study to a larger number of esters **2** (R = alkyl, R′ = Et, Me) (3). These later workers arrived at essentially the same fragmentation pathway.

The mass spectra of several γ-substituted β-keto esters (**1**) which we have prepared are given in Table 1. Schemes 1 and 2 account for

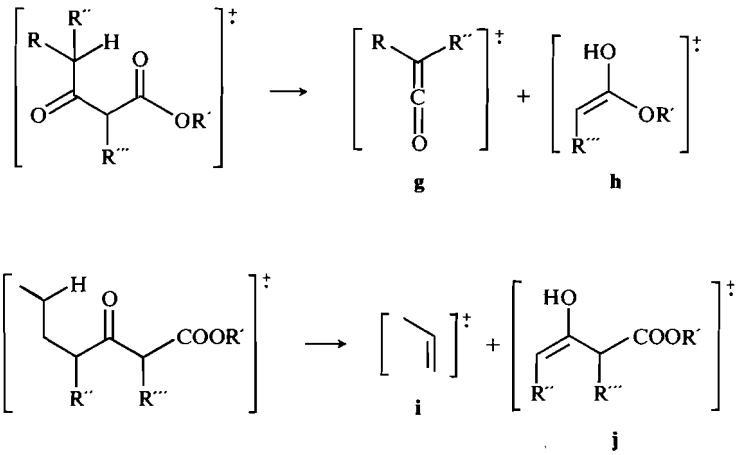
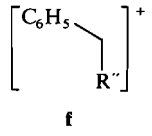


SCHEME 2. McLafferty rearrangements of β-keto esters.

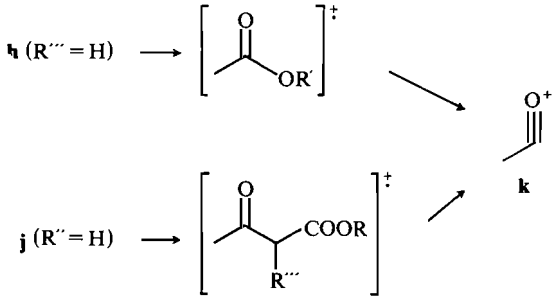
most of the significant ions observed. There is α-cleavage to the keto group to give ion **a** which is always significant and ion **b** (R‴ = H, R′ = Me; *m/e* = 101) which is a major ion in the case of the methyl esters. Ion **c** also is a significant fragment in each spectra, but ion **d** is not usually significant. The compounds which do not contain a phenyl group have peaks at *m/e* = M − OR′ and, in addition, the methyl esters which lack a phenyl group have significant peaks at *m/e* 59. This corresponds to ion **e**. The dominant peaks in the spectra of the compounds containing the phenyl group are ions with this moiety, for example, ion **f** (R″ = H, Me, *n*-Bu). The alkyl and allyl compounds also have relatively abundant ions arising from either of the McLafferty cleavages shown in Scheme 2. Ions **g**–**j** usually appear in the mass spectra of the



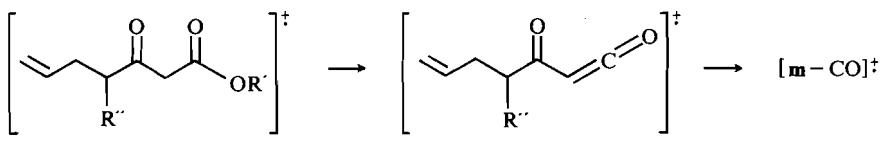
f

compounds which do not contain a phenyl group. Most of the remaining peaks in the spectra of these compounds arise from fragmentations of ions **a**–**j**. For example, the large peak at *m/e* 43 is due to ion **k**.

A few of the molecular ions lose water to give weak (M − 18) peaks and fragment ions from this. Not surprisingly we could not correlate the intensity of the (M − 18) peak with the enol content of the neutral molecule in solution from



n.m.r. data. Only the esters with an allyl group had peaks due to ion **m** (M − R′OH) and in each case ion **m** readily lost CO. Although we have written **m** as an open-chain ion it may in fact be cyclic. This might explain why only the allyl derivatives have this mode of fragmentation. It is also noteworthy that the α-substituted allyl derivative **2** (R = allyl, R′ = Et) did not readily lose EtOH and then CO (3). In most



m

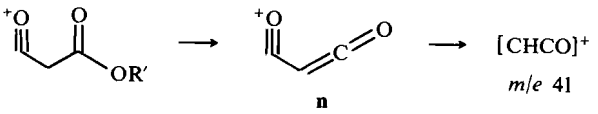
For personal use only.



n

compounds the peak at *m/e* 69 is due to ion **n**. High resolution measurements showed that the peak at 69 often was a doublet with composition C_3HO_2 and C_5H_9. Ion **n** readily loses CO to give a fragment at *m/e* 41.

In most cases the composition of the ions discussed was verified by high resolution measurements and in some cases the fragmentation paths were corroborated by a metastable analysis. Thus we can say that the mass spectra of a large number of β-keto esters fit the fragmentation pathways shown, and we can utilize the mass spectral data to determine the substitution pattern in β-keto esters.

Experimental

All of the mass spectral data were recorded on an AEI-MS 9 operating with a source temperature of 200° and an ionizing voltage of 70 eV.

The preparation and analytical data for the β-keto esters have been reported (1).

INDO MO Calculations of the Conformational Dependence of the vicinal $^{13}C,H$ Spin–Spin Coupling Constant in Propane

R. WASYLISHEN AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received March 21, 1972

Molecular orbital theory at the INDO level of approximation is used to calculate the Fermi contact contribution to three-bond carbon–proton coupling constants in propane. The calculations predict a dihedral angle dependence of $^3J(^{13}C,H)$ in the $^{13}C—C—C—H$ fragment similar to that observed for $^3J(,H,H)$, $^3J(^{19}F,H)$, and for $^3J(^{31}P,H)$ in the saturated X—C—C—H fragments.

La théorie des orbitales moléculaires au niveau des approximations INDO, est utilisée pour calculer la contribution du "Fermi-contact" aux constantes de couplage des trois liaisons carbone–hydrogène, dans le propane. Les calculs laissent prévoir une dépendance diédrale angulaire de $^3J(^{13}C,H)$ dans le fragment $^{13}C—C—C—H$ semblable à celle observée pour $^3J(H,H)$, $^3J(^{19}F,H)$, et pour $^3J(^{31}P,H)$ dans les fragments saturés X—C—C—H.

Canadian Journal of Chemistry, **50**, 2710 (1972)

The famous Karplus relationship (1), relating the proton–proton spin–spin coupling constant in the fragment H—C—C—H to the dihedral angle, has been extensively applied to the study of molecular conformations. Its applicability has recently been reviewed by Thomas (2) and by Booth (3). Similar relationships have been explored experimentally and sometimes theoretically in the fragments $^{19}F—C—C—H$ (4–6), $^{31}P—C—C—H$ (7, 8), $H—C—N^+—H$ (9), $^{15}N—C—C—H$ (8), and H—C—O—H (10–12). The finite perturbation technique in the INDO formulation of molecular orbital theory has been successful in at least qualitatively reproducing the known behavior of the coupling constants in the fragments H—C—C—H (13), $^{19}F—C—C—H$ (5, 6), and $^{15}N—C—C—H$ (6).

In view of the recent interest in organic ^{13}C magnetic resonance spectroscopy we have calculated the conformational dependence of the vicinal $^{13}C,H$ coupling in propane using the INDO formulation (14–16) in the manner we

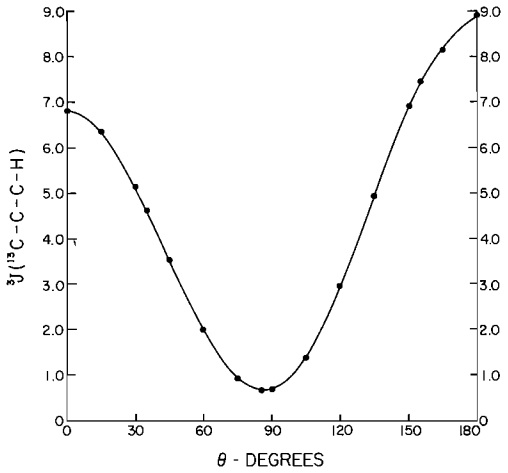

FIG. 1. The calculated vicinal coupling constant in Hz between the carbon-13 nucleus and the proton in propane is plotted *vs.* the dihedral angle in the fragment $^{13}C—C—C—H$. A staggered conformation is assumed for the $^{13}CH_3$ group.

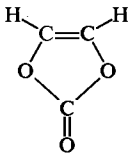
have previously described (17, 18) for other molecules. Atomic coordinates were calculated using the standard geometrical model of Pople and Gordon (19).

In Fig. 1 the computed coupling is plotted *vs.* the dihedral angle in the fragment $^{13}C—C—C—H$. In Table 1 the computed values are given at intervals of 15° or less of the dihedral angle. The curve in Fig. 1 can be reproduced to within 0.03 Hz by the equation:

$$^3J(^{13}C,H) = 4.26 - 1.00 \cos\theta + 3.56 \cos 2\theta$$

where θ is the dihedral angle. As pointed out by a referee, this formula is easy to use in that 4.26 Hz corresponds to the average coupling constant for free rotation, while 2×1.00 Hz is the difference between the couplings at $\theta = 0$ and 180°.



1

The close resemblance of the computed curve to those known for analogous vicinal couplings (minimum at approximately 90°, maxima at 0 and 180°) implies its potentially wide applicability in structural studies. At present almost no relevant experimental data, for example, for cyclohexane derivatives, is available. However, the temperature dependence of the proton spectra of propionaldehyde-3-^{13}C and its oxime indicates that *trans* $J(^{13}C—C—C—H)$ is greater than the *gauche* coupling (20), corresponding to $\theta = 180$ and 60°, respectively. The vicinal $^{13}C,H$ coupling in benzene is 7.4 Hz (21) where $\theta = 180°$ and INDO finds 9.4 Hz (15). In vinylene carbonate, **1**, we calculate[1] (6) the vicinal coupling $^3J(^{13}C—O—C—H)$ as 8.35 Hz, whereas the observed value is ± 9.26 Hz (23) and θ is again 180°.

Comparison of the last two examples with the computed data in Table 1 and Fig. 1 suggests a degree of insensitivity of the vicinal $^{13}C,H$ coupling to the hybridization state of the carbon atoms as well as to substituent effects. Further experimental and computational investigation of these effects is clearly in order.

TABLE 1. The calculated $^{13}C,H$ coupling in Hz over three bonds in propane as a function of the dihedral angle, θ

Steroids and Steroidases. XVI.[1] An Evaluation of Synthetic Routes to Variously C-17-Substituted Δ^5-3-Ketosteroids

J. BRYAN JONES AND KEITH D. GORDON

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received April 24, 1972

Several routes to variously C-17-substituted Δ^5-3-ketosteroids have been surveyed. The most convenient method was found to be oxidation of Δ^5-3β-alcohol precursors with the Collins reagent, dipyridine chromium trioxide in methylene chloride. The purities of the desired acid- and base-labile compounds obtained were $\geqslant$99% in each case.

Plusieurs voies d'accès aux divers Δ^5 céto-3 stéroides C-17 substitués ont été examinées. La méthode la plus commode est l'oxydation de précurseurs Δ^5 alcool-3β avec le réactif de Collins, le trioxyde de chrome dipyridine dans le chlorure de méthylène. Les puretés des composés obtenus labiles en milieu acide et basique sont supérieures à 99% dans tout les cas.

Canadian Journal of Chemistry, **50**, 2712 (1972)

Our previous studies (1) on the influence of the C-17 group on micelle formation of Δ^5-3-ketosteroids in aqueous solutions, and on the consequences of such aggregation with respect to the specificity of a Δ^5-3-ketosteroid isomerase, prompted us to undertake a more systematic investigation of such C-17-substituent effects. For the aggregation and enzymic studies projected, steroid-5-en-3-ones possessing C-17 groups intermediate in polarity and steric bulk between the oxo function of the standard substrate androst-5-ene-3,17-dione (**3***a*) and the C_8H_{17} group of cholest-5-en-3-one (**3***h*) were desired and the range of substitution patterns considered is recorded in Scheme 1.

At the time this investigation was begun the most convenient general approaches to the extremely labile Δ^5-3-keto steroid structures were by Pfitzner–Moffatt oxidation (1–3) of the corresponding Δ^5-3β-alcohols (**1**) or by deconjugation (1, 4) of the isomeric Δ^4-3-ketones (**2**). Of the precursor compounds **1** and/or **2** required, those needed for the preparation of all the desired Δ^5-3-ketones except **3***c*, *f*, and *g* were

Steroids and Steroidases. XVI.[1] An Evaluation of Synthetic Routes to Variously C-17-Substituted Δ^5-3-Ketosteroids

J. BRYAN JONES AND KEITH D. GORDON

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received April 24, 1972

Several routes to variously C-17-substituted Δ^5-3-ketosteroids have been surveyed. The most convenient method was found to be oxidation of Δ^5-3β-alcohol precursors with the Collins reagent, dipyridine chromium trioxide in methylene chloride. The purities of the desired acid- and base-labile compounds obtained were $\geqslant 99\%$ in each case.

Plusieurs voies d'accès aux divers Δ^5 céto-3 stéroides C-17 substitués ont été examinées. La méthode la plus commode est l'oxydation de précurseurs Δ^5 alcool-3β avec le réactif de Collins, le trioxyde de chrome dipyridine dans le chlorure de méthylène. Les puretés des composés obtenus labiles en milieu acide et basique sont supérieures à 99% dans tout les cas.

Canadian Journal of Chemistry, **50**, 2712 (1972)

Our previous studies (1) on the influence of the C-17 group on micelle formation of Δ^5-3-ketosteroids in aqueous solutions, and on the consequences of such aggregation with respect to the specificity of a Δ^5-3-ketosteroid isomerase, prompted us to undertake a more systematic investigation of such C-17-substituent effects. For the aggregation and enzymic studies projected, steroid-5-en-3-ones possessing C-17 groups intermediate in polarity and steric bulk between the oxo function of the standard substrate androst-5-ene-3,17-dione (**3***a*) and the C_8H_{17} group of cholest-5-en-3-one (**3***h*) were desired and the range of substitution patterns considered is recorded in Scheme 1.

At the time this investigation was begun the most convenient general approaches to the extremely labile Δ^5-3-keto steroid structures were by Pfitzner–Moffatt oxidation (1–3) of the corresponding Δ^5-3β-alcohols (**1**) or by deconjugation (1, 4) of the isomeric Δ^4-3-ketones (**2**). Of the precursor compounds **1** and/or **2** required, those needed for the preparation of all the desired Δ^5-3-ketones except **3***c*, *f*, and *g* were

readily available (see Experimental). Attention was thus concentrated initially on the preparation of the C-17β-methyl, -isopropyl, and -isobutyl Δ^5-3β-ol-intermediates, **1***c*, *f*, and *g*.

17β-Methylandrost-5-en-3β-ol (**1***c*) was obtained as outlined in Scheme 2. Conversion of 3β-hydroxyandrost-5-en-17-one (**1***a*) to the 17-methylene derivative **4***a* was effected smoothly by the standard Wittig procedure and following acetylation of the reaction mixture, the 3β-acetate **4***a* was obtained in 67% yield (5). Hydrolysis of **4***a* with methanolic potassium hydroxide afforded **4***b* in 90% yield. In view of the literature data on the less-substituted double bond reduction preference of tris(triphenylphosphine)rhodium catalysts (6–9) and the α-face addition of hydrogen to be anticipated for steroid olefins (7, 8), selective and stereospecific reduction of **4***b* to the 17β-methyl compound **1***c* was expected using the above catalyst. However, although reduction of the C-17,20 double bond occurred exclusively, a mixture of the C-17 methyl epimers was formed as evidenced by the two C-20 doublets at δ 0.78 and 0.83 p.p.m. in the n.m.r. spectrum of the product. Selective hydrogenation of **4***b* with a 5% palladium – calcium carbonate catalyst (10) also gave a thin-layer chromatographically inseparable mixture

SCHEME 3

of the two epimers in which the 17β-methyl isomer (δ 0.83 p.p.m.) predominated.[2] Selective and stereospecific α-face hydrogenation of **4***b* to give **1***c* in 84% yield was finally effected using 10% palladium–charcoal as the catalyst. 20-Methylpregn-5-en-3β-ol (**1***f*) was prepared similarly (Scheme 3) from **1***d* with the acetylated Wittig reaction product **5***a* being obtained in 62% yield. Following its hydrolysis to **5***b* (86% yield) selective hydrogenation of the Δ^{20}-double bond to give **1***f* was achieved almost quantitatively with the tris(triphenylphosphine)rhodium chloride catalyst.

An attempt was also made to introduce a C-17 sec-butyl substituent by a route analogous to that outlined in Scheme 3. Pregnenolone (**1***d*) was reacted with the Wittig reagent derived from ethyltriphenylphosphonium bromide to give a mixture containing the Z- and E-isomers of 20-ethylpregna-5,20-dien-3β-ol which could not be separated by a variety of chromatographic methods. Neither of the trisubstituted double bonds of the latter was reducible using the rhodium catalyst and hydrogenation in the presence of palladium–calcium carbonate resulted in saturation of both the Δ^5 and Δ^{20} bonds. Although application of 5% palladium–charcoal as a catalyst did afford some selectivity of reduction, the results generally were discouraging and in view of the further difficulties anticipated in separating the C-20,22 diastereomers of the desired product, attempts to prepare **1***g* were discontinued.

In previous applications of the Pfitzner–Moffatt oxidation procedure to the Δ^5-3β-ols **1***a*, *b*, and *h*, good yields of the corresponding βγ-unsaturated ketones had been obtained (3). However, on treatment of the 17-alkyl analogues **1***c*, *e*, and *f* under the same conditions the reactions were incomplete. When the slightly more vigorous conditions required to achieve oxidation of the majority of the starting alcohols were applied, extensive contamination of the desired Δ^5-3-keto products by the conjugated isomers was observed. Accordingly, the alternative deconjugation route (1, 4) to **3***c*, *e*, and *f* was explored.

The starting Δ^4-3-ketosteroids **2***c*, *e*, and *f* required were obtained in 75–90% yields by Oppenauer oxidation of **1***c*, *e*, and *f* respectively. Our experience (1) with the potassium *t*-butoxide-mediated deconjugation of several steroid-Δ^4-3-ketones had shown that the reactions could be carried out in air to give the corresponding βγ-unsaturated ketones uncontaminated by their conjugated isomers or by C-4 or -6 oxygenated by-products (11, 12). In contrast, when similar conditions were applied to the C-17-isopropyl Δ^4-3-ketone **2***f*, none of the expected unconjugated isomer **3***f* was formed. Instead, a 30% yield of 4-hydroxy-20-methylpregn-4,6-dien-3-one (**6**) was obtained. Although prior deoxygenation of the solutions and carrying out the deconjugation in an oxygen-free nitrogen atmosphere suppressed the formation of the 4-hydroxylated derivative to a large extent, the Δ^5-3-keto product **3***f* obtained was always contaminated with small but significant amounts of **6**. The latter impurity could be removed by preparative layer chromatography but owing to the progressive isomerization of **3***f* to **2***f* which occurred during the separation process pure samples of the 17β-isopropyl-Δ^5-3-ketone could not be obtained in this way.

Base-catalyzed oxygenation of steroid-Δ^5-3-ketones is known to be a very facile process and

[2]Sondheimer and his co-workers (10) reported a double m.p., 133–135° and 157–159°, for a sample of **1***c* prepared in this way and it now seems probable this earlier material also contained the 17α-epimer.

6

SCHEME 4

is considered to involve radical intermediates (13, 14). A mechanism for oxygenation at C-4 involving singlet oxygen has been proposed (14); however, participation of the latter species under the reaction conditions employed is questionable and the mechanism outlined in Scheme 4 incorporating a radical-chain process (15) to a hydroperoxide intermediate (13) is preferred. At present it is not understood why the dienolate anion of **2***f* should be so much more sensitive to attack by oxygen than the Δ^4-3-ketones examined earlier (1) nor why Pfitzner–Moffatt oxidations of **1***c*, *e*, and *f* should not have been facile.

As a result of the above difficulties, attention was turned to some of the alternative routes to Δ^5-3-ketones which had subsequently become available. One attractive possibility appeared to be the method developed by Mazur and his coworkers (16) in which deconjugation of $\alpha\beta$-unsaturated ketones had been effected by controlled methanolysis of dienoltrichloroacetate

7 8

SCHEME 5

derivatives. Evaluation of this procedure for the conversion of **2***f* into **3***f* indicated that it was not without its disadvantages since isomerization of the initially formed Δ^5-3-ketone was difficult to prevent unless ketonization of the intermediate trichloracetate with the recommended (16) methanol solutions was very carefully regulated. Another potential route which was considered is exemplified in Scheme 5. In contrast to thioketal formation, formation of an oxythioketal such as **7** from a Δ^4-3-ketone is accompanied by migration of the double bond to the Δ^5 position (17, 18). It was felt that since ketonization of such derivatives can be effected with Raney nickel under essentially neutral conditions (17), little or no isomerization should occur of a Δ^5-3-one prepared in this way. The validity of the method was demonstrated by the conversion of the oxythioketal **7** into **8**, but although relatively pure samples of the $\beta\gamma$-unsaturated ketone were produced, the low yields ($\sim$10%) obtained precluded any serious consideration of this approach.

The method finally adopted as providing the most satisfactory route to the variously C-17 substituted Δ^5-3-ketones desired was oxidation of the appropriate Δ^5-3β-ol precursor with the mild, neutral, dipyridine chromium trioxide in dichloromethane reagent developed by Collins and his collaborators (19). Oxidation of each of **1***a–f, h* was complete within 10 min at 0° and 40–50% yields of the corresponding Δ^5-3-ketones **3***a–f, h* were obtained. In each case the degree of purity of the desired product was found to be higher than that attainable by any of the previous methods and analyses of each sample by i.r. and u.v. spectroscopy showed less than 1% of the conjugated Δ^4-3-keto isomer to be present.

The influence of the C-17 substituents on the aggregation properties and Δ^5-3-ketoisomerase specificity of **3***a–f, h* will be reported shortly.

Experimental

The dimethylsulfoxide used in the Wittig reactions was distilled from calcium hydride and stored over molecular sieves. All other solvent purifications, criteria of purity, instrumentation used, etc. were as described previously (3). Spectral data for all compounds were as expected and selected distinguishing features only are cited. Any steroid for which a preparative procedure is not detailed below was purchased from Aldrich, Searle, Sigma, or Nutritional Biochemical Corporation.

17β-Methylandrost-5-en-3β-ol (1c)

3β-Acetoxy-17-methyleneandrost-5-ene (**4***a*), m.p. 103–104° (lit. (5) m.p. 103–105°), was obtained in 67% yield from 3β-hydroxyandrost-5-en-17-one (**1***a*) as described by Drefahl *et al.* (5). Hydrolysis of **4***a* with 3% methanolic potassium hydroxide (5) gave 3β-hydroxy-17-methyleneandrost-5-ene (**4***b*, 90%), m.p. 132–133.5° (lit. (5) m.p. 133–134°). Hydrogenation of **4***b* (200 mg) was carried out at 21° in methanol (50 ml) containing 10% palladium–charcoal (50 mg). Following the uptake of 1 equiv of hydrogen (4 h), the catalyst was filtered off and the filtrate evaporated. Recrystallization of the residue from methanol gave 17β-methylandrost-5-en-3β-ol (**1***c*, 170 mg) m.p. 160–163°;[2] i.r. ($CHCl_3$) 3571 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.83 (3, d, $J = 6$ Hz, C-17 —CH_3), and 5.38 p.p.m. (1, broad s, C-6 H).

Anal. Calcd. for $C_{20}H_{32}O$: C, 83.27; H, 11.18. Found: C, 83.15; H, 11.35.

Pregn-5-en-3β-ol (1e)

This compound, m.p. 131–134° (lit. (20) m.p. 132–133°), was obtained in 80% yield following prolonged ($\sim$2 days) Wolff–Kishner reduction (20) of 3β-hydroxypregn-5-en-20-one (**1***d*).

20-Methylpregn-5-en-3β-ol (1f)

Treatment of 3β-hydroxypregn-5-en-20-one (**1***d*) with methylenetriphenylphosphorane in dimethylsulfoxide (21), followed by acetylation of the reaction mixture, chromatography on alumina (CCl_4 elution), and recrystallization from methanol yielded 3β-acetoxy-20-methylpregna-5,20-diene (**5***a*, 62%), m.p. 133–135° (lit. (21) m.p. 128.5–129°). Hydrolysis of **5***a* with 3% methanolic potassium hydroxide for 2 h at 21° gave 20-methylpregna-5,20-dien-3β-ol (**5***b*, 86%) which after recrystallization from aqueous methanol had m.p. 133–135° (lit. (21) m.p. 133.5–134°). Selective hydrogenation of **5***b* (600 mg) was effected in benzene (50 ml) containing 60 mg of tris(triphenylphosphine)rhodium chloride (7) at 21° in a hydrogen atmosphere. After the uptake of 1 equiv of hydrogen (3 h), the benzene solution

For personal use only.

was filtered through a Florisil (50 g) column and the elution was completed with ether. Evaporation of the steroid containing fractions (first 75 ml of eluents) followed by recrystallization from methanol gave 20-methylpregn-5-en-3β-ol (**1***f*, 560 mg) m.p. 140–141°, (lit. (21) m.p. 136–137°), i.r. ($CHCl_3$), 3584 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.83 (3, d, $J = 7$ Hz, C-20 or -21 CH_3), 0.89 (3, d, $J = 7$ Hz, C-20 or -21 CH_3); and 5.36 p.p.m. (1, broad s, C-6 H).

Δ^4-3-Ketosteroids **2***b, c, e, and f*

Oppenauer oxidation of the precursor Δ^5-3β-alcohols **1***b*, *c*, *e*, and *f* with cyclohexanone and aluminum isopropoxide in toluene (22) gave 75–90% yields of the corresponding Δ^4-3-ketones. Recrystallization from methanol or aqueous methanol gave samples with the following properties: *androst-4-en-3-one (2b)* m.p. 98–100° (lit. (23) m.p. 105–106°); *17β-methylandrost-4-en-3-one (2c)* m.p. 109–110° (lit. (10) m.p. 109–110°), n.m.r. ($CDCl_3$) δ 0.82 p.p.m. (3, d, $J = 6$ Hz, C-17β CH_3); *pregn-4-en-3-one (2e)* m.p. 99–101° (lit. (20) m.p. 102–104°); and *20-methylpregn-4-en-3-one (2f)* m.p. 143–145° (lit. (21) m.p. 143–144°), n.m.r. ($CDCl_3$) δ 0.85 (3, d, $J = 6$ Hz, C-20 or -21 CH_3) and 0.92 p.p.m. (3, d, $J = 6$ Hz, C-20 or -21 CH_3).

*Formation of 4-Hydroxy-20-methylpregn-4,6-dien-3-one (**6**) During Attempted Deconjugation of 20-Methylpregn-4-en-3-one (2f)*

Potassium *t*-butoxide (375 mg, 3.5 mmol) was added to a solution of 20-methylpregn-4-en-3-one (100 mg, 0.32 mmol) in *t*-butanol (10 ml) and the mixture was stirred in air for 90 min at 21°. Ten percent aqueous acetic acid (10 ml) followed immediately by saturated aqueous sodium bicarbonate solution (15 ml) was then added and the mixture was then extracted with ether (4 × 20 ml), dried ($MgSO_4$), and evaporated. Recrystallization of the residue from methanol yielded 4-hydroxy-20-methylpregn-4,6-dien-3-one (**6**, 30 mg) m.p. 198–199°; i.r. (KBr) 3390, 1667, and 1618 cm^{-1}; u.v. λ_{max} (CH_3OH) 318 nm (ε 7500); n.m.r. ($CDCl_3$) δ 6.05 (1, d of d, $J = 9$ and 2 Hz, C-7 H), 6.2 (1, s, partially exchangeable with D_2O, C-4 OH), and 6.65 p.p.m. (1, d of d, $J = 9$ and 2 Hz, C-6 H); mass spectrum (70 eV) *m/e* 328 (parent ion).

Anal. Calcd. for $C_{22}H_{32}O_2$: C, 80.44; H, 9.82. Found: C, 80.68; H, 9.73.

Preparation of 17β-Hydroxyandrost-5-en-3-one via the Oxythioketal 7

17β-Hydroxyandrost-5-en-3-one 3-ethyleneoxythioketal (**7**), m.p. 188–190° (lit. (17) m.p. 192–194°) was obtained in 50% yield from 17β-hydroxyandrost-4-en-3-one and 2-mercaptoethanol as described by Djerassi and Gorman (17). Treatment of **7** with acetone-deactivated Raney nickel W-2 in refluxing acetone for 4 h gave 17β-hydroxyandrost-5-en-3-one, m.p. 158–160° (lit. (1) m.p. 162–164°), in 10% yield following purification by t.l.c.

Preparation of the Δ^5-3-Ketosteroids 3a–f, h using the Dipyridine Chromium Trioxide Reagent

The same general procedure was used for each $\beta\gamma$-unsaturated ketone.[3] Dipyridine chromium trioxide (1.0 g, 3.87 mmol), freshly prepared according to the procedure of Collins *et al.* (19*a*), was dissolved at 0° in dichloromethane (40 ml) and the dark red solution stirred for 10 min. The appropriate Δ^5-3β-alcohol (200 mg, ~0.5–0.75 mmol) in dichloromethane (5 ml) was then added dropwise with stirring at 0°. The mixture turned dark grey almost immediately following the addition of all the alcohol and after stirring for a further 10 min at 0°, it was filtered. The cold filtrate was washed with water (3 × 10 ml), and then *rapidly* with 3% aqueous hydrochloric acid (3 × 10 ml) followed by water (3 × 10 ml). Evaporation of the dried ($MgSO_4$) solution and recrystallization of the residual solid from *warm*[3] methanol yielded the desired Δ^5-3-ketone which i.r. and u.v. analysis showed to be ≥99% pure. Application of the above procedure proceeded without complication in each of the following preparations.

Androst-5-ene-3,17-dione (3a). From **1***a*, 74 mg, m.p. 146–150°[4] (lit. (3) m.p. 150–155°); i.r. ($CHCl_3$) 1730 and 1709 cm^{-1}.

Androst-5-en-3-one (3b). From **1***b*, 60 mg, m.p. 114–117°[4] (lit. (3) m.p. 129–131°); i.r. ($CHCl_3$) 1709 cm^{-1}.

17β-Methylandrost-5-en-3-one (3c). From **3***b*, 40 mg, m.p. 115–118°; i.r. ($CHCl_3$) 1706 cm^{-1}.

Anal. Calcd. for $C_{20}H_{30}O$: C, 83.86; H, 10.56. Found: C, 83.67; H, 10.71.

Pregn-5-ene-3,20-dione (3d). From **1***d*, 110 mg, m.p. 156–159° (lit. (24) m.p. 139–148°); i.r. ($CHCl_3$) 1701 and 1698 cm^{-1}.

Pregn-5-en-3-one (3e). From **1***e*, 69 mg, m.p. 123–126° (lit. (25) m.p. 129–133°); i.r. ($CHCl_3$) 1706 cm^{-1}.

20-Methylpregn-5-en-3-one (3f). From **1***f*, 67 mg, m.p. 136–139°; i.r. ($CHCl_3$) 1706 cm^{-1}.

Anal. Calcd. for $C_{22}H_{34}O$: C, 84.02; H, 10.90. Found: C, 84.10; H, 11.00.

Cholest-5-en-3-one (3h). From **1***h*, 80 mg, m.p. 116–120° (lit. (3) m.p. 120–122°); i.r. ($CHCl_3$) 1709 cm^{-1}.

[3]All the precautions found necessary (3) to prevent isomerization of Δ^5-3-ketosteroids by the glassware used, or by application of excessive heating during recrystallization, were applied throughout.

[4]Melting points of many Δ^5-3-ketones are not easily reproduced owing to the facility with which isomerization occurs on heating (3). Melting point determinations were carried out with the temperature increasing at 8°/min.

Synthesis of *cis*-Jasmone and Dihydrojasmone

HONOR C. HO, TSE-LOK HO, and C. M. WONG
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received February 15, 1972

cis-Jasmone and dihydrojasmone have been synthesized from levulonitrile by a four-step reaction sequence. Application of ceric ammonium nitrate for dethioketalization is described.

La Jasmone *cis* et la dihydrojasmone ont été synthétisées à partir du levulonitrile selon une séquence réactionnelle en quatre étapes. L'application du nitrate d'ammonium cérique pour la déthiocétalisation est décrite.

Canadian Journal of Chemistry, **50**, 2718 (1972)

cis-Jasmone (**1***a*) and dihydrojasmone (**1***b*) have commanded undiminished endeavors in their syntheses (1, 2) over the past three decades, owing to their importance in the perfume industry and because they often serve as testing targets pertinent to development of γ-diketone and cyclopentenone syntheses. We wish to report a simple synthesis of both of these natural products which may have certain merits since the starting materials are relatively inexpensive and easily accessible.

It appeared to us that a levulinic acid derivative would be an attractive starting point in view of the presence of differential bifunctionality in the correct positions of the carbon skeleton, amenable to the elaboration of *cis*-jasmone and dihydrojasmone precursors. In this context, levulonitrile was selected because its ketone function can be masked temporarily, while the cyano group is being transformed into another carbonyl by the action of an organometallic reagent.

Thus, levulonitrile (3) was converted to the ethylenethioketal **2** in good yield. Reaction of **2** with appropriate Grignard reagents followed by acid hydrolysis of the resulting imine complexes on work-up furnished **3***a* and *b* respectively.[1] To facilitate isolation of the products in

[1]The use of the ethyleneketal protecting group for levulonitrile was found to be unsuitable.

the scale we used, Girard T derivatives were prepared; however, this technique would not be required in larger preparations where fractional distillation would be expedient and sufficient.

The next task called for removal of the dithioketal group, and this was performed either by utilizing the elegant procedure recently disclosed by Wynberg and his collaborators (4), or by ceric ammonium nitrate oxidation (5) in aqueous acetonitrile, a novel and efficacious method which could be of wide applicability to regenerate carbonyl compounds from the corresponding 2-substituted 1,3-dithiolanes and 1,3-dithianes under very mild conditions. In our hands, this latter convenient process was found to be superior to Wynberg's method for dithioketal cleavage involved in the synthesis reported herein. Cyclization of **4***a*, *b* to *cis*-jasmone and dihydrojasmone was effected by alkali according to the literature (1*k*). These synthetic compounds were shown to be identical with authentic specimens of the natural products by spectroscopy (i.r., n.m.r.) and chromatography (t.l.c.).

The approach described in this paper defines a potentially useful general fabrication of the γ-diketone synthon, since homologues of levulonitrile can be prepared readily by the cyanoethylation of nitroalkanes followed by the Nef reaction (3).

Experimental

I.r. spectra were recorded on a Perkin-Elmer 710 Spectrophotometer using methylene chloride as solvent. N.m.r. spectra were taken on a Varian A56/60A spectrometer in the solvent indicated and with tetramethylsilane as internal standard. Mass spectra were obtained from a Finnigan 1015 mass spectrometer and high resolution mass spectra were measured with an AEI MS9 Spectrometer (University of Alberta) operating at 70 eV. Solutions were dried over anhydrous magnesium sulfate.

Levulonitrile Ethylenethioketal

A mixture of levulonitrile (4.20 g), ethanedithiol (4.0 ml), and boron trifluoride etherate (1.0 ml) and anhydrous magnesium sulfate (5 g) in benzene (40 ml) was allowed to stand at ambient temperature for 2 days. It was then diluted with benzene (100 ml), washed with 2% potassium hydroxide, dried, and evaporated *in vacuo*. Levulonitrile ethylenethioketal (6.53 g, 88.2%) was obtained as a clear oil, b.p. 78–80° (0.6 Torr). I.r. ν 2240 cm^{-1}; n.m.r. (CCl_4) τ 6.68 (4H, s), 7.56 (4H, sym. m), 8.22 (3H, s); mass (M^+): calcd. for $C_7H_{11}N^{32}S$, 173.0334; found, 173.0330.

Anal. Calcd. for $C_7H_{11}NS$: C, 48.5; H, 6.4; N, 8.1; S, 37.0. Found: C, 48.7; H, 6.2; N, 8.2; S, 36.8.

cis-Undec-8-ene-2,5-dione Monoethylenethioketal (**3***a*)

To a Grignard reagent prepared from *cis*-1-bromohex-3-ene (1.62 g) and magnesium turnings (240 mg) in dry ether (20 ml) was introduced a solution of levulonitrile ethylenethioketal (173 mg) in ether (5 ml). After stirring at room temperature for 18 h, the reaction mixture was run into dilute hydrochloric acid and extracted with ether. The crude product was treated directly with Girard T reagent (200 mg) in methanol (10 ml) containing glacial acetic acid (0.2 ml) for 3 h under reflux. T.l.c. homogeneous *cis*-undec-8-ene-2,5-dione monoethylenethioketal (**3***a*) (156 mg, 60.5%) was obtained from the Girard derivative. An analytical sample was prepared by evaporative distillation in high vacuum

(bath temperature 100–110°). I.r. ν 1710 cm^{-1}; n.m.r. ($CDCl_3$)τ4.65 (2H, m), 6.79 (4H, s), 8.25 (3H, s), 9.05 (3H, t, J=7.5 Hz); mass (M^+): calcd. for $C_{13}H_{22}O^{32}S_2$, 258.1113; found, 258.1107.

Anal. Calcd. for $C_{13}H_{22}OS_2$: C, 60.5; H, 8.5; S, 24.8. Found: C, 60.8; H, 8.6; S, 24.2.

cis-Undec-8-ene-2,5-dione (4a)

(*a*) Following the procedure of Wynberg and coworkers (4), a solution of chloramine T (570 mg) in 80% methanol (2.5 ml) was added to **3***a* (150 mg) in methanol (2 ml) and ethanol (1 ml). After stirring at room temperature for 2 min, water was added and it was extracted with ether (80 ml). The ether solution was washed with 10% sodium hydroxide, water, and dried. The crude diketone **4***a* (102 mg) secured by evaporation of solvent was purified by preparative t.l.c. on silica gel (benzene; R_f 0.2); yield 80 mg (70%). I.r. ν 1710 cm^{-1}; n.m.r. ($CDCl_3$) τ 4.65 (2H, m), 7.32 (4H, s), 7.83 (3H, s), 9.05 (3H, t, J = 7 Hz); mass spectrum m/e 182 (M^+).

(*b*) Ceric ammonium nitrate (550 mg) was added to a stirred solution of **3***a* (62 mg) in 75% aqueous acetonitrile (4 ml) at ambient temperature. At the end of 5 min the reaction was quenched with water and extracted with ether (50 ml). The ether extract was then washed with water to remove coloring material, dried, evaporated, and the resulting product was subjected to preparative t.l.c. to give **4***a* (34 mg, 77.8%).

cis-Jasmone

A mixture of *cis*-undec-8-ene-2,5-dione (80 mg), 0.5 *N* sodium hydroxide (1.0 ml), and ethanol (2.0 ml) was refluxed under nitrogen for 5 h. On cooling, the mixture was acidified with dilute hydrochloric acid and extracted with ether. The crude product was purified by preparative t.l.c. on silica gel (benzene:ether, 85:15; R_f 0.6) to give *cis*-jasmone (55 mg, 76.4%). I.r. ν 1690, 1640 cm^{-1}; n.m.r. ($CDCl_3$) τ 4.64 (2H, m), 7.02 (2H, d, J = 5 Hz), 7.92 (3H, s), 9.00 (3H, t, J = 7 Hz); mass spectrum m/e 164 (M^+). 2,4-DNP, m.p. 115–116° (lit. (*lb*) m.p. 116°).

Undecan-2,5-dione Monoethylenethioketal (3b)

A solution of levulonitrile ethylenethioketal (1.00 g) in dry ether (10 ml) was added to a stirred Grignard reagent prepared from 1-bromohexane (10.00 g) and magnesium turnings (1.44 g) in ether (80 ml). The reaction mixture was stirred at room temperature for 20 h and added dropwise to a stirred mixture of dilute hydrochloric acid and chloroform. After separation into layers, the aqueous phase was extracted with chloroform (2 × 60 ml). The combined extracts were dried and evaporated to given an oil. The diketone monoethylenethioketal **3***b* (1.035 g, 65.5%) was isolated by treatment of the crude oil with Girard T reagent (1.20 g) in refluxing methanol (40 ml, containing 1.0 ml glacial acetic acid) for **3 h**. I.r. ν 1710 cm^{-1}; n.m.r. ($CDCl_3$) τ 6.68 (4H, s), 7.1–**8.0** (**6**H, m), 8.25 (3H, s), 8.5–8.9 (8H, m), 9.11 (3H, t, J=5 Hz); mass (M^+): calcd. for $C_{13}H_{24}O^{32}S_2$, 260.1269; found, 260.1263.

Anal. Calcd. for $C_{13}H_{24}OS_2$: C, 60.0; H, 9.3; Found: C, 59.8; H, 9.4.

Undecan-2,5-dione

(*a*) A solution of **3***b* (460 mg) in methanol–ethanol (2:1, 3 ml) was treated with a solution of chloramine T (1.128 g) in 80% methanol (5 ml) at room temperature for 2 min. Water was added and the resulting mixture was extracted with ether (80 ml). The extract was washed with 10% potassium hydroxide, water, and dried. Evaporation of the organic solution yielded undecan-2,5-dione (226 mg, 67.3%) which was homogeneous on t.l.c. I.r. ν 1710 cm^{-1}; n.m.r. (CCl_4) τ 7.43 (4H, s), 7.62 (2H, t, J = 6.5 Hz), 7.90 (3H, s), 9.10 (3H, t, J = 5 Hz); mass spectrum m/e 184 (M^+).

(*b*) To a solution of **3***b* (130 mg) in 75% aqueous acetonitrile (8 ml) was added ceric ammonium nitrate (1.10 g) in portions. After swirling at room temperature for 5 min, the reaction mixture was poured into water and extracted with ether (80 ml). The ethereal solution was washed thrice with water (until colorless), dried, and evaporated. The crude product, virtually homogeneous on t.l.c., was filtered through a short column of alumina (1.5 g) with benzene as eluent to give pure undecan-2,5-dione (73 mg, 80%).

Dihydrojasmone

A mixture of undecan-2,5-dione (210 mg), 0.5 *N* sodium hydroxide (2.0 ml), and ethanol (1.0 ml) was refluxed under nitrogen for 5 h. The cooled mixture was acidified with dilute hydrochloric acid and extracted with ether. The crude product was eluted through a short column of neutral alumina with ether–benzene mixture (1:9) to furnish pure dihydrojasmone (158 mg, 83%). I.r. ν 1705, 1650 cm^{-1}; n.m.r. ($CDCl_3$) τ 7.96 (3H, s), 9.13 (3H, t, J=5 Hz); mass spectrum m/e 166 (M^+). Semicarbazone m.p. 174–175° (lit. (*2a*) m.p. 173–175°).

We thank Dr. W. I. Taylor (International Flavors & Fragrances) and Prof. E. Wenkert (Indiana University) for the most generous gifts of *cis*-jasmone and dihydrojasmone respectively. Support from the National Research Council of Canada is gratefully acknowledged.

The Photolysis of Tetra(trifluoromethyl)thiophene Vapor[1]

H. A. WIEBE,[2] SILVIA BRASLAVSKY, AND JULIAN HEICKLEN

Department of Chemistry and Center for Air Environment Studies, The Pennsylvania State University, University Park, Pa. 16802

Received March 20, 1972

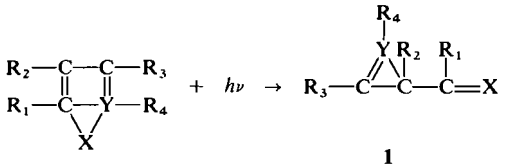
The photolysis of tetra(trifluoromethyl)thiophene (TTFT) at 2139 Å or by mercury sensitization at 2537Å yields hexafluorobutyne-2 and 1,2,3,4-tetra(trifluoromethyl)5-thiabicyclo[2,1,0]pentene-2 (also called tetra(trifluoromethyl)cyclobutadiene episulfide) as the principal gas phase products. The latter is colored a pale yellow and is stable at room temperature. These results suggest that a possible mechanism for the reaction of photoexcited thiophenes is via the formation of valence bond isomers as intermediates.

La photolyse du tétra(trifluorométhyl)thiophène (TTFT) à 2139 Å ou par sensibilisation par le mercure à 2537 Å, donne l'hexafluorobutyne-2 et le tétra(trifluorométhyl)-1,2,3,4 thia 5 bicyclo[2,1,0] penetène-2 (appelé aussi tétra(trifluorométhyl)cyclobutadiène épisulfure) comme produits principaux de la phase gazeuse. Ce dernier, de couleur jaune pâle, est stable à la température ambiante. Ces résultats laissent penser qu'un mécanisme possible dans la réaction des thiophènes photoexcités, est le passage par les isomères de liaison de valence au stade intermédiaire.

Canadian Journal of Chemistry, **50**, 2721 (1972)

Introduction

The photolysis of a number of five-membered heterocyclic compounds proceeds through the intermediate **1**, (1–8), the reaction being



1

where X is a heteroatom and Y is either carbon or a heteroatom.

Wynberg and his coworkers (9–12) have studied the photolysis of substituted thiophenes in solution and have observed that the substituted groups shift. Labelling experiments have shown that ring carbons move, carrying the substituent groups with them. Such an isomerization could proceed through a ring contracted intermediate or "benzenoid" type valence bond isomer, but Wynberg *et al.* (12) preferred a species involving valence shell expansion of the sulfur atom.

Recent studies (13–15) have shown that the irradiation of solutions of thiophenes or furans in amines leads to the formation of pyrroles. The same pyrroles are formed from furans as from the corresponding thiophenes. This was taken to imply that cyclopropenyl intermediates (ketones or aldehydes for the furan systems, thioketones or thioaldehydes for the thiophene systems) are involved in the reaction.

In an earlier report from our laboratory (16), the photolysis of thiophene was reported. The mechanistic details required that the initially formed electronically excited thiophene pass

The Photolysis of Tetra(trifluoromethyl)thiophene Vapor[1]

H. A. WIEBE,[2] SILVIA BRASLAVSKY, AND JULIAN HEICKLEN

Department of Chemistry and Center for Air Environment Studies, The Pennsylvania State University, University Park, Pa. 16802

Received March 20, 1972

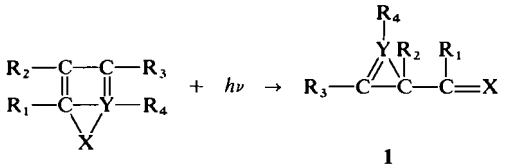
The photolysis of tetra(trifluoromethyl)thiophene (TTFT) at 2139 Å or by mercury sensitization at 2537Å yields hexafluorobutyne-2 and 1,2,3,4-tetra(trifluoromethyl)5-thiabicyclo[2,1,0]pentene-2 (also called tetra(trifluoromethyl)cyclobutadiene episulfide) as the principal gas phase products. The latter is colored a pale yellow and is stable at room temperature. These results suggest that a possible mechanism for the reaction of photoexcited thiophenes is via the formation of valence bond isomers as intermediates.

La photolyse du tétra(trifluorométhyl)thiophène (TTFT) à 2139 Å ou par sensibilisation par le mercure à 2537 Å, donne l'hexafluorobutyne-2 et le tétra(trifluorométhyl)-1,2,3,4 thia 5 bicyclo[2,1,0] penetène-2 (appelé aussi tétra(trifluorométhyl)cyclobutadiène épisulfure) comme produits principaux de la phase gazeuse. Ce dernier, de couleur jaune pâle, est stable à la température ambiante. Ces résultats laissent penser qu'un mécanisme possible dans la réaction des thiophènes photoexcités, est le passage par les isomères de liaison de valence au stade intermédiaire.

Canadian Journal of Chemistry, **50**, 2721 (1972)

Introduction

The photolysis of a number of five-membered heterocyclic compounds proceeds through the intermediate **1**, (1–8), the reaction being



1

where X is a heteroatom and Y is either carbon or a heteroatom.

Wynberg and his coworkers (9–12) have studied the photolysis of substituted thiophenes in solution and have observed that the substituted groups shift. Labelling experiments have shown that ring carbons move, carrying the substituent groups with them. Such an isomerization could proceed through a ring contracted intermediate or "benzenoid" type valence bond isomer, but Wynberg *et al.* (12) preferred a species involving valence shell expansion of the sulfur atom.

Recent studies (13–15) have shown that the irradiation of solutions of thiophenes or furans in amines leads to the formation of pyrroles. The same pyrroles are formed from furans as from the corresponding thiophenes. This was taken to imply that cyclopropenyl intermediates (ketones or aldehydes for the furan systems, thioketones or thioaldehydes for the thiophene systems) are involved in the reaction.

In an earlier report from our laboratory (16), the photolysis of thiophene was reported. The mechanistic details required that the initially formed electronically excited thiophene pass

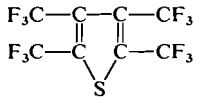
over to some other intermediate as a precursor to allene formation. At that time we preferred the valene intermediate to the ring-contracted cyclopropene carbonyl compound, because cyclopropene was not found as a product.

In order to investigate the nature of the intermediate in thiophene photolysis, we have studied the photolysis of tetra(trifluoromethyl)-thiophene (TTFT), and those results are

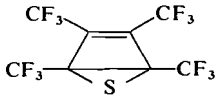


TTFT

reported here. This compound was chosen since the migration of either CF_3 groups or fluorine atoms is not likely in gas phase kinetic studies. The formation of the products resulting from H-atom migration in thiophene photolysis should be inhibited.

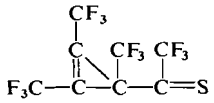
Results and Discussion

TTFT has a strong absorption starting at about 2550 Å. We have decomposed the vapor with 2139 Å radiation and by mercury sensitization at 2537 Å at room temperature (25 ± 2 °C). A pressure equal to the vapor pressure at that temperature (~ 5.5 Torr) was used. The main gas-phase products were hexafluorobutyne-2 and 1,2,3,4-tetra(trifluoromethyl)5-thiabicyclo[2,1,0]pentene-2 (**2**) (tetra-(trifluoromethyl)cyclobutadiene episulfide).



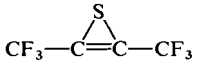
2

Originally we though the product **2** was tetra-(trifluoromethyl)cyclopropene-3-thioketone



as stated in a previous publication (17) from our laboratory based on the work here. The evidence now suggests that this is not so.

Two minor products (<1% of the total gaseous products) and a white polymer were also produced. The mass spectra of the minor products indicated molecular weights of 164 and 214. The product with mass 214 is probably



but the product with mass 164 is difficult to identify. The polymer was removed from the cell by heating after each run with an oxygen torch to about 500 °C.

The compound **2** had a gas chromatographic retention time of 14 min compared to 26 min for TTFT. It was stable at room temperature, even to prolonged irradiation (2 h) with 2139 Å light, pale yellow in color, and could be passed through the gas chromatograph without any appreciable loss.

The mass spectrum of product **2** was obtained on an AEI MS-9 mass spectrometer operating at 70 eV. The spectrum is reported in Table 1

TABLE 1. Mass spectra at 70 eV

along with that of TTFT. The similarity of the two spectra indicates that the two molecules are isomers.

If the CF_3 groups have not migrated, which seems likely, then the photo product **2** could be one of four valence bond isomers of TTFT (*a–d*). Further structural identification was obtained from i.r., u.v., and n.m.r. spectra.

The i.r. spectrum of **2** was obtained on a Beckman IR-10.[3] The product has bands at 1698, 1428, 1400, 1340, 1320, 1275, 1238, 1218, 1195, 1175, 1145, 1090, 1050, 1025, 985, 883, 805, 780, 749, 713, 647, 633, and 607 cm^{-1}. The band at 1698 cm^{-1} in **2**, which is absent in TTFT, is identified as the carbon–carbon double-bond stretch. This wavelength is in the region for a non-conjugated C=C stretching vibration (18). The intense absorptions in the remainder of the spectrum are characteristic of molecules containing a large proportion of fluorine (18). The presence of a C=C rules out isomers *a* and *b* as possible structures for product **2**.

The F^{19} n.m.r. spectrum of **2** revealed two CF_3 peaks of equal intensity at -1310 and -1047 Hz. For TTFT two n.m.r. bands of equal intensity are observed at -2040 and -1880 Hz. These results in conjunction with mass spectral and i.r. absorption data definitely establish product **2** to have the Dewar thiophene structure *d*, since product *c* would have three peaks of intensities 2/1/1.

The u.v. absorption spectrum of **2** was taken on a Cary 15 spectrophotometer. Peak absorptions occurred at 2475 Å ($\varepsilon = 1.3 \times 10^{-2}$ $Torr^{-1}$ cm^{-1} to base 10) and 3365 Å ($\varepsilon = 2.7 \times 10^{-3}$ $Torr^{-1}$ cm^{-1} to base 10).

[3]These spectra may be obtained, upon request, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2. These spectra also are contained in Report No. 164-70 of the Center for Air Environment Studies, Pennsylvania State University, University Park, Pa. 16802.

The present isolation and characterization of 1,2,3,4-tetra(trifluoromethyl)5-thiabicyclo-[2,1,0]pentene-2 in the photolysis of tetra(trifluoromethyl)thiophene establishes the importance of valance bond isomers (other than the ring-contracted intermediate found in the photolysis of other five-membered heterocyclic molecules) as intermediates in the photochemistry of thiophenes.

Experimental

Tetra(trifluoromethyl)thiophene (TTFT) was prepared by heating hexafluorobutyne-2 (Pierce Chemical Co.) with an equivalent of sulfur and one-half equivalent of iodine at 180 °C for 48 h in a stainless steel container (19). It was purified by g.l.c. on a 1/4-in. diameter by 10 ft long column packed with 30% dinonylphthalate on chromosorb W(AW) operated at 80 °C with a helium flow rate of 50 cc/min. Photolysis was done in a cylindrical (50 mm diameter by 100 mm long) quartz reaction vessel attached to a grease-free high-vacuum system. The radiation sources were a Phillips type 93106E, 25 Watt zinc resonance lamp for direct irradiation at 2139 Å and a Hanovia flat spiral low-pressure mercury-arc for the mercury-photosensitized reactions. After irradiation, the products were separated and analyzed on the same gas chromatographic column operating at 30 °C with a helium flow rate of 50 cc/min.

The n.m.r. spectra were obtained on a Varian Associates spectrometer operating at 94.1 mHz and approximately 14 000 Gauss. Calibration of the spectra was in terms of displacements in c.p.s. from the ^{19}F spectrum of trifluoroacetic acid. The negative frequency displacements indicate resonances occurring at lower field than the reference.

This work was supported by the U.S. Public Health Service, National Air Pollution Control Administration under Grant No. AP00718, for which we are grateful.

Conversion of Nonlinear Shift Reagent Plots to Linear Plots

J. W. ApSimon,[1] H. Beierbeck, and A. Fruchier
Department of Chemistry, Carleton University, Ottawa, Canada

Received May 4, 1972

A method is presented for converting partially or completely nonlinear shift reagent plots to perfectly linear plots, from which highly accurate intercepts and slope ratios can be obtained even for nuclei, whose signals can only be observed in the nonlinear region of the original plots.

On présente une méthode permettant de transformer en droites les courbes obtenues dans l'étude des substrats organiques en présence de chélates de lanthanides. A partir de ces droites on peut calculer avec précision les ordonnées à l'origine (déplacements chimiques en l'absence de chélate) et les rapports des pentes, même pour les noyaux dont les signaux ne peuvent être observés que dans la région non linéaire des courbes initiales.

Canadian Journal of Chemistry, **50**, 2725 (1972)

It is known (1, 2) that plots of chemical shifts *vs.* amount of added shift reagent are only linear for small [L]/[S] ratios ([L] and [S] are the total concentrations of shift reagent and substrate respectively). We have shown (3) that in the linear region accurate slope ratios and intercepts can be obtained, even with inaccurate shift reagent concentrations, because the chemical shifts are very accurate and because the [L]/[S] ratios must be exactly the same for all protons in a given sample. Instead of plotting the chemical shifts against the experimental [L]/[S] ratios, they are plotted against "corrected" values which are proportional to the sums of the shifts in each spectrum (3).

As the [L]/[S] ratios increase the plots of chemical shifts *vs.* [L]/[S] become nonlinear. However, since the lanthanide induced shifts are equal to the product of the fractions [LS]/[S] of the complexed substrate and the induced chemical shifts Δ in the complexed state

$$[1] \qquad \delta = \frac{[LS]}{[S]}\Delta$$

([LS] is the concentration of complexed substrate), there exists another variable, [LS]/[S], such that the chemical shifts are a linear function of this variable for any value of [L]/[S]. Since the [LS]/[S] are also the same for all nuclei in any given sample, regardless of the amount of added shift reagent, it is again possible to obtain accurate slope ratios and intercepts without any knowledge of the values of [LS]/[S]. As before the chemical shifts are simply plotted against coordinates c_j which are proportional to the sums of the shifts in each spectrum (3). If the limiting shifts (the shifts in the complexed substrate) are known these values can be normalized to the actual values for the fractions [LS]/[S] of complexed substrate. The slope ratios are equal to the ratios of the limiting shifts and the same values must be obtained from the linear part of the δ *vs.* [L]/[S] plot and from the linear δ *vs.* [LS]/[L] plot.

$$[2] \quad c_j = (c_n - c_1)(\sum \delta_{ij} - \sum \delta_{i1})/(\sum \delta_{in} - \sum \delta_{i1}) + c_1$$

Figures 1 and 2 illustrate this conversion for the methyl group signals of β-amyrin in the presence of $Pr(fod)_3$ (the assumption that the shifts in the last spectrum represent the limiting shifts is certainly incorrect in this case; however, this does not affect the following results). Table 1 shows that, within experimental error, the slope ratios are the same whether the range of [L]/[S] ratios is 0.5, 1.0, or 1.5. Similarly the intercepts vary little and are in good agreement with the experimental shifts in the spectrum of β-amyrin alone (Table 2).

*Only the chemical shifts for methyl groups 23 and 24 were used to derive relative [LS]/[S] values.
†Chemical shifts in the spectrum of β-amyrin without $Pr(fod)_3$.

This extension of the linearity of the shift reagent plots should be useful for working with ring protons, since their signals are usually hidden in the methylene envelope for small values of [L]/[S]. In order to obtain the intercepts in this case it is necessary to "calibrate" the plots with signals, such as methyl group shifts, which can be seen in the spectrum of the pure substrate. That in this case accurate intercepts can still be obtained can be demonstrated with the methyl group signals of β-amyrin. Thus, it was assumed that the signals for the methyl groups 23 and 24 were observed in every spectrum including the "zero" spectrum, but that for the remaining six methyl groups only the signals in the range $0.5 < [L]/[S] < 1.0$ were available. First the shifts for methyls 23 and 24 were used to obtain corrected shift reagent coordinates in the usual way (3). Then the remaining signals were plotted against these corrected values. As Tables 1 and 2 show, slope ratios and intercepts for methyl groups 25–30 agree well with the values obtained previously.

To conclude we have shown that the excellent correlation between the chemical shifts for the different nuclei in the substrate molecule makes it possible to convert partially or completely nonlinear plots to perfectly linear plots, from which highly accurate intercepts and slope ratios can be obtained even for nuclei whose signals can only be observed in the non-linear region of the original plots.

Kinetics of Charge Scavenging in γ Irradiated Liquids with Large Free Ion Yields[1]

JEAN-POL DODELET AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton 7, Alberta

Received February 11, 1972

The extent to which the calculated scavenging yields are affected by the form of the ion–electron spacial distribution decreases as the free ion yield increases. The increasing free ion yield may be due to larger electron ranges or to a larger dielectric constant. The free ion yields in neopentane and water are respectively 1.0 (due to large electron ranges) and 2.7 (due to large dielectric constant). The scavenging yields in neopentane calculated with three different forms of spacial distribution, using the forced diffusion (FD) approximation, are significantly affected by the form of the spacial distribution. The scavenging yields in water calculated with four different forms of spacial distribution, using the FD approximation, are all within the experimental error of the measured yields. Use of the prescribed diffusion (PD) approximation permits satisfactory yields to be calculated for neopentane, but leads to the unsatisfactory result that all of the secondary electrons in the liquid have the same range (delta function distribution YD). The scavenging yield curves obtained using the PD approximation for water did not have a steep enough slope even when the distribution YD was used; YD leads to a steeper slope than any other form of distribution. The PD approximation gives an overestimate of the breadth of the geminate neutralization time distribution. The calculated time required for half of the geminate neutralization reaction to occur is similar whether the FD or PD approximation is used, but the spread of the neutralization times is an order of magnitude greater from the latter than from the former. Calculations were also done for electron scavenging in methylcyclopentane and in methanol. Methylcyclopentane behaves like cyclohexane and methanol behaves much like water with regard to the kinetics of ion–electron reactions in the spurs.

Les courbes de capture calculées réagissent d'autant moins au changement de la distribution des interdistances initiales ion–électron que le rendement en ions libres augmente. De grandes distances de pénétration électronique ou une constante diélectrique importante peuvent, entre autres, être responsables de l'accroissement de ce dernier. Le rendement en ions libres vaut 1.0 pour le néopentane (grande distance de pénétration) et 2.7 pour l'eau (constante diélectrique importante). Les rendements de capture calculés pour le néopentane, dans l'approximation de la diffusion forcée, FD, au moyen de trois distributions spatiales, réagissent à la forme de ces distributions. Dans le cas de l'eau, quatre distributions furent utilisées pour l'approximation FD. Les différences dans les résultats sont de l'ordre de grandeur des erreurs expérimentales. L'approximation de la diffusion prescrite, PD, donne des rendements calculés en bon accord pour le néopentane mais aboutit à la conclusion gênante que les distances de pénétration attribuées aux électrons secondaires sont identiques (fonction de distribution delta: YD). Les courbes de capture obtenues avec l'approximation PD, pour l'eau, n'ont pas une pente assez raide même pour une distribution YD; cette dernière donne pourtant la pente la plus raide. L'approximation PD conduit à une surestimation de la dispersion des temps de neutralisation dans les grappes. Le temps de demi-vie des ions dans ces grappes est semblable pour les deux approximations alors que la dispersion des temps de neutralisation est environ un ordre de grandeur plus grande pour l'approximation PD. Des courbes de capture furent également calculées pour le méthylcyclopentane et le méthanol. La cinétique des réactions ion–électron dans les grappes est similaire pour le méthylcyclopentane et le cyclohexane; c'est également le cas pour le méthanol et l'eau.

Canadian Journal of Chemistry, **50**, 2729 (1972)

Introduction

In a recent article, a stochastic model of charge scavenging in γ irradiated liquids was examined to determine to what extent the calculated scavenging yields were affected by the initial shape of the ion–electron spacial distribution and by the temporal form of the drift and diffusion that was assumed for the

[1]Supported by the National Research Council of Canada.

For personal use only.

charges in an ion–electron pair (1). The examination was made for a typical saturated hydrocarbon that has often been studied, namely, cyclohexane. It was found that in the original model (2), the calculated yields at low and high scavenging concentrations were affected by the form of spacial distribution that was assumed. The yields in the middle of the scavenging range are not affected by the assumed form of the spacial distribution because the scavenging efficiency parameter is always adjusted to make the model fit in this region. It is necessary to focus one's attention on the ends of the scavenging curves. The low-concentration end is to be preferred for experimental and theoretical reasons.

It was also found (1) that use of the prescribed diffusion approximation in the model reduced the sensitivity of the model to the initial form of the ion–electron distribution. However, there was an indication that the prescribed diffusion approximation led to an exaggerated spread of neutralization times in the liquid.

The radiolyses of most liquid hydrocarbons are characterized by low free ion yields, $G_{fi} = 0.1–0.2$ (3–6), as is cyclohexane. The stochastic model has also been applied to charge scavenging in the γ radiolysis of liquids that have large free ion yields, such as neopentane (7) and water (8), which have $G_{fi} = 1.0 \pm 0.1$ (4, 7, 9) and 2.7 ± 0.1 (8, 10), respectively.[2] The free ion yield in neopentane is large because the ranges of the secondary electrons in that liquid are unusually long; the yield in water is large because of the high dielectric constant of that liquid. The magnitudes of the electron range and dielectric constant are also important in the scavenging kinetics. It is, therefore, desirable to extend the earlier examination of the kinetics model (1) to the neopentane and water systems. The purpose of this article is to report the results of the extended examination. Calculations have also been done on the methanol and methylcyclopentane systems and are briefly mentioned.

Theory

The model concerns the competition between geminate neutralization of the ions and electrons in radiolytic spurs and reaction of the ions or electrons with solute molecules.

Diffusion Approximations and Geminate Neutralization Times

The model involves the time required for geminate neutralization to occur. Two different diffusion approximations have been used (1, 2, 12, 13). In much of the earlier work (2, 8, 12, and others) a "forced diffusion" (FD) approximation was used in which only the drift of the ion and electron in their mutual electric field was considered; the "spreading" effect of Brownian motion on the geminate neutralization time was neglected. In the FD approximation, the time $t_{gn}(y)$ required for the geminate neutralization of a thermalized electron–ion pair that has an initial separation distance y is given by eq. 1 (12).

$$[1] \quad t_{gn}(y) = 2.3 \times 10^6 \, \varepsilon y^3 (u_+ + u_-)^{-1} \text{ s}$$

where ε is the dielectric constant of the liquid and u_+ and u_- are the mobilities of the ion and electron, respectively. In this approximation, for a given value of y, the probability that neutralization has occurred at time t is zero for $t < t_{gn}$ and unity for $t \geqslant t_{gn}$. A distribution of neutralization times is generated by a distribution of y values.

The second treatment of the neutralization time (13) was based on the prescribed diffusion (PD) approximation in which Brownian motion in a coulomb field was considered; it was assumed that the spacial distribution of the ions and electrons, averaged over all the spurs, remained in the Gaussian form at all times. Associated with each initial separation distance y for an assembly of pairs there is a distribution of neutralization times that is assumed to be described by eq. 2 (13).

$$[2] \quad -dF_y(t) = \frac{\xi^2 F_y(t)}{\varepsilon k T (4\pi D)^{1/2} t^{3/2}} \exp(-y^2/4Dt)\, dt$$

where $-dF_y(t)$ is the fraction of ion pairs that begin at $t = 0$ with intradistance y and undergo neutralization during the interval between the times t and $t + dt$, $F_y(t)$ is the probability that a pair beginning at y remains unneutralized at time t, ξ is the electronic charge, k is Boltzmann's constant, T is the absolute temperature, and D

[2]See also Table III of ref. 11 and references therein to the work of Allen, Hochanadel, Matheson, Gordon, Hart, and others.

is the sum of the diffusion coefficients of the ion and electron ($D = kT(u_+ + u_-)/c$, where c is the unit electronic charge).

Scavenging Equations

Introduction of an electron scavenger into the liquid puts the electron neutralization reaction into competition with scavenging. The time limit during which scavenging can occur is the normal neutralization time of the electron. The free ions have relatively long lifetimes under normal radiolysis conditions and are much more readily scavenged than are those that undergo geminate neutralization. The probability ϕ_y^{fi} that an ion–electron pair will become free ions is

$$[3] \qquad \phi_y^{fi} = \exp\ (-\xi^2/\varepsilon kTy)$$

and the probability of their being scavenged is usually taken as unity at all scavenger concentrations greater than zero (2).

Using the FD approximation, the total probability Φ_y^{FD} that an electron in a pair with an initial separation distance y will be scavenged is given by eq. 4 (1, 2).

$$[4] \quad \Phi_y^{FD} = \phi_y^{fi} + (1 - \phi_y^{fi})[1 - (1 - fN_s)^{1.4 \times 10^7\, \varepsilon y^3 \beta}]$$

where $(1 - \phi_y^{fi})$ is the fraction of the ions that undergo geminate neutralization, f is the encounter efficiency of the scavenging reaction, N_s is the mole fraction of scavenger in the solution, and β is an adjustable parameter that relates to the relative motions of the electron, its parent positive ion and the scavenger molecules. For the sake of simplicity, the value of f is taken as unity in the present work.

Alternatively, if the PD approximation is used, the total probability Φ_y^{PD} that an electron in a pair with an initial separation distance y will be scavenged is described by eq. 5 (1).

$$[5] \qquad \Phi_y^{DP} = 1 + \int_{t=0}^{\infty} (1 - fN_s)^{\alpha t}\, dF_y(t)$$

where α is the number of new molecules that an electron meets per unit time.

In any given system, there is a distribution of y values. One may represent by $F(y)dy$ as the fraction of thermalized pairs that have initial intradistances between y and $y + dy$. The final expression for the total scavenging efficiency to be used with either eq. 4 or eq. 5 is

$$[6] \qquad \Phi = \int_{y=0}^{\infty} F(y)\Phi_y\, dy$$

Nitrogen yields from nitrous oxide solutions are calculated from eq. 7. The small g is used to signify a scavenging yield (1).

$$[7] \qquad g(N_2) = \Phi g(N_2)_{max}$$

Distribution Functions F(y)

Different forms of the pair intradistance function $F(y)$ have been used by various authors; a summary is given in ref. 1. The present work includes four forms:

(*a*) YP, a power function (1, 14)

$$[8] \quad \begin{cases} F(y) = x y_{min}^{x} y^{-(x+1)} & y \geqslant y_{min} \\ F(y) = 0 & y \leqslant y_{min} \end{cases}$$

(*b*)YD, a delta function, which is the particular case of YP with $x = \infty$ and $y = y_{min} = y_d$ for all pairs;

(*c*) YG, a single parameter, 3-dimensional Gaussian function

$$[9] \qquad F(y) = (4y^2/\pi^{1/2}b^3) \exp\ (-y^2/b^2)$$

where b is the dispersion parameter.

(*d*) YSE, a semi-empirical function used in the original work (2, 3).

Calculations of Scavenging Yields

Nitrogen yields were calculated with eq. 7 for solutions of nitrous oxide in neopentane and in water. Calculations were first done using the FD approximation (eq. 4), then repeated using the PD approximation (eq. 5). In each set of calculations, all of the above mentioned forms of $F(y)$ function were tried, with the exception of YSE in neopentane because YSE is not suitable for the large y values in that liquid (7). The values of the parameters y_d and b in YD and YG, respectively, were determined with the aid of the general plots in Fig. 1.

The experimental quantities needed for the calculations are listed in Table 1.

Details of the computer calculation method were reported in ref. 1. Theoretical yields $g(N_2)_{calc}$ were calculated as functions of the mole fraction of nitrous oxide in solution. Depending upon the neutralization time approximation used, the value of the parameter α or β

was adjusted to give the best agreement with the experimental points (7, 8, 15, 16). The best agreement was chosen to give the minimum $\overline{\Delta g}$

$$[10] \qquad \overline{\Delta g} = \frac{1}{n}\sum_{i=1}^{n} |g(N_2)_{calc} - g(N_2)_{exp}|$$

where n is the number of experimental points.

It should be mentioned that the static dielectric constant was used for all the calculations in both liquids. The average value of the dielectric constant ε_{av} of the medium with respect to the pair of charges during the geminate neutralization time may be taken as (17)

$$[11] \qquad \varepsilon_{av} = \varepsilon_\infty + \frac{\varepsilon_0\tau}{t_{gn}} \times \ln\left\{\frac{1+[(\varepsilon_\infty-\varepsilon_0)/\varepsilon_0]\exp(-\varepsilon_\infty t_{gn}/\varepsilon_0\tau)}{1+[(\varepsilon_\infty-\varepsilon_0)/\varepsilon_0]}\right\}$$

where ε_∞ and ε_0 are the static and high frequency values of ε and τ is the dielectric relaxation time. Charge–dipole interactions probably reduce τ below the normal value that is measured with weak fields such as those in microwave beams (18). In neopentane $\varepsilon_{av} = \varepsilon_\infty$ because $\varepsilon_\infty = \varepsilon_0$. In water at 296 K one has $\varepsilon_0\tau/\varepsilon_\infty \leqslant 5.7\times10^{-13}$ s (19), so $\varepsilon_{av} \simeq \varepsilon_\infty$ at all times used in the present work.

The results obtained for the different $F(y)$ distributions in neopentane and in water are presented in Table 2 for the forced diffusion (FD) approximation and in Table 3 for the prescribed diffusion (PD) approximation. The findings are discussed below under several headings.

Electron Ranges

It had been found that the calculated median range y_{med} of the electrons in cyclohexane

[a] y_{med} is the median value of y.
[b] This value is slightly smaller than that in Table 2 because the static dielectric constant was used in the present calculation.

depended greatly on the form of $F(y)$ distribution used, varying from 19 to 76 Å (1). It can be seen from Tables 2 and 3 that the calculated values of the median range in neopentane and in water are much less dependent on the form assumed for $F(y)$. The electron ranges in neopentane are an order of magnitude greater than those in water.

Profiles of the different $F(y)$ distributions for neopentane and water are shown in Figs. 2 and 3, along with the escape probabilities ϕ_y^{fi}. The curves for cyclohexane are included in Fig. 2 for comparison. The total area under each distribution curve is $\int_0^\infty F(y)dy = 1$. The greater dependence of y_{med} on $F(y)$ in cyclohexane is due to the small free ion yield and the different lengths of the tails of the distributions at high y values. In these calculations, the y distributions are adjusted to fit the free ion yields (1): $g_{fi} = g_{max} \int_0^\infty F(y)\phi_y^{fi}dy$. This means that when g_{fi} is small, the entire distribution is adjusted to suit a minor portion of it, and a serious error can result if the correct form of the function is not used. When g_{fi} is large, as it is in neopentane

and water, the function is adjusted to fit a large fraction of the y distribution. In this case, a smaller error results from the use of an inexact form of the distribution function.

Comparison of Results from the FD and PD Approximations

The best yield curves calculable using the FD and PD approximations for neopentane and water are shown with the experimental points in Fig. 4. The plots for the two systems are made on the same size of scale to facilitate comparison.

Concerning the choice of $F(y)$ distribution, all four of the "best" curves are obtainable using the YP function. This is not surprising because YP contains two adjustable parameters, namely, x and y_{min}, whereas YD and YG each contain one, y_d and b, respectively, and YSE contains none (1).

The best YP distribution for use with the FD approximation has $x = 1.4$ for neopentane and $x = 2.0$ for water (Table 2 and Figs. 2 and 3). Both of these distributions have a spread of y values that does not seem unreasonable. By contrast, the best YP distribution for use with the PD approximation has $x = \infty$ in both solvents (Table 3). YP with $x = \infty$ is YD, which would imply that all of the electrons in a given liquid have the same penetration range, which cannot be true. As the value of x in YP is increased, the calculated yield curve becomes steeper in slope in its central portion. With the PD approximation, a steep enough slope could be obtained for neopentane by using $x = \infty$ (Fig. 3), but for water even $x = \infty$ did not provide a steep enough slope in the calculated yield curve (Fig. 3). The value $G_{fi} = 2.7$ in water seems to be well established (8, 10, 11), but that of G(total ionization) is not. Better results could be obtained with the PD approximation by using a larger value of $g(N_2)_{max}$ and smaller values of y_{med} (hence of y_d or b) and α. However, the difficulty of providing a steep enough scavenging curve with the PD approximation indicates that the latter leads to an overestimate of the breadth of the distribution of neutralization times.

Neutralization time distributions that were calculated using the FD approximation are shown for the best y distribution of each form in Fig. 5. All the curves begin at the total ionization yield and decrease to the free ion yield in the time range displayed. Neutralization times calculated from the PD approximation are shown in Fig. 6. To facilitate comparison of the dispersions of the ion lifetimes obtained from the two diffusion approximations, the YG curves from Fig. 6 are included in Fig. 5. The exaggeration of the dispersion of lifetimes due to the PD approximation is especially serious in water, which supports the conclusion drawn from Fig. 4.

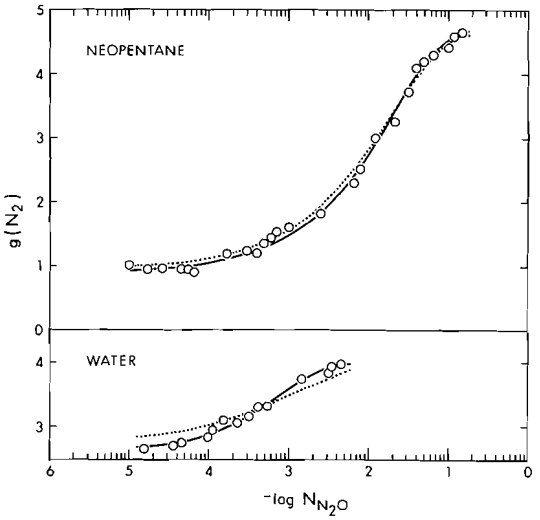

FIG. 4. Best scavenging yield curves for neopentane and water calculable using the FD (—) and PD (...) approximations. All four curves were obtainable using the YP distribution functions (Tables 2 and 3). The experimental points (○) represent nitrogen yields from nitrous oxide solutions in neopentane (7) and water (8, 15, 16). N_{N_2O} is the mole fraction of nitrous oxide.

Information derived from Figs. 5 and 6 is summarized in Table 4. It appears that geminate neutralization in neopentane is two orders of magnitude more rapid than that in water. The calculated time required for half of the geminate neutralization to occur is only slightly dependent on the diffusion approximation used. However, the dispersion of the neutralization times, represented by the spread between the times when 10% and 90% of the geminate neutralization have occurred, is an order of magnitude greater with the PD than with the FD approximation.

One should remember that all these calculations have been done with a single-pair-spur model. Introduction of a distribution of spur populations into the model would significantly reduce the calculated geminate neutralization

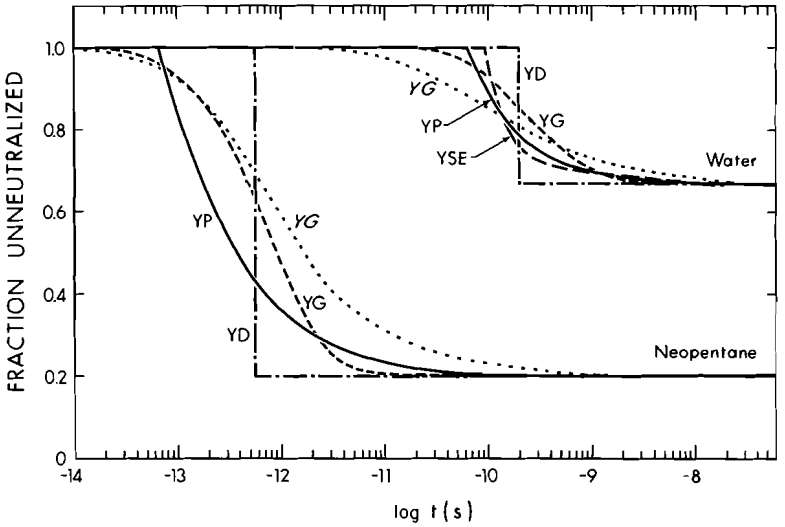

FIG. 5. Ion–electron neutralization time distributions calculated for neopentane and water, using the FD approximation and the $F(y)$ functions indicated. The ... curves were obtained using the PD approximation and YG and are included for comparison.

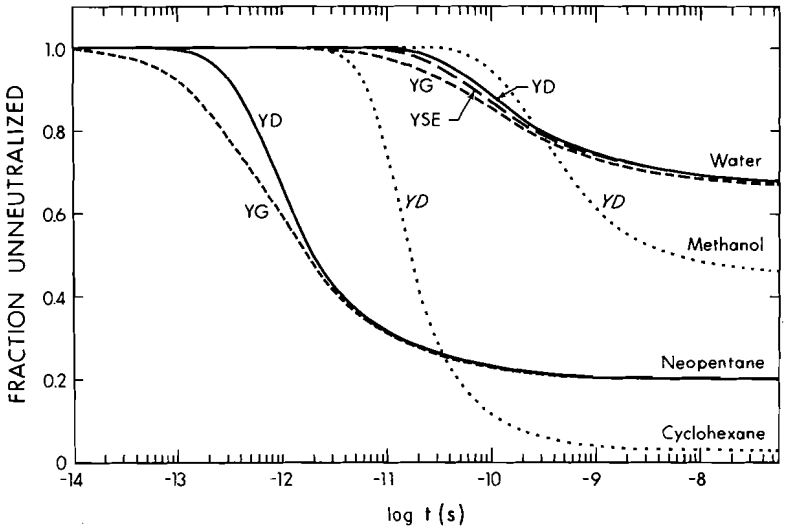

FIG. 6. Ion–electron neutralization time distributions calculated for neopentane and water, using the PD approximation and the $F(y)$ functions indicated. The ... curves were calculated for cyclohexane and methanol using the PD approximation and YD, and are included for comparison.

times, especially in water. Results of Hunt and co-workers (20, 21) seem to require shorter neutralization times than those calculated here for water. It might also be necessary to use a larger diffusion coefficient for the electrons that undergo geminate neutralization in water than that measured for the free ion-solvated electrons, as has been suggested by Hamill and co-worker (22, 23) and Mozunder (13).

Influence of Changing the Form of $F(y)$

The PD approximation does not allow satisfactory results to be obtained with reasonable forms of the $F(y)$ distribution, so the remaining discussion concerns only the model containing the FD approximation.

Values of $[g(N_2) - g(N_2)_{fi}]$ are plotted against the square root of the nitrous oxide concentration in neopentane (7) and water (8, 15, 16) in

[c]Time required for the fraction unneutralized to reach $(1.0–0.5\phi_{gn})$, where ϕ_{gn} is the fraction of electrons that undergo geminate neutralization.
[d]Time required for the fraction unneutralized to pass from $(1.0–0.1\phi_{gn})$ to $(1.0–0.9\phi_{gn})$.

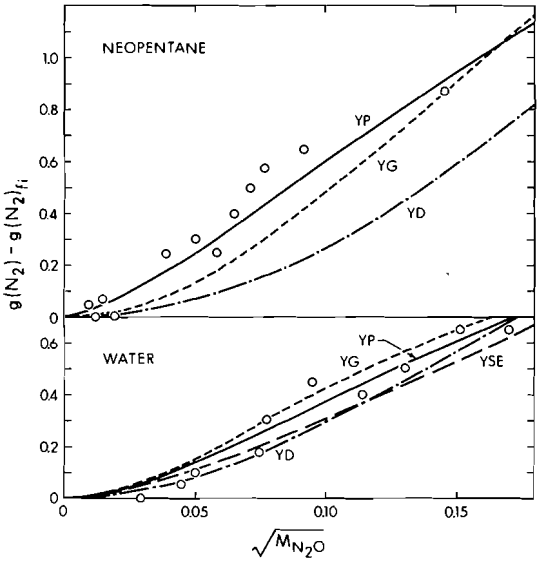

FIG. 7. Best scavenging yield curves for neopentane and water calculable using the FD approximation and the $F(y)$ distributions indicated. The experimental points (○) represent yields of nitrogen formed in spur reactions in nitrous oxide solutions in neopentane (7) and water (8, 15, 16); $g(N_2)_{fi} = 0.95$ in the former and 2.7 in the latter were used. M_{N_2O} is the molarity of nitrous oxide.

Fig. 7. The best curves calculable with the various forms of $F(y)$ distribution are also shown. Each curve was calculated for the total set of experimental results from a given solvent, shown in Fig. 4. Only the low concentration ends of the curves are displayed in Fig. 7 because only the ends of the curves can be affected by the form of the $F(y)$ distribution in the model calculations.

Calculated yields for neopentane solutions are affected by the form of $F(y)$, as shown in Fig. 7 and Table 2, but less so than were the yields in cyclohexane (1). The distribution YP gives the best agreement with experiment in both systems. The calculated yields for aqueous solutions are less affected by the form of $F(y)$; all the scavenging curves are within the uncertainty of the experimental points (Fig. 7). The influence of the form of $F(y)$ is greater when the geminate neutralization yield is greater.

Calculations for Methylcyclopentane and Methanol Systems

Electron neutralization times and scavenging probabilities were also calculated for methylcyclopentane and methanol solvents. Experimental scavenging yields were taken from refs. 24 and 25 for comparison. Other data necessary for the calculations are given in Table 1.

Calculations using the FD approximation were done for both systems and the results are summarized in Table 2. Methylcyclopentane behaves essentially the same as cyclohexane (1) and methanol behaves much like water.

The PD approximation was also used with the methanol system and it was found that a steep enough scavenging curve could not be obtained even with YP. This substantiates the conclusion that the prescribed diffusion approximation overestimates the breadth of the distribution of neutralization times.

Neutralization time distributions calculated using the PD approximation and YD for methanol and cyclohexane are shown in Fig. 6 for comparison with those obtained for neopentane and water. The cyclohexane curve falls between those of neopentane and water, while the methanol curve is near to that of water.

Mechanistic Information on the Aquations of Complexes of the Pentaamminecobalt(III) Series from Kinetic Studies at High Pressures

W. E. JONES, L. R. CAREY, AND T. W. SWADDLE[1]

Department of Chemistry, The University of Calgary, Calgary 44, Alberta

Received March 22, 1972

The logarithm of the pseudo-first-order rate coefficient k for the aquation of $Co(NH_3)_5X^{(3-n)+}$ can be represented by a quadratic equation in the pressure P, or, better, by

$$\ln k = \ln k_0 - P\Delta V_0^*/RT - (30.17x/T)[(P + 3.06)\ln(1 + P/3.06) - P]$$

where P is in kbar, ΔV_0^* is the volume of activation at $P = 0$, and x is the increase in the number of water molecules solvating the complex as it goes to the transition state. For $X^{n-} = SO_4^{2-}$, Cl^-, Br^-, NO_3^-, and N_3^- at 25° (75° for N_3^-) and ionic strength $I = 0.1$ M $LiClO_4/HClO_4$, $\Delta V_0^* = -18.5$, -10.6, -9.2, -6.3, and $+16.8$ cm^3 mol^{-1}, and $x = 8.0$, 4.1, 3.9, 1.9, and -4.2; for $X^{n-} = NCS^-$, the mean ΔV^* from $P = 0.001$ to 2.5 kbar at 88° is -4 cm^3 mol^{-1}. Detailed consideration of these data, especially their correlation with the molar volume of reaction by a straight line of unit slope for $X^{n-} = SO_4^{2-}$, Cl^-, Br^-, NO_3^-, and H_2O, provides strong evidence for a dissociative interchange mechanism. For $X^{n-} = N_3^-$, the separating entity is probably HN_3 rather than N_3^-. For $X^{n-} = NCS^-$, aquation is incomplete, at practical complex concentrations; at 88.0°, 1 bar, and $I = 0.1$ M $LiClO_4/HClO_4$, $k = 3.3 \times 10^{-6}$ s^{-1} and the stability constant of $Co(NH_3)_5NCS^{2+}$ is 490 M^{-1}.

Le logarithme du coefficient de vitesse d'ordre pseudo-un, k, pour l'hydratation de la molécule $Co(NH_3)_5X^{(3-n)+}$, peut être représenté au moyen d'une équation quadratique impliquant la pression P, soit

$$\ln k = \ln k_0 - P\Delta V_0^*/RT - (30.17x/T)[(P + 3.06)\ln(1 + P/3.06) - P]$$

où P est en kbar, ΔV_0^* est le volume d'activation à $P = 0$ et X est l'augmentation du nombre de molécules d'eau solvatant le complexe lorsqu'il passe vers l'état de transition. Dans le cas de $X^{n-} = SO_4^{2-}$, Cl^-, Br^-, NO_3^- et N_3^- à 25° (75° pour N_3^-), une force ionique $I = 0.1$ M $LiClO_4/HClO_4$, $\Delta V_0^* = -18.5$, -10.6, -9.2, -6.3 et $+16.8$ cm^3 mol^{-1}, $x = 8.0$, 4.1, 3.9, 1.9, et -4.2; pour $X^{n-} = NCS^-$, la valeur moyenne de ΔV^* à $P = 0.001$ à 2.5 kbar à 88° est de -4 cm^3 mol^{-1}. L'étude détaillée de ces résultats, spécialement leur relation avec le volume molaire de réaction par une ligne droite de pente unitaire pour $X^{n-} = SO_4^{2-}$, Cl^-, Br^-, NO_3^-, et H_2O, fournit la preuve d'un mécanisme d'échange dissociatif. Pour $X^{n-} = N_3^-$, l'entité de séparation est probablement HN_3 plutôt que N_3^-. Pour $X^n = NCS^-$ l'hydratation est incomplète, à des concentrations habituelles de complexe; à 88.0°, 1 bar et $I = 0.1$ M $LiClO_4/HClO_4$, $k = 3.3 \times 10^{-6}$ s^{-1} et la constante de stabilité de $Co(NH_3)_5NCS^{2+}$ est 490 M^{-1}.

Canadian Journal of Chemistry, **50**, 2739 (1972)

Introduction

Of the various activation parameters that characterize the kinetics of a chemical reaction in terms of transition-state theory, the volume of activation ΔV^* is potentially the most useful criterion of reaction mechanism, because the spatial requirements of the various alternative models can be visualized relatively easily. We have therefore measured the pressure dependence of the pseudo-first-order rate coefficients k of reactions of the type

$$[1]\quad Co(NH_3)_5X^{(3-n)+} + H_2O \xrightarrow{k} Co(NH_3)_5OH_2^{3+} + X^{n-}$$

In a preliminary note (1), it was remarked that ΔV^* for reaction 1 is in general pressure-dependent, but that ΔV_0^* ($= \Delta V^*$ at zero pressure) was almost equal to the molar volume of reaction ΔV for $X^{n-} = Cl^-$, Br^-, NO_3^-, and SO_4^{2-}, which suggested a dissociative mechanism (I_d or D, in the nomenclature of Langford and Gray (2)). We now present a full account of that work, together with new data for $X^{n-} = N_3^-$ and NCS^- and an analysis of the pressure dependence of ΔV^*.

Perchlorate salts of the ions $Co(NH_3)_5X^{(3-n)+}$ were used for all the kinetic measurements, and were made by precipitation of the cation from aqueous solution with 72% perchloric acid or sodium or ammonium perchlorate. Salts of the ions for which $X^{n-} = Cl^-$, Br^-, NO_3^-, and N_3^- were made by published methods (3–7). The purity of the products was checked by microanalysis and by comparing the ultraviolet–visible solution spectra with published data where available.

For $X^{n-} = SO_4^{2-}$, carbonatopentaamminecobalt(III) nitrate (11.5 g) was dissolved in 6 *M* H_2SO_4 (50 ml) and kept at 75° for 1.5 h; on adding 50 ml water and 20 g NH_4ClO_4 (not all of which dissolved) and cooling to 0° for 2 h, a red impurity was precipitated first and was rejected.[2] Further cooling yielded red crystals which, after recrystallization from 2 *M* aqueous $NaClO_4$, washing with alcohol and ether and drying *in vacuo*, were shown spectroscopically (8) to be $[(NH_3)_5CoSO_4]ClO_4$.

Anal. Calcd. for $[(NH_3)_5CoSO_4]ClO_4$: N, 20.63; H, 4.6. Found: N, 20.98; H, 4.8.

For $X^{n-} = NCS^-$, aquopentaamminecobalt(III) perchlorate (15 g) was heated in 400 ml water containing 1 ml glacial acetic acid and 15 g NaNCS for 1.5 h at 80–90°, then filtered hot into a hot solution of 30 g NH_4ClO_4 in water (total volume 80 ml). On cooling the solution in ice, red crystals of $[(NH_3)_5CoNCS](ClO_4)_2$ separated; recrystallization was found to be unnecessary.

Anal. Calcd. for $[Co(NH_3)_5NCS](ClO_4)_2$: N, 20.95; C, 2.99; H, 3.77. Found: N, 20.89; C, 3.00; H, 3.90.

At the 306 nm absorption maximum, $\varepsilon = 1500\ M^{-1}\ cm^{-1}$.

Kinetic Measurements

For the aquations of the chloro-, bromo-, nitrato-, and sulfato-complexes, the reaction mixtures were prepared by dissolving a known weight of the perchlorate salt in 100 ml 0.1 *M* $LiClO_4$ which was 5.0×10^{-5} *M* in $HClO_4$. The solution was placed in a 100 ml commercial glass syringe, and this was enclosed in a thermostated (25.00 ± 0.01°) pressure vessel as previously described (9). The assembly was left for about 1 h after initial pressurization, in every case, to attain full thermal equilibrium; this time was short relative to the half-lives of the reactions under investigation.

At selected intervals, samples were withdrawn from the syringe through a tantalum capillary tube, and were chilled at once to 0°; experiments using a Hastelloy B capillary failed because this alloy slowly reduced the cobalt complex, especially at high acidities. The optical absorbances of the samples were determined (at 20°) at 280 ($X^{n-} = SO_4^{2-}$), 282 (Cl^-), 300 (NO_3^-), and 310 nm (Br^-), using a Cary 15 spectrophotometer. Absorbances at "infinite time" were very small, and were obtained either by direct measurement after 10 half-lives of the aquation reaction, or by calculation from known molar absorbancy indices. Some runs at atmospheric pressure were made in darkened, stoppered Pyrex vessels instead of the pressure assembly, to check for possible catalysis by the components of the assembly.

The aquation of the azido-complex was studied similarly, but at 75.00 ± 0.05° and with $[HClO_4] = 1.0 \times 10^{-3}$ *M* and $[LiClO_4] = 0.10$ *M*; it was shown that, under these conditions, contributions to the aquation rate by hydrogen-ion-dependent pathways were negligible.

The aquation of the *N*-thiocyanato-complex was studied at 88.00 ± 0.05°, with $[HClO_4] = 0.10$ *M or* with $[HClO_4] = 0.01$ *M* and $[LiClO_4] = 0.09$ *M*. Runs at atmospheric pressure were carried out in sealed Pyrex tubes which were wrapped in aluminum foil to exclude light. Optical measurements were made at 306 nm.

Molar Volumes of Reaction

All attempts to measure the molar volume change ΔV for the aquation of $Co(NH_3)_5N_3^{2+}$ by Spiro's dilatometric method (10) failed because of the precipitation of hydrous cobalt oxides under the conditions of alkalinity and temperature needed to obtain sufficiently rapid hydrolysis. Trial experiments with bromopentaamminecobalt(III) perchlorate, on the other hand, confirmed the results of Spiro *et al.* (10). No attempt was made to measure ΔV for the poorly soluble and kinetically inert thiocyanato-complex.

Spectroscopic Studies at High Pressures

The apparatus previously described (11) was used to study the effects of pressure on the visible spectrum of aqueous $[(NH_3)_5CoOH_2](ClO_4)_3$.

Results

The aquations of $Co(NH_3)_5X^{(3-n)+}$ were accurately first-order in complex ion to at least 80% completion of reaction, except for $X^{n-} = NCS^-$, for which the rate of decay of optical density at 88° in 0.01 or 0.10 *M* $HClO_4$ was in accordance with incomplete aquation:

$$[2]\quad (NH_3)_5CoNCS^{2+} + H_2O \rightleftharpoons (NH_3)_5CoOH_2^{3+} + NCS^-$$

The corresponding rate law is

$$[3]\qquad kt = \frac{(c_0 - c_\infty)}{(c_0 + c_\infty)} \ln \frac{(c_0^2 - c_t c_\infty)}{c_0(c_t - c_\infty)}$$

where c represents the concentration of the thiocyanato-complex at times 0, t, and ∞. Since the dimensions cancel, and since the combined molar optical absorbances of the products were 1% of that of $Co(NH_3)_5NCS^{2+}$, absorbance readings were substituted directly into eq. 3. In practice, c_∞ could not be measured directly because of the slow decomposition of the reaction products at 88°. Thus, we have found spectrophotometrically that $Co(NH_3)_5OH_2^{3+}$ (6.0×10^{-3} *M*) in 0.1 *M* $HClO_4$ decomposes to Co^{2+} with a half-period of about 60 h at 102°. Furthermore, it is known (12, 13) that thiocyanate ion, though kinetically stable in neutral aqueous solution up to 180–200°, is hydrolyzed to H_2S, CO_2, and NH_4^+ in acidic solutions at relatively low temperatures, and indeed we have observed that 0.05 *M* NCS^- in 0.10 *M* $HClO_4$

[2]Throughout this article, *M* signifies mol l^{-1} of solution as measured at 25.0° and 1.0 bar pressure.

developed a slight but unmistakable odor of H_2S in less than 0.4 h in a sealed vessel at 90°.

Accordingly, in the analysis of rate data for experiments at 1 bar pressure, c_∞ was treated as a variable, along with k, in a least-squares fit of the data to eq. 3 using an IBM 360/50 computer. Thus, both k and (from c_∞) the stability constant K of the thiocyanato complex could be obtained; at 88.0°, $[H^+] = 0.01$ M, ionic strength $I = 0.1$ M and c ranging from 2.5×10^{-4} to 1.0×10^{-3} M, $K = (4.9 \pm 0.4) \times 10^2$ M^{-1}. In general, however, more accurate values of k (especially at high pressures) could be obtained by graphical treatment of the first 10–15% of the aquation reaction as first-order in thiocyanato-complex, assuming 100% aquation at infinite time; this procedure does not yield K values, but these were in any event neither very accurate nor germane to the purpose of this study. The k values so obtained were reliable to $\pm 0.2 \times 10^{-6}$ s^{-1} and were the same (within this uncertainty) for both 0.10 M $HClO_4$ and 0.01 M $HClO_4$/0.09 M $LiClO_4$; the value for 1 bar (Table 1) agrees satisfactorily with that interpolated from the measurements of Gay and Lalor (14), although these authors do not report the reversibility of eq. 2.

For all the other $Co(NH_3)_5X^{(3-n)+}$, the rate coefficients k were evaluated by the method of least squares and could be reproduced to within 2% at worst. Rate coefficients obtained at atmospheric pressure using conventional darkened Pyrex reaction vessels agreed within these limits with the k values obtained at atmospheric pressure in the pressure assembly, except where a Hastelloy "B" capillary was used (see under

Experimental). The results are summarized in Table 1.

Discussion

The volume of activation ΔV^* is defined by the equation

$$[4] \qquad (\partial \ln k/\partial P)_T = -\Delta V^*/RT$$

so that a plot of $\ln k$ *vs.* P is linear if ΔV^* is independent of pressure to within the experimental uncertainty. This is true (15) for the case $X^{n-} = H_2O$ in eq. 1, but not for any of the data listed in Table 1 (with the possible exception of $X^{n-} = NCS^-$, for which the experimental uncertainty is about four times that of the other cases). Thus, the problem is to choose an appropriate analytical function to give the best fit of the data with the minimum number of parameters, and so to extract the mechanistically-useful quantity ΔV_0^*. Golinkin *et al.* (16) favor an empirical quadratic in the pressure P

$$[5] \qquad \ln k = \ln k_0 + BP + CP^2$$

which yields $\Delta V_0^* = -RTB$, but which implies that $(\partial\Delta V^*/\partial P)_T$ is independent of pressure and equal to $-2RTC$. In fact, eq. 5 represents the data of Table 1 quite satisfactorily, and the corresponding values of ΔV_0^* and $(\partial\Delta V^*/\partial P)_T$ obtained in a least-squares fit are listed in Table 2.

Table 2 also lists values of ΔV, the molar volume change associated with the completed reaction 1, at 1 bar and 30.0°, corrected approximately to ionic strength $I = 0.1$ M from the data of Spiro *et al.* (10) for $I = 1.0$ M. For the aquation of $Co(NH_3)_5X^{2+}$, ΔV need only be made 1.2 cm^3 mol^{-1} more negative to accommodate this change in I; this correction originates entirely in the corresponding increase in ΔV for reaction 6, upon which the dilatometric method of Spiro *et al.* relies.

$$[6] \quad Co(NH_3)_5OH_2^{3+} + OH^- \rightarrow Co(NH_3)_5OH^{2+} + H_2O$$

We have taken the values of ΔV at $I = 0.1$ M for reaction 6, and for the aquation of $Co(NH_3)_5SO_4^+$, to be equal to those obtained by Spiro *et al.* (10) without added $NaClO_4$, as I was then not greatly different from 0.1 M.

An important deduction from the data of Table 2 is that ΔV_0^* is a linear function of ΔV for $X^{n-} = SO_4^{2-}$, Cl^-, Br^-, NO_3^-, and H_2O at least; ΔV values could not be obtained for $X^{n-} = N_3^-$ or NCS^-. Furthermore, the slope of the line is about 0.97, *i.e.*, close to unity, and this constitutes compelling evidence for a dissociative mechanism, since it indicates that the departing ion X^{n-} must be essentially as fully formed in the transition state as in the ultimate products. The straight line clearly includes the aquo-complex, and so confirms Hunt and Taube's conclusion (15) that the aquo-exchange reaction of $Co(NH_3)_5OH_2^{3+}$ is dissociatively activated.

There is substantial evidence (17–20) that the transition-state of reaction 1 may *not* be the same for all X^{n-}, and almost certainly does *not* comprise an independent $Co(NH_3)_5^{3+}$ species. Thus, the transition state probably has the structure $\{Co(NH_3)_5^{3+}, X^{n-}, y\,H_2O\}$, where X^{n-} remains within the bounds of the second

coordination sphere and y is large enough to permit full solvation of both $Co(NH_3)_5^{3+}$ and X^{n-}.

Our earlier remark (1) that ΔV_0^* was apparently *equal* to ΔV is perhaps misleading, as the near-equality resulted accidentally from the use of ΔV values for $I = 1.0$ M instead of 0.1 M. It is now clear that the ΔV_0^* values are, on the average, about 1 cm^3 mol^{-1} more negative than ΔV, *i.e.*, the intercept of the ΔV_0^* *vs.* ΔV plot is $\sim +1$ cm^3 mol^{-1} on the ΔV_0^* axis. We take this to mean that the bond-breaking component ΔV_b^* of ΔV_0^* is approximately constant for all X^{n-}, and could be conveniently set equal to ΔV^* for $X^{n-} = H_2O$, for which there is no electrostrictive component, ΔV_{el}^*. Writing ΔV_{el}^{0*} for ΔV_{el}^* at zero pressure, we have

$$[7] \qquad \Delta V_0^* = \Delta V_b^* + \Delta V_{el}^{0*}$$

This permits an approximate calculation of ΔV_{el}^{0*} for the complexes of anionic X, and, because ΔV^* (and hence ΔV_b^*) is independent of P for $X^{n-} = H_2O$ (15), the pressure dependence of ΔV^* for anionic X can be ascribed entirely to ΔV_{el}^*. The last column of Table 2 lists "electrostrictive compressibilities of activation", κ^*, defined as $-(\partial \Delta V^*/\partial P)_T/\Delta V_{el}^{0*}$; these values are not greatly different for the various X (mean value $(1.8 \pm 0.3) \times 10^{-4}$ bar^{-1}), which supports the notion that the pressure dependence of ΔV^* has in all these cases a common origin, *viz.*, increases in the degree of solvation of the complexes (or decrease, in the case of $X^{n-} = N_3^-$) as they go to the transition state of aquation.

These deductions suggest that the pressure dependence of ΔV^* might be better represented as arising entirely from the loss of compressibility of bulk water molecules when they enter the solvation sheath of an ion. The compressions $(V_0 - V_P)/V_0$ of aqueous solutions can be represented empirically by the modified Tait equation,

$$[8] \qquad (V_0 - V_P)/V_0 = \rho \log_{10} (1 + P/\Pi)$$

where ρ and Π are constants. We have

$$[9] \qquad \Delta V^* = \Delta V_b^* + x(V_{el} - V_{H_2O}) = \Delta V_0^* + 18.0x\rho \log_{10} (1 + P/\Pi)$$

where V_{H_2O} and V_{el} are respectively the molar volumes of bulk water and electrostricted water ($V_{H_2O} = 18.0$ cm^3 mol^{-1} at 1 bar and 25°), and x is the increase in the number of water molecules solvating the complex as it goes from the initial state to the transition state. V_{el} may be taken to be independent of pressure, since it is known that aqueous ions are intrinsically less compressible than bulk water. On integrating eq. 4 over the pressure range zero to P, we have

$$[10] \qquad \ln k_p = \ln k_0 - P\Delta V_0^*/RT - (18.0x\rho/2.303RT)[(\Pi + P) \ln (1 + P/\Pi) - P]$$

Table 3 lists values of ΔV_0^* and x obtained using $\Pi = 3.06$ kbar and $\rho = 0.321$, which apply for pure water at 25° over the pressure range used in these experiments (11); the data of Table 1 are significantly better represented by eq. 10 than by eq. 5 (the mean square error being 15% greater, on the average, for eq. 5). The use of Π and ρ values for 0.1 M aqueous perchlorate solutions (11) rather than pure water gave a slightly poorer fit of the experimental data; this is because the solvation of the complex ion involves bulk water *per se*, and should not be sensitive to the presence of moderate concentrations of other electrolytes in the solution.

The values of ΔV_0^* obtained from eq. 10 are only slightly numerically greater than those obtained from eq. 5, and are preferred because compression of the solvent is realistically (albeit empirically) represented by eq. 8, whereas eq. 5 has no basis in high-pressure physics. Hamann (21) has criticized Benson and Berson's (22) somewhat different application of the Tait equation in the interpretation of the pressure-dependence of ΔV^* in non-polar reactions, largely on the grounds that the Tait equation has no theoretical foundation (it is actually unrealistic,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in that it predicts negative volumes at very high pressures, *e.g.* above 4.0×10^6 bars for water) and that the Benson–Berson equation represents experimental data rather poorly. Hamann's theoretical objections obviously apply to eq. 10 also, but we have sought merely to allow for the compressibility of water as it applies to our model, without introducing an excessive number of parameters, and the quality of the fit of the data of Table 1 justifies our procedure.

Values of ΔV_0^* from Table 3 again give an excellent linear plot *vs.* ΔV (from Table 2), with a slope of 0.98 ± 0.01 and an intercept (identifiable with the mean value of ΔV_b^*) of $+1.3 \pm 0.1$ cm^3 mol^{-1}. A plot of x against ΔV_0^* is a smooth, gentle curve, rather than the straight line that would be anticipated if V_{el} were the same for all $Co(NH_3)_5X^{(3-n)+}$ aquations. Thus, it seems that V_{el} becomes somewhat greater when large numbers of water molecules are added to the complex as it goes to the transition state; this is perhaps to be expected, since, the larger the solvation sheath becomes, the less will be the central electrostatic field acting to compress the outer solvating water molecules. The slope of the curve at $x = 0$ is about -3.1 cm^3 mol^{-1}, so that $V_{el} \sim (18.0 - 3.1) = 14.9$ cm^3 mol^{-1} for the case $X^{n-} = H_2O$; thus the molar volume of water is about 1 cm^3 mol^{-1} larger in the second coordination sphere than in the first, according to Biltz's (23) estimate for the latter (14.0 ± 0.3 cm^3 mol^{-1}, mean of three different salts of $Co(NH_3)_5OH_2^{3+}$). The difference is thus comparable with ΔV_0^* ($= 1.2$ cm^3 mol^{-1}) for the aquo-exchange reaction, in accordance with the proposed I_d mechanism in which the Co—OH_2 bond is completely broken, and H_2O has a molar volume characteristic of the second coordination sphere, in the transition state.

Table 3 shows that ΔV_0^* increases monotonically as the conventional partial molal volume $\bar{V}^0$ of X^{n-}(aq) increases; an exact linear relationship would exist between $\bar{V}^0$ and the partial molal volume of the transition state, if the proposed I_d mechanism is correct, but the latter quantity is the sum of ΔV_0^* and the partial molal volume of $Co(NH_3)_5X^{(3-n)+}$(aq), which last is not known but can be expected to vary appreciably with X. Thus, ΔV_0^* is not expected to be a linear function of $\bar{V}^0$. Nevertheless, the relatively positive value of ΔV^* recorded for $X^{n-} = NCS^-$ is entirely consistent with the high $\bar{V}^0$ value of the aqueous thiocyanate ion; the discrepancy between the temperatures at which these parameters were measured is not important, since Millero's review (24) shows that $\bar{V}^0$ is not in general very sensitive to temperature over the range 0–90°.

On the other hand, the ΔV_0^* value for $X^{n-} = N_3^-$ is about 25 cm^3 mol^{-1} larger than predicted on the basis of $\bar{V}^0$. This striking aberration can be attributed to an anomalous mechanism in which HN_3 separates from a dipositive moiety, rather than N_3^- from $Co(NH_3)_5^{3+}$, so that some of the water solvating the ground state may actually be released, rather than further water electrostricted, on going to the transition state (7). The observed value of x supports this view. Alternatively, it may be that the *initial* state is unusually heavily solvated, because of hydrogen-bonding between the basic azide ligand and solvent water; probably, *both* of these factors contribute to the overall aquation mechanism, leading to extensive desolvation on going to the transition state. The nature of the dipositive moiety is an open question; the proton abstracted by the departing azide ion could come directly from the rather feebly-acidic ammine ligands, but a more likely source would be the water molecules of the solvation sheath of the cobalt complex, as these would be significantly more acidic than bulk water by virtue of the proximity of the metal ion. It should be noted that the solvation sheath can be regarded as a permanent integral part of the complex ion, for the short time needed to proceed from the ground state to the transition state.

It may be noted that ΔV_0^* tends in general to increase as the entropy of activation ΔS^* increases (for ΔS^* data, see refs. 25 and 26). However, the correlation is a rough one and does not appear to be linear (*cf.* Laidler and Chen (27)).

An intriguing feature of eq. 10 is that it purports to give the mean number x of molecules of water which are added to the complex (here considered as comprising both the first and second coordination spheres) in order to reach the transition state of aquation. As noted above, we should regard the second coordination sphere

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

as permanent for the duration of the single molecular vibration which takes the complex to the transition state and on toward the products. However, the number of water molecules in the second coordination sphere will fluctuate considerably about a statistical average; presumably, when an average of x additional waters happen to be present at a given time in the second coordination sphere, a wide excursion of a Co—X vibration can result in the transient formation of X^{n-} which, in these circumstances, can be "trapped" by solvation. On the other hand, if there are insufficient water molecules present to solvate X^{n-}, then X^{n-} will recombine with $Co(NH_3)_5^{3+}$ within the timespan of a molecular vibration.

The electrostrictive power of an ion is expected to be directly proportional to the square of its charge and inversely proportional to its effective radius (24). Indeed, we see from Table 3 that x increases ($NO_3^- < Br^- < Cl^-$) with the decreasing ionic size of X^{n-} and, for ions of comparable size, x increases sharply ($NO_3^- \ll SO_4^{2-}$) with increasing n in X^{n-}. For the anomalous case of $X^{n-} = N_3^-$, the x value indicates extensive *de*solvation on going to the transition state, in accordance with the HN_3 separation mechanism proposed above.

The slowness of substitution at cobalt(III) centers has been attributed (28, 29) to the loss of 4 Dq in ligand field stabilization energy (LFSE) on going from $Co(NH_3)_5X^{(3-n)+}$ to a $Co(NH_3)_5^{3+}$ ion of C_{4v} symmetry which, in the light of the above discussion and the fact that the aquation of *trans*-$Co(NH_3)_4(ND_3)Br^{2+}$ is stereoretentive (20), is a fairly accurate representation of the reaction mechanism as it involves the cobalt(III) center. A correlation may therefore be sought between the pressure dependence of the energy ($= 10\,Dq - C'$) of the first ligand field band ($^1T_{1g} \leftarrow {}^1A_{1g}$) of a cobalt(III) complex, and ΔV_b^*. For $Co(NH_3)_5OH_2^{3+}$, we have observed that the position of the maximum of the $^1T_{1g} \leftarrow {}^1A_{1g}$ band changes from 20 410 to 20 530 cm^{-1} ($\pm 0.2\%$), and that of the $^1T_{2g} \leftarrow {}^1A_{1g}$ band from 28 990 to 29 150 cm^{-1}, when the pressure is raised from 1 bar to 3.55 kbars. If we assume that the pressure dependences of the Racah parameter C', of ΔS^* and of ΔV_b^* can all be neglected, then we have, for aquo-exchange, $\Delta\Delta H^* = \Delta(4\ Dq) \sim 0.1_4$ kcal mol^{-1}, whence $\Delta V_b^* = \Delta\Delta H^*/\Delta P = +1._6\ cm^3\ mol^{-1}$. This is close to the experimental value of $+1.2\ cm^3\ mol^{-1}$, suggesting that LFSE loss may well be a dominant factor in determining the magnitude of ΔV_b^* for the substitution reactions of pentaamminecobalt(III) complexes at least.

We thank the International Nickel Company of Canada for a Fellowship (to W.E.J.), the National Research Council of Canada for an operating grant, and Drs. E. Whalley and J. B. Hyne for advice and assistance in the construction of the high pressure apparatus.

The Ultraviolet Flash Photolysis of Ozone and the Reaction of $O(^1D)$ with H_2O

C. J. FORTIN,[1] D. R. SNELLING,[2] AND A. TARDIF

Defence Research Establishment Valcartier and Centre de Recherches sur les Atomes et les Molecules
P.O. Box 880, Courcelette, Québec

Received March 21, 1972

The decomposition of gas mixtures containing ozone has been studied following a short duration u.v. light pulse. From an analysis of the O_3 decomposition curves for $O_3:N_2$ and $O_3:H_2O$ mixtures, it is shown that the relative rate of $O(^1D)$ reaction with H_2O and N_2 is $k_{H_2O}/k_{N_2} = 3.5 \pm 1.5$. It is also shown that less than 6% of the O_2, formed directly by photolysis, is in the $^1\Sigma_g^+$ state. The water catalyzed decomposition of ozone is also discussed.

Nous avons étudié la décomposition de mélanges de gaz contenant de l'ozone, au moyen d'une pulsation de courte durée de lumière ultraviolette. Nous montrons qu'à partir d'une analyse des courbes de décomposition des mélanges $O_3:N_2$ et $O_3:H_2O$, la vitesse relative de la réaction d'$O(^1D)$ avec H_2O et N_2 est $k_{H_2O}/k_{N_2} = 3.5 \pm 1.5$. Nous montrons aussi que moins de 6% de l'oxygène, formé directement par photolyse, est dans l'état $^1\Sigma_g^+$. Nous discutons également de la décomposition de l'ozone catalysée par l'eau.

Introduction

An understanding of the processes occurring in the u.v. photolysis of ozone in the Hartley continuum is of fundamental importance to the problem of ozone balance in the atmosphere. Ozone photolysis at wavelengths $\leqslant 3100$ Å produces $O(^1D)$ atoms (7), and the reaction of these excited oxygen atoms with H_2O is thought to be one of the principal mechanisms for producing OH and thus initiating the water-catalyzed decomposition of ozone. This indirect photodissociation of H_2O in the stratosphere is a critical process in the photochemical models of stratospheric ozone balance. Since the reactions of $O(^1D)$ with O_2 and N_2 are almost collision limited this species is always in photomechanical equilibrium in the stratosphere. Thus relative rates of $O(^1D)$ reactions with H_2O, N_2 and O_2 are sufficient to estimate the indirect H_2O photodissociation. Until recently (8–10), no information was available on the rate of the reaction of $O(^1D)$ with H_2O.

An apparatus has been built to study the time history of ozone decomposition following a short duration, ultraviolet light pulse. The ozone was monitored continuously, and the experimental ozone decay curves were fitted to a proposed mechanism by integrating the appropriate rate equations. This technique has been developed as part of a laboratory investigation (1–6) of aeronomic chemical processes.

In this paper we report a determination of the relative rates of reaction of $O(^1D)$ with N_2 and H_2O. The water catalyzed decomposition of ozone is also discussed. This apparatus will be used in the future to study a wide range of ozone photochemical processes.

Experimental

A. Apparatus

A schematic diagram of the apparatus is shown in Fig. 1. Both the cylindrical photolysis cell (53 cm long and 18 cm in diameter), and the end plates were made of stainless steel. The two quartz flash tubes (57 cm long and 1.4 cm diameter) were positioned with their axes 4.2 cm from the center of the cell. The cell contained a set of 3 multiple reflection mirrors and two quartz windows. The end plates, flash tubes, and mirror adjustment screws were all vacuum

sealed with neoprene O-rings. The tantalum electrodes were press-fitted into a brass electrode assembly which was vacuum fitted in the quartz tubing by means of O-ring seals. The flash tubes were filled with xenon through two of the brass electrode assemblies. The two split mirrors were 6.3 cm square, and the single mirror which was 6.2 cm by 7.5 cm, was notched in the upper corners to allow passage of the entrance and exit beams to the cell.

The ozone concentration was monitored by following its absorption of 2537 Å light from a low pressure mercury lamp. The optical arrangement is shown in Fig. 1. The signal from the Pen Ray lamp was detected by a Medium Quartz Hilger spectrometer fitted with a 1P28 Photomultiplier. The spectrometer was set at 2537 Å, with a band pass of approximately 2 Å, in order to reduce the scattered light from the flash. Typically, the scattered light signal had decayed sufficiently for measurements to begin in the interval 100 to 200 μs after the flash. The flash lamps were triggered after the oscilloscope to provide a short segment of oscilloscope trace showing the initial ozone absorption. The multiple-reflection mirrors provided the long, adjustable path length necessary in order to measure low ozone pressures. With this optical arrangement absorption measurements were confined to the center of the photolysis cell.

The observed region consisted of a set of cones of base 5 cm × 5 cm at the split mirrors. Thus the maximum observed cross section was a rectangle extending 10 cm horizontally and 5 cm vertically. The two flash lamps were positioned inside the cell with their axes 4.2 cm above and below the observed region, respectively. This geometry was chosen to provide uniform illumination of the observed region.

The low inductance capacitors used were either 4.88 or 14.2 μF with a maximum voltage rating of 20 kV. The voltage was controlled by a General Electric 7703 Ignitron which was fired by discharging a 0.2 μF capacitor charged to 3000 V into the firing pin. The cell was pumped by means of a 4 in. diffusion pump backed by a rotary vacuum pump.

B. Reagents and Sample Preparation

Ozone was produced by a Welsback "Ozonator" and condensed in a liquid nitrogen cooled trap. Approximately half the ozone sample was then distilled to a second liquid-nitrogen cooled trap while pumping to remove any traces of oxygen. The ozone was then evaporated into a 22 l bulb and diluent gases were added. The mixtures were stirred by a glass-enclosed magnetic stirrer. The O_2 and N_2 were Matheson "Gold Label" and "Prepurified" grades, respectively, and they were used without further purification. The CO_2 and SF_6 were purified by condensing them at liquid nitrogen temperatures to remove any air present. Water samples were degassed repeatedly to remove air. Pressures in the bulbs and in the cell were measured using a quartz Bourdon gauge supplied and calibrated by Texas Instruments.

C. Experimental Procedure

The photomultiplier signal with the cell empty (V_0) was displayed on a chart recorder. The cell was filled with a sample until a predetermined transmission was attained (usually 5 or 10%); the total pressure in the cell was recorded, and the signal leads were transferred to the dual-beam, dual-time-base oscilloscope. This procedure ensured that a constant ozone pressure was used for each experiment. With the two beams operated on separately adjustable time bases, the photolysis flash was delayed after triggering the oscilloscope to provide a short record of the initial signal (V_i) on the most sensitive time scale. This arrangement was found to be necessary since a slow decomposition (typically 20% decomposition in 5 min) of the ozone occurred after the sample was admitted to the cell. The signal voltages as a function of time (V_t) were photographed and recorded on Polaroid prints. Typically, measurements were taken in the time interval 200 μs to 0.5 s after the flash using oscilloscope time base settings of 200 μs cm^{-1}, 1 ms cm^{-1}, and 50 ms cm^{-1}. This required only two fillings of the cell since two independent time base settings were available. Finally, the photomultiplier signal was recorded approximately 10 s after the flash (V_∞) and the cell was pumped. The photomultiplier signal with the cell empty (V_0) was found to be constant to within 1% during the course of an experiment. The cell was pumped to less than 10^{-5} Torr between experiments.

The signal height of each polaroid trace was read and processed automatically and measurements were taken every 0.25 mm across the 80 mm trace. For each measurement from the polaroid trace the fraction of ozone decomposed was calculated, and all values falling within selected time intervals were averaged. Finally, the results from all the polaroid traces were averaged to provide graphs of fraction of ozone decomposed *vs.* time. The precision of these results as judged from the standard deviation of a set of measurements (5 to 10 measurements were taken at each oscilloscope time base setting) depended on the initial transmission (V_i/V_0) and the fraction of ozone decomposed. For an initial transmission of 5% and fractional O_3 decomposition (f_t) of 0.20 to 0.60 the single standard deviation was $\sim$1–2% of f_t. Thus the plotting symbols in Figs. 7 to 9 represent $\sim$3 standard deviations in the ordinate.

Initially, some measurements were made of the flash intensity as a function of time and wavelength. The latter measurements were made by replacing the 1P28 photomultiplier with Kodak 103a0 plates and recording spectra of the flash-lamp output reflected off magnesium oxide coated blocks. The plates were calibrated using an NBS calibrated quartz–iodine lamp and neutral density filters. Measurements of the flash intensity distribution with time at various wavelengths were made photometrically using the Medium Quartz Hilger spectrometer and the 1P28 photomultiplier. For these experiments the oscilloscope was triggered with a signal obtained by wrapping 3 turns of copper wire around one of the quartz flash tubes. A complete description of the apparatus, experimental technique, data reduction and some initial results has been presented previously (11).

Results

A. Characteristics of the Flash

The dashed curve in Fig. 2 shows the wavelength distribution of the photolysis flash output for an input energy of 2800 J. The solid curve, which is the product of the relative flash

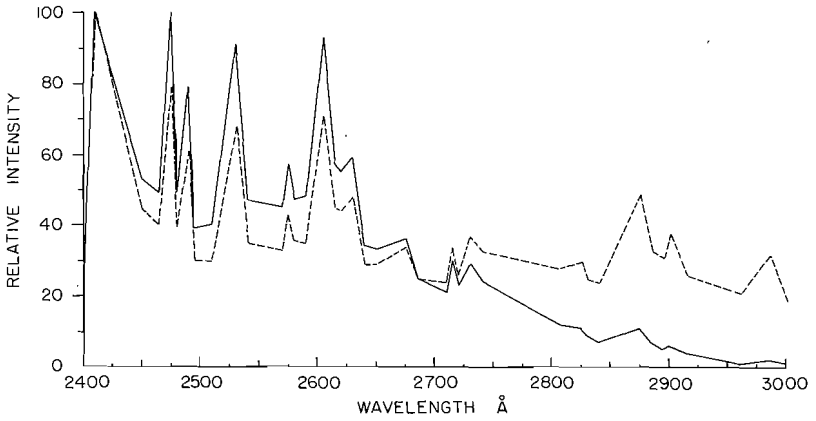

FIG. 2. Wavelength distribution of photolysis radiation. Broken curve incident radiation, solid curve radiation absorbed by ozone.

intensity and the ozone absorption coefficient, represent the wavelength distribution of the radiation absorbed by ozone. Because of the difficulties of calibrating the photographic plates, these distribution curves should be regarded as semi-quantitative, but they do show that almost all the ozone absorption occurs at $\lambda \leqslant 2950$ Å (well below the threshold for $O(^1D)$ formation). The distribution of photons absorbed by ozone in the wavelength intervals: 2400–2450, 2450–2500, 2500–2575, 2575–2625, 2625–2725, 2725–2825, and 2825–2925 Å is 0.18, 0.15, 0.21, 0.16, 0.16, 0.09, and 0.04, respectively. The corresponding photon distribution for a flash energy of 1000 J was 0.18, 0.21, 0.19, 0.18, 0.15, 0.06, and 0.03; thus there appears to be no marked change of energy distribution with flash energies in the range 1000–2800 J. The data in Fig. 2 were obtained with a pressure of 25 Torr of xenon in the flash tubes although both the total intensity and the energy distribution were independent of xenon pressure in the range 6–25 Torr.

Although the time distribution of the photolysis flash energy is only of secondary importance to the results presented in this paper, an extensive series of measurements has been made at various flash energies and xenon pressures. Some typical results, presented in Fig. 3, show that the time distribution is essentially independent of wavelength in the region where absorption by ozone occurs. Somewhat larger differences are observed in the time

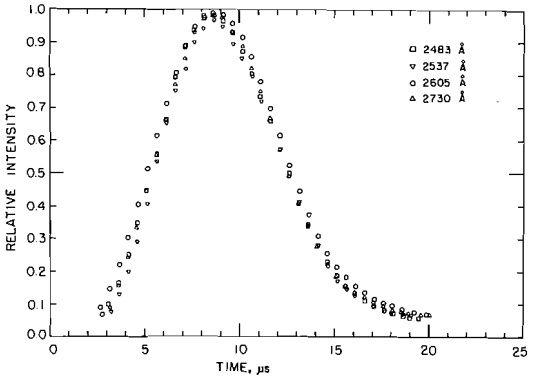

FIG. 3. Time distribution of photolysis radiations at various wavelengths for a flash energy of 2800 J.

interval 50 to 100 μs, but typically only 4% of the total flash energy occurs after 50 μs.

To take account of the small changes with wavelength, the overall time distribution was obtained using a photometer equipped with a 2550 Å interference filter and a 1P28 photomultiplier whose combined response approximated that of the ozone absorption curve.

The flash lamps were regularly refilled with xenon after 3 flashes, although experiments showed that a filling could be used at least 30 times with no significant loss of light output.

B. Photolysis of Ozone

The ozone absorption coefficient at 2537 Å (close to the ozone absorption maximum) is (12) 306 cm^{-1}. The absorption of radiation is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

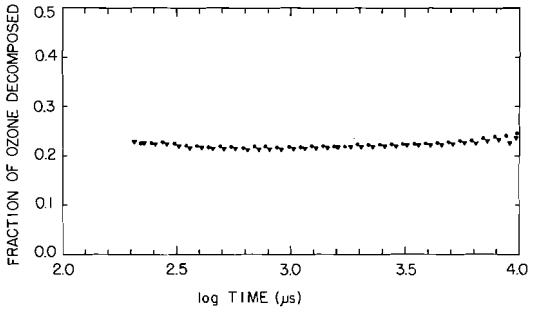

FIG. 4. Ozone decomposition: solid circles are experimental data of an $O_3/O_2/N_2/SF_6$ mixture, pressures 0.0144:0.0048:8.20:8.20 Torr, respectively; $f_\infty = 0.778$. The solid triangles are experimental data for an $O_3/O_2/N_2/CO_2$ mixture pressures 0.0144:0.0049:8.20:8.20 Torr, respectively; $f_\infty = 0.832$; flash energy 1000 J. See text for description of computed curves.

given by:

$$[1] \qquad I/I_0 = \exp\left(-306 \times \frac{P}{760} \times \frac{273}{T} \times L\right)$$

where I and I_0 are the transmitted and incident intensities, P is the ozone pressure in Torr, L is the path length in cm, and T is the absolute temperature (295 °K). For a typical ozone pressure of 0.01 Torr and an average path length of 9 cm for flash radiation in the observation region, the term in parentheses in eq. 1 above is 0.033. Thus, the linear absorption approximation holds, and the radiation absorbed $(I_0 - I)$ is proportional to ozone pressure. This point can be checked experimentally, since if the absorption is linear in ozone, the fraction of ozone decomposed is independent of ozone pressure. It will be shown later, that for O_3/N_2 mixtures in the time region 200–800 μs after the flash, the ozone decomposition is due to photolysis only. The fraction of ozone decomposed in this time interval was measured for a mixture of O_3 and N_2 in the ratio 1:1000. For ozone pressures of 0.014, 0.028, and 0.042 Torr the fraction decomposed was found to be 0.185, 0.182, and 0.185, respectively. Thus, experimentally, the linear absorption approximation holds for O_3 pressures $\leqslant 0.042$ Torr. For the data reported in this paper maximum ozone pressures between 0.01 and 0.015 Torr were used.

C. Ozone Decomposition Curves

Ozone decomposition as a function of time has been measured for various ozone added gas mixtures, and the results are shown in Figs. 4–10. The ordinate of these graphs shows the fraction of ozone decomposed (f_t) which, using Beer's law, was calculated from the formula

$$[2] \qquad f_t = \log(V_t/V_i)/\log(V_0/V_i)$$

The fractional ozone decomposition (f_∞) measured 10 s after the flash is also given. All experiments were conducted at 295 ± 2 °K. The initial ozone pressure $[O_3]_i$ was calculated from the initial transmission (V_i/V_0) using eq. 1. In all experiments there was some oxygen present due to decomposition of the ozone. When the gas mixtures were prepared the pressures of the freshly evaporated ozone and added gases were recorded, and the fractional ozone content of the mixture (F_{O_3}) was calculated. The oxygen present in the photolysis cell was then calculated from the formula $[O_2] = \frac{3}{2}(F_{O_3} \times P_T - [O_3]_i)$ where P_T is the total pressure of mixture in the cell. In deriving this equation

Ozone decomposition: the open squares are experimental data for an $O_3/O_2/N_2/H_2O$ mixture pressures 0.0141 : 0.0382:18.4:0.79 Torr, respectively; $f_p = 0.243$, $f_\infty = 0.718$; flash energy 1000 J. The open circles are experimental data for an $O_3/O_2/N_2/H_2O$ mixture pressures 0.0144:0.014:22.04:0.475 Torr, respectively; $f_p = 0.187$, $f_\infty = 0.633$; flash energy 625 J. The number associated with each calculated curve represents the value of k_5 assumed (see text).

it is implicity assumed that the ozone decomposition occurred subsequently to the initial evaporation. If the decomposition occurred during evaporation then the oxygen present would only be 2/3 of that given by the above formula. Thus the calculated oxygen pressure is an upper limit. O_3/N_2 or $O_3/N_2/SF_6$ mixtures were studied at regular intervals throughout these experiments in order to determine the fraction of O_3 photolyzed. This proved necessary since a slow decrease in flash lamp intensity, and hence O_3 photolysis, occurred throughout these experiments. This loss of intensity could be regained by cleaning the flash lamps with HF and was probably caused by deposits forming in the flash-tubes.

Discussion

A. Reaction Scheme and Integration of Rate Equations

The relevant reactions and their rate constants are listed in Tables 1 and 2, respectively. All rate constants are given in molecular units (cm^3 $molecule^{-1}$ s^{-1} or cm^6 $molecule^{-2}$ s^{-1}). The reactions have been arbitrarily divided into two groups: principal reactions and reactions which are of secondary importance because of their slow rates or because of the presence of competing reaction.

Much of the available information on O(D) reactions has been reviewed recently (13), and additional information has appeared subsequently (3, 4, 9, 10, 14, 15). The available evidence indicates that the reactions of O(D) with N_2 and O_2 are almost collision limited $(2–20) \times 10^{-11}$, and that the rates of these reactions are approximately equal. The reaction of O(D) with O_3 is some 10 times faster. The efficiency of reaction 13 in producing $O_2(\Sigma)$ is between 0.3 and 1.0. Only relative O(D) reaction rates have been used in our calculations, and the values assumed are listed in Table 2 based on $k_4 = 1.0$. An efficiency of 0.8 for $O_2(\Sigma)$ formation in reaction 13 has been adopted. Any error in these assumed rates is not important since a large excess of H_2O and/or N_2 was present in all the gas mixtures studied.

The calculated ozone decay curves were obtained by a numerical integration of the appropriate rate expressions using a Runge–Kutta integration routine. It proved difficult to integrate the rate expression directly, since the very large O(D) reaction rates necessitated too small a time step for the integration to be practical. Since $k_4 \geqslant 2 \times 10^{-11}$ (13), and the minimum N_2 pressure used in any of our experiments was 5 Torr; then the time constant for O(D) disappearance was always less than 0.3 μs. Since this time constant was short compared to the flash duration, the O(D) was taken to be in photochemical equilibrium. The steady state O(D) concentration is then given by $[O(D)] = k_1 I_t[O_3]/(k_4[N_2] + k_5[H_2O] + k_{13}[O_2] + k_{14}[O_3])$. The rate of any individual O(D) reaction, *e.g.*, deactivation by N_2, is then given by $k_4[N_2][O(D)]$, and hence only relative O(D) reaction rates are required to

*The excited states of atomic and molecular oxygen, $O(^1D)$, $O_2(^1\Delta g)$ and $O_2(^1\Sigma_g^+)$ are abbreviated to O(D), $O_2(\Delta)$, and $O_2(\Sigma)$, respectively.

†Reactions 17 and 18 have been invoked to explain the chain decomposition of O_3 in the presence of H_2O although no direct proof is available for the occurrence (17). Extrapolation of recent measurements (29) of k_{17} for vibrational excited OH ($v = 2$ to 9) indicate that the upper limit given for k_{17} is approximately correct for OH ($v = 0$).

compute the fraction of O(D) participating in the various reactions.

The rate of ozone photolysis has been shown to be proportional to ozone concentration and can be represented by $k_1 I_t[O_3]$ where I_t is the time-dependent relative flash intensity and k_1 is an empirically determined constant which depends on flash lamp intensity, cell geometry, etc. For O_3/N_2 mixtures in the period 200–800 μs following the flash no further O_3 decomposition occurs. Thus the O_3 decomposition at 200 μs results from O_3 photolysis with an additional small contribution from the reaction of O(D) with O_3[14]. k_1 was determined by integrating the rate equations with photolysis and the O(D) reactions 4 and 14 included and varying k_1 in order to obtain the observed amount of O_3 decomposition in these mixtures.

B. Mixtures Containing no Added H_2O

For O_3/N_2, $O_3/N_2/CO_2$, and $O_3/N_2/SF_6$ mixtures (Figs. 4–6), there is no O_3 decomposition in the period 200–800 μs following the flash. This is to be expected, since in the presence of excess N_2 the bulk of the O(D) is deactivated to O, and the subsequent reactions of O and $O_2(\Delta)$ with O_3 are too slow to occur in this time interval. Thus it appears that O_3 decomposition at 200 μs results from photolysis and reaction 14, only. A possible exception could arise if $O_2(\Sigma)$ were formed directed by photolysis (reaction 3) since the $O_2(\Sigma)$ would then react rapidly with O_3 (reaction 15). However, it has been shown that for O_3 photolysis at 2537 Å, less than 5% of the O_2 is in the $O_2(\Sigma)$ state (4) and that the quantum yield of $O_2(\Delta)$ production is between 0.7 and 1.0 (24). The absence of $O_2(\Sigma)$ as a product of reaction 3 can be verified by the data shown in Fig. 4 which shows that the O_3 decomposition is

*Wherever possible, rate constants have been taken from recent review articles (16–20). When this was not possible, a publication which summarizes the information available has been chosen.

†Where applicable energy of activation given in cal/mol.

‡Relative rates only with $k_4 = 1.0$; see text for discussion.

§Estimates from relative rates of SF_6 in other three body reactions.

‖These rate constants are based on a single measurement of k_{A_r}, and dependence on M was obtained from an earlier study. The value of k_{A_r} found in this earlier study was approximately 100 times less but is probably less reliable; see reference (21(*a*)) for a discussion.

¶Other results, discussed in ref. 5, indicate a lower value of E of 3100 cal/mol.

**k_{17} and k_{18} are estimated rate constants; see footnote Table 1.

identical with and without addition of CO_2 to O_3/N_2 mixtures. In the absence of CO_2 the $O_2(\Sigma)$ would react with O_3 [15] rather than be deactivated by $N_2(k(N_2) = 2 \times 10^{-15}$ (20)), but with the addition of CO_2, deactivation by CO_2 ($k(CO_2) = 3 \times 10^{-13}$ (20)) predominates. Since the O_3 decomposition is identical for both mixtures we conclude that $O_2(\Sigma)$ is not a product of reaction 3. From a detailed analysis of the data in Fig. 4 the fraction of O_3 decomposed in the time interval 200–1000 μs is 0.211 ± 0.003 ($O_3/N_2/SF_6$) and 0.217 ± 0.003 ($O_3/N_2/CO_2$). (The errors given are twice the standard deviation.) Thus the maximum difference between these two values of the fraction of O_3 decomposed, which can be attributed to $O_2(\Sigma)$ production in reaction 3, is 0.012 or 6% of the ozone photolyzed.

Nearly all the difference between the two results given above can be attributed to reaction 3. For the $O_3/N_2/SF_6$ mixture ~2.5% of the O(D) reacts with O_3 [14], while for the $O_3/N_2/CO_2$ mixture this figure is only 0.5% (a relative rate of O(D) quenching by CO_2 of 3.0 was taken (13)). Thus both of the above results are consistent with a fraction of O_3 photolyzed (f_p) of 0.210. In calculating the values of f_p used in this work the small correction for reaction 14 was always made.

A comparison of the O_3 decomposition curves

in Figs. 5 and 6 shows that addition of SF_6 reduces the rate of O_3 decomposition. Since, for these mixtures, the O_3 decomposition should only involve reactions 3, 4, 6, and 8 (which do not directly involve SF_6) the effect of SF_6 must be to remove energy from the system. This conclusion was supported by an attempt to fit the experimental O_3 decay curves by the simple mechanism outlined above. A reaction scheme involving reactions 3, 4, 6, 8, 13, 14, 15, and 16 was integrated numerically. Although reactions 13 to 16 were included they had a very minor influence on the O_3 decomposition. The results of these calculations are shown by the dotted lines in Figs. 5 and 6. It can be seen that the measured O_3 decomposition is consistently greater than the computed curves in the region 10^4 to 10^6 μs after the flash, particularly in the absence of added SF_6.

For the O_3/N_2 data the effect of gas heating was also examined. For this calculation (solid curve in Fig. 5) it was assumed that both the excess energy available in the photolysis reaction and the heat liberated by O_3 decomposition were rapidly equilibrated. The consequent temperature rise was then calculated from the known heat capacity of the mixture. Using the temperature dependence for reactions 6 and 8 given in Table 2 the observed O_3 decomposition is still much faster than the computed value.

It should be noted that for the data in Figs. 5 and 6 the final quantum yield of O_3 destruction (Φ) is 3.99 and 4.05, respectively (where $\Phi = f_\infty/f_p$). A quantum yield of 4.0 is expected for the mechanism discussed above and no energy-chain mechanism is required to explain the observations. It is only the approach to this final quantum yield which is anomalously fast.

A possible explanation of these results lies in the vibrationally excited O_2 formed in reaction 8. It is known (25) that vibrational energy released in this reaction readily transfers to O_3 and leads to enhanced O_3 reaction rates. For the O_3/N_2 mixtures used in this work, it appears unlikely that the vibrationally excited $O_2(O_2\dagger)$ will be removed sufficiently fast by vibrational–vibrational (V–V) energy transfer to N_2 (26), or by vibrational–translational (V–T) energy transfer with O (27). The $O_2\dagger$ may decay by V–V transfer to O_3 followed by V–T deactivation of the $O_3\dagger$. Deactivation may also occur through traces of water vapor since this mechanism is very rapid (28). It is difficult to model this mechanism since the energy transfer mechanism is not well defined, and the effect of O_3 vibrational energy in overcoming the energy barrier to reactions 6 and 8 is not known. However, qualitatively, if the energy released in reaction 8 were rapidly equilibrated between the vibrational degrees of freedom of O_2 and O_3 then vibrational temperatures of several thousand degrees would be anticipated. If degradation of this vibrational energy to kinetic energy is sufficiently slow, this mechanism may explain the observed results. For the purposes of further discussion the important point to be noted is the almost complete absence of O_3 reaction in the period 10^2 to 10^4 μs following the flash for these mixtures.

Anticipating later discussion, the effect of traces of water vapor in promoting the O_3 decomposition has been examined. In Fig. 6 the dashed and solid curves represent the computed O_3 decay curves for H_2O pressure of 3×10^{-3} and 6×10^{-3} Torr, respectively. A value of k_5 of 3 and a mechanism involving reactions 3 to 16 were used for these calculations. Reactions 9 and 10 together are equivalent to reaction 8 and, in effect, lead to the catalyzed reaction of O with O_3. (The mixtures containing SF_6 could possibly have contained traces of water vapor, since the SF_6 used was of lower purity than the other gases, and was simply purified by trap-to-trap distillation.) Although traces of water vapor have a profound effect on the O_3 decomposition it appears that the vibrational energy exchange mechanism must be invoked in order to explain the $O_3/N_2/SF_6$ results in Fig. 6.

C. Mixtures Containing Added H_2O

Ozone decomposition curves for various $O_3/N_2/H_2O$ mixtures are shown in Figs. 7–10. The most obvious difference between these results and those in Figs. 5 and 6 is that O_3 decomposition is now occurring in the 10^2 to 10^4 μs time interval. This decomposition can be understood in terms of the mechanism outlined at the end of the previous section where there is now considerably greater production of OH in reaction 5 because of the added water vapor. This larger OH concentration leads to very much more rapid decomposition of O_3 by reactions 9 and 10. This data will be interpre-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ted initially by fitting the experimental data in the 10^2 to 10^4 μs interval. Interpreting the data in the 10^4 to 10^6 μs time range is more uncertain, both because of the larger number of reactions involved, and also because of the problems encountered in this time interval with mixtures not containing water vapor. However, anomalous effects due to vibrationally excited O_2 are not likely with these mixtures, since first, reaction of O and O_3 occurs through reactions 9 and 10 rather than reaction 8, and secondly, water vapor is an excellent deactivator of vibrationally excited species, particularly O_2† (28).

f_p, the fraction of O_3 photolyzed (and hence k_1), was obtained as discussed earlier from $O_3/N_2/SF_6$ experiments performed both before and after each of the $O_3/N_2/H_2O$ experiments shown in Figs. 8 and 9.

The experimental data shown in Fig. 7 (and repeated in Fig. 9) were chosen to study the effects of different assumed mechanisms on the calculated ozone decay curves. For the higher $[H_2O]/[N_2]$ ratio of this experiment the production of OH in reaction 5 was correspondingly greater. With this larger OH production, the calculated O_3 decay curves were more sensitive to changes in the assumed mechanism. In particular we wish to investigate the possible effects of reactions 17 and 18 which have frequently been proposed to explain the chain decomposition observed in wet ozone mixtures (see footnotes in Tables 1 and 2).

In Fig. 7 three computed decay curves are shown. To calculate these curves the rate constants given in Table 2 were used (exceptions are noted below) with $k_5 = 3.0$ (chosen to give a close fit to the experimental data) and $k_7 = 6 \times 10^{-18}$. The following mechanisms were assumed: (*a*) For the dashed curve (Fig. 7) reactions 17 and 18 were excluded; (*b*) for the dotted curve reaction 17, but not 18, was included; (*c*) for the solid curve both reactions 17 and 18 were included; (*d*) same as (*a*) above with k_{12} reduced to 1/3 of the value shown in Table 2 (see footnote in Table 2). This latter decay curve was almost indistinguishable from (*b*), being only slightly lower (~ 0.005) in the region $\log t = (\mu s) = 3.6$ to 4.0.

The detailed computer output, which listed both the concentration of all the species, and the contribution of specific terms to the rate equations, was examined to determine the effects of specific reactions. For all the mechanisms and for $t \leqslant 10^4$ μs the reactions of $O_2(\Delta)$ were negligible ($\leqslant 1\%$ of the $O_2(\Delta)$ reacted) as were any uncertainties in the rates of reactions 13–16. Reactions 19 and 22–24 had a total negligible effect. The small differences in computed O_3 decomposition at $t \leqslant 10^4$ μs for the various mechanisms were due to different OH decay mechanisms (reactions 11, 12, and 17). (For this experiment approximately 10% of the O(D) formed in reaction 3 reacts with H_2O[5] for $k_5 = 3.0$). Both reactions 11 and 17 lead to loss of O_3, the latter directly and the former by the subsequent reactions of the O atom produced. Reaction 12 does not lead to O_3 decomposition. For mechanism (*a*) the rates of reactions 11 and 12 are approximately equal; thus the reduction of k_{12} in (*d*) leads to increased O_3 decomposition. Including reaction 17, (*b*) led to a similar small increase in O_3 decomposition. Including both reactions 17 and 18, (*c*) produced greater increases in O_3 decomposition than mechanisms (*a*) or (*b*). However, a tenfold increase in k_{20} and k_{21} above the lower limits given in Table 2 produced a curve which was almost indistinguishable from that for mechanism (*b*). Mechanisms (*a*), (*b*), and (*d*), were not sensitive to increases in k_{20} and k_{21}.

Thus, with the possible exception of (*c*), the various mechanisms assumed have a negligible effect on O_3 decomposition for $t \leqslant 10^4$ μs. Furthermore, these mechanisms are not sensitive to variations in k_{19} to k_{24}. Mechanism (*c*) (with lower limits for k_{20} and k_{21}) appears to be ruled out by the large deviations from the experimental data in the 10^4 to 10^6 μs range; this point will be discussed further in a later section. Mechanism (*d*) was arbitrarily selected to fit the remainder of the data on $O_3/N_2/H_2O$ mixtures shown in Figs. 8 and 9.

Using mechanism (*d*) the value of k_5 was varied in order to obtain the best fit to the experimental data shown in Figs. 8 and 9. The number associated with each curve in Figs. 8 and 9 represents the value of k_5 assumed. From a visual inspection of the curves in Figs. 8 and 9 it was concluded that the best fit value of k_5 was 3.5 ± 0.5.

Because of the uncertainty in k_9 and k_{10} (see Table 2), the effect of varying these reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

rates on the best fit value of k_5 was examined. For the data in Fig. 9 (upper curve) the best fit k_5 was 2.0 and 5.0 for limiting values of k_9 of 7×10^{-11} and 3×10^{-11} (*cf.* $k_5 = 3.1$ for $k_9 = 5 \times 10^{-11}$), respectively. For $k_9 = 3 \times 10^{-11}$ no entirely satisfactory fit was obtained; the computed curves were 0.015 too low in the region log t (μs) = 3.4 to 3.7. This arose because the consequent increase in k_5 leads to higher OH concentrations, and reaction 11 then produced significant reduction in OH before all the O atoms reacted through reactions 9 and 10. The smaller uncertainty in k_{10} produced correspondingly smaller changes in the best fit k_5 (2.7 and 3.5). Taking into account these additional systematic errors $k_5 = 3.5 \pm 1.5$ was adopted.

D. Possible Ozone Chain Decomposition Mechanisms

If reaction 18 is neglected the slopes of the ozone decomposition curves for $t = 10^4$ to 10^6 μs are not affected by changes in the rates of reactions involving OH, H, and HO_2. (Small differences in the absolute O_3 decomposition are produced, as discussed earlier, by the varying effects of the OH decay reactions 11, 12, and 17 in leading to O_3 destruction.) This arises since the rate controlling step is the release of O atoms in reaction 6 rather than the subsequent reaction of O atoms in reaction 8 or reactions 9 and 10. However, the computed curves are sensitive to k_7. $k_7 = 6 \times 10^{-18}$ (towards the low end of the range given in Table 2) was found to give the best fit to the data, and with this value approximately 10% of the $O_2(\Delta)$ is deactivated and 90% reacts with O_3.

The effect of including reaction 18, which leads to the chain decomposition of O_3, was indicated earlier. In Fig. 10 a set of computed O_3 decay curves are shown. The rate constants given in Table 2 were used with $k_5 = 3.2$ and $k_7 = 6 \times 10^{-18}$. For the solid curve reaction 18 was neglected, but for the dotted and dashed curves $k_{18} = 5 \times 10^{-13}$ was adopted. For the dotted curve the lower limit to k_{21} (1×10^{-11}) was assumed, and for the dashed curve this rate was increased to 1×10^{-10}. The results show that including reaction 18 leads to a much higher O_3 decomposition which is not consistent with the experimental data. However, a tenfold increase in k_{21} produces a satisfactory fit to the data. This is to be expected since reaction 21 along with reactions 11, 12, and 22 produce a net loss of hydrogen containing free radicals. We conclude that a chain mechanism involving reactions 17 and 18 is not consistent with our results unless $k_{21} \approx 1 \times 10^{-10}$.

Two mechanisms for the chain decomposition of ozone involving vibrationally excited OH (OH†) have been proposed (30, 31). These mechanisms have not been included in our model. Kaufman (30) proposed the following mechanism

[10] $$H + O_3 \rightarrow OH\ (v \leqslant 9) + O_2$$

[17*a*] $$OH\ (v \geqslant 3) + O_3 \rightarrow OH + O + O_2$$

[9] $$O + OH \rightarrow O_2 + H$$

and De More (31) modified this mechanism as follows:

[5] $$O\ (D) + H_2O \rightarrow OH\ (v \leqslant 2) + OH$$

[17*b*] $$OH\ (v \geqslant 1) + O_3 \rightarrow 2O_2 + H$$

[10] $$H + O_3 \rightarrow OH\ (v \leqslant 9) + O_2$$

Reaction 10 is sufficiently exothermic to form OH in vibrational levels $v \leqslant 9$, and recent measurements (32) have shown that OH† is preferentially formed in $v = 9$ with monotonically decreasing amounts into lower vibrational levels. Reaction 5 has been observed (33) to form OH ($v = 2$, 1, 0) with the excitation in the newly formed bond.

Very recently information on the rate of reaction of vibrationally excited OH ($v = 2$ to 9) with O_3 has become available (29). The products were not identified, so the observed k_{17} represents the sum of the rates of reactions 17, 17*a*, and 17*b*. For OH ($v = 9$) k_{17} was 7.7×10^{-12}. The rate constants decreased monotonically with vibrational level to 1.9×10^{-12} for OH ($v = 2$).

Although reaction 10 is undoubtedly occurring in our experiments we have not detected any effect which can be attributed to these chain mechanisms. As discussed earlier the ozone decomposition at $t = 10^4$ μs is entirely consistent with production of O atoms by reactions 3 and 4 followed by reactions 9 and 10. The fraction of O(D) atoms reacting with H_2O (reaction 5) is small (5 to 10%). Thus our mechanism leads to a quantum yield for ozone destruction of ~ 2.0 at $t = 10^4$ μs. Although the OH† formed in reaction 10 does not appear

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to be involved in a chain reaction with O_3, there is a possibility of enhanced reactivity in reaction 9. In order to present a semi-quantitative description of the fate of OH† we adopt an average value of k_{17} of 5×10^{-12}.

For the data in Fig. 8, immediately following the flash, the ratio $[O_3]/[0]$ is ~ 3. Then, since $k_9 = 5 \times 10^{-11}$ (*i.e.* 10 times faster than the reaction of OH† with O_3), the OH^- lifetime is controlled by reaction 9. Once an appreciable fraction of the O atoms have reacted the lifetime of OH† becomes longer, and reactions 17, 17*a*, and 17*b* become more likely. However, adopting an average O_3 pressure of 0.01 Torr the lifetime of OH† is $1/k_{17}[O_3]$ or ~ 700 μs. In this time OH† will undergo 3×10^3 and 1.5×10^5 collisions with H_2O and N_2, respectively. With the well known efficiency of water vapor in V–V transfer processes it seems likely that the OH† would be relaxed. A recent measurement (34) showed that V–V transfer from HCl† to H_2O required ~ 10 collisions. In fact the absence of any effect of OH† in reactions 17*a* or 17*b*, can be adduced as evidence for relaxation of OH†.

Returning to the possibility of enhanced reactivity of OH† in reaction 9 we note that the lifetime of OH† is $\leqslant 1/k_9[O]$. Immediately following the flash the O atom concentration is typically 0.003 Torr corresponding to an OH† lifetime of $\leqslant 200$ μs. If the reaction of OH† with O atoms were collision limited (2×10^{-10}) the OH† lifetime could be as short as 50 μs, corresponding to ~ 250 collisions with H_2O. However, no satisfactory fit to the experimental data could be found for $k_9 = (1 \text{ to } 2) \times 10^{-10}$. The best fit computed curves were too low for $\log t$ (μs) = 2.9 and markedly too high for $\log t$ (μs) = 3.5. Furthermore, the experimental data is not consistent with an initially enhanced rate for reaction 9 followed by a slower rate when the OH† lifetime becomes longer as the O atoms are consumed and the OH† is preferentially deactivated. We conclude therefore from the evidence of very fast V–V transfer rates to H_2O, and from the absence of any evidence for OH† reactions in our experiments, that enhanced reactivity of OH† is unimportant.

E. Comparison of Various k_5 Determinations

The object of this study is to provide information on the relative rates of O(D) reactions with H_2O and the major atmospheric constituents, O_2 and N_2. Accordingly, the available evidence on k_5 will be discussed in these terms. In order to refer the values to k_{air} (where $k_{air} = 0.21\,k_{13} + 0.78\,k_4$) the rate constant ratio k_4/k_{13} must be known. Most of the available evidence (4, 13, 15, 36, 37) is consistent with $k_4/k_{13} = 1.0 \pm 0.4$.

Two recent measurements (8, 9) have given $k_5/k_{14} \simeq 0.5$. Both experiments used flash photolysis techniques and involved ozone decomposition measurements on O_3/M and $O_3/M/H_2O$ mixtures where M was Ar (9) or He (8). Ar and He are gases which do not deactivate O(D). In both experiments k_5/k_{14} was obtained from an analysis of the effect of H_2O in reducing the O_3 decomposition due to reaction 14.

The recent flash photolysis measurements of Bair and co-workers (8) were interpreted to give $k_5/k_{14} = 0.45 \pm 0.2$. Using a value of k_{14}/k_4 of 15 previously determined by this group[3] (this ratio is consistent with that reported in ref. 4, namely, $k_{14}/k_4 = 13.5$) gives k_5/k_4 6.8 ± 3.0, where the uncertainty given does not include any possible error in k_{14}/k_4.

In a somewhat similar study (9) using O_3/Ar and $O_3/Ar/H_2O$ mixtures O_3 concentrations were obtained in the time period beginning 1 ms after the flash. The O_3 concentration immediately after the flash was obtained by extrapolation of these measurements. $k_5/k_{14} = 0.5$ was then obtained from these extrapolated measurements on four $O_3/Ar/H_2O$ mixtures in the ratio $1:100:M$ (where $M = 0$, 1, 5, and 10) with an O_3 pressure of 1 Torr. The details of the analysis have not been given, but only reactions

[3]Some confusion exists in the literature concerning the work of Bair and co-workers (38). The value of k_{13} deduced in ref. 35 and used subsequently (41) represents a composite rate constant for all forms of O_2 present (*i.e.*, $O_2(\Delta)$, vibrationally excited ground state O_2, and any O_2 which is present as an impurity in the O_3) and should not be compared with determinations of k_{13} for ground state O_2 only (see discussion ref. 35 p. 6124). Thus k_{13} should not be used in comparing relative rate constants obtained by this group with those of other workers. Furthermore, due to misprint in ref. 8, 35, 39, and 41 k_{14} is given, incorrectly, as 4×10^9 rather than 4×10^{11} (units l mol^{-1} s^{-1}). With this correct k_{14} the value of k_{14}/k_4 obtained from the rate constants given in ref. 8 is 20. However, because of rounding-off in the reported rate constants the "best estimate" of k_{14}/k_4 is 15 rather than 20. The authors are indebted to Dr. E. J. Bair for clarification of these points.

3, 5, 6, 8, and 14 appear to have been considered. We have calculated the O_3 decomposition for an $O_3/Ar/H_2O$ mixture (1:100:10) with $k_5/k_{14} = 0.5$ (*i.e.*, $k_5 = 7$ in terms of the relative O(D) rates of Table 2), $k_{12}(Ar) = 10^{-30}$ (19), and $k_{17} = k_{18} = 0$. Other rate constants were taken from Table 2 and k_1 was chosen to give the observed fraction of O_3 photolyzed (0.16). The results indicate that at $t = 1$ ms, approximately 15% of the total O_3 decomposition arises from reactions 9 and 10 where the O atoms are produced in reactions 6 and 11. Furthermore, the analysis predicts temperature increases of $\sim 30°$ which lead to increases in the rates of reactions 6 and 8. The final observed O_3 decomposition was 0.29 (9), which corresponds to a quantum yield for O_3 destruction of 1.8. This is hard to explain in terms of the mechanism used (9), since reactions 3, 6, and 8 (or the equivalent reactions 9 and 10) should lead to a minimum quantum yield of 3.0. (The computed final O_3 decomposition was ~ 0.50 corresponding to a quantum yield of ~ 3.0.) Because of the higher O_3 pressure (1 Torr) used in this study (9) compared to the 0.01 to 0.02 Torr used by Bair *et al.* and the present authors, it becomes much more difficult to isolate the slower processes 6 and 8 from the faster reactions 3, 5, 13, and 14. Because the complete mechanism has not been considered the extrapolation procedure used (9) is somewhat uncertain.

The authors further claim (9) that since the quantum yield for O_3 destruction is small (~ 1.8) then $k_{17} \leqslant 10^{-16}$ cm^3 molecule^{-1} s^{-1}. In the absence of detailed modelling of the full mechanisms such a conclusion is unwarranted since the OH can be preferentially removed by reactions 11, 12, 24, and 21 with reaction 17 being of only minor importance. A much more detailed analysis of these results is required in order to justify the conclusion drawn.

There are further problems associated with flash photolysis experiments performed in the absence of an excess of an O(D) deactivant. These problems have been encountered, refs. 11 and 35, in interpreting the results of O_3/Ar and O_3/He mixtures containing small quantities of O_2. If the initial O_3 decomposition ($t \leqslant 1$ ms for O_3 pressures of 0.01 to 0.02 Torr) is interpreted in terms of the fast reactions 3, 13, 14, and 15 then a large $O_2(\Sigma)$ production is required at relatively low $[O_2]/[O_3]$. This interpretation (11, 35) leads to a large value of k_{13} (or k_{13}/k_{14}) which is not consistent with the existing information in this rate constant. It has been suggested (4, 35) that the reaction

$$O(D) + O_2(\Delta) \rightarrow O_2(\Sigma) + O$$

may be responsible for part of the $O_2(\Sigma)$ production. The $O_2(\Sigma)$ may also arise from enhanced reactivity of O(D) with the vibrationally excited O_2 produced in reaction 14. The product formed is not necessarily $O_2(\Sigma)$; any species which would react with O_3 with a rate constant of $\sim 10^{-11}$ cm^3 molecule^{-1} s^{-1} could explain the results. Thus it is possible that the products of reaction 14 could also lead to further O_3 decomposition. It has been suggested that these products include O atoms (40, 41) or $O_2(^3\Sigma_u^+)$ (42) (but not $O_2(\Sigma)$ or $O_2(\Delta)$ (4)) as well as vibrationally excited ground state O_2. However, O atoms would not react sufficiently fast to effect the initial O_3 decomposition unless the rate of reaction 8 was enhanced by vibrational excitation of the O_3. Evidence for excited product formation in reaction 14 is also discussed in ref. 4.

Because of the obvious complexity of the reaction mechanism involving reactions 13 and 14 the value of k_5/k_{14} of ~ 0.5 should be adopted with some caution. However, using $k_{14}/k_4 \simeq 14$ (see above discussion) the ratio k_5/k_{air} obtained from this result is ~ 7. (It is because of the problems discussed above that we have made all our measurements in mixtures containing an excess of an O(D) deactivant (H_2O and/or N_2) when reactions 13 and 14 are unimportant.)

Cvetanović *et al.* have recently determined the rate of reaction 5 relative to nitrous oxide (10) ($k_5/k_{N_2O} = 1.50$) and neopentane (15) ($k_5/k_{neop} = 0.376$). They converted the neopentane rate to $k_5/k_{13} = 10.7$ and $k_5/k_4 = 9.6$ using the previously determined ratios k_{13}/k_{neop} and k_4/k_{neop}. The k_5/k_{N_2O} value was converted to $k_5/k_{13} = 4.2$ using the k_{13}/k_{N_2O} ratio determined in the same experiment (10). Because of the unknown cumulative errors in such conversions it is difficult to assess the accuracy of the final results. However, a value of k_5/k_{air} of 4 to 11 is indicated.

Recent experiments conducted in our laboratories[4] using the technique described in ref. 4

[4]M. Gauthier and D. R. Snelling, private communication.

have given $k_5/k_{13} = 6.0 \pm 2.0$. For consistency we use the value of $k_4/k_{13} = 0.72 \pm 0.08$ previously determined (4) by this technique to give $k_5/k_{air} = 8 \pm 3$.

The value of k_5/k_{air} obtained in the present study (3.5 ± 1.5) is somewhat lower than the values discussed above. Therefore, we have investigated the possible effect of water absorption in our experiments which could lead to a lower k_5/k_{air}. Direct analyses of the gas mixtures used for fractional water content indicated that less than 15% of the water vapor was lost by absorption. Thus applying this maximum correction for loss of water vapor would only increase k_5/k_{air} from 3.5 to 4.0.

The consistency of the various determinations of k_5/k_{air} discussed above is not very satisfactory but a value of k_5/k_{air} of 7.5 ± 4.0 includes all the measurements.

In applying these values of k_5/k_{air} to atmospheric calculations our determination has the following advantages. The rate of k_5 was determined relative to the major atmospheric constituent, N_2. Furthermore, k_5 was calculated from the effects of reactions 9 and 10 which are responsible for the mesospheric control of ozone. Thus any errors in k_9 or k_{10} are partially compensated for in the final k_5/k_{air} value.

The authors are indebted to J. Oman for his pains-taking help in performing these experiments.

Infrared Band Progressions in the CH_2 Scissoring Region and the Ring Puckering Vibration of Trimethylene Oxide and some Deuterated Analogs[1]

H. WIESER AND M. DANYLUK

Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received February 28, 1972

Band progressions have been observed in the CH_2 scissoring region of the i.r. spectra of trimethylene oxide (C_3H_6O) and three of its deuterated analogs (α-d_2, β-d_2, and α,α'-d_4). With the aid of the pure ring puckering transitions (published previously) and a simple theoretical model of puckering–vibrational interactions the absorptions have been assigned to combination tones of CH_2 scissoring vibrations with the ring puckering mode and its overtones. The scissoring fundamentals of the α- and β-methylene groups have been identified and assigned. Of all the vibrations for which combination progressions are observed, only the β-CH_2 scissoring mode of the normal compound exhibits significant differences between the ring puckering transitions in the ground state and the vibrational excited state.

Nous avons observé les progressions de bande dans la région de cisaillement du CH_2 du spectre i.r. de l'oxyde de triméthylène (C_3H_6O) et trois de ses analogues deutériés (α-d_2, β-d_2 et α,α'-d_4). A l'aide des transitions de pulsation cycliques pures (publié précédemment) et d'un modèle théorique simple d'intéractions de pulsation vibrationnelles, nous avons assigné les absorptions comme étant dues aux tons de combinaison des vibrations de cisaillement du CH_2, avec le mode cyclique de pulsation et ses harmoniques. Les fondamentales de cisaillement des groupes méthylène en α et en β ont été identifiées et assignées. De toutes les vibrations pour lesquelles on observe des progressions de combinaison, seul le mode de cisaillement du CH_2 en β du composé non-deutérié montre des différences marquées entre les transitions de pulsation cycliques dans l'état fondamental et dans l'état vibrationnel excité.

Canadian Journal of Chemistry, **50**, 2761 (1972)

Introduction

In connection with some other work in this laboratory we have recently undertaken a comprehensive vibrational analysis of trimethylene oxide, C_3H_6O (TMO), and four of its deuterated analogs, *viz.* α-d_2, β-d_2, α,α'-d_4, and d_6 TMO. In particular, it was of interest to study the band sequences occurring in the CH_2 scissoring regions resulting from the combination of the scissoring fundamentals with the low-frequency, out-of-plane torsional vibration (the ring puckering mode) of the four-membered ring. The only previous work in this regard is that of Green (1) who has reported ring puckering transitions determined from "combination" and "difference" i.r. bands observed in the CH_2 scissoring region of normal trimethylene oxide. Since there are three CH_2 scissoring modes in TMO, the study of the partially deuterated compounds should reveal which of the three modes is responsible for the sequence observed by Green, and further, whether or not the other two modes also combine with the puckering vibration in a similar fashion.

This communication summarizes the analysis of our i.r. spectra of normal, α-d_2, β-d_2, and α,α'-d_4 TMO in the CH_2 scissoring region, while the following paper describes the corresponding Raman results (2).

Theoretical Considerations

It is customary to separate the low frequency, large amplitude puckering motion from the remaining $3N-7$ vibrational degrees of freedom (3). Solution of the separate wave equations will define puckering potential functions which may be different for various vibrational states. As a first approximation one can assume that this potential does not alter significantly with vibrational excitation. For normal trimethylene oxide, Chan *et al.* (4) have been able to fit their far-infrared data to a double minimum function of the type $A(Z^4 - BZ^2)$, Z the puckering coordinate; accordingly, TMO appears to have only a small barrier to inversion (15.3 cm^{-1}) whereby the lowest energy level still lies 12 cm^{-1} above the barrier top. The spacing between two consecutive puckering levels in the ground state increases with increasing puckering quantum numbers for all molecules investigated here (4, 5). We may therefore expect to find

combination band sequences in various fundamental regions corresponding to simultaneous changes in the vibrational quantum number of $\Delta v = +1$, and in the puckering quantum number of $\Delta v_p = 0$ or $\Delta v_p = \pm 1$, selection rules permitting.

As a result of the low inversion barrier, TMO can be considered to be essentially planar. Hence, the normal and the symmetrically deuterated molecules have C_{2v} symmetry, whereas α-d_2 TMO belongs to C_s point group. The out-of-plane puckering vibration is, respectively, B_1 and A''. The selection rules may be established in a fashion similar to that outlined in detail recently by Stone and Mills (3) for cyclobutane. The dipole moments are expanded as a function of the $3N-7$ vibrational coordinates Q_r and the puckering coordinate Z in the usual manner. In this expansion, all first derivatives and, due to the large displacements in Z, only the second derivatives in Q_r and Z, (*i.e.* $\partial^2\mu/\partial Q_r \partial Z$) are retained, all other higher order terms neglected. Considering only the symmetry allowed components in this expansion, the puckering–vibrational matrix element of, for example, the μ_x component[2] is:

$$|\mu_x|_{nm} = \sum_{B_1} \left(\frac{\partial \mu_x}{\partial Q_{B_1}}\right)_0 \langle \Psi_n | Q_{B_1} | \Psi_m \rangle \langle \phi_n | \phi_m \rangle + \sum_{A_1} \left(\frac{\partial^2 \mu_x}{\partial Q_{A_1} \partial Z}\right)_0 \langle \Psi_n | Q_{A_1} | \Psi_m \rangle \langle \phi_n | Z | \phi_m \rangle$$

where the Ψ's and ϕ's are the wavefunctions for the vibrational and puckering levels, respectively, and n and m refer to the vibrational excited and ground states. The first term in this expression gives the μ_x component of the B_1 modes, the intensities of which are modified by the overlap integral $\langle \phi_n | \phi_m \rangle$.[3] This integral limits the transitions to those for which the puckering quantum number does not change; *i.e.*, it results in the fundamental and higher $\Delta v_p = 0$ transitions. The second term gives rise to the μ_x component of A_1 vibrations which, however, are modified by the factor $\langle \phi_n | Z | \phi_m \rangle$.[3] This restriction clearly allows only transitions for which $\Delta v_p = \pm 1$ (or 3, 5, etc.).

Assuming that the geometry of the deuterated compounds is the same as that of normal TMO, we can use the geometrical parameters determined by Chan *et al.* (6) to estimate the principal moments of inertia. We find that all molecules are near oblate symmetric tops with the axis of the greatest moment of inertia, the C axis, being perpendicular to the molecular plane. Accordingly, we expect to find the vapor phase band contours resembling those compiled in Table 1 corresponding to the dipole moment changes in the specified directions.

TABLE 1. Vapor phase band contours for trimethylene oxide and some deuterated analogs

β-d_2	*C*	*B*	*A*
α,α'-d_4	*C*	*A*	*B*

*The *x*-axis is defined as being perpendicular to the molecular plane and the *z*-axis as lying along the C—O diagonal.

For the analysis of the spectra it is of particular importance to note, for example, the following. For some A_1 vibration of the normal compound which by chance has a small dipole moment derivative, we would expect weak *A*-type i.r. bands for the $\Delta v_p = 0$ transitions (and probably quite strong Raman bands, see following paper (2)), but relatively stronger *C*-type $\Delta v_p = \pm 1$ combinations.

Experimental

The synthesis of the deuterated compounds has been described previously (5). The i.r. spectra were obtained on a Perkin–Elmer Model 621 spectrophotometer purged with dry air. A Perkin–Elmer variable path length gas cell, with a range from 1.25–10 m in 1.25 m intervals, was used with sample pressures ranging from 10–40 Torr at room temperature. The calculated spectral slit width was better than 0.8 cm^{-1} in all cases. The instrument was calibrated against water vapor absorptions in the 1600–1400 cm^{-1} region. The reported frequencies constitute averages of several measurements and are believed to be accurate to within ± 0.5 cm^{-1}. Traces of water vapor were often difficult to eliminate, particularly at long path lengths. Residual water bands have been marked with an asterisk in the spectra.

Results and Discussion

The spectra of the four trimethylene oxide molecules between 1650 and 1300 cm^{-1} are shown in Figs. 1–4. In order to make the assignments we proceeded as follows. The difference between $\Delta v_p = +1$ and $\Delta v_p = -1$ transi-

[2]The *x*-axis is defined as being perpendicular to the molecular plane and the *z*-axis as lying along the C—O diagonal.

[3]The significance of these factors has been discussed by Stone and Mills in some detail (3).

tions which have a common puckering level in the vibrational excited state corresponds to the sum of two consecutive puckering transitions in the vibrational ground state. If such combination bands can be observed, and since the values for the pure puckering transitions are known (5), it is possible to identify the various absorptions. In Table 2 we summarize the assignments that we were able to make in this manner. If the position of the fundamental is known, the

first $\Delta v_p = -1$ band can be located readily. Conversely, if it is possible to identify the first $\Delta v_p = -1$ band one can deduce a value for the fundamental. In either case, these transitions must be consistent with the first $\Delta v_p = +1$ band and the first two $\Delta v_p = 0$ bands (if observed). In a similar manner, all transition energies must be internally consistent whichever way they are deduced. The assignments so derived are tabulated in Tables 3–5. Finally, once we have values assigned to the various transitions we may estimate the energy differences between the puckering levels in the vibrationally excited states. This we have done in Table 6, which also shows estimated differences between the corresponding puckering transitions in the ground and excited states. The accuracy of these differences is of the order of ± 1.6 cm^{-1}.

α-CH_2 Scissoring Vibrations

Normal and *β*-d_2 TMO are expected to show an in-phase (A_1) and out-of-phase (B_2) combination of the α-CH_2 scissoring vibration. These should be most easily detected in the *β*-d_2 compound. As Fig. 3 shows, there is no prominent absorption in the entire region that could be readily assigned to either of these fundamental modes, even though they are i.r. active. This is not entirely unexpected as experience has shown that scissoring vibrations of methylene groups adjacent to an oxygen atom are relatively weak (7). However, we do find a sequence of absorptions which shows an excellent correlation with the pure ring puckering transitions (Table 2). Since the first $\Delta v_p = -1$ band is clearly visible at 1452.7 cm^{-1}, the fundamental can be placed near 1502.3 ± 0.8 cm^{-1} (Table 5). There is indeed a weak absorption at 1502.2 cm^{-1} (Fig. 3) which, moreover, corresponds to a Raman line at 1502.4 cm^{-1} (2). Correlation with the $\Delta v_p = +1$ and $\Delta v_p = -1$ bands of the same series allows us to assign the neighboring weak absorptions (*i.e.* 1503.9 and 1500.9 cm^{-1}) to $\Delta v_p = 0$ transitions (Table 5). The preceding simple theoretical analysis suggests that an A_1 fundamental mode may give rise to puckering combination tones whereas they are symmetry forbidden for B_2 vibrations. We can therefore assign the band at 1502.2 cm^{-1} to the in-phase combination of the α-CH_2 scissoring vibration. The apparent *C*-type contours of the accompanying $\Delta v_p = \pm 1$ bands seem to corroborate this, since these combination transitions have B_1 symmetry for which *C* bands are expected (Table 1).

For normal TMO we expect to find corresponding band progressions. Figure 1 and Table 2 confirm this. Unfortunately, the first $\Delta v_p = -1$ band is masked so that the fundamental cannot be located. There is, however, a distinct Raman line at 1505.0 cm^{-1} (2) which we assign to the vibration in question. This is consistent with its absence in the i.r. spectrum. It is this band sequence which Green had reported earlier and for which he was able to deduce correctly the same band origin (1).

For the out-of-phase combination (B_2 symmetry) of the α-CH_2 scissoring in both compounds we expect to find *B*-type contours. Moreover, as stated above, the puckering com-

bination tones should be absent since they are not allowed by symmetry. Indeed, no corresponding absorptions in the spectrum of normal TMO can be found. The spectrum of β-d_2 TMO, on the other hand, shows an apparent *B* band with its central gap at 1479 cm^{-1}. We tentatively assign this position to the vibration in question.

Finally, the single α-CH_2 group of α-d_2 TMO is also seen to give rise to band progressions (Fig. 2 and Table 2). Again, it is not possible from the i.r. spectrum to infer the band origin. We are, however, able to place the fundamental transition at 1492.7 cm^{-1} from a Raman line at 1492.4 cm^{-1} (2).

β-CH_2 Scissoring Vibration

The β-CH_2 scissoring vibration should appear most distinctly in the spectrum of α,α'-d_4 TMO. In fact, Fig. 4 exhibits the anticipated *B* band, centered at 1464.0 cm^{-1}. It is interesting to note that deuteration in the α positions reverses the values of the moments of inertia in the *y* (parallel to the C—C diagonal) and *z* (along the C—O diagonal) directions. Thus *A*-type contours are expected for the same vibration in normal and β-d_2 TMO (Table 1). On either side of the main absorption, weak $\Delta v_p = \pm 1$ bands can be identified (Table 2) which we have assigned as indicated in Table 5. Again, these combination bands have *C*-type contours as expected. It is also noteworthy that, in contrast to the α-CH_2 scissoring mode, the fundamental transition is more intense than its combination tones.

With the aid of Table 2 we were able to identify the corresponding band progressions in normal TMO (Fig. 1). The first $\Delta v_p = -1$ band in this progression at $\sim$1398 cm^{-1} apparently coincides with the $0,3 \rightarrow 1,2$ transition of the α-CH_2 scissoring mode, explaining the anomalous intensity of that band. This places the fundamental absorption at $\sim$1452 cm^{-1}. With the aid of the $\Delta v_p = \pm 1$ progressions the sequence of peaks between 1450–1470 cm^{-1} can then be assigned to $\Delta v_p = 0$ transitions. The fact that these bands are spread over such a wide region must indicate that the puckering energy levels in the excited state of the β-CH_2 scissoring mode are significantly altered from those in the ground state. As was observed for α,α'-d_4 TMO, the fundamental and apparently also the other $\Delta v_p = 0$ transitions are again considerably more intense than the corresponding $\Delta v_p = \pm 1$ bands.

Finally, the β-CH_2 scissoring vibration is seen to give rise to $\Delta v_p = \pm 1$ sequences also in α-d_2 TMO (Tables 2 and 4, Fig. 2). The first $\Delta v_p = -1$ band at 1412.2 cm^{-1} allows one to locate the fundamental near 1460.9 $\pm$ 0.8 cm^{-1}. The spectrum exhibits an apparent *B*-type contour with its central gap at 1461.5 cm^{-1}, so that we may consider this to be the origin for the band progressions of the mode in question.

Puckering Potentials

As has been pointed out in a preceding section, it may be assumed in some cases that the puckering potential essentially has the same form in the vibrational ground state and various vibrationally excited states. Ample verifications of this assumption have been reported in literature (see for example refs. 1 and 3 and refs. cited therein). It appears that also for the scissoring vibrations of trimethylene oxide and its deuterated analogs the puckering potentials in the vibrationally excited states are the same, or nearly so, as the potential in the ground state. As Table 6 shows, the differences between the puckering transitions observed in the ground state (5) and those estimated for the first excited states of the various scissoring modes are well within the experimental uncertainties in most cases. It should be noted that the average excited state transitions have been estimated invariably from at least two independent sources, *i.e.* $\Delta v_p = +1$ and -1 bands, and in a few instances additionally also from $\Delta v_p = 0$ transitions.

There is one notable exception to the overall trend exhibited in Table 6. Namely, for the β-CH_2 scissoring vibration of normal TMO we find significantly large differences that are well beyond the experimental uncertainties. Moreover, these differences appear to alternate in sign for the first five transitions. Although it is difficult to see explicitly how the form of the potential may vary, it seems peculiar that this phenomenon occurs only when the β-methylene group is flanked by two α-CH_2 groups. We are presently engaged in investigating whether or not a suitable potential function can be found to explain these differences. Stone and Mills (3) have recently also suggested other mechanisms that may alter the puckering potential function upon excitation of a vibra-

tional mode. In any event, this interesting variation in the excited state transitions must remain unexplained at this time.

Conclusions

A series of combination transitions arising from an interaction between the ring puckering vibration and several CH_2 scissoring modes have been observed in the i.r. spectra of trimethylene oxide and some of its deuterated analogs. By means of a simple theoretical model for the puckering–vibrational interactions (3) and with the help of the pure puckering transitions (5) the observed absorptions can be explained and assigned. In particular this sort of analysis of the spectra enables us to locate accurately the scissoring vibrations of the CH_2 groups in trimethylene oxide for the first time. The corresponding assignments, summarized in Table 7, are fundamentally different from the only other previous assignments for normal TMO which have been made by Zürcher and Günthard (8) some time ago.

It was also possible to estimate the puckering transitions in the first excited states of some of the CH_2 scissoring vibrations. In all cases except one the form of the puckering potential in the vibrationally excited states appears to be similar to that in the ground state, at least within the experimental accuracies. The β-CH_2 scissoring mode of the normal compound constitutes the only exception, where the differences between the ground state and excited state transitions are significantly large and alternate in sign.

Received February 28, 1972

The vapor phase Raman spectra of trimethylene oxide (TMO) and two of its deuterated analogs (α-d_2 and β-d_2) each show one sharp line on a weak, broad, and unresolved band in the CH_2 scissoring region. Under high resolution these lines are resolved into several components. They are assigned to the fundamentals of the scissoring mode of α-CH_2 (in-phase, A_1 symmetry, in the case of the normal and β-d_2 compound) and overlapping bands resulting from interaction with the low frequency puckering vibration. The agreement between Raman and i.r. data is excellent and the assignments are entirely consistent. Raman lines corresponding to the out-of-phase combination (B_2 symmetry) of the α-CH_2 scissoring vibration and the scissoring mode of the β-CH_2 group (in normal, α-d_2 and α,α'-d_4 TMO) cannot be resolved.

Les spectres Raman en phase gazeuse de l'oxide de triméthylène (OTM) et de ses deux homologues deuteriés (α-d_2 et β-d_2) résultent en une raie prononcée incluse dans une bande faible, large et non-résolue, dans la région du cisaillement des CH_2. Ces raies se séparent en plusieurs composantes dans le spectre à haute résolution. Nous avons assigné celles-ci aux fondamentales du mode de cisaillement du CH_2 en α (en phase, symétrie A_1; cas des composés normal et β-d_2) et à les bandes chevauchantes que résultent de l'interaction avec la vibration de pulsation à basse fréquence. Les résultats des spectres i.r. et Raman concordent très bien et l'assignation des bandes se fait facilement. Les raies Raman correspondant à la combinaison hors-phase (symétrie B_2) de la vibration de cisaillement du CH_2 en α et du mode de cisaillement du groupe CH_2 en β (dans l'OTM normal, α-d_2 et α,α'-d_4) n'ont pas être résolues.

Canadian Journal of Chemistry, **50**, 2771 (1972)

Introduction

During the past few years a number of investigators have reported observing combination band progressions in the mid- and near-infrared regions of four- and five-membered ring compounds resulting from the interaction between the low-frequency out-of-plane ring vibration (ring puckering motion) and some other suitable vibrational mode (1–3). Observation of the same phenomenon by means of vapor phase Raman spectroscopy has so far been rare. Recently we have reported combination progressions in the C—H stretching region observed in the Raman spectrum of normal trimethylene oxide (4). It appears that for some normal modes at least, the i.r. and Raman spectra are complementary in nature and thus facilitate the assignment of the fundamental and combination transitions. As part of a vibrational analysis of trimethylene oxide and several of its deuterated analogs (α-d_2, β-d_2 and α,α'-d_4) it was therefore of considerable interest to obtain the Raman data corresponding to the i.r. band sequences found in the CH_2 scissoring region of these compounds (5).

Theoretical Considerations

In a manner similar to the dipole moments, the polarizabilities may be expanded as a function of the $3N-7$ vibrational coordinates, Q_r, and the puckering coordinate, Z (5). Considering only the symmetry-allowed components of this expansion the puckering–vibrational matrix element of, for example, the α_{x^2} component is

$$|\alpha_{x^2}|_{nm} = \sum_{A_1}\left(\frac{\partial\alpha_{x^2}}{\partial Q_{A_1}}\right)_0 \langle\Psi_n|Q_{A_1}|\Psi_m\rangle\langle\phi_n|\phi_m\rangle + \sum_{B_1}\left(\frac{\partial^2\alpha_{x^2}}{\partial Q_{B_1}\partial Z}\right)_0 \langle\Psi_n|Q_{B_1}|\Psi_m\rangle\langle\phi_n|Z|\phi_m\rangle$$

where the Ψ's and ϕ's are the eigenfunctions for the vibrational and puckering levels, respec-

tively, and n and m refer to the vibrational excited and ground states. The factor $\langle \phi_n | \phi_m \rangle$ in the first term gives rise to transitions for which the puckering quantum number, v_p, does not change (*i.e.* $\Delta v_p = 0$), while the factor $\langle \phi_n | Z | \phi_m \rangle$ in the second term will permit only $\Delta v_p = \pm 1$ bands (the vibrational quantum number changing by $+1$ in both cases) (5). It follows that, for example for an A_1 mode, the fundamental and higher $\Delta v_p = 0$ bands should show measurable intensity only by virtue of their α_{x^2}, α_{y^2}, and α_{z^2} components, whereas the α_{xz} component should give rise only to $\Delta v_p = \pm 1$ bands. B_1 vibrations follow the reverse order. For A_2 and B_2 modes only α_{yz} and α_{xy} are permissible, again in the similar complementary fashion as A_1 and B_1. Clearly, whatever is observed in the Raman spectra depends very much on the relative magnitudes of the polarizability derivatives. It should be noted that this analysis is valid for the symmetric molecules (C_{2v} symmetry) as well as the α-d_2 compound (C_s symmetry) since isotopic substitution should change primarily the moments of inertia and leave the electronic distribution essentially unchanged.

Referring specifically to the scissoring vibrations, we note that the α-CH_2 groups of the symmetrically substituted TMO molecules give rise to an in-phase (A_1) and an out-of-phase (B_2) combination of the bending mode. The analogous β-CH_2 scissoring vibrations also belong to the A_1 symmetry species. It is generally accepted that totally symmetric vibrations normally exhibit higher Raman intensities than non-totally symmetric ones. Moreover, as a result of rotation–vibration interactions, totally symmetric Raman bands (*i.e.* the α_{x^2}, α_{y^2}, and α_{z^2} polarizability components) are characterized by a strong central line-like Q branch, whereas non-totally symmetric Raman bands may resemble type C, B or A infrared contours when α_{xy}, α_{xz} or α_{yz}, respectively, are non-zero depending on the asymmetry of the molecules (6).[2] In the CH_2 scissoring region of the symmetric molecules of the TMO series we may therefore expect to find the fundamentals and the higher $\Delta v_p = 0$ bands of the A_1 vibrations as the most prominent features. The $\Delta v_p = \pm 1$ bands of A_1 modes and all transitions corresponding to the B_2 modes should give rise only to diffuse bands. For α-d_2 TMO one would again expect to see predominantly the $\Delta v_p = 0$ transitions of the single α-CH_2 and the β-CH_2 group.

[2]Normal TMO and all its deuterated modifications considered here are near oblate symmetric top molecules; one could therefore also say that totally symmetric Raman bands resemble parallel i.r. contours, and non-totally symmetric Raman bands resemble perpendicular i.r. contours (6).

Experimental

The synthesis of these compounds (7) and the experimental method used for obtaining the vapor phase Raman spectra (8) were described on previous occasions. The line positions reported in this communication have been measured several times, using superimposed discharge lines from neon and argon lamps for calibration. The accuracy is therefore believed to be $\pm 0.5\ cm^{-1}$. As the Raman signals were very weak especially with the high resolution desired, it was not possible to get polarization data. Gas pressures were about 250–280 Torr (saturated vapor pressure at room temperature).

Results and Discussion

The low-resolution vapor phase Raman spectra of normal trimethylene oxide and its three deuterated modifications (α-d_2, β-d_2, and α,α'-d_4) in general show a weak unresolved band around $1500\ cm^{-1}$ extending over a region of about $50\ cm^{-1}$. In addition, they all exhibit one relatively more intense and sharp line in the same area. For α,α'-d_4 TMO this line (at $1441\ cm^{-1}$) does not correspond to a CH_2 scissoring vibration; the single β-CH_2 group gives rise to an A_1 scissoring vibration which has been clearly assigned to a distinct B-type i.r. band centered at $1464.0\ cm^{-1}$ (5). For the other three compounds we were able to examine the sharp lines under high resolution. The corresponding spectra are reproduced in Figs. 1 to 3. The lines shown in these spectra are all clearly resolved and entirely reproducible.

The line positions are summarized in Table 1. In the same table we also compare these positions with observed infrared bands and values for $\Delta v_p = 0$ transitions derived from infrared $\Delta v_p = \pm 1$ bands (5). The agreement is seen to be excellent and well within the experimental uncertainties. Moreover, the assignment of these Raman lines to $\Delta v_p = 0$ transitions of the α-CH_2 (A_1 in the case of normal and β-d_2 TMO) scissoring mode is confirmed by the internal consistency among the complete infrared and Raman data.

As suggested in the preceding theoretical

section, the A_1 $\Delta v_p = 0$ transitions are indeed the most prominent feature at least for the α-CH_2 vibrations of normal and β-d_2 TMO. The corresponding out-of-phase combinations (B_2 symmetry) do not appear to give rise to Raman bands with measurable intensities. In

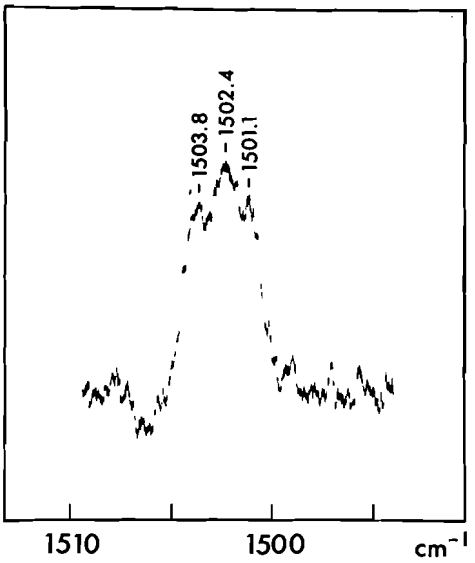

FIG. 3. Vapor phase Raman spectrum in the CH_2 scissoring region of β-d_2 trimethylene oxide: 1 W at 4880 Å excitation; slits 1.0 cm^{-1}.

α-d_2 TMO the most intense Raman lines originate from the $\Delta v_p = 0$ transitions of the single α-CH_2 scissoring mode. It is of particular interest to note that corresponding infrared absorptions for all three compounds are observed either only very weakly or not at all (5). Indeed, it is the $\Delta v_p = \pm 1$ bands of these modes which constitute the prominent features in the infrared spectra of these compounds.

The β-CH_2 scissoring mode does not exhibit the same pattern, even though the vibration has A_1 symmetry (in normal, β-d_2, and α,α'-d_4 TMO). There are no distinct Raman lines in the spectra of any of the compounds which may be assigned to the vibration in question. One can only conclude that these Raman intensities are intrinsically low by virtue of a small polarizability change during the vibration. It is of interest to note that in the i.r. spectrum, especially in the case of α,α'-d_4 TMO, the fundamental transition of β-CH_2 scissoring was found to be significantly more intense than its $\Delta v_p = \pm 1$ bands (5).

Mass Spectrometry in Structural and Stereochemical Problems. CCXVII.[1] Electron Impact Promoted Fragmentation of *O*-Methyl Oximes of some α,β-Unsaturated Ketones and Methyl Substituted Cyclohexanones

YOUNUS M. SHEIKH, RAYMOND J. LIEDTKE, A. M. DUFFIELD, AND CARL DJERASSI

Departments of Chemistry and Genetics, Stanford University, Stanford, California 94305

Received February 15, 1972

Deuterium labeling and high resolution mass spectrometry have been utilized to delineate the modes of mass spectrometric fragmentation of *O*-methyl oximes of α,β-unsaturated ketones and methyl substituted cyclohexanones. α,β-Unsaturated ketone and 2- and 4-methylcyclohexanone *O*-methyl oxime ether derivatives fragment upon electron impact in a manner reminiscent of the carbonyl derivatives from which they were prepared. However, several fragmentation sequences characteristic of the *O*-methyl oxime ether group were observed.

Le marquage au deutérium et la spectrométrie de masse à haute résolution ont été utilisés pour décrire le spectre de fragmentation des oximes *O*-méthylés de cétones α,β insaturées et de cyclohexanones substituées par le méthyle. La cétone α,β insaturée et les dérivés de la méthyl-2 et -4 cyclogexanone oxime *O*-méthyle éther se fragmentent lors de l'impact électronique, de façon semblable aux dérivés carbonylés à partir desquels ils ont été préparés. Cependant, plusieurs séquences de fragmentation caractéristiques du groupe oxime *O*-méthyl éther ont été observées. [Traduit par le journal]

O-Methyl oxime ether derivatives have found extensive use in g.c. and g.c./m.s. studies of relatively complex molecules (1). Recent publications (2) described for the first time the electron impact sponsored fragmentation processes of *O*-methyl oxime ethers. The present paper extends the knowledge of the mass spectral fragmentation behavior of this class of compound to α,β-unsaturated ketones and methyl substituted cyclohexanone derivatives and defines, using deuterium labeling, some of the rearrangement processes accompanying their fragmentation.

O-Methyl Oxime Ethers of Aliphatic α,β-Unsaturated Ketones

Prominent molecular ions are an important and useful feature of the mass spectra (see for example Figs. 1–4) of the *O*-methyl ether oxime derivatives of the α,β-unsaturated ketones

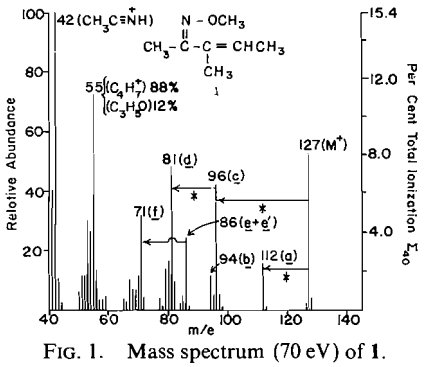

FIG. 1. Mass spectrum (70 eV) of **1**.

examined. Loss of a methyl radical from the molecular ion of **1** could involve either the two alkyl branches or the methyl group of the oxime ether function. Deuterium labeling (**1**, R = CD_3) established that 10% of the methyl lost in this fragmentation arose from C-1. Since ions due to M − CH_3 occur in the spectra of compounds **1–6** the most likely position for the remaining loss of CH_3 in **1** is the *O*-methyl oxime ether group (formation of **a**) but other sources not completely eliminated include the alkyl chains of **1–6**. The facile expulsion of the methyl ether entity in aliphatic α,β-unsaturated ketone *O*-methyl ether oxime derivatives (see Figs. 1–4) should be contrasted to the behavior observed (2) with the same derivative of aromatic aldehydes and ketones in which this process was not observed.

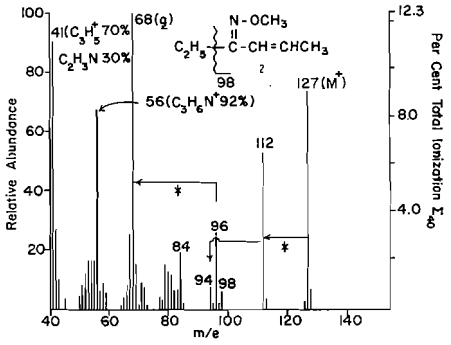

FIG. 2. Mass spectrum (70 eV) of **2**.

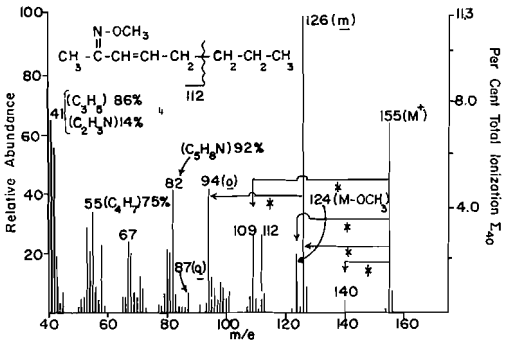

FIG. 3. Mass spectrum (70 eV) of **4**.

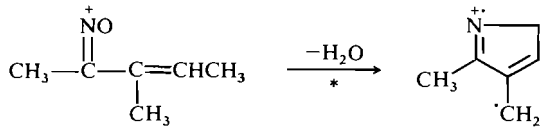

a, *m/e* 112 **b**, *m/e* 94

SCHEME 1

A characteristic fragmentation of the species **a** occurs by the elimination of water (metastable ion observed in all instances) and one representation for the product ion, using **1** as an example, is **b**, *m/e* 94 (Scheme 1). In the trideuterio derivative (**1**, R = CD_3) most (80%) of the label was retained.

The ion of mass 96 (M − OCH_3) in the mass spectrum (Fig. 1) of **1** is moved predominantly to *m/e* 99 in the corresponding trideuterated analog (**1**, R = CD_3). This ion, assigned structure **c**, *m/e* 96, is envisaged as arising from a four-centered reaction in which the methoxyl radical attached to nitrogen is expelled. The species **c** decomposes by the elimination of a methyl radical (metastable ion observed) and the product is rationalized in terms of **d**, *m/e* 81. Only 60% of the ion yield at *m/e* 81 in Fig. 1 was located at *m/e* 84 in the spectrum of the tri-

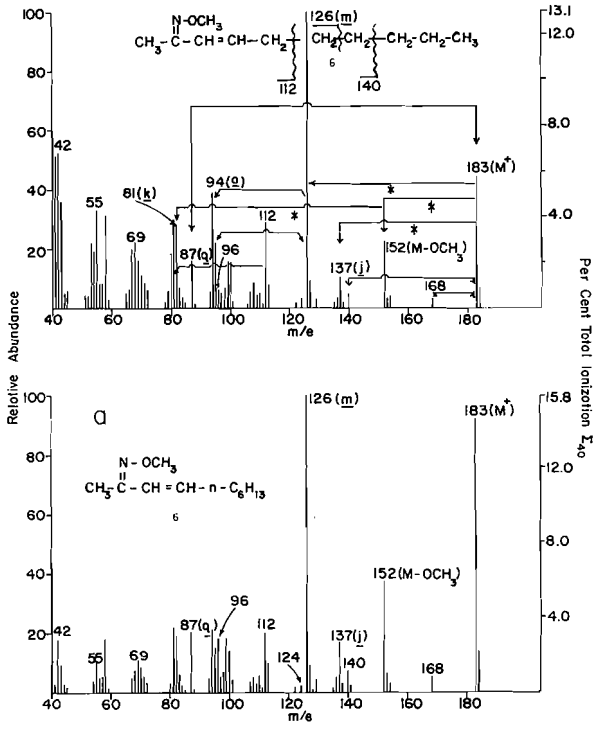

FIG. 4. Mass spectrum (70 eV) of **6**. (*a*) Mass spectrum (15 eV) of **6**.

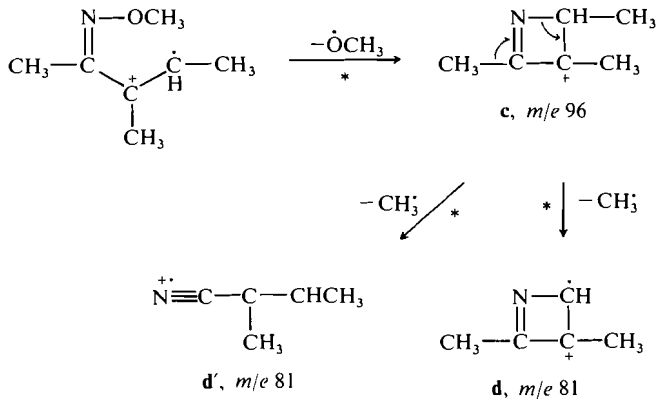
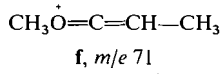


SCHEME 2

deuterated compound **1** ($R = CD_3$) indicating that other modes of formation of *m/e* 81 exist. One possibility, which accounts for 25% of the ion yield, is depicted by **1** → **d′**, *m/e* 81 (Scheme 2).

The ion of mass 86 ($M - CH_3CN$) in the spectrum (Fig. 1) of **1** is analogous to the low abundance ion of mass 72 ($M - C_2H_5CN$) observed in the mass spectrum (Fig. 2) of the ethyl analog **2**. These processes presumably occur by a four-centered transition state (for instance **1** → **e**, *m/e* 86) (see Scheme 3). The CD_3 analog of **1** ($R = CD_3$) surprisingly indicated that 70% of the trideuteriomethyl label was eliminated while loss of CHD_2CN (15%), CH_2DCN (40%), and CH_3CN (11%) contributed to the overall process. Clearly some hydrogen–deuterium exchange must precede the formation of **e**. One rationalization for H–D scrambling is depicted by **1** → **1***a*.

Further loss of a methyl radical from **e** serves as the origin for the ion (97% $C_4H_7O^+$) of mass 71 in Fig. 1. In the CD_3 analog of **1** ($R = CD_3$) the peak in question is distributed between *m/e* 71, 72, and 73. This indicates that further randomization of the label occurs prior to the formation of a species which we represent as **f**, *m/e* 71.



f, *m/e* 71

High resolution mass spectrometry established the composition of *m/e* 55 in the mass spectrum (Fig. 1) of **1** as 88% $C_4H_7^+$; 10% $C_3H_5N^+$, and 2% $C_3H_3O^+$ while the corresponding ion in the ethyl analog (**2**, Fig. 2) at *m/e* 41 consisted of $C_3H_5^+$ (70%) and $C_2H_3N^+$ (30%). The hydrocarbon ions can be interpreted as arising from the alkenyl portions of **1** and **2** respectively.

The abundant ion of mass 68 in the spectrum

c′, *m/e* 96 **g**, *m/e* 68

SCHEME 4

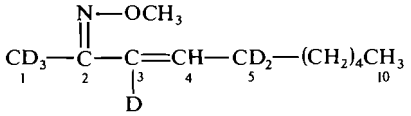
(Fig. 2) of **2** owes its genesis (mestastable ion recognized) to the loss of ethylene (high resolution) from the ion **c′**, *m/e* 96 ($M - OCH_3$). This process could be rationalized in terms of a five-membered transfer of hydrogen to nitrogen (**c′** → **g**) (Scheme 4). Protonated acetonitrile (**h**, $R = CH_3$) and propionitrile (**h**, $R = C_2H_5$) ions respectively account for the appearance of charged fragments of mass 42 and 56 in the mass spectra (Figs. 1 and 2) of **1** and **2**. These conclusions are in agreement with the results from high resolution mass spectrometry.

$$R{-}C{\equiv}\overset{+}{N}H$$

h; **1**, $R = CH_3$, *m/e* 42
2, $R = C_2H_5$, *m/e* 56

The effect of substituting an alkyl chain for the methyl group (R″) can be gauged from the mass spectra (Figs. 3 and 4) of compounds **4** and **6** which contain an *n*-butyl and *n*-hexyl chain respectively. In the case of the *n*-hexyl derivative (**6**) extensive deuterium labeling has made possible the presentation of plausible fragmentation pathways.

The molecular ions of compounds (**3**–**6**) are abundant (see for instance Figs. 3 and 4) while the M − 15 species is of reduced ion yield. The expulsion of a methyl radical from the parent species of these compounds is ascribed in 50% yield to a process analogous to that postulated for the formation of **a** since equal losses of CD_3 and CH_3 were observed in the spectrum of **6***a*. On lowering the ionizing voltage to 15 eV loss of CH_3 was twice as frequent in **6***a* as loss of CD_3. The low ion yield resulting from the elimination of CD_3 in **6***a* should be contrasted to the situation observed (3) for the parent α,β-saturated ketone (**7**) where expulsion of C-1 accounted for the origin of the base peak at 12 eV.



6*a*

The loss of a methoxyl radical from the molecular ions of the alkyl substituted derivatives (**3**–**6**) is explicable by a process analogous to that suggested for the formation of ion **c**. The ion of mass 137 ($M - CH_4NO$ by high resolution) in the mass spectrum (Fig. 4) of **6** is accompanied by metastable ion formation, indicating the molecular ion to be its precursor, and similar expulsions are observed in the mass spectra of **3**, **4**, and **5**. Deuterium labeling in the *n*-hexyl derivative indicated that hydrogen was eliminated from C-6 (0.55), C-7 (0.20), and a combined total of 0.25 from C-1 and -3. This process, using the *n*-hexyl analog **6** as example, would yield **j**, *m/e* 137 (see Scheme 5). A metastable ion established a parent–daughter relationship between **j** and the species of mass 81 which we designate as **k**. High resolution mass spectrometry confirmed the loss of C_4H_8 in this process since the ion of mass 81 was composed of $C_6H_9^+$ (60%), $C_5H_7N^+$ (33%), and $C_5H_5O^+$ (7%).

The peak at *m/e* 126 is the base peak in the spectra (see for instance Figs. 3 and 4) of the C-4 alkyl substituted methoxy oximes (**3**–**6**) studied. The results obtained from deuterated analogs of **6** are consistent with the assignment of structure **m**, *m/e* 126 to this ion. At low ionizing voltages (15 eV) the ion **m** remains the base peak (see Fig. 4*a*) and it should be noted that a similar process (γ-cleavage) generated an abundant ion in the mass spectra of the α,β-unsaturated ketones (3) from which the methoxy oximes were prepared. Loss of methanol from **m** (verified by a metastable ion) affords the fragment **o**, *m/e* 94 and high resolution mass spectrometry established this ion's composition as 97% $C_6H_8N^+$ and 3% $C_7H_{10}^+$. Deuterium labeling indicated that only 0.30 of one hydrogen atom (see Scheme 6, **m** → **o**) originated from

SCHEME 6

C-6 together with a total of 0.25 from C-1 plus C-3. This result indicates essentially a random loss of hydrogen in the formation of the species of mass 94 from that of mass 126.

In a previous publication (3) concerned with the mass spectral fragmentation of α,β-unsaturated ketones we observed the expulsion of acetone from the molecular ion of **7** to be a significant process at 70 eV and the second most intense fragmentation (86% relative abundance) at 12 eV. The analogous fragmentation in the case of the *O*-methyl oxime ether (**6**) would generate the species **p**, *m/e* 96 and **q** would be the neutral molecule (*O*-methyloxime of acetone) eliminated (see Scheme 7). High resolution mass spectrometry confirmed the composition of **q**, *m/e* 87 but no ion corresponding to **p** was observed.[2] The appearance of **q** in the *O*-methyl ether oxime derivatives can be attributed to charge localization on the nitrogen atom. The sources of hydrogen in this double hydrogen rearrangement (formation of **q**) were determined (from the mass spectra of **6***b*, **6***c*, and **6***d*) to be: C-5 (0.35), C-6 (0.40), and C-7 (0.55). In the case of the ketone **7** the values for hydrogen transfer leading to acetone elimination and the formation of a hydrocarbon ion

[2]The composition of the ion of mass 96 in Fig. 4 was determined to be 84% $C_6H_{10}N^+$ and 16% $C_6H_8O^+$. The nitrogen-containing component at this ion yield could arise from the loss of formaldehyde (CH_2O) from the species **m** but no metastable ion was found to support this contention.

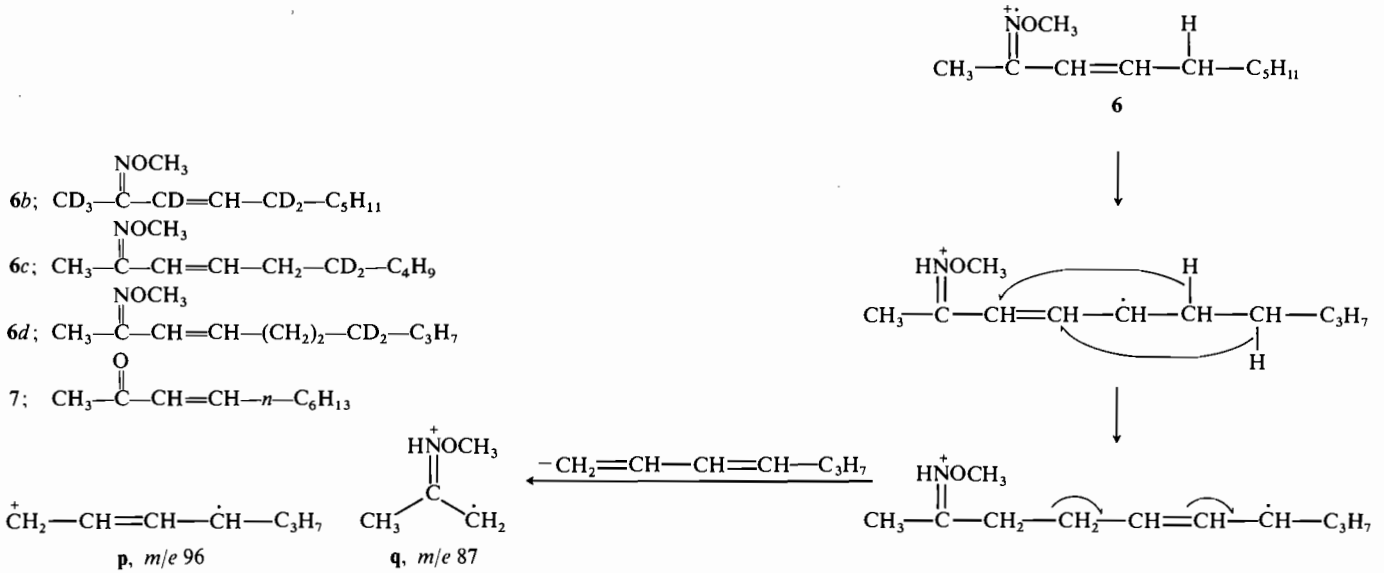

SCHEME 7

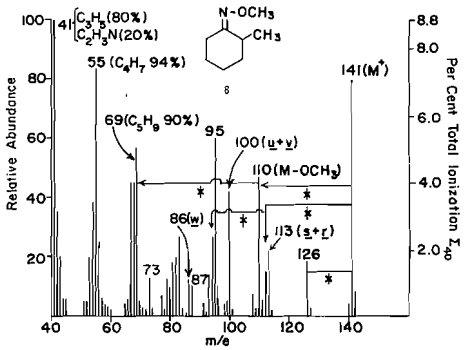

FIG. 5. Mass spectrum (70 eV) of **8**.

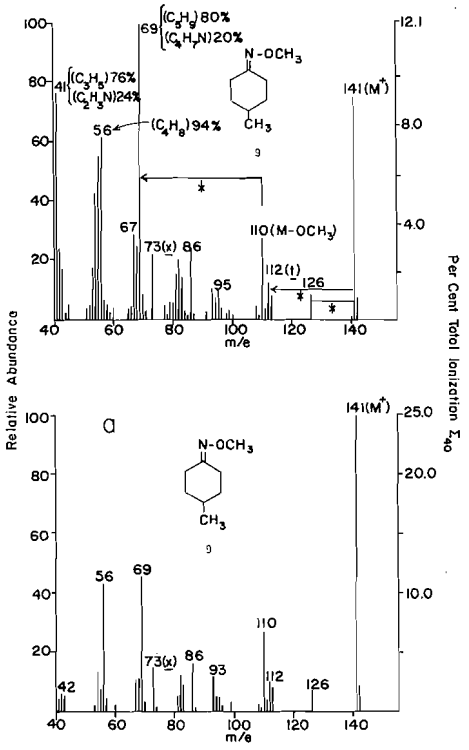

FIG. 6. Mass spectrum (70 eV) of **9**. (*a*) Mass spectrum (15 eV) of **9**.

species were C-5 (0.50), C-6 (0.80), and C-7 (0.30) (3).

The ions below mass 80 in the four alkyl *O*-methyl ether oximes investigated (**3**–**6**) do not appear to contain any ions of appreciable diagnostic utility and no discussion of their possible geneses will be presented.

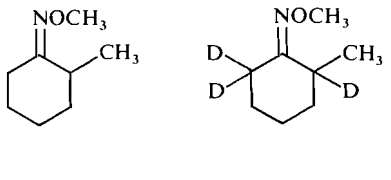
Except for the presence of an abundant molecular ion, the mass spectra of *O*-methyl oxime ethers of α,β-unsaturated ketones offer no diagnostic advantages, as compared to the ketones from which they are derived, in interpretation because of the large number of fragment ions observed.

O-Methyl Oximes of 2- and 4-Methylcyclohexanone

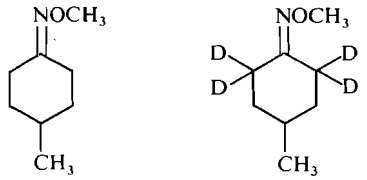
The base peak in the mass spectra (Figs. 5 and 6) of 2-methyl and 4-methylcyclohexanone *O*-methyl oxime (**8** and **9**) and of cyclohexanone *O*-methyl oxime (2*a*) corresponds to their respective molecular ions. This behavior is in contrast to cyclohexanone oxime where the parent ion attains only 20% relative abundance (4). Loss of a methyl radical from the parent ions of **8** and **9** yields low abundance ions which are rationalized as arising from loss of the *O*-methyl group.

Loss of 28 a.m.u. (ethylene) from the molecular ion of **8** and **9** yields the peak at *m/e* 113 in Figs. 5 and 6. Deuterium labeling (**8***a*) indicated that for the 2-methyl isomer 50% of the ethylene expropriated originated from C-5 and -6 allowing the rationalization **8** → **r**, *m/e* 113 to be presented (Scheme 8). The remaining source of extruded ethylene could be explained by β-fission of the molecular ion (see **8** → **s**, *m/e* 113) followed by homolytic fission of the C_3—C_4 bond. This process has analogy with that found to operate in the extrusion of ethylene from cyclohexanone oxime (4).

In contrast the 4-methyl derivative (**9**) expelled ethylene by a more complex route since 40% of this species' yield involved the loss of a single deuterium atom from the parent ion of **9***a*. The remaining 60% of this ion contribution could arise by a process similar to that depicted



8 **8***a*



9 **9***a*

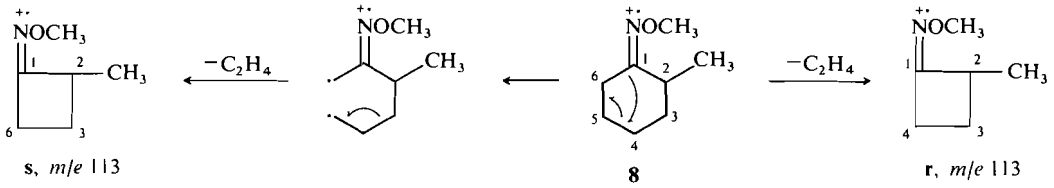
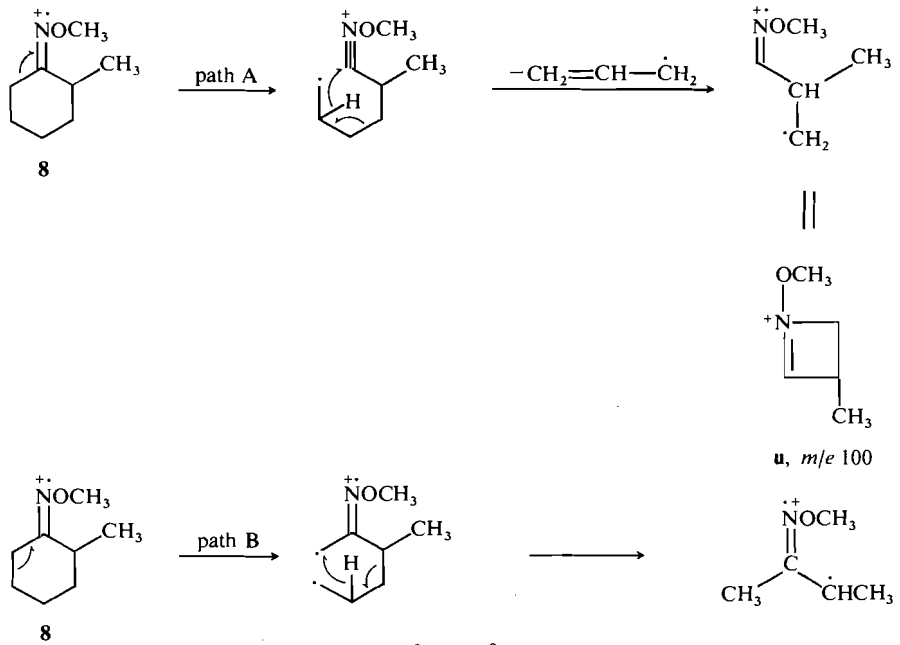


SCHEME 8

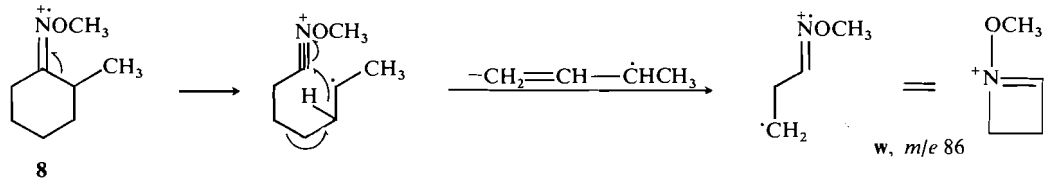
by **8** → **r** but the presence of an M − 29 ion in the unlabeled compound ruled against a quantitative answer being presented. In contrast to the process **8** → **s**, suggested for the loss of ethylene from 2-methylcyclohexanone *O*-methyl oxime, the elimination of propene from the parent ion of **9** yielded only a low (3% relative abundance, see Fig. 6) intensity ion of mass 99.

The ion of mass 110 (M − OCH_3) in the mass spectra of **8** and **9** (Figs. 5 and 6) requires no discussion. However, both of these compounds, as did the *O*-methyl ether oxime of cyclohexanone (2*a*), eliminate 41 a.m.u. (C_3H_5) from their respective molecular ions. In the case of the 2-methyl derivative (**8**) 55% of the ion in question arose from loss of C-6, -5, and -4 (less one hydrogen atom) while the remainder (45%) could be explained by loss of C-5, -4, and -3 (less one hydrogen atom). These results are explicable by invoking an initial α-cleavage (path A) or β-cleavage (path B) of the molecular ion relative to the imine bond (Scheme 9).

If the rationalization depicted as path A occurred by fission of the C_1—C_2, bond of **8** the peak at *m/e* 86 (M − C_4H_7) in Fig. 5 would result (Scheme 10). However, no more than 50%



SCHEME 9



SCHEME 10

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

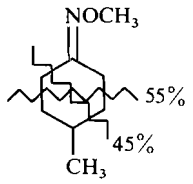
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of this ion's (**w**) yield can arise from this process since only this portion was displaced to *m/e* 88 in the spectrum of **8***a*. The proximity of other ions did not allow an indication of the remaining disposition of this peak in the spectrum of **8***a*.

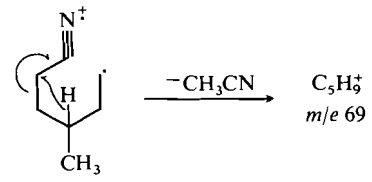
The loss of 55 a.m.u. (C_4H_7) in the mass spectrum (Fig. 6) of **9** occurred by the following two fragmentations as shown from the mass spectrum of **9***a* where this ion was located at *m/e* 90 (55%, β-cleavage) and *m/e* 88 (45%, α-cleavage).



9

Loss of C_5H_8 (high resolution) from the molecular ion of **9** generates (Fig. 6) a fragment of mass 73 and this species remains prominent at low ionizing (15 eV) voltages (see for instance Fig. 6*a*). This ion was located at mass 75 (60%) and mass 76 (40%) in the tetradeuterio derivative **9***a*. The rationalizations (**9** → **x**, *m/e* 73 by paths A and B) explain the distribution of the fragment **x** at *m/e* 75 (path A) and *m/e* 76 (paths A and B) in the spectrum of the labeled analog **9***a* (Scheme 11).

Analogous rationalizations to **9** → **x**, *m/e* 73 (paths A and B) can be applied to the formation of the ions of mass 73 and 87 in the mass spectrum (Fig. 5) of **8**. The former was shifted to *m/e* 76 in 70% yield in the trideuterio analog (**8***a*) while *m/e* 87 was located at *m/e* 89 (70%) in the spectrum of this labeled derivative.



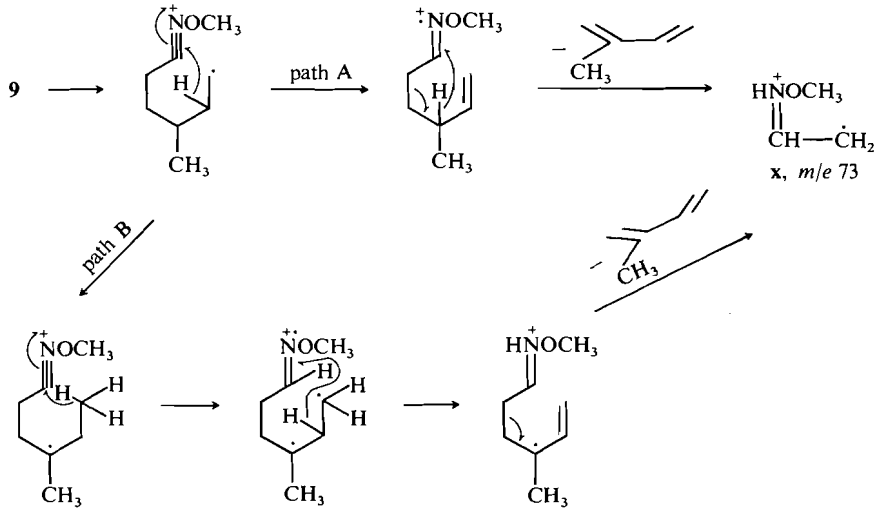
y, *m/e* 110

SCHEME 12

The prominent ions of mass 69 in Figs. 5 and 6 were shown to consist of (for **8**) $C_5H_9^+$ (92%), $C_4H_7N^+$ (5%), and $C_4H_5O^+$ (3%) and (for **9**) $C_5H_9^+$ (80%) and $C_4H_7N^+$ (20%). The hydrocarbon contribution in each instance could arise (metastable ions observed) from the M − OCH_3 species (**y**, *m/e* 110) by the elimination of CH_3CN and formation of $C_5H_9^+$ (Scheme 12). As suggested previously (2*a*), and confirmed from this investigation of labeled methyl cyclohexanone *O*-methyl oxime ethers, their electron impact fragmentation processes are relatively complex with the formation of many ions which serve to complicate interpretation of these mass spectra.

Experimental

Mass spectra were obtained by Mr. R. G. Ross with an



SCHEME 11

MS-9 mass spectrometer operating at 70 eV, 100 μA trap current and an ion source temperature of 180°. Samples were introduced by the heated inlet system (150°) and low voltage measurements refer to nominal values only. High resolution mass measurements were obtained using the MS-9 mass spectrometer interfaced to the ACME computer system of the Stanford University Medical School. The hydrogen transfer processes determined by deuterium labeling are considered accurate to $\pm 5\%$.

Deuterated and non-deuterated α,β-unsaturated ketones were either obtained commercially or prepared according to previously reported procedures (3).

Preparation of O-Methyloximes

The appropriate α,β-unsaturated ketone or cyclic ketone (100 mg) in pyridine (0.2–0.3 ml) was warmed with methoxyamine hydrochloride (100 mg) to 80° for 15 min and then allowed to stand overnight. The reaction was worked up with ether in the usual way and a final purification was achieved by preparative gas chromatography over a 10% SE 30 on Gas Chrom W (60–80) column (1/4 in. × 10 ft).

Preparation of 8a and 9a

The appropriate cyclohexanone was exchanged twice in an excess of D_2O/NaOD for 2 days under reflux. The ketone was isolated by ether extraction and the exchange procedure repeated for an additional 2 days. The deuterated cyclohexanones were then converted to their *O*-methyl oxime derivatives as described above.

The following isotopic purities were obtained: **8***a*, 92% d_3, 5% d_2, 3% d_1; **9***a*, 94% d_4, 4% d_3, 2% d_2.

A New Preparative Method of 1,6-Diketones from Fatty Acids and Vinylmagnesium Chloride

SHOJI WATANABE, KYOICHI SUGA, TSUTOMU FUJITA, AND YUKIO TAKAHASHI

Department of Applied Chemistry, Faculty of Engineering, Chiba University, Yayoicho, Chiba, Japan 280

Received April 11, 1972

The reaction of vinylmagnesium chloride with a fatty acid or its ester in the presence of cuprous chloride gives a 1,6-diketone. From *n*-valeric acid, *n*-tetradecane-5,10-dione is obtained in 53% yield. From methyl *n*-valerate, a mixture of *n*-tetradecane-5,10-dione (33%) and 5-oxo-1-nonene (34%) is obtained.

La réaction du chlorure de vinyle magnésium avec les acides gras et leurs esters, en présence de chlorure cuivreux, donne une dicétone-1,6. A partir de l'acide *n*-valérique, on obtient la *n*-tétradécanedione-5,10 avec un rendement de 53%. A partir du *n*-valérate de méthyle, on obtient un mélange de *n*-tétradécanedione-5,10 (33%) et d'oxo-5 nonène-1. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2786 (1972)

Various preparative methods of diketones are known (1). However, a direct synthesis of 1,6-diketones from a fatty acid or its ester has not been known. These authors reported that the reaction of vinylmagnesium chloride with benzoic acid gave 5-oxo-5-phenyl-1-pentene (2). We have found that such a reaction in the presence of cuprous chloride with fatty acids gives 1,6-diketones, and that with methyl esters leads to a mixture of 1,6-diketones and vinyl ketones.

Thus, vinylmagnesium chloride (0.2 mol) in tetrahydrofuran was added to a mixture of *n*-valeric acid (**1**) (0.05 mol) and cuprous chloride (0.05 mol), the reaction mixture was agitated for 8 h, and allowed to stand overnight. Decomposition of excess Grignard reagent with saturated ammonium chloride solution, and work-up gave *n*-tetradecane-5,10-dione (**2**) in 53% yield. Various 1,6-diketones were prepared

$$\underset{\mathbf{1}}{CH_3CH_2CH_2CH_2COOH} \xrightarrow[CuCl]{CH_2=CHMgCl} CH_3CH_2CH_2CH_2\overset{\overset{O}{\|}}{C}CH_2CH_2CH_2CH_2\overset{\overset{O}{\|}}{C}CH_2CH_2CH_2CH_3$$

2

from fatty acids and the results are listed in Table 1.

From the reaction of methyl *n*-valerate with vinylmagnesium chloride in the presence of cuprous chloride, a mixture of compound **2** (yield, 33%) and 5-oxo-1-nonene (**3**) (yield, 34%) was obtained. From the reaction of other esters of fatty acids, similar mixtures were obtained (Table 1). However, the reaction of benzoic acid gave 1,6-diphenyl-1,6-hexanedione in poor yield.

$$CH_3CH_2CH_2CH_2COOCH_3 \xrightarrow[CuCl]{CH_2=CHMgCl} CH_3CH_2CH_2CH_2\overset{\overset{O}{\|}}{C}CH_2CH_2CH_2CH_2\overset{\overset{O}{\|}}{C}CH_2CH_2CH_2CH_3$$

2

$$CH_3CH_2CH_2CH_2\overset{\overset{O}{\|}}{C}CH_2CH_2CH{=}CH_2$$

3

This procedure for the synthesis of 1,6-diketones from fatty acids or their esters and vinylmagnesium chloride is a new useful method.

Experimental

Reaction of Vinylmagnesium Chloride with n-Valeric Acid (1)

A solution of vinylmagnesium chloride (0.2 mol) in tetrahydrofuran was prepared from magnesium and gaseous vinylchloride as reported previously (3, 4). The solution was then added to a mixture of *n*-valeric acid (5.1 g, 0.05 mol) and cuprous chloride (4.95 g, 0.05 mol) at room temperature. The reaction mixture was agitated for 10 h at room temperature and worked-up with aqueous ammonium chloride. The mixture was repeatedly extracted with isopropylether, the extract dried, solvent removed, and the residue distilled *in vacuo* to give 3.0 g of compound **2**; b.p. 120°/5 Torr; m.p. 57°; i.r. (cm^{-1}): 1700 (>C=O); n.m.r. (δ, p.p.m.): 1.4 (6H, triplet, CH_3—), 1.9 (12H, multiplet, —CH_2—), 2.3 (8H, triplet, —CH_2—CO—CH_2—).

Anal. Calcd. for $C_{14}H_{26}O_2$: C, 74.30; H, 11.58. Found: C, 74.29; H, 11.53.

The same technique was used on the reaction of vinylmagnesium chloride with other carboxylic acids. These products are listed in Table 1. The physical constants of these compounds are as follows.

Doubling Proton Magnetic Resonance Signals by Use of Tris(dipivalomethanato)europium(III)

P. JOSEPH-NATHAN, J. E. HERZ, AND V. M. RODRÍGUEZ[1]

Departamento de Química del Centro de Investigación y de Estudios Avanzados, Instituto Politécnico Nacional, P.O. Box 14-740, México 14, D.F., México

Received January 18, 1972

Doubling of some p.m.r. signals from some steroidal diastereoisomers following treatment with the shift reagent, $(DPM)_3Eu(III)$, is reported for the first time. Similar examination of the hemithioethyleneketal of methyl isopropyl ketone provided the first evidence for the diastereotopic nature of the methyl groups of the isopropyl moiety of this compound. The resolution of signals from diastereoisomers and the failure to detect the diastereotopic nature of the methylene protons of different hemithioethyleneketals is discussed briefly in terms of inhibition of free rotation in pseudocontact association.

Le dédoublement de certains signaux p.m.r. à la suite du traitement par le $(DPM)_3Eu(III)$ de certains stéroïdes diastéréoisomères, est rapporté pour la première fois. De même, l'examen de l'hémithioéthylénecétal de la méthyl isopropyl cétone fournit la première preuve de la nature diastéréotopique des groupes méthyles de la partie isopropyle dans ce composé. La résolution des signaux à partir des diastéréoisomères et l'échec dans la détection de la nature diastéréotopique des protons du méthylène de divers hémithioethylènecétals sont discutés brièvement en fonction de la rotation libre inhibée dans l'association par pseudo contact.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2788 (1972)

The determination of the optical purity of enantiomeric mixtures by n.m.r. has been approached in several ways (1, 2). The magnetic non-equivalence of diastereotopic nuclei is detected either by suitable derivation (2–5) or by the use of chiral solvents (6).

Nuclei which are diastereotopic[2] must have different chemical shifts in both achiral and chiral solvents. However, in many cases the non-equivalence is not large enough to be observed even with superconducting magnets and therefore the nuclei show apparent accidental coincidence of n.m.r. signals. In extreme cases, it has been found that while the p.m.r. spectra gave only one doublet for two methyl groups of an isopropyl moiety, the carbon-13 magnetic resonance spectra (7, 8) showed a signal for each methyl.

Achiral solvent-induced changes in the magnitude of the chemical shift non-equivalence for diastereotopic nuclei are well known (*i.e.* the use of benzene). Because this method is limited in application by the nature of solvent–substrate interaction, the use of shift reagent was investigated to determine the utility of these agents in pseudocontact interaction with diastereotopic substrates. Recently the use of optically active shift reagents has been reported for the determination of enantiomeric purity (9–11).

In the present communication we describe the use of tris(dipivalomethanato)europium(III) in carbon tetrachloride solutions for both the resolution of the p.m.r. signals of diastereoisomeric mixtures and for the detection of the diastereotopic nature of the methyl groups of an isopropyl moiety. In both cases, doubling of the p.m.r. signals was caused by the shift reagent.

The formation of tetrahydropyranyl ethers from steroidal alcohols and dihydropyran results in the creation (12) of a new chiral center. The product is a mixture of diastereoisomers and we know of no case where the presence of both constituents has been visualized unequivocally.

When 3β-tetrahydropyranyloxy-5α-cholestane (**1**) (13), 3β-tetrahydropyranyloxy-cholest-5-ene (**2**) (14), 3β-(1′-methoxyethoxy)-5α-cholestane (**3**), and 3β-(1′-methoxyethoxy)-cholest-5-ene (**4**) were subjected to p.m.r. analysis in the

[1]Present address: Escuela de Ciencias Químicas, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Mich., México.

[2]This description was introduced by Kessler (19) in reference to "degenerate isomers" for which he proposed the term "topomers"; thus magnetically non-equivalent groups are also termed "diastereotopic groups"; see also Ref. 20.

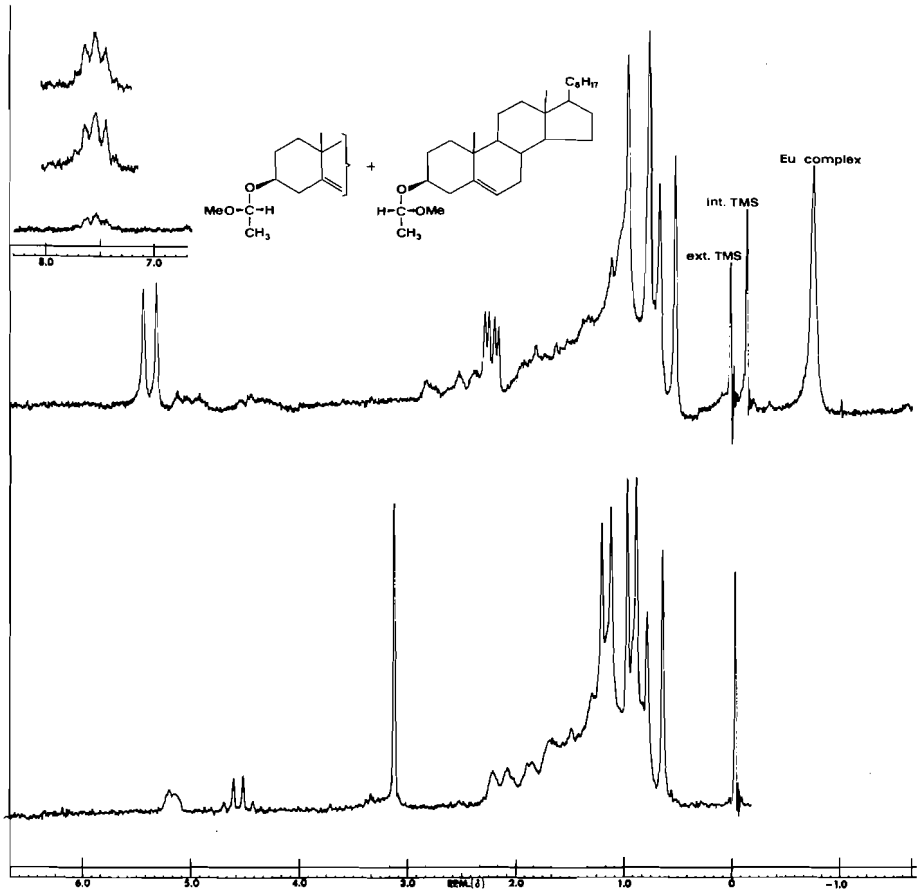

FIG. 1. P.m.r. spectra of 0.1 mmol of 3β-(1′-methoxyethoxy)-cholest-5-ene before and after the addition of 0.014 mmol of $(DPM)_3Eu(III)$ in 0.3 ml of CCl_4.

presence of $(DPM)_3$(III), various signals showed duplicity. This is attributable to the two diastereoisomeric constituents of these ketals. The results obtained with 3β-(1′-methoxyethoxy)-cholest-5-ene (**4**) are shown in Fig. 1.

It can be seen that the doublet ($J = 5.2$ Hz) centered at 1.20 p.p.m., which corresponds to the methyl group of the acetaldehyde moiety, is resolved into two partially superimposed doublets ($J = 5.2$ Hz each) centered at 2.18 and 2.22 p.p.m. (from external TMS (15)). The singlet at 3.15 p.p.m., corresponding to the methoxyl group, is resolved into two singlets at 5.32 and 5.43 p.p.m. respectively, which can be integrated for diastereoisomeric ratio estimations. The signal of the proton attached to the carbon bearing both oxygens of the ketal is originally found as a quartet ($J = 5.2$ Hz) centered at 4.58 p.p.m. After the addition of the shift reagent (Fig. 1) the signal appears as a quintet ($J = 5.2$ Hz) of relative intensities 1:4:6:4:1 centered at 7.55 p.p.m. which results from a partial overlap of two quartets of relative intensities 1:3:3:1 arising from a first order spin–spin coupling with the protons of the 2′-methyl group. In this experiment the C-19 methyl group shifts from 1.00 to 0.95 p.p.m. while the C-18 angular methyl shifts from 0.67 to 0.50 p.p.m. The C-21 protons are obscured by the rest of the signals and could not be assigned but the isopropyl methyl groups of the side chain shift from 0.87 to 0.72 p.p.m.

Straight lines are obtained when the shifts of the various protons (abscissa) are plotted (15)

against increasing quantities of europium complex (ordinate). The inverse of the slopes of these lines, which represent the shift in p.p.m. when 1 mol of $(DPM)_3Eu(III)$ per mol of the substrate is present, are listed in Table 1.

The first entries in Table 1 correspond to the signal which is shifted most and the second one to the same proton of the other diastereoisomer. Some multiplets became broader due to partial resolution of the signals of the diastereoisomers but it is very difficult to assign chemical shifts to each constituent of such signals. In these cases Table 1 shows the overall center of the multiplets.

Although it is very difficult to determine which of the two diastereoisomers shifts more, the difference in chemical shifts is in some cases sufficient to observe two separated resonances for the protons of the C-19 angular methyl group when an adequate amount of the shift reagent is added to the diastereoisomeric mixture.

Although the ketals (**1**–**4**) are mixtures of two diastereoisomers, in the absence of shift reagents they display p.m.r. spectra of a single compound. There should be a fast (on the n.m.r. time scale) free rotation of the steroidal 3β-substituents and the chemical shifts of the various protons will therefore correspond to averages of conformers. Since europium complexes interact with 3-substituted steroids in a stereospecific way (15), upon addition of the bulky shift reagent, the association will decrease the conformational liberty of the 3β-substituent, which will now have different chemical environment, thus permitting the observation of both constituents of the mixture.

In order to obtain additional evidence for the free rotation inhibition process, a series of simple pure molecules (no stereoisomeric mixtures), which should fulfill the sterical requirements for the duplication of p.m.r. signals, were prepared and analyzed.

The most striking results were obtained with the hemithioethyleneketal of methyl isopropyl ketone (**5**). Its n.m.r. spectrum showed the presence of the methyl group as a singlet at 1.45 p.p.m., the isopropyl moiety as a heptet ($J = 7$ Hz) centered at 2.00 p.p.m. and a doublet ($J = 7$ Hz) centered at 0.96 p.p.m. The ethylene protons appeared as two complex signals at 4.05 and 2.95 p.p.m. The chemical shifts of all signals were measured from the TMS signal of a capillary tube containing also carbon tetrachloride (*vide infra*). In the absence of shift reagents this external TMS signal is coincident with the internal TMS resonance frequency. It is important to mention that the line widths at half height of the signals of the doublet at 0.96 p.p.m. were similar to the line width of the TMS signals. Upon addition of the $(DPM)_3Eu(III)$ complex only small shifts of several signals to lower fields occur, since the ketal does not associate well with the europium reagent. However the isopropyl methyl groups now appear as two partially superimposed doublets ($J = 7$ Hz each) at 0.93 and 0.87 p.p.m. from external TMS.

The doubling of the signals of the isopropyl group of compound **5** indicates the diastereotopic nature of the methyl groups. The association process inhibits the free rotation of the group and therefore the methyl groups are now found in different chemical environments. When the isopropyl group is separated by an additional carbon atom from the association site, as in the hemithioethyleneketal of methyl isobutyl ketone (**6**) (16), the doubling of signals is no longer observed, nor is it observed to

reveal the diastereotopic nature of the methylene protons of the hemithioethyleneketals derived from methyl ethyl ketone (**7**) (16), methyl propyl ketone (**8**) or diethyl ketone (**9**). This suggests that the process of inhibition of rotation must fill some strict steric requirements to be observable. The only other cases in which similar observations are reported correspond to some sulfoxides (17).

Experimental

Melting points are uncorrected. Optical rotations were measured in chloroform solution using a Perkin–Elmer 141M polarimeter. N.m.r. measurements were performed on a Varian Associates A-60 spectrometer operated at normal probe temperature in carbon tetrachloride solutions with internal TMS and a capillary containing TMS in carbon tetrachloride. Solutions of 0.1 mmol of the compounds in 0.3 ml solvent were utilized. Microanalytical determinations were carried out by Mr. Joseph F. Alicino, New Hope, Pa.

The hemithioethylene ketals derived from methyl isopropyl ketone, from methyl propyl ketone, and from diethyl ketone were prepared using the method of Djerassi and Gorman (16). N.m.r. spectra confirmed their structures and purity.

The steroidal ketals were prepared according to the procedure of Herz *et al.* (18). 3β-(1′-Methoxyethoxy)-5α-cholestane (**3**) showed m.p. 62–63°, $[\alpha]_D$ +15°.

Anal. Calcd. for $C_{30}H_{54}O_2$: C, 80.65; H, 12.18. Found: C, 80.50; H, 12.21.

3β-(1′-Methoxyethoxy)-cholest-5-ene (**4**) showed m.p. 91–92°, $[\alpha]_D$ −55°.

Anal. Calcd. for $C_{30}H_{52}O_2$: C, 81.02; H, 11.79. Found: C, 80.85; H, 11.54.

Proton Magnetic Resonance Measurements

Solutions of 0.1 mmol of the substrate were weighed directly in an n.m.r. tube to which 0.3 ml of CCl_4 were added. The capillary was inserted and the spectrum recorded. Successive additions of 5 mg of $(DPM)_3Eu(III)$ and spectra determination were carried out until no more shift reagent could be dissolved. The shifts of the various protons and the corresponding substrate shift reagent ratios were graphed as previously shown (15).

A Curious Synthesis of some μ_4-Oxo-hexa-μ-halotetracopper(II) Complexes

B. CARR AND J. F. HARROD

Department of Chemistry, McGill University, Montreal, Quebec

Received March 29, 1972

The thermal decomposition of a series of phenoxo complexes of copper(II), in solution, containing either trichlorophenoxo or tribromophenoxo ligands and a variety of neutral ligands, has led to a rather unique method for the synthesis of μ_4-oxo-hexa-μ-halotetracopper(II) complexes. The yield of this complex was found to increase considerably with the ability of the solvent to autoxidize, and also with the addition of hydroperoxides.

La décomposition thermique d'une série de complexes phenoxo cuivre(II), en solution, contenant des ligands soit de trichlorophenoxo ou de tribromophenoxo et une variété de ligands neutres, a conduit à une méthode de synthèse plutôt unique de complexes de μ_4-oxo-hexa-μ-halotétra-cuivre(II). On constate que le rendement en complexe croît considérablement avec le pouvoir d'autoxydation du solvant ainsi que par addition d'hydroperoxydes.

Canadian Journal of Chemistry, **50**, 2792 (1972)

Introduction

For several years the mechanism of the reactions in [1] has been investigated in our laboratory. These reactions may be carried out in solution in organic solvents, or in the solid state (1, 2).

It has long been recognized that reaction 1 is an idealized equation since the polymers **3** are well known to be branched (1). Even more important, it is also known that these polymers have only modest number average molecular weights ($10^4 - 10^5$), not essentially infinite molecular weights as required by the exact stoichiometry of reaction 1.

In the course of a spectrophotometric study of reaction 1 in benzene, or toluene as solvent and with the complex bis(2,4,6-trichlorophenoxy)bis(pyridine)copper(II), **1***a*, as reactant, it was noted that the absorbance of the solutions did not go to negligibly small levels at 22 500 cm^{-1} on completion of reaction, as expected. The dichloro complex, **2***a*, is completely insoluble, and even on removal of **3***a* from solution, the anomalous absorption remained. This result suggested the presence of a hitherto unidentified reaction product.

A careful workup of reaction products yielded a small amount of golden crystals which proved to be the complex μ_4-oxo-μ-hexahalotetrakis(pyridine copper(II)), previously prepared and characterized by Kilbourn and Dunitz (3). The structure of the complex was confirmed by X-ray crystallography.[1] Further work described in the present paper revealed that formation of μ_4-oxo-copper(II) complexes is a common feature of the decomposition of phenoxocopper(II) complexes in the presence of oxygen, or hydrocarbon hydroperoxides.

Several μ_4-oxo-hexa-μ-halotetracopper(II) complexes have been prepared by other workers, where X is bromine or chlorine, and L is a variety of neutral and anionic ligands (4–8). These complexes were usually prepared in a straightforward manner by refluxing $CuCl_2$ and CuO in various reaction media, and collecting the desired crystals after a few days. Because of the importance of these complexes in understanding the mechanism of reaction 1, we decided to investigate the generality of our own observations.

Results

Decomposition of Bis(2,4,6-trichlorophenoxy) bis(pyridine)copper(II)

The decomposition of **1***a* in benzene in air produced a coarse crystalline precipitate of **2***a* in almost quantitative yield. After filtration and drying, the latter precipitate, under microscopic examination, was found to be contaminated by a small amount of crystalline **4***a* which could be removed by extraction with methylene chloride or acetone. The amount of **4***a* in the precipitate was usually about 3% by weight, and a trace amount was in solution in the reaction solvent.

Repetition of the above procedures in toluene and in cumene as reaction solvents gave **4***a* in *ca.* 15 and 100% yields, respectively. Repetition of the reaction in benzene in the presence of a five-to-one molar ratio of cumylhydroperoxide to **1***a* gave a near quantitative yield of **4***a*.

A series of decomposition of **1***a* in benzene in the presence of some common free radical initiators was followed spectrophotometrically. The results are shown in Fig. 1. Although all of the initiators caused a diminution of the normally observed induction period, the behavior of hydroperoxides was distinctly different from that of peroxide and azo initiators. It is evident that hydroperoxides undergo a very rapid reaction with the starting complex that is qualitatively different from that occurring with other initiators. This difference is also reflected in the difference in the reaction products, as listed in Table 1.

Synthesis of Other μ_4-Oxo-copper(II) Complexes

The synthesis of a number of other μ_4-oxo-copper(II) complexes was attempted by first preparing the starting complex **1** and then decomposing in the same manner as with the formation of **4***a*.

ture of approximately 60% **2***b* and a dark brown complex which on extraction with THF and recrystallization by evaporation was shown to be $Py_4Cu_4Br_6\cdot O$ (**4***b*), by infrared spectroscopy and elemental analysis. Repetition of the decomposition in benzene, in the presence of a one-to-one molar ratio of cumene hydroperoxide to **1***b* gave only a small trace of the μ_4-oxo complex.

μ_4-Oxo-hexa-μ-chlorotetrakis ((ethylamine)copper(II))

Thermal decomposition of **1***c* in benzene, toluene, or cumene, or in benzene in the presence of a hydroperoxide yielded only intractable products, possibly due to autoxidation of the ethylamine ligand. However, catalyzed decomposition in the presence of traces of carbon tetrachloride[2] yielded a precipitate which contained 75% of a lime-green methylene chloride – soluble complex and an intractable gold colored residue. Spectra and elemental analyses of the methylene chloride soluble complex were in accord with those expected for the complex $(C_2H_5NH_2)_4Cu_4Cl_6O$ (**4***c*).

μ_4-Oxo-hexa-μ-chlorotetrakis ((triphenylphosphine oxide)copper(II))

We have thus far been unable to prepare and characterize a stable bis(trichlorophenoxo)bis(triphenylphosphine oxide)copper(II) (**1***d*), because of the extreme ease with which this complex loses neutral ligand. However, a mixture of copper(II) trichlorophenolate and triphenylphosphine oxide (both individually completely insoluble in cumene) in cumene gave a dark brown solution which on thermal decomposition precipitated a large amount of orange-yellow powder, admixed with a small amount of green material. Extraction of this mixture with methylene chloride, followed by evaporation, produced a large yield of beautiful well-formed orange crystals. All physical measurements agreed with the formulation of this complex as $(Ph_3PO)_4Cu_4Cl_6O$ (**4***d*), previously synthesized by Bertrand and Kelley by a different method (7).

Other Attempted Syntheses

Attempts have been made to synthesize μ_4-oxo complexes with dimethylformamide, dimethylsulfoxide, or hexamethylphosphoramide as ligand. Although strong evidence for the formation of the desired products in the former two cases was obtained, the extreme facility with which these ligands dissociate has thus far frustrated complete isolation and characterization.

Bis(trichlorophenoxo)diammine copper(II) (**1***e*) was decomposed under all of the various conditions described above. In all cases the complexes produced were intractable and could not be satisfactorily characterized.

Spectra of μ_4-Oxo Complexes

Tables 2 and 3 list the principal infrared and far-infrared absorptions, respectively, of the

[2]Reaction 1 is powerfully catalyzed by traces of carbon tetrahalides. Full details of this phenomenon will be published elsewhere.

[3] 
dihalo and μ_4-oxo complexes. tom Dieck and Brehm (5) have reported that a band at 588–515 cm^{-1} assigned to an asymmetric group vibration of the Cu_4O tetrahedron is a facile method of identifying the μ_4-oxo-copper complexes. These reported values in this region, along with values reported by other authors (3, 7) provide substantial support for identification of the μ_4-oxo complexes reported in the present work.

Discussion

The present study indicates that reaction 1 is only a rather poor first approximation to the actual reactants and products involved in the thermal decomposition of **1**. In fact, under the best conditions of purity we have been able to achieve, the decomposition of complex **1***a* exhibits an exceedingly long, perhaps infinite, induction period, suggesting the need for an initiator. There is no doubt that oxygen can function as an initiator and reactions in air exhibit quite reproducible behavior, unlike those carried out under vacuum.

The trends observed for the dependence of yield of **4** on solvent strongly indicated that **4** was a product associated with solvent autoxidation. In the case of reactions in benzene, the small amount of **4** produced possibly results from direct reaction of a copper(I) species with molecular oxygen. The most likely first step in reaction 1 is a homolytic dissociation as shown in reaction 2. Apparently reaction 2 does not occur spontaneously, but may be induced by such species as oxygen, radical initiators, and carbon tetrahalides. If Cu(I) is produced it will be subject to competitive oxidation either by phenol-derived oxidants, as in reaction 3 (9), or by added initiator species.

Oxidation as in reaction 3 will eventually produce the complexes **2**, but introduction of an oxide, or hydroxide, ligand during oxidation by O_2, or ROOH, will produce **4**.

The facts that the effectiveness of non-hydroperoxide initiators follows their ease of decomposition, *cf.* Fig. 1, and that no initiator fragments appeared in product copper complexes with such initiators favor the hypothesis that these initiators function by rapid radical attack on coordinated phenoxide, as in reaction 4, rather than by attack at copper.[3] The extremely rapid reactions of hydroperoxides, as manifest by the very rapid fall in absorbance in Fig. 1, are out of line with their ease of homolytic dissociation relative to the other initiators examined (10). The initial rapid reaction is possibly a simple solvolysis of the phenoxo-copper(II) complex by the moderately acidic hydroperoxide.

Since the μ_4-oxo-μ-hexahalotetracopper(II) nucleus has the stoichiometry $3CuCl_2 \cdot CuO$, the

[3]A study of the decomposition of **1***a* in solution by e.p.r. has shown that no detectable concentrations of free radicals build up in the presence of phenoxo-copper complexes. However, phenoxy radicals do appear *after* the phenoxo-copper complex has largely decomposed, due to the slow dissociation of quinol ethers. Details of this study will be reported elsewhere.

[4] 
reaction of **1** with hydroperoxides cannot be occurring to the exclusion of reaction 3 and it is clear that a great deal of additional information is required before a definitive understanding of these reactions is achieved.

The much greater reluctance of **1***b* to yield a μ_4-oxo complex is presumably due to a lower reactivity of bromocopper(I) species towards oxidation and a greater selectivity with respect to the appropriate analog of reaction 3. Bromophenoxocopper(II) complexes decompose much more readily than their chloro-analogs and this presumably reflects a greater facility for reaction 2.

Both **1***c* and **1***e* are difficult to decompose in solution and in the presence of oxygen, or hydroperoxides, yield intractable products. It seems very likely that the neutral ligands become involved in an autoxidation sequence in these cases to give polymerized complexes as products. The decomposition of **1***c* in the presence of CCl_4, although probably still a radical chain process, does not involve oxygen and side reactions of the ligand are less serious. Ethylamine complexes of Cu(II) are often oxidatively unstable (11).

The complexes **4***a*, **4***b*, **4***d*, **4***f*, and **4***g* have been reported previously, and their structures have been established either crystallographically or by infrared spectroscopy in the region of 588–515 cm^{-1}. In addition, a number of other $Cu_4OX_6L_4$ complexes have been prepared and their structures determined. The structural features of these complexes have been discussed in some detail by Bertrand and Kelley (7).

The present study indicates that decomposition of halophenoxocopper(II) complexes may provide a fairly general route to the preparation of μ_4-oxo-copper(II) derivatives. However, their appearance as products in reaction 1 is a complicating and avoidable feature, specifically related to the involvement of oxygen in the initiation process. Our continuing studies of the mechanism of reaction 1 are being carried out under conditions where autoxidation does not occur. Unfortunately, the autoxidation feature is unavoidable in the commercially important catalytic oxidative coupling of phenols, but its influence on the reaction is unknown (13, 14).

Experimental

Materials

For the preparation and isolation of the stable L_2Cu(trihalophenolate)$_2$ complexes, all chemicals, including solvents, were of reagent-grade quality and were used without further purification. For the thermal decomposition of these complexes, all solvents were refluxed over CaH_2 and distilled.

Preparation of Phenoxo-Cu(II) Complexes

Copper(II) Trichlorophenolate

Copper(II) trichlorophenolate was prepared by dissolving sodium hydroxide (0.04 mol) in 150 ml of water, adding 2,4,6-trichlorophenol (0.04 mol), and stirring for about 1 h. A solution of $CuSO_4 \cdot 5H_2O$ (0.02 mol) in 150 ml of water was then added. The resulting dark purple-brown precipitate was then washed with methanol to remove any excess phenol. A near quantitative yield of product was obtained.

Pyridine, Ammonia, or Ethylamine as Neutral Ligand

The complexes L_2Cu(trihalophenolate)$_2$, where the halogen is Cl or Br and L is pyridine, ammonia, or ethylamine, were prepared as described previously (2).

Dimethylformamide or Dimethylsulfoxide as Neutral Ligand

Complexes containing dimethylformamide or dimethylsulfoxide as neutral ligand were prepared by dissolving copper(II) trichlorophenolate (0.02 mol) in an excess (100 ml) of either dimethylformamide or dimethylsulfoxide and stirring for 1 h. The solutions were then added to water, with stirring.

In the case of dimethylformamide a dark brown precipitate was obtained which was recrystallized by dissolution in benzene and addition of hexane. The resulting product had the empirical formula $[(CH_3)_2N \cdot CHO] \cdot Cu \cdot [C_6H_2Cl_3O]_2$ and was presumably a formamide bridged dimer analogous to the hexamethylphosphoramide-bridged dimer described by Tsuruya *et al.* (12).

Anal. Calcd. for $[(CH_3)_2N \cdot CHO] \cdot Cu \cdot [C_6H_2Cl_3O]_2$: C, 33.99; H, 2.07; N, 2.64. Found: C, 34.40; H, 2.11; N, 2.53.

In the case of dimethylsulfoxide, deep purple crystals were obtained which decomposed readily in solution precluding purification of the product. Infrared spectroscopy indicated the presence of both trichlorophenolate and dimethylsulfoxide in the complex.

Decomposition of Phenoxo-Cu(II) Complexes

Spectrophotometric Study

Spectrophotometric studies were carried out with a Perkin–Elmer 124 ultraviolet–visible spectrophotometer. Since $(C_5H_5N)_2Cu$(trichlorophenolate)$_2$, **1***a*, shows a maxi-

mum absorption at 22 500 cm^{-1}, this is a convenient region for following the decomposition of this complex. The temperature used in all cases was 72 °C.

Preparation of μ_4-Oxo-Copper(II) Complexes

μ_4-Oxo-hexa-μ-chlorotetrakis[pyridine copper(II)]

$(C_5H_5N)_2Cu(trichlorophenolate)_2$ (5 g) was dissolved in cumene (100 ml) and heated in air at 72 °C for 24 h. The resulting precipitate was filtered and extracted with methylene chloride to give gold needle-shaped crystals of $(C_5H_5N)_4Cu_4Cl_6{\cdot}O$ (1.6 g, 97% yield).

Anal. Calcd. for $C_{20}H_{20}N_4Cl_6Cu_4{\cdot}O$: C, 30.03; H, 2.50; N, 7.01; Cl, 26.65; Cu, 31.78; O, 2.00. Found: C, 30.48; H, 2.50; N, 7.04; Cl, 27.06; Cu, 32.29; O, <0.5%.

Molecular weight in methylene chloride, 797. Melted with decomposition at 251 °C.

μ_4-Oxo-hexa-μ-bromotetrakis[pyridine copper(II)]

$(C_5H_5N)_2Cu(tribromophenolate)_2$ (5 g) was dissolved in cumene (100 ml) and heated in air at 50 °C for 24 h. The resulting dark green precipitate was extracted with tetrahydrofuran and recrystallized by evaporation, giving dark brown crystals of $(C_5H_5N)_4Cu_4Br_6{\cdot}O$ (0.6 g, 40% yield).

Anal. Calcd. for $C_{20}H_{20}N_4Br_6Cu_4{\cdot}O$: C, 22.51; H, 1.88; Br, 23.80; Cu, 45.30. Found: C, 23.70; H, 2.01; Br, 23.71; Cu, 45.30.

Melted with decomposition at 217 °C.

μ_4-Oxo-hexa-μ-chlorotetrakis(ethylamine copper(II))

$(Ethylamine)_2Cu(trichlorophenolate)_2$ (2 g) was dissolved in toluene (75 ml) containing carbon tetrachloride (5 ml) and heated at 72 °C for 4 h. The resulting olive-green precipitate (0.7 g), upon extraction with methylene chloride and recrystallization with hexanes, gave a lime-green complex (0.5 g, 82% yield).

Anal. Calcd. for $C_8H_{28}N_4Cl_6Cu_4{\cdot}O$: C, 14.48; H, 4.22; N, 8.45; Cl, 32.31. Found: C, 15.51; H, 4.77; N, 8.91; Cl, 31.44.

Melted with decomposition at 162 °C.

The poor analysis for this compound is probably due to the fact that it decomposes slowly in air.

μ_4-Oxo-hexa-μ-chlorotetrakis(triphenylphosphine oxide copper(II))

The phenoxo-copper(II) complex containing triphenylphosphine oxide as neutral ligand could not be isolated in the solid state, but appeared to be readily obtained in solution by the addition of copper(II) trichlorophenolate (0.01 mol) to triphenylphosphine oxide (0.02 mol) in cumene (125 ml), resulting in a brown solution which was filtered to remove any unreacted materials. This solution was then reacted in air at 72 °C for 24 h. Extraction of the precipitate with methylene chloride and recrystallization gave orange crystals of **4***d*.

Anal. Calcd. for $C_{72}H_{60}P_4Cl_6Cu_4{\cdot}O_5$: C, 54.17; H, 3.76; Cu, 15.92. Found: C, 53.53; H, 3.79; Cu, 15.72.

Melted with decomposition at 239 °C.

μ_4-Oxo-hexa-μ-chlorotetrakis(dimethylformamide copper(II))

(Dimethylformamide)Cu(trichlorophenolate)$_2$ (2 g) was dissolved in cumene (100 ml) and heated in air at 50 °C for 24 h. The resulting yellow-brown precipitate was extracted with methylene chloride. Evaporation gave a yellow crystalline product with an infrared spectrum corresponding to that reported for compound **4***f*.

μ_4-Oxo-hexa-μ-chlorotetrakis(dimethylsulfoxide copper(II))

(Dimethylsulfoxide)Cu(trichlorophenolate)$_2$ (2 g) was dissolved in cumene (100 ml) and heated in air at 50 °C for 24 h resulting in a yellow-brown precipitate containing a mixture of copper complexes. Isolation by extraction with methylene chloride led to further decomposition. However, an infrared spectrum of the unextracted yellow-brown precipitate gave an absorption at 583 cm^{-1}, suggesting the presence of $[(CH_3)_2SO]_4Cu_4Cl_6{\cdot}O$ (5).

Infrared Spectroscopy

Infrared spectra in the range 4000–625 cm^{-1} were measured with a Perkin–Elmer Model 257 Grating Spectrophotometer. Samples were dispersed in potassium bromide pellets.

Infrared spectra in the range 625–470 cm^{-1} were measured with a Perkin–Elmer Model 521 Spectrophotometer. Samples were measured in a Nujol mull on potassium bromide plates.

Far-infrared spectra were measured in a Nujol mull using a Perkin–Elmer Model FIS-3 Spectrophotometer.

The authors would like to thank Dr. P. Bird of Sir George Williams University, Montreal, Quebec, for the X-ray analysis of μ_4-oxo-hexa-μ-chlorotetrakis(pyridine copper (II)) complex. Financial support for this work from the National Research Council of Canada is gratefully acknowledged.

Dielectric Studies. Part XXXIV. Relaxation Evidence for Complex Formation of 1,4-Dioxan with Chelated Ring Systems

M. D. MAGEE AND S. WALKER

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received January 31, 1972

The dielectric constant (ε') and loss factor (ε'') of solutions of (*i*) 8-hydroxyquinoline in cyclohexane, carbon tetrachloride, *p*-xylene and 1,4-dioxan, (*ii*) *o*-nitrophenol in *n*-heptane, cyclohexane, carbon tetrachloride, and 1,4-dioxan, (*iii*) 2,4-dinitrophenol in 1,4-dioxan, and (*iv*) 2,6-dinitrophenol also in 1,4-dioxan have been recorded at four microwave frequencies and at 25 °C. A comparison of the relaxation time data of 1-nitronaphthalene with that of 8-hydroxyquinoline in a number of solvents indicates that a strong specific interaction occurs between the latter solute and the solvent 1,4-dioxan which leads to the formation of a complex. In addition, a comparative study of nitrobenzene and *o*-nitrophenol indicates a similar phenomenon. Strong interaction of the 1,4-dioxan with an atom or atoms in the chelated ring system appears to take place which produces a larger reorienting species than the solute molecule itself and appreciably lengthens the relaxation time, although the data do not establish the point of attachment of the 1,4-dioxan to the chelated ring. The complex formation is accompanied by an additional component to the dipole moment. For the dinitrophenols significant interaction with the solvent *p*-xylene complicates the interpretation of the relaxation time data, although in the 2,4-dinitrophenol the formation of a complex is indicated in 1,4-dioxan.

Nous avons enregistré la constante diélectrique (ε') et le facteur de perte (ε'') de solutions de (*i*) 8-hydroxyquinoline dans le cyclohexane, le tétrachlorure de carbone, le *p*-xylène et le 1,4-dioxanne, (*ii*) de l'*o*-nitrophénol dans le *n*-heptane, le cyclohexane, le tétrachlorure de carbone et le 1,4-dioxanne, (*iii*) du 2,4-dinitrophénol dans le 1,4-dioxanne et (*iv*) du 2,6-dinitrophénol dans le 1,4-dioxanne, à quatre fréquences microondes, à une température de 25 °C. La comparaison des résultats de temps de relaxation du 1-intronaphtalène avec ceux du 8-hydroxyquinoline dans plusieurs solvants indique qu'il existe une forte interaction spécifique entre ce soluté et le solvant 1,4-dioxanne, ce qui conduit à la formation d'un complexe. De plus, une étude comparative du nitrobenzène et de *o*-nitrophénol révèle un phénomène semblable. Il semble se produire une forte interaction entre le 1,4-dioxanne et l'atome ou les atomes dans le système cyclique chelaté, ce qui a pour effet de produire une plus grande réorientation que dans le cas de la molécule de soluté même et d'allonger considérablement le temps de relaxation, quoiqu'on ne puisse pas tirer des résultats le site d'attachement du 1,4-dioxanne à l'anneau chelaté. La formation de complexe est accompagnée d'une composante additionnelle au moment dipolaire.

Dans le cas des dinitrophénols, une interaction importante avec le *p*-xylène complique l'interprétation des résultats de temps de relaxation, quoique pour le 2,4-dinitrophénol, on peut remarquer la formation d'un complexe avec le 1,4-dioxanne. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2799 (1972)

The free phenolic hydroxyl group is well known to form an intermolecular hydrogen bond with suitable electron donor molecules (1). Mecke's (2) early near infrared work was followed by extensive investigations in the infrared region by, for example, Bellamy (3) and Hallam (3, 4), and Josien (5). The considerable frequency shifts which occur can be related to specific solute–solvent effects, principally hydrogen bonding, rather than to bulk effects (4). These interactions are also effective in enhancing dipole moments (6) and altering the n.m.r. chemical shift to high or low field strengths (7).

Part of the work of the present series of papers has been devoted to a comprehensive investigation of hydroxyl group relaxation, more specially in phenols. In previous papers (8, 9) the influence of self-association of phenols has been considered. Strong concentration dependence of relaxation times, distribution coefficients and dipole moments has been noted and also the apparent concentration dependence of the weight factor C_2 for hydroxyl relaxation under certain conditions of analysis (9). However, hydroxyl group relaxation, with possibly one exception (10), has usually been considered to be absent (11, 12) in phenols possessing an intramolecular hydrogen bond strong enough to shift the hydroxyl stretching frequency by more than about 150 cm^{-1}, although hydroxyl group relaxation has been detected in phenols with weaker hydrogen bonds (13).

In a recent study Magee and Walker (14)

showed that the *trans* forms of *o*-nitrophenol and *o*-chlorophenol hydrogen bonded with 1,4-diazabicyclo-2,2,2-octane (DBO) in non polar solution in such a way that the *trans/cis* ratio increased in the presence of DBO. The net effect was that the DBO complexes with the *trans* form of phenols via the hydrogen bond involving the hydroxyl hydrogen and competes with the intramolecular hydrogen bonded system causing rupture of a proportion of the latter. The effect was more appreciable in the *o*-chlorophenol than in the *o*-nitrophenol, and the increase in moment in the latter ranged between $0.2_7 - 0.5_8$ D while in the former $0.3_6 - 0.7_2$ D the increment increases with increased DBO concentration. With 1,4-dioxan as solvent polarization studies have previously shown that the dipole moments of *o*-nitrophenol and 2,6-dinitrophenol significantly decrease compared with the values in the more inert solvent benzene, whereas that of 2,4-dinitrophenol increases. The magnitude of the change in moment is too appreciable to be ascribed to a normal solvent effect. Both dipole moment and infrared evidence favor a strong interaction of the chelated ring system with 1,4-dioxan in which, somehow, an additional moment component is brought about from the attachment of the 1,4-dioxan (6). This moment appears to lie approximately along or parallel to the direction of the N—O bond in the chelated ring, and could be attributed to dipolar attachment of the 1,4-dioxan along the N—O bond in the chelated ring (6) or even a bifurcated hydrogen bond involving an oxygen atom from the nitro group of the chelated ring and one from an interacting oxygen atom of a 1,4-dioxan molecule. The work reported here is not aimed at deciding between these two possibilities.

The dipole moment evidence for the chelated nitrophenols rules out a switch from a *cis* O—H to a *trans* on passing from an inert solvent to 1,4-dioxan, since if this occurred for *o*-nitrophenol the moment would increase and not decrease (~0.15 D) as, in fact, is observed, while for 2,6-dinitrophenol no change in moment would be anticipated from the switching of the O—H from one planar position to the other, whereas ~0.2 D decrease in moment is observed. The dipole moment change for 8-hydroxyquinoline on passing from cyclohexane to 1,4-dioxan is ~0.3 D decrease while the O—H stretching frequency (3) exhibits only an 18 cm^{-1} change on passing from *n*-hexane to 1,4-dioxan, whereas for phenol it is 307 cm^{-1}.

It seemed of interest to explore the interaction of 1,4-dioxan with these chelated ring systems by the dielectric absorption technique since this method yields information on both shift of charge and size of species. For all these chelated ring systems where interaction with 1,4-dioxan may be inferred from the dipole moment or infrared evidence it would be a more convincing indication of complex formation if it could be shown that the size of the reorienting species had increased.

Experimental

The apparatus and procedure for determining the dielectric constant (ε') and loss factor (ε'') have been described previously (15). Assessments of the accuracy of the method (16) and validity of the procedure (17) have also been given. Measurements were made at 25 ± 0.01 °C at all the following frequencies 34.86, 23.98, 16.20, and 9.313 GHz, known as Q, K, P, and X-bands, respectively. The static dielectric constant (ε_0) was measured at 2 MHz for all the solutions.

Evaluation of α, τ_0, *and* ε_∞

The procedure for the determination of the dielectric constant at very high frequency (ε_∞), the distribution parameter (α) and the mean relaxation time (τ_0) is to fit the experimental data to the equations:

$$[1] \qquad \frac{\varepsilon' - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} = \frac{1 + \omega\tau_0^{(1-\alpha)} \cos(1-\alpha)(\tfrac{1}{2}\pi)}{1 + 2\omega\tau_0^{(1-\alpha)} \cos(1-\alpha)(\tfrac{1}{2}\pi) + (\omega\tau_0)^{2(1-\alpha)}}$$

$$[2] \qquad \frac{\varepsilon''}{\varepsilon_0 - \varepsilon_\infty} = \frac{\omega\tau_0^{(1-\alpha)} \sin(1-\alpha)(\tfrac{1}{2}\pi)}{1 + 2\omega\tau_0^{(1-\alpha)} \cos(1-\alpha)(\tfrac{1}{2}\pi) + (\omega\tau_0)^{2(1-\alpha)}}$$

The input data to a computer program include the following (*a*) the measured values of ε'_{obs} and ε''_{obs} at the appropriate angular frequencies, (*b*) guesses for the variables *e.g.* an initial estimate of τ_0 can often be made from an ε' *vs.* $\varepsilon''\omega$ plot and initial estimates of α and ε_∞ from the Cole–Cole plot, (*c*) ε_0. The dielectric constant value of the solvent provides a restraint (a lower limit) for ε_∞, and the computer program turns out a value for ε_∞ which best fits. In the sequence of operations the ε'_{calc} and ε''_{calc} values obtained from eqs. 1 and 2 are compared with the observed values by the use of a function A where

$$[3] \qquad A = \sum (\varepsilon''_{obs} - \varepsilon''_{calc})^2 + \sum \left\{ \frac{\varepsilon'_{obs} - \varepsilon'_{calc}}{n} \right\}^2$$

where n is a scaling factor chosen to reduce the errors in ε' to about the same magnitude as those in ε'' and the sum is taken over the number of frequencies employed. A value of 2 to 4 is appropriate for n, although its value is not critical providing that it is sufficient to prevent ε' from dominating the function. For the wavebands reported here n was taken to be 4.

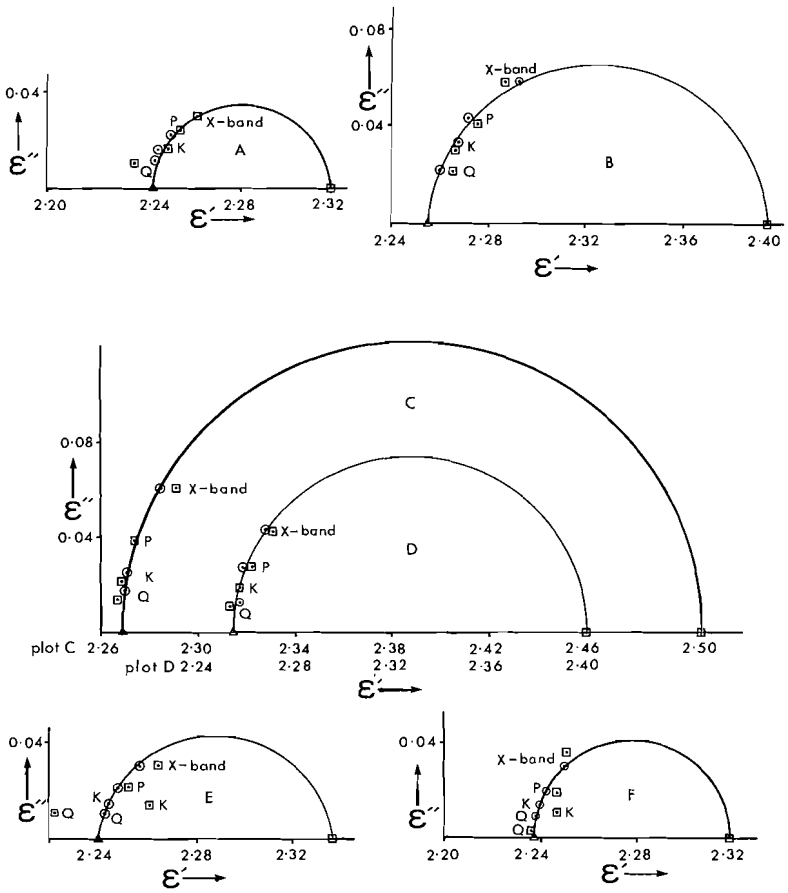

FIG. 1. Cole–Cole plots of the nitrophenols and 8-hydroxyquinoline in 1,4-dioxan solution at 25 °C. Plots are: (*A*) *o*-nitrophenol ($f_2 = 0.0063$); (*B*) *o*-nitrophenol ($f_2 = 0.012$); (*C*) 2,4-dinitrophenol ($f_2 = 0.0158$); (*D*) 2,4-dinitrophenol ($f_2 = 0.099$); (*E*) 2,6-dinitrophenol ($f_2 = 0.0058$); (*F*) 8-hydroxyquinoline ($f_2 = 0.010$). The points designated by □ are experimental ones; ○ are those calculated from τ_0, α, and ε_∞ while ε_∞ is represented by △.

The computer takes each variable of eqs. 1 and 2 in turn and augments it by given step sizes so that A is reduced. The variables have upper and lower limits within which the computer works, and the step sizes are reduced until two complete cycles fail to improve A. At this stage the final value of the variables and the dielectric constant and loss at each frequency are recorded together with the current step sizes, the final function value and the number of evaluations of A performed during the program. The size of A indicates how well the final analysis fits the experimental points.

Materials

8-Hydroxyquinoline was recrystallized from light petroleum spirit (b.p. 60–80 °C). The purification of *o*-nitrophenol, 2,4-dinitrophenol, and 2,6-dinitrophenol has been given elsewhere (6). Cyclohexane, *n*-heptane, *p*-xylene, and 1,4-dioxan were dried, then distilled from sodium and stored over sodium in dark, stoppered bottles. Carbon tetrachloride was distilled from phosphorus pentoxide. The solutes were kept in spring stoppered bottles and stored in dark cupboards. When not in use solutions were also kept in tightly stoppered bottles.

Results and Discussion

Experimental dielectric constant and loss data have been placed in the Depository of Unpublished Data.[1] Corrections for the slight solvent losses were made where appropriate (18).

For the systems described here the lowest loss points are the least accurate and are mostly found in the 1,4-dioxan solutions. To gain some appreciation of the accuracy for these cases the Cole–Cole plots are given in Fig. 1 for the 1,4-

[1]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

*The distribution parameter α, the relaxation time (τ_0) in picoseconds evaluated from the experimental data, the high frequency dielectric constant (ε_∞) the static dielectric constant (ε_0) and dipole moment (μ) in Debye units for some intramolecularly hydrogen bonded aromatic molecules in various solvents at 25 °C. Values for nitrophenols in *p*-xylene are from ref. 14.

dioxan solutions. The experimental points are compared with the ones calculated from the τ_0, α, and ε_∞ values.

The calculated dipole moments for the *cis* and *trans* isomers of *o*-nitrophenol are 2.6 and 5.2 D, respectively (6), while the measured value in cyclohexane at 25 °C is 3.1 D (see Table 1). The difference in calculated and observed moments may be attributed to (*a*) a predominance of *cis* form with the presence of a small amount of *trans* or (*b*) redistribution of charge in the chelated ring (this would include inductive effects) or (*c*) contributions from (*a*) and (*b*). Thus, it is not possible to establish from the measured dipole moment whether any significant amount of *trans* form is present. Further, although the dielectric data can be analyzed into contributions from two relaxation times (τ_1 and τ_2) where the weight factor of the shorter relaxation time (τ_2) is only ~0.2 or less, the interpretation of τ_2 in terms of a meaningful molecular or intramolecular motion is uncertain and in the light of recent studies on, for example, the microwave and far-infrared absorption of chlorobenzene in *p*-xylene (19) may be attributed to a process other than that of (hydroxyl) group relaxation. Fortunately, however, for the four chelated ring systems considered, since the C_2 value (10) if meaningful is less than 0.2, then this results in the τ_1 value being within the normal error of the order of the mean relaxation time value (τ_0); for example, the τ_1 value for *o*-nitrophenol in *p*-xylene at 25 °C is 15×10^{-12} s, and the τ_0 is 13.3×10^{-12} s, while for 8-hydroxyquinoline the τ_1 and τ_0 values are 16×10^{-12} and 15×10^{-12} s. For our purposes we shall take the τ_0 value as being equal to the relaxation time of the reorienting species (molecule or complex) which would correspond with the case where $\alpha = 0$. This could result in our underestimating but not overestimating the size of a reorienting species.

The relaxation time of 8-hydroxyquinoline in cyclohexane at 15 °C of 11.4×10^{-12} s is slightly longer than the value for isoquinoline (20) in cyclohexane at 20 °C of 10.5×10^{-12} s as would be expected from molecular volume considerations. The relaxation time of 8-hydroxyquinoline in carbon tetrachloride (18.6×10^{-12} s) is similar to that of isoquinoline (21) in the same solvent at 20 °C and a little shorter than the relaxation time of 1-nitronaphthalene in carbon tetra-

TABLE 2. Relaxation times of *o*-nitrophenol and nitrobenzene at ambient temperatures in different solvents expressed relative to the value in *n*-heptane*

Solvent	Relative solvent viscosities	Relative relaxation times	
		o-Nitrophenol	Nitrobenzene (21)
n-Heptane	1	1	1
Cyclohexane	2.3	1.3	1.3
Carbon tetrachloride	2.3	2.2	2.3
p-Xylene	1.5	2.0	2.1
1,4-Dioxan	2.8	4.5	2.3 (24)

*The behavior of *o*-nitrophenol parallels that of nitrobenzene in each solvent except 1,4-dioxan in which the relaxation time of *o*-nitrophenol is considerably enhanced. Viscosities of the solvents relative to that of *n*-heptane are given for purposes of comparison.

chloride (21) at 20 °C. Again this is in agreement with the relative volumes of the two molecules.

The hydroxyl is smaller than the nitro group, and it would be reasonable to expect that the molecular relaxation time of *o*-nitrophenol would be only slightly longer than that of nitrobenzene. In fact, the τ_0 of *o*-nitrophenol in *n*-heptane at 25 °C is within experimental error, the same as that of nitrobenzene (22) (6.8×10^{-12} s) in the same solvent at 20 °C as is expected from the volumes of the molecules, and this is true also for *o*-nitrophenol in cyclohexane ($\sim 8.5 \times 10^{-12}$ s) since the nitrobenzene value at 20 °C is 8.8×10^{-12} s in the same solvent (21). Whiffen (22) gives 15.2×10^{-12} s for the relaxation time of nitrobenzene in carbon tetrachloride at 20 °C, and this is to be compared with the value in Table 1 for *o*-nitrophenol of 14.5×10^{-12} s at 25 °C in the same solvent. In *p*-xylene at 25 °C the τ_0 of *o*-nitrophenol was found to be 13.3×10^{-12} s which again is similar to the relaxation time of nitrobenzene under the same conditions (13.1×10^{-12} s) (14). Thus, in each case, the relaxation times of nitrobenzene and *o*-nitrophenol in a common solvent are either the molecular relaxation time or a value close to it.

8-Hydroxyquinoline in Flett's classification (23) is in the category of hydrogen bonds of medium strength, but the shift of the OH stretching frequency due to intramolecular hydrogen bonding is smaller (180 cm^{-1}) than that of typical compounds in this category, such as *o*-nitrophenol, for which the shift is 368 cm^{-1} (23).

Direct comparison amongst the observed relaxation times for a particular solute in different solvents is open to the objection that the observed relaxation time in 1,4-dioxan is expected to be longer than that in the other solvents in Table 1 because 1,4-dioxan has the greatest viscosity. To make some allowance for this the relaxation times in Table 2 are expressed relative to the value in *n*-heptane, together with the viscosities of the solvents relative to that of *n*-heptane and the relaxation times of nitrobenzene also relative to the value in *n*-heptane. Nitrobenzene is a very similar molecule to *o*-nitrophenol, being very slightly smaller, incapable of relaxation by an intramolecular process and having a rather larger dipole moment (which, in the absence of hydrogen bonding, should make it more likely to interact). Viscosity and non-specific environment effects should be similar for *o*-nitrophenol and nitrobenzene so that differences in relaxation behavior are attributable to specific interaction.

From Table 2 it can be seen that the relaxation times of *o*-nitrophenol have a closely similar dependence on the solvent to those of nitrobenzene in the solvents, *n*-heptane, cyclohexane, carbon tetrachloride, and *p*-xylene. However, in 1,4-dioxan solution a striking deviation occurs between the behavior of the two solutes where for *o*-nitrophenol the relative observed relaxation time value is almost double that of the nitrobenzene value. It seems that the difference in behavior can be accounted for by a specific interaction between *o*-nitrophenol and 1,4-dioxan which increases the size of the reorienting species so that it is appreciably greater than that of the nitrobenzene in 1,4-dioxan system.

In Table 3 the data for 8-hydroxyquinoline are treated similarly, the relaxation times being

TABLE 3. Relaxation times of 8-hydroxyquinoline and 1-nitronaphthalene at ambient temperatures and in different solvents expressed relative to the value in carbon tetrachloride*

Solvent	Relative solvent viscosities	Relative relaxation times	
		8-Hydroxyquinoline	1-Nitronaphthalene (21)
Cyclohexane	2.3	1.4	1.5
Carbon tetrachloride	2.3	2.3	2.3
p-Xylene	1.5	1.9	1.9
1,4-Dioxan	2.8	5.0	2.1

*Values are scaled by the factor of 2.3 to permit comparison with the previous table. Solvent viscosities relative to that of *n*-heptane are also given.

expressed relative to carbon tetrachloride as 2.3 so that direct comparison can be made with the previous table.

1-Nitronaphthalene is a slightly larger molecule than 8-hydroxyquinoline but of similar shape and, in the absence of special interactions with the chelated ring, should be more capable of interacting than 8-hydroxyquinoline by virtue of its much larger dipole moment. Yet Table 3 indicates a pronounced interaction between 8-hydroxyquinoline and 1,4-dioxan relative to the 1-nitronaphthalene and 1,4-dioxan system, even though the behavior of the two solutes is similar in the more inert solvents. In fact, the relative relaxation time for the 8-hydroxyquinoline–1,4-dioxan system is $\sim 2\frac{1}{2}$ times that for the 1-nitronaphthalene–1,4-dioxan one. Thus a significantly larger reorienting species is to be inferred in the former system.

It is revealing to compare the ratio of the relaxation time values for the two chelated ring systems, *o*-nitrophenol and 8-hydroxyquinoline, in 1,4-dioxan and cyclohexane which are 3.5 and 3.6, respectively, with the value for *o*-hydroxyacetophenone (12) which is 1.9. *o*-Hydroxyacetophenone is classified by Flett (23) as a strongly intramolecularly hydrogen bonded compound and behaves as a rigid molecule (12). Thus the two types of chelated ring system exhibit quite different behavior. The ratio obtained for *o*-hydroxyacetophenone may be compared with that of 1.8 for nitrobenzene in the two solvents (see Table 3) and is a fairly typical ratio for a non-interacting solute in the two solvents. Similarly, the data of Chitoku and Higasi (24) for nitrobenzene, *m*-dinitrobenzene, *p*-nitrotoluene, and 4-nitrodiphenyl in the solvents 1,4-dioxan and *n*-hexane give ratios of the same order, that is 1.8, 2.0, 2.0, and 2.2, respectively. *n*-Hexane is a very similar solvent to *n*-heptane both in viscosity and inertness. Altogether from the relaxation data it may be inferred that the chelated ring system of *o*-hydroxyacetophenone exhibits no appreciable interaction with 1,4-dioxan whereas for those of *o*-nitrophenol and 8-hydroxyquinoline the size of the reorienting species is significantly greater in 1,4-dioxan than in cyclohexane as solvent. Altogether, there is good evidence for strong complex formation in the former solvent.

The dinitrophenols were insufficiently soluble in the inert solvents to permit dielectric measurements of the necessary accuracy so only *p*-xylene and 1,4-dioxan were used. Their relaxation times in 1,4-dioxan were almost twice as long as in *p*-xylene, a ratio which is similar to the solvent viscosity ratio. However, 2,4- and 2,6-dinitrophenols, like picric acid, are likely to interact appreciably (25) with *p*-xylene as we have already noted (14). The relaxation times in *p*-xylene are therefore probably enhanced, and any further increase in 1,4-dioxan would not appear so pronounced. A comparison can be made, however, with the relaxation times of *m*-dinitrobenzene in benzene (24) and in 1,4-dioxan. The ratio of these is only 1.5, significantly less than the predicted ratio of almost 2 from the ratio of viscosities and only slightly less than the observed ratio of relaxation times for the 2,4-dinitrophenol in Table 1. 2,6-Dinitrophenol apparently behaves in a similar fashion to *m*-dinitrobenzene, $\tau_0(\text{diox})/\tau_0(p\text{-xylene})$ being 1.6. The low frequency measurements indicate a similar behavior for picric acid in xylene and 1,4-dioxan (26). There can be no doubt that the relaxation times for 2,4- and 2,6-dinitro-

phenol in *p*-xylene at 25 °C, which are 34×10^{-12} and 29×10^{-12} s, are anomalously long; this follows from comparisons of their values with *m*-iodobenzene in *p*-xylene (27) at 15 °C which has a value of 23×10^{-12} s and is a larger solute molecule with a similar shape.

For the dinitrophenols it is clear that the relaxation time ratios do not unequivocably demonstrate interaction with 1,4-dioxan but are not incompatible with such an interaction, and, in fact, the relaxation time for 2,4-dinitrophenol in this solvent must be more than $2\frac{1}{2}$ times the value for *m*-iodobenzene at the same temperature in *p*-xylene. This is a similar ratio obtained for 8-hydroxyquinoline and *o*-nitrophenol in these two solvents. In addition, the dipole moment evidence shows interaction of the 1,4-dioxan with both the 2,4-dinitrophenol and 2,6-dinitrophenol since in the former the moment is increased by ~ 0.4 D while in the latter there is a decrease of ~ 0.2 D from *p*-xylene to 1,4-dioxan. These results bear out those of the polarization (6) method and establish their values since they do not suffer from having to equate n_D to the refractive index for infrared radiation which is implicit in the latter method. Further, the difference in dipole moment for 8-hydroxyquinoline in 1,4-dioxan and cyclohexane is -0.3 D while for *o*-nitrophenol it is -0.15 D. All these dipole moment changes are well beyond experimental errors and simple solvent effects. The changes in moment and their signs between 1,4-dioxan and the less interacting solvent can be explained by invoking an additional moment arising from the attachment of the 1,4-dioxan molecule to an atom or atoms of the chelated ring.

Conclusions

Both the dipole moment and dielectric data favor strong attachment of the 1,4-dioxan to *o*-nitrophenol, 8-hydroxyquinoline and 2,4-dinitrophenol. The attachment is such that the observed relaxation time lengthens (compared with the value in an inert solvent) far beyond that which could be expected for a non-complexed molecule in such a solvent, and an increase in size of the reorienting species may be inferred. In fact, interaction of 1,4-dioxan with an atom or atoms of the chelated ring system seems likely for all four solute molecules. For *o*-nitrophenol and 2,4-dinitrophenol the infrared (6), dipole moment, and relaxation data favor this conclusion, while for 8-hydroxyquinoline (6) the key evidence is from the latter two approaches.

Kinetics of Pentadienyl Cation Cyclizations

R. BLADEK AND T. S. SORENSEN

The Department of Chemistry, University of Calgary, Calgary, Alberta

Received February 22, 1972

A series of methyl-substituted pentadienyl cations has been prepared and characterized. A careful study was then made of the rate at which these cations cyclize to give cyclopentenyl cation products. Rate constants and activation parameters have been determined for this rearrangement in several different solvents and at several different cation concentrations. There is an unexpectedly large factor of 10^8 difference in rate between the extremes of the cations studied and a rationalization of this is presented.

The cyclopentenyl cation products themselves undergo numerous rearrangements involving methyl or hydride shifts and a detailed discussion of the tetramethyl case is given. It is shown that a 3-cyclopenten-1-yl cation intermediate is involved in these rearrangements.

Une série de pentadiènylcations substitués par le méthyle a été préparée et caractérisée. Une étude soignée est faite sur la vitesse à laquelle ces cations se cyclisent pour donner les produits du cyclopenténylcation. Les constantes de vitesse et les paramètres d'activation ont été déterminés pour ce réarrangement dans une grande variété de solvants et pour diverses concentrations en cation. Un facteur inattendu de 10^8 a été trouvé dans la différence de vitesse entre les cations extrêmes étudiés; une rationalisation de ce fait est présentée.

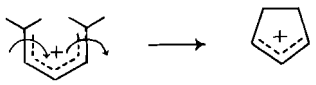
Les produits du cyclopentènylcation subissent eux-mêmes de nombreux réarrangements impliquant des déplacements du méthyle ou d'hydrure et une discussion détaillée du composé tétramethylé est donnée. On a montré que l'intermédiaire cyclopentène-3 yl-1 cation est concerné dans ces réarrangements.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2806 (1972)

Introduction

The cyclization of pentadienyl cations **1** to cyclopentenyl cations **2** is an electrocyclic reaction proceeding in a conrotatory manner (1). The product ions from various methyl-substituted pentadienyl cation cyclizations have previously been characterized (2) but no systematic study of the rates of these reactions has been published. The electrocyclic ring closure



1 **2**

of an ionic molecule has an added feature over and above those of most hydrocarbons, namely, a large change in the charge density of various atoms in the course of proceeding over the transition state barrier to products. Since methyl groups stabilize a positively charged carbon atom, it is possible to use these as probes, *i.e.*, if a methyl-substituted carbon atom experiences a large increase in charge density in going to the transition state, then the reaction will be facilitated compared to that of a hydrogen substituent. The replacement of hydrogen by methyl will result however in sizable non-bonded interactions (2, 3*a* and *b*) which may become severe in certain cases and therefore tend to mask the charge stabilizing effects.

Nine methyl-substituted pentadienyl cations (**3**–**11**) were studied. Of these, **3**, **4**, **8**, and **10**

have previously been reported and some crude rate data were available (2–7).

In each case, except **11**, the dienylic cation was initially observed (*in situ*) and the cyclization kinetics measured. Activation parameters were obtained for each system except for ions **5** and **11**. Ions **4** and **8** were each studied in two and three different acid solvents respectively, sulfuric acid, chlorosulfonic acid, and also for **4**, 1:1 fluorosulfonic acid–antimony pentafluoride.

Results

Characterization of the Dienylic Cations

The dienylic ions were prepared by adding either a conjugated triene or a dienol to the strong acid solvents following published procedures appropriate for the particular solvent (1). The dienols were prepared mainly by the reaction of a substituted vinyl lithium and an α,β-unsaturated carbonyl compound (see Experimental). Most of the dienylic cation solutions exhibited exceedingly clean and clear-cut n.m.r. spectra, summarized in Table 1.

The Rate Measurements

Preliminary rate measurements in sulfuric acid using ion **8** in concentrations of 2.7, 5.0, and 10.0% w/v solutions showed that the rate and activation parameters did not vary significantly with ion concentration. A 10% w/v cation concentration was subsequently used in all cases. The kinetic procedures were unexceptional. In all cases, simple (singlet or doublet), mutually non-interfering n.m.r. peaks could be found for both the dienylic cation and the cyclopentenyl cation product and these were used for area measurements. The temperature range used for the activation energies was not large since fast or slow rates are not conveniently measured in an n.m.r. probe. This meant that the temperature had to be very carefully controlled and measured and this was accomplished by inserting a thermocouple directly into the n.m.r. tube for the duration of the run and monitoring the temperature frequently. The

[a]Within ±0.1°. In most cases, the range of temperatures used was about 15° and this results in considerable uncertainty in ΔH^* and especially ΔS^*. However, several completely independent runs, using a different solvent, gave reasonably similar ΔS^* values. It is, nevertheless, difficult to account for the apparent variation in ΔS^* (37 e.u.). The measured activation entropy, like the other thermodynamic parameters, is a complex term involving ΔS changes in the equilibria processes together with a true entropy of activation. We concede that the error in ΔS^+ could be of a magnitude so that the quoted values are meaningless.

The particular values quoted for the rate constants in this Table are in general those for temperatures nearer the lower end of the temperature range covered and have lower than average standard deviations. The rate constants are for the disappearance of the dienylic cations.

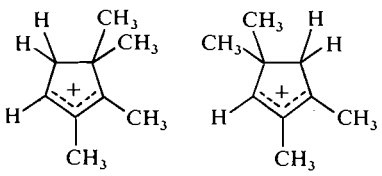
[b]In kcal/mol.

[c]In e.u.

data obtained analyzed well for a first order reaction, as expected, and the rate constants and activation parameters are given in Table 2.

Product Ions

The cyclization reactions are characteristically extremely clean with no extraneous base-line absorptions present even at high gain. The cyclopentenyl cations themselves show rather simple spectra with several sharp peaks present in most cases. Even with a multi-component product, *e.g.* from ion **6**, sharp peaks characteristic of each of the four product ions can easily be located. Table 3 lists the product ions formed and in Table 4, the n.m.r. spectra of some of these ions are tabulated. Only ions **17** and **26** were new and these could be unambiguously characterized. For ion **26**, there is no alternative structure; for ion **17**, the n.m.r. spectrum is broadly consistent with either structure **17** or **27**. However, ion **27** would rearrange to ion **18** much more rapidly than observed; the formation of **27** is mechanistically improbable and on closer consideration, does not fit the n.m.r. spectra (in particular, the C-1 methyl group is a triplet and this has been shown in other cases (9) to be the result of coupling with a methylene group at C-4).



17 **27**

The products from dienylic ion **10** are **23** and **25**. This result has also been found by Brouwer and Van Doorn (7) using the FSO_3H–SbF_5 solvent system and, as reported by these authors, the products reported (5) in an earlier study of this system are not those first formed.

In the last column of Table 3 are listed the cyclopentenyl cation products eventually formed and in Table 5 the rate constants for several of these processes are given. The last measurements show, for example, that the dienylic ion **6** produces the 50% of cyclopentenyl cation **18** from some intermediate ion and that this ion is not produced from **17**, **19**, or **20** since these reactions occur at much higher temperatures. By contrast, in the case of the dienylic ion **9**, the cyclopentenyl ion product **23** is quite possibly the primary product with the others, **21**, **22**, and **24**, being formed at a rate comparable with the rate of disappearance of the dienylic cation. The further rearrangement of the cyclopentenyl cations derived from the

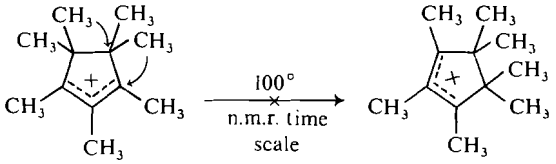
cyclization of cations **9** or **10** is quite dependent on the solvent. In H_2SO_4, only **24** is formed (3*a*), while in 1:1 FSO_3H–SbF_5, **24**, **21**, and **22** are formed (7). In $ClSO_3H$, an intermediate situation is realized with only small amounts of **21** and **22** present. In addition, the rate constant for this process (Table 4), for the $ClSO_3H$ solvent, is intermediate between the other two.

The ion **26** was heated to 100° and showed no indication of a line-broadening at this temperature from a degenerate methyl migration.



26

Discussion

Nomenclature of Dienylic Cations

Linear dienylic cations should, in our opinion, be named as derivatives of the basic pentadienyl unit,[1] numbering from 1 to 5. This procedure conveys a clearer mental picture of the structures under consideration than use of the "longest chain" criterion. A further drawback of the "longest chain" criterion occurs because one names these "by the rules" as undelocalized

TABLE 5. Rates of rearrangement of some cyclopentenyl cations[a]

Reaction	Solvent	$k_{obs} \times 10^4$ (s^{-1})	Temperature (°C)
12 → **13**	$ClSO_3H$	0.99	−10.4
14 → **15**	$ClSO_3H$	0.625	+25.0
17 → **18**	$ClSO_3H$	0.93	+25.0
23 → **24** + **21** + **22**	$ClSO_3H$	0.98[b]	+25.0

[a]The rates for **19** → **18** and **20** → **18** will be reported separately. The reactions are slow at 25°.
[b]Rate for the disappearance of cation **23**. Cations **21** and **22** are formed only in small amounts.

[1]The penta prefix might be considered redundant. It would in theory be possible however to have a butadienyl or a hexadienyl cation, *i.e.* C=C=C—$\dot{C}$ or C=C—C—C=C—$\dot{C}$. The penta therefore denotes a chain of five consecutive sp^2 centers.

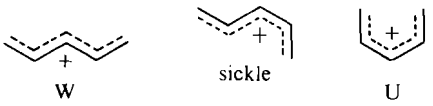
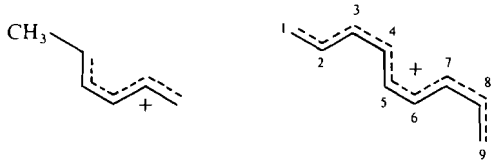
structures; thus, the following resonance structures are penta-2,4-dien-1-yl and penta-1,4-dien-3-yl cation respectively.

A dienylic cation is a delocalized system and the dotted line formulation commonly used conveys this. A disadvantage of the dotted line formulation is the implication (false) that each bond order is the same in a completely charge delocalized structure. The dotted lines should therefore be taken only as an indication of charge delocalization with the bond orders generally alternating along the chain. In all finite-length chains, Hückel calculations will give each bond at least some π-bond order. In the case of pentadienyl cations, both theory and experiment (1) show that the 1–2 "bond" is stronger than the 2–3 "bond".

Two further nomenclature problems arise. (*1*) Theoretically, there are three possible planar structures for a pentadienyl cation, the so-called W, sickle and U forms (1). These designations



are apt in describing a pentadienyl cation but are not applicable to the higher polyenylic systems. (*2*) Substituents at the 1 or 5 positions can occupy two geometrically different positions and this needs to be designated in a complete description of the ion. We suggest that the E,Z nomenclature system (11) be used to designate both the shape of the pentadienyl cation and the position of terminal substituents. Thus, the following ions would be named:



1E-Methyl-(2Z,3E)-pentadienyl cation

(2E,3Z,4E,5Z,6E,7Z)-Nonatetraenyl cation

For cyclic ions, where in general there are few, if any, geometrical isomers possible, it is probably more useful to employ the ring size criterion in naming the ion.

TABLE 6. Relative cyclization rates

Ion	Relative rate (25°)
8	1.0
9	2.4×10^3
4	5.4×10^3

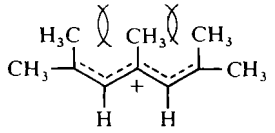
10	3.2×10^5
5[a]	*ca.* 2×10^8

[a]Activation energy not measured. The extrapolation to 25° was made assuming $\Delta F^* \sim \Delta H^*$.

Structure of the Pentadienyl Cations in this Work

The coupling constants observed between vicinal protons of the chain are usually in the region 13–14 Hz, characteristic of a *trans* configuration. As previously postulated (2, 3*a*), the ground-state shape of the dienylic cations is very probably (2E,3E). Attempts in this laboratory to prepare a (2E,3Z) cation have so far failed, only the (2E,3E) isomer being observed.

Molecular model studies indicate that ions such as **10** would likely be non-planar (2, 3*a*) but



10

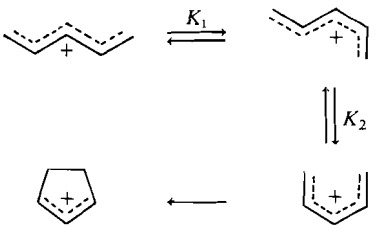
this does not appear to affect the chemical shift positions noticeably (Table 1).

The Cyclization Reaction

The cyclizations have very nearly the same rate in solvents of very different acid strength, adding to the previously observed stereospecificity (1) in showing that the reaction is in fact an electrocyclic one (12). This is also, of course, consistent with the observed invariance of the rates to concentration changes.

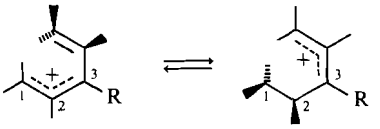
Taking the rate of the slowest member of the series, cation **8**, as unity, the relative cyclization rates at 25° are given in Table 6. The extreme values occur between two isomeric systems involving simply the placement of a methyl group at either C-1 or -3. These rate constants are not identical to the rate constants for the actual electrocyclic process since two equilibria are probably involved before the rate-determining

step. These equilibria are between the observed (2E,3E) ion and the less stable (2E,3Z or 2Z,3E) and (2Z,3Z) isomers.



The first process is almost certainly an equilibrium situation since attempted preparation of the (2E,3Z) ion leads not to product but to the (2E,3E) ion. No experiments aimed at generating the (2Z,3Z) ion have been performed so that a rate-determining k_2 step is not precluded. However, analogy to the K_1 process makes this seem unlikely and if both equilibria are involved, $k_{obs} = K_1 K_2 k_{cyclization}$. Since a factor of 10^8 in cyclization rate between ions **8** and **5** seems inexplicable for $k_{cyclization}$, it is tempting to ascribe most of this difference to K_1 and K_2. There is, however, no steric or electronic reason why K_1 should be very different for these two ions and while K_2 might be larger because of the less serious 1,5-interaction in **5**, this particular effect cannot be very important since both cations **10** and **11** (like **5**) cyclize very rapidly.

From Table 2, one observes that all ions with a C-3 methyl-substituent cyclize very rapidly; other published (1) and unpublished examples confirm this. Conceivably a C-3 methyl group might radically change K_1, K_2, or $k_{cyclization}$. Once again, however, molecular model studies indicate that K_1 should not be radically changed. The effect on K_2 is less certain. In a non-planar (2Z,3Z) ion, one might preserve a planar allyl resonance by having the remaining double bond twisted out of the plane. In these circumstances, a C-3 substituent would certainly act to stabilize the ion. In a completely orthogonal system,[2] *i.e.* a purely allyl cation, one can estimate that a methyl *vs.* H at C-3 will be worth at least 5 kcal/mol (7, 13) energy difference. In a symmetrical dienylic cation, there are two equivalent structures but in an unsymmetrical case, it is possible that one form would be preferred.



R = H or CH_3

An additional factor may be involved if one compares a non-planar (2E,3E) ion equilibrated with the corresponding, also non-planar (2Z,3Z) ion and a planar (2E,3E) ion equilibrated with the corresponding non-planar (2Z,3Z) ion. Then, if the (2Z,3Z) ions are of similar energy, there is clearly less energy difference in the former case (K larger).

Before culminating this discussion, it is worth examining the possible effects of methyl substituents on $k_{cyclization}$. The model reaction is the electrocyclic conversion of a (2Z,3Z)-pentadienyl cation to a cyclopentenyl cation. In this reaction, charge density is transferred from carbon atoms 1, 3, and 5 to atoms 2 and 4.

If this charge migration has partially occurred at the transition state, then methyl substitution at C-2 and -4 should aid the reaction. This is found experimentally but it is difficult to rule out a steric explanation for this.

In summary, we believe that the origin of the "C-3 methyl effect" lies mainly in the stabilizing effect of this group on a non-planar (2Z,3Z) intermediate ion, further increased in certain cases, by the destabilizing effect this group has on the ground state planarity of the (2E,3E) ion.

Rearrangements Within the Product Ions

At this point it should be made clear that the structure of the primary cyclopentenyl cation product produced in an electrocyclic reaction is known if one knows the structure of the dienylic cation. In our present examples, only cyclopentenyl cation **26** is a primary product. In the other cases, a rearranged cyclopentenyl cation (often of intermediate stability) is initially observed. This then rearranges to the final room temperature stable product ion in an observable reaction (Table 5). For this to happen, the rate

[2]In this extreme case, the distinction between a (2E,3Z) and a (2Z,3Z) ion disappears since the rotation occurs about an essentially single bond.

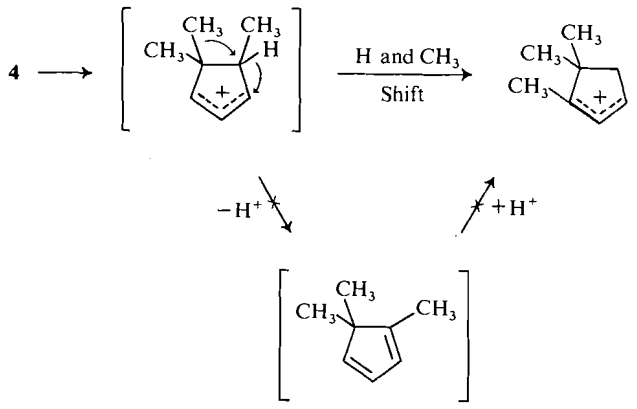


SCHEME I

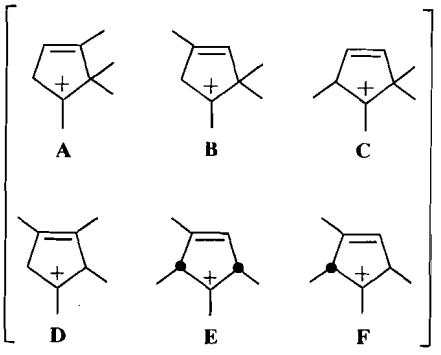
of this latter process is comparable with or slower than the cyclization rate of the dienylic cation. One will therefore *observe* the least stable product ions in those cases where the dienylic cation cyclizations are fastest.

Several of the rearranged ions contain the same methyl substitution pattern as the primary product ions (**12**, **14**, and **16**). These ions could have been formed by way of methyl and/or hydride shifts or by a deprotonation–protonation mechanism (10, 14) (see Scheme 1). However, in cases where these reactions have been carried out in D_2SO_4 solvent (9), no deuterium atoms were initially observed in the product and it seems very likely that only methyl and/or hydride shifts are involved in the reactions of the very unstable, primary, cyclopentenyl ions. Some of the subsequent, much slower, observable rearrangements occur however by the deprotonation–protonation mechanism (10, 14).

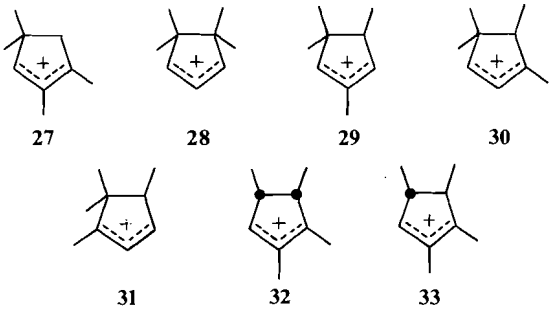
The product ions observed from the cyclization of pentadienyl cations **6**, **7**, **9**, and **10**, although more complex, offer in many ways a better insight into the mechanism of the reactions than do the simpler cases. Since the cyclization of **9** has been discussed in considerable detail (7), we will concentrate mainly on the others.

The Tetramethyl Case

The four isomeric dienylic cations **5**, **6**, **7**, and **8** each gives its own characteristic product mixture (Table 3). At this juncture, we shall assume that these rearrangements involve only methyl and/or hydride shifts and, like Brouwer and Van Doorn (7), that the intermediate obtained by these shifts be a tertiary cation. For a tetramethyl system, there are only six possible non-conjugated cation structures, labelled **A**–**F**.



In the conjugated cyclopentenyl cations, there are twelve isomers possible; those observed in this work (Table 3) are **16**, **17**, **18**, **19**, and **20**. The remainder, **27**–**33**, are shown below:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The cyclization reactions of ions **5**, **6**, **7**, and **8** can now be written:

$$\mathbf{5} \rightarrow [\mathbf{29}] \rightarrow [\mathbf{B}] + [\mathbf{E}] + [\mathbf{F}]$$

$$\mathbf{6} \rightarrow [\mathbf{30}] \rightarrow [\mathbf{C}] + [\mathbf{E}] + [\mathbf{F}]$$

$$\mathbf{7} \rightarrow [\mathbf{31}] \rightarrow [\mathbf{C}] + [\mathbf{A}]$$

$$\mathbf{8} \rightarrow [\mathbf{28}] \rightarrow [\mathbf{C}]$$

When the intermediates **A**–**F** rearrange back to the conjugated compounds we will assume that this process will occur preferentially so as to leave a tertiary center on what now will become part of the developing allyl cation. This then results in the following:

$$[\mathbf{A}] \rightarrow \mathbf{17}$$

$$[\mathbf{B}] \rightarrow \mathbf{16}$$

$$[\mathbf{C}] \rightarrow [\mathbf{30}] + [\mathbf{31}]$$

$$[\mathbf{D}] \rightarrow \mathbf{18}$$

$$[\mathbf{E}] \rightarrow \mathbf{20} + [\mathbf{32}]$$

$$[\mathbf{F}] \rightarrow \mathbf{19} + [\mathbf{33}]$$

Each of the bracketed ions is still an unobservable intermediate under the conditions of these experiments. The ions **30** and **31** can re-enter the previous reaction scheme. The ions **32** and **33** give the following:

$$[\mathbf{32}] \rightarrow [\mathbf{E}] + [\mathbf{D}]$$

$$[\mathbf{33}] \rightarrow [\mathbf{F}] + [\mathbf{D}]$$

Exit via intermediate [**D**] should then give ion **18** as the ultimate product. Putting all these predictions together, one gets the following:

$$\mathbf{5} \rightarrow \mathbf{16} + \mathbf{18} + \mathbf{19} + \mathbf{20}$$

$$\mathbf{6} \rightarrow \mathbf{17} + \mathbf{18} + \mathbf{19} + \mathbf{20}$$

$$\mathbf{7} \rightarrow \mathbf{17} + \mathbf{18} + \mathbf{19} + \mathbf{20}$$

$$\mathbf{8} \rightarrow \mathbf{17} + \mathbf{18} + \mathbf{19} + \mathbf{20}$$

The predictions work in the case of **6** and probably also for **8** since it can be shown that **17**, **19**, and **20** all yield **18** in reactions which are considerably faster than the initial cyclization reaction of **8**. However, the dienylic cation **5** forms only **16** and **7** forms only **17**. This suggests that cyclopentenyl cation **29** does not give the intermediate **E** and that **31** does not give the intermediate **C**. Both these processes are methyl migrations and it appears that hydride shifts may involve a slightly lower activation energy in most cases.

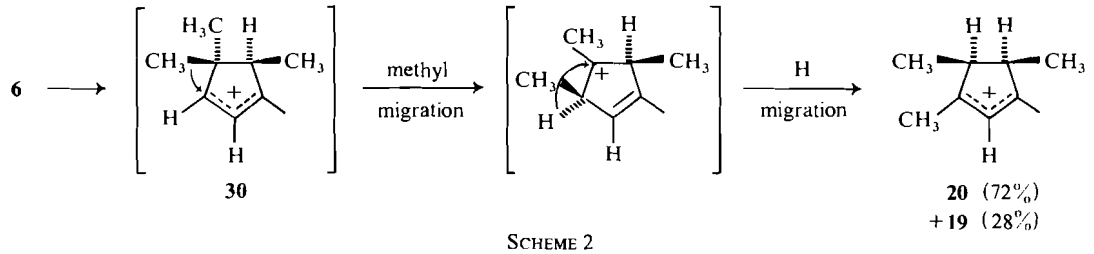
Further Rearrangements within This Series

The observable cations **17**, **19**, and **20** eventually rearrange to **18** (see Tables 3 and 5). Based on our previous rules, cation **17** is in a blind maze and cannot exit to a more stable product, *i.e.*, $\mathbf{17} \rightarrow [\mathbf{A}] \rightarrow \mathbf{17} \rightarrow [\mathbf{A}]$, etc. This process could for example be followed with an isotopic label. One could relax the game rules in any one of three ways: (*1*) one could allow secondary cation intermediates; (*2*) one could allow migration back from the intermediate in which a secondary allyl cation center was generated; or (*3*) one could change the mechanism to a deprotonation–protonation process. Only the first process can explain the reaction of $\mathbf{17} \rightarrow \mathbf{18}$ and the high energy of the secondary intermediate accounts for the fact that **17** can even be observed. The mechanism of the rearrangement of **19** and **20** to **18** will be published separately.

Proof of the Existence of Intermediates (i.e. **A**–**F**)

The methyl and hydride migrations could plausibly have occurred via a direct 1,3-shift (although this is not allowed as a thermal, suprafacial, sigmatropic reaction (12)) or by two concerted 1,2-shifts (*3a*). The present results can be added to those of Brouwer and Van Doorn (7) in showing that an actual intermediate must be involved. The dienylic cation **6** gives both the *trans* and *cis* ions **19** and **20**. These could only have been formed by conducting both migrations between the *same* two carbon atoms, an obviously non-concerted process (see Scheme 2). The formation of more of the *cis* ion **20** than of the *trans* ion **19** indicates that the more sterically hindered methyl group in **30** preferentially migrates. Little can be said about the charge delocalization in these "unconjugated intermediates" beyond the observation that considerable charge must be situated at the formal cation center since there appears to be a large difference in energy between secondary and tertiary structures.

The general principles discussed in this paper can be used to rationalize the formation of the rearrangement products in the cyclization of the dienylic cations **3**, **4**, **9**, and **10**.



SCHEME 2

Experimental

Preparation of the Cations

The cations **8** and **9** were prepared by the gas phase addition of the corresponding trienes, to the acids, as described previously (*3a*). In all other cases, the alcohols were added directly to the acids using a microlitre syringe to reduce the drop size. The sulfuric acid solutions were supercooled to *ca.* $-30°$ during the addition. The chlorosulfonic acid was BDH reagent grade and was cooled in a Dry-Ice bath during the alcohol addition operation. A magnetic stirring bar was used to stir both solutions. In the chlorosulfonic acid case, care is needed to ensure that the addition is carried out slowly since the alcohol droplets mostly solidify on contact with the cold acid. Under these conditions, cation formation is relatively slow and in some cases this necessitates a slight warming of the acid solution. The alcohol addition to 1:1 FSO_3H–SbF_5 was carried out at about $-30°$ since this mixture becomes very viscous at lower temperatures. The very low temperature preparations were accomplished by adding the dienol to 4:1 SO_2ClF–FSO_3H, contained in an n.m.r. tube at $-130°$. The dienol was frozen in small amounts onto the end of a cold, coiled platinum wire and this was then introduced into the n.m.r. tube and vigorously moved up and down in the acid. The cation concentrations, unless specified, were *ca.* 10% weight of alcohol per volume of acid. The n.m.r. spectra of the cations are reported in Tables 1 and 4.

Kinetic Procedures

Initially, the methanol calibration method was used to obtain the temperatures of the solutions in the n.m.r. probe, but this proved hopeless, partly because of the large temperature uncertainty ($\pm 1°$) and partly the unknown temperature change which may have accompanied the switch of n.m.r. tubes for the calibration. Temperatures were therefore monitored using a 40 gauge copper–constantin thermocouple in a sealed glass capilliary immersed directly into the acid solution. The n.m.r. tubes spun around the stationary thermocouple and the lower level of this was adjusted to be just outside the cavity region, since no appreciable temperature gradient was observed. Placing the thermocouple directly into the cavity region was possible but this tended to upset the leakage and therefore gave erratic peak sizes. A Honeywell model 2781 potentiometer combined with a model 3131 millivolt galvanometer was used for the e.m.f. measurement. It was usually necessary, to counter gradual temperature drifts within the samples, to maintain a constant liquid nitrogen level and to periodically adjust the nitrogen gas flow level. It is difficult to put an error value on the temperatures quoted for the kinetics. Runs in which the temperature range of recorded values exceeded 0.1° were discontinued so an outside error range of $\pm 0.05°$ seems reasonable. The cyclization rates for cation **8** were obtained using a constant temperature bath, periodically quenching the solutions in Dry-Ice, and then recording the spectra at a temperature where the reaction rate is very slow. The first order rate constants for each reaction, using the integrated rate law form, were obtained from an unweighted least squares fit, the computer input being the peak height and peak width at half peak height or the planimeter area, together with the number of protons that the peak represents. The actual dienylic cation peaks used in each case are denoted in Table 1. In Table 4, some of the cyclopentenyl cation peaks used are also noted. Where several products result, the area of the product peak followed was corrected for the percentage of the total that this particular product represented. The errors were calculated in two ways: (*1*) The standard deviations were obtained by least squares analysis, having first rejected points $> 1.7\,\sigma$ from the mean in an iterative process. Relatively few points were actually rejected. (*2*) The regression equation of $\ln(a/a - x)$ on t (*s*) had the analytical error applied to the ln term as a plus and minus quantity at the start and finish respectively. The analytical error was based on the reproducibility of peak heights, areas, etc. and temperature variations, although the latter do not contribute much. These data can be found in ref. 15. Repeat runs are difficult to do because the temperature cannot be exactly matched. All runs were therefore single determinations. The thermodynamic parameters were calculated using a simple least squares fit of the rate data. Rate constant values were not used if $\sigma/k \times 100$ was greater than 7%. The error in E_a was estimated using the analytical errors estimated for the rate constants using the vector sum method (16). These ranged from ± 1.5 to $\pm 7.7\%$ ($\Delta E_a/E_a \times 100$).

Preparation of the Dienols

The n.m.r. spectra of the dienols (10% solutions in CCl_4 or $CDCl_3$) were recorded on a Varian Assoc. A-60 n.m.r. spectrometer and are reported in the τ scale relative to internal TMS. All compounds were checked for purity using g.l.c. (5% SE-30 on Chromosorb), but most of the dienols dehydrate under these conditions. The dienols were therefore carefully fractionated using an 18 in. spinning band column, employing a high reflux ratio, and purity judgements were based on the n.m.r. spectra observed. All boiling points are uncorrected. The n.m.r. spectra are reported in the text using the following abbreviations, s = shoulder, d = doublet, t = triplet, (3H) = integrates approximately for three protons, all coupling constants are in Hz units, and each peak of the presumed multiplet is listed. No

attempt was made to completely analyze complex multiplets beyond ascertaining that this complexity was expected.

(3E,5E)-3,5-Heptadien-2-ol

This alcohol was prepared by the addition of methyl lithium to sorbaldehyde (3*a*).

(5E)-2-Methyl-2,5-heptadien-4-ol, (5E)-2,3-Dimethyl-2,5-heptadien-4-ol, and (5E)-2,4-Dimethyl-2,5-heptadien-4-ol

These alcohols were prepared as described by Braude and co-workers (18, 19, 20).

2,4,6-Trimethyl-2,5-heptadien-4-ol

This alcohol and the dehydration products were prepared as described in the literature (17).

(5E)-2,5-Dimethyl-2,5-heptadien-4-ol

To 3.7 g (0.50 mol) of lithium metal (1% Na) in 500 ml of dry ether, under an argon atmosphere, and contained in a 2 l three-necked flask fitted with a condenser, gas inlet tube, and mercury vent and stirred with a magnetic stirring bar, at 0°, was added, over a 1 h period, 33.5 g (0.25 mol) of 1-bromo-2-methyl-1-propene in 200 ml of ether. The reaction started immediately. After standing for an additional hour, 21 g (0.25 mol) of (2E)-2-methylbut-2-enal in 100 ml of ether was slowly added. The excess lithium was filtered off and water added cautiously. The aqueous layer was separated and extracted with a further 200 ml of ether and the combined ether layer washed three times with water (3 × 100 ml). The solution was dried over anhydrous $MgSO_4$ and, after removal of the ether, distilled through an 18 in. spinning band column to give 19.6 g (56%) of the title alcohol, b.p. 82° (8.5 mm).

Anal. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 77.44; H, 11.34.

The n.m.r. spectrum showed: 8.46 (3H); 8.35, 8.33, 8.30, and 8.28 (9H); 7.40 (1H) OH peak; 5.51 and 5.37, d, $J = 8$, (1H); multiplets centered at 4.91 and 4.77, (1H), with a primary coupling constant of *ca.* 8; a series of peaks from 4.4–5.1 (1H).

2,3,6-Trimethyl-2,5-heptadien-4-ol

The title alcohol, b.p. 57.5° (0.85 mm), was prepared in 59% yield from 2-bromo-3-methyl-2-butene (21) and 3-methyl-2-butenal (22), 0.13 *M* scale, using the above procedure.

Anal. Calcd. for $C_{10}H_{18}O$: C, 77.87; H, 11.76. Found: C, 77.82; H, 11.73.

The n.m.r. spectrum showed: 8.20, 8.10, and 8.03, complex multiplets, *ca.* (13H); 5.05 and 4.93, broad, d, $J = 7$ (1H); 3.78 and 3.65, d, $J = 7$, both halves further split by methyl groups (1H).

3,4-Dimethyl-1-pentyne-3-ol

This alcohol was prepared by the procedure of Naves and Ardizio (23), except that the 3-methyl-2-butanone was added after the acetylene addition to the sodium amide–liquid ammonia.

3,4-Dimethyl-3-penten-2-one

This ketone was prepared from 3,4-dimethyl-1-pentyne-3-ol using the procedure of Takeshima *et al.* (24). The crude compound was purified from what appeared to be an aldehydic impurity by column chromatography on basic alumina.

2,3,4,5,6-Pentamethyl-2,5-heptadien-4-ol

The title alcohol, b.p. 43.5° (0.01 mm), was prepared from 2-bromo-3-methyl-2-butene and 3,4-dimethyl-3-penten-2-one using the standard procedure (0.4 *M* scale). The yield of pure alcohol obtained was 0.5 g (7%) but there is further impure material in the forerun and residue fractions.

Anal. Calcd. for $C_{12}H_{22}O$: C, 79.06; H, 12.16. Found: C, 79.29; H, 12.25.

The n.m.r. spectrum showed: 8.68 (3H); 8.41, 8.34, and 8.25, a complex series of peaks, *ca.* (19H).

Adiabatic Calorimetric Studies of the Adsorption of Sulfur Dioxide at 423 °K on Heat-treated Magnesias Characterized by Electron Microscopy

R. W. GLASS AND R. A. ROSS

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received April 4, 1972

Calorimetric heats of adsorption of sulfur dioxide at surface coverages from 0.2 to 7.7 μmol m^{-2} have been measured on a series of magnesias heat-treated at 600, 700, and 800 °C. Structural features of the adsorbents have been characterized by analysis of nitrogen adsorption–desorption isotherms and by transmission electron microscopy.

Heats of adsorption at 423 °K for adsorbed amounts of 0.3 μmol m^{-2} were respectively, 86.0, 87.0, and 77.0 kcal mol^{-1} for the 600, 700, and 800 °C samples. The values for the 600 and 700 °C samples fell rapidly above a coverage of 2.0 μmol m^{-2} to around 44.0 kcal mol^{-1} at 5.0 to 7.0 μmol m^{-2}, while the values for the 800 °C sample decreased continuously to 39.0 kcal mol^{-1} at the same coverage.

Crystallite shapes tended increasingly towards the cubic form as the temperature of heat-treatment was increased and average particle sizes were 80, 240, and 320 Å for the 600, 700, and 800 °C samples, respectively.

It is proposed that the very high heats obtained on all the samples are due to interactions with high-energy defect centers in the oxide and with the formation of magnesium sulfite initially, and magnesium sulfate towards monolayer completion.

Les chaleurs calorimétriques d'adsorption du dioxyde de soufre pour des recouvrements de surface de 0.2 à 7.7 μmol m^{-2}, ont été mesurées sur une série de magnésies, traitées à 600, 700 et 800 °C. Les caractéristiques structurales des adsorbants ont été identifiées par analyse des isothermes d'adsorption et de désorption de l'azote et par microscopie électronique par transmission.

Les chaleurs d'adsorption à 423 °K pour des quantités adsorbées de 0.3 μmol m^{-2} sont respectivement de 86.0, 87.0, et 77.0 kcal mol^{-1}, pour les échantillons à 600, 700, et 800 °C. Les valeurs pour les échantillons à 600 et 700 °C tombent rapidement pour un recouvrement supérieur à 2.0 μmol m^{-2}; environ 44.0 kcal mol^{-1} pour 5.0 à 7.0 μmol m^{-2}; tandis que les valeurs pour l'échantillon à 800 °C décroissent de façon continue jusqu'à 39.0 kcal mol^{-1} pour le même recouvrement. Les formes cristallines tendent de façon croissante vers la forme cubique, au fur et à mesure que la température du traitement augmente; les dimensions moyennes des particules sont de 80, 240, et 320 Å respectivement pour les échantillons pris à 600, 700, et 800 °C.

Il a été proposé que les très fortes chaleurs obtenues sur tous les échantillons sont dues aux interactions entre les centres de défaut de haute énergie dans l'oxyde et la formation initiale du sulfite de magnésium et de sulfate de magnésium avec la monocouche de saturation.

Canadian Journal of Chemistry, **50**, 2817 (1972)

Introduction

Studies have been reported recently of the adsorption of sulfur dioxide on transition metal oxides supported on silica gel (1), on silica gels (2), and on γ-aluminas (3). Calorimetric heats of adsorption and adsorption isotherms were determined at 423 °K. The adsorbents were characterized by measurement of surface area, pore size distributions, and hydroxyl group concentrations. These data were used to interpret the nature of the adsorbate–adsorbent interactions (1–3).

The results obtained for the sorption of sulfur dioxide on silica gels (2), largely covalent solids, and γ-aluminas (3), covalent solids with some ionic sites, indicated that a study of the sorption of sulfur dioxide on an oxide adsorbent in which ionic bonds predominate would help to elucidate any general features regarding the rôle of the solids in the surface reactions. Magnesia was chosen for this purpose with the added incentive that little or no work has been reported on the sorption of sulfur dioxide on this material.

Useful previous studies of the sorption of gases on magnesia of some relevance to this work include those on water vapor (4) and carbon dioxide (5, 6). Results from the latter have been used to estimate the number (5) and type (6) of basic sites present on the surface of the oxide.

Experimental

Materials

Magnesia was prepared by decomposing "Baker An-

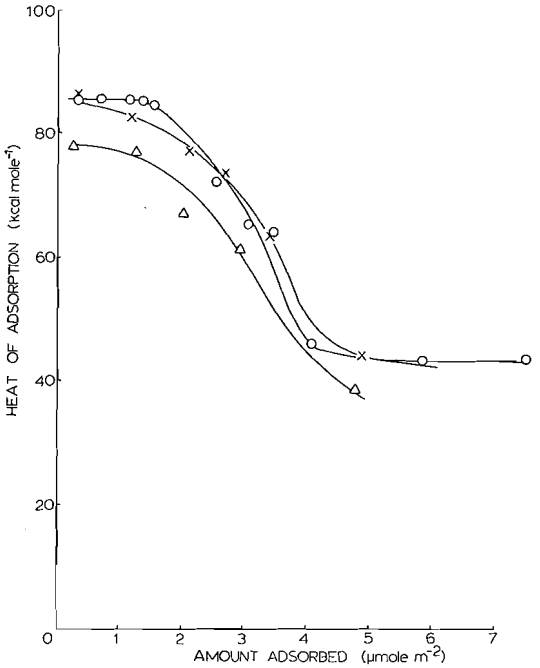

FIG. 1. Heat curves for the adsorption of sulfur dioxide at 423 °K on heat-treated magnesias. Heat treatment at ○, 600 °C; ×, 700 °C; △, 800 °C.

alyzed" basic magnesium carbonate in air at 550 °C for 1 h. Samples of this material were then heat-treated in air at 600, 700, and 800 °C for 24 h. X-Ray powder diffraction photographs showed the characteristic lines of magnesium oxide (7) for all the samples. However, the lines for the 600 °C sample were more diffuse than for the others.

Immediately after heat-treatment, samples were cooled over phosphoric anhydride, transferred to the appropriate apparatus and then outgassed at 150 °C overnight at $<10^{-4}$ mm.

The quality of the nitrogen and sulfur dioxide has been described (1).

Apparatus

Heats of adsorption were determined calorimetrically in a similar apparatus to that described earlier (1). Nitrogen adsorption–desorption isotherms (77 °K) were measured in a standard apparatus (8) and pore size distributions (9) calculated with the aid of an IBM 360/50 computer. Mercury "lump" densities were measured as described previously (10).

The "water content" of the magnesias was determined gravimetrically (8) to constant weight at 1200 °C in a static air atmosphere using a recording thermobalance (Stanton–Redcroft Model HT5A). This method gives the total amount of water released by the sample at 1200 °C and was not used to distinguish among the various states of water or its dissociated forms that may be present in the bulk or surface of the magnesias.

Electron micrographs were taken with a Philips EM 300G instrument and crystallite structures examined by the direct transmission technique described earlier (3).

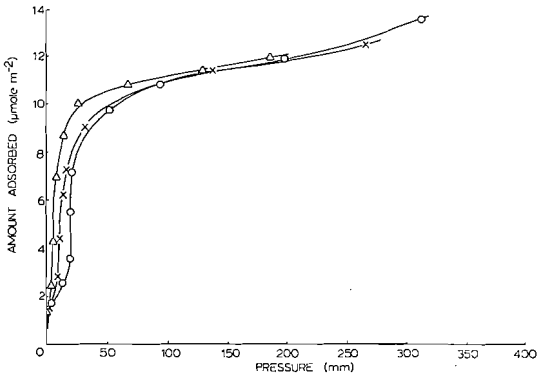

FIG. 2. Adsorption isotherms for sulfur dioxide at 423 °K on heat-treated magnesias. Heat treatment at ○, 600 °C; ×, 700 °C; △, 800 °C.

Results

Heats of Adsorption and Adsorption Isotherms for Sulfur Dioxide

Heats were determined at 423 °K for surface coverages from 0.2 to 7.7 μmol m^{-2} for the 600 °C sample, and between 0.2 and 4.9 μmol m^{-2} for the 700 and 800 °C samples.

High heats of adsorption were observed on all the adsorbents even at coverages approaching a monolayer (7.0 μmol m^{-2} (1)), Fig. 1. The heat curves are of similar general shape although the curve for the 600 °C sample exhibits a sharper heat drop than the others at a coverage of about 2.0 μmol m^{-2}. In addition, although the heats evolved could be measured up to coverages of 11.4 μmol m^{-2} for all the samples, the volume of gas adsorbed was too small (<0.1 cc) to be measured accurately. A minimum estimate of these heats could be made by taking the volume of gas adsorbed as 0.1 cc for heats at coverages greater than a monolayer. On this basis these heats are of the order of 45 ± 10 kcal mol^{-1}.

Figure 2 shows the adsorption isotherms for sulfur dioxide at 423 °K. With the 600 °C sample a definite change in the shape of the isotherm occurs at a coverage of approximately 2.0 μmol m^{-2}. Adsorption equilibrium times for all the adsorbents were of the order of 15 to 45 min for coverages up to 2.0 to 5.0 μmol m^{-2}, respectively, and up to 24 h for coverages greater than 7.0 μmol m^{-2}.

Analysis

Samples of the desorbed gas from all surfaces were analyzed using a Beckman IR-12 infrared

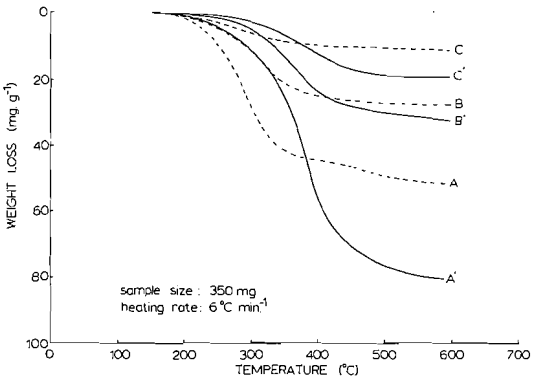

FIG. 3. Thermograms of MgO and MgO residues after adsorption of sulfur dioxide at 423 °K. Samples pre-heated to constant weight at 423 °K. *A*, MgO_{600}; *B*, MgO_{700}; *C*, MgO_{800}; the primes refer to MgO residues. Sample size, 350 mg; heating rate, 6 °C min^{-1}.

spectrophotometer. Neither water nor any other impurity was detected in any of these samples.

The residues were pumped at 150 °C at $< 10^{-4}$ mm for 30 min and then subjected to qualitative chemical analysis (11). The presence of magnesium sulfite and a very small amount of magnesium sulfate was detected on all samples. Tests for the presence of magnesium sulfide and elementary sulfur were inconclusive.

Samples of the residues were analyzed thermogravimetrically in a static air atmosphere. The samples were heated until constant weight at 150 °C and then programed at a uniform rate of 6 °C min^{-1}, Fig. 3. All three residues exhibited a maximum rate of weight loss at about 375 °C. Although some water had been adsorbed onto the samples in the act of transfer prior to thermogravimetric analysis, approximately 90% of this water was removed at 350 °C, Fig. 3. Taking this factor into account, the weight losses observed for the 600, 700, and 800 °C residues correspond to adsorbed amounts of sulfur dioxide at 423 °K of 7.5, 5.5, and 6.0 μmol m^{-2}, respectively.

Nitrogen Adsorption–Desorption Measurements

The nitrogen adsorption–desorption isotherm for the 600 °C sample has a different shape from those of the 700 and 800 °C samples, Fig. 4. A relatively large amount of nitrogen is adsorbed below $p/p_0 = 0.03$ while above this value the amount adsorbed increased rapidly as $p/p_0 \rightarrow 1$. The desorption isotherm formed a very narrow hysteresis loop which extended

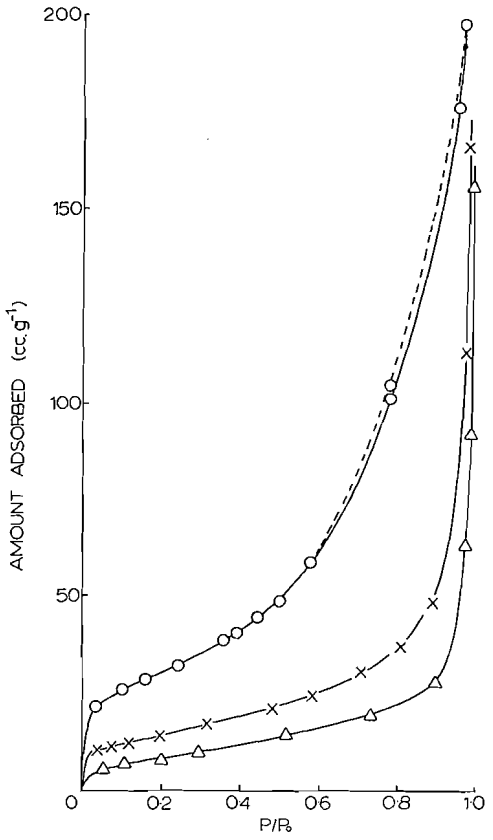

FIG. 4. Nitrogen adsorption–desorption isotherms at 77 °K on heat-treated magnesias. Heat treatment at ○, 600 °C; ×, 700 °C; △, 800 °C.

from $p/p_0 \sim 1$ to $p/p_0 = 0.6$ and closed smoothly with the adsorption leg.

The isotherms of the 700 and 800 °C samples were very similar in shape. Above $p/p_0 = 0.03$ the isotherms were linear up to $p/p_0 = 0.7$. Above $p/p_0 = 0.9$ the amount of nitrogen adsorbed increased very rapidly as $p/p_0 \rightarrow 1$. The isotherms of the 700 and 800 °C samples were completely reversible and no hysteresis was observed.

The pore size distributions, calculated from the desorption leg of the isotherm on a differential basis, are shown in Fig. 5. The 600 °C sample exhibited two maxima, one at 55 Å and a smaller one at 38 Å. The pore diameter range extended from 22 to 180 Å. The distributions for the 700 and 800 °C samples were very similar: both samples showed principal maxima at 22 and 35 Å. The pore diameter range extended from 19 to 200 Å for both samples.

TABLE 1. Surface area, "water contents", and mercury densities for the heat-treated magnesias

Temperature of heat-treatment (°C)	Surface area ($m^2 g^{-1}$)	"Water content" ($\mu mol\ H_2O\ m^{-2}$)	Mercury density ($g\ cc^{-1}$)
600	110	7.1	0.3656
700	50	5.0	0.4166
800	30	3.0	0.4982

Table 1 summarizes the data obtained for surface areas (BET plots), "water contents", and mercury densities for each magnesia sample.

Electron Microscope Examinations

The direct transmission micrographs of the three samples (total magnification × 250 000; microscope magnification × 125 000) are shown in Fig. 6. The 600 °C sample has a porous structure, in which the majority of pores have diameters of about 60 Å. The 700 °C sample has an irregular array of crystallites of average size about 240 Å. A small number of pores about 20 to 25 Å diameter can be observed in the crystallites. The 800 °C sample has crystallites of a more regular shape with an average size of 320 Å. Again, a small number of pores about 20 to 25 Å diameter can be observed in the crystallites. In general, an increase in the size and regularity of the crystallites occurs with increase in the temperature of heat-treatment.

Figure 6 also shows typical electron micrographs of the residues. The straight edges observed with the "fresh" 700 and 800 °C samples have a much rougher appearance after sulfur dioxide adsorption. In addition, small, dark areas approximately 50 Å diameter can be seen clearly in both the 700 and 800 °C residues.

Discussion

The heat values for all the samples are similar in magnitude at all points on the curves, Fig. 1. Heats greater than 35.0 kcal mol^{-1} were exhibited over the entire range of surface coverage studied and values of this order of magnitude clearly indicate that chemical adsorption and/or reaction of the sulfur dioxide has occurred (12).

The principal sulfur compound detected in the residues was magnesium sulfite which has a heat of formation (13) of −27.7 kcal mol^{-1} at 423 °K according to the reaction

[1] $$MgO_{(s)} + SO_{2(g)} \rightarrow MgSO_{3(s)}$$

Thus, in the absence of any significant quantities of other residues, substantial surface phenomena other than purely chemical combination have taken place.

Studies of the effect of small water vapor pressures (<5mm) on the sintering of MgO (4) suggest that the presence of H_2O provides a mode of surface transport for the O^{2-} ion and possibly, also, for electrostatic reasons, induces cation migration. The postulated mechanism involves dissociative chemisorption of H_2O on

For personal use only.

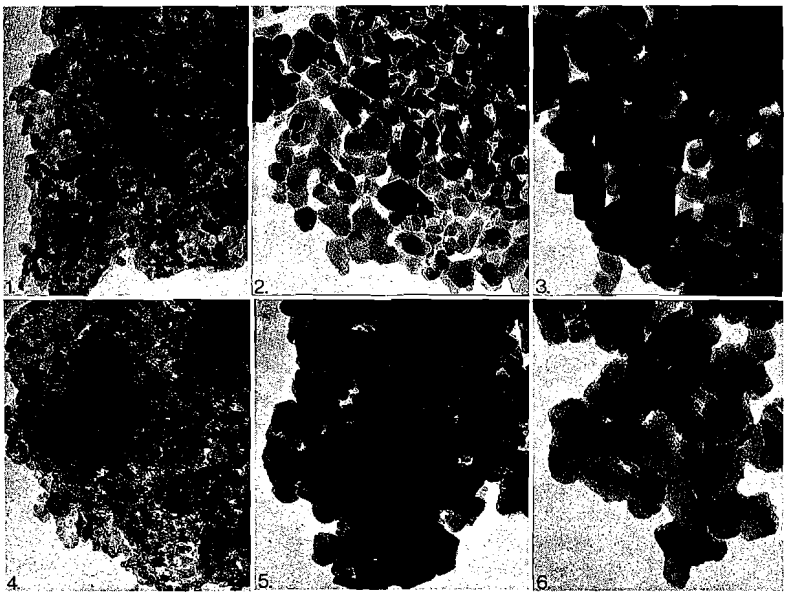

FIG. 6. Transmission electron micrographs (total magnification × 250 000; microscope magnification × 125 000) of (*a*) MgO heat-treated at 600 (*1*), 700 (*2*), and 800 °C (*3*); and (*b*) MgO heat-treated at 600 (*4*), 700 (*5*), and 800 °C (*6*) after adsorption of sulfur dioxide at 423 °K.

the Mg^{2+} and O^{2-} ions, and desorption of water from adjacent hydroxyl groups. Since water vapor pressures of this order of magnitude are present on calcining in air at temperatures up to 800 °C, similar active centers are probably generated on the surfaces of the heat-treated magnesias used in the present study. In addition such active anion sites may be created purely by the calcination process which involves a dehydration mechanism among adjacent hydroxyl groups. Figure 1 shows that the fairly steady high heats for the 800 °C sample do not occur at higher coverages than those obtained with the 600 and 700 °C samples. This may be explained by the greater degree of agglomeration of the 800 °C material with the formation of larger crystallites which act to reduce the number of active sites and lattice defects (14).

The heat values of around 75 and 80 kcal mol^{-1} for the 800 °C sample at coverages up to 2 μmol m^{-2} indicate the possibility of the sulfur dioxide reacting directly with the active anion centers. Similar observations can be made for the 600 and 700 °C samples. Thus sulfite formation probably occurs at these centers with a consequent readjustment of the position of lattice ions in the magnesia matrix.

Above a surface coverage of 4.0 μmol m^{-2} the levelling off of the heat values, particularly noticeable with the 600 °C sample, is paralleled by a large increase in the amount of sulfur dioxide adsorbed, Fig. 2. The major weight loss observed on heating the residues above 350 °C, the decomposition temperature of magnesium sulfite (15), together with the observation that the amounts of gas lost are approximately equivalent to one monolayer coverage of sulfur dioxide, strongly suggest that predominantly magnesium sulfite is formed in this region of the heat curves. However, the possibility of some reaction of sulfur dioxide with the magnesium sulfite has to be considered. Thus the difference between the theoretical heat of formation of magnesium sulfite and the observed heat, around 40 kcal mol^{-1}, could be explained if some sulfur dioxide was preferentially adsorbed on the magnesium sulfite prior to the apparent completion of the monolayer

[2] $$2MgSO_{3(s)} + SO_{2(g)} \rightarrow 2MgSO_{4(s)} + \tfrac{1}{2}S_{2(s)}$$

$$\Delta H_f(423\ °K) = -58.8\ \text{kcal mol}^{-1}\ (14)$$

The rapid fall in the heats for all samples between 2.0 and 4.0 μmol m^{-2} can be explained by a gradual increase in the contribution of reaction 2 to the overall process. Above mono-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

layer coverage, the estimated heats of 45 ± 10 kcal mol^{-1} suggest that reaction 2 may predominate. These suggestions are supported by the presence of small amounts of sulfate ions detected on all the residues.

Although disproportionation of magnesium sulfite is thermodynamically possible at 423 °K (15)

[3] $$4MgSO_3 \rightarrow 3MgSO_4 + MgS$$

only about 5% of the change would occur (15). It would not account for the very slow, but significant, adsorption of sulfur dioxide on the samples. Further, no magnesium sulfide could be detected in the residues.

It is expected that some interaction of the sulfur dioxide with hydroxyl groups on the magnesia surfaces occurs but it is difficult to ascertain the influence of such interactions on the measured heats since the numbers of surface hydroxyl groups are unknown. However, infrared evidence (5) suggests that these numbers are relatively small at the temperatures of heat treatment used, and thus the "water content" must largely consist of bulk water/hydroxyl groups.

The nitrogen adsorption–desorption isotherms are similar to those observed earlier (16), although no hysteresis loops were formed with the 700 and 800 °C samples. However, this is not unexpected (17) since the present 700 and 800 °C samples are essentially nonporous, having only a few pores in the region of 20 to 25 Å diameter. The difference between these observations and those made earlier (16) is explained simply by differences in the methods of preparation.

The electron micrographs, Fig. 6, support the surface area and mercury density results of Table 1. At 600 °C, significant sintering has not occurred which agrees with earlier postulates that sintering is not expected below 640 °C (14). At 700 and 800 °C, particles have clearly agglomerated with cubic crystallites formed in the 800 °C sample. This sintering has clearly occurred within rather than between the aggregates of magnesia crystals in accord with earlier observations (4).

It is particularly significant that the electron micrographs of the 700 and 800 °C residues, Fig. 6, indicate that the edges of the magnesia crystallites have been attacked by the sulfur dioxide as indicated by the irregularity and smoothness of the edges. The presence of the small dark areas in the large, sintered crystallites may suggest that small crystallites of some other material, probably magnesium salts, may be present.

When these heat curves of sulfur dioxide on magnesias at 423 °K are compared with those determined earlier on heat-treated silica gels (2) and γ-aluminas (3), a general trend is apparent. The heats of adsorption at a given coverage increase with an increase in the degree of ionicity of the solid, thus: magnesia > γ-alumina > silica. A feature which is clearly related to the known ability of these materials to form compounds with sulfur dioxide.

Photolyse dans l'ultraviolet à vide du *Cis*- et du *trans*-butène-2

GUY J. COLLIN ET PATRICK M. PERRIN

Département des sciences pures et appliquées, Université du Québec à Chicoutimi, Chicoutimi, Québec

Reçu le 14 mars 1972

Lors de la photolyse en phase gazeuse du *cis*- et du *trans*-butène-2 avec les raies de résonnance du xénon et du krypton (8.4 et 10.0 eV), on a mis en évidence les principales réactions de décomposition de la molécule butène-2 excitée. Les produits principaux formés dans ces décompositions sont le butadiène-1,3 (0.4), l'acétylène (0.3), l'allène + le propyne (0.2), et l'éthylène (0.1) à 8.4 eV. Nous avons également suivi la décomposition du radical butyle secondaire chimiquement activé en fonction de la pression. De ces études il ressort qu'aumoins à 10.0 eV, certains atomes d'hydrogène ne peuvent plus être considérés comme thermiques, bien que leur énergie cinétique ne soit probablement pas considérable. Finalement la molécule butène-2 excitée à 8.4 eV se décompose en donnant un atome d'hydrogène et un radical libre.

In the far u.v. photolysis of *cis*- and *trans*-2-butene in the gas phase with the xenon and krypton resonance lines (8.4 and 10.0 eV), we show the main decomposition reactions of the excited 2-butene molecules. Main products from these reactions are 1,3-butadiene (0.4), acetylene (0.3), propadiene + propyne (0.2), and ethylene (0.1) at 8.4 eV. The pressure effect on the decomposition reaction of the chemically activated *s*-butyl radical was also examined. From these studies, it appears that some of the hydrogen atoms are not "thermal", but carry kinetic energy, although this amount is probably not very large. Decomposition reactions of excited 2-butene molecules (8.4 eV) give one hydrogen atom plus a free radical.

Introduction

La photolyse des alcènes est déjà bien connue en ce qui concerne la région de l'ultraviolet comprise entre 185 et 203 nm (1). Dans la région de l'ultraviolet à vide (région de 145 à 105 nm) les résultats sont eux aussi nombreux en ce qui concerne les oléfines simples (2–5). L'irradiation de l'isobutène a été rapportée (6), et un rapport préliminaire sur le butène-1 a aussi été présenté (7). Le présent travail est une suite logique des travaux déjà entrepris.

Procédure expérimentale

Les techniques expérimentales ont déjà fait l'objet d'une description dans la littérature (8). Les lampes d'irradiation ont été elles aussi décrites (9). La lampe au krypton est équipée d'une fenêtre en LiF de 1.0 mm d'épaisseur. Placée dans la cavité d'un générateur microonde, Unité Raytheon 2450 Mc, son spectre d'émission entre 100 et 200 nm comprend essentiellement deux raies, plus de 99% du total, l'une située vers 124 nm (89%) et l'autre située vers 116 nm (11%). Ce spectre a été enregistré sur un appareil McPherson, modèle 235, et il correspond aux deux raies de résonnance émises par le krypton, c'est-à-dire à 123.58 et à 116.49 nm (9). En ce qui concerne la lampe au xénon, la préparation et l'irradiation des échantillons, la dosimétrie, le lecteur trouvera toutes les indications dans une autre publication (8).

Le butène-2-d_8 (mélange *cis–trans*, 50/50) provient de Merck, Sharp and Dohme of Canada et contient 9.0% de butène-2-d_7. Toutes les analyses isotopiques ont été faites sur un spectromètre de masse CEC 21-104 et ont été corrigées pour la présence de l'impureté isotopique.

Résultats

Les résultats obtenus sont donnés dans les différents tableaux et figures de ce texte. Il faut essentiellement retenir pour le moment la linéarité des rendements relativement à celui de l'allène en fonction du temps d'irradiation (voir figs. 1–4). Ainsi, sans plus entrer dans le détail, les réactions faisant intervenir comme réactif l'un quelconque des produits de l'irradiation sont à ignorer. Les analyses des produits principaux formés dans l'irradiation des mélanges isotopiques C_4H_8:C_4D_8-2:O_2 (50:50:5) dans différentes conditions sont rapportées ci-après: (*a*) irradiation xénon; pression totale 1.3 Torr: C_3D_6:C_3D_5H:C_3H_5D:C_3H_6 = 14.1:12.7:34.8:38.4; (*b*) irradiation krypton: pression totale 10.0 Torr: C_3D_6:C_3D_5H:C_3H_5D:C_3H_6 = 15.3:12.7:32.4:39.8.

Les irradiations des mélanges butène-2:oxygène (100:5) ne donnent pas lieu à la formation d'hydrocarbures en C_6, C_7, et C_8.

Caractéristiques générales

Le potentiel d'ionisation de la molécule butène-2, qu'elle soit de configuration *cis*- ou *trans*-, est de 9.13 eV (10). Avec la lampe au

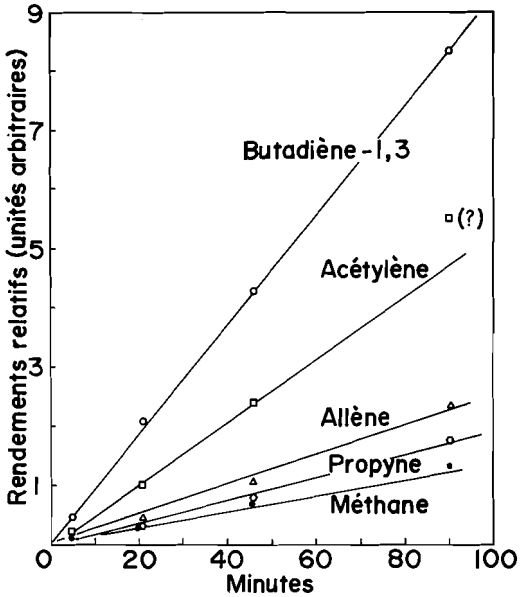

FIG. 1. Photolyse xénon du *cis*-butène-2 (1.32 Torr – 175 N m^{-2}) en présence d'hélium (147 Torr – 19 500 N m^{-2}) et d'oxygène (0.07 Torr – 9.3 N m^{-2}).

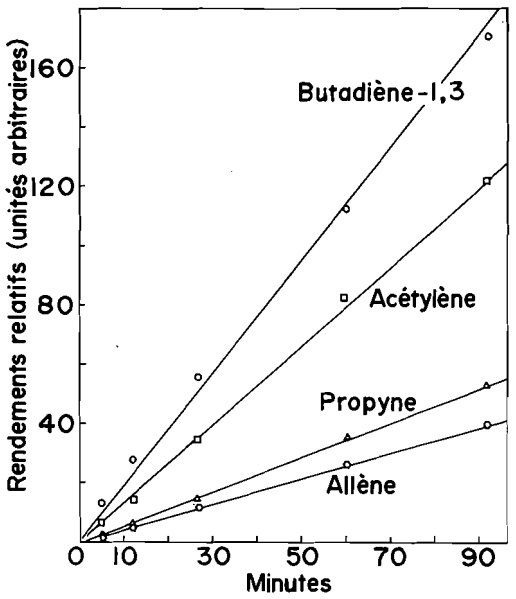

FIG. 3. Photolyse xénon du *trans*-butène-2 (1.32 Torr – 175 N m^{-2}) en présence d'hélium (129 Torr – 17 150 N m^{-2}) et d'oxygène (0.24 Torr – 32 N m^{-2}).

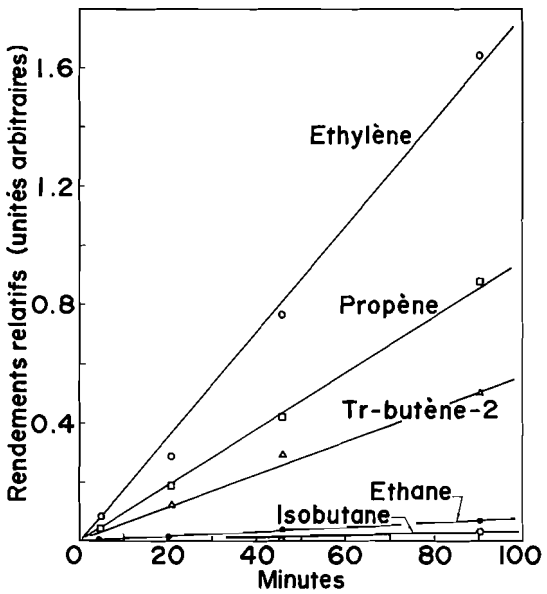

FIG. 2. Photolyse xénon du *cis*-butène-2 (1.32 Torr – 175 N m^{-2}) en présence d'hélium (147 Torr – 19 500 N m^{-2}) et d'oxygène (0.07 Torr – 9.3 N m^{-2}).

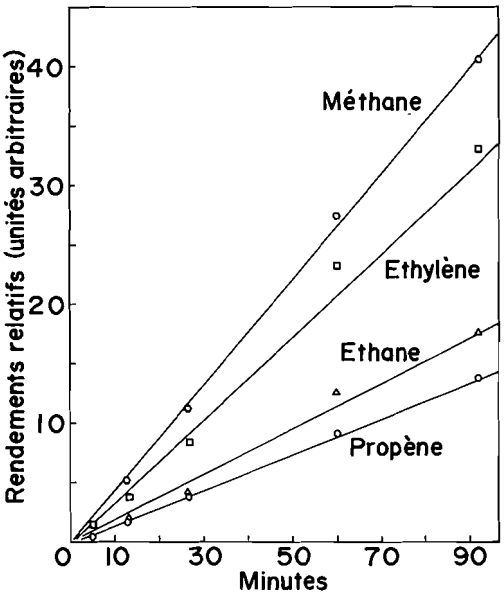

FIG. 4. Photolyse xénon du *trans*-butène-2 (1.32 Torr – 175 N m^{-2}) en présence d'hélium (129 Torr – 17 150 N m^{-2}) et d'oxygène (0.24 Torr – 32 N m^{-2}).

xénon, l'énergie des photons (8.44 eV) n'est pas suffisante pour ioniser les molécules. Cependant avec la lampe de krypton, l'énergie des deux raies de résonnance est supérieure au potentiel d'ionisation. A 123.6 nm le rendement quantique d'ionisation est de 0.25_5 (9), par conséquent une molécule sur quatre ayant absorbé un photon est ionisée. L'énergie de la raie à

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

116.5 nm est inférieure au potentiel d'apparition de la première fragmentation de l'ion $(C_4H_8\text{-}2)^+$ excité; aucun des ions formés n'est donc fragmenté (10). Comme nous ne dirons rien des réactions ioniques, toutes les considérations qui suivent se rapportent aux molécules neutres excitées et les rendements mesurés seront indiqués comme M/N_{Exc} où M est le nombre de molécules formées pour le nombre total de molécules butène-2 excitées.

La première constatation qui se dégage des résultats (voir tableau 1) est la similitude de la répartition des produits de décomposition dans la photolyse du *cis*- et du *trans*-butène-2. Ce résultat est en fait prévisible car la différence de structure des deux composés est négligeable, et d'autre part la hauteur de la barrière de potentiel qu'il faut franchir pour isomériser une structure dans l'autre est de 62.8 kcal mol^{-1} (*11a*) ce qui est, somme toute, peu devant l'énergie minimum des photons utilisés ici, soit 194.5 kcal mol^{-1}. Ainsi donc, le fait d'augmenter l'énergie d'excitation initiale ne modifie pas beaucoup la distribution des produits de décomposition, si ce n'est pour l'apparition des ions $(C_4H_8\text{-}2)^+$. Cette observation a déjà été faite dans le cas de l'isobutène (6) et de celui du butène-1 (7).

Il faut enfin noter la faible part des rendements d'isomérisation des butènes-2 en butène-1, isobutène, ou même cyclobutane (voir les tableaux 1 et 2). Ceci est également le fait de la grande quantité d'énergie disponible dans la molécule excitée vis-à-vis de l'énergie requise pour briser l'une quelconque des liaisons. Même si le rendement en *trans*-butène-2 est élevé ($M/N = 0.14$) dans la photolyse du *cis*-butène-2 (tableau 1), celui-ci vient essentiellement des réactions radicalaires de dismutation mettant en cause le radical butyle secondaire (voir plus loin).

Décomposition du monomère excité

L'absorption d'un photon par une molécule butène-2 entraîne la formation d'une molécule très excitée qui se décompose rapidement.

[1] $C_4H_8\text{-}2 + h\nu \rightarrow (C_4H_8\text{-}2)^{**}$

[2] $(C_4H_8\text{-}2)^{**} \rightarrow H\cdot, R_1R_2\cdot, R_3 \ldots$ etc.

R_1R_2 représente un produit moléculaire stable et $R_3\cdot$ un radical lui aussi stable, c'est-à-dire ayant une énergie interne insuffisante pour donner lieu à d'autres fragmentations. En présence de quelques pourcents d'oxygène, hormis les atomes d'hydrogène, ou quelques radicaux excités, ou "chauds", tous les radicaux réagissent avec l'oxygène pour donner des composés peroxygénés non analysés. Par conséquent la majorité des produits moléculaires formés en présence d'oxygène peuvent être formés dans la réaction 2. Puisque la molécule butène-2 excitée contient une énergie de beaucoup supérieure à l'énergie requise pour briser l'une quelconque ses liaisons, elle se décompose bien avant la première collision. Par conséquent, aux pressions relativement basses de ce présent travail, la réaction 2 n'est pas sensible à la variation de pression et les rendements des produits moléculaires R_1R_2 de cette réaction sont indépendants de la variation de pression. C'est en effet le cas de la plupart des produits formés en présence d'oxygène, sauf pour le propène. Le rendement de ce produit subit une décroissance très importante lorsque la pression de l'échantillon passe de 0.05–300 Torr (tableau 1, figs. 5 et 6). Il est donc formé dans une ou plusieurs réactions différentes de la réaction 2. Une première possibilité de décomposition de l'espèce butène-2 excitée est donnée dans les réactions 3 et 4.

[3] $(C_4H_8\text{-}2)^{**} \rightarrow C_3H_4 + CH_4 \qquad \Delta H = 30$ kcal mol^{-1}

[4] $(C_4H_8\text{-}2)^{**} \rightarrow C_3H_4 + \cdot CH_3 + H\cdot \qquad \Delta H = 126$ kcal mol^{-1}

L'énergie requise pour ces deux réactions est inférieure à l'énergie déposée dans chaque molécule par les photons les moins énergétiques utilisés dans ce travail: 194.5 kcal mol^{-1}. Le produit moléculaire C_3H_4 est soit l'allène, soit le propyne. Puisque le rendement du méthane "moléculaire", c'est-à-dire celui formé en présence d'oxygène, est plus faible que celui de l'allène et du propyne, le rapport $k_3/(k_3 + k_4)$ est inférieur ou égal à 0.5. Ceci est normal, car les deux produits de la réaction 3 ont plus de 160 kcal mol^{-1} d'énergie à se partager. Il en résulte une grande probabilité que l'une ou l'autre des deux molécules produites dans cette réaction se décompose avant une collision moléculaire (6, 12). Il est enfin fort possible que le méthane soit formé dans une ou plusieurs autres réactions.

Un autre type de réactions de décomposition

du butène-2 excité permet d'expliquer la formation du butadiène.

[5] $(C_4H_8\text{-}2)^{**} \rightarrow C_4H_6\text{-}1,3 + H_2$ (ou -1,2)

$\Delta H = 28$ kcal mol^{-1}

[6] $(C_4H_8\text{-}2)^{**} \rightarrow C_4H_6\text{-}1,3 + 2H\cdot$ (ou -1,2)

$\Delta H = 132$ kcal mol^{-1}

Pour les mêmes raisons que celles précédemment émises pour les réactions 3 et 4, la réaction 6 est *a priori* plus probable que la réaction 5. Comme l'hydrogène n'a pas été mesuré, rien ne peut être dit de l'importance relative de ces deux réactions. Une autre série de produits est également formée dans l'une ou l'autre des réactions de décomposition du butène-2.

[7] $(C_4H_8\text{-}2)^{**} \rightarrow C_2H_6 + C_2H_2$

$\Delta H = 36$ kcal mol^{-1}

[8] $(C_4H_8\text{-}2)^{**} \rightarrow 2\cdot CH_3 + C_2H_2$

$\Delta H = 112$ kcal mol^{-1}

[9] $(C_4H_8\text{-}2)^{**} \rightarrow \cdot C_2H_5 + C_2H_2 + H\cdot$

[10] $(C_4H_8\text{-}2)^{**} \rightarrow \cdot C_2H_3 + C_2H_4 + H\cdot$

Avec des considérations similaires à celles déjà rapportées, la réaction 7 a peu d'importance, et d'après le rendement en éthane moléculaire, celui formé en présence d'oxygène, la réaction 7 compte pour moins de 1% dans la formation de l'acétylène. Quant à la réaction 8, elle est observée dans la photolyse du butène-2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

à 185 nm (1). Le rendement élevé en radicaux méthyles (voir plus loin) est de plus en faveur de cette réaction. Les réactions 9 et 10 sont semblables. Dans la première rupture de la molécule excitée, il se forme les radicaux éthyles et vinyles. L'un des deux radicaux contient encore suffisamment d'énergie pour se décomposer à nouveau en un atome d'hydrogène et en acétylène ou éthylène selon le cas. Les rendements en radicaux éthyles et vinyles ont déjà été estimés être de l'ordre de 0.08 et 0.04. Aux très faibles pressions, le seul radical important, est donc le radical méthyle. Par conséquent, les radicaux éthyles doivent se retrouver sous forme de propane. Aux erreurs expérimentales près, le rendement en propane est inférieur à 0.03, confirmant ainsi la faible valeur du rendement en radicaux éthyles.

D'autres réactions, thermiquement acceptables, peuvent rendre compte de la formation d'éthylène (13, 14). Il est cependant, dans l'état actuel des présentes mesures, spéculatif d'entrer plus avant dans la discussion de ce sujet. Une autre réaction mineure de décomposition du monomère excité est clairement démontrée par les résultats.

[11] $(C_4H_8\text{-}2)^{**} \rightarrow C_3H_6 + :CH_2$

[12] $:CH_2 + cis\text{-}C_4H_8\text{-}2 \rightarrow cis\text{-diméthyle-1,2-cyclopropane}$

A haute pression, en présence de 300 Torr d'hélium, le rendement en propylène est de l'ordre de 0.03, et il est probablement formé par réaction 11. Cette réaction est mise en évidence par la formation relativement plus importante du propène-d_0 et -d_6 que de propène-d_1 et -d_5 dans l'irradiation du mélange butène-2-d_0: butène-2-d_8: oxygène (50:50:5). D'après ces résultats le rendement de la réaction 11 est de 0.04 dans la photolyse à 10.0 eV, alors qu'il est de 0.02 à 8.4 eV (voir résultats des analyses isotopiques).

Les radicaux méthylènes réagissent avec le *cis*-butène-2 qu'ils soient dans leur état fondamental triplet ($^3\Sigma_g$) ou dans leur premier état excité singulet ($^1A_1$). Dans les deux cas le produit d'insertion est en majorité le *cis*-diméthyle-1,2-cyclopropane (15, 16), composé qui n'est pas détecté par chromatographie (voir tableau 2). Par conséquent les radicaux méthylènes, s'ils sont formés, le sont avec un rendement relativement faible. En admettant une limite supérieure compatible avec le pouvoir de détection de l'appareillage analytique, la valeur $M/N(CH_2)$ est inférieure ou égale à 0.03 à 8.4 eV en accord avec les deux valeurs rapportées plus haut.

Réactions des atomes d'hydrogène

L'analyse des fragments radicalaires démontre essentiellement la présence d'atomes d'hydrogène et de radicaux méthyles et butyles (8). Les atomes d'hydrogène thermiques réagissent avec le butène-2, soit par abstraction d'un atome d'hydrogène, soit par addition sur la double liaison.

[13] $H\cdot + C_4H_8\text{-}2 \rightarrow H_2 + C_4H_7\cdot$

[14] $H\cdot + C_4H_8\text{-}2 \rightarrow (s\text{-}C_4H_9)^*$ $\quad \Delta H = -39$ kcal mol^{-1}

Ces deux réactions ne sont pas affectées par la présence d'hydrogène sulfuré (8), ou d'oxygène (voir plus loin) en accord avec les constantes de vitesse publiées dans la littérature (17*a*–*c*). Le rapport des constantes de vitesse k_{13}/k_{14} est de l'ordre de 0.07 (18) et la réaction 13 est peu importante. Le radical butyle secondaire formé dans la réaction 14 contient plus d'énergie qu'il ne lui en faut pour se décomposer (19).

[15] $(s\text{-}C_4H_9)^* \rightarrow CH_3\cdot + C_3H_6$ $\quad \Delta H = 25$ kcal mol^{-1}

[16] $(s\text{-}C_4H_9)^* + M \rightarrow s\text{-}C_4H_9\cdot + M$

Cependant, comme l'indique la réaction précédente, si la pression est suffisante, le radical butyle secondaire est stabilisé par collision et à haute pression la réaction 15 est à ignorer. La variation du rendement en propène démontre l'activité d'un tel processus (figs. 5 et 6). Tout comme le rendement en propène, le rendement en éthylène décroît légèrement lorsque la pression de l'échantillon passe de 0.02–300 Torr. A 8.4 eV, la décroissance du rendement en éthylène relativement à celui du propène est de 3.5%. A 10.0 eV, ce pourcentage est de 11% (tableau 3). Or l'éthylène dans ce cas est formé par décomposition du radical butyle primaire lui-même formé par isomérisation du radical butyle secondaire (11*b*):

[17] $(s\text{-}C_4H_9)^* \rightarrow (n\text{-}C_4H_9)^*$

[18] $(n\text{-}C_4H_9)^* \rightarrow C_2H_5\cdot + C_2H_4$

Puisqu'à 10.0 eV, les réactions 17 et 18 sont favorisées par rapport à la réaction 15, cela entraîne que certains atomes d'hydrogène, au

*Pour le calcul de chaque valeur $M/N(R\cdot)_1$, voir les explications dans le texte.

†Voir réf. 8; Valeurs déterminées par l'usage d'H_2S comme intercepteur radicalaire.

‡Valeurs estimées indépendantes de l'énergie incidente.

moins à 10.0 eV, transportent une quantité d'énergie cinétique non nulle. Les radicaux butènyles formés dans la réaction 13 peuvent avoir initialement la structure $\cdot CH_2—CH{=}CH—CH_3$ ou $CH_3—\dot{C}{=}CH—CH_3$. La première structure est bien entendu en résonnance avec la forme $CH_2{=}CH—\dot{C}H—CH_3$. Ces radicaux réagissent en particulier avec les radicaux méthyles présents:

[19] $CH_3\cdot + \cdot CH_2—CH{=}CH—CH_3 \rightarrow C_2H_5—CH{=}CH—CH_3$

[20] $CH_3\cdot + CH_2{=}CH—\dot{C}H—CH_3 \rightarrow CH_2{=}CH—CH—(CH_3)_2$

[21] $CH_3\cdot + CH_3—\dot{C}{=}CH—CH_3 \rightarrow (CH_3)_2—C{=}CH—CH_3$

L'absence de méthyle-2-butène-2 (tableau 2) indique que s'il est formé, le radical $CH_3—\dot{C}{=}CH—CH_2$ a disparu avant de réagir avec le radical méthyle. Cela est l'indication que l'abstraction d'un atome d'hydrogène de deux groupements méthyles est plus favorable et il est donc probable que le radical butènyle $CH_3—\dot{C}{=}CH—CH_3$ n'est pas formé dans la réaction 13. Les rendements similaires en pentène-2 et en méthyle-3-butène-1 indiquent que la réaction d'isomérisation du radical $\cdot CH_2CH{=}CH—CH_3$ est importante. D'après l'importance du rendement en radicaux méthyles (voir plus loin), et en supposant que ceux-ci réagissent avec les radicaux butènyles par addition, on peut estimer à 0.12 ± 0.03 le rendement de ces derniers. En retenant la valeur du rapport k_{13}/k_{14} égale à 0.066 (18) et en connaissant le rendement de la réaction 14, ce rendement devrait être de 0.07. Les deux valeurs sont assez éloignées l'une de l'autre et la différence peut indiquer la participation non encore discutée de la réaction de décomposition du monomère excité suivante:

[22] $(C_4H_8\text{-}2)^{**} \rightarrow C_4H_7\cdot + H\cdot$

Mesure des rendements radicalaires

Avant d'entrer plus avant dans ce sujet, il faut distinguer deux sortes de radicaux: ceux directement formés lors de la décomposition du monomère excité (réactions 2 à 11 et 22) et ceux provenant d'un tout autre processus. Puisque les réactions de décomposition du monomère excité sont en principe indépendantes de la pression, il en est de même des radicaux primaires, mais cela n'est pas nécessairement la même chose pour les autres radicaux formés dans les réactions 13 à 21. Les rendements en radicaux primaires seront notés $M/N(R\cdot)_1$ (tableau 4).

En plus des atomes d'hydrogène, qui conduisent soit aux radicaux méthyles à très basses pressions, soit aux radicaux butyles à hautes pressions, il existe d'autres sources de radicaux méthyles, et en particulier dans les réactions de décomposition du monomère excité (réactions 4 et 8). A pression "nulle", c'est-à-dire aux plus basses pressions présentées dans ce travail, les radicaux méthyles sont les plus importants, car tous les radicaux butyles secondaires se décomposent en radicaux méthyles et en propène. Ils constituent plus de 90% du total. Par conséquent, la mesure du rendement en éthane est la meilleure indication du rendement en radicaux méthyles:

[23] $\cdot CH_3 + \cdot CH_3 \rightarrow C_2H_6$

A pression "infinie", aux environs de 300

‖Indéterminé.

Torr, la réaction 15 est inactive, puisque les radicaux butyles secondaires sont en majorité stabilisés. Le rendement en radicaux méthyles à pression infinie, est donc égal au précédent diminué de la décroissance du rendement en propène, et il est probablement alors égal au rendement en radicaux méthyles primaires.

Le rendement en atomes d'hydrogène primaires est égal aux rendements des réactions 15, 18, et 22 à basses pressions, augmentés du rendement de la réaction 13. Les rendements en radicaux éthyles et vinyles ont été obtenus ailleurs (8) et celui des radicaux méthylènes a déjà été discuté. Le rendement total en radicaux primaires est ainsi calculé en faisant la somme des rendements en atomes d'hydrogène, des radicaux vinyles et méthylènes et des radicaux méthyles et éthyles à haute pression. Il est enfin intéressant de remarquer que l'absorption d'un photon de 8.4 eV conduit à la formation de deux fragments radicalaires: un atome d'hydrogène et un radical libre (tableaux 4–6).

Il existe d'autres possibilités de mesurer les rendements des radicaux, comme par exemple

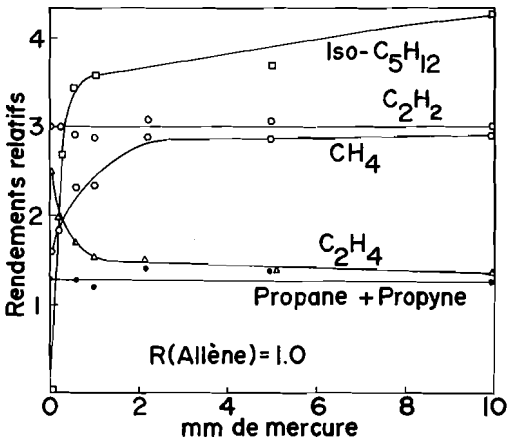

FIG. 7. Photolyse krypton du *cis*-butène-2 pur; temps d'irradiation 60 min.

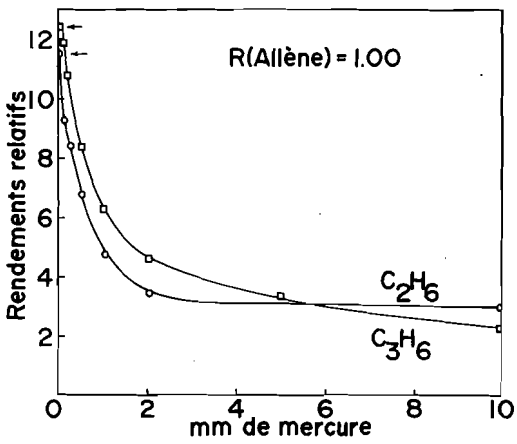

FIG. 8. Photolyse krypton du *cis*-butène-2 pur; temps d'irradiation 60 min.

l'usage de l'hydrogène sulfuré (8). En outre la mesure des radicaux butyles à hautes pressions permet d'estimer le rendement en atomes d'hydrogène. Lorsque les réactions de stabilisation des radicaux butyles jouent complètement leur rôle, ces radicaux ne peuvent réagir qu'avec eux-mêmes ou avec les radicaux méthyles dans le système réactionnel suivant auquel il faut adjoindre la réaction 23 (figs. 7 et 8):

[24] $CH_3\cdot + s\text{-}C_4H_9\cdot \rightarrow CH_4 + C_4H_8$

[25] $CH_3\cdot + s\text{-}C_4H_9\cdot \rightarrow iso\text{-}C_5H_{12}$

[26] $2\ s\text{-}C_4H_9\cdot \rightarrow n\text{-}C_4H_{10} + C_4H_8$

[27] $2\ s\text{-}C_4H_9\cdot \rightarrow C_2H_5CH(CH_3)CH(CH_3)C_2H_5$

La somme $M/N([24] \text{ et } [25])$ peut être estimée en connaissant le rapport des constantes de vitesse k_{24}/k_{25}. Celui-ci est égal à 0.3 ou à 0.07 (17*d*). La mesure du rendement en isopentane permet donc d'évaluer le rendement des réactions 24 et 25. En admettant que l'éthane radicalaire n'est formé que dans la réaction 23, il est alors possible d'estimer le rendement des réactions 26 et 27 à travers la relation suivante (20):

$$\frac{M/N([24]+[25])}{M/N([23])^{\frac{1}{2}}\cdot M/N([26]+[27])^{\frac{1}{2}}} = 2$$

Ces calculs sont résumés dans le tableau 5, ainsi que le rendement en atomes d'hydrogène primaires. Celui-ci est bien entendu, obtenu en faisant la somme des rendements du radical butyle secondaire, de celui du propène (réaction 15), de la réaction d'isomérisation 17 et enfin de la réaction 13. Les résultats sont en bon accord avec ceux déjà calculés étant donné la précision de chaque mesure et l'hypothèse qui est faite: à savoir que dans le présent système, les réactions radical–radical suivent une loi statistique simple.

Conclusions

Le tableau 6 indique l'importance relative de chacun des processus de décomposition du monomère excité en même temps que ceux obtenus à 184.9 nm (21). A 147 et à 123.6 nm, il manque probablement un certain nombre de processus non mis en évidence comme par exemple le montre l'insuffisance du rendement en atomes d'hydrogène à 10.0 eV. Alors qu'à 184.9 nm, la réaction essentielle est celle de la rupture d'une seule liaison C—H; à plus courtes longueurs d'onde, il y a rupture de deux liaisons, soit C—H, soit C—C ou les deux simultanément.

Nous remercions l'Université du Québec à Chicoutimi pour le salaire qu'elle a fourni à l'un de nous (P.M.P.) et le Conseil National de Recherches du Canada qui nous a assisté financièrement. Nous voulons également exprimer notre gratitude au groupe Propulsion du Centre de Recherches de la Défense de Valcartier qui a mis son spectromètre de masse à notre disposition, et le Docteur J. A. Herman, de l'Université Laval qui a enregistré le spectre de la lampe au krypton.

The pulse radiolysis of the proteolytic enzyme papain has been studied in nitrogen-purged and N_2O-purged aqueous solutions at p*H* 6.4. The rate constant for reaction of OH with papain is $4.7 \times 10^{10}\ M^{-1}\ s^{-1}$. The initial spectrum of the intermediate formed by this radical is consistent with a major fraction of attack at tyrosine residues with smaller proportions reacting at tryptophan and other sites. Subsequent spectral changes are also consistent with the preferential attack of OH on tyrosine. The overall rate constant for reaction of e^-_{aq} with papain is $4.1 \times 10^{10}\ M^{-1}\ s^{-1}$ and the spectrum of the electron adduct closely resembles that of the disulfide anion —SS$\dot{-}$. However, there is evidence that not all reactions of e^-_{aq} with papain lead to the formation of this species. The results are discussed in the light of deactivation yields for $Co^{60}\gamma$ radiolysis measured by biochemical techniques.

Nous avons étudié la radiolyse par pulsation de l'enzyme protéolytique papain dans des solutions aqueuses purgées à l'azote et au N_2O, à un p*H* de 6.4. La constante de vitesse pour la réaction de OH avec le papain est de $4.7 \times 10^{10}\ M^{-1}\ s^{-1}$. Le spectre initial de l'intermédiaire formé par ce radical suggère qu'une fraction importante de l'attaque s'effectue sur les résidus de tyrosine, une autre fraction se produisant, de façon moins importante, sur le tryptophane et d'autres sites. Les changements apportés aux spectres subséquents suggèrent aussi une attaque préférentielle des résidus OH sur la tyrosine. La constante de vitesse globale pour la réaction de e^-_{aq} avec le papain est de $4.1 \times 10^{10}\ M^{-1}\ s^{-1}$ et le spectre de l'espèce électronique ressemble fortement à celui de l'anion disulfure —SS$\dot{-}$. Il semble toutefois que ce ne sont pas toutes les réactions de e^-_{aq} avec le papain qui donnent naissance à ces espèces. Nous discutons de ces résultats à la lumière des rendements de désactivation, dans le cas de la radiolyse par rayons-γ du ^{60}Co, mesurée par des techniques biochimiques.

Introduction

Damage to DNA molecules is now generally accepted as the main cause for the radiation-induced death of living cells (1, 2). However, most cells contain "repair enzymes", which can restore damaged DNA molecules to their normal structure during or after the period of exposure to radiation. The radiation-resistance of these is also crucial for the survival of the cell (3) and studies of the radiolysis of enzyme molecules in aqueous systems are therefore germane to an understanding of radiobiology at the molecular level. We have chosen papain as a model enzyme for studying radiation effects, because the amino acid sequence, three-dimensional structure and components of the active site are all well known (4). Also papain contains the biologically important CysSSCys and CysSH residues, the radiation chemistry of which has interested us for some time (5, 6).

In an earlier paper (7) we reported the results of a ^{60}Co γ-radiolysis of papain. The enzyme exhibited a high sensitivity to inactivation by e^-_{aq}, a large part of which could be repaired by postirradiation treatment with cysteine. The sensitivity to OH was less, but in this instance the damage was largely irrepairable. The purpose of the present pulse radiolysis study was to determine the rate constants for the reactions of e^-_{aq} and OH with papain and to examine the absorption spectra of the transients formed. The rate constants are of interest in assessing the sensitivity of the enzyme to radiation damage and the concentrations of radical scavengers which would be required to protect it. The absorption spectra of the transients are a potentially valuable source of information concerning the structures of the intermediates formed by e^-_{aq} and OH (8, 9). Also the lifetimes and decay kinetics of these intermediates are of interest since they can lead to information concerning the mechanism of deactivation of the molecule by e^-_{aq} and OH.

Experimental

Papain in the crude powder form as obtained from

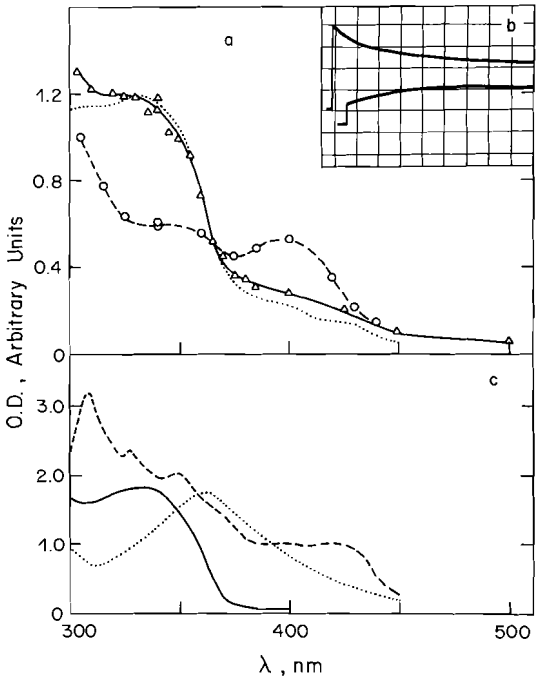

FIG. 1. (*a*) Absorption spectra in N_2O saturated papain solution: △, after 5 μs; ○, after 800 μs. Dotted line, a calculated composite spectrum (see text). Sigma Chemical Company was purified by the affinity chromatography method of Blumberg (10). All irradiations were carried out using unbuffered solutions of papain in triply distilled water at the elution p*H* of 6.4. This p*H* remained unchanged with doses of up to 20 krad. Solutions were irradiated with 0.04–0.5 μs pulses of 35 MeV electrons with doses of 0.8–2.4 krad per pulse. Spectra were measured in the range 300–600 nm, the lower limit resulting from the strong absorption and photosensitivity of papain below this wavelength (11).

Absorbance measurements were made with a split light beam system which included Bauch and Lomb high intensity monochromators, Philips XP1003 photomultipliers and suitable filters to reduce scattered light. N_2O-saturated aqueous potassium thiocyanate solutions were used for dosimetry with $G\varepsilon$ taken as 4.22×10^4 (12).

Results

The Reaction of Papain with OH Radicals

The solid line in Fig. 1*a* shows the absorption spectrum taken 5 μs after the pulse for N_2O-saturated papain solutions at p$H = 6.4$. This was independent of papain concentration in the range $2.3–7.5 \times 10^{-5}$ *M*. From additional experiments outlined below the contribution of H atoms is relatively small and the spectrum in Fig. 1*a* is attributed mainly to the products of OH radical reactions. The absorption in the wavelength range 310–350 nm was found to build up in a first order manner during the first 3 μs after the pulse, at a rate which was within experimental error proportional to the papain concentration. Typical plots of this behavior are

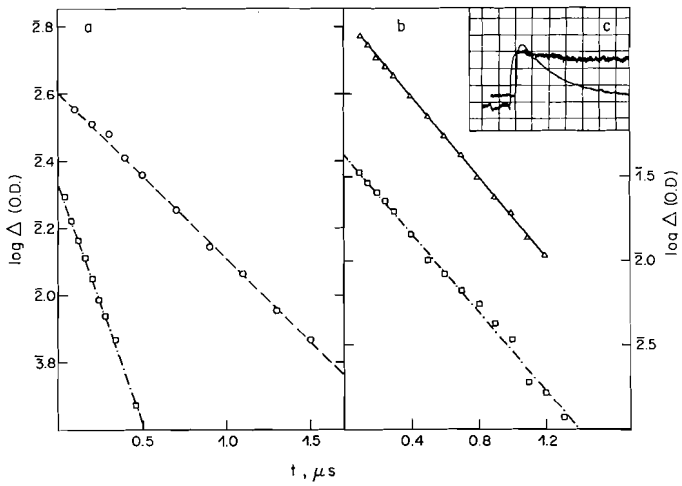

FIG. 2. (*a*) First order plots for the growth of the OH adduct of papain in N_2O saturated solutions: ○, 23×10^{-5} *M* papain, 325 nm; □ 7.3×10^{-5} *M* papain, 310 nm. (*b*) 6.8×10^{-5} *M* papain with 100 m*M* isobutanol: △, decay of e^-_{aq} at 700 nm; □ growth of e^-_{aq} adduct of papain at 425 nm. (*c*) Oscillogram corresponding to Fig. 2*b*. Time base: 0.2 μs/division. Indented trace, 700 nm; other trace, 425 nm.

shown in Fig. 2*a*. From the mean of several experiments the rate constant for the reaction of OH with papain was found to be 4.7×10^{10} M^{-1} s^{-1}.

On longer time scales the time dependence of the absorption spectrum in N_2O-saturated solutions is complex. During the first millisecond there is decay of the absorption below 360 nm and a growth above this wavelength. The behavior is illustrated by the traces of oscilloscope photographs in Fig. 1*b*. The dashed line in Fig. 1*a* shows the absorption spectrum taken 800 μs after the pulse.

The Reaction of Papain with e^-_{aq} and H

The absorption spectrum of the H atom adduct was observed by pulsing 6.5×10^{-5} M papain solutions which had been purged with N_2O and contained 0.5 M *t*-butanol. At these concentrations *t*-butanol scavenges 98% of OH (13) but not more than 10% of H (14) if $k_{H + papain} > 5 \times 10^9$ M^{-1} s^{-1}. The transients produced from *t*-butanol do not absorb above 300 nm (15). As shown by the square points in Fig. 3*a*, the absorption of the H adduct is small and no attempt was made to measure its build up. A similar spectrum was obtained when the *t*-butanol was replaced with 20 mM isobutanol, which will scavenge over 90% of the OH radicals (13). At low wavelengths (~305 nm) in these solutions a small component of decay, attributable to isobutanol radicals (15), was observed during the first 10 μs after the pulse. There was, however, no growth of the absorption at wavelengths above 310 nm during this period. Thus there is no reason to suppose that attack of isobutanol radicals on papain contributes to the absorption above this wavelength.

The absorption spectrum observed in Ar-purged 6.5×10^{-5} M papain solutions containing 20 mM isobutanol is shown by the solid line in Fig. 3*a*. This was taken 5 μs after the pulse, when the e^-_{aq} absorption had become negligible. The spectrum at 0.3 μs, when approximately half of e^-_{aq} had reacted, was determined by subtracting the contribution of e^-_{aq} and found to be essentially the same. The strong resemblance to the spectrum of the disulfide anion of cystamine (16), which is shown by the dashed line, confirms an earlier observation (17) that e^-_{aq} reacts with the —S—S— bonds in papain.

The rate constant for the reaction of e^-_{aq} with

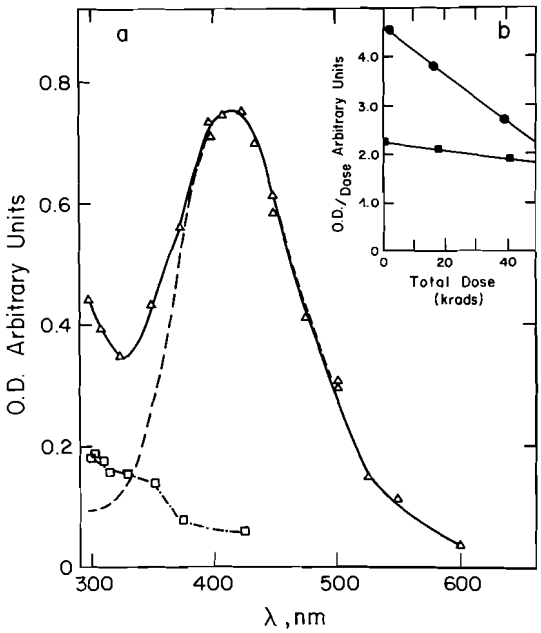

FIG. 3. (*a*) Solid line, absorption spectrum in Ar-purged, 6.5×10^{-5} M papain solutions containing 20 mM isobutanol, 5 μs after the pulse. Dash–dot line, absorption spectrum in N_2O-purged 6.5×10^{-5} M papain solutions containing 0.5 M *t*-butanol, 3 μs after the pulse. Dashed line, disulfide anion of cystamine (16). (*b*) Effect of large doses on spectrum of e^-_{aq} adduct in 2.3×10^{-5} M papain solutions containing 100 mM isobutanol. ●, 415 nm; ■, 310 nm.

papain in previously unirradiated solutions was determined by following the first order decay of the e^-_{aq} absorption at 700 nm. An example of this is given in Fig. 2*b*. From several experiments the mean rate constant for the reaction of e^-_{aq} with papain was found to be 4.1×10^{10} M^{-1} s^{-1}, independent of papain concentration in the range $2–7 \times 10^{-5}$ M.

The indented oscillograph trace in Fig. 2*c* shows an example of the absorption due to e^-_{aq} at 700 nm in the presence of 6.8×10^{-5} M papain. The second trace shows the behavior of the optical density at 425 nm, which is close to the isobestic point in the absorption spectra of e^-_{aq} and the —SS⁻ anion. The contribution of the latter species to the optical density at this wavelength was calculated at various times after the pulse by subtracting the e^-_{aq} absorption, taking for e^-_{aq} $\varepsilon_{425/700} = 0.178$ (18). The difference between the optical density due to —SS⁻ at "infinite time" and time "t" was then plotted in a first order fashion as shown by the square

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

points in Fig. 2*b*. The slope of this line gives a rate constant which agrees within 3% with that calculated from the e^-_{aq} decay (see Discussion section). The same correspondence between the growth of —SS⁻— and decay of e^-_{aq} was observed with a 1.37×10^{-5} *M* papain solution, for which the lifetimes of e^-_{aq} decay and —SS⁻— growth are five times longer than in the 6.8×10^{-5} *M* solution.

Papain solutions which had been subjected to sequences of pulses giving total doses of 10 krad or more showed enhanced rate constants for reaction with e^-_{aq} as calculated from the decay of its absorption at 700 nm. At 100 krad, when each papain molecule would on the average have reacted with ten e^-_{aq}, the rate constant had increased to 6.7×10^{10} M^{-1} s^{-1} and was still rising. It is known that the denaturation of enzymes leads to enhanced rate constants for reaction with e^-_{aq} (19) and it seems probable that the increasing value of $k_{e_{aq}+\text{papain}}$ with dose is caused by denaturation due to radiation damage. Cleavage of the S—S bonds and formation of SH has already been demonstrated in the ^{60}Co γ-radiolysis (7), and further evidence for loss of —S—S— groups was obtained in this study in the following way. The spectrum of the e^-_{aq} adduct in Fig. 3*a* was taken with papain solutions which had received doses of 0–3.5 krad and was independent of dose in this range. After very high doses (~15 krad) delivered in a sequence of pulses the spectrum changed appreciably. As shown in Fig. 3*b* the intensity per unit dose in the region of the —SS⁻— peak at 415 nm fell markedly. The drop in the 310 nm absorption is much less.

Discussion

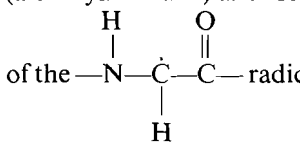
Reactions of OH

The magnitudes of the rate constants for the reactions of OH radicals with the individual amino acid constituents of papain can provide valuable information concerning the relative sensitivities of various side groups and the probable sites of the enzyme at which this free radical will react. The rate constants for the nine most reactive amino acids which occur in papain have been measured by competition kinetics using CNS^- and thymine as primary standards (13). Their values, corrected for new determinations (20) of k_{OH+CNS^-} and $k_{OH+\text{thymine}}$ are listed in Table 1 with other data. The remaining amino acid residues have been assigned an average rate constant of 3×10^8 M^{-1} s^{-1}. This is larger than the weighted mean rate constant for the free acids because of the activating effect of peptide bond formation on the α-hydrogens (21). Thus for the remaining amino acids, attack at the α-hydrogens is considered to be the dominant effect for the purpose of these calculations.

We have calculated the value of $n_{exp}k_{OH+A}$ for each amino acid (A), or peptide unit and expressed it as a fraction of the sum $\sum_{i=1}^{212} n_{exp}k_{OH+A}$. The sources of information concerning n_{exp}, the number of residues of each type considered to be exposed, are presented in footnotes in Table 1.

It is evident from column 5 that the residue of highest $n_{exp}k_{OH+A}$ is tyrosine, with significant reaction of OH also expected at the α-hydrogens of the peptide backbone and the tryptophans. If the fractional values of $n_{exp}k_{OH+A}$ are used as a measure of the fraction of OH radicals attacking each type of group, it is found that the above three sites should account for approximately 70% of all OH radical reactions. The remaining 30% are expected to be spread over all other amino acids.

The absorption spectra of the transients produced by reaction of OH with free tyrosine (25) (also Lynn *et al.*[1]) and free tryptophan (26) and



of the —N—C—C— radical observed by Hayon and Simic (27) in the pulse radiolysis of cyclic dipeptides are shown in Fig. 1*c*. All these are initial spectra obtained in aqueous solutions of p*H* 5 to 7. A composite spectrum was constructed assuming that the spectra produced by OH attack on these residues when incorporated in papain were the same. The contribution of each residue to the total absorption at each wavelength was calculated from the known dose per pulse, $G(OH) = 5.9$ molecules per 100 eV in N_2O-saturated solutions (12) and the fractional values of $n_{exp}k_{OH+A}$. This calculated spectrum is compared with the observed spectrum on an absolute basis in Fig. 1*a* (see dotted line).

*n_{exp} is the number of amino acid residues of each type considered to be exposed. In the case of amino acids for which experimental values of n_{exp} were not available these were estimated on the basis of static accessibility probabilities for amino acids in proteins (24) and the known main chain configuration of papain (4).
†X-ray crystallography (4).
‡Perturbation difference spectroscopy (22).
§Selective photo-oxidation (23).

Although there are some unexplained absorptions, the agreement with the observed spectrum in terms of both shape and intensity of absorption is good, implying that in general terms the conclusions derived from the fractional values of $n_{exp}k_{OH+A}$ are borne out for the OH radical. Thus tyrosine appears to be the amino acid residue most frequently hit, reacting with about 47% of the OH radicals.

More direct evidence for reaction with tyrosine is seen in the decay of the transient absorption below 370 nm and the growth above this wavelength in the 0–800 μs period after its formation. This behavior is similar to that observed by Land and Ebert (25) with free tyrosine at low doses per pulse. As in their work the build up at 400 nm and the decay at 340 nm are both approximately first order with the same rate constant. For the case of papain solutions at pH 6.4 the value of the rate constant calculated for the first two half-lives is 4.5×10^3 s^{-1}, which is comparable to 1×10^3 s^{-1} for the decay of the OH adduct of free tyrosine in neutral solution (25). The spectral change was attributed to the elimination of H_2O:

[1] 
and formation of the phenoxyl radical. This has a maximum in its absorption at ~400 nm, a feature which is also exhibited by the 800 μs spectrum in Fig. 1*a*.

Of the thirteen exposed tyrosines in papain only two are located in the active center (Tyr-61 and Tyr-67), and, although these are believed to play a role in determining the specificity of papain toward peptide substrates,[2] they are not directly involved in the catalytic activity.

Thus our conclusion that approximately 47% of the OH radicals attack tyrosine is consistent with the inefficient (less than one in five) nonrepairable inactivation by OH (7). In fact a large portion of this small yield may be the result of the 10% of OH radicals which attack the highly reactive indole groups of the tryptophan residues. Trp-69 is very accessible, while Trp-177 is largely buried. Both lie in the region of the active center but only loss of Trp-177 affects the esterase activity of papain (23). Of the three other tryptophans, Trp-26 and Trp-181 are deeply buried and nonreactive, while Trp-7 is exposed but not near the active site. Abstraction of hydrogen from the active site sulfydryl

[2] $$OH + Cys—SH \rightarrow Cys—S\cdot + H_2O$$

may also contribute to inactivation, since this reaction is well known for free cysteine (5) and its smaller peptides (6). The absorption of Cys—S· above 300 nm is small and could not make an appreciable contribution to the observed spectrum (28, 29). Reaction with the

catalytically important His-159 may also be involved in the inactivation of papain by OH radicals. The attacks of OH radicals on other residues such as cystine, arginine, etc., should be widely spread over the enzyme and should only contribute to inactivation if they caused significant conformational changes.

For purposes of comparison it may be noted that Adams *et al.* (8) have investigated the radiolysis of chicken egg white lysozyme. Their G values in N_2O saturated solutions suggest that about one in three OH radicals causes inactivation and from kinetic and other evidence they conclude that this occurs through attack of OH on Trp-108, which is one of three tryptophans lying in the region of the active center. This enzyme contains a total of six tryptophans and only three tyrosines. Therefore a greater proportion of OH attack on tryptophans is expected than occurs in papain. In fact calculations[3] similar to those above predict 40% of OH reactions at tryptophan and only ~13% at tyrosine residues. The spectrum of the OH adduct of chicken egg white lysozyme (8) bears this out, for it strongly resembles that of the OH adduct of free tryptophan shown in Fig. 1*c*.

Reactions of e^-_{aq}

Evidence from radiation chemistry and other sources (30, 31) suggests that electrons may be conducted quite efficiently through large areas of protein molecules. Therefore the products of reaction of e^-_{aq} with a protein are likely to be determined on energetic rather than kinetic grounds, and we have made no attempt here to calculate fractional values of $n_{exp}\, k_{e^-_{aq}+A}$ as was done for the OH radical. Nonetheless by virtue of their appreciable electron affinities the disulfide bridges are recognized as likely targets. Thus it is not surprising that the absorption spectrum of the solvated electron adduct of papain resembles that of the —SS⁼— anion of cystamine very closely in the region of the 415 nm peak and at higher wavelengths (see Fig. 3*a*). This peak was found to be extremely long lived. About 20% of the absorption disappeared within 100 μs after the pulse with $t_{1/2} \approx 30$ μs. The remainder had a half-life longer than 0.05 s, which is beyond the range of observation of our present equipment. This indicates that the observable —SS⁼— ions in papain are highly stable. In this respect they resemble —SS⁼— ions in organic glasses (32).

In discussing the reactions of e^-_{aq} with a molecule of the complexity of papain it is necessary to consider the possibility that intermediates of significant lifetime may be formed prior to migration of electrons through the enzyme to —S—S— bonds. If —SS⁼— is formed without the involvement of an intermediate of measurable lifetime the instantaneous concentrations of —SS⁼— and e^-_{aq} will be related by expression 3

$$[3] \qquad (\text{—SS}^{=}\text{—})_t = \frac{k'}{k_T}\left[(e^-_{aq})_0 - (e^-_{aq})_t\right]$$

where k' is the rate constant for the reaction giving —SS⁼— and the overall rate constant k_T is the sum of this and the rate constants for all other reaction paths between e^-_{aq} and papain (see below). From this expression the first order integrated rate expression

$$[4] \quad \ln\left[(O.D.\text{—SS}^{=}\text{—})_\infty - (O.D.\text{—SS}^{=}\text{—})_t\right] = \ln\left[(O.D.\text{—SS}^{=}\text{—})_\infty\right] - k_T(\text{papain}) \times t$$

can be derived, so that k_T can be evaluated from the growth of the disulfide absorption as well as from the disappearance of e^-_{aq}. The plot of our results in Fig. 2*b* conforms to eq. 4 and gives the same value of $k_T(= 4.0 \pm 0.2 \times 10^{10})$ as the first order plot for the e^-_{aq} disappearance ($4.1 \pm 0.1 \times 10^{10}$). From the error limits on these rate constants it can be shown that any intermediate involved in the production of —SS⁼— must be short lived ($t_{1/2} \lesssim 0.03$ μs).

The highly stable nature of the observed disulfide anions and the rapidity of their formation would imply that each e^-_{aq} which encounters a papain molecule should form —SS⁼—. However, there are several features of the present results which indicate that this is not so. In the first place there is excess absorption on the low wavelength side of the 415 nm peak, leading to a rising absorption below 320 nm. This cannot be accounted for entirely by the H atom adduct and the 8% of unscavenged OH radicals which still react with papain in the presence of 20 mM isobutanol. Furthermore, as shown in Fig. 3*b* the intensity per unit dose of the absorption in the region of the peak at 415 nm falls with

[3] G. M. Gaucher and F. E. Robertson. Unpublished data.

increasing dose. This can be attributed to the destruction of one or more of the three disulfide bridges of papain, evidence for which has already been obtained in the ^{60}Co γ-radiolysis of the enzyme (7). The fact that the absorption at 310 nm changes less with increasing dose suggests that much of the intensity at the lower wavelengths is due to different species. In the second place, if the extinction coefficient at 410 nm for —SS^{-}— in papain is similar to that in cystamine (9.4×10^3 (16)) and other —SS^{-}— ions ($\varepsilon_{(PenS)_2} = 7.5 \times 10^3$ (29), $\varepsilon_{(HOC_2H_4S)_2} = 8.3 \times 10^3$ (33)), one would have expected an approximately four fold greater absorption at this wavelength than was observed. The discrepancy implies that only a small fraction (about 25%) of e^-_{aq} produces —SS^{-}— which are detected 5 μs after the pulse.[4] Since we have seen that the observable disulfide ions are long lived it appears probable that there are competing reactions of e^-_{aq} which do not yield *stable* disulfide anions.

A more complete picture of the reactions of e^-_{aq} with papain cannot be given at this time. However, it should be noted that the different environments (4) of the disulfide bridges between $\frac{1}{2}$ cystine residues 22–63, 56–95, and 153–200 may not all give stable disulfide anions. For example, the proximity of amino acid residues with aromatic sidechains might provide reaction pathways which could reduce the lifetime of —SS^{-}— ions below the limit of observation and give products that do not absorb strongly in the 340–600 nm range. Another possibility is that e^-_{aq} reacts with peptide units

to produce the radical anion —Ċ—N—C— (27). This has been shown to react with disulfides at an appreciable rate, although the products are as yet unknown. While highly speculative, it is evident that reactions of the kinds mentioned above may have important implications for the high efficiency of e^-_{aq} in deactivating papain and the fact that this deactivation is largely repairable by CysSH and certain other nucleophiles (7) (also footnote 5).

[4]It may be noted that similar observations in the pulse radiolysis of trypsin indicate that only 60% of e^-_{aq} form stable —SS^{-}— ions on attacking this enzyme (9).

Quantitative Investigation of the Ozonolysis Reaction. XVII. Relative Reaction Rates for the Ozone Attack on Phenylethylenes[1]

G. KLUTSCH AND S. FLISZÁR

Department of Chemistry, Université de Montréal, Montréal, Québec

Received March 14, 1972

The relative rate constants for the reaction of ozone with a variety of ring-substituted phenylethylenes in CCl_4 solution obey Hammett's equation $\log k_{rel} = \log k^0_{rel} + \rho\sigma$, with $\sigma \approx -0.9$. Non-conjugating β-substituents affect the rate constants in Taft's σ^* order $k^0_{rel}(CH_3) > (H) > k^0_{rel}(COOCH_3)$. These results illustrate the electrophilic mode of attack of ozone.

Les constantes de vitesse relatives pour l'ozonolyse de phényléthylènes substitués dans le noyau, en solution dans le CCl_4, obéissent à l'équation de Hammett $\log k_{rel} = \log k^0_{rel} + \rho\sigma$, avec $\sigma \approx -0.9$. Les substituants β ne conjugant pas avec la double liaison éthylénique affectent k^0_{rel} dans l'ordre polaire de Taft $k^0_{rel}(CH_3) > (H) > k^0_{rel}(COOCH_3)$. Ces résultats illustrent le mode d'attaque électrophile de l'ozone.

The dipolar character of ozone has been stressed by Huisgen (1), who advocated that the reaction between ozone and olefin is in general a 1,3-dipolar cycloaddition. This is confirmed by recent kinetic studies (2) which demonstrated the electrophilic nature of the ozone attack. Cvetanović's results (2*a*) illustrate this point clearly: the rate of ozone attack on chloroethylenes (in CCl_4 solution) decreases strongly as the number of chlorine atoms in the olefin molecules is increased. In terms of the 1,3-cycloaddition model for the reaction it would, thus, appear that, although the two new σ bonds are formed quasi-simultaneously, their rates of formation seem to differ because the ozone appears to attack by its positive pole.

Earlier kinetic studies (2*b*, *c*) indicated, however, that the observed trends in reactivity cannot be explained only in terms of an electrophilic attack by ozone, although this appeared to be the predominant factor in many cases. The possible participation of an alternative reaction path via a π or a σ complex has been considered by several authors (2–5). The kinetic results were interpreted in terms of the mechanisms represented in Scheme 1 (2, 5).[2]

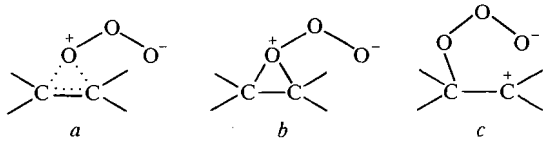
The study of the relative reaction rates for the ozone attack on alkyl-substituted ethylenes in inert solvents (5) also contributes in supporting the participation of a reaction path implying a reversible intermediate complex formation. Contrasting with the situation in which the overall electrophilic character of the ozone attack is preserved, the relative reaction rates for the ozone attack on alkyl-substituted ethylenes follow an overall nucleophilic trend. In CCl_4 solution, the kinetics are described adequately by Taft's equation

$$[1] \qquad \log k = \log k^0 + \rho^* \sum \sigma^*$$

where $\sum\sigma^*$ is the sum of Taft's polar constants for the two substituents, and $\rho^* = 7.58$ (*trans*) and $\rho^* = 5.37$ (*cis*) are the polar reaction constants (5). These positive ρ^* values suggest, within the mechanism outlined in Scheme 1, that electron-releasing alkyl groups delay the oxygen O^- attack on the corresponding carbon atom to give the primary ozonide (1,2,3-trioxolane). Hence, the global process appears to be nucleophilic in nature when the final step is the ring-closure, implying, thus, that the determining step is not the formation of the initial olefin–ozone complex but its conversion to give the primary ozonide.[3]

[1]Extracted from the Ph.D. Thesis of G. Klutsch, Université de Montréal, Montréal, Québec, 1971.

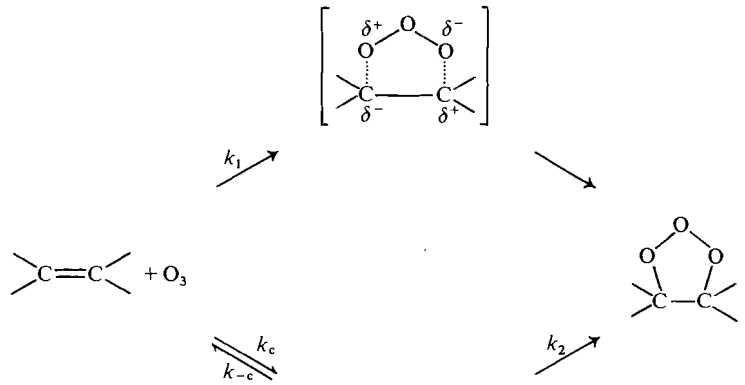
[2]The following structures were suggested for the intermediary complex (3–5).



a *b* *c*

The contribution of c is not considered likely; the possible rotation about the C—C σ bond would result in a non-stereospecific ozone addition on the olefin, in violation with Greenwood's observations (6) that a *trans* (or *cis*) olefin yields only *trans* (or *cis*) primary ozonide.

[3]The results in ref. 5 indicated only a minor, if any, steric effect to be attributed to the alkyl groups.



SCHEME 1

As pointed out by Huisgen (1), the exaltation of the polarizability of the olefinic carbon–carbon double bond is expected to favor the concerted 1,3-cycloaddition. This should namely occur in the ozonolysis of phenylethylenes, where the important conjugation increases significantly the polarizability of the reacting ethylenic π bond. For phenylethylenes it is hence expected that the ring-closure is not the rate determining step. Consequently, an overall electrophilic character should prevail for the ozone attack on phenylethylenes, which reflects the initial ozone–olefin complex formation. This aspect is investigated in the present paper, by the study of the substituent effects on the relative rates of ozonolysis of selected ring-substituted phenylethylenes.

Experimental

On the basis of the evidence (2*a*) that, in solution, the ozone–olefin reaction takes place with a 1 : 1 stoichiometry, the consumption of olefin i may be written

$$-\mathrm{d}x_i/\mathrm{d}t = k_i[O_3]x_i$$

where x_i = concentration of olefin i at time = t. Hence, in the conventional ozonolysis of a mixture of two olefins which are identified by the subscripts 1 and 2, it is

$$\log (x_1/x_{1,0}) = -k_1[O_3]t/2.3$$

$$\log (x_2/x_{2,0}) = -k_2[O_3]t/2.3$$

and, consequently,

$$[2] \qquad k_1/k_2 = \log (x_1/x_{1,0})/\log (x_2/x_{2,0})$$

where $x_{1,0}$ and $x_{2,0}$ are the concentrations of the olefins at time $t = 0$. Equation 2 enables the relative rate constants $k_{rel} = k_1/k_2$ (with respect to olefin 2) to be measured in a simple way, from the analyses of the unreacted olefins.

TABLE 1. Relative rate constants for the ozonolysis of *trans* 1-phenylpropene (1) with respect to styrene (2), in CCl_4 at 0°, calculated by means of eq. 2

TABLE 2. Effect of the initial olefin concentration on k_{rel}, with respect to styrene (2)

Olefin 1	x_1^0 (M)	x_2^0 (M)	k_{rel}*	n
β-Methylstyrene	0.106	0.100	5.2	7
	0.063	0.111	5.1	7
Isosafrole	0.110	0.118	8.9	3
	0.037	0.103	8.9	7

*Calculated from n determinations.

The fact that k_{rel} is independent of the ozone concentration and of reaction time considerably facilitates the measurements of k_{rel}. The example given in Table 1 indicates that k_{rel} does not depend on the progress of the reaction, *i.e.*, on the time of reaction.

The values of k_{rel} were obtained by a least-square analysis of the lines constructed from the plots of log $(x_1/x_{1,0})$ *vs.* log $(x_2/x_{2,0})$ (Fig. 1), using data such as those given in the example (Table 1).

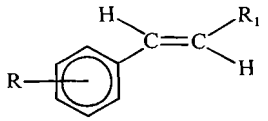
The examples given in Table 2 confirm that k_{rel} is independent of the initial olefin concentrations.

In the present work, k_{rel} is always expressed with reference to styrene (subscript 2), and the results are indicated with a 95% confidence limit, from 6–8 individual experiments. Carbon tetrachloride was used as solvent. Most of the experiments were carried out at 0 °C, but it has been verified that k_{rel} does not depend on the temperature, at least not in the temperature interval from 0 to 25 °C.

Most of the olefins are commercial products. Some β-substituted phenylethylenes with a substituent on the phenyl ring were prepared by Granger (7). The purity of the olefins was controlled by g.l.c. and by the standard KI test. The ozonolyses were carried out on 5–10 ml of the olefin solutions. Immediately after completion of the ozonolysis, the solutions were analyzed for unreacted olefins by g.l.c., using a Hewlett–Packard F&M 5750 gas chromatograph with flame detector and a 6 ft UCW-98 column. The intensities of the g.l.c. peaks were measured by planimetry and compared to the appropriate references. Control experiments were also made using internal standards.

Results and Discussion

The relative rate constants with respect to styrene, as determined at 0° in CCl_4 solution, for a series of *trans* substituted phenylethylenes are reported in Table 3.



As indicated by Fig. 2, the relative rate constants for any series with an invariant R_1 substituent obey satisfactorily Hammet's equation

$$[3] \qquad \log k_{rel} = \log k_{rel}^0 + \rho\sigma$$

where k_{rel}^0 represent the relative rate constants for the compounds having no substituent in the aromatic ring, *i.e.*, R = H. The reaction constants ρ which are calculated by means of eq. 3 from the results reported in Table 3 are given in Table 4.

These results indicate that, within experimental error, the slopes ρ are similar for the different series of phenylethylenes which were examined, irrespective of the nature of R_1. The negative ρ value which is observed in each case clearly indicates that the overall character of the ozone attack on phenylethylenes is electrophilic in nature. The process of cycloaddition, favored by the exaltation of the polarizability of the ethylenic π bond due to its conjugation with the aromatic ring, implies postulates similar to those discussed by Huisgen (1) in terms of a 1,3-dipolar cycloaddition. Although the extent of simultaneity in the formation of the two carbon–oxygen bonds is an open question, it may be assumed that the transition state resembles closely the final state, *i.e.*, the 1,2,3-trioxolane, and that its

*The values for R_1 = H are extracted from ref. 8.

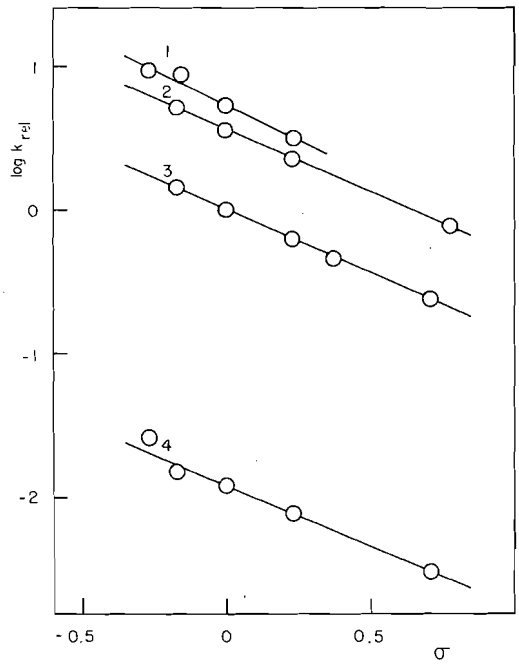

FIG. 2. Hammett plots (eq. 3), from the results of Table 3. $R_1 = CH_3$ (1), C_6H_5 (2), H (3), $COOCH_3$ (4).

final conversion to give the primary ozonide occurs most rapidly. The rate determining step is, hence, the addition of ozone on the olefin. The dual role, *i.e.*, a dipolar character of ozone, exhibiting both an electrophilic and a nucleophilic tendency in the cycloaddition to give the primary ozonide has been discussed earlier by Williamson and Cvetanović (2*a*). The present results suggest that in its reaction with phenylethylenes the ozone molecule prefers an attack by its positive pole.

This aspect is confirmed by the effects exhibited by the β-substituents R_1. These can be evaluated from a comparison of their corresponding k^0_{rel} values which, as indicated by eq. 3 with $\sigma = 0$ (*i.e.*, R = H) depend solely on the nature of R_1.

The behavior exhibited by the CH_3, H, and $COOCH_3$ groups indicates that k^0_{rel} decreases markedly as the polar electron-releasing ability of R_1 is decreased. This confirms the electrophilic trend of the ozone attack on the olefinic double bond revealed by the negative slopes ρ describing the effects of ring substitution.

With $R_1 = C_6H_5$ and $COCH_3$ the relative rate constants are significantly higher than those expected from a consideration of the polar effects of these groups alone. This exaltation of the reaction rates can be attributed to their conjugation with the ethylenic carbon–carbon double bond. In the case of the *trans* methyl cinnamate, such a resonance would be negligible because of the resonating structure $-C(O^-) = O^+ - CH_3$ of the ester group, which appears, hence, to contribute only by its polar effect.

Finally, the similarity in the ρ slopes (Table 4) suggests that the substituents in position 2 influence the kinetics always in the same manner, irrespective of the substituent in position 1. This may suggest an additivity rule for the substituent effects, similar to that observed for the 1,2-dialkyl substituted ethylenes (5). This conclusion, however, can at present only be drawn for ethylenes with a phenyl group in position 1, and should, therefore, not be generalized.

TABLE 4. Hammett's reaction constants ρ (eq. 3) for the ozonolysis of ring- and β-substituted styrenes

Conductances, Densities, and Viscosities of Solutions of Sodium Nitrate in Water and in Dioxane–Water, at 25 °C

ELINOR M. KARTZMARK

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received March 14, 1972

The conductances, densities, and viscosities of solutions of sodium nitrate in water and in 20, 40, 60, 70, and 80 wt. % dioxane–water have been measured at 25 °C, from $C \simeq 5 \times 10^{-4}$ *M* to saturation. The data have been fitted to the Fuoss–Onsager equation, yielding values of Λ_0, $\mathring{a}$, and K_A; and in concentrated solutions to the equations of Wishaw–Stokes and Gellings. Apparent molar volumes have been calculated.

No appreciable ion association is apparent in solutions whose dioxane content is less than 60% by weight. Passing from water to 80% dioxane, the values of $\mathring{a}$ obtained from the Fuoss–Onsager equation increased from 2.74 to 7.60 Å, a sharp increase occurring beyond 60%.

Les conductances, densités et viscosités des solutions de nitrate de sodium dans l'eau et dans des mélanges à 20, 40, 50, 70, et 80% en poids de dioxane et d'eau; ont été mesurées à 25° pour $C \simeq 5 \times 10^{-4}$ *M* jusqu'à saturation. Les données ont été rajustées à l'équation de Fuoss-Onsager donnant ainsi les valeurs de Λ_0, $\mathring{a}$, et K_A; et pour les solutions concentrées, aux équations de Wishaw–Stokes et Gellings. Les volumes molaires apparents ont été calculés.

Il n'y a pas d'association ionique appréciable dans les solutions dont la teneur en dioxane est inférieure à 60% en poids. En passant de l'eau au dioxane à 80%, les valeurs de å obtenues à partir de l'équation de Fuoss–Onsager augmentent de 2.74 à 7.60 Å, avec un accroissement marqué au-delà de 60%.

Canadian Journal of Chemistry, **50**, 2845 (1972)

Previously in this laboratory, the conductances of solutions of lithium and of sodium chlorates in water and in water–dioxane have been measured, and the degrees of association calculated (1). The present paper is a report on a similar study, using sodium nitrate. The only previous work on the conductance of sodium nitrate in aqueous solution, at 25 °C, in the dilute region, is that due to Jones (2). The concentrated region has been investigated by Gellings (3), up to 4.84 *M*. No previous studies have been made on sodium nitrate in water–dioxane mixed solvents.

Conductance measurements in the dilute region yield Λ_0 as a function of dielectric constant and values of $\mathring{a}$ and K_A can be calculated using the Fuoss–Onsager equation. The concentrated region is of great interest, compounding as it does the problems of viscosity, association, and solvation. For some salts, the Wishaw–Stokes equation gives a relatively good quantitative representation of the concentrated region but it has been found to be quite inadequate for others (1). This paper reports measurements of density, viscosity, and conductance over the complete concentration range, that is, from 5×10^{-4} *M* to saturation in water and in 20, 40, 60, 70, and 80 wt.% dioxane–water.

Experimental

Purity of Materials

Sodium Nitrate

Fisher "Certified" sodium nitrate was recrystallized twice from conductance water, dried in an oven at 120 °C with periodic grinding.

Conductance Water

This was prepared by distillation of water which had passed through a mixed resin demineralization column, using a silica still and collecting flasks. Dissolved carbon dioxide was removed by purging with purified nitrogen.

Dioxane

Fisher "Certified" dioxane was further purified by the method of Hess and Frahm (4). The purified dioxane had a density of 1.0278 g/ml and refractive index of $n_{25}^{D} = 1.4202$. Lind and Fuoss (5) report a density of 1.02794 after a week's refluxing over sodium. Frey and Gilbert (6) report a refractive index of 1.42025.

Potassium Chloride

This was recrystallized from conductance water, dried and fused in air.

Procedure

The experimental procedures have been recorded in ref. 1; only minor changes have been made. A Beckmann conductance bridge, Model RC-18 A, was used. All weighings were reduced to vacuum. The temperature was controlled at 25.00 ± 0.005 °C. The dielectric constants of pure dioxane and 60 and 80 wt. % dioxane were measured with a Sargent Model 5 Oscillometer, thermostated to 25.00 °C. It was calibrated using spectroscopically pure benzene, nitrobenzene, and ethylene dichloride. The dielectric constants of 20 and 40% dioxane were taken from Harned and Owen (7). Viscosities were measured with a Cannon and Fenske

(8) type viscometer, with a run-time with water of 340.4 s. The viscosity values for dioxane–water mixtures compared very well with the data of Lind and Fuoss (5). A silica cell of the Shedlovsky type was used for the conductance measurements of the dilute solutions. At the end of each series of measurements with the Shedlovsky cell, the density of the solution was determined; no detectable change was observable from the density of the solvent (*i.e.* within 0.0001).

Results

The equivalent conductances in the dilute region are to be found in Table A in the Depository of Unpublished Data, together with calculations from the Fuoss–Onsager equation.[1] The data of Jones which extend from $c = 5 \times 10^{-4}$ to 0.5 *M*, range from 3 to 6 mhos lower than the present data and do not fit the Debye–Hückel slope in the limiting region.

In the concentrated region, densities, viscosities, and equivalent conductances were measured and are shown in Table 1, together with the deviation in Λ calculated using the

equations of Wishaw–Stokes and of Gellings. An extended form of this table, including calculations of the apparent molar volume, is given as Table B in the Depository of Unpublished Data.

Discussion

Dilute Region

Λ_0 was determined in all solvents, either by extrapolation of the Λ *vs.* $\sqrt{c}$ plot (for water, 20, and 40% dioxane), or by the best fit of the data with the Fuoss–Onsager equation:

$$[1] \qquad \Lambda = \Lambda_0 - Sc^{1/2} + Ec \log c + Jc$$

$$[2] \quad \Lambda = \Lambda_0 - Sc_i^{1/2} + Ec_i \log c_i + Jc_i - K_A c_i f^2 \Lambda$$

where $c_i = c\gamma$, concentration of free ions, and $K_A = (1-\gamma)/(c\gamma^2 f^2)$, the association constant. The activity coefficient, f, was calculated from the Debye–Hückel equation

$$-\log f = \frac{\beta'' C^{1/2}\gamma^{1/2}}{1 + K\mathring{a}C^{1/2}\gamma^{1/2}}$$

For solvents containing 0, 20, and 40% dioxane, no ionic association was found; eq. 1 was thus used. Following the procedure of Fuoss and Accascina (9), a preliminary graphical determination of Λ_0 allowed calculation of S and E, from which $\Lambda' = \Lambda + Sc^{1/2} - Ec \log c$ was calculated. Λ' was plotted *vs.* c, yielding a straight line whose slope is J. From the value for J, the parameter $\mathring{a}$ was determined. The limit $K\mathring{a} < 0.2$ was adhered to. Finally $\delta = \Lambda'_{obs} - (\Lambda'_0 + Jc)$ was calculated for each concentration. Solutions containing 60, 70, and 80% dioxane showed ion association and were treated using eq. 2. Again the method outlined in Fuoss and Accascina was followed. Here the graphical method of finding Λ_0 was not as clear-cut and necessitated several trials until a straight line y *vs.* x was obtained. J, the intercept, was used to calculate $\mathring{a}$, the new value was introduced in the expression for f^2 and the procedure repeated. K_A is obtained as the slope of the y *vs.* x line. The whole procedure was tested for consistency by substituting S, E, J, K_A, f^2, and γ back into eq. 2 and obtaining the difference from Λ exp.

Λ_0 decreases from 121.55 in aqueous solution to 41.00 in 80% dioxane–water. The values of $\mathring{a}$ increase from 2.74 in water to 7.60 in 80% dioxane. These results are shown in Fig. 1. The viscosity of dioxane–water mixtures passes through a sharp maximum at 60% dioxane. This seems to have no marked effect on Λ_0, because the Λ_0 *vs.* D plot shows no change in curvature in this range. The $\mathring{a}$ values begin to increase steeply at around 60% dioxane, suggesting that the solvation sheath may be predominantly dioxane. Indeed, the change in Λ_0 with dioxane content can only be explained in terms of solvation. A plot $\Lambda_0\eta_0$ *vs.* dioxane content shows a marked decrease beyond 40% dioxane, even though the viscosity increases by 17% in the range 40 → 60% dioxane.

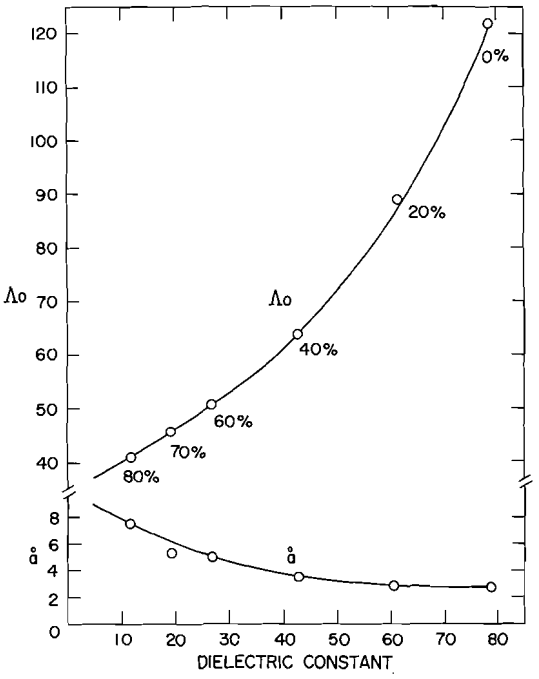

FIG. 1. Λ_0, $\mathring{a}$ *vs.* dielectric constant.

Ion association as determined by K_A does not become marked until a dioxane content of approximately 60% has been attained. The data of Table A may be summarized in Table 2. The $\mathring{a}$ and K_A are very similar to those of Lind and Fuoss for potassium chloride.

The Concentrated Region

The conductance–viscosity data in the concentrated region were fitted to the Wishaw–Stokes equation (10)

$$\Lambda = \left(\Lambda_0 - \frac{B_2\sqrt{c}}{1 + B\mathring{a}\sqrt{c}}\right)\left(1 - \frac{B_1\sqrt{c}}{1 + B\mathring{a}\sqrt{c}}F\right)\frac{\eta_0}{\eta}$$

Generally, the $\mathring{a}$ obtained from the Fuoss–

TABLE 2. Summary of Table A in the Depository of Unpublished Data

Wt.% Dioxane	D	η (P)	Λ_0 (mho)	J	$\mathring{a}$	K_A
0	78.54	0.008903	121.55	143	2.74	—
20	60.79	0.01262	87.20	197	2.93	—
40	42.98	0.01673	63.50	418	3.70	—
60	26.80	0.01929	50.75	1 270	5.00	12.5
70	19.40	0.01897	46.00	3 580	5.25	107.0
80	11.90	0.01703	41.00	16 600	7.60	1 980.0

Onsager equation gave the best results. Where the dilute region showed marked association, *i.e.*, in dioxane > 40%, the Wishaw–Stokes equation failed completely. Taking a 3% error as maximum, the data for aqueous solutions fitted the equation up to $c \simeq 1.95\ M$; the range was very much reduced in solutions containing dioxane ($c \simeq 0.15\ M$). The failure of the equation in aqueous solution at higher concentrations may be attributed to inadequacy of the viscosity correction but is probably due also to association. The viscosity factor is more pronounced in 20 and 40% dioxane.

Table B gives calculations of Λ, using Gellings' equation

$$\frac{\Lambda}{\Lambda_0} = (1 - zc) \exp - \frac{\left(\alpha + \frac{\beta}{\Lambda_0}\right)\sqrt{c}}{1 + B\mathring{a}\sqrt{c}}$$

where a, β, B, $\mathring{a}$ have the same significance as in Debye–Hückel theory and z is an empirical constant. For $\mathring{a}$, Gellings used the effective radii of the ions in the solution as calculated by Böttcher (11) from refractive index and density of electrolytic solutions. Z is evaluated from the conductance data by the method of least squares. No correction is made for the viscosity of the solution. The data of Gellings for sodium nitrate in water plot on the same Λ *vs.* $\sqrt{c}$ curve but do not extend to saturation nor to the very dilute region. The present paper extends Gellings' data to $c = 7.79\ M$ in aqueous solution. With $\mathring{a} = 2.74$ (the value obtained from the dilute region) and $z = 0.0842$, the equation fits the data over the entire concentration range, within about 5%. The 20 and 40% dioxane solutions are equally well handled but, at higher dioxane concentrations, no constancy in z was found for reasonable $\mathring{a}$ values. Admittedly, while Gellings' equation fits the experimental data over a much wider range than Wishaw–Stokes', it contains an empirical constant, which has no obvious theoretical basis and it ignores the viscosity correction entirely.

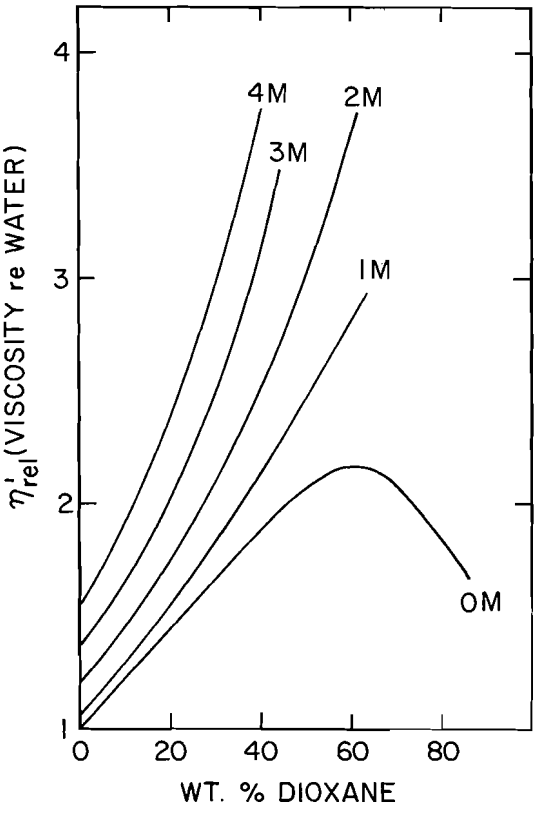

FIG. 2. η'_{rel} *vs.* wt. % dioxane.

Viscosities and Associated Properties

The relative viscosities (solvent = 1) of sodium nitrate solutions increase with concentration (to 2.98 in saturated aqueous solution) and also with increase in dioxane content in the mixed solvents. When the viscosities relative to water (η'_{rel}) are plotted against % dioxane, for 1, 2, 3, and 4 M solutions of sodium nitrate, Fig. 2

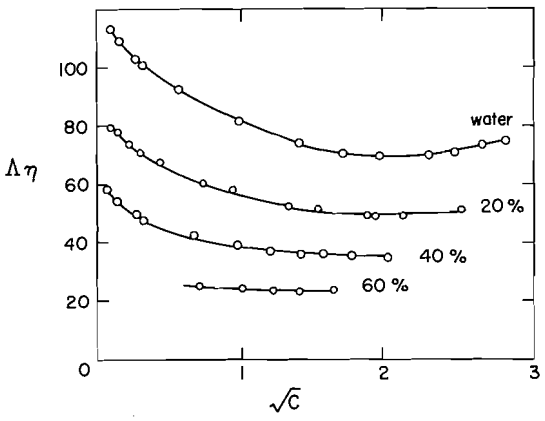

FIG. 3. $\Lambda\eta$ *vs.* $\sqrt{c}$.

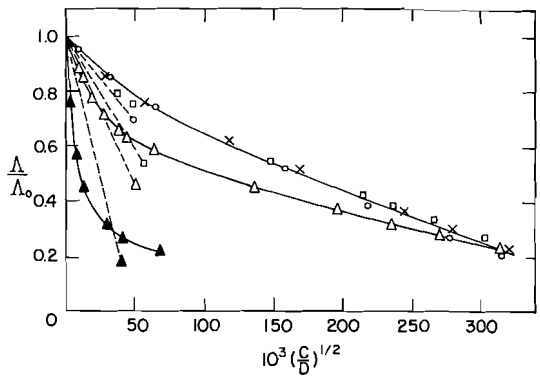

FIG. 4. Λ/Λ_0 *vs.* $(c/D)^{1/2}$.

is obtained. The ratios of η'_{rel}/η_{rel} increase with dioxane content and this indicates that the same concentration of salt increases the viscosity of solvent to a greater extent, the greater the dioxane content. The viscosity of dioxane–water solutions (0.0 *M* curve) passes through a maximum at 60% and falls off rapidly. The limited solubility of sodium nitrate does not allow investigation beyond the solvent maximum; from 1 to 4 *M* there is no suggestion of a maximum. In 80% dioxane–water two liquid layers are produced shortly after 0.054 *M* sodium nitrate.

The apparent molar volumes ϕ_v (Table B) increase with concentration of sodium nitrate and also with dioxane content to an apparent maximum between 40 and 60% dioxane. This was also found to be true of sodium chlorate (12), which approached a maximum at 64.5% dioxane. The difference ϕ_v $(ClO_3^- - NO_3^-)$ remains roughly constant between 1 and 6 *M*, in water, and in 40% dioxane, the values being around 1.3 ml/mol greater in the latter.

A plot of $\Lambda\eta$ *vs.* $\sqrt{c}$ (Fig. 3) shows a minimum around 4 *M* in aqueous and 20% dioxane solutions; the minimum is not observable in solutions of higher dioxane content, which have limited solubility of sodium nitrate.

Figure 4, a plot of Λ/Λ_0 *vs.* $(c/D)^{1/2}$, shows an interesting regularity in solutions in 0, 20, and 40% dioxane. All data points fall on the same curve, to within about 5%, a type of reduced conductance. In the very dilute region, solutions with dioxane content less than 60% show the well known "anabatic phoreogram" typical of complete dissociation, *i.e.*, the limiting slope lies below the Λ *vs.* $\sqrt{c}$ plot. For 60 and 80% dioxane, the limiting slope lies above the Λ *vs.* $\sqrt{c}$ plot, "catabatic phoreogram", a sign of association.

The Oxygenation of 2-Oxazolin-5-ones: A New Synthesis of Imides[1]

R. BISSON, R. B. YEATS,[2] AND E. W. WARNHOFF
Department of Chemistry, University of Western Ontario, London, Ontario

Received February 21, 1972

In the presence of mild base such as triethylamine, the two 4-alkylidene-2-phenyl-2-oxazolin-5-ones, **1** and **8**, rapidly absorb oxygen at room temperature with the loss of carbon dioxide and the formation of the imides **4** and **10**. The imide probably arises by decomposition of a hydroperoxide resulting from the reaction of oxygen and the anion of the oxazolinone. A hydroperoxide intermediate will also account for the origin of the acidic by-products **6***a* and **11***a*. The 2-methyl-2-oxazolin-5-one **14** did not react with oxygen at room temperature; at 60° some reaction occurred but no imide was formed.

Lorsque mis en présence d'une base faible comme la triéthylamine, les deux alkylidène-4 phenyl-2 oxazolin-5-ones, **1** et **8** absorbent rapidement de l'oxygène à la température ambiante pour ensuite libérer du gaz carbonique et conduire aux imides **4** et **10**. La formation d'un imide peut être attribuée à la décomposition d'un hydroperoxyde issu de la réaction entre l'oxygène et l'anion de l'oxazolinone. L'intermédiaire hydroperoxyde peut aussi expliquer l'origine des produits secondaires acidiques **6***a* et **11***a*. La méthyl-2-oxazolin-5-one **14** ne réagit pas avec l'oxygène à la température ambiante: toutefois à 60° une transformation fut observée mais non la formation d'un imide.

Canadian Journal of Chemistry, **50**, 2851 (1972)

In the course of synthetic approaches to peptide alkaloid derivatives (1), a conjugate addition of a phenol to the isobutylidene-2-oxazolin-5-one (isobutylidene azlactone) **1** was attempted (2). When *N*-(*N'*-carbobenzoxyphenylalanyl)-tyramine and **1** were allowed to react in acetonitrile solution containing some triethylamine, instead of the desired addition product there was isolated a colorless solid, $C_{12}H_{13}NO_2$, m.p. 113°, which contained no feature of the protected phenylalanyltyramine group. It was established that the product, whose formula was that of the azlactone minus one carbon atom, arose from the azlactone when it was found that **1** alone in acetonitrile–triethylamine became bright yellow at room temperature and rapidly gave the same compound in up to 58% yield. The suspicion that oxygen was also involved was confirmed when the product was not formed in an attempted reaction in CH_3CN–Et_3N solution under a nitrogen atmosphere. Moreover, oxygen was presumably reacting with the anion **2** of the azlactone since no reaction occurred when an acetonitrile solution of **1** was exposed to oxygen in the absence of base. The choice of solvent was not critical since the same product was formed in acetone and dimethylformamide solutions.

The oxidation product absorbed 1 mol of hydrogen to form the dihydro derivative, m.p. 83°. Comparison of the n.m.r. spectra of these two compounds uniquely defined the dihydro derivative to be benzoyl isovaleryl imide **5**, and the oxidation product itself to be benzoyl β,β-dimethylacrylyl imide **4** with which structure the u.v. and i.r. spectra were in agreement. Final proof of identity was obtained by comparison with an authentic specimen of **4** prepared by reaction of the *N*-lithio salt of benzamide with β,β-dimethylacrylyl chloride.

The reaction probably occurs (Scheme 1) through electron transfer (3) from the resonance stabilized anion **2** of the oxazolinone to oxygen and either recombination of the resulting radical and radical anion, or else reaction of the radical with oxygen and **2**, to produce a peroxide which could have a number of formulations, **3***a*, *b*, or *c*.[3,4] Involvement of the

[1]Presented in part at the 54th Canadian Chemical Conference of the Chemical Institute of Canada, Halifax, Nova Scotia, June 1, 1971.

[2]Department of Chemistry, Bishop's University, Lennoxville, Québec.

[3]It is recognized that in principle oxygen could become attached at three other positions to produce hydroperoxides **i**, **ii**, and **iii** or their cyclic peroxide addition products, two of which can readily explain the carboxylic acid by-products. However, since a peroxide of type **3** most readily explains the formation of imide, and since the carboxylic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

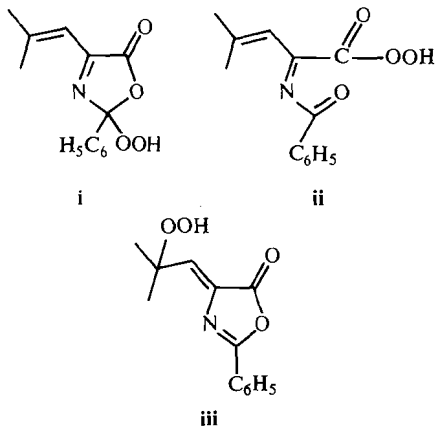
anion **2** is supported not only by the failure of **1** to react in the absence of base, but also by the ready exchange of the allylic methine hydrogen of **1** when D_2O was added to the CH_3CN–Et_3N solution in the absence of oxygen. The oxazolinone **1** also exchanges this tertiary hydrogen slowly at room temperature in acetone-d_6–Et_3N solution. Breakdown of the peroxide (Scheme 1) with loss of carbon dioxide would yield the imide **4** directly, and in fact carbon dioxide was isolated as $BaCO_3$ in a yield almost equal to that of the imide **4**.

A peroxide intermediate can also explain the formation of a major carboxylic acid by-product. The bicarbonate soluble portion of the oxygenation reaction was esterified with diazomethane, and the predominant one of seven compounds isolated by t.l.c. Since this product was clearly a dienoic ester from its u.v. absorption, the structure **6***b* follows and is in agreement with the n.m.r. spectrum. Hydrogenation of the ester gave racemic *N*-benzoylleucine methyl ester **7** whose i.r. and n.m.r. spectra were identical with those of authentic *N*-benzoyl-L-leucine methyl ester. The possible origin of the dienoic acid **6***a* by an elimination reaction of the peroxide[5] followed by acylimine ⇌ enamide tautomerism is depicted for **3***b* in Scheme 2.[5]

To test the generality of this new oxidation, two other oxazolinones were treated with oxygen in CH_3CN–Et_3N solution. The azlactone **8** from hippuric acid and phenylacetone also rapidly absorbed oxygen with the formation of the imide **10** in 43% yield (Scheme 3). In fact the uptake of oxygen was faster than with **1** as would be expected from the greater acidity of the methylene hydrogens in **8** which are both allylic and benzylic. The product was identical with an authentic specimen made by the reaction of the *N*-lithio salt of benzamide and the acid chloride of (*E*)-α-methylcinnamoyl chloride. Also in this oxygenation there was a carboxylic acid by-product formed in 36% yield. The n.m.r. and u.v. spectra identified the methyl ester of the acid to be methyl 3-benzylidene-2-oxobutyrate **11***b*. Oxidative degradation of the α-keto acid **11***a* gave (*E*)-α-methylcinnamic acid. The α-keto acid **11***a* could also have arisen from the hydroperoxide, *e.g.* **9**, which could not in this case give a dienoic acid of the **6***a* type because of the absence of a δ-hydrogen atom. However, the hydroperoxide (*e.g.* **9**) could undergo ring opening[5] and hydrolysis of the benzoylimine **9** → **12** → **11***a*.

The final azlactone tested was the 4-isobutylidene-2-methyl derivative **14**. At room temperature under the same conditions resulting in rapid oxygen absorption by both 2-phenyloxazolinones **1** and **8**, the 2-methyl compound did not react. At 60° over a period of 3 days the azlactone was consumed but no imide **15** was produced. Apparently additional stabilization such as provided by a 2-phenyl substituent is required for facile oxygenation, and the reaction may not be as general as first thought.[6]

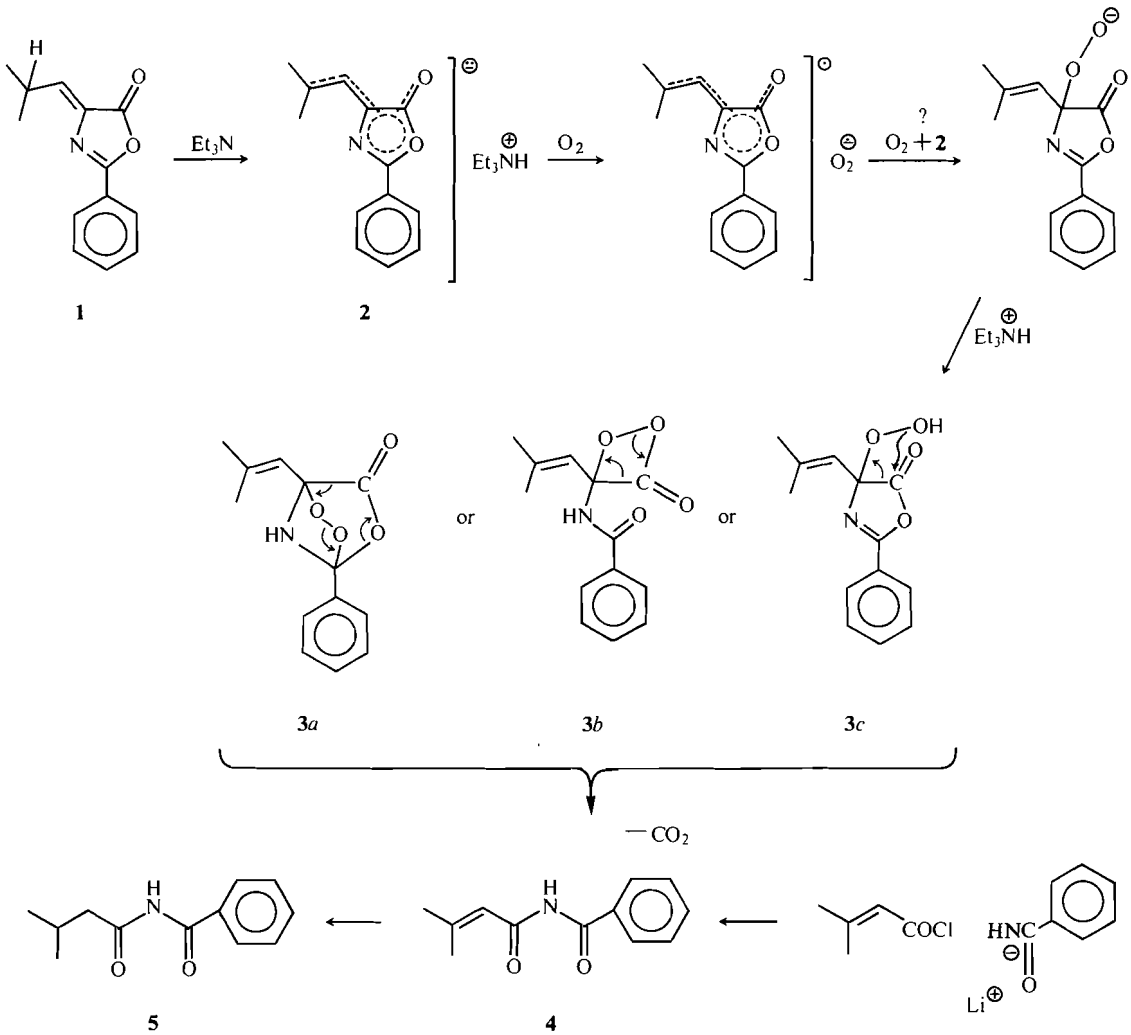
acid by-products can be rationalized on the basis of **3***a*–*c*, there is no need to invoke the alternative peroxide formulations in the absence of evidence for them.



[4]The oxygenation of Schiff base anions (4*a*) and 3,7-dihydroimidazo[1,2-*a*]pyrazin-3-ones (4*b*) follows a similar path. In these cases the breakdown of cyclic four-membered peroxides often radiates visible light, but the absence of observable visible *luminescence* in the present oxygenations (the reactions did become bright yellow) does not necessarily exclude a structure such as **3***b*.

[5]The peracid so formed would break down to the carboxylic acid either by exchange or oxygen loss. Although the formation of the carboxylic acid by-products is shown for one of the possible peroxide structures, similar mechanisms can be written for the other peroxide formulations, and no preference is intended. Some of the other compounds present in the acid fraction may result from attack of the peracid on double bonds.

[6]The apparent failure to form any hydroperoxide which would lead to **15** is probably not due to the acidity of the 2-methyl group. Although in 2-alkyloxazolin-5-ones the α-hydrogens of the 2-alkyl group are acidic enough to be removed to some extent by triethylamine, the pK_a's of the



SCHEME 1

Experimental

General

Melting points were determined on a Reichert–Kofler microscope hot stage and are corrected.

I.r. spectra were recorded on a Beckman IR-10 instrument with chloroform solutions. N.m.r. spectra were recorded on Varian A-60 and T-60 spectrometers with deuteriochloroform solutions. Peak positions are given in p.p.m. from internal tetramethylsilane = 0(δ); s = singlet, d = doublet, m = multiplet, b = broad. Aromatic peaks are not reported for most spectra. U.v. spectra were recorded on a Cary 14 spectrometer with methanol solutions.

Silica gel GF_{254} (Merck, Germany) was used for thin and thick layer (20 g/20 × 20 cm plate) chromatography. Thin layer plates were visualized by u.v. and/or by charring (H_2SO_4:HNO_3, 4:1). B.D.H. silica gel was used for column chromatography.

Organic solutions from work-up of reactions were washed to neutrality with aqueous $NaHCO_3$ and water, dried over anhydrous $MgSO_4$ and then evaporated to dryness under reduced pressure on a rotary evaporator. Petroleum ether refers to the fraction boiling at 60–80°.

allylic and 2-methyl hydrogens of **14** are probably close enough to allow formation of both monoanions in which case the allylic anion could lead to some imide **15**. However, the ability of oxygen to abstract an electron from the allylic anion will depend on the energy difference between the anion and its corresponding radical. Provided that phenyl stabilizes the radical more than the anion, a 2-phenyl group may serve to lower the activation energy enough for electron abstraction to occur, while the effect of the 2-alkyl group may not be sufficient to make electron abstraction by oxygen facile.

SCHEME 2

*(Z?)-4-Isobutylidene-2-phenyl-2-oxazolin-5-one (**1**)*

The procedure of Galantay *et al.* (5) was used. A mixture of hippuric acid (17.9 g, 0.10 mol), $Pb(OAc)_2 \cdot 3H_2O$ (16.0 g, 0.04 mol), acetic anhydride (30 g, 0.30 mol), isobutyraldehyde (7.7 g, 0.12 mol), and tetrahydrofuran (230 ml) was stirred magnetically at reflux temperature for 5 h. After cooling, the mixture was filtered and concentrated under vacuum. The residue was diluted with 350 ml of benzene and treated with an excess of H_2S. The filtered solution was evaporated to leave an orange oil that crystallized at room temperature. Recrystallization from petroleum ether to constant melting point gave 5.75 (26%) of pure oxazolinone **1**, m.p. 86–87° (lit. (6) 87°); ν_{max} 1800 (C=O) and 1675 cm^{-1} (C=N); δ 1.19 (Me_2CH, d, $J = 7$ Hz), 3.30 (Me_2CH, m), and 6.51 p.p.m. (=CH—, d, $J = 10$ Hz).

(E) or *(Z)-4-(2'-Phenylisopropylidene)-2-phenyl-2-oxazolin-5-one (**8**)*

A mixture of hippuric acid (18.6 g, 0.10 mol), $Pb(OAc)_2 \cdot 3H_2O$ (16 g, 0.04 mol), acetic anhydride (40 g, 0.40 mol), phenylacetone (16.6 g, 0.12 mol), and tetrahydrofuran (240 ml) was stirred magnetically during 8 h at reflux temperature and then left overnight. The ether soluble material after concentration under vacuum was distilled under reduced pressure to allow the recovery of 11.7 g (70%) of phenylacetone. Column chromatography of the distillation residue on silica gel gave 1.4 g (14%) of crude oxazolone **8** (mixture of stereoisomers) in the petroleum ether:ether (97:3) eluate. Recrystallization from petroleum ether afforded 536 mg (5%) of silky needles of pure (*E*)- or (*Z*)-oxazolinone **8**, m.p. 88–89°, ν_{max} 1790, 1760 shoulder (C=O), and 1665 cm^{-1} (C=N); δ 2.28 (CH_3, s) and 4.00 ($—CH_2—$, s).

Anal. Calcd. for $C_{18}H_{15}NO_2$ (277.3): C, 77.96; H, 5.45. Found: C, 77.97; H, 5.47.

*(Z?)-4-Isobutylidene-2-methyl-2-oxazolin-5-one (**14**)*

The experimental procedure followed was patterned closely on that of Herbst and Shemin (7). A mixture of *N*-acetylglycine (14.6 g, 0.12 mol), anhydrous NaOAc (7.5 g, 0.09 mol), isobutyraldehyde (13.0 g, 0.18 mol), and acetic anhydride (31 g, 0.45 mol) was stirred magnetically at 105° for 2 h. The mixture was stirred at room temperature for 2 h more, then diluted with water and extracted with ether. After washing and drying, the combined ether layers were concentrated under vacuum to leave 20.3 g of reddish brown oil (acetic anhydride still present). Fractional distillation through an 8-cm Vigreux column under reduced pressure gave the following four fractions: (*i*) b.p. 30–47° (0.9 Torr), 3.8 g, Ac_2O and *i*-$PrCH(OAc)_2$; (*ii*) b.p. 47–48° (0.9 Torr), 3.8 g, *i*-$PrCH(OAc)_2$ (mostly) and **14**; (*iii*) b.p. 50–75° (0.9 Torr), 3.7 g, mostly **14**; and (*iv*) b.p. 78–80° (0.9 Torr), 3.8 g, unknown mixture. The oxazolinone **14** was not readily purified in quantity and decomposed on standing in a sealed tube. However, successive preparative layer chromatography in petroleum ether:ether (85:15) afforded enough **14** (mixture of *cis* and *trans* isomers) for spectroscopic characterization, b.p. ~48° (0.8 Torr) (lit.

(8) 68–69° (0.15 Torr)), ν_{max} 1800 (C=O) and 1675 cm^{-1} (C=N); δ 1.09 and 1.11 (Me_2CH, d, $J \sim 6$ Hz), 2.23 and 2.28 (Me—C=, s), 2.9–3.8 (Me_2CH), b.m.), and 6.32 and 6.40 p.p.m. (—CH=, d, $J \sim 10$ Hz); *m/e* 153 (molecular ion).

Oxygenation of Oxazolinone ***1***

Oxygen was bubbled through a solution of oxazolinone **1** (538 mg, 2.5 mmol) and triethylamine (513 mg, 6.3 mmol) in acetonitrile (30 ml) at room temperature for 4 h at which point t.l.c. showed the absence of **1**. The yellow reaction mixture was evaporated to dryness to leave 683 mg of brownish solid whose t.l.c. (petroleum ether:ether, 70:30) gave a spot corresponding to the imide **4** and a spot near the application point. The crude product was partitioned between ether and 10% aqueous $NaHCO_3$. From the ether layer was recovered 295 mg (58%) of brownish solid which after recrystallization from cyclohexane gave colorless flat prisms of ***N*-benzoyl-β,β-dimethylacrylamide (4)**, m.p. 112.5–113°, λ_{max} 246 nm (36 000), found to be identical with the authentic sample whose preparation is described below.

Anal. Calcd. for $C_{12}H_{13}NO_2$ (203.2): C, 70.92; H, 6.45; N, 6.89; O, 15.74. Found: C, 70.82; H, 6.37; N, 6.88; O, 15.86.

Acidification of the $NaHCO_3$ solutions and extraction with ether gave 230 mg of yellowish solid amorphous carboxylic acids which were esterified with ethereal diazomethane. The 270 mg of methyl esters gave seven spots on t.l.c. (petroleum ether:ether, 70:30). The major compound (R_f 0.13) was separated by preparative t.l.c. in the same solvent system, and after two recrystallizations from ether–petroleum ether there was obtained 37 mg (6%) of colorless crystals of **2-benzamido-4-methyl-2,4-pentadienoic acid methyl ester (6*b*)**, m.p. 123–124°; λ_{max} 235 (10 400) and 260 nm (11 500); ν_{max} 3400 (NH), 1710 (ester C=O), and 1675 cm^{-1} (amide C=O; δ 1.97 (CH_3, s), 3.80 (CH_3O, s), 5.30 (=CH_2, b.s), and 7.10 p.p.m. (=CH—, s) (NH not apparent).

The ratio of the imide **4** to the acid **6*a*** in the crude oxygenation mixture was about 3:1 from n.m.r. integration.

In an experiment to measure the volume of oxygen absorbed, a solution of **1** (107 mg, 0.50 mmol) and triethylamine (102 mg, 1.0 mmol) in 6 ml of acetonitrile gently shaken under an atmosphere of oxygen at 25° absorbed 11.8 ml (theor. 12.5 ml) in 27 h at 745 Torr. Most of this absorption occurred during the first 9 h. From the 127 mg of crude oxygenation product there was obtained 50 mg (50%) of **imide 4** by preparative layer chromatography.

Trapping of the Carbon Atom Lost from ***1***

Oxygen freed from carbon dioxide by passage through Ascarite was bubbled through a solution of oxazolinone **1** (215 mg, 1.00 mmol) and triethylamine (205 mg, 2.5 mmol) in acetonitrile (12 ml), and the exiting gas was passed through a clear saturated aqueous solution of $Ba(OH)_2$. At the end of the reaction 93 mg (47%) of precipitated $BaCO_3$ was collected by filtration. Preparative t.l.c. (petroleum ether:ether, 70:30) of the crude product and recrystallization from cyclohexane gave 93 mg (45%) of **imide 4**.

Hydrogenation of Oxygenation Product from ***1***

A solution of 36 mg of the oxygenation product from **1** in 5 ml of ethanol absorbed 4.28 ml (1.0 mol) of hydrogen in the presence of 8 mg of 10% Pd/C catalyst at 29° and 743 Torr. Filtration, evaporation, and recrystallization from ether–petroleum ether gave colorless crystals of **benzoyl isovaleryl imide 5**, m.p. 82–83°; ν_{max} 3400 (NH), 1715 (imide C=O), and 1690 cm^{-1} (imide C=O); δ 1.03 (Me_2CH, d, $J \sim 6$ Hz), 1.8–2.7 (Me_2CH, m), 2.92 (CH—CH_2, d, $J \sim 6$ Hz), and 9.07 p.p.m. (NH, b.s.).

Anal. Calcd. for $C_{12}H_{15}NO_2$ (205.3): C, 70.22; H, 7.37; N, 6.82. Found: C, 69.93; H, 7.15; N, 6.80.

Hydrogenation of Methyl Ester ***6b***

A solution of ester **6*b*** (37 mg) in methanol (6 ml) was shaken for 1.5 h under a hydrogen atmosphere in the presence of 5% Pd/C (10 mg). Filtration and concentration left 29 mg (78%) of **(±)-*N*-benzoylleucine methyl ester (7)**, m.p. 94–95° (lit. (9) 95–95.5°) after recrystallization from petroleum ether, whose i.r. and n.m.r. spectra were identical with an authentic specimen of *N*-benzoyl-L-leucine methyl ester, m.p. 102–102.5° (lit. (10) 102°); ν_{max} 3440 (NH), 1740 (ester C=O), and 1660 cm^{-1} (amide C=O); δ 0.99 (Me_2CH, d, $J \sim 5$ Hz), 1.5–2.1 (3H, m), 3.78 (CH_3O, s), 4.93 (O=C—N—CH—C=O, m) and 6.66 p.p.m. (NH, b.d., $J \sim 8$ Hz).

*N-Benzoyl-β,β-dimethylacrylamide (****4****)*

β,β-Dimethylacrylic acid, prepared from mesityl oxide as reported by Smith *et al.* (11), was converted into the acyl chloride by treatment with PCl_5 according to the procedure of Feuer and Pier (12).

A solution of benzamide (500 mg, 4.1 mmol) in tetrahydrofuran (20 ml) was placed in a septum-sealed flask into which was injected a solution of *n*-butyllithium in hexane (2 ml, 4 mmol). The precipitated *N*-lithio salt was washed with three portions (10 ml) of tetrahydrofuran and then suspended in the same solvent (10 ml). A solution of β,β-dimethylacrylyl chloride (450 mg, 3.8 mmol) in tetrahydrofuran (4 ml) was injected into the *N*-lithio salt suspension. The reaction mixture was diluted with ether, washed with saturated aqueous NaCl, dried, and evaporated at reduced pressure to leave 700 mg of yellow solid. Recrystallization from cyclohexane gave 117 mg (15%) of colorless crystals, m.p. 110–111.5°, ν_{max} 3430 (NH), 1705 (imide C=O), 1675 (imide C=O), and 1630 cm^{-1} (C=C); δ 2.02 (CH_3, d, $J \sim 1$ Hz), 2.22 (CH_3, b.s.), 6.97 (C=CH, b.s.), and 9.53 (NH, b.m.).

Oxygenation of Oxazolinone ***8***

Oxygen was bubbled through a mixture of **8** (348 mg, 1.26 mmol) and triethylamine (260 mg, 2.5 mmol) in acetonitrile (16 ml) during 0.5 h at which point t.l.c. showed the absence of starting material **8**. The reaction mixture was concentrated under reduced pressure to leave 540 mg of dark yellow oil whose t.l.c. (petroleum ether:ether, 70:30) gave two spots, one corresponding to the imide **10** and the other at the point of application. The product was partitioned between ether containing a little chloroform and 10% aqueous $NaHCO_3$ solution. Evaporation of the dried ethereal layer left 148 mg (43%) of crude yellow imide. Preparative layer chromatography and recrystallization from petroleum ether–chloroform gave 60 mg of pure **(*E*)-*N*-benzoyl-2-methylcinnamamide (10)**, identical (mixed m.p., t.l.c., i.r., and n.m.r.) with the authentic sample prepared as described below.

Acidification of the $NaHCO_3$ solution and ether extraction gave 239 mg of greenish oily carboxylic acid mixture. Esterification with ethereal diazomethane and preparative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

t.l.c. of the methyl esters (petroleum ether–ether, 80:20) yielded 97 mg (36%) of yellow liquid **methyl (*E*)-3-benzylidene-2-oxobutyrate (11*b*)**, λ_{max} 222 (4200) and 292 nm (19 400); ν_{max} 1735 (ester C=O), 1665 (ketone C=O), and 1615 cm^{-1} (C=C); δ 2.13 (CH_3, b.s.), 3.97 (CH_3O, s), 7.28 (=CH—, b.s.), and 7.43 p.p.m. (5 phenyl H, s). Some **benzamide** was also isolated from the crude methyl ester.

In another oxygenation the crude acidic fraction (263 mg) was esterified with diazomethane and the crude methyl ester mixture was recrystallized from chloroform–petroleum ether to give 25 mg of **benzamide**, m.p. 125–126°, identical (i.r. and n.m.r.) with an authentic specimen.

Trapping of the Carbon Atom Lost from 8

With the same procedure for trapping CO_2 used for oxazolinone **1**, the oxygenation of a solution of oxazolinone **8** (277 mg, 1.00 mmol) and triethylamine (205 mg, 2.0 mmol) in acetonitrile (12 ml) gave 47 mg (24%) of $BaCO_3$ and 80 mg (30%) of **imide 10**.

(E)-N-Benzoyl-2-methylcinnamamide (10)

The procedure of Perkin (13) was used to prepare (*E*)-2-methylcinnamic acid from benzaldehyde and propionic acid. The acid was converted into its acid chloride by treatment with PCl_5 according to the procedure of Feuer and Pier (12).

Into a suspension of the *N*-lithio salt of benzamide, prepared from benzamide (500 mg, 4.1 mmol) in the same manner described for the preparation of **4**, in tetrahydrofuran (4 ml) was injected a solution of (*E*)-2-methylcinnamoyl chloride (508 mg, 2.8 mmol). The reaction mixture was diluted with ether, washed with three portions of water, dried, and evaporated at reduced pressure to leave an orange residue. Recrystallization of the ether soluble material from chloroform–ether yielded 28 mg (4%) of long feathery needles, m.p. 128.5–129.5°; ν_{max} 3390 (NH), 1740 (imide C=O), 1675 (imide C=O), and 1625 cm^{-1} (C=C); δ 2.14 (CH_3, d, $J \sim 1.5$ Hz) and 9.20 (NH, b.s.) (the olefinic H was hidden in the aromatic proton absorption).

Anal. Calcd. for $C_{17}H_{15}NO_2$ (265.7): C, 76.96; H, 5.70; N, 5.28. Found: C, 76.45; H, 5.69; N, 5.31.

Oxidative Cleavage of α-Keto Acid 11a

In a procedure similar to the one outlined by Stecher and Gelblum (14), crude α-keto acid **11*a*** (130 mg, 0.68 mmol) was dissolved in dioxane (6 ml) and treated at room temperature alternately with small portions (magnetic bar stirring) of 1% aqueous Na_2CO_3 solution and a total of 8 ml of 30% aqueous H_2O_2. Care was taken to maintain a p*H* of ~8 in the reaction mixture which was stirred for 4 h. Acidification and ether extraction yielded an oily residue after removal of ether. The residue was further purified by solution in petroleum ether. Evaporation of the petroleum ether soluble portion left 80 mg of yellowish oil whose t.l.c. (petroleum ether:ether:acetic acid, 86:10:4) revealed the presence of *(E)*-α-methylcinnamic acid. Preparative t.l.c. in the same solvent system yielded 31 mg (28%) of **(*E*)-α-methylcinnamic acid**, m.p. 79.5–80.5° (lit. (13) 81°) after recrystallization from petroleum ether; λ_{max} 207 (14 300) and 267 nm (17 400); ν_{max} 1685 (C=O) and 1630 cm^{-1} (conj. C=C); δ 2.12 (CH_3, d, $J \sim 1.5$ Hz), 7.30 (5 phenyl H, s), 7.73 (=CH—, b.s.), and 11.63 (—COOH, b.s.).

Oxygenation of Oxazolinone 14

When a solution of oxazolinone **14** (153 mg, contaminated with *i*-PrCH$(OAc)_2$) and triethylamine (225 mg) in acetonitrile (25 ml) was shaken under an oxygen atmosphere in a mercury sealed burette system for 3 h no uptake of oxygen occurred. However, after oxygen was bubbled through the same solution at 60° with stirring for 3 days, the reaction mixture no longer contained **13**. T.l.c. comparison of the crude product with authentic ***N*-acetyl-β,β-dimethylacrylamide (15)** prepared as described below, showed the absence of this imide. When this oxygenation was carried out at room temperature to check the evolution of any CO_2 in an experiment similar to the ones with **4** and **8**, no $BaCO_3$ precipitated.

N-Acetyl-β,β-dimethylacrylamide (15)

A mixture of sublimed acetamide (540 mg, 9.1 mmol), sodium hydride (430 mg, 56% oil suspension, ~9 mmol), and dioxane (20 ml) was stirred magnetically for 30 min and then treated with a solution of β,β-dimethylacrylyl chloride (1.18 g, 10 mmol) in dioxane (10 ml). The resulting mixture was stirred magnetically at reflux temperature for 30 min. The cooled reaction mixture was diluted with chloroform, filtered, and evaporated to leave 1.07 g of brownish solid. Several recrystallizations from ether–petroleum ether afforded 173 mg (13%) of white needles, m.p. 92–93°; ν_{max} 3400 (NH), 1720 (imide C=O), 1680 (imide C=O), and 1640 cm^{-1} (C=C); δ 1.95 (CH_3, d, $J \sim 1.5$ Hz), 2.21 (CH_3, d, $J \sim 1.5$ Hz), 2.41 (CH_3, s), 6.10 (=CH—, b.s.), and 9.43 p.p.m. (NH, b.s.).

Anal. Calcd. for $C_7H_{11}NO_2$ (141.2): C, 59.56; H, 7.85; N, 9.92. Found: C, 59.83; H, 7.87; N, 10.16.

Hydrogen Exchange of Oxazolinone 1

(a) In CD_3CN–D_2O

To a solution of **1** in CD_3CN used for recording of the n.m.r. spectrum was added a drop of Et_3N and a drop of D_2O. The 1-H multiplet near δ 3.3 decreased rapidly and a sharp singlet from DOH appeared at δ 3.6 before much of the **1** had been changed by the D_2O.

(b) In Acetone-d_6

A solution of 50 mg of **1** in 0.25 ml of acetone-d_6 gave an n.m.r. spectrum unchanged by time. One drop of Et_3N was added (solution became yellow) and the n.m.r. spectrum was recorded periodically during 2 days. The methine hydrogen gradually disappeared, and the expected simplification of the methyl (d → b.s.) and olefinic (d → b.s.) signals slowly occurred at room temperature.

Studies on Nucleation from Solution of some Nickel Dioximates

J. D. HANNA AND O. E. HILEMAN, JR.[1]
Department of Chemistry, McMaster University, Hamilton, Ontario
Received September 23, 1971[2]

Nucleation studies on two nickel dioximates have been carried out by using a direct mixing technique coupled with rapid particle counting. It is concluded that homogeneous nucleation was being observed. The Volmer–Weber, Becker–Doring model of the nucleation process was used to correlate the data.

Nous avons effectué des études de nucléation sur deux différents dioximates de nickel au moyen d'une technique de mélange directe associée à un comptage rapide des particules. On en conclut qu'une nucléation homogène se produit. Pour faire une corrélation entre les résultats, nous avons utilisé le modèle Volmer–Weber, Becker–Doring du processus de nucléation.

It was recognized long ago that the phenomenon of supersaturation observed in nucleation from solution implies the existence of an energy barrier which opposes the initiation of crystallization. The objective of any experimental study or theory concerned with nucleation from solution is to account for this barrier and, further, to suggest a mathematical model which permits calculation of various nucleation parameters. Much of the literature reporting on nucleation from solution, however, presents conflicting and inconsistent evidence about the process. In addition, the Volmer–Weber, Becker–Doring model of the nucleation process, the one used most often to help interpret nucleation data, has recently been criticized by several authors when applied to liquid nucleation from the vapor phase. Apparently then, its adequacy as a model for the more complex process of nucleation from solution is somewhat limited. Thus, any advancement in the understanding of the initial formation of crystals from solution seems to await new or improved experimental techniques for its study. Recently, in our laboratories, we have been developing such techniques. This communication reports and discusses some experimental results obtained by one of them during studies on two nickel oximates.

Experimental

Apparatus

Mixing System: Two 10-ml syringes were separately connected to the input ports of a Roughton Cell (1). The plungers of the syringes were interlocked so that they operated simultaneously. The appropriate metal ion buffer solution was placed in one of the syringes and a solution of the chelating agent was placed in the second. After mixing, the resulting solution was led through the outlet port of the cell to a third syringe.

Particle Counting System: The particle counting system was a component system made up of a "Coulter Counter" (Industrial Model B, Coulter Electronics Industrial Division), a multichannel analyzer (Model ND 161F, Nuclear Data Inc.), and a magnetic tape recording unit (Model MT36, Potter Instrument Co. Inc.). Part of the signal appearing in the line connecting the main amplifier to the oscilloscope of the "Coulter Counter" was fed to the input of the multichannel analyzer. The data collected during each step of the particle size analysis by the analyzer were dumped onto magnetic tape, thus freeing the analyzer for a subsequent step. The data on the tapes were processed and recovered by computer.

Reagents and Solutions

Calibration Dispersions for the Particle Counting System: 1.099, 3.49, 11.7, and 18.8 μ diameter particles (polystyrene spheres (Dow Chemical Co.) or rag weed pollen (Coulter Electronics, Industrial Division)) were separately dispersed in 1% (w/v) NH_4Cl solutions. Triton X-100 was added to the dispersion containing the smallest particles to prevent agglomeration. Each dispersion contained approximately 10^5 particles/ml. Mixtures of these were used to determine the resolution of the system.

Nucleation Studies: Stock solutions of Ni^{2+} (0.1 *M*), from nickel chloride, nioxime (1.0×10^{-2} *M*) and heptoxime (1.0×10^{-2} *M*) were each prepared in aqueous 1% (w/v) NH_4Cl. All other concentrations of these reagents were prepared by dilution with 1% (w/v) NH_4Cl solution. p*H* adjustments were made with NH_3 or HCl solutions. Before use, each solution was filtered at least twice through 0.1 μ PVC membrane filters.

Procedures

Calibration of the Particle Counting System: The particle counter probe (30 μ aperture) was inserted into 100 ml of a calibration dispersion. The number and size distribution of the standard-sized particles in this dispersion were deter-

mined for each of the ten amplification settings of the instrument using 0.5 ml for each measurement.

The data from each setting were dumped onto magnetic tape and stored for later processing and recovery. This procedure was followed for each calibration dispersion and also for mixtures of standard-sized particles.

Nucleation Studies: Appropriate Ni^{2+} and dioxime solutions were added respectively to each of the 10-ml syringes connected to the input ports of a Roughton Cell. These solutions were mixed and led to the third syringe. After a certain time, part of the contents of the latter syringe were transferred to a beaker containing enough 1% (w/v) NH_4Cl solution to yield 200.0 ml of a dispersion containing about 10^5 countable particles/ml. Then the same counting procedure was carried out as described above for the calibration of the system. The specific data for each set of experiments are shown in Table 1.

Data Handling: To produce composite size distribution curves the data from each of the ten amplification settings were correlated by averaging the overlapping portions. These data along with the total area under the size distribution curves were recovered in tabular form.

Results and Discussion

Particle Counting System

Part of the electronic signal appearing at various points in the particle counter circuit were fed to an oscilloscope. Photographs of the pulse shapes appearing on the screen were taken and the results compared with the pulse shapes required by the multichannel analyzer. Figure 1 shows typical pulse shapes and sizes for standard particles when the signal was interrupted in the line between the main amplifier and the oscilloscope of the particle counter. The characteristics of most of the pulses fall within those recommended for best resolution and linearity of the analyzer. Similar results were found when the spherical particles were replaced by an actual precipitating system.

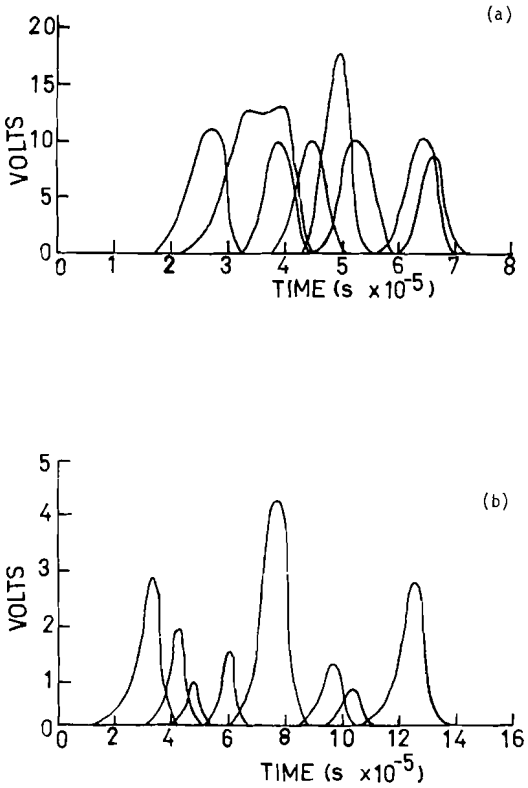

FIG. 1. (*a*) Pulse shapes for 3.49 μ diameter spheres. (*b*) Pulse shapes for nickel dimethylglyoximate crystals.

Figure 2 shows the results of an analysis of a mixture of 1.099 and 3.49 μ standard-sized particles. From such data, the standard deviation for each of the standard-sized particles was calculated and compared with the manufacturers' specifications where available (see Table 2). The ten calibration curves, one for each

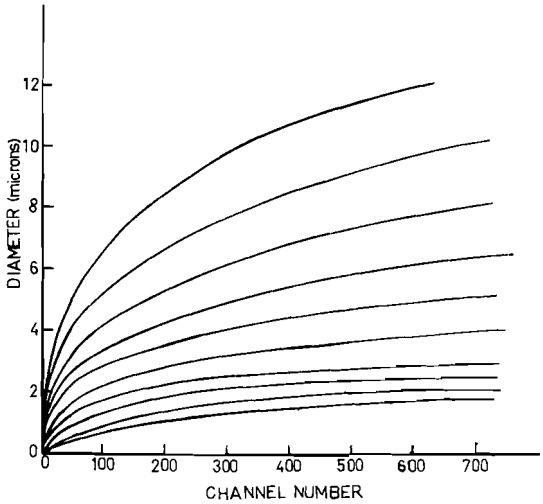

FIG. 3. Calibration curves for the 30 μ aperture. (Each curve represents the data for a separate amplification setting.)

amplification setting on the particle counter, shown in Fig. 3 were also calculated from these data by using eq. 1. This equation accurately describes the functional relationship between channel number of the multichannel analyzer, p, and particle size, d, over a range of 4 to 5 μ.

$$[1] \qquad p = \frac{\pi d^3}{6IBK}$$

where I = the current in the detector system; B = the amplification setting; and K = a collection of instrumental constants.

The results of the experiments described above led to the conclusion that our combination of a particle counter–multichannel analyzer–magnetic tape unit could be used to measure the total number of particles above 1 μ in size, the particle size distribution, and the variation of the particle size distribution with time during a nucleation and growth experiment.

Nucleation Studies

For each initial concentration of the metal chelate being studied several sets of size distri-

bution curves, determined at specific reaction times, were measured using the particle counter – multichannel analyzer – magnetic recording tape combination. Typical results for a single set, shown as size distribution curves for various reaction times for each of three different initial concentrations of nickel hepoximate are illustrated in Fig. 4. Similar results were observed for nickel nioximate. To increase the mass available for crystal growth the intrinsic solubility of each was increased by decreasing the pH of the reaction mixture. Consequently, there was an increase in the number of particles which surpassed the sensitivity limit of the particle counter.

Study of about 300 such size distribution curves has led to three general observations. Firstly, in all but the very early size distributions in any one set a large maximum with a small shoulder on the larger particle side in the curve is observed. Secondly, for increasing initial supersaturations there was a marked increase in the total number of particles formed. Thirdly, as the mass of material available for nucleation and growth increased, the average size of the particles formed decreased. Taken together these observations indicate that homogeneous nucleation is the primary type of initial transformation taking place in these experiments. Therefore, nucleation rates derived from the data are rates of homogeneous nucleation.

The rate of nucleation for a set of size distribution curves is defined by eq. 2.

$$[2] \qquad J = \frac{\partial N(t)}{\partial t}$$

where J = the rate of nucleation; N = the total number of particles formed with diameter "d" > $2r^*$ cm; t = the time after mixing the reactants; and r^* = the radius of the nucleus (critical). The total number of particles with a diameter greater than $2r^*$ formed in an experiment up to time "t" is given by eq. 3.

$$[3] \qquad N(2r^*,t) = \int_{2r^*}^{\infty} \frac{\partial N(d,t)}{\partial d}$$

The slope of a plot of $N(2r^*,t)$ *vs.* time, then, is the rate of nucleation for any particular initial supersaturation. Because the particle counter had a lower sensitivity limit of about 1 μ $N(2r^*,t)$ was replaced by $N(1\ \mu,t)$ in all of the data analyses. Plots of $N(1\ \mu,t)$ *vs.* time constructed from the data of Fig. 4 are shown in Fig. 5. The slope of each of these curves measures the rate of appearance of particles to the sensor of the particle counter. Over the initial linear portion of these curves this slope was equated with the rate of nucleation. The change in sign of the slope at later times in each set is probably due to agglomeration (see Figs. 4 and 5).

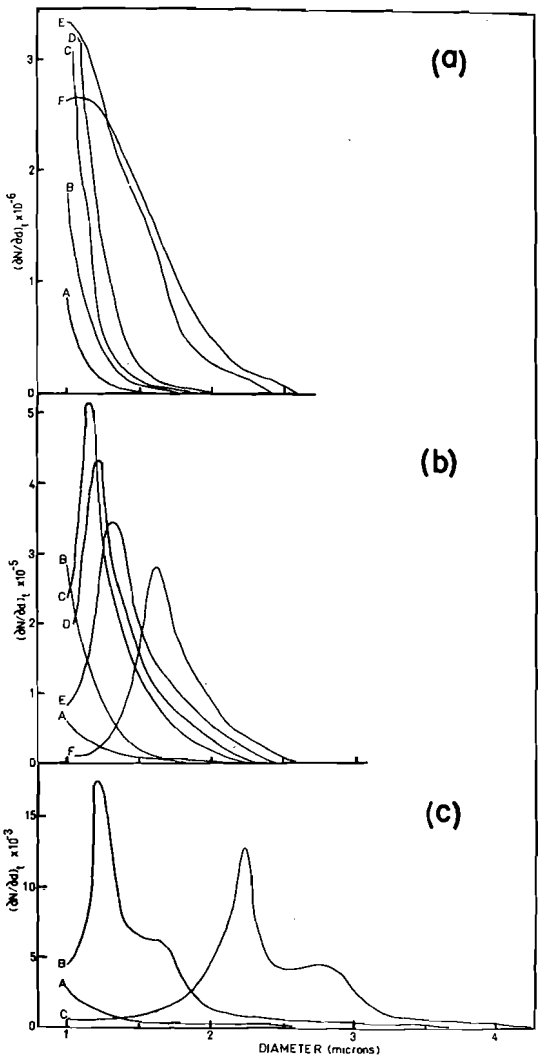

FIG. 4. Nickel heptoximate size distributions: (*a*) size distributions A, B, C, D, E, and F taken after 23, 41, 80, 100, 180, 300 s, respectively ($c_0 = 1.25 \times 10^{-3}$ M); (*b*) size distributions A, B, C, D, E, and F taken after 100, 160, 251, 313, 600, and 1260 s, respectively ($c_0 = 0.75 \times 10^{-3}$ M): and (*c*) size distributions A, B, and C taken after 7, 26, and 45 min, respectively ($c_0 = 3.75 \times 10^{-4}$ M).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

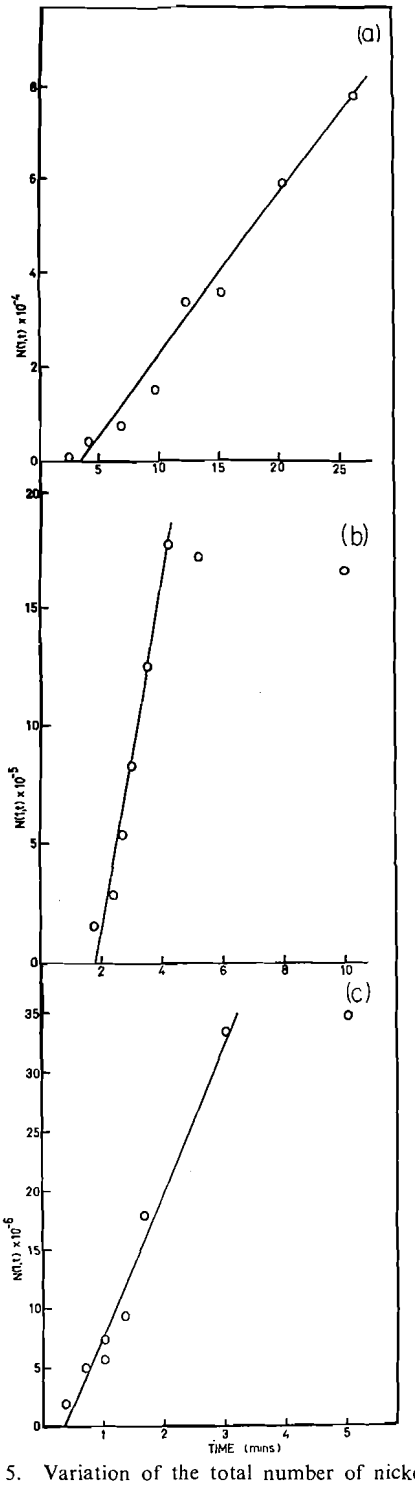

FIG. 5. Variation of the total number of nickel heptoximate crystals formed (above 1 μ) *vs.* time: (*a*) $c_0 = 1.25 \times 10^{-3}\ M$; (*b*) $c_0 = 0.75 \times 10^{-3}\ M$; and (*c*) $c_0 = 3.75 \times 10^{-4}\ M$.

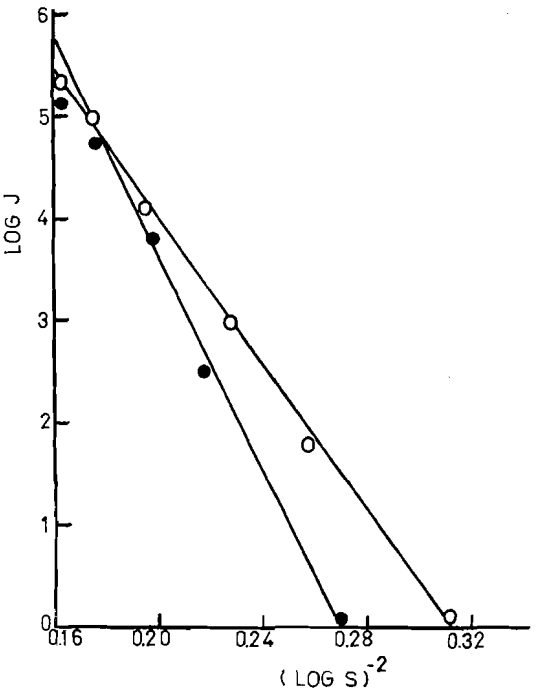

FIG. 6. Variation of log J with (log S)$^{-2}$ for nickel heptoximate and nickel nioximate (filled circles).

Plots of the functional relationship between J and S, the supersaturation within the system, predicted by the Volmer–Weber, Becker–Doring (V–W, B–D) model of the nucleation process are shown for each of the chelates in Fig. 6. In light of the recent criticism of the model, the linearity of this plot may be somewhat surprising (2–4). We have found, however, linear V–W, B–D plots in all of our studies on both molecular and ionic substances and find them to be useful for correlating and comparing rate-supersaturation data even though they may be fortuitous.

Using the slopes and intercepts of the plots of Fig. 6 along with eqs. 4 and 5 various parameters important in the V–W, B–D model were calculated.

$$[4] \qquad J = A \exp\left[-\frac{\beta\sigma^3 v^2}{(kT)^3\ (\ln S)^2}\right]$$

$$[5] \qquad r\dagger = \frac{2\sigma v}{kT \ln S}$$

where A = an empirical constant theoretically identified with $(2D/d_0^5 n^*)\,(4\Delta G^*/3\pi kT)^{1/2}$; β = a shape factor; σ = the surface tension; v = the

molecular volume in the solid phase; D = the diffusion coefficient of the molecules in solution; d_0 = the molecular diameter; ΔG^* = the critical free energy change; and $n\dagger$ and $r\dagger$ = the number of molecules in and the radius of the nucleus when $J = 1$, respectively.

The results are shown in Table 3.

Parameter values, calculated from data obtained by using Vonnegut's droplet technique in combination with precipitation from homogeneous solution and previously reported by one of us (5), are shown in Table 3 for comparison. The rather close agreement between the two sets of parameters derived from two entirely different experimental approaches tends to confirm our earlier conclusion that the rates observed are rates of homogeneous nucleation. Values of "A" many orders of magnitude lower than the calculated value have been reported before for these metal chelates (5), for other molecular compounds (6, 7), and for ionic salts (8). Some possible reasons for this discrepancy have been discussed in other publications (5–8).

Received April 11, 1972

The electrical conductivity of liquid vanadium pentoxide was measured as a function of temperature and oxygen partial pressure. A positive temperature coefficient and a negative oxygen partial pressure coefficient of conduction were found for the temperature range 670 to 1000 °C and oxygen partial pressures from 0.1 to 1.0 atm. The activation energy of conduction was 0.77 eV and the oxygen partial pressure coefficient was −0.16. At oxygen partial pressures less than 0.1 atm, for the same temperature range, a negative temperature coefficient and a negative oxygen partial pressure coefficient of conduction were found.

An n-type semiconduction model was used to explain the electrical conduction properties of liquid vanadium pentoxide at oxygen partial pressures greater than 0.1 atm. At lower oxygen partial pressures, electrical conduction was considered to occur by collective-electron conduction in partially filled 3d bands, due to an overlapping of the diffuse valence and conduction bands. The overlapping could result from a decrease in the cation separation distance in the melt due to the removal of oxygen ions from the melt.

Nous avons mesuré la conductivité électrique du pentoxyde de vanadium liquide en fonction de la température et de la pression partielle d'oxygène. Nous trouvons un coëfficient de température positif et un coëfficient de pression partielle de conduction négatif, sur une gamme de température allant de 670 à 1000 °C et de pressions partielles d'oxygène de 0.1 à 1.0 atm. L'énergie d'activation de conduction est 0.77 eV et le coëfficient de pression partielle de l'oxygène −0.16. A des pressions partielles d'oxygène plus faibles que 0.1 atm, pour une même gamme température, nous trouvons un coëfficient de température négatif et un coëfficient de pression partielle de conduction négatif.

Nous avons utilisé un modèle de semi-conduction de type n afin d'expliquer les propriétés de conduction électrique du pentoxyde de vanadium liquide à des pressions partielles d'oxygène plus grandes que 0.1 atm. A des pressions partielles d'oxygène plus faibles, nous considérons que la conduction électrique se produit au moyen de sauts d'électrons dans les orbitales 3d partiellement remplies, causés par le recouvrement des couches de valence et de conduction diffuses. Le recouvrement proviendrait d'une diminution de la distance de séparation des cations dans la fondue, à cause du départ des ions oxygène de la fondue.

Introduction

A number of alloys which normally show excellent high-temperature oxidation resistance are known to undergo accelerated corrosion in the presence of vanadium-containing fly-ash deposits or slags at temperatures greater than 500 °C (1). This accelerated corrosion, which is commonly called "catastrophic" vanadate corrosion, is thought to occur because of the presence of liquid vanadates in the fly-ash deposits (2). Liquid vanadates have been shown to increase the corrosion rate of metals by fluxing or altering the normally protective oxide layers present on the surface of the alloys and by providing a source of oxide ion for the corrosion reaction (3).

Only limited information is available on the physical and chemical properties of such liquid vanadates as iron, nickel, cobalt, chromium, sodium, and magnesium, which are commonly found in fly-ash deposits. In order to gain a better understanding of the mechanism of liquid vanadate corrosion, a program was initiated to characterize more fully the physical properties of the liquid vanadates, in particular their phase relationships and electrical conduction properties (4). The electrical conduction properties are reported in this series of articles.

The electrical conduction properties of solid (5–22) and liquid (18–25) vanadium pentoxide have been reported previously. There are a number of discrepancies in the reported data,

due in part to the presence of impurities. Vanadium pentoxide was found to show predominantly n-type semiconduction in both the solid and liquid states. Several mechanisms have been proposed to account for the semiconduction properties of solid vanadium pentoxide. A number of authors (13, 15, 22) consider the semi-conduction to occur via the hopping of electrons (small polarons) between V^{4+} and V^{5+} centers in the vanadium pentoxide lattice. The relationship between V^{4+} ion concentration and magnitude of electrical conduction has been confirmed by electron spin resonance (e.s.r.) and nuclear magnetic resonance (n.m.r.) measurements (26). Perlstein (17) considered the electronic conductivity above 170 °K to result from thermal excitation of electrons from vanadium-pair traps with an activation energy of 0.15 eV and electron hopping from one vanadium site to another with an activation energy of 0.05 eV. McCulloch (14) proposed a two-step process in which the electron was ionized from a V^{4+} – oxygen vacancy center and then moved through the lattice via polaron movement.

Allersma *et al.* (22), Pantony and Vasu (24), and Pastukhov *et al.* (25) have recently reported studies of the electrical conduction properties of liquid vanadium pentoxide. The electrical conductivity increased with temperature and with decreasing oxygen partial pressure. The activation energy of conduction was reported as 0.73 (22), 0.75 to 1.13 (24), and 2.2 eV (25). Allersma *et al.* found that the activation energy decreased with decreasing oxygen partial pressure, while the other workers reported no effect. The conductivity was reported to vary with oxygen partial pressure by a power of −0.167 (22), −0.240 at oxygen partial pressures greater than 0.033 atm and −0.580 at lower oxygen partial pressures (24), and −0.17 at temperatures between 660–770 °C and −0.27 at temperatures between 830–1500 °C (25). The magnitude of the specific electric conductance in oxygen at 1 atm at 900 °C was reported as 0.2 (22), 0.47 (24), and 0.35 $ohm^{-1}\ cm^{-1}$ (25). Because of the significant discrepancies between the reported electrical conduction properties of liquid vanadium pentoxide, these properties were re-examined as part of a study of the electrical conduction properties of the liquid vanadates.

Experimental

The electrical conductivity was measured using a dipping electrode cell, which has been found to be satisfactory for use with many molten oxides (27). The corrosiveness of liquid vanadates towards many oxides and metals limited the choice of construction materials. A gold (80 at.%) – palladium (20 at.%) alloy was found to show good corrosion resistance and was used in the apparatus.

Two gold–palladium electrodes, 2 mm in diameter and mounted in a pyrophyllite block, were dipped into a gold–palladium cylindrical crucible contained in an Inconel 600 crucible. The depth of the electrodes in the melt (0.500 in.) was accurately controlled by a threaded rod mechanism. A chromel–alumel thermocouple was positioned within 1 mm of the bottom of the crucible in order to estimate the temperature of the melt. The conductivity cell was contained in a vacuum-tight, grounded Inconel 600 tube fitted with flanges, which allowed the oxygen and argon gas mixtures over the melt to be accurately controlled. Operating temperatures, in the super Kanthal wound tube furnace, were maintained to better than ±1 °C.

Electrical conductivity measurements were made using a General Radio 1608-A Impedance Bridge with an auxiliary audio oscillator and a tuned amplifier and null detector. An oscilloscope was used as an auxiliary null detector. The conductivity cell was calibrated with 1.0 and 0.1 Demal KCl solution at 25.00 ± 0.01 °C (28). The resistance change with temperature of the shielded leads from the conductivity cell was accounted for. Negligible frequency dependence from 10^3 to 10^4 Hz was found for the molten vanadium pentoxide. An analysis of the experimental errors involved indicated the measurements were accurate to within ±2%.

Two grades of vanadium pentoxide were used. Fisher A.R. grade vanadium pentoxide had the following major impurities (in p.p.m.): Fe(150), Si(75), Co(75), Ni(75), Ca(30), Mn(20), Mg(20), Mo(15). Johnson and Matthey "specpure" vanadium pentoxide had the following impurities: Ti(20), Si(5). The two grades are identified in this paper as 99.9% and 99.997% vanadium pentoxide, respectively. These numbers do not refer to the stoichiometric composition of the oxides. Ultrahigh purity gases (O_2 = 99.9%, Ar = 99.999%) were used to give controlled atmospheres above the melt. The flow rates were controlled using calibrated rotometers.

Results

The temperature dependence of the electrical conduction of molten vanadium pentoxide under pure oxygen at a pressure of 1 atm is shown in Fig. 1. The data can be represented by the equations

$$\log K = 2.480 - \frac{3864}{T} \quad [1]$$

for the "specpure" vanadium pentoxide and

$$\log K = 2.412 - \frac{3669}{T} \quad [2]$$

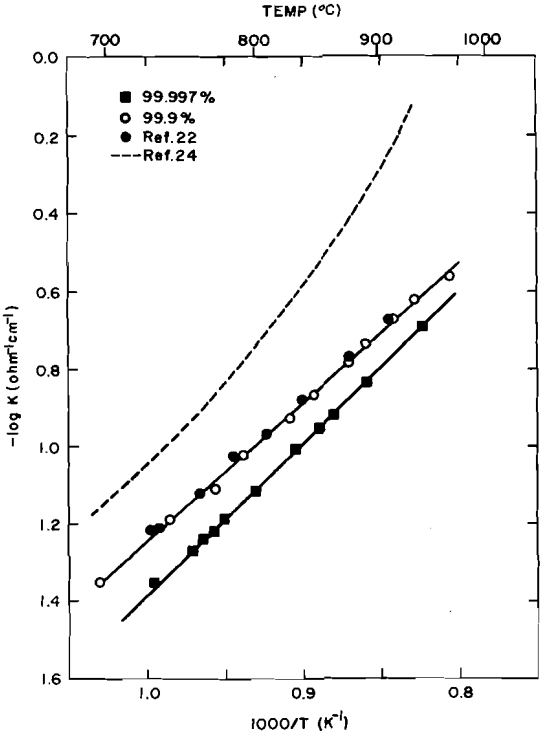

FIG. 1. Temperature dependence of the electrical conductivity of liquid V_2O_5.

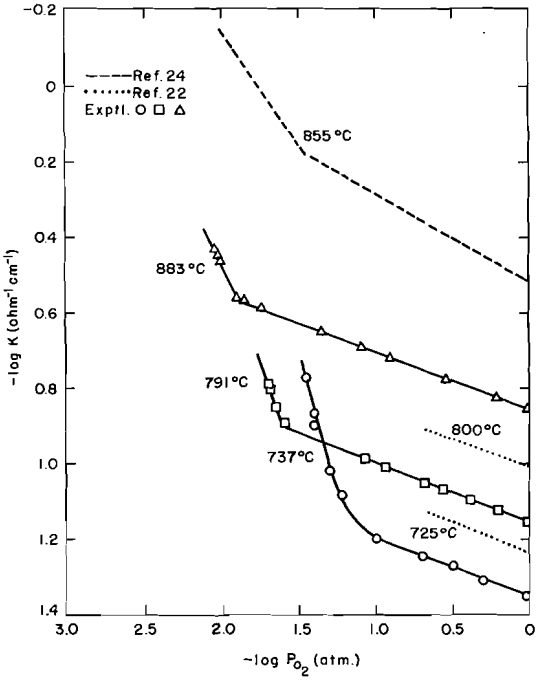

FIG. 2. Oxygen partial pressure dependence of the electrical conductivity of liquid V_2O_5.

for the A.R. grade vanadium pentoxide, where K is the specific conductance in ohm^{-1} cm^{-1} and T is the temperature in deg. Kelvin. The results for the A.R. grade of vanadium pentoxide compare favorably with those reported by Allersma *et al.* (22) for the same grade of material. Several hours were required for the electrical conductivity to reach a steady value between various temperature or oxygen partial pressure settings for the "specpure" vanadium pentoxide, but the A.R. grade vanadium pentoxide required only about an hour between settings.

The temperature dependence of the specific conductance can be represented by an equation of the type

$$[3] \qquad K = A \exp(-E/RT)$$

where E is the activation energy for conduction and A is a constant. The "specpure" V_2O_5 had an activation energy of conduction of 17.8 kcal/mol or 0.77 eV and the A.R. grade V_2O_5 had an activation energy of 16.7 kcal/mol or 0.73 eV under oxygen at 1 atm pressure.

The variation of the electrical conduction with oxygen partial pressure for "specpure" molten vanadium pentoxide is shown in Fig. 2. The oxygen partial pressure dependence of electrical conduction can be expressed by the equation:

$$[4] \qquad K = cP_{O_2}^{1/x}$$

where c is a constant and $1/x$ is the power of the oxygen partial pressure dependence. The present results indicate that the power of the oxygen partial pressure dependence is -0.16 at oxygen partial pressures greater than 0.1 atm in the temperature range 700 to 900 °C. A large increase in the power of the oxygen partial pressure dependence of electrical conduction was found below a specific oxygen partial pressure, depending on the temperature. When the data from Fig. 2 is replotted on the Arrhenius diagram of Fig. 3, the temperature dependence of the electrical conductivity of liquid vanadium pentoxide is found to change from positive to negative as the oxygen partial pressure decreases. The point at which the change in temperature dependence is found to occur takes

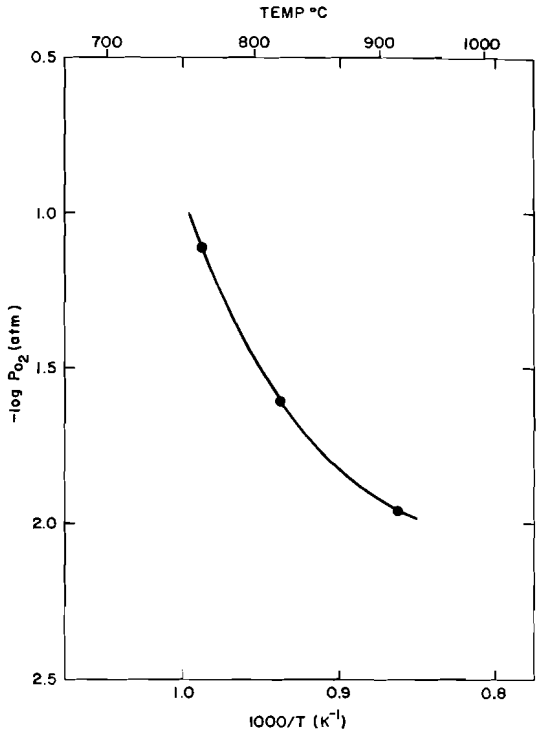

FIG. 4. Temperature–oxygen partial pressure dependence of the semiconduction–metallic conduction transition of liquid V_2O_5.

place at lower oxygen partial pressures as the temperature increases, as shown in Fig. 4.

Discussion

Liquid vanadium pentoxide exhibits several n-type semiconduction characteristics, such as a positive temperature coefficient and a negative oxygen partial pressure coefficient at oxygen partial pressures greater than 0.1 atm. The presence of impurities in vanadium pentoxide has a large effect on the magnitude of electrical conduction, as indicated by the different conductivities of the two grades used. The effect of impurities could account for some of the discrepancies in the reported electrical conduction properties of liquid vanadium pentoxide. As has been shown elsewhere (4), the addition of impurities to the melt has the effect of increasing the magnitude of electrical conduction and decreasing the oxygen partial pressure dependence.

The mechanism of n-type semiconduction in liquid vanadium pentoxide at higher oxygen partial pressures likely occurs via the hopping or the small-polaron model (29), in which electrons travel from V^{4+} ions to V^{5+} ions by a thermally activated diffusion mechanism. The dislocation model proposed by Perlstein (17) for electronic conduction in solid V_2O_5 would probably not apply as such to liquid V_2O_5.

The concentration of V^{4+} ions in the liquid state is dependent on the oxygen partial pressure above the melt, as shown below

$$[5] \qquad 2V^{5+} + O^{2-} \rightleftharpoons 2V^{4+} + \tfrac{1}{2}O_{2(g)}$$

Decreasing oxygen partial pressure will lead to an increased V^{4+} ion concentration, with a corresponding increase in electrical conduction. The existence of a relationship between an increase in V^{4+} ion concentration and an increase in electrical conduction was indicated by e.s.r. measurements on vanadium pentoxide samples quenched under various oxygen partial pressures.

Several authors (22, 24, 25) have analyzed the oxygen partial pressure dependence of electrical conduction of liquid vanadium pentoxide by means of an oxygen-deficient semiconducting oxide model. It was assumed that sufficient short-range order existed in the melt to allow transfer of charge between V^{5+} and V^{4+} ions. The power of the oxygen partial pressure dependence was predicted to be -0.167 if the conducting electrons, which were derived from fully ionized anion vacancies, associated with the cations to form V^{4+} ions. The value of -0.16 found for the power of the oxygen partial dependence in the present study would indicate that electrical conduction in liquid vanadium pentoxide at oxygen partial pressures greater than 0.1 atm occurred predominately by thermally activated polaron conduction between the vanadium cations, which is in agreement with two previous studies (22, 25).

At low oxygen partial pressures (<0.1 atm), liquid vanadium pentoxide shows a negative temperature dependence of electrical conduction (Fig. 4). Mott (30) has predicted that semiconductors should show a transition to metallic conduction if the distance between lattice points is reduced enough to allow overlapping of valence and conduction bands. Rogers *et al.* (31) and Goodenough (32) have proposed that localized-electron conduction will switch to collective-electron conduction when the cation separation becomes less than a critical separation defined as

$$[6] \quad R_c(\text{Å}) = 3.20 - 0.05m - 0.03(Z - Z_{T_1}) - 0.04S(S+1)$$

where m is the cation charge, Z is the cation atomic number, and S is the cationic spin. A study of several vanadium spinels indicated that the critical separation between vanadium ions was close to 2.972 Å.

Semiconduction to metallic conduction transitions have been observed for the lower solid oxides of vanadium. This was indicated by the conductivity increasing sharply by a factor of four to six times as the temperature was increased (33). The oxides VO, V_2O_3, and VO_2 undergo these temperature induced transitions near 120, 160, and 340 °K, respectively. The transitions were considered to be due, at least partially, to phase transitions involving a shortening of the distance between vanadium ions (32–34). The oxide V_2O_3 has also been found to switch to metallic conduction when put under pressure (30). The semiconductor to metallic conduction transition has not yet been observed with solid V_2O_5, however.

In the present case, it is possible that the vanadium ions in the liquid vanadium pentoxide were brought closer together than some critical separation distance when the oxygen ions were removed from the melt by the reduction in oxygen partial pressure. This could result in an overlapping of the diffuse valence and conduction bands, allowing collective-electron conduction in partially filled 3d bands to predominate over thermally activated polaron conduction between vanadium ions. No data is at present available on what effect the oxygen partial pressure has on the cation–cation separation distance in liquid vanadium pentoxide. An increase in temperature would be expected to increase the separation between the cations, so that the switching effect would be observed at lower oxygen partial pressures as the temperature was increased. This effect was observed experimentally (Fig. 3).

Conclusions

(*1*) Liquid vanadium pentoxide is an n-type semiconducting oxide in the temperature range 670 to 1000 °C and at oxygen partial pressures greater than 0.1 atm, as indicated by a positive temperature coefficient of conduction and a negative dependence of electrical conduction on oxygen partial pressure. Liquid vanadium pentoxide can have a negative temperature coefficient of conduction at oxygen partial pressures less than 0.1 atm.

(*2*) Electrical conduction in liquid vanadium pentoxide was considered to occur via the small polaron model, with electrons "hopping" from V^{4+} to V^{5+} centers, at oxygen partial pressures greater than 0.1 atm. At oxygen partial pressures less than 0.1 atm, conduction was thought to occur by collective-electron conduction in partially filled 3d bands, provided the diffuse valence and conduction bands overlapped due to the cation separation in the melt becoming less than some critical distance.

Received April 20, 1972

The liquid sodium vanadates exhibited n-type semiconduction properties at sodium oxide concentrations less than 10 mol% and ionic conduction properties at concentrations greater than 25 mol%. The transition from semiconduction to ionic conduction occurred gradually as the sodium oxide concentration increased. The activation energy of conduction decreased with increasing sodium oxide concentration and increasing temperature. Negative oxygen partial pressure coefficients of conduction were found for sodium oxide concentrations less than 25 mol%. The oxygen partial pressure coefficient decreased with increasing temperature and sodium oxide concentration. The electrical conduction mechanism was considered to change from delocalized electron or polaron movement between V^{4+} and V^{5+} centers for the semiconducting liquid sodium vanadates to the probable movement of sodium and oxygen ions as the charge-carrying species for the ionic liquid sodium vanadates.

Les vandanates de sodium liquides manifestent des propriétés de semiconduction de type n, à des concentrations d'oxyde de sodium plus faibles que 10 mol% et des propriétés de conduction ionique à des concentrations plus grandes que 25 mol%. La transition de la semiconduction à la conduction ionique se produit graduellement, au fur et à mesure que diminue la concentration d'oxyde de sodium. L'énergie d'activation de conduction diminue si on augmente la concentration d'oxyde de sodium et la température. Nous trouvons des coëfficients de conduction de pression partielle d'oxygène négatifs pour des concentrations d'oxyde de sodium plus faibles que 25 mol%. Le coëfficient de pression partielle d'oxygène diminue avec la température et la concentration d'oxyde de sodium croissantes. Nous considérons que le mécanisme de conduction électrique change d'un mouvement d'électron délocalisé ou polaron entre les centres V^{4+} et V^{5+} pour les vandanates de sodium liquides semiconducteurs à un mouvement probable des ions sodium et oxygène, comme les espèces porteuses de charges dans les vandanates de sodium liquides ioniques.

Introduction

The electrical conduction properties of the solid sodium vanadates, in particular the sodium–vanadium "bronzes", have been well characterized (1–5). The sodium–vanadium "bronzes" are oxygen-deficient solid sodium vanadates of several compositional ranges, of which the following are representative: $Na_xV_2O_5$, where $[0.1 < x < 0.67]$ and $Na_{(1+y)}V_3O_8$, where $[0.0 < y < 0.8]$ (6–8). These compounds generally exhibit n-type semiconduction properties, although p-type semiconduction properties have also been reported (4). Incorporation of sodium into the V_2O_5 lattice structure causes a reduction in valence of the vanadium atoms from V^{5+} to V^{4+}, due to donation of the alkali metal valence electron to a vanadium atom. The reduced valence states of the vanadium atoms are not localized, but can move from one site to another, giving rise to semiconduction via the hopping of electrons or small polarons from one vanadium atom to the next (2).

Only two limited studies have been reported on the measurement of the electrical conductivities of the liquid sodium vanadates (9). Increasing conductance and decreasing activation energies were reported for increasing sodium oxide concentrations. In the present study, the electrical conductivities of several liquid sodium vanadates and the viscosity of one liquid sodium vanadate were measured as part of a program to characterize more fully the physical properties of the liquid vanadates (10).

Experimental

The apparatus used to measure the electrical conductivity of the liquid vanadates has been described in detail elsewhere (10). The electrical conductivity was measured in a dipping electrode cell constructed from an 80/20 gold/palladium alloy. Electrical conductivity measurements were made

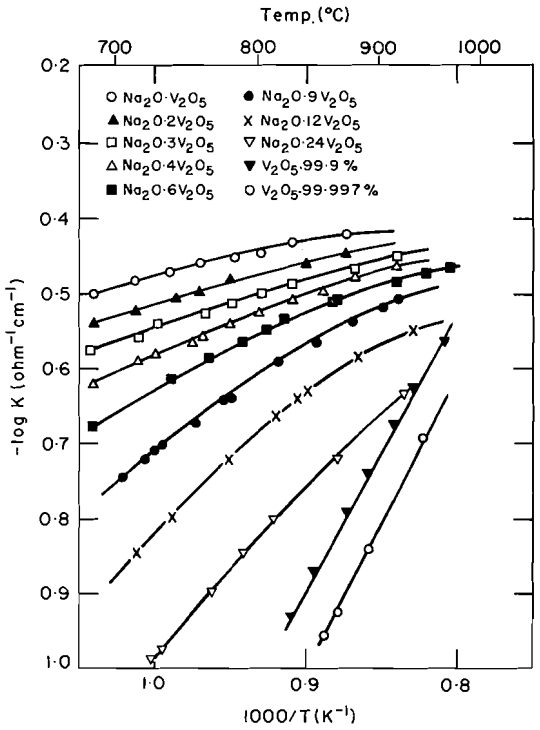

FIG. 1. Arrhenius plot of the electrical conductivities of the molten sodium vanadates.

using a General Radio 1608-A Impedance Bridge with an auxiliary audio oscillator and tuned amplifier and null detector. A.C. frequencies up to 10^4 Hz were used. Oxygen partial pressures over the melt were controlled by the use of regulated, high-purity oxygen–argon mixtures.

The sodium vanadates were prepared by thoroughly mixing the required amounts of sodium carbonate and vanadium pentoxide and then fusing the mixtures. On fusion, carbon dioxide was evolved for several minutes and then evolution ceased. No evidence was found for any carbonate remaining in the melt. Reagent grade sodium carbonate and Johnson and Matthey "specpure" vanadium pentoxide, containing 20 p.p.m. titanium and 5 p.p.m. silicon, were used.

Viscosity measurements were made by the rotating crucible method, in which the outer crucible is rotated and the torque is measured on an inner concentric crucible (18, 19). Platinum crucibles and cylinders were used in these measurements.

Results

The temperature dependence of the electrical conductivities of the liquid sodium vanadates, in the presence of oxygen at a pressure of 1 atm, is shown in the Arrhenius plot of Fig. 1. The data for vanadium pentoxide, which are also shown in the diagram, have been taken from previously published data (10). The data have been fitted to an equation of the form

[1] $$K = a + bT + cT^2$$

where K is the specific conductance in $\text{ohm}^{-1}\,\text{cm}^{-1}$, T is the temperature in Kelvin and a, b, and c are constants. The calculated coefficients for each composition, as determined by a least squares polynomial analysis of the data, are listed in Table 1. Isotherms of the electrical conductivities of the liquid sodium vanadates were determined from the data listed in Table 1. They are plotted as a function of sodium oxide concentration in Fig. 2. From this diagram, it can be seen that the conductivity increases with increasing temperature and sodium oxide concentration.

Activation energies of conduction were calculated from the data shown in the Arrhenius plots of Fig. 1 and are illustrated in Fig. 3. The activation energy decreases with increasing sodium concentration. The activation energies of conduction of the liquid sodium vanadates decrease with increasing temperature, although no effect of temperature was observed for the activation energy of conduction of liquid vanadium pentoxide (10).

The variation of the electrical conductivity with oxygen partial pressure for the molten sodium vanadates is shown in Fig. 4. The oxygen partial pressure dependence of electrical conduction can be expressed by the equation

[2] $$K = cP_{O_2}^{1/x}$$

where c is a constant and $1/x$ is the power of the oxygen partial pressure dependence. The power

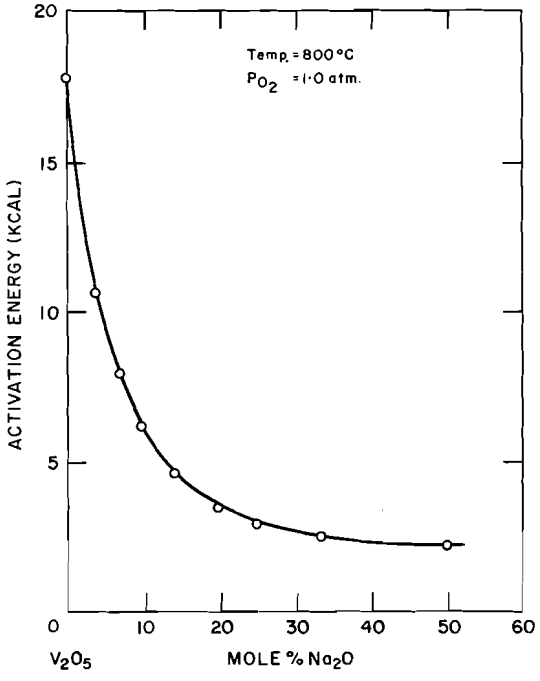

FIG. 3. Activation energies of conduction of the molten sodium vanadates.

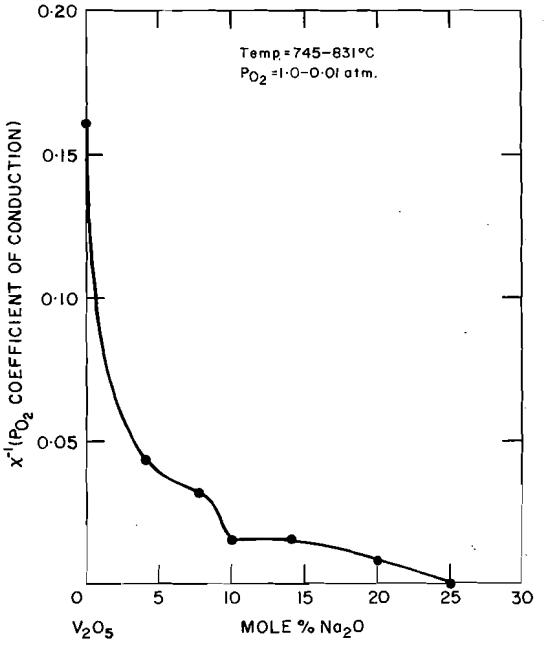

FIG. 5. Variation of the oxygen partial pressure dependence of conduction with Na_2O concentration for the molten sodium vanadates at 800 °C.

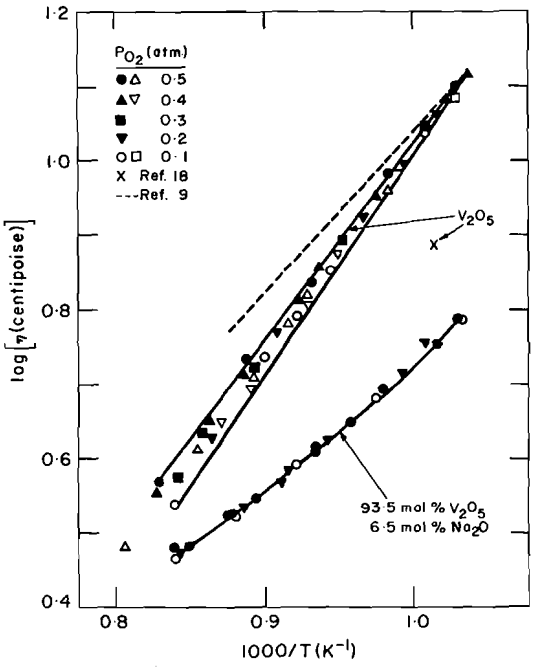

FIG. 6. Viscosity of liquid V_2O_5 and a liquid sodium vanadate.

of the oxygen partial pressure dependence decreases as the sodium oxide concentration increases, as shown in Fig. 5. No oxygen partial pressure dependence is observed at sodium oxide concentrations greater than 25 mol%, *i.e.*, for sodium oxide concentrations greater than the liquid sodium vanadate $Na_2O{\cdot}3V_2O_5$.

The viscosities of liquid vanadium pentoxide and a liquid mixture of 93.5 mol% vanadium pentoxide and 6.5 mol% sodium oxide were measured and are shown in Fig. 6. There is an appreciable decrease in viscosity with the addition of sodium oxide. Oxygen partial pressures did not greatly affect the viscosity. An increase in temperature had a larger effect in decreasing the viscosity of liquid vanadium pentoxide than in decreasing the viscosity of the liquid sodium vanadate.

Discussion

The liquid sodium vanadates of low sodium oxide concentration (< 20 mol%) were found to exhibit some n-type semiconduction properties, such as a negative oxygen partial pressure coefficient and a positive temperature coefficient of conduction. However, the n-type semiconduction properties differed significantly from those found for liquid vanadium pentoxide (10). No sharp increases in the oxygen partial pressure coefficients, at lower oxygen partial pressures, were observed for the sodium vanadates. The activation energies of these melts were found to decrease with increasing temperature and increasing sodium oxide concentration.

The mechanism of semiconduction probably involves the movement of delocalized electrons or polarons between V^{4+} and V^{5+} centers in these liquid sodium vanadates, similar to that proposed for the sodium vanadium "bronzes" (2) and liquid vanadium pentoxide (10). However, the presence of mobile sodium ions in the liquid should also give rise to some ionic conduction via sodium and oxygen ions.

When the sodium oxide concentration is increased above 25 mol%, ionic conduction becomes the predominant conduction mechanism. The evidence for ionic conduction predominating at higher sodium concentrations includes the lower activation energies of conduction (2 to 5 kcal/mol), the absence of an oxygen partial pressure effect on the conductance, and an increased tendency to show polarization effects at low frequencies during resistance measurements. The decrease in the activation energy of conduction with temperature which was detected for the sodium vanadates is commonly observed with many ionic liquids. This phenomenon is considered to be due to the expansion of the melt with a consequent decrease in the coulombic forces associated with the movement of ions through the melt (11).

The change in the conduction mechanism from semiconduction to ionic conduction as the sodium oxide content of the melt increases probably results from a breakdown of the short-range order about the complex vanadium ions in the melt. Solid vanadium pentoxide is considered to consist of layers of VO_4 tetrahedra (12). Since liquid V_2O_5 shows considerable viscosity (Fig. 6), it is likely that there is considerable short-range order in the liquid state, with oxygen ions closely associated about the vanadium ions and possibly some V—V homopolar bonding (13). Other amorphous vanadium-containing oxygen compounds, such as a number of glasses, also show semiconduction properties and considerable short-range order (14, 15). Long chains of VO_4 tetrahedra are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

believed to be present in these glasses. The solid sodium vanadates of the sodium–vanadium "bronze" composition range consist of sodium ions located between layers of VO_4 tetrahedra (10). In the liquid state, the oxygen ions from the added sodium oxide would tend to associate with the complex vanadate ions to form simpler vanadate ions such as the metavanadate ion $[VO_3]^-$. Much the same process has been shown to occur in the case of silicate melts, where the network structure breaks down and the polyanions reduce in size with the addition of sodium oxide until they are reduced to the simplest silicate anions (16). An indication of the breakdown of the complex vanadate ions is shown by the decrease in viscosity of liquid vanadium pentoxide as sodium oxide is added (Fig. 6).

The semiconduction process involving electron or polaron transfer between V^{4+} and V^{5+} centers requires some association between vanadium atoms to assure an overlapping of conduction bands; therefore, the breakup of the complex vanadate ions due to the addition of sodium oxide to liquid vanadium pentoxide is associated with a decrease in semiconduction and an increase in the ionic conduction. The ionic conduction mechanism probably involves the transport of sodium and oxygen ions, as in the case of sodium silicate melts (16), and possibly vanadate ions.

The oxygen partial pressure dependence of conduction decreased with increasing temperature (Fig. 4). This could result from the increased dissociation of the complex vanadate ions with temperature, resulting in a decrease in semiconduction and an increase in ionic conduction. The oxygen partial pressure dependence remained at a steady value (0.016 at 775 °C) in the concentration range 10 to 15 mol% sodium oxide (Fig. 5). This compositional range corresponds approximately to the solid sodium vanadium bronze, $Na_2O \cdot xV_2O_4 \cdot (6-x)V_2O_5$, which has been shown to exist as a stable compound (17). Therefore, it is possible that a stable, complex vanadate ion may exist in the liquid sodium vanadate over this compositional range.

Conclusions

(*1*) The liquid sodium vanadates of low sodium oxide concentration are n-type semiconduction compounds in the temperature range 670 to 1000 °C. As the sodium oxide concentration is increased, the electrical conduction mechanism becomes progressively more ionic; for solutions contaning more than 25 mol% sodium oxide, electrical conduction is primarily ionic. The activation energy of conduction decreases and the specific conductivity increases with increasing sodium oxide concentration. Negative oxygen partial pressure coefficients of conduction which decrease with increasing sodium oxide concentration and temperature are found for sodium oxide concentrations less than 25 mol%.

(*2*) The mechanism of electrical conduction of the semiconducting liquid sodium vanadates is considered to involve the movement of delocalized electrons or polarons between V^{4+} and V^{5+} centers in the liquid. When sodium oxide is added to the liquid, the additional oxygen ions associate with the complex vanadate ions to form simpler vanadate ions such as the metavanadates $[VO_3]^-$. The reduction in association between vanadium atoms is associated with a reduction in semiconduction, but the increased concentration of mobile sodium ions results in an increase in ionic conduction involving sodium and oxygen ions.

Received April 20, 1972

The liquid ferric vanadates exhibited n-type semiconduction properties at oxygen partial pressures greater than 0.1 atm. For ferric oxide concentrations less than 16 mol%, the activation energy of conduction was less than the activation energy associated with liquid vanadium pentoxide, but at greater ferric oxide concentrations, the activation energy increased to values greater than that associated with liquid vanadium pentoxide. The negative oxygen partial pressure coefficients of conduction were found to decrease with increasing ferric oxide concentration. The addition of sodium oxide to the liquid ferric vanadates decreased the activation energies of conduction. The electrical conductivities of these sodium ferric vanadates were found to be independent of oxygen partial pressure.

The electrical conduction mechanism of the ferric vanadates was considered to involve the movement of delocalized electrons or polarons between V^{4+} and V^{5+} centers at low ferric oxide concentrations and the additional movement of delocalized electrons between Fe^{2+} and Fe^{3+} centers for ferric oxide concentrations greater than 16 mol%. The addition of sodium oxide to the liquid ferric vanadates apparently changed the electrical conduction mechanism from semiconduction to ionic conduction. Sodium and oxygen ions are probably the charge-carrying species in these ionic melts.

Les vanadates ferriques liquides présentent des propriétés de semi-conduction du type n pour des pressions partielles en oxygène supérieures à 0.1 atm. Pour des concentrations en oxyde ferrique inférieures à 16 mol%, l'énergie d'activation de conduction est inférieure à l'énergie d'activation associée au pentoxyde de vanadium liquide; mais pour des concentrations plus élevées en oxyde ferrique, l'énergie d'activation croît jusqu'à des valeurs supérieures à celles associées au pentoxyde de vanadium liquide. Les coefficients négatifs de pression partielle d'oxygène dans la conduction ont été trouvés décroissants lorsque les concentrations en oxyde ferrique augmentaient. L'addition d'oxyde de sodium aux vanadates ferriques liquides fait décroître les énergies d'activation de conduction. Les conductivités électriques des vanadates ferriques de sodium sont alors indépendantes de la pression partielle en oxygène. Le mécanisme de conduction électrique dans les vanadates ferriques est considéré comme impliquant le mouvement des électrons délocalisés ou polarons entre les centres V^{4+} et V^{5+} pour de faibles concentrations en oxyde ferrique; et le mouvement supplémentaire des électrons délocalisés entre les centres Fe^{2+} et Fe^{3+} lorsque les concentrations en oxyde ferrique sont supérieures à 16 mol%. L'addition d'oxyde de sodium aux vanadates ferriques liquides change apparemment le mécanisme de la conduction électrique, on passe alors de la semi-conduction à la conduction ionique. Les ions sodium et oxygène sont les espèces chargées probables dans ces masses fondues ioniques.

Introduction

The electrical conduction properties of liquid vanadium pentoxide and the sodium vanadates have been reported previously (Parts I and II, see refs. 1 and 2). Liquid vanadium pentoxide was found to exhibit n-type semiconduction properties at oxygen partial pressures above 0.1 atm in the temperature range 670° to 1000 °C, but, at oxygen partial pressures less than 0.1 atm, a positive temperature coefficient of resistance was found. The liquid sodium vanadates exhibited n-type semiconduction properties at low sodium oxide concentrations. As the sodium oxide concentration was increased, ionic conduction became the principal electrical conduction mechanism. The electrical conduction properties of the ferric vanadates and the sodium ferric vanadates are reported in this paper.

Esin and Zyazev (3) and Pantony and Vasu (4) have measured the electrical conductivities of several liquid ferric vanadates. They were

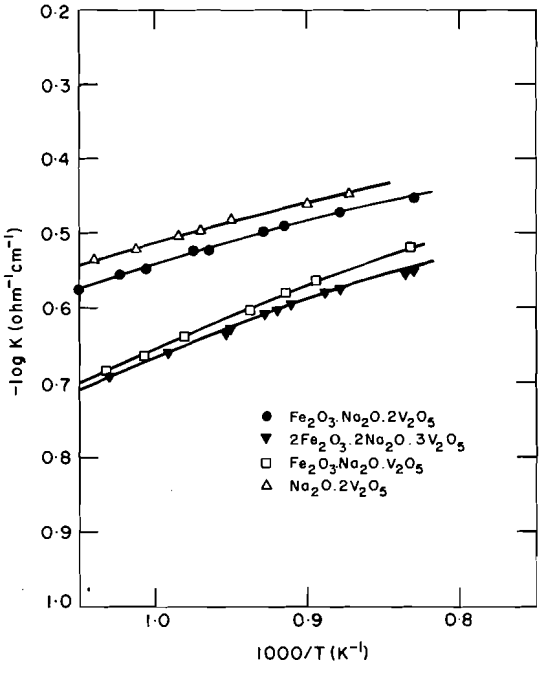

FIG. 2. Temperature dependence of the electrical conductivity of the molten ferric sodium vanadates.

reported to be semiconducting liquids. The specific conductance was found to increase as the ferric oxide concentration increased. The electrical conductivity of solid vanadium pentoxide has been found to increase with increasing ferric oxide concentration (5). The Fe^{3+} ions replaced the V^{5+} ions isomorphically in the lattice. This had the effect of introducing more oxygen vacancies into the lattice. The excess electrons collected at vanadium centers and increased the electrical conduction.

Experimental

The apparatus used to measure the electrical conduction of the liquid vanadates has been previously described in detail (1). The electrical conductivity cell was of the dipping electrode design and was constructed from a 80/20 gold/palladium alloy. A General Radio 1608-A Impedance Bridge with an auxiliary audio oscillator and a tuned amplifier and null detector was used for electrical conductivity measurements. A.C. frequencies up to 10^4 Hz were used. Oxygen partial pressures over the melt were controlled by the use of regulated, high-purity oxygen–argon mixtures.

The ferric vanadates and the sodium ferric vanadates were prepared by thoroughly mixing the required amounts of powdered ferric oxide, sodium carbonate, and vanadium pentoxide together and then fusing the mixture. Reagent grade ferric oxide and sodium carbonate and "specpure" vanadium pentoxide (Johnson and Matthey), containing 20 p.p.m. titanium and 5 p.p.m. silicon, were used.

Results

The temperature dependence of the electrical conductivities of the liquid ferric vanadates and the ferric sodium vanadates, in the presence of oxygen at a pressure of 1 atm, is shown in Figs. 1 and 2, respectively. The data for vanadium pentoxide, also shown in Fig. 1, are taken from previously published data (1).

The data have been fitted to an equation of the form

$$[1] \qquad K = a + bT + cT^2$$

where K is the specific conductance in ohm^{-1} cm^{-1}, T is the temperature in Kelvin, and a, b, and c are constants. The calculated coefficients for each composition, as determined by a least squares polynomial analysis of the data, are listed in Table 1. Isotherms for the liquid ferric vanadate conductivities, as illustrated in Fig. 3, were determined from the data listed in Table 1. The electrical conductivity increases with ferric oxide additions up to 16 mol%, but at greater concentrations, the conductivity decreases. The

pressure dependence of electrical conduction can be expressed by the equation

$$[2] \qquad K = cP_{O_2}^{1/x}$$

where c is a constant and $1/x$ is the power of the oxygen partial pressure dependence. For the liquid ferric vanadates, the power of the oxygen partial pressure dependence decreases as the ferric oxide concentration increases for oxygen partial pressures greater than 0.1 atm (Table 2). At oxygen partial pressures less than 0.1 atm, a large increase in the oxygen partial pressure dependence of conduction is observed. A similar observation was previously reported for liquid vanadium pentoxide (1). No oxygen partial pressure dependence of electrical conduction is observed for the ferric sodium vanadates (Table 2).

Discussion

The addition of ferric oxide to liquid vanadium pentoxide did not cause any large change in the semiconduction behavior of these melts, although the oxygen dependence of conduction at oxygen partial pressures greater than 0.1 atm decreased with increasing concentrations of ferric oxide. At ferric oxide concentrations less than 16 mol%, the semiconduction mechanism probably involves the movement of delocalized electrons or polarons between V^{4+} and V^{5+} centers, similar to that reported for liquid vanadium pentoxide (1). The increase in electrical conduction and decrease in the activation energy of conduction with increasing ferric oxide concentration could be explained by assuming that the ferric ions replace the vanadium ions in the structured melt, in much the same manner as when ferric ion impurities are introduced into solid vanadium pentoxide (5). The ferric ions would have the effect of decreasing the oxygen stoichiometry present in the melt and allowing the excess electrons, resulting from the loss of oxygen, to collect at vanadium centers. The resultant increase in V^{4+} concentration would then lead to increased electrical conduction, in the same manner as a decrease in oxygen partial pressure results in an increase in V^{4+} concentration and hence an increase in the electrical conductivity.

The decrease in electrical conduction and increase in the activation energy of conduction at ferric oxide concentrations greater than 16 mol% could be due to dissociation of the complex vanadate ions which allowed semiconduction to occur in liquid vanadium pentoxide (1). Phase diagram studies (6) have indicated that the iron vanadate $FeVO_4$ will precipitate from solution at concentrations greater than 20 mol%. Thus, there is a marked tendency for the vanadate ion $[VO_4]^{3-}$ to exist in the solution in these concentration ranges. As electronic conduction via polaron hopping between V^{4+} and V^{5+} centers in the melt becomes less important with increasing ferric oxide concentration, electronic conduction via polaron hopping between Fe^{2+} and Fe^{3+} centers would tend to become more important. If ferric oxide concentrations are greatly increased, ionic conduction via ferric and oxide ions could predominate, although this was not shown in the results presented here.

At oxygen partial pressures less than 0.1 atm, the conductivity of the liquid ferric vanadates showed a sharp increase with respect to the oxygen partial pressure dependence. A similar effect was found for liquid vanadium pentoxide and was considered to be due to a transition from semiconduction to metallic behavior (1). A similar transition may be occurring in the case of the liquid ferric vanadates, although insufficient data is available from the present study to verify this.

The addition of sodium oxide to the liquid ferric vanadates tended to make the melts more ionic, as indicated by the absence of a dependence of the electrical conduction properties on oxygen partial pressure and by the low activation energy of conduction. As was postulated in the case of the sodium vanadates (2), the addition of sodium oxide tends to break down the complex vanadate ions which are likely present in those melts containing predominately vanadium pentoxide. Simpler vanadate ions such as the metavanadate ion $[VO_3]^-$ will then be present in the melts. The decrease in association between vanadium atoms, and between iron and vanadium atoms, results in a decrease in semiconduction, allowing ionic conduction via sodium and oxygen ions, and possibly vanadate ions, to predominate.

Conclusions

(*1*) The liquid ferric vanadates exhibit n-type semiconduction properties, such as a negative

oxygen partial pressure coefficient and a positive temperature coefficient of conduction, at oxygen partial pressures greater than 0.1 atm. At ferric oxide concentrations less than 16 mol%, the activation energy of the liquid ferric vanadates was less than that observed for liquid vanadium pentoxide. The oxygen partial pressure coefficient decreases and the conductivity increases with increasing ferric oxide concentration. For ferric oxide concentrations greater than 16 mol%, the activation energy increases to above the value observed for liquid vanadium pentoxide.

(*2*) The addition of sodium oxide to the liquid ferric vanadates results in ionic conduction predominating in the melts. The activation energies of conduction are all less than 4.0 kcal/mol. The oxygen partial pressure has no effect on the conduction.

(*3*) The mechanism of electrical conduction of the liquid ferric vanadates is considered to primarily involve the movement of delocalized electrons or polarons between V^{4+} and V^{5+} centers in the liquid at low ferric oxide concentrations. Electron movement involving Fe^{2+} and Fe^{3+} centers is probably also important for ferric oxide concentrations greater than 16 mol%. When sodium ions are present at concentrations greater than 10 mol% in the liquid, electrical conduction is considered to primarily involve the movement of sodium and oxygen ions in the liquid.

Etude de la réaction gaz–solide organique entre l'isobutène et le paraphénylphénol

R. LAMARTINE ET R. PERRIN

Groupe de Recherches sur les Phénols, Université Claude Bernard-Lyon I, Unité de Chimie et de Biochimie, 43, Bd du 11 Novembre 1918, 69, Villeurbanne, France

Reçu le 7 mars 1972

Dans le cadre de l'étude des réactions gaz–solide organique, nous avons considéré la réaction de l'isobutène gazeux avec le paraphénylphénol solide dopé à l'acide sulfurique. Parallèlement à la réaction de polymérisation de l'isobutène conduisant aux hydrocarbures en C_8 et C_{12}, le ditertiobutyl-2,6 phényl- 4 phénol est produit avec un très bon rendement par rapport au phénol de départ. La réaction d'alcoylation correspondante a pour ordre apparent 1 par rapport au paraphénylphénol; l'énergie d'activation est égale à 21 kcal/mol.

La réaction s'effectue à partir de centres actifs et se transmet à la presque totalité de la substance solide, le proton étant probablement l'entité migrante.

Within the scope of the study of organic gas–solid reactions, we considered the reaction of gaseous isobutene with solid paraphenylphenol doped with sulfuric acid. Parallel to the polymerization of isobutene leading to C_8 and C_{12} hydrocarbons, there is a very good yield of 2,6-di-*t*-butyl-4-phenylphenol production as compared to initial phenol. The corresponding alkylation reaction is apparently of the order 1 as compared to paraphenylphenol; the activation energy of the reaction is equal to 21 kcal/mol.

The reaction spreads out from active centers and is transmitted to almost the entirety of the solid substance; the proton is probably the migrating entity.

Canadian Journal of Chemistry, **50**, 2882 (1972)

Le comportement des réactifs organiques est principalement étudié lorsque ceux-ci sont à l'état liquide, à l'état gazeux ou en solution. Peu de travaux concernent l'étude de la réactivité de l'état solide organique et ce n'est que récemment que certains auteurs (1–4) s'y sont intéressés. La première question qui se pose est de savoir si l'on a affaire à une véritable réaction de l'état solide organique. Morawetz (2) a indiqué des critères qui apparaissent comme indiscutables; il s'agit essentiellement de montrer que l'on a des produits de réaction différents ou des vitesses de transformation différentes suivant la modification cristalline considérée ou suivant l'état dans lequel se trouve la substance étudiée. Il n'est pas toujours facile de mettre en évidence de tels phénomènes; aussi peut-on d'une manière plus générale considérer que des réactions concernent l'état solide organique lorsque l'un au moins des réactifs est solide à la température de la réaction.

Exception faite pour les réactions de décomposition thermiques unimoléculaires, les réactions propres à l'état solide font intervenir comme facteur important le phénomène de diffusion des entités réactives. En chimie minérale, ces entités réactives sont généralement des atomes métalliques ou de petits ions qui se déplacent dans les positions interstitielles ou dans les lacunes du réseau. En chimie organique, on peut considérer de la même façon que les réactions de l'état solide nécessitent pour avoir lieu l'existence d'entités réactives de petite taille. La diffusion de ces entités permet l'avancement de la réaction. Enfin, il est important d'avoir présent à l'esprit le rôle que peuvent jouer dans les réactions de l'état solide organique, l'état de division de la substance et les défauts que présentent ses cristaux.

L'étude de la réaction entre l'isobutène et le paraphénylphénol contenant des traces d'acide sulfurique a été entreprise pour plusieurs raisons. Tout d'abord, le phénol retenu présente un point de fusion relativement élevé pour une substance organique (165 °C) (5) et peut, de ce fait, constituer facilement un réactif solide à différentes températures; de plus, son insolubilité dans les solvants d'alcoylation habituels justifie l'étude de la réaction à l'état solide; enfin, le produit de réaction, le ditertiobutyl-2,6 phényl-4 phénol pourrait constituer un excellent antioxydant. Parallèlement à cette réaction, l'isobutène se condense sur lui-même et conduit à des hydrocarbures en C_8 et C_{12}. L'étude

For personal use only.

suivante consiste à déterminer les conditions précises de la réaction, son aspect quantitatif et sa cinétique.

Partie expérimentale

Nous avons utilisé du paraphénylphénol pur (Eastman Kodak), de l'isobutène très pur et de l'acide sulfurique R.P. (Prolabo) de densité 1.83.

L'introduction d'acide sulfurique dans le paraphénylphénol a été réalisée de la manière suivante: au paraphénylphénol fondu, on ajoute 1.1% en poids d'acide sulfurique, on agite puis on laisse recristalliser. Le phénol ainsi dopé est réduit en grains qui sont calibrés par tamisage.

Pour l'étude cinétique, nous avons employé des grains de tailles comprises entre 200 et 315 μ. La réaction a lieu à pression constante. Le degré d'avancement de la réaction est déterminé par mesure du volume d'isobutène absorbé.

L'appareil permettant de mesurer l'isobutène consommé comporte essentiellement: (*a*) une burette à gaz de 100 cm^3 reliée par l'intermédiaire d'un tube flexible à un réservoir à mercure permettant ainsi de compenser la diminution de pression résultant de la consommation d'isobutène; (*b*) un système de pompage constitué par une pompe à palettes conduisant à une pression limite inférieure à la tension de vapeur du phénol aux températures étudiées; (*c*) une chambre à réaction thermorégularisée permettant d'opérer en couche mince et d'éliminer à chaque instant les énergies qui pourraient être mises en jeu.

Les analyses chromatographiques ont été réalisées à l'aide d'un appareil Intersmat modèle I.G.C. 12M équipé d'un catharomètre. La colonne est remplie de chromosorb W 60/80 imprégné de silicone SE 30. L'aire des pics a été déterminée grâce à un intégrateur numérique LTT M 924 couplé avec le chromatographe. Tous les échantillons analysés ont été traités au préalable par l'eau carbonatée car en présence d'acide et dans les conditions d'analyse choisies, le ditertiobutyl-2,6 phényl-4 phénol perd des groupes tertiobutyle.

Les spectres de r.m.n. ont été effectués avec un appareil Varian A 60.

Les spectres de masse ont été enregistrés dans les laboratoires Firmenich à Genève sur un appareil M.A.T. CH_4.

Les solubilités des phénols étudiés ont été déterminées dans le mélange d'hydrocarbures en C_8 et C_{12}. Les tertiobutyl-2 et ditertiobutyl-2,6 phényl-4 phénols sont solubles. Le paraphénylphénol est pratiquement insoluble. Ses solubilités limites ont été déterminées par évaporation du mélange d'hydrocarbures et dosage par spectrophotométrie u.v. du mélange restant repris dans l'alcool. Ces solubilités sont à 60 °C: 5/1000 et à 50 °C: 3.5/1000.

Caractérisation du ditertiobutyl-2,6 phényl-4 phénol: p. de f.: 104–106 °C; spectre de masse: pic moléculaire $M = 282$; spectre r.m.n. δ ($(CD_3)_2C{=}O$): 1.45 (s, $(CH_3)_3C$), 6(s, O*H*), 7.2–7.6 (m, *H* aromatiques).

Anal. calc. pour $C_{20}H_{26}O$: C, 85.10; H, 9.21; O, 5.67. Trouvée: C, 85.20; H, 9.18; O, 5.78.

Les hydrocarbures en C_8 et C_{12}, dimère et trimère de l'isobutène ont été mis en évidence par chromatographie et caractérisés par cryométrie dans le benzène.

Le tertiobutyl-2 phényl-4 phénol a été obtenu en appliquant le mode opératoire décrit dans le brevet de Preston (10).

Caractérisation du tertiobutyl-2 phényl-4 phénol: p. de f.: 42 °C; spectre r.m.n. δ ($(CD_3)_2C{=}O$): 1.45 (s, $(CH_3)_3C$), 8.45 (s, O*H*), 6.9–7.6 (m, *H* aromatiques).

Anal. calc. pour $C_{16}H_{18}O$: C, 84.97; H, 7.96; O, 7.07. Trouvée: C, 85.22; H, 8.01; O, 7.02.

Résultats et discussion

(1) Bilan réactionnel

La détermination volumétrique des quantités d'isobutène entré en réaction au cours du temps et l'analyse chromatographique des mélanges réactionnels obtenus pour différents degrés d'avancement de la réaction mettent en évidence qu'une certaine quantité d'isobutène consommée ne sert pas à former des tertiobutylphénols. Pour différentes températures et différents degrés d'avancement de la réaction, pour le paraphénylphénol et le tertiobutyl-2 phényl-4 phénol, le rapport d'isobutène absorbé à la quantité d'isobutène fixé sur le phénol est voisin de 2. Dans ces conditions, la transformation chimique étudiée peut être traduite par les réactions concurrentes, [1] et [2].

[1] 
[2] $$\begin{cases} 2(CH_3)_2C{=}CH_2 \xrightarrow{H_2SO_4} \text{Diisobutène} \\ (CH_3)_2C{=}CH_2 + \text{Diisobutène} \xrightarrow{H_2SO_4} \text{Triisobutène} \end{cases}$$

Les réactions de formation du dimère et du trimère de l'isobutène s'effectuent bien dans les conditions expérimentales adoptées comme le montrent différents auteurs (6–8). Il est à noter que les réactions [2] n'ont jamais été prises en considération à notre connaissance, lors de l'étude de la tertiobutylation des phénols.

(2) Etude de la réaction

La réaction entre l'isobutène et les phénols a été réalisée en solution dans le benzène par Stillson *et al.* (9). Malheureusement, dans le cas du paraphénylphénol, ces auteurs ne précisent ni la proportion de benzène, ni la température de la réaction, ni le rendement en produits formés. Aussi, avons-nous effectué la même expérience dans les conditions suivantes (5 g de paraphénylphénol à 1.1% d'acide sulfurique à 94% dissous dans 200 ml de benzène, 50 °C, temps de réaction 5 h). Dans ces conditions, le taux de transformation est très faible, de l'ordre de quelques pour cent. A l'état solide, un échantillon de la même préparation conduit à un taux de transformation beaucoup plus élevé (70%). D'autre part, la même réaction effectuée dans le diméthyl-3,5 phénol conduit aux tertiobutyl-2, ditertiobutyl-2,4′, et tritertiobutyl-2,6, 4′ phényl-4 phénols suivant les conditions adoptées (10).

Ainsi, il apparaît que la différence de réactivité observée en solution d'une part et à l'état solide d'autre part, laisse supposer que l'on a affaire à une réaction de l'état solide organique conformément au critère retenu par Morawetz. De plus, l'écart important entre la température de fusion de la substance étudiée et la température de la réaction fait que celle-ci doit bien concerner l'état solide organique, tout au moins dans sa première étape. Naturellement, la présence de traces d'acide sulfurique peut toujours amener à penser qu'à l'échelle microscopique, l'isobutène réagit avec un liquide.

L'examen photographique d'une préparation permet de préciser le phénomène. Celle-ci correspond à un échantillon de paraphénylphénol à 1.1% d'acide sulfurique placé à 55 °C, au bout d'une demi-heure de réaction avec l'isobutène. On observe à l'échelle macroscopique que la réaction s'effectue en des points déterminés, se propage à partir de ces centres actifs et conduit à des monocristaux du produit de transformation que l'on distingue très nettement. Il n'est cependant pas possible de conclure à une transformation solide–solide. En effet, la formation simultanée de di et triisobutène conduit à une phase liquide dans laquelle peuvent se dissoudre les tertiobutylphénylphénols. On notera cependant que le paraphénylphénol est pratiquement insoluble dans le mélange de di et triisobutène et de ce fait, doit bien réagir à l'état solide. Là encore, il est possible de dire que ce corps ne réagit pas à l'état solide parce qu'il serait soluble dans un mélange de di et triisobutène et de ditertiobutyl-2,6 paraphénylphénol formé au cours de la réaction. Il apparaît ainsi difficile de montrer d'une façon absolue que l'on a affaire à une réaction de l'état solide organique. Aussi considérons-nous la réaction étudiée comme une réaction gaz–solide organique au sens large, c'est-à-dire lorsque l'un des réactifs est solide, à l'échelle macroscopique, à la température de la réaction.

(3) Etude de l'influence de différents facteurs

Influence de la taille des grains

Il a été observé que lorsque le diamètre des grains de phényl-4 phénol augmente de 63–315 μ par exemple, la quantité d'isobutène absorbée augmente. Toutefois, lorsque le diamètre des grains augmente considérablement, cette vitesse diminue. De plus, on constate que lorsque les grains deviennent très fins, ils s'agglomèrent entre eux; ils ne sont plus individualisés. On peut penser que la diminution de la quantité d'isobutène absorbé lorsque les grains deviennent très gros, semble pouvoir s'expliquer par la diminution de la surface réactive et des possibilités de diffusion. Lorsque les grains deviennent petits et s'agglomèrent, les possibilités de diffusion doivent être réduites.

Influence du dégazage

A une poudre non soumise à un dégazage préalable, correspond une vitesse d'absorption d'isobutène très faible. De plus, la vitesse d'absorption trouvée varie d'une expérience à l'autre. Le chauffage préalable de l'échantillon accélère la réaction d'autant plus que le temps de chauffage est long et la température élevée. Cependant, la technique la meilleure pour obtenir des résultats reproductibles, consiste à placer la substance sous vide à la température ambiante pendant au moins une heure. Des temps de dégazage supérieurs ne modifient pas les résultats obtenus.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

L'influence du dégazage sur la vitesse d'évolution de la réaction étudiée nous apparaît comme un argument supplémentaire en faveur d'une véritable réaction à l'état solide. Il est rare en effet que le dégazage d'un liquide modifie sensiblement la vitesse de réaction.

Influence de la concentration en acide sulfurique et de la pression d'isobutène

De faibles concentrations en acide sulfurique, de l'ordre de 0.4% conduisent à de très faibles vitesses de transformation. Lorsque les concentrations sont beaucoup plus élevées, 5% par exemple, la réaction étudiée n'est pas sélective; au moins cinq substances sont produites et l'on peut penser que les deux noyaux aromatiques sont alcoylés. La concentration de 1.1% a été retenue parce qu'elle correspond à une réaction sélective et de vitesse aisément mesurable dans le domaine de températures choisi.

En ce qui concerne l'influence de la pression d'isobutène, on observe que la marche globale de la réaction n'est pas modifiée pour des pressions comprises entre 400 et 760 Torr. On note seulement une augmentation de la vitesse de réaction lorsque la pression s'élève.

(4) Etude cinétique de la réaction d'alcoylation du paraphénylphénol

Soit x le volume d'isobutène fixé sur le noyau phénolique au temps t et a le volume correspondant à la réaction totale. La vitesse s'écrit $dx/dt = k\,(a-x)$; ce qui donne après intégration $\log\,(a/(a-x)) = kt$, expression générale pour des réactions du premier ordre. En portant $\log\,(a/(a-x))$ en fonction du temps et à différentes températures, nous avons obtenu le faisceau de droites de la fig. 1 qui sont les transformées logarithmiques des courbes donnant la marche globale de la réaction en fonction du temps. Les constantes de vitesse trouvées à différentes températures sont les suivantes:

T (°C)	$k \times 10^{-4}$ (s^{-1})
60	0.388
55	0.253
50	0.144
45	0.088
40	0.047

Elles vérifient d'une façon remarquable (fig. 2) la relation d'Arrhénius

$$k = k_0\, e^{-E/RT}$$

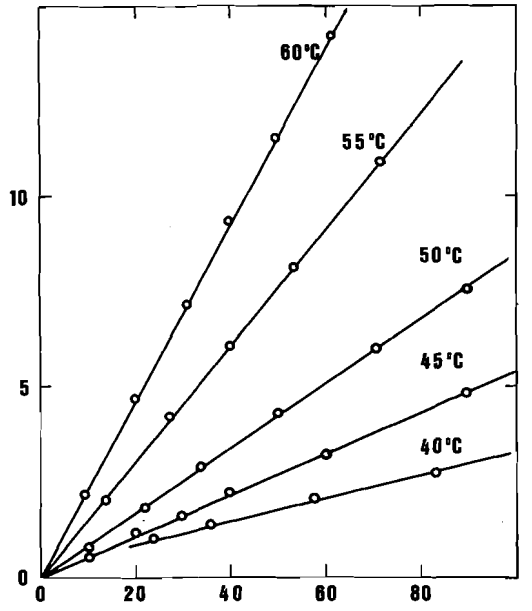

FIG. 1. Variation de la fonction $\log\,(a/(a-x)) \times 10^2$ en fonction du temps (min) pour la réaction de tertiobutylation du paraphénylphénol à différentes températures.

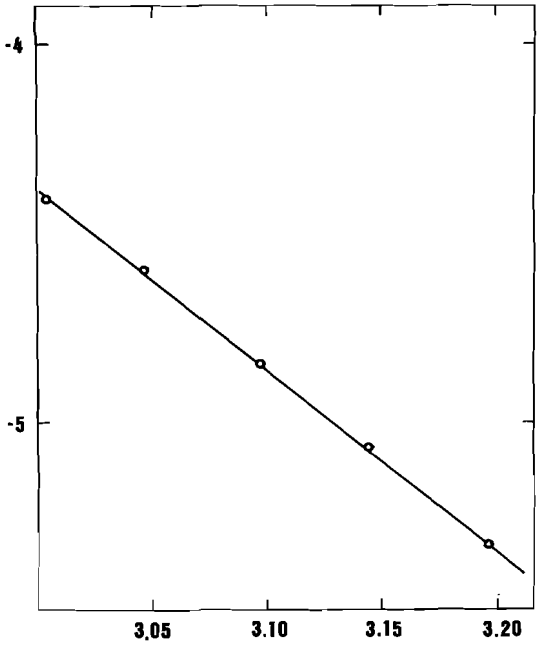

FIG. 2. Variation de la fonction $\log k$ en fonction de $10^3/T$ (°K).

on trouve ainsi pour énergie d'activation de la réaction étudiée 21 ± 1 kcal/mol^{-1}.

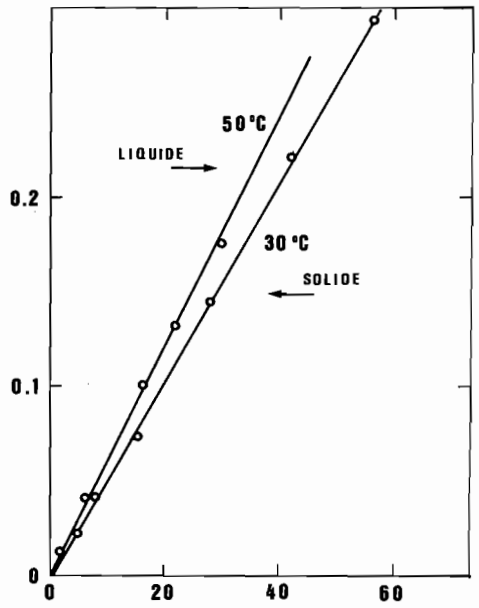

FIG. 3. Variation de la fonction log $(a/(a-x))$ en fonction du temps (min) pour la réaction de tertiobutylation du tertiobutyl-2 phényl-4 phénol.

(5) Etude cinétique de la réaction d'alcoylation du tertiobutyl-2 phényl-4 phénol

La fig. 3 met en évidence que la réaction de tertiobutylation du tertiobutyl-2 phényl-4 phénol contenant 1.1% d'acide sulfurique est une réaction d'ordre 1, que le phénol soit à l'état solide ou à l'état liquide. La différence de vitesse aux deux températures choisies est de faible importance (50 °C: $k = 1 \times 10^{-4}\ s^{-1}$; 30 °C: $k = 0.84 \times 10^{-4}\ s^{-1}$). On note par contre la très grande différence de vitesse de cette réaction, à la température de 50 °C, avec celle correspondant à la tertiobutylation du paraphénylphénol ($k = 0.144 \times 10^{-4}\ s^{-1}$).

(6) Conclusions

De l'ensemble des résultats ainsi obtenus, il apparaît que l'une des réactions étudiées, la réaction d'alcoylation du paraphénylphénol, pourrait être une réaction de l'état solide organique tout au moins dans sa première étape. Il est surprenant de constater que pour des degrés variés d'avancement de la réaction, le produit principal formé est le dérivé dialcoylé. L'étude cinétique explique aisément ce résultat puisqu'elle montre que la vitesse d'alcoylation du phénol monoalcoylé est environ sept fois la vitesse d'alcoylation du phénol de départ. Une molécule de monoalcoylphénol est transformée en dialcoylphénol dès qu'elle est formée; l'étape limitante correspond ainsi à la monoalcoylation.

D'autre part, les réactions de polymérisation de l'isobutène et d'alcoylation du phénol choisi s'effectuant dans les mêmes conditions, on peut penser que les entités réactives sont les mêmes dans les deux cas. Etant donné que les mécanismes proposés pour la réaction de polymérisation font intervenir comme entité migrante le proton (11, 12, 8), il est fort probable que celui-ci est l'entité migrante de petites dimensions, permettant à la réaction d'alcoylation de se propager.

Application of Cusp-Satisfying Orbitals to Some Two-Electron Systems

J. E. BROWN[1] AND D. P. CHONG

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received April 5, 1972

The kind of cusp-satisfying orbitals used earlier for the lithium atom is tested on the helium isoelectronic series and the hydrogen molecule. Excellent values are obtained for the electron density at the nucleus, $Q^e(0)$, for the atoms. The results for various wavefunctions for the hydrogen molecule are not as systematic, but are still quite reasonable.

Nous appliquons le type d'orbitales (cusp-satisfying), utilisées précédemment pour l'atome de lithium, aux séries isoélectroniques de l'hélium et à la molécule d'hydrogène. Nous obtenons ainsi d'excellentes valeurs pour la densité électronique au noyau $Q^e(0)$ des atomes. Les résultats concernant les différentes fonctions d'onde de la molécule d'hydrogène ne sont pas aussi systématiques, mais sont toutefois raisonnables.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2887 (1972)

Introduction

In a recent paper, Chapman and Chong (1) defined a cusp remainder operator for the coalescence of the ith electron with nucleus A as

$$[1] \quad R_A(i) = \lim_{r_{iA}\to 0} (Z_A + \partial/\partial r_{iA})(4\pi)^{-1} \int d\Omega_{iA}$$

Among the hierarchy of cusp conditions, they decided to impose the cusp constraint

$$[2] \quad R_A\varphi_j = 0$$

on the one-electron basis orbitals $\{\varphi\}$. If each φ_j is expanded as a linear combination of Slater-type orbitals (S.t.o.)

$$[3] \quad \varphi_j = \sum_k a_{jk}\chi_k$$

then, eqs. 2 and 3 can be expressed alternatively as

$$[4] \quad \varphi_j = \sum_{k\neq l} a_{jk}\xi_k$$

$$[5] \quad \xi_k = \chi_k - (R_A\chi_k)(R\chi_l)^{-1}\,\chi_l$$

where χ_l is any S.t.o. for which $R_A\chi_l$ is not zero.

In the calculation of the electron and spin densities at the nucleus of the ground-state lithium atom, Chapman and Chong (1) found that very simple wavefunctions[2] constructed from cusp-satisfying orbitals give excellent results. On the other hand, Poling and co-workers (2) did not find cusp satisfaction as useful.

The purpose of this work is to test the effect of similar cusp-satisfying orbitals on the calculated electron densities at the nucleus, $Q^e(0)$, for some two electron systems.

He Isoelectronic Series

In this study, we follow the procedure of Chapman and Chong (1): (*a*) simple wavefunctions Φ are chosen from the literature; (*b*) each 1s S.t.o. is augmented[3] with a "spike" function δ (*i.e.*, a 1s orbital with an unusually large exponent)

$$[6] \quad \xi_{1s} = 1s - (R_A 1s)(R_A\delta)^{-1}\,\delta$$

(*c*) the expansion in eq. 4 is limited to a single term, so that $\varphi_j = \xi_j$; (*d*) cusp-satisfying wavefunctions Ψ are constructed by replacing each 1s orbital in the original wavefunction Φ with φ_{1s}; (*e*) the orbital exponent of each spike function ζ_δ is optimized; (*f*) the resulting wavefunctions are then scaled with a uniform scale

[1]Present address: Department of Chemistry, College of the Holy Cross, Worcester, Mass., 01610 U.S.A.

[2]The expansion in eq. 4 is limited to a single term.

[3]For comparison, Bishop (3) augmented one-center orbitals with a special cusp-satisfying function ψ: χ = (one-center orbital) + $a\psi$, where a is determined variationally and $R_A\chi \neq 0$.

*See text.

factor η to minimize the energy; (g) finally, we calculate the electron densities at the nucleus, $Q^e(0)$.

For the helium isoelectronic series, with $Z_A = 1$ through 6, the simple wavefunctions chosen are

$$\Phi_1 = 1s^2 \quad [7]$$

$$\Phi_2 = 1s1s' + 1s'1s \quad [8]$$

$$\Phi_3 = 1s1s' + 1s'1s + c2p^2 \quad [9]$$

taken from Silverman *et al.* (4). All computations were performed in double precision on an IBM 360/67 computer. The cusp-satisfying wavefunctions Ψ_1, Ψ_2, and Ψ_3 are presented in Table 1. The ratio of δ and 1s orbital exponents is given by k; that of δ' and 1s' exponents, by k'. When a 1s' orbital is present, we choose $\zeta_{1s} > \zeta_{1s'}$. It is interesting to note that the "spike" function for Ψ_1 is not as sharply peaked as those in Ψ_2 and Ψ_3. On the other hand, the energy improvements are about 0.01 atomic units in going from Φ_1 to Ψ_1, but are less than 0.001 for the other two functions. We are inclined to conclude that δ in Ψ_1 acts partly as an additional basis orbital while it is making Ψ_1 satisfy the cusp condition.

Finally, the calculated $Q^e(0)$ are summarized in Table 2. For the purpose of comparison, we have made use of the accurate values obtained by Pekeris (6–9) and listed the percentage errors[4] only. It is gratifying to see that our procedure of satisfying the cusp condition has led to improvements in the calculated $Q^e(0)$ in

[4]% error in $Q^e(0) = 100 \times$ (calculated − Pekeris)/(Pekeris).

VIII	1.40	10.433	2.956	1.013329	−1.1606712	−1.1597294

*The energies for Φ_i are also listed for comparison. The exact energy at $R = 1.4011$ a.u. is −1.1744746 a.u. (ref. 14).

all eighteen cases considered. The improvements of Ψ_1 over Φ_1 are the least drastic and may be associated with the low values of ζ_δ already discussed. On the other hand, the % errors in $Q^e(0)$ for the other two wavefunctions are reduced by an order of magnitude! For comparison, the % error in $Q^e(0)$ calculated from Clementi's 5-term self-consistent field wavefunction for helium (10) is −0.69% (11).

Hydrogen Molecule

A slight modification was made in our procedure for H_2. Instead of eq. 6, we write

$$[10] \qquad \varphi_A = 1s_A + \lambda\delta_A + \mu\delta_B$$

$$[11] \qquad \varphi_B = 1s_B + \lambda\delta_B + \mu\delta_A$$

where λ and μ are determined from

$$[12] \qquad R_A\varphi_A = 0 = R_B\varphi_A$$

Among the numerous wavefunctions for the hydrogen molecule available in the literature, we have chosen two sets. The first set, Φ_4, Φ_5, and Φ_6, includes the usual minimal-basis Coulson molecular-orbital (m.o.), Wang valence-bond (v.b.), and Weinbaum configuration-interaction (c.i.) wavefunctions, respectively. However, we use the parameters obtained by Benston and Kirtman (12). The second set, Φ_{II}, Φ_{IV}, Φ_{VII}, and Φ_{VIII}, were taken from the c.i. study of McLean *et al.* (13), with the same Roman designation.[5] The presence of 2s orbitals would complicate our procedure and therefore those wavefunctions containing them were omitted. Otherwise, the parameters of McLean *et al.* at $R = 1.40$ a.u. were used.

TABLE 4. % errors* in $Q^e(0)$ and in $\langle\delta(r_{1A})\delta(r_{2B})\rangle$ for ground-state H_2

	$Q^e(0)$		$\langle\delta(r_{1A})\delta(r_{2B})\rangle$

VIII	+6.84	+1.73	+24.6	+12.8

*See text.

The cusp-satisfying wavefunctions are presented in Table 3. The calculated $Q^e(0)$ are listed in Table 4 again as percentage errors, based on the accurate value of 0.22990 obtained at $R = 1.4011$ a.u. by Kolos and Wolniewicz (14). Although these results are not as systematic as those for the atoms, they are still fairly reasonable. Except when the percentage error in $Q^e(0)$ is less than 1% in magnitude, the introduction of cusp-satisfying orbitals improves the calculated $Q^e(0)$.

Finally, the expectation values $\langle\delta(r_{1A})\delta(r_{2B})\rangle$ were also calculated for these wavefunctions. The percentage errors based on the accurate value of 0.0637 are also listed in Table 4.[6] These disappointing results are somewhat surprising. The only trend seems to be a decrease of $\langle\delta(r_{1A})\delta(r_{2B})\rangle$ in going from Φ_i to Ψ_i.

The authors are grateful to the National Research Council of Canada for financial support.

E. TOMCHUK

Department of Physics, University of Winnipeg, Winnipeg, Manitoba

Received April 27, 1972

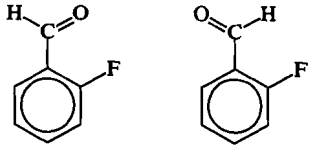
The dipole moments of ortho-, meta-, and para-fluorobenzaldehyde were determined in dilute benzene solutions at 25 °C. The experimental data are in complete agreement with the conclusions reached by Wasylishen and Schaefer (1), *viz.* the *O-trans* conformer is the more stable conformer for ortho- and meta-fluorobenzaldehyde.

Les moments dipolaires de l'ortho-, méta-, et para-fluorobenzaldéhyde ont été déterminés en solution benzénique diluée à 25 °C. Les données expérimentales sont en accord total avec les conclusions de Wasylishen et Schaefer (1) à savoir que le conformère *O-trans* est le plus stable pour l'ortho- et méta-fluorobenzaldéhyde. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2890 (1972)

Introduction

In a recent paper, Wasylishen and Schaefer (1) concluded on the basis of n.m.r. data and INDO calculations that the *O-trans* conformer was the more stable conformer for ortho- and meta-fluorobenzaldehyde (see Fig. 1). In their paper, Wasylishen and Schaefer suggested that electric moment measurements would provide conclusive evidence for the correct conformation of the fluorobenzaldehyde molecules. In this work we report on the electric moments of *o*-, *m*-, and *p*-fluorobenzaldehyde.



O-cis *O-trans*

FIG. 1. *o*-Fluorobenzaldehyde.

Experimental

Solvent

Fisher certified reagent benzene was used as solvent. The benzene was dried by repeated shaking with Linde molecular sieve 4A. The purity of the solvent was checked by gas chromatography as well as by determining the usual physical constants, *i.e.* the boiling point, density, and refractive index, and comparing the latter with the appropriate literature values.

Solute

The solute molecules were obtained from Pierce Chemical Co. of Rockford, Ill., and were used without further purification. The solutes used were the same solutes used

by Wasylishen and Schaefer (1). Their n.m.r. analyses showed that the impurities amounted to less than 1%. In particular no presence of water or alcohol in the solutes was detected (see Fig. 2 of ref. 1).

Experimental Procedure

The dipole moment apparatus and experimental procedure have been described elsewhere (2). The experimental error in the dipole moment values is estimated to be ±0.05 D.

Results and Discussion

The experimental results are shown in Table 1. The dipole moments derived from these data by the method of Smith (3) are summarized in Table 2. Included in Table 2 are the moment values calculated from group moments (4) and using the INDO calculation as well as experimental literature values. From a perusal of Table 2 it is evident that for *o*-fluorobenzaldehyde the *O-trans* conformation is the most stable conformation and that *m*-fluorobenzaldehyde exists in benzene (a nonpolar solvent) in roughly equal proportions of *O-trans* and *O-cis* conformations. Wasylishen and Schaefer (1) found that at 31 °C in acetone solution the mole fraction of *O-cis* and *O-trans* conformer of *o*-fluorobenzaldehyde was 0.14 and 0.86, respectively. And that for *m*-fluorobenzaldehyde under similar conditions the mole fraction of the *O-cis* and *O-trans* conformer was 0.43 and 0.57, respectively. Using our experimental value for *o*-fluorobenzaldehyde at 25 °C in benzene solution and the estimated dipole moments of the *O-trans* and *O-cis* conformer for *o*-fluorobenzaldehyde derived from group moment calculations, we calculate the mole fraction of the *O-cis* conformer as 0.27 and that of the *O-trans* conformer as 0.73. A similar calculation for *m*-fluorobenzaldehyde yielded a mole fraction of 0.34 and 0.66 for the *O-cis* and *O-trans* conformer, respectively. Bearing in mind that group moment calculations are accurate to only 0.2–0.3 D at best, our experimental results may be said to be in complete agreement with the conclusions reached by Wasylishen and Schaefer (1) based on n.m.r. data.

The Use of Polymer Supports in Organic Synthesis. The Synthesis of Monotrityl Ethers of Symmetrical Diols

CLIFFORD C. LEZNOFF AND JACK Y. WONG
Department of Chemistry, York University, Downsview, Ontario

Received May 15, 1972

A modified Merrifield polymer containing acid chloride groups was used in the selective synthesis of the monotrityl ethers of the symmetrical diols, HO—$(CH_2)_n$—OH, where $n = 2, 4, 6, 8$, and 10. This procedure constitutes a unique method of blocking one functional group of a completely symmetrical difunctional compound.

Une résine modifiée du type Merrifield comprenant des groupes chlorure d'acide, a été utilisée dans la synthèse sélective d'éthers monotritylés de diols symétriques HO—$(CH_2)_n$—OH avec $n = 2, 4, 6, 8$, et 10. Ce procédé constitue une méthode unique pour bloquer un groupe fonctionnel dans un composé bifonctionnel complètement symétrique. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2892 (1972)

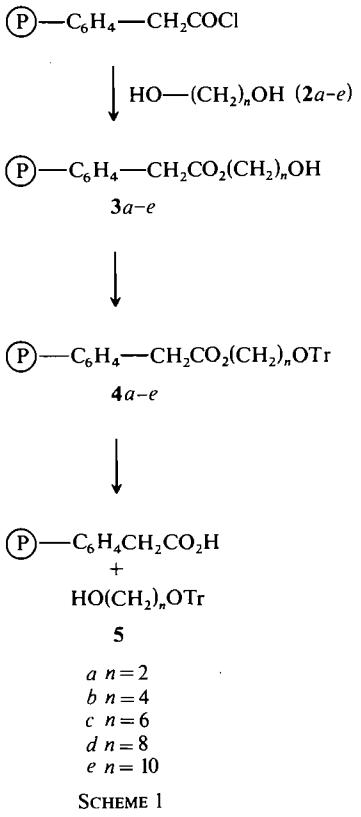
The use of insoluble polymer supports in the synthesis of polypeptides (1), polynucleotides (2), and even polysaccharides (3) has been well documented. The unique potential of solid phase synthesis, however, has not generally been applied to organic synthetic problems. The synthesis of a threaded carbocycle by Harrison and Harrison (4), hydrogenation on polymer supported catalysts (5), polymer supported Wittig reagents (6), and the base condensation of mixed esters (7, 8), are, however, some of the few attempts to use insoluble polymer supports to solve specific synthetic problems.

The concept of using blocking groups in organic synthesis is well established. For example, the use of trityl chloride in specifically blocking only the 5′-hydroxyl group of deoxyribonucleosides is well known (9), but this procedure depends on the fact that the 5′-hydroxyl group is a primary alcohol and hence reacts much faster than the 3′-hydroxy group which is a secondary alcohol. It is this difference in the nature of the alcohol groups that allows selective blocking to occur. In this communication, we propose a general method whereby one can selectively block one alcohol group of a completely symmetrical diol.

The selective blocking of one functional group of a completely symmetrical difunctional compound can be accomplished using functionalized insoluble polymer containing acid chloride available Merrifield resin (2% cross-linked polystyrene beads with 1.7 mmol of —CH_2Cl groups per gram of resin, obtained from Schwarz/Mann) was modified, according to the procedure of Kusama and Hayatsu (10), to an insoluble polymer containing acid chloride groups, Ⓟ—C_6H_4—CH_2COCl (**1**). The acid chloride **1** contained 0.8 mequiv Cl^1/g of polymer as determined by the modified Vollhard procedure (11). Polymer **1** contains only one in six functionalized phenyl groups along the polymer chain and hence the acid chloride polymer **1** acts as a dilute reagent.

In a typical experiment, 4.2 g of resin **1** and 4.0 g of 1,4-butanediol (**2***b*) in 40 ml of pyridine were stirred for 48 h at room temperature and for 24 h at 105 °C, to yield a resin ester (**3***b*) in which the diol is attached to the polymer by only one of the alcohol moieties.[1] The use of the insoluble polymer support allows one to use a large excess of diol, the excess of which can be recovered, after reaction has occurred, by simple filtration of the polymer. The quantity

[1]The possibility exists that two adjacent phenyl rings are functionalized and hence both ends of the symmetrical diol (**2***b*) could attach themselves to the polymer. Although Kraus and Patchornik have demonstrated that this in fact can happen (7), the use of a large excess of diol greatly diminishes the chance of this occurring.



SCHEME 1

of diol **2***b* attached to the polymer was determined by hydrolysis of 4.7 g of resin **3***b* with 20 ml of a 1:1 mixture of dioxane and concentrated ammonia for 94 h. The recovery of 78.5 mg of diol **2***b* showed that the polymer **1** has a capacity of being charged with 0.20 mmol of **2***b* per gram.

Reaction of resin ester **3***b* with trityl chloride in pyridine (9, 12) gave the resin trityl ether (**4***b*). Hydrolysis of 3.71 g of **4***b* as described above and purification on t.l.c. gave 90 mg of 1-*O*-trityl-1,4-butanediol (**5***b*) in 37% yield based on amount of diol charged on the polymer. The properties and yields of a series of 1-*O*-trityl-1,*n*-alkanediols, synthesized by the polymer support method are listed in Table 1. Hydrolysis of **5***a–e* with 80% acetic acid led to quantitative recovery of trityl alcohol and starting diols **2***a–e* (9).

As shown in Table 1, only the monotrityl ether of ethylene glycol (**2***a*) had been previously prepared by classical methods (12). It is interesting to note that the yield of compound **2***a* was not recorded (12). Our own attempts to prepare the monotrityl ether of 1,10-decanediol (**5***e*) by classical methods (12) gave a mixture of four compounds, **2***e*, **5***e*, di-*O*-trityl-1,10-decanediol, and trityl alcohol, which proved difficult to separate even by preparative t.l.c.

TABLE 1. Physical data of 1-*O*-trityl-1,*n*-alkanediols

Compound*	M.p. (°C)	Yield (mmol/g polymer)	Yield† (%)
TrO(CH2)2OH	95–96‡	0.087	44
TrO(CH2)4OH	65–67	0.074	37
TrO(CH2)6OH	68–69	0.085	47
TrO(CH2)8OH	oil	0.072	51
TrO(CH2)10OH	oil	0.048	51

*All compounds showed satisfactory elemental analyses.
†Based on amount of diol released from the polymer on base hydrolysis.
‡Literature 98–100° (12).

The modification of one functional group of symmetrical difunctional compounds by the use of insoluble polymer supports will be further explored.

We thank the National Research Council of Canada for a grant in aid of this research.

Sulfur-free Penicillin Derivatives. I. Functionalization at C-5

SAUL WOLFE,[1] WHA SUK LEE, GÉRARD KANNENGIESSER, AND JEAN-BERNARD DUCEP
Department of Chemistry, Queen's University, Kingston, Ontario

Received May 17, 1972

Direct chlorination of an anhydropenicillin produces a sulfur-free dichloride in which the two C—S bonds are replaced by two C—Cl bonds. The reaction is general for anhydropenicillins and proceeds with predominant retention of configuration at C-5 except in the case of anhydro-6-phthalimidopenicillin, which gives variable stereochemical results.

Hydrolysis of the COCl function to COOH, conversion of the acids or acid chlorides to methyl, *t*-butyl, and benzhydryl esters, and regeneration of the acids from the latter two esters are described.

Nucleophilic substitution at C-5 of these compounds proceeds smoothly and with inversion of configuration. The rate of the reaction depends on the C-6 substituent in the direction H_2N > acylamino > phthalimido.

La chloration directe de l'anhydropénicilline conduit à un dérivé dichloré avec absence de soufre, dans lequel les deux liaisons C—S sont remplacées par deux liaisons C—Cl. Cette réaction est générale pour les anhydropénicillines et se fait avec prédominance de rétention de configuration sur le C-5, sauf dans le cas de l'anhydro phtalimido-6 pénicilline qui donne des résultats variables concernant la stéréochimie.

L'hydrolyse de la fonction COCl en COOH, la conversion des acides ou chlorures d'acides en esters méthylique, t-butylique et diphenyl méthylique et la regénération des acides à partir de ces deux derniers esters, sont décrites.

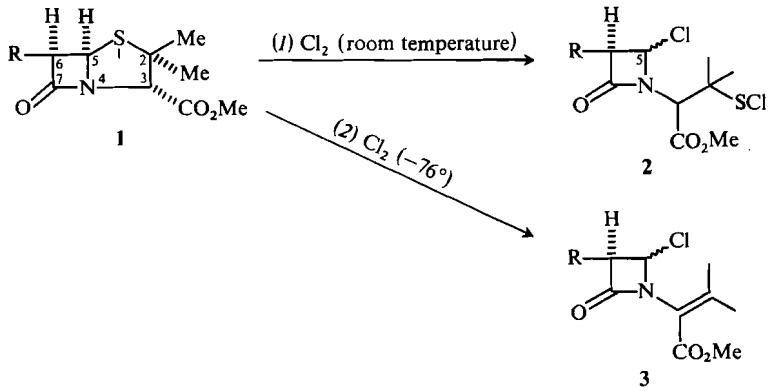
La substitution nucléophile au niveau du C-5 de ces composés se fait de façon douce, avec inversion de configuration. La vitesse de la réaction dépend du substituant sur le C-6, avec dans l'ordre NH_2 > acylamino > phtalimido. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2894 (1972)

There is much current interest in chemical modifications of the penicillin nucleus which retain the β-lactam ring (1). Most of these transformations produce compounds which also retain the sulfur atom, but there are three exceptions (2–4) which are relevant to the work reported here and in the accompanying communications (5). In the work of Kukolja (4), shown in eq. 1, both C5-epimers[2] of **2** were obtained in crystalline form, but the epimers of **3** were not,[3] and the reaction conditions indicate that fission of the *thiazolidine* ring requires careful attention to experimental detail.

We report here a *general* reaction of *anhydro*-penicillins which, like that shown in eq. 1, involves a chlorinolysis. In the present reaction, quantitative conversion to sulfur-free compounds is achieved and, with the exception

[1]



[1]This work was presented in the Merck, Sharp and Dohme Award Lecture, Quebec City, Quebec, June, 1972.
[2]The penicillin numbering system is employed here (*cf.* **1**).
[3]A 4:1 mixture of 5S:5R epimers was obtained "in high yield".

of anhydro-6-phthalimidopenicillin[4] (**4***a*; see below), the opposite stereoselectivity is observed, *i.e.*, the **R** configuration predominates at C-5. In addition, careful control of solvent composition, temperature, and chlorine concentration is not necessary. Thus, direct chlorination (excess chlorine, CH_2Cl_2, 20°, 3 min) of **4***a*, followed by removal of the solvent under reduced pressure, afforded a quantitative yield (by n.m.r.) of a 3:2 mixture of two isomeric compounds (**5***a* and **6***a*). The major isomer **5***a*, m.p. 210° (dec.), was crystallized from $CHCl_3$–petroleum ether, λ_{max} ($CHCl_3$) 242 (10 000).

Anal. Calcd. for $C_{16}H_{12}N_2O_4Cl_2$: C, 52.3; H, 3.31; N, 7.69; Cl, 19.4. Found: C, 52.03; H, 2.96; N, 7.76; Cl, 19.53.

The i.r. spectrum (KBr) of **5***a* (and of the mixture of **5***a* and **6***a*) shows peaks at 5.48 (COCl), 5.55 (β-lactam), 5.62, 5.79 μ (phthalimido). The n.m.r. spectrum[5] has peaks at 2.13 (4H, d), 3.78 (1H, d, 4.2 Hz), 4.75 (1H, d, 4.2 Hz), 7.57 (3H, s), 7.65 (3H, s).

The relative amounts of **5***a* and **6***a* were not significantly affected by chlorination in the presence of excess $Et_4N^+Cl^-$ or by a change in the temperature of the reaction; other chlorinating agents (SO_2Cl_2, pyridinium trichloride, pyrrolidone hydrotrichloride) gave more complex mixtures.

Interestingly, in some reactions, under otherwise identical experimental conditions, the opposite stereoselectivity[4] was obtained. The difference appears to be related to the origin and purity of the starting material **4***a*. The R stereoselectivity described above was achieved from **4***a* prepared by rearrangement (1*a*) of the penicillanic acid, and containing trace amounts (*ca.* 1%) of *N*-carboethoxyphthalimide (7). In contrast a 3:1 5S:5R ratio of epimers was obtained following chlorination of rigorously purified **4***a* or **4***a* prepared from anhydrotritylaminopenicillin (1*b*). The pure dichloride **6***a* could be isolated from such mixtures.

[4]Phthalimidopenicillanic acid and its derivatives often display different chemical properties from the (biologically more significant) 6-acylaminopenicillanic acids (2*b*, *c*, 6).

[5]Unless otherwise mentioned, all n.m.r. spectra were recorded in $CDCl_3$ at 60 MHz. Chemical shifts are given in τ values relative to internal TMS. Although, to conserve space, spectroscopic data are not quoted in detail for all new compounds, all of these gave i.r., n.m.r., and high resolution mass spectra in full accord with the assigned structures and stereochemistry. In addition, all crystalline compounds gave satisfactory elemental analyses (C, H, N, Cl).

(8), aqueous acetone, or aqueous THF) gave the acid **7***a*, m.p. 168–174° (dec.) in 73–90% yield. Methylation of **7***a* (CH_2N_2, Et_2O–CH_2Cl_2) produced the ester **8***a*, m.p. 178–180° (dec.), $[\alpha]_D^{20}$ −8.9° ($CHCl_3$) in 97% yield. The same compound was obtained from **5***a* in 93% yield upon treatment with absolute methanol (30 min, 20°). Similarly, hydrolysis of **6***a* afforded the acid **9***a*, m.p. 164–166° (dec.), which was converted to the corresponding methyl ester **10***a*, m.p. 192–194°, $[\alpha]_D^{20}$ −144° ($CHCl_3$).

The *t*-butyl ester **8***b* was obtained in 33% yield by *refluxing* **5***a* in anhydrous *t*-BuOH for 21 h. The C5-epimer **10***c*, prepared similarly, melted at 170–172°. Dissolution of **8***b* in trifluoroacetic acid (TFA), and evaporation of the solvent after 3 min, gave **7***a* in quantitative yield. The benzhydryl ester **10***b*, prepared (Ph_2CN_2) in 99% yield from **9***a*, also underwent ready reconversion to **9***a* upon treatment with TFA.

Anhydrotritylaminopenicillin (1*b*) decomposed during chlorination. However the derived (1*b*) *p*-toluenesulfonic acid salt **4***b* reacted smoothly to give a 4:1 5R:5S mixture of **5***b* and **6***b* as a stable (below 20°) white powder, m.p. 148–149° (dec.). Hydrolysis of this powder afforded a 4:1 mixture of the acids **7***b* and **9***b*. Phenylacetylation of this mixture ($NaHCO_3$, $PhCH_2COCl$, H_2O–CH_3COCH_3) gave the penicillin G analog **7***c*, whose methyl ester **8***c* was crystallized in 51% yield (from **4***b*), m.p. 111–115° (dec.). Alternatively, methanol treatment of the mixture of **5***b* and **6***b*, and crystallization from chloroform–hexane, produced the pure 5R ester **8***d*, m.p. 125–130° (dec.), in 67% yield (from **4***b*).

Neutralization of **8***d* and reaction of the free base **8***e*, m.p. 67–70° (dec.), with Nefkens' reagent (7) yielded **8***a*, confirming that chlorinolysis proceeds in the same manner with both side chains. Phenylacetylation of **8***e* gave **8***c* in 82% yield. This provides an alternative to the sequence **5***b* → **7***b* → **7***c* → **8***c*, and indicates that **7***b* can serve as a general intermediate for acylamino members of this class of compounds.

The anhydro derivatives (**4***c*–*e*) of benzyl, benzyloxycarbonyl,[6] and trichloroethoxycarbonylpenicillin[7] underwent ready chlorination–hydrolysis to give quantitative yields of the acids **7***c* + **9***c*, **7***d* + **9***d*, and **7***e* + **9***e*. In each case a 3–4:1 mixture of 5R (**7**): 5S (**9**) epimers was obtained and the proportion of epimers was not significantly affected by changes in the experimental conditions. Methylation of the mixture of **7***c* + **9***c* afforded **8***c*, completing the interrelation of the phthalimido, amino and acylamino series of derivatives.[8]

Equilibration of **8***a* and **10***a* proceeded smoothly, upon refluxing (acetone, 12 h; 2-butanone, 4 h) in the presence of tetraethylammonium chloride. The same equilibrium mixture, containing in all cases an excess (1.5–2.5:1) of the *trans*-isomer **10***a* was obtained starting with either pure epimer, the position of equilibrium depending upon solvent, temperature, and concentration of tetraethylammonium chloride. The compounds recovered from equilibrium mixtures were identical in all respects to those prepared directly from **4***a*.

Reaction of **8***a* with sodium azide (DMF, 90°, 3 h) afforded the 5S azide **10***d*, m.p. 144–145°, in 67% yield, uncontaminated by the 5**R** isomer **8***f*. Under the same conditions **10***a* yielded **8***f*, m.p. 183–187° in 52% yield, uncontaminated by **10***d*. With tetraethylammonium acetate ($CHCl_3$, reflux, 17 h) **10***a* gave **8***g* in 62% yield. These various observations demonstrate that nucleophilic displacement on a β-lactam ring proceeds with inversion of configuration (9).

Equilibration of **8***e* and **10***e* was best achieved (**10***e*:**8***e* = 6:1) with tetramethylguanidinium chloride (CH_2Cl_2, reflux, 12 h). Reaction of **8***e* with tetramethylguanidinium azide (10) (2 equiv, $CHCl_3$, reflux) yielded **10***f* (90%); the epimer **8***h*, m.p. 116–117°, was obtained similarly from **10***e* in 85% yield. Phenylacetylation of **8***h* ($C_6H_5CH_2COOH$, DCC, CH_2Cl_2) afforded the 5-azidopenicillin G analog **8***i*, m.p. 102–103° (97%); the C5-epimer **10***g* was obtained similarly from **10***f* or by reaction of **8***c* with tetramethylguanidinium azide (2 equiv, $CHCl_3$, reflux).

Each of the reactions **8***a* → **10***d*, **8***e* → **10***f*, **8***c* → **10***g* represents the conversion of a 5R-chloro into a 5S-azido compound. Reaction

[6]Prepared in 90% yield from **4***b*.

[7]Prepared in 85% yield from **4***b*.

[8]Structure proofs of the benzyloxycarbonyl and trichloroethoxycarbonyl acids are based on their subsequent reactions (2).

8*e* → **10***f* was complete in 0.5 h; under the same conditions **8***c* → **10***g* was complete in 2 h and **8***a* was recovered unchanged. Consequently the effect of the C6-substituent on the rate of nucleophilic displacement from C-5 is H_2N > acylamino > phthalimido.

The sequences established here provide general routes to carboxyl-protected sulfur-free penicillin derivatives, with control over the substituent at C-6 and the functionality and stereochemistry at C-5.

We thank Bristol Laboratories for financial support of this work.

Sulfur-free Penicillin Derivatives. II. Functionalization of the Methyl Groups

SAUL WOLFE,[1] WHA SUK LEE, JEAN-BERNARD DUCEP, AND GÉRARD KANNENGIESSER
Department of Chemistry, Queen's University, Kingston, Ontario

Received May 17, 1972

Allylic bromination of anhydropenicillin chlorination products by *N*-bromosuccinimide (NBS) is described. With two molar-equivalents of NBS both methyl groups are functionalized; with one molar-equivalent of NBS a mixture of Z and E monobrominated isomers is obtained.

Nitrogen and oxygen nucleophiles attack the dibrominated derivatives at the β-lactam carbonyl group, with concomitant ring-opening. However, the mono-brominated derivatives undergo ready displacement by azide and formate ions. The mechanism of these reactions, leading to preferred formation of Z-isomer, is discussed.

Cyclization of the allylic formates yields sulfur-free derivatives corresponding to the cephalosporin C_c class of compounds.

La bromation allylique des produits de chloration de l'anhydropénicilline par la *N*-bromosuccinimide (NBS) est décrite. Avec deux équivalents molaires de NBS les deux groupes méthyles sont fonctionnalisés en même temps; avec un seul équivalent de NBS, un mélange d'isomères Z et E de monobromation est obtenu.

Les nucléophiles azote et oxygène attaquent les dérivés dibromés au niveau du carbonyle du β-lactame, avec ouverture simultanée du cycle. Les dérivés monobromés subissent cependant un déplacement facile par les ions azoture et formiate. Le mécanisme de ces réactions, qui conduisent préférentiellement à l'isomère Z, est discuté.

La cyclisation des formiates allyliques conduisent aux dérivés, avec absence de soufre, de la classe des composés de la céphalosporine C_c. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2898 (1972)

Anhydropenicillins (**1**) are stable to the action of lead tetraacetate and selenium dioxide (1). Reactions are observed with chlorine, *N*-bromoacetamide (2), *N*-bromosuccinimide (NBS), palladium acetate (3), and mercuric acetate (4), but in each case the products are formed by attack on nitrogen (1) or sulfur (5) rather than the double bond.

The stability of **1** towards allylic oxidation has been rationalized (1, 6, 7) in terms of enamine-type character of the carbon–carbon double bond, causing functionalization of the methyl groups to correspond to attack at the β-position of a masked carbonyl. The effect of opening of the five-membered ring (*e.g.*, **1** → **2**) on the properties of the double bond could not have been predicted *a priore*, but this question was answered by the demonstration (7) that the anhydropenicillin rearrangement can be reversed. The Michael addition **2** → **3** which must have occurred during the latter process is possible only if **2** reacts as an α,β-unsaturated acid rather than an enamine. It follows that functionalization of the methyl groups of an anhydropenicillin ought to become feasible following lysis of the five-membered ring.

In agreement with this conclusion, and in direct contrast to the recent work of Nayler and coworkers (8),[2] anhydropenicillin chlorination products (5) undergo rapid allylic bromination by NBS.[3] The reaction of **4***a* with two molar-equivalents of NBS[2] was complete within 5 min. The product **5***a* crystallized from CCl_4 – petroleum ether in 81% yield, m.p. 70–72° (dec.).[4] Under identical conditions the C_5-epimer **4***b* afforded **5***b* in 70% yield. The extraordinary facility of this oxidation is seen in the successful functionalization, under the same conditions, of **4***c*.

The methyl groups of **4***a* showed no difference

[1]This work was presented in the Merck, Sharp and Dohme Award Lecture, Quebec City, Quebec, June, 1972.

[2]These workers reported that 1,2-secopenicillins (9) do not undergo allylic oxidation with NBS or lead tetraacetate.

[3]For general reaction conditions, see ref. 2.

[4]The compositions of **5***a*, **5***b*, **6***a* + **6***b* and **7***a* + **7***b* were confirmed by elemental analysis. Other compounds were obtained in chromatographically pure form and their constitutions confirmed by high resolution mass spectrometry, in addition to their n.m.r. spectra, summarized in Table 1.

in reactivity. Oxidation of this compound with one molar-equivalent of NBS afforded a crystalline 1:1 mixture of **6***a* + **6***b*. The methyl groups of **4***b* showed a slight difference in reactivity, and a 3:2 mixture of **7***a* + **7***b* was obtained from this compound.

The brominated substances described above contain the functionality found in C3-substituted cephalosporins (**8**) (10). Nucleophilic displacement at the C3-methylene group of these compounds proceeds (10) by one of two paths, shown in eqs. 1 and 2. In the present work the dibrominated derivatives **5** apparently reacted with nucleophiles (N_3^-, $OCHO^-$,[5] OH^-) via path [2], since rapid incorporation of the nucleophile was observed together with concomitant loss of the β-lactam. However, the monobrominated derivatives **6***a* + **6***b* and **7***a* + **7***b* underwent ready displacement of bromine without loss of the β-lactam, presumably via path [1].

Treatment of the mixture **6***a* + **6***b* with tetramethylguanidinium azide (**11**) (1 equiv, $CHCl_3$, 3 h, 20°) afforded a mixture of **6***c* + **6***d* (λ_{max} ($CHCl_3$) 4.7, 5.55, 5.62, 5.78, 5.79 μ). The mixture of **7***a* + **7***b* similarly afforded **7***c* + **7***d*. Alternatively the 1:1 mixture of **6***a* + **6***b* reacted with tetramethylguanidinium formate (**12**) (5 molar equivalents, $CHCl_3$, 9 h, 20°) to give, in 53% yield, a 2:1 mixture of **6***e* + **6***f*,[4] containing an excess of the Z-isomer **6***f* (λ_{max} ($CHCl_3$) 5.52, 5.58, 5.79 μ). The assignment of configurations

[5]Displacement of the C_3-acetate of cephalosporins by oxygen nucleophiles has not been observed (10).

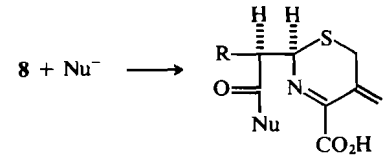
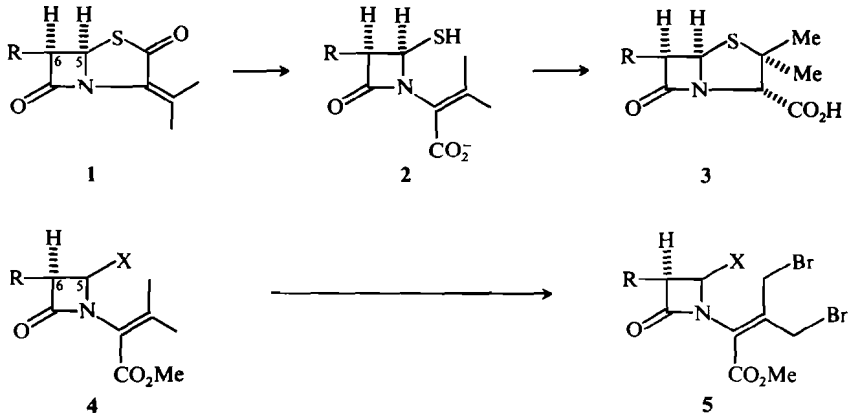
[2]





a R = $C_6H_4(CO)_2N$; X = 5R-Cl (*cis*)
b R = $C_6H_4(CO)_2N$; X = 5S-Cl (*trans*)
c R = $C_6H_5CH_2CONH$; X = 5R-N_3 (*cis*)

to **6***e* + **6***f* is based on the finding that chromatography (alkaline alumina, ethyl acetate) of the mixture gave, in 67% yield, the crystalline lactone **6***g*, m.p. 124–128° (dec.) (λ_{max} (KBr) 5.54, 5.62, 5.69, 5.79 μ). An analogous sequence on **7***a* + **7***b* afforded **7***e* + **7***f* in 70% yield as a 1:1 mixture of Z- and E-isomers; this mixture produced the lactone **7***g* in 50% yield upon treatment with alumina.

The lactones **6***g* and **7***g* are sulfur-free analogs of the cephalosporin C_c class of compounds (**9**). If displacement of bromine from the mixtures **6***a* + **6***b* or **7***a* + **7***b* does proceed via path [1], the same intermediate (**10**) will be generated from the Z- and E-isomers. This intermediate can exist in *s-trans* (**10***a*) or *s-cis* (**10***b*) conformations. In general the *s-trans* conformation is more stable (13) and inspection of molecular models suggests that the steric interaction between the methyl and carbomethoxy groups will enhance this tendency. Completion of the reaction by S_N2' attack of nucleophile on **10** should therefore lead to preferred formation of Z-isomer and, subsequently, lactone.

Sulfur-free Penicillin Derivatives. III. Regeneration of Fused β-Lactams via Intramolecular Displacement

SAUL WOLFE,[1] JEAN-BERNARD DUCEP, GÉRARD KANNENGIESSER, AND WHA SUK LEE

Department of Chemistry, Queen's University, Kingston, Ontario

Received May 17, 1972

Recyclization of a variety of sulfur-free penicillin derivatives is described. Fused oxazoline-azetidinones, a fused oxazolidone-azetidinone, an *oxa*anhydropenicillin and an *aza*cephem have been prepared.

La recyclisation d'une variété de dérivés de la pénicilline avec absence de soufre, est décrite. Des oxazoline-azétidinones et oxazolidone-azétidinones fusionnées, une *oxa*anhydropenicilline et un *aza*céphem ont été préparés. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2902 (1972)

Sheehan (1) and Barton *et al.* (2, 3) have reported the conversion of **1**, the methyl ester of penicillin G, into the fused β-lactam-oxazoline **2***a* upon treatment with *t*-butyl hypochlorite–triethylamine (1) or iodobenzene dichloride (2). Low yields of **2***a* were obtained in each case and it was not possible to define the mechanism of the reaction. A thiazoline analog (**3**) of **2***a* has also been prepared (4) and converted (5) to an array of penam and cephem derivatives. These latter observations have led to the interesting speculation (5) that **4** could represent a common intermediate for the biosynthesis of both penicillins and cephalosporins.

We report here rational syntheses of **2***a*, **2***b*, a trichloroethoxy analog of **2***a*, and **2***c*, an oxygen analog of **4**, via intramolecular recyclization of appropriate anhydropenicillin chlorination products (6). Various other fused β-lactam systems are also described, including the oxazolidone **5**, the 1-oxa-5-epianhydropenicillin **6** and the 1-aza-6-epicephem **7**.

Phenylacetylation of **8***a* afforded **9***a* (82%).[2] This compound cyclized in over 70% yield, upon refluxing or bicarbonate washing of a CH_2Cl_2 solution, to give **2***a*, m.p. 126.5–127° (1, 3).[2,3] The cyclization presumably proceeds by anti-displacement of chlorine by the amide oxygen (7) since, under the same conditions, the C5-epimer **9***b* is recovered unchanged.

[1]This work was presented in the Merck, Sharp and Dohme Award Lecture, Quebec City, Quebec, June, 1972.

[2]I.r. and n.m.r. spectra are in full accord with the proposed structure.

[3]Satisfactory elemental analyses or high resolution mass spectra were secured.

We thank Bristol Laboratories for financial support of this work.

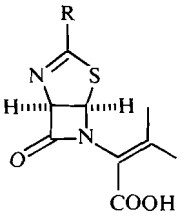
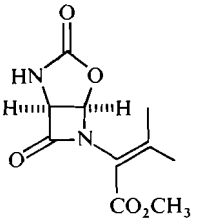
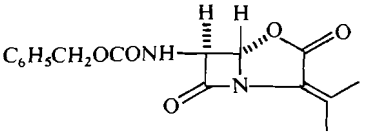
c R = $C_6H_5CH_2$; R′ = H



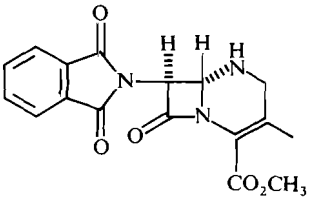
4



5



6



7

However, the latter could also be converted to **2***a*, upon silica gel or (neutral) alumina chromatography; we suggest that **10***a* is an intermediate in this case. Bicarbonate treatment and reacidification of the acid **9***c* (6) afforded **2***c* in 53% yield, m.p. 119–122° (dec.)[3] $[\alpha]_D^{20}$ +13.2° (H_2O–$NaHCO_3$); λ_{max} (KBr) 4.0 (br), 5.64, 5.92, 6.1 μ (zwitterionic structure); n.m.r. (D_2O): τ 2.67 (5H), 3.88 (1H, d, 3.8 Hz), 4.75 (1H, d, 3.8 Hz), 6.25 (2H), 8.09 (3H), 8.69 (3H).[4] The cyclization with apparent retention of configuration at C-5 may proceed via the intermediate **10***b*.[5]

The benzhydryl ester **11***b*[2,3] was obtained in 70% yield from anhydrotrichloroethoxycarbonyl penicillin (**11***a*) by the sequence shown. Epimerization at C-5 (tetramethylguanidinium chloride) afforded a 2:1 mixture of **11***c*[2] and **11***b*, from which **2***b* was obtained in 24% yield upon refluxing with tetramethylguanidinium formate (8);[6] M^+ 522; i.r. 5.61, 5.76, 5.81, 6.07 μ; n.m.r. ($CDCl_3$): τ 2.68 (10H), 3.08 (1H), 3.99 (1H, d, 3.5 Hz), 4.86 (1H, d, 3.5 Hz), 5.15 (1H, d, 12 Hz), 5.27 (1H, d, 12 Hz; the methylene protons of the trichloroethyl group are non-equivalent), 7.73 (3H), 8.06 (3H).

Reaction of **8***a* with benzyl chloroformate and triethylamine afforded **9***d* (24%)[2,3] together with the fused oxazolidone-azetidinone **5** (12%); M^+ 240; i.r. 3.0, 5.56, 5.62, 5.78, 6.10 μ; n.m.r. ($CDCl_3$): τ 2.87 (1H, br), 3.92 (1H, d, 4.0 Hz), 5.08 (1H, d, 4.0 Hz), 6.20 (3H), 7.70 (3H), 8.02 (3H). In this case cyclization of **9***d* seems to be followed by loss of benzyl alcohol.

[4]This acid has no antibacterial activity at concentrations up to 250 γ/ml.

[5]A referee has suggested that **9***b* is epimerized to **9***a* during chromatography and that **2***c* is formed (by a double inversion) via the phenylacetamido analog of **6**. We have been unable to obtain experimental support for either of these suggestions.

[6]This is a necessary reagent for the cyclization.

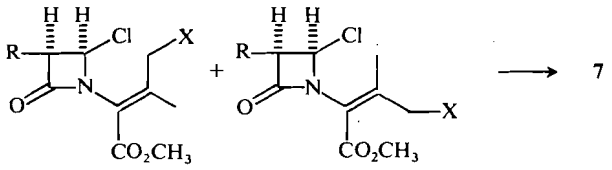
11a **11b** **11c**

R = $C_6H_5CH_2OCO$; R′ = $(C_6H_5)_2CH$



12a **12b**

R = $C_6H_4(CO)_2N$

The relative ease of intramolecular substitution by amide oxygen and carboxylate is seen in the behavior of the *acid* **9e** (6). Within 1 min after addition of $NaHCO_3$ to an aqueous acetone solution of **9e** a crystalline precipitate was formed. This compound, isolated in 40% yield,[3] was assigned the *oxa*anhydropenicillin structure **6** (*cf.* ref. 9); m.p. 170–172° (dec.); $[\alpha]_D^{25}$ −64.5° ($CHCl_3$) (anhydrocarbobenzoxypenicillin has $[\alpha]_D^{25}$ +259° ($CHCl_3$)); M^+ 316; λ_{max} (KBr) 2.98, 5.55, 5.65, 5.88, 6.51 μ; τ ($CDCl_3$): 2.44 (6H), 4.14 (1H, d, 1.8 Hz), 4.82 (2H), 4.98 (1H, q, 1.8, 8 Hz), 7.82 (3H), 7.88 (3H).

Finally, hydrogenation (PtO_2, benzene, 45 psi, 6 h) of the mixture **12a** + **12b** (X = N_3) (6) afforded the mixture **12a** + **12b** (X = NH_2).[2] This mixture was recovered unchanged following refluxing in chloroform. Treatment with *t*-BuOK–*t*-BuOH (20°, 1 h), followed by careful chromatography (neutral alumina, activity II, elution with graded mixtures of benzene–methylene chloride) afforded **7** in 12% yield, m.p.

Automatic Sorting of Signals in Shift Reagent Spectra

J. W. APSIMON,[1] H. BEIERBECK, AND A. FRUCHIER
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received June 15, 1972

This communication shows a simple algorithm for the automatic sorting of signals in shift reagent spectra with an implicit plot of chemical shifts *vs.* improved shift reagent coordinates.

Un algorithme simple est décrit permettant un triage automatique des signaux dans les spectres r.m.n. de substrats organiques étudiés en présence de chélates de lanthanide. La méthode utilise implicitement un graphe des déplacements chimiques en fonction de coordonnées indépendantes de la concentration en chélate.

Canadian Journal of Chemistry, **50**, 2905 (1972)

Lanthanide induced chemical shifts are a linear function of the fraction [LS]/[S] of complexed substrate and, for low shift reagent concentrations, of the molar ratio [L]/[S] of shift reagent and substrate (1, 2) ([L], [S], and [LS] are the total concentrations of shift reagent and substrate and the concentration of bound substrate respectively). It has been demonstrated (2) that accurate slope ratios and intercepts can be obtained without a knowledge of the ratios [LS]/[S] or [L]/[S] by plotting the chemical shifts against coordinates which are proportional to the sum of the shifts in each spectrum. Sometimes, it can be difficult to trace the signal of a given nucleus through a series of spectra, especially if the number of signals is great and if the lines cross in the studied range of molar ratios, as in noise decoupled ^{13}C spectra of a substrate with a large number of carbon atoms. The correlation between the chemical shifts and the improved shift reagent coordinates has been found to be good enough to permit automatic sorting of the signals, and this communication describes a simple algorithm.[2]

Suppose the chemical shifts of m nuclei or groups of magnetically equivalent nuclei are measured in the absence of shift reagent and for n different concentrations of shift reagent. Let the chemical shifts in the shift reagent spectra be arranged as a matrix Δ of dimensions $m \times n$ in which the signals in the i'th spectrum are found in the i'th column. This matrix has

[1]Author to whom correspondence should be addressed.

[2]This method has been found to work well in cases where LS_2 species are formed. In these cases the ratios of the induced shifts were independent of the shift reagent concentrations, suggesting that either LS_2 adducts were exclusively formed or that the limiting shifts were the same in the LS and LS_2 complexes.

to be rearranged so that all signals for any given nucleus are in one row. The chemical shifts in the spectrum without shift reagent then have to be matched with the data in the shift reagent matrix.

Step 1. Corrected shift reagent coordinates are derived in the usual way (2).

Step 2. The signals in the shift reagent spectra are sorted out. Lines are drawn from δ_{1n} (the first signal in the n'th spectrum) to each of the m points δ_{i1} from the first spectrum (see Fig. 1) and the m slopes are calculated. For each of the m lines every column of points is searched for that signal which is closest to the line and the standard deviation of these points is calculated for each line (see Table 1). That combination $(\delta_{i1}, \delta_{1n})$ is taken to be the correct one for which the standard deviation is a minimum. The slope is recalculated using all n points which are then removed from the matrix Δ and form a row in the new matrix Δ'.

This procedure is repeated with the reduced matrix Δ until all signals are sorted out and the new matrix Δ' is completed in which all signals for any nucleus are in one row. If it is not already the case, the rows are ordered according to increasing slopes.

Step 3. The m chemical shifts in the spectrum before addition of shift reagent are matched with the m slopes. First the correction procedure for the shift reagent coordinates is applied to the zero position. In general, the best zero position after correction will not be exactly at the coordinate origin, and it is brought back to zero by displacing the whole plot. Then the intercepts are calculated and the experimental shifts are ordered accordingly.

Spectra in which not all signals can be observed are excluded and the slopes of the best lines are calculated with the shifts in the remaining spectra. If the experimental shift reagent coordinates are accurate enough to permit the assignment of some of the signals, these signals can be used to obtain improved shift reagent coordinates. The remaining signals can then be sorted out as in step 3.

The method is illustrated with the shifts for the eight ($m = 8$) methyl groups of β-amyrin (**1**). 100 MHz spectra for 10 different concentrations ($n = 10$) of $Pr(fod)_3$ in $CDCl_3$ were

I

obtained at ambient temperature. The signals above -50 Hz are plotted in Fig. 1 (shifts upfield from TMS are negative) which illustrates the first stage in step 2, the combination of δ_{1n} with each of the eight δ_{i1}. The standard deviations for each of the eight combinations are found in column 1 of Table 1. Both the table and the figure indicate that the match $\delta_{21}-\delta_{1n}$ is the correct one. Since δ_{21} is now removed from Δ, there are no further entries in row 2.

The adjustment of the shift reagent coordinates may be unnecessary if the molar ratios of shift reagent and substrate are determined very accurately. However, we prefer to apply these corrections as they guarantee accurate results from routine measurements.

A sorting routine based on the described algorithm is a part of the program that we use for all calculations of slopes, slope-ratios, and intercepts in shift reagent plots for proton and ^{13}C n.m.r. spectra. As part of a program to fit the pseudo contact equation of McConnell–Robertson (3) to the shift reagent data, it is the first stage in the automatic assignment of chemical shifts and structure elucidation with the help of shift reagents.

Cyclopropylcarbinyl-oxo-carbonium Ions. Part V.[1] Synthesis and Chemistry of some Cyclopropyl Glycopyranosides[2]

BRUNO RADATUS AND BERT FRASER-REID

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received March 7, 1972

The synthesis of five cyclopropanated glycopyranosides, **6**α, **6**β, **7**α, **7**β, and **11** capable of providing access to the title ions has been examined. Simmons–Smith methylenation of methyl 4,6-*O*-benzylidene-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside (**8**α) under carefully controlled conditions gives an excellent yield of the α-D-*allo* adduct (**6**α). A homoallyl iodide, 4,6-*O*-benzylidene-1,2,3-trideoxy-3-*C*-iodomethyl-D-*ribo*-hex-1-enopyranose, (**9**), is also produced and upon methanolysis undergoes ring closure to an equal mixture of α-D and β-D anomers of **6**. Methylene insertion into the aglycon of the starting olefin **8**α occurs giving small amounts of the ethyl hex-2-enopyranoside (**10**), the cyclopropanated glycoside derived therefrom, **11**, being also obtained. Methylenation of the β-D-hex-2-enopyranoside, **8**β, gives a complex mixture containing at least eight substances, although the expected β-D-*manno* adduct, **7**β, is the major product. There is considerable anomerization of **8**β and of the primary product, **7**β; thus the anomer **7**α is also produced. The 3-epimer (**14**) of the above-mentioned homoallyl iodide (**9**) is obtained in small yield.

The cyclopronated glycosides are very susceptible to prolonged exposure to the Simmons–Smith medium. Particularly in the case of **8**β the yields of the various products can be optimized by judicious choice of the duration of the reaction.

Proton magnetic resonance data for the adducts are presented. The value of the spacing J_{34} provides a clear basis for determining the configuration of the ring. However anisotropy due to the cyclopropane ring-current causes the equatorial H-1 in the β-D-*manno*-anomer (**7**β) to resonate at higher field than H-1 in the α-D anomer **7**α.

On a étudié la synthèse de cinq glycopyranosides cyclopropyles **6**α, **6**β, **7**α, **7**β, et **11** capables de donner accès aux ions du titre annoncé. La méthylénation selon Simmons–Smith du méthyl-*O*-benzylidène-4,6 didéoxy-2,3-α-D-*érythro*-hexeno-2 pyranoside (**8**α) dans des conditions soigneusement contrôlées conduit au composé d'addition α-D-*allo* (**6**α) avec un rendement excellent. Un iodure homoallyle, *O*-benzylidène-4,6 tridéoxy-1,2,3 iodométhyl-3-*C*-D-*ribo*-hexeno-1 pyranose (**9**) est également obtenu, qui subit une fermeture de cycle dans la méthanolyse en un mélange égal d'anomères α-D et β-D de **6**. L'insertion de méthylène dans l'aglycone de l'oléfine de départ **8**α se produit et conduit à de petites quantités d'éthylhexèno-2 pyranoside (**10**), le glycoside cyclopropyle qui en dérive **11**, étant obtenu également. La méthylénation du β-D-hexeno-2 pyranoside **8**β conduit à un mélange complexe de huit composés au moins, bien que le composé d'addition attendu, β-D-manno **7**β, soit le produit majeur. Une anomérisation considérable se produit sur **8**β et sur le produit primaire **7**β, expliquant ainsi l'obtention de l'anomère **7**α. L'épimère-3 (**14**) de l'iodure homoallyle mentionné ci-dessus (**9**) est obtenu avec un rendement faible.

Les glycosides cyclopropylés sont très sensibles à une exposition prolongée dans le milieu du Simmons–Smith. Dans le cas de **8**β en particulier, les rendements des divers produits peuvent être rendus optima selon un choix judicieux de durée de réaction.

Les données de la r.m.n. du proton pour les composés d'addition, sont présentées. La valeur de l'écart J_{34} permet de déterminer de façon claire, la configuration du cycle. Toutefois, l'anisotropie due au courant de cycle du cyclopropane provoque une résonance à des champs plus élevés pour H-1 équatorial de l'anomère β-D-*manno* (**7**β) que pour H-1 dans l'anomère α-D de **7**α. The interconversion of cyclopropylmethyl, cyclobutyl, and homoallyl compounds, discovered by Demjanov in 1907 (1) was given its first interpretation in terms of modern carbonium ion theory by Roberts and Mazur (2). Since then, under the name of the cyclopropylcarbinyl or homoallyl rearrangement (3),[3] the interconversion has been utilized in several synthetic sequences (4). Our interest in this system was aroused by the possible inter-

conversion of ions **2**–**5** which are some of the individual species contributing to the highly delocalized ion **1** named a *cyclopropylcarbinyl-oxo-carbonium ion* for reasons described previously (5). Compounds cognate with ions **2**–**5** would be of potential utility in synthetic carbohydrate chemistry, and as a first step towards their obtainment, we have been concerned with the preparation of molecules which upon solvolysis would generate ion **1**.

Cyclopropanated glycosides capable of filling this need were unknown at the inception of this work although in the interim one such member, **6**α, has been obtained by Horton and coworkers (6). We describe herein the syntheses of these four possible glycosides **6**α, **6**β, **7**α, **7**β and report on certain aspects of their chemistry.

*Simmons–Smith Reaction of Methyl 4,6-O-Benzylidene-2,3-dideoxy-*α*-*D*-erythro-hex-2-enopyranoside,* **8**α *(Scheme 1)*

Simmons–Smith cyclopropanation (7) of olefin **8**α (8) gave a complex mixture from which the four products shown in Scheme 1 were obtainable by chromatography on silica. The starting olefin comprised 24% of the mixture under the conditions of optimum product formation. The desired compound, **6**α, was obtained in 82% based on reacted olefin. The material was identical in all respects with a sample kindly supplied by Professor Horton (6).

The second major product, **9**, is configurationally related to **6**α, because silver-ion induced methanolysis converts **9** to an equal mixture of **6**α and **6**β (9). This reaction was particularly significant from the synthetic standpoint, since it proved to be the best route to the latter glycoside, **6**β. The mechanism of these interconversions and the mechanism of the formation of **9** are discussed in the following and adjoining paper in this series (10).

Two minor products from the reaction were **10** and **11**. The n.m.r. parameters for **10** (see Experimental) and the elemental analysis were indicative of an ethyl hex-2-enopyranoside (11–13) which implied that methylene had inserted into the aglycon of the starting olefin **8**α. However, assignment of the anomeric configuration was difficult because (*i*) the identical material was obtained when the anomeric olefin **8**β was cyclopropanated (Scheme 3), and (*ii*) its specific rotation (91.3°) lay nearly midway between the values for the methyl α-D (**8**α) and β-D (**8**β) analogues (129 and 45°, respectively) (12). For this reason

†For details of preparation of **6β** see ref. 10.
‡The ethoxy group in **11** is an ABX system (*cf.* ref. 33). The diastereotopic methylene protons occur as octets at τ 6.28 and 6.48: $J_{AB} = 10.0$; $J_{AX} = J_{BX} = 7.0$. The methyl group is a triplet at τ 8.80.
§Read directly from the spectra run at 500 Hz sweep width.

justification of the configuration of **10** is deferred until after the anomerization phenomena shown in Scheme 4 have been discussed. The elemental analysis for compound **11** and the similarity of its n.m.r. parameters and optical rotation to those of **6α** (Tables 1 and 2) pointed to the assigned structure.

In order to determine the effects of prolonged exposure to the reaction medium, the cyclopropyl glycoside **6α** was placed in the Simmons–Smith conditions for 8 h (Scheme 2). In addition to the already encountered homoallyl iodide **9** and methylene insertion product **11**, three new compounds were obtained. Two of these emerged an an inseparable mixture in 13% from a silica column chromatogram. They were judged to be the diastereomers implied in structure **12** because of the mass ion, *m/e* 372.

SCHEME 3

TABLE 2. Specific rotations of some cyclopropanated glycopyranosides in chloroform

Compound	$[\alpha]_D^{23°}$	Concentration (g/100 ml)
6α	+115.2	2.86
6β	−8.0	3.06
7α	+104.7	4.75
7β	−40.0	5.40
11	+137.5	2.82

This was substantiated by showing that cyclopropanation of **9** produced an identical mixture. The n.m.r. spectrum of the mixture, **12**, showed two complex signals integrating for one proton at τ 7.0 and 7.2, ascribed to H-3 of the assigned structures by analogy with the H-3 resonance of **9** (14). Furthermore dehydroiodination of the mixture leads to inseparable olefins, **13** (M^+, *m/e* 244). The terminal methylene group was apparent from i.r. signals at 3012, 978, and 894 cm^{-1} (15); absorption for four protons τ 8.33–9.63 indicated that the cyclopropane ring had been preserved.

A third new substance was obtained as a syrupy material whose structure is currently being determined and therefore labelled *unknown* "*a*".[4]

*Simmons–Smith Reaction of Methyl 4,6-O-Benzylidene-2,3-dideoxy-β-D-erythro-hex-2-enopyranoside, **8**β (Scheme 3)*

As may be gathered from Scheme 3, Simmons–Smith reaction of **8**β gave a very complex mixture, and the yields of the components varied markedly with the duration of the reaction (Table 3). However, advantage was taken of this feature when it was deemed desirable to accumulate a given product at the expense of the others.

Products listed in Scheme 3 previously encountered are **6**α, **8**α, **8**β, **9**, **10**, and **11**, and a substance with the same R_f as *unknown* "*a*", Scheme 2, was obtained and is designated *unknown* "*b*".[4]

The α-D-*manno* skeleton ascribed to **7**α followed from the n.m.r. parameters listed in Table 1. The value $J_{34} = 2.0$ Hz was different to those listed for *allo*-derivatives (**6** and **11**) and therefore implied different configuration. Furthermore the coupling $J_{12} = 0.0$ Hz agrees precisely with the value found in the analogous α-D-*manno*-epimino, epoxy, and epithio compounds (16). Following this reasoning, the expected reaction product (**7**β), was recognized as *manno* by (*i*) a value of $J_{34} = 2.0$ Hz, and (*ii*) the coupling $J_{12} = 3.5$ Hz which is consistent with β-D orientation.

[4]*Unknown* "*a*" and *unknown* "*b*" were obtained as by-products when the *allo*-(**6**) and *manno*-(**7**) cyclopropyl glycosides were exposed to the Simmons–Smith reaction medium for lengthy periods of time. Both unknowns are syrupy, isomeric with **6** and **7**, homogeneous on t.l.c., and have identical R_f values. Nevertheless, their n.m.r. spectra, which are also similar (!), reveal that each is in fact a mixture, because there are two benzylidene–methine spikes whose relative intensity varies (within each unknown) from one preparation to the next. The structure of the unknowns is currently being investigated and will be published in due course.

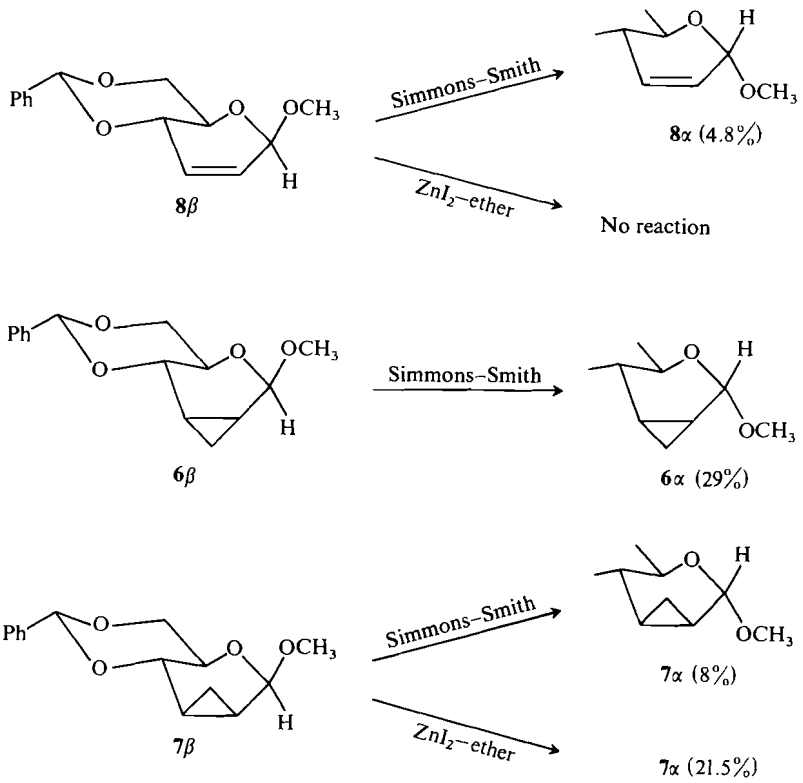

SCHEME 4

The structure of the iodoglycal **14** was determined by an independent synthesis (17) originating with the epimer **9** described in detail in the adjoining paper (10). Interestingly, attempts to convert **7β** to **14** by means of the Simmons–Smith reagents (*cf.* **6α** → **9** Scheme 2) were unsuccessful. The only products obtained were **7α** (Scheme 4) and *unknown* "*b*".[4]

The formation of α-D-cyclopropyl glycosides **6α** and **7α** from the β-D olefin **8β** in Scheme 3 needed explanation because methylene addition to 2-cyclohexenols and their ethers usually occurs *syn* to the oxygen function (18). The ICH_2ZnI complex (19) coordinates through a zinc atom to the allylic oxygen and is thereby constrained to deliver the methylene group on the same side.[5] The formation of **6α** would therefore require that the starting olefin must be anomerized to **8α** prior to reaction with methylene. Compound **7α** however would most likely arise by anomerization of the principal reaction product, **7β**. Both of these anomerizations seemed plausible in view of the Edward–Lemieux effect (21, 22) which stabilizes most α-D-hexopyranosides *vis à vis* their β-D anomers. Acid catalysis required for the anomerization (23), could be provided by ZnI_2 or ICH_2ZnI present in the reaction medium. Already from Scheme 3 it is apparent that **8β** can be anomerized to **8α**, and experiments summarized in Scheme 4 revealed that β-D cyclopropyl glycosides are partially anomerized under the Simmons–Smith conditions. However, as expected, the α-D anomers were not converted to their β-D analogues. Zinc–iodide in ether anomerized the cyclopropyl glycoside **7β** → **7α** in even higher yield, but interestingly the latter conditions were without effect on the *olefinic* glycoside, **8β**. This result reflects the superiority of a suitably-disposed cyclopropyl group over an olefinic group, to stabilize an α-carbonium ion (24).[6]

[5]This does not necessarily hold for rings of larger size (20).

[6]For further evidence, compare the rates of aqueous-dioxan hydrolysis of structures **6** and **10** in ref. 25.

The α-D configuration assigned to the ethyl hex-2-enopyranoside occurring in Schemes 1 and 3 (*vide supra*) can now be justified. Theoretically the material could have *either* anomeric configuration arising by methylene insertion into the methoxyl group of **8**α or **8**β and yielding, respectively, **10** or its β-D anomer. However, the ethyl hex-2-enopyranoside produced in Scheme 1 *cannot* have β-D configuration since that would require either (*a*) anomerization of **8**α → **8**β followed by methylene insertion, or (*b*) **8**α → insertion product followed by anomerization to a β-D olefin. In either case α → β anomerization is required and as was shown in the preceding paragraph this does not occur in the reaction medium. The α-D configuration for **10** is therefore indicated, and independent proof comes from the fact that the H-1 resonance at τ 5.00 is closer to that for **8**α (τ 5.05) than for **8**β (τ 4.68) (12).

Nuclear Magnetic Resonance Spectra of the Cyclopropanated Glycosides (Table 1)

Nuclear magnetic resonance parameters obtained from 200 MHz spectra of the cyclopropanated glycosides are shown in Table 1. Perusal of the data shows that the value of J_{34} provides a clear basis for deciding the orientation of the cyclopropyl group in these derivatives. The value $J_{34} = 2.0$ Hz for **7** seems unduly small for two formally *trans*-diaxial protons; it undoubtedly reflects the distortion of six-membered ring and electronic effects associated with the cyclopropyl ring (26).

The chemical shifts of H-1 within each anomeric pair present an interesting contrast. The equatorial proton in **6**α occurs 0.23 p.p.m. to lower field than the axial proton in **6**β in accordance with the situation in saturated hexopyranosides (27). However, the equatorial proton in **7**α occurs 0.36 p.p.m. to *higher* field than the axial proton in the related anomer, **7**β. This result must be due to abnormal shielding effects, due to the anisotropy of the cyclopropane ring. It has been suggested that the cyclopropane ring may have a ring current such that protons near to the equatorial plane are deshielded while those above and below the plane and near to the three-fold axis of the ring would be shielded (26). If this is correct, H-4 in the *manno*-(**7**) derivatives being nearer to the center of the cyclopropane ring, should be more shielded than H-4 in the corresponding *allo*-(**6**) derivatives. In fact the data in Table 1 shows this to be the case. With regard to H-1 in the β-anomers, models show that as one goes from **6**β to **7**β, the axial H-1 moves away from the ring center, and should therefore be less shielded. This is observed. *The overall effect in the cases studied appears to be for the cyclopropane ring to shield vicinal cis-oriented protons located on the pyran ring.*

The assignment of *endo* and *exo* orientation to the geminal cyclopropyl protons rested upon their couplings to H-2 and -3, because *cis*-couplings on a cyclopropane ring are much larger than *trans*-couplings (28). Accordingly the large couplings (Table 1) were assigned as $J_{2\,7_{exo}}$ and $J_{3\,7_{exo}}$. Thus H-7_{exo} and by corollary H-7_{endo} were readily identifiable.

The remaining parameters in Table 1 are in good accord with the trends recognized previously in relation to the relative chemical shifts H-2 (27, 29), the methoxyl protons (30), and the chemical shifts and couplings of the H-6 protons for such benzylidene compounds (12).

Experimental

General

Melting points were determined on a Fischer–Johns heating stage and are uncorrected. The n.m.r. spectra whose analyses are given in Table 1 were recorded using either a Varian T-60, a Varian HA 100, or a Varian HR 220 spectrometer, and unless otherwise specified, the solvent was deuteriochloroform containing 1% tetramethylsilane as internal standard. Coupling constants were obtained by measuring spacings of spectra judged to be first-order. All geminal and allylic (through four bonds) couplings were assigned negative signs as predicted for these systems (31).

I.r. spectra were determined on a Beckman model I.R. 5 spectrometer using 0.1 mm sodium chloride solution cells (chloroform as solvent) and silver chloride plates for smears. Mass spectra were determined on a Hitachi Mass Spectrometer model RMU-6E.

T.l.c. was performed on glass plates coated with silica gel (HF-254, E. Merck) to a thickness of 0.3 mm. The most useful developing phase was petroleum ether (35/60 °C)–ethyl acetate (4:1) and the chromatograms were first viewed under u.v. light, then exposed to iodine vapor, and finally sprayed with concentrated sulfuric acid. For column chromatography E. Merck Silica Gel (0.05–0.20 mm, 70–325 mesh A.S.T.M.) was used.

Simmons–Smith Reaction of Methyl 4,6-O-Benzylidene-2,3-dideoxy-α-D-erythro-hex-2-enopyranoside, 8α (see Scheme 1)

A well-stirred mixture of methylene iodide (1.44 ml; 0.0179 mol), zinc–copper couple (32) (1.0 g; 0.0153 mol),

For personal use only.

TABLE 4. Fractions obtained from column chromatography of the mixture (2.45 g) from Simmons–Smith reaction on compound **8α**

Fraction	R_f	Compound	Weight of material in g (%)
a	0.77	**9**	0.217 (7.5)
b	0.59	**10**	0.050 (2)
c	0.51	**8α**	0.480 (24)
d	0.45	**11**	0.045 (2)
e	0.38	**6α**	1.3093 (62)

diethyl ether (6 ml; 0.0576 mol), and a small crystal of iodine was refluxed for 1 h.[7] The title compound **8α** (8) (2.0 g; 0.008 mol) was added as a solid, and also more diethyl ether (4 ml; 0.0384 mol) and reflux was continued for a further 8 h. *However it was found essential to add dimethoxyethane (7) (0.8 ml; 0.0072 mol) in 0.16 ml portions at times 0.0, 0.5, 1, 3, and 5 h after the addition of compound* **8α** *to the reaction mixture.* After the 8 h reflux period the reaction mixture was poured into a separatory funnel, washed with saturated aqueous ammonium chloride solution, and then with saturated bicarbonate solution. The ether layer was dried and evaporated under reduced pressure, whereby 2.45 g of white crystalline material was obtained. T.l.c. indicated five components with R_f values of 0.77, 0.59, 0.51, 0.45, and 0.38 using 4:1 petroleum ether–ethyl acetate as developing solvent. The mixture was put on a column (100 cm × 1.8 cm) prepared from 200 g Silica Gel and eluted with the same solvent mixture. The results are shown in Table 4.

Fraction a was identified as *4,6-O-benzylidene-1,2,3-trideoxy-3-C-iodomethyl-*D*-ribo-hex-1-enopyranose,* ***9*** *(5, 10).*

Fraction b, obtained from cyclopropanation of both **8α** and **8β** (Schemes 1 and 3), was identified as *ethyl 4,6-O-benzylidene-2,3-dideoxy-α-*D*-erythro-hex-2-enopyranoside,* ***10***, by the following definitive n.m.r. features: ~τ 2.5 (m, 5, Ph), 4.7 (s, 1, PhC*H*), 5.0 (bs, 1, H-1), 3.90 (d, J_{23} = 10 Hz, H-2), 4.30 (dt (partly obscured by benzylidene proton) 1, H-3), 5.57–6.70 (m, 6, H-4, -5, -6a, -6e, —O*H*CH′CH_3, and —OHC*H*′CH_3), $[\alpha]_D^{23}$ +91.3 (*c*, 1.9 in $CHCl_3$). Assignment of the anomeric configuration as α-D was justified in the Discussion.

Fraction c was the starting olefin **8α**.

Fraction d was identified as *ethyl 4,6-O-benzylidene-2,3-dideoxy-2,3-C-methylene-α-*D*-allopyranoside,* ***11***. The material crystallized spontaneously and recrystallization from ethanol afforded an analytical sample, m.p. 156–158°; $[\alpha]_D^{23}$ +137.5° (*c*, 2.82 in $CHCl_3$).

Anal. Calcd. for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30. Found: C, 69.39; H, 7.37.

N.m.r. parameters for **11** are given in Table 1. The appearance of the ring protons was as follows: H-1 (d), -2 (m), -3 (m), -4 (q), -5 (td), -6a (t), -6e (q), -7_{exo} (td), -7_{endo} (q). The optical rotation is reported in Table 2.

[7]It should be noted that the methylene iodide was in excess of the zinc–copper couple (0.0153 mol), the reverse of the usual practice (7, 32). It was found that if the molar amount of methylene iodide was equal to or less than the molar amount of zinc–copper couple, the yields were low and variable or the reaction did not proceed at all.

Fraction e which was crystallized from methanol was identified as *methyl 4,6-O-benzylidene-2,3-dideoxy-2,3-C-methylene-α-*D*-allopyranoside,* **6α**, by spectral comparisons and mixed melting point with a sample of the authentic material kindly supplied by Professor Horton (6).

*Prolonged Exposure of Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-C-methylene-α-*D*-allopyranoside,* **6α**, *to the Simmons–Smith Medium (Scheme 2)*

Compound **6α**, (2.0 g, 7.6 mmol) was treated for 8 h with the Simmons–Smith reagents as described above for **8α**, the relative ratio of the reactants being maintained, excepting dimethoxyethane which was not needed. The reaction product (see Scheme 2) on t.l.c. showed starting material (R_f 0.38), the homoallyl iodide **9** (R_f 0.77), the ethyl glycoside **11** (R_f 0.45), *unknown "a"*[4] (R_f 0.62) and a new substance R_f 0.66. Silica column chromatography afforded the components as follows, the percentages being referred to the amount of starting material: 39.4, 25.6, 7.3, 15, and 13% respectively.

The substance of R_f 0.66 gave a positive iodine test with ethanolic silver nitrate and its mass spectrum gave M^+ *m/e* 372. The n.m.r. spectrum showed in addition to benzylidene resonances (see Table 1) τ 8.33–9.63 (m, 4, H-1, -2, -7_{endo}, -7_{exo}), 5.50–7.33 (m, 7, H-3, -4, -5, -6a, -6e, -8, -8′), and two complex patterns at 7.0 and 7.2 amounting to one proton, ascribed to H-3 of the mixture of *4,6-O-benzylidene-1,2,3-trideoxy-3-C-iodomethyl-1,2-C-methylene-α,*D*-allo- and β,*D*-altro-pyranose,* ***12***. Treatment of the material (50 mg) with a refluxing solution of sodium hydroxide in aqueous dioxan afforded a new substance M^+ *m/e* 244. This material did not crystallize but showed i.r. absorptions at 3012, 978, 894 cm^{-1} for terminal methylene (15). Assuming **12** to be correct, this olefin is therefore **13**.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-β-*D*-erythro-hex-2-enopyranoside,* **8β**

Methyl β-D-glucopyranoside was converted to the 4,6-*O*-benzylidene derivative (33) in the usual way (34), and the resulting substance was treated with excess methanesulfonyl chloride and pyridine. The 4,6-*O*-benzylidene-2,3-di-*O*-methanesulfonyl-β-D-glucopyranoside, **8β**, so obtained (9.0 g, 0.02 mol) was added to an efficiently-stirred mixture of potassium iodide (17 g, 0.1 mol) and zinc–copper couple (32) (6.5 g, 0.1 g atom) in 50 ml of dry dimethyl formamide. The solution was refluxed until t.l.c. indicated completion (~3 h) and then the hot solution was poured into ice-water (~100 ml). Chloroform (50 ml) was added and the mixture was stirred for *ca.* 15 min. The insoluble material was removed by filtration through Celite and the filter cake was stirred with an equal mixture of chloroform and water. After repeating the latter process twice, the washings were combined and the chloroform phase separated. After washing with sodium thiosulfate solution and water, the organic layer was dried ($CaCl_2$) and evaporated to a residue which crystallized (4.52 g, 90% yield). The melting point 95–96° and n.m.r. data were in excellent agreement with those reported for the title compound by Lemieux and coworkers (12).

*Simmons–Smith Reaction of Methyl 4,6-O-Benzylidene-2,3-dideoxy-β-*D*-erythro-hex-2-enopyranoside,* **8β** *(Scheme 3)*

Compound **8β** (10.0 g; 0.0403 mol) was subjected to the Simmons–Smith reaction as described above for **8α**, using

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

proportionate amounts of the reagents. However dimethoxyethane was *not* required here, and an olefin (21%) was still present after 4 h. The product was isolated in the usual way, and afforded a complex mixture weighing 11.4 g, which was chromatographed on a silica column (75 cm × 5 cm) using petroleum ether (35–60 °C)–ethyl acetate (4:1) as eluant. Each fraction was rechromatographed on a 100 cm × 1.8 cm column which afforded the pure compounds listed in column four of Table 3 with the exception of compounds **9** and **14** which could not be separated.

Of the compounds listed in Table 3 compounds **8**α and **8**β are starting olefins, while **6**α, **9**, and **10** were encountered in Scheme 1 and **14** has been described previously (17, 10). Structure proof of **7**β and **7**α is offered below.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-C-methylene-β-*D*-manno-pyranoside, 7β*

When compound **7**β was the main product required from the preparation, the Simmons–Smith reaction of **8**β was allowed to go for 1.5 h only (Table 3). The material isolated by chromatography as described immediately above, was crystallized from ethyl acetate; m.p. 133–134.5 °C; $[\alpha]_D^{23}$ −40.2° (*c*, 5.4 in $CHCl_3$).

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92. Found: C, 68.60; H, 7.15.

N.m.r. parameters for **7**β are given in Table 1. The appearance of the ring protons was as follows: H-1 (d), -2 (m), -3 (m), -4 (q), -5 (td), -6a (t), -6e (q), -7_{exo} (td), -7_{endo} (q).

The optical rotation of **7**β is reported in Table 2.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-C-methylene-α-*D*-manno-pyranoside, 7α*

(*i*) When compound **7**α was the main product desired from the preparation, the Simmons–Smith reaction of **8**β was allowed to go for 8 h (Table 3). The material was obtained by silica column chromatography as detailed two sections above and was recrystallized from ethyl acetate; m.p. 106–108 °C, $[\alpha]_D^{23}$ +104.7 (*c*, 4.75 in $CHCl_3$).

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92. Found: C, 68.82; H, 7.18.

(*ii*) The title compound could be obtained by anomerization of compound **7**β. The latter substance (0.1 g) was dissolved in ether (10 ml) containing zinc iodide (0.1 g) and the mixture was refluxed for 14 h. After cooling the solution was washed with dilute sodium thiosulfate and then water. The dried ether layer gave a product which by n.m.r. analysis contained starting material (46%), the desired substance, **7**α (22%) and *unknown "b"*[4] (32%).

N.m.r. parameters for **7**α are given in Table 1. The appearance of the ring protons was as follows: H-1 (s), -2 (m), -3 (m), -4 (q), -5 (td), -6a (t), -6e (q), -7_{exo} (td), -7_{endo} (td).

The optical rotation is given in Table 2.

Cyclopropylcarbinyl-oxo-carbonium Ions. Part VI.[1] Synthesis and Chemistry of an Epimeric Pair of Homoallyl Iodides (3-Iodomethyl Glycals)[2,3]

BERT FRASER-REID AND BRUNO RADATUS

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received March 7, 1972

The homoallyl iodide 4,6-*O*-benzylidene-1,2,3-trideoxy-D-*ribo*-hex-1-enopyranose, **4**, is the second major product from Simmons–Smith reaction of methyl 4,6-*O*-benzylidene-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside, **6α**. The major product is the cyclopropyl glycoside **7α**, which when treated separately with the Simmons–Smith reagents furnishes an 85% yield of **4**. The mechanism of this transformation is investigated. It is not simply a Lewis-catalyzed iodinolysis since zinc iodide in a variety of solvents does not convert **7α** to **4**. Methylene iodide is essential, as is the organo-zincate complex, operative in Simmons–Smith reactions.

The 3-epimer of the homoallyl iodide **4**, *i.e.* 4,6-*O*-benzylidene-1,2,3-trideoxy-D-*arabino*-hex-1-enopyranose, **5**, is produced in only 0.9% yield in the methylenation of the anomeric olefinic glycoside, **6β**. The low yield is attributable to the extensive anomerization experienced by **6β** itself, and by the primary reaction products. This leads to a plethora of compounds including *both* epimeric homoallyl iodides **4** and **5**.

In order to get it all together, the homoallyl iodide **4** is transformed into its epimer **5** by an unambiguous synthetic sequence. Some of the intermediates in this sequence are polyfunctional molecules of considerable synthetic potential.

The possibility of an alternative route to compound **4** directly from the olefinic glycoside **6α** is discussed. Coordination of the methoxyl oxygen of **6α** to the organo-zincate complex could achieve an ideal S_Ni transition state in which ICH_2^- is delivered at C-3 with synchronous departure of the methoxyl group. This mechanism, called the "reverse" allylic rearrangement for reasons outlined in the text, is discussed.

L'iodure homoallyle *O*-benzylidène-4,6 tridéoxy-1,2,3 D-*ribo* hexeno-1 pyranose **4**, est le second produit majeur de la réaction de Simmons–Smith sur le méthyl *O*-benzylidène-4,6 didéoxy-2,3-α-D-*erythro* hexeno-2 pyranoside, **6α**. Le produit majeur est le cyclopropylglycoside **7α** qui, traité séparément avec les réactifs de Simmons–Smith, conduit à **4** avec un rendement de 85%. Le mécanisme de cette transformation est examinée. Il ne s'agit pas d'une simple iodinolyse catalysée par un acide de Lewis car l'iodure de zinc dans divers solvants, ne transforme pas **7α** en **4**. L'iodure de méthylène est essentiellement, comme l'organozincate, le complexe agissant dans les réactions de Simmons–Smith.

L'épimère-3 de l'iodure homoallyle **4**, à savoir l'*O*-benzylidène-4,6 tridéoxy-1,2,3-D-*arabino* hexeno-1 pyranose **5**, est obtenu avec un rendement de 0.9% seulement lors de la méthylénation de l'anomère glycoside oléfinique, **6β**. Le faible rendement est attribué à l'anomérisation extensive subie par **6β** et par les produits de la réaction primaire. Une pléthore de composés est obtenue incluant à la fois les iodures homoallyliques épimères **4** et **5**.

En vue de les obtenir tous ensembles, l'iodure homoallyle **4** est transformé en son épimère **5** selon une séquence réactionnelle connue. Quelques intermédiaires de cette séquence sont des molécules polyfonctionnelles d'un potentiel synthétique considérable.

La possibilité d'obtenir **4**, par une autre voie d'accès directement à partir du glycoside oléfinique **6α**, est discutée. La coordination de l'oxygène méthoxyle de **6α** au complexe organozincate, permettrait de réaliser un état de transition idéal S_Ni dans lequel $^-CH_2I$ attaque le C-3 avec départ synchronisé du groupe méthoxyle. Ce mécanisme, appelé, "réarrangement allylique inverse" pour les raisons soulignées dans le texte, est discuté.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2919 (1972)

In the preceding paper (1) we discussed the promise held by the *cyclopropylcarbinyl-oxo-carbonium ion*, **1**, (2) for fundamental structure modification of the carbohydrate skeleton, and outlined the syntheses of some cyclopropanated glycosides (**2**) from which **1** might be generated by loss of alkoxyl. The homoallyl system **3** being formally related to **2** by virtue of the cyclopropylcarbinyl rearrangement (3), represents a potential alternative source of ion **1** and for this reason we describe herein two homoallyl iodides **4** and **5** which complement the cyclopropyl derivatives described previously (1).

[1]For Part V see ref. 1.

[2]Portions of this work have appeared as preliminary communications in refs. 2, 8, and 9.

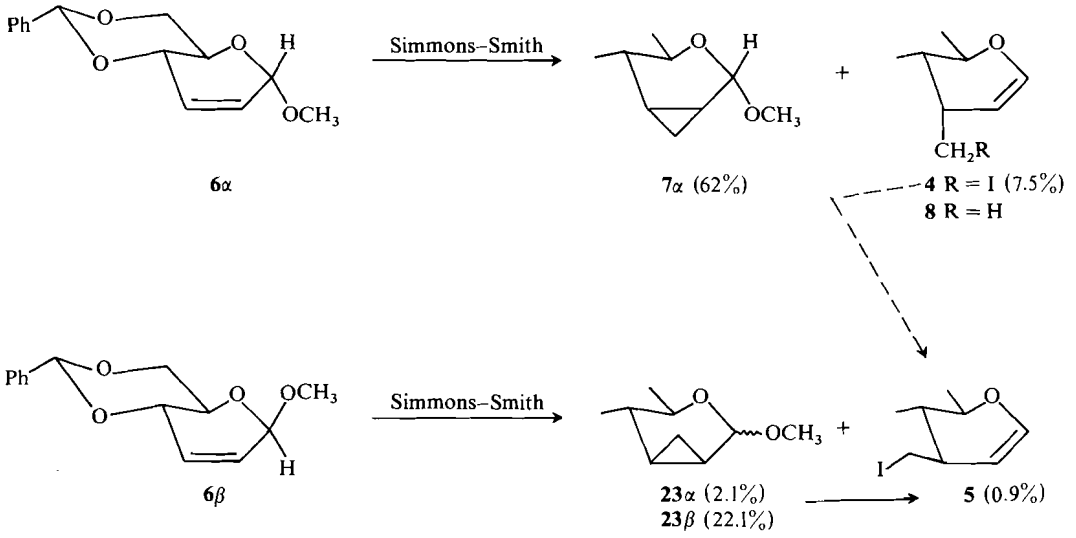
2 1 3

Compound **4** was obtained in 7.5% yield from Simmons–Smith reaction of olefin **6α** (see (Scheme 1). The n.m.r. spectrum[4] indicated the absence of a methoxyl group but the preservation of the benzylidene group. There were quartets at τ 3.66 and 5.00 reminiscent of carbohydrate glycals (5), and this was supported by i.r. absorptions at 1645, 1235, and 1081 cm^{-1} indicative of a vinyl ether (6). The principal product of the Simmons–Smith reaction, the cyclopropanated glycoside **7α**, when subjected independently to the Simmons–Smith conditions afforded the iodoglycal, **4**. Proof for the latter structure was readily supplied by lithium aluminum hydride reduction whereby a substance displaying a methyl doublet at τ 8.86 ($J = 7.5$ Hz) was obtained. The latter was therefore **8**.

The foregoing discussion in fact indicates the presence but not the orientation of the iodomethyl group in **4**. The material underwent "instantaneous" silver-ion assisted methanolysis which afforded a 96% yield of crystalline material whose n.m.r. spectrum showed two methoxyl resonances of equal intensity at τ 6.61 and 6.53. The substances responsible were separated and identified as the cyclopropyl glycosides **7α** and **7β** respectively by comparison with the authentic substances (1, 7).[5] In view of the *allo* configuration of **7**, the iodomethyl group in **4** must be axial.

Further proof of structure **4** was obtained by transformation into the 3-epimer **5** as summarized in Scheme 2 (9).

Dehydroiodination of the iodoglycal **4** gave a diene **9** whose structure was upheld by absorptions in the i.r. at 3012, 1645, and 1600 cm^{-1}, (6) and in the u.v. at 243 nm, ε 4600 (*cf.* ref. 10). Methoxybromination of **9** (11) gave a single substance judged to be the α-D-1,4-addition product **10**, the anomeric configuration being indicated by the fact that the n.m.r. resonance



SCHEME I

[4]A detailed computer-assisted analysis of the 220 MHz n.m.r. spectra of the epimeric iodides **4** and **5** has been presented in Part IV of this series (4).

[5]The formation of the anomers **7α** and **7β** in equal amounts implies that there is no bicyclobutonium ion contribution to the intervening cyclopropylcarbinyl-oxo-carbonium ion, **1**, (8). The geometry of these ions will be discussed fully in a forthcoming publication.

for H-1 at τ 5.12 was closer to that for α-D-hex-2-enopyranosides (τ 5.0) than for the α-D-analogues (τ 4.6)(4*b*). Treatment of **10** with lithium aluminum hydride gave **11** whose allylic methyl group at τ 8.18 was weakly coupled to H-2 and -4.

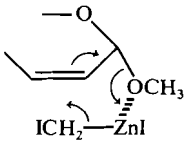
The allylic bromide **10** reacted readily with silver nitrate solution to give a mixture of **12** and **13** and spectral comparison of each (see Experimental) with the parent bromide indicated that there had not been any gross structural changes. Each substance on reaction with lithium aluminum hydride gave the 3-deoxy glycal **14**. Thus when compound **14** was the desired material, it was superfluous to separate **12** from **13**.

The structure of **14** rests upon the presence of a vinyl ether (μ_{max} 1645 cm^{-1}) (6) and the n.m.r. quartets at τ 3.73 (H-1) and 5.37 (H-2) (5, 12). The configuration at C-3 follows from the values for J_{13} and J_{23} (−2.5 and 2.0 Hz respectively) which are different from those (−1.3 and ~5.5) for allal derivatives **4** and **8** (4).[4] Chemical proof follows from the stereochemical course of lithium aluminum hydride reductive rearrangement of 2,3-unsaturated glycosides (*e.g.* **12** and **13**) since the hydride adds *syn* to the departing aglycon (13).

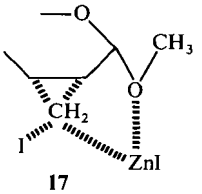
p-Toluenesulfonylation of **14** proceeded smoothly to give **15** which underwent iodinolysis in methylisobutyl ketone to the iodide **5**. This substance was identical in all respects to the material produced in 0.9% yield by Simmons–Smith reaction of compound **6**β (Scheme 1) (1). The overall yield in Scheme 2 was 20–25%. That **4** and **5** were indeed epimers was substantiated by treating the latter with methanolic silver nitrate, whereupon the diene **9** previously produced from **4** was also obtained.

Mechanistic Aspects of the Formation of Homoallyl Iodides in Simmons–Smith Reactions

Having established the stereochemistry of the original homoallyl iodide **4**, a question arose as to the mechanism of its formation during the Simmons–Smith reaction of **6**α (Scheme 1). The transformation depicted in its essence in **16** is the addition of the iodomethyl anion with synchronous expulsion of the allylic methoxyl substituent. This mechanism is attractive since it provides for the usually observed *cis* relationship between entering and departing nucleophiles (14). An additionally attractive feature is the fact that the reactive complex depicted in **16** is geometrically closely allied with that in **17** through which the major reaction (*i.e.* cyclopropanation) leading to the cyclopropyl glycoside 7α is thought to proceed (1, 15). Hence the organometallic agent, represented for simplicity as a monomer, (*cf.* ref. 16), approaches the double bond of **6**α and becomes ligated to the oxygen. Subsequent collapse of the complex can then lead either (*a*) to a cyclopropyl or (*b*) to a homoallyl compound. The latter eventuality requires that considerable *nucleophilic* character reside on the methylene group of the complex producing virtually ICH_2^-. The former eventuality suggests that the complex possesses electrophilic character more fully developed in $:CH_2$. The concept of nucleophilic character of the Simmons–Smith complex has been raised before (17), but was shown *not* to be operative in *cyclopropanation* reactions (18). However, the reaction under discussion here is not a cyclopropanation but a nucleophilic (S_Ni) displacement. The process does not appear to depend upon any special activation supplied by the lactol oxygen of **6**, for methylenation of 5,5-dimethylcyclohex-2-enol was found to be accompanied by small amounts of 3-(iodomethyl)-5,5-dimethylcyclohexene (19).

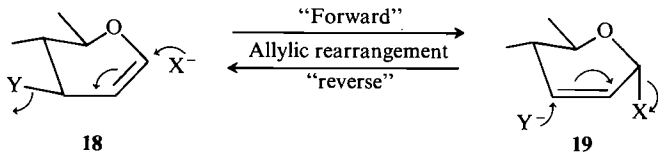


16



17

"Forward" allylic rearrangements whereby certain acetylated glycals (**18**, Y = OAc) are converted to hex-2-enopyranose derivatives (**19**) are well known in carbohydrate chemistry (20). However the "reverse" process had not been reported prior to the preliminary account (2) in which it was raised as a possibility. Since then there have been a number of interesting reports (13, 21) which may be generalized as "reverse" allylic rearrangements **19** → **18**. These reports support the possibility that such a rearrangement might be occurring in the present case. If a substantial O—Zn bond exists in the complex **16**, then the rearrangement may be appreciated as a simple [3:3] sigmatropic rearrangement

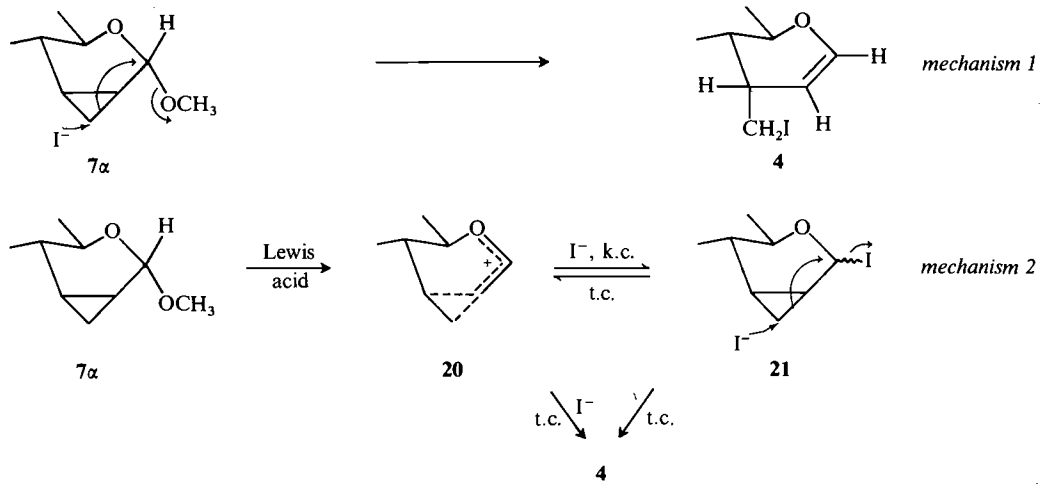


18 19

(22). The possibility that the "forward" allylic rearrangements (*vide supra*) may also fall into this mechanistic category has been discussed by Ferrier and Vethaviyaser (23).

The formation of iodide **4** from the cyclopropyl glycoside **7α** under the Simmons–Smith conditions suggests that some (if not all!) of compound **4** is formed by a mechanism different from the allylic rearrangement depicted in **16**. Four pathways shown in Scheme 3 may be envisaged starting with **7α**. The major difference between mechanisms 1 and 2 is the intermediacy in the latter of the cyclopropylcarbinyl-oxocarbonium ion **20** which might react under thermodynamic control (3*a*, 24) to give **4** directly, or under kinetic control to give the glycosyl iodide **21**. The latter would subsequently rearrange to the homoallyl iodide, **4**. The major difference between mechanisms 3 and 4 is the involvement in the former of 1 mol of methylene iodide. Some experiments were done to differentiate between these four mechanisms.

The conversion **7α** → **4** could not be accomplished by using sodium iodide in diethyl ether,



k.c., kinetic control; t.c., thermodynamic control

TABLE 1. Simmons–Smith reaction on compounds 7α and 7β under various conditions

Experiment	Initial period of reflux (h)*	Compounds added†	Products (% composition)‡			
			7α	7β	4	Unknown "a"§
1	1.0	7α	46	—	46	8
2	1.0	7β	50	12	30	8
3	1.0	7α, CH_2I_2	36	—	47	17
4	2.5	7α	57	—	28	15
5	2.5	7α, CH_2I_2	23	—	50	27
6	8.5	7α	69	—	—	31

*Zinc (0.1 g), methylene iodide (0.15 ml), a crystal of iodine, and 0.6 ml of ether were refluxed for the time shown in column.

†The substrate (0.1 g), 0.4 ml ether, and 0.15 ml of methylene iodide (as indicated) were added after the period of initial reflux, and reflux was then continued for a further 2 h.

‡Determined from the n.m.r. spectrum of the crude reaction product.

§For information on this substance see footnote 4 in ref. 1.

acetone, methylethyl ketone, or methylisobutylketone which indicates that *mechanism 1* cannot be operative. *Mechanism 2* may also be rejected since zinc iodide in a variety of solvents was also ineffective.

Evaluation of *mechanism 3* required the series of experiments summarized in Table 1. The initial reflux period of 1 h was selected because after this time an appreciable amount of ICH_2ZnI, the functioning agent in *mechanism 3*, has formed (25); the period of 2.5 h, because ICH_2ZnI has then just begun to react appreciably with methylene iodide to form, eventually, ethylene (25); and the period of 8.5 h, because at this time the ICH_2ZnI has virtually all decomposed (25). It can be seen from experiment 6 that the iodomethyl zinc complex is required for the formation of compound **4**. Experiments 1, 3, and 5 show that in order to obtain a 45–50% yield of compound **4** an appreciable amount of methylene iodide is required. Experiments 4 and 5 show dramatically the importance of methylene iodide. Thus the stature of mechanism 3 is enhanced and, by corollary, mechanism 4 is rendered unlikely.

An added requirement of *mechanism 3* is that there be *cis*-relationship between the anomeric methoxy group and the cyclopropane ring. This is indicated by comparison of experiments 1 and 2 (Table 1). Applying corrections for unrecovered starting material, iodide **4** is formed in 85% in experiment 1 but only 34% in experiment 2. In the latter, the principal reaction is anomerization of $7\beta \rightarrow 7\alpha$; it is therefore reasonable to conclude that the 34% of **4** in experiment 2 arose from 7α formed *in situ*. The formation of the D-*arabino* iodide **5** in 0.9% yield during the Simmons–Smith reaction of **6** (Scheme 1) may be envisaged as proceeding from **23**β via *mechanism 3*. Whether a "reverse" allylic rearrangement, such as **19**, is operative to any appreciable extent in the methylenation of **6**α or **6**β (Scheme 1) cannot be answered by means of the present data. Certainly *mechanism 3* would seem quite adequate to explain the formation of **4** and **5**. However, the recently reported "reverse" allylic rearrangements (21) suggest that this option should be kept open.

Experimental

For general experimental conditions see ref. 1. Unless otherwise stated, the n.m.r. spectra in this paper were taken on a Varian T-60 instrument and *J*-values are in Hz.

*4,6-O-Benzylidene-1,2,3-trideoxy-3-C-iodomethyl-*D*-ribo-hex-1-enopyranose (4)*

*(a) From Simmons–Smith Reaction of 6*α

Methyl 4,6-*O*-benzylidene-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside, **6**α, was subjected to the Simmons–Smith reaction as described in the accompanying paper (1) and silica column chromatography (1) afforded the title compound in 7.5% yield based on the starting olefin. The substance crystallized after evaporation of the eluant, and recrystallization from methanol afforded the pure sample, m.p. 130–132° $[\alpha]_D^{23}$ +129.0° (*c*, 2.8 in $CHCl_3$).

*(b) From Iodinolysis of Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-C-methylene-*α*-*D*-allopyranoside, 7*α

The addition of the reactants was done as indicated in Table 1. At the end of the reaction period the mixture was poured into a separatory funnel and washed with aqueous saturated ammonium chloride then sodium bicarbonate solution. The ether layer was dried and evaporated and the residue examined by n.m.r. The composition of the mixtures given in Table 1 was determined from the integrated in-

tensities in the spectra. The conditions in experiment 1 are optimum for the formation of the title compound **4**. The latter was recovered by silica column chromatography as used for the Simmons–Smith reaction product (1).

Anal. Calcd. for $C_{14}H_{15}IO_3$: C, 46.92; H, 4.22; I, 35.47. Found: C, 46.87; H, 4.22; I, 34.67.

The n.m.r. spectrum for **4** shows: τ 2.62 (m, 5, Ph), 4.43 (s, 1, PhC*H*), 3.66 (q, 1, $J_{12} = 6.2$, $J_{13} = -1.3$, H-1), 5.00 (q, 1, $J_{23} = 5.2$, H-2), 7.24 (m, 1, $J_{34} = 6.0$, $J_{37} = 11.0$, $J_{37'} = 4.0$, H-3), 6.00 (q, 1, $J_{45} = 9.5$, H-4), 6.21 (td, 1, $J_{56_a} = 10.0$, $J_{56_e} = 4.5$, H-5), 6.24 (t, 1, $J_{6_a6_e} = -10.5$, H-6a), 5.58 (q, 1, H-6e), 7.01 (q, 1, $J_{77'} = -9.5$, H-7), 6.37 (q, 1, H-7′). I.r. shows: μ_{max} 1645, 1235, and 1081 cm^{-1} associated with a vinyl ether (6).

*4,6-O-Benzylidene-1,2,3-trideoxy-3-C-methyl-*D*-ribo-hex-1-enopyranose, **8***

Compound 4 (0.1 g, 0.28 mmol) was treated with lithium aluminum hydride (0.1 g, 2.6 mmol) in refluxing diethyl ether (10 ml) for 18 h when t.l.c. indicated complete disappearance of the starting material. Customary work-up (1) gave a crystalline residue (0.05 g, 75% yield) which was recrystallized from methanol, m.p. 85–86° $[\alpha]_D^{23}$ +158.4 (*c*, 4.95 in $CHCl_3$).

Anal. Calcd. for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94. Found: C, 72.36; H, 6.88.

The n.m.r. spectrum of compound **8** shows: τ 2.60 (m, 5, Ph), 4.42 (s, 1, PhC*H*), 3.73 (q, 1, $J_{12} = 6.0$, $J_{13} = -1.3$, H-1), 5.22 (t, 1, $J_{23} = 6.0$, H-2), 7.43 (m, 1, $J_{34} = 6.0$, $J_{3CH_3} = 7.5$, H-3), 6.02 (q, 1, $J_{45} = 9.5$, H-4), 6.08 (td, 1, $J_{56_a} = 10.0$, $J_{56_e} = 4.5$, H-5), 6.23 (t, 1, $J_{6_a6_e} = -10.5$), 5.59 (q, 1, H-6e), and 8.86 (d, 3, CH_3).

Irradiation of the proton at τ 7.3 simplified the doublet at τ 8.86 to a singlet. The i.r. spectrum shows a strong absorption at 1645 cm^{-1} for a vinyl ether (6).

*4,6-O-Benzylidene-2,3-dideoxy-2,3-C-methylene-α and β-*D*-allopyranoside, **7α and 7β**.*

Compound **6**, (0.9793 g; 2.74 mmol), was dissolved in 75 ml of dry methanol; then 0.5 g of silver carbonate and 10 ml of saturated methanolic silver nitrate were added. Judging from the precipitated silver iodide, the reaction was complete in seconds but water (75 ml) was not added until 1 min later. The reaction product was recovered by extraction into chloroform which afforded 0.6851 g (0.00261 mol; 96%) of crystalline material. The n.m.r. spectrum of the substance showed two methoxyl absorptions at τ 6.61 and 6.53 of equal area. The two components were separated on a silica column (100 cm × 1.8 cm) eluted with petroleum ether (35–60°)–ethyl acetate (4:1). The slower running substance, **7α**, (0.2632 g) was identified by mixed m.p. (126–128 °C) and spectral comparison (1, 7).

The faster running component **7β**, (0.2135 g) was recrystallized from methanol, m.p. 92–93 °C $[\alpha]_D^{23}$ −8.0° (*c*, 3.06 in $CHCl_3$)

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92. Found: C, 68.73; H, 7.03.

The n.m.r. spectrum shows: τ 2.60 (m, 5, Ph), 4.37 (s, 1, PhC*H*), 6.53 (s, 3, OCH_3), 5.23 (bs, 1, $J_{12} = 1.0$) obtained from 220 MHz spectrum of H-2), H-1, 9.00 (m, 1, $J_{23} = 9.0$, $J_{27_{exo}} = 8.0$, $J_{27_{endo}} = 5.5$, H-2), 8.88 (m, 1, $J_{34} = 5.0$, $J_{37_{exo}} = 8.0$, $J_{37_{endo}} = 5.5$, H-3), 9.14 (td, 1, $J_{7_{exo}7_{endo}} = -5.5$, H-7*exo*), 8.93 (q, 1, H-7*endo*), 5.70 (q, 1, $J_{45} = 9.5$, H-4), 6.71 (td, 1, $J_{56_a} = 10.0$, $J_{56_e} = 4.5$, H-5), 6.29 (t, 1, $J_{6_a6_e} = -10.5$, H-6a), 5.78 (q, 1, H-6e).

*4,6-O-Benzylidene-1,2,3-trideoxy-3-C-methylene-*D*-erythro-hex-1-enopyranose, **9** (Scheme 2)*

(*a*) 4,6-*O*-Benzylidene-1,2,3-trideoxy-3-*C*-iodomethyl-D-*ribo*-hex-1-enopyranose, **4** (1.374 g; 0.00384 mol) was dissolved in 50 ml of dioxan, *N* sodium hydroxide solution (50 ml) was added; and the solution refluxed for 5 min. The solution was cooled then extracted with chloroform, which afforded 0.862 g (0.00374 mol; 97.4%) of crystalline compound **10**. The compound was recrystallized from ethanol: m.p. 98–100 °C; $[\alpha]_D^{23}$ +98.4° (*c*, 3.6 in $CHCl_3$).

(*b*) Methyl 4,6-*O*-benzylidene-1,2,3-trideoxy-3-*C*-iodomethyl-D-*arabino*-hex-1-enopyranose, **5**, (*vide infra*) (0.02 g) was treated with saturated methanolic silver nitrate (10 ml) for 1 h at room temperature. Precipitate formation was much slower than in the case of compound **6**. Water was added and the mixture was extracted with chloroform. The chloroform layer was washed with saturated sodium bicarbonate, dried, and evaporated under reduced pressure to give a crystalline material whose n.m.r. spectrum was identical to that given by the substance obtained in part *a*.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.02; H, 6.13. Found: C, 72.90; H, 6.38.

The n.m.r. spectrum of **9** shows τ 2.53 (m, 5, Ph), 4.30 (s, 1, PhC*H*), 3.60 (d, 1, $J_{12} = 6.0$, $J_{17} \leqslant 0.5$, $J_{17'} = 1.0$, H-1)[6] 4.53 (d, 1, H-2), 5.11 (bs, 1, H-7),[6] 4.91 (bs, 1, H′-7),[6] 5.67 (q, 1, J_{47} or $J_{47'} = 2.0$, $J_{45} = 8.0$, H-4), 6.06–6.21 (m, 2, $J_{56_a} = 10.0$, $J_{56_e} = 4.5$, H-5, H-6a), 5.60 (q distorted, 1, $J_{6_a6_e} = -10.5$, H-6e).

The i.r. spectrum shows: μ_{max} 3012 cm^{-1} (terminal = CH_2), 2849, 1645 (vinyl ether), 1600 (terminal = CH_2), 978, and 894 (terminal = CH_2) (6). The u.v. spectrum shows: λ_{max} (ethanol) 243 nm (ε 4600) (*cf.* 10).

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-C-bromomethyl-α-*D*-erythro-hex-2-enopyranoside, **10***

Diene **10** (0.862 g; 3.74 mmol) was dissolved in a mixture of dry methanol (100 ml) and silver acetate (0.5 g). Bromine (0.3 ml) was diluted to 10 ml with dry methanol, and added slowly with stirring until the solution had a persistent yellow color (8 ml) (11). The solution was poured into water (100 ml), filtered, and the filtrate extracted with chloroform. The chloroform layer was washed with saturated sodium bicarbonate solution, dried, and evaporated under reduced pressure to give the title compound. The material was recrystallized from ethanol, m.p. 119–122 °C with decomposition; $[\alpha]_D^{23}$ −7.35° (*c*, 16.32 in $CHCl_3$).

Anal. Calcd. for $C_{15}H_{17}BrO_4$: C, 52.80; H, 5.02; Br, 23.42. Found: C, 52.68; H, 4.81; Br, 23.21.

The n.m.r. spectrum of compound **10** shows: τ 2.63 (m, 5, Ph), 4.38 (s, 1, PhC*H*), 6.58 (s, 3, OCH_3), 5.12 (bd, 1, $J_{12} = 2.5$, H-1), 4.22 (bs, 1, H-2), 5.53–6.33 (m, 6, H-7, -7′, -4, -5, -6a, -6e).

Compound **10** decomposes readily at room temperature but may be stored in the freezing compartment of a refrigerator.

[6]The assignment of the exocyclic methylene protons as *trans* (H′-7, τ 4.91) and *cis* (H-7, τ 5.11) rests on the precedent that the five-bond coupling is larger for *trans* than for *cis* protons (26). Thus the couplings of 1.0 and ~0.5 Hz are assigned as *trans* ($J_{17'}$) and *cis* (J_{17}) respectively.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-C-methyl-α-D-erythro-hex-2-enopyranoside, 11

Compound **10** (0.2 g; 0.59 mmol) was dissolved in a mixture of diethyl ether (25 ml) and LAH (0.1 g) and refluxed for 15 h. The excess LAH was destroyed by the dropwise addition of water and then the aluminum hydroxide was filtered. The ether solution was dried and evaporated under reduced pressure and resulted in 0.1408 g of crystalline material. T.l.c. in petroleum ether (35–60 °C)–ethyl acetate (4:1) indicated the presence of several components. The mixture was put on a silica column (100 cm × 1.8 cm) and eluted with 4:1 petroleum ether (35–60 °C)–ethyl acetate. The first fraction (R_f 0.64) was starting compound **10** (0.02 g) and the second fraction (R_f 0.47) was compound **11** (0.097 g; 0.00037 mol; 63%). The other fractions contained impurities and were rejected.

Compound **11** was recrystallized from ethanol, m.p. 139–140 °C; $[\alpha]_D^{23}$ +60.6° (*c*, 4.15 in $CHCl_3$).

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92. Found: C, 68.56; H, 6.77.

The n.m.r. spectrum of compound **11** shows: τ 2.58 (m, 5, Ph), 4.40 (s, 1, PhC*H*), 6.57 (s, 3, OCH_3), 8.18 (s, 3, $J_{2CH_3} <$ 0.5 Hz, CH_3), 5.14 (bs, 1, $J_{12} = 2.5$, H-1), 4.57 (bs, 1, H-2), 5.96 (d, 1, $J_{4CH_3} < 0.5$, $J_{45} = 8.0$, H-4), 6.11 (m, 1, $J_{56_a} =$ 10.0, $J_{56_e} = 4.5$ (assumed), H-5), 6.20 (t, 1, $J_{6_a6_e} = -10.5$, H-6a), 5.70 (q distorted, 1, H-6e). Double irradiation experiments showed that the methyl group was coupled to both H-2 and -4 with coupling less than 0.5 Hz.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-C-(hydroxymethyl and O-nitromethyl)-α-D-erythro-hex-2-enopyranosides, 12 and 13 respectively

Compound **10** (1.0 g; 2.94 mmol) was dissolved in dioxane (50 ml) containing suspended silver acetate (1.0 g), and a solution of silver nitrate (5 g) in water (50 ml) was then added. The mixture was stirred for 6 h in the dark at room temperature and then filtered to remove silver salts. The filtrate was extracted with chloroform and the chloroform layers washed with saturated aqueous sodium bicarbonate solution and distilled water. The chloroform layer was dried and evaporated under reduced pressure and resulted in a syrup weighing 0.935 g. T.l.c. using petroleum ether (35–60 °C)–ethyl acetate (7:3) indicated two main components, R_f 0.43 and 0.09 which were separated on a silica column (10 cm × 1.8 cm) eluted with the same solvent mixture. The faster-running component (compound **13** 0.3397 g, 37%) came off first, and then the irrigant was changed to pure ethyl acetate to afford the second component (compound **12**, 0.4487 g; 55%).

The ratio of compound **12** to compound **13** could be varied by changing the reaction conditions. When compound **10** (1.05 g, 3.08 mmol) was treated with 50 ml dioxane, 25 ml water, 1 g silver acetate, and 5 g silver nitrate, the result was 0.279 g (32.5%) of compound **12** and 0.571 g (58%) of compound **13**.

Compound **12** was recrystallized from ethyl acetate, m.p. 120–122 °C; $[\alpha]_D^{23}$ +45.4° (*c*, 4.20 in $CHCl_3$).

Anal. Calcd. for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52. Found: C, 64.44; H, 6.32.

The n.m.r. spectrum of compound **12** shows: τ 2.60 (m, 5, Ph), 4.42 (s, 1, PhC*H*), 6.55 (s, 3, OCH_3), 7.97 (bs, 1, exchangeable, OH), 5.02 (bs, 1, $J_{12} = 2.5$, H-1), 4.27 (bs, 1, H-2), 5.53–6.30 (m, 6, CH_2—OH, H-4, -5, -6a, -6e). Double irradiation at τ 5.89 (—CH_2—OH) caused H-1 and -2 to become doublets with $J_{12} = 2.5$. The chemical shifts for H-1 and -2 are characteristic of 2,3-unsaturated sugars (5, 7).

Compound **13** was recrystallized from ethanol, m.p. 130–132 °C; $[\alpha]_D^{23}$ +35.7° (*c*, 6.0 in $CHCl_3$).

Anal. Calcd. for $C_{15}H_{17}NO_7$: C, 55.72; H, 5.30; N, 4.33. Found: C, 56.41; H, 5.13; N, 4.32.

A satisfactory elemental analysis for this reactive allylic nitrate, **13**, could not be obtained, but (*i*) the manner of its obtainment, (*ii*) the spectral similarities to **12**, and (*iii*) its subsequent reaction with LAH to give alcohol **14**, all indicate that the assigned structure is correct.

The n.m.r. spectrum of compound **13** shows: τ 2.58 (m, 5, Ph), 4.38 (s, 1, PhC*H*), 6.55 (s, 3, OCH_3), 5.06 (bs, 1, H-1), 4.13 (bs, 1, H-2), 5.05 (bd, 1, $J_{77'} = -13.0$, H-7), 4.84 (bd, 1, H-7′), 5.79 (bd, 1, H-3′), 5.79 (bd, 1, $J_{45} = 8.0$, H-4), 6.10 (td, 1, $J_{56_a} = 10.0$, H-5), 6.18 (t, 1, $J_{6_a6_e} = -10.5$, H-6a), 9.68 (m distorted, 1, H-6e).

4,6-O-Benzylidene-1,2,3-trideoxy-3-C-hydroxymethyl-D-arabino-hex-1-enopyranose 14, its p-Toluenesulfonate 15

(*a*) Compound **12** (0.262 g; 0.94 mmol) or compound **13** (0.340 g; 1.05 mmol) was dissolved in 60 ml of dry diethyl ether, lithium aluminum hydride (0.1 g) added, and the mixture was refluxed with stirring for 1 h. The excess LAH was destroyed with water and the mixture was filtered to remove the aluminum hydroxide. The ether layer was dried and evaporated under reduced pressure. Compound **12** yielded 0.204 g (87%) of compound **14** while compound **13** yielded 0.241g (92%) of compound **14**.

(*b*) Alternative to the foregoing, the mixture of compounds **12** and **13** obtained from solvolysis of **10** was purified by passage through a silica column (10 cm × 1.8 cm) using ethyl acetate as eluant and making no attempts at fractionation. LAH reduction of the eluted mixture (as described for the individual components) afforded compound **14** in ~90% yield.

The n.m.r. spectrum of compound **14** shows: τ 2.60 (m, 5, Ph), 4.68 (s, 1, PhC*H*), 8.02 (bs, 1, exchangeable, OH), 3.73 (q, 1, $J_{12} = 7.0$, $J_{13} = -2.5$, H-1), 5.37 (q, 1, $J_{23} = 2.0$ H-2), 7.35 (m, 1, $J_{37} = J_{37'} = 5.5$, H-3), 6.03–6.23 (m, 3, H-4, -5, -6a), 5.58 (q, 1, $J_{6_a6_e} = -10.5$, H-6e), 6.26 (m, 2, H-7, -7′). The i.r. spectrum shows: μ_{max} 1645 cm^{-1} (vinyl ether) (6).

Compound **14** was recrystallized from carbon tetrachloride, m.p. 138–140 °C; $[\alpha]_D^{23}$ −57.2 (*c*, 8.6 in $CHCl_3$). The material was converted to the *p*-toluenesulfonate for characterization by treatment with pyridine and excess tosyl chloride.

Compound **15** so obtained was recrystallized from methanol, m.p. 121.5–123 °C; $[\alpha]_D^{23}$ −50.5° (*c*, 5.20 in $CHCl_3$).

Anal. Calcd. for $C_{21}H_{22}O_6S$: C, 67.72; H, 5.51; S, 7.97. Found: C, 67.68; H, 5.54; S, 8.17.

The n.m.r. spectrum of compound **15** shows: τ 2.60 (m, 5, Ph), 4.50 (s, 1, PhC*H*), 7.62, 2.67, 2.17 (s, d, d, 3, 2, 2, *p*-tolyl), 3.62 (q, 1, $J_{12} = 7.0$, $J_{13} = -2.5$, H-1), 5.37 (q, 1, $J_{23} = 2.0$, H-2), 7.27 (m, 1, $J_{37} = J_{37'} = 5.0$, H-3), 6.07–6.57 (m, 3, H-4, -5, -6a), 5.82 (q, 1, H-6e), 5.82 (d, 2, H-7, -7′).

4,6-O-Benzylidene-1,2,3-trideoxy-3-C-iodomethyl-D-arabino-hex-1-enopyranose, 5

(*a*) Compound **15** (0.085 g); was dissolved in a solution of acetone (25 ml) and sodium iodide (1 g) and refluxed for 20 h. The reaction was followed by t.l.c. using 4:1 petroleum ether–ethyl acetate in which the R_f values of **15**

and **5** are 0.55 and 0.73 respectively. If the reaction was carried beyond 20 h there was considerable decomposition. Decomposition also occurred if compound **15** was not recrystallized at least once after its preparation.

The acetone was evaporated under reduced pressure, 10 ml of water was added, and the solution extracted with chloroform. The chloroform layer was dried and evaporated under reduced pressure. T.l.c. of the crystalline residue showed that there were traces of starting material and other impurities. The material was put on a silica column (10 cm × 1.8 cm) and eluted with 4:1 petroleum ether (35–60 °C)–ethyl acetate. The result was 0.050 g (67%) of the title compound.

Compound **5** was recrystallized from methanol, m.p. 100–102 °C; $[\alpha]_D^{23}$ −125.9° (*c*, 4.76 in $CHCl_3$).

Anal. Calcd. for $C_{14}H_{15}IO_3$: C, 46.94; H, 4.22; I, 35.43. Found: C, 46.84; H, 4.18; I, 35.10.

The n.m.r. spectrum of compound **5**[4] shows: τ 2.57 (m, 5, Ph), 4.38 (s, 1, PhC*H*), 3.55 (q, 1, $J_{12} = 7.0$, $J_{13} = -2.7$, H-1), 5.73 (q, 1, $J_{23} = 2.0$, H-2), 7.48 (m, 1, $J_{34} = 9.0$, $J_{37} = 6.2$, $J_{37'} = 3.5$, H-3), 6.20 (t, 1, $J_{45} = 9.0$, H-4), 6.10 (td, 1, $J_{56_a} = 10.0$, $J_{56_e} = 4.5$, H-5), 6.32 (t, 1, $J_{6_a6_e} = -10.5$, H-6a), 5.54 (q, 1, H-6e), 6.66 (q, 1, $J_{77'} = -10.0$, H-7), 6.56 (q, 1, H-7′).

The overall yield of compound **5** and **4** using the tosylate **15** for the last step was about 20–25%. The overall yield using compound **16** for the last step was 50–60%.

Financial assistance from the National Research Council of Canada and Bristol Laboratories of Syracuse is gratefully acknowledged. We express our gratitude to the staff of the Canadian 220 MHz NMR Centre for their assistance.

The Synthesis of some α-Cyclopropylcarbonyl Glycopyranosides[1]

BERT FRASER-REID AND BERNARD J. CARTHY[2]

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received May 1, 1972

The syntheses of three α-cyclopropylcarbonyl compounds of carbohydrate origin, **1**, **2**, **3**, are described. The cyclopropyl carboxaldehyde **1** was obtained from the corresponding carbinol by manganese dioxide oxidation of the primary alcohol. However, the secondary cyclopropyl alcohol in **8** did not respond to manganese dioxide and its oxidation (in the tritylated derivative (**14**), to the cyclopropyl ketone, **2**, had to be achieved by ruthenium tetroxide. The sequence leading to **2** (via **8**) began with ethyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside **11**, which added methylene to give the α-D-*allo* configuration with the cyclopropane ring *syn* to the glycosidic ethoxy group. The diastereomeric tritylated cyclopropyl ketone **3**, possessing the cyclopropyl ring *anti* to the ethoxy group, resulted from cyclopropanation of the αβ-unsaturated ketone, **15**. In the latter case, the acetoxy group apparently provides greater directing influence to the incoming methylene than does the allylic ethoxy group.

Les synthèses de trois composés α-cyclopropylcarbonyles d'origine carbohydrate, **1**, **2**, **3** sont décrites. Le cyclopropyl carboxaldéhyde **1** a été obtenu à partir du carbinol correspondant, par oxydation au dioxyde de manganèse de l'alcool primaire. Cependant, le cyclopropylalcool secondaire dans **8** ne réagit pas sur le dioxyde de manganèse et son oxydation (dans le dérivé tritylé **14**) en cyclopropylcétone **2** a dû être effectuée par le tétroxyde de ruthénium. La séquence conduisant à **2** (via **8**) commence avec l'éthyl di-*O*-acétyl-4,6 didéoxy-2,3-α-D-*érythro* hexeno-2 pyranoside **11**, qui par addition de méthylène conduit à la configuration α-D-*allo* avec le cycle cyclopropane en *syn* par rapport au groupe éthoxy glycosidique. La cyclopropylcétone tritylée diastéréoisomère **3**, avec le cyclopropyl en *anti* par rapport au groupe éthoxy, résulte de la cyclopropanation de la cétone αβ insaturée **15**. Dans ce dernier cas, le groupe acétoxy oriente apparemment de façon plus grande le méthylène qui entre, que ne le fait le groupe éthoxy allylique.

Canadian Journal of Chemistry, **50**, 2928 (1972)

α-Cyclopropylcarbonyl compounds undergo several unique rearrangements upon reaction in the ground (2) or excited (3) states, which make them very intriguing synthetic intermediates (4). These compounds caught our attention because of our interest in structural modification of the carbohydrate nucleus, and because they present a logical extension of our studies on cyclopropanated (5) and α,β-unsaturated carbonyl (6, 7) monosaccharides. We have therefore been concerned with some representative cases **1**, **2**, **3**, whose syntheses from readily available precursors we describe herein.

The cyclopropyl carboxaldehyde **1** was chosen as our initial objective since it ought to be readily available from the ester **5** via the alcohol **6**. Meyer zu Reckendorf and Kamprath-Scholtz reported the reaction of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside, **4**, with ethyl diethoxyphosphonylacetate (8) (Scheme 1).[3] The authors experienced some difficulty in isolating the expected product (methyl 2,3-

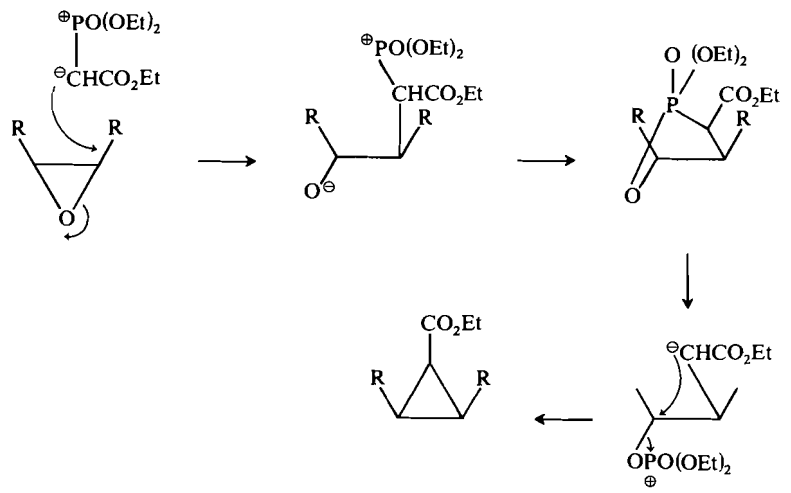

SCHEME 2

dideoxy-2,3-*C*-(*exo*-carbethoxy-*C*-methylene)-α-D-mannopyranoside, **5**) and because of this, the crude reaction product was saponified. The resulting acid was isolated and esterified with diazomethane to give the methyl ester **7**. In the present work the difficulty with isolation of the reaction product has been overcome and the ethyl ester **5** was obtained directly in crystalline condition from the product mixture in 54% yield.

The α-D-*manno* configuration of **7** had been assigned on the basis of the coupling constant, $J_{12} = 0$ Hz; and the *exo* orientation of the carboxy group, on the basis of the coupling constants ($J_{37} = 4.6$; $J_{27} = 5.0$ Hz) indicative of *trans* protons on the cyclopropyl ring (8). We assign the 7-carbethoxy substituent as *exo* on the basis of the proposed mechanism of Wittig cyclopropanation of epoxides (9) (Scheme 2). The α-carbethoxy carbanion intermediate would undoubtedly assume the least hindered orientation prior to the final ring closure leading to the cyclopropyl ring. Certainly the alternative addition leading to the 7-epimer of **5** would possess more severe non-bonded interactions for the *endo*-carbethoxy group. Lithium aluminum hydride reduction of **5** in ether for 15 min gave the known (8) alcohol **6** in quantitative yield.

We were interested to test the response of compound **6** to manganese dioxide oxidation in the hope of providing a model route from α-cyclopropyl alcohols to their carbonyl counterparts. This reaction is not without precedent (10) although it is rarely applied. In the event, treatment of the alcohol **6** in chloroform with manganese dioxide (11) afforded 23% conversion to the desired carboxaldehyde, **1**, recognized by its i.r. (1916 cm^{-1}) and n.m.r. (τ 0.83) data. That there had been no skeletal changes in going from **6** to **1** followed from the preserved n.m.r. parameters for H-1 (see Experimental).

In view of the success of the foregoing, an attempt was made to extend the oxidation to the secondary alcohol in **8** in the hope of obtaining ketol **9**. The cyclopropanated diacetate **10** needed to furnish the desired substrate **8**, was itself obtained *via* cyclopropanation (12) of the olefinic diacetate **11** (13). The conversion was only 27% effective judging from the n.m.r. spectrum of the crude product. Chromatography or recrystallization before or after deesterification gave, at best, a heavily contaminated sample of **8**. However, this was used for preliminary testing and it was found that **8** was in fact inert to manganese dioxide.

This failure could now be used to advantage. The entire reaction product from the incomplete cyclopropanation of **11** was deacetylated and the mixture now containing **8** and **12** was oxidized with manganese dioxide. The olefinic diol **12** went to ketone **13** (6) while **8** remained unchanged. Silica column chromatography now readily separated **8** from **13**.

Prior to attempting more vigorous oxidations, compound **8** was protected as the trityl ether **14**.

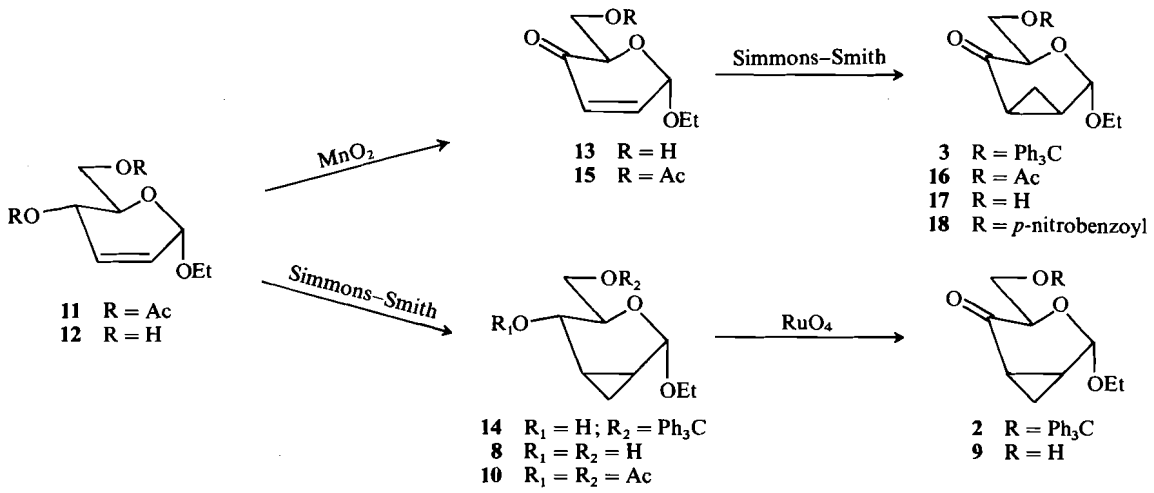
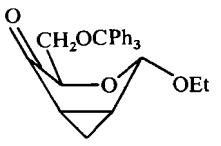


SCHEME 3

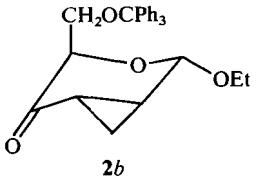
Dimethyl sulfoxide/acetic anhydride oxidation (14) proved too messy to be pursued. However, ruthenium tetroxide oxidation of **14** according to the procedure of Lawton *et al.* (15) proceeded smoothly to give ketone **2** in 80% yield based on unrecovered **14** (Scheme 3).

The assignment of *ribo*-configuration to the skeleton of **2** follows from its geneology. Judging from experience in this (16) and Horton's (17) laboratories, the addition of methylene during the Simmons–Smith reaction of **11** is expected to occur *syn* to the glycosidic alkoxyl, giving diacetate **10**. That this had been fulfilled was indicated by n.m.r. examination of the derived diol **8** in deuteriochloroform. The anomeric proton is a doublet whose spacing ($J_{12} = 5.0$ Hz) is exactly that observed in the analogous α-D-*allo*-cyclopropanated glycopyranosides reported previously (16). (Opposite orientation of the cyclopropane ring (*i.e.* the *manno*-configuration) causes a much smaller spacing ($J_{12} \simeq 0$) (16).) Tritylation (to **14**) and oxidation would not be expected to affect the configuration of the ring in the final product, **2**.

In the conversion of **14** to **2**, there is a substantial change in the spacing, J_{12}, for H-1 from 6.0 to 0 Hz. This reflects the extreme distortion of a pyranoside ring forced to accommodate an α-cyclopropyl ketone. Although the Karplus relationship might not apply to a system as strained as this (18), it may be noted that the conformation predicted by the value $J_{12} = 0$ Hz is that shown in **2***a* in which the dihedral angle between H-1 and -2 is 90°. Interestingly, in this arrangement the stabilizing conjugative p–π overlap between the C_2—C_3 bond and the carbonyl group (19) is a maximum. In an alternative conformation **2***b*, preserving the dihedral angle of 90° between H-1 and -2, the conjugative overlap would be between the C_3—C_7 bond and the carbonyl group. However, this conformation (**2***b*) is less favorable than **2***a* because it requires the bulky C-6 substituent to be axial.



2*a*



2*b*

In the hope of finding a more economical route to these cyclopropyl ketones, the ketone **15** described in an earlier report from this laboratory (6) was examined (see Scheme 3). Simmons–Smith (12) reaction was allowed to proceed for 2 h at which time a new substance formed in the reaction was present in optimum amount. Silica column chromatography afforded this substance as a syrup which showed cyclopropyl protons (τ 8.00–8.83) in the n.m.r. spectrum and carbonyl (1705 cm^{-1}) and acetate (1735 cm^{-1}) absorptions in the i.r. spectrum. The cyclopropane ring in the product could have either *ribo*-orientation (as in com-

For personal use only.

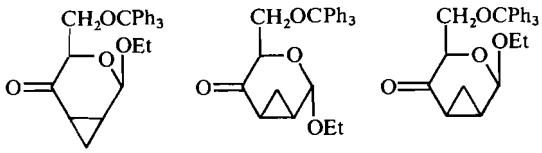
pound **2** described above), or *lyxo*-orientation. In order to determine which, the syrupy product (**16**) was de-esterified to give a non-crystalline ketol (**17**) which was immediately converted to a tritylate (**3**) so as to effect direct comparison with the other trityl ketone **2**. Neither **16** nor **3** crystallized, and so the material was characterized as the *p*-nitrobenzoate, **18**.

The two trityl ketones **2** and **3** gave different n.m.r. spectra. Although H-1 in both appeared as a singlet, it occurred at τ 4.45 in the former and τ 4.83 in the latter. In a recent publication from this laboratory (16) it was shown that a cyclopropyl group shields vicinal *cis*-oriented protons. This effect is again apparent here in the higher frequency of H-1 in **3**. On the assumption that the structure assigned above for **2** is secure, the new trityl ketone must have either (*i*) the β-D-anomeric arrangement of **2**, *i.e.* **19**; (*ii*) the α-D-*lyxo* structure already suggested in **3**; or (*iii*) the anomeric β-D-*lyxo*



19 **3** **20**

configuration of **20**. The β-D structures **19** and **20** would require, among other things, that the glycosidic ethoxy group of **15** be anomerized from $\alpha \rightarrow \beta$ orientation during the Simmons–Smith reaction. This would be highly unlikely, for although $\beta \rightarrow \alpha$ anomerization has been observed during the cyclopropanation of β-D-hex-2-enopyranosides, it was found that the converse process did not occur during cyclopropanations of the corresponding α-D olefins (16).

The difference in the stereochemical outcome of Simmons–Smith cyclopropanation of **11** and **15** is interesting. In the former, the incoming methylene adds *syn* to the ethoxy group as expected for cyclic six-membered allyl ethers (20). However, with **15** the directing influence apparently comes from the acetoxy group. Conceivably the ester-carbonyl group coordinates with the organo-zinc reagent causing addition *syn* to the C-5 acetoxymethyl group.

The study of access to and transformations of these and other cyclopropyl ketones is continuing and will be reported in due course.

Experimental

General

Melting points were determined on a Fischer–Johns heating stage and are uncorrected. The n.m.r. spectra were recorded using either a Varian T-60, a Varian HA 100, or a Varian HR 220 spectrometer, and unless otherwise specified, the solvent was deuteriochloroform containing 1% tetramethylsilane as internal standard. Coupling constants were obtained by measuring spacings of spectra judged to be first-order. The following abbreviations are used in describing the spectra: s, singlet; m, multiplet; d, doublet; t, triplet; q, quartet; td, triplet of doublets, etc. I.r. spectra were determined on a Beckman model I.R. 5 spectrometer using 0.1 mm sodium chloride solution cells (chloroform as solvent) and silver chloride plates for smears. Optical rotations were determined on a Carl Zeiss model LEP nur 370740 Lichtelektusches Prazisionpolarimeter at 546 and 578 nm at 23 °C, the two values obtained being used to calculate the optical rotation at the sodium D (589 nm) line.

T.l.c. was performed on glass plates coated with silica gel (HF-254, E. Merck) to a thickness of 0.3 mm. The chromatograms were first viewed under u.v. light, then exposed to iodine vapor, and finally sprayed with concentrated sulfuric acid. For column chromatography E. Merck Silica Gel (0.05–0.20 mm, 70–325 mesh A.S.T.M.) was used.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-C-(exo-carbethoxy-C-methylene)-α-D-mannopyranoside (5)[3]

A 50% oil dispersion of sodium hydride (11 g; 0.46 mol) was washed three times with petroleum ether (30–60°) to remove the oil, and was placed in a flask under dry nitrogen with 225 ml of dry dioxane. Ethyl diethoxyphosphoryl acetate (49.3 g; 0.22 mol) was added dropwise over a period of 1 h, after which time methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside, **4**, (21) (50 g; 0.22 mol) and a further 225 ml of dry dioxane were added. The whole was refluxed and stirred for 90 h, after which time the reaction was worked-up as follows. The reaction mixture was cooled to room temperature and poured into 500 ml of water. This aqueous solution was extracted twice with 500 and 300 ml portions of chloroform; the chloroform extracts were combined and were extracted with small volumes of water until the aqueous extract was no longer colored. The organic layer was dried (Na_2SO_4), filtered, and the solvent removed under reduced pressure. The crude reaction product was taken up in a small volume of diethyl ether and filtered to remove unreacted epoxide, yielding crude **5** (39.7 g; 54%). Recrystallization from absolute ethanol gave the pure material, m.p. 140–141 °C and optical rotation $[\alpha]_D^{23}$ +26.86° (*c*, 4.2 in chloroform).

Anal. Calcd. for $C_{18}H_{22}O_6$: C, 64.66; H, 6.63. Found: C, 64.63; H, 6.89.

The n.m.r. spectrum of compound **5** showed the following features: τ 5.13 (s, 1, $J_{12} = 0$ Hz, H-1), 7.77–8.45 (complex multiplet, 3H, H-2, -3, -8), ~6.3 (complex multiplet, 3H, H-4, -5, -6a), 5.68 (m, 1, H-6e), 4.43 (s, 1H, PhC*H*), 2.58 (m, 5, Ph), 8.73 (t, 3H, $J = 7.0$ Hz, $-OCH_2-CH_3$), 5.85 (q, 2H, $J = 7.0$ Hz; $O-CH_2-CH_3$), 6.60 (s, 3H, $-OCH_3$).

The i.r. spectrum shows μ_{max} 1720 cm^{-1}.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-(exo-hydroxymethyl-C-methylene)-α-D-mannopyranoside, 6

Compound **5** (1.002 g; 0.003 mol) was dissolved in 50 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of dry diethyl ether, and lithium aluminum hydride (1.0 g) was added. The reaction mixture was stirred and refluxed for 15 min, after which time the reaction was judged to be complete by t.l.c. The excess lithium aluminum hydride was destroyed by careful addition of water, and the inorganic salts were filtered. The solution was dried (Na_2SO_4), filtered, and the solvent removed to yield the title compound, **6**, (0.8665 g; 98.3%), m.p. 140–143 °C, (lit. 140–142 °C (8)) used without further purification.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-(exo-formyl-C-methylene)-α-D-mannopyranoside, **1***

Compound **6** (0.4108 g; 0.0014 mol) was dissolved in 250 ml of chloroform. Active manganese dioxide (11), 2.0 g, was added and the suspension was stirred at room temperature for 27 h, after which time the reaction was worked-up by removal of the manganese dioxide by filtration over Celite filter aid. The solvent was removed under reduced pressure to yield a product which was judged by i.r. spectroscopy to be a mixture of starting material and aldehyde **1**. Consequently, the mixture was chromatographed using 1:1 ethyl acetate–petroleum ether (30–60°) as eluent. This yielded 0.0931 g (23%) of compound **1** which was recrystallized from absolute ethanol to give a m.p. of 188.5–189.5 °C and optical rotation $[\alpha]_D^{23}$ +48.9° (*c*, 3.96 in chloroform).

Anal. Calcd. for $C_{16}H_{18}O_5$: C, 66.20; H, 6.25. Found: C, 66.06; H, 6.47.

The n.m.r. spectrum of compound **1** showed the following features: τ 5.10 (s, 1H, $J_{12} = 0$ Hz, H-1), 7.87–8.23 (complex multiplet, 3H, H-2, -3, -7), 6.37 (complex multiplet, 3H, H-4, -5, -6a), 5.73 (*q*, 1H, $J_{56e} = 4.0$, $J_{6a,6e} = -7.0$ Hz, H-6e), 4.48 (s, 1H, PhC*H*), 0.83 (t, 1H, $J = 2.0$ Hz, —C*H*O), 6.58 (s, 3H, OCH_3), 2.57 (complex multiplet, 5H, Ph).

The i.r. spectrum shows μ_{max} 1716 cm^{-1}.

*Ethyl 2,3-Dideoxy-2,3-C-methylene-α-D-allopyranoside, **8***

*(a) Cyclopropanation of Ethyl 4,6-di-O-acetyl-2,3-dideoxy-α-D-erythro-hex-2-enopyranoside, **11** (13)*

Zinc/copper couple (22) (5.0 g; 0.256 mol), methylene iodide (7.2 ml; 0.0896 mol), dry diethyl ether (30 ml; 0.288 mol), and a single crystal of iodine were stirred and refluxed under anhydrous conditions for 75 min. Compound **11** (10 g; 0.0388 mol) and a further 20 ml (0.192 mol) of dry diethyl ether were then added, and the reaction continued for 48 h, at which point the reaction was worked up, since n.m.r. spectroscopy indicated 50% conversion to the cyclopropanated compound. The cooled reaction mixture was washed twice with 50 ml of saturated aqueous ammonium chloride and once with 50 ml of saturated aqueous sodium bicarbonate. Both aqueous layers were washed once with water, dried (Na_2SO_4), filtered, and the solvent removed. The product, a mixture of starting material, **11**, and ethyl 4,6-di-*O*-acetyl-2,3-dideoxy-2,3-*C*-methylene-α-D-allopyranoside, **10**, weighing 12.2 g, could not be separated by recrystallization or conventional chromatographic techniques. Hence chemical separation was effected via steps *b* and *c* which follow.

(b) De-esterification of the Partially Cyclopropanated Product

The product (12.2 g) was dissolved in a mixture of methanol (71.0 ml), water (31.5 ml), and triethylamine (15.7 ml), and was allowed to stand for 8 h. At this point, t.l.c. indicated that deacetylation was complete, and the solvent was removed under reduced pressure to yield 7.42 g of a syrupy residue. Again, this mixture could not be separated by the usual techniques.

(c) Manganese Dioxide Oxidation

The de-esterified mixture (7.42 g) was dissolved in 4 l of chloroform and active manganese dioxide (11) (40 g) was added. The whole was stirred at room temperature, and after 12 h a further 40 g of manganese dioxide was added. The stirring was continued for a further 24 h, after which time n.m.r. spectroscopy indicated no further increase in the concentration of ketone **13**. The reaction was thus worked-up by filtration of the manganese dioxide and evaporation of the solvent. T.l.c. showed the product to be a complex mixture, partial separation of which was achieved by column chromatography. Ethyl acetate–petroleum ether (30–60°) 1:1 mixture, was used as eluent to remove the faster running fractions, followed by elution with ethyl acetate to recover pure compound **8** (0.9895 g; 27%) as an oil.

The n.m.r. spectrum of the title compound (**8**) showed the following features: τ 4.85 (d, 1H, $J_{12} = 5.0$ Hz, H-1), 8.53 (complex multiplet, 2H, H-2, -3), 6.20 (d, 2H, H-6, -6′), 9.32 (complex multiplet, 2H, H-7, -7′), 6.55 (s, 1H, O*H*), 8.78 (t, 3H, $J = 7$ Hz, —OCH_2CH_3), 6.60 (m, 2H, —OCH_2 —CH_3).

*Attempted Synthesis of Ethyl 2,3-Dideoxy-2,3-C-methylene-α-D-ribohexopyranosid-4-ulose (**9**) by Manganese Dioxide Oxidation of Ethyl 2,3-Dideoxy-2,3-C-methylene-α-D-allopyranoside (**8**)*

Compound **8** (0.453 g; 0.0024 mol) was dissolved in 250 ml of chloroform and active manganese dioxide (10 g) was added. The mixture was stirred at room temperature for 7 days, during which time a further 10 g of manganese dioxide was added periodically in small portions. After this time, the reaction was worked-up by removal of the manganese dioxide by filtration, followed by removal of the solvent. The n.m.r. spectrum of the product showed this to be unchanged **8**, whilst t.l.c. showed no high-running component which might correspond to the ulose **9**. I.r. spectroscopy showed no absorption in the carbonyl region.

*Preparation of Ethyl 2,3-Dideoxy-2,3-C-methylene-6-O-triphenylmethyl-α-D-allopyranoside, **14***

Compound **8** (0.8015 g; 0.0043 mol) was dissolved in 10 ml of dry pyridine, together with triphenylmethyl chloride (2.0 g, 0.0072 mol). After 17 h, crystalline material had deposited on the bottom of the flask and t.l.c. showed two spots, neither of which corresponded to the starting material **8**. The reaction mixture was dropped slowly into 25 ml of iced water, with constant stirring. A white amorphous solid formed during the addition. The supernatant liquid was decanted, and the solid triturated with saturated aqueous sodium bicarbonate. The aqueous solution was again decanted and the solid residue finally washed with a little water. Most of the triphenylcarbinol was crystallized out from diethyl ether–ethanol mixture. The mother liquors were evaporated to dryness and the residue was separated by column chromatography, eluting the column first with methylene chloride to remove the triphenylcarbinol, then with 1:1 ethyl acetate–petroleum ether (30–60°) mixture to recover the desired product (**14**). This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was an amorphous solid, 1.81 g (79.5%), optical rotation $[\alpha]_D^{23}$ +27.9° (*c*, 4.1 in chloroform), *m/e* 430.

The n.m.r. spectrum showed the following: τ 4.88 (d, 1H, J_{12} = 6.0 Hz, H-1), 9.02 (complex multiplet, 2H, H-2, -3), 9.38 (complex multiplet, 2H, H-7, -7'), 8.10 (s, 1H, —O*H*), 8.77 (t, 3H, *J* = 7.0 Hz, —OCH_2—CH_3), 2.98 (complex multiplet, 15H, Ph).

Satisfactory elemental analysis could not be obtained for this substance, but the assigned structure is correct in view of the subsequent transformation described immediately below.

*Ethyl 2,3-Dideoxy-2,3-C-methylene-6-O-trityl-α-*D*-ribo-hexopyranosid-4-ulose*, **2**

(a) Attempted Manganese Dioxide Oxidation

Compound **14** (0.200 g; 0.465 mmol) was dissolved in 100 ml of chloroform, active manganese dioxide (2 g) was added, and the whole stirred for 48 h, during which time two additional amounts of 1 g each of manganese dioxide were added. After this time, the reaction was worked-up by filtration of the solution, and removal of the solvent. Both i.r. and n.m.r. spectroscopy showed the product to be starting material **14**, with no trace of the desired 4-ulose **2**.

(b) Ruthenium Tetroxide Oxidation

Compound **14** (0.169 g; 0.393 mmol) in 2 ml of freshly prepared ethanol–free chloroform, 2 ml of water, potassium periodate (0.117 g; 0.510 mmol), and potassium carbonate (0.0226 g; 0.164 mmol) were stirred together with catalytic amount of ruthenium dioxide for 9½ h. At this time the reaction was worked-up by the addition of 5 ml of isopropyl alcohol, filtered to remove the ruthenium dioxide, and the organic layer separated. The aqueous layer was washed with a small amount of chloroform and the chloroform layers were combined, dried (Na_2SO_4), filtered, and the solvent was removed. T.l.c. showed the product to be comprised of two components, one being the starting material. These were separated by chromatography on a short column to yield pure ethyl 2,3-dideoxy-2,3-*C*-methylene-6-*O*-trityl-α-D-ribohexopyranosid-4-ulose, **2** (0.0807 g; 48%), which was recrystallized from ethyl acetate, m.p. 169–170.5 °C, $[\alpha]_D^{23}$ +33.20° (*c*, 2.36 in chloroform).

Anal. Calcd. for $C_{28}H_{28}O_4$: C, 78.48; H, 6.59. Found: C, 78.30; H, 6.38.

The n.m.r. spectrum of compound **2** showed the following features: τ 4.45 (s, 1H, J_{12} = 0 Hz, H-1), 8.03 (complex multiplet, 3H, H-2, -3, -7_{endo}), 5.85 (q, 1H, J_{56} = 2.0, $J_{56'}$ = 5 Hz, H-5), 6.73 (q, 1H, $J_{66'}$ = 10.0 Hz, H-6), 6.27 (q, 1H, H-6'), 8.73 (m, 1H, H-7_{exo}), 8.80, (t, 3H, *J* = 7.0 Hz, —OCH_2CH_3), 6.27 (complex multiplet, 2H, —OCH_2CH_3), 2.65 (m, 15H, Ph).

The i.r. spectrum shows μ_{max} 1703 cm^{-1}.

*Ethyl 2,3-Dideoxy-2,3-C-methylene-6-O-p-nitrobenzoyl-α-*D*-lyxo-hex-2-enopyranoside-4-ulose*, ***18***

Compound **16** (0.1911 g; 0.84 mmol) was dissolved in 10 ml of a 5:4:1 methanol–water–triethylamine mixture, and allowed to stand for 2¼ h. After this time, the liquids were removed by evaporation under reduced pressure to yield ethyl 2,3-dideoxy-2,3-*C*-methylene-α-D-*lyxo*-hexopyranosid-4-ulose, **17** (0.1451 g; 93%), which was taken immediately and treated with *p*-nitrobenzoyl chloride (0.300 g; 0.0016 mol) in dry pyridine. Subsequent work-up of this reaction yielded the title material, **18**, which was recrystallized from absolute ethanol, 128.5–129.5 °C, $[\alpha]_D^{23}$ +29.5° (*c*, 1.7 in chloroform).

Anal. Calcd. for $C_{16}H_{17}NO_7$: C, 57.31; H, 5.11; N, 4.18. Found: C, 57.29; H, 5.07; N, 4.16.

*Ethyl 2,3-Dideoxy-2,3-C-methylene-6-O-triphenylmethyl-α-*D*-lyxo-hexopyranosid-4-ulose*, **3**

The acetate **16** (0.0793 g; 0.35 mmol) was deacetylated as in the preceding section, and the resulting sample of **17** (0.0615 g) was dissolved in 5 ml of dry pyridine and treated with triphenylmethyl chloride (0.300 g; 1.08 mmol). After 2 days at room temperature, the reaction was driven to completion by heating on the steam bath for several minutes, after which t.l.c. showed no trace of compound **17** in the reaction mixture. Dropwise addition of 50 ml of ice-water caused a solid to form, which was removed by filtration and washed with saturated aqueous sodium bicarbonate, water, and then dried. Triphenylcarbinol in the product was removed by chromatography on a short column, eluting first with methylene chloride to remove the triphenylcarbinol and finally with ethyl acetate–petroleum ether (30–60°), 1:1 to obtain pure ethyl 2,3-dideoxy-2,3-*C*-methylene-6-*O*-triphenylmethyl-α-D-*lyxo*-hexopyranosid-4-ulose, **3**, (0.0446 g; 22%), a syrup, showing only one spot on t.l.c.

The n.m.r. spectrum of the title compound, **3**, showed the following features: τ 4.83, (s, 1H, H-1), 8.07 (m, 2H, H-2, -3), 5.97 (t, 1H, *J* = 4.5 Hz, H-5) 6.60 (m, 2H, H-6, -6'), 8.73 (m, 2H, H-7, -7'), 8.80 (t, 3H, *J* = 7.0 Hz, —OCH_2—CH_3), 6.37 (m, 2H, —OCH_2CH_3), 2.67 (m, 15H, Ph).

*Ethyl 6-O-Acetyl-2,3-Dideoxy-2,3-C-methylene-α-*D*-lyxo-hexopyranosid-4-ulose*, ***16***

Zinc/copper couple (22) (0.375 g; 0.0192 mol), dry diethyl ether (2.25 ml; 0.0216 mol), methylene iodide (0.537 ml; 0.0067 mol), and a single crystal of iodine were stirred and refluxed for 1 h. After this time, ethyl 6-*O*-acetyl-α-D-*glycero*-hex-2-enopyranosid-4-ulose, **15** (6) (0.642 g, 0.003 mol) was added, along with 1.5 ml (0.014 mol) of diethyl ether and the whole stirred and refluxed under anhydrous conditions for 2 h. After this period, n.m.r. analysis of an aliquot of the reaction mixture showed the reaction to be 70% complete. Preliminary experiments had shown that a signal at τ 4.88 (H-1 of the adduct) reached an optimum intensity at this time and depreciated thereafter. Hence ammonium chloride solution (5 ml) was added to the reaction mixture. The organic layer was separated, the aqueous layer washed with a small portion of ether and the combined ethereal solutions treated with saturated aqueous sodium bicarbonate. After separation and washing the aqueous layer with ether, the organic layer was finally washed with water, dried (Na_2SO_4), filtered, and the solvent removed. T.l.c. of this material indicated at least three components, one of which was the starting olefin, hence this material was chromatographed using 1:1 ethyl acetate–petroleum ether (30–60°) as eluent. This afforded 0.1321 g (22.4%) of pure **16** as a syrup $[\alpha]_D^{23}$ +74.3° (*c*, 5.16 in chloroform).

The n.m.r. spectrum of compound **16** showed the following features: τ 4.88 (s, 1H, H-1), 8.05 (m, 2H, H-2, -3), 5.87 (t, 1H, *J* = 5 Hz, H-5), 5.67 (d, 2H, H-6a, -6e), 8.37 (q, 1H, $J_{7endo} = J_{3endo} = 5.5$, $J_{7endo\ 7exo} = -5.5$ Hz, H-7_{endo})

8.88 (m, 1H, H-7$_{exo}$), 8.77, (t, 3H, $J = 7.0$ Hz, —OCH$_2$CH_3), 6.30 (m, 2H, —OCH_2CH$_3$), 7.95 (s, 3H, —O—CH$_2$—CH_3). The i.r. spectrum shows μ_{max} 1735 and 1705 cm^{-1}.

Determination of the Heat of Formation of Hexafluorobenzene

M. KRECH
Chemistry Department, Waterloo Lutheran University, Waterloo, Ontario

AND

S. J. W. PRICE AND W. F. YARED
Chemistry Department, University of Windsor, Windsor, Ontario

Received March 10, 1972

A new method has been developed for determining the heat of combustion of perfluoro aromatic compounds. The basic differences from previous methods are that no auxiliary substance is used and no water is present in the bomb. The combustion of hexafluorobenzene in a platinum lined bomb yields CO_2, CF_4, and F_2. Visual inspection and the material balance indicate that complete combustion is obtained. The value of $\Delta H^0_{f\,298}(C_6F_6,g)$ obtained by this method is -224.0 ± 2.0 kcal/mol. Recalculation of the result of Cox *et al.* (1, 2) obtained from combustion of C_6F_6 in mylar bags in the presence of hydrocarbon oil and water leads to $\Delta H^0_{f\,298}(C_6F_6,g) = -224.3$ kcal/mol.

Une nouvelle méthode a été développée pour déterminer la chaleur de combustion des composés aromatiques perfluorés. Les différences de base par rapport aux méthodes précédentes, sont l'absence de toute substance auxiliaire et d'eau dans la bombe. La combustion de l'hexafluorobenzène dans une bombe à revêtement de platine, conduit au CO_2, CF_4, et F_2. L'examen visuel et la balance pondérale indiquent une combustion complète. La valeur de $\Delta H^0_{f\,298}(C_6F_6,g)$ obtenue par cette méthode est -224.0 ± 2.0 kcal/mol. Le résultat de Cox *et al.* (1, 2) recalculé, donne $\Delta H^0_{f\,298}(C_6F_6,g) = -224.3$ kcal/mol, à partir de la combustion de C_6F_6 dans une enceinte étanche en présence d'huile d'hydrocarbure et d'eau.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2935 (1972)

Introduction

The determination of the heats of combustion of perfluoro aromatic compounds has received relatively little attention. Cox and co-workers (1) determined the heat of combustion of hexafluorobenzene in a platinum lined rotating bomb calorimeter using hydrogen-containing organic auxiliary substances. The value determined by Cox and co-workers for the heat of combustion of hexafluorobenzene in the ideal gas state was -220.4 kcal/mol. Based on a new value for $\Delta H_{f\,298}(HF.2OH_2O)$, this value was later revised to -228.4 kcal/mol (2).

The present paper describes the measurement of the heat of combustion of hexafluorobenzene in a platinum lined rotating bomb calorimeter without the use of any auxiliary substances. This work determines that complete combustion, substantiated by a product mass balance, makes it unnecessary to use any auxiliary substance and that the liquid hexafluorobenzene need not be contained in any manner but simply weighed into the platinum crucible.

Experimental

Hexafluorobenzene

The hexafluorobenzene used was obtained from Imperial Smelting Corporation and was analyzed by means of a thermal conductivity gas chromatograph using 6 ft × 1/4 in. o.d., polypropylene glycol column (110 °C, 60 cc/min He). The only detectable impurity was approximately 0.02% pentafluorobenzene.

Index of refraction at 25 °C, 1.3762 ($n_D^{25} = 1.3761$ (3)). Boiling point, 80.1 °C; freezing point, 5.2 °C (published values, 80 °C and 5.2 °C, respectively (3)).

A modified Ramsay–Young system was used to measure the vapor pressure of C_6F_6 over the range 8 to 62 °C. Approximately 80 vapor pressure measurements were made in four separate runs. The conventional plot of log p *vs.* $10^3/T$ was very slightly curved. The data are adequately represented by

$$[1] \quad \log P\,(\text{cm}) = 27.498 - 2{,}797.2/T - 6.945 \log_{10} T$$

The resulting heat of vaporization and average heat capacity difference (vapor − liquid) are $\Delta H^0_{298} = 8.69 \pm 0.02$ kcal/mol and $\langle \Delta C_p \rangle_{8-62\,°C} = -13.8 \pm 2.0$ cal deg^{-1} mol^{-1}. The error limits on ΔH are representative of the uncertainty in the precision only. The value of ΔH^0_{298} is in good agreement with the previously reported value (1), 8.65 kcal/mol. It is interesting to note that the boiling point of C_6F_6 is virtually identical to that of C_6H_6 and that the $\langle \Delta C_p \rangle$ value

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

over 8–62 °C is close to $\langle \Delta C_p \rangle_{25\,°C}$ for benzene, −13.0 cal deg^{-1} mol^{-1} (4).

Apparatus and Calorimetric Procedure

The rotating bomb calorimeter used was similar to that used in the Bureau of Mines Laboratory, Bartlesville (5). The combustion bomb was a platinum lined Parr Model 1004C bomb, 320 cc in volume. It was equipped with a geared rotating mechanism which rotated the bomb axially and end-over-end beneath the water in the calorimeter bucket.

The calorimetric jacket was maintained at 25.000 °C by using a Thermotrol Proportional Temperature Controller Model 1053 to balance the output of small heaters against cooling by a cooling coil supplied from a bath regulated to 16 ± 0.01 °C.

The rotating bomb calorimeter was used only as a matter of convenience. A static system of the same precision would have worked equally well provided it was equipped with a platinum lined bomb. A limited number of combustions was done in a static steel bomb but these combustions produced a green coloration on the inside of the bomb which was visual indication of the formation of compounds presumed to be iron fluorides.

The temperature of the water in the bucket was monitored by a 2000 ohm thermistor in conjunction with a Honeywell Wheatstone Bridge Model 1081 and a Leeds and Northrup D.C. Null Detector with variable sensitivity. The thermistor was calibrated against a Parr certified thermometer capable of being read to 0.001 °C. The resistance of the thermistor could be estimated to 0.01 ohm (about 0.0001 °C) with the null detector at low to moderate sensitivity. Time was measured and recorded on a Simplex timer capable of recording time to 0.01 min.

In a determination of the heat of combustion of hexafluorobenzene only the compound and oxygen were used in the bomb. Care was taken to insure that the interior of the bomb and the inner portion of the bomb lid were clean and moisture free. The sample of hexafluorobenzene to be combusted was weighed in a platinum crucible which was then placed in the gimbal which had previously been fitted with a weighed platinum fuse wire (12 cm long, 36 gauge) fixed to the terminals of the ignition circuit. The lid containing the crucible, compound, and fuse wire was then fitted into the bomb which was in an inverted position and the bomb was sealed by means of the screw cap and sealing bolts.

The length of time from taking the weight of the crucible and hexafluorobenzene to the insertion of the lid into the bomb was measured by means of a stopwatch to the nearest 0.1 s. The amount of hexafluorobenzene lost by evaporation could then be calculated from the rate of evaporation which was determined prior to each experiment. The time between weighing the crucible and compound and the closing of the bomb was such that evaporation of the compound was 0.5% of the total sample weight or less. The correction for evaporation is estimated to be accurate to within at least ±3%. The error in weight generated by the correction procedure therefore should be less than ±0.02% of the sample weight.

After a 15 min period during which the bomb achieved thermal equilibrium with the water in the calorimeter bucket, time and temperature readings were taken every 10–15 s for about 10 min. After this pre-run period, ignition was affected by discharging a pair of 250 mF capacitors charged to a measured voltage (approximately 140 V) and time and temperature readings were taken as often as every 0.05 min for the ensuing 25 min. Rotation of the bomb was started 3 min after ignition and was continued throughout the remainder of the calorimetric experiment.

A computer program was used to calculate the corrected temperature rise (6). The procedure used was based essentially on Dickinson's method (7, 8). The correction to standard states followed the method of Good and Scott (9). The energy equivalent of the calorimeter as determined using standard benzoic acid was 4250.9 ± 0.2 cal/deg.

Analysis of Reaction Products

Before analysis the lid of the bomb was thoroughly dried with special attention being given to the inlet and outlet valves so that no moisture was present. The bomb was then connected by means of Tygon tubing to an analysis train consisting of a Teflon bubbler, a drying tube containing magnesium perchlorate, a gas sample collection tube and a carbon dioxide collection vessel. The bomb outlet valve was opened and the gases were allowed to pass through the analysis train until all the gases had been emptied from the bomb. Analytical grade oxygen was then passed through the inlet valve of the bomb and into the analysis train for about 1½ h to flush the bomb of any remaining combustion products. The entire process of emptying the bomb and flushing with oxygen lasted approximately 16 h.

The solution from the bubbler was analyzed for F^- using a fluoride specific ion electrode in conjunction with an Orion Model 701 digital p*H* meter capable of reading relative millivolts to the nearest 0.1 mV. The 4 cc gas collection tube was removed periodically for analysis on a Perkin–Elmer 154D thermal conductivity gas chromatograph (6 ft × 1/4 in. o.d., silical gel column, 25 °C, He carrier 15 cc/min). When the gas collection tube was removed from the analysis train it was replaced with a short length of Tygon tubing. The chromatographic conditions used gave separation of the tetrafluoromethane peak from the massive oxygen peak and thus permitted a determination of the ratio of carbon dioxide to tetrafluoromethane. The carbon dioxide collection tube contained Lithasorb and magnesium perchlorate. It was evacuated to a constant weight prior to use in the analysis train and was again evacuated to a constant weight subsequent to the flushing procedure (through the magnesium perchlorate end to prevent loss of liberated water). Allowance was made for the small amount of carbon dioxide removed in the gas chromatography samples. Analysis of the gases at the exit of the carbon dioxide collection tube by gas chromatography did not show any carbon dioxide.

Results and Discussion

Gas chromatographic analysis of the gases contained in the gas collection tube gave peaks for CO_2, CF_4, and O_2. Both gas chromatographic and mass spectromatic tests failed to show even traces of F_2O. From Table 1 the average molar ratio of CO_2 to CF_4 is 4.54 ± 0.05 (omitting runs 1 and 3, ±0.02). It should be noted that a change of 0.01 in this ratio leads

11	1.373	0.8368	4.54	1.594		−223.2

*Molar ratio. Additional typical data (see ref. 7 for notation): ΔE, ign/cal = 2.41, ε(cal)$(-\Delta t_c)$/cal = −3706.79, $\Delta E^0_c/M$ (compound)/cal g^{-1} = −2628.36.

to a change in $\Delta H^0_{f\,298}(C_6F_6,g)$ of about 0.25 kcal/mol. Since only the relative amounts of CO_2 and CF_4 are important many of the possible errors normally associated with absolute gas chromatographic calibration are unimportant. However, in establishing the relative response of CF_4 it is important to use a CF_4–O_2 mixture whose composition is similar to that of the samples from the combustion experiment. Use of pure CF_4 leads to a response factor that is lower by 4.6%. The CO_2 calibration is unaffected. The net result is that if relative response factors determined with pure CF_4 and CO_2 are used a value for $\Delta H^0_{f\,298}(C_6F_6,g)$ is obtained that is about 5 kcal/mol too high.

Based on the observed products and the CO_2/CF_4 ratio the combustion reaction may be written

[2] $C_6F_6 + 4.917O_2 \rightarrow 4.917\ CO_2 + 1.083\ CF_4 + 0.834\ F_2$

The F_2 data in Table 1 average out to within 0.4% of the value predicted from this equation (if $CO_2/CF_4 = 4.53$ rather than 4.54, then exact agreement is obtained). In three of the nine runs in which CO_2 analyses were done the CO_2 yield is also in good agreement. In the other six runs the CO_2 yield was 0.8 to 1.6% low indicating a small loss of CO_2, possibly due to surges in flow which sometimes occurred when the bomb valve was opened too quickly.

In applying eq. 2 to the experimental combustion process it must be remembered that the C_6F_6 sample is not contained in any way and that combustion occurs in a 320 cc bomb with an initial temperature of 23.5 °C and an initial pressure of 450 p.s.i. The experimental procedure therefore involves the combustion of 0.30 g C_6F_6 vapor and $(W - 0.30)$ g C_6F_6 liquid where W = weight C_6F_6 sample in grams. This presence of just over 20% of the samples in the vapor state undoubtedly aids combustion and in fact is probably responsible for the fact that complete combustion is obtained in the absence of any auxiliary compound.

For calculation of $\Delta H^0_{f\,298}(C_6F_6,g)$ the standard heat of formation of the combustion products were taken as (10)

$$\Delta H^0_{f\,298}(CO_2,g) = -94.0517 \text{ kcal/mol}$$

$$\Delta H^0_{f\,298}(CF_4,g) = -221.0 \text{ kcal/mol}$$

and the required correction for the C_6F_6 in the liquid state, $[(W - 0.30)/W]\Delta H^0_{f\,298}(vap)$ was based on a heat of vaporization of 8.7 kcal/mol.

The average value of $\Delta H^0_{f\,298}(C_6F_6,g)$ obtained is -224.0 ± 2.0 kcal/mol. The previously reported values −220.4 (1) and −228.7 kcal/mol (2) were based on $\Delta H^0_{f\,298}(HF.2OH_2O) = -75.63$ and −76.96 kcal/mol, respectively. The NBS selected value (10) is −76.28 kcal/mol. A recent determination of the heat of solution of HF (11) lends strong support to this value. If the NBS value is used to recalculate the result of Cox *et al.* (1, 2) then a value of $\Delta H^0_{f\,298}(C_6F_6, g) = -224.3$ kcal/mol is obtained, a result in excellent agreement with the present work.

Although for the present, the NBS values for the heat of formation of CF_4 and HF are preferred, if for no other reason than the check for internal consistency made on all NBS data, both the present result and that of Cox *et al.* can also

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

be calculated using the slightly more recent value $\Delta H^0_{f\,298}(CF_4,g) = -223$ kcal mol^{-1} (12). This result leads to a value of about -76.35 kcal mol^{-1} for $\Delta H^0_{f\,298}(HF.2OH_2O)$. Based on these values the present value for $\Delta H^0_{f\,298}(C_6F_6$, g) becomes -226.0 kcal mol^{-1} and that of Cox *et al.* -225.1 kcal mol^{-1}.

In conclusion the present experimental method seems to provide a simpler and more direct method for determining the heat of formation of perfluoroaromatic compounds. Complete combustion is easily obtained without the aid of heat shields, auxiliary oils, etc. and a simple static bomb calorimeter should produce just as good a result as a rotating bomb system. With slight modification the procedure should be suitable for compounds of the type C_6F_5X where X is another halogen and also possibly for other related compounds.

Alkyl Shifts in Cyclohexenyl Cations

K. RAJESWARI AND T. S. SORENSEN
The Department of Chemistry, University of Calgary, Calgary, Alberta

Received February 22, 1972

The possible ways in which alkyl rearrangements can occur in cycloalkenyl cations are described. With cyclohexenyl cations, two rearrangements unique to this system are discussed and experimental evidence for both of these is presented. Use is made of the n.m.r. spin saturation transfer technique in one case.

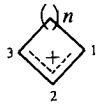
In the final part of the paper, we show how, by repeatedly using both rearrangements, it is possible in theory to scramble the relative positions of all of the carbon atoms with respect to both the different positions within a cyclohexenyl cation framework and with respect to the bonding order of consecutive atoms within the framework. In the unsubstituted case, this corresponds to a 360-fold degenerate rearrangement.

Les voies possibles de réarrangements d'alkyle dans les cations cycloalkényles sont décrites. Avec les cations cyclohexènyles, deux réarrangements uniques à ce système sont discutés et une preuve expérimentale pour chacun d'eux est présentée. Dans un cas, la technique de transfert de la saturation de spin en r.m.n. a été utilisée.

Dans la dernière partie du mémoire, nous montrons comment, par l'usage répété de ces deux réarrangements, il est possible en théorie de bouleverser les positions relatives de tous les atomes de carbone par rapport à ces deux positions différentes à l'intérieur du squelette cyclohexènyle cation et par rapport à l'ordre de liaison des atomes consécutifs du squelette. Dans le cas du squellette non-substitué, cela donne un réarrangement dégénéré d'ordre 360. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2939 (1972)

In cycloalkenyl cations in general, the highest positive charge density is located at the C-1 and -3 positions, a lesser amount at C-2, and even less on the remaining saturated carbon atoms (n) of the ring.



Since alkyl groups stabilize a positive charge, it follows that the most stable alkyl-substituted cations will be those in which the alkyl groups occupy the C-1, -2, and -3 positions. In other words, the most stable monoalkyl cation will be the C-1 or -3 alkyl derivative; for a dialkyl, the C-1,3 derivative, and for a trialkyl, the C-1,2,3 derivative. In those cases where sufficient alkyl groups are present within the ring system but are not located at these centers, the molecules are presented with a tantalizing problem in somehow "moving" the substituents. In a case where $n = 1$, such an operation can be accomplished directly by well-known 1,2-alkyl or hydride shifts,[1] for example, reaction Scheme 1 would be expected. Even in the $n = 2$ case, the process is reasonably efficient and the intermediacy of the 3-cyclopenten-1-yl cation **1** is involved (1–3).

1

The symmetry of this cation (in an unsubstituted case) is an important feature here since one can return to the conjugated cycloalkenyl cation by a different pathway. For example, the rearrangements shown in Scheme 2 are probable. In both the cyclopentenyl and cyclohexenyl cations (but not likely in the cyclobutenyl for obvious reasons) one can sometimes have effective alkyl rearrangements which operate via a base-catalyzed proton loss to give an intermediate diene which can then reprotonate at the opposite end (4–7). However, if one uses a strong enough acid system, it is generally possible to damp this process and in the present experiments, strong acid conditions apply.

When one comes to consider the $n = 3$ (cyclohexenyl) case, the situation becomes more involved. A normal 1,2-substituent shift produces an intermediate which may be considered as a homoallylic cation **2** or as a 2-bicyclo[3.1.0]hexyl cation **3** (a cyclopropylcarbinyl system) (8) (see

[1]The discussion here centers on thermodynamics. In some cases, the rates of these shifts may be quite different because of favorable or unfavorable steric or electronic factors.

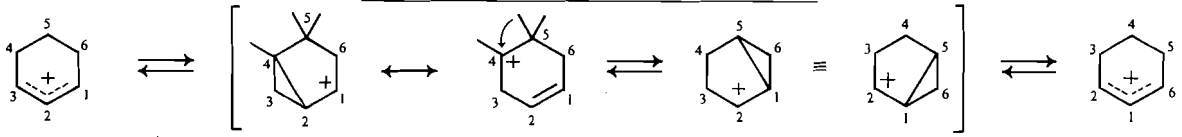
Process 2: Degenerate C-5,4(6) Substituent Shift[3]



SCHEME 4

Scheme 3). One might get rearrangements in a quite analogous way to that shown for the cyclopentenyl cation case (H shift pathway). In addition to this however, we have recently suggested (9) that intermediates **2** and/or **3** can undergo two kinds of degenerate rearrangements (in the absence of substituents) and that where substituents are present to lift this degeneracy, effective alkyl rearrangements take place. The two processes are shown in Scheme 4, with the atoms keeping their original numbers to indicate what happens in the degenerate rearrangement. Simply for brevity of presentation, the intermediate is pictured as a cyclopropylcarbinyl cation system in both cases. The unique differ-

[2]Only one of two possibilities is shown, *i.e.* migration of either the C-4 or -6 substituent produces the intermediate. No mechanistic details are implied by the formulations. There are in fact some grounds for believing that the process may be a "two-step shuffle".

[3]A resonance formulation of the cyclopropylcarbinyl cation system is employed here to make the electron "bookkeeping" during the rearrangement more obvious.

4 5

SCHEME 5

entiating feature of the first rearrangement is that consecutive atoms in the ring become interchanged.

These mechanisms were postulated in earlier work (9) to explain several puzzling methyl group arrangements which were found in the product cyclohexenyl cations derived from some cyclopropylallyl cation rearrangements. The evidence was indirect since we were never able to observe directly a methyl-substituted cyclohexenyl cation actually rearranging by either of these processes.

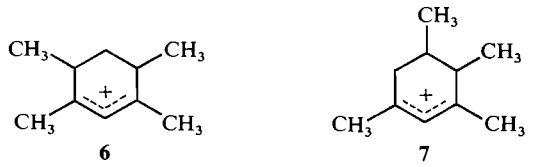
In the present paper, we describe cation rearrangements which we believe are due to these two processes. The rearrangements are inferred by the very specific way in which alkyl groups are "moved" in the directly observable cyclohexenyl–cyclohexenyl cation rearrangements. In the present examples, the extent of the alkylation at the C-1, -2, and -3 positions of the cyclohexenyl cations is not changed but the validity of the postulates is in no way negated by this fact. Actually, this may be the reason that these rearrangements could be observed at all (*i.e.* otherwise too fast to measure) in our systems since an added driving force may exist when, because of increased alkyl substitution at the active centers, a more stable cation is being formed.

Process 1, Scheme 4

At low temperatures (*ca.* $-90°$), cation **4** can be directly observed by n.m.r. spectroscopy, but on warming to $-50°$, is converted to the isomeric species **5** (Scheme 5). This rearrangement is readily observed because the C-5 methyl peak in **5** is at a characteristically high field.[4] The geometry of the C-4 and -6 methyl groups in **4** is not known with certainty but an unequal doubling of some n.m.r. peaks was observed. This doubling could be due to the presence of both the *cis* and *trans* isomers of **4** or by the "freezing out" of non-equivalent axial–equatorial pairs of a predominantly *trans* form (12). The former situation seems more likely (with the *cis* isomer probably predominant). In the formation of **5**, a similar doubling was fleetingly observed but the spectrum rapidly reduced to one interpretable in terms of a single isomer, presumably that with the *trans* geometry. The rearrangement **4** → **5** is explicable in terms of Process 1 although one is not certain why cation **5** should be more stable.

Process 2, Scheme 4

As the cation **5** solution is further warmed, an n.m.r. line broadening just becomes observable ($-10°$) before a further irreversible rearrangement occurs to give cations **6** and **7**. In these



6 7

circumstances, the n.m.r. spin label method of Forsén and Hoffman (13, 14) is invaluable in deciding what n.m.r. exchange processes are actually occurring. The spectrum of cation **5** is described in Fig. 1. At $-10°$, irradiation of the

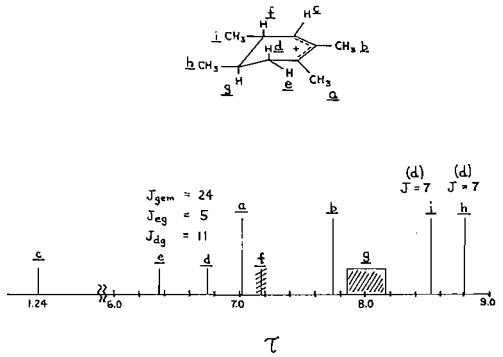


FIG. 1. Schematic n.m.r. spectrum of cation **5**.

Comments: The positions of the *f* and *g* protons were located by noting where the maximum decoupling occurred in the *h* and *i* methyl doublets. Both *f* and *g* give complex peaks which could not be interpreted in detail. The protons *d* and *e* are assigned the above positions and coupling constants. The J_{gem} value seems rather high and one cannot be very certain of this particular assignment except to say that this region in general is certainly due to *d* and *e*. The specific assignment of *d* and *e* is made on the basis of the magnitude of the vicinal coupling constants apparently observed.

[4]The chemical shifts of these alkyl groups are generally a function of their bonded distance from the cation centers (10, 11).

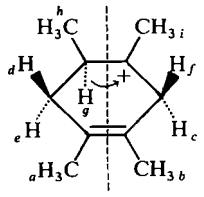
d and *e* protons region causes a marked decrease in the *c* proton peak area and irradiation at the *a* methyl causes a marked decrease in the *b* methyl peak area and vice-versa. Other exchanges could not be studied because the presumed exchanging groups are located too close together for this technique to be workable. The *d* and *e* protons peak area covers a wide frequency range and the maximum decrease in the *c* proton area appeared to occur when the lower field portion (assigned the equatorial position *e*) was irradiated.[5] It therefore appears that the *c* and *e* protons are actually involved in this exchange. This degenerate rearrangement is ascribed to Process 2 and the complete group exchange expected is shown below:

$$\left[\begin{array}{c|c} a & b \\ c & e \\ d & f \\ h & i \\ & g \end{array}\right]$$

The proton *g*, although migrating in each sequence, treadmill-like stays the same.

If protons *c* and *e* are exchanging then the process is rather stereospecific. The following structure (see footnote 3) shows the step in which *c* and *e* become equivalent. This then requires that the original migrating proton *f* stay on the top side of the molecule ($f = d$).



The results and discussion to this point have been concerned primarily with the experimental evidence that Processes 1 and 2, Scheme 4, can occur, at least in the specific cases discussed here, and on the way in which these rearrangements (singly) can then produce "effective" alkyl shifts within the cations. The overall sequence shown in this work can be written:

$$\mathbf{4} \xrightarrow{\text{Process 1}} \mathbf{5} \xrightarrow{\text{Process 2}} \mathbf{5'}$$

[5]The irradiating frequency is quite wide so that the effect of small changes in the center of the irradiating frequency is not large.

Although the previous discussion has emphasized the individual nature of each process it is of interest to examine theoretically the intriguing possibility that multiple rearrangements may occur in some cases (although not in the examples studied here; see later). For this theoretical discussion we will use the unsubstituted cyclohexenyl cation and one is therefore describing degenerate rearrangements.

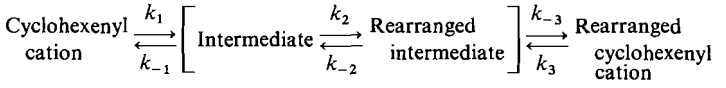
Theoretical Consequences of Multiple Rearrangements

Each single rearrangement process involves a minimum of three distinct steps with the first and last probably symmetrical. The way in which multiple rearrangements might occur is critically dependent on the rate constants k_1, k_2, k_{-1}, and k_{-3}, the latter two being assumed to be very similar (see Scheme 6). Two limiting situations might arise:

(1) k_2 *and* $k_{-2} \gg k_{-1}$ *or* k_{-3}. In this case, the intermediate would undergo multiple rearrangements before returning to the cyclohexenyl cation. If one alternates the Processes 1 and 2, a 12-fold degenerate rearrangement of the intermediate can be predicted to occur in an unsubstituted case (shown in Fig. 2). Each intermediate could exit to a "different" cyclohexenyl cation and then begin a "different" cycle.

(2) k_{-1} *or* $k_{-3} \gg k_2$ *and* k_{-2}. This is perhaps more likely and in this case, only one intermediate rearrangement, at best, would occur for each k_1 step. However, in an unsubstituted cyclohexenyl cation, one might still get degenerate rearrangement cycles because of the symmetry of this cation. A sequence of Process 1 steps gives five degenerate cyclohexenyl cation structures while a sequence of Process 2 steps gives six degenerate structures (Fig. 3). A combination of the two would allow the formation of all 360 possible degenerate "structures" for the parent cyclohexenyl cation. Whether these reactions occur in the unsubstituted cyclohexenyl cation will have to await labelling experiments.

With alkyl substituents certain "structures" will represent energy minima and effectively quench a multiple process regardless of the actual kinetics of the individual steps (*i.e.* either limiting situation could apply). We believe the results of this paper nicely illustrate this principle. In the situation shown in Scheme 7, cations **4** and **5** can only break out of the box by



SCHEME 6

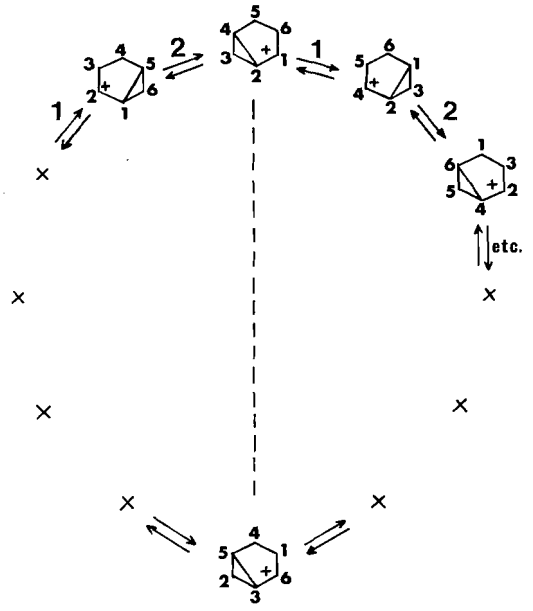


FIG. 2. Degenerate rearrangement cycle of a 2-bicyclo-[3.1.0]hexyl cation. The diagonal structures correspond to the complete reversion of the carbons 1–6, 2–3, and 4–5 diatomic fragments. The cyclopropane ring is "up" in all cases.

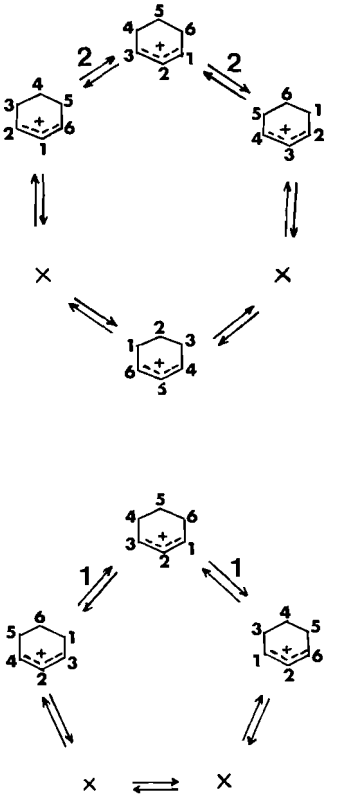

FIG. 3. *Lower:* Degenerate rearrangement cycle of a cyclohexenyl cation using Process 1, Scheme 4. The cycles require the hydride migration, *i.e.* from equivalent C-4 or -6 sites in the upper structure, to alternate in order to produce the cycle.

Upper: Degenerate rearrangement cycle of a cyclohexenyl cation using Process 2, Scheme 4. The same comments as in Process I apply.

forming the intermediates **10** and **11** and then having these rearrange by either Process 1 or 2. These intermediates would be of higher energy than **8** or **9** because of less substitution at the charged centers. We would predict that this sort of behavior would be typical of alkylsubstituted cyclohexenyl cations in general.

Experimental

Preparation of the Cations

Cation **4** was generated by the addition of 2-(α-methylcyclopropyl)-3-methyl-3-*cis*-penten-2-ol to fluorosulfonic acid–sulfuryl chlorofluoride (1:4) at −130° and then allowing the solution to warm to −90°.[6] The n.m.r. peaks of ions **4**, **6**, and **7** are reported in Table 1. Although these cations are unreported, the spectra of a number of similar cyclohexenyl cations have been (9, 11, 12), making the assignments relatively straightforward.

[6]To be published separately. Similar cyclopropylallyl cation rearrangements have previously been reported in ref. 9.

Spin Saturation Transfer Experiments

All n.m.r. spectra were recorded using a Varian Associates HA-100 spectrometer equipped with standard decoupling equipment and a variable temperature probe. Speed of operation was essential in the spin saturation experiments since the cation **5** was disappearing rapidly (to **6** and **7**) at the temperatures used for the experiments (from −10 to −30°). The formation of **6** and **7** made a quantitative measure of the rate difficult and necessitated using fresh solutions frequently. The usual precautions in the spin saturation procedure were used (14). It was not possible to irradiate proton *c* and monitor the proton *e* region since *c* is too close to the acid proton internal lock. Several different tempera-

Received February 17, 1972

The results of a study of the electronic absorption spectrum of cobalt(II) in Li_2SO_4–DMSO solution, an equimolar $NaHSO_4$–$KHSO_4$ melt, a eutectic melt of Li_2SO_4–Na_2SO_4–K_2SO_4, single salt melts of Li_2SO_4 and Na_2SO_4 and a doped single crystal of $K_2Zn_2(SO_4)_3$ have been combined with previous results in sulfate media; all the results can be explained in terms of a blue dodecahedral $[Co(O_2SO_2)_4]^{6-}$ species, a pink octahedral $[Co(OSO_3)_6]^{10-}$ species or an equilibrium mixture of the two.

Nous avons combiné les résultats d'une étude par spectroscopie d'absorption électronique du cobalt(II) en solution dans une solution Li_2SO_4–DMSO, un mélange équimolaire de $NaHSO_4$–$KHSO_4$ fondu, un mélange eutectique de Li_2SO_4–Na_2SO_4–K_2SO_4 fondu, des sels fondus tels Li_2SO_4 et Na_2SO_4 et un cristal contaminé de $K_2Zn_2(SO_4)_3$, avec des résultats ultérieurs en milieu sulfate; les résultats s'expliquent tous en termes de spécimens dodécaédriques bleus $[Co(O_2SO_4)_4]^{6-}$ octaédriques roses $[Co(OSO_3)_6]^{10-}$ ou d'un mélange des deux à l'équilibre. Introduction

Previous investigations of the electronic absorption spectrum of cobalt(II) in sulfuric acid solutions (1–3), a sodium hydrogen sulfate–potassium hydrogen sulfate glass and melt (2), a potassium sulfate–zinc sulfate glass (2, 4, 5), and several sulfate melts (4, 6) have led to the conclusion that several distinct sulfato complexes of cobalt(II) exist. In concentrated sulfuric acid and the hydrogen sulfate glass at room temperature Duffy and co-workers (1, 2, 7) characterized a low-temperature, pink, octahedral species which, they suggested, contained monodentate ligands. The same workers have argued that on heating the sulfuric acid solution and the hydrogen sulfate glass the sulfate groups changed from unidentate to bidentate behavior, thus forming the high-temperature, violet, octahedral species $[Co(O_2SO_2)_3]^{4-}$; this has also been claimed to exist in the potassium sulfate–zinc sulfate glass at room temperature (5). In the sulfate melts we have characterized a blue species which we believe to be a tetra-sulfato complex involving bidentate sulfate ligands producing an essentially dodecahedral complex (4). A distorted octahedral species has also been postulated to exist in sulfuric acid solutions (3). None of the postulated structures of these four species have been confirmed by independent means. In this paper, we present the results of further work on cobalt(II) complexes in sulfate environments which provides a complete characterization of the low-temperature pink species. Furthermore, we have discovered the existence of several equilibria which, we believe, allow all the results available at present to be explained in terms of an equilibrium mixture of only two species.

[1]Present address: Centre for Materials Science, University of Birmingham, Birmingham, B15 2TT, England.

Experimental

Absorption spectra were recorded with a Cary 14H spectrophotometer having the furnace assembly and temperature control system described by Griffiths and Scarrow (8).

Anhydrous lithium sulfate was prepared by heating Analar $Li_2SO_4 \cdot H_2O$ at 200 °C for 24 h. Analar grade sodium sulfate and potassium sulfate were also dried in this manner and used without further purification. The ternary alkali sulfate eutectic melt was prepared as previously described (6). The equimolar sodium hydrogen sulfate–potassium hydrogen sulfate melt was prepared by the method used by Duffy *et al.* (2). We were unable to

obtain hydrogen sulfate glasses of sufficiently high quality to make accurate spectral measurements worthwhile.

The dimethylsulfoxide–lithium sulfate solution, approximately 0.4 *M* in sulfate, was prepared from reagent grade dimethylsulfoxide and anhydrous lithium sulfate. Cobalt(II) was added as the anhydrous sulfate, the concentrations being such that the $Co:SO_4^{2-}$ ratio was 1:20. Similar solutions containing sodium and potassium sulfates were also examined but did not show the same spectral changes as the lithium sulfate system. This difference was almost certainly due to the much lower solubilities of the sodium and potassium sulfates in dimethylsulfoxide.

A single crystal of cobalt-doped $K_2Zn_2(SO_4)_3$ was grown from the melt by the Stockbarger technique.

Results and Discussion

In the present study the visible region electronic absorption spectrum of cobalt(II) in molten lithium sulfate, molten sodium sulfate, an equimolar melt of sodium hydrogen sulfate and potassium hydrogen sulfate, a eutectic melt of lithium sulfate–sodium sulfate–potassium sulfate, a dimethylsulfoxide solution in which a large excess of anhydrous lithium sulfate had been dissolved, and a doped single crystal of $K_2Zn_2(SO_4)_3$ have been examined. The results, together with all the previously published spectra of cobalt(II) in sulfate media, are collected in Table 1. A close examination of the table shows that the results can be divided into four classes as indicated in the last column of the table.

Comparison of the spectrum of the cobalt-doped single crystal of $K_2Zn_2(SO_4)_3$ to the room-temperature spectra of cobalt(II) in the hydrogen sulfate glass, 98% sulfuric acid and the lithium sulfate–dimethylsulfoxide solution shows that in all four environments the cobalt species are identical. These systems give rise to a Class 1 spectrum which consists of a broad, relatively weak, band centered at 18.4 kK with a shoulder at higher energy (20.5–20.8 kK) and a very much weaker band at lower energies (12.0–13.3 kK); it is often difficult to determine the position of the last band precisely, as it is usually overlapped by the main band. Now, a crystal-structure determination of langbeinite, $K_2Mg_2(SO_4)_3$ (10), has shown that in this compound each sulfate group is bonded to three different magnesium atoms and each magnesium is octahedrally surrounded by six sulfate groups. Since both the zinc and cobalt analogs of langbeinite are known to be isomorphous with the parent compound, our single crystal spectrum can be confidently assigned to an octahedral $[Co(OSO_3)_6]^{10-}$ species in which the sulfate ligands are unidentate with respect to the cobalt. In the protonic media it is unlikely that all the ligating groups would be sulfate. We should certainly expect that in the hydrogen sulfate glass the ligating group would be HSO_4^-, whilst in concentrated sulfuric acid solutions SO_4^{2-}, HSO_4^- and, perhaps, H_2SO_4 may act as unidentate ligands. Although the available results do not permit the exact degree of protonation of the cobalt species to be specified, any protonation that does occur must be concentrated on the outer oxygen atoms, rather than the ligating atoms, such that $[Co(OSO_3H)_6]^{4-}$ is present in the hydrogen sulfate glass and $[Co(OSO_3)_x(OSO_3H)_y(OSO_3H_2)_z]^{(2x+y-2)-}$ $(x + y + z = 6)$ in sulfuric acid. This follows from the fact that inner oxygen protonation in such complexes would, as pointed out by Duffy *et al.* (2), be expected to lead to differences in ligand field parameters, and thus in absorption band maxima, between those complexes in which it is possible and those in which it is not.

The second type of spectrum, consisting of a moderately strong band peaking at 16.6–17.3 kK with shoulders to lower (15.4–15.9 kK) and higher (18.5–18.9 kK) energies, is typified by that found in the ternary alkali sulfate melt at 550 °C; we have previously assigned this to the blue, dodecahedral, bidentate species $[Co(O_2SO_2)_4]^{6-}$. We believe that this species also occurs in the hydrogen sulfate melt, since our spectrum in the melt at 237 °C clearly shows the presence of a shoulder at 15.9 kK, which is typical for this class of spectra. Because of the intermediate values of the spectral parameters, in particular the "low" molar absorptivity values, there have been attempts to assign the spectrum in the $Li_2SO_4–Na_2SO_4–K_2SO_4$ eutectic melt at 550 °C to a distorted octahedral species (11) or to an equilibrium mixture of octahedral and tetrahedral complexes (2). Both these possibilities can now be firmly ruled out by the present results. If an octahedral–tetrahedral equilibrium were present, an increase in temperature would lead to a substantial increase in optical density as some of the octahedral complex was converted into the tetra-

hedral form, which would have absorption bands of far greater intensity. The distorted octahedral model also leads to the prediction that an increase in optical density, although a smaller increase than for the equilibrium case. However, the results for the ternary alkali metal eutectic melt showed that as the temperature was increased from 550 to 770 °C the optical density decreased. Although we have not measured the density of the melt over this temperature range and so cannot calculate accurate values for the molar absorptivity, it seems likely that, even after correction for the change in density, the molar absorptivity would be lower than that obtained at 550 °C. A decrease in molar absorptivity with increasing temperature has been previously observed for $[CoCl_4]^{2-}$ (12) and $[Co(NCS)_4]^{2-}$ and we suggest that this behavior is typical of tetrahedral cobalt(II) complexes.[2] A similar result has been obtained for $[Co(CH_3CO_2)_4]^{2-}$ but in this case the structure is not strictly tetrahedral, being rather dodecahedral.[2] This has been shown by Duffy and Ingram (13) who compared the spectra of $[Co(CH_3CO_2)_4]^{2-}$ and $[Co(CF_3CO_2)_4]^{2-}$. The trifluoroacetate complex was known to be 8-coordinate dodecahedral involving two sets of Co—O bonds with lengths of 2.00 and 3.11 Å (14). As Lippard (15) points out, a dodecahedron can be regarded as two interpenetrating tetrahedra, one elongated and one flattened. It is possible to visualize the long Co—O bond breaking and a conversion to a tetrahedral complex taking place; the greater the disparity between the long and the short bonds the closer the geometry approaches tetrahedral. Consequently, one would expect dodecahedral complexes to behave in a similar fashion to tetrahedral ones, to a first approximation at least. The temperature dependence observed in the ternary alkali sulfate melt is, therefore, compatible with a description of the melt species as a dodecahedral tetrasulfato complex, as suggested earlier (4).

The third class of spectra, characterized by a strong band at 17.3–17.5 kK with a shoulder at 18.6–18.7 kK, was first identified in the potassium sulfate–zinc sulfate glass and ascribed to a violet, octahedral, bidentate species (2). As Table 1 shows, a similar spectrum was also found for the lithium sulfate–dimethylsulfoxide solution at 179 °C. Although it has been suggested that the same species is present in the $NaHSO_4-KHSO_4$ melt at 230 °C (2), evidence has been presented earlier to suggest that this assignment is incorrect. The structure of the violet species is unknown, although a trisulfato structure $[Co(O_2SO_2)_3]^{4-}$ has been suggested (5). We shall return to discussion of this species.

The only example of the fourth class of spectra found so far is obtained in the 98% sulfuric acid solution at temperatures of ~190 °C. It has the strongest band at 17.4–17.6 kK with a shoulder at 20.2–20.5 kK. The species responsible for this spectrum has been assigned a distorted octahedral structure, primarily on the basis of the molar absorptivity value (3).

Equilibrium Studies

We have discussed in some detail the four types of cobalt(II) spectra that are found in sulfate media. The characterization of two of these, namely those due to the pink, octahedral, monodentate species and the blue, dodecahedral, tetra-sulfato complex, must be regarded as fairly complete. It may be argued, however, that both types 3 and 4 represent equilibrium mixtures of the pink and blue forms. In order to test this proposition, detailed investigations of the Li_2SO_4–DMSO solution and the $NaHSO_4-KHSO_4$ melt over the entire temperature range were undertaken.

The peak positions and intensities in the $NaHSO_4-KHSO_4$ melt spectra, at temperatures between 131 and 237 °C, are shown in Table 2. Over this temperature range, the spectra were found to be internally linear with respect to temperature (16). They were tested by two methods (17): firstly, a plot of the absorbance at 18.2 kK *vs.* that at 16.4 kK showed a good linear relationship over the entire temperature range. Secondly, the more rigorous residual method (17) was applied and it was found that the residual (δ) between calculated and experimental absorbances was very close to zero over the temperature and wavelength range of interest. In spite of our failure to obtain glass spectra of reasonable quality, we were able to show that the region of internal linearity extended down to room temperature by using the data published by Duffy

[2]Unpublished results of J. R. Dickinson and T. R. Griffiths.

TABLE 2. Spectra of cobalt(II) in an equimolar $NaHSO_4$–$KHSO_4$ melt

Temperature (°C)	Band maxima in kK (ε_{max})*		
131	18.1(18)		20.1(sh)
145	18.0(20)		20.1(sh)
160	17.9(22)		20.0(sh)
176	17.7(25)		20.0(sh)
187	17.6(27)		20.0(sh)
198	17.5(29)	18.9(sh)	20.0(sh)
220	17.4(34)	18.9(sh)	
230	16.0(sh) 17.4(37)	18.7(sh)	
237	15.9(sh) 17.3(38)	18.5(sh)	

*sh = shoulder.

et al. (2). We can, therefore, conclude that the complete set of spectra are internally linear. By a similar method, internal linearity was also found in the following systems: Li_2SO_4–DMSO solution at 21–179 °C and 98% H_2SO_4 at 12–199 °C (data from previous work (3, 9) were used). The significance of the internal linearity relationship is that it could have occurred only for an equilibrium mixture.

In all three systems above, the room-temperature component of the equilibrium mixture has been identified as the pink, octahedral $[Co(OSO_3)_6]^{10-}$ species. The results for the $NaHSO_4$–$KHSO_4$ system (Table 2) indicate that, in this case, the high-temperature component is the blue dodecahedral complex $[Co(O_2SO_2)_4]^{6-}$. It is likely that the spectrum of the hydrogen sulfate system at 237 °C represents an equilibrium mixture of the octahedral and dodecahedral forms, its classification as Class 2 arising because the dodecahedral spectrum is much more intense than the octahedral spectrum. Examination of the spectra at intermediate temperatures shows clearly that spectra of Class 4 (187 °C) and of Class 3 (220 °C) occur as Class 1 changes to Class 2. We believe that the high-temperature components in the DMSO–Li_2SO_4 and 98% H_2SO_4 systems can also be identified as the dodecahedral species, so that spectra of Classes 3 and 4 are, in fact, due to equilibrium mixtures of the octahedral and dodecahedral forms.

Our present results show that there are two distinct cobalt(II) sulfato complexes: namely pink, octahedral, monodentate $[Co(OSO_3)_6]^{10-}$ (suitably protonated in protonic media) and blue, dodecahedral, bidentate $[Co(O_2SO_2)]^{6-}$. In general, the former occurs at low temperatures and the latter at high temperatures; if the former is heated, it is converted to the latter, an equilibrium mixture being formed at intermediate temperatures.

This work was supported by the Science Research Council. We should like to thank Dr. T. R. Griffiths for the use of the Cary 14H spectrophotometer.

Ion Pair Formation in $NaNO_3/D_2O$ Solutions: Raman and Infrared Spectra, Partial Molal Volumes, Conductance, and Viscosity[1]

J. D. RIDDELL, D. J. LOCKWOOD,[2] AND D. E. IRISH[3]

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received February 2, 1972

Laser Raman and infrared vibrational spectra of solutions of $NaNO_3$ in deuterium oxide reveal the presence of both $Na^+NO_3^-$ ion pairs and solvated nitrate ions. The degree of association has been measured. The concentration quotients are remarkably independent of concentration and almost equal to the thermodynamic association constant, 0.060 ± 0.006 kg mol^{-1} at 25.0 °C. The latter quantity was obtained by an extrapolation procedure, taking account of the activity coefficients. Values are reported for the activity coefficient of the ion pair. Interpretation is also considered in terms of a place-exchange equilibrium involving the solvent. Vibrational assignments are made to the two forms of nitrate ion present. Density, partial molal volume, conductance, and viscosity data are also presented and discussed in terms of the reported constitution.

Les spectres vibrationnels infrarouge et Raman au laser de solutions de $NaNO_3$ dans l'oxyde de deutérium révèlent la présence de paires d'ions $Na^+NO_3^-$ et d'ions nitrate solvatés. Nous avons mesuré le degré d'association. Les quotients de concentration sont indépendants de façon remarquable de la concentration et presqu'égaux à la constante d'association thermodynamique, 0.060 ± 0.006 kg mol^{-1} à 25.0 °C. Nous obtenons cette dernière quantité par extrapolation, en tenant compte des coëfficients d'activité. Nous rapportons des valeurs pour le coëfficient d'activité de la paire d'ions. L'interprétation est faite en termes d'un équilibre d'échange impliquant le solvant. Les assignations vibrationnelles sont faites pour les deux formes d'ions nitrate présentes. Nous présentons aussi la densité, le volume molal partiel, la conductance et la viscosité et en discutons en termes de la structure proposée. [Traduit par le journal]

An extensive study of the vibrational frequencies, half-widths, intensities, and line shapes of aqueous solutions of lithium, sodium, potassium, and cesium nitrate was previously reported (1). Solutions of $LiNO_3$ received the greatest attention and studies were possible over the greatest concentration range at 25 °C. It was shown that, for solutions more concentrated than 7 *M*, nitrate ion exists in two types of environment. In one environment vibrational lines are generated which resemble crystal frequencies and nitrate can be considered to be bound directly to lithium. In the other environment nitrate is free of such a direct linkage to the cation. The comparisons were later extended and interpreted in terms of a quasi-lattice model (2). A place-exchange equilibrium constant was tentatively estimated as 0.24 at 25 °C for the process

$$Li^+(H_2O)_3 + NO_3^- \rightleftarrows Li^+(H_2O)_2NO_3^- + H_2O$$

The early study suggested that $NaNO_3$ solutions were similar to $LiNO_3$ solutions; however, the spectral features of the ion pair were more difficult to detect. In particular an infrared line at about 740 cm^{-1} was detected, as for $LiNO_3$, and it was believed that the lower solubility was the chief factor preventing detection of the Raman counterpart (1). Subsequently Raman experiments were carried out at elevated temperatures on liquids with as little as two moles water per mole salt but, using 435.8 nm mercury excitation, no asymmetry in the shape of the 718 cm^{-1} Raman line could be detected (3). This observation was apparently at variance with the earlier work and thus an extensive study was in order.

D_2O was chosen as solvent because the 700–800 cm^{-1} infrared region is less obscured than with H_2O. Also the 689 cm^{-1} feature (1) is not present in the Raman spectrum of the D_2O solutions and thus it becomes easier to detect asymmetry on the high frequency side of the 718 cm^{-1} line. Furthermore, knowledge of the infrared and Raman frequencies for the same solvent, D_2O, is desirable in case the extent of interaction is different in H_2O and

D_2O. (In previous work i.r. spectra were obtained with D_2O solvent and Raman spectra with H_2O in the 700 cm^{-1} region (1).) Using the 488.0 nm line of an argon ion laser it has been possible to detect the high frequency Raman component. As noted previously (1), the 740 cm^{-1} i.r. component is inherently more intense and thus can be detected when the Raman counterpart is virtually absent. A quantitative Raman intensity study has been made and the results of this study and the implications concerning the constitution of concentrated aqueous $NaNO_3$ solutions are described below. Conductance, viscosity, and density have also been measured to ascertain to what extent the existence of ion pairs is revealed by these macroscopic properties.

Experimental

Thirty solutions were prepared in a nitrogen-purged dry box from dried $NaNO_3$ (Fisher certified reagent) and D_2O. Solutions were filtered through a 0.45 μ Millipore filter prior to spectral measurements. Raman spectra were recorded on a Cary 81 spectrophotometer specially adapted for the use of a Coherent Radiation Model 54 Argon ion laser. The laser beam was directed down the length of a cylindrical glass cell 5 mm in diameter which terminated in a blackened horn to reduce stray light. The cell was positioned parallel to the horizontal slit of the Cary 81 monochromator by means of a specially built adjustable platform. The Raman radiation was focused onto the slit by a cylindrical lens. Thus all of the fore optics of the Cary 81 were bypassed. The gain, slit width, scan speed, and time constant were varied in preliminary studies to determine the combination which would insure no introduction of band distortion. The laser was operated at 488.0 nm and 250 mW. After a 1 h warm up excellent laser power stability was achieved and a yellowish-green fluorescence seen on first introducing the sample had disappeared.

No carbon tetrachloride external standard was used in this laser work because of the difficulty in reproducing the sample cell position relative to the laser beam. Instead, an internal standard was used; namely, the integrated intensity of the 1050 cm^{-1} band of the aqueous $NaNO_3$ solutions. We have assumed a direct proportionality between the integrated intensity of this band and the stoichiometric concentration of the $NaNO_3/D_2O$ solution, based on the work of Davis (4) and Sze (5). Both of these workers employed carbon tetrachloride as an external standard for intensity measurements in their studies. Relative integrated intensities were effectively obtained in this work by dividing the integrated intensity of a given band by that of the 1050 cm^{-1} line of a 1 mol l^{-1} solution of $NaNO_3/D_2O$.

Infrared spectra were obtained on a Beckman IR-9 spectrophotometer operated with the slit program at three times standard and the gain control at 0.8%. In order to eliminate water vapor interference, the instrument was continuously purged by a stream of dry nitrogen. The solutions were contained in a thermostated (25 ± 0.05 °C) R.I.I.C. cell fitted with silver bromide windows that were separated by a 0.012 mm Teflon spacer. Band areas, designated as "integrated absorbances" were measured with a polar planimeter. Since the cell was dismantled and cleaned between solutions, band areas are relative only within a given spectrum, and the infrared spectra are generally of qualitative value. The infrared spectra were run concurrently with the laser Raman spectra of the $NaNO_3/D_2O$ solutions.

The curve resolving of spectral envelopes into component bands was accomplished by means of the CURVER program of the 360/44 IBM computer. This facility is given a more detailed description elsewhere (6), but in essence the program employs one of three distribution functions to fit the Raman bands by an operator-controlled, visual procedure. These model band shapes come from the Lorentzian, Gaussian, and the Lorentz–Gaussian product function. The program provides a measure of the goodness-of-fit.

Soon after the first laser Raman spectra were analyzed, however, it became clear that none of these mathematical functions satisfactorily fitted a single, symmetrical band shape excited by the 488.0 nm laser line. A new model band shape was developed, therefore, specifically for the laser Raman spectra of the $NaNO_3/D_2O$ system. This band shape is a mathematical copy of the 1050 cm^{-1} symmetric stretch of nitrate ion obtained from a spectrum of 4.2 M $NaNO_3/D_2O$. Frequencies and half-widths of band components were maintained at approximately constant values for all spectra of a series of solutions.

Viscosity measurements were taken for a series of $NaNO_3/D_2O$ solutions at 25 ± 0.05 °C using a Cannon–Ubbelohde viscometer. All viscosity efflux times were greater than 100 s and within 0.1 s for at least three repetitions for a given solution. Conductance measurements were performed concurrently with the viscosity measurements at the same temperature using a 1 kHz Industrial Instruments Inc. conductivity bridge with the cell and variable decade resistance in adjacent arms of the Wheatstone bridge arrangement. The cell electrodes were separated by about 15.0 cm of 3 mm i.d. capillary tubing. After a thorough cleaning with dilute HCl and a fresh electrode coating of platinum black, the conductance cell had a cell constant of 319.7 cm^{-1}. This constant was checked periodically using a 0.1000 and a 1.000 mol l^{-1} aqueous solution of KCl. All solutions were allowed at least 20 min to come to temperature equilibrium before measurements were made. Densities were measured at 25 ± 0.05 °C, either with a calibrated pycnometer or in volumetric flasks. The accuracy of the latter method was sufficient for concentrative properties and agreed well with the more accurate measurements.

Results and Discussion

The Degree of Dissociation

The measurement of α, the degree of dissociation of $NaNO_3$, is possible because two Raman lines are observed in the ν_4 region of the Raman spectrum; one at 718 cm^{-1} assignable to the solvated nitrate ion and a second at 728 cm^{-1}

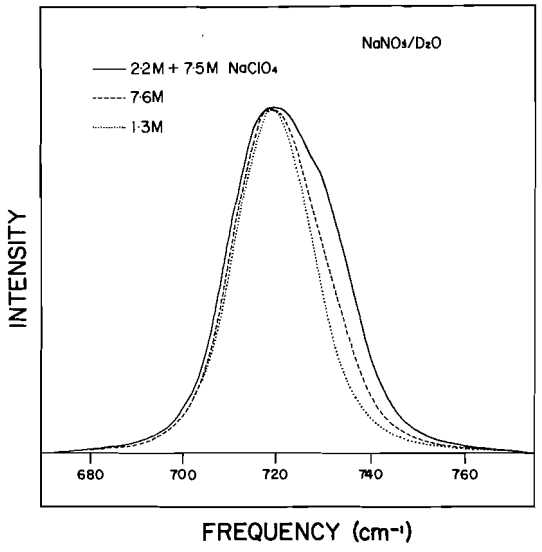

FIG. 1. Comparison of the Raman 720 cm^{-1} regions of ···, 1.3 *M* $NaNO_3/D_2O$; ---, 7.6 *M* $NaNO_3/D_2O$; —, 7.5 *M* $NaClO_4$ + 2.2 *M* $NaNO_3/D_2O$.

assignable to an ion pair (7). The latter frequency is close to that observed for anhydrous sodium nitrate crystal (8). In dilute solution ($C < 1$ mol l^{-1}) the 718 cm^{-1} band is a single symmetrical line. At a concentration of 7.67 mol l^{-1} a small but significant amount of intensity distorts the high frequency side of this band. Increasing the sodium:nitrate concentration ratio to 4.48:1 (a "common ion" effect obtained by mixing $NaClO_4$ and $NaNO_3$) increases the intensity of the 728 cm^{-1} shoulder as expected if an equilibrium was displaced

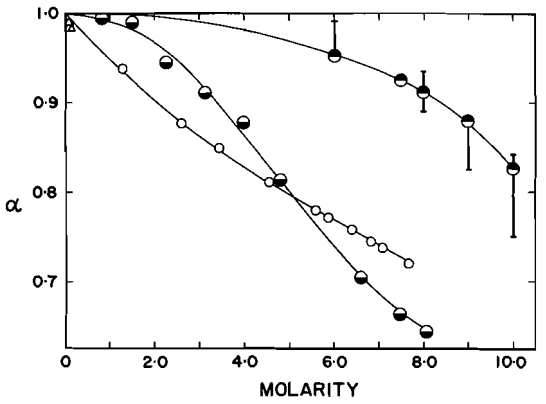

FIG. 3. The degree of ionization, α, *vs.* molarity of nitrate at 25 °C: ◓, $LiNO_3/H_2O$; ◒, HNO_3/H_2O; ○, $NaNO_3/D_2O$; △, Davies' values for $NaNO_3/H_2O$.

to favor a higher concentration of ion-pair (728 cm^{-1}) and a lower concentration of free ion (718 cm^{-1}) (Fig. 1). Using the computer procedure it was possible to fit two bands to the intensity envelope in this spectral region, each with constant half-width and frequency. The relative integrated intensities of the total contour and the components are plotted against concentration in Fig. 2.

The total integrated intensity (I_T) is directly proportional to the stoichiometric concentration. Dividing this concentration into that of ion pairs C_B and that of free ions C_F, one has

$$[1] \qquad I_T = I_{718} + I_{728} = J_B C_B + J_F C_F$$

where J is the molar intensity of the bound (B) or the free (F) forms of nitrate ion. If $J_B = J_F$, eq. 1 will reduce to

$$I_T = J_B(C_B + C_F) = J_B C_T$$

a linear equation with zero intercept consistent with experiment. Thus J_B can be obtained from the slope of I_T *vs.* C_T in Fig. 2. The implication is that although ion association changes the force constant and hence frequency associated with the deformation mode of the nitrate ion, it does not change the molar intensity of the mode. It now follows that

$$[2] \quad C_B = I_{728}/J_B \quad \text{and} \quad \alpha = 1 - C_B/C = C_F/C$$

α is plotted against molarity in Fig. 3. Two data obtained from conductance studies of dilute solutions by Davies (9) are also shown. For comparison the more scattered data (2)

for $LiNO_3/H_2O$ and the values for HNO_3/H_2O obtained by Krawetz from Raman intensity measurements (10) are shown.

The equilibrium process is formulated as

$$Na^+_{(aq)} + NO^-_{3(aq)} \rightleftarrows Na^+\cdot NO^-_{3(aq)}$$

The thermodynamic equilibrium constant for the association can be written as the product of a concentration quotient Q_C and an activity coefficient quotient Q_γ

$$[3]\quad {}^TK_A = \frac{a_u}{a_{Na^+}\cdot a_{NO_3^-}} = \frac{m_u}{m_{Na^+}\cdot m_{NO_3^-}}\cdot\frac{\gamma_u}{\gamma_{Na^+}\cdot\gamma_{NO_3^-}} = Q_C\cdot Q_\gamma$$

where a, m, and γ refer to activity, molality, and activity coefficient, respectively. Solution concentrations are converted from molarity to molality units, through the measured densities, for convenience when using activity coefficients described below.

Considering first $Q_C = (1-\alpha)/\alpha^2 m$ we find that the concentration quotient is remarkably constant, changing from 0.057 to 0.059 kg mol^{-1} for a concentration change from 9.35 to 1.23 m (Table 1). The system's behavior is surprisingly ideal. Such constant Q_C's obtained for salt solutions by Raman spectroscopy have been noted before (11, 12). The same is not true for acid solutions however (13).

It is possible to incorporate values for $\gamma_{Na^+}\cdot\gamma_{NO_3^-}$ and thus explore the concentration dependence of ${}^TK_A\gamma_u^{-1}$. In terms of the mean ionic activity coefficients, $\gamma_{Na^+}\cdot\gamma_{NO_3^-}$ equals $\gamma^2_\pm$ for the free ions. Following the treatment given by Robinson and Stokes (ref. 14, pp. 37, 38)

$$\gamma^2_\pm = (\gamma^2_\pm)_{ST}\alpha^{-2}$$

$(\gamma^2_\pm)_{ST}$, the mean stoichiometric activity coefficients, are reported by Robinson and Stokes (ref. 14, p. 492) for the $NaNO_3/H_2O$ system. In order to use these values a correction has been applied for the fact that the D_2O solutions contain fewer moles of solvent than the H_2O solutions of the same molality. Values of $\gamma_\pm$ were chosen corresponding to the molality of the D_2O solution multiplied by the factor 55.51/49.93. These values are consistent with the trends presented by Bonner (15) for activity coefficients of other salts dissolved in D_2O.

Thus ${}^TK_A\gamma_u^{-1}$ equals $[(1-\alpha)/m]\cdot(1/(\gamma_\pm)^2_{ST})$. Figure 4 is a plot of both ${}^TK_A\gamma_u^{-1}$ and Q_C *vs.* molality. Data are presented in Table 1. $(1-\alpha)$ is zero at zero concentration and thus the experimental values of $(1-\alpha)$ can be expressed

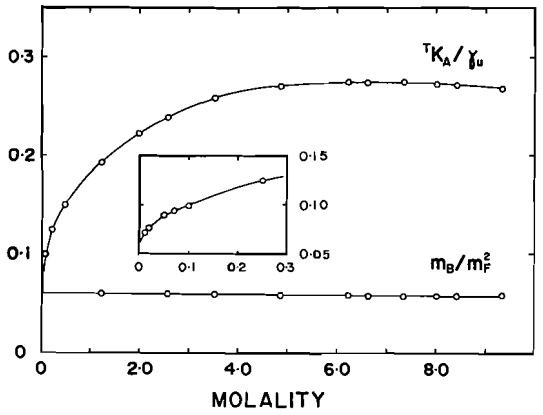

FIG. 4. $^TK_A/\gamma_u$ and m_B/m_F^2 *vs.* molality for $NaNO_3/D_2O$ at 25 °C. The inset shows the horizontal scale expanded and the extrapolation of $^TK_A/\gamma_u$ to zero concentration.

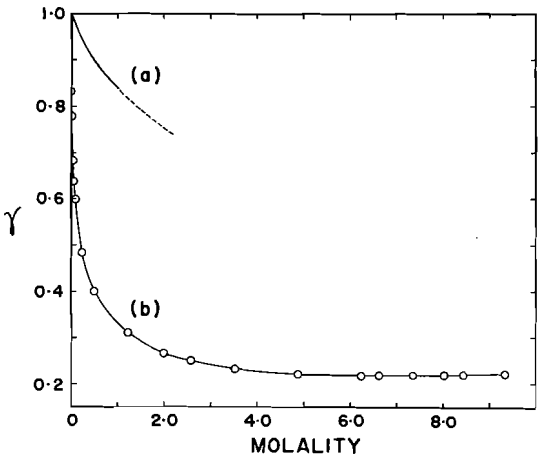

FIG. 5. (*a*) Activity coefficient of glycine (dipolar ion) *vs.* molality of KCl at 25 °C; (*b*) activity coefficient of the $Na^+ \cdot NO_3^-$ ion-pair *vs.* molality of $NaNO_3/D_2O$ at 25 °C.

as a polynomial in m with a required zero intercept:

$$(1-\alpha) = 0.05762_6 m - 0.004827 m^2 + 0.0001989_4 m^3$$

The plot of $^TK_A\gamma_u^{-1}$ has been extrapolated by interpolations using the above polynomial. In the limit of infinite dilution, γ_u is unity and ^TK_A is 0.060 ± 0.006 kg mol^{-1}. As the concentration increases, $^TK_A\gamma_u^{-1}$ rises smoothly and then levels off (Fig. 4). This can be attributed to a decrease of γ_u, as shown in Fig. 5. There are few examples where γ_u is known for an ion pair over such a wide concentration range. Roberts and Kirkwood measured the activity coefficient of glycine in aqueous solutions of KCl (16). Glycine forms a dipolar ion of large electric moment in solvents with a high dielectric constant. Figure 5 shows γ_u for glycine plotted against molality of KCl. The trend is similar to that of γ_u for $NaNO_3$. On the other hand, for HNO_3, γ_u calculated from the data of Krawetz rises continuously from unity.

Davies (9) obtained a value of 0.26 for the association constant of $NaNO_3$ in water at 18 °C. His approach, $\alpha = \Lambda/\Lambda_x$, necessitates questionable assumptions about the form of Λ_x. It is worth noting, however, that Davies' value of α for 0.1 M is 0.985 and ours is 0.995 while at 0.05 M Davies' value is 0.991 and ours is 0.997. The value of $^TK_A\gamma_u^{-1}$ changes by a factor of about four when α changes by only 6 parts in 1000. This comparison serves to point out the extreme sensitivity of $^TK_A\gamma_u^{-1}$ to small differences in α in dilute solutions for an electrolyte as strong as $NaNO_3$. Robinson (17) combined Davies' conductance data and activity coefficient data to obtain a value of 0.38 for K_A.

The near constancy of Q_C implies that Q_γ is almost constant over most of the concentration range. To a good approximation $\gamma_u\gamma_\pm^{-2}$ equals 1.04 when $0.01 < m < 9.35$ but γ_u approaches unity faster than $\gamma_\pm^2$, accounting for the sharp change of slope in Fig. 4 as m approaches zero.

With reference to Fig. 4, the strength of the electrolytes decreases in the order $LiNO_3 > HNO_3 > NaNO_3$ for $C < 5$ M. In keeping with this trend Krawetz reports ^TK_A of HNO_3 equal to 0.042 kg mol^{-1} (10), smaller than our value of 0.060 kg mol^{-1} for $NaNO_3$. The trend of increasing values of ^TK_A with increasing alkali metal radius seems probable (18).

Reliability

In the above analysis an uncertainty of 10% in the value of K has been implied. This is a realistic estimate. When D_2O is used as solvent the spectral base lines are straight. The noise level was less than 1% of the maximum peak height except for the most dilute solutions for which it did not exceed 1.5%. The 1050 cm^{-1} line is an ideal internal standard because it is intense and isolated. Its use also circumvents intensity corrections which may arise because of a changing refractive index.

The principle source of uncertainty is the partition of the signal into two components. This problem is common to many types of experimentation and is often more severe than that encountered here. The precision obtainable in this work is a consequence of the singular features of the computer procedure *viz.* an exactly reproduceable, defined line shape and a criterion for the goodness-of-fit (6). Because of this severe overlap, however, an estimated 10% uncertainty may exist in each ratio I_{728}/I_{718}, which leads to an uncertainty of about 8% in individual values of $(1-\alpha)$. Once the equality of J_F and J_B is established or assumed the results are independent of the intensity of the 1050 cm^{-1} line because $(1-\alpha)$ can be expressed as $(I_{728}/I_{718})(1+I_{728}/I_{718})^{-1}$, from which the 8% estimate is derived. To some extent this uncertainty is reduced by the averaging procedure which was used to fit all the points to a smooth curve. Thus 10% reliability is believed to be a reasonable upper limit. The values in Table 1 imply greater precision; the three significant figures quoted there are in fact an indication of our internal consistency. The trends and conclusions are not changed by rounding off.

The Place-Exchange Equilibrium Constant

An alternative way of considering the association process is in terms of a competition between water molecules and nitrate ions for sites in the first coordination sphere of the cation. A place-exchange equilibrium constant for this quasi-lattice model (19) can be expressed in terms of the process

$$Na^+(D_2O)_x + NO_3^- \rightleftarrows Na^+ \cdot NO_3^-(D_2O)_{x-1} + D_2O.$$

The constant (a concentration quotient) is defined as

$$^cK_A = \frac{C_B C_W}{(C - C_B)^2}$$

where C_B is the concentration of bound nitrate and C_W the concentration of free solvent molecules. C_W is calculated from density and weight percent data such that $C_W = [D_2O]_T - x(C - C_B) - (x-1)C_B$. The constant has been evaluated for $1 \leqslant x \leqslant 6$ (Fig. 6). At infinite dilution ^cK_A has a value of 2.98_3, independent of x. With increasing concentration the values decrease.

The less certain data for $LiNO_3/H_2O$ were consistent with the almost constant value for ^cK_A of 0.24 when x is 3. The smaller value is consistent with the view that Li^+ binds waters more strongly than Na^+ and thus nitrate ion competes less successfully with the solvent molecules for a position in the primary solvation sphere of the smaller cation. The sodium ion appears to display little or no preference for a fixed value of x, unlike lithium, magnesium, or zinc for example. The value probably decreases as concentration increases.

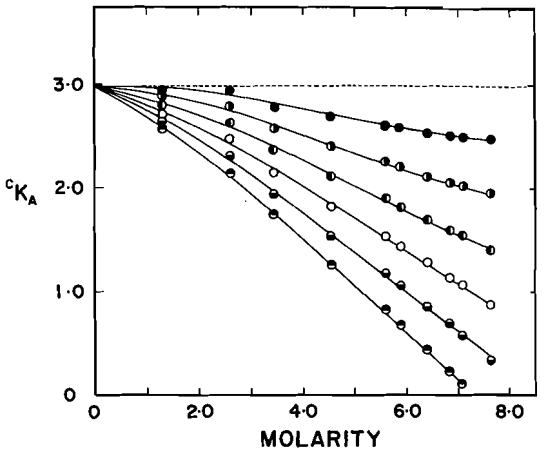

FIG. 6. ^cK_A *vs.* molarity of $NaNO_3/D_2O$ at 25 °C: ●, $x=1$; ◑, $x=2$; ◐, $x=3$; ○, $x=4$; ◒, $x=5$; ◓, $x=6$.

Spectral Properties of the Ion-Pair

The normal modes of vibration of an isolated nitrate ion with D_{3h} symmetry and their approximate frequencies are: $\nu_1(A_1')$ 1050 cm^{-1}; $\nu_2(A_2'')$ 825 cm^{-1}; $\nu_3(E')$ 1385 cm^{-1}; and $\nu_4(E')$ 720 cm^{-1}. Solvation in water causes the $\nu_3(E')$ mode to split into a doublet with maxima about 1356 and 1410 cm^{-1}, the separation also depending on the concentration and cation (12). Attachment of a cation subjects nitrate ion to a larger perturbation and the symmetry is lowered to C_{2v}, C_s or C_1. It is probable that the cation and anion will be oriented in a number of different ways to each other such that no single symmetry designation will be applicable to all ion pairs. This will cause the vibrational lines to broaden. But, for all symmetries above, the effect is to remove the degeneracy of the E' modes. For simplicity we will describe the vibrations of the ion pair in terms of C_{2v} symmetry. Thus the correlations will be: $A_1' \rightarrow A_1$;

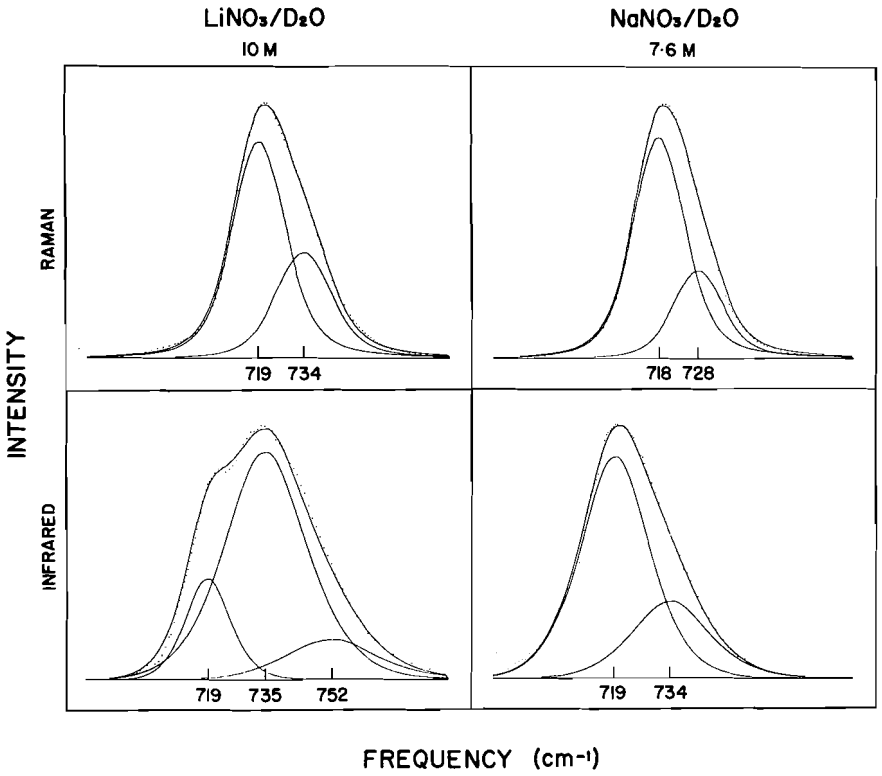

FIG. 7. Comparison of the computer-analyzed Raman and infrared 720 cm^{-1} regions of saturated solutions of $LiNO_3/D_2O$ and $NaNO_3/D_2O$. The 752 cm^{-1} infrared band is due to water in the $LiNO_3$ salt.

$E' \rightarrow A_1 + B_2$ and $A_2'' \rightarrow B_1$. All six modes are allowed in both infrared and Raman.

No lines were detected which could be attributed to a Na^+–nitrate vibration. This suggests that the interaction is largely electrostatic. The ion pair exhibits a Raman line at 728 cm^{-1} as already discussed which is assigned to an A_1 mode; the observed polarization of this line is weak but probably genuine. The infrared contour has two components, the 719 cm^{-1} line of free nitrate and an intense line at about 734 cm^{-1}. This line is ascribed to the B_2 mode of the ion pair. It is assumed that the Raman counterpart is of inherently low intensity. (The observations contrast sharply with those for $LiNO_3$ where infrared and Raman lines are almost identical in frequency at 734 cm^{-1} (see Fig. 7).)

A low intensity band at 831 cm^{-1} is detectable in Raman spectra of solutions more concentrated than 2 mol l^{-1}. The integrated intensity of this band appears to vary directly with the integrated intensity of the 1050 cm^{-1} band which is proportional to total nitrate concentration. It was not detected in the spectrum of the mixture containing $NaNO_3$ and $NaClO_4$ in D_2O where ion–ion contact is forced. This band is therefore assigned to solvated nitrate, perturbed by the solvent such that the normally Raman inactive $\nu_2(A_2'')$ vibration is allowed. The overtone was a single, somewhat more intense symmetric band at 1660 cm^{-1}. The greater intensity is consistent with the fact that it is Raman allowed under D_{3h} selection rules. The 831 cm^{-1} vibration is a single intense line in the infrared spectrum and is assigned to both bound and free nitrate ions.

The line shape of the intense Raman line at 1050 cm^{-1} was studied carefully with 1 cm^{-1} slit width. It is symmetrical. This does not entirely preclude the possibility that more than one band is present under the contour, however. There is a small increase of frequency with increasing concentration and a slight broad-

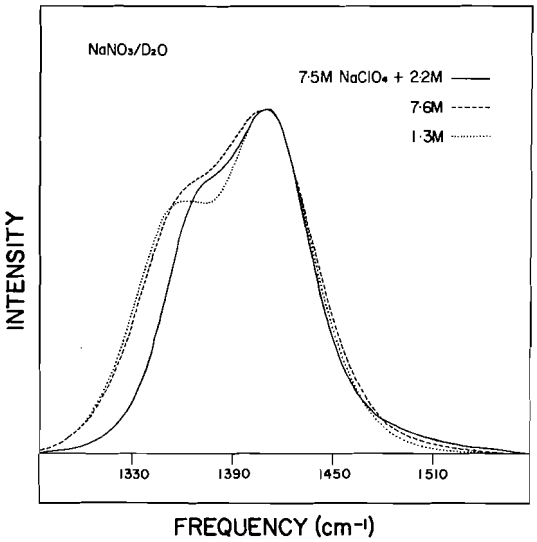

FIG. 8. Comparison of the Raman 1400 cm^{-1} regions of ···, 1.3 *M* $NaNO_3/D_2O$; ---, 7.6 *M* $NaNO_3/D_2O$; —, 7.5 *M* $NaClO_4$ + 2.2 *M* $NaNO_3/D_2O$.

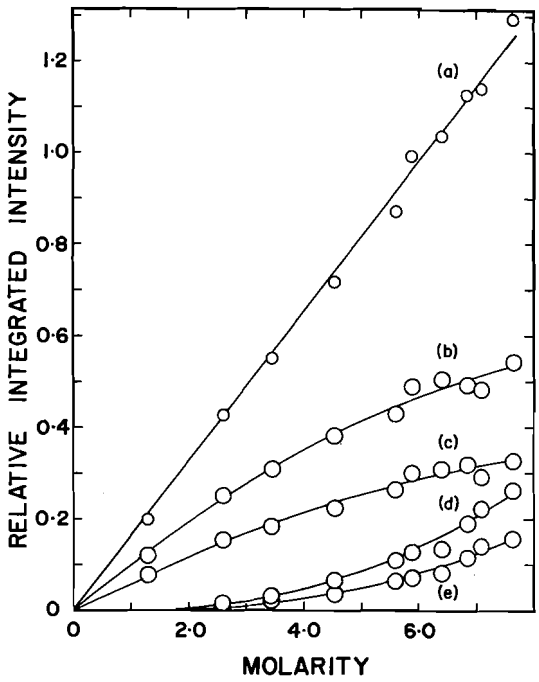

FIG. 9. Relative integrated intensity *vs.* molarity for the 1400 cm^{-1} region of the Raman spectrum of $NaNO_3/D_2O$: (*a*) I_T; (*b*) I_{1415}; (*c*) I_{1355}; (*d*) I_{1417}; (*e*) I_{1368}.

ening. A weak infrared counterpart is observed about 2 cm^{-1} lower in frequency. We believe the ion pair and solvated nitrate ion both contribute to this line (*cf.* ref. 12).

A broad envelope extends from approximately 1300 to 1500 cm^{-1} in the Raman spectrum. For dilute solutions ($C < 1$ mol l^{-1}) this region can be resolved into two components by computer techniques, *viz.* 1355 and 1415 cm^{-1}. At higher concentrations subtle changes in the contour of the band envelope become apparent. As ion pairing is enhanced the intensity *between* the two maxima is enhanced and the overall width of the envelope decreases (Fig. 8). Attempts were made to fit the envelope with two, three, and four bands. Although a two and three band fit can be achieved, it is obtained only by allowing the positions and half-widths to continually change in an inconsistent manner. A four band fit which allows the retention of the frequencies, half-widths, and intensity ratio of the 1355 and 1415 cm^{-1} bands over the entire concentration range is most acceptable. Two new bands, located at 1368 and 1417 cm^{-1}, and assigned to the A_1 and B_2 modes of the ion-pair, respectively, have almost constant line parameters over the concentration range and account for the overall narrowing of the contour. The concentration dependence of the intensities is similar to that observed for the 719–740 cm^{-1} region (Fig. 9). The infrared contours in this region have very high absorbance and are not amenable to study. The assignments are summarized in Table 2.

Density and Partial Molal Volumes

The concentrative properties of the $NaNO_3/D_2O$ system are given in Table 3. The density of D_2O at 25 °C has been taken from Millero *et al.* (20). Smooth values of the density are given by the polynomial, obtained from a least-squares analysis of the data,

$$D = 1.1043_5 + 0.0523_9C - 0.0007_0C^2$$

where C is measured in mol l^{-1}. Similarly, weight percent is given by

$$\text{Wt. percent} = 7.6778C - 0.3574C^2 + 0.02031C^3 - 0.000743C^4$$

The values in Table 3 are for the unsmoothed experimental data.

To a good approximation direct proportionality exists between density and molarity, specific volume and weight percent, and mean molal volume and mole fraction over the con-

§Region not studied because of the high infrared absorbance.
‖Line required by selection rules but obscured or weak.

centration range studied. Similar linearities also exist for comparable plots of the $LiNO_3/H_2O$ data (21).

The partial molal volumes were obtained from apparent molal volumes by an analytical procedure (22). Values of ϕV_2, the apparent molal volume, were computed from the smoothed density, concentration data and fitted to a polynomial in molality, m

$$\phi V_2 = 29.538 + 0.69772m - 0.01975m^2 - 0.00149m^3 + 0.00049m^4$$

The expression for $\bar{V}_2$ is then obtained by differentiation. The partial molal volume of the solvent, $\bar{V}_1$, was obtained from

$$\bar{V}_1 = \frac{20.028}{1000}\left[\frac{1000 + mM_2}{D} - m\bar{V}_2\right]$$

where 20.028 is the molecular weight of the solvent, M_2 is the molecular weight of the solute, m is the concentration in mol kg^{-1}, and D is the density. The linearity of the mean molal volume against mole fraction plot arises because the partial molal volumes balance each other, superficially indicating ideal behavior. This feature can be compared with the ideality revealed by the constancy of Q_C in the previous section.

Conductance and Viscosity

It has long been recognized that the degree of dissociation, α, should be obtainable from conductance measurements. One approach is to adopt the relation $\Lambda/\Lambda_x = \alpha$ where Λ is the observed equivalent conductance and Λ_x is the hypothetical conductance the electrolyte would have if it were completely dissociated into ions and at a concentration αC (23, 24). Much uncertainty exists concerning the appropriate expression for Λ_x which in general is a function of Λ_0, viscosity, concentration, charge type, temperature, and solvent. Considerable effort has been expended on this problem (23) since the interpretation of Davies (9), referred to in the first section of this discussion, was advanced. It is of interest to be able to correlate constitution, a microscopic property measured by Raman spectroscopy, and conductance, a macroscopic property, for this 1:1 electrolyte with a relatively small degree of ion association. The experiments were conducted with this objective in mind.

The Λ_0 value for the $NaNO_3/D_2O$ system is obtainable from Walden's Rule, using the known values for the $NaNO_3/H_2O$ system, because the solvents are comparable (25). Thus

$$\Lambda_0 = \frac{(\eta_0\Lambda_0)_{H_2O}}{(\eta_0)_{D_2O}} = \frac{0.8903 \times 121.56}{1.096_6} = 98.69 \text{ ohm}^{-1} \text{ cm}^2 \text{ equiv}^{-1}$$

The experimental data for specific conductance, κ, equivalent conductance, Λ, and viscosity, η, are presented in Table 4. The viscosity and specific conductance data have also been smoothed by means of a least squares computer

*From Walden's Rule (see text).
†From equation with $C = 10^{-6}$ mol l^{-1} and $\mathring{a} = 4.10$ Å.

program and the smoothed data are given by the polynomials in C (mol l^{-1}):

$$\eta = 1.096_2 + 0.05671C + 0.01077C^2 + 0.00208C^3$$

$$\kappa = 0.00209 + 0.06899C - 0.00941C^2 + 0.00043C^3$$

We anticipate that the ion pairing in $NaNO_3/D_2O$ will be similar to that in $NaNO_3/H_2O$ although some Raman evidence has been accumulated which suggests that the degree of association may be somewhat larger in D_2O. A plot of $\kappa\eta$ against concentration was compared for the two systems. For $NaNO_3/H_2O$ the conductance data of Nelson were used (3) and the viscosity data were measured in our laboratory by Walker (*cf.* Janz *et al.* (26)). The polynomials for these quantities are:

$$\kappa = 0.00062 + 0.09245C - 0.02120C^2 + 0.00332C^3$$

$$\eta = 0.8904 + 0.05234C + 0.009883C^2 + 0.00166C^3$$

The two $\kappa\eta$ curves exhibit the same trends and inflections. Since $\kappa\eta$ is sensitive to solution constitution, such as ion-pair formation, differences are probably not large.

An empirical expression for Λ_x was obtained by dividing the observed conductance by the observed α. The expression

$$\Lambda_x = \Lambda_0 - 50.146C^{1/2} + 30.781C - 14.476C^{3/2} + 3.059C^2 - 0.226C^{5/2}$$

fits the data to within 0.1%. The two conductance curves are shown in Fig. 10. Efforts to develop an equation for Λ_x whose coefficients have real physical meaning for the system at moderate to high concentrations have so far been unsuccessful. Such a theoretical equation, together with measured values of Λ, would allow the computation of α for any concentration.

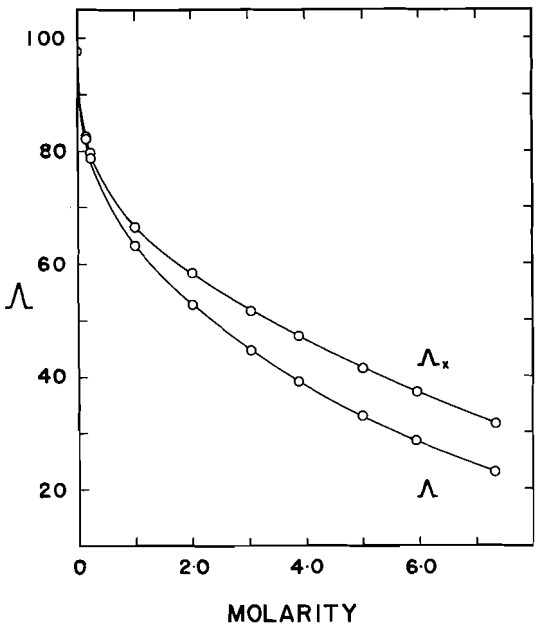

FIG. 10. Λ and Λ_x *vs.* molarity of $NaNO_3/D_2O$ at 25 °C.

Wishaw and Stokes (27) obtained satisfactory agreement between experimental data and conductance calculated from the equation

$$\Lambda = \left(\Lambda_0 - \frac{B_2\sqrt{C}}{1 + B\mathring{a}\sqrt{C}}\right)\left(1 - \frac{B_1\sqrt{C}}{1 + B\mathring{a}\sqrt{C}}F\right)\frac{\eta_0}{\eta}$$

for NH_4Cl/H_2O when $\mathring{a} = 4.35$ Å. This equation also fits the $NaNO_3$ data fairly well when $\mathring{a}$ is given the reasonable value 4.10 Å (Table 4). The constants used are: $B = 0.32999$; $B_1 = 0.23167$; $B_2 = 49.366$; $F = (e^x - 1)x^{-1}$ where $x = 0.09667\sqrt{c}\,\mathring{a}$ (*cf.* 28). There is no reason to believe that the difference between measured and calculated values should be attributed to ion association; rather it reflects the limitations of the equation; *i.e.*, the equation, with no allowance for ion association, does not give values which differ from the experimental values in any systematic way attributable to the known ion-pair formation.

Aspects of this work were supported by the Department of the Environment, the National Research Council of Canada, and the University of Waterloo Research Grant Programme. We are also grateful to Atomic Energy of Canada, Ltd., for deuterium oxide. Particular appreciation is extended to Dr. W. L. Elsdon for many helpful discussions. D.E.I. also expresses his thanks to Professor R. A. Robinson for his suggestions. J.D.R. acknowledges with thanks an Ontario Graduate Fellowship (1970–1971). We also thank Mr. John Walker for measuring the viscosity of the $NaNO_3/H_2O$ system.

Conformations of Bridged Diphenyls. I. Crystal Structure of 2-(3′-Methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene

E. A. H. GRIFFITH, W. D. CHANDLER, AND B. E. ROBERTSON[1]

Division of Natural Sciences and Mathematics, University of Saskatchewan, Regina, Saskatchewan

Received May 1, 1972

The structure of 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene, $C_{19}H_{23}NO_3$, has been determined by X-ray diffraction. The crystals are triclinic, $a = 12.422(24)$, $b = 13.180(25)$, $c = 11.241(30)$ Å, $\alpha = 89.99(20)$, $\beta = 95.81(15)$, $\gamma = 105.46(12)°$, $P\bar{1}$ with $Z = 4$. The intensities of 8153 independent reflections were measured on a four circle diffractometer, of which 3701 were used in the refinement of the structure to give a final least-squares weighted residue of 0.053.

The ether oxygen bond angle in each of the two independent molecules is 120°. The two phenyl rings are nearly orthogonal in each case, while the ring containing the electron withdrawing nitro group is conjugated with the ether oxygen atom. The rings show significant deviations from hexagonal symmetry and the nitro-substituted ring is bent away from the other ring.

Nous avons déterminé la structure du 2-(3′-méthyl-4′-nitrophenoxy)-1,3-diisopropylbenzène, $C_{19}H_{23}NO_3$ par diffraction de rayons-X. Les cristaux sont tricliniques avec $a = 12.422(24)$, $b = 13.180(25)$, $c = 11.241(30)$ Å, $\alpha = 89.99(20)$, $\beta = 95.81(15)$, $\gamma = 105.46(12)°$, $P\bar{1}$ avec $Z = 4$. Nous avons mesuré les intensités de 8153 réflexions indépendantes au moyen d'un diffractomètre à quatre cercles; 3701 réflexions ont été utilisées pour le raffinement de la structure pour obtenir une moyenne pondérée par moindres carrés de résidu de 0.053.

L'angle impliquant l'oxygène de la liaison éther dans chacune des deux molécules indépendantes est de 120°. Les deux cycles phényl sont presque orthogonaux dans chaque cas, tandis que le cycle contenant un groupe nitro attracteur d'électrons, est conjugué avec l'atome d'oxygène de l'éther. Les cycles dévient de façon importante de la symétrie hexagonale et le cycle nitro-substitué est éloigné de l'autre cycle.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2963 (1972)

This is the first in a series of reports which will describe studies of substituted, bridged diphenyl compounds using X-ray diffraction. In addition, the results obtained by this technique will be compared with n.m.r. data for the same systems in solution. We intend to examine the effects of several variables, such as the steric and electronic character of the substituents and the nature of the bridging group, on the relative orientations of the phenyl rings and the central plane containing the bridging group.

The bridging groups which have received some attention in the past are O, S, SO, SO_2, CH_2, and CO, with diphenyl ethers having been studied most extensively: (*i*) Infrared and Raman spectroscopy have been employed to a limited extent in the study of diphenyl ether (1, 2). (*ii*) The modes of internal rotation of these compounds have been studied by dielectric relaxation methods (3–7). (*iii*) Comparisons of the sums of the group moments with the measured dipole moment of the molecule have been of some value in predicting the preferred orientations of phenyl rings (8–12). (*iv*) More recently, magnetic shielding of the aromatic hydrogen atoms by currents in the adjacent ring, as measured by n.m.r. (13–19), has proven to be a valuable technique for the study of aromatic molecules. However, the scarcity of more direct observations and verification of the conformation of these molecules by diffraction techniques has hindered the development of the dipole moment and n.m.r. methods as quantitative tools for the study of conformations.

The information obtained by gas phase electron diffraction experiments (20, 21) is of limited value because of the relative complexity of this system. Hamilton and Steinrauf (22) have recently reported the crystal structure of the alkaloid vertaline which contains oxygen bridged phenyl rings and provides information on the geometry in the vicinity of the bridging atom. The freedom of the rings to adopt an optimum conformation is restricted, however, by their being linked through a quinolizidine ring and a lactone group. Camerman and Camerman have recently reported the structure of the thyroid hormone 3,5,3′-triiodo-L-thyro-

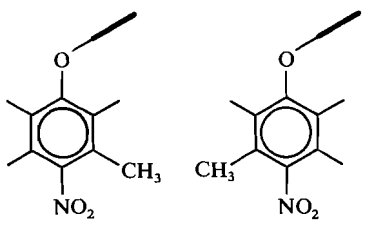
nine (35). They found an ether oxygen bond angle of 125.6° with the phenolic ring nearly coplanar with the central C—O—C plane. The angle between the diiodotyrosine ring and the phenolic ring is 82°. Toussaint has studied diphenyl ether and 4,4′-dibromodiphenyl ether by X-ray diffraction (23, 24). The structural parameters given for these two ethers have been used to some extent for the calculation of n.m.r. shielding parameters (17–19) but the relatively low accuracy of these structural determinations, together with the serious discrepancies between the C—O bond lengths and the C—O—C angles in the two similar molecules suggest that further studies are required.

The use of solid phase structural data for the calculation of n.m.r. shielding parameters has the obvious limitation that the internal rotations of the molecule in the liquid phase are frozen out. The observed n.m.r. data may represent an averaging over a range of conformations associated with the internal motion. Nevertheless, the use of accurate structural parameters in these calculations can be of considerable value in correlating changes in ring current shielding with conformational changes.

The present diphenyl ether has bulky isopropyl groups in the ortho positions of one ring and an electron withdrawing nitro group on the other ring. Montaudo and co-workers (18, 19) have suggested that electron withdrawing groups may enhance conjugation between unshared electrons on the bridging atoms and π electrons in the phenyl ring, although in the liquid phase at least two electron withdrawing substituents are necessary to produce a significant conjugation effect. Variable temperature n.m.r. studies (34) have indicated that the net result of the steric effect of the isopropyl groups and the conjugative effect of the nitro group in solution is an equilibrium of the two conformations **1**, and **2**.[2] This study was undertaken partly to see if the same two conformations (with rings nearly perpendicular) were present in the solid phase.



1 **2**

Experimental

Data Collection

2-(3′-Methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene was synthesized by the method of Wright and Jorgensen (25) and recrystallized from 95% ethanol. The melting point was determined to be 90–91°.

A sample was selected with near orthogonal faces and dimensions 0.92 × 0.20 × 0.76 mm. The crystalline quality, symmetry, approximate cell constants and orientation of the crystal were examined by film techniques and it was then mounted on a Picker FACS-I four circle diffractometer. Accurate cell constants were determined by least-squares from the centered positions of 12 reflections with 2θ values between 28 and 42°, where the $K\alpha_1$ and $K\alpha_2$ diffraction maxima were resolved. The cell constants are given below with estimated errors which are three times the estimated standard deviations calculated from the least-squares procedure. Comparison between cell constants determined from different sets of reflections and from different samples suggest that this is a realistic estimate of error. Crystal data are as follows:

2-(3′-Methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene
f.w. = 313

Triclinic $P\bar{1}$, $a = 12.422(24)$, $b = 13.180(25)$, $c = 11.241(30)$ Å, $V = 1764$ Å^3, $\alpha = 89.99(20)$, $\beta = 95.81(15)$, $\gamma = 105.46(12)$°, $\rho_0 = 1.15$ g cm^{-3} (flotation), $Z = 4$, $\rho_c = 1.18$ g cm^{-3}, $F(000) = 672$ e (22 °C, $\mu(\text{MoK}\bar{\alpha}) = 0.85$ cm^{-1}, $\lambda(\text{MoK}\alpha_1) = 0.70926$ Å).

Data were collected with MoKα radiation and a "highly oriented graphite" monochromator. The integrated intensities of 8153 reflections were measured between the 2θ values of 3.5 and 55°. The θ–2θ scan mode was used with a scan rate of 2° min^{-1} and a base width of 3.2°. Background counts (10 s) were made at each end of the scan. The intensities of three standard reflections were collected after every 100 reflections and showed no significant variations. However a machine malfunction, resulting in a collision when the data had been collected out to *ca.* 34° in 2θ, necessitated realignment of the crystal, and the standards showed a small change in intensity after realignment. Two scale constants were used in the subsequent analysis of the data.

The data were reduced to observed structure factors by standard calculations. The polarization factor used was

$$(\cos^2 2\theta_m + \cos^2 2\theta_s)/2 \sin 2\theta_s$$

where θ_m and θ_s are the Bragg angles of the monochromator and sample, respectively. $\sigma(F)$ was calculated from

$$\sigma(F) = A\{NS + (T(NS)/T(BG))^2 BG\}^{1/2}/2\text{Lp}|F|$$

where A is the attenuator constant, NS the number of scan counts, BG the total background count, and $T(NS)$ and

[2]The conformation found for 3,5,3′-triiodo-L-thyronine corresponds to **1**, and may account for the larger ether oxygen bond angle.

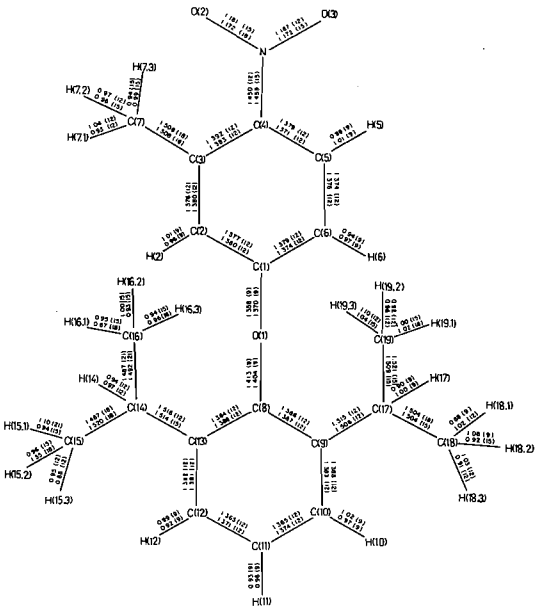

FIG. 1. Bond lengths and atom sequence. The numbers nearest the line refer to molecule 1. The numbers in parentheses are estimated errors based on the errors in Table 2.

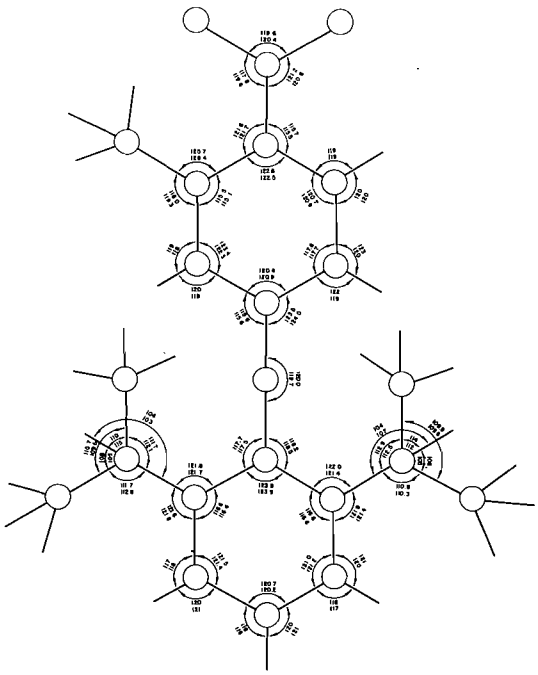

FIG. 2. Bond angles. The number nearest the atom refers to molecule 1. The estimated errors in the angles not involving a hydrogen atom are *ca.* 1.4°. The estimated errors in the angles involving hydrogen atoms are *ca.* 10°.

$T(BG)$ are the scan times and total background count times. No corrections were made for extinction or absorption. The scattering factors of the carbon, nitrogen, and oxygen atoms were taken from Cromer and Mann (26). The scattering factors of the hydrogen atoms were taken from Stewart *et al.* (27).

Determination and Refinement of the Structure

The observed density and cell volume correspond to four molecules in the unit cell. A Wilson statistical calculation gave an overall temperature factor of 4.3 Å^2. Normalized structure factors, E, were calculated and the average values of $|E|$ and $|E^2 - 1|$ were 0.757 and 1.021, indicating the centrosymmetric space group $P\bar{1}$. The 418 reflections with $|E| > 2.0$ were selected and used in the multiple solution, logical symbolic addition method programs of Germain and Woolfson (28). An E map calculated from the solution with highest figures of merit, not associated with a trivial solution, yielded 42 of the 46 non-hydrogen atoms of the two molecules. One cycle of full matrix least-squares refinement, using 2400 low angle reflections reduced the residual R_w, defined as

$$R_w = \{\sum w||F_o| - |F_c||^2 / \sum w|F_o|^2\}^{1/2} \quad \text{with} \quad w = \sigma^{-2}$$

from 0.41 to 0.34. A modified version of the Busing *et al.* program ORFLS (29) was used for least-squares refinement. The program FORDAP, written by Zalkin (30) was used for all Fourier calculations. An electron density Fourier calculation revealed the remaining non-hydrogen atoms and the residual was lowered to 0.18 using individual isotropic temperature factors.

Refinement of anisotropic temperature factors reduced R_w to 0.15. A difference Fourier map revealed 24 hydrogen atoms of a total of 46. Further refinement and difference Fourier calculations revealed the remaining hydrogen atoms. The weighting scheme was changed to $w^{-1/2} = 1.0177 - 0.0887|F_o| + 0.0027|F_o|^2$. The coefficients were determined by fitting the average value of $\Delta = ||F_o| - |F_c||$ to $|F_o|$. 3701 reflections for which $|F_o| > 1.43\,\sigma(F)$ were used in the final cycles of full matrix least-squares refinement. The final values of R_w and the conventional R factor were 0.053 and 0.060, respectively.

The observed and calculated structure factors have been placed in the Depository for Unpublished Data.[3] The final positional and thermal parameters are listed in Table 1. The estimated errors are given as three times the estimated standard deviations calculated from the diagonal components of the inverse least-squares matrix. The U_{ij} in Table 1 are the coefficients in the expression

$$\exp\{-2\pi^2(h^2b_1^2U_{11} + \ldots + 2hkb_1b_2U_{12} + \ldots)\}$$

where the b_i represents the reciprocal lattice constants. The bond lengths and the atom numbering sequence are given in Fig. 1 and the bond angles are given in Fig. 2.

[3]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Discussion

The bond lengths to hydrogen atoms range from 0.87 to 1.10 Å, except for H(15,2) on molecule 1 which has a least-square minimum 1.35 Å from the C(15) atom. The angles subtended at the C(15) atom by this hydrogen atom are reasonable, however, and it has been included in the calculation of R_w.

4,5	56.1	43.3
4.6	78.1	79.3

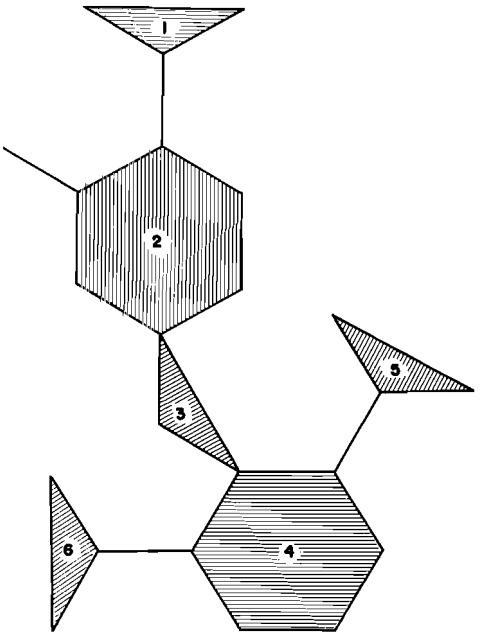

FIG. 6. Labelling nomenclature of the planes of both molecules.

hydrogen atoms mentioned above are oxygen atoms. The shortest contact involves the hydrogen atom H(15,2) on molecule 1. If this atom is removed to a more realistic distance from C(15), the contact length becomes approximately 2.85 Å. This leaves the 2.57 Å distance between O(1) on molecule 2 and H(19,3) on molecule 1 as the shortest contact distance.

The interplanar angles are given in Table 2. The labelling of the planes of the molecules is shown in Fig. 6. The rotation of the plane of the nitro group from the plane of the phenyl ring in the case of both molecules is within the range of such rotations as observed for para-substituted nitrobenzenes (32). Although the N—C(4) distances are similar to those in nitrobenzenes, substituted in the para position with electron donating groups, there is no evidence for the existence of the "edge shortening effect" that has been observed in some of them. The ellipsoid representing the nitro oxygen atom O(2) nearest the methyl group shows large thermal motion perpendicular to the plane of the nitro group. This is unexpected because the methyl hydrogen atom nearest to the plane of the phenyl ring is pointed away from the nitro group, leaving the O(2) atom between the other two methyl hydrogen atoms on either side of the phenyl ring. The N—C(4)—C(3) angles are *ca.* 6° larger than the N—C(4)—C(5) angles and the CH_3—C(3)—C(4) angles are 8.4 and 6.4° larger than the CH_3—C(3)—C(2) angles in molecules 1 and 2, respectively, showing the steric repulsion between the methyl and the nitro groups.

The nitro-substituted phenyl ring is nearly coplanar with plane 3, formed by the ether oxygen atoms and the two ring carbon atoms bonded to it, *i.e.* C(1) and C(8). Also, the length of the C(1)—O(1) bonds are 0.034(14) and 0.055(14) Å shorter than the O(1)—C(8) bonds in the two molecules. It appears that, in the solid state as well as in solution (34), one electron withdrawing substituent such as a nitro group is sufficient to cause significant enhancement of conjugative effects between the phenyl ring and the unshared electrons in the ether oxygen atom.

The angles subtended at the ether oxygen

atom by C(1) and C(8) do not differ significantly from 120°. The diisopropyl substituted ring is within 13° of being perpendicular to plane 3. The range in the orientation of this plane is limited by the contacts between the isopropyl substituents and the nitro-substituted ring. One of these isopropyls is brought closer than the other by the deviation from the perpendicular conformation. Both isopropyl groups on each of the two molecules are oriented with the methine hydrogen atom pointing approximately in the direction of the ether oxygen atom. The isopropyl groups, which are brought closer to the nitro-substituted ring by the twist of the diisopropyl-substituted ring from orthogonality with plane 3, are tilted slightly away from the nitro-substituted ring. They are oriented such that the angle between the planes of the three carbon atoms in the groups and the planes of the phenyl rings to which they are bonded is approximately 80°. The contact distances between the other isopropyl groups and the nitro-substituted ring are increased by the twist of the diisopropyl-substituted ring and they are tilted in the opposite direction. The orientation of these substituents appears to be determined in part by steric hindrances imposed by neighboring molecules, resulting in a 13° difference in the angle between the normals to the planes of the three carbon atoms and the normals to the planes of the diisopropyl-substituted phenyl rings in the two molecules.

The bond lengths within the phenyl rings fall within expected values. The terminal bonds to oxygen and carbon atoms are affected by thermal motion. If "riding motion corrections" as proposed by Busing and Levy (33) are applied, the length of the N—O(3) bonds are increased to 1.195 and 1.218 Å in molecules 1 and 2, respectively. The N—O(2) bonds are increased to 1.376 and 1.347 Å. However, this type of bond length correction is not meaningful when applied to an atom such as O(2), showing anomalous thermal behavior or positional disorder. Riding motion corrections to the terminal C—C bond lengths are given in Table 3.

In the solid state both molecules have the conformation II as discussed earlier (34) in contrast to 3,5,3′-triiodo-L-thyronine (35). The conformation of the latter may be driven by the interaction between the 3′-iodine atom and the π electrons of the thyronine ring, but the ether oxygen angle is increased by *ca.* 6° over the values found here for conformation II.

The geometry of the phenyl rings of 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene shows a number of significant deviations from the full symmetry assumed in previous calculations of magnetic shielding parameters. The inner ring angles subtended at the atoms C(9) and C(13) which are bonded to the isopropyl groups are decreased to *ca.* 116.5°. This serves to lengthen the distance between the atoms in the isopropyl groups and the rest of the molecules. The deviations from hexagonal symmetry of the internal angles of the nitro-substituted phenyl ring cause the C(3)—C(6) distances to be approximately 0.010 Å longer than the C(2)—C(5) and C(1)—C(4) distances. This distortion removes H(5), but not H(6), further from the diisopropyl-substituted ring.

In each molecule the angle C(6)—C(1)—O(1) is greater than the angle C(2)—C(1)—O(1), indicating a bending of the nitro-substituted ring away from the other ring. A measure of this bending is the difference in these angles, divided

For personal use only.

by 2, giving 4.0° for molecule 1 and 4.2° for molecule 2. This distortion should decrease the expected effect of magnetic shielding at both H(5) and H(6).

Although the bond lengths to the ether oxygen atom are similar to the values 1.395 and 1.410 Å reported for vertaline (22), the bond angle at the ether oxygen atom is larger than the value 116.1 Å for vertaline. Other reports of structural data (20, 23, 24) are of low accuracy, and most comparisons with our results are of little value. However, the short bond (1.28 Å) between the phenyl carbon atoms and the bridging oxygen atom in 4,4′-dibromodiphenyl ether is clearly inconsistent with our data. The crystal structure of a halogen-substituted diphenyl ether will be reported in the near future.

The authors thank Mr. Simon van der Heijden for the preparation of the stereoscopic drawings and the National Research Council of Canada for financial support.

Conformations of Bridged Diphenyls. II.[1] Crystal Structure of 2-(2′,4′-Dinitrophenoxy)-1,3,5-tri-*t*-butylbenzene

E. A. H. GRIFFITH, W. D. CHANDLER, AND B. E. ROBERTSON[2]

Division of Natural Sciences and Mathematics, University of Saskatchewan, Regina, Saskatchewan

Received May 10, 1972

The structure of 2-(2′,4′-dinitrophenoxy)-1,3,5-tri-*t*-butylbenzene, $C_{24}H_{32}N_2O_5$, has been determined by X-ray diffraction. The crystals are triclinic, $a = 12.160(30)$, $b = 10.564(17)$, $c = 10.684(16)$ Å, $\alpha = 119.23(10)$, $\beta = 96.06(15)$, $\gamma = 96.55(15)°$, $P\bar{1}$ with $Z = 2$. The intensities of 5359 independent reflections were measured on a four circle diffractometer of which 2471 were used in the refinement to give a final least-squares weighted residue of 0.063. The presence of two electron withdrawing groups on one of the phenyl rings increases the conjugation between the ring and the ether oxygen atom to a greater degree than was found in the previous work. The tri-*t*-butyl-substituted ring is nearly orthogonal to the other ring. The bond angle at the ether oxygen atom is less than the value found earlier but ring distortions are similar.

Nous avons déterminé la structure du 2-(2′,4′-dinitrophénoxy)-1,3,5-tri-*t*-butylbenzène, $C_{24}H_{32}N_2O_5$ par diffraction de rayons-X. Les cristaux sont tricliniques: $a = 12.160(30)$, $b = 10.564(17)$, $c = 10.684(16)$ Å, $\alpha = 119.23(10)$, $\beta = 96.06(15)$, $\gamma = 96.55(15)°$, $P\bar{1}$ avec $Z = 2$. Les intensités de 5359 réflexions indépendantes ont été mesurées sur un diffractomètre à quatre cercles; 2471 de ces réflexions ont été utilisées dans le raffinement, ce qui donne un poids moyen de résidu final par moindres carrés de 0.063. La présence de deux groupements attracteurs d'électrons sur un des noyaux phényl augmente la conjugaison entre le cycle et l'atome d'oxygène de type éther de façon plus importante que ce qu'on avait pu croire à la suite des travaux ultérieurs. Le cycle substitué de groupements *t*-butyl est presqu'orthogonal à l'autre cycle. L'angle de liaison à l'atome d'oxygène du groupe éther est moindre que la valeur trouvée précédement, mais les distortions de cycle sont semblables. [Traduit par le journal]

This is the second in a series of reports which describes n.m.r. and X-ray diffraction studies of bridged diphenyl compounds. A previous paper (1) reported the structure of 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene, which showed conjugation effects relating to the electron withdrawing character of the ring substituents and steric effects relating to the size of ortho-substituents. The phenyl rings were distorted from hexagonal symmetry and the nitro-substituted ring, which was very nearly coplanar with the central plane containing the ether oxygen atom, was bent away from the other ring. The compound which will be discussed here has even larger ortho substituents which further limit the orientation of the alkyl-substituted ring. In addition, the other ring has two electron withdrawing substituents which should enhance some of the features observed in the previous work as being due to conjugation effects. The substitution of one of the nitro groups in the ortho position could influence the relative orientation of the two aromatic rings.

Experimental

The synthesis of 2-(2′,4′-dinitrophenoxy)-1,3,5-tri-*t*-butylbenzene, $C_{24}H_{32}N_2O_5$, has been reported earlier (2). It was recrystallized from absolute ethanol, m.p. 147–148°.

A sample with well defined faces and approximate dimensions of 0.4 mm on an edge was examined by film techniques. The cell constants and the orientation of the crystal were determined on a Picker FACS-I four circle diffractometer by a least-square fit to the observed settings of 12 reflections with 2θ values between 25 and 30°. The $K\alpha_1$ and $K\alpha_2$ peaks of the Mo radiation were not resolved at these angles. The cell constants are given below with estimated errors calculated as three times the estimated standard deviations obtained from the least-squares analysis. Crystal data are as follows:

$C_{24}H_{32}N_2O_5$ f.w. = 428

Triclinic $P\bar{1}$, $a = 12.160(30)$, $b = 10.564(17)$, $c = 10.684(16)$ Å, $V = 1162$ Å^3, $\alpha = 119.23(10)$, $\beta = 96.06(15)$, $\gamma = 96.55(15)°$, $\rho_o = 1.1$ g cm^{-3} (flotation), $Z = 2$, $\rho_c = 1.2$ g cm^{-3}, $F(000) = 460$ e (21 °C, $\mu(MoK\bar{\alpha}) = 0.91$ cm^{-1}, $\lambda(MoK\bar{\alpha}) = 0.71069$ Å).

The integrated intensities of 5359 independent reflections with 2θ values between 3.5 and 55° were collected with MoKα radiation using a graphite monochromator. The θ, 2θ scan mode was used with a 2° min^{-1} scan rate, a base width of 3.0° and 20 s background counts at each limit of the scan. Although only a small fraction of the reflections collected at 2θ angles greater than 45° were significantly above the background rate of *ca.* 3 counts/s, data were collected to 55° in 2θ in order to obtain adequate accuracy

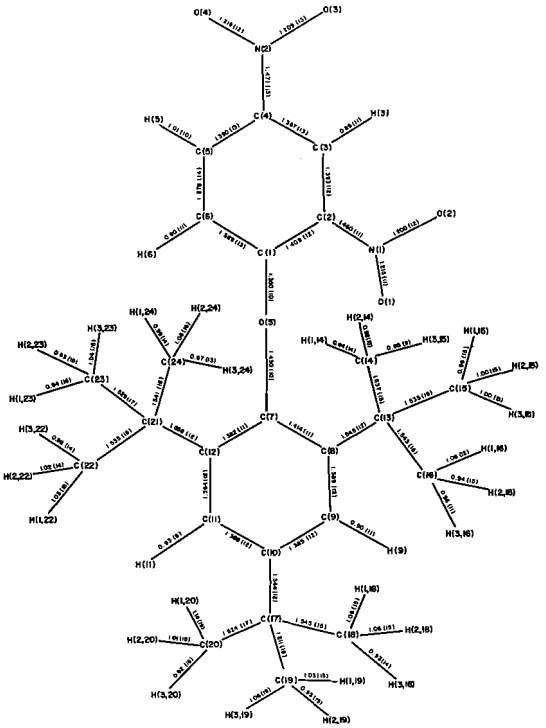

FIG. 1. Bond lengths and atom labelling sequence. Numbers in parentheses are estimated errors.

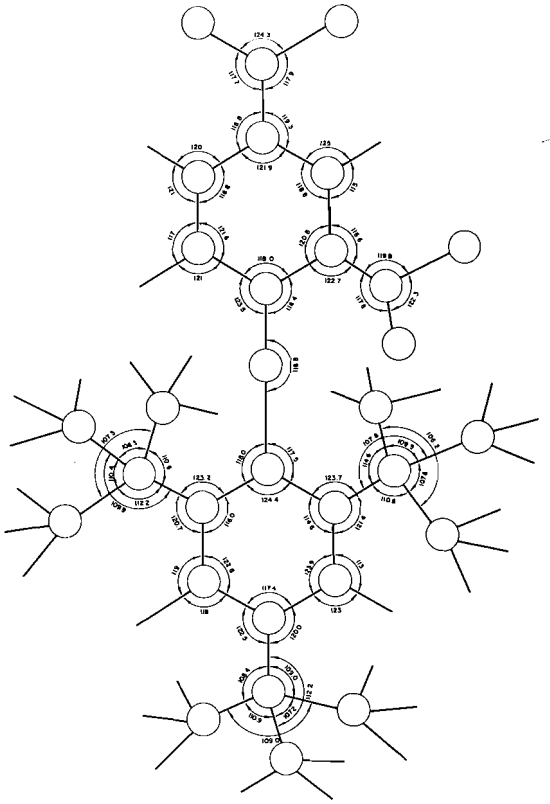

FIG. 2. Bond angles. The estimated errors of the angles not involving hydrogen atoms are *ca.* 1.2°. The estimated errors of the angles involving hydrogen atoms are *ca.* 10°.

in the molecular parameters for comparison of the geometry of this compound with that of related compounds. The intensities of three standard reflections were measured after every 100 reflections and were not found to vary significantly. The data were reduced to observed structure factors using standard procedures. The standard deviation $\sigma(F)$ was calculated as $1.0 + 0.10\,|F| + \sigma'$ where σ' is the error associated with the statistics of the integrated peak counts and the background counts. A Wilson statistical calculation gave an overall temperature factor of 3.6 Å^2. No corrections were made for absorption or extinction effects. The scattering factors for the carbon, oxygen, and nitrogen atoms were taken from those given by Cromer and Mann (3). The scattering factors for the hydrogen atoms were taken from Stewart *et al.* (4). The average values of $|E|$ and $|E^2 - 1|$ were 0.756 and 1.021 indicating the centrosymmetric space group $P\bar{1}$. The 397 reflections with $|E| > 1.8$ were used in the multiple solution, logical symbolic addition method programs of Germain and Woolfson (5). The E map calculated with the solution with the second highest figure of merit yielded 29 of the 31 non-hydrogen atoms. The program FORDAP written by Zalkin (6) was used for all Fourier calculations. Subsequent isotropic least-squares and Fourier calculations using 1623 low angle reflections revealed all non-hydrogen atoms and reduced the least-squares residue, R_w to 0.156, assuming unit weights. The full-matrix Busing *et al.* program ORFLS (7) was used for least-squares calculations. Refinement using anisotropic temperature factors lowered R_w to 0.120. The hydrogen atoms were found by different Fourier calculations and R_w was lowered to 0.070. The 2471 reflections for which $|F_o|/\sigma > 1.0$ were used in the final cycles of refinement with the least-square weights now calculated from

$$w^{-1/2} = 0.47597 - 0.01746|F_o| + 0.00124|F_o|^2$$

The final values of R_w and the conventional R factor were 0.063 and 0.053, respectively.

The observed and calculated structure factors have been placed in the Depository for Unpublished Data.[3] The final positional and thermal parameters are listed in Table 1. The estimated errors are calculated as three times the estimated standard deviations from the least-squares analysis. The U_{ij} in Table 1 are the coefficients in the expression

$$\exp[-2\pi^2(h^2a^{*2}U_{11} + \ldots + 2hka^*b^*U_{12} + \ldots)]$$

The bond lengths and angles and the atom numbering sequence are given in Figs. 1 and 2.

[3]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Discussion

All of the hydrogen atoms appear to be in reasonable positions. The bonds to hydrogen atoms range in length from 0.88(11) to 1.14(18) Å and the isotropic hydrogen temperature factors, B range from 2 to 11 Å^2. A stereoscopic view of the packing of the molecules is shown in Fig. 3. This drawing was prepared with the program ORTEP, written by Johnson (8). Each molecule is involved in 20 intermolecular contacts less than 2.8 Å in length. Of these, 16 are between hydrogen atoms, and the other four are

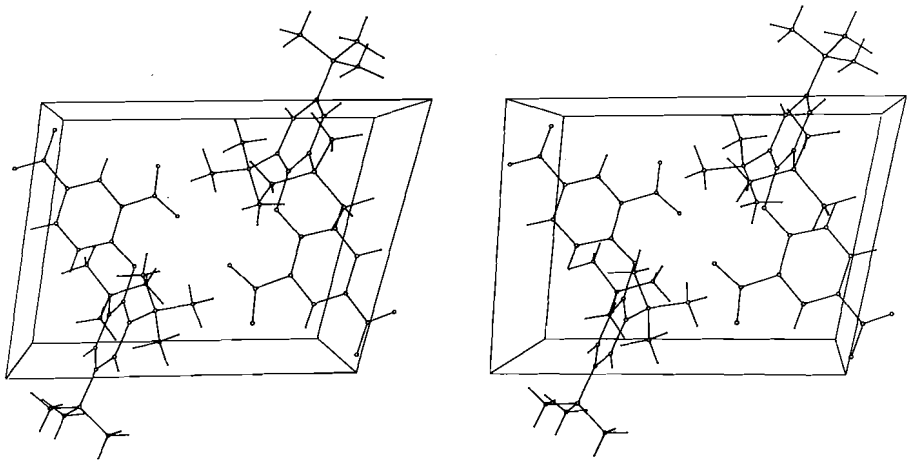

FIG. 3. Sterescopic view of the molecular packing. The origin of the unit cell is in the upper left rear corner. The ***a*** axis points to the left, the ***b*** axis points forward, and the ***c*** axis points down.

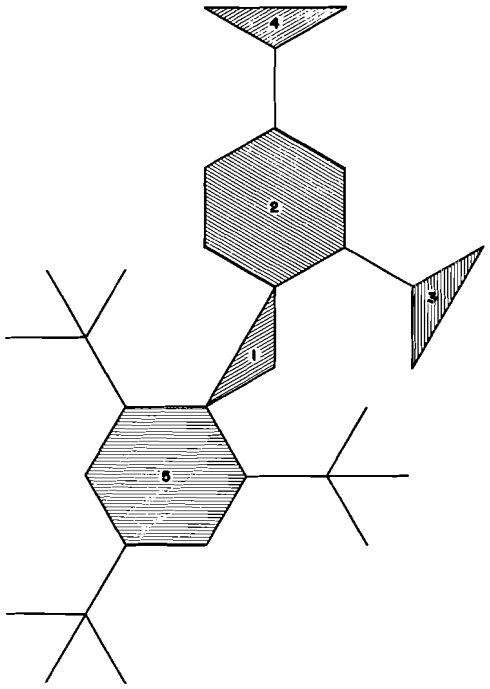

FIG. 4. Labelling sequence of the least-square planes.

between hydrogen atoms and nitro oxygen atoms. The shortest H—H contact is the 2.42 Å distance between H(15,2) and H(18,2). The shortest H—O contact is the 2.60 Å distance between H(14,1) and O(3).

The interplanar angles as labelled in Fig. 4 are given in Table 2. The plane of the para-substituted nitro group is rotated 5.2° from that of the ring to which it is bonded. This rotation is within the range observed for nitrobenzenes substituted in the para position (9). The ortho-substituted nitro group is rotated by 15.8° which is slightly outside the range. A comparison may be made with the ortho nitro group of picric acid which is not hydrogen bonded to the adjacent hydroxy group. The plane of this nitro group has been observed to be rotated 16.5° from the plane of the phenyl ring (14). The twist

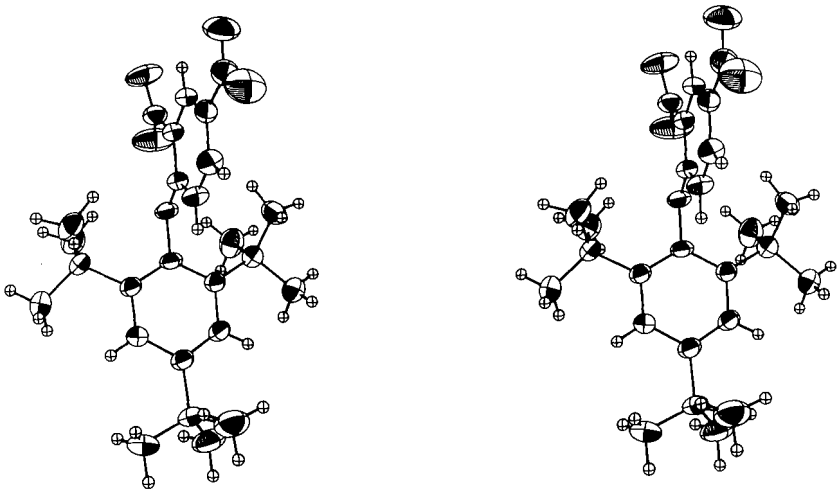

FIG. 5. Sterescopic view of the molecule. The thermal ellipsoids are scaled to include 50% probability.

observed here allows the nitro oxygen atom nearest the ether oxygen atom to be rotated away from the latter. The ortho nitro group is also bent slightly away from the ether oxygen atom at the ring carbon atom C(2) to which it is bonded. The angle between the dinitro-substituted phenyl ring and the plane formed by the ether oxygen atom and the two aromatic carbon atoms bonded to it is 3.2°. Also the C(1)—O(5) bond length is 0.080(18) Å shorter than the O(5)—C(7) bond length. This difference is approximately twice the value found for 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene (1), reflecting the presence of two electron withdrawing nitro groups on the phenyl ring. This indicates enhancement of the conjugation effect between the π electrons on the ring and the unshared electrons on the ether oxygen atoms, beyond the degree of conjugation which occurs in the presence of one electron withdrawing group. The plane of the tri-*t*-butyl-substituted ring is within 3° of being perpendicular to plane 1, as opposed to *ca.* 12° in the previous study (1). The twist of this ring from orthogonality with plane 1 and the dinitro-substituted ring is limited by the greater bulkiness of the *t*-butyl groups over the isopropyl groups.

The internal ring angles of the tri-*t*-butyl-substituted ring at the three carbon atoms bonded to the *t*-butyl groups are decreased by 2.6 to 5.4° from the 120° expected in a hexagonal ring. This effect was also observed in 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene and serves to increase the distance between the substituents and the rest of the molecule. The entire dinitro-substituted ring is bent away from the tri-*t*-butyl-substituted ring by a 2.5° twist at atom C(1), similar to the result found in the previous study. However, the bond angle subtended at the ether oxygen atom is smaller than the value found previously. The net result is to bring H(6) closer to the π-electron cloud of the other ring than was the case for the ether of the previous paper. This partly explains the as-yet-unpublished result that the n.m.r. chemical shift of H(6) is far *smaller* than expected. A stereoscopic view of the molecule is shown in Fig. 5.

The bond lengths C(2)—N(1) and C(4)—N(2) to the nitro groups are consistent with the value found earlier and the values reported for nitrobenzenes substituted at the para position with electron donating groups. The terminal bonds to oxygen and carbon atoms are significantly affected by thermal motion. Corrections to these bond lengths assuming "riding motion" (10) are given in Table 3. If these corrections are assumed, all bond lengths in the molecule fall within the range of accepted values. The general conformation of the molecule is essentially the same as that of 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene, and is the H-inside conformation inferred from solution n.m.r. spectra for similar, triply ortho-substituted diphenyl

Conformations of Bridged Diphenyls. III.[1] Crystal Structure of 2-(2′-Carbomethoxy-4′-nitrophenoxy)-1,3,5-trichlorobenzene

E. A. H. GRIFFITH, W. D. CHANDLER, AND B. E. ROBERTSON[2]

Division of Natural Sciences and Mathematics, University of Saskatchewan, Regina, Saskatchewan

Received May 24, 1972

The structure of 2-(2′-carbomethoxy-4′-nitrophenoxy)-1,3,5-trichlorobenzene, $C_{14}H_8NO_5Cl_3$, has been determined by X-ray diffraction. The crystals are triclinic, $a = 8.862(10)$, $b = 15.164(10)$, $c = 13.028(14)$ Å, $\alpha = 90.35(8)$, $\beta = 116.28(8)$, $\gamma = 97.54(8)°$, $P\bar{1}$ with $Z = 4$. The intensities of 6417 independent reflections were measured on a four circle diffractometer of which 4526 were used in the refinement to give a final least-squares residue of 0.047. The two independent molecules in the unit cell show a similar conformation to that found in earlier studies of diphenyl ethers, and the conformation appears to be determined partly by steric effects, since conjugation between the nitro-substituted ring and the ether oxygen atoms is less pronounced than found previously.

Nous avons déterminé la structure du 2-(2′-carbométhoxy-4′-nitrophénoxy)-1,3,5-trichlorobenzène, $C_{14}H_8NO_5Cl_3$ par diffraction de rayons-X. Les cristaux sont tricliniques: $a = 8.862(10)$, $b = 15.164(10)$, $c = 13.028(14)$ Å, $\alpha = 90.35(8)$, $\beta = 116.28(8)$, $\gamma = 97.54(8)°$, $P\bar{1}$ avec $Z = 4$. Les intensités de 6417 réflexions indépendantes ont été mesurées sur un diffractomètre à quatre cercles; 4526 de ces réflexions ont été utilisées dans le raffinement pour donner un résidu final par moindres carrés de 0.047. Les deux molécules indépendantes dans la maille possèdent des conformations semblables à celles trouvées au cours d'études ultérieures de diphényl éthers et la conformation semble partiellement déterminée par des effets stériques, puisque la conjugaison entre le cycle substitué par un groupe nitro et l'atome d'oxygène du groupe éther est moins prononcée que ce qu'on avait découvert précédemment. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2979 (1972)

Previous reports in this series have described the structures and conformations of doubly and triply ortho-substituted diphenyl ethers with electron withdrawing substituents on one aromatic ring and large electron donating alkyl groups on the other (1, 2). The compound whose structure is reported here differs from the former in that the ortho alkyl groups of one ring have been replaced by halogen atoms which are both smaller and electron withdrawing. The conformation of the trichloro-substituted ring might be expected to be less sterically restricted than was found in the previous work because the substituents in the ortho position are less bulky.

The lengths of the bonds to the ether oxygen atom and the bond angle at that atom might also differ from the previous results because of the presence of electron withdrawing groups on both rings. Toussaint (3) has reported unusually short C—O bond lengths in 4,4-dibromodiphenyl ether. Compounds similar to 2-(2′-carbomethoxy-4′-nitrophenoxy)-1,3,5-trichlorobenzene have been used extensively in previous studies of the effects of ring currents on aromatic hydrogen atoms using n.m.r. techniques (4).

Experimental

The synthesis of 2-(2′-carbomethoxy-4′-nitrophenoxy)-1,3,5-trichlorobenzene, $C_{14}H_8NO_5Cl_3$, has been reported earlier (5). It was recrystallized from 95% ethanol, m.p. 137–138°. A sample with length 0.8 mm and nearly rectangular cross section 0.5 × 0.6 mm was used for data collection. The cell constants and the orientation of the crystal were determined on a Picker FACS-I four circle diffractometer by a least-squares fit to the observed settings of 12 reflections with 2θ values between 38 and 41°, where the Mo $K\alpha_1$ and $K\alpha_2$ diffraction peaks were well resolved. The cell constants are given below with estimated errors calculated as three times the estimated standard deviations obtained from the least-squares analysis. The crystal was oriented with the $(\bar{1}10)$ diffraction vector nearly colinear with the *phi* rotation axis of the diffractometer. Crystal data are as follows:

$C_{14}H_8NO_5Cl_3$ f.w. = 376.5

Triclinic $P\bar{1}$, $a = 8.862(10)$, $b = 15.164(10)$, $c = 13.028(14)$ Å, $V = 1552$ Å^3, $\alpha = 90.35(8)$, $\beta = 116.28(8)$, $\gamma = 97.54(8)°$, $\rho_o = 1.58$ g cm^{-3} (flotation), $Z = 4$, $\rho_c = 1.61$ g cm^{-3}, $F(000) = 760$ e (20 °C, $\mu(\text{MoK}\bar{\alpha}) = 6.27$ cm^{-1}, $\lambda(\text{MoK}\bar{\alpha}_1) = 0.70926$ Å).

The integrated intensities of 6417 independent reflections with 2θ values between 3.5 and 55° were collected with MoKα radiation using a graphite monochromator. The θ–2θ scan mode was used with a 2° min^{-1} scan rate, a base width of 3.4° and 20 s background counts at each limit of the scan. The intensities of three standard reflections were checked after each group of 100 reflections had been measured. The average intensity of the standards increased to approximately 103% of their initial values over the period

in which the data were collected. The data were scaled to the initial intensities using linear interpolations between each set of standards.

The data were reduced to observed structure factors using standard procedures. The standard deviation $\sigma(F)$ was calculated as $1.0 + 0.10|F| + \sigma'$ where σ' is based on counting statistics. A Wilson statistical calculation gave an overall temperature factor of 4.5 Å^2. No corrections were made for absorption or extinction effects. The scattering factors for the carbon, oxygen, nitrogen, and chlorine atoms were taken from the series coefficients given by Cromer and Mann (6). The scattering factors for the hydrogen atoms were taken from Stewart *et al.* (7). The average values of $|E|$ and $|E^2 - 1|$ were determined to be 0.767 and 1.025 indicating the centrosymmetric space group $P\bar{1}$. The 463 reflections with $|E| > 1.85$ were used in the multiple solution, logical symbolic addition method programs of Germain and Woolfson (8). The solution with the third highest figure of merit gave the first non-trivial E map, showing the positions of 42 of the 46 non-hydrogen atoms. The E map and all other Fourier maps were prepared with the program FORDAP, written by Zalkin (9). An electron density Fourier map using phases calculated with the 42 atoms revealed the positions of the remaining 4 non-hydrogen atoms. Full matrix least-squares refinement with unit weights and individual isotropic temperature factors reduced the weighted residue R_w to 0.169. The program ORFLS (10) was used for least-squares refinement. A difference map calculated at this point revealed 7 of the 16 hydrogen atoms. The temperature factors of the non-hydrogen atoms were then refined anisotropically, lowering R_w to 0.106. Further cycles of difference Fourier and least-squares calculations revealed the remaining hydrogen atoms. Only 2270 low angle reflections were used up to this point and now all 4526 reflections for which $|F|/\sigma > 1.03$ were used in the refinement. The least-squares weights, w, were calculated from

$$w^{-1/2} = 1.0948 - 0.07368|F| + 0.00173|F|^2$$

The final values of R_w and the conventional R factor were 0.047 and 0.052, respectively.

The observed and calculated structure factors have been placed in the Depository for Unpublished Data.[3] The final positional and thermal parameters are listed in Table 1. The estimated errors are calculated as three times the estimated standard deviations from the least-squares analysis. The U_{ij} in Table 1 are the coefficients in the expression

$$\exp[-2\pi^2(h^2a^{*2}U_{11} + \ldots + 2hka^*b^*U_{12} + \ldots)]$$

The bond lengths, bond angles, and the atom numbering sequence used for both of the independent molecules in the asymmetric unit of the structure are given in Figs. 1 and 2.

Discussion

All of the hydrogen atoms appear to be well behaved with the bond lengths to hydrogen

[3]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

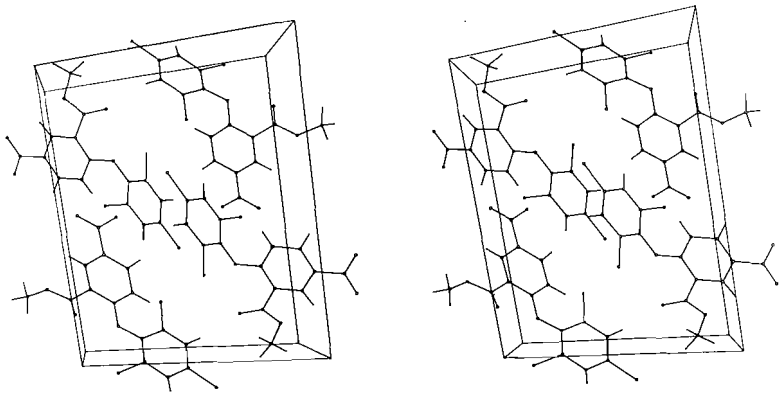

FIG. 3. Stereoscopic view of the molecular packing. The origin is in the lower left front corner. The ***a*** axis points back into the page, the ***b*** axis points up, and the ***c*** axis points to the right. Molecule 1 is nearer the origin.

atoms ranging from 0.85(20) to 1.03(16) Å, and the hydrogen atom temperature factors, B, ranging from 3 to 15 Å^2. A stereoscopic view of the packing of the molecules is shown in Fig. 3. Stereoscopic drawings were prepared with the aid of the program ORTEP (11). Molecule 1 is involved in a total of 6 intermolecular contacts less than 2.8 Å in length, and molecule 2 is involved in 10 such contacts. For each molecule, three of the contacts shorter than 2.8 Å involve

a non-hydrogen atom. The shortest contact is between the atom O(2) of molecule 2 and H(3) of molecule 1 and has the length 2.43 Å.

The dihedral angles between the molecular planes which are labelled in Fig. 4 are given in Table 2. In both molecules the nitro group is nearly coplanar with the nitro-substituted ring. Lehmann and Shefter (12) have recently determined the structures of 1-(2′,4′-dinitro-6′-bromophenoxy)-naphthalene and 2-(2′,4′-dinitrophenoxy)-1,3-diiodo-5-methylbenzene. The nitro-inside conformation of the former forces the ortho-nitro substituent near the naphthyl moiety, causing it to rotate so that its plane makes an angle of 25° with the dinitro-substituted ring. The latter compound has the "H-inside" conformation which allows the ortho-nitro substituent to point away from the diiodo-substituted ring and yet this nitro group is rotated 40° from the plane of the dinitro-substituted ring, increasing the contact distance between the ether oxygen atom and the nearest oxygen atom on the ortho nitro group to 2.70 Å. The equivalent rotation found previously for 2-(2′,4′-dinitrophenoxy)-1,3,5-tri-*t*-butylbenzene (2) was 15.8° which gave a nitro oxygen atom to ether oxygen atom intramolecular contact of 2.570 Å. In the present study, the carbomethoxy substituents occupy the equivalent position and are rotated by 23.1 and 20.1° from the plane of the nitro-

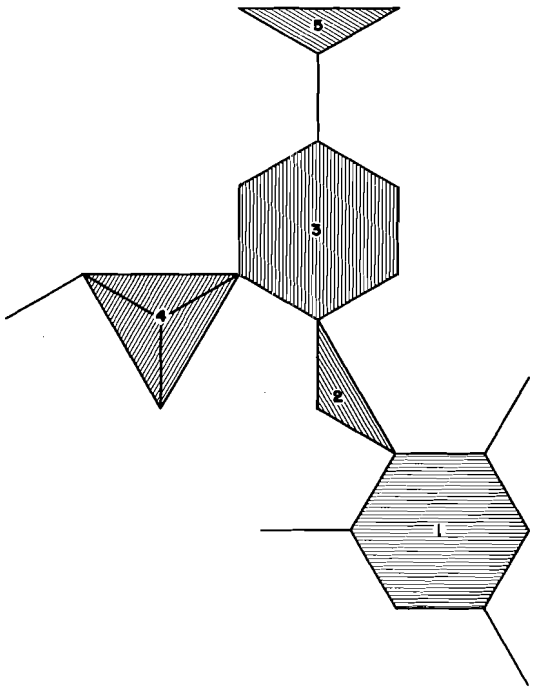

FIG. 4. Labelling sequence of the least-square planes in the two molecules.

substituted ring, giving carbonyl oxygen to ether oxygen distances of 2.715 and 2.690 Å, respectively, in the case of molecule 1 and molecule 2.

The nitro substituted rings are 8.8 and 4.6° from being coplanar with the central plane formed by the ether oxygen atom and the two carbon atoms bonded to it. The former value, relating to molecule 1, is somewhat larger than the values found previously; but the general conformation of both molecules is similar to that found for both 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene and 2(2′,4′-dinitrophenoxy)-1,3,5-tri-*t*-butylbenzene (1, 2). However, the differences between the two C—O bond lengths, which are 0.033(24) and 0.000(21) Å, are on the average less than the values found previously. This change is related to the presence of the mildly electron withdrawing chlorine substituents rather than electron donating alkyl groups. The results for 1-(2′,4′-dinitro-6′-bromophenoxy)naphthalene indicate a slight difference in C—O bond lengths and those for 2(2′,4′-dinitrophenoxy)-1,3-diiodo-5-methylbenzene do not (12), which is consistent with our results. However, the accuracy with which these structures have been determined is low.

In molecule 2, the plane of the trichloro-substituted ring is perpendicular to the central plane, but in molecule 1, the trichloro-substituted ring is turned 14° from the perpendicular position. Presumably, this difference in the two molecules is imposed by the molecular packing and shows the greater freedom of orientation of the doubly ortho-substituted ring associated with the less bulky character of the chlorine atoms. Stereoscopic views of the molecules are given in Figs. 5 and 6. The thermal ellipsoids of all the non-hydrogen atoms of both molecules show an elongation in the ***a*** direction. This effect may be related to the increased absorption in these crystals over that occurring in the previous studies of this series because of the presence of the chlorine atoms. However, the maximum possible variation in $|F_o|$ resulting from absorption is only 4% for the crystal used for data collection. An alternative explanation is that the long range order of the sample is greater in the plane perpendicular to the ***a*** axis than in the direction parallel to the ***a*** axis. An examination of the packing diagram shows that the crystal is constructed of layers perpendicular to the ***a*** axis and containing the aromatic parts of the molecules, which are interposed by regions containing the polar substituents. The degree of ordering of these layers may be less than the order within the individual layers.

The nitro-substituted ring is bent away from the trichloro-substituted ring by a 2.4° twist at the atom C(7), a value similar to those found earlier (1, 2). The internal ring angles at the carbon atoms bonded to the chlorine atoms are increased from the 120° expected for a hexagonally symmetric ring by an average of 1.2° for the two molecules. This deviation is in the opposite sign to that found for the alkyl groups and may manifest either the smaller size of the chlorine atoms or their electron withdrawing character.

The terminal bonds to the chlorine substituents, the nitro oxygen atoms, the carbonyl oxygen atom, and the methyl carbon atom are significantly affected by thermal motion. Table 3 shows the corrections to those bond lengths assuming *riding motion* as discussed by Busing and Levy (13). The average C—Cl bond length is increased from 1.724 to 1.749 Å. The correc-

tions for some of the other bond lengths do not appear to be realistic, reflecting the limitations of the *riding motion* model.

The average bond length to the ether oxygen atoms, 1.376(7) Å, is slightly less than the average values of 1.386(6) Å in 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene and 1.387(7) Å in 2-(2′,4′-dinitrophenoxy)-1,3,5-tri-*t*-butylbenzene, but much larger than the value given by Toussaint for 4,4′-dibromodiphenyl ether (3), and the C—O bond length of 1.28 Å for that compound appears to be inaccurate.

Table 4 shows the ether oxygen atom bond angles of the diphenyl ethers whose structures

have been determined by X-ray diffraction methods. The values given for diphenyl ether and 4,4′-dibromodiphenyl ether are assumed to be inaccurate and are only shown for comparison. The two aromatic rings of the alkaloid vertaline are joined by bridging groups and this appears to cause a small increase in the bending at the ether oxygen atom. The thyroid hormone 3,5,3′-triiodo-L-thyronine has the conformation with the 3′ iodine substituent inside, toward the diiodo-substituted ring, which causes an increase in the ether bond angle. All of the other examples with a meta or ortho substituent adopt the "substituent outside" conformation and the ether bond angle for these samples and those with no meta or ortho substituents on the equivalent ring, is between 116.8 and 121°.

The results which have been obtained to date

allow some observations regarding the conformational tendencies of diphenyl ethers with one diortho-substituted ring. The structure of 3,5-diiodo-L-thyronine, as reported recently by Cody *et al.* (17), shows the diiodo-substituted ring to be approximately perpendicular to the central C—O—C plane. The diortho substituted ring of 1-(2′,4′-dinitro-6′-bromophenoxy)naphthalene has a similar orientation although it is rotated 22° from the position perpendicular to the central plane. This indicates that the steric effects of the two ortho substituents cause the ring to which they are bonded to be approximately perpendicular to the central C—O—C plane. Further, this effect takes precedence over the tendency for the aromatic ring with the electron withdrawing groups to be coplanar with the central plane in order to allow conjugation between the π electrons of the ring and the unshared electrons of the ether oxygen atom. The diphenyl ethers with one meta or ortho substituent on the other ring adopt a similar conformation.

The other ring adopts an orientation nearly perpendicular to the diortho-substituted ring. This applies to rings with only a para substituent or with one ortho or meta substituent. All examples with one ortho-substituent adopt the substituent outside conformation. 2-(3′-Methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene, with one meta substituent, adopts the substituent outside conformation, but 3,5,3′-triiodo-L-thyronine adopts a substituent inside conformation. Camerman and Camerman have attempted to rationalize this conformation using extended Hückel molecular orbital calculations which show the substituent inside conformation to be marginally favorable. This conformation might also be favored on the basis of the relative steric effects of the packing of the molecules for each of the two possible conformations.

Within the limits imposed by the bulkiness of the ortho substituents on the diortho-substituted ring, the planes of the two rings may be rotated from the perpendicular position to accommodate steric interactions with other molecules determined by the molecular packing in the crystal. A rotation about the C—O bond to the diortho-substituted ring brings one ortho substituent near the other ring and tends to *open up* the space between the second ortho substituent and the other ring to utilization by another molecule, thus allowing efficient use of space in the packing of the molecules. Rotation about the C—O bond to the ring which is not diortho-substituted closes up both spaces between the ortho substituents on the diortho-substituted ring and the other ring, which may in some cases allow more efficient packing than that resulting from the previous type of rotation. However, rotation about this bond may be restricted by a strong conjugation effect. 2-(2′,4′-Dinitrophenoxy)-1,3-diiodo-5-methylbenzene shows a rotation of the latter type (12). 1-(2′-4′-Dinitro-6′-bromophenoxy)-naphthalene shows some of each type of rotation (12). 2-(2′,4′-Dinitrophenoxy)-1,3,5-tri-*t*-butylbenzene has large ortho substituents and exhibits very small rotations (2). 2-(3′-Methyl-4′-nitrophenoxy-1,3-diisopropylbenzene shows a rotation of the former type. One molecule of 2-(2′-carbomethoxy-4′-nitrophenoxy-1,3,5-trichlorobenzene exhibits rotations of both types and the other remains nearly unrotated from the position with one plane perpendicular to the central plane and the other coplanar with the central plane.

Lehmann (19) has postulated the existence of intramolecular π complexes with the iodine and bromine atoms substituted on the opposite ring in order to explain the conformations of 2-(2′,4′-dinitrophenoxy-1,3-diiodo-5-methylbenzene and 1-(2′,4′-dinitro-6′-bromophenoxy)-naphthalene. This would seem improbable because in each case the halogen atom is not directly above the opposing ring but rather is slightly outside and above it.

The crystal structure of 2-(2′,4′-dinitrophenoxy)-1,3-diiodo-5-methylbenzene does, in fact, contain an intermolecular O---I charge transfer complex which has not been noted by the original investigators. One of oxygen atoms of the para nitro substituent is 3.11 Å from an iodine atom on an adjacent molecule. This distance is 0.44 Å shorter than the sum of van der Waals radii. The O---I—C angle is 161° which is only slightly smaller than the range of values reported elsewhere (18). The N—O(I) distance, at 1.24 Å, is 0.14 Å longer than the N—O distance to the other oxygen atom of the para nitro substituent, and the O—N—O angle for this group is opened to 139°. This interaction may be partly responsible for the large rotation (26°) of the dinitro substituted ring from the position coplanar with the central C—O—C plane.

INDO Molecular Orbital Calculations of Nitrogen–Proton Spin–Spin Coupling Constants Over Two and Three Bonds. Effects of Lone-pair Orientation, of Dihedral Angles, and of Protonation

R. WASYLISHEN[1] AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received April 12, 1972

Molecular orbital theory at the INDO level of approximation is used to calculate the Fermi contact contribution to two-bond and three-bond nitrogen–proton coupling constants for a wide variety of compounds. The dependence of calculated N,H coupling constants upon the spatial orientation of the nitrogen lone-pair is examined for selected molecules. For both saturated and unsaturated compounds the calculated $^2J(^{15}N,H)$ is large and negative when the lone-pair is oriented *cis* to the proton, and is small and of either sign when the lone-pair lies *trans* to the proton. Calculated $^3J(N,H)$ depends both on the orientation of the nitrogen lone-pair and on the *HCCN* dihedral angle. Computed $^2J(N,H)$ and $^3J(N,H)$ generally follow the experimentally known substituent and structural effects. It is suggested that observed phosphorus–proton coupling constants in tervalent phosphorus compounds are dependent on lone-pair orientation in a manner analogous to the corresponding nitrogen–proton coupling constants. The influence of the nitrogen lone-pair orientation on geminal proton–proton coupling constants in methylamine is computed and compared with experiment. Calculated barriers to pyramidal inversion and methyl group rotation are in reasonable agreement with available experimental data.

Nous utilisons la théorie des orbitales moléculaires associée à l'approximation INDO pour calculer la contribution du contact de Fermi aux constantes de couplage à deux et à trois liaisons entre l'azote et le proton pour une grande variété de composés. Nous examinons la dépendance des constantes de couplage N,H calculées sur l'orientation spatiale de la paire d'électrons libres de l'azote, dans le cas de certaines molécules. Pour les composés saturés ou insaturés, le $^2J(^{15}N,H)$ calculé est grand et négatif si la paire d'électrons libres est *cis* par rapport au proton; il est petit et positif ou négatif si la paire est *trans* par rapport au proton. Le $^3J(N,H)$ calculé dépend à la fois de l'orientation de la paire d'électrons libres de l'azote et de l'angle dièdre *HCCN*. Les $^2J(N,H)$ et $^3J(N,H)$ compilés obéissent généralement aux effets connus expérimentalement de structure et de substituant. Nous suggérons que les constantes de couplage phosphore–proton observées dans les composés de phosphore trivalent dépendent de l'orientation de la paire d'électrons libres, d'une façon semblable aux constantes de couplage correspondantes azote–proton. Nous étudions l'influence de l'orientation du doublet libre de l'azote sur les constantes de couplage géminé proton–proton du méthylamine et comparons avec l'expérience. Les barrières à l'inversion pyramidale calculées et la rotation des groupes méthyle concordent avec les résultats expérimentaux disponibles. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 2989 (1972)

Introduction

There exists considerable experimental and theoretical interest in the correlation of the signs and magnitudes of nuclear spin–spin coupling constants with molecular structure (1–5). Attention has been focussed on the derivation of empirical relationships between coupling constants and parameters such as the electronegativity and spatial orientation of substituents, the direction of lone-pair electrons,[2] as well as bond angles and bond orders. These relationships have proved useful in conformational studies (5). Recently (2, 3) the success of the INDO molecular orbital approximation in the calculation of geminal and vicinal proton–proton coupling constants has been demonstrated (6–9).

Detailed mapping of structural and substituent effects on two- and three-bond nitrogen–proton coupling constants has been hampered by experimental difficulties arising from the electric quadrupole moment of ^{14}N (natural abundance of 99.635%). Consequently $J(^{14}N,H)$ is only observable in molecules where the fluctuating electric field gradients at the nitrogen atom are small. The other isotope of nitrogen, ^{15}N, has spin 1/2 but its low natural abundance (0.365%) makes the measurement of $J(^{15}N,H)$ values difficult in unenriched samples. Nevertheless, a considerable body of data is now available (10, 11) for comparison with theory.

In the present paper, the technique of Pople *et al.* (6–8) is employed in the study of structural and substituent effects on two- and three-bond nitrogen–proton coupling constants. In particular, the dependence of the calculated N,H coupling constants on the orientation of the nitrogen lone-pair, on the *NCCH* dihedral angle, and on the substituent electronegativity is examined. Computed N,H coupling constants are compared with experimental values when these are available. An attempt is made to compare the angular dependence of the calculated N,H coupling constants with that observed for phosphorus–proton coupling constants in certain molecules. The change in N,H couplings caused by protonation at nitrogen is also calculated and is compared to experiment.

Computational Method

In the finite perturbation formalism, the Fermi contact contribution to nuclear spin–spin coupling between two nuclei A and B is given by eq. 1 (6–8).

$$[1]\quad J_{AB} = \frac{\hbar}{2\pi}[(8\pi/3)\beta]^2\gamma_A\gamma_B S_A^2(0)S_B^2(0) \times [(\partial/\partial h_B)\rho^{spin}_{S_AS_A}(h_B)]h_B = 0$$

h_B is the perturbation due to the nuclear moment μ_B and has the form

$$h_B = \frac{8}{3}\pi\,\beta\mu_B S_B^2(0)$$

$\rho^{spin}_{S_AS_A}(h_B)$ is the diagonal element of the spin density matrix (in the presence of the contact perturbation h_B) corresponding to the valence s orbital of atom A, γ_A and γ_B are the magnetogyric ratios of nuclei A and B, β is the Bohr magneton, and $S_A^2(0)$ and $S_B^2(0)$ are the valence s-orbital electron densities of atom A and atom B at their respective nuclei. Using the method of finite differences Pople *et al.* (7) have shown that the derivative in eq. 1 can be approximated by $\rho^{spin}_{S_AS_A}(h_B)/h_B$. Thus the coupling constant (in Hz) is approximated by the expression

$$[2]\quad J_{AB} = \frac{\hbar}{2\pi}[(8\pi/3)\beta]^2\gamma_A\gamma_B S_A^2(0)S_B^2(0) \times [\rho^{spin}_{S_AS_A}(h_B)/h_B]$$

The error in the approximation has a minimum when h_B is approximately 10^{-3} hartrees and $\rho^{spin}_{S_AS_A}(h_B)$ is calculated using open-shell semi-empirical molecular orbitals at the INDO level of approximation (8, 12).

All coupling constants were calculated using eq. 2 with the same parameterization as used previously by Pople *et al.* (7, 8). Because all other terms in eq. 2 are taken as constant, it is the sensitivity of the spin density in the orbital S_A to the presence of the perturbation h_B which determines the spin–spin coupling constants. Because h_B is small, the spin densities are extremely small and therefore the spin density matrix must be known very accurately in the calculation of coupling constants. For nitrogen–proton coupling constants, $J(^{14}N,H) = 141174.7016\ \rho^{spin}_{H_sH_s}$ Hz when $h_N = 10^{-3}$ hartrees. In order to obtain reasonably accurate coupling constants the usual energy criterion for convergence of the SCF iteration was changed to the requirement that

$$[3]\quad 10^{-4} \leqslant \frac{\rho_{ii}^{old} - \rho_{ii}^{new}}{\rho_{ii}^{old}}$$

for all i. By this criterion one can estimate the accuracy of the calculated coupling constants since J_{AB} is directly proportional to ρ^{spin}_{AA}/h or ρ^{spin}_{BB}/h depending on whether A or B is perturbed. For example, consider the accuracy of a calculated $J(^{14}N,H)$ with a magnitude of 14.12 Hz. If the convergence criterion given by eq. 3 is satisfied then the change in $J(^{14}N,H)$ in one SCF cycle is less than 0.00141 Hz. When coupling constants did not converge in 90 SCF cycles using the criterion given by eq. 3, 100 SCF cycles were carried out. An attempt was made to calculate the N,H coupling constants in nitromethane, methylnitrate, and *N*,*N*-dimethylnitrosoamine, but even after 100 SCF cycles the energy and the coupling constants did not converge. Therefore the results of these calculations are not given.

The input data for a calculation required the cartesian coordinates of all atoms, the total charge, and the multiplicity of the molecule. Since the calculated coupling constants were often very sensitive to the molecular geometry, an attempt was made to use the best available structural parameters. The atomic coordinates were usually calculated from these structural parameters with the aid of the "Model-Builder"

For personal use only.

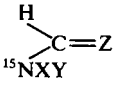
program MBLD (13). The sources of the structural parameters or atomic coordinates are given in the appropriate tables and are discussed in the text.

All calculations were carried out on an IBM 360/65 computer.

Results and Discussion

(1) Two-bond Nitrogen–Proton Coupling Constants

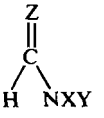
In Table 1 calculated two-bond ^{15}N,H coupling constants in the ^{15}N—C—H fragment are given for 31 compounds. Available experimental data are presented for comparison. In a few cases, where couplings have been observed for large molecules (greater than 40 valence electrons), comparison is made with values calculated for closely related smaller molecules. To simplify the discussion, the compounds in Table 1 are divided into three groups. The compounds in the first group (1–9) contain the



fragment. In the second group (10–15) the carbon atom of the ^{15}N—C—H fragment is bound to four atoms (approximately sp^3 hybridized) or to two atoms (approximately sp hybridized). The compounds in the third group (16–31) are either molecules with which one may associate a "localized nitrogen lone-pair" or are their protonated derivatives.

(a) Compounds 1–9, Table 1

The observed values of $^2J(^{15}N,H)$ in the



fragment range from −19.0 Hz in formamide (Z = O) through (−)8.3 Hz in *N,N*-dimethyl-^{15}*N*-phenyl-formamidine (Z = NC_6H_5) to ±0.2 Hz in diethylanilinomethylene malonate (Z = CR'_2). The calculated values are in fair agreement with experiment: −17.23 Hz in formamide, −6.65 Hz in formamidine (Z = N—H), and 0.23 Hz in vinylamine (Z = ). This large range of $^2J(^{15}N,H)$ values is analogous to the range of $^2J(H,H)$ values observed and calculated in the C=Z fragment (2, 18).

The observed decrease in $^2J(^{15}N,H)$ between Z = and Z = O has been attributed to the higher electronegativity of the oxygen atom as well as to the increase in the π-bond order of the C—N bond (10, 11, 23). In Table 2 calculated values of $^2J(^{15}N,H)$ are compared with calculated C—N bond orders and with calculated charge densities at the carbon atom of the *NCH* fragment. As the electronegativity of Z decreases, the C—N bond orders decrease and the positive charge on the carbon atom of the NCH fragment also decreases, confirming the qualitative arguments (10, 11, 23).

The effect of an electronegative substituent placed β to the carbon atom of the N—C—H fragment was also investigated. In Table 3 the calculated values of $^2J(^{15}NCH)$ for three *trans*-X-vinylamines are compared with the calculated and observed $^2J(HCH)$ values in the corresponding substituted ethylenes (2). From Tables 2 and 3, it is apparent that the calculated reduced coupling constants $^2K(NCH)$ show the same trends as the $^2K(HCH)$ values (2, 38).[3]

(b) Compounds 10–15, Table 1

In molecules where the carbon atom of the N—C—H fragment is bound to four atoms (compounds 10–13 and 16–21) the known two-bond ^{15}N,H coupling constants are usually less than 3.5 Hz in magnitude (10). Exceptions have been observed in cyclic molecules where the relevant dihedral angle[4] is fixed on the n.m.r. time scale (see compounds 19–21). In the next section it is shown that when the carbon atom is bound to four groups, one of them being a nitrogen atom with a "localized lone-pair", $^2J(^{15}N,H)$ is predicted to vary over a wide range. However, internal rotation has the consequence that the observed values of these coupling con-

[3]The reduced coupling constant is defined as $K_{AB} = 2\pi J_{AB}/\hbar\gamma_A\gamma_B$. Since $\gamma(^1H)$ and $\gamma(^{15}N)$ are of opposite sign, $K(^{15}N,H)$ and $J(^{15}N,H)$ are also of opposite sign.

[4]In the simple hybridization picture the nitrogen lone-pair has directional character; therefore it is reasonable to define a dihedral angle between the plane containing the NCH fragment and the plane containing the lone-pair, NC fragment.

stants are small (see compounds 16 and 18, for example).

Calculated values for compounds 10–15 agree fairly well with experiment. Both the calculated and observed $^2J(^{15}N,H)$ increase on going from ethylisocyanide to methylisocyanide. The calculated $^2J(^{15}N,H)$ in protonated hydrogen cyanide is 11.39 Hz, significantly lower than the observed value of 19.0 Hz (27). This discrepancy is probably due in part to the choice of geometry for the protonated species.

(c) Compounds 16–31, Table 1

It is known that the observed two-bond $^{15}N,H$ coupling constants in compounds 19–23, 25, 27, and 29 are stereospecific, depending on the orientation of the nitrogen lone-pair (10, 11, 33). Specifically, if the lone-pair is directed *cis* to the C—H bond then $^2J(^{15}N,H)$ is observed and calculated (see Table 1) to be large and negative; if the nitrogen lone-pair and C—H bond lie *trans* to one another then the absolute value of $^2J(^{15}N,H)$ is small. To test the generality of this rule, the angular dependence of $^2J(^{15}N,H)$ was calculated for methylamine, methylisocyanate, methylenimine, and aziridine. The results of these calculations are presented in Figs. 1, 2, 3, and 4. In each calculation bond lengths were taken to be the same as those in the ground state conformation (see geometry references in Table 1).

(i) Methylamine

In Fig. 1, $^2J(^{15}N,H)$ is plotted as a function of the angle, θ, defined in **I** and **II**. This angle can also be described as the dihedral angle defined by the lone-pair, NC fragment and the NCH fragment.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

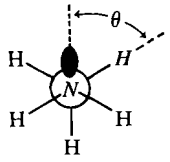
I



II

For $\theta = \theta^\circ$ one of the C—H bonds eclipses the lone-pair and $^2J(^{15}N,H)$ for the proton in that bond is calculated as large and negative, -14.90 Hz. For $\theta = 180^\circ$, one of the C—H bonds sits *trans* to the lone-pair and $^2J(^{15}N,H)$ is -0.40 Hz. Notice that $^2J(^{15}N,H)_{cis}$ and $^2J(^{15}N,H)_{trans}$ predicted for methylamine are similar to those observed for unsaturated compounds such as formaldoxime (compound 22).

To compare experimental and calculated couplings in methylamine, one need only consider the staggered conformation because the barrier to rotation about the C—N bond is 1.98 kcal/mol (39). For the staggered conformation one calculates an average of -2.70 Hz while the observed value is -1.0 Hz (28) (INDO calculates the barrier to rotation of the methyl group as 1.74 kcal/mol).

Few observations are available for two-bond $^{15}N,H$ coupling constants in saturated systems of fixed geometry. However, it is of some interest to compare calculations for methylamine with those observed for the saturated 1,3-oxazine (**III**). Riddel and Lehn (40) measured $^2(J^{15}N, H_{2a})$ and $^2J(^{15}N,H_{4a})$ as approximately zero, while $^2J(^{15}N,H_{4e})$ was about 1.5 Hz. The sign of the latter coupling is almost certainly negative since on protonation of the nitrogen atom these couplings are no longer resolved.[5] Notice that the relevant angle is approximately 180° for H_{2a} and H_{4a} while for H_{4e} it is approximately 60°. For $\theta = 180 \pm 5^\circ$ and $\theta = 60 \pm 5^\circ$, INDO calculates $^2J(^{15}N,H)$ as -0.4 ± 0.1 and -3.8 ± 1.3 Hz, respectively, for methylamine.

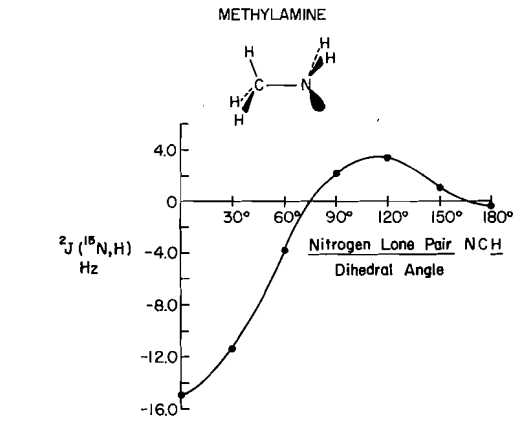


FIG. 1. A plot of the calculated $^2J(^{15}N,H)$ *vs.* the dihedral angle defined by the lone-pair—N—C—H fragment in methylamine.

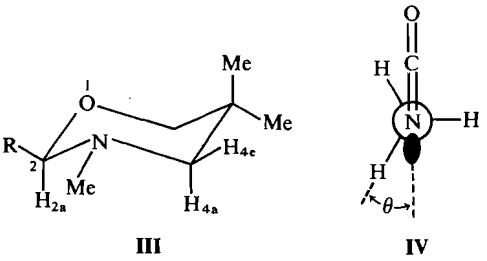

III IV

(ii) Methylisocyanate

In Fig. 2 the calculated $^2J(^{15}N,H)$ in methylisocyanate is plotted as a function of the angle θ, defined in **IV**. The plot closely resembles that calculated for methylamine. For a given θ, this

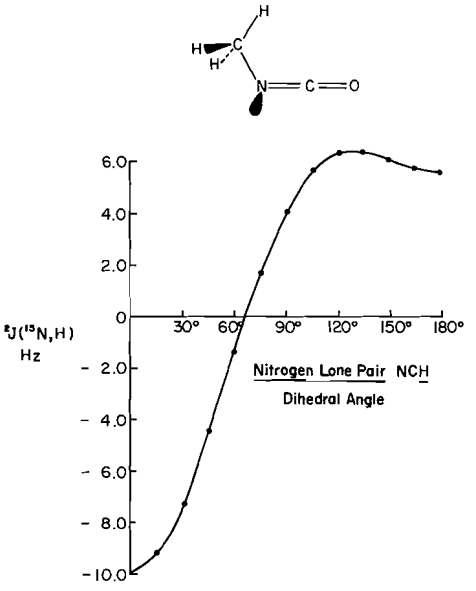

FIG. 2. A plot of the calculated $^2J(^{15}N,H)$ *vs.* the dihedral angle defined by the lone-pair—N—C—H fragment in methylisocyanate.

[5]The choice of sign is based on the observation that $^2J(^{15}N,H)$ usually increases on protonation (33). This observation is supported by the MO calculations. For example, in protonated methylamine INDO calculates $^2J(^{15}N,H) = 2.43 \pm 0.05$ Hz, independent of the HNCH dihedral angle.

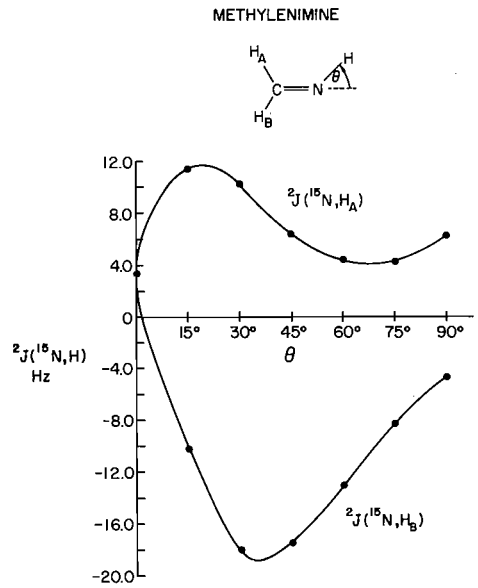

FIG. 3. A plot of the calculated $^2J(^{15}N,H)$ *vs.* the indicated angle θ in methylenimine.

coupling in methylisocyanate is calculated to be larger than in methylamine. $^2J(^{15}N,H)$ is 5.52 Hz when the C—H bond lies *trans* to the lone-pair ($\theta = 180°$); when the C—H bond lies *cis* to the lone-pair ($\theta = 0°$), $^2J(^{15}N,H)$ is -9.93 Hz.

The conformation of lowest energy is calculated as one in which a C—H bond eclipses the nitrogen lone-pair ($\theta = 0°$). The barrier to rotation of the methyl group is calculated as 102 cal/mol, in good agreement with the experimental barrier of 83 ± 15 cal/mol (41). Because the barrier is so small, comparison of calculated with experimental coupling constants entails an average over all angles and one finds $^2J(^{15}N,H) = 0.88$ Hz. This coupling constant has not been measured in methylisocyanate; in the related compound, methylisothiocyanate, $^2J(^{15}N,H) = \pm 3.3$ Hz (29).

TABLE 4. Calculated values of $^2J(^{15}N,H)$ for some substituted methylenimines*

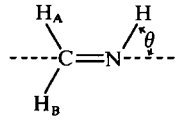
F	−6.48	10.04

*Standard geometries (8, 37) were used for all calculations.
†The C—Li bond length was taken as 2.1 Å.

(iii) Methylenimine

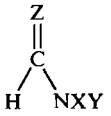
For methylenimine (**V**), $^2J(^{15}N,H)$ is plotted against θ in Fig. 3. INDO finds the lowest energy when $\theta \simeq 65°$. At this angle $^2J(^{15}N,H_A) = 4.18$ and $^2J(^{15}N,H_B) = -11.41$ Hz.



V

The barrier to pyramidal inversion is calculated to be 25.5 kcal/mol, in good agreement with the values of 27.9 and 26.2 kcal/mol found by *ab initio* SCF–LCAO–MO methods (42, 43).

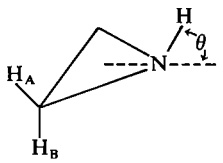
The INDO method was employed to examine substituent effects on $^2J(^{15}N,H)$ values in three hypothetical *syn*- and *anti*-substituted methylenimines (Table 4). As the electronegativity of X increases, $^2J(^{15}N,H)$ increases for both the *syn* and *anti* isomers. Notice that the change in $^2J(^{15}N,H)$ is opposite to the trend observed and calculated in the



fragment.

(iv) Aziridine

In Fig. 4 the calculated values of $^2J(^{15}N,H)$ in aziridine (**VI**) are plotted as a function of the angle θ between the bisector of the CNC angle and the N—H bond. INDO finds a minimum energy when $\theta \simeq 68°$, and then $^2J(^{15}N,H_A) = -0.62$ and $^2J(^{15}N,H_B) = -9.14$ Hz. The barrier to pyramidal inversion is calculated as 24.5 kcal/mol, somewhat larger than the values of 16–19 kcal/mol observed for aziridine derivatives (44).



VI

For oxaziridine (see compounds 19 and 20 in Table 1), $^2J(^{15}N,H)$ was also calculated as a

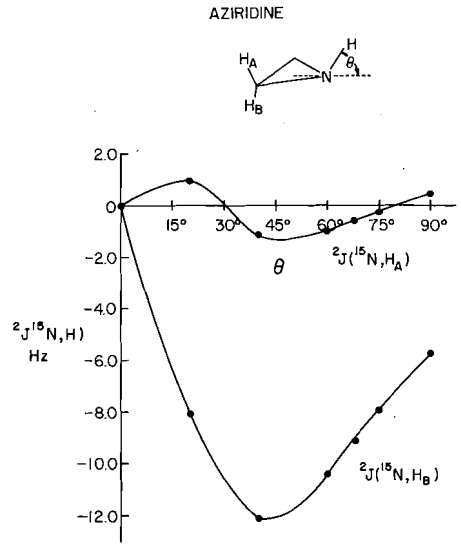


FIG. 4. A plot of the calculated $^2J(^{15}N,H)$ in aziridine *vs.* the angle θ between the N—H bond and the extension of the bisector of the CNC angle.

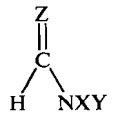
function of θ. Its angular dependence was very similar to that obtained for aziridine although $^2J(^{15}N,H)$ in oxaziridine was more positive than in aziridine. When $\theta = 64°$, $^2J(^{15}N,H_A) = 0.95$ and $^2J(^{15}N,H_B) = -5.78$ Hz, in excellent agreement with the measurements of Becker (30, 31) on some substituted oxaziridines. INDO calculates the barrier to pyramidal inversion to be approximately 10 kcal/mol larger than the 32 kcal/mol (44, 45) observed for oxaziridine derivatives.

From Figs. 3 and 4 the very similar calculated angular dependence of $^2J(^{15}N,H)$ in methylenimine and aziridine is apparent. In methylenimine and aziridine the hybridization of the nitrogen atom changes with variations in θ. This is not so for methylamine and methylisocyanate in which the hybridization of the nitrogen atom remains essentially unchanged for all values of θ. Because of this difference one does not expect the same angular dependence of $^2J(^{15}N,H)$ in methylamine and methylisocyanate as in methylenimine and aziridine.

In summary, the overall agreement between observed and calculated $^2J(^{15}N,H)$ values in Table 1 is good. Many experimental trends are reproduced by the calculations. For all compounds (with the exception of vinylamine) nitrogen protonation increases $^2J(^{15}N,H)$, in agreement with the experiment. The calculated substituent effects on $^2J(^{15}N,H)$ in the



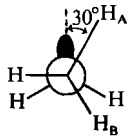
fragment also agree with experiment. The calculated angular dependence of $^2J(^{15}N,H)$ in the methylamine and methylisocyanate seems reasonable in view of the values observed in aziridine and oxaziridine derivatives.

(2) The Influence of the Phosphorus Lone-pair on $^2J(^{31}P,H)$

The effect of the phosphorus lone-pair on two-bond $^{31}P,H$ coupling constants in tervalent phosphorus compounds has been investigated (46–48). For a series of cyclic phosphines, Albrand *et al.* (46, 47) plotted the observed $^2J(^{31}P,H)$ against the dihedral angle involving the phosphorus lone-pair and the PCH fragment. These data are replotted in Fig. 5 along with a plot of $^2J(^{15}N,H)$ as calculated[6] for methylamine in Fig. 1. The similar shape of these two curves suggests a similar mechanism by which spin information is transferred between the nuclei.

(3) The Influence of the Nitrogen Lone-pair on $^2J(H,H)$ in an Adjacent Methylene Group

The effect of lone-pairs on geminal proton–proton coupling constants has been calculated for several conformations of methylamine, two of which are shown in **VII** and **VIII**. $^2J(H_A,H_B)$ is plotted as a function of θ in Fig. 6. According to an earlier MO theory (38) back-donation from the lone-pair into antisymmetrical CH_2 orbitals leads to an increase in $^2J(H,H)$: the present calculations indicate maximum donation for $\theta = 30°$ (**VII**) and minimum donation for $\theta = 120$ and $300°$ (**VIII**).



$\theta = 30°$, $^2J(H_A,H_B) = -0.85$ Hz

VII

[6]In comparing the angular dependence of $^2J(^{15}N,H)$ and $^2J(^{31}P,H)$ it is convenient to multiply either parameter by -1 because the magnetogyric ratios of ^{15}N and ^{31}P have opposite sign.

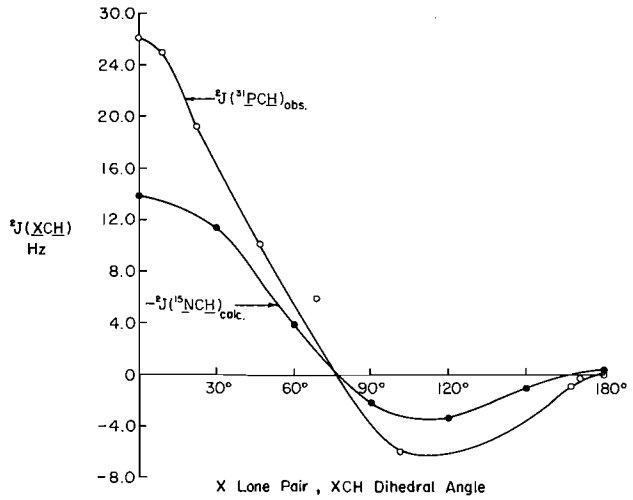

FIG. 5. A plot of the observed $^2J(^{31}P,H)$ in some tervalent phosphorus compounds (46, 47) and of the calculated $-^2J(^{15}N,H)$ in methylamine *vs.* the dihedral angle defined by the lone-pair—X—C—H fragment. See section 2 of the text.

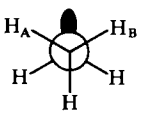

$\theta = 300°$, $^2J(H_A,H_B) = -4.79$ Hz

VIII

In Table 5 the calculated angular dependence of $^2J(H,H)$ is compared with the experimental values for a series of compounds with bridgehead nitrogen atoms (49). The calculated values of $^2J(H,H)$ are obviously too large (2), although the relative values are in fair agreement with experiment. Chivers and Crabb (49) predict $^2J(H,H)$ as most positive when $\theta = 0°$ but INDO calculates $^2J(H,H)_{\theta=30°} > {}^2J(H,H)_{\theta=0°}$. To show that the observed variations in $^2J(HCH)$ are due to lone-pair effects, $^2J(HNH)$ was calculated for the staggered conformation, $^2J(HNH) = -6.57$ Hz, and for the eclipsed conformation, $^2J(HNH) = -7.10$ Hz. The difference was only 0.53 Hz.

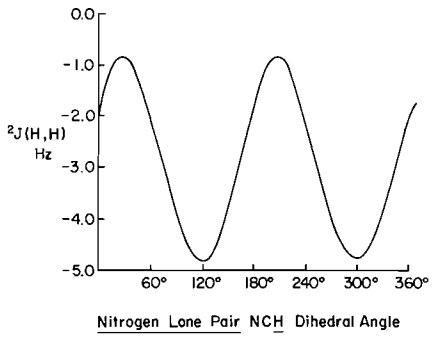

FIG. 6. A plot of the calculated $^2J(HCH)$ in methylamine *vs.* the lone-pair—N—C—H dihedral angle.

$^*\Delta \equiv J_\theta - J_{300°}$.

(4) Three-bond Nitrogen–Proton Coupling Constants, $^3J(N,H)$

In Table 6 the calculated $^3J(^{15}N,H)$ are presented for 15 compounds with rigid geometries. The paucity of experimental data makes a critical evaluation of the calculated $^3J(^{15}N,H)$ values difficult. However, several experimental trends appear to be reproduced by the calculations. On protonation of the nitrogen atom, $^3J(^{15}N,H)$ is predicted to decrease, (see compounds 1 and 2, 3 and 4, 7 and 8, and 11 and 12, Table 6) in line with an experimental rule (33): on quaternization of the nitrogen atom, $^3J(^{15}N,H)$ decreases. In vinyl isocyanide $^3J(^{15}N, H_{trans})$ is calculated as approximately twice

*References to the geometries and observed coupling constants for the first ten molecules are given in Table 1. The geometries used, and the experimental values observed, for compounds 11, 13, 14 and 15 are given in ref. 50. For the anilinium ion, standard geometries (8, 37) were used to calculate the atomic coordinates of the atoms in the benzene ring fragment. The C—N and N—H bond lengths were taken as 1.431 and 1.03 Å, respectively (5). All CNH and HNH angles were taken as 109.47°.

†This is the experimental value of $^3J(^{15}N,H)$ in α-nitronaphthalene, see Y. Kawazoe, M. Araki, S. Sawaki, and M. Ohnishi. Chem. Pharm. Bull. (Tokyo), **18**, 381 (1970).

$^3J(^{15}N,H_{cis})$, in good agreement with experiment. For aniline, 2-aminoacetophenone, acetanilide, and nitrobenzene, the calculated $^3J(^{15}N,H)$ values range from −2.52 to −3.90 Hz. If $^3J(^{15}N,H)$ in nitrobenzene is negative the observed $^3J(^{15}N,H)$ values fall between −1.85 and −2.5 Hz, in fair agreement with the calcu-

*Standard geometries (8, 37) were used for all calculations. The C—Li bond length was taken as 2.1 Å. Computed and observed values of $^3J(H_1,H_2)$ are cited from ref. 3.

lated values. With the exception of $^3J(^{15}N,H_5)$ in isoxazole, all $^3J(^{15}N,H)$ coupling constants are correctly calculated as negative.

In Table 7 the $^3J(^{15}N,H)$ values calculated for three vinylamines are compared with $^3J(H,H)$ calculated in three ethylene derivatives (3). As the electronegativity of X increases, $^3J(^{15}N,H)$ increases while $^3J(H,H)$ decreases. Thus, for the vinyl fragment the reduced coupling constants, $^3K(N,H)_{cis}$ and $^3K(H,H)_{cis}$, show similar substituent effects.

To anticipate future experiments, the angular dependence of $^3J(^{15}N,H)$ was evaluated for ethylamine, protonated ethylamine, ethylisocyanide, *cis*- and *trans*-acetaldoxime, and protonated *cis*- and *trans*-acetaldoxime. Since the

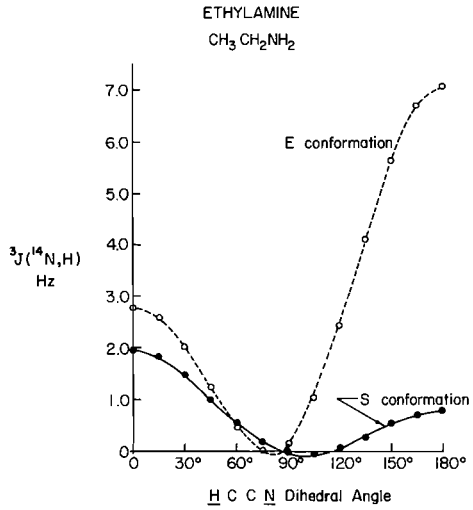

FIG. 7. A plot of the calculated $^3J(^{14}N,H)$ *vs.* the NCCH dihedral angle for the E and S conformations of ethylamine. The E and S conformations are depicted in **IX** and **X** of the text.

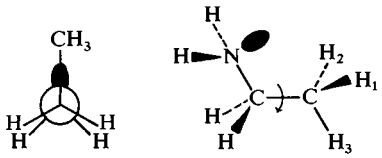
experimental plots (52) present $^3J(^{14}N,H)$ *vs.* the *NCCH* dihedral angle, the same convention will be followed here. This facilitates a comparison between $^3J(^{14}N,H)$ and the analogous couplings $^3J(H,H)$, $^3J(F,H)$, and $^3J(P,H)$; all these nuclei having positive gyromagnetic ratios.

(a) The Angular Dependence of $^3J(^{14}N,H)$ in the  *Fragment*

(i) Ethylamine

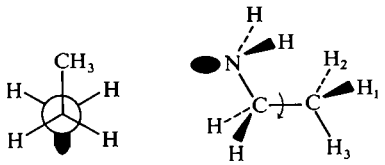
In Fig. 7 the NCCH dihedral angle, θ, in ethylamine is plotted against calculated $^{14}N,H$ coupling constants. Two conformations of the amino group are considered: in the E conformation (**IX**) the N—H bonds and the C—H bonds of the adjacent methylene group are eclipsed,



E conformation
$\theta = 180°$ (H_3); $60°$ (H_1 and H_2)

IX

while in the S conformation (**X**) they are staggered. Note that in the E conformation the nitrogen lone-pair lies *cis* to the methyl group while in the S conformation it lies *trans* to the methyl group. The E conformation is calculated to be more stable than the S conformation for all angles θ.



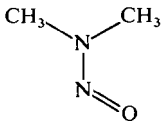
S conformation
$\theta = 180°$ (H_3); $60°$ (H_1 and H_2)

X

From Fig. 7 it is apparent that $^3J(^{14}N,H)$ is dependent both on the orientation of the nitrogen lone-pair and on the NCCH dihedral angle. Both the E and S conformations of ethylamine are most stable when the C—H bonds of the methyl and methylene groups are staggered, *i.e.* for $\theta = 60$ (H_1 and H_2) and $180°$ (H_3). Then $^3J(^{14}N,H)_{ave}$ is 2.65 Hz for the E conformation, and is 0.61 Hz for S. In rigid compounds a similar dependence of $^3J(N,H)$ on lone-pair

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

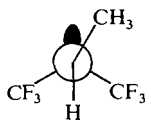
orientation is observed (53–56). For example, in *N,N*-dimethylnitrosamine (**XI**), $^3J(^{15}N,H) = \pm 2.2$ Hz when the methyl group lies *cis* to the lone-pair while $^3J(^{15}N,H) = \pm 0.8$ Hz when the methyl group lies *trans* to the lone-pair (53).



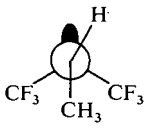
XI

The coordinates of the amino group nuclei were calculated assuming equal C—N and N—H bond lengths in ethylamine and methylamine (ref. *l* in Table 1). In addition, the following bond angles were assumed: angle HNC = 109.47° and dihedral angles HNCC = ±120 (E conformation) and ±60° (S conformation). The atomic coordinates of the ethyl group were taken from the literature (57).

$^3J(^{31}P,H)$ in aminophosphines depends on the orientation of the phosphorus lone-pair (58–60). Below −120 °C the p.m.r. spectrum of methylaminobis(trifluoromethyl)phosphine, $CH_3NH{\cdot}P(CF_3)_2$, indicates the presence of two rotational isomers (**XII***a*) and (**XII***b*). The most abundant isomer is assigned to **XII***a* where $^3J(^{31}P,H) = 13.9$ Hz while in **XII***b*, $^3J(^{31}P,H) \simeq$



XIIa

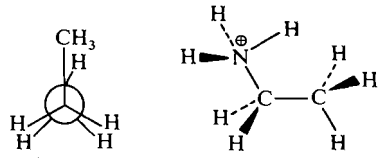


XIIb

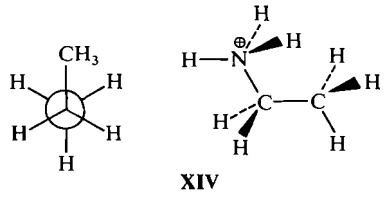
4 Hz (58). In phosphines and in nitrogen compounds containing a lone-pair, $^3J(^{31}P,H)$ and $^3J(^{14}N,H)$ apparently display a similar dependence on the orientation of the lone-pair.

(ii) Protonated Ethylamine

In Fig. 8, $^3J(^{14}N,H)$ in protonated ethylamine is plotted against the dihedral angle in the fragment $^+$NCCH. Both the E (**XIII**) and S (**XIV**) conformations of the amino group are considered. The atomic coordinates for protonated ethylamine were essentially the same as those used for the unprotonated species. All H—N—X angles were taken as 109.47° and the N—H bond length was assumed to be 1.03 Å. For every angle θ the S conformation (**XIV**) was more stable than the E conformation (**XIII**).



XIII



XIV

The curves of $^3J(^+NCCH)$ *vs.* θ in Fig. 8 are very similar, in contrast to those of the unprotonated molecules (Fig. 7). Note the increase in $^3J(^{14}N,H)$ over its values in the unprotonated species.

(iii) Ethylisocyanide

In Fig. 9 the curve depicting the calculated angular dependence of $^3J(^{14}N,H)$ closely resembles the rough experimental curves assembled by Bothner-By and Cox (52). INDO finds 2.345 kcal/mol as the barrier to rotation about C—C bond. Therefore it is best to use the cal-

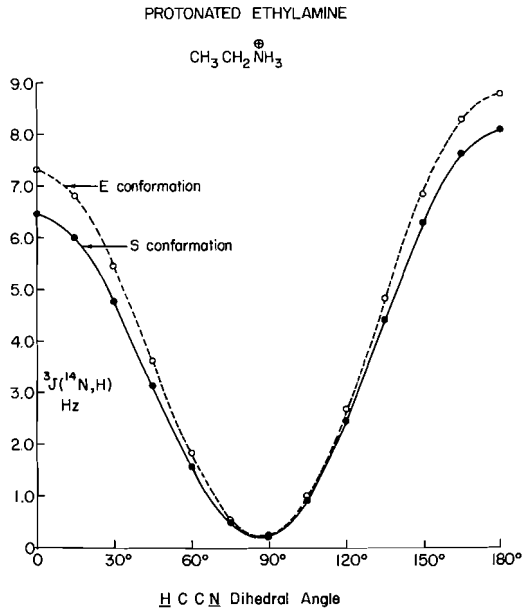


FIG. 8. A plot of the calculated $^3J(^{14}N,H)$ *vs.* the dihedral angle of the NCCH fragment in the E and S conformations of protonated ethylamine.

For personal use only.

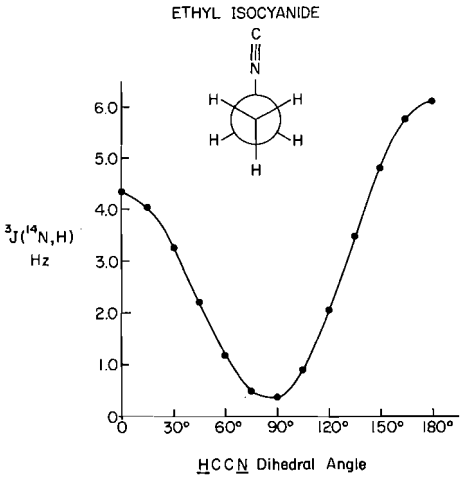

FIG. 9. A plot of the calculated $^3J(^{14}N,H)$ *vs.* the NCCH dihedral angle in ethylisocyanide.

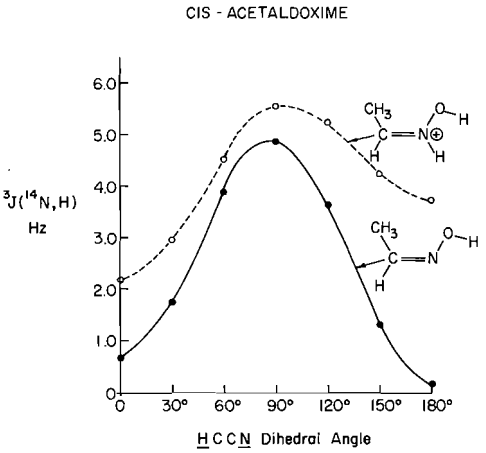

FIG. 10. A plot of the calculated $^3J(^{14}N,H)$ *vs.* the NCCH dihedral angle in *cis*-acetaldoxime and in protonated *cis*-acetaldoxime.

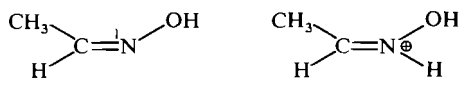
culated average $^{14}N,H$ couplings in the staggered conformation. One has $^3J(^{14}N,H)_{ave} = 2.81$ and $^2J(^{14}N,H)_{ave} = -2.78$ Hz. Maher (25) and MacFarlane (24) observe $^3J(^{14}N,H) = 2.5$ and $^2J(^{14}N,H) = -2.0$ Hz.

The bond lengths and angles in the C—N≡C and the ethyl fragments were taken as those in methylisocyanide and ethane, respectively (refs. *i* and *h* in Table 1).

(b) The Angular Dependence of $^3J(^{14}N,H)$ *in the* $N\equiv C-C^{H}$ *Fragment*

(i) cis-Acetaldoxime and Protonated cis-Acetaldoxime

In Fig. 10 the calculated $^3J(^{14}N,H)$ in **XV** and **XVI** is plotted *vs.* the N=C—C—H dihedral angle. The maximum occurs at an angle of 90° indicating the importance of the π orbitals of the C=N bond in the transmission of the spin information.



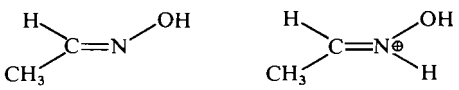
XV **XVI**

The structure used to calculate the atomic coordinates in **XV** was that of Rogowski and Schwendeman (61). With the exception of the methyl group, the protonated species was assumed planar, with all bond angles and bond lengths the same as those used for the unprotonated species; the N—H bond length was taken as 1.03 Å and the CNH angle as 120°. INDO calculates the barrier to rotation of the methyl group to be 208 cal/mol while the observed barrier is 373 cal/mol (61). The barrier in the protonated species is calculated to be slightly larger, 363 cal/mol.

Averaging over all angles yields $^3J(^{14}N,H)$ as 2.65 and 4.22 Hz, respectively, for *cis*-acetaldoxime and protonated *cis*-acetaldoxime.

(ii) trans-Acetaldoxime and Protonated trans-Acetaldoxime

In Fig. 11 the H—C—C=N dihedral angle in **XVII** and **XVIII** is plotted against the calculated $^3J(^{14}N,H)$.



XVII **XVIII**

The structural parameters for *trans*-acetaldoxime were obtained from Rogowski and Schwendeman (61). Except for the additional proton, the protonated species was assumed to have the same structure as the unprotonated species: the N—H bond length was taken as 1.03 Å, the CNH bond angle as 120° and the CCNO dihedral angle as 180°.

INDO finds the barrier to rotation of the methyl group to be 1080 cal/mol while the experimental barrier is 1835 cal/mol (61). The barrier in the protonated species was calculated as 1185 cal/mol. Since the observed barrier is

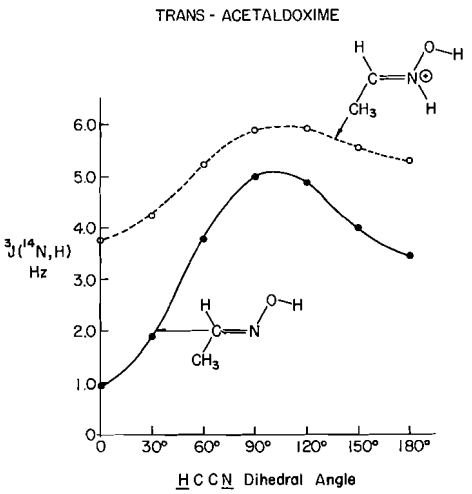


FIG. 11. A plot of the calculated $^3J(^{14}N,H)$ *vs.* the NCCH dihedral angle in *trans*-acetaldoxime and in protonated *trans*-acetaldoxime.

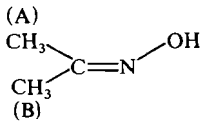
greater than $3kT$ one can compare the calculated and observed coupling constants by considering only the most stable conformation. The average values of $^3J(^{14}N,H)$ for the most stable conformations are 3.57 and 5.25 Hz for *trans*-acetaldoxime and protonated *trans*-acetaldoxime, respectively.

Notice that in the *trans* isomer (**XVII**), the nitrogen lone-pair is *cis* to the methyl group and $^3J(^{14}N,H)$ is calculated to be larger than in the case where the methyl group is *trans* (**XV**) to the lone-pair. This is in good agreement with experiment. For the oxime (**XIX**) $^3J[^{14}N,CH_3(A)]$ is 1.57 and $^3J[^{14}N,CH_3(B)]$ is 2.86 Hz (33). When **XIX** is studied in trifluoroacetic acid, each of



XIX

the $^{14}N,H$ coupling constants becomes larger: $^3J[^{14}N,CH_3(A)]$ is 2.36 and $^3J[^{14}N,CH_3(B)]$ is 3.27 Hz (33). Although all the calculated coupling constants are a little too large, their relative values agree with experiment.

In summary, SCF calculations at the INDO level predict a dihedral angle dependence of $^3J(^{14}N,H)$ in the N—C—C—H fragment similar to that observed for $^3J(H,H)$ (1, 3, 5), for $^3J(^{19}F,H)$ (62, 63), and for $^3J(^{31}P,H)$ (52, 64) in the saturated X—C—C—H fragments. The angular dependence of $^3J(^{14}N,H)$ in the N=C—C—H fragment is computed as different from that in the saturated fragment.

(5) The Effect of Protonation on J(N,H) in Pyridine, Aniline, Ammonia, and Methylamine

In Tables 8 and 9 the calculated and observed $^{15}N,H$ couplings are given for pyridine and the pyridinium ion, and for aniline and the anilinium ion. In Table 10, $^1J(^{15}N,H)$ is presented for ammonia, the ammonium ion, methylamine, and protonated methylamine.

INDO predicts a decrease in $^1J(^{15}N,H)$ on protonation, in agreement with experiment for ammonia and methylamine but not for aniline, where uncertainty about the geometry of the amino group may be the cause of the disagreement. Thus, a planar amino group entails a calculated $^1J(^{15}N,H)$ of −92.5 Hz (50).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

TABLE 10. Calculated and observed $^1J(^{15}N,H)$ in ammonia and methylamine*

Compound	$^1J(^{15}N,H)$ calc.	$^1J(^{15}N,H)$ obs.	Reference
NH_3	−42.64	−61.2	66
$^{\oplus}NH_4$	−73.52	−73.2	29
CH_3NH_2	−34.78	−65.0	28
$CH_3\overset{\oplus}{N}H_3$	−75.38	−75.6	29

*Standard geometries (8, 37) were used to calculate the atomic coordinates of ammonia. The N—H bond length was taken as 1.03 Å for ammonia. The geometries used for methylamine and protonated methylamine are given in Table 1.

On protonation, the calculations predict an increase in $^2J(^{15}N,H)$ in pyridine, a decrease in $^3J(^{15}N,H)$ in aniline and pyridine, an increase in $^4J(^{15}N,H)$ in pyridine, and a decrease in $^5J(^{15}N,H)$ in aniline. Such an alternating effect due to protonation has been observed by Crépaux *et al.* (33).

Conclusions

A comparison of theoretical with the available experimental two- and three-bond nitrogen–proton spin–spin coupling constants encourages their combined use in conformational and structural work.[7]

[7]After completion of this work, a paper (69) appeared giving the results of CNDO/2 and INDO calculations on N,H; C,H; and H,H coupling constants in several of the molecules discussed above. There are some large discrepancies in the two sets of N,H couplings. Our calculations are in exact agreement with previous data for $^1J(^{14}N,H)$ in ammonia (7, 8), $^1J(^{15}N,^{13}C)$ in methyl cyanide (70), and $^1J(^{13}C,H)$ in methylenimine (71).

Pyrolysis of 3-Chloro-3-aryldiazirines, Kinetics and Mechanism

MICHAEL T. H. LIU AND K. TORIYAMA

Department of Chemistry, University of Prince Edward Island, Charlottetown, Prince Edward Island

Received April 26, 1972

The thermal decomposition of 3-chloro-3-aryldiazirines in various solvents has been investigated over the temperature range 60–100 °C. The intermediate carbenes have been isolated as norcaranes by the use of cyclohexene. Substituent effects on rates of reaction are small and a Hammett correlation was unsuccessful with either σ or σ^+ constants. Possible mechanisms for the decompositions are discussed.

La décomposition thermique des chloro-3 aryl-3 diazirines dans divers solvants, a été examinée dans un domaine de température de 60 à 100 °C. Les carbènes intermédiaires ont été isolés sous forme de norcaranes en présence de cyclohexène. Les effets des substituants sur les vitesses de réaction sont faibles et une corrélation de Hammett est appliquée sans succès que ce soit avec les constantes σ ou σ^+. Les mécanismes possibles pour ces décompositions sont discutés. [Traduit par le journal]

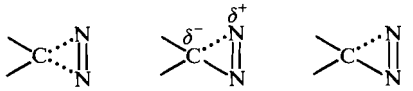
Introduction

The nature of the pathway of ring rupture in diazirine is not well understood. In the thermal decomposition of 3-chloro-3-alkyldiazirines (1, 2) Frey *et al.* proposed transition state I as the simplest representation for a diazirine decomposition, where the two carbon—nitrogen bonds are broken simultaneously. Schmitz (3) has postulated an ionic mechanism, II, as the most probable pathway on the grounds of the relative instability of α-ketopentamethylenediazirine as compared with pentamethylenediazirine. Mitsch and co-workers (4, 5) prefer a mechanism involving the transient existence of a diazomethane intermediate prior to the loss of nitrogen. It is likely that such a mechanism would require transition state III. Bottomly and



I II III

Nyberg (6) have studied the thermal decomposition of 3,3-dimethyldiazirine at relatively low temperature and suggested that the transition state was non-cyclic and probably radical in nature.

In our recent work (7, 8), we observed that the rate of diazirine decomposition shows very little solvent effect and we concluded that the transition state of the rate determining step is likely to be more radical than ionic. The present work was undertaken to examine the effect of para-substituents on the rates and activation parameters in the thermal decompositions of a series of 3-chloro-3-aryldiazirines, in the hope that a further elucidation of the transition state would be provided.

Experimental

I.r. and n.m.r. spectra were obtained with Perkin–Elmer Model 257 and Varian Associates, T 60 instruments respectively. The chemical shifts are given in τ scale together with splitting patterns, assignments, and relative integrated areas. The u.v. spectra were measured with a Unicam sp. 800 spectrophotometer. V.p.c. analyses were carried out using a Perkin–Elmer model F 11 equipped with a hydrogen flame detector; the peak areas were integrated by a ball and disc integrator. Elemental analyses were by Franz Pascher, Bonn, Germany.

Solvents

Cyclohexene was passed through alumina column to remove impurities and was fractionally distilled. Diethyleneglycol monoethyl ether (DEGME) and dimethyl sulfoxide (DMSO) were stirred with calcium hydride for 1 day and fractionally distilled under anhydrous conditions.

3-Chloro-3-aryldiazirines

These compounds were prepared from the corresponding amidine hydrochlorides by oxidation with aqueous sodium hypochlorite in DMSO according to the method of Graham (9). The phenyl, *p*-tolyl and *p*-chlorophenyl compounds were purified by column chromatography (silica gel – pentane or pentane and dichloromethane). The *p*-methoxyphenyl and *p*-nitrophenyl compounds were recrystallized from pentane (Norite). Yields and physical properties are listed in Table 1.

Kinetics Procedure

(a) By Vapor Phase Chromatography

The rates of reaction were measured by following the disappearance of diazirine, as described previously (8).

(b) By Nitrogen Evolution Method

The reaction was carried out by mixing a specific amount

TABLE 1. Yields and physical properties of 3-chloro-3-aryldiazirines

Aryl	Yield* (%)	I.r.† (N=N, cm^{-1})	U.v. λ max (ε)‡ (nm in cyclohexane)
p-Methoxyphenyl	57	1565	412 (416), 391 (492), 372 (307), 354 (164), 337 (93)
p-Tolyl	58	1566	400 (314), 396 (305), 390 (285), 379 (346), 361 (220), 343 (130)
Phenyl	54	1570	395 (213), 389 (210), 384 (194), 374 (229), 370 (204), 355 (125), 339 (53)
p-Chlorophenyl	59	1570	396 (304), 391 (308), 386 (324), 375 (345), 357 (276), 340 (132)

TABLE 2. Observed wavelengths (nm) of 3-chloro-3-aryldiazirines

Solvent	*p*-Methoxyphenyl	*p*-Tolyl	Phenyl	*p*-Chlorophenyl	*p*-Nitrophenyl
Cyclohexene	395	412	403	396	384
DMSO	394	410	400	392	—
DEGME	390	414	400	390	380

of diazirine with appropriate thermo-equilibrated solvent in the reaction vessel, which was immersed in the oil bath and connected to a gas burette. The first order rate coefficients were determined graphically from the plot of log $(V_\infty - V_t)$ against time where V_∞ is the volume of nitrogen measured at infinite time and V_t is that at time t.

(c) By Ultraviolet Spectrophotometry

The detailed experimental procedure was as described in our earlier work (8). The first order rate coefficients were determined graphically from the plot of log $(D_t - D_\infty)$ against time, where D_t is the optical density at the wavelength of observation and D_∞ corresponds to that of the complete reaction. The wavelengths of observation are given in Table 2.

Product Analyses

(a) Decompositions in Cyclohexene

(a-1) 7-Chloro-7-p-nitrophenylnorcarane

One gram of 3-chloro-3-*p*-nitrophenyldiazirine in 50 ml of cyclohexene was heated at 80° for 7 h. The solvent was removed under reduced pressure, leaving 1.3 g of yellow oil whose t.l.c. had one main spot with trace amount of other compounds. The n.m.r. of this material showed major peaks at 1.6 ~ 2.7 (m, aromatic-H, 4) and at 7.8 ~ 8.8 (m, cyclohexane ring-H, 10). Other minor absorptions showed two small sharp doublets of equal intensity at 5.27 and 5.40, and a small detectable multiplet at 4.1 ~ 4.8; these absorptions were probably due to the products (~15% estimated from peak area ratio in n.m.r. spectra) resulting from the insertion of carbene into the saturated C—H bonds of the cyclohexene ring. After leaving the oil at room temperature to air for several weeks, the major part crystallized. Repeated crystallization from petroleum ether (b.p. 30–80°) gave pale yellow crystals, m.p. 73.5–74.5: n.m.r. (in $CDCl_3$), 1.6–2.7 (m, aromatic H, 4); 7.7–9.0 (m, $-CH_2-$ and $-\underset{|}{C}H-$, 10).

Anal. Calcd. for $C_{13}H_{14}ClNO_2$: C, 62.03; H, 5.61; N, 5.56; Cl, 14.09. Found: C, 61.75; H, 5.43; N, 5.47; Cl, 14.04.

(a-2) 7-Chloro-7-p-methoxyphenylnorcarane

The decomposition of 3-chloro-3-*p*-methoxyphenyl diazirine was carried out essentially as described in section *a-1*. A yellow oil (2.59 g) was obtained after removal of the solvent from a reaction mixture initially containing 2.0 g of diazirine. The n.m.r. spectrum (CCl_4) of the crude oil showed signals from aromatic protons at 2.5 ~ 3.5, cyclohexane ring protons at 7.8 ~ 9.3, two small sharp doublets at 5.4 and 5.5, and small multiplets at 4 ~ 5; the methyl protons of the methoxy groups showed a triplet centered at 6.30. Unsuccessful attempts were made to separate the mixture by means of column chromatography. After the mixture was left to the atmosphere at room temperature for several weeks, crystals appeared which were extracted with petroleum ether yielding 0.65 g of crude

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

crystal. After two recrystallizations from methanol, 7-chloro-7-*p*-methoxyphenylnorcarane (0.4 g) was obtained, m.p. 45.0–45.5: n.m.r. (CCl_4) 2.5 ~ 3.3 (m, aromatic H, 4); 6.30 (s, OCH_3, 3); 7.7–9.0 (m, $—CH_2—$ and $—\underset{|}{C}H—$, 10).

Anal. Calcd. for $C_{14}H_{17}ClO$: C, 71.03; H, 7.24; Cl, 14.98. Found: C, 70.81; H, 7.29; Cl. 14.88.

(a-3) Decomposition of 3-chloro-3-phenyl, 3-chloro-3-p-chlorophenyl and 3-chloro-3-p-tolyldiazirine in cyclohexene

In the decomposition of the above diazirines, the same method was employed as described in the previous section, *a-1*. After the removal of solvent, the oils gave similar n.m.r. spectra as in sections *a-1* and *a-2*, showing the aromatic and cyclohexane ring protons (and methyl protons in the case of *p*-tolyl) as the major, and two small sharp doublets at 5.1 ~ 5.5 together with a multiplet at 4 ~ 5 as the minor. Distillation and column chromatography were ineffective in separating the mixture and no further attempts were made to isolate the products.

(b) Decomposition in DEGME

(b-1) Isolation of p-nitrobenzaldehyde ethylene acetal

3-Chloro-3-*p*-nitrophenyldiazirine (1.8 g) in 80 ml of DEGME was heated at 80–90° for 7 h. On dilution with water, a precipitate was obtained which was dissolved in hot cyclohexane and refluxed with Norite for 5 min. After filtering the warm solution, the collected crystals were recrystallized from ethanol, yielding 0.6 g, m.p. 89.5–90.0°, lit. m.p. 90.59° (10); n.m.r. ($CDCl_3$), 1.6 ~ 2.5 (m, aromatic -H, 4); 4.10 (s,  , 1); 5.90 (s, $—CH_2—O—$, 4).

From the extraction of the filtrate with chloroform, an additional 0.6 g of crude acetal was obtained. The acetal was decomposed in 2,4-dinitrophenylhydrazine–sulfuric acid–ethanol solution to give *p*-nitrobenzaldehyde-2,4-dinitrophenylhydrazone; m.p. 317–319° (dec.), lit. m.p. 320° (dec.) (11).

(b-2) Decomposition of other diazirines in DEGME

The procedures are similar to those described in section *b-1*. In the case of the *p*-methoxyphenyl derivative, the crude reaction mixture contained ~95% anisaldehyde and a trace amount of impurity. The n.m.r. spectrum in CCl_4 showed absorptions at 0.20 (s, CHO, 1); 2.1–2.8 (m, aromatic-H, 4) and 4.17 (s, $O—CH_3$, 3) and the i.r. compared well with the authentic sample. In the decompositions of 3-chloro-3-*p*-tolyl, 3-chloro-3-phenyl, 3-chloro-3-*p*-chlorophenyl diazirines, mixtures of aldehydes and acetals were obtained.

(c) Decomposition in DMSO

3-Chloro-3-phenyldiazirine (1 g) in 50 ml DMSO was heated at 80–85° for 3 h. The resulting mixture was diluted with water and extracted with ether. The extract was identified with authentic samples as a mixture of benzoic acid and benzaldehyde, which was left in air and oxidized to benzoic acid, 0.35 g. Similar results were obtained with other diazirines: 0.46 g of *p*-nitrobenzoic acid from 1 g of 3-chloro-3-*p*-nitro-phenyldiazirine and 0.42 g of *p*-toluic acid from 1 g of 3-chloro-3-*p*-tolyldiazirine.

Results

All the compounds were unstable at room temperature; however, except for the *p*-methoxyphenyl derivative, they can be kept in Dry Ice for several weeks without significant decomposition. Owing to the instability of these diazirines, the elemental analyses were not possible. All the diazirines obtained gave the following characteristics: one clear spot on t.l.c. with various solvents, sharp i.r. spectra, complicated u.v. absorption between 420 and 320 nm (in cyclohexane), quantitative nitrogen evolution when heated in diethyleneglycol monoethyl ether (DEGME), crystallization at low temperature, and symmetrical v.p.c. peaks for *p*-tolyl, phenyl, and *p*-chlorophenyl derivatives. Three representative solvents were chosen for the decompositions: cyclohexene for non-polar; DMSO for polar aprotic, and DEGME for polar protic solvent. The concentrations of diazirine in various solvents were adjusted in such a way as to suppress the formation of azine (8). The reactions obeyed first order

kinetics up to 90% completion (the first order rate constants were determined graphically from a minimum of eight runs). Rate constants for the thermal decompositions of the 3-chloro-3-aryldiazirines in cyclohexene are given in Table 3. The reproducibilities of the rate constants were ±2–6% by v.p.c. and ±1–3% by u.v. spectrophotometry. The Arrhenius plots of the rate data are shown in Fig. 1 and the least-squares treatment of the data gave the following expressions with the errors quoted in standard deviation: k_1 (*p*-methoxyphenyl) = $10^{13.41\pm0.35}$ exp $(-26{,}490 \pm 560/RT)$ s^{-1}; k_1 (*p*-tolyl) = $10^{13.94\pm0.20}$ exp $(-27{,}870 \pm 310/RT)$ s^{-1}; k_1 (phenyl) = $10^{13.87\pm0.13}$ exp $(-28{,}000 \pm 215/RT)$ s^{-1}; k_1 (*p*-chlorophenyl) = $10^{13.81\pm0.24}$ exp $(-27{,}720 \pm 390/RT)$ s^{-1}; k_1 (*p*-nitrophenyl) = $10^{13.80\pm0.07}$ exp $(-27{,}850 \pm 100/RT)$ s^{-1}. Table 4 gives the rate constants for the thermal decomposition of 3-chloro-3-aryldiazirines in various solvents at 75°.

Nature of Products

In the thermal decompositions of diazirines in cyclohexene, the major products were 7-chloro-7-aryl norcaranes, addition products of arylchlorocarbene to the double bond of cyclohexene (see Scheme 1). As the melting points for the isolated norcaranes were sharp, it was assumed that the products consisted of only one of the two isomers whose conformation was not identified. The minor products are probably mixtures of isomers formed from the insertions of carbene to the saturated C—H bonds at the 3- and 4-positions in cyclohexene.

In the decomposition of 3-chloro-3-*p*-nitrophenyl diazirine in DEGME, the major product was benzaldehyde ethylene acetal. On the other hand, anisylaldehyde was isolated as the major product from the decomposition of 3-chloro-3-*p*-methoxyphenyldiazirine. For the decomposition of the *p*-tolyl, phenyl, and *p*-chlorophenyl

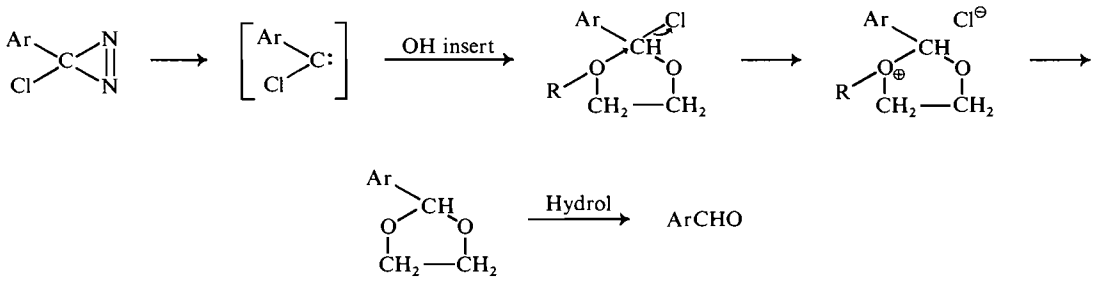

SCHEME 2

derivatives, mixtures of aldehyde and acetals were obtained. The above products were presumably formed via the mechanism shown in Scheme 2. The minor products are probably a mixture of isomers resulting from the insertion of arylchlorocarbene into the C—H bond neighbored to an oxygen atom (12, 13). From the n.m.r. peak area ratio of aldehyde (—CHO), aromatic protons, ethylene acetal (—CH_2—O—), and the methyl proton of —O—CH_2—CH_3 group, the yields of O—H insertion products (aldehydes and acetals) were estimated to be 95, 71, 88, 86, and 80% for the decomposition of *p*-methoxyphenyl, *p*-tolyl, phenyl, *p*-chlorophenyl, and *p*-nitrophenyl derivatives respectively. Since the rates of hydrolysis of benzaldehyde ethylene acetals have a negative ρ value in the Hammett equation (14), the different ratios of acetal/aldehyde are reasonable.

From the thermolysis of 3-chloro-3-aryldiazirines in DMSO, mixtures of substituted benzaldehydes and benzoic acids were isolated. No further attempts were made to study the mechanism of these reactions.

Discussion

For the purpose of comparison, pertinent data from previous workers are summarized in Table 5. The present results confirm the conclusions of the earlier workers. The thermal decomposition of diazirines both in gas phase and in solution are typically unimolecular reactions with A factor equal to $10^{13.7\pm0.5}$. The minor solvent effects from Table 4 also agree with data reported in earlier studies. The decomposition of 3-chloro-3-aryldiazirines in each of the three solvents gave similar organic products and all the free energies of activation

are in the range of 26.0 ± 0.3 kcal/mol. The differences in the activation energy between 3-chloro-3-aryldiazirines and 3-chloro-3-alkyldiazirines are reasonably explained by resonance stabilization effects by the aryl group in terms of either mechanism I, II, or III.

The observed substituent effects on reaction rates are not explicable either by the charge separated transition state II or by the simultaneous bond breaking process as proposed by Frey *et al.* in I. If the reaction proceeds by mechanism II, the rate for the following substituents would be in the order of p-NO_2 > p-Cl > H > p-CH_3 > p-CH_3O, which is almost opposite to the observed order: p-CH_3O > p-CH_3 > p-Cl > $H \simeq p$-NO_2. Thus, from the observed effects of substituents and the lack of solvent effects, the contribution of the ionic transition state II is not likely to be important in the thermal decomposition of diazirines. Schmitz (3) suggested that if mechanism I were to take place, the electron distribution on the carbon atom in the transition state must tend towards a sextet and such a transition cannot be stabilized by withdrawal of electrons. Taking the above into consideration, one would expect the rates to be p-CH_3O > p-CH_3 > H > p-Cl > p-NO_2, but these do not agree with the observed results.

Several examples of abnormal Hammett relation have been reported (16), but their explanations could not be applied to our present results. It is seen in Fig. 2 that plots of log k against σ (or σ^+) do not yield straight lines. However, a smooth curve (concave upward) may be drawn through all the points except that for the unsubstituted compound. Further, that the shape of the curves in each solvent is identical and increase in polarity of the solvent only displaces the curve upward. The curvature observed in each solvent is ascribed to varying resonance interactions in the transition state of the para-substituted compounds. Although the Hammett correlation was unsuccessful with our present results, a linear plot was obtained by plotting log k *vs.* $\sigma^+ - \sigma$ as shown in Fig. 3. The differences between σ^+ and σ are p-CH_3O, -0.510; p-CH_3, -0.141; p-Cl, -0.113; H, 0; p-NO_2, $+0.012$, and fall in the order of the kinetic data. These differences may be taken as a measure of the strength of conjugation of the substituents.

The possible structures of the transition state could be drawn as III*a*, *b*, and *c*. However, III*c* contributes little or nothing, as the nitrogen atom is more electronegative than the carbon atom. The free radical form III*a* may

III*a* III*b* III*c*

be classified as an S radical in Walter's concept (17) in which the observed properties are shifted in the same direction with donor and acceptor substituents. On the other hand, the degree of contribution of different substituents to structure III*b* is likely to produce results such as these; p-CH_3O at best; p-CH_3 next in order; p-Cl very

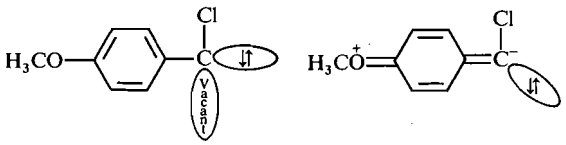
little; and a negative effect by the *p*-NO_2 substituent as compared with the unsubstituted compound. Hence, the fastest rate of decomposition is expected for 3-chloro-3-*p*-methoxyphenyl diazirine because its transition state is stabilized through both structures III*a* and *b*. The transition state of the 3-chloro-3-*p*-tolyldiazirine is also stabilized by both III*a* and *b* to a lesser extent owing to its smaller resonance ability. In the case of 3-chloro-3-*p*-chlorophenyldiazirine, the transition state is stabilized by structure III*a*, but the contribution resulting from III*b* may be little or nothing due to its inductive effect, which is opposite to that of the resonance effect. The contribution of *p*-NO_2 substituent to structure III*a* is likely to be of the same order as the *p*-CH_3O substituent; however, its strong electronegative nature does not favor the resonance structure III*b* and tends to cancel out the stabilization effect resulting from III*a*. Therefore, the observed rate appears to be similar to that of the unsubstituted compound.

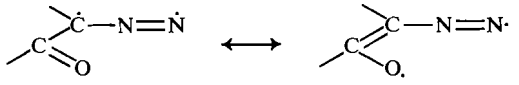
The fate of the diazirine after the achievement of the transition state is as interesting as the decomposition mechanism itself. Frey and Liu (2) have confirmed the formation of carbene in the thermal decomposition of 3-chloro-3-*t*-butyldiazirine by observing the formation of 1-chloro-2,2-dimethylcyclopropane. Evidence for carbene formation was also reported in the photolysis of 3-halo-3-phenyldiazirine (18). In our present work, the formation of 7-chloro-7-arylnorcaranes from the reactions in cyclohexene is good evidence for the carbene intermediate. In addition, the formation of the insertion isomers (1:1) into the 3- and 4-positions of cyclohexene was detected. The carbene generated from the thermal decomposition of 3-chloro-3-aryldiazirine is probably in its singlet state which is in agreement with the results from the selectivity studies of halophenyl carbenes (19, 20). Furthermore, if the carbene were singlet and collapsed to a sextet, there could be strong interaction between the empty orbital and an electron-donor species like the methoxy. Thus, the energy of the carbene might be lowered.



The relative rates for the thermal decomposition of 3-chloro-3-aryldiazirines at 75° are given in Table 6. For each of the compounds studied it is observed that the rate acceleration effect given by $k_{solvent}/k_{cyclohexene}$ shows an increase in going from a non-polar to a polar solvent. The relative magnitude of this effect is in the order of *p*-NO_2 < *p*-Cl < H < *p*-CH_3 < *p*-CH_3O. Although all compounds show an increase in rate constant with polar solvents, the comparison of substituted compounds with the unsubstituted compound shows that k_{Ar}/k_{Ph} increases for *p*-CH_3O and *p*-CH_3 and decreases for *p*-Cl and *p*-NO_2 compounds as the polarity of the solvent is increased. The magnitude of the solvent effect is not large, with a factor of two being the largest increase in going from nonpolar to polar solvents. A much larger effect would be expected if the transition state polarization was a dominant factor in determining the rate of decomposition of diazirines. If a radical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

mechanism were operative, very little solvent effect would be expected. A rather small contribution from a mechanism involving the structure III*b* could account for the observed results. In the photolysis of diazirine, Amrich and Bell (21) have reported that 20% of the primary decomposition of diazirine is an isomerization to diazomethane. There is evidence that substituted diazirines can isomerize to diazo compounds (14, 22). However, most of the available data can also be interpreted by means of the homolytic process. As an example, the instability of α-ketodiazirine (3) could be attributed to the strong resonance effects of the α-carbonyl group. The decomposable nature of 3-chloro-3-methoxydiazirine (9) and the isomerization of 3-methyl-3-vinyldiazirine to 3-methyl-pyrazole (23) could be explained in a similar manner.



In conclusion, we suggest a mechanism involving the breaking of one of the C—N bonds. This leads to a diradical (III*a*) and a diazomethane (III*b*) intermediate of which the latter contribution is probably small due to the lack of solvent effects. It is likely that the transition states have more radical character. Recently nonempirical self-consistent field and configuration–interaction studies of aziridine and oxazirane have been reported by Hayes and Siu (24). They have concluded that the electronic structure of open forms of these species is essentially a linear combination of the resonance system $B{=}A{-}\overset{+}{C}{\leftrightarrow}\overset{-}{B}{-}\overset{+}{A}{=}C$, and a diradical $\cdot B{-}A{-}C\cdot$ where A, B, and C are CH_2 NH, or O. These studies lend support to the possibility of homolytic and heterolytic dissociation.

Kinetics and Mechanism of Decarboxylation of some Pyridinecarboxylic Acids in Aqueous Solution[1]

G. E. DUNN, GORDON K. J. LEE,[2] AND HAROLD THIMM

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received April 24, 1972

The first-order rate constants for decarboxylation of picolinic and five substituted picolinic acids in buffered aqueous solution at 150° and ionic strength 1.0 increase as p*H* increases above 0, go through a maximum at p*H* near 1, then level off at about half the maximum. For quinolinic acid at 95° the rate maximum occurs at the isoelectric p*H*. It is therefore concluded that the anion decarboxylates about half as fast as the isoelectric species. Anion and isoelectric species show similar carboxyl-carbon kinetic isotope and substituent effects, so they probably decarboxylate by similar mechanisms. The methyl betaine of picolinic acid decarboxylates about 200 times faster than the anion. From these facts it is concluded that the isoelectric species which decarboxylates is probably zwitterion rather than neutral acid, and that anion and zwitterion decarboxylate by loss of carbon dioxide to form 2-pyridyl carbanion and ylid, respectively. The slower decarboxylation of isoelectric species compared to betaine suggests that only a small fraction of the isoelectric species is zwitterion. However, qualitative estimates from spectra of the fraction of zwitterion present in the isoelectric species at 150° suggest that this cannot be the whole explanation. The relative reactivities of the 2- and 4-positions are similar for decarboxylation and hydrogen exchange in pyridinium ions, but not in the unprotonated species.

Les constantes de vitesse du premier ordre pour la décarboxylation de l'acide picolinique et cinq de ses dérivés substitués, en solution aqueuse tamponnée à 150° et de pouvoir ionique 1.0 augmentent avec un p*H* au-dessus de 0, passent par un maximum pour un p*H* proche de 1, et se stabilisent ensuite à environ la moitié de ce maximum. Pour l'acide quinolinique à 95°, le maximum de vitesse se produit au p*H* isoélectrique. On a conclu par conséquent que l'anion se décarboxyle à une vitesse qui est de moitié celle de l'espèce isoélectrique. L'anion et l'espèce isoélectrique montrent des effets similaires de substituants et de cinétique isotopique carboxyle-carbone, aussi les mécanismes de décarboxylation sont probablement voisins. La bétaine méthylée de l'acide picolinique a une vitesse de décarboxylation de 200 fois supérieure à celle de l'anion. Ces faits ont amenés à conclure que l'espèce isoélectrique qui subit la décarboxylation est probablement le zwitterion plutôt que l'acide neutre et que la décarboxylation de l'anion et du zwitterion se fait par perte de gaz carbonique pour donner respectivement le pyridyl-2 carbanion et l'ylure. La décarboxylation plus lente de l'espèce isoélectrique comparée à la bétaine, laisse penser que seule une petite fraction de l'espèce isoélectrique est à l'état de zwitterion. Toutefois, les estimations qualitatives à partir des spectres de la fraction de zwitterion présente dans l'espèce isoélectrique à 150°, suggère que cette explication ne puisse pas être la seule. Les réactivités relatives des positions -2 et -4 sont semblables pour la décarboxylation et l'échange d'hydrogène dans les ions pyridiniums mais pas dans les espèces non-protonées.

Canadian Journal of Chemistry, **50**, 3017 (1972)

Introduction

The mechanism of decarboxylation of pyridinecarboxylic acids was first examined by Hammick, who found that when the 2-, but not the 3- or 4-, pyridine and quinoline carboxylic acids are heated in high-boiling aldehyde or ketone solvents they give α-pyridyl carbinols (1, 2). He postulated that the reaction is a decarboxylation of the zwitterionic form of the amino acid to give a nitrogen ylid which acts as a nucleophile toward the carbonyl solvent as illustrated in eq. 1. All the evidence produced since Hammick's original work can be accommodated by the ylid mechanism. For example, the reaction has a large carboxyl-carbon kinetic isotope effect (3, 4), and is faster

[2]

for the methylbetaine than for the acid itself (5, 6).

Much of the work since Hammick's first paper has concerned the timing of the proton transfer from oxygen to nitrogen in the decarboxylation reaction. Solvent and substituent effects have been used to argue that proton transfer and decarboxylation occur in sequence (*i.e.*, zwitterion decarboxylates, as in path 2, eq. 2) (5, 7) or in concert (*i.e.*, neutral acid decarboxylates as in path 1, eq. 2) (8, 9).

No one has ever suggested that either the cation or anion decarboxylates, or that decarboxylation is preceded or accompanied by electrophilic attack at the ring carbon. Perhaps these possibilities have not been considered because all the work up to now has been done in non-aqueous solvents, where ionic species are not favored. In fact, the decarboxylation of a pyridine or quinoline monocarboxylic acid in aqueous solution has not been reported, although quinolinic acid (2,3-pyridinecarboxylic acid) is known to decarboxylate in water at 120° (10). Obviously, water would have many advantages as a solvent for studying this reaction: it favors ionic intermediates such as zwitterion or ylid, and makes possible through pK data a precise knowledge of the state of protonation of the acid. With these considerations in mind, we undertook a study of the decarboxylation of pyridinecarboxylic acids in aqueous solution.

Results and Discussion

Pyridinemonocarboxylic Acids

It was found that to obtain convenient rates of decarboxylation of picolinic acid in aqueous solution it was necessary to use a temperature as high as 150°. In attempts to find suitable acids which would decarboxylate at lower temperatures, 6-methyl- and 5-nitro-picolinic acids were tried. The data for these acids are shown in Fig. 1.

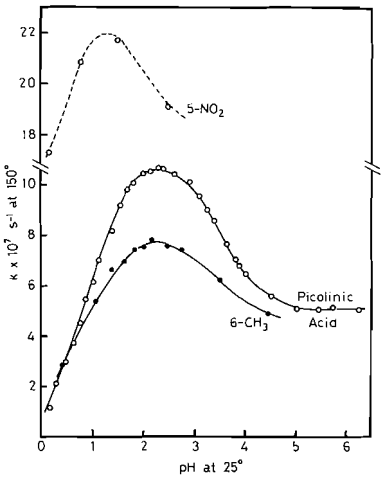

FIG. 1. First-order rate constants for the decarboxylation of substituted picolinic acids at 150° and ionic strength 1.0.

There are several interesting features of the data in Fig. 1. First, the rates of decarboxylation of all three acids are a maximum at an intermediate pH, and decrease at both higher and lower acidities. This is what is predicted by the ylid mechanism or any other in which the species decarboxylating is the isoelectric species, whether neutral acid or zwitterion. More specifically, such a mechanism predicts that the rate maximum should occur at the isoelectric pH. Unfortunately, neither pH's nor pK's are known at 150°, so this prediction cannot be tested.

Second, the rate constant *vs.* pH profile is not symmetrical. At low pH the rate constants decrease sharply, showing that the cation does not decarboxylate. This resembles the behavior of other aromatic acids, where the unionized carboxyl group decarboxylates with great difficulty or not at all (11–13). On the other hand, as pH increases beyond that at the rate maximum, the rate constants at first decrease but then level off, so that at $pH > 5$ the rate is independent of pH. This shows that not only the isoelectric species decarboxylates, as re-

For personal use only.

quired by the ylid mechanism, but so does the picolinate anion. Furthermore, the anion decarboxylates at as much as half the maximum rate. Anion decarboxylation has not previously been reported and, in terms of the generally accepted mechanism, is unexpected. It has been supposed that picolinic acid decarboxylates more readily than benzoic or nicotinic acids because protonation of the ring nitrogen, either prior to or in concert with, carbon–carbon bond breaking provides a strongly electronegative center to stabilize developing negative charge on the adjacent carbon. But, since the anion is now found to decarboxylate almost as easily without the aid of nitrogen protonation, it must be concluded either that protonation is not very important or that the isoelectric species contains very little zwitterion. Attempts to distinguish between these two interpretations will be described below.

Third, substituent effects are unusual. The 5-nitro- group accelerates and the 6-methyl-group retards decarboxylation, as would be expected for the ylid or any other mechanism in which negative charge develops at the reaction site. However, the effect is much smaller than those shown by most other ionic aromatic substitutions. (Hammett's ρ-constant is less than -4 for most electrophilic, and greater than +4 for most nucleophilic aromatic substitutions.) Furthermore, it is surprising that 6-methyl retards the decarboxylation about as much as 5-nitro accelerates it. (Hammett's $\sigma^- = +1.27$ for *p*-nitro- and $\sigma = -0.069$ for *m*-methyl.) Clearly, substituent effects are very different from those found in the benzene series.

A fourth striking feature of the data in Fig. 1 is that the rate in water is distinctly slower than in non-aqueous solvents. The maximum value of the rate constant for decarboxylation of picolinic acid in water at 150° is 1×10^{-6} s^{-1}. In phenetole at 150.7° it is 4×10^{-5} s^{-1}, and it does not vary by more than a factor of 2 for a wide variety of other non-aqueous solvents (8). This leads to the conclusion that, if the same mechanism applies in aqueous and non-aqueous solvents, the transition state is less polar than the initial state, which would be a fairly strong argument for zwitterion as the isoelectric species undergoing decarboxylation. On this interpretation the solvent effect is even more striking, because the percentage of zwitterion in the isoelectric species should be much less in non-aqueous solvents than in water.

TABLE 1. First-order rate constants for decarboxylation of pyridinedicarboxylic acids in aqueous HCl at 150° and ionic strength 1.0

Acid	λ^* (nm)	p*H* at 25°	k (s^{-1})

2,6-	280	1.52	1.28×10^{-6}

*Wavelength at which concentration of starting material was followed.
†HCl–NaH_2PO_4.

Pyridinedicarboxylic Acids

An attempt was next made to find a pyridinecarboxylic acid which would decarboxylate in water at temperatures below 100° so that its p*K*'s, isoelectric p*H*, and possibly the percent zwitterion in its isoelectric species, could be determined under decarboxylation conditions. Since pyridine-2,3-dicarboxylic (quinolinic) acid is reported to decarboxylate in water at 120° (10), the pyridinedicarboxylic acids were examined. The rate data are shown in Table 1. It is seen that quinolinic acid decarboxylates more than 500 times faster than picolinic or any of the other pyridinedicarboxylic acids. This very large ortho-substituent effect contrasts strongly with the small meta- and para-substituent effects previously noted for methyl and nitro groups.

Quinolinic acid decarboxylates readily enough so that rates can be measured at temperatures below 100°. The product of decarboxylation in water at 120° has been reported to be exclusively nicotinic acid (10) and at 95° the u.v. spectrum of the decarboxylation product coincides precisely with that of nicotinic acid. Table 2 shows the first-order rate constants for decarboxylation of quinolinic acid in water at 95° and ionic strength 1.0. It is seen that the rate profile closely resembles that for picolinic acid.

The ionization equilibria for quinolinic acid are shown in eq. 4. At 25°, pK_2 and pK_3 are reported to be 2.43 and 5.06, respectively (14). No value for pK_1 of quinolinic acid is available, but the value for pyridine-2,5-dicarboxylic acid

is 0.5 (10). Since the data of Table 2 were all obtained at pH's less than 4, pK_3 is not important for their interpretation. At 95° and ionic strength 1.0, pK_2 was found to be 1.90 ± 0.03 using a spectrophotometric method described elsewhere (15). The data for this determination are given in Table 3. Attempts to apply the same method to the determination of pK_1 failed because the absorbance change corresponding to this protonation falls in the pH range -1 to 1 where it is impossible to maintain ionic strength 1.0. It appears that pK_1 would be approximately 0. The lack of an accurate value for pK_1 makes it impossible to determine precisely the isoelectric pH under decarboxylation conditions. However, a reasonable estimate would be $pK_2/2 = 0.95$, and this is in good agreement with the pH of about 1.0 at which the rate of decarboxylation is a maximum.

Carbon Isotope Effects

A rate maximum at the isoelectric pH can be explained either by a rate-controlling decarboxylation of the isoelectric species, as postulated by Hammick, or by a rate-controlling protonation of the monoanion, such as that found at low acidities for salicylic (11), anthranilic (13), azulene-2-carboxylic (12), and pyrrole-2-carboxylic acids (16) and shown in eq. 3. In the former case carbon–carbon bond breaking is the rate-controlling process, so there should be a carboxyl–carbon kinetic isotope effect on the rate; in the latter case there should not.

Table 4 records the ^{13}C-carboxyl kinetic isotope effects for quinolinic acid at 95° and for picolinic acid at 150°. It is seen that there is a fairly large carbon isotope effect both at the isoelectric point and at higher pH. Evidently carbon–carbon bond breaking is rate determining for decarboxylation of both the isoelectric species and the monoanion. The isotope effect is slightly less in the anion than in the isoelectric species for both picolinic and quinolinic acids, presumably because the zero-point energy difference in the starting material is a smaller fraction of the activation energy for the slower reaction. The size of the isotope

*The pH of quinolinic acid solutions were measured at 95°, those of picolinic acid at 25°. Buffers were $HClO_4$–$NaClO_4$ at pH < 2; $HClO_4$–NaH_2PO_4–$NaClO_4$ at pH > 2.

effect suggests that carbon–carbon bond breaking is well advanced in the transition states derived from both anion and isoelectric species; that is, the transition states resemble carbanion and ylid, respectively.

Kinetics

Since neither the rate profiles nor the isotope effects require protonation at the α-carbon prior to decarboxylation, the reaction is formulated in eq. 4 as unimolecular decompositions of the isoelectric species, as postulated by Hammick, and of the monoanion. Of course, HA and A^- can each exist in three isoprotonic forms, and any or all of them may decarboxylate without changing the pH profile. As was pointed out

[4]

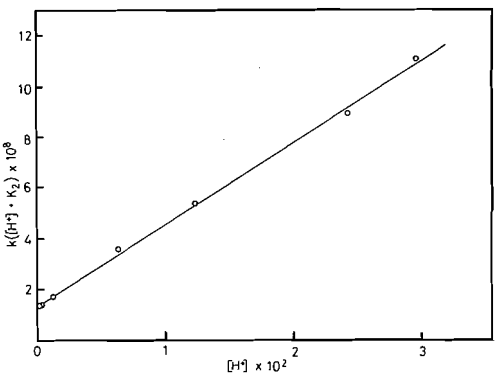

FIG. 3. Rate data at $1 < pH < 4$ for the decarboxylation of quinolinic acid at 95° and ionic strength 1.0 plotted according to eq. 7.

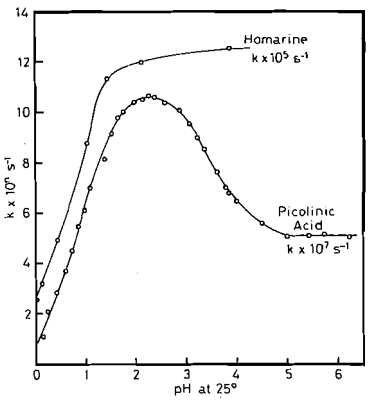

FIG. 4. First-order rate constants for the decarboxylation of picolinic acid and homarine at 150° and ionic strength 1.0.

earlier, the concentration of dianion is so small at the pH's where rates were measured that K_3 and $[A^{2-}]$ can be omitted from the rate expression. Equation 4 will then apply to picolinic as well as to quinolinic acid.

The rate expression is given by eq. 5 in which $[C] = [H_2A^+] + [HA] + [A^-]$ = the stoichiometric concentration of pyridinecarboxylic acid.

$$[5] \quad \frac{d[CO_2]}{dt} = k_{HA}[HA] + k_A[A^-] = \frac{k_{HA} + \dfrac{k_A K_2}{[H^+]}}{\dfrac{[H^+]}{K_1} + 1 + \dfrac{K_2}{[H^+]}}[C] = k_{obs}[C]$$

Because pK_2 for quinolinic acid was found to be 1.90 under the reaction conditions, and because $k_A < k_{HA}$, the terms in K_2 can be neglected at $pH < 0.9$. This produces the approximate eq. 6.

$$[6] \quad \frac{1}{k_{obs}} = \frac{[H^+]}{k_{HA}K_1} + \frac{1}{k_{HA}}$$

Figure 2 shows a plot of eq. 6 for quinolinic acid, from which it is calculated that $k_{HA} = 3.2 \times 10^{-6}$ s^{-1} and $K_1 = 0.96$ at 95° and ionic strength 1.0. This value of K_1 agrees well with the estimate from spectra that $pK_1 \simeq 0$. Accepting this value leads to the conclusion that at $pH > 1$ eq. 5 reduces to eq. 7.

$$[7] \quad k_{obs}([H^+] + K_2) = k_{HA}[H^+] + k_A K_2$$

Figure 3 shows a plot of eq. 7 for quinolinic acid using the experimental value $K_2 = 1.26 \times 10^{-2}$. This plot gives $k_{HA} = 3.3 \times 10^{-6}$ s^{-1} and $k_A = 1.0 \times 10^{-6}$ s^{-1}. The rate constants for decarboxylation of the isoelectric species (k_{HA}) obtained from eqs. 6 and 7 agree very well and are about three times larger than that for decarboxylation of the monoanion (k_A). Insertion of these values into eq. 5 produces the calculated rate constants of Table 2.

Equations 6 and 7 can also be used to fit the rate data for picolinic and 6-methylpicolinic acids to eq. 5. Since K_1 and K_2 are not known at 150° and ionic strength 1.0, values for these constants were chosen to fit the data. The results are given in Table 5, where it is seen that

TABLE 5. Constants for eq. 2 at ionic strength 1.0

Acid	pK_1*	pK_2*	k_{HA} (s^{-1})	k_A (s^{-1})
Quinolinic at 95°	0.02	1.90(2.43)	3.3×10^{-6}	1.0×10^{-6}
Picolinic at 150°	1.09(1.08)	3.70(5.32)	1.1×10^{-6}	5.0×10^{-7}
6-Methylpicolinic at 150°	0.89(0.90)	3.95(5.83)	7.7×10^{-7}	3.9×10^{-7}

*The numbers in parentheses are pK values at 25° for quinolinic (14), picolinic (18), and 6-methylpicolinic acids (19).

it is necessary to assume a much larger temperature effect on K_2 than on K_1. This is, in fact, what is observed for other amino acids such as glycine (17). The values shown for k_{HA} and k_A will, except in the case of quinolinic acid, contain the errors introduced by using pH's measured at 25° instead of 150°. Since the pH of the buffers used increased by only about 0.06 units from 25 to 95°, the error at 150° is probably not large and is the same for k_{HA} and k_A. The data from Table 5 were used with eq. 5 to generate the solid lines in Figs. 1 and 4.

Homarine

It is surprising to see in Table 5 that the three pyridinecarboxylic acids decarboxylate only two to three times faster in the isoelectric form than as anions. Since neither 3- nor 4-pyridinecarboxylic acids decarboxylate detectably at 150°, it is evident that nitrogen adjacent to the carboxyl group has a profound influence on the decarboxylations. The obvious explanation is that the inductive or field effect of electronegative nitrogen facilitates development of negative charge on the 2-position (1, 2). The fact that other electron-attracting substituents (*e.g.*, 5-nitro-) increase and electron-releasing substituents (*e.g.*, 6-methyl-) decrease the rate of decarboxylation supports this interpretation. It would be expected, then, that the introduction of a positive charge on nitrogen would produce a further large increase in the rate of decarboxylation. To test this hypothesis homarine, the *N*-methyl betaine of picolinic acid, was decarboxylated. Haake and Mantecón showed that homarine hydrochloride decarboxylates 720 times faster than picolinic acid in a mixture of ethylene glycol and quinoline (6), but it is uncertain what species are present in such a solution, and it was not then known that picolinate anion also decarboxylates.

Figure 4 shows that homarine, like the other pyridine-carboxylic acids, does not decarboxylate when the carboxyl group is un-ionized but does readily when the carboxyl group ionizes. The pH *vs.* rate profile can be interpreted in terms of eq. 8. The rate data give $k = 1.3 \times 10^{-4}\ s^{-1}$ and $pK = 0.67$ at 150° and ionic strength 1.0. When this rate constant is compared with that for the unmethylated anion from Table 5, $k_A = 5.0 \times 10^{-7}$, it is seen that quaternization of the picolinate nitrogen does indeed produce a large increase in rate constant, as expected.

Zwitterion

If *N*-methylation of the picolinate anion increases its rate of decarboxylation by a factor of about 250, why does protonation only double it? The most obvious explanation would be that protonation of the anion occurs not on the nitrogen where methylation does, but on the carboxylate group; that is, that picolinic acid in water at 150° and ionic strength 1.0 is mostly neutral acid, not zwitterion.

The protonation equilibria for picolinic acid are shown in eq. 9. The experimental ionization

[8]

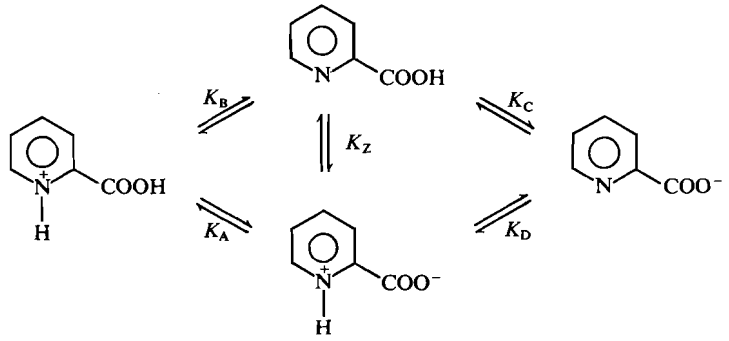
[9]



constants, K_1 and K_2, are related to those of eq. 9 as follows:

$$K_1 = K_A + K_B$$

$$\frac{1}{K_2} = \frac{1}{K_C} + \frac{1}{K_D}$$

$$K_Z = \frac{K_A}{K_B} = \frac{K_D}{K_C}$$

Green and Tong, by assuming that K_B is the same as that of the methyl ester, calculated that $K_Z = 15$ for picolinic acid at 25° and ionic strength 0 (20). This corresponds to 94% zwitterion. However, the decarboxylation conditions are distinctly different from these. Increasing the ionic strength to 1.0 would certainly increase the percentage of zwitterion, but increasing the temperature to 150° might well diminish it. Edsall and Blanchard have estimated that K_Z for glycine is exothermic by 11.5 kcal/mol (21). A similar enthalpy for picolinic acid ionization, if it were independent of temperature, would reduce K_Z to 0.05 at 150°. This would reduce the percentage of zwitterion in the isoelectric species from 94% at 25° to 5% at 150° which, if zwitterion were the only species to decarboxylate, would at least partly explain the difference in decarboxylation rates between isoelectric species and betaine.

In an attempt to test this hypothesis, the u.v. spectra of picolinic acid at 25 and 150° were compared. Green and Tong observed that at 25° the spectra of picolinic acid closely resemble those of its methyl ester in both acidic and basic media (20). From this fact they concluded that protonation or alkylation of the picolinate anion has little effect on its u.v. spectrum, whereas protonation of the ring nitrogen has a pronounced effect. In Fig. 5 the spectrum of the isoelectric form of picolinic acid is compared with those of the cation and anion. At 25° the close resemblance of the curves for isoelectric species and cation suggested to Green and Tong that the nitrogen of the isoelectric species is protonated, which agrees well with their conclusion from pK measurements that the isoelectric species is mainly zwitterion at that temperature. Figure 5 also shows the spectra of the same species at 150°. It is seen that the spectra of the isoelectric species is less like cation than at 25°, but is still far from resembling anion. It seems probable, therefore, that the percentage of zwitterion in the isoelectric species decreases at high temperatures, but we estimate that it is still greater than 40% at 150° and ionic strength 1.0.

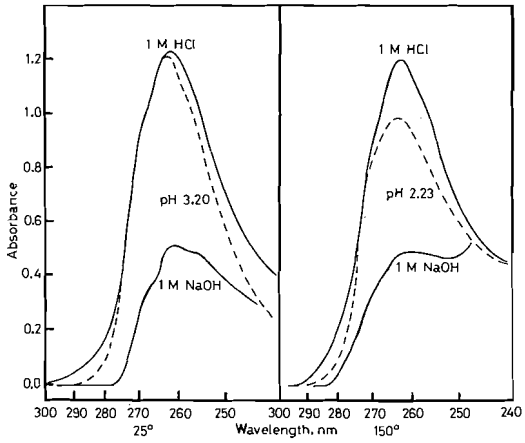


FIG. 5. Ultraviolet spectra of picolinic acid cation, anion, and isoelectric species at ionic strength 1.0. The isoelectric pH at 25° is calculated from K_1 and K_2; at 150° it is obtained from the rate maximum in Fig. 1.

Conclusions

The decarboxylation of any acid involves three processes: O—H bond breaking, C—C bond breaking, and C—H bond making. In all the decarboxylations which have been examined mechanistically, O—H breaking precedes or coincides with C—C breaking. C—C breaking and C—H making have been found to occur in three sequences. First, C—H making may precede C—C breaking, as in the aromatic hydroxy and amino acids where, at low acidity C—H making is rate determining. Second, C—H making and C—C breaking may be concerted, as in the β-keto acids where a cyclic intramolecular proton transfer can produce a tautomer of the final decarboxylation product. Third, C—H making may follow C—C breaking in those acids which yield a stable carbanion on loss of carbon dioxide, such as trihalocarbanions from trihaloacetate salts, or enolate anions from β-ketocarboxylate and malonate salts.

For pyridine-2-carboxylic acids in aqueous solution decarboxylation of the isoelectric species, the anion, and the methyl betaine are observed. Neither the anion nor the betaine have a proton for intramolecular transfer, so they cannot belong to the second mechanistic type of the preceding paragraph. Both decarboxylate at rates which are independent of hydrogen ion concentration, so they are not of the first mechanistic type. Hence, the anion and betaine probably fall into the third type: rate-determining loss of the ionized carboxylate group to form a reactive carbanion.

Classification of the decarboxylation of isoelectric species is not so obvious. However, there is much evidence to suggest that the isoelectric species decarboxylates by the same mechanism as the anion and the betaine. First, the rate of decarboxylation of the isoelectric species is intermediate between those of the anion and betaine. Second, the anion and the isoelectric species have almost the same kinetic carbon isotope effect, showing that C—C breaking is well advanced in the transition states of both. Third, substituent effects are almost the same for anion and isoelectric species, with 6-methyl- retarding and 5-nitro- accelerating the rates of both species by nearly the same amount. This means that the 2-position of the pyridine ring is more negative in the transition state than in the ground state by about the same amount for both species. We therefore conclude that the isoelectric species, like the anion, decarboxylates by rate-controlling loss of the ionized carboxyl group.

It is important to note that this conclusion applies only to decarboxylation in aqueous solution. In *m*-nitrotoluene solution, substituent effects vary, but many are in the opposite direction to those in water (9) and it is not unreasonable to expect that zwitterion would have less advantage as an intermediate in organic solvents than in water.

Finally, there remain the questions why the isoelectric species decarboxylates so much slower than the betaine, and why it decarboxylates slower in water than in organic solvents. No doubt part of the answer to the first question lies in the fact that the isoelectric species is only partly zwitterion at 150°, but this cannot be the whole answer. Possibly stabilization of the transition state is less for *N*-protonation than for *N*-methylation because the positive charge on the protonated species is dissipated by solvation of the proton.[3] The answer to the second question would be easy if the isoelectric species decarboxylated by the same mechanism in aqueous and non-aqueous solvents; water stabilizes the zwitterionic ground state more than organic solvents can. However, it seems probable, as mentioned above, that the mechanisms are different in aqueous and non-aqueous solvents, so the question has no simple answer.

Comparison with Proton Exchange

The hydrogens of pyridine exchange with D_2O or DCl only in the 2- and 6-positions (22), but in $NaND_2$–ND_3 (23) and in NaOD–D_2O (22) the order of ease of exchange is $4 > 3,5 > 2,6$. This has been interpreted by Zoltewicz and Smith (22) as meaning that *N*-protonated pyridine exchanges fastest in the 2,6-positions whereas pyridine itself exchanges fastest in the 4-position. They suggest that both exchanges involve proton abstraction by base and that the 4-carbanion of pyridine is more stable than the 2-carbanion, but that the 4-ylid derived from pyridinium ion is less stable than the

[3]The authors are indebted to Dr. R. Breslow for this suggestion.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2-ylid because of coulombic stabilization of the latter.

Since we have proposed, largely on the basis of carbon isotope effects, that the transition state for decarboxylation of pyridine-2-carboxylic acids resembles carbanion or ylid, it might be expected that the rates of decarboxylation would parallel those of hydrogen exchange. That is, that the zwitterion would decarboxylate fastest in the 2-position while the anion would decarboxylate fastest in the 4-position. To test this hypothesis, 3×10^{-4} *M* solutions of picolinic and isonicotinic acids in 1 *M* NaOH were thermostatted at 150°. The rate constant for decarboxylation of picolinic acid was 5×10^{-7} s^{-1}, but the isonicotinate salt showed no decarboxylation after 20 days ($k < 10^{-9}$ s^{-1}). Evidently the 2-acid decarboxylates faster than the 4-acid both as isoelectric species and as anion. Consequently, we must conclude that, although the relative reactivities of the 2- and 4-positions in both decarboxylation and hydrogen exchange of pyridinium ions may be governed by the stabilities of transition states which resemble ylides, the same cannot be true for the corresponding reactions of unprotonated pyridines. In the latter case, either one or both transition states do not resemble anions, or else other factors, such as ground state stabilities, are of increased importance. This question is being investigated.

Experimental

Materials

5-Nitropicolinic acid (m.p. 210–212°) was synthesized from 2-bromo-5-nitropyridine in 34% yield by the method of Thome and Goebel (24).

Homarine bisulfate was prepared, according to the method of Nienburg (25), by methylating ethyl picolinate using dimethyl sulfate, and hydrolyzing the *N*-methyl ester with HCl. The very hygroscopic product, after crystallization from isopropyl alcohol (90% yield, m.p. 113–125°), neutralized 93.3% of the theoretical amount of base. Further recrystallization from isopropyl alcohol did not improve the titer, perhaps because of decarboxylation.

All other reagents were commercial products. Pyridines were distilled before use and pyridinecarboxylic acids were recrystallized to constant melting point from benzene.

Buffers

Two criteria were used in the choice of buffers: they must not absorb in the u.v. where substrate absorbance was used to follow the rate of reaction, and their p*H* at 25° must not have changed after they have been heated to 150° for 500 h. The organic acids commonly used in buffers failed one or both of these requirements, so the buffering agents used were hydrochloric acid, sodium dihydrogen phosphate, and disodium hydrogen phosphate. Perchloric acid replaced hydrochloric when carbon dioxide was to be recovered for isotopic analysis. Buffers were adjusted to constant ionic strength with potassium chloride. p*H* measurements were made with a Radiometer Model 4C meter, using the electrodes specified by the manufacturer at 25 and 95° respectively, and were reproducible to ±0.005 units.

Spectra

Ultraviolet absorption spectra were obtained with a Perkin–Elmer Model 450 spectrophotometer. At 150 ± 0.5° an electrically heated aluminum block was used as cuvette holder. The temperature of the block was measured by a copper–constantan thermocouple and adjusted by a variable transformers in the heating circuit. The sample was sealed in a cuvette made from 1-cm square quartz tubing (Vitro Dynamics QS110), scanned at 25°, then placed in the pre-heated block. After about 20 min, block and cuvette were placed in the sample compartment of the spectrophotometer, and scanned. Repeated scanning showed no change in absorbance, which was taken to mean that the sample had reached constant temperature. Since the half life for decarboxylation at this temperature is about 200 h, no significant decarboxylation was anticipated. That none occurred was shown by rescanning the sample after it had cooled to 25°.

Rate Measurements

About 20–30 mg of pyridinecarboxylic acid was dissolved in 50 ml of buffer, and 1.5 ml portions of this solution were sealed in 2 ml serum ampoules. These were thermostatted at 150 ± 0.1° or 95 ± 0.1°, withdrawn at intervals, chilled, and diluted by weight to 25 ml in 1 *M* NaOH. Absorbances were measured at 25 ± 0.1°, using a Beckman DU spectrophotometer, at wavelengths where the carboxylate ion absorbs but the decarboxylation product does not. These were for homarine 273.5 nm, picolinic acid 275 nm, 6-methylpicolinic and quinolinic acids 280 nm, and 5-nitropicolinic acid 285 nm. The p*H* of the last ampoule in each run, after cooling to 25°, did not differ from that of the original reaction mixture by more than 0.008 units. Excellent first-order plots were obtained to three or more half lives.

Isotope Effects

^{13}C-Carboxyl kinetic isotope effects were measured as described previously (13).

The Synthesis of (±)-Ochrobirine. A New Route to the Spirobenzylisoquinoline System[1]

N. E. CUNDASAWMY AND D. B. MACLEAN

Department of Chemistry, McMaster University, Hamilton, Ontario

Received March 27, 1972

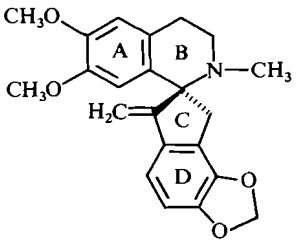
The spirobenzylisoquinoline system has been synthesized from substituted 2-phenyl-1,3-indandiones as starting materials. Ring B of the spiro system was constructed by a modified Pomeranz–Fritsch reaction. The reaction sequence has been applied to the synthesis of an analog of ochrobirine and then to (±)-ochrobirine itself.

Le système spirobenzylisoquinoline a été synthétisé à partir des phényl-2 indanediones-1,3 substituées en tant que produits de départ. Le cycle B du système spirannique a été construit selon une réaction modifiée de Pomeranz–Fritsch. La séquence réactionnelle a été appliquée à la synthèse d'un analogue de l'ochrobirine et de l'ochrobirine (±) elle-même. [Traduit par le journal]

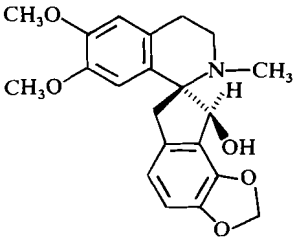
Canadian Journal of Chemistry, **50**, 3028 (1972)

The spirobenzylisoquinoline alkaloids were first isolated some 30 years ago (1) but it was not until 1964 that a structure was assigned to ochotensimine, an alkaloid of this group (2–4). In the intervening years structures have been proposed for other related alkaloids (5–10) and the total synthesis of several of them has been realized. The alkaloids of this family vary in the nature of the substituents present on aromatic ring A and in the type and number of substituents on the spiro ring. The main structural variants are exemplified in ochotensimine, fumaricine, and ochrobirine shown below.

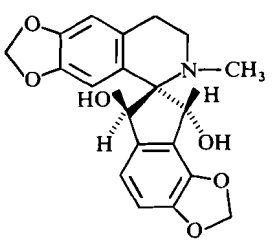
The synthesis of alkaloids related to ochotensimine and fumaricine has been realized by a route in which the key step is a Pictet–Spengler condensation of the appropriately substituted 1,2-indandione with an appropriately substituted phenylethylamine as shown in Scheme 1. The first synthesis of this type was reported by McLean *et al.* (11, 12) for ochotensimine. Several variants of this scheme have since been reported (13–17). By using ninhydrin instead of an indandione in the Pictet–Spengler condensation the groups of Manske and Ahmed (18) and Kametani *et al.* (19) synthesized model compounds in which two oxygens were incorporated into the spiro ring. Both groups have recently completed the total synthesis of (±)-ochrobirine by this method (20, 21). Other routes to the spiro system have been developed by Kametani *et al.* (22) and by Shamma *et al.* (23–25). In the former a phenylpyruvic acid is substituted for the indandione in the Pictet–Spengler reaction and the spiro ring completed by a cyclization of the acid function. In the latter a protoberberine system is rearranged to the spiro system. Here we report a new synthesis of the spirobenzylisoquinolines by a route different from those previously reported. We have used this method to synthesize (±)-ochrobirine. Our method utilizes the readily



Ochotensimine



Fumaricine



Ochrobirine

[1]Presented in part at the 54th Canadian Chemical Conference of the Chemical Institute of Canada, Halifax, N.S., May, 1971.

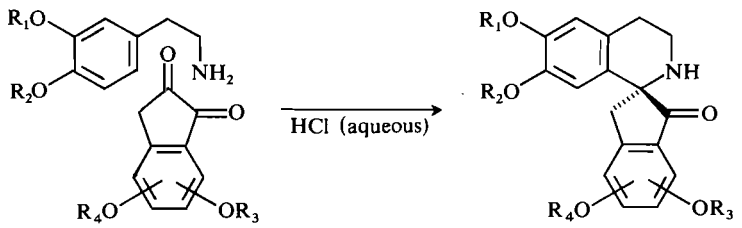


SCHEME 1

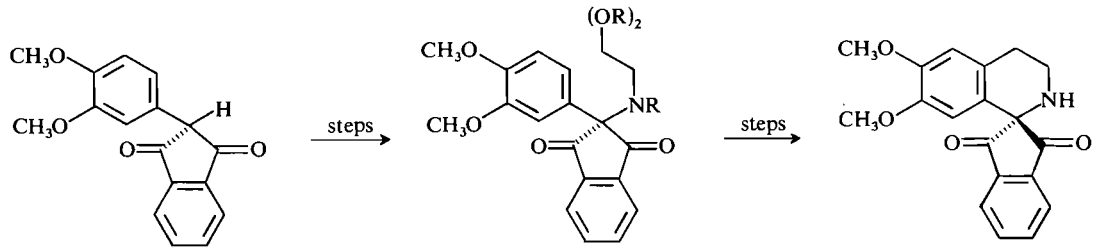
available 2-phenyl-1,3-indandiones as starting compounds and completes the synthesis of the spiro system by construction of ring **B** through a modified Pomeranz–Fritsch synthesis as shown in Scheme 2. The scheme was tested using 2-(3,4-dimethoxyphenyl)-1,3-indandione (**1**) before proceeding to the synthesis of (±)-ochrobirine.

2-Phenyl-1,3-indandiones are available by two routes. For example, 3-benzylidenephthalides, prepared by a Perkin condensation of a phthalic anhydride and a phenylacetic acid (26), rearrange in base to 1,3-indandiones (27). In another method, reported by Shapiro *et al.* (28, 29), benzylidenephthalide formation and rearrangement are carried out in the same reaction vessel by interacting a phthalide with an aromatic aldehyde in the presence of an alkoxide and an ester, used as a scavenger to remove the water liberated in benzylidenephthalide formation. Both methods, outlined in Scheme 3, gave high yields of the model compound, 2-(3,4-dimethoxyphenyl)-1,3-indandione (**1**).

The introduction of the nitrogen and the two carbons required to complete the carbon framework was brought about by bromination followed by displacement of bromine by aminoacetaldehyde diethyl acetal. The bromination of 2-phenyl-1,3-indandiones has been studied previously (30) as has the displacement of the bromines with amines (31). Compound **1** brominated readily in glacial acetic acid to 2-bromo-2-(3,4-dimethoxyphenyl)-1,3-indandione (**2**), but the compound proved unstable to heat and light. Purification of **2** was not attempted, therefore, but it was used directly in the next step. The product, 2-(2,2-diethoxyethylamino)-2-(3,4-dimethoxyphenyl)-1,3-indandione (**3**), was obtained in 73% yield based on **1**. These and subsequent steps of the synthesis are outlined in Scheme 4.

Following the procedure of Bobbitt *et al.* (32, 33) the cyclization of **3** in 6 *M* aqueous ethanolic HCl was attempted. Instead of the expected spiroisoquinoline we obtained the dione, **1**, formed by cleavage of the C_2—N bond; glyoxal, as its bis-2,4-dinitrophenyl hydrazone was also isolated. The formation of these products and ammonia is rationalized in Scheme 5 where the driving force for the elimination is postulated to be the protonation at nitrogen. Accordingly, the nitrogen was acetylated and cyclization of the *N*-acetyl compound **4** attempted again. The reaction now proceeded normally to yield **5** (Scheme 4). Reduction of **5** to **6** was brought about with H_2 over Adams catalyst. Hydrolysis of the *N*-acetyl group yielded **7** which had previously been prepared by another route (34).

The identity of the two products was established by comparison of their melting points, their i.r. and their n.m.r. spectra. *N*-methylation of **7** to **8** by the Eschweiler–Clarke procedure proceeded in very low yield



SCHEME 2

In the model synthesis: $R_1 = R_2 = OCH_3$; $R_3 = R_4 = H$.
In the ochrobirine synthesis: $R_1 + R_2 = R_3 + R_4 = OCH_2O$.

SCHEME 3

which was surprising since this reaction had already been applied successfully to similar systems (18, 34). However the reduction of **8** to the corresponding diol had already been reported (34) and we found that the diol was readily *N*-methylated with formaldehyde and sodium borohydride to **9**. The configuration of the diol was not established in this study. With the successful completion of the model synthesis attention was turned to the synthesis of (±)-ochrobirine.

The starting compounds required for the synthesis of ochrobirine are piperonal and 6,7-methylenedioxyphthalide in one case and 3,4-methylenedioxyphenylacetic acid and 3,4-methylenedioxyphthalic anhydride in the other depending upon the route chosen for the preparation of the substituted 2-phenyl-1,3-indandione. All compounds are available commercially or by procedures described in the literature but it is worthwhile to note that the preparation of the phthalic acid derivatives is lengthy and cumbersome and is a major shortcoming of this synthesis.

The preparation of the 2-phenyl-1,3-indandione in the model series proceeded in high yield by both methods but such was not the case when the methylenedioxy compounds were used. Yields of less than 10% were obtained in both routes. The starting materials were not recovered and the desired product was accompanied by polymeric material. The reasons for the failure in these condensations were not established. However, we found that, when the phenylacetic acid was treated with acetic anhydride, presumably to give an anhydride, prior

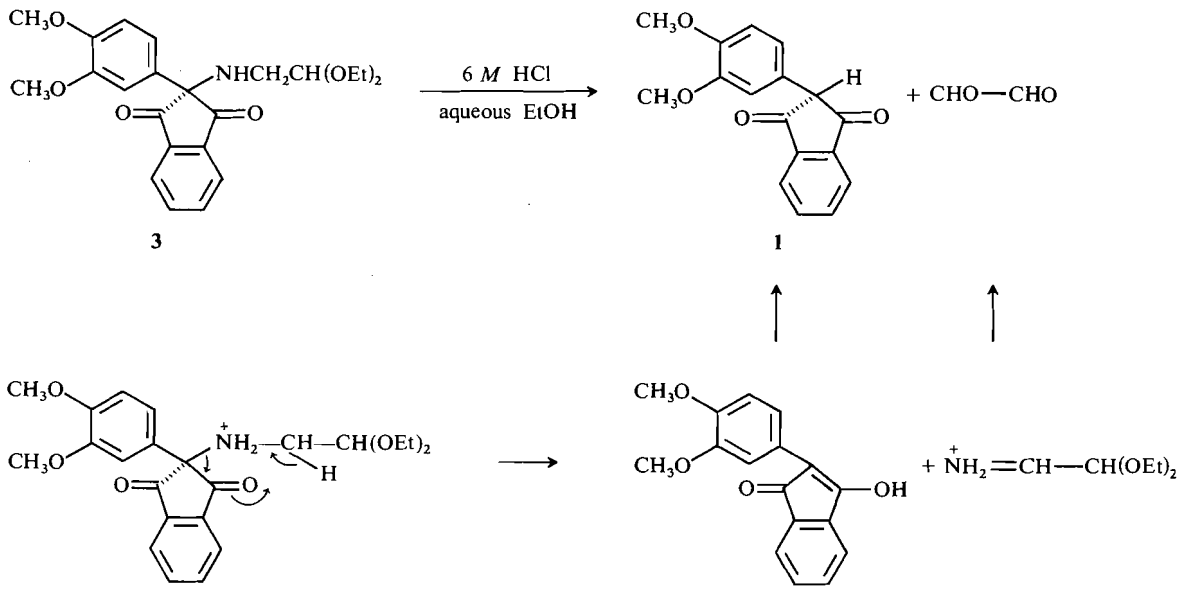
In the model synthesis: $R_1 = R_2 = OCH_3$; $R_3 = R_4 = H$.
In the ochrobirine synthesis: $R_1 + R_2 = R_3 + R_4 = OCH_2O$.

SCHEME 4



SCHEME 5

to addition of the phthalic anhydride and fused sodium acetate, a satisfactory yield (60–65%) of the benzylidenephthalide (**10**) was obtained. Rearrangement to the dione (**11**) proceeded in nearly quantitative yield. The remainder of the synthesis proceeded in a manner analogous to that in the model series (see Scheme 4) and in satisfactory yield. It was possible, however, to methylate the secondary amine (**17**) by the Eschweiler–Clarke method in satisfactory yield. Compounds **17** and **18** isolated by us have melting points identical with those found by Nalliah *et al.* (21) but considerably higher than those reported by Kametani *et al.* (20 *a*, *b*). Our (±)-ochrobirine melted at nearly the same temperature as that reported for the lower melting modification of Nalliah *et al.* (21). The spectral properties (i.r. and mass spectrum) of synthetic (±)-ochrobirine are identical with those of the natural base. The high degree of specificity found in the borohydride reduction of **18** to **19** was unexpected but has been observed by others (20, 21).

The absolute configuration of (±)-ochrobirine and other alkaloids of this family (35) has recently been established and conforms to that in the formulas.

Experimental

Apparatus, Methods, and Materials

Melting points were recorded on a Köfler micro hot stage apparatus and are uncorrected. Infrared spectra were recorded on a Beckmann IR5 or a Perkin–Elmer 337 spectrophotometer in chloroform solution unless otherwise stated. The p.m.r. spectra were recorded on a Varian A60 or a T60 spectrophotometer in solution in $CDCl_3$ using tetramethylsilane as an internal standard. Chemical shifts are reported in p.p.m. (δ) from TMS. The symbols s = singlet, d = doublet, t = triplet, q = quartet and m = multiplet are used in reporting spectra. Mass spectra were routinely run on all samples to check their molecular weights either on a Hitachi RMU 6A mass spectrometer or on a C.E.C. 21-110B double focusing instrument. High resolution mass spectrometry was used to confirm the composition of several compounds and mass measurements were made by procedures described elsewhere (34).

The microanalyses were performed by Gygli Microanalytical Laboratory, Toronto, Ontario.

3-(3,4-Dimethoxybenzylidene)-phthalide

A mixture of 3,4-dimethoxyphenylacetic acid (0.025 mol), phthalic anhydride (0.021 mol), and freshly fused sodium acetate (150 mg) was rapidly heated in an oil bath to 240–245° and the temperature maintained there until the reaction was complete (1–2 h). The reaction mixture was cooled, dissolved in the minimum amount of hot methanol, and the solution filtered. Upon cooling, yellow crystals of the phthalide were deposited melting at 133–134°; yield, 78%.

I.r.: ν_{max} 1775 cm^{-1}; p.m.r.: 3.80 (3H, s, OCH_3), 3.85 (3H, s, OCH_3), 6.24 (1H, s, benzylic H), and 6.74–6.90 (7H, m, aromatic H's).

*3-(3,4-Methylenedioxybenzylidene)-6,7-methylenedioxyphthalide (**10**)*

The method described above for the preparation of the 3-(3,4-dimethoxybenzylidene)-phthalide gave very low yields when applied to the preparation of the methylenedioxy compound. It was found, however, that the following procedure was satisfactory. A mixture of 3,4-methylenedioxyphenyl acetic acid (0.025 mol) and freshly distilled acetic anhydride (0.05 mol) was heated on a steam bath for 15 min. 3,4-Methylenedioxyphthalic anhydride (0.021 mol) and freshly fused sodium acetate (200 mg) were added and the mixture was heated rapidly to 170–180° until the distillation of acetic acid and other volatile components was complete (45–60 min). The solid was dissolved in hot methanol, the solution filtered and cooled. The bright yellow crystals which separated melted at 259–261°; yield, 60–62%. I.r.: ν_{max} 1772 cm^{-1}.

Anal. Calcd. for $C_{17}H_{10}O_6$: C, 65.80; H, 3.23. Found: C, 65.70; H, 3.33.

*2-(3,4-Dimethoxyphenyl)-1,3-indandione (**1**) from 3-(3,4-Dimethoxybenzylidene)-phthalide (Method A)*

The benzylidenephthalide (0.025 mol) in boiling absolute methanol (200 ml) was treated with a solution of sodium methoxide freshly prepared from sodium (750 mg) and absolute methanol (25 ml). The bright red solution so obtained was heated under reflux for 1 h, cooled, and the solvent removed under vacuum. The red residue was dissolved in water and extracted with ether. The aqueous layer was separated, acidified to p*H* 4 with 10% sulfuric acid and extracted several times with chloroform. The extract was washed several times with water, dried over anhydrous sodium sulfate and evaporated to dryness. The white solid residue was recrystallized from benzene and melted at 196–197°; yield, 92–95%.

Anal. Calcd. for $C_{17}H_{14}O_4$: C, 72.35; H, 4.97. Found: C, 72.51; H, 4.83.

I.r.: ν_{max} 1710, 1745 cm^{-1}; p.m.r.: 3.79 (6H, s, 2 × OCH_3), 4.17 (1H, s, benzylic H), 6.69 (3H, m, aromatic H), 7.73–8.10 (4H, m, aromatic H's).

*2-(3,4-Dimethoxyphenyl)-1,3-indandione (**1**) from 3,4-Dimethoxybenzaldehyde and Phthalide (Method B)*

A boiling mixture of phthalide (0.025 mol), aldehyde (0.025 mol) and freshly distilled methyl formate (12 ml) was treated with a solution of sodium methoxide in methanol prepared from sodium (1.95 g) in anyhydrous methanol (24 ml). The solution, which became red immediately upon addition of the methoxide, was boiled for 1 h under reflux and then worked-up as in the procedure above. Compound **1** was obtained in 95% yield.

*2-(3,4-Methylenedioxyphenyl)-4,5-methylenedioxy-1,3-indandione (**11**)*

This compound was prepared from the phthalide (**10**) by the procedure outlined previously (method A) for the rearrangement of 3-(3,4-dimethoxybenzylidene)-phthalide. Like its analog, this compound was recrystallized from benzene and then melted at 209–210°; yield, 93%. When its preparation from piperonal and 6,7-methylenedioxyphthalide (method B above) was attempted only 5–10% of the desired product was obtained.

Anal. Calcd. for $C_{17}H_{10}O_6$: C, 65.81, H. 3.23. Found: C, 65.66; H, 3.11.

I.r.: ν_{max} 1708, 1740 cm^{-1}; p.m.r.: 4.17 (1H, s, benzylic H), 5.88 (2H, s, OCH_2O), 6.16 (2H, s, OCH_2O), 6.89, 7.46 (2H, AB quartet, $J = 8$ Hz, C-6 and C-7 H's), 6.70–7.42 (3H, m, aromatic H's).

*2-Bromo-2-(3,4-dimethoxyphenyl)-1,3-indandione (**2**)*

A stirred solution of dione **1** (0.005 mol) in glacial acetic acid (100 ml) under an atmosphere of oxygen-free nitrogen at room temperature was treated rapidly with a solution of bromine (0.005 mol) in glacial acetic acid (15 ml). The absorption of bromine was instantaneous but the reaction was stirred for 5 min before removing the glacial acetic acid under vacuum. It was necessary to keep the temperature below 20° at this stage to avoid decomposition of the bromo compound. The residue was a yellow crystalline material melting at 133–134°. In most cases it was used directly in the next step because attempts to recrystallize it resulted in its decomposition. I.r.: ν_{max} 1710, 1745 cm^{-1}; p.m.r.: 3.78 (3H, s, OCH_3), 3.83 (3H, s, OCH_3), 6.70–8.3 (7H, m, aromatic H's).

*2-Bromo-2-(3,4-methylenedioxyphenyl)-4,5-methylenedioxy-1,3-indandione (**12**)*

Compound **11** was brominated by a procedure identical with that used for the preparation of **2**. The crude product melted at 176–178°. I.r.: ν_{max} 1708, 1745 cm^{-1}; p.m.r.: 5.90 (2H, s, OCH_2O), 6.16 (2H, s, OCH_2O), 7.03, 7.57 (AB quartet, $J = 8$ Hz, C-6 and C-7 H's), 6.6–7.3 (3H, m, aromatic H's).

*2-(2,2-Diethoxyethylamino)-2-(3,4-dimethoxyphenyl)-1,3-indandione (**3**)*

A stirred solution of compound **2** (0.01 mol) in anhydrous ether (75 ml) was cooled in an ice bath and to it was added dropwise a solution of freshly distilled aminoacetaldehyde diethyl acetal (0.02 mol) in anhydrous ether (15 ml). The resulting solution was stirred for a total of 15 h under an atmosphere of dry nitrogen. The reaction mixture, containing suspended solids, was washed twice with water, the ether layer separated, dried over anhydrous sodium sulfate, and evaporated to dryness. The yellow gum that resulted was used directly in the next step; yield, 74%. I.r.: ν_{max} 1715, 1750 cm^{-1}; p.m.r.: 1.08 (6H, t, $J = 7$ Hz, 2 × OCH_2CH_3), 2.68 (2H, d, $J = 5$ Hz, N—CH_2—CH), 3.24–3.74 (4H, m, 2 × OCH_2CH_3), 3.72 (3H, s, OCH_3), 3.76 (3H, s, OCH_3), 4.54 (1H, t, $J = 5$ Hz, N—CH_2—CH), 6.7–8.2 (7H aromatic H's).

*2-(2,2-Diethoxyethylamino)-2-(3,4-methylenedioxyphenyl)-4,5-methylenedioxy-1,3-indandione (**13**)*

Compound **13** was prepared from **12** in a manner identical with the preparation of **3** from **2** above; yield, 71–73%. I.r.: ν_{max} 1710, 1748 cm^{-1}; p.m.r.: 1.14 (6H, t, $J = 6$ Hz, 2 × OCH_2CH_3), 2.64 (2H, d, $J = 5$ Hz, N—CH_2CH), 2.30 (1H, broad s, NH), 3.27–3.74 (4H, complex m, 2 × O—CH_2—CH_3), 4.57 (1H, t, $J = 5$ Hz, N—CH_2—CH), 5.87 (2H, s, OCH_2O), 6.15 (2H, s, OCH_2O), 6.87, 7.44 (AB quartet, $J = 8$ Hz, C-6 and C-7 H's), and 6.70–7.00 (3H, m, aromatic H's).

Treatment of **3** *with 6 M Aqueous Ethanolic Hydrochloric Acid*

A solution of 0.005 mol of **3** in 75 ml of 6 *M* aqueous ethanolic hydrochloric acid was stirred for 16 h at room temperature. The resulting mixture contained a white precipitate. The solvent was removed under vacuum and the white residue so obtained was washed with water and filtered. Recrystallization from benzene afforded 1.35 g of needle-like crystals, m.p. 194–196°. A mixture melting point of the product and compound **1** showed no depression. The i.r. spectrum in $CHCl_3$ and the p.m.r. spectrum in $CDCl_3$ were superimposable on those of compound **1**.

The filtrate was concentrated to about 10 ml and was treated with a solution of 2,4-dinitrophenylhydrazine in ethanol and allowed to stand at room temperature for 15 min. The reddish precipitate that formed was filtered, washed with water, and air dried. Recrystallization from aqueous ethanol gave orange crystals which melted at 328–330°. Authentic glyoxal bis-2,4-dinitrophenylhydrazone is reported to melt at 328° (36).

*N-Acetyl-2-(2,2-diethoxyethylamino)-2-(3,4-dimethoxyphenyl)-1,3-indandione (***4***)*

A mixture of amine **3** (0.001 mol) in anhydrous pyridine (1 ml) and freshly distilled acetic anhydride (3 ml) was stirred at room temperature for 48 h. The solution was added to water and the mixture extracted several times with chloroform. The chloroform extract was washed several times with cold aqueous hydrochloric acid and with water, dried over anhydrous sodium sulfate, and evaporated to dryness. The residue was adsorbed on basic alumina and the column eluted with chloroform. After removal of chloroform from the eluant a crystalline residue was obtained which, after recrystallization from ethanol, melted at 132–133°; yield, 83%.

Anal. Calcd. for $C_{25}H_{29}NO_7$: C, 65.94; H, 6.37; N, 3.08. Found: C, 66.02; H, 6.63; N, 3.12.

I.r.: ν_{max} 1635 (amide), 1712, 1748 cm^{-1}; p.m.r.: 0.97 (6H, t, $J = 6$ Hz, $2 \times OCH_2CH_3$), 2.09 (3H, s, $COCH_3$), 3.04–3.60 (6H, m, $2 \times OCH_2{-}CH_3 + N{-}CH_2{-}CH$), 3.61 (3H, s, OCH_3), 3.67 (3H, s, OCH_3), 4.37 (1H, t, $J = 5$ Hz, $N{-}CH_2{-}CH$), 6.6–7.9 (7H, m, aromatic H's).

*N-Acetyl-2-(2,2-diethoxyethylamino)-2-(3,4-methylenedioxyphenyl)-4,5-methylenedioxy-1,3-indandione (***14***)*

Compound **14** was prepared from **13** in a manner analogous to the preparation of **4** above. After recrystallization from ethanol it melted at 172–174°; yield, 80%.

Anal. Calcd. for $C_{25}H_{25}NO_9$: C, 62.12; H, 5.18; N, 2.90. Found: C, 62.37; H, 5.30; N, 3.08.

I.r.: ν_{max} 1640, 1710, 1740 cm^{-1}; p.m.r.: 1.13 (6H, t, $J = 6$ Hz, $2 \times OCH_2CH_3$), 2.24 (3H, s, $COCH_3$), 3.27, 3.74 (6H, complex m, $2 \times OCH_2CH_3 + N{-}CH_2CH$), 4.47 (1H, t, $J = 5$ Hz, $N{-}CH_2{-}CH$), 5.90 (2H, s, OCH_2O), 6.17 (2H, s, OCH_2O), 6.87, 7.44 (2H, AB quartet, $J = 8$ Hz, C-6 and C-7 H's), and 6.97–7.10 (3H, m, aromatic H's).

*2-Acetyl-6,7-dimethoxy-1,2-dihydroisoquinoline-1-spiro-2'-(1',3'-indandione) (***5***)*

A mixture of **4** (0.003 mol) in 6 *M* aqueous ethanolic hydrochloric acid (50 ml) was stirred at room temperature for 18 h. The ethanol was removed under vacuum, the aqueous acid solution neutralized with ammonia, and the solution extracted twice with chloroform. The chloroform extract was dried over anhydrous sodium sulfate and then evaporated to give a reddish brown residue which was purified by chromatography over basic alumina using chloroform as eluant. Evaporation of the chloroform gave an orange solid which crystallized readily from hot ethanol, m.p. 263–264°; yield, 47–52%.

Anal. Calcd. for $C_{21}H_{17}NO_5$: C, 69.42; H, 4.68; N, 3.86. Found: C, 69.39: H, 5.02; N, 3.96.

I.r.: ν_{max} 1642 ($N{-}COCH_3$), 1668 ($\geq C{=}C \leq$), 1715, 1750 cm^{-1}; p.m.r.: 2.26 (3H, s, $COCH_3$), 3.37 (3H, s, OCH_3), 3.81 (3H, s, OCH_3), 5.64, 6.77 (2H, AB quartet, $J = 8$ Hz, C-3 and C-4 H's), 5.90 (1H, s, C-8 H),[2] 6.60 (1H, s, C-5 H), 7.80–8.15 (4H, m, aromatic H's).

*2-Acetyl-6,7-methylenedioxy-1,2-dihydroisoquinoline-1-spiro-2'-(4',5'-methylenedioxy-1',3'-indandione) (***15***)*

This compound was prepared from **14** in a manner analogous to the preparation described above of **5** from **4**. After recrystallization from hot ethanol the compound melted at 305–308°; yield, 57–61%.

Anal. Calcd. for $C_{21}H_{13}NO_7$: C, 64.44; H, 3.33; N, 3.58. Found: C, 64.33; H, 3.30; N, 3.49.

I.r.: ν_{max} 1640 ($N{-}COCH_3$), 1675 ($\geq C{=}C \leq$), 1715 and 1745 cm^{-1}; p.m.r.: 2.17 (3H, s, $N{-}COCH_3$), 5.54, 6.71 (2H, AB quartet, $J = 8$ Hz, C-3 H and C-4 H's), 5.81 (2H, s, OCH_2O), 6.24 (2H, s, OCH_2O), 6.05 (1H, s, C-8 H), 6.54 (1H, s, C-5 H), 7.21, 7.61 (2H, AB quartet, $J = 8$ Hz, C-6' H and C-7' H's).

*2-Acetyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2'-(1',3'-indandione) (***6***)*

Compound **5** (0.001 mol) dissolved in acetic acid (20 ml) was shaken with hydrogen at 35 p.s.i.g., in the presence of Adams catalyst (25 mg) for 1 h. The catalyst was removed by filtration and the acetic acid evaporated under vacuum. The pale yellow residue was recrystallized from ethanol and melted at 238–240°; yield, 95%.

Anal. Calcd. for $C_{21}H_{19}NO_5$: C, 69.23; H, 5.22; N, 3.85. Found: C, 69.40; H, 5.37; N, 3.85.

I.r.: ν_{max} 1640 ($N{-}COCH_3$), 1718 and 1750 cm^{-1}; p.m.r.: 2.35 (3H, s, $COCH_3$), 3.15, 3.94 (4H, A_2B_2m, C-3 and C-4 H's); 3.55 (3H, s, OCH_3), 3.85 (3H, s, OCH_3), 6.01 (1H, s, C-8 H), 6.85 (1H, s, C-5 H), 7.85–8.1 (4H, m, aromatic H's).

*2-Acetyl-6,7-methylenedioxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2'-(4',5'-methylenedioxy-1',3'-indandione) (***16***)*

This compound was prepared from **15** in the same way that **6** was prepared from **5**. Recrystallization from ethanol gave yellow crystals melting at 300–301°, yield, 91%.

Anal. Calcd. for $C_{21}H_{15}NO_7$: C, 64.27; H, 3.87; N, 3.56. Found: C, 64.33; H, 3.76; N, 3.56.

I.r.: ν_{max} 1640 ($N{-}COCH_3$), 1715 and 1740 cm^{-1}; p.m.r.: 2.13 (3H, s, $N{-}COCH_3$), 3.01, 3.85 (4H, A_2B_2m, C-3 and C-4 H's), 5.82 (2H, s, OCH_2O), 6.20 (2H, s, OCH_2O), 6.18 (1H, s, C-8 H), 6.67 (1H, s, C-5 H), 7.16, 7.55 (2H, AB quartet, $J = 8$ Hz, C-6 H and C-7' H's).

[2]Assignment of the high field aromatic singlet of ring A to C-8 H is based on analogy with other spirobenzylisoquinoline systems (6, 7, 8). Moreover, the signal assigned to C-8 H is sharper than that assigned to C-5 H because the para benzylic coupling between C-8 H and the protons at C-4 is smaller than the ortho benzylic coupling between C-5 H and the protons at C-4.

6,7-Dimethoxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2'-(1',3'-indandione) (7)

The amide **6** (0.5 mmol) was boiled under reflux with 6 *M* ethanolic-aqueous HCl (25 ml) for 2 h. The mixture was taken to dryness, water added, the solution basified, and extracted with chloroform. The extract was washed, dried, and evaporated to a residue which crystallized from ether–hexane and melted at 180–182°; yield, 80%.

Anal. Calcd. for $C_{19}H_{17}NO_4$: C, 70.60; H, 5.26; N, 4.64. Found: C, 70.52; H, 5.30; N, 4.50.

I.r.: ν_{max} 1715 and 1750 cm^{-1}; p.m.r.: 2.79, 3.48 (4H, A_2B_2m, C-3 and -4 H's), 3.50 (3H, s, OCH_3), 3.81 (3H, s, OCH_3), 5.92 (1H, s, C-8 H), 6.71 (1H, s, C-5 H), 7.8–8.2 (4H, m, aromatic H's).

6,7-Methylenedioxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2'-(4',5'-methylenedioxy-1',3'-indandione) (17)

The amide **16** was hydrolyzed in the same way that **6** was converted to **7**. The resulting amine was recrystallized from ether–hexane and melted at 198–199°; yield, 82–84%.

Anal. Calcd. for $C_{19}H_{13}NO_6$: mol. wt. 351.074; C, 64.95; H, 3.70; N, 3.99. Found: mol. wt. 351.071 (high resolution mass spectrum); C, 64.91; H, 3.91; N, 4.04.

I.r.: ν_{max} 1715 and 1748 cm^{-1}; p.m.r.: 2.74, 3.37 (4H, A_2B_2m, C-3 and -4 H's), 5.78 (2H, s, OCH_2O), 6.28 (2H, s, OCH_2O), 5.99 (1H, s, C-8 H), 6.60 (1H, s, C-5 H), 7.20, 7.64 (2H, AB quartet, $J = 8$ Hz, C-6' and C-7' H's).

2-Methyl-6,7-methylenedioxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2'-(4',5'-methylenedioxy-1',3'-indandione) (18)

Amine (**17**) (100 mg), 92% formic acid (2 ml), and formaldehyde (2 ml) were heated on a steam bath for 10 h. Water was added to the mixture which was then basified with sodium bicarbonate solution and extracted twice with chloroform. The chloroform extract was washed with water, dried over sodium sulfate, and evaporated to dryness. The yellow residue after recrystallization from ether–hexane melted at 195–196°; yield, 79%.

Anal. Calcd. for $C_{20}H_{15}NO_6$: mol. wt. 365.090; C, 65.75; H, 4.10; N, 3.84. Found: mol. wt. 365.089 (high resolution mass spectrum); C, 65.52; H, 4.03; N, 3.88.

I.r.: ν_{max} 1705 and 1737; p.m.r.: 2.41 (3H, s, N—CH_3), 2.97–3.47 (4H, complex m, C-3 and -4 H's), 5.81 (2H, s, OCH_2O), 6.31 (2H, s, OCH_2O), 5.96 (1H, s, C-8 H), 6.62 (1H, s, C-5 H), 7.24, 7.64 (2H, AB quartet, $J = 8$ Hz, C-6' and C-7' H's).

2-Methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2'-(1',3'-indandiol) (9)

6,7-Dimethoxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2'-(1',3'-indandiol) (410 mg) obtained by reduction of **7** with sodium borohydride (34) was treated without purification with 2.5 ml of formalin (37%) at reflux for 2 h. The mixture was taken to dryness under vacuum, the residue so obtained was dissolved in methanol (5 ml), the solution cooled in ice, and then treated with 200 mg of $NaBH_4$. The mixture was stirred for 30 min, the solvent removed under reduced pressure, water added, and the resulting mixture extracted with methylene chloride. The dry methylene chloride solution was evaporated to dryness and crystallized from benzene–petroleum ether gave an analytical sample melting at 161–162°.

Anal. Calcd. for $C_{20}H_{23}NO_4$: C, 70.29; H, 6.73; N, 4.10. Found: C, 70.57; H, 6.81; N, 3.99.

P.m.r.: 2.04 (2H, broad s, 2 × O*H*); 2.65 (3H, s, N—CH_3), 2.78 (2H, t, N—CH_2), 3.48 (2H, t, Ar—CH_2), 3.27 (3H, s, OCH_3), 3.83 (3H, s, OCH_3), 5.35 (2H, broad s, 2 × C*H*—OH), 5.92 (1H, s, C-8 H), 6.67 (1H, s, C-5 H), 7.4 (4H, m, aromatic H's). The two proton singlet at 2.04 δ disappeared in the presence of D_2O.

(±)-Ochrobirine (19)

Compound **18** (32 mg) in absolute ethanol (35 ml) was treated with sodium borohydride (90 mg) and the mixture was stirred at room temperature for 15 h. The solvent was then removed under reduced pressure, the residue taken up in H_2O, and extracted with ether. The ether extract was dried over anhydrous sodium sulfate and evaporated to dryness giving 26 mg of white residue. Examination by t.l.c. showed the presence of two components, one of which (the major one) had the same R_f value as natural ochrobirine. Crystallization from benzene–hexane gave 21 mg of crystalline product melting at 210–212° which on t.l.c. showed only traces of the minor component noted above. Recrystallization from methanol removed the traces of impurity without altering the melting point. The i.r. spectrum in chloroform, the p.m.r. spectrum in $CDCl_3$, and the mass spectrum of the synthetic sample were identical with those of natural ochrobirine.

Mol. Wt. Calcd. for $C_{20}H_{19}NO_6$: 369.121. Found (high resolution mass spectrum): 369.120.

An ^{129}I Mössbauer Study of Novel Polyhalogen Ions Formed by Radioactive Decay in the Tellurium Halides

J. J. JOHNSTONE, C. H. W. JONES, AND P. VASUDEV

Chemistry Department, Simon Fraser University, Burnaby 2, British Columbia

Received March 16, 1972

The ^{129}I Mössbauer emission spectra of the compounds $(NH_4)_2{}^{129m}TeX_6$ and $^{129m}TeX_4$ (X = Cl, Br, I) have been reported against a $Na^{129}I$ absorber at 4 °K. The spectra give evidence in the case of the $(NH_4)_2TeX_6$ compounds for the formation in the radioactive decay of the octahedral ions ICl_6^-, IBr_6^-, and II_6^-. In the TeX_4 compounds, the emission spectra are much more complex and indicate that the ^{129}I atoms are not found in an environment iso-structural and iso-electronic with that of the parent.

The ^{125}Te Mössbauer absorption spectra of the parent compounds were studied to aid in their identification, and the parameters obtained are compared with those in the literature. The ^{125}Te isomer shifts for the TeX_6^{2-} anions are interpreted in terms of pure p-bonding and, in conjunction with data from the emission spectra and data from previously reported n.q.r. work, an isomer shift *vs.* p-hole density relationship is established for tellurium.

Nous rapportons le spectre d'émission Mössbauer de ^{129}I des composés $(NH_4)_2{}^{129m}TeX_6$, et $^{129m}TeX_4$ (X = Cl, Br, I) en fonction d'un absorbant $Na^{129}I$ à 4 °K. Le spectre prouve, dans le cas des composés $(NH_4)_2TeX_6$, la formation des ions octaédriques ICl_6^-, IBr_6^-, et II_6^- durant la désintégration radioactive. Les spectres d'émission des composés TeX_4 sont beaucoup plus complexes et indiquent qu'on ne trouve pas les atomes de ^{129}I dans l'environnement iso-structural et isoélectronique où se trouvent leurs analogues.

Nous avons étudié le spectre d'absorption Mössbauer du ^{125}Te des composés analogues afin de faciliter leur identification; nous avons ensuite comparé les paramètres obtenus avec ceux de la littérature. Nous interprétons les déplacements d'isomère ^{125}Te pour les anions TeX_6^{2-} en termes de liaisons p pures et, en plus des données tirées des spectres d'émission et celles venant d'un travail de n.q.r. rapporté antérieurement, nous établissons la relation entre le déplacement d'isomère et la densité de trous p pour le tellure.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3037 (1972)

Introduction

In a previous publication (1), the ^{129}I Mössbauer emission spectrum of $(NH_4)_2{}^{129m}TeCl_6$ as measured against a $Na^{129}I$ absorber at 80 °K was reported. It was observed that in a large fraction of the radioactive decay events, the daughter ^{129}I atoms remained bonded to the chlorine ligands over the lifetime of the Mössbauer transition, with the formation of the octahedral ICl_6^- ion. This was evidenced by the presence in the spectrum of a single line with an isomer shift corresponding to a large positive value in an absorption experiment. It was shown that the isomer shift for this ion was in good agreement with that to be expected for an ICl_6^- ion from the previously reported Mössbauer data for the ICl_2^- and ICl_4^- ions.

In the present work the investigation was extended to study the three $(NH_4)_2{}^{129m}TeX_6$ (X = Cl, Br, I) compounds at 4 °K and evidence was found for the formation of the octahedral ions IX_6^- in each case. However, in the $(NH_4)_2TeI_6$ lattice the radioactive decay was also found to produce molecular rearrangement in a large fraction of events with the formation of another ^{129}I labelled product.

The $^{129}TeX_4$ compounds (X = Cl, Br, I) have also been studied and the Mössbauer emission spectra again recorded against a $Na^{129}I$ absorber at 4 °K. Here it was found that effectively none of the ^{129}I daughter atoms remained bonded in a lattice environment isoelectronic or isostructural with that of the parent tellurium. In each lattice, the decay was evidently accompanied by molecular rearrangement with the formation of a number of ^{129}I products. The resulting spectra were complex showing the presence of several very broad, unresolved lines. These spectra are tentatively interpreted as showing the presence of the $^{129}IX_4^-$ square planar ions among other products.

A further point of interest lay in the ^{125}Te Mössbauer absorption spectra of the parent TeX_6^{2-} and TeX_4 compounds (X = Cl, Br, I) used in this work. The Mössbauer parameters reported in the literature for these compounds

TABLE 1. The Raman spectra of sample preparations of the compounds studied

Compound	Raman spectra (cm^{-1})*				
$TeCl_4$ white solid	375s	348s	341s	150w	
$TeBr_4$ orange solid	245s	231s	224s	133vw	124vw
$(NH_4)_2TeCl_6$ yellow solid	299s	250s	143s		
$(NH_4)_2TeBr_6$ orange solid	178s	155s	91s	75w	
$(NH_4)_2TeI_6$ black solid		108vw	74vw	59vw	

*s = strong, w = weak, vw = very weak.

vary widely and it was important to attempt to define these parameters more closely. Thus, a comparison of the isomer shifts for ^{125}Te and ^{129}I could then be used in attempting to identify the products of the $^{129}Te \rightarrow {}^{129}I$ decay in the solids.

Experimental

The techniques used were essentially as described previously (2). Mössbauer spectra were recorded as 2×256 channel spectra using an NSEC AM1 constant acceleration spectrometer fitted with a Texas Instruments cryoflask and coupled to a Nuclear Data 2000 series 1024 channel analyzer.

The ^{125}Te spectra were recorded with the source and absorber at 80 °K using an $^{125}I/Cu$ (N.E.N.) source of *ca.* 20 mCi, and a Xe/CO_2 proportional detector gated on the 6 keV escape peak of the 35.5 keV γ-ray. The absorbers (5–10 mg cm^{-2} ^{125}Te) were prepared from enriched ^{125}Te and were mounted in Teflon holders with thin windows. The ^{129}I emission spectra were recorded against a $Na^{129}I$ absorber, which was confirmed as a single line absorber against a $Zn^{129m}Te$ source. The source and absorber were at ca. 4 °K. A NaI/Tl scintillation detector was used. The mirror-image spectra were computed separately, using a program kindly provided by Stone (3), and the average value of the δ and e^2qQ values obtained from the computed fits. The spectrometer was routinely calibrated using a variety of Fe standards (4) including $Na_2[Fe(CN)_5NO]2H_2O$ ($\delta = 0.442$ mm s^{-1}, $\Delta = 1.712$ mm s^{-1}) Fe metal foil and α-Fe_2O_3, the spectra being recorded at room temperature against a $^{57}Co/Pd$ source.

The tellurium compounds studied in this work were synthesized using standard techniques (5). The $(NH_4)_2TeX_6$ compounds were obtained by dissolving $^{125}TeO_2$ in HX and adding the appropriate ammonium salt in excess. The TeX_4 compounds were generally prepared by precipitation from a solution of TeO_2 in HX by the addition of a large excess of concentrated H_2SO_4. Several samples of TeI_4 were also prepared by heating tellurium metal with iodine in a sealed evacuated tube. These samples gave identical results to those obtained from aqueous solution preparations. The compounds TeX_4 are readily hydrolyzed and anhydrous preparations throughout would have been preferable. However a simple, very rapid preparation was required to allow the study of both ^{129}Te (69 min) and ^{129m}Te sources where possible. The samples of TeX_4 obtained by precipitation with concentrated H_2SO_4 were filtered off and immediately used in Mössbauer experiments at 80 or 4 °K.

The compounds were characterized by their Raman spectra (Table 1), although a spectrum could not be obtained for TeI_4. These spectra are in good agreement with those reported in the literature (11). Chemical analyses were performed on sample preparations of the compounds shown in Table 2. Analyses were not obtained for the more unstable $TeCl_4$ and $TeBr_4$ compounds.

Results and Discussion

The ^{125}Te Mössbauer Absorption Spectra

The ^{125}Te absorption parameters are shown in Table 3 in comparison with the values reported in the literature. For the $(NH_4)_2TeX_6$ compounds the values of the present work are in reasonable agreement with those reported by Gukasyan *et al.* (9). It should be noted that while the data of Gibb *et al.* (10) were reported as being relative to an $^{125}I/Cu$ source, their isomer shift values, not only for the tellurium hexahalides but also for ZnTe, and H_6TeO_6, show a systematic shift with respect to the data of other workers. It would appear that their

TABLE 2. Chemical analyses of several of the compounds studied

	Analysis (%)

*With respect to an ^{125}I/Cu source.
†Conversion into $e^2qQ(1+\eta^2/3)^{1/2}$ in Mc s^{-1} is obtained by multiplying by 57.4.

source gave considerably more positive isomer shifts than observed in other studies. Erickson and Maddock (12) have commented on the wide variations in ^{125}Te isomer shifts reported by different workers for the same compounds and which apparently arise from differences in ostensibly the same sources.

The values for δ and Δ for $TeCl_4$, $TeBr_4$, and TeI_4 reported here are in reasonable agreement with those of Jung and Trifsthäuser (6). The large errors in the isomer shifts and quadrupole splittings for these compounds, and particularly for TeI_4, reflect the low % resonance absorption at 80 °K and the fact that the broad natural line-widths lead to unresolved lines for small quadrupole splittings.

It is apparent that $TeCl_4$ has a relatively small quadrupole splitting and that the values for $TeBr_4$ and TeI_4 are even smaller. The crystal structure of $TeCl_4$ has been reported (13) and is shown in Fig. 1. Each tellurium forms three short bonds to chlorine atoms and three long bonds to bridging chlorines. The tellurium then exhibits a quadrupole coupling characteristic of the $TeCl_3^+$ unit modified by the three

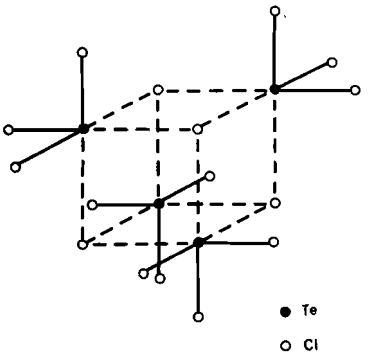

FIG. 1. A representation of the crystal structure of $TeCl_4$ (13).

long Cl^- contacts. Assuming similar structures for the other tetrahalides, the smaller quadrupole splittings in $TeBr_4$ and TeI_4 may then reflect the decreasing electronegativity of the ligand. The environment around the tellurium may approach octahedral symmetry in TeI_4, the "short" and "long" Te—I bonds now being very similar in length.

The ^{129}I Emission Spectra of the $(NH_4)_2TeX_6$ Compounds

The spectra were recorded for several independently prepared sources for each compound and sample spectra are shown in Fig. 2. It is apparent that for $(NH_4)_2{}^{129m}TeCl_6$ and $(NH_4)_2{}^{129m}TeBr_6$ an intense single line was observed in the spectra, with a large negative isomer shift (corresponding to a positive isomer shift for an absorption experiment), indicating a high s-electron density at the iodine nucleus in these decay events. These emission lines are identified as arising from the $^{129}ICl_6^-$ and $^{129}IBr_6^-$ ions formed in the respective matrices in the radioactive decay. The computed Mössbauer parameters are shown in Table 4. In addition to the intense single line in these spectra, other resonance absorption lines were also observed. However, these lines were of such low intensity that an unequivocal assignment could not be made. A brief discussion of the possible origin of these lines is presented later in the paper and reference is made at that point to the tentative assignments shown for the low intensity lines in the $(NH_4)_2TeCl_6$ and $(NH_4)_2TeBr_6$ spectra.

For $(NH_4)_2{}^{129m}TeI_6$ it is apparent that the spectrum comprised a number of lines of about

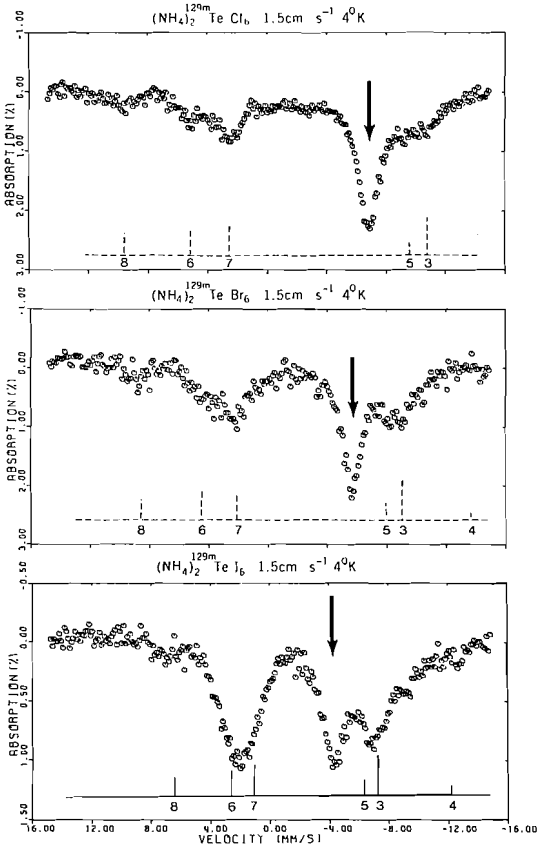

FIG. 2. The ^{129}I Mössbauer emission spectra of the $(NH_4)_2{}^{129m}TeX_6$ compounds measured at *ca.* 4 °K against a $Na^{129}I$ absorber. The arrows denote the emission lines corresponding to the proposed $^{129}IX_6^-$ ions.

*With respect to ZnTe in an absorption experiment. The parameters obtained in an emission experiment were converted into those of an absorption experiment by adding 0.46 mm s^{-1} and reversing the sign (1). (Note: ref. 2 should have read by *adding* 0.46 mm s^{-1}.)

equal intensity. However, even here it is possible to identify a single line with a large negative isomer shift, which probably arises from the octahedral II_6^- ion. The remaining lines in the spectrum may be identified with a single quadrupole split species with the (absorption) parameters $\delta = 1.9 \pm 0.4$ mm s^{-1} and $e^2qQ = 1242 \pm 123$ Mc s^{-1}, the large errors arising from the unresolved nature of the spectrum.

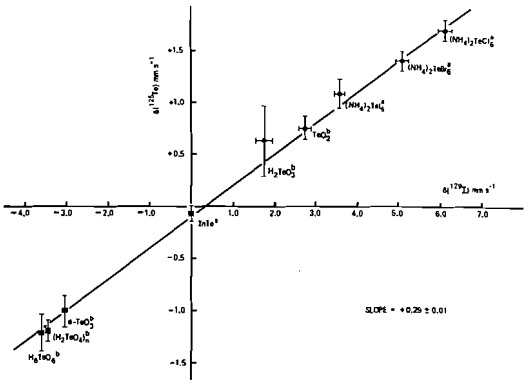

FIG. 3. A plot of the ^{125}Te isomer shifts, relative to an $^{125}I/Cu$ source, *vs.* the ^{129}I isomer shifts, relative to ZnTe, obtained in the same tellurium lattice in emission experiments; (*a*) this work; (*b*) ref. 2.

In support of the above proposal that the single lines of large isomer shift arise from the $^{129}IX_6^-$ ions we may examine the relationship between the ^{125}Te isomer shifts for the parent compounds and the ^{129}I isomer shifts. In a previous publication (2), we have reported a plot of $^{125}\delta$, measured in an absorption experiment, against $^{129}\delta$, measured in an emission experiment in the same matrix, for a series of tellurium oxycompounds. It was observed that a straight line relationship was obtained, of slope $^{125}\delta/^{129}\delta = 0.29$, in reasonable agreement with the isomer shift ratio obtained by Ruby and Shenoy (14). It was concluded that in these oxycompounds the tellurium and daughter iodine were in isoelectronic and isostructural environments. Some of the data for those compounds are reproduced in Fig. 3 together with the $^{125}\delta$ and $^{129}\delta$ values for the $(NH_4)_2TeX_6$ compounds of the present work. The slope of the plot $^{125}\delta/^{129}\delta = 0.29$. It is concluded that the isomer shifts of the single lines indicated in Fig. 2 are indeed consistent with the IX_6^- anions and that these ions are isoelectronic and isostructural with the parent TeX_6^{2-} ions.

It should also be noted that the isomer shift of the proposed ICl_6^- ion is consistent with that to be expected on the basis of the Mössbauer spectra of $^{127}ICl_2^-$ and $^{127}ICl_4^-$. This point was discussed at length in the previous paper (1).

It must be emphasized that the formation of the IX_6^- ions is only observed over the lifetime of the Mössbauer transition ($t_{1/2} = 15$ ns). These ions may be chemically unstable over longer times. The linewidths in the emission spectra were observed to be in the range $2\tau = 1.5$ to 2.3 mm s^{-1} and these compare with a linewidth of 1.1 mm s^{-1} observed for the $Na^{129}I$ absorber against a $Zn^{129m}Te$ source at 4 °K. The broadened linewidths in the emission spectra may be evidence of a change in the chemical form of the ^{129}I atoms over the lifetime of the Mössbauer transition. Certainly the spectra at 4 °K indicated the presence of some ^{129}I species other than that of the IX_6^- ion, this being most pronounced in the case of the TeI_6^{2-} lattice.

The fact that ^{129m}Te sources rather than ^{129}Te sources were used in these experiments introduces a further degree of uncertainty in the interpretation of the results. The $^{129m}Te \rightarrow {}^{129}Te$ isomeric transition is highly internally converted, and it is known (2) that Auger charging accompanying the decay can lead to extensive molecular decomposition in, for example, $H_6{}^{129m}TeO_6$. Thus the products other than the IX_6^- ions observed in the TeX_6^{2-} lattices as shown in Fig. 2 may have originated from decomposition products formed in the $^{129}Te \rightarrow {}^{129}Te$ isomeric transition rather than as a result of the chemical instability of the IX_6^- ions themselves. This point could have been checked if it had been possible to prepare the ^{129}Te labelled $(NH_4)_2TeX_6$ compounds. However, the short half-life of ^{129}Te (69 min) and the time involved in the chemical preparation and cooling the sample and Dewar to 4 °K precluded these measurements.

The firm conclusion to be drawn from the above is that there is evidence for the formation of the IX_6^- ions in the radioactive decay, over the lifetime of the Mössbauer transition. This is of some interest since the ICl_6^-, IBr_6^-, and II_6^- (octahedral) ions have not previously been observed (15). Compounds of the form $N(C_2H_5)_4I_7$ are known to contain a three-dimensional array of I_3^- ions and I_2 in which the I_3^- ion is surrounded by four I_2 molecules and each I_2 molecule by two I_3^- ions.

A Comparison of the Charges on Te and I in the TeX_6^{2-} and IX_6^- Ions

Perlow and Perlow (16) have studied the effects of the $^{129}I \xrightarrow{\beta^-} {}^{129}Xe$ radioactive decay in compounds containing the ICl_2^- and ICl_4^- ions. They observed that the xenon analogs of these iodine molecules were stable over the lifetime of the Mössbauer transition. They were able to calculate the charge on the iodine and on the daughter xenon following the decay and observed that following the decay the increased electronegativity of the daughter atom led to an increased electron withdrawal from the Cl ligand. In ICl_4^- the charge on iodine before the decay was +0.39 and following the decay the xenon had a net charge of +1.0 rather than +1.4 *i.e.*, 0.4 electrons had been recalled from the ligands. It is possible to carry out a similar analysis for the present work, using previously reported n.q.r. data to determine the charge on the parent tellurium and the Mössbauer emission data to determine the charge on iodine following the decay.

TABLE 5. The charge on tellurium in the TeX_6^{2-} anions, obtained from n.q.r. data, and the charge on the daughter iodine

Anions	Charge on Te*		Charge on I†

*Determined from the halogen n.q.r. data of Nakamura *et al.* (17) with (*a*) assuming 15% s-bonding character on the halogen and (*b*) assuming pure p-character on the halogen.
†Determined from the Mössbauer emission data.

Thus Nakamura *et al.* (17) have studied the halogen n.q.r. spectra of the tellurium hexahalides. Using the theory of Townes and Dailey they were able to calculate the number of p-electrons on the ligand halogen whose participation in bonding would be required to produce the observed quadrupole coupling. They then assumed that the ligand halogen employs 15% s-character in bonding and calculated the effective charge on the central tellurium atom. The results are shown in Table 5.

A number of workers have shown that, with the exception of IF_5 and IF_7, the iodine Möss-

For personal use only.

bauer data of the interhalogen compounds may be interpreted in terms of pure p-bonding by the iodine, the $[\Psi_s(0)]^2$ at the iodine nucleus increasing linearly with the removal of 5p electrons. Bukshpan *et al.* (18) have established the relationship

$$\delta(^{129}\mathrm{I}) = 1.50\ \mathrm{hp} - 0.54$$

where $\delta(^{129}\mathrm{I})$ is the isomer shift in mm s^{-1} with respect to ZnTe and hp is the number of holes in the closed $5p^6$ I^- configuration. If we assume pure p-bonding by the central iodine in the IX_6^- anions then the Mössbauer isomer shifts of Table 4 may be used to calculate the charge on the iodine, as reported in Table 5. Since we are assuming that the iodine does not employ any s-character in bonding, this calculation yields the smallest net charge that may reside on the central iodine. It should be emphasized that the charge calculated in this way for the ICl_6^- ion is in agreement with the ^{127}I Mössbauer and n.q.r. data for ICl_2^- and ICl_4^-.

A comparison of the charges calculated for the tellurium and iodine (Table 5) indicates that there is a discrepancy, since the charge on the daughter iodine appears to be more than +1 unit greater than that on the tellurium, and this is not to be expected in the light of the increased electronegativity of the central atom. A possible explanation for part of this discrepancy may lie in the assumption by Nakamura *et al.* (17) that the ligand halogen in the TeX_6^{2-} ions employs 15% s-character in bonding. If this assumption is not made, then the charges on the central tellurium increase to the values shown in column *b* of Table 5. In the present context these would appear to be more realistic charges for the tellurium, but even then there is no measurable "recall" in the $TeCl_6^{2-} \rightarrow ICl_6^-$ transition while in the case of $TeBr_6^{2-}$ and TeI_6^{2-} there is recall of 0.23 and 0.64 electrons in each case.

The ^{125}Te Isomer Shifts

As discussed above, Bukshpan *et al.* (18) have established a linear relationship between isomer shifts and hp values for ^{129}I. The question arises whether a similar relationship may be derived for tellurium (19). There has been much discussion in the past of the nature of the bonding in the tellurium hexahalides and, notwithstanding the experiments of Couch *et al.* (20), the general conclusion arrived at is that the tellurium employs essentially pure p-orbitals in bonding, the $5s^2$ electrons being stereochemically nonactive. Thus the TeX_6^{2-} ions are octahedral (21), have relatively long weak Te—X bonds and the ^{125}Te Mössbauer isomer shifts show a simple trend of increasing positive values (increasing $|\Psi_s(0)|^2$ assuming $\Delta R/R$ is positive) with increasing electronegativity of the ligand. We have therefore used the data of Nakamura *et al.* (17) to determine hp on tellurium in the TeX_6^{2-} ions and have plotted these against the Mössbauer isomer shifts of Table 4. The plots are shown in Fig. 4. The additional data point is that for CaTe ($^{125}\delta_{1/Cu} = -0.14 \pm 0.07$ mm s^{-1}), where it is assumed hp = 0. The plots yield:

$$^{125}\delta = 0.45 \pm 0.01\ \mathrm{hp} - 0.15 \pm 0.03$$

Nakamura charges

$$^{125}\delta = 0.41 \pm 0.03\ \mathrm{hp} - 0.16 \pm 0.10$$

Modified charges

It is interesting that if we take Bukshpan's expression (18) for ^{129}I, $^{129}\delta = 1.50\ \mathrm{hp} - 0.54$ (with respect to ZnTe), and $^{125}\delta/^{129}\delta = +0.29$,

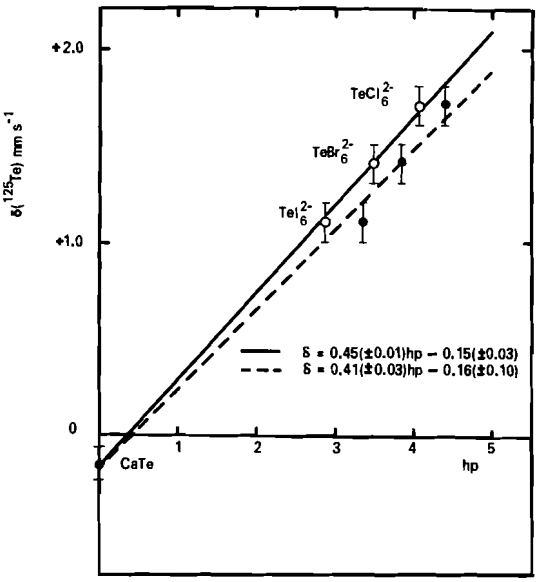

FIG. 4. A plot of the ^{125}Te isomer shifts *vs.* the hp values on tellurium arrived at from n.q.r. data (17). The solid line corresponds to hp values derived assuming 15% s-character on the ligand halogen, while the dotted line corresponds to hp values with no s-character (see Table 5).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

then it is found that

$$^{125}\delta = 0.44 \pm 0.01 \text{ hp} - 0.16 \pm 0.01$$

(with respect to ZnTe)

and

$$^{125}\delta = 0.44 \pm 0.01 \text{ hp} - 0.23 \pm 0.01$$

(with respect to I/Cu)

Within the very large errors involved these different expressions are rather similar. To determine unequivocally whether or not the ligand halogen in TeX_6^{2-} employs any s-character in bonding it will be necessary to measure this parameter in a more direct way. For example the ^{129}I Mössbauer absorption spectrum of $(NH_4)_2Te^{129}I_6$ would provide some evidence for or against s-participation. It may be noted that no evidence was found (22) for s-participation in the ^{129}I spectrum of *trans*-Te(ethylenethiourea)$_2{}^{129}I_2$.

The ^{129}I Emission Spectra of the TeX_4 Compounds

Figure 5 *i* shows the emission spectrum for $^{129m}TeCl_4$. In this instance it was found possible to prepare and study the $^{129}TeCl_4$ source and the spectrum is shown in Figure 5 *ii*. In discussing the possible products of the radioactive decay in this solid, it is first necessary to predict the line positions which would be expected in the ^{129}I emission spectrum for an iodine species isoelectronic and isostructural with that of the parent tellurium. This requires not only a comparison of the isomer shifts for the two nuclides ($^{125}\delta/^{129}\delta = +0.29$) but also a comparison of the quadrupole couplings. Pasternak and Bukshpan (23) observed that

$$(e^2q^{125}Q/e^2q^{129}Q)(1 + n^2/3)^{1/2} = 0.40$$

while Warren *et al.* (2) observed a value of 0.5. The line positions for the emission spectrum were calculated using a value of 0.45 and, since the sign of $e^2q^{125}Q$ in $TeCl_4$ is not immediately apparent, the sets of lines corresponding to both positive and negative $e^2q^{129}Q$ were computed. These line positions are shown on Fig. 5 *i* and it is immediately apparent that the observed and predicted line positions do not coincide. Thus in $^{129m}TeCl_4$ and $^{129}TeCl_4$, the ^{129}I formed in the radioactive decay is not found in an environment isoelectronic or isostructural with

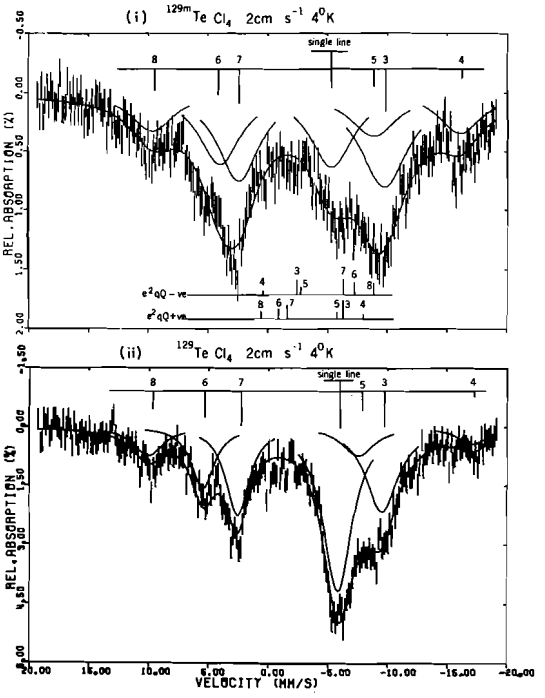

FIG. 5. The ^{129}I emission spectra of the (*i*) $^{129m}TeCl_4$ and (*ii*) $^{129}TeCl_4$ sources measured at *ca.* 4 °K against a $Na^{129}I$ absorber. The predicted line positions for the isoelectronic and isostructural iodine molecule are also shown in (*i*) assuming $\eta = 0$ and following ref. 23.

that of the tellurium and rearrangement must accompany the decay in a large fraction of events. A similar observation was made for $^{129m}TeBr_4$ and $^{129m}TeI_4$.

The question arises as to the identity of the iodine species formed in the TeX_4 lattices. The complex spectra obtained in all instances were so poorly resolved and the line-widths so broad as to make an unequivocal identification of the iodine species present extremely difficult. However, it was found possible to fit the spectra in each case, assuming the presence of a quadrupole split component and one additional single line. Such fits are shown in Fig. 5. The spectra of Fig. 5 lend support to such an interpretation since the single line appears to vary in intensity in the two sources. The computed parameters obtained for the $^{129m}TeCl_4$, $^{129m}TeBr_4$, and $^{129m}TeI_4$ sources are shown in Table 6 and the very large errors reflect the poor quality of the spectra. The parameters for the quadrupole split component in $^{129m}TeCl_4$ *i.e.*,

*With respect to ZnTe in an absorption experiment.
†Quoted as parameters for an absorption experiment.
‡The quadrupole split components were computed using the analysis described in ref. 23. Within the large errors $\eta = 0$ in all cases.

δ and the sign and magnitude of e^2qQ, are observed to be very similar to those for the square planar iodine in I_2Cl_6. Moreover for a square planar iodine molecule in which the iodine uses only p-orbitals in bonding, then the isomer shift and quadrupole splitting can be shown to be simply related (23). Thus

$$\delta = 1.50\ \text{hp} - 0.54$$

and

$$\text{hp} = 6 - (U_x + U_y + U_z)$$
$$= 4 - 2U_x$$

where U_x, U_y, and U_z are the populations of the x, y, and z orbitals, and for a square plane with 2 non-bonding electrons in the out-of-plane orbital $U_z = 2$, and $U_x = U_y$.

$$U_p = \frac{-e^2qQ\ \text{mol}}{e^2qQ\ \text{atom}}$$

and

$$U_p = -U_z + \frac{U_x + U_y}{2}$$
$$= -2 + U_x$$

where e^2qQ atom is the quadrupole coupling for 1 p_z electron on iodine ($= +1607$ Mc s^{-1}) and e^2qQ mol is the measured quadrupole coupling for a molecule. Thus hp can be calculated from δ and U_p from e^2qQ mol. But from the above

$$\text{hp} = -2U_p$$

Thus for a square planar daughter ion this simple relationship between the two parameters should be observed. Table 6 shows that, within the large errors involved, this is so for the quadrupole split iodine component in the TeX_4 lattices. We may therefore tentatively identify this fragment in each case as the IX_4^- ion.

The identification of the single line in the spectrum is far from clear. The isomer shift does not appear to correspond to an IX_6^- ion. However, it can not be ruled out that IX_6^- is not formed since it may have a somewhat different isomer shift in the TeX_4 lattice than in the $(NH_4)_2TeX_6$ lattice.

Returning to the discussion of the $(NH_4)_2$-$^{129m}TeI_6$ spectrum, the product observed in addition to the proposed II_6^- ion may have been the square planar II_4^- ion, since the computed parameters were somewhat similar to those observed in $^{129m}TeI_4$. If the structure of TeI_4 is indeed like that of $TeCl_4$, but with a more octahedral environment about the tellurium, then it would not be surprising if the products of radioactive decay in $(NH_4)_2TeI_6$ and TeI_4 were similar. The low intensity lines in the $(NH_4)_2TeCl_6$ and $(NH_4)_2TeBr_6$ spectra may also have arisen from the square planar IX_4^- ions. The tentative assignments shown in Fig. 2 in fact correspond to the line-positions for quadrupole split species with δ and e^2qQ the same as those observed in the $^{129m}TeCl_4$ and $^{129m}TeBr_4$ experiments.

The authors wish to thank Dr. F. Brown, Head Solid State Research Branch, AECL, Chalk River, for his considerable help and co-operation in carrying out the many reactor irradiations.

A grant from the National Research Council of Canada is gratefully acknowledged.

A Low Temperature Dielectric Cell and the Permittivity of Hexagonal Ice to 2 K[1]

S. R. GOUGH

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received April 28, 1972

The limiting high frequency permittivity ε_∞ of hexagonal ice, measured using a coaxial three terminal dielectric cell designed to minimize errors arising from differential thermal contraction, varies from 3.093 ± 0.003 at 2 K to 3.15 ± 0.02 at 200 K. The result is discussed in relation to the translational lattice vibrations and a comparison is made with other ices.

La permittivité limite à haute fréquence ε_∞ des cristaux de glace hexagonaux, mesurée en se servant d'une cellule diélectrique coaxiale à trois bornes coaxiales, conçue pour minimiser les erreurs provenant de la contraction thermique différentielle, varie de 3.093 ± 0.003 à 2 K à 3.15 ± 0.02 à 200 K. On discute du résultat en relation aux les vibrations translationnelles de réseau et on fait la comparaison avec d'autres formes crystallographiques de glace. [Traduit par le journal]

In accord with publications (1–3) from this laboratory concerning molecular motion in clathrate hydrate systems, the dielectric properties of hexagonal ice are of great interest. The static permittivity and relaxational behavior of hexagonal ice are well known to temperatures near −100 °C (4). The limiting high frequency permittivity ε_∞ is less well known, particularly its temperature dependence. Although general agreement exists in the literature that the radio frequency permittivity of hexagonal ice lies in the range 3.1 to 3.2 (5–9) and that a decrease occurs with decreasing temperature (6) contrary to that predicted by the Clausius–Mossotti relation, the situation is not well defined. The need for a precise determination is indicated.

In addition, the origin of a small but significant radio frequency dielectric absorption, observed near 4 K in all the clathrate hydrates so far examined (2), warrants investigation. This absorption, which probably does not arise from guest or host molecule reorientation since the molecules are apparently frozen (2) at these temperatures, is most probably associated with guest molecule librational motion rather than with the host lattice itself. Nevertheless, a low temperature examination of the related guest-free hexagonal ice lattice is certainly relevant.

The results presented below describe the temperature dependence of the limiting high frequency permittivity of hexagonal ice in the range 2 to 270 K. A dielectric cell is described also. Its design minimizes the usually deleterious effects of differential thermal contraction of the dielectric and electrode structure.

[1]NRCC No. 12703.

Experimental Method

(a) General Considerations

The major difficulties involved in the accurate permittivity measurement of a solid dielectric at low temperatures arise from the development of cracks in the dielectric and from loss of electrode contact. Both are caused by differential thermal contraction of the dielectric, electrodes, and the electrode-supporting structure. Correction may be made for an ideal series air-gap at the dielectric–electrode interface but the effect is large for high values of permittivity. For an example, see ref. 10.

The concept of utilizing the larger thermal contraction of Teflon to force an electrode system to follow smaller dimensional changes of a dielectric and so eliminate series-gap formation is due to Cole and co-workers (11). Their method, as used previously in this laboratory (2), involves supporting a parallel plate electrode system by two Teflon discs. Experience has shown that with this design the cell constant is generally not reproducible after large temperature excursions to better than a few percent. Also, the cell constant varies as both the sample thickness and the electrode area vary with temperature.

A coaxial electrode system has the advantage that its cell constant varies only with the electrode length, the electrode radius ratio being temperature independent for electrodes of the same material. The present cell, described in detail below, is a coaxial three-terminal device, the outer electrode being a very thin brass sleeve supported externally by a hollow Teflon cylinder. As before, the larger thermal contraction of Teflon is utilized to force the outer electrode to follow the radial dimensional changes of the dielectric.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The electrode radius ratio is affected ideally only to the extent that the expansivity of the dielectric is different from that of the electrode material.

Such an electrode system has been briefly described recently (12). The present design offers about a ten-fold increase in reproducibility of the measured capacitance after large thermal excursions and has the advantage that measurements may be made on the same sample over the complete temperature range of interest from 2 K upwards.

(b) The Dielectric Cell

The cell, shown schematically in Fig. 1, consisted of a central cylindrical brass electrode G, guarded by brass supports D and I and insulated by Teflon discs, and an outer electrode sub-system which comprised a hollow cylinder E of Teflon containing a brass liner F a few thousandths of an inch thick which served as the high potential electrode. The two electrode sub-systems were contained in the brass can H of 1/8 in. wall thickness and were supported by the screw I and the top plug B. The latter, held in place by screws C, served as anchorage, heat sink and shielding for the Microdot coaxial electrode leads A, electrode connections, and the various temperature sensors, K, L, and M. It was covered by the cap piece N. The whole was bifilarly wound with a 20 Ω heater winding O and was contained in a Teflon lined copper enclosure P. The assembly was suspended by thin stainless steel supports in an Andonian Associates cryogenic Dewar with leads brought out through vacuum seals.

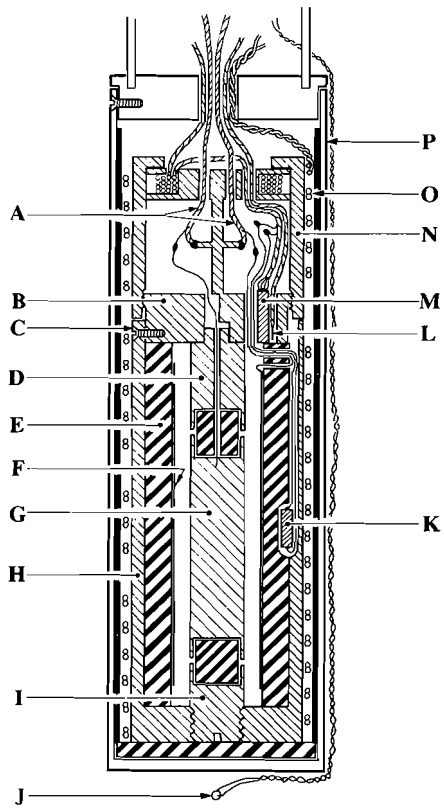

FIG. 1. Schematic of dielectric cell assembly.

(c) Electrical Measurements

Capacitance and conductance were measured below 60 kHz as described previously (27). Measurements at 1 MHz were made using a General Radio five-terminal automatic capacitance bridge whose readings were corrected to compensate for the effects of the Microdot cables leading into the cryostat system.

(d) Temperature Control

Precise temperature control was achieved by adjustment of the flow of liquid helium into the sample chamber of the Dewar and by proportional control of the energy supplied to both the Dewar's helium vaporization heater and to the heater O built into the cell. Heater control was achieved in each case by directly amplifying the voltage differences between reference e.m.f.s. and those produced by currents flowing through the appropriate carbon resistor sensors J and K. The amplified control signals drove d.c. power amplifiers which provided the proportionally regulated heater currents.

Actual temperatures were measured using a calibrated germanium resistance thermometer M below 100 K and a calibrated copper–constantan thermocouple L, referred to the ice point, above 77 K. The measuring thermocouple also served at the higher temperatures to provide a control e.m.f. (in place of the now insensitive carbon sensor K) to drive the sample heater system. Control was better than $\pm 0.01°$ at all temperatures and measurement at the site of the sensors L and M was within $\pm 0.01°$ below 20 K and $\pm 0.1°$ above 77 K.

(e) Determination of the Cell Constant

The basic requirement, to know the geometric capacitance (cell constant, C_0) at the temperature at which freezing of the ice sample took place, was met as follows. The capacitance of the empty cell was measured over the temperature range -5 to $+20$ °C, the cell was filled carefully from the bottom via a piece of Teflon spaghetti, cooled and held at -3 °C until capacitance measurements indicated the nucleation of ice. Then the temperature was raised and held at -1 °C overnight to slowly freeze and anneal the sample. It was assumed that this procedure resulted in no distortion of the outer electrode and that the true cell constant was that corresponding to the freezing temperature. Since two independent experiments, one using a relatively flimsy outer electrode of 0.001 in. brass shim stock stuck to the inside of the Teflon cylinder by silicone grease and the other using a much stronger machined hollow brass cylinder of about 0.005 in. wall thickness that was a push fit into the Teflon cylinder, gave permittivity results agreeing to within 0.1%, it was presumed that the procedures adopted were reliable.

The temperature variation of C_0 was calculated using the data compiled by Eisenberg and Kauzmann (13) for ice and by White (14) for brass. Two thermal effects dominate: (*1*) the change in the electrode radius ratio because ice contracts faster than brass above 100 K leading to an increase in C_0 as the temperature decreases, and (*2*) longitudinal contraction of the low-potential guarded electrode which reduces C_0. The net effect is illustrated in

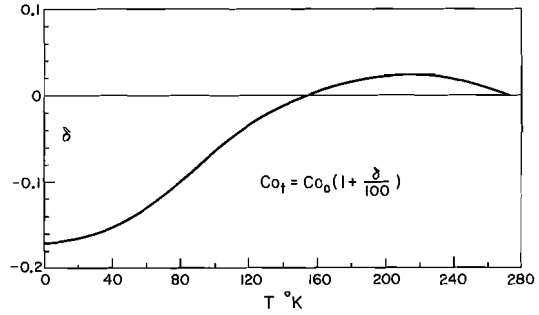

FIG. 2. Calculated temperature variation of the cell constant C_0.

Fig. 2, the maximum estimated deviation in C_0 produced by cooling being about -0.2%.

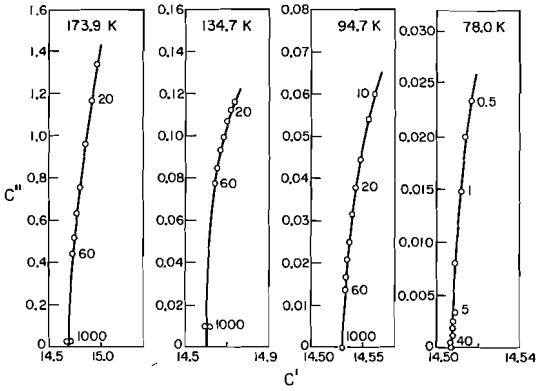

FIG. 3. Determination of the limiting high frequency capacitance C_∞ from the complex capacitance Cole–Cole plot. The numbers on the figures are frequencies in kHz.

Results

Capacitance and conductance measurements were made on three different samples at fixed temperatures over a range of frequency such that the high frequency intercepts of the Cole–Cole arcs could be defined by extrapolation of the data, as illustrated in Fig. 3. The intercepts C_∞ so obtained gave the corresponding limiting permittivity ε_∞. At the highest temperatures, where Debye semicircles were drawn, the data were consistent with those reported previously, however, the extrapolations to C_∞ were the largest and, therefore, the uncertainties greatest. At the lowest temperatures the C_∞ values were read directly from the bridge dials, the uncertainty in ε_∞ being regarded as essentially no worse than 0.2%

Error arising from plastic flow of the sample out of the electrode region caused by the inhomogeneous stress generated by contraction of the Teflon cylinder seems unlikely. Temperature excursions showed no significant hysteresis in ε_∞ (compare points ◇ and ○, Fig. 4) and different samples, despite different thermal histories once frozen and annealed, gave almost identical results. The effect of the unknown stress on the sample was probably small (15) and was neglected.

The permittivity results are illustrated in Fig. 4, where, to preserve clarity, the estimated uncertainty is indicated only for selected points. The curved line is represented by

$$\varepsilon_\infty = 3.093 \pm 0.003 + (0.72 \pm 0.60)10^{-4}T + (0.11 \pm 0.02)10^{-5}T^2$$

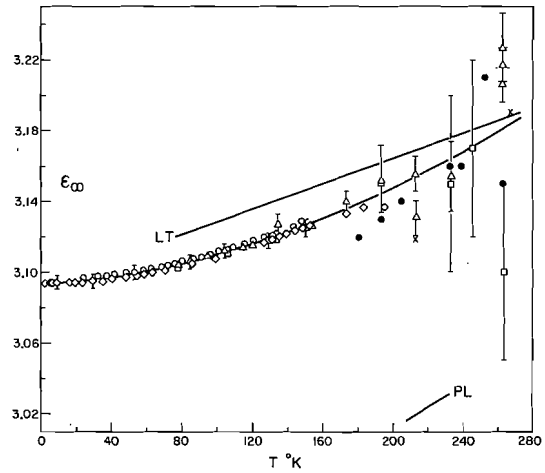

FIG. 4. Temperature variation of the limiting high frequency permittivity of hexagonal ice. Open points, this work; ●, ref. 9; ×, ref. 8; LT, ref. 6; PL, ref. 16.

where the errors quoted are standard deviations and T is the absolute temperature.

At 1 MHz no significant dielectric absorption was observed at any temperature below 100 K and, at 4.2 K, no absorption was observed whatsoever in the frequency range available.

Discussion

The present results are compared in Fig. 4 with those of four other studies of hexagonal ice. The agreement of the data (LT) of Lamb and Turney (6) is excellent considering their estimated uncertainty ($\pm 2\%$) and their dismissal of an observed temperature dependence as

a nugatory experimental effect. The recent results (PL) of Le Petit and Lafargue (16) show nearly the same slope but differ appreciably in magnitude in spite of their claimed high precision. Their results, obtained for samples of freshly frozen super-cooled water, illustrate the need for adequate conditioning before reliable permittivity measurements of ices can be made. The uncorrected[2] results (solid circles) of von Hippel *et al.* (9) referring to their sample ζ, are quite consistent with the present data. Also, Evans (8), in a review, quotes two results (crosses) of Westphal for a sample of Greenland glacier ice which are in accord with the above. The result of a recent microwave study (17) indicating an ε_∞ of 1.9 at 35.3 and 94.5 GHz is incompatible (18) with published infrared (21) and dielectric data.

The temperature dependence (Fig. 4) of the ε_∞ of hexagonal ice is similar to that of several ionic crystals in which strong lattice vibrations also occur at low infrared frequencies. The alkali halides have been extensively examined in this regard (19). The behavior of some of the other ice phases is known to be similar also (20). Since the contribution to the refractive index of a given infrared band is inversely proportional to the square of the frequency, the low lying lattice modes make the largest contribution to ε_∞. (It has been shown (21) that for hexagonal ice, the translational mode, centered near 229 cm^{-1} at 100 K, contributes about 74% of the difference between the microwave permittivity (3.11) and the square (1.74) of the optical refractive index). The observed temperature dependence of ε_∞, therefore, arises primarily from the anharmonicity of the translational lattice vibrations since it is the anharmonicity that causes the infrared absorption frequencies to be temperature dependent. The effect of density variation on ε_∞ (Clausius–Mossotti function) is much smaller and is in the opposite sense.

Provided the absorptivity is unaffected by temperature, the observed change in ε_∞ suggests a decrease in frequency of about 5 cm^{-1} over the temperature range 0 to 200 K for the 229 cm^{-1} translational band. Extrapolation of the reported (22) temperature dependence of this band indicates an actual decrease of about 13 cm^{-1} over the same temperature interval. The discrepancy implies a change in the band contour with temperature. The calculated frequency shift is hardly affected by correction of the data to constant volume.

The far infrared spectra of most of the phases of ice have been recorded (21, 23, 24) and for some the permittivity is known (20) at several temperatures. Table 1 contains the relevant data. The frequencies given are those about which the absorbence of the translational vibrational bands is centered. However, ices II and IX are orientationally ordered (20) and hence show fairly well resolved spectral features (23). Ice I, in contrast, is orientationally disordered, has all vibrations active, and hence has comparatively poorly defined spectral features (21). Nevertheless, the gross shapes of the translational bands of the three ices are reasonably similar. A qualitative comparison of the data therefore seems justifiable.

For the ices proper, the slope $\delta\varepsilon_\infty/\delta T$ shows a linear correlation with $1/\nu^2$ as may be expected since the lower the frequency the greater the

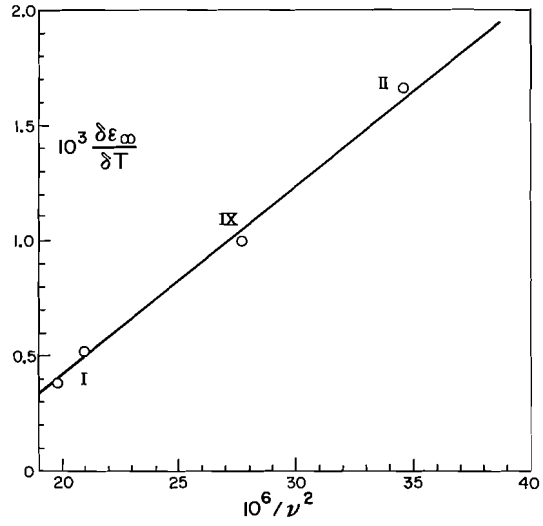

FIG. 5. Empirical correlation between the permittivity temperature dependence and the translational lattice vibrations of ices I, II, and IX.

contribution to ε_∞ and, therefore, the stronger the temperature dependence. The correlation is illustrated in Fig. 5. The line drawn must be regarded, however, as a very approximate representation since its slope depends markedly on the criterion used to establish the tabulated frequencies. Nevertheless, the linear correlation remains. The proportionality implies that the anharmonicities and therefore the potential functions describing translational displacements of the water molecules are similar for these three ices.

The three clathrate hydrates listed each contain a non polar guest and so for these hydrates the ε_∞ of the water lattice dispersion is a "true ε_∞", *i.e.*, it contains no orientational polarization contribution from the guest molecules. Thus the ε_∞ for these hydrates should behave similarly to that of ice. The lower values of permittivity reported (10, 25, 26) for the two hydrate structures are quite consistent with their lower water molecule number densities compared to the number density of ice, provided a small contribution ($\simeq 0.1$) arising from the polarizability of the guest molecules is included (10). The larger slope $\delta\varepsilon_\infty/\delta T$ observed for the two clathrate hydrate structures suggests that their translational lattice modes absorb at somewhat lower frequencies than that of ice I.

It is worth noting that none of the C′–C″ curves, some of which are illustrated in Fig. 3, approach the C′ axis as steeply as required by Debye behavior (note the vertical scales of Fig. 3 are stretched).[3] It has been suggested previously (4) that the extra high frequency absorption giving rise to this behavior is caused by somewhat faster relaxation of the water molecules adjacent to impurity centers. Analysis of the data in terms of multiple Debye-like processes (9) seems hardly justifiable if this suggestion is true.

The technical assistance of R. E. Hawkins who fabricated the cell and the advice and encouragement of Dr. D. W. Davidson are greatly appreciated.

Electron Spin Resonance Study of the Self-disproportionation of some Semiquinone Radicals in Solution

S. K. WONG, W. SYTNYK, AND J. K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ontario

Received May 10, 1972

The photolysis of 1,4-benzoquinone, duroquinone, and 1,4-naphthoquinone in isopropanol and in dioxane leads to the observation of e.s.r. spectra of the corresponding semiquinone radicals. The rates of the self-disproportionation of these radicals were measured by the rotating-sector technique. In the case of 1,4-naphthoquinone, unexpected e.s.r. emission was initially observed by photochemically induced dynamic electron polarization of the semiquinone radicals. Photolysis of anthraquinone in isopropanol gives e.s.r. spectra of the anthrasemiquinone radical anions. Their rate of decay was measured and a mechanism for the decay was suggested. The neutral anthrasemiquinone radical, however, was observed when photolyzed in dioxane.

La photolyse de la benzoquinone-1,4,duroquinone et naphtoquinone-1,4 dans l'isopropanol et dans le dioxane, permet d'observer les spectres r.p.e. des radicaux semiquinone correspondants. Les vitesses d'auto-dismutation de ces radicaux ont été mesurées par la technique du secteur tournant. Dans le cas de la naphtoquinone-1,4, on a observé initialement un spectre d'émission r.p.e. inattendu expliqué par une polarisation électronique dynamique, induite par voie photochimique, des radicaux semiquinone. La photolyse de l'anthraquinone dans l'isopropanol donne des spectres r.p.e. des radicaux anions anthrasemiquinone. Leur durée de vie a été mesurée et un mécanisme de leur extinction suggéré. Cependant, le radical neutre anthrasemiquinone a été observé par photolyse dans le dioxane.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3052 (1972)

Introduction

A continuing interest in the photochemistry of the simple quinones is closely associated with the photobiological functions of the more complex, naturally occurring quinones (1–3). The kinetics of photochemical reactions of quinones has been a topic of considerable interest in recent years (3–6). In these studies both the conventional and laser flash photolyses with optical detection have been used. While the assignment of the triplet state absorption and the confirmation of the triplet state as the precursor of the semiquinone radical have been established for duroquinone (3–6), additional e.s.r. spectroscopic information would prove to be desirable. For example, optical studies very often suffer from overlapping, unresolved transient spectra, which have caused some controversies. E.s.r. spectroscopy provides an alternate method of detecting the paramagnetic species and obtains more information about its assignment and structure (7). For kinetic studies, the absolute concentration of the paramagnetic species can be measured by e.s.r. to give the absolute rate constant.

We have undertaken an e.s.r. kinetic study of the photochemistry of 1,4-benzoquinone, duroquinone, 1,4-naphthoquinone, and anthraquinone in isopropanol and in dioxane. Steady-state e.s.r. spectra of the 1,4-benzosemiquinone radical and the durosemiquinone radical in various solvents have been studied by Gough and co-workers (8, 9). A flash photolytic study of *p*-tetrachlorobenzoquinone in alcohol by e.s.r. has recently been reported by Hales and Bolton (10). In this paper, particular attention is given to the disproportionation of the semiquinone radicals, using the increasingly popular rotating sector technique (11, 12). In another report (13) we have studied in detail the photochemistry of *p*-tetrachlorobenzoquinone in dioxane by a combination of various techniques, including the flash photolysis and the rapid scan e.s.r. methods.

Experimental

1,4-Benzoquinone (BDH), duroquinone (Aldrich), 1,4-naphthoquinone (Eastman), and anthraquinone (Matheson) were recrystallized from benzene. Isopropanol and dioxane were spectranalyzed grade from Fisher. The solutions were made to 0.5 *M* or otherwise saturated. The samples in either Pyrex or Suprasil tubes (3 mm to 0.9 mm o.d.) were degassed to less than 10^{-4} Torr by the freeze–pump–thaw method before irradiation.

A varian 4502 e.s.r. spectrometer operating at a fixed frequency of about 9400 MHz and employing 100 KHz modulation was used. The sample temperature was controlled using a V-4557 variable temperature accessory. An

TABLE 1. Hyperfine splitting constants for semiquinone radicals in solution

Radical	Solvent	HFS (G)
 (BSQ)	Isopropanol	$a_1 = 6.92$ $a_2 = 0.35$ $a_3 = a_5 = a_7 = 1.70$ $a_4 = a_6 = 0.18$
	Dioxane	$a_1 = 7.67$ $a_2 = 0.80$ $a_3 = 1.25$ $a_4 = 0.40$ $a_6 = 0.52$ $a_5 = a_7 = 1.85$
 (DSQ)	Dioxane	$a_1 = a_3 = a_7 = a_9 = 3.28$ $a_2 = a_4 = a_6 = a_8 = 0.44$ $a_5 = 0.88$

optical transmission cavity was used for the photolysis experiments.

The light source was an unfiltered 200 W super-pressure mercury DC lamp. The reproducible light pulses were provided by a rotating disk capable of varying the dark-to-light ratio between 20 to 200 and the light period being as short as 200 μs. A Fabri-Tek 1074 signal averager with pre-triggering by means of a miniature photocell was employed to measure the changes in e.s.r. signal amplitude during the intermittent illumination. Generally 10^3–10^4 sweeps were required for a decay curve.

Radical Concentration Measurements

Radical concentrations were calibrated with standard pitch samples, which were in turn standardized against weighed DPPH in benzene. The intensity I was calculated according to

$$[1] \qquad I = KW^2H$$

where W is the peak separation of the derivative curve and H is the height of the resonance. The constant K is determined by the line shape. K for pitch has been determined to be 2.73, and for the present experimental spectra with assumed Lorentzian shape, K equals 1.81 (14). This method was checked against a computer-performed double integration of the spectra for the 1,4-benzosemiquinone radical (BSQ), $C_6H_5\dot{O}_2$, and the durosemiquinone radical (DSQ), $C_{10}H_{13}\dot{O}_2$, in isopropanol and dioxane at 20 °C, and was found to be within 20% agreement.

Analysis for Kinetic Data

The second-order rate constants were obtained from plotting the inverse of concentration against time:

$$[2] \qquad \frac{1}{[SQ]} = \frac{1}{[SQ]_0} + 2k_t \cdot t$$

where $[SQ]_0$ and $[SQ]$ are initial concentration and concentration of semiquinone radicals at time t, respectively; k_t is the second-order rate constant. In the case of 1,4-naphthosemiquinone radical (NSQ), $C_{10}H_7\dot{O}_2$, and anthrasemiquinone radical (ASQ), $C_{14}H_9\dot{O}_2$, in dioxane where the signal-to-noise ratio was not good enough to allow analysis using eq. 2, a half-life method was used which involved greater errors. The Arrhenius parameters were obtained from the plot of log $2k_t$ against $1/T$:

$$[3] \qquad \log 2k_t = \log A - E_a/2.303\ RT$$

The temperature range studied was from 0 to 50 °C.

Results

Electron Spin Resonance Spectra

The photolyses of 1,4-benzoquinone, duroquinone, naphthoquinone, and anthraquinone in isopropanol and dioxane gave the expected e.s.r. spectra of the corresponding semiquinone radicals except in the case of anthraquinone in isopropanol where the anthrasemiquinone radical anions were the major species. The hyperfine splittings of 1,4-benzosemiquinone radical and durosemiquinone radical in the two solvents are in agreement with the reported values (8, 9). Since the e.s.r. hyperfine splitting constants of the 1,4-naphthosemiquinone radical and the anthrasemiquinone radical have not been reported previously, they are given in Table 1.

In the course of the study of temperature dependence of rate constants of DSQ in isopro-

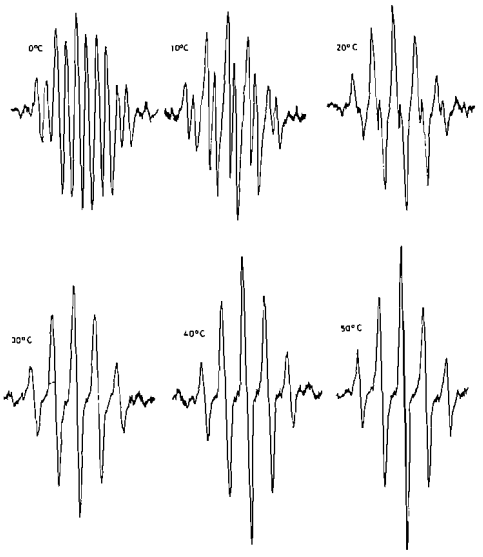

FIG. 1. E.s.r. spectra of the durosemiquinone radical in isopropanol at various temperatures (only the central portion of the spectra are shown here).

panol, it was observed that the e.s.r. spectra changed drastically from 0 to 50 °C (Fig. 1). This can be explained as being due to rapid proton exchange of the hydroxyl group with the solvent, since the doublet splitting of this proton collapsed to a singlet at higher temperatures.

Decay of Radicals

A typical time dependence of radical decay is shown in Fig. 2, indicating also the signal-to-noise ratio. Analyses of these decays show a good second order decay (Fig. 2). The rate constants $2k_t$, measured in this work at 20 ± 2 °C are listed in Table 2 together with the range in initial radical concentrations. The temperature dependence of rate constants of BSQ and DSQ radicals in isopropanol and dioxane has been recorded and is listed in Table 3.

When the radical decay of NSQ was measured during and immediately after the light pulse, the e.s.r. signal was unexpectedly found to be in the form of emission which reverted to the normal absorption mode with a time constant of about 300 μs, as the light pulse decayed (Fig. 3). The e.s.r. absorption further decayed according to a second order kinetics. Since the spin–lattice relaxation time is much shorter than the half-life of the radicals at this concentration, no correction for the concentration is necessary. The novel aspect of this observation has been reported in a preliminary communication (15) in which we proposed that initially the naphthoquinone triplet states are optically spin-polarized and their subsequent abstraction reaction with retention of electron polarization thus leads to the observed e.s.r. emission for the resultant radicals.

Discussion

In the flash photolysis of some quinones, *e.g.* duroquinone and *p*-chloranil, it has been established that the first-order build-up of semiquinone radicals (3, 6) follows closely to the first-order decay of the parent triplets. It should be noted that the lowest triplet state for 1,4-benzoquinone, 1,4-naphthoquinone and anthra-

DSQ	Isopropanol	11.0	3.3±0.3
DSQ	Dioxane	12.3	3.8±0.4

quinone is probably n–π^* in character (16–18), whereas the triplet duroquinone and triplet p-chloranil are probably π–π^* in character (3, 17, 19). In all cases, it is reasonable to assume that the precursors of the semiquinone radicals are the lowest triplet states of the corresponding quinones.

While ketyl radicals are known to dimerize to form pinacols, semiquinone radicals react via self-disproportionation to yield the hydroquinone (HQ) and the quinone (Q) as products (20–22):

$$[4] \qquad 2\dot{S}Q \xrightarrow{k_t} HQ + Q$$

The observed second-order kinetics of the semiquinone radical decay in this study is consistent with this mechanism. In general, it was found that the self-reaction rates in dioxane solvent are about four times greater than those in isopropanol for the same semiquinone radical. Similar observation has also been made in the photolysis of p-chloranil (23). This solvent effect could be partially due to the difference in viscosity of the solvents, provided the self-reaction is mainly diffusion-controlled. It is

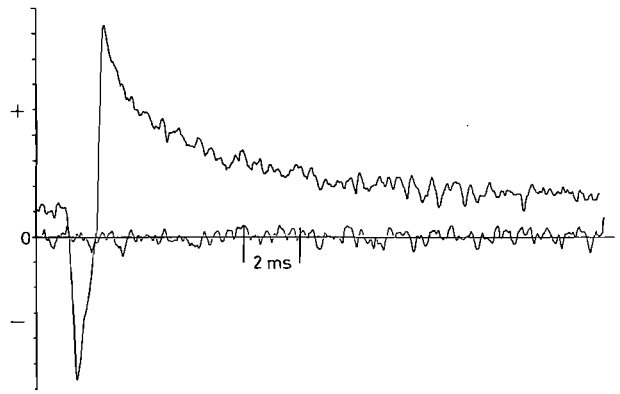

FIG. 3. Decay of the naphthosemiquinone radical in isopropanol exhibiting the conversion of the e.s.r. signal from an initial emission to an absorption mode.

well known that alcohols generally have higher viscosities than those of their corresponding ethers. On the other hand, proton exchange between the DSQ radicals and the isopropanol solvent has been observed by e.s.r. (Fig. 1) and such exchange probably involves hydrogen bonding between the semiquinone radicals and the alcohol. Such property in alcohol solvent may account partially for the slower rates of the semiquinone radical reactions. It should be pointed out, however, that the proton exchange rates are about three orders magnitude faster than the chemical decay rates.

While the experimental data at the present time do not lead to conclusive evidence that the self-reaction of the semiquinone radicals is diffusion-controlled, it is perhaps worthwhile to consider briefly the modified Debye equation (24, 25) which has been used to estimate diffusion-controlled rate-constants for like species. The equation is given in the form:

$$[5] \qquad k_{\text{diff}} = \tfrac{1}{2}(8RT/3 \times 10^3\eta)$$

where η is the viscosity of the solvent. A sample calculation using the available viscosity data for isopropanol at 20 °C gives an estimated value of $k_{\text{diff}} = 1.3 \times 10^9\ M^{-1}\ s^{-1}$ at 20 °C. This value is obviously greater than all the experimentally determined rate-constants in isopropanol as listed in Table 2. However, the modified Debye equation implies that the diffusion-controlled rate constant for a bimolecular reaction is independent of the size and nature of the reactant. This assumption is probably not valid in the present study involving fairly large radicals. Apparently the increase of the size of the radicals as indicated by their molecular weights seems to slow down the reaction rates (26, 27).

Another general criterion for diffusion-controlled reactions is that they should have an activation energy of about 3 kcal/mol in systems with most common solvents (25, 28). It should be pointed out that activation energy for viscosity variation in various solvents may be temperature dependent, particularly for solvents with hydrogen-bonding property (29). Since no data for such temperature–viscosity variation are available, it is not worthwhile to compare the experimental values of activation energy obtained in the two different solvents.

Weiner (30) has quoted that the radical termination rate constant ($2k_t$) for BSQ radicals in isopropanol is $1.2 \times 10^8\ M^{-1}\ s^{-1}$ at 30 °C. The large difference between this value and ours (Table 2) is not understood. Bridge and Porter (4) have reported a value of $1.6 \times 10^9\ M^{-1}\ s^{-1}$ for DSQ disproportionation rate constant ($2k_t$) in ethanol/water solution at ~20 °C by flash photolysis and their result is in reasonable agreement with ours (Table 2).

Next we discuss briefly the formation of anthrasemiquinone anion (ASQ^-) and its kinetic behavior in isopropanol. It is rather surprising that ASQ^- is the major photoparamagnetic species observed in the anthraquinone/isopropanol system. The e.s.r. identification of ASQ^- is reasonable from its spectrum which consists of 15 lines with splittings due to two sets of four nearly-equivalent protons (0.96 and 0.48 G) (31, 32). It has been demonstrated that semiquinone neutral radicals convert rapidly to anions in alkaline solutions (4, 18, 33); in fact the pK_a of the equilibrium of durosemiquinone radicals and the anions in ethanol/water was found to be 5.9 (4):

[6] 
Although the pK_a value is not known for the ASQ^- system, it is possible that the equilibrium in isopropanol lies well to the right. The observation of ASQ^- as a transient species has been reported in the flash photolysis of anthraquinone in ethanol (4). The second order kinetics of ASQ^- is consistent with the following mechanism:

$$[7] \qquad 2ASQ^- \rightarrow AQ^{2-} + AQ$$

However, Bridge and Porter (4) reported in their flash photolysis study that DSQ^- has a bimolecular rate constant of $4.6 \times 10^6\ M^{-1}\ s^{-1}$ in the pH range 7.9–9.1, but a much greater rate constant of $6 \times 10^7\ M^{-1}\ s^{-1}$ was obtained at pH 6.9. They believe that in the strong alkaline solution, chemical reaction analogous to eq. 7 predominates for the decay of DSQ^-, whereas in near neutral solution the following reaction

mechanism accounts for the bimolecular decay:

$$[8] \qquad DSQ^- + H^+ \overset{K_a}{\rightleftharpoons} DSQ$$

$$[9] \qquad 2DSQ \longrightarrow DQ + HDQ$$

Thus, the differential rate equation for the disappearance of DSQ^- would be second order:

$$[10] \qquad \frac{d[DSQ^-]}{dt} = \frac{k_9[H^+]}{K_a}[DSQ^-]^2$$

where k_9 is the bimolecular disproportionation rate constant of DSQ. It follows that such a mechanism could occur also for the decay of ASQ^-.

The authors are grateful to the National Research Council of Canada for financial support. We also wish to thank Mr. Terry Blake for the expert construction of the rotating sector.

Metals Intercalated in Graphite. I. Reduction and Oxidation

J.-M. LALANCETTE, G. ROLLIN, AND P. DUMAS

Département de Chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke, Québec

Received April 10, 1972

Potassium in graphite shows distinctive reducing properties towards carbonyls. The reaction products can be related to a mechanism similar to electrochemical reduction. The steric orientation of the reduction can be explained by the particular structure of potassium–graphite.

Chromic anhydride in graphite offers a new selective method of preparation of aldehydes from the corresponding primary alcohol. This method is characterized by its specificity, high yields and a simple experimental procedure.

Le potassium inséré dans le graphite présente des propriétés réductrices particulières. Les produits de réduction peuvent être expliqués par un mécanisme de type électrochimique. La stéréochimie de la réduction s'explique par la structure du potassium–graphite.

L'anhydride chromique inséré dans le graphite offre une nouvelle méthode d'oxydation sélective des alcools primaires en aldéhydes. Cette méthode est caractérisée par sa spécificité et la simplicité des opérations.

Metals intercalated in graphite present interesting features (1). First, the metal crystalline is broken into atomic particles, the distance between each atom being of the order of 5 Å or more. Secondly, the distance between the planes of graphite holding a layer of metal is from 6 to 7 Å. Such an arrangement would allow, we believe, the selective diffusion of molecules of proper geometry within the lattice of graphite, where reactions with metal atoms will be greatly enhanced. Also, when transition metals, either at zero or at low oxidation state are held between the planes of graphite, the electronic system of graphite can participate to the build-up of coordinated entities that should be quite reactive, in a way similar to dicyclopentadienyltitanium for example.

Potassium–graphite can be obtained very easily by heating a mixture of the two elements, in the absence of air, at 70°. The structure of potassium–graphite is well known from the study of Schleede and Wellmann (2). The stoichiometry of the compounds of potassium can be adjusted quite easily by the relative pressure of potassium to give C_8K, $C_{24}K$, $C_{36}K$, $C_{48}K$ corresponding to one, two, three or more layers of carbons between each plane of potassium atoms. A three dimensional representations of C_8K (3) is given in Fig. 1. Potassium–graphite has been used as catalyst for polymerization (4), alkylation (5), and Wurtz reactions (6). The reduction of carbonyls remained to be examined and it could be expected that the presence of the metal within the structure of graphite would markedly influence the reactivity of the 4s potassium electron. When potassium is inserted in graphite, the planar distance of graphite is increased from 3.35 to 5.40 Å. Since the covalent radius of potassium is 2.03 Å, it is then possible to have interaction and even partial delocalization of this electron within the conduction band of graphite. The heat of insertion of potassium is 7.8 kcal/mol (7), much too low for a quantitative formation of a truly ionic entity like K^+: the heat of insertion would then have to be of the order of 100 kcal/mol for such a complete reaction. But paramagnetic (8) and electric (9) properties have been interpreted as an indication that there is a partial transfer of the 4s electron to the π electronic system of graphite in C_8K. This should influence the mobility and accessibility of the 4s electron, the active species in the initial step of the reduction of a carbonyl.

Reduction

Several saturated and conjugated ketones have been reduced with potassium–graphite. The results of these reductions are reported in Table 1. These results must be examined in relation with the reducing capacity of alkali metals in alcohol (10, 13, 15) and the electrochemical reduction (11, 12, 14, 16). It can be noted that the reaction products obtained from

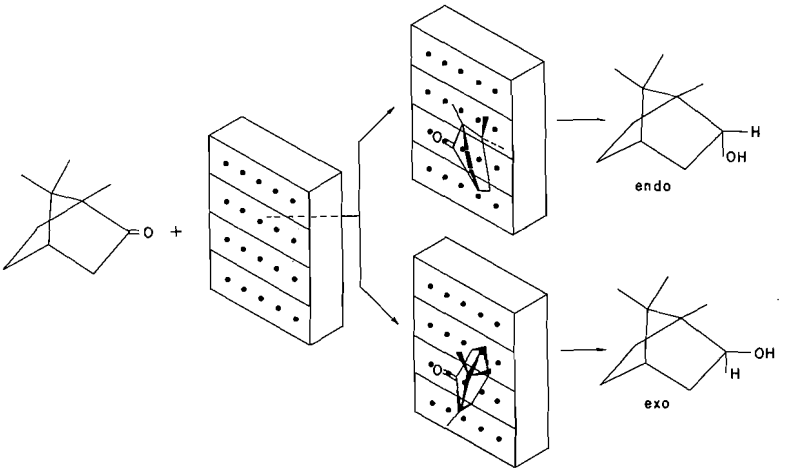

FIG. 1. Stereochemistry of reduction with C_8K.

C_8K and conjugated ketones suggest a mechanism closer to electrochemical reduction than alkali–alcohol reduction. This can be interpreted as an indication that the availability of the 4s electron of potassium in C_8K is more to the electrochemical reduction than the alkali–alcohol system. The stereochemistry of the reduction of camphor, a sterically hindered ketone, is inverted in relation with the reduction product of the alkali–alcohol reduction.

We explain the nature of the observed reduction products and the stereochemistry of the reduction of camphor with C_8K by a mechanism which is similar to the reduction at the surface of an electrode (17). With acetophenone, for example (eq. 1), the electrons of potassium are readily available at the edges of C_8K crystallites, to give the corresponding radical anion. This first intermediate can be desorbed or can abstract a second electron from C_8K to give a dianion. The hydrolysis of these intermediates leads to the corresponding pinacol or alcohol. The reduction of camphor with sodium in alcohol or with potassium, in the presence of graphite, but not intercalated in tetrahydrofuran (THF), gives predominantly the *endo* alcohol. With potassium in graphite, however, the predominant product is the *exo* alcohol. We believe that this inverted orientation can be explained by the necessity for the ketone to be adsorbed at the surface of C_8K crystallite in order to be subject to reduction. And because

this adsorption is easier in a position more favorable for the formation of the *exo* alcohol, this isomer is formed, predominantly, in spite of less favorable thermodynamic factors (Fig. 2).

The results of these reductions with C_8K can be interpreted simply if the structure of C_8K is taken into consideration. This reducing agent shows distinctive properties offering interesting synthetic alternatives to the existing methods of reduction.

Oxidation

Chromic acid can be intercalated in graphite. Several methods can be used to achieve the

§By Smith–Mitchell method.

insertion, calling for the use of acetic acid as solvent (18) or the diffusion of the vapors of CrO_3 in the lattice of graphite at reduced pressure and high temperature (19). We have found that by heating a mixture of chromic anhydride and graphite under reduced pressure, the intercalation was easy, the end product is of constant composition and without any contaminant. Consequently, this method was adopted for the present work. The insertion (55 to 60% by weight of CrO_3) was verified by X-Ray diffraction and the concentration of CrO_3 in the lattice determined by titration (20).

We have investigated the oxidizing capacity of this reagent towards various alcohols. A selection of primary, secondary, and tertiary alcohols were submitted to oxidation under various experimental conditions. Results are reported in Table 2.

From these results, it can be noted that the intercalated chromic anhydride is a very specific oxidizing agent for the conversion of primary alcohols to the corresponding aldehydes. The yields of the reaction are always good, even with sensitive structures like terpenes or allylic systems. With 1,2-diols, there is a rupture of the carbon chain, giving the corresponding aldehydes. Secondary and tertiary alcohols are not oxidized.

Experimentally, the oxidation is very simple. After contact of the alcohol with chromic anhydride–graphite, the aldehyde is obtained by filtration and evaporation of the solvent. There is no problem with chromium salts or solvents difficult to eliminate, *e.g.*, pyridine. The internal mechanism for the oxidation must be close to scheme "B" suggested by Wiberg and Schafer (21) since no internal base is involved.

The good selectivity of the reagent for primary alcohols and the very high yields of aldehydes observed with fatty alcohols must be related to its particular structure, the access to CrO_3 being restricted by the planes of graphite. After oxidation, the resulting aldehyde must be desorbed and be less prone to reenter the lattice, thus explaining the high yield of aldehyde, without secondary product. The residual chromium salts remain in the lattice of graphite under the experimental conditions used in the absence of water, thus eliminating cumbersome purification steps and undesirable secondary reactions.

Consequently, chromic anhydride intercalated in graphite has proved to be a choice reagent for specific oxidation of primary alcohols to the corresponding aldehyde. The yields are comparable to those observed with dipyridine–chromium(VI) complex (22) but a better selectivity is possible.

Experimental

The n.m.r. measurements were made with a Varian A60 apparatus. The i.r. measurements were made with a Perkin–Elmer, model 137 spectrophotometer. The v.p.c. measurements were made with a Microteck, model B.C.2000R apparatus, using an Se30, 4 ft column. Mass spectrometry measurements were performed on a Hitachi Perkin–Elmer instrument, model RMU-6

Preparation of C_8K

A three-necked 1 l flask was flushed with dry helium and briefly heated to around 300°, in order to dry the surface of the flask. After cooling, in an atmosphere of helium, 21 g

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(1.85 mol) of graphite was added and the heating repeated in order to desorb any oxygen or water from the graphite. The graphite used, supplied by Fisher Scientific, was of the Acheson type and contained 99.99% of carbon by elementary analysis. It showed an interlayer spacing of 3.35 Å (no interlayer spacing of 3.44 Å). After cooling, a magnetic stirrer was introduced in the flask and the system heated at 100° with a metal bath. Potassium previously washed with *n*-pentane (8.6 g, 0.22 mol) was then added in small portions, over a period of 40 min, the reaction mixture being continuously stirred. Under these conditions, the insertion was instantaneous, the product being a bronze-colored solid. C_8K, a highly pyrophoric substance was used *in situ* by addition, after cooling, of THF and the ketone to be reduced.

Reduction with C_8K

The reduction of benzophenone can be presented as a typical reduction. To the suspension, of 0.2 mol (27 g) of C_8K in 250 ml of anhydrous THF, 18.2 g (0.1 mol) of benzophenone were added at 25°, during a period of 10 min. The stirring at 25° was continued for 2 h. Then, 20 ml of methanol was added followed by 10 ml of water. After a further stirring of 15 min, the reaction mixture was filtered, the volume of the filtrate was doubled with ether, dried and distilled, giving 18 g of benzhydrol, a quantitative yield.

A similar technique was used for the reduction of ketones reported in Table 1. The identification of the resulting alcohols was done by n.m.r., i.r., and mass spectrometric measurements and by comparison with authentic samples.

Preparation of CrO_3–Graphite[1]

In a thick walled Pyrex tube 4 × 30 mm a 20 g portion of graphite was heated under reduced pressure, at 200°, for 24 h in order to remove any adsorbed gas. After cooling, 40 g of CrO_3 was added. The tube was then sealed under reduced pressure and heated at 200° for 48 h. After cooling, the tube was opened (carefully) and the intercalated product washed with 1 l of distilled water, 500 ml of 10% HCl, and 500 ml of distilled water. After a last washing with 1 l of acetone, the product was dried at 100° to a constant weight. By analysis (20), the content of CrO_3 in the graphite was 55%, in accordance to the value published by Croft (19).

Oxidation of a Typical Alcohol

In a 125 ml flask were added 25 ml of toluene, 10 g of CrO_3–graphite prepared as above, and 0.67 g (0.005 mol) of cinnamyl alcohol. After a reflux of 24 h, the cooled mixture was filtered on an asbestos pad. Evaporation of the solvent gave a quantitative yield of cinnamaldehyde. The molar ratio of CrO_3–alcohol was 10 to 1 in this experiment. Comparable yields were observed with a 4 to 1 ratio.

A similar technique was used with other alcohols and the determination of the yield was done by preparation of the corresponding 2,4-dinitrophenylhydrazone, by v.p.c. analysis, and by titration according to the procedure of Smith and Mitchell (23). The yields as observed with these methods were in agreement within 3%.

Benzene Complexes of Ruthenium(II)

R. A. ZELONKA AND M. C. BAIRD
Department of Chemistry, Queen's University, Kingston, Ontario
Received April 19, 1972

The complexes $[\pi\text{-}C_6H_6RuX_2]_2$ (X = Cl, Br, I, SCN) have been prepared and characterized. They react with phosphorus donors to give the monomeric $\pi\text{-}C_6H_6RuX_2PR_3$, and with cyanide and hydride ions to give cyclohexadienyl and cyclohexadiene complexes.

Les complexes du type $[\pi\text{-}C_6H_6RuX_2]_2$ (X = Cl, Br, I, SCN) ont été préparés et caractérisés. Ils réagissent avec les phosphores donneurs pour conduire au $\pi\text{-}C_6H_6RuX_2PR_3$ monomère et avec les ions cyanure et hydrure pour donner les complexes cyclohexadiènyle et cyclohexadiène.

Introduction

In recent years, π-arene metal complexes have generated considerable interest because of their potential roles as homogeneous catalysts. Much of the earlier work was concerned with complexes of zerovalent metals (1), and it was found that although the hydrocarbon ligands retain their aromatic character, they are generally deactivated toward electrophilic attack and activated toward nucleophilic attack relative to the free ligands.

In 1967, Winkhaus and Singer (2) reported the preparation of the insoluble, presumably polymeric $\pi\text{-}C_6H_6RuCl_2$, as well as the apparently dimeric $[\pi\text{-}C_6H_6RuCl_2PBu_3]_2$. The benzene rings were postulated to be bidentate in both cases, an unexpected mode of bonding for ruthenium(II), although well-established for complexes of silver(I) (3).

Aside from their rather novel structures, these compounds also seemed interesting because they offered an opportunity to investigate reactions of aromatic molecules coordinated to metal ions in relatively high oxidation states. Furthermore, although the role of such complexes in the platinum metal-catalyzed H–D exchange of aromatics has been postulated (4), few stable derivatives have previously been available for careful study.

A preliminary report of this work has appeared (5).

Experimental

$[\pi\text{-}C_6H_6RuCl_2]_2$

A soluble dimeric form of this compound was prepared by adding 6 ml of 1,3-cyclohexadiene to a solution of 1.70 g (6.5×10^{-3} mol) of $RuCl_3 \cdot 3H_2O$ in 100 ml of 90% aqueous ethanol. The solution was heated to 45° for 3 h, after which the volume of the solution was reduced to 30 ml. The resulting red precipitate was collected, washed with ethanol, and dried in vacuo (yield 85%). Analytical data are shown in Table 1.

The dimeric nature of the compound was inferred from its far i.r. spectrum (see below). The previously reported (2) brown, insoluble form was rather unreactive.

$[\pi\text{-}C_6H_6Ru(C_6H_8)][Hg_3Cl_6]_{1/2}$

Solid $HgCl_2$ was added to the filtrate obtained from the preparation of $[\pi\text{-}C_6H_6RuCl_2]_2$, yielding a pale yellow precipitate. The material was recrystallized by dissolving in DMSO, adding 1:1 ethanol–ether, and cooling (yield 10%).

Although attempts to prepare this compound by treating $[\pi\text{-}C_6H_6RuCl_2]_2$ with 1,3-cyclohexadiene were unsuccessful, a similar tetraphenylborate complex was precipitated on adding $NaBPh_4$ to the filtrate from the preparation of $[\pi\text{-}C_6H_6RuCl_2]_2$. Although this material was too unstable to purify, its i.r. and n.m.r. spectra confirmed its identity as a benzene 1,3-cyclohexadiene complex, $[\pi\text{-}C_6H_6RuCl(C_6H_8)][BPh_4]$.

$[\pi\text{-}C_6H_6RuCl(CH_3CN)_2][HgCl_3]$

Solid $HgCl_2$ (1.07 g, 4.0×10^{-3} mol) was added to a solution of $[\pi\text{-}C_6H_6RuCl_2]_2$ (0.20 g, 8.0×10^{-4} mol) in 10 ml of 80% aqueous ethanol and the mixture was stirred for 30 min. The resulting yellow–orange precipitate was collected, washed with ether, dissolved in acetonitrile and reprecipitated to give the yellow–orange crystalline product (yield 80%).

$[\pi\text{-}C_6H_6RuX_2]_2$ (X = Br, I, SCN)

Solid NaBr, NaI, or NaSCN was added to saturated solutions of the chloro compound in water. The blood-red bromide, violet iodide, and yellow thiocyanate rapidly precipitated, were collected, washed with water, and dried in vacuo at room temperature for 20 h (yield 80, 95, and 75%, respectively). They were too insoluble to be recrystallized.

$\pi\text{-}C_6H_6RuCl_2L$ (L = PPh_3, PPh_2Me, $PPhMe_2$, PEt_3, PBu_3, $P(OPh)_3$, $P(OMe)_3$, $P(OEt)_3$, $AsPh_3$)

$[\pi\text{-}C_6H_6RuCl_2]_2$ (0.20 g) was added to 2–3 ml of neat ligand and the mixture was warmed to 35° for 20 min. Petroleum ether (40 ml, b.p. 40–60°) was added to pre-

cipitate the products, which were collected, recrystallized from CH_2Cl_2–hexane, and dried in vacuo at room temperature to give 70–85% yields of orange–red products.

In the cases of the solid ligands, the reaction was carried out with a three-fold excess of the ligand in benzene for up to 4 h. Similar reactions with nitrogen donors resulted only in decomposition.

$\pi\text{-}C_6H_6RuX_2PPh_3$ (X = Br, I, SCN)

A mixture of $[\pi\text{-}C_6H_6RuX_2]_2$ (4.0×10^{-4} mol) and 0.21 g PPh_3 (8.0×10^{-4} mol) in 15 ml acetonitrile was stirred at room temperature for 1 h. The solution was filtered, 30 ml of ether were added, and the mixture was cooled to give crystals of the products (yield 80–90%).

$\pi\text{-}C_6H_6RuCl_2(Ph_2PCH_2PPh_2)$

A mixture of $[\pi\text{-}C_6H_6RuCl_2]_2$ (8×10^{-4} mol) and $Ph_2PCH_2PPh_2$ (8×10^{-4} mol) in 30 ml of acetonitrile was stirred at 45° for 1 h. As the reaction proceeded, some product precipitated, and 30 ml of ether were finally added to effect further precipitation. The orange product was collected, recrystallized from acetonitrile–ether, and dried in vacuo at room temperature (yield 76%).

$[\pi\text{-}C_6H_6RuCl_2]_2[Ph_2P(CH_2)_4PPh_2]$

The complex was prepared by the same procedure as the previous derivative (yield 87%). It appears to be completely insoluble in all solvents.

Physical Measurements

Infrared spectra were obtained on Beckman IR-10 and Perkin–Elmer 180 i.r. spectrometers, optical spectra on a Unicam SP820 spectrophotometer, mass spectra on a Jeolco JMS-01SC high resolution mass spectrometer, and n.m.r. spectra on a Bruker HX60 spectrometer with internal TMS lock. Melting points were determined using a Gallenkamp melting point apparatus and are corrected. Molecular weights were determined in chloroform or acetonitrile using a Hewlett–Packard 302B vapor pressure osmometer operating at 37 °C. Conductivity measurements of solutions were carried out using a Philips PR9501 conductivity bridge. Polarograms were obtained using a dropping electrode at negative potentials, a graphite electrode at positive potentials and a saturated calomel electrode as reference with $LiNO_3$ as base electrolyte.

Results and Discussion

Substitution Reactions

As reported by Winkhaus and Singer (2), reaction between ruthenium trichloride and 1,3-cyclohexadiene yields primarily a complex of stoichiometry $\pi\text{-}C_6H_6RuCl_2$. The red material obtained from 90% aqueous ethanol is slightly soluble in the strongly coordinating solvents water, DMSO, and acetonitrile, and undergoes metathetical reactions with bromide, iodide, and thiocyanate salts to give the corresponding bromo, iodo, and thiocyanato compounds. Similar reactions with neutral ligands L can give the adducts $\pi\text{-}C_6H_6RuX_2L$, although forcing conditions cause displacement of the benzene from the metal.

The compounds $\pi\text{-}C_6H_6RuX_2L$ are clearly monomeric in chloroform, in contrast to the conclusions of Winkhaus and Singer (2). The monomeric structures are also suggested by the presence of molecular ion clusters in the mass spectra of $\pi\text{-}C_6H_6RuCl_2PEt_3$ and $\pi\text{-}C_6H_6RuCl_2P(OEt)_3$, and by the far i.r. spectra (Table 2),

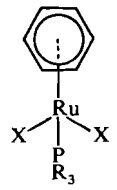
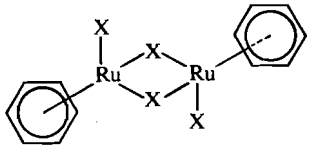
which contain two bands assignable to symmetric and asymmetric terminal ruthenium–chlorine stretching modes. On this basis, the band at 294 cm^{-1} in the spectrum of $[\pi\text{-}C_6H_6RuCl_2]_2$ may also be assigned to a terminal ruthenium–chlorine stretching mode, while the bands at 256 and 248 cm^{-1} are likely bridging chlorine modes, suggesting a dimeric structure. Similar frequencies have been reported elsewhere for terminal (7) and bridging (8) ruthenium–chlorine stretching modes.

The thiocyanate complex exhibits two CN stretching frequencies in the solid state at 2150 and 2101 cm^{-1}, the former in the region assigned to bridging thiocyanate groups (9). The infrared spectrum also shows C—S stretching modes at 822 and 714 cm^{-1} and SCN bending modes at 457 and 430 cm^{-1}, which may be attributed to the presence of both N-bonded and S-bonded thiocyanate groups, respectively (9).

Thus the two series of complexes in the solid state are probably to be formulated as octahedral complexes of ruthenium(II) (**1** and **2**).



1



2

The complex cation $[\pi\text{-}C_6H_6RuCl(CH_3CN)_2]^+$ is presumably also octahedral. The C–N stretching modes are observed at approximately 2300 cm^{-1}, as compared to 2250–2315 cm^{-1} for complexes of the type $RuCl_2(PPh_3)_2(RCN)_2$ (10).

The infrared spectrum of $[\pi\text{-}C_6H_6RuCl_2]_2$ in the region 300–4000 cm^{-1} corresponds very closely to that reported by Winkhaus and Singer (2) for the polymeric form of the compounds. Interestingly, the two ν_{CH} at 3083 and 3042 cm^{-1} and the two $\nu_{C=C}$ at 1438 and 839 cm^{-1} are rather intense bands, similar in intensities to the corresponding bands in the spectrum of benzene (11), but in contrast to the spectra of $\pi\text{-}C_6H_6M(CO)_3$ (M = Cr, Mo, W), where the corresponding bands are relatively weak (12–14).

Although dimeric in the solid state, $[\pi\text{-}C_6H_6RuCl_2]_2$ is monomeric in acetonitrile, and presumably also in DMSO and water. Although the solubilities of this compound, as well as of the bromide, iodide, and thiocyanate are very low in these solvents, the six equivalent protons of the coordinated benzene ring give a sufficiently intense line in the n.m.r. spectrum that reactions in solution can be monitored by n.m.r. Comparison of conductivity measurements (Table 2) and n.m.r. spectra (Tables 3 and 4) are very useful in determining the species present in solution.

In accord with the molecular weight measurement (Table 1), conductivity measurements indicate that $\pi\text{-}C_6H_6RuCl_2$ is a non-electrolyte in acetonitrile and DMSO (15) (Table 2). Presumably the sixth position in the octahedron is occupied by a solvent molecule; the DMSO complex has been reported (16). Addition, however, of one molar equivalent of the good Lewis acid $HgCl_2$, itself a non-electrolyte, causes an increase in conductivity to that expected for a 1:1 electrolyte (15). From the solution, the solvated complex $[\pi\text{-}C_6H_6RuCl(CH_3CN)_2][HgCl_3]$ can be isolated.

In accord with the conductivity data, the n.m.r. spectrum of $\pi\text{-}C_6H_6RuCl_2$ in CD_3CN shows the presence of only one benzene resonance. This is assigned to the complex $\pi\text{-}C_6H_6RuCl_2(CD_3CN)$. On adding $HgCl_2$, a second resonance also appears, which may be assigned to the cation, $[\pi\text{-}C_6H_6RuCl(CD_3CN)_2]^+$. There is a downfield shift of 0.31 p.p.m. on going from the neutral complex to the cationic species.

A similar situation is observed in DMSO-d_6, where the resonance at τ4.07 undoubtedly corresponds to the neutral complex, $\pi\text{-}C_6H_6RuCl_2$(DMSO-d_6). In this case the addition of $HgCl_2$ yielded two complexes with lower benzene chemical shifts, presumably the ions $[\pi\text{-}C_6H_6RuCl(DMSO\text{-}d_6)_2]^+$ and $[\pi\text{-}C_6H_6Ru(DMSO\text{-}d_6)_3]^{2+}$.

In water, the conductivity data suggest complete ionization to give $[\pi\text{-}C_6H_6Ru(H_2O)_3]^{2+}$ at mM concentrations. The addition of $HgCl_2$ did not result in increased conductivity. At the higher concentrations ($\sim 10^{-2}$ M) necessary for n.m.r. studies, however, there are two species present. Addition of $HgCl_2$ results in disappearance of the high field line, while addition of NaCl results in disappearance of the low-field line. On the basis of these data, the complexes present are probably $[\pi\text{-}C_6H_6RuCl(D_2O)_2]^+$

†In CH_3CN with $HgCl_2$ added.

(τ 4.07) and $[\pi\text{-}C_6H_6Ru(D_2O)_3]^{2+}$ (τ 3.97), although a combination of one of these cations and the neutral complex, $\pi\text{-}C_6H_6RuCl_2(D_2O)$, cannot be excluded.

The conductivity and n.m.r. data show that bromo, iodo, and thiocyanato compounds ionize to a greater extent than the chloro, the apparent relative affinity for the benzene–ruthenium(II) species being $I^- < SCN^- < Br^- < Cl^-$ in acetonitrile. The species present in CD_3CN are probably $\pi\text{-}C_6H_6RuX_2(CD_3CN)$ and $[\pi\text{-}C_6H_6RuX(CD_3CN)_2]^+$, while the species in D_2O are probably $[\pi\text{-}C_6H_6RuX(D_2O)_2]^+$ and $[\pi\text{-}C_6H_6Ru(D_2O)_3]^{2+}$.

The n.m.r. spectra of $[\pi\text{-}C_6H_6Ru(SCN)_2]_2$ in both acetonitrile and dimethylsulfoxide contain five lines; two attributable to ionized species and three attributable to neutral species. The solution infrared spectrum in CH_3CN shows a broad CN stretching mode at about 2120 cm^{-1}. As shown above, both N-bonded and S-bonded isomers exist for this system in the solid state and, if exchange is slow on the n.m.r. time scale, three isomers would be expected for the neutral species and two for the ionized in solution. The observation of five lines in the n.m.r. spectrum suggests strongly the presence of linkage isomers in solution also.

Addition of potassium cyanide and sodium hydroxide to aqueous (D_2O) solutions of $\pi\text{-}C_6H_6RuCl_2$ results in the formation of new species with resonances at τ 4.23, and τ 4.57

and 4.42, respectively. The compounds are unstable, however, as decomposition is suggested by the appearance of the resonance of free benzene.

The n.m.r. spectra of the phosphine and arsine adducts are listed in Table 4; in most cases, coupling of the benzene protons to ^{31}P was observed. The spectrum of π-$C_6H_6Ru(SCN)_2PPh_3$ contains three resonances for the benzene ring which can be attributed to the presence of S-bonded and N-bonded isomers. The spectrum of π-$C_6H_6RuCl_2PBu_3$ was independent of temperature down to -70 °C, there being no indication of the broadening which might be expected if the benzene ring were not bonded symmetrically.

Although a non-electrolyte in acetonitrile, π-$C_6H_6RuCl_2PEt_3$ does react with mercuric salts to give, presumably, the cation, $[\pi$-$C_6H_6RuCl(CH_3CN)PEt_3]^+$. The observed increase in conductivity is accompanied by a decrease in the intensity of the benzene resonance of the neutral molecule at τ 4.43 and the appearance of a new resonance at τ 4.10. Reactions with nucleophiles also yield new species. Tetraphenylarsonium cyanide reacts in CD_3CN to give a new resonance at τ 4.28, and in $CDCl_3$ to give new resonances at τ 4.30, 4.15 and 3.87. Sodium iodide and hydroxide in CD_3CN give species with resonances at τ 4.38 and 4.10, and τ 4.10, respectively. Although the identities of these new species are not known, coupling to ^{31}P is observed in all cases ($J = 0.8$ Hz), and thus substitution of the neutral ligands is not occurring. In no cases were cationic phosphine complexes isolated.

Structurally, the bis(diphenylphosphino)methane and bis(diphenylphosphino)butane adducts are of interest. The latter is highly insoluble and is formulated as $[\pi$-$C_6H_6RuCl_2]_2Ph_2P(CH_2)_4PPh_2$ with the diphos acting as a bidentate ligand. The solubility in acetonitrile can be increased by the addition of $HgCl_2$ to induce ionization of the complex, the n.m.r. of the solution indicating a ratio of 10:6 for phenyl protons relative to the π-arene protons. The phenyl protons appear as a single multiplet indicating equivalence of the phenyl groups.

In the bis(diphenylphosphino)methane complex, the phosphine acts as a monodentate ligand. The methylene resonance of the free ligand appears at τ 7.23, $J_{PH} = 1.5$ Hz (17), while the phenyl protons appear as a multiplet at τ 2.73. In the spectrum of the complex, the methylene protons appear at τ 6.58 as a double doublet, while the phenyl protons appear as three well-separated multiplets, indicating non-equivalence of the phenyl groups. The observed coupling between phosphorus and the methylene protons is 9.3 Hz (coordinated P) and 1.3 Hz (non-coordinated P). These assignments were confirmed by ^{31}P decoupling. The π-C_6H_6 doublet also collapses into a singlet on decoupling of the coordinated phosphorus while decoupling of the non-coordinated phosphorus has no effect on the π-C_6H_6 doublet.

Although π-$C_6H_6RuCl_2$ does not react with molecular nitrogen in acetonitrile, on bubbling carbon monoxide through a solution, the benzene resonance at τ 4.30 decreases in intensity and a new resonance at τ 3.98 appears. The new compound, presumably π-$C_6H_6RuCl_2CO$, is very unstable, however, and the latter line decays within minutes at room temperature to give a free benzene resonance. The i.r. spectrum of the final solutions shows a carbonyl mode at 1991 cm^{-1}, attributable to a ruthenium carbonyl complex.

The isolation of the complex π-$C_6H_6Ru(C_6H_8)(Hg_3Cl_6)_{1/2}$, obtained by adding $HgCl_2$ to the mother liquor from the preparation of $[\pi$-$C_6H_6RuCl_2]_2$, was quite unexpected. The analytical results from three determinations are consistent, and the i.r. spectrum in the region 1400–1500 cm^{-1} clearly shows the presence of both coordinated benzene and 1,3-cyclohexadiene. The mass spectrum shows lines for the ions $C_6H_6RuC_6H_8^+$ and $C_6H_6Ru^+$, as well as for $C_6H_8^+$, $C_6H_6^+$, and $HgCl_2^+$.

The complex is slightly soluble in DMSO-d_6, the solubility increasing markedly on the addition of $HgCl_2$. The fact that the n.m.r. spectrum does not change on interaction with $HgCl_2$ suggests that the species in solution is not identical with that in the solid state. However, the spectrum (Fig. 1) is nevertheless very helpful in deducing the structure. There is a singlet of relative intensity six at τ 3.53, consistent with the presence of a benzene ring coordinated to ruthenium(II), and three groups of lines with relative intensities 2:2:4, which may be attributed to the coordinated diene (3).

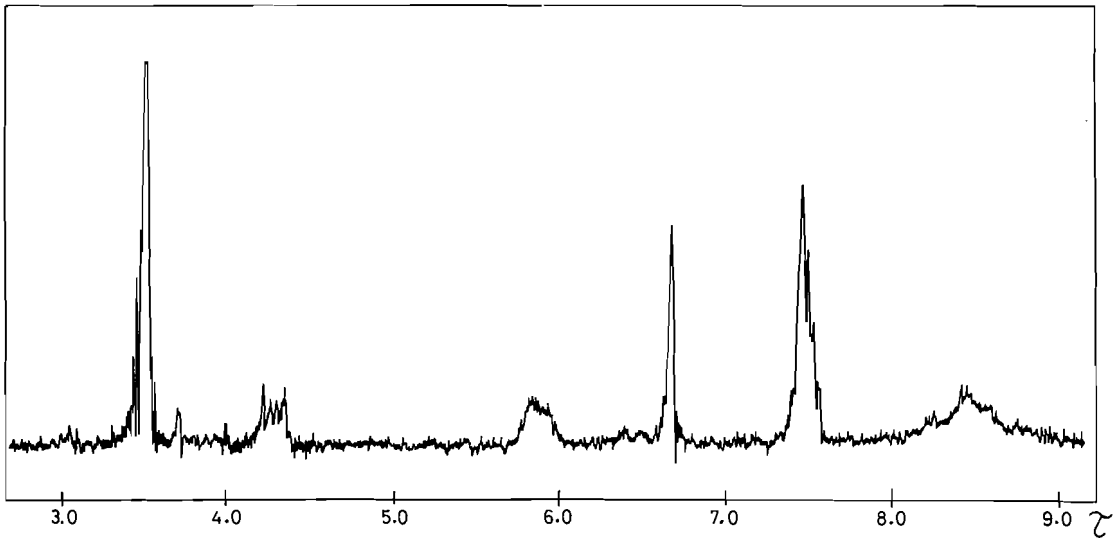

FIG. 1. N.m.r. spectrum of the π-benzenecyclohexadieneruthenium complex in DMSO-d_6.

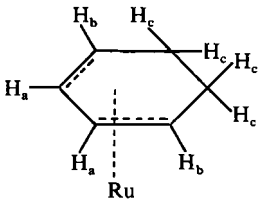
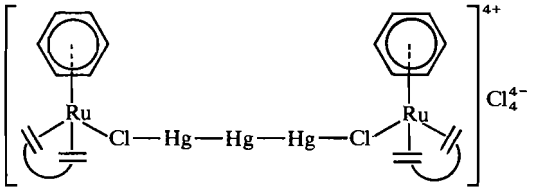


3



4

The 1:1:1:1 quartet at τ 4.32 can be assigned to H_a, the coupling constants to the two H_b, calculated on a first-order basis, being approximately 2.2 and 5.0 Hz. The unresolved multiplets centered at approximately τ 5.88 and 8.45 are assigned to H_b and H_c, respectively. The resonances at τ 6.68 and 7.47 are attributed to water and residual solvent protons, respectively. Decoupling H_b causes collapse of the resonances of H_a and H_c to singlets, while decoupling H_a causes the H_b resonance to become a broad singlet. The spectrum is very similar to that of 1,3-cyclohexadieneiron tricarbonyl (18).

The structure of the mercury-containing moiety is unknown, but may involve a linear Hg_3^{2+} group (19–21), in which the mercury would have the formal oxidation state +2/3. By analogy with other compounds containing this unusual cation (19–21), a reasonable structure for the complex would be **4**.

A similar complex can be prepared as a tetraphenylborate salt by adding $NaBPh_4$ to the mother liquor, although it is too unstable to recrystallize. The n.m.r. spectrum shows quite clearly the presence of coordinated benzene (τ 3.78) and 1,3-cyclohexadiene (τ 4.88, 7.1, 9.2), while integrations indicate the presence of one BPh_4^- ion per benzene. The far i.r. spectrum shows only one ν_{RuCl} at 249 cm^{-1} in the bridging chloride region, and thus the structure of the complex perhaps should be formulated as $[(C_6H_6)(C_6H_8)Ru^{II}—Cl—Ru^{II}(C_6H_8)(C_6H_6)]^{3+}$. On standing in solution for 30 min, the complex decomposed completely and the n.m.r. spectrum showed only free benzene and 1,3-cyclohexadiene.

Reactions of the Coordinated Benzene

It has long been known (1) that aromatic molecules bonded to zerovalent metal atoms are deactivated toward electrophilic attack, but activated toward nucleophilic attack. Kursanov *et al.* (22, 23) have shown, for instance, that acid-catalyzed H–D exchange of π-C_6H_6Cr-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

$(CO)_3$ occurs seven orders of magnitude more slowly than does exchange of benzene under the same conditions (22). In contrast, the same complex undergoes ethoxide-catalyzed H–D exchange in ethanol-d_1, conditions under which free benzene does not exchange (23).

On going to the benzene–ruthenium(II) system, it would be expected that the inductive effects of the divalent metal ion would emphasize these effects even further. Not surprisingly, therefore, π-$C_6H_6RuCl_2PMe_2Ph$ is inert to acetic anhydride at 60° in purified nitrobenzene, conditions under which free benzene is readily acetylated (24). Moreover, both π-$C_6H_6RuCl_2PEt_3$ and $[\pi$-$C_6H_6RuCl_2]_2$ are completely unaffected in solution in deuterated trifluoroacetic acid and concentrated sulfuric acid-d_2, respectively. The coordinated benzene resonances appear at τ 4.27 and 4.20, respectively, and there is no indication of either H–D exchange or sulfonation after prolonged heating at 80–100°. Free benzene in 51 mol% D_2SO_4 readily undergoes H–D exchange at room temperature, and undergoes sulfonation at higher temperatures (25).

Furthermore, there is no indication of protonation of the metal in concentrated acids as has been reported for some isoelectronic molybdenum(0) benzene complexes (26).

$[\pi$-$C_6H_6RuCl_2]_2$ does undergo H–D exchange under basic conditions. In NaOD–D_2O solution, decomposition is too rapid to give meaningful results. However, in a 4.0% solution of NaOEt in 1:1 ethanol-d_1–DMSO-d_6 ($NaOEt:Ru^{II} = 20:1$), H–D exchange of the coordinated benzene does occur at room temperature. The course of the reaction is readily followed by n.m.r. using toluene as an internal reference for integrations (free aromatics do not exchange under these conditions).

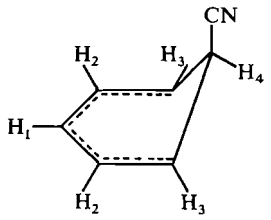
Initially, the coordinated benzene resonance at τ 4.05 broadened and shifted downfield to τ 3.77, where it became narrow again. Presumably substitution by alkoxide ion was occurring. Equilibrium was eventually reached after about 3 h, by which time 57% deuteration had occurred and 21% of the complex had decomposed, as shown by the formation of a free benzene resonance.

Kang and Maitlis (27) have recently observed base-catalyzed H–D exchange of the methyl protons of $[(CH_3)_5C_5Rh]_2(OH)_3Cl$, and suggested a mechanism involving reversible proton abstraction from the methyl groups by base. This type of mechanism is widely accepted for the base-catalyzed H–D exchange of hydrocarbons (28). Thus the activating effect of the ruthenium ion is readily understood. The strongly electron-withdrawing metal ion would increase the acidity of the benzene protons, thus increasing the rate of reaction with base.

Garnett (4) has shown that platinum(II) salts in acidic media catalyze H–D exchange of aromatics. Our results are in accord with his postulate that, although a π-benzene complex is probably an intermediate in the exchange reaction, it is not a π-benzene complex which actually undergoes exchange.

Although nucleophilic attack by strong bases in water or acetonitrile generally led to substitution and/or decomposition, reactions involving nucleophilic attack on the coordinated benzene ring were observed in DMSO-d_6. The products were, however, too unstable to isolate, and the course of the reactions could only be inferred from n.m.r.

On adding KCN to a solution of $[\pi$-C_6H_6-$RuCl_2]_2$ in DMSO-d_6, the color rapidly changed from deep red to pale yellow. In addition, the coordinated benzene resonance disappeared completely and was replaced by the series of resonances shown in Fig. 2, consistent with a cyclohexadienyl complex (**5**).



5

The resonance of H_1 appears as an unresolved multiplet at τ 4.00, while H_2 and H_3 appear as 1:2:1 triplets at τ 4.95 and 7.12, respectively, as a result of overlap of two doublets. The resonance of H_4 appears as a triplet at τ 6.17. These assignments were confirmed by decoupling experiments. Decoupling of H_1 resulted in the resonance of H_2 appearing as a 1:1 doublet, while decoupling H_2 caused collapse of the resonance of H_1 to a broad singlet and changed the resonance of H_3 to a doublet.

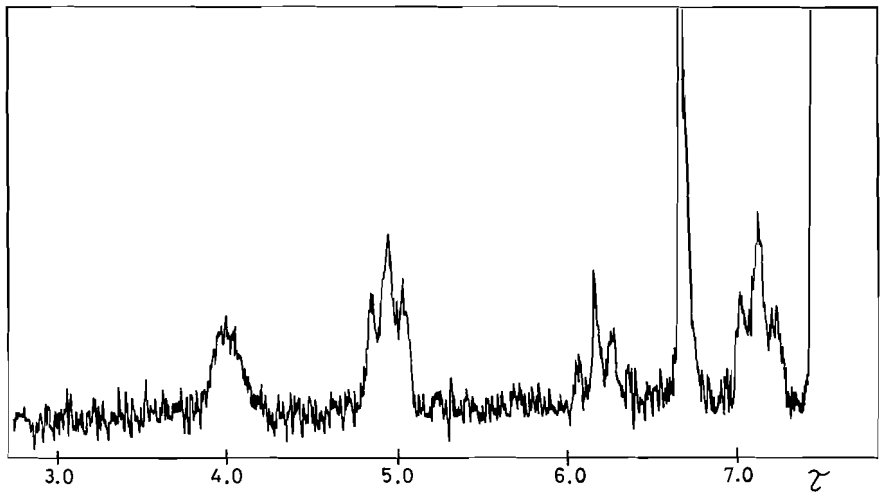


FIG. 2. N.m.r. spectrum of the cyclohexadienylruthenium complex in DMSO-d_6.

Decoupling H_3 changed the resonance of H_1 to a 1:2:1 triplet, that of H_2 to a doublet, and that of H_4 to a singlet. Decoupling H_4 changed the resonance of H_3 to a doublet. Analysis of the spectrum gave $J_{12} = 5.0$, $J_{23} = 5.7$, and $J_{34} = 6.0$ Hz. A very similar spectrum has been reported for the cyanide adduct of $[\pi\text{-}C_6H_6\text{-}Mn(CO)_3]^+$ (29).

A similar, very unstable hydroxycyclohexadienyl complex was also obtained by treating $[\pi\text{-}C_6H_6RuCl_2]_2$ in DMSO-d_6 with sodium hydroxide. The chemical shifts were: H_1, τ 4.55; H_2, τ 5.13; H_3, τ 6.83; H_4, τ 6.22.

Reaction with hydride, as $LiAlH_4$ or $NaBH_4$, in DMSO-d_6 gave yellow solutions whose n.m.r. spectra showed a transient, extremely weak cyclohexadienyl pattern. The main product, however, appeared to be a complex of 1,3-cyclohexadiene (**3**). Protons H_a appeared at τ 5.18 as a 1:1:1:1 quartet, characteristic of the AA′ part of an AA′XX′ system, while H_b and H_c appeared as multiplets at τ 7.95 and 8.52, respectively. Decoupling of H_a caused collapse of the resonance of H_b to a broadened singlet, while decoupling of H_b caused the resonance of H_a to collapse to a sharp singlet. The pattern is similar to those of $[\pi\text{-}C_6H_6Ru(C_6H_8)]^{2+}$ (see above) and $C_6H_8Fe(CO)_3$ (30). Extraction of a reaction mixture with cyclohexane after excess $NaBH_4$ had been added showed (n.m.r.) the presence of free benzene and both 1,3- and 1,4-cyclohexadiene.

There are several precedents in the literature for reactions of the types described here. For instance, the cation $[(\pi\text{-}C_6H_6)Fe^{II}(\pi\text{-}C_5H_5)]^+$ is reduced by hydride ion to the dienyl complex, $\pi\text{-}C_5H_5Fe^{II}(C_6H_7)$ (31), while the cyclohexadienyl complex, $[C_6H_7Fe^{II}(CO)_3]^+$, is reduced to the 1,3-cyclohexadiene complex, $C_6H_8Fe^0(CO)_3$ (30). Also, the cation $[(\pi\text{-}C_6H_6)_2Ru^{II}]^{2+}$ is reduced by $NaBH_4$ to a mixture of two isomers of the empirical formula $C_{12}H_{14}Ru$, benzenecyclohexa-1,3-dieneruthenium(0) and dicyclohexadienylruthenium(II) (31).

Surprisingly, $[\pi\text{-}C_6H_6RuCl_2]_2$ and $\pi\text{-}C_6H_6RuCl_2PEt_3$ appear to be inert to attack by alkyl–lithium and Grignard reagents in ethers, although attack on coordinated arenes in other systems is well-known (32–34). In the case of the dimer, the lack of reaction may be a result of the low solubility of the compound. The phosphine complex is quite soluble in tetrahydrofuran, however, and it is possible that the arene ring is deactivated toward nucleophilic attack because of the presence of the strongly donating phosphine. Substitution of the chlorides by carbanions in this low spin d^6 system must be slow for kinetic reasons, as complexes of the type $\pi\text{-}C_6H_6RuClRPPh_3$ (R = alkyl, aryl) can be prepared by other methods and are quite stable (35).

Miscellaneous

Few redox reactions of $[\pi\text{-}C_6H_6RuCl_2]_2$ have been studied. As described above, reduction with $NaBH_4$ causes destruction of the complex

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to unidentifiable products. Reduction by the complex of hydrogen peroxide in water appears to be catalytic, but the resonance of free benzene appears in the n.m.r. spectrum of a carbon disulfide extract of the reaction mixture, and thus the peroxide appears to oxidize the metal rather than the arene ring.

Polarographic studies showed that $[\pi\text{-}C_6H_6RuCl_2]_2$ undergoes reduction at $E_{1/2} = -0.80$ V *vs.* s.c.e. in aqueous solution, but no oxidation wave was observed in the range +2.0 to −2.0 V. In DMSO, however, using a carbon electrode, an oxidation wave at $E_{1/2} = +0.65$ V and a reduction wave at $E_{1/2} = -1.03$ V were observed.

The π-arene–ruthenium complexes also form charge-transfer complexes with tetracyanoethylene (TCNE), apparently of the same type as does benzene (36). In acetonitrile, charge-transfer bands appear at 355, 401, and 409 mμ for benzene, $\pi\text{-}C_6H_6RuCl_2PEt_3$, and $[\pi\text{-}C_6H_6RuCl_2]_2$, respectively, on interacting with TCNE. Using standard procedures (37), equilibrium constants of 1.1 ± 0.2, 4.4 ± 0.5, and 10 ± 2 l mol^{-1} were calculated for the interactions of TCNE with benzene, $\pi\text{-}C_6H_6RuCl_2PEt_3$, and $[\pi\text{-}C_6H_6RuCl_2]_2$, respectively.

Assuming that TCNE is behaving as Lewis acid, coordination of benzene to ruthenium(II) should decrease its ability to take part in a charge-transfer interaction. We have no explanation for the observed trend, although the errors in the cases of the two complexes may be rather large because of partial overlap of the charge-transfer bands with bands in the spectra of the complexes.

We thank the National Research Council of Canada for financial assistance and the International Nickel Company of Canada for a scholarship to R.A.Z. We also thank Mr. Clint Smith for assistance with the electrochemistry.

Solvent Structure Effects and Diffusion Control in the Reaction Between Solvated Electrons and Solvated Protons in Alcohols and Water[1]

K. N. JHA, G. L. BOLTON, AND G. R. FREEMAN
Chemistry Department, University of Alberta, Edmonton 7, Alberta

Received April 4, 1972

The rates of reactions 1 and 2 are diffusion controlled in alcohols

[1] $e^-_{solv} + H^+_{solv} \rightarrow$ neutralization

[2] $RO^-_{solv} + H^+_{solv} \rightarrow ROH$

In water reaction 1 is slower and reaction 2 (where RO^- is HO^-) is faster than one would estimate from the Debye equation for diffusion controlled reactions. The solvent dependence of the relative values of k_1 and k_2 is attributed to the solvent dependence of the structures of H^+_{solv}, RO^-_{solv}, and e^-_{solv}; H^+ and RO^- are strong solvent structure makers in alcohols and in water, whereas e^- is a weak solvent structure maker in alcohols and a strong structure breaker in water. Effects of the solvent structure making and breaking properties of ions on their reaction rates have been proposed by Gurney and Frank.

Les vitesses des réactions 1 et 2 dans les alcools sont contrôlées par la diffusion

[1] $e^-_{solv} + H^+_{solv} \rightarrow$ neutralization

[2] $RO^-_{solv} + H^+_{solv} \rightarrow ROH$

Dans l'eau reaction 1 est moins rapide et réaction 2 (où RO^- est HO^-) est plus rapide que la vitesse estimée à partir de l'équation de Debye pour les réactions contrôlées par la diffusion. L'effet du solvant sur les valeurs relatives de k_1 et k_2 est attribué à la configuration de solvatation des ions H^+_{solv}, RO^-_{solv}, et e^-_{solv}: H^+ et RO^- augmentent la structure locale du solvant dans le voisinage des ions; e^- pourrait augmenter un peu la structure dans un alcool, mais il la detruit dans l'eau. Gurney et Frank ont proposé un effet des ions sur la structure du solvant qui augmenterait ou diminuerait la vitesse "normale" d'une réaction.

Canadian Journal of Chemistry, **50**, 3073 (1972)

The values of the rate constant of reaction 1

[1] $e^-_{solv} + H^+_{solv} \rightarrow$ neutralization

in water and alcohols were measured by kinetic spectroscopy several years ago (1) and found to be only about half as large as diffusion controlled values would be (2). The result was interpreted as a reluctance of the solvated proton to accept an electron (3). However, the rate constants have recently been measured in alcohols by an electrical conductance technique (4–6) and found to equal the diffusion controlled values (Table 1). This important result warrants checking by kinetic spectroscopy. Knowledge of the correct values of k_1 is important to the development of the theory of radiolysis kinetics because both e^-_{solv} and H^+_{solv} are intermediate products in the radiolysis systems. We have therefore measured the effect of acid concentration on the decay rate of the optical absorption of solvated electrons in ethanol, methanol and water in an attempt to resolve the conflicting information.

Absolute reagent quality U.S.P. ethyl alcohol was used as received from the U.S. Industrial Chemical Co. It is the highest purity ethanol that has been obtained by any method in this laboratory (7). Absolute methanol, analyzed reagent spectrophotometric grade from Baker Chemical Co. was refluxed for 12 h after addition of 2 g of 2,4-dinitrophenylhydrazine and 0.5 g of concentrated sulfuric acid to 1 l of the alcohol. The refluxing system was flushed with ultrahigh purity argon (Matheson) before and during the treatment. The alcohol was then

*Calculated from data in refs. 5 and 6.
†Average of results from six series with separate preparations of solvent and solutions.
‡Two series with separate preparations of solvent and solutions gave the same results.

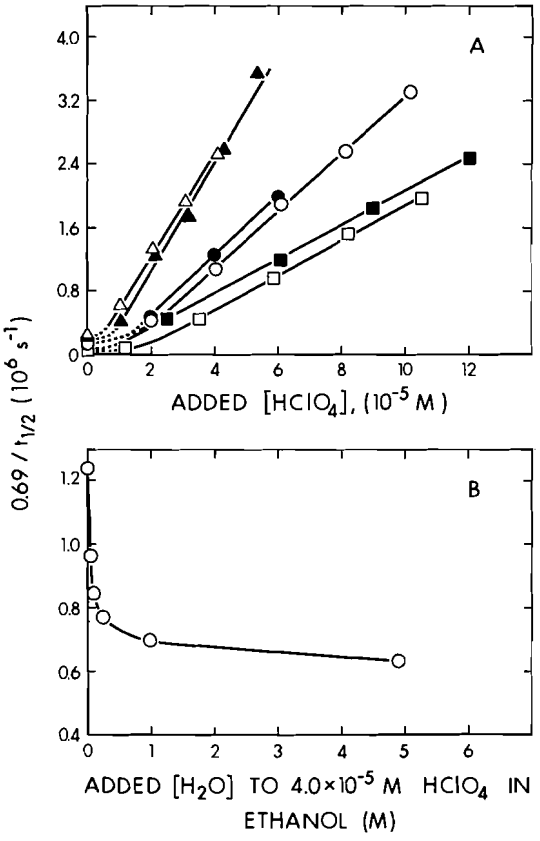

FIG. 1. (*A*) $0.69/t_{1/2}$ at 293 K as a function of $HClO_4$ concentration added to: ○, ● ethanol; △, ▲ methanol; □, ■ water. Open and closed points distinguish results from separate series of experiments. (*B*) $0.69/t_{1/2}$ as a function of water concentration added to a solution of 4.0×10^{-5} *M* $HClO_4$ in ethanol at 293 K.

distilled and the center 50% collected. Water was distilled from a Barnsted still, then from alkaline permanganate, then from a Pyrex still and collected in a quartz reservoir.

Stock solutions of perchloric acid (Baker and Adamson Analytical Reagent, mole ratio $HClO_4/H_2O = 1/2$) were prepared by weighing. The final solutions were de-oxygenated in the Spectrasil optical cells by bubbling for 20 min with the ultrapure argon.

The radiation pulses were 100 ns of 1.7 MeV electrons, giving a dose of 3×10^{16} eV/cm^3. The response time of the optical measuring system was 35 ns.

Typical results are shown in Fig. 1 (*A*). In all cases the plots of $0.69/t_{1/2}$ against added acid concentration were linear, but they extrapolated to intercepts on the "wrong" axis. Some acid was evidently removed from the solution by adsorption on the cell walls. The values of k_1 obtained from the linear slopes are listed in Table 1. The results from the optical and the conductance techniques now agree with each other, within experimental error.

The early values reported for the alcohols (1) are low by a factor of two. The error might have been caused by assuming that a plot such as those in Fig. 1 (*A*) would be linear and have an intercept at $0.69/(t_{1/2}$ pure alcohol). It should also be mentioned that the presence of water in the alcohol reduces the value of the rate constant (Fig. 1 (*B*)), due to a decrease in the diffusion coefficient of the protons (5, 8, 9).

Reaction 1 is diffusion controlled in both

For personal use only.

alcohols, but not in water (Table 1). The reason for this difference is related to the difference in the structures of e^-_{solv} and H^+_{solv} in the different solvents, which are in turn related to the structures of the liquids. There is no reluctance of $H^+(ROH)_n$ to accept an electron from $e^-(ROH)_m$, although there seems to be for $H^+(H_2O)_n$ to accept one from $e^-(H_2O)_m$.

The fact that reaction 2 is diffusion controlled

[2] $$H^+_{solv} + RO^-_{solv}(OH^-_{solv}) \rightarrow ROH_{solv}(H_2O_{solv})$$

in alcohols (5) but is apparently *faster* in water ($k_2 = 11.2 \times 10^{10}\ M^{-1}\ s^{-1}$ (5)) than one would calculate from the bulk diffusion coefficients of H^+_{aq} and OH^-_{aq} ($7.9 \times 10^{10}\ M^{-1}\ s^{-1}$ (5)) is probably also related to the structure of the solvents in the vicinity of the ions. The relative rates of reactions 1 and 2 in water and in alcohols are consistent with the suggestion (10) that e^-_{solv} is a solvent structure breaker in water and a weak structure maker in alcohols; H^+, OH^-, and RO^- are strong structure makers in water and alcohols (ref. 11, pp. 168, 176, 183). A structure-making ion such as H^+_{aq} has difficulty approaching one that breaks structure, such as e^-_{aq}, so there is a sort of repulsion between the two species in solution (ref. 11, chap. 16, 12). This offers at least a partial explanation of why k_1 in water is smaller than would be expected from the Debye equation (2). Conversely, two strong structure makers approach each other more rapidly than "normal" at close distances. This, combined with the structure dependent proton jumping mechanism of migration of both H^+ and OH^- in water, may explain why k_2 in water is greater than would be expected from the Debye equation.

A New Synthesis of 6-Hydroxydopamine

Pius A. Wehrli,[1] F. Pigott, and V. Chu

Chemical Research Department, Hoffmann-La Roche Inc., Nutley, N.J. 07110

Received March 23, 1972

An efficient synthesis of 6-hydroxydopamine is described. The key step involves oxidation of an *N*-protected 3-hydroxy-4-methoxyphenethylamine to the corresponding *p*-quinone by means of Fremy's salt.

On décrit une synthèse efficiente de 6-hydroxydopamine. Le pas décisif entraîne l'oxydation au moyen de sel de Fremy d'un *N*-protégé 3-hydroxy-4-méthoxyphènéthylamine au *p*-quinone correspondant.

Canadian Journal of Chemistry, **50**, 3075 (1972)

Introduction

In 1967 Tranzer and Theonen (1) recognized in 6-hydroxydopamine (7) the capacity for selectively destroying adrenergic nerve terminals. The compound was previously described and synthesized by Harley-Mason (2) and Lee and Dickson (3), starting from 2,4,5-trimethoxy- and 2,4,5-tribenzyloxybenzaldehyde respectively. Senoh and Witkop's multistep synthesis (4) involves the addition of methanol to a suitable *o*-quinone intermediate. Because of the generally low yields and the relatively involved pro-

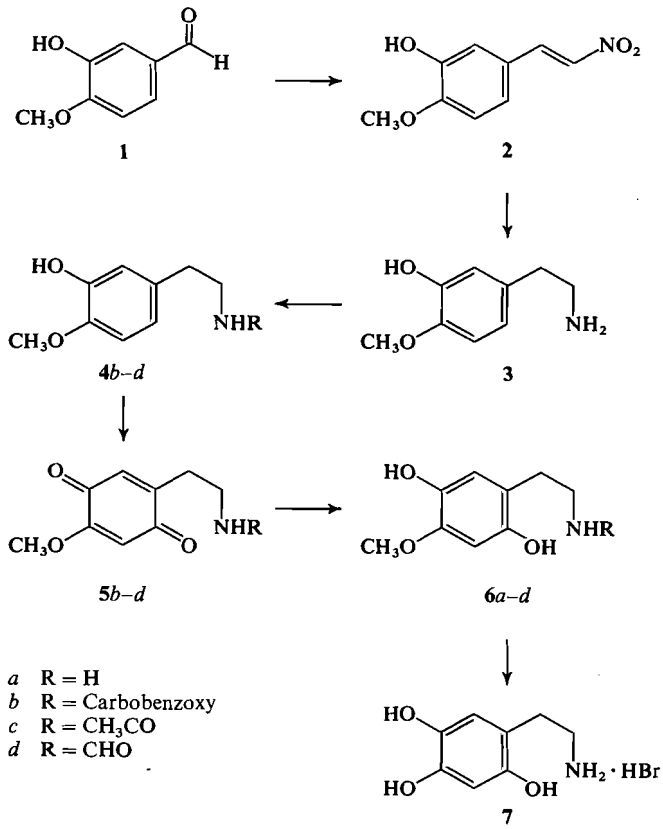

SCHEME 1

cedures, we now wish to report an efficient alternate scheme for the synthesis of this pharmacologically fascinating compound (see Scheme 1).

Starting from isovanillin (**1**), the corresponding phenethylamine **3** was prepared via the known nitrostyrene **2** (5) in about 60% overall yield. The projected central step in our scheme was a Fremy's salt oxidation (6) of 3-hydroxy-4-methoxyphenethylamine (**3**) to the corresponding *p*-quinone **5***a*, but a number of attempts to oxidize **3** failed to give identifiable products. It was only after the amino function was protected by carbobenzoxylation, acetylation, or formylation that the Teuber reaction (7) could be effected successfully. Almost quantitative yields of the corresponding *p*-quinones were obtained with the *N*-carbobenzoxy derivative **4***b* and the *N*-acetyl derivative **4***c*. Why a lower yield was obtained with the *N*-formyl substrate **4***c* is uncertain, but it may have been due to appreciable hydrolysis of the protecting group. Catalytic reduction to the corresponding hydroquinone derivatives **6***a–d* proceeded as expected. Cleavage of the aromatic methoxyl group was effected in good yield with refluxing 48% HBr, 6-hydroxydopamine hydrobromide (**7**) being obtained as pure white crystals. The hydrobromide **7** was obtained directly from the *N*-acetyl derivative **6***c*. Based on isovanillin, **7** was obtained in an overall yield of 40% in our best experiments via the sequence **1** → **2** → **3** → **4***b* → **5***b* → **6***a*·HOAc → **7**.

Experimental

Melting points are uncorrected and were taken in capillary tubes with a Thomas-Hoover apparatus. Infrared spectra were recorded on a Perkin-Elmer 21 spectrophotometer. The symbols s, m, and w refer to strong, medium, and weak bands respectively. All u.v. spectra were recorded on a Carey Model 14 spectrophotometer and the n.m.r. spectra were measured with a Varian A-60 apparatus. Unless otherwise indicated, all t.l.c. was done on silica gel plates.

3-Hydroxy-4-methoxy-β-nitrostyrene (2)[2]

A methanolic buffer solution of methyl ammonium acetate was prepared by adding 2.6 g (0.0245 mol) of anhydrous sodium carbonate to a solution of 1.65 g (0.0245 mol) of methylamine hydrochloride in 25 ml of methanol. After stirring for 30 min, the suspension was filtered directly into a solution of 2.2 g (0.0365 mol) of acetic acid in 25 ml of methanol. The p*H* of this buffer solution must be *5.8–6.0*[3] (measured with a glass electrode). Meanwhile 50 g (0.33 mol) of isovanillin was dissolved in 200 ml of warm methanol and then cooled to room temperature.[4] Nitromethane (20 g, 0.33 mol) was added and mixed well and the reaction flask (1 l Erlenmeyer flask) was then wrapped with aluminum foil. The previously prepared methylamine buffer solution was added dropwise with mechanical stirring to the isovanillin–nitromethane mixture over a period of 30 min. The reaction mixture was allowed to stand in the *dark* for 88 h. The resulting yellow crystals were filtered, washed with 25 ml of cold methanol and air dried to give 49 g (76%) of **2**, m.p. 154–155°; λ_{max} (CH_3OH) 243 (sh, ε 6430), 260 (ε 8360), 320 (infl, ε 6400), 367–368 mμ (ε 16 200); δ(DMSO) 3.9 (s, 3H), 6.85–7.3 (m, 3H), 7.8 (s, 2H), 9.9 (s, 1H); R_f 0.55 (EtOAc:C_6H_6, 1:1, u.v. light; R_f 0.45 for isovanillin).

Anal. Calcd. for $C_9H_9NO_4$: C, 55.38; H, 4.65; N, 7.18. Found: C, 55.68; H, 4.58; N, 7.18.

3-Hydroxy-4-methoxyphenethylamine (3)

The nitrostyrene **2** (260 g, 1.33 mol) was suspended in a mixture of 1 l of water and 260 ml of concentrated hydrochloric acid. The volume was adjusted to 3.5 l with water, 50 g of 10% Pd–C catalyst was added, and the heterogeneous mixture was hydrogenated in a glass-lined, rocking autoclave at 80°, initial pressure 800 p.s.i., for 6 h. Most of the hydrogen was absorbed in the first hour. After cooling for 16 h, the catalyst was filtered and the colorless filtrate was evaporated with a rotary evaporator. The solid residue was scraped loose and 360 ml of concentrated ammonium hydroxide was added with ice-cooling. The white salt dissolved gradually and the amine precipitated simultaneously. The crystalline solid was then slurried mechanically for 1 h, filtered, washed with ice-water, and dried *in vacuo* at room temperature. The yield of crude **3** was 173 g (78%), m.p. 144–148° (5). This material was used for further transformation.

N-(3-Hydroxy-4-methoxyphenethyl)carbamic Acid Benzyl Ester (4b)

To a 500-ml resin jar equipped with a stirrer, nitrogen inlet tube, p*H* electrode, two dropping funnels, and an ice bath were added 200 ml of distilled water and 11.03 g (0.066 mol) of amine **3**. The p*H* of this suspension was 9.2. Benzyl chloroformate (9.15 ml) and 1 *N* sodium hydroxide were added simultaneously over 20 min, the p*H* reaching a maximum of 11.3. After stirring for 1 h, the p*H* was 9.6, the solid was filtered, washed well with water, and air-dried; yield 16.64 g (84%), m.p. 113°. Purification was effected by slurrying the crystals with 100 ml of a 1:1 hexane–ether mixture followed by the addition of 200 ml of hexane prior to filtration. The product was washed with hexane and dried *in vacuo*; yield, 13.5 g (68%), m.p. 114.5°; δ($CDCl_3$) 2.70 (t, $J = 6$ Hz, 2H), 3.42 (q, $J = 6$ Hz, 2H), 3.83 (s, 3H), *ca.* 4.8 (broad, 1H), 5.1 (s, 2H), 5.72 (s, 1H), 6.7–6.9 (m, 3H), 7.35 (s, 5H); *m/e* 301 (M^+), 166, 150, 137, 91 (P); R_f 0.7 (EtOAc:$CHCl_3$, 1:1, u.v. light).

Anal. Calcd. for $C_{17}H_{19}NO_4$: C, 67.76; H, 6.36; N, 4.65. Found: C, 67.94; H, 6.37; N, 4.60.

N-(3-Hydroxy-4-methoxyphenethyl)acetamide (4c)

Amine **3** (25.05 g, 0.15 mol) was heated in 15.3 g (0.15 mol) of acetic anhydride for 2 h under nitrogen with stirring at 145° in an oil bath. The reaction mixture was cooled to room temperature and the acetic acid was removed with a rotary evaporator at 50°. To the brown oily residue was added 10 ml of ethyl acetate and, on seeding, the solution turned into an almost solid mass of crystals. It was then crushed, filtered, and washed with three 10 ml-portions of ethyl acetate to give, after drying *in vacuo*, 25 g (80%) of white crystals, m.p. 123°. This material was characterized without further purification; λ_{max} ($CHCl_3$) 3550 (m), 3450 (m), 1670 (s), 1515 (s), 1275 (s) cm^{-1}; δ (DMSO) 1.54 (s, 3H), 2.5 (m, 2H + DMSO), 3.25 (m, 2H), 3.75 (s, 3H), 6.0 (m, 3H), 7.8 (broad, 1H), 8.7 (s, 1H); R_f 0.75 (EtOAC:MeOH, 2:1).

Anal. Calcd. for $C_{11}H_{15}NO_3$: C, 63.14; H, 7.03; N, 6.69. Found: C, 63.22; H, 7.21; N, 6.60.

N-(3-Hydroxy-4-methoxyphenethyl)formamide (4d)

Amine **3** (50 g, 0.3 mol) was refluxed for 21 h with stirring in 250 ml of methyl formate. The reaction mixture was turbid for the duration of the reaction. Before filtering and washing the crystals with some methyl formate, the batch was cooled to 0° and stirred at this temperature for 2 h. After drying *in vacuo* at room temperature the white crystals weighed 44.5 g (76%), m.p. 111–113°. The product was characterized without purification: δ (DMSO) 2.65 (t, $J = 7$ Hz, 2H), 3.3 (q, $J = 7$ Hz, 2H), 3.8 (s, 3H), 6.5–6.9 (m, 3H), *ca.* 7.9 (broad, 1H), 8.1 (s, broad, 1H), 8.5 (s, broad, 1H); R_f 0.1 (EtOAc:$CHCl_3$, 1:1).

Anal. Calcd. for $C_{10}H_{13}NO_3$: C, 61.52; H, 6.71; N, 7.18. Found: C, 61.35; H, 6.78; N, 7.01.

N-[2-(4-Methoxy-3,6-dioxo-1,4-cyclohexadien-1-yl)-ethyl] carbamic Acid Benzyl Ester (5b)

In a 1 l round-bottomed flask, equipped with a mechanical stirrer, dropping funnel, and ice water bath were placed 500 ml of 0.028 *M* aqueous sodium dihydrogen phosphate and 135 g (0.5 mol) of Fremy's salt (8). While stirring vigorously in an ice bath, 37 g (0.123 mol) of **4**, dissolved in 350 ml of acetone, was added within *ca.* 5 min and the suspension was stirred for 68 h. This was over a weekend and may not be necessary; the course of the reaction may be conveniently followed by t.l.c. The heterogeneous mixture was diluted to 6 l with water and extracted with a total of 2.5 l of ethyl acetate. The organic phases were combined and washed once with 250 ml of saturated sodium bi-

[2]The procedure of Ramirez and Burger (5) gave erratic results.

[3]Use of buffers with p*H* > 6.5 promoted the formation of an undesired substance (no movement on t.l.c., ethyl acetate–benzene (1:1), short u.v.) whereas buffers with p*H* < 5.6 tended to keep the reaction from going to completion.

[4]Some isovanillin may crystallize. This can be minimized by adding the other reagents as soon as room temperature is reached. Poorer results are obtained if the reaction is carried out at higher temperatures.

For personal use only.

carbonate solution followed by two 250 ml-portions of water. The yellow solution was dried over sodium sulfate, filtered, and concentrated to *ca.* 250 ml. After cooling with ice, the crystals were filtered and washed with 25 ml of cold ethyl acetate. The mother liquor was evaporated to 25 ml, chilled, filtered, and washed with cold ethyl acetate. The product was obtained in two crops: 32.6 g (m.p. 130°) and 3.2 g (m.p. 125°); total yield, 35.8 g (92%).

A sample of the first crop was analyzed without further purification; λ_{max} (isopropanol) 259 (ε 8700), 360–362 mμ (ε 450); λ_{max} ($CHCl_3$) 3450 (m), 1720 (s), 1680 (s), 1655 (s), 1610 (s) cm^{-1}; δ ($CDCl_3$) 2.65 (t, $J = 7$ Hz, 2H), 3.43 (q, $J =$ 7Hz, 2H), 3.75 (s, 3H), 5.1 (s, 2H), *ca.* 5.4 (broad, 1H), 5.9 (s, 1H), 6.55 (broadened singlet, 1H), 7.3 (s, 5H); *m/e* 317 ($M^+ + 2H$), 315 (M^+), 313 ($M^+ - 2H$), 91 (P); R_f 0.4 ($CHCl_3$:EtOAc, 9:1, u.v. light).

Anal. Calcd. for $C_{17}H_{17}NO_5$: C, 64.75; H, 5.43; N, 4.44. Found: C, 64.88; H, 5.40; N, 4.43.

2-(2-Acetamidoethyl)-5-methoxy-p-benzoquinone (5c)

In a 250-ml one neck round-bottomed flask, equipped with stirrer and ice bath were placed 12.54 g (0.06 mol) of **4***c*, 160 ml of 0.056 *M* aqueous NaH_2PO_4 buffer, and 40 g (0.149 mol) of Fremy's salt. The heterogeneous reaction mixture was stirred well in an ice bath for 3.5 h (completeness of the reaction is monitored by t.l.c.: EtOAc, u.v. light, followed by phosphomolybdic acid spray). It was worked-up by extracting with a total of 2.1 l of ethyl acetate (this large amount of solvent is necessary, because the quinoid material is somewhat water soluble). The combined yellow extracts were then dried over $MgSO_4$ and evaporated *in vacuo* at 40° to give 13.4 g (100%) of bright yellow crystals. T.l.c. of this material showed only trace impurities.

For characterization purposes a similarly prepared sample was recrystallized from acetone, m.p. 140–142°; λ_{max} ($CHCl_3$) 3450 (m), 1680 (s), 1660 (s), 1610 (s), 1180 (s) cm^{-1}; λ_{max} (MeOH) 261 (ε 13 600), 360 (ε 620) mμ; δ ($CDCl_3$) 1.93 (s, 3H), 2.68 (t, $J = 7$ Hz, 2H, signals slightly split $J \sim 1$ Hz), 3.46 (q, $J = 7$ Hz, 2H), 3.82 (s, 3H), 5.95 (s, 1H), *ca.* 6.2 (broad, 1H), 6.6 (t, $J = \sim 1$ Hz, 1H); *m/e* 225 ($M^+ + 2H$), 223 (M^+), 221 ($M^+ - 2H$), 43 (P); R_f 0.07 (EtOAc, u.v. light).

Anal. Calcd. for $C_{11}H_{13}NO_4$: C, 59.18, H, 5.87; N, 6.28. Found: C, 59.00; H, 5.71; N, 6.53.

N-[2-(4-Methoxy-3,6-dioxo-1,4-cyclohexadien-1-yl)-ethyl] formamide (5d)

Formamide **4***d* (4.88 g, 0.025 mol) was stirred vigorously for 4 h at 0° in a slurry of 20 g (*ca.* 0.075 mol) of wet, water-washed Fremy's salt in 55 ml of 1 *M* NaH_2PO_4 solution. The lemon yellow reaction mixture was filtered (very slow filtration), washed with a total of 120 ml of ice water, and dried overnight *in vacuo* to give 13 g of crude product. The organic material was dissolved by refluxing in 250 ml of ethyl acetate. The hot solution was filtered over a bed of Celite and washed with 50 ml of hot ethyl acetate. The clear filtrate was refrigerated overnight, the crystals were filtered and washed with a small amount of cold ethyl acetate to give after drying *in vacuo* at room temperature, 2.85 g (54%) **5***d*, m.p. 135–138°; λ_{max} ($CHCl_3$) 3450 (m), 1690 (s), 1655 (s), 1603 (s), 1175 (s) cm^{-1}; λ_{max} (EtOH) 260–261 (ε 14 420), 360–370 (ε 780) mμ; δ ($CDCl_3$ + DMSO) 2.6 (t, signals slightly split, $J = 7$ Hz, 2H), 3.4 (q, $J = 7$ Hz, 2H), 3.82 (s, 3H), 6.0 (s, 1H), 6.65 (s, slightly split, $J \sim 0.5$ Hz, 1H), 7.75 (broad, 1H), 8.05 (d, $J \sim 1$ Hz, 1H).

Anal. Calcd. for $C_{10}H_{11}NO_4$: C, 57.41; H, 5.30; N, 6.70. Found: C, 57.16; H, 5.31; N, 6.66.

2,5-Dihydroxy-4-methoxyphenethylamine acetate (6a·HOAc)

The yellow quinone **5***b* (10 g, 0.0318 mol) was dissolved in 200 ml of methanol. Acetic acid (2.5 ml, 0.0438 mol) and 1.5 g of 10% Pd–C was added and the mixture was hydrogenated for 3 h at room temperature, initial pressure 300 p.s.i., in a glass lined rocking autoclave. After filtering the catalyst, the faintly reddish solution was evaporated with a rotary evaporator at 50° to give a light brown oily residue which was dissolved in 30 ml of isopropanol. The product crystallized on cooling for 2 h at 0°. After filtering, washing with cold isopropanol followed by ether, and drying *in vacuo* there was obtained 5.2 g (68%) of off-white crystals, m.p. 183–185°. An analytically pure sample was prepared by recrystallization from methanol; λ_{max} (Nujol) 3350 (m), 1640 (m), 1530 (m), 1270 (s), 1220 (s), 1195 (s), 1170 (s), 1155 (s), 870 cm^{-1} (s, doublet); λ_{max} (EtOH) 220 (infl. ε 5980), 294–295 (ε 5640) mμ; δ (DMSO) 1.8 (s, 3H), 2.8 (m, 4H), 3.7 (s, 3H), 6.47 (s, 1H), 6.50 (s, 1H), 8.15 (s, 5H); *m/e* 183 (M^+ for free base), 166, 154, 60 (HOAc), 30 (P).

Anal. Calcd. for $C_9H_{13}NO_3 \cdot C_2H_4O_2$: C, 54.31; H, 7.04; N, 5.76. Found: C, 54.40; H, 6.92; N, 5.78.

N-(2,5-Dihydro-4-methoxyphenethyl)carbamic Acid Benzyl Ester (6b)

The hydroquinone **6***b* was obtained from an uncontrolled reaction. Catalyst (10% Pd–C) was added to a methanolic solution of the quinone starting material under nitrogen. An exothermic reaction resulted which brought the mixture almost to the reflux temperature. After cooling to room temperature, the catalyst was filtered, and on standing for several hours, small needles crystallized from the filtrate. This product was collected, washed with methanol, dried *in vacuo*, and analyzed without further purification; m.p. 135.5–138°; δ (DMSO) 2.64 (t, broad, 2H), 3.25 (t, broad, 2H), 3.7 (s, 3H), 5.05 (s, 2H), 6.5 (s, 1H), 6.6 (s, 1H), 7.1 (broad, 1H), 7.33 (s, 5H), 8.0 (s, 1H), 8.57 (s, 1H); *m/e* 317 (M^+), 153, 91 (P); R_f 0.15 (EtOAc:$CHCl_3$, 1:9, phosphomolybdic acid spray).

Anal. Calcd. for $C_{17}H_{19}NO_5$: C, 64.34; H, 6.03; N, 4.41. Found: C, 64.32; H, 5.91; N, 4.30.

N-(2,5-Dihydroxy-4-methoxyphenethyl)acetamide (6c)

Quinone **5***c* (6.19 g, 0.0278 mol) was dissolved in 50 ml of methanol and hydrogenated over 120 mg of 10% Pd–C in a Brown hydrogenator.[5] After filtration, evaporation of the filtrate gave 6.3 g (100%) of tan solid; 2.5 g was recrystallized from 250 ml of ethyl acetate to give 1.92 g of the hydroquinone **6***c*, m.p. 158–159°; δ (D_2O) 2.2 (s, 3H), 2.95 (t, broad, 2H), 3.65 (t, broad, 2H), 4.1 (s, 3H), 6.86 (s, 1H), 7.0 (s, 1H); *m/e* 225 (M^+), 166 (P), 153 ($M - CH_2NHAc$); R_f 0.05 (polyamide, $CHCl_3$, phosphomolybdic acid spray).

Anal. Calcd. for $C_{11}H_{15}NO_4$: C, 58.65; H, 6.71; N, 6.22. Found: C, 58.91; H, 6.71; N, 6.09.

[5]Delmar Scientific Laboratories, 317 Madison Street, Maywood, Ill.

N-(2,5-Dihydroxy-4-methoxyphenethyl)formamide (6d)

Quinone **5d** (1.0 g) was dissolved in 30 ml of methanol and hydrogenated in a Brown hydrogenator with 100 mg of 10% Pd–C catalyst. Hydrogen uptake ceased after 10 min. The mixture was stirred 20 min longer and then it was filtered over a bed of filter aid. Evaporation and recrystallization of the solid residue from 3 ml of methanol and 10 ml of ethyl acetate yielded 600 mg of tan-colored, *i.e.* air sensitive crystals, m.p. 129–131°. This material was analyzed without further purification: λ_{max} (EtOH) 220 (ε 6700), 293 (ε 4990) mμ; δ (DMSO) 2.55 (t, $J = 8$ Hz, 2H), 3.25 (q, $J = 8$ Hz, 2H), 3.7 (s, 3H), 6.42 (s, 1H), 3.48 (s, 1H), *ca.* 7.9 (broad, 1H), 8.0 (s, 2H), 8.53 (s, 1H); *m/e* 211 (M^+), 166, 153.

Anal. Calcd. for $C_{10}H_{13}NO_4$: C, 56.86; H, 6.20; N, 6.63. Found: C, 56.67; H, 6.27; N, 6.50.

6-Hydroxydopamine Hydrobromide (7)

(a) From 2,5-Dihydroxy-4-methoxyphenethylamine Acetate (6a·HOAc)

Compound **6a** (11.5 g, 0.0473 mol) was refluxed for 5 h in 62.5 ml of 48% hydrobromic acid under nitrogen. The light brown reaction mixture was seeded, cooled to 0°, filtered, washed with three 20 ml-portions of isopropanol followed by three 20 ml-portions of hexane. After drying *in vacuo* the white, crystalline 6-hydroxydopamine hydrobromide (**7**) weighed 11.31 g (95%), m.p. 211–212°.[6]

(b) From N-(2,5-Dihydroxy-4-methoxyphenethyl) acetamide (6c)

In a 100 ml flask, equipped with a stirrer and a nitrogen inlet, was placed 5.04 g (0.0224 mol) of **6c** and 10 ml of 48% hydrobromic acid. After refluxing for 4 h under nitrogen, the brown reaction mixture was evaporated with a rotary evaporator. The brown crystals were slurried with isopropanol, filtered, and washed with the same solvent to give 2.16 g (31%) of tan-colored **7** which was identical (i.r. and t.l.c.) with the material obtained in section *a*.

[6]The reported melting points for 6-hydroxydopamine hydrobromide are 218–219° (see lit. ref. (2)) and 216–218° (see lit. ref. (4)).

We are indebted to the staff of our Physical Chemistry Department directed by Dr. R. P. W. Scott. In particular thanks are due to Dr. H. Wyss for i.r., Dr. V. Toome for u.v., Dr. T. Williams for n.m.r., and Dr. W. Benz for mass spectra. Dr. F. Scheidl carried out the microanalyses and Mr. D. Wagner, of our hydrogenation laboratory, was most helpful in carrying out the high pressure reductions. Dr. A. I. Rachlin's help in preparing the manuscript is greatly appreciated.

Five-membered Heterocyclic Thiones. Part I. 1,3,4-Oxadiazole-2-thione

D. E. Horning and J. M. Muchowski[1]

Bristol Laboratories of Canada, Candiac, Quebec

Received April 17, 1972

1,3,4-Oxadiazole-2-thione was prepared by decarboxylation of the corresponding 5-carboxylic acid. Spectral data supported the predominant, if not exclusive, existence of the thione form in solution.

L'oxadiazole-1,3,4 thione-2 a été préparée par décarboxylation de l'acide carboxylique-5 correspondant. Les données spectrales viennent à l'appui de l'existence prédominante, voire exclusive, de la forme thione en solution. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3079 (1972)

Although numerous 5-substituted-1,3,4-oxadiazole-2-thiones have been prepared (1, 2) the parent member, to our knowledge, has not been described. The synthesis of that compound constitutes the subject of this publication.

The formation of 1,3,4-oxadiazole-2-thiones from potassium-3-acyldithiocarbazates was first observed by Hoggarth (3). This synthesis,

though extraordinarily versatile (see ref. 1, p. 532) is reported (4) to be unsuccessful when applied to formic acid hydrazide, the only product obtained in this instance being 1,3,4-thiadiazole-2,5-dithione.

It occurred to us that 1,3,4-oxadiazole-2-thione (**6**) might be prepared by decarboxylation of the corresponding 5-carboxylic acid **5**. The synthesis of the latter compound was accomplished in the following manner. Ethyl oxalyl hydrazine (**1**) was converted to the potassium dithiocarbazate **2**, which on heating in ethanol containing a small amount of dimethyl sulfoxide (DMSO),[2] was transformed into the potassium salt **3**. This salt was not purified, instead, it was converted, under remarkably mild conditions, to the dipotassium salt **4**, by titration with 1 equiv of alcoholic potassium hydroxide. Alternatively, **4** could be obtained directly from **1**, carbon disulfide, and 2 equiv of potassium hydroxide. As expected, 1,3,4-oxadiazole-2-thione-5-carboxylic acid (**5**), when heated to its melting point *in vacuo*, lost the elements of carbon dioxide to give the parent thione.

1,3,4-Oxadiazole-2-thione was a stable solid with physical properties (see Table 1) which closely resembled those of the 5-methyl derivative. On the basis of i.r. (4) and u.v. (5) spectral data, it has been concluded that 5-methyl-1,3,4-oxadiazole-2-thione existed in solution in the thione rather than the thiol form. The near identity of the u.v. spectrum of **6** to that of 5-methyl-1,3,4-oxadiazole-2-thione and its 3-*N*-methyl derivative, and the absence of i.r. absorptions in the 2600–2550 cm^{-1} region,[3] indicated that **6** also existed as the thione in solution.

1,3,4-Oxadiazole-2-thione was an acidic substance ($pK'_a = 3.85$) *ca.* four times stronger than the 5-methyl derivative. The reduced acidity of the latter compound was consistent with the known acid weakening effect of a methyl group (8).

Experimental

The melting points were determined in a Gallenkamp melting point apparatus and are not corrected. The n.m.r. spectra were recorded with a Varian A-60A spectrometer in perdeuteriodimethylsulfoxide and are expressed in p.p.m. (δ) from internal tetramethylsilane. The i.r. spectra were recorded with a Unicam SP-200G i.r. spectrometer and the u.v. spectra were measured with a Unicam SP-800 u.v. spectrometer.

Ethyl oxalyl hydrazine was prepared from hydrazine hydrate and diethyl oxalate according to the method of Curtius and Hochschwender (9).

Ethyl-1,3,4-oxadiazole-2-thione-5-carboxylate Potassium Salt (3)

To a stirred solution of ethyl oxalyl hydrazine (35.3 g, 260 mmol) in absolute alcohol (250 ml) was added carbon disulfide (70 ml) followed by a solution of potassium hydroxide (16.5 g of 88% KOH, 260 mmol) in absolute ethanol (150 ml). The mixture was heated to reflux temperature, dry DMSO (40 ml) was added, and the mixture was then main-

[2]The conversion of potassium-3-acyldithiocarbazates to the corresponding oxadiazole thiones is known (4) to require reaction periods of up to 1 week in boiling ethanol. The addition of DMSO to the mixture accelerated the above transformation to such an extent that most reactions were completed in less than 2 days. For example, in ethanol containing *ca.* 10 vol. % DMSO, the potassium salt of 5-methyl-1,3,4-oxadiazole-2-thione (m.p. 230–232°) was obtained in 85% yield (pure) after 36 h under reflux.

[3]The S—H stretching absorption of thiophenols is reported (6) to occur in this region. 2-Methyl-1,2,3-triazole-4-thiol has a strong absorption at 2540 cm^{-1} (7).

TABLE 1. Properties of some 1,3,4-oxadiazole-2-thiones

		Melting point (°C)	89–91	76–78[a]
pK_a' (water—25°)	3.85	4.45[b]
N.m.r. (δ, p.p.m.)[c] thiol	14.52(w_H = 6 Hz), 8.88	14.30(w_H = 16 Hz), 2.42

[a]Literature (3) m.p. 78°. A sample of this thione was obtained from Dr. D. N. McGregor, Bristol Laboratories, Syracuse, N.Y.
[b]Sandstrom and Wennerbeck (5) reported pK_a = 5.01 under the same conditions.
[c]Measured in perdeuteriodimethylsulfoxide.
[d]Prepared *in situ* from the potassium salt and methyl iodide.
[e]It is not known which resonance is due to the *C*-methyl group. In the *S*-ethyl derivative (prepared *in situ* from ethyl iodide and the potassium salt) this absorption occurs at δ 2.55.
[f]Measured in 95% ethanol.
[g]Literature (5), λ_{max} (ethanol) 262 (log ε 4.15).
[h]Shoulder.
[i]Literature (5), λ_{max} (ethanol) 219.5 (log ε 3.92).
[j]Data taken from ref. 5.

tained at reflux temperature until the evolution of hydrogen sulfide had become slow (26 h). A small amount of a solid was removed by filtration and the filtrate was evaporated *in vacuo*. The syrup thus obtained was shaken vigorously with several portions (100 ml) of ether to remove DMSO. The ether extracts were discarded, the residue was evaporated *in vacuo* and then dried at room temperature and 0.01 mm for 24 h. The viscous residue (36.0 g) had i.r. (neat) absorptions at 1732 and 1594 (w) cm^{-1}, and n.m.r. bands at δ 1.33 (t, 3H, J = 7.2 Hz), 2.60(s, 10.8 H), 4.37(q, 2H, J = 7.2 Hz). The singlet at δ 2.60 was due to DMSO (1.8 mol/mol of product) which had not been removed. The yield of the potassium salt of the product was therefore 21.7 g (39%). It was not readily purified further and was used as such in subsequent reactions.

1,3,4-Oxadiazole-2-thione-5-carboxylic Acid Dipotassium Salt (4)

(a) From Ethyl-1,3,4-oxadiazole-2-thione-5-carboxylate Potassium Salt (3)

A stirred solution of the crude potassium salt (15.0 g, 42.6 mmol) in ethanol (150 ml) was treated in a dropwise manner with 45 wt. % aqueous potassium hydroxide (6.23 g, 50 mmol). The precipitated solid (9.5 g, 100%) was collected by filtration and dried *in vacuo*. The product, m.p. 250–252° dec., on crystallization from aqueous ethanol (1:2) gave material with m.p. 255° dec.

Anal. Calcd. for $C_3K_2N_2O_3S$: C, 16.21; N, 12.60; S, 14.42. Found: C, 16.16; N, 12.57; S, 14.37.

The i.r. spectrum (Nujol mull) had an intense band at 1622 cm^{-1} and a medium intensity absorption at 1547 cm^{-1}.

(b) From Ethyl-1,3,4-oxadiazole-2-thione-5-carboxylate

A solution of crude **3** (10.0 g) in water was made acidic with hydrochloric acid and then saturated with sodium chloride. The thiol was extracted into ethyl acetate, the extract was dried over sodium sulfate and evaporated *in vacuo* leaving a yellow oil (7.14 g) which solidified on standing. The i.r. spectrum (neat) had a series of strong broad absorptions at 2300–3300 cm^{-1}, an intense band at 1752 cm^{-1}, and a weak absorption at 1593 cm^{-1}. The crude ester (7.14 g) in alcohol (100 ml) was treated as above with 45% potassium hydroxide solution (8.1 g, 65 mmol). The product (6.3 g, 100%) which had m.p. 251–252° was identical to the dipotassium salt described above.

(c) From Ethyl Oxalylhydrazine, Carbon Disulfide, and 2 mol KOH

A solution of the hydrazide (19.7 g, 145 mmol) in alcohol (150 ml) containing carbon disulfide (41 ml) was treated in the usual way with potassium hydroxide (19.2 g of 88% KOH, 291 mmol) in ethanol (150 ml). To the boiling mixture was added DMSO (30 ml) and two further portions (30 ml) of DMSO were added at the end of 5 and 22 h under reflux. After 48 h, the reaction mixture was worked-up in the usual manner to give a solid which was slurried with ethanol (300 ml), diluted with ether (1 l), and the gummy solid was collected by filtration. A solution of this material in water was made basic with sodium carbonate solution (200 g/l, 50 ml) and extracted with ethyl acetate. The aqueous phase was saturated with salt, made acidic with hydrochloric acid, and extracted with ethyl acetate. The extract was dried over sodium sulfate and then evaporated *in vacuo* to give a yellow solid (12.75 g). An ethanol (150 ml) solution of this solid was treated in the usual way with 45% potassium hydroxide (21.8 g) to give a solid (10.3 g, 32% yield based on the hydrazide), m.p. 248–250° dec. identical to the dipotassium salt obtained by methods *a* or *b*.

1,3,4-Oxadiazole-2-thione

A solution of the dipotassium salt (10.0 g, 45.1 mmol) in water was made acidic with dilute hydrochloric acid, extracted with ethyl acetate (3 × 100 ml), the extract was dried over sodium sulfate and then evaporated *in vacuo*. The residual 1,3,4-oxadiazole-2-thione-5-carboxylic acid (m.p. 88–91° dec., i.r. (Nujol mull), 3285, 2200–3200 (broad, structureless), 1715, 1603, and 1589 cm^{-1}) was placed in a short path distillation apparatus and then heated to 95–100°/0.005 mm. When gas evolution had ceased, the bath temperature was raised to 140–150° and the product was distilled over as rapidly as possible by heating the stillhead with a free flame. The material which had solidified in the condenser was crystallized from benzene to give 1,3,4-oxadiazole-2-thione (2.91 g, 64.5%) with m.p. 88–91°. On recrystallization, material with m.p. 89–91° was obtained.

Anal. Calcd. for $C_2H_2N_2OS$ (equiv. wt. 102.18): C, 23.53; H, 1.97; N, 27.44. Found (101): C, 23.78; H, 2.00; N, 27.51.

We thank Dr. D. N. McGregor of Bristol Laboratories, Syracuse, N.Y. for a generous gift of 5-methyl-1,3,4-oxadiazole-2-thione.

[a]Literature (3) m.p. 150–152°.
[b]Literature (2) m.p. 137°.
[c]Recorded with a Varian A-60A spectrometer in perdeuteriodimethylsulfoxide containing tetramethylsilane as an internal standard.
[d]d, doublet; q, quartet; other absorptions had singlet multiplicity. The *J*-values and peak widths at half height are given in Hz.
[e]Measured in 95% ethanol on a Unicam SP800 u.v. spectrophotometer.
[f]3-Phenyl-3,4-di-*n*-propyloxazole-2-thione is reported (5) to have λ_{max} 285 (log ε 4.09).
[g]Recorded in chloroform with a Unicam SP-200G i.r. spectrophotometer.

N- and *S*-alkyl derivatives. A similar conclusion was reached from i.r. spectroscopic data (6, 7). On the basis of the i.r. spectral data given in Table 1, in particular the absence of absorptions in the 2600–2500 cm^{-1} region,[3] it is apparent that oxazole-2-thione, and its 4-methyl and 4,5-dimethyl derivatives all exist in solution in the thione rather than the thiol form.

Experimental

4-Methyloxazole-2-thione and 4,5-dimethyloxazole-2-thione were prepared by the method of Willems and Vandenberghe (2).

Oxazole-2-thione

A solution of dihydroxymaleic acid (10) (19.0 g, 128 mmol) in water (300 ml) was maintained at 60° until carbon dioxide evolution had ceased (*ca.* 20 min). A thiocyanic acid solution was prepared in a separate vessel by adding concentrated hydrochloric acid (15 ml) to a solution of potassium thiocyanate (16.5 g, 170 mmol) in absolute alcohol (375 ml) and then filtration to remove the precipitated potassium chloride. The glycolic aldehyde solution (11) and the thiocyanic acid solution were combined and heated under reflux in a nitrogen atmosphere for 16 h. The solvent was removed *in vacuo* ($\leqslant 40°$) and the solid residue was heated with 5% methanolic chloroform (100 ml). The mixture was filtered through anhydrous sodium sulfate (50 g), the filtrate was placed on a dry packed column of silica gel (Brinkman, Activity II, 350 g), and the column was developed with 5% methanolic chloroform. The first 600 ml of the eluate was discarded, the next 600 ml contained the product. After crystallization from dichloromethane a white solid (4.5 g, 35%), m.p. 145° dec. was obtained. One crystallization from benzene gave the analytical specimen with m.p. 147° dec.

Anal. Calcd. for C_3H_3NOS: C, 35.63; H, 2.99; N, 13.85. Found: C, 35.65; H, 2.95; N, 13.74.

[3]The S—H stretching band for thiophenols is reported (8) to occur at 2600–2550 cm^{-1}, while thiophene-2- and 3-thiols absorbed in the 2540–2510 cm^{-1} region (9).

Electrochemical Oxidation of Trifluoroacetic Acid in an Organic Medium. I. Synthesis of Trifluoroethane-1,1,1-d_3 and Pentafluoropropane-1,1,1-d_3 [1]

R. N. RENAUD AND D. E. SULLIVAN[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received June 8, 1972

"Crossed" Kolbe reactions are generally not very appropriate for the synthesis of short-chain hydrocarbons. However, trifluoroethane-d_3 and pentafluoropropane-d_3 were prepared in high yields by electrolysis of mixtures of the corresponding perfluoro-acids and acetic-d_3 acid under specific conditions.

La réaction de Kolbe est rarement employée pour la préparation d'hydrocarbures à courte chaîne à partir de deux acides carboxyliques différents. Par contre, le trifluoroéthane-d_3 et le pentafluoropropane-d_3 ont été obtenus en bons rendements à partir de mélanges d'acides perfluorés correspondants et d'acide acétique-d_3 en suivant des conditions expérimentales bien spécifiques.

Canadian Journal of Chemistry, **50**, 3084 (1972)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Deuterio-fluorohydrocarbons were needed for spectroscopic studies (1) and the only reported synthesis in the literature is that of trifluoroethane-1,1,1-d_3 (2). It was obtained by fluorination of trichloroethane-1,1-1-d_3 with antimony trifluoride (3). This reaction has the disadvantage of being conducted in a metal container under very specific conditions in order to obtain a yield of 30%. Also, the starting material can only be prepared with an overall yield of 40% from dichloroethylene by a four-step synthesis (4). Hasek *et al.* (5) described a method for the synthesis of trifluoroethane, in 50% yield, which could be applied to the preparation of the deuterated analogue. It consists of fluorinating acetic anhydride in the presence of sulfur tetrafluoride, carried out in a stainless steel pressure tube and shaken at 300 °C. Great care must be exercized in working with the poisonous compounds employed in this reaction.

In general "crossed" Kolbe reaction cannot be employed with satisfaction for the synthesis of low molecular weight hydrocarbons. The three possible hydrocarbons formed are difficult to separate (6). Petersen *et al.* (7) obtained only hexafluoroethane from the electrolysis of a mixture of trifluoroacetic acid in acetic acid and concluded that the very high ionization of trifluoroacetic acid was responsible for this result. Acetate ions, which are necessary for the success of the Kolbe reaction, were not present in the solution. However, it was found that controlled concentration of trifluoroacetic acid in the presence of an excess of acetate anions in acetic acid favored the formation of trifluoroethane in 68% yield, and completely eliminated the formation of hexafluoroethane. The only other product formed was ethane, which could be easily separated by a vacuum line distillation at −120 °C.

Pentafluoropropane was prepared in yields of over 75% under the same experimental conditions using pentafluoropropionic acid instead of trifluoroacetic acid.

Experimental

Trifluoroethane-1,1,1-d_3

A solution of trifluoroacetic acid (5.3 g) in acetic-d_3 acid (3.5 ml) was added dropwise during a period of 7 h to a solution of potassium acetate-d_3 (4.5 g) in acetic-d_3 acid (75 ml) at 45° in a 100 ml round-bottom flask equipped with a pressure equilibrated separatory funnel, a thermometer, a reflux condenser, a magnetic bar stirrer and two pieces of smooth platinum foil (1.4 × 1.9 cm) 3 mm apart. The electrodes were sealed into glass tubings which were extended down from a 24/40 glass head. At the top of the condenser, attached in series, was a gas washing bottle containing a 20% solution of sodium hydroxide, a Drierite U tube, a Stock trap and a gas bubbler. The system was flushed continuously with a slow stream of nitrogen from a gas inlet attached at the top of the separatory funnel. The electrolysis was carried out at a current density of 0.34 A/cm^2 and the gaseous materials formed were collected in the Stock trap in liquid nitrogen. The electrolysis was continued for an additional 0.5 h after the addition.

The trap was attached to a vacuum line and the high

[1]NRCC No. 12714.

[2]NRCC Summer Student, 1971.

vapor pressure fraction at $-120°$ (mostly ethane) was collected in a trap in liquid nitrogen. The distillation was continued until the vapor pressure dropped to nearly zero. The solid residue at $-120°$ proved on analysis by v.p.c. and mass spectrometry to be nearly pure trifluoroethane-d_3 (m.p. -105 to $-108°$, lit. $-107°$) (8). The yield based on the trifluoroacetic acid was 68% (2.7 g).

The deuterio-acetic acid remaining in the cell can either be recovered by distillation or kept in the cell for the generation of more trifluoroethane as needed.

Pentafluoropropane-1,1,1-d_3

When the reaction was repeated with pentafluoropropionic acid in place of trifluoroacetic acid, pentafluoropropane-1,1,1-d_3 was obtained in 75% yield.

N.M.R. Study of Base-Catalyzed Hydrolysis of Trimethylfluorosilane

J. A. GIBSON[1] AND A. F. JANZEN

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, R3T 2N2

Received April 13, 1972

The diethylamine catalyzed hydrolysis of trimethylfluorosilane in acetonitrile solution has been studied by the nuclear magnetic resonance technique. The concentration and temperature dependence of the pre-exchange lifetime of a fluorine in the exchange reaction was determined from the collapse of the trimethylfluorosilane doublet. The order with respect to trimethylfluorosilane, water, and diethylamine was experimentally determined. Approximate values of the equilibrium constant for the hydrolysis reaction were obtained at several temperatures.

L'hydrolyse catalysée par la diéthylamine, du triméthylfluorosilane en solution dans l'acétonitrile, a été étudiée par la technique r.m.n. L'influence de la concentration et de la température sur la durée de vie de prééchange d'un fluor, dans la réaction d'échange, a été déterminée à partir de la coalescence du doublet du triméthylfluorosilane. L'ordre par rapport au triméthylfluorosilane, eau et diéthylamine a été déterminé expérimentalement. Les valeurs approchées de la constante d'équilibre pour la réaction d'hydrolyse, ont été obtenues à des températures diverses. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3087 (1972)

The kinetics of hydrolysis and alcoholysis of organosilicon fluorides and chlorides have been studied by a variety of techniques (1 and references therein, 2). Despite these studies, a number of unresolved features remain, among them: (*a*) the variable order with respect to water, (*b*) order with respect to base catalyst, and (*c*) the negative temperature coefficients. We have applied the nuclear magnetic resonance technique and studied the diethylamine catalyzed hydrolysis of trimethylfluorosilane in acetonitrile solution as a function of trimethylfluorosilane, water, and diethylamine concentration and temperature.

Hydrolysis of $(CH_3)_3SiF$ yields an equilibrium system

$$[1] \qquad (CH_3)_3SiF + H_2O \rightleftarrows (CH_3)_3SiOH + HF$$

with an equilibrium constant $K_{eq} = [(CH_3)_3SiOH][HF]/[(CH_3)_3SiF][H_2O]$ of about 3.7×10^{-3} at $-10°$ and 1.0×10^{-3} at 25° (extrapolated). The equilibrium constant may be roughly estimated from the n.m.r. spectrum by integrating the $(CH_3)_3SiOH$ and $(CH_3)_3SiF$ peaks at low temperature under conditions of slow exchange (see Experimental). Similar equilibrium systems exist for other R_3SiF compounds where K_{eq} has been found to vary between 10^{-2} and 10^{-4} (ref. 2, p. 140).

Trimethylsilanol is converted to hexamethyldisiloxane (3)

$$[2] \qquad 2(CH_3)_3SiOH \rightarrow (CH_3)_3SiOSi(CH_3)_3 + H_2O$$

and, in the presence of diethylamine, hydrogen fluoride is complexed as diethylammonium fluoride and bifluoride. However, the condensation reaction (eq. 2) was monitored by n.m.r. and found to be too slow to interfere with the fluorine exchange studies based on eq. 1.

The fluorine involved in the exchange reaction gives rise to a spin–spin doublet ($J = 7.5$ Hz) in the proton n.m.r. spectrum under conditions of very slow fluorine exchange. As exchange increases, the spin–spin doublet collapses to a single peak. Collapse of the doublet due to intermolecular methyl exchange as found, for

example, in organoaluminum (4) or organothallium (5) compounds, is unlikely since CH_3–^{29}Si coupling is unaffected by the exchange process. On the other hand, collapse of the doublet is accompanied by loss of ^{19}F–^{29}Si coupling, consistent with intermolecular fluorine exchange represented by eq. 1.

An alternative mechanism of exchange, represented by eq. 3,

[3] $(CH_3)_3SiF + (C_2H_5)_2NH \rightleftarrows (CH_3)_3Si—N(C_2H_5)_2 + HF$

was considered, but eliminated by the following experiments: firstly, no exchange occurred before addition of water; secondly, if rapid exchange (single n.m.r. peak) was observed in a sample containing $(CH_3)_3SiF$, H_2O, and $(C_2H_5)_2NH$, then addition of $(CH_3)_3Si—N(C_2H_5)_2$ immediately stopped exchange (n.m.r. doublet). Evidently, reaction 3 is displaced essentially to the left, and the effect of adding $(CH_3)_3Si—N(C_2H_5)_2$ must be to stop the fluorine exchange of reaction 1 by removing HF.

In the n.m.r. method, kinetic and activation parameters may be obtained by studying the variation of the pre-exchange lifetime of fluorine with concentration and temperature, as described in recent review articles (6, 7). Following the description by Ham and Mole (7) we express the pre-exchange lifetime of $(CH_3)_3SiF$ by

$$(f\tau')^{-1} = \frac{-1}{[(CH_3)_3SiF]} \frac{d[(CH_3)_3SiF]}{dt}$$

where f is the appropriate statistical factor which converts the pre-exchange lifetime of a nucleus to that of the molecule undergoing exchange. In this case $f = \frac{1}{2}$ since after exchange the fluorine may have spin state $+\frac{1}{2}$ or $-\frac{1}{2}$.

If

$$1/\tau = (\tau'/2)^{-1}$$

then

$$1/\tau = k[(CH_3)_3SiF]^{n-1}F([\text{other species}])$$

where k is the specific rate constant, n is order of reaction in $(CH_3)_3SiF$, and $F([\text{other species}])$ describes the dependence of rate on concentration of other species. If concentration of other species is kept constant, $1/\tau$ should be independent of $[(CH_3)_3SiF]$ for a reaction first order in $(CH_3)_3SiF$.

Figure 1 shows a plot of $1/\tau$ *vs.* $[(CH_3)_3SiF]$ at constant $[H_2O]$ and $[(C_2H_5)_2NH]$ at 38°. The slope, by least-squares method, is 0.05, hence $1/\tau$ is independent of $[(CH_3)_3SiF]$ within experimental error[2] and the reaction is first order in $(CH_3)_3SiF$.

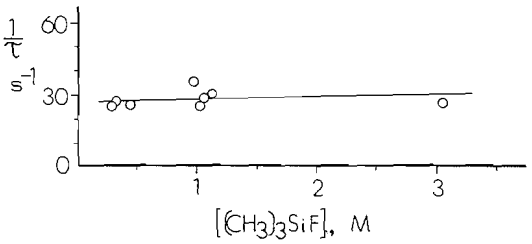

FIG. 1. A plot of $1/\tau$ *vs.* $[(CH_3)_3SiF]$ at 38° at constant $[H_2O] = 0.033$ *M* and $[(C_2H_5)_2NH] = 0.67$ *M*.

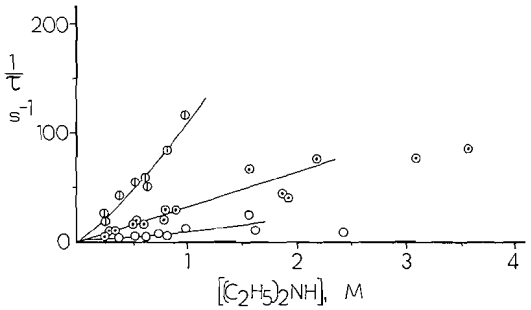

FIG. 2. Plot of $1/\tau$ *vs.* $[(C_2H_5)_2NH]$ at 38°: ○, $[H_2O] = 0.014$ *M*; ⊙, $[H_2O] = 0.028$ *M*; ⊕, $[H_2O] = 0.055$ *M*. $[(CH_3)_3SiF]$ was varied randomly between 0.16 and 0.79 *M*.

Figure 2 shows a plot of $1/\tau$ *vs.* $[(C_2H_5)_2NH]$ as a function of $[H_2O]$ at 38°. Since $1/\tau$ is independent of $[(CH_3)_3SiF]$ the concentration of $(CH_3)_3SiF$ was varied randomly between 0.16 and 0.79 *M*. The zero intercept, within experimental error, suggests that solvent acetonitrile is not an effective catalyst for hydrolysis of $(CH_3)_3SiF$.

If the data of Fig. 2 are re-plotted as ln $1/\tau$ *vs.* ln $[(C_2H_5)_2NH]$, a linear plot is obtained over the concentration range $[(C_2H_5)_2NH] < 1.6$ *M*, and the order with respect to $(C_2H_5)_2NH$ is 1.0, within experimental error, as shown in Table 1. At $[(C_2H_5)_2NH] > 1.6$ *M*, the ln $1/\tau$ *vs.* ln $[(C_2H_5)_2NH]$ plot departs from linearity and ln $1/\tau$ decreases with increasing ln $[(C_2H_5)_2$-

[2]Standard deviations are not quoted since the n.m.r. method generally involves larger errors (6, 7). We assume that our maximum errors are within ±10% of the values quoted in the text.

0.028	1.07
0.014	0.95

*Least-squares slope from plot of ln $1/\tau$ *vs.* ln $[(C_2H_5)_2NH]$ using data of Fig. 2 for $[(C_2H_5)_2NH] < 1.6$ M. $[(CH_3)_3SiF]$ varied randomly between 0.16 and 0.79 M.

TABLE 2. Order with respect to H_2O as a function of $(C_2H_5)_2NH$ concentration at 38°

$[(C_2H_5)_2NH]$ (M)	n*
0.24	1.9
0.51	1.7
1.56	1.5
4.66	1.0

*Least squares slope from plot of ln $1/\tau$ *vs.* $[H_2O]$ using data of Fig. 3. $[(CH_3)_3SiF]$ varied randomly between 0.49 and 1.18 M.

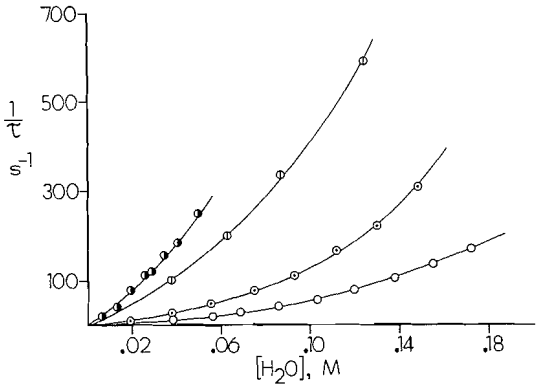

FIG. 3. Plot of $1/\tau$ *vs.* $[H_2O]$ at 38°: ○, $[(C_2H_5)_2NH] = 0.24$ M; ⊙, $[(C_2H_5)_2NH] = 0.51$ M; ◑, $[(C_2H_5)_2NH] = 1.56$ M; ●, $[(C_2H_5)_2NH] = 4.66$ M. $[(CH_3)_3SiF]$ was varied randomly between 0.49 and 1.18 M.

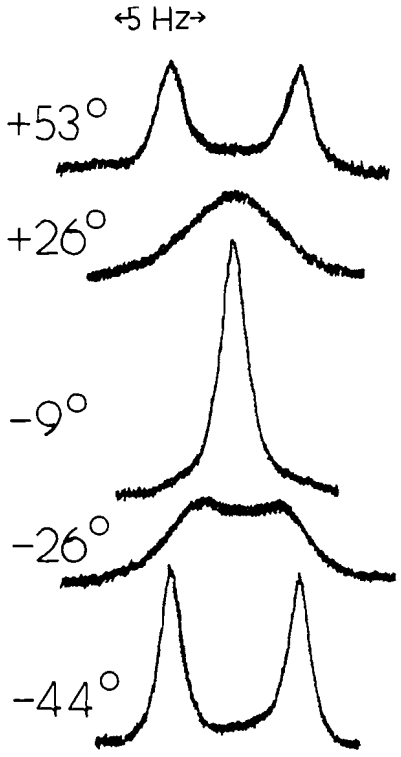

FIG. 4. Typical temperature dependent proton n.m.r. spectra: $[(CH_3)_3SiF] = 0.29$ M, $[H_2O] = 0.038$ M, $[(C_2H_5)_2NH] = 0.35$ M.

NH], resulting in an apparent decrease in order with respect to $(C_2H_5)_2NH$. The anomalous behavior at $[(C_2H_5)_2NH] > 1.6$ M is most readily explained by a decrease in rate of hydrolysis resulting from a decrease in the order with respect to water at high $(C_2H_5)_2NH$ concentration (*cf.* Fig. 3 and Table 2).

Figure 3 shows a plot of $1/\tau$ *vs.* $[H_2O]$ as a function of $(C_2H_5)_2NH$ concentration at 38°. $[(CH_3)_3SiF]$ was varied randomly between 0.49 and 1.18 M. The zero intercept is important since it confirms the absence of adventitious moisture in solvent and reagents.

If the data of Fig. 3 are re-plotted as ln $1/\tau$ *vs.* ln $[H_2O]$, linear plots are obtained and the least-squares slopes are shown in Table 2. The order with respect to H_2O varies between 1.0 and 1.9 and the order is seen to decrease with increasing $(C_2H_5)_2NH$ concentration.

The effect of temperature on rate of hydrolysis was studied and Fig. 4 shows typical temperature dependent spectra. Initial cooling from +53 to −9° results in collapse of the doublet and increase in rate of fluorine exchange. On further cooling below −9°, however, the rate decreases and at −44° the doublet re-appears.

The initial increase in rate of fluorine exchange with decreasing temperature was confirmed for various mixtures of $(CH_3)_3SiF$, $(C_2H_5)_2NH$,

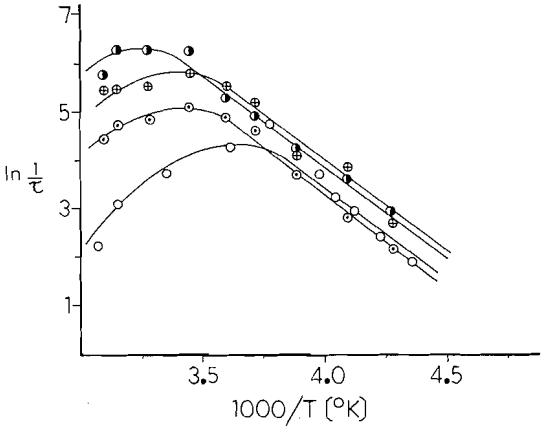

FIG. 5. Plot of $1/\tau$ *vs.* $1/T$: ○, $[(CH_3)_3SiF] = 0.29$ *M*, $[(C_2H_5)_2NH] = 0.35$ *M*, $[H_2O] = 0.038$ *M*; ⊙, $[(CH_3)_3SiF] = 0.66$ *M*, $[(C_2H_5)_2NH] = 0.39$ *M*, $[H_2O] = 0.084$ *M*; ⊕, $[(CH_3)_3SiF] = 0.46$ *M*, $[(C_2H_5)_2NH] = 0.86$ *M*, $[H_2O] = 0.090$ *M*; ◑, $[(CH_3)_3SiF] = 0.48$ *M*, $[(C_2H_5)_2NH] = 0.74$ *M*, $[H_2O] = 0.084$ *M*.

and H_2O, as shown in the Arrhenius plot of $\ln 1/\tau$ *vs.* $1/T$ (Fig. 5). If all the points from the low temperature straight line portion of the Arrhenius plot of Fig. 5 are used to calculate a least-squares slope, an activation energy of 7.8 kcal/mol is obtained for the low temperature process.

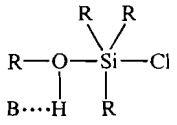
Possible Intermediates in Hydrolysis Reaction

Any proposed mechanism must be consistent with the rate expression which, at 38°, is given by

$$R = k[(CH_3)_3SiF][(C_2H_5)_2NH][H_2O]^n$$

where n varies from 1.0 to 1.9, depending on $(C_2H_5)_2NH$ concentration (Table 2), and also consistent with the temperature effects in the Arrhenius plot (Fig. 5).

A mechanism has been proposed by Allen and Modena (8) and others (9) to account for hydrolysis and alcoholysis of organosilicon chlorides, involving a rate-controlling transition

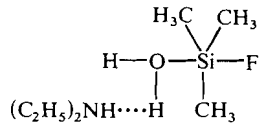


state in which B is a base capable of assisting proton removal from ROH. Chipperfield and Prince (10) studied the hydrolysis of organosilicon and organogermanium chlorides and suggested a transition state involving a water aggregate, *i.e.* $ROH{=}H_2O$ and $B = [H_2O]_{n-1}$, to explain the multiple order in H_2O and the negative temperature coefficient, the latter effect arising from the heat of association of $[H_2O]_n$.

Although the mechanism of Chipperfield and Prince could, in theory, also account for the hydrolysis of $(CH_3)_3SiF$, we do not favor such an explanation for several reasons. Firstly, the order in H_2O in our study does not exceed 1.9, despite variation in H_2O concentration from 0.06 to 0.18 *M*, and $(C_2H_5)_2NH$ from 0.24 to 4.66 *M*, hence the postulate of a water aggregate $(H_2O)_n$ where $n > 2$ is unnecessary. Secondly, the variation in order in H_2O is seen to be inversely proportional to $(C_2H_5)_2NH$ concentration (Fig. 2) and the postulate of a water aggregate with variable n is unnecessary. Thirdly, although the deviation in the Arrhenius plot may be explained in terms of the heat of association of $(H_2O)_n$, a variety of other effects summarized by Hulett (11) may also explain deviations from the Arrhenius equation.[3]

Of the effects discussed by Hulett, the most consistent with the well known tendency of silicon and other group IV elements to form five or six coordinate complexes of the type SiX_4.base and SiX_4.2base (12, 13) would appear to be a change in mechanism with temperature, either involving two (or more) processes of different activation energies with five or six coordinate intermediates, or a reaction involving a pre-equilibrium in which the equilibrium constant varies with temperature.

At 38° the rate law with $n = 1$ is consistent with the five coordinate transition state proposed by Allen and Modena.



[3]It is of interest that Chipperfield and Prince observed a negative temperature effect for chlorosilanes but not triphenylchlorogermane; however, since they report rate constants for the latter at only two temperatures, 25 and 40°, it is not clear whether their results are real or fortuitous. Only a rate study over wider temperature range would determine whether chlorogermanes differ from chlorosilanes, or whether the behavior parallels that of trimethylfluorosilane shown in Fig. 5.

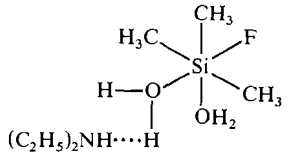
The increase in order in H_2O to 1.9 suggests a second reaction pathway with a six coordinate transition state in which two water molecules are coordinated to silicon.



A possible explanation for the decrease in order in H_2O with increasing $(C_2H_5)_2NH$ concentration may be as follows: H_2O and $(C_2H_5)_2NH$ may compete for the sixth coordinate site around silicon, therefore at high $[(C_2H_5)_2NH]$ the order in H_2O decreases to 1.0, whereas at low $[(C_2H_5)_2NH]$ the order increases to 1.9. However, only the transition state in which H_2O occupies the sixth coordinate site is involved in the rate controlling step since the order in $(C_2H_5)_2NH$ does not exceed 1.0 (Table 1).

The fluorine exchange reaction does not appear to be catalyzed by hydroxide ion, since addition of small amounts of solid or aqueous sodium hydroxide to trimethylfluorosilane in acetonitrile solution did not broaden the trimethylfluorosilane doublet (however, condensation of trimethylsilanol is accelerated by addition of hydroxide ion). This result argues against a mechanism involving a pre-equilibrium of $(C_2H_5)_2NH$ and H_2O to give $(C_2H_5)_2NH_2^+$ and HO^- ions.

Other five or six coordinate intermediates, $(CH_3)_3SiF{\cdot}NH(C_2H_5)_2$ or $(CH_3)_3SiF{\cdot}2NH(C_2H_5)_2$ (probably of lower stability than $SiX_4{\cdot}$base and $SiX_4{\cdot}2$base where X = halogen, since the effect of replacing halogen with alkyl groups is known to decrease the stability of the complex (14)), seem reasonable, but their effect on the mechanism is unknown.

To suggest a more detailed mechanism for this complex reaction is not justified at this stage, particularly in view of the generally low precision of kinetic results obtained by the n.m.r. method.

Experimental

Moisture was rigorously excluded from chemicals and equipment. A conventional glass vacuum manifold was dried by silylation (with $(CH_3)_3Si{-}N(C_2H_5)_2$), evacuated, and thoroughly flamed out. Acetonitrile (Spectroquality, Matheson, Coleman and Bell) was redistilled and stored over P_2O_5 in the vacuum manifold. Trimethylfluorosilane (Peninsular Chem Research) was purified by trap-to-trap distillation and stored over activated molecular sieves and diethylamine (Reagent, Fisher) was redistilled twice and stored over sodium amalgam in the vacuum manifold.

N.m.r. tubes were dried at 400° for several days and flamed out under vacuum. Reagents were condensed into the n.m.r. tubes, which were flame sealed, and average concentrations determined by at least five n.m.r. peak integrations. N.m.r. tubes were then opened and capped with silicone rubber septum caps. Solutions made up by this method had negligible moisture content since a plot of $1/\tau$ *vs.* H_2O concentration had zero intercept (Fig. 3). Furthermore, even at high diethylamine concentration, no collapse of the trimethylfluorosilane doublet was observed before addition of water.

Small amounts of water were then added by means of dilute water–acetonitrile solutions of known concentration using 10 or 50 μl syringe and injecting through n.m.r. caps. Samples were shaken and allowed to equilibrate in the n.m.r. probe (38°) for at least 5 min. Blank determinations showed that negligible amounts of adventitious moisture were introduced by this technique.

All proton n.m.r. spectra were recorded using Varian A-56/60A spectrometer at 60 MHz equipped with variable temperature probe. For the temperature runs, n.m.r. tubes were flame sealed to prevent possible moisture condensation. Temperatures were calibrated with the aid of a methanol temperature *vs.* chemical shift chart (15) and are accurate to ±1°.

Theoretical values of τ', the pre-exchange lifetime of a fluorine in the exchange reaction, were obtained for different values of τ', using a program written by B. W. Goodwin of this department, based on the McConnell formulation of the Bloch equations (16). For particular τ' values, the program tabulated peak separation, half-height peak width, ratio of maximum to minimum intensity, and half-height width of collapsed peak (for fast exchange region). These values were then compared with the observed spectra. One component of the $(CH_3)_3SiF$ doublet (in degassed acetonitrile solution) was used to estimate that $T_2 = 1.06$ s.

The end products of hydrolysis after about 8 days at room temperature were $(CH_3)_3SiOSi(CH_3)_3$, identified by comparison with n.m.r. spectrum of an authentic sample, and mixture of diethylammonium fluoride and bifluoride. The latter were precipitated from CH_2Cl_2 solution and identified by elemental analysis (A. Bernhardt, West Germany).

Anal. Calcd. for 1:4 molar ratio of $(C_2H_5)_2NH_2F$: $(C_2H_5)_2NH_2HF_2$: C, 44.0; H, 11.8; N, 12.8. Found: C, 44.27; H, 11.14; N, 12.70.

Estimate of Equilibrium Constant of Hydrolysis Reaction

The diethylamine catalyzed hydrolysis in acetonitrile is

$$(CH_3)_3SiF + H_2O \rightleftarrows (CH_3)_3SiOH + HF$$

rapid at 38° but is slowed down at low tem-

TABLE 3. Values of K_{eq} at various temperatures

263	1.01	0.060	0.015	3.7×10^{-3}
252	1.01	0.057	0.018	5.6×10^{-3}
240	1.01	0.051	0.024	1.12×10^{-2}

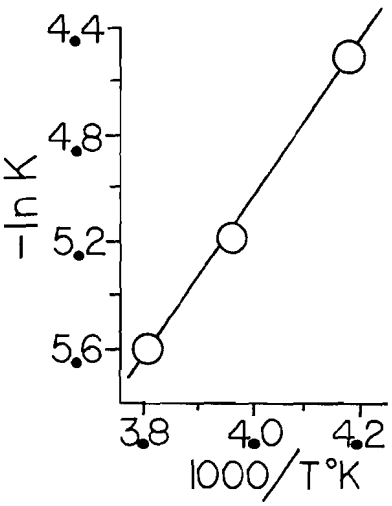

FIG. 6. Plot of ln K_{eq} *vs.* $1/T$ for hydrolysis of trimethylfluorosilane.

perature and a separate n.m.r. peak of low intensity is observed which may be assigned to $(CH_3)_3SiOH$ by comparison with the chemical shift of an authentic sample of $(CH_3)_3SiOH$ prepared by hydrolysis of $(CH_3)_3SiCl$ (17). The equilibrium constant $K_{eq} = [(CH_3)_3SiOH][HF]/[(CH_3)_3SiF][H_2O]$ was estimated at several temperatures by integrating n.m.r. peaks and assuming $[(CH_3)_3SiOH] = [HF]$ (Table 3).

From the relation $d \ln K/d(1/T) = -\Delta H/R$ it is possible to obtain ΔH, the heat of reaction, by plotting ln K *vs.* $1/T$ (18). As shown in Fig. 6, the plot is linear and gives $\Delta H = -6.0$ kcal/mol. Extrapolating K_{eq} to 25° gives K_{eq} $(25°) = 1.0 \times 10^{-3}$. Although values for K_{eq} and ΔH may be obtained quite readily by the n.m.r. method, the numerical results are only approximate estimates.

Ammine Complexes of Osmium(II)

A. D. ALLEN AND J. R. STEVENS
Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received March 27, 1972

Several ammine complexes of osmium(II) containing one or two π-acceptor ligands have been prepared. They have been characterized by analytical techniques and their infrared and electronic spectra have been recorded and assignments proposed. Comparison with similar ruthenium(II) complexes has been made when possible.

Plusieurs complexes entre l'amine et l'osmium(II) contenant un ou deux ligands π-accepteurs ont été préparés. Ils ont été caractérisés par les techniques analytiques, leurs spectres infrarouge et électronique ont été enregistrés et des attributions proposées. Une comparaison avec les complexes analogues du Ruthénium(II) a été faite quand c'était possible. [Traduit par le journal]

Introduction

Following the publication of the preparation of $[Ru(NH_3)_6]^{2+}$ in 1959 (1) and of $[Ru(NH_3)_5(N_2)]^{2+}$ in 1965 (2), the investigation of ruthenium(II) ammine complexes has increased rapidly (3). A large number of octahedral complexes containing four or five ammonia ligands with a wide variety of ligands in the remaining coordination sites have been prepared. Although the chemistry of divalent osmium generally parallels that of divalent ruthenium (4), no osmium(II) ammine complexes had been prepared prior to 1967.

We reported the preparation of $[Os(NH_3)_5(N_2)]X_2$ (X = Cl, Br, I, BF_4, ClO_4, and $B(C_6H_5)_4$ in 1967 (5) and subsequently *cis*-$[Os(NH_3)_4(N_2)_2]X_2$ (X = Cl, Br, and I) was prepared by diazotization of the former cation (6). We now report the detailed preparation and characterization of halide salts of the ions $[Os(NH_3)_5(N_2)]^{2+}$, $[Os(NH_3)_5CO]^{2+}$, and *cis*-$[Os(NH_3)_4CO(N_2)]^{2+}$.

Experimental

The instruments used in this work were Perkin–Elmer 521 and 180 spectrophotometers for the infrared studies (Nujol mulls between KBr plates) and a Bausch and Lomb 505 spectrophotometer for the electronic spectra (1 cm fused silica cells). Magnetic measurements were made using a Gouy balance. Microanalyses (Table 1) were performed by A. B. Gygli, Toronto or Huffman Laboratories, Wheatridge, Colorado. Halide was determined potentiometrically following the method of Lingane (7).

Preparations

1. Nitrogenpentaammineosmium(II) Chloride, $[Os(NH_3)_5(N_2)]Cl_2$

Two g of ammonium hexachloroosmate were slowly added to 25 ml of ice-cold 85% hydrazine hydrate being rapidly stirred in a single necked flask. Two ml of water were used to rinse the neck of the flask and the solution was refluxed for 15 h. It was then cooled to 0° and the yellow precipitate collected, washed with 95% ethanol and diethyl ether, and air-dried. The product was recrystallized by dissolution in cold dilute hydrochloric acid and reprecipitated by the addition of concentrated hydrochloric acid. Yield of the pale yellow powder 1.1 g (65%).

2. Nitrogenpentaammineosmium(II) Bromide, $[Os(NH_3)_5(N_2)]Br_2$, and Iodide, $[Os(NH_3)_5(N_2)]I_2$

These salts were prepared by metathetical reactions of the chloride salt of the cation with the appropriate sodium salt of the anion. $[Os(NH_3)_5(N_2)]Cl_2$ (0.25 g) was dissolved in 75 ml of water at 20 °C and 10 ml of a saturated solution of sodium bromide or iodide were added. The precipitate was collected, redissolved in the minimum amount of water at 20 °C, and reprecipitated by the further addition of saturated sodium halide solution. The bromide salt is very pale yellow in color and the iodide salt is off-white.

3. cis-Bisnitrogentetraammineosmium(II) Bromide, cis-$[Os(NH_3)_4(N_2)_2]Br_2$

This salt was prepared as previously reported (6).

4. Carbonylpentaammineosmium(II) Halide, $[Os(NH_3)_5CO]X_2$ (X = Cl, Br, I)

Chloropentaammineosmium(III) chloride (0.2 g) was added to 20 ml of approximately 5 *M* formic acid. Freshly amalgamated mossy zinc (3–5 g) was added and carbon monoxide was passed through the solution. The solid slowly dissolved to form a yellow solution which gradually became colorless. After 20 h the zinc was filtered off and the required salt of the carbonylpentaammineosmium(II) cation was precipitated by the addition of the appropriate potassium halide to the filtrate. The complexes were purified by dissolution in cold dilute ammonium hydroxide and reprecipitated as white powders by the addition of a saturated solution of the appropriate potassium halide. Yield of the chloride salt 0.13 g (75%).

5. cis-Carbonylnitrogentetraammineosmium(II) Halides, cis-$[Os(NH_3)_4CO(N_2)]X_2$ (X = Cl, Br, I)

Carbonylpentaammineosmium(II) chloride (0.4 g) and sodium nitrite (0.075 g) were dissolved in 75 ml of water and argon was passed through the solution for 15 min. Ten ml of 1 *M* hydrochloric acid were slowly added to the

solution which was being rapidly stirred at 25 °C under argon. Considerable gas evolution was observed and after this had subsided (15 min) the solution was saturated with the appropriate potassium halide. The resulting precipitate, pale pink in color, was collected, washed with 95% ethanol and diethyl ether, then air-dried. When reprecipitated from dilute ammonium hydroxide solution, the products were a light cream color. Yield of the chloride salt, 0.15 g (25%).

Results and Discussion

The preparation of the $[Os(NH_3)_5(N_2)]^{2+}$ ion has been reported previously (5). Attempts to replace the N_2 ligand with CO by direct reaction were unsuccessful. In the synthesis of the $[Os(NH_3)_5CO]^{2+}$ ion via reduction of the trivalent complex, $[Os(NH_3)_5Cl]^{2+}$, by amalgamated zinc in formic acid under carbon monoxide, the formic acid is required for formation of the product but the carbon monoxide is not. The reaction proceeds equally well under nitrogen or argon.

No evidence has been obtained for the formation of $[Os(NH_3)_5(N_2)]^{2+}$ or $[(NH_3)_5OsN_2Os(NH_3)_5]^{4+}$ from the reduction of $[Os(NH_3)_5Cl]^{2+}$ in sulfuric or fluoroboric acid under nitrogen. Similarly, $[Os(NH_3)_5CO]^{2+}$ cannot be prepared by reduction of $[Os(NH_3)_5Cl]^{2+}$ in sulfuric acid under carbon monoxide. It thus appears that a reactive intermediate, analogous to the $[Ru(NH_3)_5H_2O]^{2+}$ ion in the ruthenium system which is known to react with CO (14) and N_2 (8), is not formed in the osmium system. During the preparation of $[OsCl_5CO]^{3-}$ from formic acid and $[OsCl_6]^{2-}$, Cleare and Griffith (9) noticed formato intermediates of unspecified osmium oxidation states. However, formic acid and $[Os(NH_3)_5Cl]^{2+}$ do not react even after prolonged heating. This suggests that in the reaction which produces an osmium–carbonyl complex, the osmium is first reduced by the zinc and then a formate group replaces the chloride to form a formato–osmium(II) species which decomposes to $[Os(NH_3)_5CO]^{2+}$. Formate ion may react with the osmium(II) species when N_2 and CO do not because it is a better nucleophile. The decarbonylation of the formate group occurs because it results in the formation of a strong osmium—carbon bond and stabilization of the divalent osmium state.

The diazotization reaction used to prepare *cis*-$[Os(NH_3)_4(N_2)_2]^{2+}$ from $[Os(NH_3)_5(N_2)]^{2+}$ also produces *cis*-$[Os(NH_3)_4CO(N_2)]^{2+}$ from $[Os(NH_3)_5CO]^{2+}$. Since this type of reaction usually involves an unprotonated primary amine, it implies that a definite concentration of a coordinated amido species is present. Curiously the reaction does not succeed with $[Ru(NH_3)_5(N_2)]^{2+}$ (6). One possible explanation of this difference is an equilibrium of the type

$$[1] \quad [Os(NH_3)_5L]^{2+} \rightleftharpoons [Os(NH_3)_4(NH_2)HL]^{2+} \quad (L = N_2, CO)$$

where one of the ammonia protons can bind to the osmium producing formally an osmium(IV) hydride complex. This can be regarded as an intramolecular protonation of a filled metal d-orbital. Since two of the filled d-orbitals of the osmium are involved in π-bonding with the π^*-orbitals of the ligand L, the third orbital at right angles to the molecular axis would be most readily protonated. Thus the protons on the ammonias *cis* to the ligand L are most favorably located to shift to the metal orbital, and the amide ligand, the site of the electrophilic attack in the diazotization reaction,

would be *cis* to the ligand L. The resulting complexes thus have a *cis* stereochemistry. Attempts to identify a *trans* species such as *trans*-$[Os(NH_3)_4(N_2)_2]^{2+}$ or *trans*-$[Os(NH_3)_4(H_2O)(N_2)]^{2+}$ as a minor product in the reaction have not been successful.

An interaction of this kind was previously suggested by Palmer and Basolo (10) to explain the slower rate of proton exchange of $[Ir(NH_3)_6]^{3+}$ compared to $[Rh(NH_3)_6]^{3+}$. More recently Taube and co-workers (11) have proposed the protonation of a d-orbital of $[Ru(NH_3)_6]^{2+}$ to explain the dependence on acid concentration of the rate of aquation of this ion. Attempts to prepare $[Os(NH_3)_5(H_2O)]^{2+}$ by electrochemical reduction of $[Os(NH_3)_5Cl]^{2+}$ have been unsuccessful.[1] The reduced species appear to reduce the solvent, probably via interaction of solvent protons with the filled osmium(II) d-orbitals, which reflects the greater basicity of these orbitals on osmium relative to ruthenium, for which complex the reduction proceeds smoothly. Thus $[Ru(NH_3)_5(N_2)]^{2+}$ is not diazotized because the ruthenium d-orbitals are not sufficiently basic to form $[Ru(NH_3)_4(NH_2)H(N_2)]^{2+}$ while $[Ru(NH_3)_6]^{2+}$ is in fact oxidized by nitrous acid, probably via attack of NO^+ on a d-orbital.

$$[2] \quad [Ru(NH_3)_6]^{2+} + NO^+ \rightarrow [Ru(NH_3)_6]^{3+} + NO$$

In this case the ammonia protons are not sufficiently acidic to protonate the d-orbital since the NH_3 ligands are not sufficiently strongly bound to the metal (ν(Ru-NH_3) < 250 cm^{-1} (12), *cf.* ν(Os—NH_3) at 549 cm^{-1} in $[Os(NH_3)_5(N_2)]Cl_2$). Thus it is only in complexes in which highly basic d-orbitals are accompanied by strong metal–ammonia bonds, leading to acidic ammine protons, that intramolecular protonation occurs to a sufficient extent to permit the diazotization reaction.

The presence of a single π-acceptor ligand is probably a necessary requirement to meet these conditions. A ligand of this type would help to provide a low oxidation state and hence basic d-orbitals but, because it affects the d-orbitals differently, it leaves one exposed. It also strengthens the metal–ammonia bonds. With two *cis* π-acceptor ligands all the d-orbitals will be contracted and further diazotization is inhibited.

[1]Personal communication from J. A. Page and J. Gulens.

The infrared vibrational frequencies and their assignments for the complexes prepared in this work are listed in Tables 2, 3, and 4. The data for two ruthenium complexes are listed for comparison. The assignment of the NH_3 frequencies was made via a straightforward comparison with other ammine complexes (13, 14). All three series exhibit small to moderate dependence of the NH_3 vibrations due to the counter-ion, which can be attributed to different degrees of hydrogen bonding between the ammonia-hydrogens and the anions (15). The pentaammine complexes exhibit lower $\rho(NH_3)$ frequencies than do the tetraammine complexes of the corresponding halide. This is indicative of an increased effective electronegativity of the osmium in the tetraammines (16) reflecting electron withdrawal from the metal by the second π-acceptor ligand.

The carbonylpentaammine salts exhibit correlation coupling of the ν(CO) mode similar to that observed with ν(NN) of $[Os(NH_3)_5(N_2)]X_2$ (5, 17). The low energy spike on the ν(CO) band, which is also prominent in the spectra of the analogous ruthenium complexes, can be assigned to the ^{13}CO component. Its appearance from only 1% of the material is an indication of the extreme intensity of the carbonyl absorption. It is also present as a weak shoulder in the spectra of the chloride and bromide salts of the *cis*-$[Os(NH_3)_4CO(N_2)]^{2+}$ ion. The bands at ~2180 and ~1960 cm^{-1} in the spectra of this ion cannot strictly be assigned to ν(NN) and ν(CO) because of mutual interaction, but the higher energy one is almost certainly basically ν(NN). In the spectrum of the bromide salt it occurs at a similar frequency to the higher energy ν(NN) band of *cis*-$[Os(NH_3)_4(N_2)_2]Br_2$. The carbon-13 shoulder appears on the lower energy band of *cis*-$[Os(NH_3)_4CO(N_2)]^{2+}$ confirming its assignment as basically ν(CO). The frequency of this band is about 75 cm^{-1} higher than in the $[Os(NH_3)_5CO]^{2+}$ salts, suggesting a decrease in the π-back bonding from the osmium to the carbonyl ligand. This results from the π-bonding requirements of the π-acceptor N_2 ligand.

The far infrared spectra of the carbonyl complexes exhibit a different pattern from those of the nitrogen complexes. The moderately intense band(s) at 590–608 cm^{-1} can be assigned to δ(Os—C—O) and the weak band at 557–569

cm^{-1} to ν(Os—C) by analogy with other carbonyl complexes (9, 14). This leaves a single weak absorption above 400 cm^{-1} at 433–450 cm^{-1} assignable to ν(Os—NH_3). By contrast, the $[Os(NH_3)_5(N_2)]^{2+}$ ion exhibits a moderate intensity band at 499–524 cm^{-1} assigned by Borod'ko *et al.* (17) to ν(Os—N_2), but by comparison with carbonyl and nitrosyl complexes, more likely to be δ(Os—N—N). A weak band appears in these spectra similar to that assigned to ν(Os—NH_3) in the carbonyl complexes. In addition a more intense band at much higher energy (533–549 cm^{-1}), exhibiting a large isotope shift on deuterium substitution and assigned to ν(Os—NH_3) is also found. Neither this band nor a very weak band at 471–493 cm^{-1} have counterparts in the spectra of the carbonyl complexes.

Comparison of the infrared spectra of $[Os(NH_3)_5CO]^{2+}$ and *cis*-$[Os(NH_3)_4(N_2)_2]^{2+}$ with those of *cis*-$[Os(NH_3)_4CO(N_2)]^{2+}$ enables the two peaks ~600 cm^{-1} in the latter ion, to be assigned to δ(Os—C—O). The degeneracy of this mode has been removed since in-plane bending is now different from out-of-plane bending because of the N_2 ligand. This would not be the case if the CO and N_2 ligands were mutually *trans*. The remainder of the far infrared spectrum (to 400 cm^{-1}) cannot be assigned with certainty.

The electronic spectral data for the complexes prepared in this work and several similar ruthenium complexes are listed in Table 5. Previous studies of the ruthenium complexes have assigned the single peak in the spectrum of $[Ru(NH_3)_5(N_2)]^{2+}$ to a metal to ligand ($d_\pi \rightarrow \pi^*(N_2)$) charge transfer transition (18) and the 36 100 cm^{-1} peak in the spectrum of $[Ru(NH_3)_5(CO)]^{2+}$ to this transition (19). The weaker peak in the latter complex was considered to be the $^1A_1 \rightarrow {}^1T_1$ ligand field transition. The analogous osmium complexes exhibit very similar spectral features. The 48 100 cm^{-1} band in the spectrum of $[Os(NH_3)_5(N_2)]^{2+}$ can be assigned to a $d_\pi \rightarrow \pi^*(N_2)$ transition. It occurs at higher energy than in the ruthenium complex because the N_2 ligand is more strongly bonded to the osmium atom causing the antibonding π^* orbitals to be destabilized to a greater degree than in the ruthenium complex.

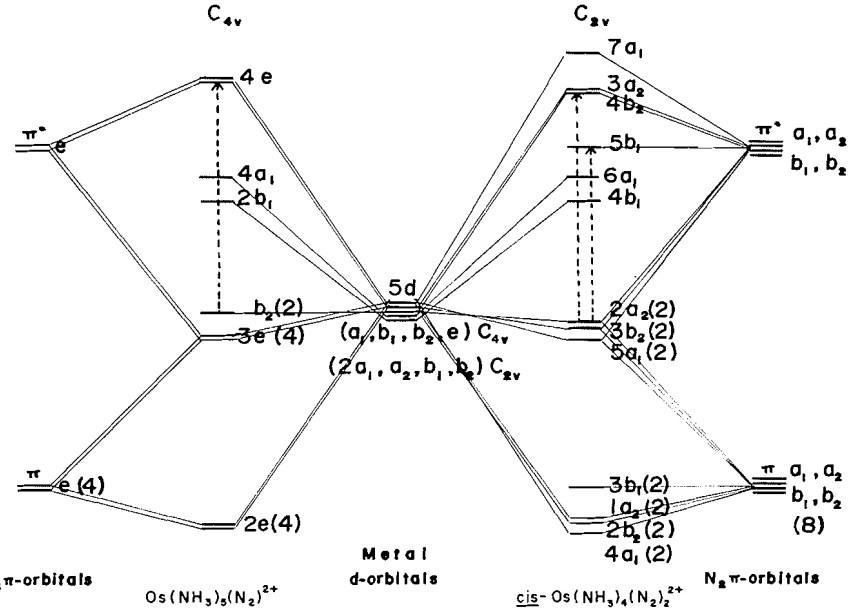

FIG. 1. Schematic diagram of ligand π-orbitals and osmium d-orbitals of osmium(II) nitrogen complexes.

In Fig. 1 it can be seen that the lowest energy charge transfer transition of the *cis*-$[Os(NH_3)_4(N_2)_2]^{2+}$ ion involves the $5b_1$ orbital which is not involved in bonding with the metal. A second transition is expected at higher energy but is not observed below 50 000 cm^{-1}. Mulliken has shown that the π^* orbitals of CO lie at higher energy than the π^* orbitals of N_2 (20). Thus in the *cis*-$[Os(NH_3)_4CO(N_2)]^{2+}$ ion, the first charge transfer band occurs at higher energy than in the *cis*-$[Os(NH_3)_4(N_2)_2]^{2+}$ ion because the upper level is partially formed from π^* (CO) in place of $\pi^*(N_2)$.

Caulton *et al.* (21) have calculated that CO interacts more strongly than N_2 with a low-spin d^6 metal ion because of the synergic effect of the larger σ-bonding capability of CO. Thus the π^* orbitals in the complexes will lie at higher energy in the $[M(NH_3)_5CO]^{2+}$ ions than in the $[M(NH_3)_5(N_2)]^{2+}$ ions (M = Os, Ru). The $d_\pi \rightarrow \pi^*$ transition would thus be expected to occur at higher energy in the CO complexes and in fact is not observed below 50 000 cm^{-1} for either metal. Stanko and Starinshak (19) noted a strong absorption up to the limit of their spectrophotometer and a similar absorption is present in the spectrum of $[Os(NH_3)_5CO]^{2+}$. This probably represents the $d_\pi \rightarrow \pi^*$ transition.

The less intense bands in the electronic spectra of the carbonyl complexes probably represent the two spin allowed ligand field transitions, $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ of an octahedral low-spin d^6 ion. The reason for the wide difference in intensity between the two absorptions is not known although similar behavior is found for the $[Ru(NH_3)_6]^{2+}$ ion (22).

Representative salts ($[Os(NH_3)_5(N_2)]Cl_2$, $[Os(NH_3)_5CO]Br_2$, and *cis*-$[Os(NH_3)_4CO(N_2)]Br_2$) of the complexes were found to be diamagnetic at room temperature as expected for spin-paired octahedral osmium(II) ions.

The chemistry of these osmium(II) complexes is characterized by their extreme inertness. There is little obvious labilization of the *trans*-NH_3 in the $[Os(NH_3)_5(CO)]^{2+}$ ion. Both $[Ru(NH_3)_5CO]^{2+}$ and *cis*-$[Ru(NH_3)_4(H_2O)CO]^{2+}$ lose the NH_3 *trans* to the carbonyl in acidic solutions (14) but $[Os(NH_3)_5CO]^{2+}$ is unaffected by prolonged treatment with hydrochloric acid at elevated temperatures. Hydrazine hydrate does not react with $[Os(NH_3)_5CO]^{2+}$, even to produce $[Os(NH_3)_5(N_2)]^{2+}$, although the latter ion is formed from the reaction of $[Os(NH_3)_5Cl]^{2+}$ with hydrazine hydrate and is the end product (contaminated with *cis*-$[Os(NH_3)_4(N_2)_2]^{2+}$ (17)) in the reaction of osmium(IV) chloro complexes with hydrazine hydrate. Neither carbon monoxide nor sulfur dioxide displace the N_2 ligand from $[Os(NH_3)_5(N_2)]^{2+}$ and likewise this ion is unaffected by prolonged treatment with aqueous ammonia or pyridine in the absence of oxygen. This behavior may be contrasted with that of $[Ru(NH_3)_5(N_2)]^{2+}$ which undergoes several substitution reactions in which the N_2 is displaced (12).

The authors would like to thank the National Research Council of Canada for their financial assistance and the Province of Ontario for a fellowship (J.R.S.).

Thermal Transformation in Anhydrous Rare Earth Acetates

G. ADACHI AND E. A. SECCO

Department of Chemistry, St. Francis Xavier University, Antigonish, Nova Scotia

Received February 7, 1972

The thermal transformation in anhydrous acetates of Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, and Y has been studied by thermal analysis. The enthalpy change, ΔH, and the entropy change, ΔS, accompanying the transformation process are reported and related to ionic radius of the rare earth element.

The acetates of the rare earth elements, La, Pr, and Nd did not exhibit the thermal transformation property.

La transformation thermique dans les acétates anhydres de Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu et Y a été étudiée par analyse thermique. On a determiné les changements d'enthalpie ΔH et d'entropie ΔS, qui accompagnent le processus de transformation et établi la relation au rayon ionique de la terre rare.

Les acétates de terre rare La, Pr, et Nd ne démontrent aucune propriété de transformation thermique.

Introduction

The mode of thermal decomposition of the anhydrous rare earth acetates has already been reported (1, 2) to occur via the oxycarbonate above 300 °C leading to the oxide as the final residue. The rare earth acetate hydrate was stated to release an appreciable amount of water at ~200 °C (2) as evidenced by an endotherm on the DTA heating curve.

The purpose of this paper is to report the results of a more detailed investigation of the dehydration process in the rare earth acetate hydrates up to 300 °C.

Experimental

All the rare earth acetates used in this study were prepared in this laboratory by dissolving the oxides (American Potash and Chemical Corp., Rare Earth Division, with stated purities ranging from 99.999% for Eu, 99.99% for Nd and La, to 99.9% for the remaining members of the group) in dilute acetic acid, Fisher Reagent Grade, and evaporating the solution to dryness (3). The crude acetate precipitate was recrystallized in de-ionized water followed by drying in air or vacuum.

The heating traces for thermogravimetry, differential thermal analysis, and calorimetry were recorded on a duPont Thermal Analyser, DTA-900 and TGA-950 with the appropriate accessories and programming adjustments, as previously described (4, 5). The heating rate used for the heating curves was 20 °C/min; an ambient atmosphere of dry N_2 (Matheson prepurified grade with stated impurity of 0.003% oxygen) was maintained during all the experiments except where otherwise specified.

The X-ray diffraction patterns of the samples were recorded on a Norelco X-ray diffractometer unit using CuK_α radiation or MoK_α radiation (6).

The infrared spectra were obtained by using the standard KBr and CsI disc technique in a Perkin–Elmer 180 spectrophotometer equipped with a high temperature cell, maximum 350 °C.

Results and Discussion

The results described below for $Eu(CH_3COO)_3$ are representative of the rare earth acetate group studied.

A table of results of thermogravimetry leading to the three product stages (Table 1) is placed with the Depository of Unpublished Data;[1] the agreement between the calculated and observed percentage weight losses is within the expected experimental limits. A typical TG curve of the rare earth acetate hydrate is represented by $Eu(CH_3COO)_3 \cdot H_2O$) in Fig. 1. The trace shows that after the initial dehydration process, a plateau persisted over two heat–cool cycles in a static atmosphere of the dehydrated gaseous products in the temperature interval 50–250 °C. Furthermore, no weight change is indicated in N_2 atmosphere between 170 and 350 °C.

The DTA behavior of the acetate hydrates up to 250 °C is also represented by $Eu(CH_3COO)_3 \cdot H_2O$ in Fig. 2. The first heating cycle revealed an asymmetric endotherm doublet at 100 °C and a less intense second endotherm at 155 °C, curve 1; no thermal effect appeared on cooling from 180 °C, curve 1′. The weak endotherm at 155 °C was not reproducible and was ascribed to the release of occluded H_2O re-

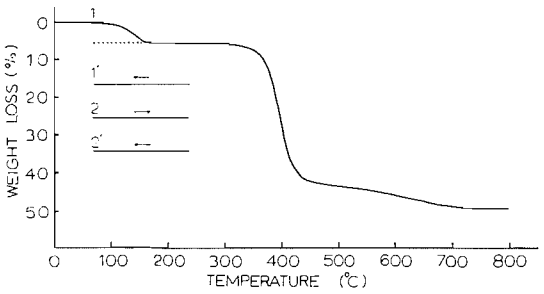

FIG. 1. Thermogravimetric trace of $Eu(CH_3COO)_3 \cdot H_2O$. Curve *1*: first heating cycle stopped at 250 °C; curve *1'*: cooling cycle; curve *2*: second heating cycle; curve *2'*: second cooling cycle; curve (···—): third heating cycle carried to 800 °C.

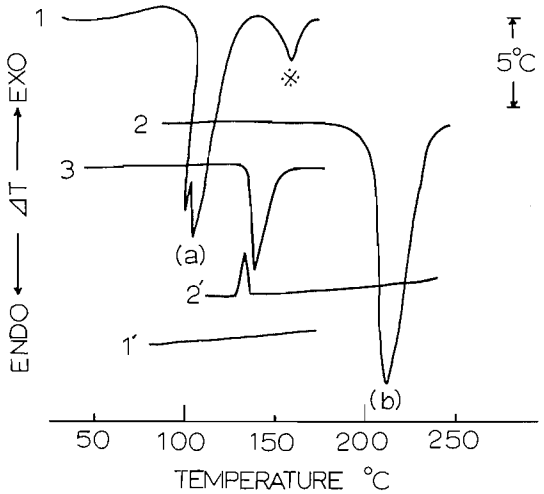

FIG. 2. Differential thermal analysis of $Eu(CH_3COO)_3 \cdot H_2O$. Curve *1*: first heating cycle; curve *1'*: cooling cycle; curve *2*: second heating cycle; curve *2'*: cooling cycle; curve *3*: third heating cycle; peak (*a*): dehydration; peak ·※·: occluded H_2O; peak (*b*): polymeric → monodentate transition.

sulting from dehydration; this endotherm was assessed to be a function of physical factors, such as sample packing, quantity of sample, etc. The second heating cycle, curve 2, showed an intense endotherm at 220 °C which was previously attributed to the final dehydration state (2); cooling the sample from 250 °C revealed a weak exotherm at 130 °C, curve 2'. The third heating cycle, curve 3, showed the reversible thermal effect near 130 °C.

To identify the origin of the endotherms at 155 and 220 °C, the i.r. spectra of the acetate hydrate were recorded at different temperatures

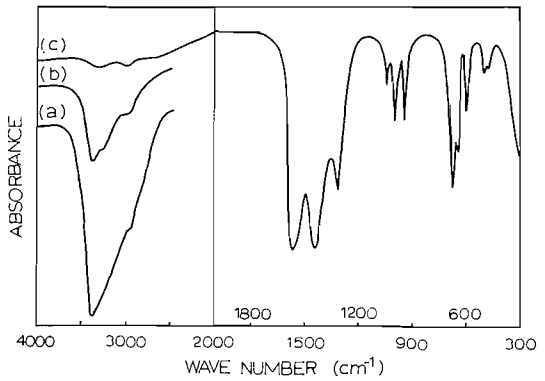

FIG. 3. Infrared spectra of $Eu(CH_3COO)_3 \cdot H_2O$ in high temperature cell. (*a*) room temperature; (*b*) 120 °C; (*c*) 175 °C.

and displayed in Fig. 3. There is no evidence of the characteristic water absorption bands in the spectrum at 175 °C. The assignment of dehydration to the 220 °C must be ruled out on the basis of i.r. and thermogravimetry. No melting action or gas evolution was discernible on the melting point apparatus up to 270 °C. The endotherm at 220 °C was determined by calorimetry to have an enthalpy value of 7.1 ± 0.2 kcal/mol.

The reversible thermal effect at 130–140 °C, hitherto unreported in the literature, attracted our attention; this effect was invariably preceded by the 220 °C endotherm for $Eu(CH_3COO)_3$. This reversible DTA effect was observed in the rare earth acetate series from Sm to Lu excepting Pm; the acetates of La, Pr, and Nd did not display this thermal effect.

X-Ray diffraction patterns of $Eu(CH_3COO)_3$ hydrate, after heating to 200 °C, taken at room temperature were similar to that reported by Karraker (8). However, all the characteristic diffraction peaks disappeared after subsequent heating to 220 °C suggesting a structural transition to an amorphous state. Examination of the sample on the melting apparatus exhibited no discernible melting action.

The i.r. spectra of anhydrous $Eu(CH_3COO)_3$ dried at 200 °C, recorded during some heat–cool cycles, are presented in Fig. 4. The faint doublet on trace (1) at room temperature merges into a single band at 80–90 °C, trace (2). Heating the sample to 220 °C shifts the peak by 10 cm^{-1}, trace (3). Trace (4) is the spec-

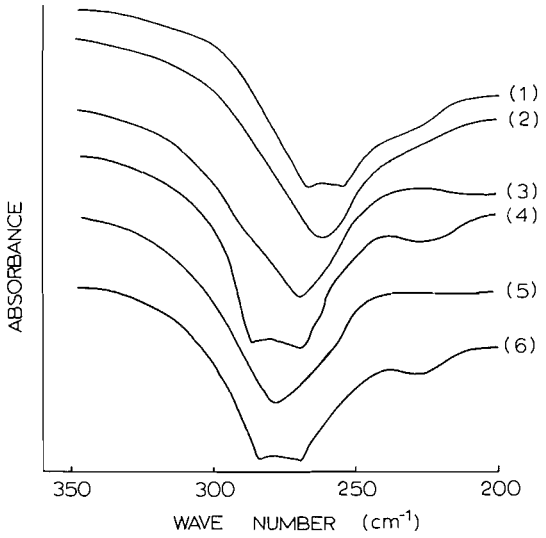

FIG. 4. Infrared spectra of $Eu(CH_3COO)_3$ in frequency region where effect of heat treatment is observed. (*1*) room temperature, after heating to 200 °C; (*2*) 80–90 °C; (*3*) 220 °C; (*4*) room temperature, after heating to 220 °C; (*5*) 160–170 °C; (*6*) room temperature, after heating to 160–170 °C.

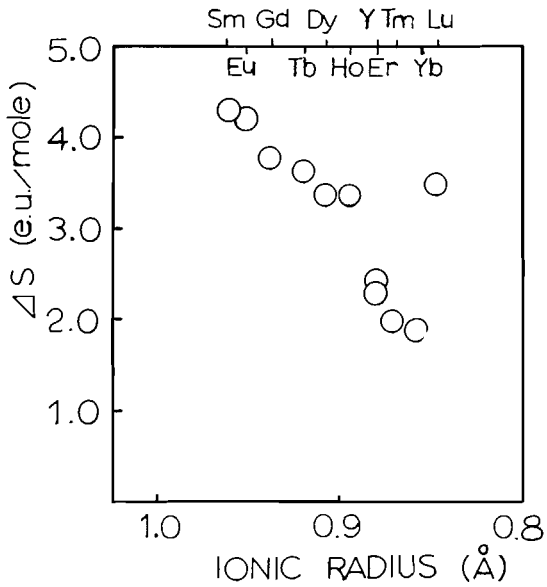

FIG. 5. Plot of ΔS *vs.* ionic radius of rare earth element ion.

trum at room temperature after heating to 220 °C. Trace (5) is the spectrum at 160–170 °C and trace (6) is the room temperature spectrum after heating to 160–170 °C.

The peak temperatures of the exo- and endotherms, along with the enthalpy and entropy values accompanying the transformation were determined. A table of these numerical results (Table 2) is placed with the Depository of Unpublished Data.[1] The plot of ΔS *vs.* ionic size, Fig. 5, shows a direct relationship, with discontinuities discernible (*i*) between Ho and Er, and (*ii*) at Lu. These discontinuities are consistent with the differences in coordination number of the central ions (8).

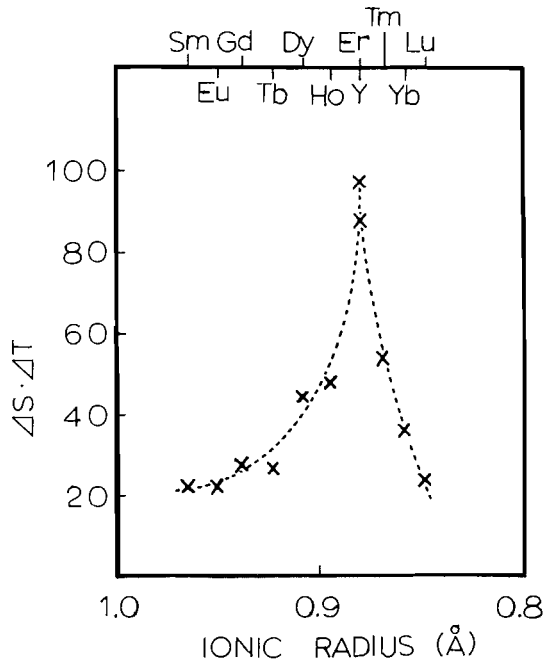

FIG. 6. Plot of $\Delta T.\Delta S$ *vs.* ionic radius of rare earth element ion.

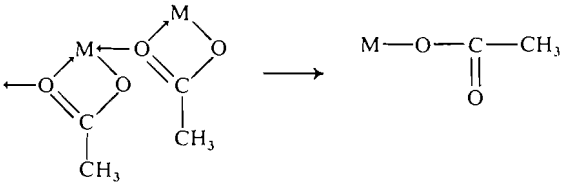
The reported peak temperatures[1] of the exo- and endotherms show thermal hysteresis effects, ΔT characteristic of many reversible transformations, $\Delta T = T_p^f - T_p^r$, where T_p^f represents the peak temperature on heating and T_p^r the peak temperature on cooling. It has been pointed out (7) that hysteresis is a necessary consequence of the coexistence mechanism of continuous transformations with the main factor controlling the hysteresis being the strain energy E_s and that thermodynamic considerations relate the strain energy to $\Delta T.\Delta S$, *i.e.*, $E_s \propto \Delta T.\Delta S$. The plot of $\Delta T.\Delta S$ *vs.* ionic size, Fig. 6, exhibits a lambda-type relationship with a maximum at Er and Y. This maximum in strain energy could be interpreted in terms of a mixed coordination number in Er and Y

acetates consistent with previously reported observations (8).

Infrared evidence does not support an intramolecular configurational rearrangement as in tautomerism for the reversible phenomenon at 130–140 °C. The alteration in the i.r. absorption bands does suggest, however, the possibility of a polymeric–bidentate–monodentate transition phenomenon as postulated by Karraker (8). The observed transitions are assigned to $M(CH_3COO)_3$ as follows:

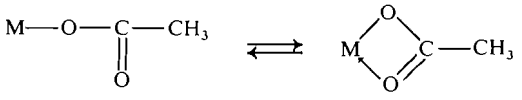
(1) Irreversible endotherm occurring at 220 °C involving 7.1 kcal/mol

polymeric ⟶ monodentate



(2) Reversible endotherm occurring at 140 °C involving 1.7 kcal/mol

monodentate $\underset{\text{heating}}{\overset{\text{cooling}}{\rightleftharpoons}}$ bidentate



The rupture of the inter-and intramolecular O → M bonds is the critical action on heating to 220 °C and the subsequent formation of the intramolecular O → M on cooling. The change in i.r. band profile and shift of 10–25 cm^{-1} may be expected for ν_{O-M} and δ_{O-M-O} in the polymeric–bidentate–monodentate transition.

On the basis of the transformation enthalpy values, *viz.* 7.1 ± 0.2 kcal/mol at 220 °C and 1.7 ± 0.1 kcal/mol at 140 °C, we assess the multiplicity of the polymeric state to be *ca.* 4.

A Novel Solution to the Master Equation for Chemical Reaction

R. K. BOYD

Chemistry Department, University of Guelph, Guelph, Ontario

Received May 8, 1972

It was found by McElwain and Pritchard (1*c*), as a result of numerical experiments on the transport matrix for the dissociation of H_2, that an apparent correspondence existed between the eigenvalues λ_i and the pairs of transition probabilities $(A_{i,i-1}; A_{i-1,i})$. In the present work, a qualitative understanding of this result is attempted, using an unusual form of solution of the master equation.

McElwain et Pritchard (1*c*) ont trouvé qu'il existe une correspondance apparente entre les valeurs quantifiées λ_i et les paires de probabilités de transition $(A_{i,i-1}; A_{i-1,i})$, à la suite de nombreuses expériences sur la matrice de transport de la dissociation de H_2. Nous tentons, dans ce présent travail, d'illustrer ce résultat de façon qualitative, au moyen d'une forme inhabituelle de solution de l'équation principale.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3104 (1972)

Pritchard and his collaborators (1) have devised very efficient computer techniques for obtaining numerical solutions to the master equation for dissociation of a diatomic gas dispersed in high dilution in some inert gas M. The development of these techniques has permitted various numerical experiments to be performed, which have led to an increased understanding of such problems as the bottleneck phenomenon (1*d*). The intention of the present work is to attempt to improve the qualitative understanding of one particular result obtained by these workers (1*c*).

For present purposes, it is sufficient to consider a simplified system of n interconverting levels, with one level (say level n) designated a no-return level; it will prove convenient to assume that these levels are numbered in order of increasing energy. Then the master equation for levels 1 to $(n-1)$ may be written as

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix} x_1 \\ x_2 \\ \cdot \\ \cdot \\ \cdot \\ \cdot \\ x_n \end{pmatrix} = \begin{pmatrix} -\alpha_1 & A_{12} & \cdot & \cdot & \cdot & \cdot & A_{n-1,1} \\ A_{21} & -\alpha_2 & & & & & \cdot \\ \cdot & & \cdot & & & & \cdot \\ \cdot & & & \cdot & & & \cdot \\ \cdot & & & & \cdot & & \cdot \\ \cdot & & & & & \cdot & \cdot \\ A_{n-1,1} & \cdot & \cdot & \cdot & \cdot & \cdot & -\alpha_n \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ \cdot \\ \cdot \\ \cdot \\ \cdot \\ x_n \end{pmatrix} \qquad [1]$$

where $x_i(t)$ is the instantaneous concentration of molecules in level i, A_{ij} is the pseudo-first-order rate constant for $j \rightarrow i$ transitions, and

$$\alpha_i = \sum_{\substack{j=1 \\ \neq i}}^{n} A_{ji},$$

the total rate constant for depopulation of level i; clearly, $x_i(\infty) = 0$, in this model, for $i < n$. By defining $\xi_i(t) = x_i/\tilde{x}_i$, where $\tilde{x}_i$ is the local equilibrium population (*i.e.*, the equilibrium population in the limit where transitions into level n are not permitted), and using detailed balance, eq. 1 may

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

be rewritten (1) as

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\xi_1\\ \xi_2\\ \cdot\\ \cdot\\ \cdot\\ \cdot\\ \xi_n\end{pmatrix}=\begin{pmatrix}-\alpha_1 & A_{21} & \cdot & \cdot & \cdot & \cdot & A_{n-1,1}\\ A_{12} & -\alpha_2 & & & & & \cdot\\ \cdot & & \cdot & & & & \cdot\\ \cdot & & & \cdot & & & \cdot\\ \cdot & & & & \cdot & & \cdot\\ \cdot & & & & & \cdot & \cdot\\ A_{1,n-1} & \cdot & \cdot & \cdot & \cdot & \cdot & -\alpha_{n-1}\end{pmatrix}\begin{pmatrix}\xi_1\\ \xi_2\\ \cdot\\ \cdot\\ \cdot\\ \cdot\\ \xi_n\end{pmatrix}$$

or, in matrix notation

$$[2]\qquad (\mathrm{d}/\mathrm{d}t)|\xi\rangle = \mathbf{A}_0|\xi\rangle$$

The usual analytic solution to this equation is

$$[3]\qquad \xi_i(t) = \sum_{r=1}^{n-1} C_r\phi_r^0(i)\exp(\lambda_r^0 t)$$

where the C_r are constants determined by the initial conditions, $\phi_r^0(i)$ is the ith component of the rth eigenvector of $\mathbf{A}_0$, and λ_r^0 is the rth eigenvalue. The λ_r are real and negative, and are hereinafter assumed to be labelled in order of increasing absolute magnitude, *i.e.*, $|\lambda_1| < |\lambda_2|$, etc.

The unexpected result obtained by McElwain and Pritchard (1*c*), referred to above, involved an approximate one-to-one correspondence between the eigenvalues λ_r^0, and the pairs of rate constants $(A_{r,r-1}; A_{r-1,r})$. Thus, scaling the latter by some factor resulted (1*c*) in similar scaling of the corresponding eigenvalue, with only mild perturbations of neighboring eigenvalues; this correspondence was not exact, and became less apparent for the highest-energy levels, from which dissociation could occur directly (1). That the qualitative meaning of this *numerical* result is unclear may be conveniently shown as follows; let the pair of rate constants $(A_{i,i-1}; A_{i-1,i})$ be increased by the *same* factor $(b+1)$ (thus preserving detailed balance), so that the new perturbed transport matrix may be written as

$$\mathbf{A} = \mathbf{A}_0 + \mathbf{A}'$$

where $\mathbf{A}_0$ is as given in eq. 2, and

$$\mathbf{A}' = \begin{pmatrix}\cdot & & & & & & 0 & & \\ & \cdot & & & & & & & \\ & & \cdot & & & & & & \\ & & & 0 & & & & & \\ & & & 0 & (-bA_{i,i-1}) & (bA_{i,i-1}) & 0 & & \\ & & & 0 & (bA_{i-1,i}) & (-bA_{i-1,i}) & 0 & & \\ & & & & & & 0 & & \\ & & & & & & & \cdot & \\ & & & & & & & & \cdot \\ & & 0 & & & & & & \cdot\end{pmatrix}$$

The first-order perturbation correction to λ_r^0 is

$$[4]\qquad \lambda_r' = \langle\phi_r^0|\mathbf{A}'\phi_r^0\rangle = b[\phi_r^0(i) - \phi_r^0(i-1)][A_{i,i-1}\phi_r^0(i-1) - A_{i-1,i}\phi_r^0(i)]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Equation 4 gives an accurate estimate of λ'_r provided b is sufficiently small; this was not true of the factors used by McElwain and Pritchard (1*c*), but the qualitative difficulty is now more explicit, *viz.* how can the results $\lambda'_i \approx b\lambda_i^0$ and $\lambda'_{r\neq i} \approx 0$, be accounted for, bearing in mind that each of the $\phi_r(i)$ is a complicated function of *all* the A_{ij}?

It should first be noted that scaling the pair of rate constants $(A_{i,i-1}; A_{i-1,i})$ by a factor $(b+1)$ implies that

$$\alpha_i = \sum_{\substack{j=1 \\ \neq i}}^{n} A_{ji}$$

is approximately scaled by $(b+1)$, while α_{i-1} is only mildly perturbed. This is because $(A_{i-1,i}/A_{i,i-1}) \gg 1$, due to the large Boltzmann factors corresponding to the vibrational spacings in H_2 at 2000 to 3000 °K (1); in addition, the rate constants for multiple-quantum transitions were considerably smaller (1) than those for nearest-neighbor transitions. Thus, to this degree of approximation, what is sought is a correspondence between the α_i and the λ_i^0. The most obvious mathematical condition under which this correspondence would be *exact* requires $\mathbf{A}_0$ to be a triangular matrix, since the α_i form the main diagonal elements. If $\mathbf{A}_0$ were, for example, a lower triangular matrix, with $A_{ij} = 0$ for $j \leqslant i$, the corresponding physical picture would be a completely irreversible one-way cascade, with no upward transitions; the λ_r^0 in eq. 3 could then be replaced by the entirely equivalent $(-\alpha_r)$.

This same result for this very special case will now be derived by an alternative method due to Curtis (2); this method, which bears a certain resemblance to the "many-shot" expansion technique of Serauskas and Schlag (3), will be briefly applied to the one-way cascade model (2), to establish notation, and then extended to the present, more general, problem. For the special case of a one-way downwards cascade, eq. 2 may be rewritten as

$$0 = [1]\, d\xi_i + \left[\sum_{j=i+1}^{n-1} A_{ji}\xi_j(t) - \alpha_i\xi_i\right] dt$$

which is readily integrated, using $\exp(\alpha_i t)$ as an integrating factor (2), to give

$$[5] \qquad \xi_i(t) = \xi_i(0)\exp(-\alpha_i t) + \sum_{j=i+1}^{n-1}\left[A_{ji}\int_{t'=0}^{t}\exp(\alpha_i t')\xi_j(t')\,dt'\right]$$

where

$$\alpha_i = \sum_{j=1}^{i-1} A_{ji}$$

for the present one-way model. Since ξ appears on both sides of eq. 5, it may be successively iterated (2) to yield a series of nested sums and nested integrals

$$[6] \quad \xi_i(t) = \exp(-\alpha_i t)\left\{\xi_i(0) + \sum_{j=i+1}^{n-1}\xi_j(0)A_{ji}\int_{t'=0}^{t}\exp[(\alpha_i-\alpha_j)t']\,dt' + \sum_{j=i+1}^{n-1}\sum_{k=j+1}^{n-1}\xi_k(0)A_{ji}A_{kj}\int_{t'=0}^{t}\exp[(\alpha_i-\alpha_j)t']\int_{t''=0}^{t'}\exp[(\alpha_j-\alpha_k)t'']\,dt''\,dt' + \cdots\right\}$$

Due to the completely irreversible nature of the one-way cascade, this series terminates when the upper and lower limits of the most interior summation coincide. Each order of the series contains all those cascades which move from initial levels to the level of interest in a number of steps equal to the order of the term (2). Furthermore, the integrals are all straightforward, and may be performed exactly. Thus, for example, the contribution to $\xi_i(t)$ by a two-step cascade into level i is given by

$$[7] \qquad \{k \to j \to i\} = \xi_k(0)A_{kj}A_{ji}\left[\frac{\exp(-\alpha_k t)}{(\alpha_j-\alpha_k)(\alpha_i-\alpha_k)} + \frac{\exp(-\alpha_j t)}{(\alpha_k-\alpha_j)(\alpha_i-\alpha_j)} + \frac{\exp(-\alpha_i t)}{(\alpha_k-\alpha_i)(\alpha_j-\alpha_i)}\right]$$

For this completely irreversible case (2), the general contribution to $\xi_i(t)$ is

$$[8] \quad \{v \to u \to \cdots \to k \to j \to i\} = \xi_v(0)\left[\prod_{(x,y)=(u,v)}^{(j,i)} (A_{x,y})\right]\left\{\sum_{z=v}^{i}\left[\exp(-\alpha_z t)\Big/\prod_{\substack{w=v \\ \neq z}}^{i}(\alpha_w - \alpha_z)\right]\right\}$$

By collecting together terms involving $\exp(-\alpha_r t)$ for each r, an expression for $\xi_i(t)$ of the form [3], with each eigenvalue λ_r^0 replaced by the corresponding $(-\alpha_r)$, is obtained as required.

When a more realistic case is considered, wherein both upward and downward transitions are allowed, the matrix $\mathbf{A}_0$ is no longer triangular, and the problem exemplified by eq. 4 remains. However, it is still possible to obtain a solution for $\xi_i(t)$ analogous to eq. 5, since $\exp(\alpha_i t)$ is again an integrating factor; the difference lies in the limits of the nested sums. Whereas in eq. 6 the lower limits of the sums progressively approached the upper limit (reflecting the one-way nature of the model), the summations are now all unrestricted. The expansion of $\xi_i(t)$ thus does not terminate, but this occurs in a particular fashion; eq. 8, derived for the one-way cascade, still holds provided no two of the states $\{v, u, \ldots, k, j, i\}$ are identical. When a state is repeated in the sequence, the coefficient of the corresponding exponential contains time explicitly. Thus, the simplest conceivable example of such a repetition is

$$\{i \to j \to i\} = \xi_i(0)A_{ji}A_{ij}\left[\frac{\exp(-\alpha_j t)}{(\alpha_i - \alpha_j)^2} + \frac{\exp(-\alpha_i t)}{(\alpha_j - \alpha_i)(\alpha_i - \alpha_j)} + \frac{\exp(-\alpha_i t)}{(\alpha_j - \alpha_i)}\,t\right]$$

In general, the highest power of t in the coefficient of an exponential corresponds to the number of repetitions of the corresponding level in the sequence. Some examples are

$$\{j \to i \to j \to i\} = \xi_j(0)A_{ji}^2 A_{ij}\left[\frac{2\exp(-\alpha_j t)}{(\alpha_j - \alpha_i)^3} + \frac{2\exp(-\alpha_i t)}{(\alpha_i - \alpha_j)^3} + \frac{\exp(-\alpha_j t)}{(\alpha_i - \alpha_j)^2}\,t + \frac{\exp(-\alpha_i t)}{(\alpha_j - \alpha_i)^2}\,t\right]$$

$$\{i \to l \to i \to j \to i\} = \xi_i(0)A_{ji}A_{ij}A_{li}A_{il}\left[\frac{\exp(-\alpha_i t)}{(\alpha_l - \alpha_i)}\left\{\frac{t^2}{2(\alpha_j - \alpha_i)} + \frac{t}{(\alpha_l - \alpha_i)(\alpha_i - \alpha_j)} + \frac{t}{(\alpha_j - \alpha_i)(\alpha_i - \alpha_j)}\right.\right.$$
$$\left.\left. + \frac{1}{(\alpha_l - \alpha_i)^2(\alpha_j - \alpha_l)} + \frac{(\alpha_l - \alpha_i)}{(\alpha_j - \alpha_i)^3(\alpha_l - \alpha_j)}\right\} + \frac{\exp(-\alpha_l t)}{(\alpha_i - \alpha_l)^3(\alpha_j - \alpha_l)} + \frac{\exp(-\alpha_j t)}{(\alpha_i - \alpha_j)^3(\alpha_l - \alpha_j)}\right]$$

$$\{i \to m \to i \to l \to i \to j \to i\} = \xi_i(0)A_{ji}A_{ij}A_{li}A_{il}A_{mi}A_{im}$$
$$\times\left\{\frac{\exp(-\alpha_i t)}{(\alpha_m - \alpha_i)}\left[\frac{t^3}{6(\alpha_l - \alpha_i)(\alpha_j - \alpha_i)} + \frac{t^2}{2(\alpha_j - \alpha_i)^2(\alpha_i - \alpha_l)} + \frac{t^2}{2(\alpha_l - \alpha_i)^2(\alpha_i - \alpha_j)}\right.\right.$$
$$\left.\left. + \frac{t^2}{2(\alpha_i - \alpha_m)(\alpha_l - \alpha_i)(\alpha_j - \alpha_i)} + (\text{terms in } t) + (\text{terms independent of } t)\right] + (\text{other exponentials})\right\}$$

Thus, although $\xi_i(t)$ may still be expanded as a sum of exponentials $\exp(-\alpha_r t)$, the coefficients of these exponentials are explicit functions of time, unlike eq. 3, the expansion in terms of the eigenvalues. Any correspondence between the α_r and λ_r^0 can now be only approximate, and its existence will clearly depend on whether or not the coefficients of the $\{\exp(-\alpha_r t)\}$ converge to limiting values more rapidly than the exponentials themselves. If such were true, so that the time-dependence of the coefficients was relatively weak, an approximate correspondence between the α_r and λ_r^0 should exist, since the two expansions for $\xi_i(t)$ must be identical for all times and for all initial conditions. The physical meaning of this required weak time-dependence may be seen from the above discussion; the time-dependence arose from the repetition of levels along a given sequence. Any factor tending to make such a repetition less likely should weaken the time-dependence of the coefficients, and thus strengthen the correspondence between the α_r and λ_r^0. On purely statistical grounds, an increase in the number of levels considered would presumably create such an effect. On the other hand, a general equalization of the A_{ij} would tend to produce

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the opposite effect, since the probability of a return to a given level would be thereby increased; an increase in temperature, or increase in the number of levels for a given dissociation energy, (*e.g.* D_2 instead of H_2) would cause such an equalization. At the opposite extreme is the one-way model (2), where the transition probabilities are completely imbalanced, and the correspondence is exact.

It has been pointed out by a referee that certain general aspects of the present problem were considered some time ago by Carrington (4). In particular, Carrington discussed the effect of a perturbation of the transport matrix, similar to that described here, on the (observable) population distribution; the extremely important converse problem of the effect of small differences, in observed populations, on the deduced transition probabilities, was also treated in detail (4). However, the present, rather more specialized, problem was not treated (4), as the numerical results of Pritchard and co-workers (1) were not then available.

As observed above, the expansion technique of Curtis (2), as applied and extended here, bears some resemblance to the many-shot expansion (3); this relationship may be summarized, in very general terms, by the observation that the latter is essentially an expansion around the strong collision (one-shot) approximation, while the former expands around the one-way cascade.

Free Radical Bromination of Saturated Hydrocarbons using Bromine and Mercuric Oxide

N. J. BUNCE

Department of Chemistry, University of Guelph, Guelph, Ontario

Received March 14, 1972

The reaction of alkanes with a mixture of bromine and mercuric oxide gives alkyl bromides in preparatively useful yields. The reagent is significantly more reactive than elemental bromine, and it is believed that bromine monoxide, formed *in situ* by the interaction of bromine and mercury oxide, is the reactive intermediate. Bromination by bromine monoxide is a free radical chain process in which hydrogen abstraction is carried out predominantly by bromoxy (BrO·) radicals, and to a lesser extent by bromine atoms.

La réaction des alcanes sur un mélange de brome et d'oxyde mercurique, conduit aux bromures d'alkyles avec des rendements utiles à l'échelle préparative. Le réactif possède une réactivité nettement plus grande que le brome élémentaire et on pense que l'intermédiaire réactif est le monoxyde de brome formé *in situ* dans la réaction du brome sur l'oxyde mercurique. La bromation par le monoxyde de brome est un processus en chaîne par radicaux libres, dans lequel l'arrachement de l'hydrogène est réalisé de façon prédominante par les radicaux bromoxy (BrO·) et à une échelle moindre, par les atomes de brome.

In the course of extending our studies on the bromodecarboxylation of carboxylic acids using bromine and mercuric oxide (1), it was observed that treatment of acid chlorides (2) with bromine and mercuric oxide in tetrachloroethane solution led to consumption of the bromine without the formation of any decarboxylated products. Control experiments showed that bromine is not appreciably reactive towards refluxing tetrachloroethane, but that addition of mercuric oxide to the hot solution causes a vigorous reaction to ensue with the production of bromotetrachloroethane. It was thus apparent that bromine and mercuric oxide constitute a brominating agent more reactive than elemental bromine alone, and the present study was undertaken to investigate the synthetic scope of the reaction and to try to elucidate details of its mechanism.

Synthesis of Alkyl Bromides

Photobromination of alkanes as a synthetic procedure has the disadvantages of giving an obnoxious byproduct, HBr, and of being inconveniently slow for many substrates. Attack on methyl groups is particularly slow, and alkanes such as neopentane are essentially unreactive except above 100° (3). Alkanes bearing electron withdrawing polar substituents also react very sluggishly, an extreme case being chloroform (4) for which bromination is reversible, the equilibrium favoring bromotrichloromethane only slightly. Using mercury oxide and bromine, however, chloroform reacts rapidly at reflux giving a good yield of bromide, and even 2,2,3,3-tetramethylbutane gives the corresponding primary bromide easily. Since no hydrogen bromide is evolved in these reactions, they may be carried out successfully in the open laboratory.

More reactive substrates such as cyclohexane react quite violently at reflux, and within a few minutes at room temperature if the alkane is in excess and the mixture is well stirred. For this substrate the stoichiometry of the reaction is represented approximately by eq. 1, although as may be seen from the results of quantitative experiments listed in Table 1, additional mercuric bromide is consistently formed at the expense of some of the alkyl bromide.

$$[1] \quad 2RH + 2Br_2 + HgO \rightarrow 2RBr + H_2O + HgBr_2$$

The yield of bromide is little affected by changes in reaction temperature or concentration of reagents and better than 90% of the initial bromine concentration can consistently be accounted for. The expense of using mercuric oxide as a reagent is offset by its ease of recovery from the mercuric oxide/mercuric bromide residue (5).

While the reaction is thus applicable to substitution of primary and secondary C—H

bonds, bromination at tertiary positions is less successful. For example 2,3-dimethylbutane affords almost no 2-bromo-2,3-dimethylbutane, but gives a complex mixture in which 2,3-dibromo-2,3-dimethylbutane predominates. A similar problem attends the bromination of this substrate with elemental bromine (6) where it is believed that the first formed monobromide undergoes a subsequent dark reaction with molecular bromine.

Something of the scope of the new reaction is seen from Table 2, where the action of bromine and mercuric oxide is documented for several substrates.[1] Alkylbenzenes are unsuitable for side chain attack with this reagent as nuclear bromination occurs rather readily. Thus *t*-butylbenzene exclusively, and *p*-xylene chiefly afford the aryl bromide, although *p*-nitrotoluene, being less susceptible to electrophilic substitution, gives a moderate yield of the benzylic bromide. This competing reaction is not a serious limitation since benzylic groups may be brominated conveniently using either elemental bromine or *N*-bromosuccinimide (NBS) (7–10). The nuclear bromination was not further investigated since the reaction appears to offer no advantage over conventional (11) methods of electrophilic bromination.

[1]An attempt to extend the reaction to the synthesis of alkyl iodides using iodine and mercuric oxide was unsuccessful.

Possible Reaction Mechanisms

The observation of short induction periods in some of the reactions already described suggests a free radical chain mechanism. Confirmation of this idea was obtained in a qualitative study of the rate of bromination of cyclohexane under various conditions, see Table 3. While light acts as a promoter for the reaction, oxygen, iodine,[2] galvinoxyl, and *t*-butyl mercaptan are inhibitors.

Two distinct free radical chain pathways can be proposed for the reaction, and are represented as mechanisms A and B.

Mechanism A

[2] $$Br_2 + RH \rightarrow HBr + RBr$$

[3] $$2HBr + HgO \rightarrow HgBr_2 + H_2O$$

[2]On the assumption that the inhibiting action of iodine is by way of the reaction $R^{\cdot} + I_2 \rightarrow RI + I^{\cdot}$, an attempt was made to prepare iodocyclohexane using cyclohexane, mercuric oxide, and a mixture of iodine and bromine; *cf.* the method of Speier (12) for bromination using a mixture of chlorine and bromine. No iodocyclohexane was obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Mechanism B

[4] $2Br_2 + HgO \rightarrow HgBr_2 + Br_2O$

[5] $Br_2O + 2RH \rightarrow 2RBr + H_2O$

In mechanism A, bromination is envisioned as a normal free radical bromination where reaction 2 is comprised of the sequence [2*a*], [2*b*], and the mercury oxide serves simply to remove the hydrogen bromide formed in reaction 2.

[2*a*] $Br^{\cdot} + RH \rightleftharpoons HBr + R^{\cdot}$

[2*b*] $R^{\cdot} + Br_2 \rightarrow RBr + Br^{\cdot}$

This sequence could account for the increased reactivity of the reagent over elemental bromine as follows. Abstraction of hydrogen by bromine atoms is well known to be reversible (10, 13–16); the reverse of reaction 2*a* serves both to slow the reaction down and to increase the proportion of products derived from more stable radicals at the expense of those formed from less stable radicals (17). If the removal of hydrogen bromide by mercuric oxide were fast, the reverse of hydrogen abstraction would be suppressed with a corresponding increase in the apparent reactivity of the reagent.

In mechanism B, it is proposed that bromine and mercury oxide first interact to form bromine monoxide, a precedented process (18, 19). Bromination of the alkane is then effected by bromine monoxide rather than molecular bromine; again this will result in increased reactivity if bromine monoxide is a more reactive brominating agent than bromine itself. Although this seems a plausible argument, there are no data reported for bromine monoxide, the closest analogy being the reaction of chlorine monoxide with alkanes (20, 21). A detailed study by Tanner and Nychka (21) indicated that in CCl_4 solution chlorine monoxide chlorinates by way of the chain sequence [6]–[11] where hydrogen abstraction is accomplished by $Cl^{\cdot}$ and $ClO^{\cdot}$ radicals.

[6] $RH + ClO^{\cdot} \rightarrow HOCl + R^{\cdot}$

[7] $R^{\cdot} + Cl_2O \rightarrow RCl + ClO^{\cdot}$

[8] $RH + Cl^{\cdot} \rightarrow R^{\cdot} + HCl$

[9] $HCl + HOCl \rightarrow Cl_2 + H_2O$

[10] $R^{\cdot} + Cl_2 \rightarrow RCl + Cl^{\cdot}$

[11] $2HOCl \rightleftharpoons Cl_2O + H_2O$

Previously Phillips and Shaw (20) had found that in the gas phase at 100° the sequence [6]–[7] accounted for the reaction at low conversions of chlorine monoxide. Likewise Tanner and Nychka found that the product distribution from the chlorination of 1-chloropropane by chlorine monoxide in CCl_4 varied with percentage conversion. This also may be interpreted to mean that reactions 6 and 7 predominate early in the reaction when little HOCl has become available to undergo steps [9] and [11] of the complete scheme.

Distinction between mechanisms A and B is difficult for the following reasons. For mechanism A there is the problem of determining the "true" reactivity of the bromine atom in the absence of reversible hydrogen abstraction, for comparison with the new reagent. In this paper data on bromine atom abstraction have been taken from the literature only when it is clear whether or not abstraction was reversible. For mechanism B where bromine monoxide is the brominating agent there is the difficulty that no data on Br_2O are available, and it is not known, moreover, whether bromination by bromine monoxide would be mechanistically similar to chlorination by chlorine monoxide.

method of comparing the reactivities of different hydrogen abstracting radicals is through their selectivities, defined as the ratio per hydrogen of the rate constants for attack on hydrogen atoms in primary, secondary, and tertiary environments. The data for HgO/Br_2, calculated from Table 4 and from the isomer ratio in the bromination of *n*-hexane, are given in Table 5, together with data for other reagents.

From Table 5 it is clear that the abstracting species from the HgO/Br_2 reagent is of intermediate reactivity, along with typical oxyradicals. It is neither as reactive as atomic chlorine, nor as selective as the trichloromethyl radical or the bromine atom.[3]

It was demonstrated that hydrogen abstraction by the new reagent is not significantly reversible. A mixture of cyclohexane and cyclohexane-d_{12} was brominated with HgO/Br_2; the excess of the alkane mixture was recovered and shown by mass spectrometry not to have undergone any scrambling of the protium and deuterium (17).

$$[12] \qquad Br^{\cdot} + RH \rightarrow HBr + R^{\cdot}$$

$$[13] \qquad HBr + (CH_2CO)_2NBr \rightarrow Br_2 + (CH_2CO)_2NH$$

$$[14] \qquad R^{\cdot} + Br_2 \rightarrow RBr + Br^{\cdot}$$

[3]The data on bromine atoms were obtained using NBS as the brominating agent, to minimize reversible hydrogen abstraction. From the accepted (10) mechanism for NBS brominations, the hydrogen bromide is removed by reaction with NBS, and is thus unavailable for reversal with $R^{\cdot}$.

The selectivity of the HgO/Br_2 reagent was also compared with that due to bromine monoxide, and found to be closely similar. Both reagents however exhibit a selectivity rather greater than that of other typical oxyradical abstractors, and it would be reasonable to suppose that a mechanism analogous to eq. 6–11 would account for this, with abstraction by the more reactive bromoxy ($BrO^{\cdot}$) radical predominating over the unreactive bromine atom.

Another measure of the reactivity of a free radical is the primary deuterium isotope effect for hydrogen abstraction. For the HgO/Br_2 reagent k^H/k^D was found to be 2.6 for cyclohexane, and 7.0 for the less reactive substrate, chloroform (Table 6). This increase in k^H/k^D for a deactivated substrate is expected because of the larger activation energy for abstraction from the less reactive material (28), and makes comparison of the HgO/Br_2 data with those reported for other radicals difficult, since not all investigators have used the same hydrocarbon substrate. Thus we would expect that for bromine atom abstractions k^H/k^D (cyclohexane) would be larger than the value observed for toluene because toluene is the more reactive substrate towards this radical (29). For the *t*-butoxy radical k^H/k^D for cyclohexane is smaller than the value reported for toluene (30) since in this case cyclohexane is the more reactive hydrocarbon (32).

†Early stages of reaction.
‡Completion of reaction.

Although fewer comparative data are available for isotope effects than for selectivity, it is again clear from Table 6 that the new reagent is more reactive than atomic bromine, comparably reactive with an oxyradical, and less reactive than atomic chlorine.

Polar Effects

The response of a radical to a polar effect, exemplified by discrimination against abstraction of hydrogens close to an electron-withdrawing substituent, depends on the deficiency of charge at the C—H bond under attack, and on the electronegativity of the attacking radical. It is thus a characteristic of the radical different from its selectivity or deuterium isotope effect, where bond energy considerations predominate (33). Thus the reactive but electrophilic chlorine atom attacks propionic acid mainly at the methyl group (34).

The response of the HgO/Br_2 reagent to such polar effects was measured for three substrates, 1-chloropropane, 1-chlorobutane, and 1-bromobutane. The results are presented in Table 7, with comparative data for other reagents. For all three substrates the polar effect is quite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

different from that due to molecular bromine. The case of 1-bromobutane is of interest since this substrate has recently been shown (15, 36) to suffer attack by bromine atoms quite differently according to whether abstraction by Br· is reversible or irreversible. The fact that the HgO/Br_2 reagent shows a polar effect unlike either of these two situations finally excludes abstraction by atomic bromine as the major abstraction mode.

With 1-chloropropane both the HgO/Br_2 reagent and bromine monoxide show similar polar effects, which are also strikingly similar to that observed for chlorine monoxide at low percentage conversions (21). As already mentioned, it is believed that at low conversions the chloroxy (ClO·) radical is the major hydrogen abstractor, and the polar effect thus reinforces the earlier conclusion that the HgO/Br_2 reagent and bromine monoxide both involve bromoxy radicals as the predominant hydrogen abstracting agents.

Conclusions

The reaction of alkanes with bromine and mercuric oxide appears to be a reaction of some synthetic promise; the new reagent is more reactive than elemental bromine or NBS, and might thus find application where these latter reagents are insufficiently vigorous. The reaction appears to involve bromine monoxide as the reactive brominating agent, since solutions of this substance have a reactivity very similar to that of the HgO/Br_2 reagent. Comparison of the reactivity of the reagent towards C—H bonds of different strengths, and its response to polar effects show that the reactivity is greater than that of the bromine atom, but less than that of various oxyradicals. It seems reasonable to conclude that hydrogen abstraction, which has been shown to be irreversible, is carried out mainly by bromoxy radicals, with a smaller contribution from bromine atoms. The reaction mechanism is thus analogous to that previously proposed for chlorination by Cl_2O involving chlorine atoms and chloroxy radicals. Both the selectivity and the polar effects of HgO/Br_2 and of Cl_2O are strikingly similar under conditions where the latter reagent chlorinates by way of chloroxy radicals abstracting.

The proposed mechanism permits the explanation of the deviation of the stoichiometry of bromination from that of eq. 1. Since bromine monoxide is known (18) to be thermally unstable, bromination is in competition with decomposition of the reagent. By analogy with chlorine monoxide (5) this is most likely to give bromine and oxygen. The bromine released may then be reoxidized by mercuric oxide, the result being that mercuric bromide is produced in excess of that required by eq. 1, while alkyl bromide formation is reduced. For unreactive compounds *e.g.* *p*-nitrotoluene, relatively more decomposition of the reagent occurs, with a corresponding decrease in the yield of bromide.

Experimental

Solvents and substrates were reagent grade materials whose purities were checked by vapor phase chromatography (v.p.c.) before use. Freon 113 was obtained from Matheson, and Freon 112 was a gift from E. I. Du Pont de Nemours Co. Inc. Cyclohexane-d_{12} was obtained from Stohler Isotope Chemicals; chloroform-*d* from British Drug Houses Ltd.

Quantitation of products by v.p.c. was as described previously (37). Mass spectra were run on a Varian MAT model CH7; for g.c./m.s. work (gas chromatography with mass spectrometry) the mass spectrometer was interfaced through a Biemann–Watson helium separator to a Varian Aerograph Model 1700 v.p.c. equipped with $\frac{1}{8}$ in. stainless steel columns.

Reactions were carried out either at room temperature with stirring or at reflux in round bottomed flasks equipped with reflux condensers, under normal laboratory illumination except as noted. Normally the reactions were carried out in triplicate, and reported values are the average with the deviations calculated as probable statistical errors (38). Mercuric oxide was recovered from the residues for further use (5).

Reaction of Cyclohexane with Bromine and Mercuric Oxide (Table 1)

The following experiment is typical.

A mixture of mercuric oxide (2.0 g) and cyclohexane (4 ml) was stirred at room temperature in a 25 ml roundbottomed flask equipped with reflux condenser: 2.0 ml of a 2.02 *M* solution of bromine in carbon tetrachloride was added and the mixture was stirred for 20 min by which time the color of bromine was discharged. When the reaction was over, 2.0 ml of a 1.97 *M* solution of bromobenzene in carbon tetrachloride was added as a v.p.c. standard. V.p.c. analysis (10 ft × $\frac{1}{4}$ in. 10% SE30 on acid washed Chromosorb W, 105°) indicated that 1.58 mmol (79%) of bromocyclohexane had been formed. The solution was decanted from the solids at the bottom of the flask, washed with fresh CCl_4 and decanted again. The residue was extracted twice with 25 ml portions of acetone to dissolve mercuric bromide, then filtered with suction through a sintered glass filter of 10–20 μ porosity. Evaporation of the acetone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

afforded 0.736 g (2.04 mmol) of mercuric bromide as off-white crystals m.p. 226–232° (lit. (38) 236°).

Small Scale Preparations of Alkyl Bromides using HgO/Br_2 (Table 2)

The reactions were carried out on a scale of 10–50 mmol using at least a 50% molar excess of mercuric oxide as exemplified below.

p-Nitrobenzyl Bromide:

A mixture of *p*-nitrotoluene (2.0 g), mercuric oxide (6 g) and bromine (5 g) in CCl_4 (60 ml) was heated to reflux for 1.5 h. The hot solution was filtered, and on cooling 0.1 g of an unidentified material of m.p. 145–50° was deposited. V.p.c. (SE30, 250°) indicated that only one compound was present besides starting material. Removal of the solvent and two recrystallizations from ethanol afforded *p*-nitrobenzyl bromide 0.7 g m.p. 96–98° (lit. (38) 99°) and 0.3 g of less pure material m.p. 80–85°.

1-Bromo-2,2,3,3-tetramethylbutane:

A mixture of 2,2,3,3-tetramethylbutane (3.0 g), mercuric oxide (8 g), bromine (1.9 g) and CCl_4 (60 ml) was heated to reflux for 0.5 h. Filtration and removal of solvent and excess alkane afforded a residue of the desired bromide (1.7 g), which was purified by preparative v.p.c. (SE30, 135°). N.m.r. (CCl_4): δ 0.90 ($(CH_3)_3C$—); 0.95 ($(CH_3)_2C<$); 3.45 (CH_2Br).

Reaction of Cyclohexane with HgO/Br_2 in the Presence of other Reagents (Table 3)

The reaction mixtures consisted of 5 ml aliquots of a 80:20 v/v mixture of CCl_4 and cyclohexane, to which were added the appropriate reagents, mercuric oxide (2.0 g), and 1.0 ml of a 1.5 *M* solution of bromine in CCl_4. The contents of the flasks were stirred, or agitated by a gaseous flush as appropriate. Reaction times were estimated (*i*) by comparing the color of the mixture visually with the color of a reaction mixture containing no alkane and 5% of the normal quantity of bromine and (*ii*) when the bromine color was completely discharged.

Competitive Reaction of Hydrocarbon Substrates with HgO/Br_2 (Table 4)

The reactions were carried out in Freon 113 solution using flasks equipped with reflux condensers. Carbon tetrachloride and Freon 112 were used as inert internal standards as appropriate for v.p.c. analysis on SE30 or diisodecyl phthalate (DIDP) columns. The reactions were carried out in at least triplicate, and the reactivities were evaluated as described previously (31). From the results obtained (Table 4) were calculated the data of Tables 5 and 6 pertaining to the HgO/Br_2 reagent.

Reaction of HgO/Br_2 with a Mixture of Cyclohexane and Cyclohexane-d_{12}

A mixture of cyclohexane (0.753 g) and perdeuteriocyclohexane (0.763 g) was made up to 5 ml with Freon 113. Reaction mixtures were prepared containing HgO (1.0 g), Freon 113 (3 ml), bromine (0.5 g), and 1.0 ml of the substrate solution, and stirred until colorless. G.c./m.s. (SE30, 35°) was used to determine the isotopic composition of the alkane mixture before and after reaction. Several mass spectra were run for the control mixture and for each of three reaction mixtures. In no case was there any enhancement of the peaks at m^+/e 85 relative to 84, or of m^+/e 94 and 95 relative to 96.

Selectivity of NBS towards Alkanes (Table 5)

The primary:secondary selectivity was obtained from bromination of hexane (3 ml) with NBS (0.5 g) under the illumination of one 100 W tungsten lamp with stirring. The mixtures were analyzed by v.p.c. (SE30, 100°). The major component was assigned as a mixture of a 2-bromohexane and 3-bromohexane, since photobromination of hexane with Br_2 gave this product exclusively. The minor product, which eluted later, had a retention time identical to that of 1-bromohexane, prepared by the degradation of heptanoic acid with Br_2/HgO (1). The ratio of (2 + 3)-bromohexane to 1-bromohexane was 1: 0.0037 ± 0.0002.

The secondary to tertiary selectivity was obtained by competitive photoinitiated bromination of 2,3-dimethylbutane and *n*-hexane by NBS using CCl_4 as the inert standard and Freon 113 as solvent. V.p.c. analysis of the alkane before and after the reaction (SE30, 50°) gave k(hexane) to k(2,3-dimethylbutane) as 1:7.5 ± 0.9 (six determinations).

The secondary to tertiary selectivity was also determined in homogeneous acetonitrile solutions at 50°. These reactions were conducted in sealed evacuated ampoules, irradiated to initiate the reaction. V.p.c. analysis (DIDP, 75°) gave k(hexane) to k(2,3-dimethylbutane) as 1:7.9 ± 1.5.

Selectivity of Br_2O towards Alkanes

The selectivity per hydrogen was measured by direct bromination of butane and of isobutane with bromine monoxide. A convenient preparation of a bromine monoxide solution was as follows. A mixture of 20 g mercuric oxide and 20 ml of 1 *M* bromine in Freon 113 was swirled for 3 min in a stoppered flask with light excluded. After this time filtration gave a solution that was usually ~0.9 *M* in bromine and ~0.05 *M* in Br_2O (5). For the selectivity experiments 10 ml of such a solution was filtered through a glass sinter of 10–20 μ porosity directly on to *ca.* 1 ml of either butane or isobutane previously condensed. The mixtures were allowed to warm to 0° and after 10 min in the dark, they were quenched with aqueous sodium thiosulfate solution. Control experiments showed that elemental bromine did not react with the alkanes under these conditions. The reaction mixtures were analyzed by v.p.c. (DIDP, 80°) for the appropriate isomeric bromobutanes, whose rentention times were identical with those of authentic samples. Butane gave 1-bromobutane and 2-bromobutane in the ratio 1: 20.0 ± 0.3; isobutane gave isobutyl bromide and *tert*-butyl bromide in the ratio 1: 22.1 ± 0.2.

Kinetic Isotope Effect for t-Butoxy Radical Abstraction

Mixtures of cyclohexane, *n*-hexane, and Freon 113 (standard), each ~1 *M* in CCl_4 were allowed to react with *t*-butyl hypochlorite in sealed degassed ampoules at 0° using photoinitiation. After reaction, the mixtures were analyzed by v.p.c. (DIDP, 50°); $k_{C_6H_{12}}/k_{C_6H_{14}}$ was found to be 2.05 ± 0.02; $k_{C_6D_{12}}/k_{C_6H_{14}}$ was 0.45 ± 0.01.

Reaction of HgO/Br_2 with Haloalkanes (Table 7)

These reactions were all carried out in duplicate using the haloalkane as its own solvent.

1-Chloropropane

Four products were obtained (DIDP, 80°) of which the last to elute comprised about 3% of the total product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mixture. The first three products were shown to be bromochloropropanes by g.c./m.s. (DIDP, 55°). Of these three products, the third to elute was assigned to 3-bromo-1-chloropropane, because it was absent from the mixture obtained by bromination of 1-chloropropane with elemental bromine alone. The second product was assigned as 2-bromo-1-chloropropane, since it had retention time identical with that of the major product of photo-chlorination of 2-bromopropane. By elimination, the first product was 1-bromo-1-chloropropane.

1-Chlorobutane

Four products were obtained, and were shown to be bromochlorobutanes by g.c./m.s. (SE30, 50°). The elution order was the same using either SE30, 80° or DIDP, 125°, and was concluded to be 1,1-; 1,2-; 1,3-; 1,4-chloro-bromobutane from previously reported studies (39).

1-Bromobutane

The four products obtained on v.p.c. analysis (SE30, 100°) were shown to be dibromobutanes by g.c./m.s. (SE30, 80°). The elution order has previously (15) been shown to be 1,1-; 1,2-; 1,3-; 1,4-dibromobutane.

Reaction of Bromine with Mercuric Oxide with no Added Substrate

A mixture of bromine (0.8 g), mercuric oxide (4 g) and CCl_4 (10 ml) was heated to reflux for 12 h by which time the color due to bromine was discharged. The CCl_4 solution and the solid residue were each treated with an acidified sodium iodide solution. The CCl_4 phase was unreactive, while the residuum gave a deposit of mercuric iodide. In neither case an oxidant was present to liberate molecular iodine.

The author wishes to thank the National Research Council of Canada for supporting this work financially. Thanks are also due to E. I. Du Pont de Nemours Co. Inc. for a gift of Freon 112, and to Miss Linda MacDonald of this department for running the mass spectrometer.

Etude cinétique des systèmes Cu(II).Adénosine et Cu(II).D-Ribose

G. BOIVIN ET M. ZADOR
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 27 avril 1972

La cinétique de formation et de dissociation des complexes entre le Cu(II) et l'adénosine a été étudiée en milieu acide ainsi qu'en milieu basique. En milieu acide, les paramètres cinétiques ont été obtenus par la méthode de relaxation et ils correspondent au complexe formé avec le groupement adénine. En milieu basique seule la dissociation des complexes a pu être étudiée par la méthode du "flux stoppé", en utilisant l'EDTA ou un acide fort pour dissocier les complexes, formés dans ce cas avec les groupes hydroxyles du ribose. A titre de comparaison, le D-ribose a été également étudié dans ces conditions. Le mécanisme de ces réactions est discuté.

The kinetics of the formation and dissociation of Cu(II) complexes of adenosine have been determined in acidic and basic medium. In acidic medium, the complex is formed between the Cu(II) and the adenine base and the kinetic parameters have been obtained in this case using a temperature jump method. In basic medium, only the dissociation of the complexes could be studied by a stopped-flow method, by addition of EDTA or strong acid solutions. In these complexes, Cu(II) is bridged with ribose hydroxyls. Finally, D-ribose has also been studied for comparison in the same conditions. The mechanism of these reactions is discussed.

Introduction

Pendant les deux dernières décades, la biochimie du cuivre a pris une importance considérable surtout par la mise en évidence du cuivre dans certains enzymes et certaines protéines jouant un rôle de premier plan dans les organismes vivants (1).

Plus que tout autre ion métallique, le cuivre forme des chélates très stables avec les substances biologiquement actives (2). Une partie du cuivre contenu dans l'organisme se trouve liée à l'ADN. On a pu démontrer *in vitro* que l'ion cuivrique a la propriété de dénaturer l'ADN en formant des chélates avec les bases puriques telles l'adénine et la guanine (3).

Les nombreux travaux effectués dans ce domaine concernent le site de fixation du cuivre dans l'ADN et la détermination des constantes de stabilité avec l'ADN, ses nucléosides et ses bases constituantes (3, 4).

La nature des complexes du cuivre avec l'adénosine et l'adénine dépend de l'acidité du milieu réactionnel. Ainsi, on a montré qu'il pouvait être lié au groupement adénine en milieu acide ou neutre sans départ de proton (5). Dans le cas de l'adénosine, il pouvait également former deux types de complexes en milieu basique (6, 7). La complexation se faisait alors avec le départ d'un ou de deux protons des groupements hydroxyles du ribose.

La détermination des constantes de stabilité des complexes a été effectuée principalement par potentiométrie (5, 6), par spectrophotométrie (8) et par une méthode cinétique indirecte de dosage du cuivre basée sur son action catalytique dans une réaction d'oxydation (9).

Jusqu'à présent, très peu de travaux cinétiques ont été effectués sur la formation de complexes de l'ion cuivrique avec les bases puriques. Les seules études existantes portent sur la cinétique de formation des complexes avec l'ADP et l'ATP, mais dans ces cas, le cuivre se trouve principalement lié au groupement polyphosphate (10).

Dans ce travail, nous nous sommes proposés d'étudier le mécanisme de formation des complexes du Cu(II) avec l'adénosine et le sucre constituant le D-ribose.

Partie expérimentale

Les réactifs

L'adénosine et le D-ribose sont des produits de Nutritional Biochemicals Co. Le perchlorate cuivrique a été obtenu en dissolvant l'oxyde cuivrique dans l'acide perchlorique. La solution stock a été dosée par iodométrie et par absorption atomique. L'EDTA est un produit Fisher Scientific Co. Les solutions d'adénosine et de D-ribose ont été fraîchement préparées avant chaque série d'expériences. La force ionique des solutions a été maintenue constante à l'aide du perchlorate de sodium.

Appareillage

La cinétique des réactions a été étudiée par les méthodes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

de la relaxation thermique et du "flux stoppé", dont les principes ont déjà été décrits dans la littérature (11).

L'appareil de relaxation provient de Messanlagen Studiengessellschaft m.b.H., Göttingen, Allemagne. L'appareil du "flux stoppé" est constitué d'un système à mélange rapide Durrum–Gibson et d'un monochromateur Jarrel Ash 0.25 m. Dans chaque cas, les variations de densité optique ou de transmission des solutions sont enregistrées sur un oscillographe cathodique et le signal obtenu est photographié. Les spectres visibles et ultraviolets ont été mesurés sur un spectrophotomètre Cary-14. Les cellules réactionnelles sont thermostatées et, dans le cas de la relaxation, la température est mesurée avant chaque expérience à l'intérieur de la cellule à l'aide d'un thermocouple. Le pH des solutions a été controlé à l'aide d'un pH-mètre Radiometer-26.

Méthodes cinétiques

La cinétique de relaxation du système Cu(II).adénosine en milieu acide a été suivie par la diminution de l'absorption sur une des extrémités de la bande de l'adénosine, c'est-à-dire à des longueurs d'onde variant de 280 à 310 nm. Dans ces conditions, il est possible de travailler à des concentrations suffisamment grandes pour étudier la formation du complexe. La dissociation des complexes en milieu basique est étudiée par la méthode du "flux stoppé", on choisit une longueur d'onde où la variation de l'absorption est la plus grande possible entre l'état initial et final du système étudié. Dans les cas où l'on suit la cinétique à une longueur d'onde où le complexe absorbe, on enregistre la diminution de l'absorption; dans quelques cas c'est l'apparition du complexe Cu(II).EDTA qui a été mesurée, on avait alors une augmentation de l'absorption. Les solutions ont été dégazées pour empêcher la formation de bulles. Les solutions à mélanger ont la même force ionique pour éviter des phénomènes provoqués par une chaleur de mélange. Dans chaque cas, des vérifications ont été faites pour s'assurer qu'un des réactifs seul ne présentait pas de relaxation.

Résultats et discussion

Relaxation du système Cu(II)–Adénosine en milieu acide

L'adénosine en milieu acide est protonée selon l'équilibre [1],

$$[1] \qquad AH_2^+ \rightleftharpoons AH + H^+$$

$$pK_{a_1} = 3.51 \text{ à } 25\ ^\circ\text{C (12)}$$

et en milieu basique, elle se dissocie d'après [2],

$$[2] \qquad AH \rightleftharpoons A^- + H^+$$

$$pK_{a_2} = 12.35 \text{ à } 25\ ^\circ\text{C (13)}$$

où AH représente l'adénosine.

Nous avons travaillé en excès de cuivre par rapport à l'adénosine. Ceci permet d'obtenir des cinétiques plus simples étant donné que la concentration en adénosine libre n'intervient pas dans l'équation donnant le temps de relaxation.

TABLEAU 1. Temps de relaxation du système $Cu^{2+} + AH \rightleftharpoons CuAH^{2+}$*

$[Cu^{2+}]$ (M)	τ (ms) 9 °C	21 °C	31 °C
0.20	2.4	1.6	1.1
0.30	2.0	1.2	0.9
0.40	1.6	1.0	0.7
0.50	1.4	0.85	0.6

*[AH] = 0.01 à 0.02 M, pH = 4.0, force ionique = 1.5 M. Les temps de relaxation correspondent à une moyenne de plusieurs expériences et la reproductibilité est meilleure que 10%.

En milieu acide, on observe une relaxation que l'on peut attribuer à la formation du complexe $Cu.AH^{2+}$, suivant la réaction:

$$[3] \qquad AH + Cu^{2+} \underset{k_d}{\overset{k_f}{\rightleftharpoons}} (Cu.AH)^{2+}$$

Les temps de relaxation, τ, obtenus dans différentes conditions expérimentales sont groupés dans le tableau 1. Ils sont indépendants de la concentration en adénosine et du pH. A cause de la faible stabilité du complexe, les mesures de relaxation à une concentration inférieure à 0.2 M en Cu(II) ne sont pas significatives puisque nous sommes à la limite de sensibilité de l'appareil.

Les résultats peuvent être interprétés par une équation de vitesse simple découlant de l'équilibre [3],

$$[4] \qquad 1/\tau = k_f([\overline{Cu(II)}] + [\overline{AH}]) + k_d$$

où les concentrations sont celles à l'équilibre. Avec un grand excès de Cu(II) on obtient l'équation 5.

$$[5] \qquad 1/\tau = k_f[Cu(II)] + k_d$$

La fig. 1 montre que l'éq. 5 est vérifiée et permet d'obtenir les valeurs de k_d et de k_f à diverses températures.

La constante d'équilibre de l'équation 3, se définissant comme suit: $K = [Cu.AH]^{2+}/[Cu^{2+}][AH]$, peut être calculée en faisant le rapport des constantes de vitesse de formation et de dissociation, $K = k_f/k_d$. Le tableau 2 représente les différentes constantes de vitesse et d'équilibre ainsi que les énergies d'activation correspondantes.

Les résultats montrent clairement que le phénomène observé correspond à la réaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

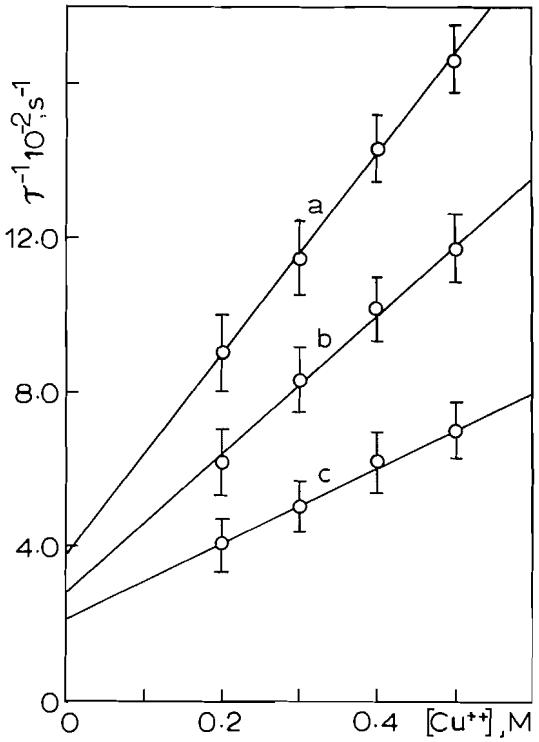

FIG. 1. Variation de τ^{-1} en fonction de la concentration en Cu^{2+}: [adénosine] = 0.01 à 0.02 *M*, p*H* = 4.0, force ionique = 1.5 *M*; (*a*) *T* = 31 °C, (*b*) *T* = 21 °C, (*c*) *T* = 9 °C.

3 et non pas à celle où la formation du complexe s'accompagne du départ d'un proton, ce qui a été mis en évidence à des p*H* plus élevés.

Les énergies d'activation sont du même ordre de grandeur que celles mises en évidence par l'étude r.m.n. des complexes du Cu(II) avec l'éthylènediamine (14).

La valeur de la constante d'équilibre de formation du complexe ($K = 7 \pm 2$) est plus forte que celle du complexe Ni(II).adénosine (15), ce qui est en accord avec la série Irving–Williams (16). Cette valeur correspond bien à celles déterminées dans la littérature par des méthodes différentes. Brintzinger et coll. (8) ont trouvé par spectrophotométrie une constante d'équilibre de 7.0 à 20 °C. Fiskin et Beer (5) en observant par potentiométrie le déplacement de l'équilibre [1], ont trouvé comme constante d'équilibre 5.0 ± 2.3 à 20 °C.

TABLEAU 2. Constantes de vitesse de formation et de dissociation du complexe $CuAH^{2+}$ et les énergies d'activation correspondantes*

T (°C)	k_f (M^{-1} s^{-1})	k_d (s^{-1})	*K* (M^{-1})
9	1100	200	5.5
21	1800	270	7.0
31	2680	340	8.0

*$E_f = 7 \pm 2$ kcal/mol; $E_d = 5 \pm 2$ kcal/mol.

*Etude des constantes de vitesse de dissociation des complexes Cu(II).adénosine et Cu(II).*D*-ribose en milieu basique*

Sur les spectres d'absorption, on observe la présence de deux complexes, le premier apparaissant vers p*H* 10 est de couleur vert pâle tandis que le deuxième vers p*H* 12 a une couleur bleu foncé. La nature exacte de ces complexes n'est pas connue avec certitude, des études potentiométriques montrent néanmoins qu'ils se font par départ de un ou de deux protons (12, 17).

La structure proposée par Reinert et Weiss (17) implique la formation de complexes contenant des ligands hydroxydés du type: $(CuA)_I \equiv CuA(OH)_2^-$, complexe vert et $(CuA)_{II} \equiv CuA(OH)_2^{2-}$, complexe bleu, dans lesquels l'adénosine a perdu un et deux protons respectivement. Ces protons viennent des groupements hydroxyles 2′ et 3′ du ribose. Ceci est confirmé par le fait que le D-ribose forme dans les mêmes conditions des complexes ayant des caractéristiques spectrales identiques, donc un complexe vert, $(CuR)_I$ et un complexe bleu, $(CuR)_{II}$.

Dissociation du complexe bleu $(CuA)_{II}$ par l'EDTA

A p*H* élevé (p*H* > 5) il y a formation d'un hydroxyde très peu soluble. On ne peut obtenir une solution homogène que si la formation des complexes est complète. Dés lors, il est impossible d'utiliser des méthodes de relaxation. Notamment, il n'y a pratiquement plus de perturbation des concentrations à l'équilibre et, de plus, à cause des concentrations élevées, les réactions deviennent trop rapides pour être mesurées. On peut néanmoins étudier la dissociation des complexes par la méthode du "flux stoppé".

Il est possible de dissocier les complexes au moyen d'un ligand formant des chélates encore plus stables avec le Cu(II), tel que l'EDTA. En effet, le complexe Cu(II).EDTA est bien connu; on a déterminé sa constante de stabilité (log

TABLEAU 3. Constantes de vitesse expérimentales des complexes $(CuA)_I$, $(CuA)_2$, et $(CuR)_{II}$*

[EDTA] (M)	k_{exp} (s^{-1})		
	$(CuA)_I$†	$(CuA)_{II}$‡	$(CuR)_{II}$§
0.080	210	5.3	0.073
0.063	170	4.3	0.062
0.050	125	3.6	0.055
0.025	70	2.2	0.042

*$[Cu^{2+}] = 2.5\ 10^{-3}$ M, $T = 25$ °C, force ionique = 0.5 M.
†Complexe vert du Cu(II).adénosine, $[AH] = 2.5 \times 10^{-2}$ M, pH = 10.2, λ = 360 et 730 nm.
‡Complexe bleu du Cu(II).adénosine, $[AH] = 2.5 \times 10^{-2}$ M, pH = 12.5, λ = 360 et 730 nm.
§Complexe bleu du Cu(II).D-ribose, $[R] = 5 \times 10^{-3}$ M, pH = 11.0, λ = 360 nm.

$\beta_1 = 18.8$) (18) et, de plus, la formation de ce complexe est très rapide (19). Par conséquent, cette réaction d'échange conduit à la disparition totale des complexes du Cu(II) avec l'adénosine ou le D-ribose.

L'étude de la dissociation du complexe avec l'EDTA permet de travailler à pH constant; ceci élimine la formation intermédiaire du complexe $(CuA)_I$, présent à pH plus bas et facilite l'interprétation des résultats.

En utilisant un excès d'EDTA par rapport au complexe, nous obtenons une cinétique d'ordre un. Le tableau 3 groupe les constantes de vitesse expérimentales en fonction de la concentration en EDTA. La constante expérimentale d'ordre un varie avec la concentration en EDTA. Si nous portons graphiquement les constantes expérimentales en fonction de la concentration en EDTA, nous obtenons une droite avec une ordonnée à l'origine non nulle.

Ceci correspond à deux réactions simultanées: (*i*) la dissociation du complexe $(CuA)_{II}$, suivie d'une réaction très rapide du Cu(II) formé, avec l'EDTA (étapes [6] et [7]), et (*ii*) la réaction d'échange direct, de type S_N2, entre le complexe et l'EDTA (étape [8]).

$$[6] \qquad (CuA)_{II} \xrightarrow[\text{lente}]{k_d} AH + Cu(II)$$

$$[7] \qquad Cu(II) + EDTA \xrightarrow[\text{rapide}]{} (Cu.EDTA)$$

$$[8] \qquad (CuA)_{II} + EDTA \xrightarrow[\text{lente}]{k_{EDTA}} AH + (Cu.EDTA)$$

La vitesse de disparition du complexe est donnée par:

$$[9] \qquad V = k_d[(CuA)_{II}] + k_{EDTA}[(CuA)_{II}][EDTA]$$

TABLEAU 4. Constantes de vitesse des réactions des complexes avec l'EDTA*

Complexe	k_d (s^{-1})	k_{EDTA} (M^{-1} s^{-1})
$(CuA)_I$	<20	2500
$(CuA)_{II}$	0.80	57
$(CuR)_{II}$	0.03	0.52

*$T = 25$ °C, force ionique = 0.5 M.

et la constante de vitesse expérimentale par:

$$[10] \qquad k_{exp} = k_d + k_{EDTA}[EDTA]$$

Les deux constantes de l'éq. 10 peuvent être déterminées graphiquement (fig. 2(*b*)). La réaction bimoléculaire, [8], se fait probablement en plusieurs étapes dont la première serait la complexation d'un site de coordination du cuivre du complexe $(CuA)_{II}$.

La formation intermédiaire de complexes mixtes CuA.(EDTA) est une étape possible. Expérimentalement la disparition totale de la bande $(CuA)_{II}$ indiquerait que la concentration de ce complexe devrait être faible, ce qui est raisonnable étant donné la très grande stabilité du complexe Cu(II).EDTA qui devient l'espèce prédominante.

Il est à noter que cette méthode ne peut être appliquée au complexe prépondérant à p$H < 5$, CuA^{2+}, la valeur des constantes de vitesse impliquées étant trop élevée pour une méthode de "flux stoppé".

Dissociation du complexe $(CuR)_{II}$ par l'EDTA

Le complexe bleu avec le D-ribose prédomine en milieu basique à p$H > 9$. La dissociation de ce complexe par l'EDTA peut être étudiée de la même manière que celle du $(CuA)_{II}$. Les résultats sont présentés dans le tableau 3.

L'interprétation des résultats est analogue à celle faite précédemment, (fig. 2(*c*)). Les constantes de vitesse obtenus sont toutefois plus faibles d'un facteur de 50–100 que dans le cas de l'adénosine (tableau 4).

Dissociation du complexe vert, $(CuA)_I$

Le complexe vert, $(CuA)_I$, peut être aussi dissocié en utilisant l'EDTA. Les résultats obtenus à pH 10.2 sont présentés au tableau 3. Les valeurs des constantes de vitesse expérimentales sont d'environ 50 fois plus grandes que pour $(CuA)_{II}$; ceci montre bien que les deux phénomènes peuvent être séparés et que les cons-

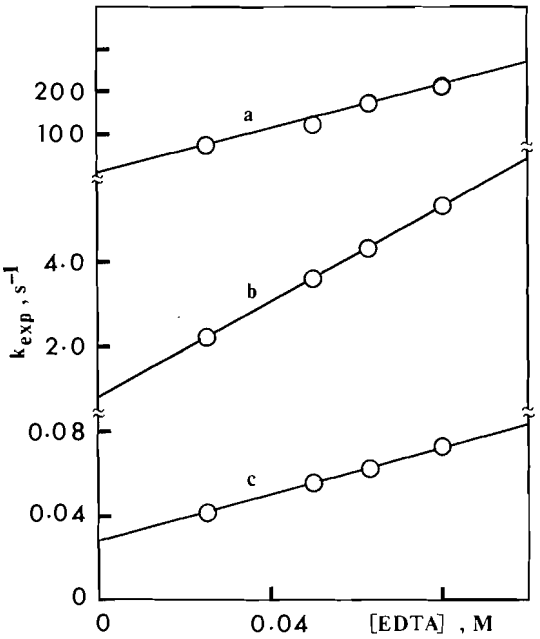

FIG. 2. Variation de la constante de vitesse expérimentale de dissociation des complexes $(CuA)_I$, $(CuA)_{II}$, et $(CuR)_{II}$ en fonction de la concentration en EDTA: $[Cu^{2+}] = 2.5 \times 10^{-3}$ *M*, force ionique 0.5 *M*, $T = 25$ °C; (*a*) complexe $(CuA)_I$: [adénosine] $= 2.5 \times 10^{-2}$ *M*, p*H* = 10.2; (*b*) complexe $(CuA)_{II}$: [adénosine] $= 2.5 \times 10^{-2}$ *M*, p*H* = 12.5; (*c*) complexe $(CuR)_{II}$: [D-ribose] $= 5.0 \times 10^{-3}$ *M*, p*H* = 11.0.

tantes pour $(CuA)_{II}$ sont significatives. L'interprétation graphique est représentée par la fig. 2(*a*). On note que l'ordonnée à l'origine de la droite obtenue est très petite par rapport aux constantes de vitesse expérimentales. Ceci implique que dans ce cas particulier le mécanisme correspondant aux éq. 6 et 7 est quasi négligeable par rapport à celui de l'éq. 8 correspondant à la réaction bimoléculaire avec l'EDTA. La valeur de k_d du tableau 4 ne représente qu'une limite supérieure.

Dans le cas du complexe $(CuA)_I$, on peut utiliser un acide fort pour étudier la dissociation. L'addition de l'acide permet de déplacer les équilibres [1] et [2] vers la formation de AH^+, ce qui entraîne la dissociation du complexe. Dans ce cas là on dissocie le complexe en captant l'adénosine, alors qu'en utilisant l'EDTA on captait le Cu(II).

Cette méthode a déjà été utilisée dans d'autres cas (15, 20, 21). On remarque que la constante de vitesse expérimentale de dissociation augmente avec l'acidité. Les résultats du tableau 5 peuvent être interprétés par un schéma analogue aux éqs. 6, 7, et 8.

TABLEAU 5. Constante de vitesse de dissociation de $(CuA)_I$ en fonction de l'acidité*

$[HClO_4]$ (*M*)	k_{exp} (s^{-1}) $(CuA)_I$
0.25	410
0.20	345
0.15	255
0.10	190
0.05	90
0.037	75

*$k_d < 20$ s^{-1}, $k_{H^+} = 1750$ M^{-1} s^{-1}. $[Cu^{2+}] = 2.5 \times 10^{-3}$ *M*, $[AH] = 5 \times 10^{-3}$ *M*, force ionique = 0.5 *M*, $T = 25$ °C, p*H* initial = 10.2, $\lambda = 750$ nm.

$$[11] \qquad (CuA)_I \xrightarrow[\text{lente}]{k_d} A^- + Cu(II)$$

$$[12] \qquad A^- + 2H^+ \xrightarrow[\text{rapide}]{} AH_2^+$$

$$[13] \qquad (CuA)_I + H^+ \xrightarrow[\text{lente}]{k_{H^+}} Cu(II) + AH$$

$$[14] \qquad AH + H^+ \xrightarrow[\text{rapide}]{} AH_2^+$$

L'ensemble de ces équations conduit à l'expression suivante pour la constante de vitesse expérimentale de disparition du complexe:

$$k_{exp} = k_d + k_{H^+}[H^+]$$

L'influence de l'acidité s'explique bien en admettant la protonation du ligand, ce qui diminue la stabilité du complexe. Ceci conduirait, à acidité très élevée, vers une valeur limite correspondant à la protonation complète et dans certains cas cette valeur limite est atteinte (20).

Bien que la valeur faible de l'ordonnée à l'origine, (fig. 3), implique que la réaction 11 est peu importante, comme avec l'EDTA, cela n'exclue pas la généralité du mécanisme. En effet, Wilkins (20) a trouvé que la dissociation des complexes du Cu(II) avec quelques composés diaminés, était fonction de l'acidité dans une certaine gamme de p*H*, mais que le p*H* n'avait pas d'influence entre p*H* 4 et 7. Dans le cas de l'adénine un comportement analogue fut observé (résultats non publiés). Il faut aussi noter que les valeurs des constantes de vitesse expéri-

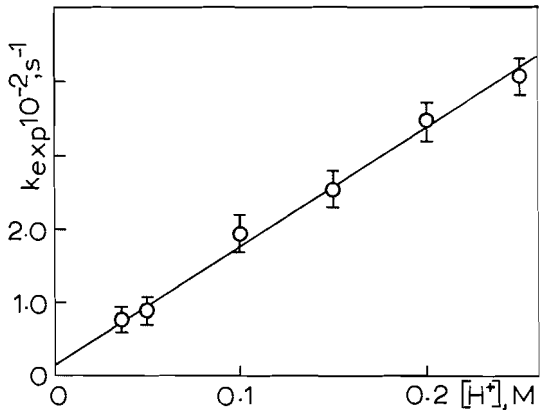

FIG. 3. Variation de k_{exp} du complexe $(CuA)_I$ en fonction de la concentration en acide: [adénosine] = 5×10^{-3} *M*, $[Cu^{2+}] = 2.5 \times 10^{-3}$ *M*, force ionique = 0.5 *M*, p*H* initial = 10.2, *T* = 25 °C.

mentales de dissociation obtenues à acidité élevée n'ont pas la signification d'une vraie constante de dissociation et certains résultats publiés, sans une interprétation adéquate, doivent être considérés avec précaution (20).

Bien que la valeur de k_d obtenue soit entachée d'une erreur importante, il y a au moins accord entre les deux séries de résultats quant à la valeur limite.

On a envisagé l'étude du complexe vert $(CuR)_I$. Ce dernier est prépondérant entre p*H* 5 et 9. A ces p*H* il se forme des précipités d'hydroxyde de cuivre, étant donné que la stabilité de ce complexe n'est pas assez grande pour empêcher leur formation (à p*H* 7, $K = 60$ (9)). Pour cette raison il n'est pas possible d'étudier ce complexe.

Conclusion

Les études sur le site de coordination et sur la stabilité des complexes formés entre le Cu(II) et l'adénosine ont déjà permis de montrer qu'il y avait plusieurs complexes. Nos résultats montrent que ceux-ci se différencient également quant à la cinétique de leur formation et de leur dissociation.

Les constantes de vitesse du complexe en milieu acide, impliquant comme ligand le groupe adénine, sont de loin plus grandes que celles de la dissociation des complexes avec les groupes hydroxyles du ribose, mesurées en milieu basique. Ces derniers sont prépondérants aux p*H* physiologiques. Il est à noter que dans les cas où des groupes desoxyriboses sont impliqués (17), il n'y a pas de formation de complexe avec ce groupement et alors, le complexe avec le groupe adénine est présent même à p*H* = 7 avec ses caractéristiques cinétiques propres.

Les résultats obtenus pour le D-ribose pourraient probablement être appliqués à d'autres sucres possédant deux groupements hydroxyles en position similaire.

Finalement la dissociation des complexes en présence d'EDTA en milieu basique se fait par deux mécanismes simultanés: dissociation unimoléculaire suivie de la formation du complexe Cu(II).EDTA et par une réaction bimoléculaire entre le complexe et l'EDTA. La connaissance du mécanisme de cette réaction est importante pour la compréhension de l'influence de l'EDTA sur l'action physiologique du cuivre.

Par exemple, l'effet inhibiteur de l'EDTA sur certaines réactions enzymatiques (p. 27 réf. 2), est reconnu comme étant dû à son affinité pour les ions métalliques, en particulier les ions cuivriques.

Les auteurs remercient le Ministère de l'Education du Québec pour la subvention de recherche accordée pour la réalisation de ces travaux. Le Conseil National de Recherches du Canada est remercié pour la bourse d'entretien accordée (G.B.).

Aqueous Nonelectrolyte Solutions. Part XI. Mercury Solubility in 6.10 molal Sodium Chloride[1]

D. N. GLEW AND D. A. HAMES

Research and Development Department, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received March 1, 1972

The solubility of mercury in aqueous 6.10 *m* NaCl has been determined between 5 and 70 °C. Solubility equations and thermodynamic functions are derived and compared with those for mercury in water. Salting-out constants are given.

La solubilité du mercure dans une solution aqueuse de NaCl 6.10 *m* a été déterminée entre 5 et 70 °C. Les équations de solubilité et les fonctions thermodynamiques ont été dérivées et comparées à celles du mercure dans l'eau. Les constantes de relargage sont données. [Traduit par le journal]

Introduction

The solubility equilibrium of liquid mercury with air-free water has been reported recently (1). In this work the solubility equilibrium of liquid mercury has been determined with concentrated sodium chloride solutions between 5 and 70 °C.

Experimental

Material

Mercury of technical electrolytic grade was purified as follows: agitated with a stream of air and washed with (*i*) 10% NaOH, (*ii*) distilled water, (*iii*) 5% HNO_3 and filtered through a gold foil, rewashed with (*iv*) 5% HNO_3, (*v*) distilled water and then distilled three times. A.C.S. grade sodium chloride, supplied by Fisher Scientific Company, was dried by evacuation before use. Technical grade hydrazine hydrate was supplied by Matheson, Coleman and Bell, Grade A helium and Hi-Pure nitrogen by Liquid Carbonic Canadian Corporation, and reagent grade mercuric chloride by Fisher Scientific Company. Water was laboratory distilled.

Method

The solubility cell and temperature measuring equipment have been described elsewhere (1, 2).

The water and mercury were distilled into the evacuated solubility cell as described earlier (1) and sufficient sodium chloride was added under helium to make the solution about 6.1 *m* NaCl. Approximately 0.001 *m* hydrazine hydrate was added to ensure that no mercury was oxidized by residual trace amounts of air. The solubility cell was stoppered, evacuated, and restored to a slight positive pressure with helium. As in the earlier work the solubility cell was continuously stirred and mercury solubilities were determined at preselected temperatures starting from both above and below saturation. The stirrer was stopped 2 h before sampling and 5 to 15 g samples of solution were expressed into a tared flask containing 1 ml 2% $K_2Cr_2O_7$ and 1 ml 20% H_2SO_4. The flask was reweighed and heated to boiling.

Analysis

The train for the flameless atomic absorption analysis of mercury consisted of a gas washing bottle series-connected to an empty trap to catch water droplets, a drying tube containing molecular sieves, and a 10 cm path-length quartz absorption cell (3).[2]
