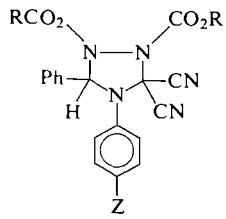
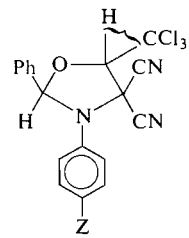
chemical shifts and coupling constants were obtained, as before, by comparison with the 2-deuterated analogs giving values of $J_{2,3} = 6$ and $J_{3,4} = 10$ Hz for **7***a* and $J_{2,3} = 9.2$ and $J_{3,4} = 8$ Hz for **11***a*. Comparison of the relative magnitudes of $J_{2,3}$ vicinal coupling constants in such structurally similar compounds as **7***a* and **11***a* seems reasonable. Therefore it appears that **7***a* and **11***a* have opposite configurations of the phenyl groups at the 2-positions.

Heteromultiple bonds in dipolarophiles react readily with **4**. Thus dimethyl azodicarboxylate affords the triazolidine **12***a* in 28% yield. Similarly diethyl azodicarboxylate gives **12***b* in 40% yield.

The highly polarized carbonyl bond in chloral reacts readily with tetracyanoethylene oxide and substituted benzalanilines in a regiospecific manner to give the oxazolidines **13***a–c*. The orientation of addition is evident from the n.m.r. spectra of **13** which show clean singlets for the methine protons. Cycloaddition of polarized carbonyl compounds to azomethine ylides with the above regiospecificity to give oxazolidines is well documented (6, 12, 17).



12
a R = CH_3; Z = H
b R = CH_2CH_3; Z = H
c R = CH_3; Z = OCH_3



13
a Z = H
b Z = OCH_3
c Z = Cl

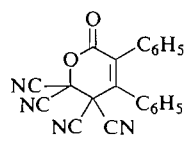
The highly polarized and dipolarophilic carbonyl group of diphenylcyclopropenone (8) might have been expected to behave similarly to that of chloral. However, a rapid prior competing reaction between the tetracyanoethylene oxide and the cyclopropenone ensued giving **14** or **15**. The product shows strong nitrile and carbonyl absorption in the i.r. spectrum which is not sufficiently characteristic to distinguish **14** and **15**. Chemical precedents (*e.g.* the reaction of tetracyanoethylene oxide with benzaldehyde to form **16** (14)) and mechanistic considerations however, favor structure **14**.

In contrast diphenylcyclopropenethione **17** reacted readily with tetracyanoethylene oxide to form the known 1,2-diphenyl-3-dicyanomethylenecyclopropene **18** in good yield. By analogy with the reported reaction of thiobenzophenone with tetracyanoethylene oxide (14) this plausibly proceeds as follows (see Scheme 3). The yield of **18** obtained here (67%) is superior to that obtained in previously reported syntheses of **18**, 19.5 (18), 23 (19), and 4.8% (20) and now represents the method of choice.

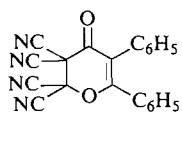
The present study supports the findings of Linn and Ciganek and extends them by showing that nucleophilic opening of tetracyanoethylene oxide by a variety of substituted Schiff bases provides a convenient route to tetrasubstituted azomethine ylides, and thus widens the scope of azomethine ylides presently available.

Experimental

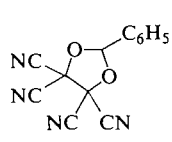
Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100



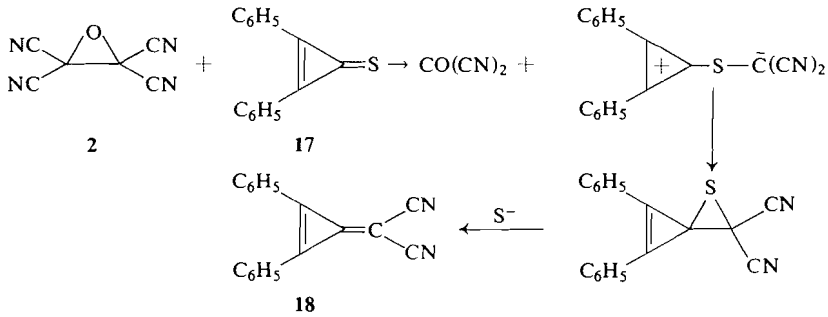
14



15



16



SCHEME 3

analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for t.l.c. Microanalyses were carried out by Dr. C. Daesslé, Organic Microanalysis Ltd., Montreal, Quebec and by Mrs. D. Mahlow of this Department.

Preparation of Starting Materials

Tetracyanoethylenoxide was prepared according to the method of Linn *et al.* (21).

The Schiff bases required in this study were readily obtained by the condensation of an aromatic aldehyde with an equimolar quantity of the substituted aniline by heating briefly on the steam bath and were purified by recrystallization from 95% ethanol.

Generation of Tetrasubstituted Azomethine Ylides and 1,3-Dipolar Cycloadditions

The general reaction conditions and purification procedures are exemplified by the following three examples. Thereafter the analytical and spectral data on adducts prepared by similar procedures are summarized in Tables 1 and 2.

(a) Reaction of Tetracyanoethylene Oxide and Benzylidene Aniline in the Presence of N-Phenylmaleimide

To a refluxing solution of 3.2 g (22 mmol) of tetracyanoethylene oxide and 7.6 g (44 mmol) of *N*-phenylmaleimide in 50 ml of dry benzene under nitrogen, there was added dropwise a solution of 4.0 g (22 mmol) of *N*-benzylidene aniline in 50 ml of dry benzene. After completed addition some solvent was distilled out (*ca.* 50 ml) under a continuous stream of nitrogen. A further 50 ml of benzene was added and the distillation under nitrogen was continued until the volume of the solution was *ca.* 50 ml. Cooling of this solution resulted in the precipitation of 0.83 g of excess *N*-phenylmaleimide. The filtrate was made up to 100 ml with benzene and 40 ml of this solution was subjected to chromatography on Florisil. Successive elution with 100 ml fractions of (*i*) hexane, (*ii*) hexane:benzene (9:1), (*iii*) hexane:benzene (4:1), (*iv*) hexane:benzene (3:2), (*vi*) benzene (200 ml) afforded one main fraction. Evaporation of the solvent gave a pale yellow solid, recrystallization of which from chloroform: 95% ethanol gave the pyrrolidine **7***a* as a colorless solid, 2.23 g (60% yield overall), m.p. 253–254°.

Anal. Calcd. for $C_{26}H_{18}N_4O_2$ (mol. wt. 418.1430): C, 74.64; H, 4.34; N, 13.39. Found (418.1426 (mass spectrum)): C, 74.39; H, 4.57; N, 13.13.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 3.69 (q, 1H, $J_{2,3}$ = 6 Hz), $J_{3,4}$ = 10 Hz, H_3); 4.39 (d, 1H, $J_{3,4}$ = 10 Hz, H_4); 5.14 (d, 1H, $J_{2,3}$ = 6 Hz, H_2), 7.0–7.6 (m, 15H, aromatic protons). The i.r. spectrum ν (KBr disc) 1785, 1718 cm^{-1} (C=O).

(b) Reaction of Tetracyanoethylene Oxide and Benzylidene Aniline in the Presence of Dimethyl Fumarate

To a refluxing solution of 3.2 g (22 mmol) of tetracyanoethylene oxide and 6.5 g (44 mmol) of dimethyl fumarate in 50 ml of dry benzene under nitrogen was added dropwise (more slowly than in the case of *N*-phenylmaleimide) a solution of 40 g (22 mmol) of benzylidene aniline in 50 ml of dry benzene. Some of the benzene was distilled out (50 ml) and replaced as before. The reaction mixture when cooled deposited excess of dimethyl fumarate 0.88 g as a colorless solid. The filtrate was made up to 100 ml with benzene and 40 ml of the solution was subjected to chromatography on Florisil. Successive elution with 100 ml portions of hexane, hexane:benzene (9:1), hexane:benzene (4:1), hexane:benzene (3:2) then benzene and evaporation of the solvent gave as the main product a solid consisting of a mixture of adduct **8***a* and unreacted dimethyl fumarate. Two recrystallizations of the solid from chloroform: 95% ethanol afforded pure **8***a*, 1.06 (32% yield overall), m.p. 111–113°.

Anal. Calcd. for $C_{22}H_{19}N_3O_4$ (mol. wt. 389.1376): C, 67.86; H, 4.92; N, 10.79. Found (389.1370 (mass spectrum)): C, 67.98; H, 4.97; N, 10.44.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 3.57 (q. 1H, $J_{2,3}$ = 9, $J_{3,4}$ = 11.5 Hz, H_3); 4.38 (d, 1H, $J_{3,4}$ = 11.5 Hz, H_4); 5.10 (d, 1H, $J_{2,3}$ = 9 Hz, H_2), 6.7–7.5 (m, 15H, aromatic protons). The i.r. spectrum ν ($CHCl_3$) 1750 cm^{-1} (C=O).

(c) Reaction of Tetracyanoethylene Oxide with Benzal-p-chloroaniline in the Presence of Chloral

To a refluxing solution of 1.7 g (12 mmol) of tetracyanoethylene oxide and 5 ml of chloral in 25 ml of dry benzene there was added dropwise under nitrogen a solution of 5.18 g (22 mmol) of benzal-*p*-chloroaniline in 25 ml of

dry benzene. After the addition was completed the reaction mixture assumed a dark red color and a continuous stream of nitrogen was passed through the solution to remove some of the benzene. When the volume of the mixture was about 20 ml, a further 25 ml of dry benzene was added, and distillation continued to a total volume of reaction mixture of about 20 ml. After cooling the solution excess of solvent and unreacted chloral was removed under reduced pressure. Benzene (20 ml) was added and a grey precipitate collected 0.45 g which proved to be a mixture of unreacted tetracyanoethylene oxide and benzal *p*-chloroaniline. The filtrate was chromatographed on Florisil with elution by benzene which gave one main yellow fraction. Evaporation of the solvent gave a yellow oil, trituration of which with cold 95% ethanol afforded the adduct **13***c* as a yellow solid, 1.50 g (29% yield), m.p. 140–142°.

Anal. Calcd. for $C_{18}H_{11}Cl_4ON_3$ (mol. wt. 424.9658): C, 52.58; H, 2.70; N, 10.22; Cl, 34.50. Found (424.9682): C, 51.80; H, 2.91; N, 10.42; Cl, 32.21.

The n.m.r. spectrum: 5.35 (s, 1H, H_5), 6.48 (s, 1H, H_2), 6.6–7.7 (m, 10H, aromatic protons).

Preparation of 2-Cyano-3,4-dibenzoyl-1,5-diphenyl-2-pyrroline

A dilute chloroform solution of adduct **9** was set aside at room temperature for 1 week during which time the progress of the elimination of hydrogen cyanide was monitored by the n.m.r. spectrum. At the end of this period the original methine ABC spectrum of **9** had been replaced by a clean AB quartet $J_{4,5} = 10$ Hz of **10**. Evaporation of the solvent gave a white solid of **10**, 2-cyano-3,4-dibenzoyl-1,5-diphenyl-2-pyrroline in quantitative yield, m.p. 124–126°.

Anal. Calcd. for $C_{30}H_{22}N_2O_2$ (mol. wt. 454.1672): N, 6.50. Found (454.1681 (mass spectrum)): N, 6.87.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 5.38, 5.62 (ABq, 2H, $J = 10$ Hz, methine protons); 6.88–8.18 (m, 20H, aromatic protons). The i.r. spectrum ν ($CHCl_3$): 1670, 1731 cm^{-1} (C—O).

Preparation of Benzal-[^2H]-2,4,6-[^2H]$_3$-aniline

(i) 2,4,6-N,N-Pentadeuteroaniline

A mixture of 13 g (0.1 mol) of aniline hydrochloride and 20 ml of deuterium oxide (Merck, Sharp and Dohme, Montreal, Canada, 99.7%) was sealed in a pressure bottle and heated on the steam bath for 24 h. After removal of excess of deuterium oxide *in vacuo* the residue was treated with a further 20 ml of fresh deuterium oxide and the sealed mixture heated for a further 24 h. This procedure was repeated four times. The pentadeuteroaniline deuterochloride was neutralized in deuterium oxide with anhydrous potassium carbonate, extracted with anhydrous ether, and the extract dried ($CaSO_4$). After removal of the solvent, distillation under reduced pressure afforded aniline-d_5, 9.0 g (93% yield).

Mass spectrum: parent peak at 98. $C_6H_2D_5N$ requires 98. The n.m.r. spectrum confirmed complete replacement of the amine protons.

(*ii*) A mixture of 1 g (10 mmol) of benz [^{2}H]aldehyde (99.5% deuteration, Merck, Sharp and Dohme, Montreal, Canada) was heated on a steam bath for a few minutes. The resulting solid was recrystallized from 95% ethanol affording benzal-[^{2}H]-2,4,6-[^{2}H]$_3$-aniline, 1.8 g (90% yield), m.p. 51–52°.

The n.m.r. spectrum confirmed virtually complete isotopic replacement of the benzal proton (>98% incorporation).

Reaction of Tetracyanoethylene Oxide and Benzal-[^2H]-2,4,6-[^2H]$_3$-aniline in the Presence of N-Phenylmaleimide

To a boiling solution of 0.72 g (5 mmol) of tetracyanoethylene oxide and 1.73 g (10 mmol) of *N*-phenylmaleimide in 13 ml of dry benzene under nitrogen there was added dropwise a solution of 0.91 g (5 mmol) of benzal-[^{2}H]-2,4,6-[^{2}H]$_3$-aniline in 13 ml of dry benzene. After the addition was completed some of the benzene was distilled out in a stream of nitrogen. When the volume of the reaction mixture was about 15 ml, a further 20 ml of dry benzene was added and distillation was continued to a final volume of about 15 ml. The resulting dark green solution was subjected to chromatography on Florisil. Elution with benzene gave one band, evaporation of which gave a yellow oil which upon trituration with cold 95% ethanol gave a pale yellow solid of **7***b*. The product was purified by recrystallization from chloroform–95% ethanol as a colorless solid, 0.85 g (40% yield), m.p. 252–254°.

The n.m.r. spectrum confirmed the complete disappearance (±2%) of the H_2 signal while the H_3 resonance became a doublet $J_{3,4} = 10$ Hz.

Reaction of Diphenylcyclopropenone with Tetracyanoethylene Oxide

Initially the reaction was carried out as described previously in the presence of benzal aniline. However, the only isolable product was a 1:1 adduct between tetracyanoethylene oxide and diphenylcyclopropenone (22) in 59% yield. This was confirmed by an independent reaction carried out in the absence of benzal aniline. A mixture of 0.90 g (6 mmol) of tetracyanoethylene oxide and 1.24 g (6 mmol) of diphenylcyclopropenone in 25 ml of dry benzene was heated under reflux for 2 h. When cooled a colorless solid deposited, 1.53 g (71% yield), m.p. 165° **14**.

Anal. Calcd. for $C_{20}H_{10}N_4O_2$ (mol. wt. 350.0804): C, 71.99; H, 2.88; N, 16.00. Found (350.0800): C, 72.21; H, 2.76; N, 15.87.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$) 7.1–8.1 (m, aromatic protons). The i.r. spectrum ν ($CHCl_3$): 1787, 1843 (C=O), 2250 cm^{-1} (C=N).

Reaction of Diphenylcyclopropenethione with Tetracyanoethylene Oxide

To a stirred solution of 1.11 g (5 mmol) of diphenylcyclopropenethione (23, 24) in 25 ml of dry benzene, there was added 0.72 g (5 mmol) of tetracyanoethylene oxide in portions. Stirring was continued for about 4 h. A pale grey solid which had precipitated was collected, 0.48 g. The filtrate on setting aside at room temperature for 3 days deposited a further 0.37 g of the product, representing a total yield of 0.87 g (67% yield) of 1,2-diphenyl-3-dicyanomethylenecyclopropene m.p. 295–298° (from tetrahydrofuran) (lit. m.p. 299° (18)).

The i.r. spectrum of this material was superimposable with an authentic sample.

This research was supported by a National Research Council of Canada grant to J. W. Lown and by the University of Alberta. We thank Mr. R. Swindlehurst and Dr. A. Hogg for the n.m.r. and mass spectra.

Valence-shell Transitions in the Vacuum-Ultraviolet Spectra of Fluorobenzenes[1]

R. GILBERT, P. SAUVAGEAU, AND C. SANDORFY
Département de Chimie, Université de Montréal, Montréal, Québec

Received August 12, 1971

The vacuum–ultraviolet spectra of a nearly complete series of fluorinated benzene derivatives were measured. The assignments of $\pi^* \leftarrow \pi$ and $\sigma^* \leftarrow \sigma$ valence-shell type transitions are discussed as well as the influence that the fluorine substituents exert on these.

Les spectres dans le lointain ultraviolet de la série presque complète des dérivés fluorés du benzène sont présentés. On discute l'attribution des transitions du type $\pi^* \leftarrow \pi$ et $\sigma^* \leftarrow \sigma$ et l'influence du nombre et des positions des fluors sur ces transitions.

Introduction

The near-ultraviolet spectra of the fluoroderivatives of benzene are well known. The α-band ($^1B_{2u} \leftarrow {}^1A_{1g}$ in benzene) is in all cases similar to that of benzene. Sponer (1) correlated its shifting with the number of fluorine atoms and the geometry of the molecule, and a thorough theoretical study has been carried out by Petruska (2).

We shall not be concerned with this band. The p and β bands ($^1B_{1u} \leftarrow {}^1A_{1g}$ and $^1E_{1u} \leftarrow {}^1A_{1g}$, respectively, in benzene) have received less attention but Kimura and Nagakura (3) measured the spectra of fluorobenzene down to 1600 Å, and Hammond, Price, Teegan, and Walsh (4) down to 1350 Å. Petruska also considered these bands in his perturbation treatment (2).

Recently we published our new results on monofluorobenzene (5) for both the valence-shell and Rydberg transitions. In the present paper we communicate results concerning the $\pi^* \leftarrow \pi$ and (presumably) $\sigma^* \leftarrow \sigma$ transitions found in the 2100–1200 Å part of the u.v. spectrum for a nearly complete series of di-, tri-, tetra-, penta-, and hexafluorobenzenes in the vapor phase. In all these spectra we find numerous Rydberg transitions. These will be dealt with in subsequent publications. Here we shall discuss the assignment of the bands having valence-shell characteristics. These are expected to be the p and β bands, higher $\pi^* \leftarrow \pi$ transitions, and transitions of the bonding σ electrons at the high frequency end of the given spectral range.

The photoelectron spectra of several fluorobenzene derivatives are known (6–10). The lone pairs of the fluorine atoms have ionization potentials of 16–17 eV and their electronic transitions are expected to appear at wavelengths shorter than 1200 Å. The fluorine atoms should influence the spectrum mainly by their inductive effect which is expected to affect the σ orbitals much more than the π orbitals (6, 11–13).

The following abbreviations will be used: B, benzene; FB, fluorobenzene; (1,2), 1,2-difluorobenzene and so on.

Figures 1, 3, and 5 give the spectra of (1,2,4), (1,2,3,5), and (6) from 2100–1200 Å as typical examples. Figures 2, 4, and 6 give the 1600–1200 Å part of the same spectra with an extended scale for the extinction coefficients.

Experimental

The spectra were measured with a McPherson model 225 monochromator with a hydrogen discharge tube as the light source, a double beam attachment, and photoelectric recording. Instrumental details were given in previous publications from this laboratory (14, 15).

The samples were commercial products from the Pierce Chemical Co. They were purified by gas chromatography using a 20 ft column containing CHROMOSORB-W with 30% of KEL-F oil no. 3 as adsorbent. Mass spectrographic analysis yielded purities higher than 99.9%.

Vapor pressures in the absorption cell varied from 0.02–0.5 Torr.

Results and Discussion

Table 1 lists the p and β bands. No clear cor-

*Approximate overall oscillator strength of the 1350–1200 Å region (integrated over the whole area).

relation is found between the number and location of the F atoms and the frequency of the broad p band except that in the tetra-, penta-, and hexafluorobenzenes, they are shifted to higher frequencies by about a thousand wavenumbers. In the case of the (1,2,3,5) derivative we find two bands in this part of the spectrum. We are not trying to interpret this since contamination by another tetrasubstituted isomer cannot be excluded. The oscillator strength of the p band is of the order of $f = 0.075$.

The β bands shift much more (1600–3200 cm^{-1}) and again the tetra-, penta-, and hexa compounds shift significantly more than the others (4000–5500 cm^{-1}). The oscillator strength is of the order of $f = 1.10$.

What other $\pi^* \leftarrow \pi$ transitions can we expect? As is well known, B and (6) have only one allowed transition, $^1E_{1u} \leftarrow {}^1A_{1g}$. In particular, all transitions originating from the a_{2u} level or arriving

at the b_{2g} level are electronically forbidden. Under D_{3h} symmetry (1, 3, 5) only $^1E' \leftarrow {}^1A_1'$ is allowed but in this case there are three such transitions: one resulting from a transition between the two degenerate levels and two others corresponding to transitions between one non-degenerate a_2'' and one degenerate level (e''). The spectra of the D_{6h} and D_{3h} derivatives are not very different, however, and this is the first indication of the fact that in the case of fluorine substituted benzenes, the transitions between π levels are not profoundly affected by the substituents.

Under D_{2h}, C_{2v}, and C_s symmetries the β bands should be split and a number of other

For personal use only.

transitions should become possible. If we compare the spectra, however, we find that they are all of the same general type. The β band is by far the most intense in all of them. In all the spectra we find a broad band at the high frequency side having about the same intensity as the p band (between 65000 and 63000 cm^{-1}; the sharp bands superimposed on it are Rydberg bands). Ironically it is strongest in (6) which has D_{6h} symmetry. In benzene this could correspond to one of the forbidden $^1E_{2g} \leftarrow {}^1A_{1g}$ transitions. The fact that its intensity is about the same in all our molecules, regardless of their symmetry, seems to show that this band does not result from the splitting of the β band. Vibronic coupling with the allowed β band is probably a more important factor in providing intensity to the other bands; the lowering of the symmetry of benzene by fluorine substitution being of secondary importance.

It is surprising that no clear indication is found for the splitting of the β band. According to available photoelectron ionization potential data (6), (7) the splitting between π_2 and π_3 amounts to 0.2–0.6 eV for the different derivatives.

One more $\pi^* \leftarrow \pi$ transition remains to be located, the one corresponding to $b_{2g} \leftarrow a_{2u}$ in benzene. It is impossible to do it, however, with any degree of certainty, although some weak and broad features are observed in some of the spectra around 1500 Å.

There are two other areas of broad absorption, one between 1400 and 1300 Å and another between 1300 and 1200 Å which are, in most cases, overlapped by Rydberg bands. These could possibly be $\sigma^* \leftarrow \sigma$.

There has been some controversy relating to the highest σ levels in benzene (13, 16, 17). One of these should lie between (π_2,π_3) and π_1 or slightly below π_1. Large deviations from Koopmans' theorem are likely to occur (18). This makes any attempt of ordering the orbitals on the basis of photoelectron spectra difficult. Even less is known about the σ^* levels. We know, however, that in ethane the first band due to σ electrons is located between 1400 and 1300 Å (15). In ethylene there is no evidence for σ transitions down to 1200 Å (18).

In benzene it is expected to appear again at somewhat longer wavelengths, quite possibly in the 1300–1200 Å region, where we observe broad bands. Now, we know that in paraffins, fluorine substitution stabilizes the σ levels and shifts the $\sigma^* \leftarrow \sigma$ bands to higher frequencies, while decreasing their intensity (19). The data of Table 1 (last column) are significant in this respect. They show that the intensity in the 1300–1200 Å region decreases by a large factor for the highly substituted derivatives. This we take as an indication that most of the intensity in that part of the spectrum comes from $\sigma^* \leftarrow \sigma$ transitions. Usually two weaker bands remain, one closer to 1300 Å, the other to 1200 Å. These might be due to Rydberg transitions which could be first members of series converging toward the higher π ionization potential.

$\pi \leftrightarrow \sigma$ transitions are possible, but are expected to be very weak. They are likely to contribute to background absorption.

Conclusion

In conclusion we should like to point out that the number of fluorine substituents appears to be more important in determining the characteristics of these spectra than their location, or the symmetry of the corresponding molecules. Their influence on the $\pi^* \leftarrow \pi$ transitions is moderate, but it is stronger on the σ transitions which appear at wavelengths shorter than 1400 Å.

Dipole Moments and Conformation of Sultones, Thiosultones, and Sultines

O. EXNER

J. Heyrovský Institute of Polarography, Czechoslovak Academy of Sciences, Prague 1, Czechoslovakia

AND

DAVID N. HARPP AND JOHN G. GLEASON[1]

Department of Chemistry, McGill University, Montreal, Quebec

Received July 23, 1971

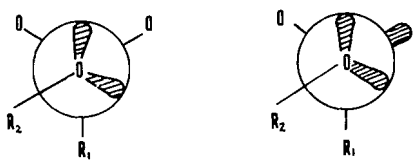
Dipole moments of five- and six-membered sultones and thiosultones have been used to establish the values of bond moments used in conformational studies of open-chain analogues. Hence, the gauche conformation of acyclic sulfonic esters has been confirmed and the same conformation deduced from published data for thiolsulfonate esters. The dipole moment of a five-membered sultine has been interpreted similarly, while in the case of the six-membered derivative, the axial sulfinyl conformation has been determined in agreement with n.m.r. data.

On a utilisé les moments dipolaires des sultones et thiosultones en cycles à cinq ou à six dans le but de déterminer les valeurs des moments des liens utilisés dans des études conformationnelles d'analogues à chaîne ouverte. On a ainsi confirmé la conformation gauche des esters sulfoniques acycliques et déduit la même conformation à partir des résultats publiés pour les esters thiolsulfonates. On a interprété le moment dipolaire d'une sultine dans un cycle à cinq de façon similaire, alors que dans le cas du cycle à six, on a déterminé la conformation du sulfinyl axial en accord avec les résultats de la r.m.n.

Canadian Journal of Chemistry, **50**, 548 (1972)

Introduction

In the course of our recent interest in the conformation of simple functional groups, we have measured dipole moments of acyclic sulfonates (1) and sulfinates (2) and attributed them the *a priori* unexpected gauche conformations **1** and **2**, respectively (Newman projection viewed along the O—S bond). As usual with this method, several assumptions had to be made concerning the values of bond moments since suitable model compounds of rigid cyclic structure were not available to us.



1 2

Recent syntheses furnished some missing members of this class of compounds (3) and enabled us to study dipole moments of the cyclic derivatives **3**–**8**. Slight deviations from planarity in the five-membered derivatives (**3**, **5**, **7**) will not seriously affect the resulting moments, thus these compounds can serve well to check the bond moments used previously (1, 2). In addi-

†Estimated values, see Experimental.

tion, the conformation of thiolsulfonates may now be estimated on the basis of published dipole moment data (4). The six-membered sultone **4** and thiosultone **6** likely exist in one conformation only, while for sultine **8**, the axial (**8***a*) and equatorial (**8***b*) forms are theoretically possible. On the basis of experimental dipole moment measurements, results of a prior n.m.r. study (5) can now be compared.

Experimental

Materials

Compounds **3–8** were prepared as previously described (3, 5).

Measurements of Dipole Moments

The same technique was used as in previous work (1, 2), based on the method of Halverstadt and Kumler (6). Molar refractions (R_D) of liquid compounds **4**, **7**, and **8** were determined experimentally, the values at 20° being preferred enabling comparison with most reported values. The value found for **4** is only 0.2 cm^3 lower than the sum of Vogel's additive increments (7) while those of **7** and **8** show somewhat greater deviations; the former is 1.3 cm^3 higher and the latter 0.8 cm^3 lower than values computed with the increment (2) 10.02 cm^3 for the S(O)O group. This makes the estimation of R_D for the remaining compounds rather difficult. We took the same R_D for **3** as for **7**, relying on similar increments of the SO and SO_2 groups (2, 7), and calculated R_D values for **5** and **6** from those of **3** and **4**, respectively, by adding 6.16 cm^3 (*i.e.* the difference between increments (7) of bivalent S and O). The inaccuracy in the whole procedure does not markedly affect dipole moment values.

Experimental polarization, dipole moments, and refractions are collected in Table 1. The values of dipole moments with 5 and 15% correction are to be viewed as formerly, but in the particular case under consideration the differences are unimportant.

Calculation of Theoretical Dipole Moments

In the case of the five-membered rings, calculations were performed graphically with the accuracy of *ca.* 0.03 D. For six-membered rings, Dreiding models were used; the accuracy achieved is significantly lower.

Results and Discussion

The molecule 1,2-oxathiolane 2,2-dioxide (**3**) can exist in a planar form with common bond lengths and with angles of 114° on O, 100° on S, and 106, 108, and 112° on C_{1-3}, respectively. These angles agree reasonably with values measured in crystals of similar compounds (8, 9). The deviation from planarity cannot be of such an extent to markedly influence the calculated moments. With bond moments used in our previous papers (1, 2) (H—C_{a1}, 0.3; C—O, 0.74; C—S, 0.7; S—O, 0.2 D) and with the moment of the SO_2 group as a vector of 3.0 D bisecting the angle O—S—O, we obtain a moment of 4.70 D, distinctly lower than the experimental value. Using the higher value of 3.7 D for SO_2 (which was found necessary for chlorosulfonates (2)) the final result is somewhat high (5.38 D). (See Table 2 for a comparison of calculated and experimental values of μ.) The general applicability of five-membered heterocycles as true models for open-chain compounds has been questioned, since the computed results were usually too high (10). For this reason we considered that 3.2 D is a reasonable estimate of the SO_2 group moment in sulfonate esters, and will use it for subsequent calculations although it yields only 4.89 D for **3**.

For 1,2-oxathiane 2,2-dioxide (**4**), the calculated moment was 4.70 D, using the mentioned bond moments (3.2 D for SO_2) and the geometry given by Dreiding models. The agreement with experiment is still somewhat worse than previous, the apparent reason being an imperfect knowledge of the geometry of the molecule. However, the molecule in the chair conformation[2] should be stable since it has the

[2]It should be noted that the calculated moment for a twist conformation is only slightly different: 4.79 D.

same conformation (**1**) of the functional group as open-chain analogues.[3]

For purposes of calculation, 1,2-dithiolane 1,1-dioxide (**5**) may also be considered planar with the required bond lengths (8, 9) and with angles of 98° on the two sulfur atoms and 114, 114, and 116° on C_{1-3}, respectively. The necessary deformation of bond angles is larger than in the case of compound **3**. The expected moment calculated with the previously mentioned bond moments (4.91 D) meets better with experiment than in the case of **3**. It seems that the SO_2 group moment is effectively somewhat smaller in **5**. In the calculation, the S—S bond was taken with a zero moment although it is likely appreciably polarized. However, this polarization is of little effect on the resulting moment.

For 1,2-dithiane 1,1-dioxide (**6**), the calculation yields 4.74 D, so that in all cyclic derivatives the calculated values are somewhat low. The deviations could be compensated in a formal manner by raising the SO_2 group moment. However, we feel this would not be fully substantiated with respect to dipole moments of open-chain derivatives and to general reservations (10) against cyclic derivatives as model compounds in the quantitative sense.

With these bond moments, the conformation of thiolsulfonates in solution can be solved on the basis of experimental moments of Grishko and Guryanova[4] (4). The calculated values for various conformations are plotted as μ^2 in a graph (Fig. 1) according to our original method (11) on the x-axis for ethyl benzenethiolsulfonate and on the y-axis for its para-bromo derivative. The experimental point (showing approximately the inaccuracy inherent in the whole procedure) coincides unambiguously with that one for the gauche conformation (as in **1** with S instead of O). Similar graphs can be constructed for phenyl benzenethiolsulfonate and its 4,4′-dichloro derivative, however, it is still necessary to account for higher experimental moments (4) of phenyl esters. Probably polarization of the phenyl group effectively enhanced the SO_2 moment by some 0.3 D.

[3]When the determination of the conformation of sulfonic esters (1) is now repeated with the SO_2 moment 3.2 D instead of 3.0 D, the conclusions are not appreciably changed. The agreement is better in some instances, worse in the others, but the gauche form **1** remains the best possible solution.

[4]In ref. 4 no correction to atomic polarization was taken. Hence we have recalculated the results to $P_A = 15\%$, P_E to be comparable with our data; however, the correction is unimportant.

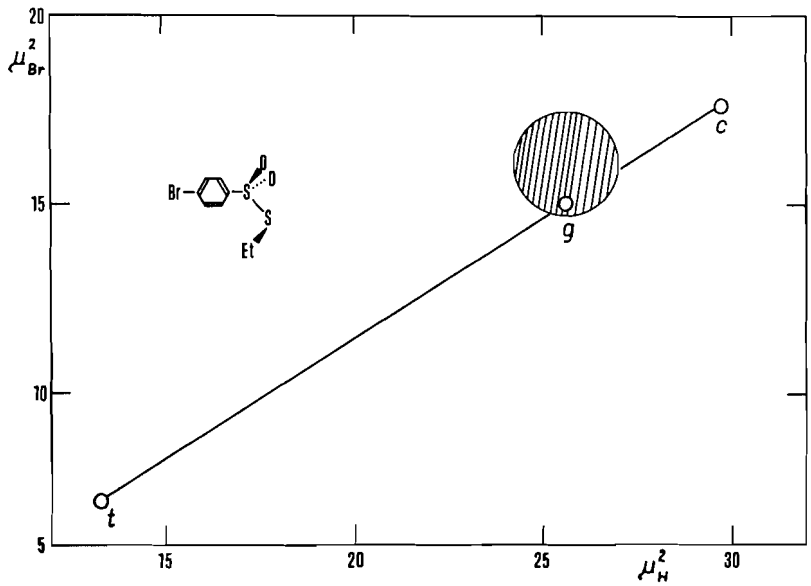

FIG. 1. Determination of conformation of aromatic thiolsulfonates by comparison of computed and experimental (4) dipole moments (*x*-axis ethyl benzenethiolsulfonate, *y*-axis its 4-bromo derivative, the experimental point hatched): t, *trans*; c, *cis*; g, *gauche*.

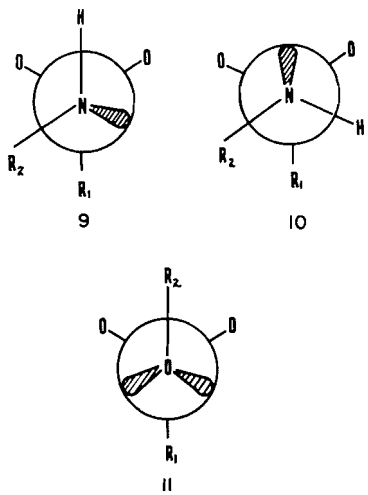
The gauche conformation of thiolsulfonates in solution (the same as in the crystalline state (8)) agrees with that of sulfonates in solution (1) and *N*-monosubstituted sulfonamides in the crystal (12). In the latter case one of the lone electron pairs in conformation **1** is replaced by a hydrogen atom, however, the decision between **9** and **10** does not follow from X-ray crystallography (12). In a dipole moment study of sulfonanilides, only eclipsed forms were considered (13); in the other one free rotation around the S—N bond was claimed (14). In our opinion, the conformation of sulfonamides in solution is probably similar as in the crystal, *i.e.* either **9** or **10**.



The *a priori* unexpected stability of gauche forms **1**, **9**, or **10** is to be discussed as a part of the general problem of the conformation of molecules with lone electron pairs and strongly polar bonds. Recent calculations accounting for various kinds of attractive and repulsive forces lead to the following simplifying rules (15): gauche interactions between polar bonds and/or lone electron pairs are preferred except the conformation which places a polar bond between two electron pairs; this is disfavored (the so-called Edward–Lemieux effect (15)). In the gauche form **1** as well as in the alternative *trans* form **11** there are four bond–lone pair interactions, two bond–bond interactions, and one Edward–Lemieux effect; in the former, the S—O bond, and in the latter the S—C bond is situated between two electron pairs. If only the strongly polar S—O bonds were considered, form **11** would be preferred. Apparently the simplified rules cannot cover all possibilities: *e.g.* in sulfinates the direction of the σ S—O bond moment is not accounted for since the conformation (C—C bond) is considered (15) such that all polar bonds are oriented with the

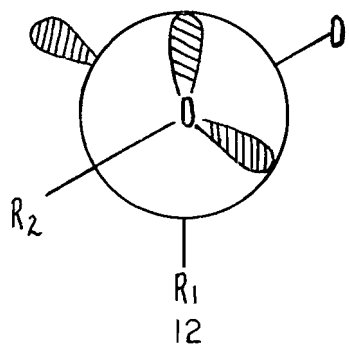
negative end outside. Nevertheless, these rules meet with experiment in a number of cases (10).

To compute the dipole moment of 1,2-oxathiolane 2-oxide (**7**) it is either necessary to attribute a partial moment to the lone electron pair, or to account for it by giving the S—O group a moment non-collinear with the S—O bond. Taking the S—O value applied for chlorosulfinates (2.80 D, with an angle of 37° to the S—O bond (16)) we obtain a predicted moment of 4.40 D, *i.e.* significantly larger than the experimental value. When the supposed contribution of the lone pair is reduced, the final result is not much altered. Apparently this group moment is too high for simple sulfinates. With a non-collinear bond moment of 2.6 D for S—O, a calculation of 4.20 D results.[5]

Nevertheless, the accuracy of computation (using 2.6 D for S—O) seems sufficient to decide between the axial (**8***a*) and equatorial (**8***b*) forms of 1,2-oxathiane 2-oxide (**8**). Using Dreiding models, the calculated values are 3.58 and 4.27 D, respectively,[6] and confirm unambiguously the axial form **8***a* deduced previously from an n.m.r. study (5).[7] The unusual conformational stability of these compounds was discussed in terms of dipole–dipole interactions (5). However, since the axial conformation **8***a* corresponds to **2** in open-chain compounds, (**8***b* would correspond to **12**), a similar explanation is formally possible as for sulfonates. A strong Edward–Lemieux effect (15) clearly disfavors form **12**. Pure electrostatic considerations in terms of dipole–dipole interactions lead to the same result (5) and would be thus satisfactory in this case. However, with conformations **1** and **11** they would yield a false prediction. We thus feel that complex factors controlling conformation may not necessarily be reduced to simple electrostatic forces.



12

[5]Our determination of the conformation of sulfinates (2) was carried out simply with a group moment collinear with the S—O bond. However, the qualitative conclusions leading to form **2** remain unchanged whether the non-collinear bond moment of 2.80 or 2.60 D is employed; the latter value cannot be further significantly lowered with respect to moments of simple aliphatic sulfoxides.

[6]Theoretical calculations (CNDO with Prof. James P. Snyder) also predict the axial form to have a dipole moment of about 1 D less than the equatorial isomer although the absolute values are higher.

[7]Both axial (17–19) and twist (20, 21) conformations have been attributed to the structurally similar sulfites.

The measurements of dielectric constants and densities have been carried out by Mrs. M. Kuthanova under the supervision of Dr. V. Jehlicka; the aid of both is gratefully acknowledged.

Synthesis and Properties of Substituted Germylhydrazines

L. K. PETERSON AND K. I. THÉ

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received June 18, 1971

By using reactions between Me_3GeBr or Me_2GeCl_2 and appropriate lithium hydrazide salts, the following new compounds were prepared: $Me_2NN(R)GeMe_3$ (R = H, **1**; Me, **2**; $GeMe_3$, **3**; $SiMe_3$, **4**), $Me_3GeN(Me)NHGeMe_3$, **5***a*, $MeNHN(GeMe_3)_2$, **5***b*, $(Me_3Ge)_2NN(Me)GeMe_3$, **6**, $Me_3GeNHNHGeMe_3$, **7***a*, $(Me_3Ge)_2NNH_2$, **7***b*, $(Me)_{11}Ge_4N_6H$, **11**, $(Me_2GeNNMe_2)_3$, **12**, $Me_2Ge[N(R')NMe_2]_2$ (R′ = Me, **13**; $SiMe_3$, **14**). Thus the reaction of Me_3GeBr with $Li(MeN_2H_2)$ and with LiN_2H_3 gave mixtures of disubstituted isomers, **5***a* and *b*, and **7***a* and *b*, respectively, rather than mono-substituted derivatives. Reactions of Me_2GeCl_2 gave (*i*) an unresolvable, highly condensed product with LiN_2H_3; (*ii*) the high molecular weight compound **11**, with $Li(MeN_2H_2)$; and (*iii*) the cyclic trigermazane **12** with Me_2NNHLi; the extent of self-condensation is a function of the degree of substitution of the hydrazine moiety. Reactions with protic reagents (H_2O, MeOH, anhydrous HCl) effect cleavage of the Ge—N bond in germylhydrazines. New compounds were characterized on the basis of i.r., n.m.r., and mass spectral measurements.

Par utilisation de réactions entre Me_3GeBr ou Me_2GeCl_2 et les sels d'hydrazide de lithium appropriés, les nouveaux composés suivants furent préparés: $Me_2NN(R)GeM_3$ (R = H, **1**; Me, **2**; $GeMe_3$, **3**; $SiMe_3$, **4**), $Me_3GeN(Me)NHGeMe_3$, **5***a*, $MeNHN(GeMe_3)_2$, **5***b*, $(Me_3Ge)_2NN(Me)GeMe_3$, **6**, $Me_3GeNHNHGeMe_3$, **7***a*, $(Me_3Ge)_2NNH_2$, **7***b*, $(Me)_{11}Ge_4N_6H$, **11**, $(Me_2GeNNMe_2)_3$, **12**, $Me_2Ge[N(R')NMe_2]_2$ (R′ = Me, **13**; $SiMe_3$, **14**). Ainsi la réaction de Me_3GeBr avec $Li(MeN_2H_2)$ et avec LiN_2H_3 donna des mélanges d'isomères disubstitués, **5***a* et *b*, et **7***a* et *b* respectivement, plutôt que les dérivés monosubstitués. Les réactions de Me_2GeCl_2 donnèrent (*i*) un produit, hautement condensé, indéterminable, avec LiN_2H_3; (*ii*) un composé à haut poids moléculaire **11** avec $Li(MeN_2H_2)$; et (*iii*) le trigermazane cyclique **12** avec Me_2NNHLi; le développement de l'auto-condensation est fonction du degré de substitution d'une partie de l'hydrazine. Les réactions avec les réactifs protiques (H_2O, MeOH, HCl anhydre) provoque le clivage de liaisons Ge—N dans les germylhydrazines. Les nouveaux composés furent caractérisés sur la base des spectres: i.r., de r.m.n., et de masse.

Canadian Journal of Chemistry, **50**, 553 (1972)

Results and Discussion

Aminogermanes (1), aminosilanes (2), and silylhydrazines (2) may be prepared by the aminolysis and hydrazinolysis of the appropriate metalloid–halogen bond, the halogen displacement reaction being favored by the simultaneous formation of an ionic, poorly soluble hydrohalide salt; an added strong base may be used for the latter purpose (2, 3), in cases where the amine or hydrazine is very weakly basic. The hydrazinolysis of the Ge—X bond is difficult to effect, even in the presence of strong base, in contrast to the facile reactions of the Si—X bond (2). Both halo-silanes (4) and halo-germanes (5) form donor–acceptor complexes with nucleophiles, hence no mechanistic barrier to the formation of an intermediate complex is apparent, but because of uncertainties in M—N bond energy data (M = Si, Ge), comparisons of the enthalpies of conversion of M—Br to M—N are inconclusive (E_{Si-Br} 74 (6); E_{Si-N} 73–79 (6, 7); E_{Ge-Br} 66 (6, 8); E_{Ge-N} 55–64 kcal/bond (8)). The use of lithium amide (9, 10) or hydrazide (11), however, is generally effective in the synthesis of metalloid-nitrogen systems. In the synthesis of a lithium hydrazide salt via the reaction of butyllithium with an appropriate hydrazine (11), an excess of hydrazine must be used to preclude formation of di-lithio salt, and the excess must be removed from the product before adding bromogermane and solvent (ether); without this latter precaution, much hexamethyldigermane is found. Using appropriate lithium hydrazide salts and Me_3GeBr or Me_2GeCl_2, all of the compounds **1**–**14** (Table 1) were obtained, except for **8**–**10** (eqs. 1 and 2).

$$[1]\quad [RR'R''N_2]Li + Me_3GeX \rightarrow LiX + RR'R''N_2GeMe_3$$

$$[2]\quad [RR'R''N_2]Li + Me_2GeX_2 \rightarrow LiX + Me_2Ge(N_2RR'R'')_2$$

(R groups = H, Me, $SiMe_3$, $GeMe_3$)

Compounds **8** and **10** were made according to the method of Wannagat and Höfler (11). Compound **9**, previously prepared by the action of methyl iodide on $Me_2NN(Li)SiMe_3$ (12), was obtained in improved yield from the reaction

†M = Si or Ge.

of Me_2NNHMe with Me_3SiCl in the presence of triethylamine. The end-products of the reaction of lithium hydrazide with Me_3GeBr are hydrazine and a mixture of the isomers of bis(trimethylgermyl)hydrazine, **7***a* and *b*; the analogous reaction of lithium methylhydrazide yields methylhydrazine and a mixture of the isomers of bis(trimethylgermyl)methylhydrazine, **5***a* and *b*. It may be assumed that one or both of the monosubstituted isomers $Me_3GeN(R)NH_2$ (*a*) and $Me_3GeNHNHR$ (*b*) are initially formed, followed by disproportionation via four-center intermediate transition states, as in the case of silylhydrazines (12, 13), thus giving the parent hydrazine and both isomers of the bis(trimethylgermyl)hydrazine (eq. 3*a*–c); then isomerization may occur via a mechanism involving intramolecular migration of organogermyl groups between the two nitrogen atoms, and catalyzed by the presence of the basic hydrazide ion (base B, eq. 4), in the manner postulated by West *et al.* (14) for the isomeriza-

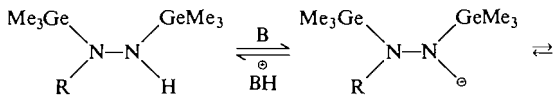
Isomer *b*

[3c] 
Isomer *b*



[4] 
tion of bis(organosilyl)hydrazines. A similar isomerization mechanism is possible for the monosubstituted germylhydrazines.

The bis(alkylhydrazine)germanes are even less stable than the germylhydrazines with respect to self-condensation; thus, the derivative, $Me_2Ge(NHNMe_2)_2$, rapidly evolves Me_2NNH_2, ultimately yielding compound **12** (eq. 5). By contrast, the dimethylsilyl analogue $Me_2Si(NHNMe_2)_2$ is stable against self condensation (15).

[5] $3Me_2Ge(NHNMe_2)_2 \rightarrow (Me_2GeNNMe_2)_3 + 3Me_2NNH_2$

In the reactions of Me_2GeCl_2 with lithium methylhydrazide or lithium hydrazide, the possible intermediates $Me_2Ge(NHNHMe)_2$ and $Me_2Ge(NHNH_2)_2$ were not detected; in the former case, one of the ultimate products, the high molecular weight compound **11**, was formulated as $Me_{11}Ge_3N_6H$ on the basis of mass spectral observations; a possible bicyclic structure is shown in Fig. 1.

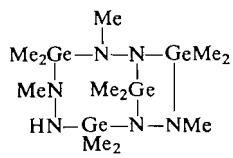


FIG. 1. A possible bicyclic structure: compound **11**.

Mass Spectral Measurements

The polyisotopic mass spectral fragmentation patterns of the germylhydrazines (Table 2) were of particular value in the identification of species containing more than one germanium atom. The relative intensities of the isotopic lines were calculated, using the method of Carrick and Glockling (16); the discrepancies between calculated and observed intensities are due to the fact that the loss of small neutral fragments (mostly H atoms) gives rise to overlapping patterns. The spectra show that facile cleavage occurs at the Ge—N bond, giving Me_3Ge and hydrazino fragments; a characteristic feature of the bis(trimethylgermyl) derivatives **3**, **5***a*, **6**, and **7**, was the formation of large amounts of hexamethyldigermane. The mixed silylgermyl derivative, $Me_2NN(SiMe_3)GeMe_3$, **4**, however, gave $Me_3SiGeMe_3$ in very small amounts; in this case, and for compound **14**, the preferential cleavage of the Ge—N, rather than the Si—N bond is noted.

Proton Magnetic Resonance Spectra

The p.m.r. spectra of compounds **1**–**14**, given in Table 1, were consistent with the given formulations; in most cases, assignments were readily made on the basis of the positions and relative intensities of bands. Two mixtures of isomers, however, were encountered: the mixture of **5***a* and *b* could not be completely separated by fractionation, and gave absorption bands in the Me_3Ge region at τ 9.75, 9.78, and 9.83. The last two bands, of equal intensity, were assigned to germyl-methyl protons of the $NHGeMe_3$ and $MeNGeMe_3$, respectively, in compound **5***a*, on the basis of the inductive, and

‖This work.

hence shielding, effect of the methyl group on N. The NH and MeN bands of appropriate intensities occur at τ 8.42 and 7.46, respectively. The remaining bands were consistent for compound **5***b*, $MeNHN(GeMe_3)_2$, the groups being $(Me_3Ge)_2$ (τ 9.75) NH(7.16), and MeN (two peaks, at 7.55 and 7.66, in a 2:1 ratio). A similar splitting pattern is reported for the MeN protons of $MeNHN(SiMe_3)_2$ (12). In compound **12**, a cyclotrigermazane (Fig. 2), the chemical shifts for the MeGe and MeN protons have the lowest values in the series **1–14** studied; this may mean that delocalization of the lone pairs on nitrogen into the vacant 4d orbitals of germanium occurs, such that σ-electron density is withdrawn from the ring-Ge and exocyclic-Me_2N groups; however, changes in hybridization resulting from bond angle requirements at germanium could equally well explain the observed spectral features. Substituent effects, summarized in Tables 3 and 4, have been discussed in terms of inductive and π-bonding effects (17–21).

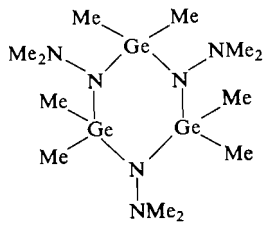

FIG. 2. A cyclotrigermazane: compound **12**.

Chemical Characteristics

Since typical reactions of aminogermanes with nucleophiles and with electrophiles involve cleavage of the Ge—N bond (9), we were particularly interested in the possibility of forming stable adducts, or salts, between hydrazino germanes and Lewis acids, a mode of reaction

which would demonstrate the overriding basicity of the terminal N atom, relative to the central N atom. A study of reactions involving BX_3 (X = Me, F, Cl) and CY_2 (Y = O, S) is described elsewhere (22), while reactions with protic reagents HX (X = Cl, OH, OMe) are described here, since cleavage patterns demonstrated the composition and corroborated our formulations of new compounds.

Representative reactions involving protic reagents HX (X = Cl) were carried out with compounds **1**—**4** and **13**, while for X = OH and OMe, *i.e.* with water and methanol, compound **2** was used. In all cases cleavage of N–metalloid bonds was indicated, according to eqs. 6–9.

[6] $$RR'NNR''GeMe_3 + 2HCl \rightarrow Me_3GeCl + RR'NNHR''HCl$$

[7] $$2RR'NNR''GeMe_3 + H_2O \rightarrow (Me_3Ge)_2O + 2Me_2NNHMe$$

[8] $$RR'NNR''GeMe_3 + MeOH \rightarrow Me_3GeOMe + Me_2NNHMe$$

[9] $$Me_2Ge[N(SiMe_3)NMe_2]_2 + 6HCl \rightarrow Me_2GeCl_2 + 2Me_3SiCl + 2Me_2NNH_2HCl$$

On the basis that the above cleavage reactions proceed quantitatively, the nitrogen atoms are not of sufficiently different basicity to give rise to stable salts

$$Me_2N—N(R)MMe_3$$
$$\quad\quad\downarrow$$
$$\quad\quad H—X$$

instead, the cleavage reaction may proceed via an unstable intermediate of the type

$$[Me_2N—N(R)MMe_3]$$
$$\quad\quad\quad\downarrow$$
$$\quad\quad\quad H—X$$

Experimental

Standard high vacuum methods were used to handle volatile, air-sensitive compounds, while inert atmosphere systems were used for involatile materials. Sealed, all-glass reaction vessels were used for most reactions; wherever filtration operations were required, a sintered filter disc was incorporated in the design of the reaction vessel. Solvents were dried before use. Mass spectra were measured with a double focussing RMU-6E Hitachi Perkin–Elmer instrument, n.m.r. spectra with a Varian A56/60, and i.r. spectra with a Beckmann I.R. 12 spectrophotometer. A Bendix Series 2200 instrument was used for gas phase chromatographic separations. Saturated vapor pressure measurements were obtained using mercury tensimeters.

Hydrazine, methylhydrazine, and *N,N*-dimethylhydrazine, purchased from Fisher Scientific Co., were dried over anhydrous barium hydroxide, and were distilled from calcium hydride. Trimethylamine (Matheson) and triethylamine (K & K) were dried in a similar way, and fractionated. Triethylhydrazine was prepared according to the method of Class, *et al.* (23). Trimethylchlorosilane and dimethyldichlorogermane (Alfa Inorganics) were fractionated through a suitable train of cold traps. Butyllithium (Alfa) was obtained as a 2 *M* solution in hexane.

Trimethylsilyltrimethylhydrazine (**9**), was obtained in high yield from the reaction of Me_3SiCl and trimethylhydrazine, in ether solution, using Et_3N as hydrogen halide acceptor. An alternative method, using $Me_2NN(Li)SiMe_3$ and methyl iodide, gives poor yields (12). *N,N*-dimethyl-*N'*-(trimethylsilyl)hydrazine (**8**) and *N,N*-dimethyl-*N',N'*-bis(trimethylsilyl)hydrazine (**10**) were prepared according to methods of Wannagat and Höfler (11). Trimethylbromogermane was made from Me_4Ge (Alfa), using the method of Brown and Fowles (24).

(1) Preparation of Lithium Hydrazide Salts

The following general procedure, described in detail for the synthesis of $Me_2NN(Li)Me$, was used to make Me_2NNHLi, $MeNHNHLi$ (or $MeN(Li)NH_2$), $MeN(Li)N(GeMe_3)_2$, $Me_3GeN(Me)N(Li)GeMe_3$, N_2H_3Li, $Me_2NN(Li)GeMe_3$, and $Me_2NN(Li)SiMe_3$.

Lithium trimethylhydrazide was prepared according to the method of Wannagat and Höfler (11), by treating Me_2NNHMe (14.5 mmol) in solution in hexane with a slight deficiency of butyllithium (13 mmol) in the same solvent. The reaction vessel was sealed and heated at 85–90° for 12–16 h, with the upper part of the vessel at room temperature, thus effecting reflux action. The evolved butane was estimated, and solvent and unreacted Me_2NNHMe were removed from the flask; to remove final traces of the hydrazine from the lithium salt, the flask was immersed in an oil bath at 85–90° for 12–24 h while still connected to the high vacuum pumping system. The yield of lithium trimethylhydrazide was calculated on the basis of the evolved butane.

(2) Reaction of Me_2NNHLi with Me_3GeBr

Preliminary experiments with Me_2NNH_2 and Me_3GeBr indicated the formation of the 1:1 adduct, $Me_2NNH_2 \cdot Me_3GeBr$, together with small quantities of $Me_2NN(H)GeMe_3$ and $(Me_3Ge)_2$.

The salt Me_2NNHLi (15 mmol) was treated with ether and Me_3GeBr (12 mmol); the only volatile reaction product was $Me_2NNHGeMe_3$ (**1**) (11.3 mmol, 99%), identified by mass spectral ($P_{obsd.}$ 178; $P_{calcd.}$ 178), p.m.r. and i.r. measurements; the saturated vapor pressure was 4.40 mm/0.0°.

The i.r. spectrum of $Me_2NNHGeMe_3$ (**1**) (gas phase):[1] 450(6), 530(6), 575(16), 610(82), 680(15), 720(11), 760(46), 825(100), 855(89), 899(48), 910(54), 1010(33), 1035(26), 1050(26), 1155(28), 1245(66), 1440(sh), 1460(59), 1590(23), 1610(sh), 2770(89), 2820(85), 2850(72), 2920(69), 2960(74), 3000(97), 3220(21).

(3a) Reaction of Me_2NNHMe with Me_3GeBr, with Et_3N Present

An exploratory experiment indicated the absence of reaction between Me_2NNHMe (4.52 mmol) and Me_3GeBr

[1]The i.r. bands are given in cm^{-1}. The numbers in parentheses denote relative intensities, with an arbitrary value of 100 assigned to the most intense band.

(4.41 mmol) in solution in diethylether (4.8370 g). Triethylamine (4.37 mmol) was added to the mixture, causing immediate formation of white precipitate. The most volatile reaction products, separated by gas chromatography (column, 30% SE-52 on chromosorb W, 45–60 mesh) into $(Me_3Ge)_2$ and $Me_2NN(Me)GeMe_3$ (**2**) were identified by p.m.r. and mass spectral measurements ($P_{obsd.}$ 237 and 192; $P_{calcd.}$ for $(Me_3Ge)_2$ 237; $P_{calcd.}$ for $Me_2NN(Me)GeMe_3$ 192); a solid product, obtained in small quantity, was believed to be $Me_3GeGe(Me)_2N(Me)NMe_2$ ($P_{obsd.}$ 292; $P_{calcd.}$ 294; isotope pattern indicative of two Ge atoms in the molecule).

(3b) Reaction of $Me_2NN(Li)Me$ with Me_3GeBr

Lithium trimethylhydrazide (~12 mmol), ether (7.69 g), and Me_3GeBr (10.4 mmol) were heated together in a sealed flask for 16 h at 65–70°, the upper walls of the flask being sufficiently cool to maintain reflux action. The only volatile product, other than solvent, was $Me_2NN(Me)GeMe_3$ (9.1 mmol, 90% yield), identified by p.m.r. and mass spectral analysis ($P_{obsd.}$ 192; $P_{calcd.}$ 192); the vapor phase molecular weight was 195 ($M_{calcd.}$ 192), and the saturated vapor pressure was 8.00 mm/24.20°.

The i.r. spectrum of $Me_2NN(Me)GeMe_3$ (**2**) (gas phase): 560(70), 600(77), 750(38), 820(100), 880(34), 960(5), 1010(13), 1085(43), 1150(19), 1245(68), 1410(sh), 1455(32), 1465(30), 1480(30), 2780(68), 2830(79), 2850(79), 2890(78), 2920(79), 2950(89), 2990(96).

(4) Reaction of $Me_2NN(Li)GeMe_3$ with Me_3GeBr

$Me_2NN(Li)GeMe_3$, (5.8 mmol) prepared from $Me_2NNHGeMe_3$ by the method described above, and Me_3GeBr (5.8 mmol) in solution in ether, were heated together for 14 h at 90°. The product, separated from the LiBr residue by heating and pumping, was $Me_2NN(GeMe_3)_2$ (**3**) (4.6 mmol, 80%; $P_{obsd.}$ 294; $P_{calcd.}$ 294; for p.m.r. spectrum, see Table 1). Saturated vapor pressure readings were 2.75 mm/20.0° and 6.55 mm/50.0°.

The i.r. spectrum of $Me_3NN(GeMe_3)_2$ (**3**) (pure liquid film): 460(34), 480(sh), 570(59), 600(87), 750(70), 810(100), 860(sh), 1010(29), 1085(14), 1150(10), 1235(89), 1400(43), 1430(31), 1450(40), 1470(26), 2770(49), 2820(59), 2850(65), 2870(54), 2910(83), 2930(83), 2980(89).

(5) Reaction of $Me_2NN(Li)SiMe_3$ with Me_3GeBr

A mixture of $Me_2NN(Li)SiMe_3$ (~20 mmol), ether, and Me_3GeBr (10 mmol) was heated together to yield $Me_2NN(SiMe_3)GeMe_3$ (8.0 mmol, 80%), liberated from the LiBr precipitate by pumping and heating (90°, 4 h). The product was identified as $Me_2NN(SiMe_3)GeMe_3$ by mass ($P_{obsd.}$ 250; $P_{calcd.}$ 250) and p.m.r. spectral measurements. The saturated vapor pressure at 50° was 5.05 mm.

The i.r. spectrum of $Me_2NN(SiMe_3)GeMe_3$ (**4**) (pure liquid film): 470(44), 495(47), 570(59), 600(84), 625(40), 680(46), 750(66), 830(100), 920(sh), 950(96), 1015(39), 1085(16), 1150(6), 1225(sh), 1240(86), 1260(sh), 1300(6), 1410(23), 1440(26), 1450(27), 1465(sh), 2780(37), 2820(43), 2850(56), 2880(49), 2910(60), 2940(73), 2980(70).

(6a) Reaction of Lithium Methylhydrazide with Me_3GeBr

Lithium methylhydrazide (~12 mmol) was treated with ether and Me_3GeBr (5.7 mmol); the volatile products were methylhydrazine (2.5 mmol) and a liquid, held at −33°, with a parent peak indicative of $(Me_3Ge)_2(Me)N_2H$ ($P_{obsd.}$ 280; $P_{calcd.}$ 280). The presence of the two isomeric species, $Me_3GeN(Me)NHGeMe_3$ (**5***a*) and $MeNHN(GeMe_3)_2$ (**5***b*) was indicated by the p.m.r. spectra. The overall yield was 80%.

(6b) Reaction of the Two Isomers of Bis(trimethylgermyl)-methylhydrazine with Butyllithium and Me_3GeBr

A mixture of $Me_3GeN(Me)NHGeMe_3$ and $MeNHN(GeMe_3)_2$ (6.0 mmol) in hexane was treated with butyllithium according to the method described above, the resulting salt was treated with ether and Me_3GeBr (6.5 mmol). The products were $(Me_3Ge)_2$ (3.0 mmol) and tris(trimethylgermyl)methylhydrazine $(Me_3Ge)_2NN(Me)GeMe_3$ (**6**) (0.9 mmol); the latter product, obtained only after pumping and heating the reaction vessel, with its residue of LiBr, for 4 h at 90° was identified by its mass spectrum ($P_{obsd.}$ 397; $P_{calcd.}$ 397) and by its p.m.r. spectra.

The i.r. spectrum of $Me_3GeN(Me)N(GeMe_3)_2$ (**6**) (pure liquid film): 400(69), 560(97), 595(97), 620(sh), 750(100), 800(100), 850(sh), 970(66), 1120(55), 1200(55), 1235(90), 1400(67), 1425(sh), 1465(34), 2770(72), 2820(sh), 2840(76), 2910(86), 2970(86), 3020(sh).

(7) Reaction of Lithium Hydrazide with Me_3GeBr

A mixture of lithium hydrazide (~10 mmol), ether, and Me_3GeBr (9.2 mmol) were heated together at 65° for 12 h. The products were (*a*) a small quantity of nitrogen, (*b*) a small quantity of ammonia, (*c*) hexamethyldigermane, (*d*) hydrazine, (*e*) a mixture of the isomers *N,N'*- and *N,N*-bis(trimethylgermyl)hydrazine, (*7a* and *b*, respectively), from which a pure sample of *N,N*-bis(trimethylgermyl)-hydrazine, $(Me_3Ge)_2NNH_2$ was obtained on repeated fractionation. The i.r., p.m.r., and mass spectral measurements were used in the identification of these products.

The i.r. spectrum of $(Me_3Ge)_2NNH_2$ (*7b*) (pure liquid film): 510(49), 570(82), 600(99), 660(45), 750(87), 800(100), 860(sh), 1010(sh), 1070(28), 1100(sh), 1150(5), 1240(89), 1320(16), 1400(53), 1430(sh), 2800(28), 2860(sh), 2910(83), 2980(91), 3020(sh), 3290(16).

(8) Reaction of Lithium Hydrazide, LiN_2H_3, with Me_2GeCl_2

A mixture of lithium hydrazide (~20 mmol) was heated at 90° for 12 h; on removing the solvent, an involatile white solid residue remained in the flask. Attempts to release products of low volatility, by heating the flask to 100°, led to the evolution of hydrazine. The residue was partly soluble in THF; the soluble fraction showed a "parent" peak of 458, believed to be a fragment of a larger polymeric structure.

(9) Reaction of MeN_2H_2Li with Me_2GeCl_2

A mixture of lithium methylhydrazide (~16 mmol), ether, and Me_2GeCl_2 (8.1 mmol) was heated at 90° for 12 h, yielding $MeNHNH_2$ (8.5 mmol) and a colorless, oily liquid, held at 20°, believed, from its mass and p.m.r. spectra, to be $Me_{11}Ge_4N_6H$ (**11**) (see Fig. 1) ($P_{obsd.}$ 540; $P_{calcd.}$ 540).

(10) Reaction of Me_2NNHLi with Me_2GeCl_2

A mixture of Me_2NNHLi (~30 mmol), ether, and Me_2GeCl_2 (8.6 mmol) was heated at 90° for 12 h, to yield Me_2NNH_2, and a liquid held at −16°; the latter product decomposed into Me_2NNH_2 (total recovery, 7.6 mmol) and an involatile yellow oil during subsequent fractionation. The p.m.r. and mass spectra ($P_{obsd.}$ 482; $P_{calcd.}$ 482) of the

yellow oil were consistent for $(Me_2GeNNMe_2)_3$ (**12**) yield, 65%.

The i.r. spectrum of $(Me_2GeNNMe_2)_3$ (**12**) (pure liquid film): 470(64), 570(sh), 590(78), 620(83), 750(100), 790(sh), 820(87), 865(86), 1010(53), 1030(sh), 1085(40), 1150(36), 1215(sh), 1235(74), 1410(56), 1435(53), 1445(54), 1460(49), 2760(59), 2800(42), 2040(64), 2910(71), 2930(71), 2980(67).

(11) Reaction of $Me_2NN(Li)Me$ with Me_2GeCl_2

A mixture of $Me_2NN(Li)Me$ (~8 mmol), ether, and Me_2GeCl_2 (4.5 mmol) was heated together, yielding unreacted Me_2GeCl_2 (0.6 mmol), and $Me_2Ge[N(Me)NMe_2]_2$ (**13**) held at −33°, and identified by its mass ($P_{obsd.}$ 250; $P_{calcd.}$ 250) and p.m.r. spectra. The saturated vapor pressure at 50° was 5.85 mm; yield, ~90%.

The i.r. spectrum of $Me_2Ge[N(Me)NMe_2]_2$, (**13**) (pure liquid film): 425(28), 480(33), 575(27), 610(45), 745(30), 810(sh), 820(100), 850(sh), 980(17), 1010(38), 1085(67), 1150(30), 1215(sh), 1240(55), 1435(sh), 1455(55), 1470(50), 2770(73), 2820(91), 2850(95), 2870(89), 2940(63), 2980(85).

(12) Reaction of $Me_2NN(Li)SiMe_3$ with Me_2GeCl_2

A mixture of $Me_2NN(Li)SiMe_3$ (~19 mmol), ether, and Me_2GeCl_2 (7.5 mmol) was heated at 90° for 12 h; upon recovering the solvent, a white residue remained, which released the desired product, $Me_2Ge[N(SiMe_3)NMe_2]_2$ (**14**) (3.4 mmol, 45%) only after heating at 125–160° for 14 h. The p.m.r. and mass ($P_{obsd.}$ 366; $P_{calcd.}$ 366) spectra established the given formulation. The saturated vapor pressure at 100° was 3.45 mm; yield, 45%.

The i.r. spectrum of $Me_2Ge[N(SiMe_3)NMe_2]_2$, (**14**), (pure liquid film): 470(56), 500(51), 570(48), 590(51), 630(33), 680(55), 750(71), 800(88), 830(100), 910(sh), 950(92), 1020(59), 1090(21), 1230(sh), 1250(92), 1310(7), 1410(29), 1450(41), 1460(44), 1470(33), 2790(52), 2830(59), 2860(71), 2890(62), 2920(69), 2950(82), 2970(78), 2990(sh).

(13) Reactions Involving Anhydrous Hydrogen Chloride

(a) With $Me_2NNHGeMe_3$

In a typical procedure, a mixture of $Me_2NNHGeMe_3$ (0.82 mmol), ether (0.7996 g), and anhydrous HCl (1.70 mmol) was kept in a sealed tube for 3 h. The recovered products were: Me_3GeCl (0.74 mmol) Me_2NNH_2HCl (0.81 mmol), and an "ether fraction" (0.8178 g); products were characterized by m.p., molecular weight, i.r. and mass spectral measurements, as appropriate. Thus the stoichiometry of the reaction is

$$\underset{\text{obsd. } 0.82}{Me_2NNHGeMe_3} + \underset{1.70}{2HCl} \rightarrow \underset{0.74}{Me_3GeCl} + \underset{0.81 \text{ mmol}}{Me_2NNH_2\cdot HCl}$$

Using similar procedures with other compounds the following cleavage reactions were observed:

(b) With $Me_2N(N)MeGeMe_3$

$$\underset{\text{obsd. } 0.80}{Me_2NNMeGeMe_3} + \underset{1.76}{2HCl} \rightarrow \underset{0.78}{Me_3GeCl} + \underset{0.81 \text{ mmol}}{Me_2NNHMe\cdot HCl}$$

(c) With $Me_2NN(GeMe_3)_2$

$$\underset{0.45}{Me_2NN(GeMe_3)_2} + \underset{1.55}{3HCl} \rightarrow \underset{0.82}{2Me_3GeCl} + \underset{0.41 \text{ mmol}}{Me_2NNH_2HCl}$$

(d) With $Me_2NN(SiMe_3)GeMe_3$

$$\underset{0.74}{Me_2NN(SiMe_3)GeMe_3} + \underset{2.60}{3HCl} \rightarrow \underset{0.76}{Me_3GeCl} + \underset{0.72}{Me_3SiCl} + \underset{0.77 \text{ mmol}}{Me_2NNH_2\cdot HCl}$$

(e) With $Me_2Ge(NMeNMe_2)_2$

$$\underset{0.43}{Me_2Ge(NMeNMe_2)_2} + \underset{\text{excess}}{HCl} \rightarrow \underset{0.45 \text{ mmol}}{Me_2GeCl_2} + Me_2NNHMe$$

(14) Reactions with Hydroxylic Protic Reagents

(a) With Methanol

A mixture of $Me_2NN(Me)GeMe_3$ (0.60 mmol) and methanol (0.60 mmol) yielded, after 12 h at room temperature the products Me_2NNHMe (0.62 mmol) and Me_3GeOMe, identified by i.r. and mass spectroscopic methods. The stoichiometry of the reaction is:

$$\underset{\text{obsd. } 0.60}{Me_2NN(Me)GeMe_3} + \underset{0.60}{MeOH} \rightarrow \underset{0.62}{Me_2NNHMe} + \underset{0.59 \text{ mmol}}{Me_3GeOMe}$$

(b) With Water

After 2 days at room temperature, a mixture of $Me_2NN(Me)GeMe_3$ (0.77 mmol) and water (0.97 mmol) yielded Me_2NNHMe (0.78 mmol), $(Me_3Ge)_2O$ (0.25 mmol), and a small amount of a mixture of H_2O and $(Me_3Ge)_2O$ that could not be separated by fractionation. The stoichiometry approximates to the equation

$$2Me_2NN(Me)GeMe_3 + H_2O \rightarrow 2Me_2NNHMe + (Me_3Ge)_2O$$

the deficiency in $(Me_3Ge)_2O$ (0.25 *vs.* 0.38 mmol) being due to experimental difficulties.

The authors acknowledge the financial assistance of the National Research Council of Canada, and Miss E. Cheah and Mr. G. Owen for n.m.r. and mass spectral measurements.

The Reactions of Substituted Germyl- and Silylhydrazines with BX_3 and CY_2 Acceptor Species

L. K. PETERSON AND K. I. THÉ

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received June 18, 1971

Boron trimethyl reacts with each of the organometalloid-hydrazine derivatives $Me_2NN(R)GeMe_3$ (R = H, Me, $SiMe_3$) except $Me_2NN(SiMe_3)GeMe_3$, and with $Me_2NNHSiMe_3$, forming 1:1 adducts. With $Me_2NN(SiMe_3)GeMe_3$ and BMe_3, no adduct was formed even at low temperatures. On the basis of p.m.r. spectra, the metalloid-substituted nitrogen atom rather than the terminal nitrogen, is indicated as the basic center at which adduct formation occurs. With BF_3, the Si—N and Ge—N bonds of the hydrazine derivatives were cleaved, again indicating attack at the central nitrogen atom. In a series of experiments involving CY_2 (Y = O, S) and $Me_2NN(R)MMe_3$ (R = H, Me, $SiMe_3$; M = Si, Ge), reaction occurred readily for R = H, but less readily for R = Me and for the compound $Me_2NN(GeMe_3)_2$, while no reaction was observed for the compounds $Me_2NN(SiMe_3)_2$ and $Me_2NN(SiMe_3)GeMe_3$, even when heat or basic catalysts were employed. Reaction products, carbamate and thiocarbamate derivatives, $Me_2NN(R)C(Y)YMMe_3$, were characterized on the basis molecular weight, i.r., p.m.r., and mass spectroscopy, and m.p. data. Ease of formation is discussed in terms of electronic and steric effects.

Le bore triméthyle réagit avec les dérivés organométalliques de l'hydrazine $Me_2NN(R)GeMe_3$ (R = H, Me, $SiMe_3$) sauf $Me_2NN(SiMe_3)GeMe_3$ et $Me_2NNHSiMe_3$, en donnant des composés d'addition 1:1. Aucune réaction n'est obtenue avec $Me_2NN(SiMe_3)GeMe_3$ et BMe_3, même à basse température. Le spectre r.m.n. montre que le site de l'addition est l'atome d'azote substitué par le métalloide plutôt que l'atome d'azote terminal. Avec BF_3, les liaisons Si—N et Ge—N des dérivés de l'hydrazine sont coupées, indiquant là encore une attaque sur l'atome d'azote central. Dans une série d'expériences entre CY_2 (Y = O, S) et $Me_2NN(R)MMe_3$ (R = H, Me, $SiMe_3$; M = Si, Ge); la réaction est facile pour R = H, moins facile pour R = Me et pour le composé $Me_2NN(GeMe_3)_2$, tandis qu'aucune réaction n'est observée pour les composés $Me_2NN(SiMe_3)_2$ et $Me_2NN(SiMe_3)GeMe_3$ même avec l'emploi de la chaleur et des catalyseurs basiques. Les produits de réactions, dérivés de carbamate et de thiocarbamate, sont caractérisés par leur masse moléculaire, leurs spectres i.r. et r.m.n., leur spectre de masse et leur points de fusion. La facilité de réaction est discutée en fonction des facteurs électronique et stérique.

Canadian Journal of Chemistry, **50**, 562 (1972)

Results and Discussion

In organometalloid-hydrazine systems

the lone pairs of electrons may occupy distinct valence bond orbitals, or, alternatively, they may occupy delocalized molecular orbitals associated with the whole or part of the skeleton. This paper describes a study of the structural features of adduct formation by such systems, as an attempt to distinguish between the two different electron density models. On steric and electronic grounds, the central nitrogen atom is expected to be least basic, thus allowing for the possibility of salt or adduct formation between Lewis acids and the terminal nitrogen site of metalloid-hydrazines; such mode of reaction would contrast with the typical cleavage of metalloid–nitrogen bonds by many electrophiles (1).

A series of reactions between germylhydrazines and protic Lewis acids led exclusively to cleavage of the Ge—N bond (2). With acids of the type BX_3, however, a range of acceptor power is available, thus permitting a selective study of the differing basicities of the hydrazino nitrogen atoms. The use of n.m.r. methods for this purpose has been described (3, 4).

With trimethylboron, the only adducts stable at room temperature were $Me_2NNHMMe_3 \cdot BMe_3$ (M = Si, Ge), both distillable under vacuum. Contrary to expectations, a comparison of the p.m.r. spectra of the adducts, and of the parent hydrazines, indicate 1:1 complexation at the metalloid–N site, even for $Me_2NNHSiMe_3$, where the silyl group might be expected to diminish the basicity of the adjacent nitrogen atom. While the p.m.r. bands for the Me_2N and Me_3M groups show fine structure, resolution into a 6:2:1 intensity pattern was effected only for the latter.

The 1:1 adduct $Me_2NN(Me)GeMe_3 \cdot BMe_3$ is stable only at $-78°$, being fully dissociated at

$-45°$. Attempts to construct molecular models of the adduct revealed severe steric congestion, obviously compensating the enhanced basicity expected from the additional methyl group. Similarly, the basic centres in $Me_2NN(SiMe_3)$-$GeMe_3$ are even more crowded, precluding adduct formation even at low temperatures.

Reactions involving BF_3 resulted in the cleavage of M—N bonds (M = Si, Ge), with formation of Me_3MF, as is generally the case with aminosilanes (5, 6). With $Me_2NN(SiMe_3)$-$GeMe_3$, it appears that one of the M—N bonds is cleaved initially, and, from the relative amounts of Me_3SiF and Me_3GeF produced, the difluoroborane intermediate $Me_2NN(BF_2)$-$SiMe_3$ readily undergoes further self-condensation (eqs. 1*a* and 1*b*).

$$[1a]\quad 2Me_2NN(SiMe_3)GeMe_3 + 2BF_3 \rightarrow Me_2NN(BF_2)GeMe_3 + Me_3SiF + Me_2NN(BF_2)SiMe_3 + Me_3GeF$$

$$[1b]\quad xMe_2NN(BF_2)SiMe_3 \rightarrow (Me_2NNBF)_x + xMe_3SiF$$

Analogous studies of adduct formation between phosphinohydrazines $RR'NNR''P(CF_3)_2$-(R, R′, R″ = H, Me) and BX_3 Lewis acids have shown that BMe_3 does not form an adduct with the trifluoromethylphosphino derivative of trimethylhydrazine, as observed for the trimethylgermyl and trimethylsilyl derivatives; but stable adducts are obtained with BF_3, without cleavage of the P—N bond. In one case, *viz.* $(CF_3)_2$-$PNMeNH_2BX_3$, n.m.r. evidence indicated that complexation occurred at the terminal, least substituted N atom (3).

Insertion Reactions with CO_2 and CS_2

While CS_2 forms simple 1:1 adducts with bases such as Et_2NH (7), the reaction with metalloid-substituted amines, such as trialkylstannyl- (8), germyl- (1), and silyl- (7) dialkylamines, proceeds further to yield thiocarbamate derivatives (1, 8, 9). Similar reactions occur with CO_2 (1, 8, 10) and COS (10). With trialkylmetalloid-hydrazines $Me_2NN(R)MMe_3$ (R = H, Me, $GeMe_3$; M = Si, Ge) two modes of reaction with CS_2 are possible, the insertion mode, described above, or the formation of 1:1 adducts, utilizing the terminal nitrogen atom. With CO_2, the trisubstituted hydrazines (R = H) readily reacted, forming carbamate derivatives $Me_2NNHC(O)OMMe_3$ (M = Ge, Si). The fully substituted sterically hindered compounds (R = Me, $GeMe_3$) required forcing conditions (heating at 90° for several hours) to yield $Me_2NN(Me)C(O)OMMe_3$. The behavior of the bis-organometalloid derivatives Me_2NN-$(MMe_3)M'Me_3$(M, M′ = Si, Ge) is of interest in that reaction could be effected in only one case, *viz.* the conversion of $Me_2NN(GeMe_3)_2$ into $Me_2NN(GeMe_3)C(O)OGeMe_3$. Prolonged heating, and the use of basic catalysts (7), such as Et_2NH and Me_2NNH_2 failed to induce reaction by $Me_2NN(SiMe_3)GeMe_3$ and Me_2NN-$(SiMe_3)_2$ with CO_2. The steric resistance to reaction, due to two organometalloid groups, must be approximately the same for all three molecules, hence the electronic reduction in the basicity of the central nitrogen atom of Me_2NN-$(SiMe_3)GeMe_3$ and $Me_2NN(SiMe_3)_2$ by Me_3Si groups is an important factor in preventing reaction. With CS_2, similar results were obtained, in that thiocarbamate derivatives Me_2NN-$(R)C(S)SMMe_3$ (R = H, Me; M = Si, Ge) and $Me_2NN(GeMe_3)C(S)SGeMe_3$ were formed from the appropriate organometalloid-hydrazine, while the compounds $Me_2NN(SiMe_3)$-$GeMe_3$ and $Me_2NN(SiMe_3)_2$ again failed to react. The reaction of $Me_2NNHSiMe_3$ with CS_2 was noticeably slower than the corresponding reaction of the trimethylgermyl analogue, presumably due to the lower basicity of the former substance. The reaction of $Me_2NN(GeMe_3)_2$ with CS_2 gave rise to some hexamethyldigermane, a product not observed in the corresponding reaction with CO_2.

Mass Spectra of Carbamate and Thiocarbamate Derivatives

Parent ions appropriate to the given formulations were observed in all cases except Me_2-$NNHC(O)OGeMe_3$ and $Me_2NN(GeMe_3)C(S)$-$GeMe_3$, as were small fragments such as CY_2 (Y = O, S), MMe_3 (M = Si, Ge), and Me_2NNR (R = H, Me, $GeMe_3$). The fragments Me_3SiO, Me_3SiS, Me_3SiOCO and $Me_3SiSCSMe$ were observed for the trimethylsilylhydrazines; the corresponding trimethylgermyl fragments were not observed, presumably reflecting the weaker Ge—Y, relative to Si—Y, bond energies (E_{Ge-O} 82 (11); E_{Si-O} 103 (12); E_{Ge-S} 59 (11); E_{Si-S} 79 kcal (12)). Hexamethyldigermane was eliminated from $Me_2NN(GeMe_3)C(O)OGeMe_3$, as was also observed with the bis(trimethylgermyl)-hydrazines of the type $MeN(R)N(GeMe_3)_2$ (R = H, Me, $GeMe_3$), $Me_3GeNHNHGeMe_3$, and $(Me_3Ge)_2NNH_2$ (2). The facile formation

§$NMMe_3$ protons.

of the Ge—Ge bond, with elimination of $(Me_3Ge)_2$, appears to be a common transition for parent ions containing two Me_3Ge groups. Both $Me_2NNHC(O)OGeMe_3$ and $Me_2NN(GeMe_3)C(S)SGeMe_3$ decomposed in the heated inlet system of the mass spectrometer. A study of the thermal decomposition of the former indicated the formation of $Me_2NN(GeMe_3)C(O)OGeMe_3$, Me_2NNH_2, and CO_2, rationalized according to eq. 2. The decomposition products of $Me_2NN(GeMe_3)C(S)SGeMe_3$ were $(Me_3Ge)_2$, $(Me_3Ge)_2S$, and brown residues. It is puzzling that $Me_2NNHC(S)SGeMe_3$ is more stable than the corresponding carbamate, $Me_2NNHC(O)OGeMe_3$, whereas $Me_2NN(GeMe_3)C(O)OGeMe_3$ is more stable than the thiocarbamate $Me_2NN(GeMe_3)C(S)GeMe_3$.

[2] $2Me_2NNHC(O)OGeMe_3 \rightarrow Me_2NN(GeMe_3)C(O)OGeMe_3 + Me_2NNH_2 + CO_2$

Proton Magnetic Resonance Spectra of Carbamate and Thiocarbamate Derivatives

The p.m.r. data for the compounds $Me_2NN(R)C(Y)YMMe_3$ (R = H, Me, $GeMe_3$; M = Si, Ge) are given in Table 1. The methyl protons of the groups $YMMe_3$ (Y = O, S; M = Si, Ge) are more shielded in the carbamate derivatives than in the thiocarbamate derivatives, i.e. greater shielding occurs with Y = O than with Y = S, the converse of what is expected simply on the basis of the relative electronegativities of oxygen and sulfur. This apparent anomaly has been interpreted in terms of greater dative π-bonding between O and Si or Ge, an effect which compensates the σ-electron withdrawal (13). In the conversions $Me_2NN(R)MMe_3 \rightarrow Me_2NN(R)C(Y)YMMe_3$, the $—C(Y)YMMe_3$ substituent causes a deshielding of both the central RN and terminal Me_2N protons. In the corresponding pairs $Me_2NNHC(Y)YGeMe_3$ and $Me_2NNHC(Y)YSiMe_3$ (Y = O, S), the deshielding effect of thiocarbamate is greater than that of carbamate, whereas in the fully substituted derivatives $Me_2NN(R)C(Y)YMMe_3$, the deshielding effects are quite similar for the two cases. These observations may be interpreted in terms of varying contributions among the resonance structures shown in Fig. 1.

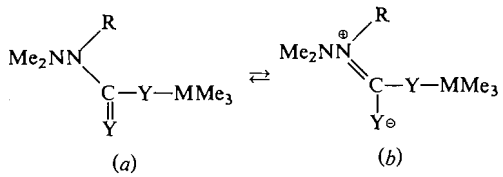

FIG. 1. Resonance structures for carbamate and thiocarbamate derivatives.

Infrared Spectra of Carbamate and Thiocarbamate Derivatives

The carbonyl stretching vibration (10) occurs at 1690–1700 cm^{-1} in the trimethylsilyl derivatives $Me_2NN(R)C(O)OSiMe_3$ (R = H, Me), and at 1660–1680 in the corresponding trimethylgermyl compounds. These observations are consistent if the imine form is dominant for the trimethylgermyl derivatives (Fig. 1*b*), while the π-bonded structure (Fig. 1*a*) is of

*See footnote, Table 2.

major importance in the trimethylsilyl compounds. In the thiocarbamate series, ν(C=S) (10) occurs at 1180 cm^{-1} in $Me_2NNHC(S)SMMe_3$, and at 1220–1230 cm^{-1} in $Me_2NN(Me)C(S)SMMe_3$ (M = Si, Ge); in these compounds, π-bonding between S and the metalloid does not appear to play a significant role. The i.r. data for carbamate and thiocarbamate derivatives are collected in Tables 2 and 3, respectively.

Experimental

Apparatus, instrumentation, and experimental procedures for the synthesis of trimethylsilyl and trimethylgermyl derivatives of hydrazines have been described (2, 14, 15). Boron trifluoride, boron trichloride, trimethyl boron, and anhydrous hydrogen chloride, obtained from Matheson, were fractionated through a suitable train of cold traps. Solvents were dried and distilled before use.

In a typical procedure, the substituted hydrazine and BX_3 were mixed, either in a 1:1 molar ratio, or with BX_3 in known excess. After 1 h at room temperature, the products were separated by fractionation, and estimated, thus giving the stoichiometry of the reaction. If necessary, the reaction tube was cooled (not lower than $-78°$) in order to check for adduct formation at low temperatures; in other cases, solutions of the hydrazine and BX_3 were prepared, and their p.m.r. spectra were recorded at various temperatures. With BMe_3, 1:1 adducts were obtained according to eq. 3,

[3] $Me_2NN(R)MMe_3 + BMe_3 \rightarrow Me_2NN(R)MMe_3 \cdot BMe_3$

for R = Me, H and M = Ge, and for $Me_2NNHSiMe_3$. The compound $Me_2NN(Me)GeMe_3BMe_3$, stable at $-78°$, was fully dissociated at $-45°$. With BF_3, cleavage of metalloid–nitrogen bonds was observed in all cases; typically, the products of the reaction of $Me_2NN(Me)GeMe_3$ (0.69 mmol) and BF_3 (0.71) were: BF_3 (trace), Me_3GeF (0.67 mmol), and a white solid residue.

Reactions between organometalloid-hydrazines and CO_2 or CS_2 were carried out according to modified procedures of Lappert and coworkers (8). The following compounds, characterized on the basis of m.p., molecular weight, and mass, i.r., and p.m.r. spectral measurements, were obtained: $Me_2NNHC(O)OGeMe_3$, m.p. 60–61°; $Me_2NN(Me)C(O)OGeMe_3$, m.p. $-18.5°$ ($P_{obsd.}$ 236, $P_{calcd.}$ 236, plus the fragments CO_2, Me_2NNMe, Me_3Ge); $Me_2NN(GeMe_3)C(O)OGeMe_3$, liquid at room temperatures, glassy solid ($P_{obsd.}$ 338, $P_{calcd.}$ 338, plus CO_2, $Me_2NNGeMe_3$, $(Me_3Ge)_2$); $Me_2NNHC(O)OSiMe_3$, m.p. 76.6–77.0° ($P_{obsd.}$ 176, $P_{calcd.}$ 176; plus CO_2, Me_3SiOCO, Me_3SiO, Me_3Si); $Me_2NN(Me)C(O)SiMe_3$, m.p. $-12.5°$ ($P_{obsd.}$ 190, $P_{calcd.}$ 190; plus CO_2, Me_3SiOCO, Me_3SiO, Me_3Si); no reaction was observed for $Me_2NN(SiMe_3)_2$ and $Me_2NN(SiMe_3)GeMe_3$ with CO_2. $Me_2NNHC(S)SGeMe_3$, m.p. 103–104° ($P_{obsd.}$ 253, $P_{calcd.}$ 254; plus CS_2, Me_3Ge); $Me_2NN(Me)C(S)SGeMe_3$, m.p. 72–73° ($P_{obsd.}$ 268, $P_{calcd.}$ 268; plus CS_2, Me_3Ge); $Me_2NN(GeMe_3)C(S)SGeMe_3$, liquid at room temperature, glassy solid; $Me_2NNHC(S)SSiMe_3$, white solid ($P_{obsd.}$ 209, $P_{calcd.}$ 208; plus CS_2, Me_2NNH, Me_3SiS, Me_3Si); $Me_2NN(Me)C(S)SSiMe_3$, m.p. 58–59° ($P_{obsd.}$ 222, $P_{calcd.}$ 222; plus CS_2, Me_2NNMe, $Me_3SiC(S)SMe$, Me_3Si); no reaction was observed for $Me_2NN(SiMe_3)_2$ and $Me_2NN(SiMe_3)GeMe_3$ with CS_2. The observed reactions with CO_2 and CS_2 corresponded to eq. 4.

[4] $Me_2NN(R)MMe_3 + CY_2 \rightarrow Me_2NN(R)C(Y)YMMe_3$

Metal Halide Ammines. II.[1] Thermal Analyses, Calorimetry and Infrared Spectra of Fluoride Ammines and Hydrates of Bivalent Metals

K. C. PATIL AND E. A. SECCO

Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received August 13, 1971

Thermal analyses of bivalent metal fluoride ammines reveal that decomposition occurs in two or more steps. Calorimetric measurements along with related enthalpic values of the various decomposition steps are given. The infrared spectral data of the ammines and hydrates are compared with theoretical and some experimental values already in the literature.

Les analyses thermiques d'ammines de métaux fluorés bivalents indiquent que la décomposition se fait en deux étapes ou plus. Des mesures calorimétriques ainsi que les valeurs d'enthalpie correspondantes sont données pour les différentes étapes de décomposition.

Les données infrarouges des amines et des hydrates sont comparées avec les valeurs théoriques et quelques valeurs expérimentales déjà dans la littérature.

Canadian Journal of Chemistry, **50**, 567 (1972)

Introduction

Although metal chloride, bromide, and iodide ammines (1, 2) have attracted the interest of chemists for some time, surprisingly little effort has been directed towards the metal fluoride ammines.

Alkali and alkaline earth metal fluorides are not known to form ammines with ammonia gas or liquid since such a reaction is expected to be highly endothermic with a large amount of energy required to expand the fluoride lattice (3). Fluorides of Ag(I) and the bivalent metals Cu, Mn, Fe, Co, and Ni add NH_3 to form ammoniate complexes (4); these complexes are explained in terms of the large coordination energy released in surrounding the strongly polarizing cation with the polarizable ammonia molecules (5).

Recently, Cavell and Clark (6, 7) have reported the preparation of V, Nb, and W fluoride ammines. In this laboratory, we have prepared a number of bivalent metal fluoride ammines by reacting the fluoride hydrate with liquid ammonia. The purpose of this work was to study the mode of decomposition, heat of decomposition, relative thermal stability, and infrared spectra of fluoride ammines of some bivalent transition metals; the analogous hydrates were also studied and included for comparison purposes.

[1]For Part I, see ref. 22.

Experimental

$ZnF_2.4H_2O$ and $CdF_2.2H_2O$ were obtained by treating ZnO and CdO, respectively, with aqueous HF in plastic ware. $CuF_2.2H_2O$ was obtained by following a known procedure (8). $CoF_2.4H_2O$ and $NiF_2.4H_2O$, used in this work were obtained by recrystallization in aqueous HF of the commercially available compounds.

The fluoride tetra- and hexa-ammines were prepared by refluxing the freshly prepared fluoride hydrate with anhydrous liquid ammonia as previously described in Part I of this series. No color change was noticed with ZnF_2 and CdF_2 for the hydrate → ammine conversion whereas distinct color changes were observed for the following:

$$CuF_2.2H_2O \text{ (blue)} \rightarrow CuF_2.6NH_3 \text{ (deep blue)}$$

$$CoF_2.4H_2O \text{ (pink)} \rightarrow CoF_2.4NH_3 \text{ (red)}$$

$$NiF_2.4H_2O \text{ (green)} \rightarrow NiF_2.6NH_3 \text{ (blue-violet)}$$

The monoammines of ZnF_2 and CdF_2 were prepared by heating ZnO and CdO, respectively, with NH_4F thoroughly mixed in 1:4 molar ratio for 8–10 h at 150 °C and eliminating the excess NH_4F by washing with methanol.

The composition, and purity, of the hydrates and ammines was assessed by their infrared spectra and thermal analyses along with identification of their decomposition products.

The heating curves recorded for differential thermal analysis, thermogravimetry, and calorimetry were obtained using the instrumentation and following the procedure described (9, 10). The electrical thermal analyzer, ETA-960, a plug-in accessory to the duPont 900 console, was used according to supplier's instruction manual to monitor the electrical conductivity as a function of temperature. The sample material was packed in a holder between two Pt electrodes. A d.c. potential of 10 V was applied across the sample and the current developed, from a low current limit of 10^{-10} A, was recorded as a function of temperature at a constant heating rate.

The infrared spectra of the compounds were recorded on a

X-Ray diffraction patterns of solid specimens were recorded on a Norelco X-ray diffractometer unit using Cu K_α radiation with Ni filter or Mo K_α radiation with Zr filter as previously described (11).

Results and Discussion

A. Thermal Analyses of Hydrates

The results of thermogravimetry presented in Table 1 show that all the fluoride hydrates studied, except $CuF_2.2H_2O$ which was reported earlier, undergo dehydration in a single step represented by the general equation

$$[1] \qquad MeF_2.xH_2O_{(s)} \rightarrow MeF_{2(s)} + xH_2O_{(g)}$$

The DTA heating curves show two endotherms in the case of Zn, Cd, and Fe but a single endotherm for Co and Ni. The first endotherm is identified with dehydration while the second endotherm in Zn and Cd compounds is due to melting of the anhydrous fluoride. Dehydration of $FeF_2.4H_2O$ yields a mixture of oxide, fluoride, and/or oxyfluoride in the solid residue as reported earlier by Ostrovskaya and Amirova (12).

The heats of dehydration are presented in Table 2. The column of values for ΔH per mole of H_2O liberated shows a constant value of 12–13 kcal for the tetrahydrates and a higher value of 16 kcal for the dihydrate.

B. Thermal Analyses of the Ammines

The results of thermogravimetry and DTA measurements are presented in Tables 2 and 3, respectively. The proposed reactions for each compound are those which best fit the observed weight loss in TG and correlated with DTA heating curves along with identification of the intermediate and final products by X-ray diffraction. Each compound is discussed in sequence.

Zinc Fluoride Ammines

According to TG the hexammine decomposed to zinc fluoride in two steps:

$$[2] \qquad ZnF_2.6NH_{3(s)} \rightarrow ZnF_2.2NH_3 + 4NH_{3(g)}$$

$$[3] \qquad ZnF_2.2NH_{3(s)} \rightarrow ZnF_{2(s)} + 2NH_{3(g)}$$

The DTA heating curve showed the two endotherms corresponding to reactions 2 and 3 along with an exotherm at 580 °C and an additional endotherm at 640 °C. The exotherm

is assigned to the formation of the nitride Zn_3N_2, a product of the reaction between ZnF_2 and NH_3 during the decomposition of diammine. The X-ray diffraction pattern of the DTA residue halted at 580 °C displays the lines characteristic of both ZnF_2 and Zn_3N_2. The endotherm at 640 °C is then identified with the dissociation of Zn_3N_2 (13). The endotherm expected from the melting of ZnF_2 *ca.* 850 °C was not observed; however, the DTA heating curve of the residue from TG arrested at 350 °C showed the 850 °C endotherm due to ZnF_2 fusion. The apparent disparity between the presence of Zn_3N_2 and absence of ZnF_2 in DTA and *vice versa* in TG is accounted for in terms of the dynamic conditions prevailing in TG relative to the static conditions in DTA where NH_3 is accumulated and interacts with the metal fluoride.

The monoammine decomposed to ZnF_2 in one step as shown by TG and DTA; the melting endotherm of ZnF_2 also appeared in the DTA heating curve.

Cadmium Fluoride Ammines

The hexammine decomposed to CdF_2 via reactions 4 and 5

$$[4] \quad CdF_2.6NH_{3(s)} \rightarrow CdF_2.NH_{3(s)} + 5NH_{3(g)}$$

$$[5] \quad CdF_2.NH_{3(s)} \rightarrow CdF_{2(s)} + NH_{3(g)}$$

The DTA heating trace showed two endotherms consistent with reactions 4 and 5 in addition to an exotherm at 430 °C and another endotherm at 580 °C. Parallel to the zinc fluoride hexammine DTA features assignment, the 430 °C exotherm represents the formation of Cd_3N_2 with its subsequent decomposition giving rise to the 580 °C endotherm. The formation of Cd_3N_2 was confirmed by X-ray diffraction of the DTA residue obtained at 450 °C and by reaction of CdF_2 in NH_3 atmosphere under simulated DTA conditions.

The monoammine decomposed in one step to yield CdF_2. In addition to the decomposition endotherm, the melting endotherm of CdF_2 was also evident in the DTA trace.

Copper Fluoride Ammine

The decomposition pattern of copper fluoride hexammine was observed to be influenced by the nature of the atmosphere in contact with the ammine. The decomposition sequence under a static atmosphere or an atmosphere of flowing N_2 is represented as follows

$$[6] \quad CuF_2.6NH_{3(s)} \rightarrow CuF_2.2NH_{3(s)} + 4NH_{3(s)}$$

$$[7] \quad CuF_2.2NH_{3(s)} \rightarrow CuF_2.NH_{3(s)} + NH_{3(g)}$$

$$[8] \quad CuF_2.NH_{3(s)} \rightarrow CuF_{2(s)} + NH_{3(g)}$$

$$[9] \quad CuF_{2(s)} \rightarrow \text{volatilization } (>800\ ^\circ C)$$

Under an atmosphere of flowing NH_3, there is a rapid initial uptake of NH_3 by the hexammine with the quantitative data of the subsequent decomposition steps indicating the initial formation of the octaammine and its breakdown as follows

$$[10] \quad CuF_2.8NH_{3(l)} \rightarrow CuF_2.2NH_{3(s)} + 6NH_{3(g)}$$

$$[11] \quad CuF_2.2NH_{3(s)} \rightarrow CuF_2.NH_{3(s)} + NH_{3(g)}$$

$$[12] \quad 6CuF_2.NH_{3(s)} \rightarrow 2Cu_3N_{(s)} + 2NH_{3(g)} + 12HF_{(g)} + N_{2(g)}$$

$$[13] \quad Cu_3N_{(s)} \rightarrow 3Cu_{(s)} + \tfrac{1}{2}N_{2(g)}$$

The DTA heating curve displayed four endotherms assigned to reactions 6, 7, 8, 12*a*,

$$[12a] \quad 3CuF_{2(s)} + 2NH_{3(g)} \rightarrow Cu_3N_{(s)} + 6HF + \tfrac{1}{2}N_{2(g)}$$

along with one exotherm identified with reaction 13. As mentioned above, *viz.* zinc fluoride ammine, the conditions in DTA allow NH_3 to accumulate and, in the final stage, to interact with the fluoride to form the nitride paralleling the TG experiment under ammonia atmosphere. Copper nitride is reported to form when anhydrous copper fluoride is heated in the presence of NH_3 gas (14). A sharp rise in the ETA conductivity trace at 350 °C supports the transition of CuF_2 to Cu_3N via reaction 12*a*.

The intermediates from thermogravimetry and differential thermal analysis were identified by their characteristic X-ray diffraction patterns and infrared spectra.

Cobalt Fluoride Ammine

The thermogravimetry of the tetraammine showed the mode of decomposition to occur via the monoammine,

$$[14] \quad CoF_2.4NH_{3(s)} \rightarrow CoF_2.NH_{3(s)} + NH_{3(g)}$$

$$[15] \quad CoF_2.NH_{3(s)} \rightarrow CoF_{2(s)} + NH_{3(g)}$$

The DTA trace exhibited two endotherms interpreted in terms of reactions 14 and 15.

The residue from TG and DTA, CoF_2, was confirmed by its X-ray diffraction patterns.

Nickel Fluoride Ammine

According to TG data the hexammine decomposed to NiF_2 through the diammine intermediate. The DTA curve exhibited three endo-

*Over temperature range in °C.
†All determinations were done in duplicate; ΔH values accompanied by average deviations.

therms, none was reversible, which prompts us to suggest the following reaction sequences:

[16] $NiF_6.6NH_{3(s)} \rightarrow NiF_2.2NH_{3(s)} + 4NH_{3(g)}$

[17] $NiF_2.2NH_{3(s)} \rightarrow NiF_2.NH_{3(s)} + NH_{3(g)}$

[18] $NiF_2.NH_{3(s)} \rightarrow NiF_{2(s)} + NH_{3(g)}$

C. Calorimetric Results

The heats of decomposition of both the hydrates and the ammines are presented in Table 4. The last column shows the values of ΔH per mole of H_2O liberated to be slightly higher (by 2–5 kcal) than the ΔH per mole of NH_3 liberated for the same metal fluoride. This fact suggests that the water molecule is more strongly bound to the fluoride lattice relative to the ammonia molecule; most likely due to the stronger H-bonding in the hydrates than in the ammines taking into account oxygen to be more electronegative than nitrogen. It must be noted that the reactivity of the metal fluoride is much greater towards H_2O than towards NH_3; evident by hydrolysis of the fluoride to yield basic fluorides on storage whereas ammonolysis of the fluoride was undetectable over the same time interval.

It may be worth noting that the observed ΔH per mole of H_2O formed *ca.* 13.6 kcal/mol is consistent with the assigned bond energy of 13 kcal/mol for each O—H...F^- bond assumed for hydrogen bonds between F^- and ligated water molecules (21).

D. Infrared Spectral Data

The infrared absorption frequencies of metal fluoride hydrates and ammines, with their assignments, in the 4000–180 cm^{-1} region are presented in Tables 5 and 6, respectively. The vibrational assignments for the ammines are made on the basis that the site symmetry of the complex ion in the compound of formula $[Me(NH_3)_6]F_2$ is O_h (18); the assignments for the hydrates are given in accordance with the model considered by Fujita *et al.* (15).

Our data show a high degree of internal consistency for the various assignments; the data are also in agreement with the existing literature values, both theoretical and experimental, for other metal halide hexammines.

The infrared spectra of metal halide complexes serve as a useful means to assess the nature of bonding of the ligands to the metals. In the case of the fluoride hydrates where one considers Me—OH_2 and O—H...X (X = halogen) distances as a measure of the strength of coordination and of H-bonding, respectively, one

can expect the rocking frequency of H_2O in aquo complexes to shift to higher frequency with increasing coordination as is evident for metal–ammine complexes (15–17). The $\nu_{(H_2O)_R}$ of medium intensity in Table 5 increases in the order Fe > Ni > Co > Cd indicating a decrease in the O—H...X distance in the direction Fe < Ni < Co < Cd. The absorption band in the 2450–2350 cm^{-1} region is assigned to a combination of $\delta_{(H_2O)}$ and $\nu_{(H_2O)_R}$. In contrast to the above aquo complexes, the infrared spectra of Zn and Cu fluoride hydrates are interpreted in terms of simple hydrates and not aquo complexes.

The metal fluoride ammines in Table 6 show the characteristic frequencies of coordinated ammonia; characteristic frequencies of analogous halide ammines are included for com-

Theory of Ionic Conduction in Solids

L. YOUNG

Department of Electrical Engineering, The University of British Columbia, Vancouver 8, British Columbia

Received July 20, 1971

When a constant field in the 10^6 V cm^{-1} range is applied to annealed anodic oxide films the ion current builds up in accelerating fashion. It is shown that a model in which the ions move through channels in the oxide and in which the moving ions clear the initially blocked channels reproduces the general form of the ion current *vs.* time behavior. Dignam's theory of this process is discussed. A recent claim that considerations of mean free path render inapplicable to these films models in which the concentration of ions changes with field due to homogeneous generation of Frenkel defects is shown to be unjustified.

A further observed phenomenon in which the latent ionic conductivity of the films decays at zero field is also discussed in terms of the competing models.

Quand un champ constant dans le domaine de 10^6 V cm^{-1} est appliqué à des films d'oxyde anodique après traitment thermique, le courant ionique s'établit d'une façon accélérée. On montre qu'un modèle dans lequel les ions se déplacent à travers les canaux de l'oxyde tout en dégageant les canaux initialement bloqués, reproduit la forme générale d'un courant ionique dans le temps. La théorie de Dignam sur ce processus est discutée. Récemment, on a déclaré que à partir de considérations sur le libre parcous moyen on ne peut appliquer a ces films les modèles dans lesquels la concentration des ions change avec le champ en raison de la génération homogène des défauts de Frenkel. On montre que ceci est injustifié. Un phénomène observé plus avant dans lequel la conductivité ionique latente des films décroît à champ nul, est aussi discuté en termes de modèles mis en compétition.

Canadian Journal of Chemistry, **50**, 574 (1972)

Models Consistent with Constant-field Transients

The correct model for the ionic conduction process involved in the growth of anodic films is uncertain (1). It has been suggested by Bean, Fisher, and Vermilyea (2) that the concentration of mobile ions is field-dependent. The model proposed by these authors involved the removal of metal ions from network-forming sites in the amorphous oxide by ordinary field-assisted thermal activation. Each such event would create an interstitial metal ion and a vacant cation site, *i.e.*, a Frenkel defect. The vacancies were supposed to be negatively charged. This was expected since the oxide was supposed to be neutral before the creation of the vacancy–interstitial pair. The interstitial ions were supposed to be mobile and the vacancies not. Bean *et al.* tacitly assumed that the two components of the Frenkel defects would remain in equal concentrations. Dewald (3) showed explicitly that this would occur due to assuming electroneutrality and equal charges on the two components of the Frenkel defects. Interstitial ions were supposed to be destroyed by capture by vacancies. A steady state concentration of mobile ions would hence exist for any given electrostatic field. When the field was changed the concentration of the mobile interstitials would not immediately jump to its new value and, consequently, various transient phenomena would be expected for step changes in either field or current. Dewald showed that this model explained his experimental data on transients. However, it was later found by Young (4) that if a relatively large and constant field is applied to films prepared in such a way that, if the theory is correct, they would contain a low concentration of defects, the ion current increases in accelerating fashion (Fig. 1). Since the rate of production of defects is, in this model, a function of the field only, whereas the rate of destruction is supposed to be given by σJn (where σ is a capture cross-section, J is the ionic current density (in units of (ions/area × time)), and n is the defect concentration); n and hence J should build up rapidly at first and then more slowly. The result was first observed for tantalum but similar experiments on aluminum by Dignam and Ryan (5) gave similar results. However, these experiments by no means offer unique support to Dignam's model (to be outlined below). The experiment certainly shows that if the transients are due to the changes in concentration of carriers, then the rate of generation of carriers cannot be

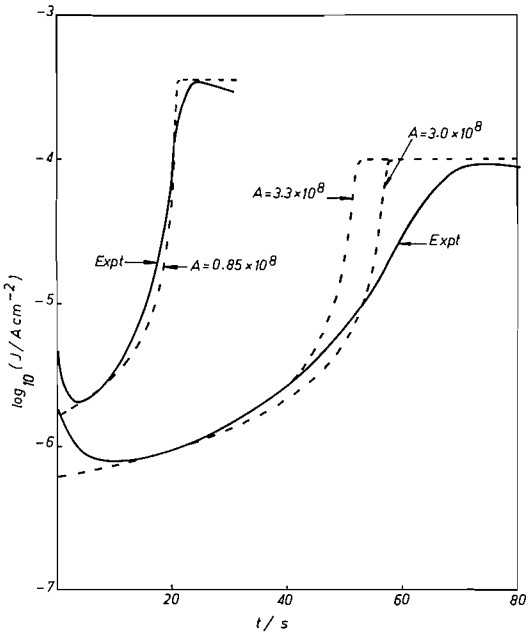

FIG. 1. Computed curves from channel model and experimental data from Fig. 6 of ref. 4 on ionic current density after application at 0 °C of 131 and 126 V to 2040 Å film annealed at 100 °C.

controlled by the field only (4). It was suggested (4) that a momentum transfer process causes moving ions to generate further Frenkel defects (a sort of ionic avalanche effect) and a speculation about a detailed mechanism leading to agreement with the rate of acceleration was suggested.[1] The model proposed by Dignam (6) involves the concept (7, 8) that an effective field (*i.e.* a field containing a contribution from the dielectric polarization of the oxide) causes ionic motion. The central new assumption was that the rate of build-up of one part of the polarization towards its equilibrium value at a given field was taken to be dependent on the current density, again due to a momentum-transfer process involving the moving ions.

Channel Model

A rather simple and apparently physically realistic model of these glassy oxides leads to the type of non-linearity in log $J-E$ which is found with these films (9). It has been suggested that the mobile ions pass through channels in the rather open atomic structures. Due to the randomness of the structure some parts will contain deeper potential energy wells which may act as traps. If these traps may be represented as coulombic, then following the well-known derivation for field-assisted thermally activated release of electrons from traps (Poole–Frenkel law) we expect a steady state current density

$$J = J_0 \exp(-(W - \gamma E^{1/2})/kT$$

where J_0, W, and γ are constants. This form of equation was shown to represent the experimental data quite well for so simple a model. However, it has since been shown (10) that the duplex nature of the films contributes to non-linearity in the steady-state dependence of log J on E. The overall situation on the non-linearity is therefore unclear. The model was not discussed in relation to the transients.

Even if the ions do not move freely through most of their path it seems clear that each metal ion entering the oxide will find a path of least resistance, so that channels exist in a formal sense. Also some potential wells along the path will be deeper than others and will therefore be more effective as traps.[2]

Whether or not the above explanation of non-linearity in log $J-E$ is correct, the model appears to offer a means of explaining some of the transient effects since it naturally evokes the idea that the build-up of current in the constant-field transients is due to the unblocking of the channels (9). The unblocking process must again be postulated to involve momentum transfer from moving ions, perhaps in neighboring channels. As a crude treatment of this channel model, we may assume that the current density is proportional to the fraction θ of unblocked channels

$$J = B(E,T)\theta$$

and that

$$\frac{d\theta}{dt} = AJ^2(1-\theta)$$

[1]The momentum transfer process need not supply the full activation energy.

[2]As supporting evidence for the reasonableness of this model it is noted that in α-quartz dielectric losses are observed corresponding to impurity ions moving along the spiral channels (along the *c*-axis) for distances much greater than single atomic jumps before being blocked by obstructions in the channel; presumably larger impurity ions (11).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

This gives

$$t(J) = (1/AB)(1/J_0 - 1/J) + (1/AB^2)\log((B/J_0 - 1)/(B/J - 1))$$

where $J = J_0$

at $t = 0$

This scheme reproduces the main feature of the transient, as shown in Fig. 1. The initial excess current observed in experiments may be a polarization current or current due to cracks in the film which become sealed. The fall-off in the experimental current is due to a decrease in field as the film starts to grow at appreciable rates: the experiments were done at constant voltage. To obtain a better fit a re-blocking term would be needed which increased more rapidly with current. It is notable (and unsatisfactory) that A has to be chosen smaller for larger fields. A distribution of channel parameters could be used to improve the fit.

Dignam's model, in the simplified form with which it was tested by Dignam and Ryan, is represented by the following equations

$$J = \alpha \exp \beta E^*$$

where E^* is an effective field which is taken to be proportional to the electric displacement D

$$D = \varepsilon_0 E + P$$

and the polarization

$$P = P_0 + P_s$$

where P_0 is ordinary dielectric polarization (time dependence neglected) and P_s is a special polarization and obeys

$$\frac{dP_s}{dt} = BJ(\varepsilon_0 \chi_s E - P_s)$$

where B is a constant and χ_s is the susceptibility for this special polarization. This equation is the same as for Debye-type losses except BJ replaces $1/\tau$, where τ is the relaxation time. The first equation would give a linear dependence of log J on E which is not observed. In this system we again have

$$\frac{dJ}{dt} \propto J^2$$

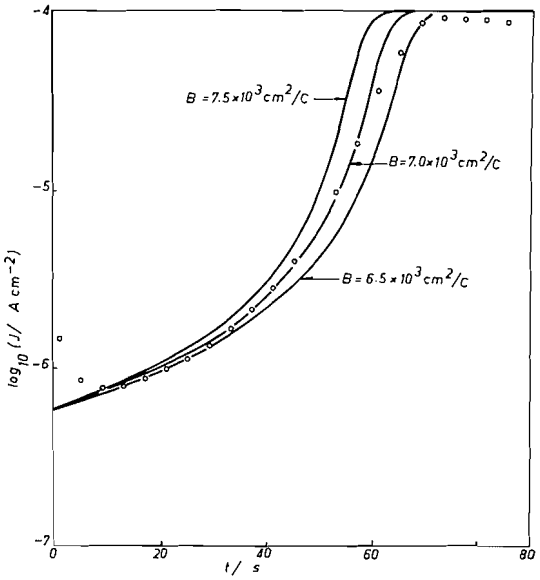

FIG. 2. Computed curves on Dignam's model and experimental data as Fig. 1 at 126 V.

for the initial stages of the transient. The saturation of J arises from the saturation of P_s.

By straightforward manipulation, as shown by Dignam and Ryan (eq. 9, ref. 5), for the constant field transients

$$\frac{dJ}{dt} = J^2 B \log(J_s/J)$$

where J_s is the final steady ionic state current density for this field. Dignam and Ryan apparently integrated experimental data for Al and Ta and plotted $1/J$ *vs.* $\int_0^t \log(J_s/J)dt$ obtaining a straight line as required.

Figures 2 and 3 show computed curves for various values of B and experimental data for tantalum at two fields (experimental details in ref. 4). Values for the initial and final current densities were assumed to fit the experimental data making three adjustable parameters in all (as for the channel model). The calculated curves were obtained by 4th-order Runge–Kutta method on the U.B.C. Computing Centre's IBM 360. These figures show that a good fit is obtained except (*cf.* Fig. 2) in the later stage of the transient where the current density is noticeably low for a value of B which gives a good fit in the early stages. A very noteworthy point in favor of Dignam's equations as they

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

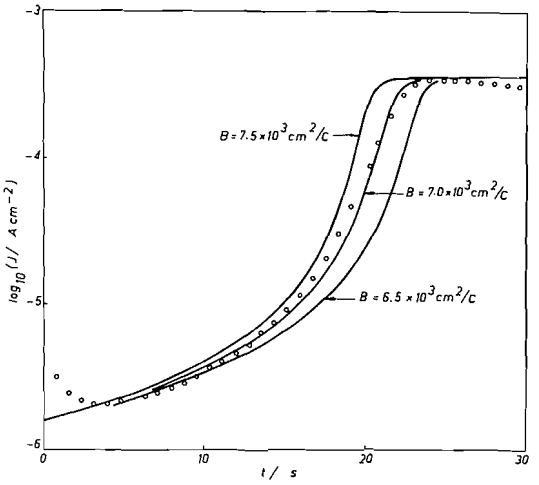

FIG. 3. Computed curves on Dignam's model and experimental data as Fig. 1 at 131 V.

stand is that the same value of B (0.70×10^4 cm^2/C) gives the best fit for both transients (*i.e.*, for two fields). This point was not noted in the paper by Dignam and Ryan who tested their data on Al and the present author's data for tantalum at only one field and did not test the later stage of the transient (Fig. 4, ref. 5). Actually, however, one might expect τ to depend on E as well as on J and T.

To sum up, it is clear that Dignam's equations do give a remarkably good description of the available data. However, it may be considered that the nature of the special polarization mechanism and the way in which moving ions tend to accelerate its approach to equilibrium are not very clearly specified in atomic terms. It is quite possible that a physically simpler model could lead to equally good agreement with the data. More experimental data are certainly required, *e.g.*, for different temperatures. It should be mentioned that the constant field transients are slower with films formed in dilute phosphoric acid (19).

As regards other possibilities, it is possible that a model could be devised in terms of space charge effects due to oxygen ion motion.

As regards Dignam's claim that the model explains the comparable mobility of both ions, the argument presented would not seem specific to the polarization model. Any model involving momentum transfer could be supported by the same arguments. An electronic activation step preceding ion hopping is suggested as an alternative to a momentum transfer mechanism. Charge transfer from metal to oxygen would increase the force on both species. Such an effect is suggested by the u.v. stimulation of ion current.

Mean Free Path

Dignam and Taylor (12) have recently claimed to eliminate all theories involving homogeneous production of defects in the films. This would include the original and the modified Bean, Fisher, and Vermilyea models. Their argument involves the mean free path or, more accurately, the schubweg defined as the distance travelled by a newly-freed ion before capture by a vacant lattice site. It is claimed (12, p. 420) that "for any conduction model in which the mobile defects are generated within the transport medium, motion in the direction of the field can be characterized by a mean free path, λ. The net flux of defects is simply the product of their rate of formation and the mean distance travelled by each defect in the field direction before annihilation". In Dignam and Taylor's notation $J = \lambda(dn_+/dt)$ where dn_+/dt is the rate of creation of defects. On p. 421 the second leg of the argument is introduced (2): "from a consideration of the physical system, λ_s (*i.e.*, the steady state value of λ) cannot be smaller than one jump distance, nor as large as one-half of film thickness". This is elaborated on p. 422 ref. 12: "the steady state mean free path must be in fact substantially less than $X/2$, otherwise it will not be controlled entirely by kinetic phenomena in the film but will be greatly influenced by film thickness". The argument proceeds by evaluating λ_s using

$$J = \lambda(dn_+/dt)$$

plus the equations of the Frenkel defect theory and showing that λ_s varies by too much with experimental conditions to obey $X/2 > \lambda_s \gtrsim 3$ Å. The deduction, of course, is that this model would not give the observed independence of thickness of $J(E,T)$ in the steady state.

This argument seems incorrect. Thus, if λ is the actual schubweg defined as the mean resolved path before the ion is destroyed or leaves the film, then the first quoted statement and the equation

$$J = \lambda(dn_+/dt)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

are only true if $\lambda \ll X$. For each ion that leaves the film (or rather reacts at the oxide/solution interface in this model), another must enter the film from the metal to preserve electrical neutrality. The total distance covered by the original ion and its replacements until the given vacancy is destroyed might be equated to an effective λ. Alternatively, if the equation is taken as defining λ in terms of the current density and the rate of production of defects (which are given by known expressions in this model) then λ is by definition the mean free path which an ion would have if X was big enough. So long as the film thickness X is such that electroneutrality may be assumed, and the film has properties independent of thickness, then the equations given by Bean *et al.* (2) for the volume rates of creation and destruction of Frenkel defects should be good for their model independent of thickness, and hence their expression for J in terms of film parameters should be good. The schubweg does not enter the picture. For each ion that leaves the film in the steady state, another enters; for each vacancy destroyed another is created. It is the concentration of interstitials that is controlled by the competing processes of Frenkel defect creation and annihilation.[3]

It should be noted that the assumption that the bulk of the film is free from space charge must theoretically breakdown for thin enough films. The arguments have been reviewed at length elsewhere (17). It has generally been supposed that one has the typical macroscopic situation in which relatively narrow space charge layers exist at the interfaces and adjust the field so that current continuity occurs between the interfaces and the neutral bulk of the film. In most of the film the field is constant and is independent of the interfaces. The reason for this assumption is that existing experimental evidence points to an (average) field at a given current independent of thickness. This could be Mott and Gurney's (13) case in which space charge is negligible and the interface controls the field, but if so a dependence on, say, crystal face would be expected. More usually it has been assumed that one has Verwey's case of essentially macroscopic conduction. For thin enough films such a situation can no longer hold: the space charge layers would occupy a significant fraction of the thickness of the film or would be incomplete. Experimentally, this effect has not been detected. However, Dignam did not show that mean free path was involved in this situation.

A.C. Response

Some comment should perhaps be made on Dignam and Taylor's rebuttal (15) of a recent note (16) on a.c. response during constant field transients. Our point was that it is known that the losses in the audio range require a wide distribution of relaxation type processes: not just one or two relaxation times. The distribution presumably arises from the amorphous nature of the material, *i.e.*, the processes are all basically the same but with a range of parameters. If these same dielectric processes are identified as those involved in Dignam's model then if one such process behaves as Dignam claims, all should. Hence the capacitative response at 1 kHz should increase with J during constant-field transients. Naturally a single process which builds up over 60 seconds will not respond to a 1 kHz signal. Our argument thus referred to a modified version of Dignam's model and not to the original model. It should also be noted that no change in *a.c.* response at 1 kHz was observed which correlated with the large change in d.c. current during the transient. This justifies the neglect of out-of-phase ionic current.

Decay of Latent Conductivity at Zero Field

As a further test of the theory it is of interest to examine the following experimentally-observed phenomenon which has not previously been used to test Dignam's model. A film is grown at constant ionic current density J_1 (and hence at constant field) till a certain voltage is reached. The film is then held at zero voltage (*i.e.*, field) for time t; the same voltage is then re-applied and the "instantaneously" observed ionic current density $J_2(t)$ is obtained by backwards extrapolation of a current *vs.* time recording.

[3]Dignam and Taylor's argument is analogous to the effect of the schubweg on the primary photo currents observed with blocking cathodes as discussed by Mott and Gurney (13). In the present case of Bean *et al.*'s (2) model and the modifications of it a more relevant analogy is the Bube model of the effect of trapped holes on photoconduction in CdS in which the electron concentration maintains the value giving electroneutrality in the presence of a variable space charge due to the trapped holes (14). The above correction is agreed by Dignam and Taylor (20).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

It is found that $J_2(t)$ is less than J_1. The latent ionic conductivity may be said to have decayed during the period t at $E = 0$. This effect is expected on any Frenkel defect theory since the interstitial ions and vacant lattice sites will recombine due to thermally activated jumps assisted by the local electric field acting on a given interstitial vacancy by a neighboring vacancy. Experimental data and a discussion on the basis of the Frenkel defect model have been published some time ago (18).

In terms of Dignam's model, the decay of the latent conductivity has to be due to the decay of the special polarization process. The decay of this process occurs, despite $E = 0$, since $J \neq 0$: the ionic current continues to flow since the effective field goes to zero only when P_s is zero.

$$J = \alpha \exp \beta E^* = \alpha \exp \beta\gamma P_s(t)$$

where

$$E^* = \gamma D$$

$$dP_s/dt = BJ(0 - P_s(t))$$

or, putting

$$\beta\gamma P_s(t) = y$$

$$[1] \qquad \frac{dy}{dt} = -BJy = -B\alpha\,(\exp y)y$$

On reapplying E at t

$$J_2(t) = \alpha \exp \beta\gamma(\varepsilon_0 E + P_o + P_s(t))$$

whereas before putting $E = 0$

$$J_1 = \alpha \exp \beta\gamma(\varepsilon_0 E + P_o + P_{s,o})$$

where $P_{s,o}$ is the steady state value of P_s. Hence

$$[2] \quad R(t) = J_2(t)/J_1 = \exp \beta\gamma(P_s(t) - P_{s,o}) = \exp\,(y(t) - y(0))$$

To obtain $y(0)$, the fact is used that, on this model, the minimum value of $R = R(\infty)$ is the ratio of initial and final currents in a constant field transient, if it can be assumed that the film is initially "fully annealed" as regards P_s. For the conditions of one of the curves in Fig. 1,

$$R(\infty) = \exp\,(-y(0)) = (6 \times 10^{-7})/(1 \times 10^{-4})$$

or

$$y(0) = 2.303 \ln (1.67 \times 10^2) = 5.1$$

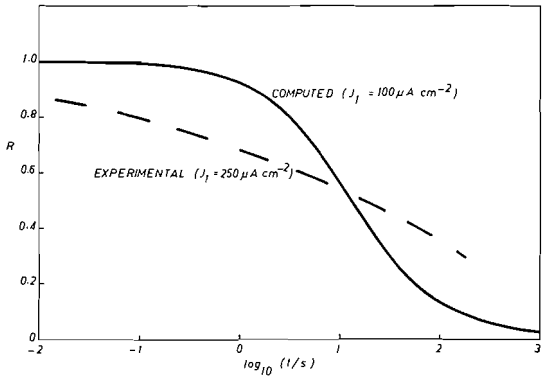

FIG. 4. Computed curve on Dignam's model and experimental curve from ref. 18 of decay of latent conductivity.

With a value of $B\alpha = 10^{-4}$, chosen purely to obtain a reasonable time scale, we obtain the data in Fig. 4 which may be compared with the experimental data in ref. 18. The difference is chiefly in the S-shaped nature of the calculated curve. On the Frenkel defect theory the curve has to be considered (essentially) as a superposition of a wide range of exponential decays corresponding to the different spacings of the components of the defects. The decay of R is faster if J_1 is larger. This is expected on the Frenkel defect theory since the average spacing is smaller. On Dignam's theory it is also expected since P_s and hence $y(0)$ is larger for larger initial E. Thus, Dignam's model shows the required effects here but some form of Frenkel defect theory seems more likely to give the observed wide distribution of relaxation times.

A Critical Test of the Hammett Acidity Function

KEITH YATES AND STANLEY A. SHAPIRO
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received September 15, 1971

The applicability of the H_0 acidity function to primary aromatic amines in general has been tested by using a set of five aniline indicators bearing no nitro-substituents. Up to 45% sulfuric acid the scale generated by these bases is the same (within experimental uncertainty) as that based entirely on nitro-anilines.

La possibilité d'application de la fonction d'acidité H_0 aux amines aromatiques primaires en général a été testée en utilisant une série de cinq indicateurs aniline ne portant pas de substituants nitro jusqu'à 45% d'acide sulfurique, l'échelle produite par ces bases est la même (dans les limites de l'incertitude expérimentale) que celle fondée uniquement sur les nitro-anilines.

Canadian Journal of Chemistry, **50**, 581 (1972)

It is now clear that the applicability of any acidity function is largely restricted to a particular class of organic base. In the case of the original acidity function H_0, this class is the primary aromatic amine series. However, in order to establish the H_0 scale of acidity it was necessary to employ nitro-substituents to produce indicators of progressively weaker basicity in order to extend measurements over a wide range of acidity. In fact every indicator used by Hammett and Deyrup (1), and subsequently those used by Jorgenson and Hartter (2), contained at least one such group; even the primary reference indicator used to anchor the scale to the dilute aqueous standard state was *p*-nitroaniline.

From what is currently known of the medium variation of activity coefficients for typical organic bases and their cations (3), it is evident that substituent groups such as nitro- can produce as marked variations in individual f_B and f_{BH^+} values as changing the nature of the basic group itself (4). Thus, if the contributions to the ratio f_{BH^+}/f_B (which determines different acidity function behavior) by nitro-substituents were atypical of substituents in general, the H_0 function would not be generally applicable even to primary amine bases. It is therefore very important to test this possibility, since it is a necessary condition for the establishment of any acidity function that the medium variation of the ratio f_{BH^+}/f_B be the same (or very similar) for each member of the particular class of base which defines it, *i.e.*, that it be independent of the nature of the other substituent groups.

We have therefore investigated a set of primary anilines of differing basicity, which contain no nitro groups, to determine whether the H_0 function generated by these bases coincides with that reported for nitroanilines.[1]

Results and Discussion

Nitro groups are strongly electron withdrawing oxygen-containing groups which would be expected to interact strongly and specifically with the solvent through formation of strong O^-—H—O type hydrogen bonds. This is particularly true of the free base forms, since the nitro- and amino- group are directly conjugated in *o*- and *p*-substituted nitroanilines. We have therefore chosen anilines substituted only by such groups as —F, —Cl, —Br, —CF_3; which although electron withdrawing, would be expected to produce weaker and less specific solute–solvent interactions. The set of indicators chosen and their pK_{BH^+} values are listed in Table 1. The pK_{BH^+} values of the primary

[1]Note that it is not a sufficient test merely to plot ionization curves for individual non-nitro-substituted anilines against H_0. This would only investigate their approximate obedience to this function in terms of an indicator slope near unity.

TABLE 1. pK_{BH^+} values of substituted aniline indicators

Substituted aniline	pK_{BH^+}	% H_2SO_4 at $\frac{1}{2}$ ionization
2-Chloro-5-trifluoromethyl-	+1.195 ±0.004	0.4
2,5-Bis(trifluoromethyl)-	+0.38 ±0.005	2.4
Pentafluoro-	−0.36 ±0.016	9.3
4-Bromo-2,3,5,6-tetrafluoro-	−0.93 ±0.020	18.4
2,4-Dichloro-3,5,6-trifluoro-	−1.28 ±0.028	25.2

indicator 2-chloro-5-trifluoromethylaniline was determined spectrophotometrically in dilute hydrochloric acid and values of $K = C_B C_{H^+}/C_{BH^+}$ extrapolated to infinite dilution (see Fig. 1) in the usual procedure (5), so that the pK_{BH^+} reported in Table 1 is a thermodynamic pK value. This is important since any subsequently derived H_0 scale depends strongly on both the nature and the pK of the first indicator. The remaining pK values were obtained by the standard overlap method (6) using spectrophotometrically determined log I values (I = ionization ratio = $[BH^+]/[B]$).[2] The overlap and parallelism between successive indicator curves was excellent.

Acidity function values were calculated from the equation $H_0 = pK_{BH^+} - \log I$ using all pK and log I data available for any given acid, using the method given by Katritzky (7). These are listed in Table 2, with two sets of reported values for H_2SO_4 at 25° based on nitroaniline indicators, for comparison. It can be seen that the present H_0 values, entirely based on non-nitro-substituted anilines, are in very good agreement with the previously reported values. The maximum difference, at the highest acidity available for comparison, is only of the order of 0.1 logarithmic unit.[3] This demonstrates that the H_0 scale is independent of the number and type of non-basic substituents, at least up to 45% acid. It seems unlikely that extension of the scale by the present approach would produce variations significantly outside the normally accepted range of uncertainty of acidity function values in more concentrated acids. In any

[2]Tabulated values can be obtained from the authors on request.

[3]It is noteworthy that differences of this magnitude arise between independently determined H_0 scales even using essentially the same indicator set of nitro-substituted anilines. See, for example, the data of Ryabova and co-workers (8).

event, further extension would be difficult to accomplish experimentally since there are few suitable substituent groups which could achieve the necessary diminutions in base strength comparable with those of dinitro- or trinitroanilines.

It is very reassuring that the H_0 function meets the above test adequately, since if it had not, the damage to the Hammett acidity function concept (even with its presently recognized limited generality) would have been irreparable. It would be of interest to determine whether other acidity functions meet the same critical test as adequately as H_0.

Experimental

2-Chloro-5-trifluoromethylaniline and pentafluoroaniline were commercial samples and were purified by repeated distillation.

2,5-Bis(trifluoromethyl)aniline

1,4-Bis(trifluoromethyl)benzene was nitrated by the method of Ross (9) to yield 2,5-bis(trifluoromethyl)nitrobenzene. The nitro compound was dissolved in ethanol and reduced with hydrogen using Raney nickel as a catalyst. The amine was purified by distillation. Boiling point 50–51 °C (5 mm). Melting point of acetyl derivative, 143–145 °C; literature (9): b.p., 70.5 °C (145 mm). Melting point of acetyl derivative 146.5–147 °C.

4-Bromo-2,3,5,6-tetrafluoroaniline

This compound was obtained by the bromination of 2,3,5,6-tetrafluoroaniline according to the method of Castellano and co-workers (10), and purified by recrystallization and sublimation. Melting point, 60–61 °C; literature (11): 60–61 °C.

2,4-Dichloro-3,5,6-trifluoroaniline

1,3-Dichlorotetrafluorobenzene (supplied by I.C.I. of England) and a slight excess of concentrated aqueous ammonia were added to ethanol to give a homogeneous solution. This was then heated in a sealed autoclave at 140 °C for 24 h. The solution was diluted with water and extracted with methylene chloride. The methylene chloride extract was treated with 60% sulfuric acid and the acid layer diluted with water yielding a white solid. After washing well and drying, the solid was purified by repeated sublimation: m.p. 73–74 °C.

Anal. Calcd. for $C_6H_2Cl_2F_3N$: C, 33.37; H, 0.93; N, 6.48; Cl, 32.83. Found: C, 33.39; H, 0.96; N, 6.29; Cl, 32.68.

Reaction of Diphenylcyclopropenethione with Pyridinium Imines

J. W. LOWN AND K. MATSUMOTO[1]

Department of Chemistry, University of Alberta, Edmonton 7, Alberta

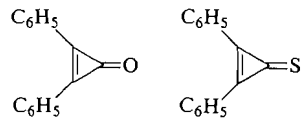
Received August 31, 1971

Reaction of diphenylcyclopropenethione with a variety of *N*-substituted pyridinium imines in refluxing benzene gives 2,4,5-trisubstituted-6*H*-1,3-oxazin-6-thiones in good to excellent yields. The structure of 2,4,5-triphenyl-6*H*-1,3-oxazin-6-thione prepared in this manner was proven by oxidation and by hydrolysis to the known 2,4,5-triphenyl-6*H*-1,3-oxazin-6-one. In the preparation of 4,5-diphenyl-2-ethoxy-6*H*-1,3-oxazin-6-thione changing the heteroaromatic residue in the imine from pyridine to 3-picoline to 3,5-lutidine had little effect on the yield (about 60%).

La réaction de la diphénylcyclopropènethione avec une variété d'imines de pyridinium *N*-substituées dans le benzène à reflux donne des trisubstituées-2,4,5-6*H*-1, oxazine-3-thione-6 avec un excellent rendement. La structure de la triphényl-2,4,5-6*H*-1, oxanine-3-thione-6 préparée de cette manière est prouvée par oxydation et par hydrolyse jusqu'à la triphényl-2,4,5-6*H*-1, oxazine-3-one-6 qui est connue. Dans la préparation de la diphényl-4,5-éthoxy-2-6*H*-1, oxanine-3-thione-6, le changement du résidu hétéroatomique dans l'imine de la pyridine à la picoline-3 et à la lutidine-3,5 a un faible effet sur le rendement (autour de 60%).

Canadian Journal of Chemistry, **50**, 584 (1972)

Since its initial preparation by Breslow *et al.* (1) and Vol'pin *et al.* (2) diphenylcyclopropenone **1** has proven to be a versatile synthetic intermediate leading to *e.g.* 3,4,6-triaryl-2*H*-pyran-2-ones (3), indolizine derivatives (1,4), cyclic dienones (5,6), a 4-pyridazone (7), aziridinyl enamides (8), methylene cyclopropenes (9), pyrroles (10), pyrrolines (10), furans (11–13), 4-oxazolines (11–13), a 3,4-benzotropone (10), and pyrrolo[1,2-*b*]pyridazines (4), 2,3,6-triphenylphenol, and esters of 3,5-hexadienoic acid (14). Its sulfur analog diphenyl-

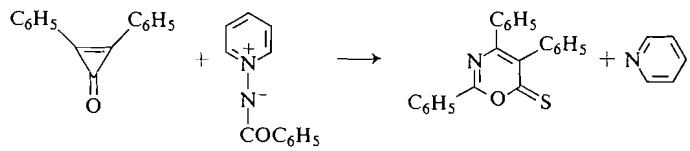


1 2

cyclopropenethione **2** might be expected to exhibit similar synthetic potential but to date relatively little success has been obtained with this compound which is thermally less stable than its oxygen counterpart. Compound **2** reacts with pyridinium ylides to give 3,4,6-triaryl-2*H*-pyran-2-thiones (3), and with 1-(*N*-pyrrolidino)-1-propene to form 2,3-diphenyl-5-methyl-4-(*N*-pyrrolidino)-2-cyclopentenethione (15), while reaction with heteroaromatic nitrogen compounds provides thionpyrazolo[1,2-*a*]pyridazine, 2,3-diphenyl-1-thionpyrazolo[1,2-*a*]benzo[*c*]cinnoline, di-(7,8-diphenylpyrrolo[1,2-*a*]-pyrazinyl)-6-sulfide, and related structures (16).

We report the reaction of diphenylcyclopropenethione with pyridinium imines which yields a variety of 6*H*-1,3-oxazin-6-thiones in good to excellent yields.

For example treatment of a suspension of pyridinium-*N*-(benzoyl)-imine (**3**) with an equimolar quantity of diphenylcyclopropenethione (**2**) in dry benzene under reflux for 12 h afforded 2,4,5-triphenyl-6*H*-1,3-oxazin-6-thione (**4**) in 88% yield as a deep orange crystalline solid (Scheme 1). The spectral characteristics of **4** and similar structures are very similar to



2 3 4

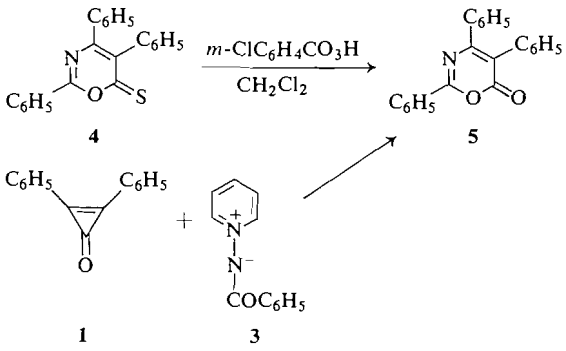

SCHEME 2

those of the 3,4,6-triaryl-2*H*-pyran-2-thiones formed in the analogous reaction of pyridinium ylides on **2** (3). The structure of **4** was proven conclusively by conversion with *m*-chloroperbenzoic acid (17) to the known 2,4,5-triphenyl-6*H*-1,3-oxazin-6-one (**5**) which was also prepared independently by the reaction of the pyridinium imine **3** on diphenylcyclopropenone (Scheme 2).

After this paper was submitted for publication, Sasaki *et al.* reported the similar formation of 2,4,5-trisubstituted-6*H*-1,3-oxazin-6-ones by the reaction of pyridinium imines on diphenylcyclopropenone (18).

Compound **5** had previously been synthesized by Sprio by the oxidation of 2,4,5-triphenylpyrrole with peracetic acid (19).

Hydrolysis of **4** with sodium methoxide in methanol followed by acidification with hydrochloric acid also gave the 6*H*-1,3-oxazin-6-one (**5**) (Scheme 3). Since the intermediate stage after alkaline hydrolysis is soluble in water, from which the orange solid **5** is precipitated upon acidification, it is plausibly represented by the salt **6**.

The generality of this preparation of 2,4,5-trisubstituted-6*H*-1,3-oxazin-6-thiones is demonstrated by the variety of substituted pyridinium imines which react with **2**. The analytical and spectral data on the new compounds are summarized in Tables 1 and 2.

In the preparation of 4,5-diphenyl-2-ethoxy-6*H*-1,3-oxazin-6-thiones, changing the heteroaromatic residue in the imine, and therefore the leaving group in the cyclization step from pyridine to 3-picoline to 3,5-lutidine had a minimal effect on the yield. The range of 6*H*-1,3-oxazin-6-thiones made available by this procedure is evident from the 2-substituents which include aryl, alkoxy, arenoyl, and heterocyclic groups. This preparation of 6*H*-1,3-oxazin-6-thiones represents an extension of the apparently general principal of the ring expansion of triafulvenes (20) with pyridinium betaines, phosphonium ylides, and sulfonium ylides (14).

The mechanism of such processes has been examined by Eicher and his coworkers (14). Three alternative pathways have been considered and recent evidence favors that involving initial attack by the α carbon of the betaine or ylide on C-1 position of the triafulvene followed by formation of a ketene with cyclization of the latter to the products. The latter intramolecular process is evidently rapid in this case compared with possible intermolecular reaction of the ketene with a protic solvent since reaction of diphenylcyclopropenethione with *N*-benzoylpyridinium imine in methanol–benzene gave **4** in 80% yield with no trace of an ester byproduct.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by

comparison with perfluorotributylamine at a resolving power of 15 000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for t.l.c. Microanalyses were carried out by Dr. C. Daesslé, Organic Microanalysis Ltd., Montreal, Quebec and by Mrs. D. Mahlow of this Department.

Preparation of Pyridinium Imines

The pyridinium imines required in this study were prepared and purified by the general procedures given by Sasaki *et al.* (21) and Snieckus and coworkers (22). New imines prepared by these procedures are summarized in Tables 3 and 4.

Diphenylcyclopropenethione

This compound was prepared by the method of Eicher and Frenzel (23), see also (17).

Reactions of Diphenylcyclopropenethione with Pyridinium Imines

The reaction conditions and purification procedures are illustrated by the following three examples. The analytical and spectral properties of other compounds similarly prepared are summarized in Tables 1 and 2.

(a) Reaction of N-(p-Toluoyl)pyridinium Imine with Diphenylcyclopropenethione

A suspension of 1.06 g (5 mmol) of *N*-(*p*-toluoyl)pyridinium imine and 1.11 g (5 mmol) of diphenylcyclopropenethione in 25 ml of dry benzene was refluxed for 12 h during which time the solution became dark red. Removal of the solvent *in vacuo* and trituration of the residual oil with cold methanol afforded the 4,5-diphenyl-2-(*p*-tolyl)-6*H*-1,3-oxazin-6-thione as a bright orange solid m.p. 180–181°, 1.68 g (94% yield).

Anal. Calcd. for $C_{23}H_{17}NOS$ (mol. wt. 355.1031): C, 77.71; H, 4.82; N, 3.94; S, 9.02. Found (355.1030 (mass spectrum)): C, 77.88; H, 4.71; N, 3.98; S, 9.11.

The n.m.r. spectrum δ_{TMS}($CDCl_3$): 2.42 (s, 3H, aromatic CH_3); 7.1–7.43 (ABq, 4H, tolyl protons); 7.1–7.55 (m, 10H, aromatic protons). The i.r. spectrum ν (KBr disc) 953, 1115, 1278, 1477 cm^{-1}.

(b) Reaction of N-(Carboethoxy)pyridinium Imine with Diphenylcyclopropenethione

A suspension of 0.84 g (5 mmol) of *N*-(carboethoxy)pyridinium imine and 1.11 g (5 mmol) of diphenylcyclopropenethione in 25 ml of dry benzene was heated under reflux for 12 h. Removal of the solvent *in vacuo* and trituration of the residual oil with methanol afforded 4,5-diphenyl-2-ethoxy-6*H*-1,3-oxazin-6-thione as orange crystals, m.p. 135°, 0.95 g (63% yield).

Anal. Calcd. for $C_{18}H_{15}NO_2S$ (mol. wt. 309.0823): C, 69.85; H, 4.89; N, 4.53; S, 10.36. Found (309.0816 (mass spectrum)): C, 69.69; H, 5.10; N, 4.57; S, 10.63.

The n.m.r. spectrum δ_{TMS}($CDCl_3$): 1.48 (t, 3H, CH_3CH_2) 4.60 (q, 2H, CH_3CH_2); 6.9–7.6 (m, 10H, aromatic protons). The i.r. spectrum (KBr disc), 950, 1052, 1300, 1483 cm^{-1}.

The identical product was obtained by the reaction of diphenylcyclopropenethione with (*i*) *N*-(carboethoxy)-3-methylpyridinium imine, (*ii*) *N*-(carboethoxy)-4-methylpyridinium imine, and (*iii*) *N*-(carboethoxy)-3,4-dimethylpyridinium imine in 60, 58, and 54% yields, respectively.

(c) Reaction of N-(Cinnamoyl)pyridinium Imine with Diphenylcyclopropenethione

A mixture of 1.12 g (5 mmol) of *N*-(cinnamoyl)pyridinium imine and 1.11 g (5 mmol) of diphenylcyclopropenethione in 25 ml of dry benzene was heated at 100° under nitrogen in a sealed tube for 24 h. Evaporation of the solvent gave a dark red oil, trituration of which with cold methanol gave 4,5-diphenyl-2-*trans*-styryl-6*H*-1,3-oxazin-6-thione 1.08 g, (61% yield), m.p. 185–186° (from benzene–methanol).

Anal. Calcd. for $C_{24}H_{17}NOS$ (mol. wt. 367.1031): C, 78.44; H, 4.66; N, 3.81; S, 8.73. Found (367.1030 (mass spectrum)): C, 78.97; H, 14.82; N, 3.98; S, 8.82.

The n.m.r. spectrum δ_{TMS}($CDCl_3$): 6.86, 8.04 (ABq, $J = 16.5$ Hz, 2H, *trans*-styryl protons); 7.05–7.8 (m, 15H, aromatic protons). The i.r. spectrum ν(KBr disc): 950, 1120, 1278, 1475 cm^{-1}.

Reaction of 2,4,5-Triphenyl-6H-1,3-oxazin-6-thione with m-Chloroperbenzoic Acid

To a stirred solution of 0.68 g (2 mmol) of 2,4,5-triphenyl-1,3-oxazin-6-thione in 20 ml of dichloromethane was added dropwise a solution of 0.43 g (2 mmol) of 80% *m*-chloroperbenzoic acid in 20 ml of dichloromethane over 10 min. A 10% aqueous solution of sodium sulfite was added to decompose the unreacted *m*-chloroperbenzoic acid and the organic layer was washed successively with 5% sodium hydrogen carbonate solution and water and then dried ($CaSO_4$). Removal of the solvent *in vacuo* gave 2,4,5-triphenyl-6*H*-1,3-oxazin-6-one 0.52 g (80% yield) which was purified by recrystallization from dichloromethane–methanol, m.p. 205–207° (lit. m.p. 207° (19)) as a pale green solid. The i.r. spectrum ν(KBr) C=O 1725 cm^{-1}. The mass spectrum: 325, $C_{22}H_{15}NO_2$ requires M, 325.

Reaction of Diphenylcyclopropenone with N-Benzoyl Pyridinium Imine

A suspension of 1.03 g (5 mmol) of diphenylcyclopropenone and 1.0 g (5 mmol) of *N*-benzoyl pyridinium imine in 30 ml of dry benzene was heated under reflux for 12 h during which time the solution turned dark green. The excess of solvent was removed *in vacuo* and trituration of the residue with cold methanol afforded 2,4,5-triphenyl-6*H*-1,3-oxazin-6-one as a light green solid which was purified by recrystallization from benzene–methanol 1.16 g (71% yield) m.p. 205–207°.

The i.r. spectrum of this compound was superimposable with that obtained in the oxidation reaction described above.

Reaction of Diphenylcyclopropenethione with N-Benzoyl Pyridinium Imine in Benzene–Methanol

A solution of 1.11 g (5 mmol) of diphenylcyclopropenethione and 1.0 g (5 mmol) of *N*-benzoyl pyridinium imine in 30 ml of 1:1 benzene–methanol was heated at 90° in a sealed tube for 12 h, during which time the solution became dark red. The solvent was removed *in vacuo* and trituration of the residual oil with cold methanol afforded 2,4,5-triphenyl-6*H*-1,3-oxazin-6-thione (**4**) as a bright orange solid 1.36 g (80% yield), m.p. 178–180°. The product was identical with that obtained in the absence of methanol.

Hydrolysis of 2,4,5-Triphenyl-6H-1,3-oxazin-6-thione with Sodium Methoxide in Methanol

A mixture of 0.34 g (1 mmol) of 2,4,5-triphenyl-1,3-oxazin-6-thione and 25 ml of a methanol solution of sodium methoxide (prepared from 1.0 g of sodium in 100 ml of methanol) was refluxed for 3 h during which time the orange solution became light green in color. The excess of methanol was removed *in vacuo*, the residue diluted with water and the solution extracted with ether (3 × 20 ml). The organic layer was dried ($CaSO_4$) and the solvent evaporated to give a trace of a green oil. Acidification of the aqueous layer resulted in the precipitation of 2,4,5-triphenyl-6*H*-1,3-oxazin-6-one (**5**) as a light orange solid, m.p. 207°. The i.r. spectrum of this compound was superimposable with that of the authentic material.

An Electron Spin Resonance Study of a Rhodium(I) Molecular Oxygen Complex in Solution

B. R. James, F. T. T. Ng, and Ei. Ochiai

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received July 9, 1971

Electron spin resonance studies on the oxygenation of the rhodium(I) cyclooctene complex $[RhCl(C_8H_{14})_2]_2$, in *N*,*N*-dimethylacetamide (DMA) solution containing chloride show the presence of a paramagnetic species. This is thought to involve a rhodium(II)–superoxide (O_2^-) species which is likely responsible for some previously reported autoxidation reactions.

Les études e.s.r. sur l'oxygénation du complexe rhodium(I) cyclooctène $[RhCl(C_8H_{14})_2]_2$, dans une solution de *N*,*N*-diméthylacétamide (DMA) contenant du chlore, indiquent la présence d'espèces paramagnétiques. Il est supposé qu'une espèce rhodium(II)–superoxyde (O_2^-) est impliquée et que celle-ci est probablement responsable des réactions d'auto-oxydation précédemment rapportées.

Canadian Journal of Chemistry, **50**, 590 (1972)

In recent communications from this laboratory (1, 2), we have reported on the catalytic activity of $[RhCl(C_8H_{14})_2]_2$ for the oxidation by molecular oxygen of DMA, cyclooctene, and cumene under mild conditions. The complex initially forms a molecular oxygen complex (one O_2 per Rh atom) in benzene, 1,2-dichloroethane, *etc.*, and also in DMA containing lithium chloride; the dimer initially dissociates to an active monomeric species. Gas uptake kinetic

data in DMA (1–3) established the overall mechanism shown in reactions 1–3.

$$[1] \quad [RhCl(C_8H_{14})_2]_2 \xrightarrow{LiCl} 2RhCl_x(DMA)_y$$

$$[2] \quad RhCl_x(DMA)_y + O_2 \rightleftharpoons O_2RhCl_x(DMA)_y$$

$$[3] \quad O_2RhCl_x(DMA)_y + \text{substrate} \rightarrow RhCl_x(DMA)_y + \text{oxidation products}$$

Reaction 2 is complete within a minute at 1 atm O_2 at 35–80°, and reaction 3 is rate determining.

An i.r. study of the system in dichloroethane or benzene (2) for the oxidation of cyclooctene showed the presence of a hydroperoxide intermediate, likely formed by hydrogen abstraction from the substrate by the oxygen complex; this mechanism suggests a free radical nature for the oxygen complex, although, except for one recently reported ruthenium(II) system (4), all such isolated and characterized species of d^6, d^8, and d^{10} complexes have been found to be diamagnetic (5). An e.s.r. signal had been observed in the DMA–LiCl media (1), and this paper reports on more detailed e.s.r. studies in DMA containing 0.2 *M* LiCl and in benzene solution. Measurements were made on a Varian Associates E3 spectrometer.

The e.s.r. data are summarized in Fig. 1. Spectrum A ($g_{\|}$, $g_{\perp}$, g'_1, g'_2, g'_3) appears to be a composite one consisting of two components: one component with $g_{\|} = 2.10$ and $g_{\perp} = 2.00$ ($g_{av} = 2.03$) is very similar to the spectra reported for the O_2^- ion (6–8); the second component appears very similar to spectrum B (g_1, g_2, g_3). This spectrum, which builds up to about twice the intensity after a further 2 days, collapses into a single broad peak at room temperature which indicates rhombic symmetry associated with the three different g values ($g_{(r.m.s.)} = 2.04$). B is attributed to a rhodium(II) species.

During catalytic oxidations at 80°, the activity slowly decreases with time and this appears to be due to a slow oxidation to a higher rhodium valency state; this is accompanied by the appearance of a greenish tinge to the orange rhodium(I)–oxygen solutions. The solutions do not contain rhodium(III) species (9), and since the active rhodium(I) species can be regenerated by hydrogen reduction, the presence of paramagnetic rhodium(II) species is indicated (3). Previously reported $g_{(r.m.s.)}$ values for rhodium(II) complexes are between 2.03 and 2.21 (10 and references therein).

The e.s.r. data fit into our previously suggested (1–3) oxidation mechanism, which can now be presented in further detail (Scheme 1).

Spectrum A is thought to represent species **1** which is in equilibrium with the diamagnetic oxygen complex. Spectrum B is attributed to species **2**.

Approximate concentrations of the paramagnetic species were estimated by using standard solutions of diphenylpicrylhydrazol and comparing areas of integrated spectra. After 1 min, spectrum A indicates the presence of *ca.* 7×10^{-5} *M* paramagnetic species; significant amounts of **2** are absent and hence the K_2 value is estimated as *ca.* 3×10^2. The intensity of the spectra increases with time but this results from a build up of **2**, and the concentration of **1** remains essentially constant at least up to the stage at which it can readily be estimated (~90 min); the concentration of **1** is governed by K_2 and the concentration of $O_2RhCl_x(DMA)_y$ which decreases by only 5% after 2 days.

Relatively weak interaction between the Rh^{II} and O_2^- centers in A would give a spectrum essentially the superimposition of those of O_2^- and Rh^{II}. The g_3 value of the latter appears to be

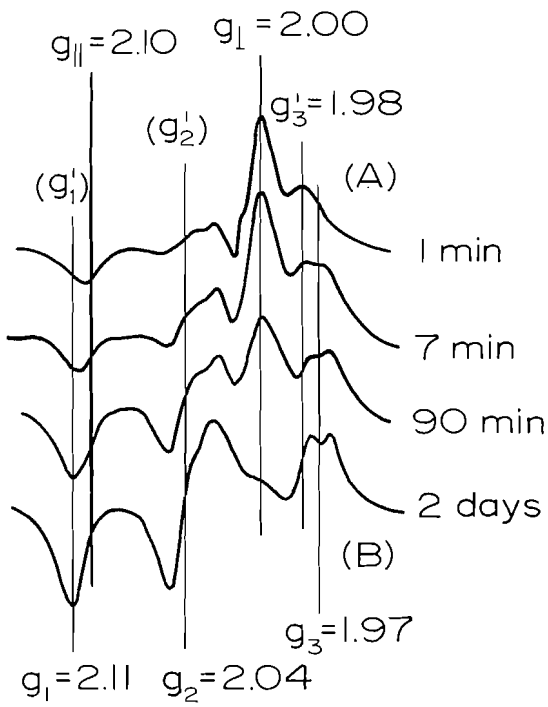

FIG. 1. Electron spin resonance spectra of [RhCl-$(C_8H_{14})_2]_2$ + O_2 in DMA (0.2 *M* LiCl), measured at 77 °K. The reaction time is the exposure time to air at room temperature (23°); $[O_2RhCl_xDMA_y] = 2.0 \times 10^{-2}$ *M*. The estimated concentrations are: $[1] \approx 7 \times 10^{-5}$ *M* at 1 min, $[1] \approx 7 \times 10^{-5}$ *M* at 7 min, $[1] \approx [2]$ at 90 min, and $[2] \approx 1 \times 10^{-3}$ *M* at 2 days. (The relative intensities are not drawn to scale.)

somewhat modified in the $Rh^{II}O_2^-$ species, and is labelled g_3' in the A spectrum; the g_1' and g_2' values for the Rh^{II} component in A appear almost indistinguishable from g_1 and g_2. The weak interaction may arise due to the relatively strong donor properties of the solvent, since the corresponding system in benzene gives an unresolved broad peak centered around $g \sim 2.5$, which may be indicative of greater interaction and a more complex spectrum. The intensity of this broad peak decreases with time at a rate paralleling that of the ν_{0-0} band observed by i.r. spectroscopy (2).

Hydrogen abstraction from the RH substrate by $[Rh^{II}\ldots\cdot O_2^-]$ is thought to constitute the catalytic effect. Stern (11) has suggested that the autoxidation of cumene catalyzed by palladium(0) phosphine complexes could proceed via a hydroperoxide free radical reaction initiated by hydrogen abstraction by a molecular oxygen complex. Whether or not electron transfer equilibria, as exemplified by K_2, are necessary requirements of such catalyzed oxidations remains to be established more fully. Catalytic ability could depend on the value of K_2. If K_2 is 10^2 times greater than the value estimated above, the catalytic activity would not be appreciable, and this corresponds to a free energy difference of only about 3 kcal mol^{-1} at 30°. Slight changes in the coordinated ligands could be significant, and it is of interest to note that while $Pd[P(p\text{-}CH_3C_6H_4)_3]_2$ is active, $Pd[P(p\text{-}ClC_6H_4)_3]_2$ is inactive.

The suggested mechanism is not the same as the Haber–Weiss type mechanism proposed by Kurkov and co-workers (12) for the autoxidation of hydrocarbons catalyzed by rhodium(I) complexes, although both involve formation of free radicals.

The mechanism outlined in Scheme 1 may be applicable to other molecular oxygen systems with d^6, d^8, and d^{10} transition metals. A theoretical discussion on this aspect will be published elsewhere.

We thank the National Research Council of Canada and the University of British Columbia for support of this research, and Johnson Matthey Ltd. for loan of the rhodium.

Rearrangement Studies with ^{14}C. XXXV. The Absence of Isotopic Scrambling in the Photolysis of 2-^{14}C-3-Phenylpropionaldehyde.

C. C. LEE AND D. UNGER

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received September 3, 1971

The photolytic decarbonylation of 2-^{14}C-3-phenylpropionaldehyde gave isotopically unrearranged β-^{14}C-ethylbenzene, indicating that under the experimental conditions employed, there was no detectable amount of 1,2-phenyl shift in the reaction.

La décarbonylation du 2-^{14}C-3-phénylpropionaldéhyde conduit au β-^{14}C-éthylène isotopiquement non transposé. Il en résulte que dans les conditions expérimentales utilisées, il n'y a aucun déplacement-1,2 de phényle dans la réaction.

Canadian Journal of Chemistry, **50**, 593 (1972)

Slaugh (1) has reported that the peroxide catalyzed decarbonylation of 2-^{14}C-3-phenylpropionaldehyde (**1**-CHO-2-^{14}C) gave rise to 2.3–5.1% rearrangement of the ^{14}C-label from C-β to C-α in the resulting ^{14}C-ethylbenzene (**2**-^{14}C). This isotopic scrambling was attributed to a 1,2-phenyl shift of the 1-^{14}C-2-phenylethyl to the 2-^{14}C-2-phenylethyl radical. On the other hand, the report of about 20% rearrangement in the reaction of 1-^{14}C-2-phenylethyl bromide (**1**-Br-1-^{14}C) with magnesium and cobaltous bromide in refluxing ether (2), also originally attributed to a 1,2-phenyl shift in the 2-phenylethyl radical, has been shown to be incorrect (3). Subsequently, the cobaltous bromide catalyzed radical reaction between **1**-Br-1-^{14}C and phenylmagnesium bromide was found to give only 0.5% isotope position rearrangement in the mixture of ethylbenzene and styrene that was obtained (4). Similarly, prolonged irradiation with ^{60}Co-γ rays of various 1-^{14}C-2-phenylethyl halides (**1**-X-1-^{14}C) resulted in the formation of small amounts of 2-^{14}C-2-phenylethyl halides (**1**-X-2-^{14}C) (5–7). It would be of interest to ascertain whether 1,2-phenyl shifts would take place in a photochemically generated 2-phenylethyl radical. The photolysis of **1**-CHO has been reported by Cohen and coworkers (8, 9) in connection with a study on the sensitization by certain ketones and mercaptans on the light-induced decarbonylation of a number of aldehydes. Radical mechanisms were proposed to explain the results, and from **1**-CHO, the liquid product was found to be ethylbenzene (**2**). In the present work, the photolytic decarbonylation of **1**-CHO-2-^{14}C was investigated in order to find out whether any isotopic scrambling has occurred in the resulting **2**-^{14}C.

1-CHO-2-^{14}C was prepared as described by Slaugh (1). After irradiation at ambient temperature for the desired length of time, ordinary **2** was added as carrier and this product was then recovered by preparative v.p.c. Isotope dilution calculations gave the yield of the **2**-^{14}C, and the results are summarized in Table 1. In all the experiments, alkaline permanganate oxidation of the recovered **2**-^{14}C (1, 3) gave benzoic acid containing no detectable ^{14}C-activity ($0.0 \pm 0.2\%$), indicating that the product was **2**-β-^{14}C with essentially no scrambling to **2**-α-^{14}C.

In the peroxide catalyzed decarbonylation of **1**-CHO-2-^{14}C, Slaugh (1) has noted that the extent of isotopic scrambling in the recovered **2**-^{14}C increased significantly with higher temperature, suggesting that the energy of activation for the 1,2-phenyl shift in the 2-phenylethyl radical was greater than that for the abstraction of hydrogen to give **2**-^{14}C. Moreover, the presence of added thiophenol was found to decrease the extent of rearrangement in the **2**-^{14}C. Since the thiol was a good hydrogen-donor, it was suggested that the presence of the thiol would allow the hydrogen abstraction step to compete more favorably with the 1,2-phenyl shift, thus in effect decreasing the lifetime of the 2-phenylethyl radical and consequently decreasing the extent of 1,2-phenyl shift. From the present work, the data in Table 1 indicated that hydrogen abstraction by the 1-^{14}C-2-phenylethyl radical would play an important role since greater yields of **2**-β-^{14}C were observed in solvents that could more readily donate hydro-

TABLE 1. Yields of β-^{14}C-ethylbenzene (**2**-β-^{14}C) from the photolytic decarbonylation of 2-^{14}C-3-phenylpropionaldehyde (**1**-CHO-2-^{14}C)

Weight **1**-CHO-2-^{14}C (g)	Solvent*	Irradiation time (h)	Yield of **2**-β-^{14}C (%)†
1.850	None	115	3.3
2.125‡	CCl_4	120	None
1.759	Benzene	119	6.8
2.081	Cyclohexane	111	17.8
2.061	Cyclohexane	111	17.7
1.700§	Cyclohexane	67	30.2

*Enough solvent was added to the **1**-CHO-2-^{14}C to give a total volume of 25 ml.
†Obtained by isotope dilution calculations.
‡Inactive **1**-CHO was used and no ethylbenzene as product was detectable by v.p.c.
§Containing an equimolar amount of benzophenone as photosensitizer.

gen. Apparently, 1,2-phenyl shifts in the 1-^{14}C-2-phenylethyl radical generated under the conditions of the present experiments could not compete appreciably with hydrogen abstraction, hence only isotopically unrearranged **2**-β-^{14}C was formed without any detectable amount of **2**-α-^{14}C.

Experimental

The u.v. spectrum of **1**-CHO showed a weak absorption at 290 mμ, $\varepsilon = 33$, due to the carbonyl chromophore, and aromatic bands at 265 and about 200 mμ. The u.v. source used in the present experiments was a utility model, 100 W, Hanovia high-pressure quartz mercury-vapor arc lamp fitted with a pyrex filter which did not transmit radiations below 280 mμ. The 25-ml pyrex reaction vessel, about 2 cm diameter × 11 cm, was joined at the open end to a narrower tubing which was fitted to a reflux condenser. About 2 g of **1**-CHO-2-^{14}C was weighted in the vessel and solvent was added to make up a total volume of 25 ml. The sample was flushed with nitrogen for 2 h and an atmosphere of nitrogen was maintained above the sample throughout the irradiation. The material was irradiated at ambient temperature at a fixed distance (7.5 cm) from the u.v. source for the desired length of time. Ordinary ethylbenzene (**2**) (1–2 g) was then added as carrier and the volatile material was removed at 30° and 5 mm pressure and collected in a receiver cooled in liquid nitrogen. In preliminary trials with inactive material without any added carrier, v.p.c. analysis (25 ft × 1/8 in. copper column packed with silicone DC 710 on 60/80 mesh chromosorb W using an Aerograph 200 chromatograph with flame ionization detector) showed that in the volatile product so obtained, only **2** and traces of unreacted **1**-CHO were present besides the solvent. In the experiments with **1**-CHO-2-^{14}C, the **2**-^{14}C, diluted by the inactive carrier, was recovered by preparative v.c.p. using a Pye Automatic Preparative chromatograph with a 12 ft × 3/8 in. copper column containing the same silicone packing as described above.

On oxidation with alkaline $KMNO_4$ (1, 3), the recovered **2**-^{14}C gave inactive benzoic acid, indicating no scrambling of the ^{14}C-label from C-β to C-α for the **2**-^{14}C. In some of the experiments, the unreacted **1**-CHO-2-^{14}C was recovered by vacuum distillation, b.p. 57–58° at 2 mm, and then oxidized to benzoic acid which was also inactive, indicating no scrambling of the ^{14}C from C-2 to -3 in the recovered aldehyde.

The Role of HgH in the $Hg(6^3P_0)$ Photosensitized Decomposition of the Alkanes and Hydrogen

A. C. VIKIS AND D. J. LE ROY

Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received November 29, 1971

Mercury hydride, arising from the $Hg(6^3P_0)$ photosensitized decomposition of hydrogen containing molecules, has been detected in the presence of H_2, D_2, CH_4, C_2H_6, C_3H_8, and n-C_4H_{10}. For the alkanes, this is the first experimental evidence that HgH is formed in the primary process $Hg(6^3P_0) + RH \rightarrow HgH + R$.

L'hydrure de mercure, provenant de la décomposition photosensibilisée au mercure $Hg(6^3P_0)$ de molécules contenant de l'hydrogène, a été détectée en présence de H_2, D_2, CH_4, C_2H_6, C_3H_8, et n-C_4H_{10}. Dans le cas des alcanes, c'est la première preuve expérimentale que HgH est formé au cours d'un procédé primaire: $Hg(6^3P_0) + RH \rightarrow HgH + R$.

Canadian Journal of Chemistry, **50**, 595 (1972)

The primary formation of HgH in the $Hg(6^3P_{1,0})$ photosensitized decomposition of the alkanes and hydrogen

[1] $$Hg(6^3P_{1,0}) + RH \rightarrow HgH + R$$

rather than the alternative primary process

[2] $$Hg(6^3P_{1,0}) + RH \rightarrow Hg(6^1S_0) + R + H$$

has been proposed in a number of publications (1–3). However, no experimental evidence of reaction 1 has been obtained except when the quencher was H_2 or D_2 (4–7), in which cases the quantum yields of reaction 1 were found to be close to unity (7). In particular, Masson and Steacie (6), and recently Callear and Hedges (7), were unsuccessful in attempts to detect HgH in any alkane system.

The lack of evidence for HgH formation in the alkanes contrasted with the results for the analogous reactions with $Cd(5^3P_{1,0})$ atoms, where CdH is formed with both H_2 and the alkanes (8, 9). For $Cd(5^3P_{1,0})$ atoms, reaction via CdH formation is the only energetically feasible reaction channel. The higher reaction exothermicity in the $Hg(6^3P_{1,0})$ reactions with RH was suggested as an explanation (6), but the results of ref. 7 obtained at $\sim$1 atm pressure seem to contradict this proposition. An alternative explanation based on HgR formation was also proposed in ref. 7.

It seemed reasonable to us to expect that even if HgH is formed by reaction 1, it could be consumed by reactions with the parent molecule RH or with a reaction product (olefin or alkyl radical). If so, the unsuccessful attempts to observe it (6, 7) may have been due to not having used the most favorable conditions for detection, and in particular, to having used too high partial pressures of RH. The strong RH pressure dependence found in this work shows that this was definitely the case in Masson and Steacie's (6) system.

The method employed in this work utilized electronic excitation of the HgH by collisions of the second kind with $Hg(6^3P_0)$, and observation of the HgH emission (4–6). A Hilger and Watts model E-517 quartz spectrograph and Kodak 103-O spectrographic plates were used for monitoring the HgH sensitized emission. The dispersion of the spectrograph was $\sim$80 Å/mm at 3500 Å. The spectrograph slit was varied in the range of 0.05 to 0.2 mm and the exposure times were of the order of 10 min to an hour. The reaction was studied in the flow system described in ref. 10 at a nitrogen flow rate of 20 std cc/min and a total pressure of 20 to 50 Torr.

The results are presented in Figs. 1 and 2. The 0,0 band of the HgH $^2\Pi_{3/2} \rightarrow {}^2\Sigma^+$ transition at 3500 Å was detected in all systems. The 0,0 band for $^2\Pi_{1/2} \rightarrow {}^2\Sigma^+$ at 4017 Å is not as evident because of interference in this region from quartz

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

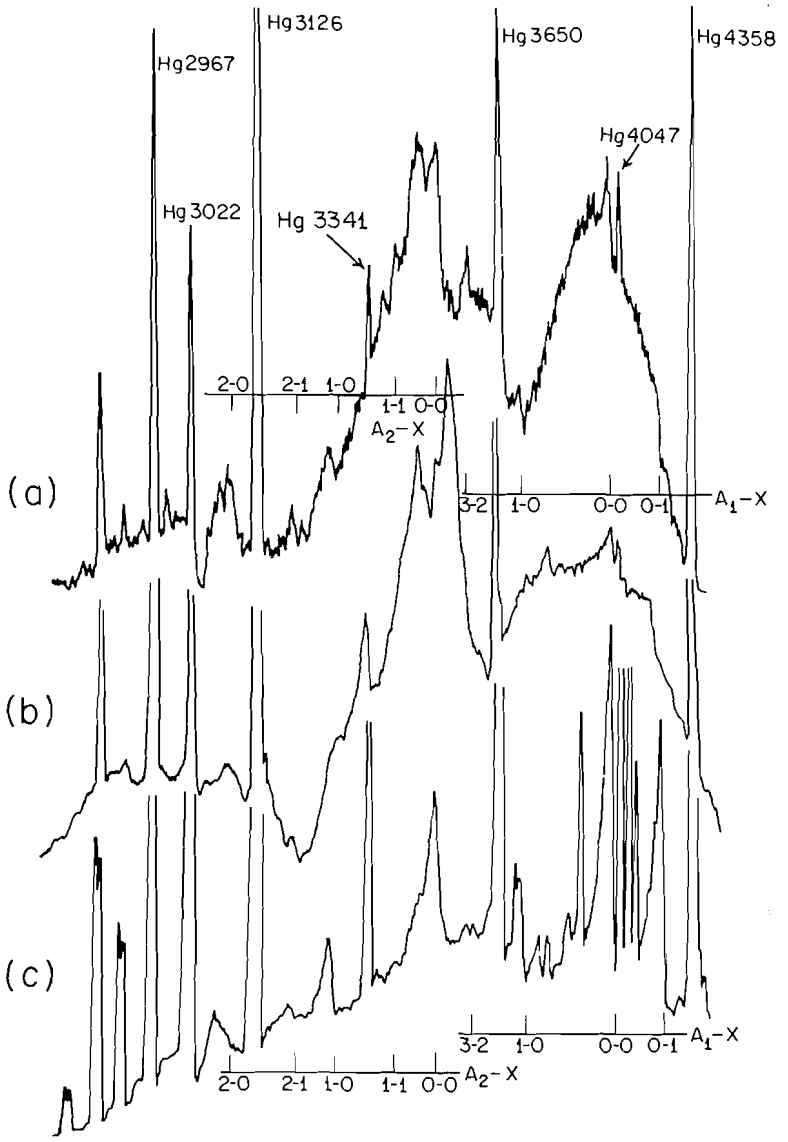

FIG. 1. HgH $^2\Pi_{3/2} \rightarrow {}^2\Sigma^+$ and $^2\Pi_{1/2} \rightarrow {}^2\Sigma^+$ band emission excited by (*a*) Hg(6^3P_0) in the presence of 0.004 Torr of H_2, 20 Torr of N_2; (*b*) Hg(6^3P_0) in the presence of 0.005 Torr of D_2, 20 Torr of N_2; (*c*) microwave discharge in a continuous flow Hg–H_2 lamp at ~2 Torr of H_2.

fluorescence. Other HgH transitions were observed at long exposures in H_2. All were identified on the basis of literature data (11) and the microwave discharge spectrum of HgH obtained in this laboratory, Fig. 1*c*.

The HgH emission intensity was found to be very sensitive to the pressure of H_2 or RH, apparently due to HgH and (HgH)* depletion processes and the depopulation of the Hg(6^3P_0), which excites the emission. The RH pressures for maximum emission were approximately 0.4, 0.2, 0.007, <0.01, and <0.002 Torr for CH_4, C_2H_6, H_2, C_3H_8, and *n*-C_4H_{10}, respectively. They represent the composite efficiency of HgH formation and decay in the presence of each RH. At higher or lower pressures the emission dropped sharply to unobservable intensities. This is the most likely explanation for the lack

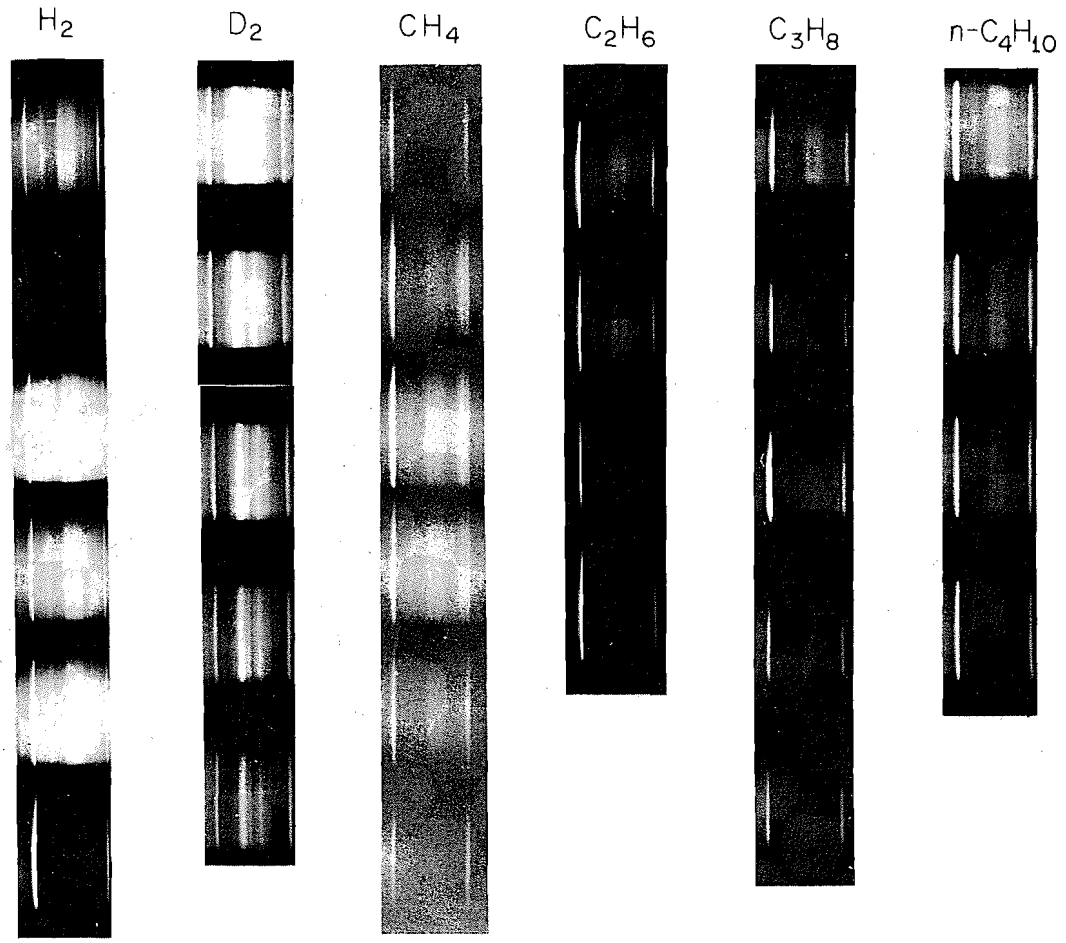

FIG. 2. Mercury hydride 3500 Å band emission excited by $Hg(6^3P_0)$ in the presence of various pressures of H_2, D_2, RH, and N_2. The atomic lines to the left and right of each of the thirty spectra are Hg 3650 Å and Hg 3341 Å, respectively. (Read from top to bottom, pressures in Torr; N_2 was added to raise the total pressure to the value given in parentheses, H_2(50): 0.010, 0.000; H_2(20): 0.006, 0.004, 0.002, 0.000; D_2(20): 0.005, 0.008, 0.009, 0.017, 0.028; CH_4(53): 0.10, 0.22, 0.38, 0.80, 1.6, 3.3; C_2H_6(20): 0.11, 0.22, 0.41, 0.00; C_3H_8(20): 0.011, 0.026, 0.0, 0.054, 0.12; n-C_4H_{10}(20): 0.002, 0.006, 0.010, 0.016. Note that only intensities in the same column and at the same N_2 pressure are directly comparable. The transition adjacent to the 3341 Å Hg line which appears in some cases was identified with the 3357 Å NH $A^3\Pi_i \rightarrow X^3\Sigma^-$ 0,0 band. Its origin is uncertain (4), although in the present work it may be due to the system's previous exposure to NH_3.)

of evidence for HgH formation with alkanes in previous work (6, 7).

The intensity of the 3500 Å band was studied as a function of the intensity of the primary lamps for H_2 and n-C_4H_{10}, and found to obey the expected second power dependence. Also a comparison of rough intensity calculations of rotational distributions with observed intensities indicated that high rotational temperatures (2000–3000 °K) prevail in the 3500 Å band. A similar conclusion can also be reached by comparison with the microwave discharge HgH spectrum. This is in agreement with Rieke's (5) work on the 4017 Å HgH band studied in H_2 with the same method. This high rotational temperature undoubtedly arises from the secondary excitation process and the subsequent vibrational cascading of excited HgH rather than from the primary HgH formation process (5).

The possible formation of HgH in an equilibrium process

[3] $$Hg + H + N_2 \rightleftarrows HgH + N_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is excluded in the present system because of low Hg ($\sim 10^{-4}$ Torr) and N_2 pressures. Approximate calculations showed that if both reactions 1 and 2 are occurring equally fast, reaction 3 would be less favored as a source of HgH than reaction 1 by a factor of ~ 100 in our experiments. This, in combination with Callear and Hedge's (7) quantum yield of near unity in the case of H_2, and the comparable emission intensity yields observed with H_2 and the alkanes in our system, indicate that the equilibrium reaction [3] is not significant.[1]

In conclusion, the present results indicate that primary HgH formation is an important reaction channel in the $Hg(6^3P_0)$ photosensitized decomposition of the alkanes. Accurate quantum yields of HgH formation for the various alkanes would be of significant value in elucidating the role of the exothermicity in these reactions. Such studies are anticipated in this laboratory and we expect to present the results in this journal as they become available.

[1]A referee has pointed out that if electronically excited $(HgH)^*$ were formed by the reaction

[4] $$Hg(6^3P_0) + H + M \rightleftarrows (HgH)^* + M$$

it would be difficult to distinguish it kinetically from reaction 1 followed by

[5] $$Hg(6^3P_0) + HgH \rightarrow (HgH)^* + Hg$$

However, if one assumes normal rate constants for reactions 4 and 5 (*ca.* $10^9\ M^{-2}\ s^{-1}$ and $10^{10}\ M^{-1}\ s^{-1}$, respectively), it can be shown that formation of $(HgH)^*$ by reaction 4 is not favored in our system.

π-Cyclopentadienylmanganese Thiocarbonyl Complexes

A. E. FENSTER AND I. S. BUTLER
Department of Chemistry, McGill University, Montreal 101, Quebec

Received November 15, 1971

The complete series of thiocarbonyl complexes, π-$C_5H_5Mn(CO)_{3-x}(CS)_x$ ($x = 1, 2, 3$), have been prepared by reaction of the appropriate *cis*-cyclooctene derivative, π-$C_5H_5Mn(CO)_{3-x}(CS)_{x-1}(C_8H_{14})$, with CS_2 in the presence of triphenylphosphine.

La série complète de complexe thiocarbonyl, π-$C_5H_5Mn(CO)_{3-x}(CS)_x$ ($x = 1,2,3$), a été preparée par la réaction de CS_2 avec les composés de *cis*-cyclooctene appropriés, π-$C_5H_5Mn(CO)_{3-x}(CS)_{x-1}(C_8H_{14})$, en présence de triphenylphosphine.

Canadian Journal of Chemistry, **50**, 598 (1972)

Recently, we reported the isolation in low yield ($< 10\%$) of π-$C_5H_5Mn(CO)_2(CS)$ (**1**), the first thiocarbonyl complex of manganese, from the reaction of π-$C_5H_5Mn(CO)_2$ (*cis*-cyclooctene) with carbon disulfide (1). We have now succeeded in obtaining **1** in about 85% yield by carrying out the same reaction under reflux conditions for 24 h in the presence of a stoichiometric amount of triphenylphosphine. In contrast to the reaction in the absence of ϕ_3P, there are no carbonyl- or thiocarbonyl-containing side-products formed. The only other products

is excluded in the present system because of low Hg ($\sim 10^{-4}$ Torr) and N_2 pressures. Approximate calculations showed that if both reactions 1 and 2 are occurring equally fast, reaction 3 would be less favored as a source of HgH than reaction 1 by a factor of ~ 100 in our experiments. This, in combination with Callear and Hedge's (7) quantum yield of near unity in the case of H_2, and the comparable emission intensity yields observed with H_2 and the alkanes in our system, indicate that the equilibrium reaction [3] is not significant.[1]

In conclusion, the present results indicate that primary HgH formation is an important reaction channel in the $Hg(6^3P_0)$ photosensitized decomposition of the alkanes. Accurate quantum yields of HgH formation for the various alkanes would be of significant value in elucidating the role of the exothermicity in these reactions. Such studies are anticipated in this laboratory and we expect to present the results in this journal as they become available.

TABLE 1. Infrared spectra of the new π-cyclopentadienylmanganese thiocarbonyl complexes

Compound	Medium	Frequency (cm^{-1})† ν_{CO}	ν_{CS}
2, π-$C_5H_5Mn(CO)(CS)_2$	CS_2	1991 s	1305 s, 1235 vs
	Nujol	1966 s	1308 s, 1240 s
3, π-$C_5H_5Mn(CS)_3$*	CS_2		1338 m, 1240 vs

*This complex has as yet only been characterized by its i.r. spectrum.
†s = strong, vs = very strong, m = medium.

that are present in any significant amount in the reaction mixture are triphenylphosphine sulfide and *cis*-cyclooctene.

It appears that the method used here to prepare complex **1** may well prove to be a general method for the synthesis of transition metal thiocarbonyl complexes because we have managed to complete the series of π-cyclopentadienylmanganese thiocarbonyl complexes by preparing π-$C_5H_5Mn(CO)(CS)_2$ (**2**) and π-$C_5H_5Mn(CS)_3$ (**3**) using the same method. The starting materials in the preparation of complexes **2** and **3** are π-$C_5H_5Mn(CO)(CS)$ (*cis*-cyclooctene) and π-$C_5H_5Mn(CS)_2$ (*cis*-cyclooctene), respectively. These olefin complexes are obtained from the photochemical reactions of **1** and **2**, respectively, with excess *cis*-cyclooctene in *n*-hexane solution.

The dithiocarbonyl complex **2** (yellow crystals, m.p. 71–72°) has been characterized by elemental analysis, i.r., n.m.r., and mass spectroscopy. Owing to extensive decomposition in the preparation of π-$C_5H_5Mn(CS)_2$ (*cis*-cyclooctene), we have as yet only obtained the trithiocarbonyl complex **3** in minute quantities. Consequently, this complex has been only characterized by its i.r. spectrum.

The i.r. spectra of complexes **2** and **3** exhibit the anticipated number of CO and CS stretching absorptions (Table 1) and the out-of-plane C—H mode at around 825 cm^{-1} characteristic of the π-cyclopentadienyl moiety.

The isolation of the new thiocarbonyl complexes indicates that such complexes may be far more widespread than is currently believed. Furthermore, it is of interest to note that the di- and trithiocarbonyl complexes reported here are the first examples of thiocarbonyl complexes having more than one CS group attached to a metal atom.

We thank the Canada Council for a scholarship (A.E.F.) and the National Research Council of Canada for financial support of this research.

^{13}C Nuclear Magnetic Resonance Studies. XVI. ^{13}C Spectra of some Substituted Acrylic Acids and their Methyl Esters. A Correlation of Olefinic Shieldings in α,β-Unsaturated Carbonyl Systems[1]

H. BROUWER[2] AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ontario

Received August 18, 1971

The carbon-13 n.m.r. spectra of 26 α,β-unsaturated methyl esters and 16 substituted acrylic acids have been determined and the ^{13}C shieldings are discussed. These data are compared with the recently reported values for several α,β-unsaturated carboxylic acids. Linear regression analysis of the olefinic shielding data for several α,β-unsaturated carbonyl derivatives yields a set of parameters which correlate the results with reasonable precision. The solvent dependence of the ^{13}C shieldings of acrylic acid and methyl acrylate has been examined briefly. The proton results for the methyl esters are discussed briefly.

Les spectres r.m.n. du carbone 13 de 26 méthyl esters α,β-insaturés et de 16 acides acryliques substitués ont été déterminés et les effets d'écran ^{13}C sont discutés. Ces données sont comparées aux valeurs récemment rapportées pour quelques acides carboxyliques α,β-insaturés. Une analyse de la régression linéaire des données de l'effet d'écran oléfinique pour quelques dérivés carbonylés α,β-insaturés permet d'obtenir une série de paramètres qui sont en corrélation, avec une précision raisonnable avec les résultats. La dépendance entre le solvant et les effets d'écran de ^{13}C pour l'acide acrylique et l'acrylate de méthyle a été examinée brièvement. Les résultats concernant les protons pour les esters méthylés sont discutés brièvement.

Canadian Journal of Chemistry, **50**, 601 (1972)

Introduction

The geometrical dependence of aliphatic ^{13}C shieldings has been recognized for several years in both unsaturated (1–7) and alicyclic systems (8–14) and, in general, it has been found that ^{13}C shieldings are much more sensitive to molecular geometry than those of the corresponding protons. Consequently ^{13}C n.m.r. spectroscopy constitutes a new and powerful tool for the investigation of stereochemistry. In alicyclic systems it is observed that carbons separated by three bonds are shielded in the *gauche* orientation relative to those in an *anti* relationship. For example, an axial carbon bonded to a cyclohexane ring absorbs at higher field than its equatorial counterpart (9, 10, 12, 14); furthermore, the C-3 and -5 cyclohexyl carbons are similarly shielded in the former orientation (9, 14). This tendency, termed a γ-effect, has been ascribed to sterically induced polarization arising from nonbonded interactions of the hydrogen atoms bonded to the γ-carbons (15). It has also been established that carbon shieldings are similarly affected by other atoms in the γ-position (8, 13) and such γ-effects have proved to be useful in the analysis of the ^{13}C spectra of steroids (16), inositols (17), and several carbohydrates (18). Because of the rigidity of the double bond it follows that the α-carbons in *cis*-olefins will be shielded relative to those in the *trans*-isomers since the former are held in an eclipsed orientation; this is found to be the case. In addition, the magnitude of the difference is comparable to the γ-effect found for alicyclic systems (*ca.* 5 p.p.m.).

As part of a detailed investigation of the geometrical dependence of ^{13}C shieldings in relative-

ly simple systems, the ^{13}C spectra of several methyl α,β-unsaturated carboxylates have been determined as well as the spectra of a number of the corresponding carboxylic acids. Recently, however, the results for an extensive series of the latter were reported by Lippmaa and coworkers (19). These data together with the earlier results for several α,β-unsaturated aldehydes and ketones (4) permit one to examine the general trends exhibited by the ^{13}C shieldings of aliphatic conjugated carbonyl derivatives as a function of substituent geometry. In this paper, these trends are discussed and a correlation of the olefinic shieldings, obtained by linear regression analysis, is presented. It has been found that the olefinic shieldings can be correlated with a set of substituent parameters comparable to those developed by Grant and Paul for saturated hydrocarbons (20). Although much of the available data for these carbonyl derivatives is less precise than that obtained from current spectrometers the quality of the correlation indicates that these parameters may be useful for the prediction of shieldings in related systems. In any event, the existence of the correlation is of theoretical interest since it offers further proof of the additivity of the factors affecting ^{13}C shieldings in aliphatic systems.

The proton spectra of the methyl esters were obtained in the course of this study and these data are recorded with a brief comment on the general trends.

Experimental

Materials

Several of the methyl esters and carboxylic acids employed in this study were obtained commercially while the others were prepared by standard methods. The halogenated compounds were formed by the addition of hydrogen halide to propynoic and butynoic acids and, in general, separation of the isomers was accomplished by conversion to the methyl esters, followed by fractional distillation. For the latter purpose an 18-inch platinum, spinning-band column was employed; in each case, the proton spectra provided a straightforward method for assessing the purity of each fraction. Subsequent hydrolysis to the solid carboxylic acid afforded an unequivocal characterization. In most cases, essentially pure samples (>99%) of each isomer were obtained. One notable exception, however, was methyl *Z*-3-methoxybutenoate which could only be obtained as the minor component in a mixture with the *E*-ester. In our hands the most favorable mixture was obtained by pyrolysis of the dimethyl ketal of methylacetoacetate at 350°. Initially the product, obtained by dropping the ketal onto an electrically-heated column of porcelain beads under a slow stream of nitrogen, was found to be a 3 : 2 mixture of *Z*- and *E*-isomers which after rapid distillation contained approximately equal quantities of each ester and some ketal. In contrast, the corresponding methyl 3-methoxypropenoates are readily separable by fractional distillation: *E*-isomer, b.p. 99–100°/85 mm and *Z*-isomer, b.p. 120–123°/85 mm; in contrast to the reported values of 80°/16 mm for each (21). Their proton and i.r. spectra are consistent with the assigned structures as was an elemental analysis.

Anal. Calcd. for $C_5H_8O_3$: C, 51.72; H, 6.94. Found: C, 51.44; H, 6.82.

Spectra

Most of the ^{13}C spectra were determined by rapid-passage dispersion-mode operation at 15.1 MHz. The samples were contained in a 15 mm concentric cell with a spherical reference cavity containing enriched methyl iodide as a standard. Calibration was accomplished by generating side bands of the reference signals with a GR1300A audio oscillator; the frequencies were monitored with a HP5245L counter. In certain cases, proton decoupling with a NMR Specialties SD60 decoupler was employed to increase the observed S/N. Each value represents the average of at least five scans in each field direction. The precision of the data obtained in this way is judged to be *ca* ± 0.3 p.p.m.

Some of the spectra were obtained under field-frequency lock conditions in which the signals are observed in the absorption mode, with noise-modulated decoupling to eliminate all proton–^{13}C coupling interactions. In these cases, the decoupled solvent signal was used as a "lock" and each spectrum repetitively scanned several times to obtain a suitable S/N. The instrument operated at 15.1 MHz and spectral accumulation was accomplished with a Varian 620i computer which also controlled the sweep unit, a Wave Tek Model 111 voltage-controlled oscillator. Decoupling was accomplished with a HP608F signal generator and HP8708A VHF synchronizer combination[3] the output of which was modulated with a HP3722A noise generator and amplified with a class C amplifier (the final stages of the NMRS SD60 decoupler). A Varian V4336 probe[4], double-tuned at 15.1 and 60 MHz, was employed in which 12 mm spinning sample tubes are used. In some cases a lock signal was obtained from a 3 mm capillary, containing 60%-enriched CS_2, which was held in the center of the sample tube with Teflon plugs. Operation with this instrument permitted measurements having a precision better than 0.1 p.p.m.

The proton spectra were obtained with a Varian HA-100 instrument; the analysis was straightforward in each case. Assignments for specific protons were checked, where necessary, by nuclear Overhauser enhancement measurements.

Results

The shielding results for the propenoic acids and methyl esters are collected in Tables 1 and 2, respectively. Since the precision of the two techniques employed to obtain these data differ

appreciably, the less precise results (±0.3 p.p.m.), measured under rapid-passage conditions, are distinguished from the high-resolution data (±0.1 p.p.m.) by italicizing the last figure in the former, *i.e.* 166.5 *vs.* 166.5 p.p.m. The rapid-passage data were measured relative to external methyl iodide and converted to the δ_C scale (TMS = 0) using the shielding value of CH_3I, −20.5 p.p.m. The high-resolution data for cyclohexane solutions, measured initially from C_6H_{12}, were converted using $\delta_C(C_6H_{12})27.7$. In other cases the following conversion factors were employed: δ_C (CS_2 (ext)) 193.7; δ_C (dioxane) 67.4; δ_C (C_6H_6) 128.7. Lippmaa's data (19) were converted to the δ_C scale using the factor 193.7 p.p.m. To examine the solvent dependence of these shieldings, methyl acrylate and acrylic acid were measured in a few solvents, using the high-resolution method; these data are listed in Table 3 together with the results reported by Lippmaa *et al.* (19*b*) for acrylic acid.

The assignment of individual absorption patterns to specific carbons in this series of compounds presented no difficulties. The carboxyl carbons are readily identified as the lowest field signals (24) while the methoxyl carbons of the COOMe groups absorb near δ_C 51. The olefinic methyl carbons were also easily identified since their signals appear at highest field. Although the signal for one of the olefinic carbons in methyl β-cyanoacrylate is near that of the cyano carbon in the decoupled spectrum, these are readily distinguished in the coupled spectrum. From these shieldings, 111.7 and 114.7 p.p.m., respectively, the assignments of the singlets arising from C-3 and C≡N in the methyl β-cyanocrotonate spectra follow because of the downfield shift of *ca.* 13 p.p.m. expected for the olefinic absorption upon methyl substitution (2).

For those compounds in which the olefinic carbons are bonded to different numbers of hydrogen atoms, the multiplicities of the patterns in the coupled spectra serve to identify the α- and β-nuclei directly. For those cases in which each olefinic carbon bears a single hydrogen atom, the relative magnitudes of the $^{13}C-^{1}H$ coupling constants provide the necessary information to complete the assignments since J_{CH} increases with increasing electronegativity of X in the fragment X—C—H (25). In the present series the β-carbons bearing halogens or a methoxyl group have J_{CH} values which are 15–40 Hz larger than those of the α-carbons. The J_{CH} values were measured in the coupled ^{13}C spectra.

The proton parameters for the methyl esters, obtained by first-order analysis are listed in Table 4.

Discussion

It is apparent that, with the exception of the methoxyl group, the configuration of β-substituents has virtually no effect on the carboxyl

carbon shieldings in either the carboxylic acids or their methyl esters. Although there is a small shift toward higher field (*ca.* 3 p.p.m.) in the case of the halo- and cyano-substituted systems the observed difference between carboxyl shieldings in the *Z*- and *E*-isomers is less than 1 p.p.m. Similarly these carbons are essentially unaffected by β-methyl groups while α-methyl substitution tends to deshield the carboxyl carbons by *ca.* 1 p.p.m. The shielding of the methoxyl carbon of the ester group is also unaffected by these β-substituents, lying in the narrow range of *ca.* 2 p.p.m. for this series. The upfield shifts of 3–4 p.p.m. observed for the carboxyl carbon signals upon esterification are qualitatively comparable to those found for saturated systems (26–28) presumably because of a decrease in the polarization caused by hydrogen bonding in the acid (see below), but it may be noted that the change is approximately 50% of that observed for saturated systems.

The shieldings of the olefinic carbons as well as those of the β-methyl and β-methoxyl carbons, however, depend markedly on the orientation of the β-substituent. In general, the olefinic carbons of the *Z*-isomers absorb at higher field than their *E*-analogs, whereas β-methyl carbons *cis* to the carboxyl function are shielded relative to those in the *trans*-orientation. For example, the β-methyl shieldings of the *E*-isomers of the 3-substituted crotonates differ from those of the *Z*-isomer by *ca.* −4 p.p.m. It is to be noted, however, that the upfield trend associated with the *cis*-orientation of the β-methyl carbon is more pronounced for *cis*-vicinal methyl groups. This is most clearly illustrated by the results for methyl angelate and methyl tiglate. In the former, the C-methyl carbons are equivalent, δ_C 20.5, while for the latter, in which these carbons are *cis*, the signals appear at δ_C 11.8 and 13.9. Presumably the major factor contributing to the upfield shifts observed for *cis*-methyl carbons arises from steric interactions between the closely-lying groups. These γ-effects, attributed to sterically induced polarization (15), are generally found for carbons in gauche or eclipsed orientations. On the basis of steric interactions it seems reasonable that a greater shift will be observed for *cis*-vicinal methyls than for a methyl carbon *cis* to a carboxyl or carbomethoxyl function.

The effects of methyl substitution on the olefinic shieldings are comparable to those found for related α,β-unsaturated carbonyl derivatives (4). Upon replacement of an olefinic hydrogen atom by a methyl group the absorption of the substituted carbon undergoes a downfield shift of 10–15 p.p.m. while the neighboring olefinic carbon is shielded (5–10 p.p.m.). Similar changes are found upon introduction of a chlorine atom but the shifts are reversed for bromine and iodine substitution. Furthermore, while the shifts exhibited by the olefinic carbons in the methyl substituted derivatives are almost in-

dependent of the stereochemistry of the methyl group this is not the case for the halogens. In one of the first discussions of the effects of polar substituents on olefinic ^{13}C shieldings (1) it was proposed that alterations in the electron density arising from steric inhibition of resonance in *cis*-isomers were the primary source of the geometrical dependence of the olefinic shieldings but this view was subsequently modified (6). It was suggested that the tendency toward charge separation and a reduced bond-order in the olefinic bond of the *cis*-isomers may be the principal factor governing the differential shifts. Although application of the Pople–Karplus treatment (29) gave results consistent with the observations for unsymmetrically substituted ethylenes this approach fails with the symmetrical systems indicating that the apparent agreement for the former cases may be fortuitous since the possible effect of variations in excitation energies and contributions from the *d*-electrons of the halogens were neglected.

It is interesting that the olefinic shieldings in a variety of alkyl-substituted α,β-unsaturated carbonyl derivatives may be correlated reasonably well with a linear expression of the form

$$[1] \qquad \delta^{i}_{C} = K + \sum_{j} A_j n_{ij}$$

where δ^{i}_{C} represents the shielding of either the α- or β-olefinic carbon, A_j is an additive shift parameter for a specific substitution j, n_{ij} the number of such substitutions, and K is a constant. Linear regression analysis of the α- and β-carbon shieldings, separately, led to the generation of the parameters listed in Table 5. This approach is exactly analogous to that employed by Grant and Paul (20) to correlate their saturated hydrocarbon shieldings with the additional feature that two types of substituent parameters are required to differentiate between effects transmitted entirely through σ-networks and those which act through the π-bond. In addition, it was found necessary to include geometrical parameters denoted "*cis* (alkyl)" and "*cis* (carbonyl)" to achieve a fit for the data. In the light of the standard error of this analysis it would appear that these parameters may be useful for predicting ^{13}C shieldings in other closely-related systems but, in any event, the existence of the correlation emphasizes the remarkable additivity of substituent effects on ^{13}C shieldings. This analysis should provide constants, K, which correspond to the shieldings of acrolein, the observed shieldings (4) for which, after conversion to the TMS scale, are 136.*4* and 136.*0* p.p.m., *i.e.* somewhat more shielded than the calculated values. A similar analysis was attempted for the 3-halo substituted examples but the results were less satisfactory; since some interesting trends emerge, however, these data are collected in Table 6 for comparison. In this case, the constant terms, K, correspond closely

to the shieldings of methyl acrylate. The methyl group was included in the regression analysis as a check with the data in Table 5 and the agreement is satisfactory. The values of the geometric parameters found for the halogens emphasize the difficulty in interpretation of the effects of these substituents. While the "direct" effects change monotonically to judge from the second, third, and fourth parameters, the geometrical effects exhibit a different trend for the series: Cl, Br, I. The results for an extensive series of polysubstituted acrylic acids have recently been analyzed to test for the existence of an additive relationship and a series of parameters has been derived in a somewhat different manner (19). Lippmaa *et al.* following an approach analogous to that originally employed by Savitsky and Namikawa (1) generated two sets of parameters for the α- and β-olefinic carbons, in each of which there are three parameters for each substituent depending on its position with respect to the carboxyl group, *i.e. gem, cis,* and *trans.* Thus, their *trans* parameters and the difference between the *cis* and *trans* parameters may be compared with the values obtained by our linear regression analysis; these data are included in Table 6. Since the latter parameters were derived from shieldings for the acids only and these were examined either as neat liquids or in DMSO solutions, it is not surprising that these values differ somewhat from our values. Lippmaa and coworkers (19) found that their parameters give predicted shieldings which are generally within 4 p.p.m. of the observed values and they pointed out that this is equivalent to an error of *ca.* 0.13 p.p.m. for ^{1}H shieldings since the ^{13}C shielding range is *ca.* 30-fold larger. Clearly these parameters should be useful for approximate estimates of the ^{13}C shieldings in related systems. As Grant and Paul (20) found in their analysis of the results for the saturated hydrocarbons, it is necessary to include additional factors for geminal substituents. In the present series, a parameter for geminal methyl and halogen was generated while Lippmaa *et al.* derived factors for geminal halogen atoms.

To examine the effect of medium on these shieldings, the spectra of acrylic acid and methyl acrylate were obtained in a few different solvents. These data together with the earlier results reported by Lippmaa *et al.* (19*b*) show (Table 3) that each carbon in the acid is affected by the solvent but the ester shieldings are virtually independent of the medium. The solvent dependencies of the carbons in acrylic acid appear to be explicable in terms of hydrogen bonding. In the neat liquid, the acid exists predominantly as a dimeric species, **1**, in which the carboxyl group is strongly polarized by hydrogen bonding. Since water and methanol can act both as donors and acceptors in hydrogen-bonded complexes, however, species such as **2** and **3** enter the equilibrium in these solvents such that the relative dimer concentration is reduced

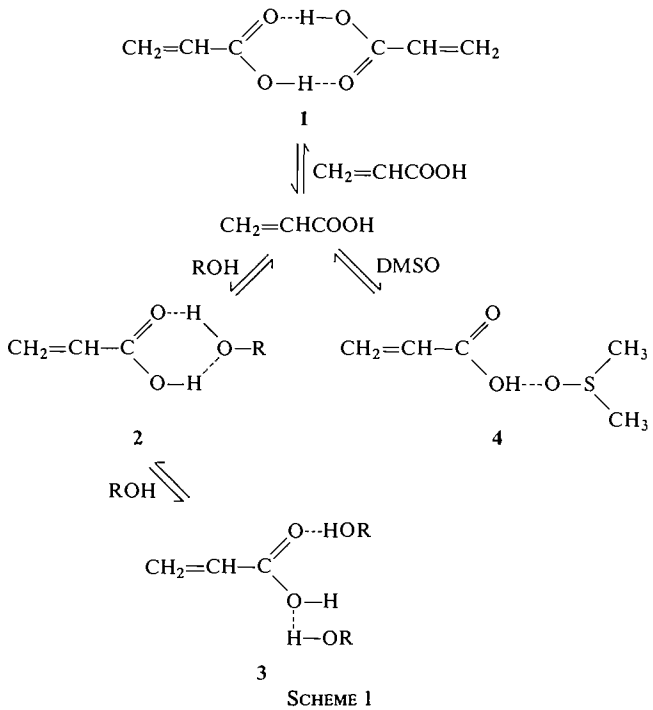
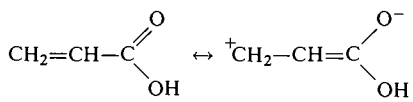


SCHEME 1

(see Scheme 1). The fact that the shieldings in water and methanol differ, with the aqueous values close to those for the pure liquid, indicates that water is the more strongly hydrogen-bonded and the polarization of the conjugated system in **2** and **3** (R = H) is comparable to that in **1**. Dioxane and dimethylsulfoxide, on the other hand, act only as acceptors and species such as **4** would be expected to be less polarized; the upfield shifts of the carboxyl and β-carbon signals in these solvents relative to the shieldings of the pure liquid are consistent with this view.



In effect, hydrogen-bonding should enhance the contribution of forms such as **5** to the overall electron distribution in the conjugated systems. To test the concentration dependence of these shieldings in a hydrogen-bonding medium, the ^{13}C shieldings of acrylic acid were measured as a function of increasing amounts of methanol. These results are illustrated in Fig. 1 from which it is apparent that the carboxyl and β-carbon nuclei are more strongly affected. It is interesting that most of the solvent shift occurs with less than 2 *M* equiv of methanol indicating that both **2** and **3** indeed are formed. These relatively small

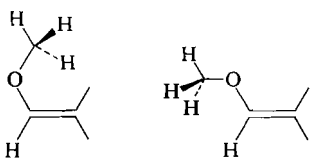
shifts of *ca.* 2 p.p.m., however, are much smaller than the 7 p.p.m. difference found for the carboxyl carbon of acetic acid upon dilution in acetone (30); this is consistent with the notion that **3** is reasonably strongly polarized although less so than the dimer, **1**. In summary, these results are comparable to those found by Maciel and Traficante (30) in their detailed examination of the solvent dependence of the acetic acid carboxyl shielding and may be interpreted in a similar manner. There is the additional feature that the β-olefinic carbon shieldings are also expected (4, 25) to reflect variations in the polarization of the carboxyl function as observed.

The proton shielding results for the methyl esters (Table 4) follow the usual trends in that the β-protons absorb at lower fields than the α-protons and β-protons or β-methyl protons *cis* to the ester grouping are consistently deshielded relative to their *trans*-counterparts. The values for the majority of the coupling constants are also unexceptional and require no specific comments. The long-range interactions between the methoxyl and olefinic protons, however, are interesting. The *E*-isomers (*i.e.* those having the methoxyl and carbomethoxyl function *trans*) exhibit readily measurable four- and five-bond couplings whereas in the corresponding *Z*-isomers these interactions are not resolved. Presumably the magnitude of these long-range coupling constants depends on the conformation of the methoxyl methyl group as proposed by Feeney and Sutcliffe (31). According to these authors coupling between the nearest olefinic proton and those on the methoxyl carbon will be greater in the rotamer **6**, having the methoxyl group close to the double bond, rather than **7**.



6 7

In **6** the olefinic and one of the methyl protons is in the familiar W arrangement known to favor long-range coupling. Since there will be steric interference with the carbomethoxyl and methoxyl groups in the *Z*-isomers, however, rotamer **7** will be the preferred form in these systems and the long-range couplings may be expected to be smaller, as is observed. Similar results were obtained for the *Z*- and *E*-isomers of 1-methoxy-1-propene. Although no long-range coupling involving the methoxyl protons is evident in the spectrum of the former, the four- and five-bond interactions are 0.28 and $\sim$0.1 Hz, respectively, in the latter. On the basis of these results it is not surprising that comparable long-range coupling was not resolved in the spectrum of 1-methoxy-2-methyl-1-propene.

We wish to acknowledge the financial support of the National Research Council of Canada through an operating grant and scholarships. We also wish to thank Varian Associates, Palo Alto, California for the loan of the V4336 probe and the Centre for Radio Science, University of Western Ontario, Dr. P. A. Forsyth, Director, for the use of the r.f. generator employed in the proton decoupler.

The Nature of the Tricyclic Dimer Formed from Acetonylacetone and Hydrazine: An Application of ^{13}C Nuclear Magnetic Resonance[1]

P. DE MAYO, J. B. STOTHERS, AND M. C. USSELMAN
Chemistry Department, University of Western Ontario, London, Ontario

Received August 27, 1971

The structure of the dimer formed from acetonylacetone and hydrazine has been re-examined. On the basis of chemical and spectroscopic data, a covalent tricyclic structure is proposed.

La structure du dimère formé à partir de l'acétylacétone et de l'hydrazine a été réexaminée. Sur la base de données chimiques et spectroscopiques, une structure covalente tricyclique est proposée.

Introduction

For another purpose we had need of the substance **2***a* (3,6-dimethyl-6-*n*-butyl-1,4,5,6-tetrahydropyridazine) and sought to prepare it by the method used by Overberger and Kesslin (1) for the preparation of the phenyl derivative **2***b*. This drew our attention to the nature of the intermediate dimeric substance **1**, to which no adequate structure had been assigned (2). The substance **1** was formed by the action of acetonylacetone on hydrazine, and on arylation gave **2***b*. Earlier workers (3–5) had attributed a structure **3** to this substance, but this was discarded by Overberger. Work is described below, both chemical and spectroscopic, which leads to the conclusion that this substance is best represented by structure **4**.

Results and Discussion

Compound **1**, a colorless solid m.p. 52–53°, was shown by Overberger *et al.* (2) to react as if it were the monomeric 3,6-dimethyl-4,5-dihydropyridazine (**5**). Under a variety of conditions, therefore, the dimer **1** must have a facile route for reversion to monomer. In confirmation of this our synthesis of the monomeric *n*-butyl adduct **2***a* proceeded cleanly and in good yield (eq. 1). It has been equally clear, however, to those who have worked with **1** that a simple monomeric structure is not possible. The earliest workers based their conclusions principally on molecular weight determinations, which gave values of *ca.* 220, corresponding to the molecular weight of a dimer. Overberger *et al.* (2), on the basis of its cryoscopic molecular weight in water, which varied with concentration, concluded that **1** existed as an associated dimer. The i.r. spectrum (2) contained NH absorption, which is not present in **5**, and yet **1** reacted with a variety of reagents, such as hydrogen cyanide and hydrogen peroxide (2), as a simple monomer. All of these facts are readily explained if **1** indeed exists as an associated dimer.

The proton spectrum of **1** clearly indicated a dimer which contained 20 protons, including one exchangeable amine hydrogen (at 5.35 p.p.m.) and four nonequivalent methyl groups (1.85, 1.70, 1.40, and 0.97 p.p.m.). The spectra were identical for samples of **1** purified by fractional distillation, recrystallization, or sub-

limation. The four methyl absorptions were singlets and no identifiable coupling patterns could be discerned for the methylene protons.

Since the proton spectra indicated the existence of a stable dimer, even in very dilute solution, the molecular weight of **1** was determined by osmometry in CCl_4 at various concentrations and found to be independent of concentration, contrary to the result reported for the aqueous solution (2). Thus, it appears that **1** is a covalent, stable dimer in neutral solution, but under basic or acidic conditions, the dimer dissociates wholly, or in part, to monomer (**5** or one of its tautomers): reactions then proceed from the monomer. Not surprisingly, the mass spectrum showed no signal at *m/e* 220, the signal of greatest *m/e* being at 110.

If **1** be stable in neutral media it should be possible to anchor the molecule in its dimeric form by acetylating the amine function. Reaction of **1** with acetic anhydride in pyridine resulted in a nearly quantitative conversion to the *N*-acetyl derivative, which was stable in polar solvents, as expected, although, like the dimer **1**, it slowly decomposed on exposure to air. Its proton spectrum in carbon tetrachloride contained three separate methyl absorptions at 2.1, 1.9, and 1.1 p.p.m. in a ratio of 2:2:1, respectively; five resolved methyl singlets appeared in benzene solution at 2.50, 2.35, 1.80, 1.60, and 0.78 p.p.m.

The u.v. spectrum of **1** in cyclohexane solution was recorded over a concentration range of 10^4 and was found to follow Beer's law over the entire concentration span, thus indicating that the dimer was unaffected by dilution, in agreement with the osmometry result. In addition, the u.v. spectrum of **1** in carbon tetrachloride (the solvent used for i.r., n.m.r., and osmometry) was identical to that in hexane, at least in the region in which carbon tetrachloride was transparent. The species examined by n.m.r., i.r., and osmometry is hence the same as that studied by u.v. spectroscopy.

From these facts it appears that **1** exists as a covalent dimer, and the first step in many of its chemical reactions is dissociation to the monomer, or tautomers thereof, which subsequently reacts to give product.

Of the possible dimeric structures, only those in which the six-membered ring of the monomer is intact were considered seriously, since all reactions of the dimer lead to substituted pyridazines as products. The formation of structures **4**, **6**, or **7** may be envisaged to arise

[2] 
as shown in eq. 2. Structures **4** and **7** are easily obtained from **6** by addition of the amino nitrogen to one or the other of the imine bonds.

Structures **4** and **7** are expected to have very similar spectral properties but **6** should give distinctly different spectra. If **6** were the correct structure, its u.v. spectrum should approximate a composite of the spectra of **2***a* (λ_{max} 230 nm (4700)) and hexamethyl-4,5-dihydropyridazine[2] (**8**) (λ_{max} 250 nm (2800)) but the dimer exhibits a single maximum at 250 nm (7200) which is much more intense than that of **8**. Although red-shifted 20 nm, the shape of the dimer spectrum is similar to that of **2***a* (**4** and **7** are approximated by two such chromophores) suggesting that **4** and **7** are more likely formulations.

Structure **6** was judged even more unlikely in light of the proton spectrum. One would expect the two methyl groups of the dihydro ring to have very similar chemical shifts but this was not observed. This discrepancy may be explained if the dimer is intramolecularly hydrogen-bonded preventing free rotation about the bond joining the two rings. To this end, i.r. spectra of the dimer in chloroform were recorded over a concentration range of 20 (the amount of dimer between the plates was held constant through the use of cells of varying path length). In the most dilute solution a sharp NH absorption at 3350 cm^{-1} appeared. With increasing concentration, the NH band broadened considerably until it extended to 3200 cm^{-1} in the most concentrated solution. This change is indicative of intermolecular rather than intramolecular hydrogen-bonding, since the latter is expected to be concentration independent. The proton spectrum was compatible with structures **4** and **7**, however, since the four methyl groups in each structure are in different environments.

We next attempted to distinguish between **6** and structures **4** and **7** by chemical means, and used two approaches, both of which were intended to demonstrate the correctness of structure **6**. The first of these was oxidation of the dihydro ring, and the second Diels–Alder addition to that ring.

As shown initially by Overberger *et al.* (2), oxidation of the dimer itself gives only dimethylpyridazine (**9**). In addition, the *N*-acetyl dimer was stable to hydrogen peroxide in refluxing 50% aqueous isopropanol and to palladium-on-carbon in *o*-xylene at 150°. Thus, structure **6** seems unlikely since its dihydro ring should be easily oxidized. Oxidation with Pd/C in refluxing *p*-cymene (180°) gave seven products, none of which was that expected. On the basis of these results structures **4** and **7** are strongly favored.

Although Diels–Alder additions of the *N*-acetyl dimer with *N*-phenyl maleimide, tetracyanoethylene, and 4-phenyl-1,2,4-triazoline-3,5-dione (**10**) were unsuccessful,[3] **10** reacted instantaneously with dimer **1** in cold benzene to produce dimethylpyridazine **9** and *N*-phenylurazole. The urazole precipitated out of solution as a fine white powder. With the addition of 2 mol of triazolinedione, 1 mol of the dimer was oxidized quantitatively to 2 mol of dimethylpyridazine, with the production of 2 mol of the urazole.

The reaction of triazolinedione with compounds containing an active hydrogen is well known. Pirkle and Stickler isolated a 1:1

[2]We thank Dr. D. A. Arnold for a generous sample of this compound.

[3]Arnold and coworkers have shown (6, 7) that triazolinedione reacts rapidly with five-membered ring isopyrazoles to give Diels–Alder adducts. However, he has found that **8** does not react with triazolinedione (8).

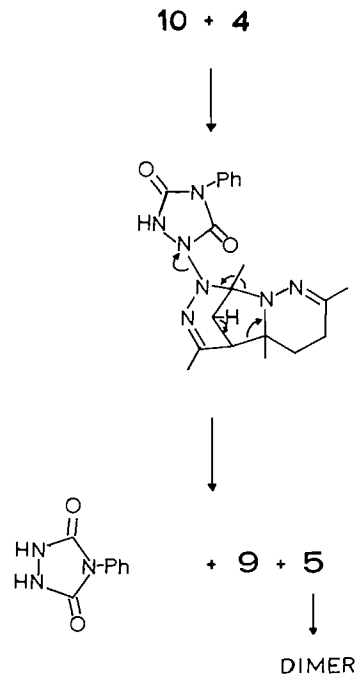
[3]

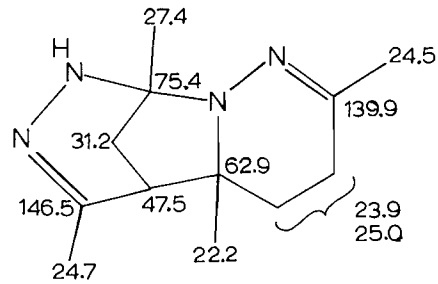


addition product from reaction of triazolinedione with olefins bearing an allylic hydrogen (9), and Cookson *et al.* were able to oxidize alcohols to ketones in high yield with triazolinedione (10). It is possible that oxidation of **1** proceeds via an addition–elimination step as illustrated in eq. 3 for structure **4**.

We propose addition to NH as the first step for two reasons. First, the *N*-acetyl derivative is stable to triazolinedione, and thus the NH function of the dimer must be responsible for overall reaction. Secondly, it was possible to isolate a similar 1:1 adduct from the reaction of triazolinedione with piperidine. The addition of triazolinedione to a benzene solution of piperidine gave an instantaneous reaction and a light yellow compound formed as the sole product. Its spectra were compatible with the 1:1 adduct **11**. It was stable at room temperature under nitrogen for about 12 h.

On the basis of the accumulated data, **4** and **7** appeared to be the most probable structures for the dimer. To reach an unambiguous conclusion, the ^{13}C n.m.r. spectra of the dimer and related compounds were examined.

The proton decoupled ^{13}C spectrum of **1** in acetone-d_6 solution contained 12 separate resonances, with two at significantly lower field (139.9 and 146.5 p.p.m.) than the others. This observation conclusively ruled out **6** as a possible structure since it contains three sp^2-hybridized carbons which are expected to absorb at $\delta_C >$ 100. Three signals at intermediate fields (47.5, 62.9, and 75.4 p.p.m.) were shown by off-resonance decoupling to arise from a tertiary and two quaternary carbons, respectively. Of the remaining seven signals, four were readily assigned to methyl carbons (22.2, 24.5, 24.7, and 27.4 p.p.m.) and three to methylene carbons (23.9, 25.0, and 31.2 p.p.m.) by off-resonance decoupling. Tentative assignments for each signal are indicated in **12**. Although these are



12

difficult to confirm because of a lack of suitable model systems, some supporting evidence is provided by the spectra of **1**-NAc, and **2***a*. The low field signals in the spectrum of the *N*-acetyl derivative appeared at 47.3, 63.0, 80.4, 141.0, and 151.4 p.p.m. and, with the exception of the first, were shown to arise from quaternary carbons. Thus, only one of the doubly-bonded carbons and the carbon absorbing at 75.4 p.p.m. in the dimer are significantly affected by acetylation, as expected for the tricyclic structures. Since the methine signal (47.5 p.p.m.) and that for one of the saturated quaternary centers (62.9 p.p.m.) are unaffected by *N*-acetylation these carbons must be more than three bonds from the N—H group in the dimer. One methylene signal, however, is shifted 4 p.p.m. upfield upon acetylation which may be expected for structure **4** but not **7** since the *N*-acetyl group is three bonds from C-12 in **4**. In general, substitution of a hydrogen three bonds from a given carbon tends to increase the shielding of that carbon because of the so-called "γ-effect";

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

several examples of this tendency have been reported (11). The imine carbon in **2***a* absorbed at 141.7 p.p.m., supporting the assignments for the corresponding carbon in **4** and the *N*-acetyl derivative. In addition to the four signals of the *n*-butyl group, two methylene carbons absorbed at 24.8 and 26.1 p.p.m. corresponding to the 23.9 and 25.0 p.p.m. signals for the dimer. The *n*-butyl signals (14.7 (CH_3), 24.1, 30.8, and 39.1 p.p.m.) were assigned by comparison with the spectra of *n*-butylcyclohexane (12) 1-, 3-, and 4-*n*-butylcyclohexanes (13). Thus, the ^{13}C spectral data unequivocally eliminate **6** from consideration and appear to favor **4** over **7** although the latter cannot be rigorously excluded. In addition, since the reaction is readily reversible and the formation of **4** is mechanistically equivalent to the formation of **7**, the product of thermodynamic control **4**, is expected.

Experimental

Preparation of Dimer (1)

The dimer was prepared and purified by the method of Overberger *et al.* (2). Recrystallization from petroleum ether (30–60°) gave transparent square crystals, m.p. 52–53°; ν_{max} (CCl_4) 3360, 2940, 1620 cm^{-1}; δ (CCl_4) 5.35 (1H, broad singlet), 2.40–1.90 (5H, multiplet), 1.85 (3H, singlet), 1.70 (3H, singlet), 1.60–1.45 (2H, multiplet), 1.40 (3H, singlet), and 0.97 (3H, singlet); *m/e* (70 eV) 43, 58, 83, 85, 95, 97, 109, and 110.

3,6-Dimethyl-3-n-butyl-2,3,4,5-tetrahydropyridazine (2a)

Compound **2***a* was prepared by a method similar to Overberger and Kesslin's synthesis (1) of the phenyl analogue (**2***b*). The crude product was a yellow oil which was fractionally distilled (N_2) through a 6 in. Vigreux column. A first fraction b.p. 30–50°/0.2 mm was collected in 20% yield, mainly dimethylpyridazine, the second, b.p. 50–70°/0.2 mm, was crude butylpyridazine (50% yield), and the remainder was mainly unreacted starting material. The crude product was purified by distillation (N_2) on a 2 ft spinning band under reduced pressure and pure **2***a* (35%) was obtained as a colorless liquid b.p. 52°/0.2 mm; λ_{max} (cyclohexane) 230 nm (ε 4700); ν_{max} (CCl_4) 3300, 2930, 1640, 1440, and 1375 cm^{-1}; δ (CCl_4) 5.00 (1H, broad singlet), 2.20–1.50 (7H, multiplet containing a methyl singlet), 1.40–1.10 (6H, multiplet), and 1.10–0.80 (6H, multiplet); *m/e* (70 eV) 28, 43, 108, 111, 153, and 168.

Anal. Calcd. for $C_{10}H_{20}N_2$: C, 71.37; H, 11.98; N, 16.65. Found: C, 71.11; H, 11.67; N, 16.70.

Preparation of the N-Acetyl Dimer

Equimolar amounts of the dimer **1** and acetic anhydride were dissolved in 5 ml of dry pyridine and let stand under nitrogen at room temperature for 24 h. The solvent was then removed under vacuum at room temperature to yield a pale yellow solid in 80–90% yield. The solid was recrystallized three times from petroleum ether (60–80°), to yield colorless, rectangular crystals, m.p. 153–153.5°; λ_{max} (cyclohexane) 235 nm (ε 11 000); ν_{max} (CCl_4) 2940, 1690, 1630, 1435, 1390, and 1360 cm^{-1}; δ (CCl_4) 2.30–2.00 (9H, multiplet containing a sharp singlet), 2.00–1.80 (8H, multiplet containing sharp singlet), 1.80–1.30 (2H, multiplet), and 1.10 (3H, singlet); δ (C_6H_6), 2.50 (3H, singlet), 2.35 (3H, singlet), 2.00–1.60 (10H, multiplet containing two sharp singlets), 1.50–0.90 (multiplet, 3H), and 0.78 (3H, singlet).

Anal. Calcd. for $C_{14}H_{22}N_4O$; C, 64.09; H, 8.45; N, 21.36. Found: C, 64.27; H, 8.45; N, 21.31.

Piperidine/4-Phenyl-1,2,4-triazoline-3,5-dione Adduct (11)

Freshly distilled piperidine was dissolved in benzene and an equimolar amount of dione in benzene was added dropwise. The red color disappeared immediately and the solution turned pale yellow. The piperidine was removed under pressure (20 mm) leaving a bright yellow oil which t.l.c. showed to be the only product. The yellow oil was purified by preparative t.l.c. (50% ether/benzene as eluent). The yellow color darkened rapidly upon exposure to air but was stable for up to 12 h under nitrogen; λ_{max} (EtOH) 240, 325 nm; ν_{max} ($CHCl_3$) 3000, 2940, 2860, 1650, 1600, 1500, and 1440 cm^{-1}; δ ($CDCl_3$) 7.4–7.0 (5H, multiplet), 6.5 (1H, broad singlet), 3.4 (4H, multiplet), and 1.6 (6H, multiplet).

Oxidation of Dimer with Triazolinedione

To 102 mg of dimer **1** in benzene at 6° was added dropwise a solution of 200 mg dione in benzene. The addition was stopped when the red color of the dione failed to disappear within 1 min, at which point 170 mg of dione (2.07 mol) had been added. The *N*-phenyl urazole which had precipitated as a fine white powder was filtered off and the solvent removed under vacuum. The residue which remained was greater than 90% dimethylpyridazine identified by comparison with an authentic sample.

Attempted Oxidations of N-Acetyl Dimer

(a) With Hydrogen Peroxide

The dimer (300 mg) was refluxed for 15 min in water/isopropanol solution with an equimolar amount of peroxide. Thin-layer chromatography showed only unreacted starting material.

(b) With 5% Palladium-on-carbon

Equal weights (300 mg) of **1** and Pd/C were heated to 150° under nitrogen in *o*-xylene for 3 days with no reaction. When repeated in refluxing *p*-cymene (180°), seven products were formed after 20 h. The n.m.r. of the crude concentrated reaction mixture showed no new peaks in the aromatic region.

Molecular Weight Determination of Dimer in CCl_4

Four solutions of the dimer in CCl_4 were made up from 0.003–0.06 *M*, and the molecular weight determined on a Hewlett-Packard 301A vapor pressure osmometer. Recrystallized acenaphthene was used as a calibrating compound. The experimentally determined molecular weight for each of the four concentrations was 208 ± 2.

Ultraviolet of the Dimer in Cyclohexane

The absorption coefficients at 225, 250, and 270 nm of the dimer absorption in cyclohexane were determined for dimer concentrations ranging from 1.37×10^{-1} to 1.37×10^{-5} *M*. The molar extinction coefficient at the wavelengths

chosen was constant over the concentration range of 10^{-4}, following Beer's law.

Effect of Dilution on NH Absorption of Dimer

The i.r. spectrum of the dimer in $CHCl_3$ was taken in 0.1, 1, and 2 mm cells with the amount of dimer between the plates held constant. In the most concentrated solution, the NH absorption was broad and extended from 3350 (free NH) to 3200 cm^{-1} (hydrogen-bonded NH). In the more dilute sample the NH absorption was sharper, and in the most dilute sample the NH absorption was very sharp at 3350 cm^{-1}.

Nuclear Magnetic Resonance Spectra

The ^{13}C spectra were obtained using a Varian XL-100-15 system operating at 25.2 MHz with proton noise decoupling at 100 MHz; the deuterium signal from the acetone-d_6 solvent served as the lock. The peak positions were measured from internal TMS (δ_C 0) with a precision better than 0.1 p.p.m. Proton spectra were obtained with Varian T-60 and HA-100 spectrometers.

Department of Chemistry, McMaster University, Hamilton, Ontario

Received August 16, 1971

The deuterionorborneols **2***a*, *b*, *c*, and *e* have been prepared and converted to the brosylates **1***a*, *b*, *c*, and *e*. The deuterium isotope effects determined spectrophotometrically for solvolysis in HOAc–KOAc are 1.00 ± 0.01, 1.01 ± 0.01, 0.99 ± 0.01, and 1.11 ± 0.01, respectively. These data establish that: (*a*) a steric deuterium isotope effect does not operate at C-5 and therefore probably not at C-6; (*b*) hyperconjugative stabilization of the norbornonium ion to the C-5 hydrogens is confirmed to be not important, and (*c*) provides the first experimental evidence that the hydrogen (deuterium) shift – internal return pathway contribution to the γ-deuterium isotope effects observed for **1***d* and *e* is minor.

Les norbornéols deutérés **2***a*, *b*, *c*, et *e* ont été préparés et transformés en brosylates **1***a*, *b*, *c*, et *e*. Les effets isotopiques du deutérium ont été déterminés par spectrophotométrie pour la solvolyse dans HOAc–KOAc et sont respectivement de 1.00 ± 0.01, 1.01 ± 0.01, 0.99 ± 0.01 et 1.11 ± 0.01. Ces données mettent en relief les faits suivants, (*a*) un effet isotopique stérique du deutérium ne se produit pas sur C-5 et par conséquent, probablement pas non plus sur C-6; (*b*) la stabilisation par hyperconjugaison de l'ion norbornium aux hydrogènes en C-5 est confirmée comme étant de peu d'importance, et (*c*) apporte la première preuve expérimentale du fait que la contribution du mécanisme de retour, par déplacement interne d'hydrogène (deutérium), aux effets isotopiques du γ-deutérium, observés pour **1***d* et *e*, est de peu d'importance.

Canadian Journal of Chemistry, **50**, 618 (1972)

Introduction

α-, β-, and γ-deuterium isotope effects have been used extensively to probe the nature of the norbornyl cation generated solvolytically (2*a*–*i*). Of special interest has been the work of Murr *et al.* (2*c*) and Jerkunica *et al.* (2*d*), which showed that the isotope effects for *exo*-norbornyl and *endo*-norbonyl brosylates-6-*d* were 1.10 and 1.00, respectively. The γ-deuterium isotope effects obtained for the *endo*-brosylates were consistent with those expected for a classical ion transition state. However, the unusually large γ-effects for the *exo*-brosylates contrast with those observed in the solvolysis of deuteriated 3-methyl-2-butyl tosylate (3) (1.00), deuterio-*n*-propyl halides and tosylates (0.93) (4*a*), deuteriocyclopropyl-methyl benzenesulfonates (0.95) (4*b*), and 6-deuteriated-1,2-dimethyl norbornyl-*p*-nitrobenzoates (1.02) (2*g*).

In this study, the 5-deuteriated-*exo*-2-norbornyl brosylates **1***a*, *b*, and *c* were prepared and solvolyzed in KOAc buffered glacial acetic acid, to determine the δ-deuterium isotope effect in the solvolysis of *exo*-norbornyl brosylate. The work was designed to (*a*) determine the possible contribution of a "steric" isotope effect of deuterium at C-5; (*b*) check for hyperconjugative stabilization of the norbornonium ion **3** via the C-5 hydrogens, and (*c*) ascertain whether or not the 6,2–6,1 hydrogen(deuterium) shift – internal return mechanism is important in the solvolysis of *exo*-norbornyl brosylate and therefore contributes to the deuterium isotope effect of 1.10 observed by Murr *et al.* (2*c*) in the solvolysis of **1***d* and *e*. That this study would give information on (*c*) is seen from a consideration of Scheme 2. If the hydrogen shift – internal return pathway is important, then **8***a*, and especially **8***c*, would be converted to deuterio brosylate **14***a*, and **14***c* in which deuterium is situated *exo* at C-3. Since the k_H/k_D values for **14***a* and *c* are 1.07 as determined by Murr *et al.* (2*i*), the conversion of the brosylates **8***a* or *c* to **14***a* and *c* would then result in a contribution of >1 to the isotope effect for **8***a* and *c*.

This study would give information on whether or not a steric isotope effect arising via inter-

3

1 X = OBs
2 X = OH

a $R_1 = D; R_2 = R_3 = R_4 = H$
b $R_1 = H; R_2 = D; R_3 = R_4 = H$
c $R_1 = R_2 = D; R_3 = R_4 = H$
d $R_1 = R_2 = R_3 = D; R_4 = H$
e $R_1 = R_2 = R_3 = H; R_4 = D$
f $R_1 = D; R_2 = H; R_3 = D; R_4 = H$
g $R_1 = R_2 = R_3 = R_4 = H$

actions between the 6-*exo*-D, 5-*exo*-H, and 7-*anti*-H contributes to the k_H/k_D of 1.10 observed for **1***d* and *e*. The *exo*-5- and *exo*-6-hydrogens(deuteriums) are identical sterically at least in the ground state. Confidence in observing a large effect was minimal, since the torsional energy of the major interactions arising from the eclipsed hydrogens in the partial butane structure, including C-1, -6, -5, and, -4 in the [2.2.1.] system, would probably not be affected by deuterium as shown by Weiss and LeRoi from a study of deuterioethanes (5). Furthermore, Jewett and Dunlap (6) have shown that the effect for nine deuteriums in the solvolysis of the non-rigid system nonadeuteriodimethylneopentylcarbinyl chloride is inverse and small (0.983). Although hyperconjugative stabilization of the norbornonium ion **3** via the C-5 hydrogens would not be expected to be important in that C-6 is essentially sp^3 hybridized (7) and bears little positive charge (8), the study would serve to confirm this premise.

To calibrate our technique *exo*-norbornyl brosylate-6-*endo*-*d* was prepared and k_H/k_D was obtained. The value of 1.11 ± 0.01 corresponds exactly to that reported by Murr *et al.* (2*c*).

Results

The 5-deuteriated brosylates were prepared via a sequence of reactions outlined in Scheme 1. The keto-acetate **4** was converted to the previously unknown 5-deuteriated-*exo*-2-norborneols by a reduction–brosylation–reduction sequence which involved the reducing agents $NaBH_4$–$LiAlD_4$ for **2***a*, $NaBD_4$–$LiAlH_4$ for **2***b*, and $NaBD_4$–$LiAlD_4$ for **2***c*. The i.r. fingerprint regions and the partial n.m.r. spectra of *exo*-norborneol, **2***a* and *b* which were isolated by preparative g.l.c. and are at least 98–99% *exo*, 1–2% *endo*, are included in Figs. 1 and 2, respectively. The d.m.r. spectroscopy of **2***a* and *b* showed the *exo*-5- and *endo*-5-deuteriums as

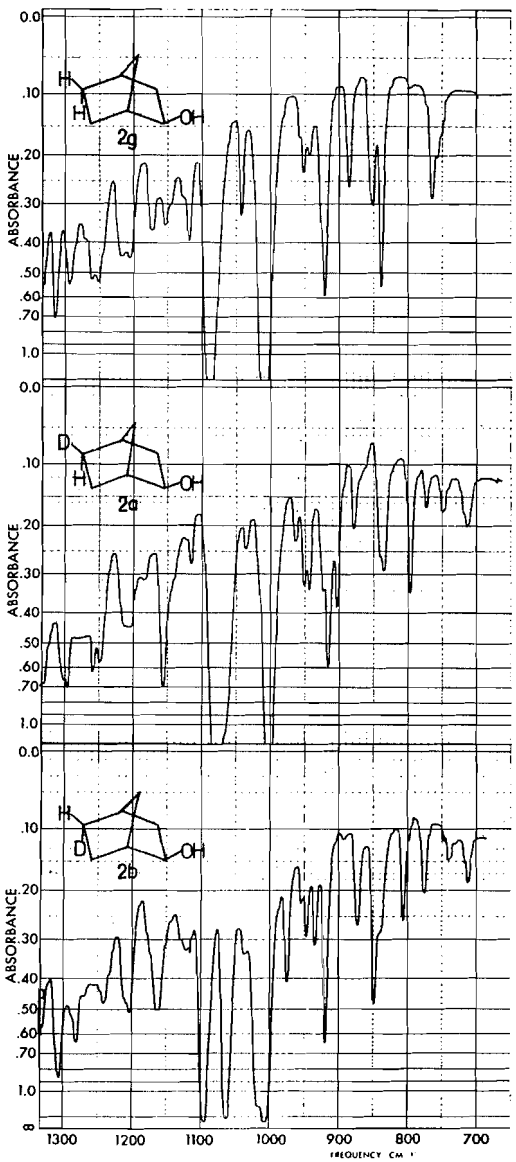

FIG. 1. The i.r. (CS_2) fingerprint regions of *exo*-norborneol (**2***g*), *exo*-norborneol-5-*exo*-*d* (**2***a*), and *exo*-norborneol-5-*endo*-*d* (**2***b*).

broad singlets at 141 and 148 Hz respectively, upfield from $CDCl_3$ in accord with the relative chemical shifts of the *exo*- and *endo*-hydrogens in norbornyl systems (9*a* and *b*). The spectra showed that **2***a* and *b* were composed of at least 95% of only one specifically deuteriated species and that the deuterium was at least 85–95% stereochemically pure in each case.

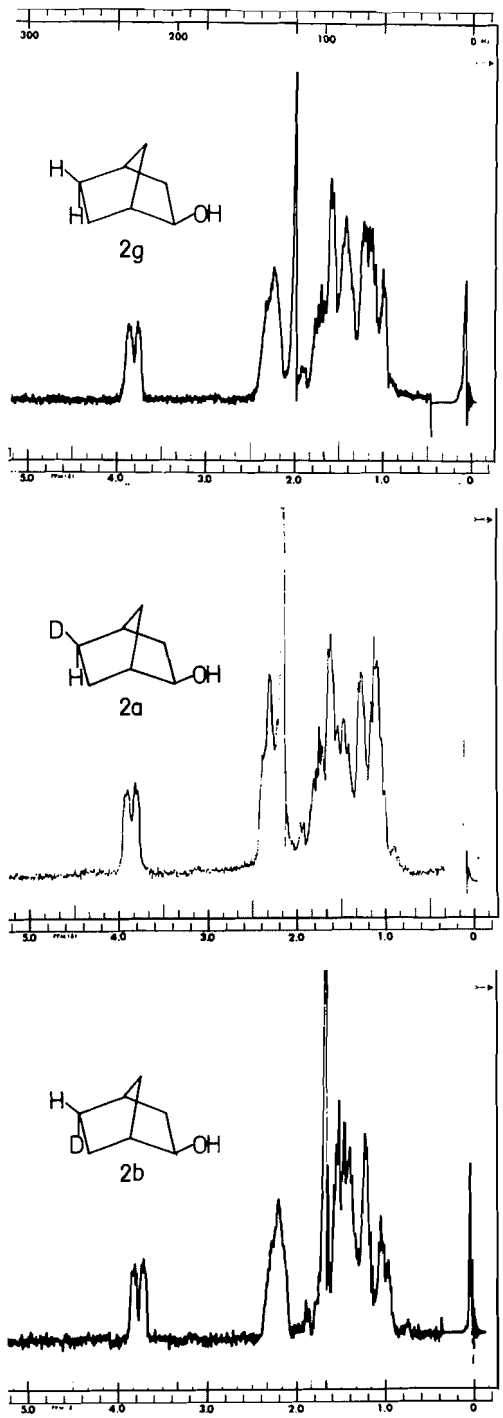

FIG. 2. The 60 MHz n.m.r. spectra ($CDCl_3$) of *exo*-norborneol (**2***g*), *exo*-norborneol-5-*exo*-*d* (**2***a*), and *exo*-norborneol-5-*endo*-*d* (**2***b*).

TABLE 1. Solvolysis of norbornyl brosylates in HOAc–KOAc at 29.40 ± 0.02°

	Substrate **1**				
Run no.	*g*	*a*	*b*	*c*	*e*
1	0.98±0.01*	0.99±0.01	1.01±0.01	1.00±0.01	1.11±0.01†
2	1.00±0.01	1.00±0.01	1.01±0.01	0.98±0.01	1.11±0.01
3	0.99±0.01	0.99±0.01	1.01±0.01	0.99±0.01	
4	1.00±0.01	1.01±0.01		0.99±0.01	
Mean	0.99±0.01	1.00±0.01	1.01±0.01	0.99±0.01	1.11±0.01

*Errors expressed as the standard deviation of the points from the least squares slope. For example, the data from the computer for run 3 of **1***a* was: slope for **1***g* $10.473 \times 10^{-3} \pm 8.339 \times 10^{-5}$, and for **1***a* $10.602 \times 10^{-3} \pm 6.148 \times 10^{-5}$.

†81.2% d_1 and 8.8% d_0 species; k_H/k_D (+0.02) corrected for incomplete deuteration.

The preparation of **1***e*, required for the calibration work, began with the opening of the cyclopropane ring in 3-nortricyclyl bromide with D_2SO_4–DOAc[5] to yield as the major products the *anti*-7-bromo-*exo*-2-norbornyl-6-*endo*-*d*- (49%) and *syn*-7-bromo-*exo*-2-norbornyl-6-*endo*-*d*-acetates (26%). The deuterium was shown to be at least 95% stereochemically pure *endo* in the two major products by reducing each to the *exo*-norborneol-*d* and comparing its i.r. fingerprint region to that of an authentic sample of **1***e*.[6] The minor products of the reaction were 5-*exo*-bromo-*exo*-2-norbornyl-deuterio-acetate (10%) in which 10% of the deuterium was in the *endo*-2-position and at least 70–90% at C-6, 5-*endo*-bromo-*exo*-2-norbornyl-deuterio-acetate (8%) of which 6% of the deuterium was in the *endo*-2-position and at least 70–80% at C-6, as well as 2–3% of unidentified material. Compound **2***e* used to prepare **1***e* was obtained by reduction of the mixture of deuteriobromoacetates with $LiAlH_4$ to give *exo*-norborneol-6-*endo*-*d* which contained 2–2.5% *exo*-norborneol-2-*endo*-*d*. That the *exo*-norborneol-6-*d* was at least 85–95% stereochemically pure *endo* was supported by comparison of its i.r. fingerprint region to that of authentic sample.[6]

The deuterio-*exo*-norborneols **2***a*, *b*, *c*, *e*, were isolated by preparative g.l.c. and analyzed on a 200 ft × 0.01 in. UCON HB capillary column, and were at least 98–99% *exo* and 1–2% *endo*. Treatment of the deuterionorborneols with brosyl chloride in pyridine gave the brosylates which were recrystallized 1–2 times prior to use in the kinetic studies, and once prior to each successive run. The k_H/k_D values listed in Table 1 were obtained from the solvolysis of **1***a*, *b*, *c*, and *e* simultaneously with **1***g* in the thermostatted compartment of a Carey Model 14 U.V. spectrophotometer.

Importantly, the results for **1***a*, *b*, and *c* show that 1–2% of *endo*-norborneol initially present in the deuterio-*exo*-norborneols had no effect on the rate data, since there is no significant change in k_H/k_D through the runs 1–4 as the brosylate was recrystallized prior to each run. That this would be expected is seen from an analysis of the contribution of up to 2% of deuterio-*endo*-brosylate to the absorbance change during a kinetic run. The half-life of **1***g* is *ca.* 1 h. Since runs were typically carried on for 13–14 h or to 99.99% completion, and $k_{exo} = 300k_{endo}$, then (13/300)(0.5)(0.02) of the *endo*-brosylate solvolyzes in 13–14 h. Since $A_t - A_\infty$ in the kinetic runs was typically *ca.* 0.7, (0.04)(0.5)(0.02)(0.7) or 0.0003 of an absorbance unit change would result from 2% *endo*-brosylate. This is insignificant in that the estimated error for determination of A for any one point is ±0.002–0.003. A typical plot, *i.e.* run 3 for **1***c*, given in Fig. 3, indicates the quality of the results.

Discussion and Conclusions

The possible contributions to the δ-deuterium isotope effect in **1***a*, *b*, and *c* and the expected effects of each on k_H/k_D are listed in Table 2.

That a steric effect of deuterium does not make a significant contribution >1 to the δ-k_H/k_D is established by the values of 1.00 ± 0.01, 1.01 ±

[5]Presented in part at the 54th Annual Meeting of the Chemical Institute of Canada, Halifax, Nova Scotia, June, 1971.

[6]We thank Professor A. Nickon for the i.r. spectrum of *exo*-norborneol-6-*endo*-*d*.

TABLE 2. Possible contributions to δ deuterium isotope effect

Entry	Contribution by	Expected effect on k_H/k_D
1	Steric effect	(*a*) < 1 if steric requirement of D > H (*b*) > 1 if steric requirement of D < H
2	Hyperconjugation	(*a*) > 1
3	H shift followed by internal return to 3*a*, *b*, or *c*	(*a*) > 1

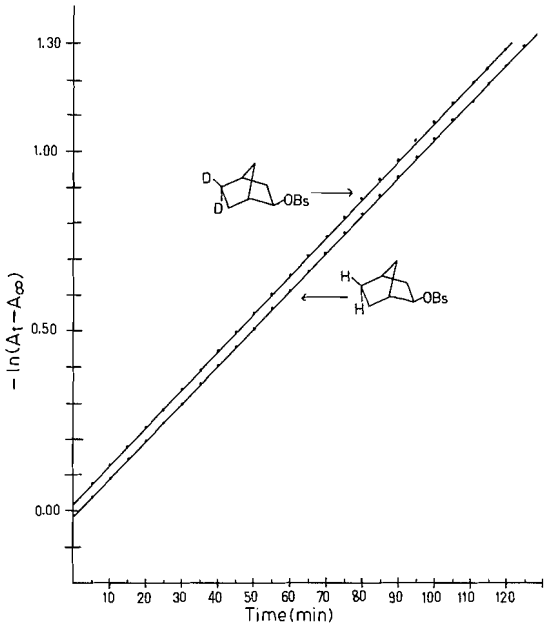

FIG. 3. First order plots for solvolysis of *exo*-norbornyl brosylate (**1***a*) and *exo*-2-norbornyl brosylate-*exo*-5-*endo*-5-d_2 (**1***d*).

0.01, and 0.99 ± 0.01, observed for **1***a*, *b*, and *c*, respectively, since the other effects (entries 2 and 3) must total > 1. Since the *exo*-5- and *exo*-6-hydrogens(deuteriums) are in the same environment sterically, with respect to the *exo*-5, *exo*-6, and-*syn*-7-interactions, at least in the ground state, the data therefore strongly suggest that there is no significant steric isotope effect contribution > 1 to the γ-k_H/k_D of 1.10 observed for **1***d* and *e* by Murr *et al.* (2*c*). The results do not give information about steric isotope effects which might result from differential interactions between *exo*- and *endo*-6-D and C-1-H and *endo*-2-H in the *exo*-brosylate. However, the effects would be expected to be small, since the γ-isotope effects for *exo*-brosylate-6-*endo*-*d* and *exo*-brosylate-6-*exo*-*d* are equal (1.10) within experimental error (2*c*).

These data provide the first experimental evidence that the hydrogen shift – internal return pathway (hs–irp) (Scheme 2) does not contribute significantly, by formation of **14***d* and **15***d*, to the k_H/k_D of 1.10 for **8***d* observed by Murr *et al.* (2*c*). This conclusion is warranted when Scheme 2 and Table 1 are considered. Attention is directed to **8***c*, since **8***a* yields equal quantities of **14***a* (k_H/k_D 1.07) and **13***a* (k_H/k_D 1.02) through **10** and **11** via equally likely 6,1- and 6,2-hydrogen(deuterium) shifts, thereby lowering the magnitude of the contribution of the hs–irp to k_H/k_D for **8***a*. Since k_H/k_D for solvolysis of **14***c* in HOAc–KOAc is 1.07 (2*i*) and the method used detects isotope effects of 1%, the results for **8***c* show that a maximum of 2 × 1/7 or 25–30% of the hs–irp may operate. The factor of 2 is included on the assumption that internal return to C-2 and -6 in **10** and **11** is equally likely to yield **12** and **15**, as well as **13** and **14**.

Since the k_H/k_D for *exo*-norbornyl brosylate-*endo*-2-*d*, **14***d* in HOAc-KOAc is 1.12 (2*h*), its contributions to k_H/k_D of 1.10 for **8***d* (2*i*), via the hs–irp would be (0.25)(0.30)(0.12) or 0.01. Furthermore, since k_H/k_D for *exo*-norbornyl brosylate-1-*d* should be a maximum of 1.12 (*c.f.* 2*c*), the hs–irp contributions a maximum of 0.02, via **14***d* and **15***d*, to the k_H/k_D of 1.10 observed for **1***d*.

The data also show that the C-5 hydrogens are not involved in the stabilization of **3** via hyperconjugation. This removes the possibility that loss of hyperconjugative stabilization contributes significantly to the rate retardation observed by Greever and Gwynn (10) in the solvolysis of *exo*-norbornyl-5-keto-brosylate. This

SCHEME 2

work also provides a general route to the previously unknown 5-deuterionorbornyl systems.

Experimental

General

Melting points were taken on a Kofler hot-stage melting point apparatus and are uncorrected. The i.r. spectra were recorded on Perkin–Elmer Model 337 and 521 spectrometers. The n.m.r. spectra were taken on Varian A-60 and HA-100 spectrometers in CCl_4 or $CDCl_3$ with tetramethylsilane as the internal standard. Pentane was stirred over fuming H_2SO_4, washed with bicarbonate solution and distilled. Preparative gas chromatographic isolations were done on a Varian-Areograph 90-P-3 instrument with 5 ft × 1/4 in., 20% Carbowax and 10 ft × 3/8 in., 15% Carbowax on Chromosorb W columns with He as the carrier. Analytical chromatograms were obtained on Varian-Areograph Model 204 and 1200 chromatographs on 10 ft × 1/8 in., 10% Carbowax, and 10% SE-30, on Chromosorb W and 200 ft × 0.01 in. UCON HB capillary columns with He as the carrier. All solutions were dried over anhydrous Na_2SO_4 and $MgSO_4$. Kinetic runs were carried out on a Carey Model 14 u.v. spectrophotometer. A Haake Model NBe constant temperature bath was used to thermostat the cell compartment to within ±0.02°.

Nortricyclyl Formate

Nortricyclyl formate (270 g, b.p. 64° (10 mm)) was prepared from 325 g of norbornadiene according to the procedure of Schmerling *et al.* (11). The g.l.c. analysis on a 10 ft × 1/3 in. 10% SE-30 on Chromosorb W column showed the mixture to be composed of 85–90% nortricyclyl formate and two other components (10–15%) of shorter retention time.

Nortricyclanol

Base-catalyzed hydrolysis of the formate mixture (260 g) was carried out as described by Schmerling *et al.* (11) to yield 180 g of nortricyclanol m.p. 106–107° (lit. m.p. 108–109° (12)) after two recrystallizations from pentane. The g.l.c. on a 10 ft × 1/3 in., 10% Carbowax on Chromosorb W column showed the nortricyclanol to be 90% pure with one component (10%) of shorter retention time.

Nortricyclanone

Nortricyclanone (46 g, b.p. 113° (88 mm)) 90% pure, was prepared from (72.0 g, 90% purity) nortricyclanol by chromic acid oxidation according to the procedure of Meinwald *et al.* (13).

exo-5-Acetoxynorboran-2-one (4)

Compound **4** (48.0 g, 90% purity by g.l.c.) was prepared from nortricyclanone (46 g, 90% purity) with acetic acid–perchloric acid according to the procedure of Meinwald

et al. (14). The n.m.r. (CCl_4); δ 4.74 (1H, doublet of doublets, $J = 7$ and 3 Hz, *endo*-5-C-H), 2.72 (1H, broad multiplet, bridgehead—C—H), 2.50 (1H, doublet, bridgehead—C—H), 2.0 (3H, singlet, CH_3COO—), and the norbornyl envelope ranging from 2.2–1.4.

endo-5-Hydroxy-exo-2-norbornyl Acetate (5a)

The ketoacetate **4** (7.2 g, 90% purity) was dissolved in absolute ethanol (50 ml). $NaBH_4$ (0.68 g) was added portion-wise to the solution over 2–3 min. The mixture was heated on the steam bath for 3–5 min then poured onto ice. The solution was saturated with NaCl and extracted with ether (1 × 100, 3 × 50 ml). Evaporation of the ether gave 6.7 g of the hydroxyacetate **5***a* (95% pure) a mixture of *ca.* 90% of the *endo* and 10% *exo* stereoisomers respectively, as was shown by gas chromatography on a 10 ft × 1/3 in. 10% SE-30 on Chromosorb W at 150°. Vacuum distillation of the mixture at 0.3 mm gave fraction 1, b.p. 106–108°, 0.8 g; fraction 2, b.p. 108–110°, 4.3 g; fraction 3, b.p. 108–110°, 0.5 g. Gas chromatography showed a new peak (10–15%) of lower retention time than the hydroxy acetates. Apparently some decomposition occurred during distillation even at 110°. This material was used for the next step without further purification. The n.m.r. (CCl_4); δ 4.60 (1H, doublet with fine structure, $J = 7$ Hz, *endo*-5-C-H), 4.08 (1H, quarter, $J = 8$, 5,4 Hz, *exo*-2-C—H), 3.00 (1H, singlet, —O—H), 1.95 (3H, singlet, CH_3—COO—), and the norbornyl envelope ranging from 2.6–1.4.

endo-5-Hydroxy-exo-5-deuterio-exo-2-norbornyl Acetate (5b)

The ketoacetate **4** (15.0 g, 90% purity) was dissolved in absolute ethanol (55 ml) and the solution was cooled in ice. To the chilled solution was added $NaBD_4$ (1.0 g, 95–98% isotopically pure) in small portions. The mixture was heated on the steam bath for 1 min and the mixture was cooled in ice. An aliquot worked-up and analyzed by g.l.c. showed unreacted ketoacetate. An additional portion of $NaBD_4$ (0.95 g) was added and the solution was heated on the steam bath 2–3 min. The hot solution was poured onto crushed ice (400 g) and extracted with ether (4 × 100, 4 × 50 ml). The ethereal layer was washed with water (1 × 100 ml) and the water layer was extracted with ether (5 × 25 ml). Evaporation of the solvent gave 16.6 g of an oil. Vacuum distillation gave 9.5 g of the deuteriohydroxyacetate **5***b* of 95% purity as was shown by g.l.c. analysis on 10 ft × 1/3 in. 10% SE-30 on Chromosorb W column at 150°. The g.l.c. showed that the ratio of *endo*:*exo*-OH at C-2 was 9:1. The n.m.r. (CCl_4); δ 4.60 (1H, doublet with fine structure, $J = 7$ Hz, *endo*-5-C—H), 3.60 (singlet, —O—H), 1.98 (3H, singlet CH_3—COO—), and the norbornyl envelope ranging from 2.6–1.7. The multiplet which corresponded to the *exo*-2-C—H in **5***a* was absent.

exo-5-Acetoxy-endo-2-norbornyl Brosylate (6a)

The hydroxyacetate **5***a* (3.0 g, 90–95% pure) and brosyl chloride (4.5 g) were dissolved in pyridine. After 10 days in the refrigerator the mixture was poured into ice-water (250 ml) and extracted with ether (150 ml). The ether layer was washed with water (5 × 50 ml) and dilute aqueous HCl (100 ml). Evaporation of the solvent gave an oil which crystallized when washed with pentane–ether. Recrystallization from pentane–ether gave 4.0 g of the brosylate acetate **6***a*, m.p. 78–81°. Repeated recrystallization from pentane–ether gave 1.0 g of the brosylate acetate, m.p. 78–81°. An analytical sample m.p. 80–81.5° was obtained by two additional recrystallizations from ether–pentane.

Anal. Calcd. for $C_{15}H_{17}O_5BrS$: C, 46.27%; H, 4.37%. Found: C, 46.37%; H, 4.37%.

The n.m.r. ($CDCl_3$); δ 7.75 (4H, singlet, aromatic C—H), 4.75 (2H, multiplet, BsO—C—H and AcO—C—H overlapping), 2.00 (3H, singlet, CH_3COO—), norbornyl envelope centered at 1.6.

exo-5-Acetoxy-exo-2-deuterio-endo-2-norbornyl Brosylate (6b)

The deuteriohydroxyacetate **5***b* (0.34 g, 95% purity) and freshly recrystallized brosyl chloride (0.51 g) were dissolved in pyridine (4 ml). After 13 days several ice crystals were added to the pyridine solution. The mixture was kept at room temperature for 10 min and poured into ice-water and extracted with an ether–pentane mixture (2 × 25 ml). The ethereal layer was washed with ice-water (4 × 50 ml), dried, and evaporated to yield a viscous oil which crystallized when placed under vacuum. The solid (0.68 g) was recrystallized twice from ether–pentane to give 0.39 g of the deuteriobrosylate acetate, m.p. 79–81°. A third recrystallization gave 0.18 g, m.p. 79–81°. The n.m.r. ($CDCl_3$); δ 7.72 (4H, singlet, aromatic C—H), 4.70 (1H, doublet with fine structure; $J = 8$ Hz, AcO—C—H), 2.00 (3H, singlet, CH_3COO—), and norbornyl envelope centered at 1.6. The *exo*-2-H in the spectrum of **6***a* which contributed to the multiplet centered at 2.75 was absent.

Interestingly, when deuteriobrosylate acetate, which was prepared in a previous experiment and which had remained in the refrigerator for 8 months was recrystallized, a m.p. of 92–93° was observed. The n.m.r. of this material was identical in overall appearance to the deuteriobrosylate which had an m.p. 78–81° except for an increase in sharpness of the absorption in the norbornyl envelope. Possibly the small amount of *exo*-brosylate, a contaminant, had slowly decomposed over the 8 month period.

$LiAlH_4$ Reduction of the Deuteriobrosylate Acetate (6b)

The deuteriobrosylate acetate (0.18 g, m.p. 92–93°) was dissolved in dry ether (25 ml) and added to a slurry of $LiAlH_4$ (0.85 g) in dry ether (50 ml). The solution was refluxed for 14 days. Water (0.9 ml), 15% NaOH (0.9 ml), water (2 ml), and ether (20 ml) were then added consecutively to the vigorously stirred solution. The granular salts were filtered off and washed with ether. The g.l.c. analysis on a 10 ft × 1/3 in., 10% Carbowax on Chromosorb W column showed that the mixture was 90–95% *exo*-norborneol, by comparison with a standard sample. The solution was concentrated to 2 ml by distillation through a 1.5 ft glass helices-packed column and the norborneol-*d* (**2***a*) (0.025 g) was isolated by preparative gas chromatography on a 5 ft, 15% Carbowax on Chromosorb W column at 140°. The norborneol-*d* was at least 99% pure and at least 98–99% *exo* as determined by g.l.c. The n.m.r. (CCl_4); δ 3.63 (1H, doublet with fine structure; $J = 8$ Hz, HO—C—H), 2.80 (1H, singlet, —O—H), 2.14 (2H, broad multiplet, bridgehead C—H's) and norbornyl envelope centered at 1.35 (7.2 H). The d.m.r. ($CDCl_3$) spectrum showed a broad absorption at 148 Hz upfield from $CDCl_3$ and indicated that the alcohol was composed of at least 85–95% of only one specifically deuteriated species.

$LiAlD_4$ Reduction of Deuteriobrosylate Acetate (6b)

The deuteriobrosylate acetate (**6b**) (0.28g, m.p. 78–82°) was dissolved in dry ether (50 ml). $LiAlD_4$ (0.9 g) was added and the mixture was stirred and refluxed for 14 days. Work-up with water (1.0 ml), 15% aqueous NaOH (1.0 ml), and water (2 ml) gave an ether solution which was concentrated to 2 ml. The dideuterionorborneol **2c** (0.027g) was isolated by preparative g.l.c. and was shown to be at least 98–99% pure and at least 98–99% *exo* by analytical g.l.c.

Chromic Acid Oxidation of exo-2-Norborneol-5,5-d_2

The dideuterionorborneol **2c** (0.003 g) was dissolved in preoxidized ether (3 ml) and Brown's reagent was added (0.01 ml). The mixture was stirred at room temperature for 24 h. An additional 0.005 ml of oxidizing reagent was added and the mixture was stirred for 2 h. Water (1 ml) was added and the ether layer was withdrawn and dried. The solution was concentrated to 1 ml and the dideuterionorcamphor was isolated by preparative g.l.c. on a 5 ft × 1/4 in., 20% Carbowax on Chromosorb W column at 120°. Mass spectral analysis showed the ketone to be a composite of 91.6% d_2, 6.4% d_1, and 2.0% d_0 species.

$LiAlD_4$ Reduction of exo-2-Acetoxy-endo-5-norbornyl Brosylate (6a)

The brosylate acetate **6a** (1.0 g, m.p. 79–81°) was dissolved in dry ether (50 ml) and $LiAlD_4$ (1.6 g) was added. The mixture was refluxed for 14 days and worked-up as described previously. Preparative g.l.c. gave *exo*-2-norborneol-*exo*-5-*d* (**2a**) (0.14 g) at least 98–99% pure and 98–99% *exo* as determined by analytical g.l.c. Approximately 1–2% of *endo*-norborneol was present. The n.m.r. ($CDCl_3$); δ 3.75 (1H, doublet with fine structure; $J = 8$ Hz, >CH—O—), 2.20 (2H, broad multiplet, bridgehead C—H's), 2.08 (1H, singlet, —O—H), and the norbornyl envelope centered at 1.3 (7.1 H). The d.m.r. ($CDCl_3$) spectrum showed a broad absorption 141 Hz upfield from $CDCl_3$ and indicated that the compound was composed of at least 95% of one specifically deuteriated species. Chromic acid oxidation as described previously gave deuterionorcamphor which was 99% d_1 and 1.0% d_0 as determined mass spectrometrically.

D_2SO_4–DOAc Opening of 3-Bromonortricyclene

3-Bromonortricyclene (2.1 g), CH_3CO_2D (30 ml, prepared from freshly distilled acetic anhydride and D_2O, 95–98% d_1) and D_2SO_4 (0.28 g) were mixed and stirred magnetically at 70° for 50 h. The mixture was added to a saturated $NaHCO_3$ solution to neutralize the acid and extracted with ether (3 × 25 ml) to give a mixture of deuteriobromonorbornyl acetates after the solution was dried and evaporated. The g.l.c. analysis showed two major components to be present. The first compound isolated by preparative gas chromatography from a previous non-deuteriated run was a bromonorbornyl acetate as deduced from consideration of spectral data (n.m.r. and i.r.). Reduction to the bromohydrin and oxidation gave a ketone which yielded a 2,4-dinitrophenylhydrazone m.p. 116–118° (lit. 116.5–117.5° and 151.5–152.5° (15) for the 2,4-DNP of *anti*-7-bromonorcamphor) identified the major product as *anti*-7-bromo-*exo*-2-norbornyl acetate (47%). When the total bromoacetate mixture was reduced with $LiAlH_4$ in ether and the reaction was closely monitored, the *syn*-7-bromo-*exo*-2-norborneol (35%) was isolated and identified by preparation of the corresponding 2,4-DNP of the *syn*-7-bromonorcamphor, m.p. 202.5–203.5° (lit. 201.5–202.5° (16)). Preliminary experiments[5] have also shown that there are at least three other components (15–20% total).

$LiAlH_4$ Reduction of the Deuteriobromonorbornyl Acetate Mixture

The deuteriobromoacetate mixture (1.1 g) prepared previously was dissolved in ether and added dropwise to a slurry of $LiAlH_4$ (1.1 g) in ether (60 ml). The mixture was stirred and refluxed for 24 h. Additional quantities of $LiAlH_4$ (1 g and 1 g) were added consecutively after 12 h intervals. Six hours after the last portion was added, 1/4 of the mixture was worked-up by the addition of H_2O (1.5 ml), 10% NaOH (2 ml), water (2 ml), and ether (50 ml). The *exo*-norborneol-*d* (0.030 g) was isolated from ether extract by preparative g.l.c. The i.r.; ν_{max} (CS_2) 952 w, 920 w, 880 w, 865 m, 840 m, 805 w, 775 w, 785 w, 710 w was identical to the spectrum of *exo*-2-norborneol-*endo*-6-*d*, 90–95% stereochemically pure *endo*, prepared by Nickon *et al.* (17). The remainder of the reaction mixture was worked-up after 2 days to give additional deuterio-*exo*-norborneol-*d* (0.091 g).

Chromic acid oxidation of the norborneol-*d* (0.0036 g) with Brown's reagent in preoxidized ether as described previously gave norcamphor-*d* which was isolated by preparative g.l.c. Mass spectroscopic analysis showed the mixture to be a composite of 1.0% d_2, 80.6% d_1, and 18.4% d_0 species.

Chromic acid oxidation of the *exo*-2-norborneol-*endo*-6-*d* (0.015 g) gave norcamphor-*endo*-6-*d*. The i.r.; ν_{max} (CS_2), 1065 m, 1028 w, 966 w, 940 m, 870 m, 775 m was essentially identical to that of *endo*-6-*d*-norcamphor (90–95% stereochemically pure) prepared by Nickon *et al.* (17) except for minor changes in weak bands at 900, 850, and 760. The norcamphor-*endo*-6-*d* is estimated to be at least 85–95% stereochemically pure *endo*.

exo-Norborneol

exo-Norborneol (>99% stereochemically pure) was prepared from norbornene and formic acid according to the procedure of Kleinfelter and Schleyer (18).

exo-2-Norbornyl Brosylate

exo-Norborneol (0.11 g) and brosyl chloride (0.27 g) were dissolved in pyridine and kept in the refrigerator for 7 days. A crystal of ice was added to the pyridine solution and after 10 min at room temperature the mixture was poured into ice-water and extracted with purified pentane (100 ml). The pentane layer was washed with ice-water (2 × 50 ml), dried, and the solvent was removed on the rotatory evaporator. The oily residue crystallized when placed under vacuum. Two recrystallizations from pentane gave *exo*-norbornyl brosylate m.p. 55.5–57.0° (lit. 55.5–56.5° (19)).

exo-Norbornyl Brosylate-endo-5-d

exo-2-Norborneol-*endo*-5-*d* (0.021 g) and brosyl chloride (0.048 g) gave *exo*-2-norbornyl brosylate-*endo*-5-*d*, m.p. 56.0–57.5°, after two recrystallizations from pentane as described previously. The n.m.r. ($CDCl_3$); δ 7.70 (4H, multiplet, aromatic C—H), 4.49 (1H, triplet; $J = 8,5$, Hz, H—C—OBs), 2.33 (2H, broad multiplet, bridgehead C—H's), norbornyl envelope centered at 1.3 (*ca.* 7.4 H). Comparison of the spectrum to that of norbornyl brosylate showed major simplification in the spectrum in the δ 1.3–0.8 region, what would be expected when an *endo*-H is replaced by deuterium.

exo-Norbornyl Brosylate-exo-5-d

Dideuterionorborneol **2***c* (0.023 g) and brosyl chloride (0.52 g) were converted to the brosylate, m.p. 55.5–57.0°, after two recrystallizations as described previously. The n.m.r. ($CDCl_3$); δ 7.74 (4H, multiplet, aromatic C—H's), 4.50 (1H, triplet with fine structure, $J = 8{,}3$ Hz, H—C—OBs), 2.35 (2H, multiplet, bridgehead C—H's), 1.70–0.9 (7H, norbornyl envelope centered at 1.3).

Kinetic Procedure

Kinetic runs were carried out spectrophotometrically using a Carey Model 14 u.v. spectrophotometer. The runs were carried out in freshly distilled glacial acetic acid which was 0.04 *M* in KOAc (anhydrous). The nondeuteriated and deuteriated brosylates were run simultaneously in the sample compartment of the spectrophotometer which was thermostatted with a Haake Model NBe constant temperature bath maintained at 29.40 ± 0.02°. The brosylates, recrystallized from pentane prior to run, were weighed (*ca.* 0.002–0.003 g) into 2 ml volumetric flasks and placed in the constant temperature bath for *ca.* 10 min. The acetic acid solution (2 ml) which was equilibrated in the bath for at least 12 h was added with a pipette insulated with several layers of kimwipes. The insulated pipette had previously been equilibrated in the cell compartment, along with the two 1 cm u.v. cells, for at least 12 h. The brosylates were dissolved, and the 2 ml volumetrics were placed back into the constant temperature bath for *ca.* 10 min. The solvolysis solutions were transferred, with thermostatted pipettes, to the equilibrated cells in the cell compartment. After 20 min the spectrum was scanned in the region of 270 nm to obtain a maximum absorbance. The slit controls were then shut off to avoid fluctuations of the slit opening. Absorbance readings were obtained at the position of the maximum (around 270 nm) at 5, 10, and 20 min intervals, by running the pen and chart paper from 10 s before to 10 s after the minute. The absorbance readings for at least three half-lives were obtained by taking the reading at the mid-point of this line and averaging out the pen fluctuations. The zero, checked on the instrument after the infinity reading was taken (12–14 h), varied less than ±0.003 of an absorbance unit from the original zero. The data, $-\ln(A_t - A_\infty)$ and t in min, were analyzed on IBM 1604 and CDC 6400 computers for slopes and standard deviations in the slopes by a least squares program.

A typical first order plot for the solvolysis of *exo*-norbornyl and *exo*-2-norbornyl brosylate-*exo*-5-*endo*-5-d_2 is given in Fig. 3.

Control experiments with nondeuteriated norbornyl brosylate in both cells showed that a ratio of the slopes of 0.99 ± 0.01 to 1.00 ± 0.01 were routinely obtainable (see Table 2).

The Infrared and Raman Spectra of 3-Chloro-1,2,5-thiadiazole

A. W. RICHARDSON
Bishop's University, Lennoxville, Quebec
Received July 12, 1971

The i.r. and Raman spectra of 3-chloro-1,2,5-thiadiazole have been recorded. Assignments have been made for all 15 fundamental vibrations on the basis of these observations plus some data from the vapor-phase u.v. absorption spectrum.

Les spectres i.r. et Raman du chloro-3 thiadiazole-1,2,5 ont été enregistrés. L'attribution des 15 vibrations fondamentales a été faite en se fondant sur ces observations et sur quelques données obtenues à partir des spectres u.v. d'absorption en phase vapeur.

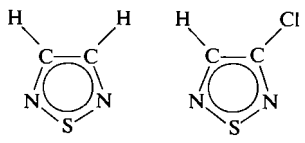
Introduction

We are currently studying the electronic absorption spectra of 1,2,5-thiadiazole (**1**) and some of its 3-mono- and 3,4-di-substituted derivatives. In particular, 3-chloro-1,2,5-thiadiazole (**2**) is under investigation. Since a knowledge of the ground state vibrational frequencies and descriptions of the normal modes of vibration are needed for complete interpretation of an electronic absorption spectrum, the i.r. and Raman spectra of **2** have been recorded and the analysis of these spectra is presented here.



1 **2**

Experimental

Compound **2** was prepared by the reaction of α-aminoacetonitrile bisulfate with sulfur monochloride in dimethylformamide (1). The product was purified by g.l.c. using a 20 ft × 3/8 in. column of 30% SE30 on 45/60 Chrom W with a Varian Aerograph autoprep 700 gas chromatograph. Analytical g.l.c. on polar and non-polar columns showed the sample purity to be in excess of 99%.

The i.r. spectra were recorded on a Perkin–Elmer model 621 i.r. spectrophotometer. Spectra of the gas were recorded with the sample at its vapor pressure around room temperature in a 10 cm cell with KBr or CsI windows while those of the liquid were recorded for a capillary film between KBr plates or sheets of polyethylene. The Raman spectrum of the liquid sealed in a melting point tube was excited by an argon ion laser and measured on a Spex double monochromator with a rotatable analyzer to measure depolarization ratios ρ.

Results and Discussion

The i.r. spectra of **2** in the gas and liquid phases are shown in Figs. 1 and 2,[1] respectively, and the Raman spectrum of the liquid is shown in Fig. 3.[1] The frequencies of all observed bands together with other information such as estimated relative intensities, band types, depolarization ratios, etc. are presented in Table 1. The accuracy of the measured frequencies is estimated to be ± 2 cm^{-1} except for weak bands where it is, of course, not as good.

Compound **2** is assumed to be planar like **1** (2) and thus belongs to the C_s point group and has $11A'$ and $4A''$ normal modes of vibration (3). The assignments of the normal modes were made using the following guides.

(i) Band Contours

In the vapor, the $11A'$ modes will have type A, B, or AB-hybrid band contours whereas the $4A''$ modes will have type C band contours. To facilitate making assignments, type A, B, and C band contours were calculated for **2** in the rigid asymmetric rotor approximation (4) using a computer program written by Pierce. The calculated contours are shown in Fig. 4 and were obtained using the rotational constants $A = 0.25903$, $B = 0.05418$, and $C = 0.04481$ cm^{-1} for both the lower and upper states. These rotational constants were calculated by assuming the structure of **2** to be exactly the same as **1** (2) and r(C—Cl) = 1.70 Å (5). Band contours calculated for rotational constants differ-

[1]Photocopies of Figs. 2 and 3 are available from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

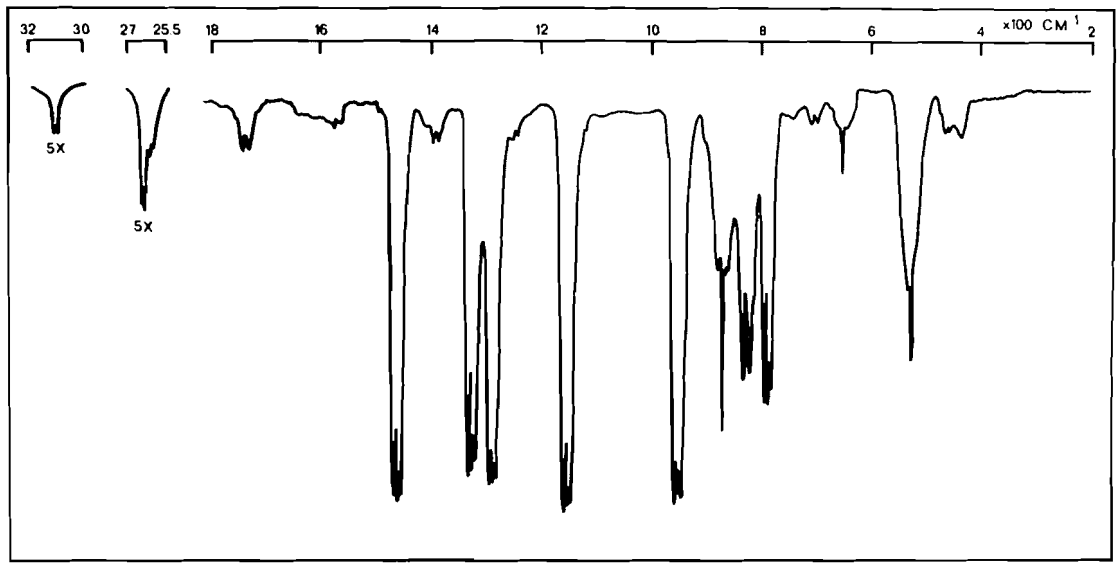


FIG. 1. The i.r. spectrum of 3-chloro-1,2,5-thiadiazole in the gas phase. The bands at the left of the diagram were recorded using an ordinate expansion of five.

ing somewhat from those above were found to differ very little from those in Fig. 4.

(ii) Depolarization Ratios

From theory, the $11A'$ modes will be polarized ($\rho < 0.75$) and the $4A''$ modes depolarized ($\rho = 0.75$) in the laser Raman spectrum. ρ values calculated from the observed spectra may differ somewhat from the theoretical values due to the experimental errors in measuring intensities.

(iii) Assignments for 1,2,5-Thiadiazole

The i.r. and Raman spectra of **1** have been studied and assignments made for all 15 fundamental vibrational frequencies and approximate descriptions of the normal modes given (6, 7). Several assignments for **2** follow directly from those made for **1**.

(iv) Assignments for the X-Sensitive Fundamental Vibrations of Chlorobenzene

Since **1** has been shown to have aromatic character (2, 8), it is reasonable to expect that the effect on the vibrational frequencies of replacing H by Cl might be similar to that in benzene. Therefore, the X-sensitive fundamentals of chlorobenzene (9, 10) were used as a guide to some low frequency assignments of **2**.

A″ Vibrations

These are discussed first since there are only four vibrations in this class. From the observed strong type C band contours, it is clear that the bands at 868, 647, and 518 cm^{-1} are due to A'' modes. The 868 cm^{-1} band is clearly the C—H out-of-plane mode since the average of the symmetric and antisymmetric C—H out-of-plane modes for **1** is 873 cm^{-1} and these modes are normally observed in the 750–950 cm^{-1} range for substituted benzenes (9), and various diazines (11). The 518 cm^{-1} band is clearly a ring-out-of-plane mode corresponding to the 520 cm^{-1} band of **1**. The 647 cm^{-1} band is also assigned as a ring out-of-plane mode.

Of the remaining bands, only the 233 and 297 cm^{-1} bands could possibly be the fourth A'' mode. The band at 233 cm^{-1} is assigned as the C—Cl out-of-plane bending mode because of its higher depolarization ratio, the assignment of certain combination bands (*vide infra*), and the observed C—Cl out-of-plane bending mode at 196 cm^{-1} in chlorobenzene (9). There is also evidence, as discussed later, for the assignment of 297 cm^{-1} as an A' mode.

A′ Vibrations

From the observed band contours, depolarization ratios, and intensities, the following bands are taken to be fundamental vibrations of A' symmetry: 3111, 1460, 1325, 1287, 1150,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

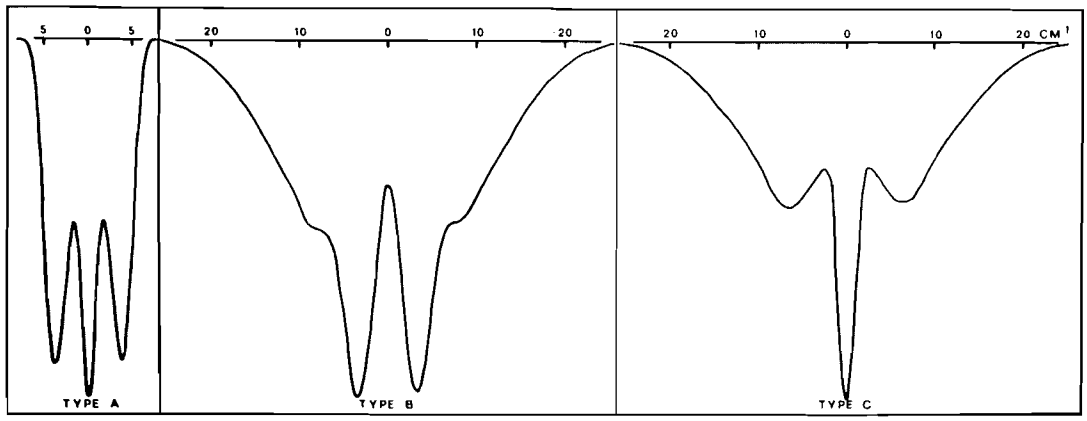

FIG. 4. Calculated type A, B, and C band contours for 3-chloro-1,2,5-thiadiazole.

949, 825, 786, 701, 430 cm^{-1}. The eleventh A' mode is chosen as 297 cm^{-1} as explained below.

Clearly, 3111 cm^{-1} is the C—H stretching mode. By comparison with the fundamentals of **1**, the bands at 1460, 1325, and 1287 can be assigned as ring-stretching modes. 1150 is close to the average value 1134 cm^{-1} for the symmetric and antisymmetric C—H in-plane bending modes for **1** and so can be assigned to the C—H in-plane bending mode. In chlorobenzene, the C—Cl stretch is at 701 and the C—Cl in-plane bend at 297 cm^{-1} (9, 10). This leads to the assignment of bands observed also at 701 and 297 cm^{-1} for **2** as the C—Cl stretch and C—Cl in-plane bend, respectively. The depolarization ratio of 0.80 for the 297 cm^{-1} band is higher than it should be; however, the assignment given for the 297 cm^{-1} band is further supported by some observations in the u.v. spectrum as discussed below.

Overtone and Combination Bands

All the stronger bands not assigned as fundamentals can be accounted for as first overtones or as binary combinations. In some cases more than one assignment is possible. For some rather weak bands no simple assignment was found. These assignments are listed in Table 1.

The assignments for some overtone and combination bands support the assignments given for the fundamentals. In particular, $2 \times 233(A'') = 466(A')$ and $233(A'') + 515(A'') = 748(A')$ agree with the bands observed at 463 and 751 cm^{-1} in the liquid while $949(A') + 296(A') = 1245(A')$ agrees with $1245(A')$. These support the assignments made for the 233 and 296 cm^{-1} bands.

Ultraviolet Data

As stated previously, this analysis was undertaken in order to determine the ground state fundamental vibrational frequencies of **2** so that they can be used in the interpretation of the electronic absorption spectrum. From the preliminary investigation of the gas phase u.v. absorption spectrum in the region 2875–2550 Å, bands have been observed at intervals of 300 ± 4, 433 ± 2, 704 ± 3, and 788 ± 3 cm^{-1} to long wavelengths of a common band at several places.[2] Since the electronic transition in **2** must be allowed and there is good agreement between the last three intervals and frequencies assigned as ground state A' fundamentals on the basis of i.r. and Raman data, the common band in each case must be acting as an origin (or pseudo-origin) for "hot" bands (12). The 300 cm^{-1} interval from the common origin band must also be due to an A' fundamental vibration (12), thus providing conclusive evidence for the assignment given for the band observed at 297 cm^{-1} in the i.r. and Raman.

[2]The figures given are the average value and standard deviation for 6, 6, 8, and 8 intervals, respectively, determined from the u.v. absorption spectrum of the vapor.

Conclusions

The assignments of the fundamental vibrational frequencies which have been made for 3-chloro-1,2,5-thiadiazole are summarized in Table 2. The i.r. and Raman spectra are consistent with the molecule being planar as expected. The majority of the fundamental vibrational frequencies are very similar to those of the parent compound 1,2,5-thiadiazole. The few which differ significantly involve the chlorine substituent and correlate very well with similar vibrational frequencies observed for chlorobenzene.

Energy Distributions of Reaction Product by Statistical Phase Space Theory

W. H. WONG[1]

Noyes Chemical Laboratory, University of Illinois, Urbana, Illinois

Received August 27, 1971

The phase space theory of chemical reaction in which all accessible channels are uniformly weighted was shown to be inappropriate for describing exothermic reactions. Modification to the theory was introduced by a concept of partial statisticity in which only that portion of the phase space available to each vibrational level was treated statistically. The product rotational and translational distributions of the reaction, Cl + HI, and its isotopic variant, Cl + DI, were computed by this modified formulation and compared with that obtained from a straight application of the phase space theory. The implication of the profound differences found from these two formulations was discussed in light of experimental data.

La théorie spatiale de la phase d'une réaction chimique dans laquelle tous les voies accessibles sont uniformément envisagées s'avère n'être pas appropriée pour la description de réactions exothermiques. Une modification à cette théorie a été introduite en envisageant une statistique partielle dans laquelle seulement chaque portion de l'espace de phase convenable à chaque niveau de vibration a été traitée statistiquement. Les distributions rotationnelles et de translation dans le produit de la réaction, Cl + HI et de sa variante, Cl + DI, ont été programmées avec cette formulation modifiée et comparées à celles obtenues à partir de l'application stricte de la théorie spatiale de la phase. L'implication des profondes différences trouvées à partir de ces deux formulations a été discutée à la lumière des données expérimentales.

Canadian Journal of Chemistry, **50**, 633 (1972)

I. Introduction

During the last decade or so, advances in experimental techniques for studying gas-phase reactions have provided significant information on the dynamics of reactive collision. The crossed molecular-beam method (see, for example, ref. 1) not only reveals the reaction cross-section as a function of collisional energy, but it can also determine the translational energy as well as the scattering angle of the product. Complementary to this, the spectroscopic technique (2), which involves direct observation of radiation from excited states, is capable of establishing the nascent distribution of internal energies before its collisional degradation. All these data are extremely valuable in unravelling the fundamental dynamics of the collision and in inferring the precise interaction between the collision partners. Stimulated by these experimental achievements, a large amount of theoretical work has appeared. One of the theories designed to predict the outcome of reactive collisions is the statistical phase space theory put forward by Light and co-workers (3). In this theory, the reactant species pass through a strong-coupling configuration which subsequently decomposes into various channels with a probability proportional to the volume of phase space available to that channel. In terms of quantum scattering theory, this is equivalent to assuming that all the non-zero elements of the **S** matrix are replaced by an average value and hence all are equal in magnitude (4, 5). Even though the formation of a long-lived reaction intermediate which has sufficient time for randomizing its energy among various degrees of freedom undoubtedly gives physical interpretation to this assumption, it is perhaps significant to emphasize that a very impulsive collision such as a hard-sphere type will also display statistical behavior. A good example for the latter justification is the success of the random phase approximation for rotational energy transfer (6). This statistical theory is particularly attractive because of its simplicity. Thus no detailed information on the potential energy surface other than the regions around the asymptotic reactant and product configurations is required and the very difficult dynamical calculation is avoided. The application of this theory to various types of reactions has been reviewed by Light and co-workers (3), and more recent works have been presented by Trular and Kuppermann (*7a*), Wolf and Haller (*7b*), Trular (*7c*), and White and Light (*7d*).

Despite the various extent of success of this theory to certain types of reaction, it consistently failed to account for the product vibrational distribution of all exothermic reactions studied so far. Since there are always more states available from a lower vibrational level than from a higher one, simply because of energy constraint, the phase space theory invariably predicts a decreasing product population with increasing vibrational quantum number. In sharp contrast to this, the chemiluminescent experiments (8) as well as trajectory calculations (9) indicated that a significant amount of the released exothermicity appeared in vibration of the newly-formed molecule and hence the product vibrational distribution peaked at higher quantum numbers. This vibrational population inversion provides, of course, the basis of chemical laser action (10). Although this statistical theory fails to account for the product vibrational distribution of exothermic reactions, it is still interesting to investigate its applicability to rotational distribution, particularly in view of the fact that the energy difference between rotational states is usually small and hence the distribution will more likely be statistical. However, in those cases in which this theory fails to predict the vibrational distribution, one can no longer uniformly treat the whole phase space available to the product. Instead, one should weigh the subspace available to the product in each vibrational level in such a way as to reflect the probability of product being formed in that level. The statistical treatment can be applied only within each subspace and thus the statistical calculation of the rotational distribution should be performed on each vibrational level separately. The overall rotational distribution can then be obtained by summing over all vibrational levels each of which carries the prescribed weight. This weighting factor can either be obtained from some simplified dynamical models, such as the non-adiabatic sudden-switch model (11), or from experimental data (8). It is interesting to note that all previously published work on the phase space theory assumed uniform weighting of the whole phase space, even in those cases in which its prediction of vibrational distribution was contrary to the observed data. From the above argument, it is obvious that the overall rotational distribution thus predicted could no longer be compared meaningfully with experiment.

In this paper we try to investigate the rotational distribution of highly exothermic reaction. We follow closely the quantum mechanical version of the phase space theory (3*a*, *c*), but modify it in such a way that the relative probability (obtained from dynamical calculation or from experimental data) of product being formed at each vibrational level could be incorporated. The weighting factors used in this paper were obtained from chemiluminescence data. The overall rotational and translational distributions were computed with this modification and were compared with those obtained by straight application of Light's (3) formulation. The systems chosen for specific consideration are Cl + HI and its isotopic variant Cl + DI. Accurate product vibrational distribution of these two reactions is available (8), and the dynamics of these two reactions has been investigated by Monte Carlo calculation (9*a*, *b*).

II. Theory

The cross-section for the formation of a strong-coupling complex (not necessarily long-lived) is given by (see for example, ref. 12)

$$[1] \qquad \sigma = \sum_{l=0}^{l_{max}} (2l+1)\,\frac{\pi\hbar}{2\mu E_t}$$

where μ, E_t, and l are the reduced mass, the relative translational energy, and the orbital angular momentum quantum number, respectively, of the collision system in the incoming channel. The upper limit of the summation, l_{max}, is the quantum number specifying the largest partial wave that could lead to the formation of a strong-coupling complex. Following the work of Light and co-workers (3), we define the boundary of the strong-coupling region as the barrier of the effective potential of the form

$$V_e(r) = -\frac{c}{r^6} + \frac{l(l+1)\hbar}{2\mu r}$$

where c is the coefficient of the long range attraction, and r is the separation between the collision partners. The requirement that the system should have sufficient energy to surmount the barrier to form the complex sets an upper limit

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to l, which is (3*b*)

$$[2a] \qquad l_{max}(l_{max}+1)\hbar^2 = 6\mu c^{1/3}\left(\frac{E_t}{2}\right)^{2/3}$$

The maximum impact parameter is then related to l_{max} by

$$[2b] \qquad 2\mu E_t b_{max}^2 = l_{max}(l_{max}+1)\hbar^2$$

If the probability of this complex decomposing into product channels is denoted by k, the total reaction cross-section is

$$[3] \qquad \sigma_R = \sum_{l=0}^{l_{max}} (2l+1)k\,\frac{\pi\hbar}{2\mu E_t}$$

where k should be understood to be a function of l, and its value is between zero and unity. In the original formulation of the phase space theory by Light and co-workers (3), the probability k is just the ratio of the number of states available in the product channels to the total number of states (reactive and non-reactive) accessible from the complex with specified total energy (E), and total angular momentum ($J\hbar$). Since the original theory is known to overestimate the reaction cross-section, we choose to leave this factor k in the formulation, and calculate the relative values. For the purpose of studying rotational distribution, we decompose the total reaction cross-section into more detailed quantities. The probabilities $P(v')$ and $P_{v'}(j')$ are defined in such a way that the cross-section for the formation of product at rotational state j' in a specified vibrational level v' is given by

$$[4] \qquad \sigma(v',j') = \sigma_R \cdot P(v') \cdot P_{v'}(j')$$

where v' and j' are product vibrational and rotational quantum numbers, respectively. Since

$$\sum_{v'} \sum_{j'(v')} \sigma(v',j') = \sigma_R$$

we have

$$\sum_{v'} P(v') \sum_{j'(v')} P_{v'}(j') = 1$$

and since

$$\sum_{j'(v')} \sigma(v',j') = \sigma(v')$$

we must have

$$\sum_{j'(v')} P_{v'}(j') = 1$$

and

$$\sum_{v'} P(v') = 1$$

Thus $P(v')$ is the normalized probability of product being formed at vibrational level v', and $P_{v'}(j')$ is the normalized probability of product being formed at state j' of the vibrational level v'. As discussed in section I, we apply statistical treatment to the rotational distribution of each vibrational level separately. From the usual argument of the statistical theory (3), the probability of product being formed at state j' is proportional to the number of quantum states, $N_{v'}(j')$, available to that j', subject to conservation of total energy and total angular momentum. That is

$$[5] \qquad P_{v'}(j') = \frac{N_{v'}(j')}{\sum_{j'} N_{v'}(j')}$$

The conservation of energy can be expressed as

$$[6] \qquad E = E_t + E_v + E_r + Q = E_t' + E_v' + \frac{j'(j'+1)\hbar^2}{2I'}$$

where E_t, E_v, and E_r are translational, vibrational, and rotational energies, respectively, of the reactant, and the primed quantities refer to product. The quantity I' is the moment of inertia of the product molecule (we only consider diatomic), and the exothermicity, Q, is taken to be positive when energy is released. From eq. 6, the upper limit of j' on a given v' level is

$$[6a] \qquad j'_{max}(j'_{max}+1)\hbar^2 = 2I'(E - E_v')$$

The conservation of total angular momentum requires that the set of orbital angular momentum quantum numbers in the exit channel (l') to be associated with each j' should obey

$$[7] \qquad |J - j'| \leqslant l' \leqslant (j + j')$$

On the other hand, the requirement that the complex should have sufficient energy to over-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

come the centrifugal barrier at the exit channel, sets an upper limit to l'. That is

$$[7a] \qquad l' \leqslant l'_{\max}$$

This maximum is again determined by eq. 2*a*, but with quantities relevant to the outgoing channel. Thus the number of states available to j' from a complex of angular momentum J, is given by

$$[8] \quad N_{v'}(J \to j') = (2J+1)(2j'+1) \times \sum_{l'_{\min}}^{l'_{\max}} H\left(E - E'_v - \frac{j'(j'+1)\hbar^2}{2I} - V_e^*(r')\right)$$

where the upper limit of the summation obeys eqs. 7 and 7*a* simultaneously, while the lower limit observes constraint eq. 7.

The Heaviside function in eq. 8 is

$$H(x) = 1, \quad x \geq 0$$
$$= 0, \quad x < 0$$

and $V_e^*(r')$ is the exit centrifugal barrier. Since at room temperature, the rotational angular momentum of the reactant molecule is small compared to the orbital angular momentum of the collision, we simply neglect its contribution to the total angular momentum of the complex. Thus $J\hbar$ is simply taken to be the orbital angular momentum of the incoming partial waves and the summing over all J is equivalent to summing over all l. The total number of states associated with j' is then

$$[9] \quad N_{v'}(j') = \sum_J N_{v'}(J \to j') = \sum_{l=0}^{l\max} (2l+1)(2j'+1) \times \sum_{l'_{\min}}^{l'_{\max}} H\left(E - E'_v - \frac{j'(j'+1)\hbar^2}{2I'} - V_e^*(r')\right)$$

The cross-section of product being formed at j' on vibrational level v' is

$$[10] \qquad \sigma(v',j') = \sigma_R P(v') \frac{N_{v'}(j')}{\sum_{j'} N_{v'}(j')}$$

The overall rotational distribution is

$$[11] \qquad \sigma(j') = \sigma_R \sum_{v'} P(v') \cdot \frac{N_{v'}(j')}{\sum_{j'} N_{v'}(j')}$$

Since the translational energy is just the difference between the total energy and the sum of rotational and vibrational energies, its distribution can readily be deduced from eqs. 10 and 11. When the cross-section is expressed as a function of energy rather than quantum numbers, we can simply write

$$[12] \qquad \sigma(E'_t) = \sigma(E - E'_v - E'_r)$$

III. Computations and Discussion

Calculations were performed on two reactions, Cl + HI and its isotopic variant Cl + DI, at a relative translational energy of 1.2 kcal. This energy was chosen to simulate the experiment at room temperature (8*b*). Both the original version of the phase space theory (3) in which the whole phase space is uniformly weighted and the modified version as expressed in eqs. 10 and 11 were employed.

The coefficient of the attractive potential for the interaction between A and BC was calculated from the well-known Landon's dispersion energy formula

$$C = \frac{3}{2} \frac{\varepsilon_A \varepsilon_{BC}}{\varepsilon_A + \varepsilon_{BC}} \alpha_A \alpha_{BC} + D_{BC}{}^2 \alpha_A$$

where ε, α, and D are the transition energy of dipole excitation, the polarizability, and the dipole moment, respectively. The vibrational energy of the diatomic molecule was calculated by the expression

$$E_v = \omega_e(v + \tfrac{1}{2}) - \omega_e\chi_e(v + \tfrac{1}{2})^2$$

These and other molecular data used in the computation were summarized in Table 1.

It is interesting to note that a relative translational energy of 1.2 kcal, the maximum impact parameter for the formation of the complex as defined by eq. 2 is 4.8 Å for both reactions, only slightly larger than the corresponding value of 4.3 Å obtained from Monte Carlo calculation (9*a*). However, the total reaction cross-section obtained from Light's formulation is 72 Å^2 for Cl + HI and 73 Å^2 for Cl + DI. The corresponding values obtained from Monte Carlo calculations are 6.8 Å^2 and 6.5 Å^2, respectively. For this type of co-valent reaction, it is very unlikely that the cross-section would far exceed 10 Å^2. This is perhaps another evidence that the phase

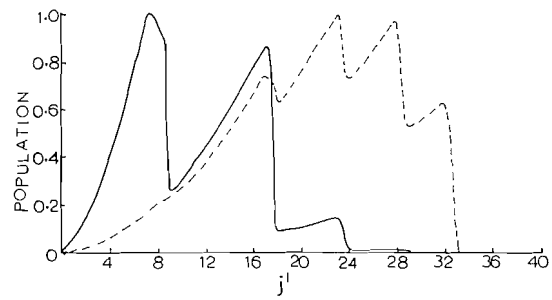

FIG. 2. Overall rotational energy distribution of HCl. Solid line computed from the modified formulation eq. 11; dashed line computed from Light's formulation.

space theory overestimates the reaction cross-section for an exothermic reaction. In fact, it is generally recognized (*7a*, *3c*) that this theory only gives an upper limit to the reaction cross-section, since the sole criterion determining the probability of reaction is the number of states accessible and the steric effect is completely ignored. Thus, with the uniform weighting of the whole phase space, the ratio of the number of accessible states for reaction to that of non-reactive collision is found to be around 1.3×10^2 for both reactions. But from Monte Carlo calculation, the average reaction probability of an encounter with an impact parameter less than the maximum value is only about 16%. It is apparent from the steric factor revealed in the Monte Carlo calculation that the uniform weighting of the whole phase space is inappropriate.

The relative vibrational distribution of the two isotopic reactions obtained from Light's formulation is displayed in Fig. 1. Also shown in the figure are the chemiluminescence data of Polanyi and co-workers (*8b*). The monotonic decrease of population with increasing quantum number is in strong contrast to the experimental trend. Similar failure of this theory for other exothermic reactions has already been pointed out by other workers (3). This, of course, supports the contention put forward in section I, that the whole phase space accessible to the product should not be equally weighted.

The relative rotational distribution on *each* vibrational level computed from eq. 10 of course is the same as that obtained from Pechukas and Light's formulation (3). All of these distributions peak at the highest j' consistent with energy conservation. Since we are mainly interested in the effect of introducing the correct weighting factors on the *overall* rotational and translational distributions, we refrain from displaying the distributions on individual levels.

The overall rotational distribution from our modified formulation was calculated from eq. 11, with the weighting factors, $P_{v'}$'s, obtained from chemiluminescent experiment (*8b*). The results are shown in Figs. 2 and 3. Also shown in these two plots are the distributions obtained from straight application of Light's formulation. Both sets of distributions are normalized to unity at the maximum. It is obvious that the two formulations give entirely different trend. For both reactions, Cl + HI and Cl + DI, Light's formulation not only predicts the maximum of the distribution at a much higher j', but also that the main body of the distribution shifts to much higher quantum numbers. Thus the average rotational energies of products HCl and DCl are 13.9 kcal and 13.6 kcal, respectively. The corresponding values from our modified formulation are 4.4 kcal and 5.1 kcal. It is interesting to note that the experimental values are around 4 kcal (13). This profound difference arises, of course, from the different weighting of the phase space. From Light's version, the most probable product vibrational state is the ground level, and on this level, the product can reach very high j' without violating energy conservation. In our modified formulation, on the other hand, we have readjusted the weighting of the phase space such that the most probable vibra-

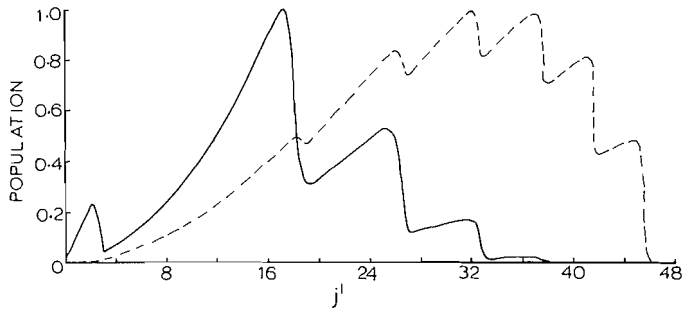

FIG. 3. Overall rotational energy distribution of DCl. Solid line computed from the modified formulation eq. 11, and dashed line from Light's formulation.

tional level is at high v', as was observed in experiment. On these higher vibrational levels, the product molecule would have insufficient energy to populate very high j' states. Thus the higher fraction of available energy being absorbed by the vibrational motion decreases proportionally the share for the rotational motion. Another feature that is worth noting in these plots is that the peaks of the distribution are better resolved in the modified version than that from Light's formulation. Thus for the product HCl (Fig. 2), our modified version predicts only two sharp peaks with their maxima separated by ten quantum numbers. Each of these two peaks can be clearly identified with the population of the two most probable vibrational levels. In Light's formulation, however, due to the overlap of the rotational populations of different vibrational levels, the peaks are much less prominent and much less resolved. The better resolution of the modified version is again evident for the product DCl, as shown in Fig. 3. Since the separation between the peaks in our modified version is well within the resolution power of chemiluminescent experiments, it seems likely that the features of the overall rotational distribution could be fruitfully applied to diagnose whether the dynamics exhibit complete or only partial statistical behavior. It would be extremely interesting to compare with accurate experimental data when available.

For convenience of comparison with crossed molecular-beam data, we have also computed the relative distribution of product translational energy of these two reactions. The translational energy was obtained by subtracting the sum of the quantized vibrational and rotational energies from the specified total energy, and the distribution was computed by eq. 12. These distributions are displayed in Figs. 4 and 5. The abscissas are in fraction of total available energy of the reaction (33.9 kcal for Cl + HI and 34.0 kcal for Cl + DI). Since the rotational energy is not a linear function of rotational quantum number, it introduces some scattering of data on the translational energy distribution plotted against a linear energy scale. To capture the essential feature and to avoid the unnecessary complications, the curves have been smoothed out. It is apparent from Figs. 4 and 5 that Light's

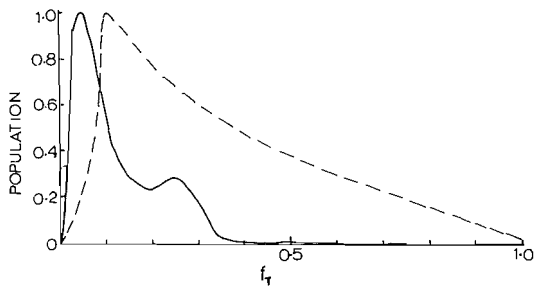

FIG. 4. Translational energy distribution of HCl. Solid line computed from the modified formulation eq. 12, and dashed line from Light's formulation.

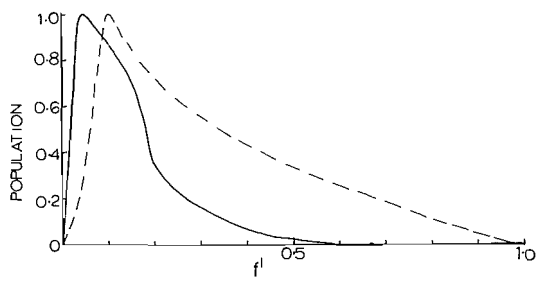

Fig. 5. Translational energy distribution of DCl. Solid line computed from the modified formulation eq. 12, and dashed line from Light's formulation.

For personal use only.

formulation again predicts a higher product translational energy. The average value is 11.3 kcal for Cl + HI, and 11.0 kcal for Cl + DI as compared with the corresponding 3.7 kcal and 4.0 kcal obtained from our modification. Although the maxima of the distributions are quite close in these two formulations, our modified version predicts a much sharper peak centered around low energy region while Light's version predicts a very broad distribution with a substantial population at the high energy end of the spectrum. This broad energy distribution seems to be the characteristic of a completely statistical theory.

IV. Summary

The phase space theory of chemical reaction was applied to study two exothermic reactions, Cl + HI and Cl + DI. It was found that this theory in which the whole phase space was uniformly weighted overestimated the reaction cross-section and predicted a reverse trend of product vibrational distribution as was observed in chemiluminescent experiments. A modified version of the theory was formulated by introducing a weighting factor to the subspace accessible to each product vibrational level. This modification as well as the original version of the phase space theory was used to compute the rotational and translational energy distributions of these two exothermic reactions. It was found that the two formulations predicted drastically different trends. The original version predicted much higher rotational and translational energies and much broader distributions. It seems that the average product rotational and translational energies obtained from our modified version are in better agreement with experimental data, although a rigorous test of its applicability can only be done when an accurate rotational energy distribution from chemiluminescent experiments and an accurate translational energy distribution from molecular-beam experiments are available. Nevertheless, if this partially statistical formulation (statistical only within that portion of the phase space corresponding to a vibrational level) still fails to agree with experiment, we may conclude that none of the motions in an exothermic reaction can be described statistically.

I am indebted to Professor R. A. Marcus for many incisive discussions.

Anomalous Ratios of Formation Constants: Possible Invalidity in the Successive Constants[1]

H. F. STEGER[1]

Mineral Sciences Division, Department of Energy, Mines and Resources, Ottawa, Canada

Received September 24, 1971

The causes of inaccuracy in the values of the successive formation constants for 1:2 metal:ligand complex systems for which $K_1 \leqslant K_2$ are discussed. The experimental error in the $\bar{n}$,pL data has been shown to become increasingly important as K_1/K_2 decreases. It has been concluded that the successive constants cannot be determined if $K_1/K_2 < 10^{-2.4}$. Their product, K_1K_2, can, however, be determined. It is also shown that the value of K_2 cannot be determined for the iron complexes with bipyridyl and 1,10-phenanthroline.

On discute des causes d'inexactitude quant aux valeurs obtenues pour les constantes de formation successive des complexes 1:2 métal:ligand pour lesquels $K_1 \leqslant K_2$. L'erreur expérimentale dans la donnée $\bar{n}$,pL devient d'autant plus importante que le rapport K_1/K_2 décroit. Il en a été conclu que les constantes successives ne peuvent être déterminées si $K_1/K_2 < 10^{-2.4}$. Cependant, leur produit, K_1K_2, peut être déterminé. Il a également été montré que la valeur de K_2 ne peut être déterminée pour les complexes du fer avec le bipyridyle et la 1,10-phénanthroline.

Canadian Journal of Chemistry, **50**, 641 (1972)

Introduction

Small values of the ratio K_1/K_2 where, $K_1 \leqslant K_2$ have been found for the Cu(II) complex with 2,9-dimethyl-1,10-phenanthroline (1) and some transition metal complexes of 2-thienyl-8-hydroxyquinoline (2). These anomalous ratios of K_1/K_2 have been attributed to changes in the stereochemistry of the metal ion caused by steric interaction between the incoming first molecule of ligand and coordinated water resulting in a decrease in K_1(1, 3). The second molecule of ligand coordinates to the distorted structure in the usual fashion without a decrease in K_2.

There is no question that the experimentally determined values of K_1 and K_2 signify the presence of a factor not usually operative in metal complex formation. However, to impart any special significance to their magnitudes other than indicating an anomalous stability effect must be done with caution for certain factors which affect the accuracy of K_1 and K_2 become increasingly important as K_1/K_2 decreases. The aim of this study is to discuss the difficulties in the calculation of accurate values of K_1 and K_2 for $K_1 \leqslant K_2$.

The discussion is extended to the iron complex systems with bipyridyl and 1,10-phenanthroline (4) for which $K_3 > K_1,K_2$. In these systems the calculation of accurate values of the successive formation constants is also shown to be subject to the same difficulties.

Discussion

Several methods are known for the calculation of metal complex formation constants by the use of $\bar{n}$, the average number of ligands bound to the metal, and [L], the concentration of free ligand anion (5). The formation constants for 1:2 metal:ligand complexes are, in general, calculated by a linear least-squares fit of $\bar{n}$,[L] data to

$$[1] \qquad K_1 = \frac{\bar{n}}{(1-\bar{n})[\mathrm{L}]} - \frac{(2-\bar{n})[\mathrm{L}]K_1K_2}{(1-\bar{n})}$$

In metal complex systems in which $K_1 \leqslant K_2$, special consideration concerning the accuracy of the values of K_1 and K_2 calculated thusly must be undertaken for two reasons. First, the experimental errors, both random and systematic, become increasingly important as the ratio of K_1/K_2 decreases. Second, the possibility of an insensitivity of the experimental $\bar{n}$,[L] data to both ligand addition reactions cannot be eliminated completely.

Due to the extraordinary nature of the systems for which $K_1 \leqslant K_2$, few such examples have been

reported. The equilibrium data for some metal 2-thienyl-8-hydroxyquinolinates (2) and the Cu(II) complex with 2,9-dimethyl-1,10-phenanthroline (1) are summarized in Table 1. Also shown are the values of log K_1, log K_2, and the corresponding standard deviation, σ, as calculated by eq. 1. The values of log K_1 at the individual data points were calculated by the back-substitution of log K_1K_2 into eq. 1 from which it had been calculated. The column "Dev" gives the values of the individual K_1's as a percentage of the terms $\bar{n}/(1-\bar{n})[L]$ and $(2-\bar{n})[L]K_1K_2/(1-\bar{n})$, whichever is the greater.

At first glance, the low standard deviation found for the metal 2-thienyl-8-hydroxyquinolinates would suggest that eq. 1 renders a more than satisfactory fit of the equilibrium data. An examination of the values of log K_1 at the individual data points, however, clearly demonstrates that this is somewhat misleading. There is appreciable scatter in the value of log K_1. The precision of log K_1 is approximately ± 0.3 units for all the metal 2-thienyl-8-hydroxyquinolinates, and is much greater than is desirable.

The cause of this large scatter in K_1 is random experimental error. The values in the column "Dev" illustrate that the value of K_1 is considerably less than either term on the right-hand side of eq. 1, *e.g.*, K_1 varies from $\sim 1\%$ to a maximum of 22, 34, 10, 12, and 38% of the larger of the terms for the Co, Ni, Cu, Zn, and Cd complex, respectively. It can readily be seen that because K_1, the difference between the terms $\bar{n}/(1-\bar{n})[L]$ and $(2-\bar{n})[L]K_1K_2/(1-\bar{n})$, is appreciably smaller than these terms, the precision of the values of log K_1 will be greatly dependent on the errors in the terms on the right-hand side of eq. 1, which, in turn, are determined by the random experimental error in the $\bar{n}$,[L] data.

The experimental error in pL, Log K_1, and log K_2 for metal complex systems in which $K_1 > K_2$ has been calculated to be ± 0.02 units (6, 7). On the assumption that this estimation of the error also applies to metal complex systems in which $K_1 \leqslant K_2$, the fractional error in pL is approximately 0.4% for the 2-thienyl-8-hydroxyquinolinates. The fractional errors in the terms $\bar{n}/(1-\bar{n})[L]$ and $(2-\bar{n})[L]K_1K_2/(1-\bar{n})$ can be calculated to be approximately 0.4% if the errors in the components containing $\bar{n}$ are assumed to be self-cancelling (8). Since the actual value of K_1 is less than either term, its fractional error must be larger than 0.4%. Indeed, the variation in log K_1 of ± 0.3 units suggests that the fractional error in K_1 has increased to approximately 5% for the metal 2-thienyl-8-hydroxyquinolinates. Since formation constants are, in general, determined with much greater precision, the increased importance of experimental error in systems in which $K_1 \leqslant K_2$ must be considered in reporting the values of the formation constants.

The question arises, however, if there is a lower limit to the value of the ratio K_1/K_2 below which the evaluation of K_1 is not possible by the use of the available equilibrium data. The answer, of course, is that such a lower limit does exist and that it is related directly to the error in experimentally determined quantities such as pL, $\bar{n}$, *etc.* The calculation of a value of K_1 which is less than the error in the terms $\bar{n}/(1-\bar{n})[L]$ and $(2-\bar{n})[L]K_1K_2/(1-\bar{n})$ cannot be justified, *i.e.*, eq. 1 will yield values of K_1 which are in fact, reflections of the experimental error instead of mono-ligand complex formation. Therefore, if K_1 is less than 0.4% of both terms above, its value cannot be calculated. For such a situation, both positive and negative values of K_1 will be obtained because of random experimental error. Herein lies a test for the reliability of the value of K_1. If all of the values of K_1 at the individual data points are positive, then $K_1 \geqslant$ experimental error and its value can be determined. It must be noted, however, that the reproducibility of the value of K_1 will decrease as its value approaches that of the experimental error.

An estimate of the value of the lower limit of the value of the ratio K_1/K_2 was made as follows. A value of log K_1K_2 was selected arbitrarily. Values of $\bar{n}$ for a given series of values of pL were then calculated for several values of the ratio K_1/K_2. These values of $\bar{n}$ and the corresponding pL, to which an error of 0.02 units was added or subtracted alternately, were used to calculate the values of K_1 at the individual data points. It was observed that for $K_1/K_2 \leqslant 10^{-2.4}$, one half of the values of K_1 at the individual data points were negative, as expected, *i.e.*, the applied error in pL is of greater significance than is the contribution made by K_1 to eq. 1. At $K_1/K_2 > 10^{-2.4}$, positive values of K_1 are obtained for those values of pL which gave negative values above, with the exception of data points for which $\bar{n}$ is close to unity and which, in general, would be omitted in the calculation of formation constants (5). Hence, the contribution of K_1 to eq. 1 has become greater than the applied error in pL.

Since the experimental error in pL can, in fact, be intermediate between 0.02 and -0.02 units, the true lower limit for K_1/K_2 for which the successive constants can be evaluated will be somewhat less than $10^{-2.4}$.

The inability to calculate the successive formation constants may also be described as an insensitivity of the equilibrium data to both ligand addition reactions. In metal complex systems for which $K_1/K_2 < 10^{-2.4}$, the formation of the 1:2 metal:ligand complex must ensue immediately upon that of the mono-ligand complex such that both addition reactions appear to act as one:

$$M^{2+} + 2HL \xrightarrow{K_1} [ML^+ + HL + H^+] \xrightarrow{\text{immediate}} ML_2 + 2H^+$$

The equilibrium equation describing this reaction is easily derived from the mathematics for 1:2 metal complex systems for which $K_1 > K_2$ by equating [ML] to zero and is

$$[2] \qquad K_1K_2 = \frac{\bar{n}}{(2-\bar{n})[L]^2}$$

Equation 2 is a convenient method of determining if the successive formation constants can be calculated for a metal complex system. It is easily seen that this equation must fail for those systems in which [ML] is significant. The values of $\frac{1}{2}\log K_1K_2$ as calculated with eq. 2 are shown in Table 1.

The data in Table 1 indicate that eq. 2 does not explain the equilibrium data for the metal 2-thienyl-8-hydroxyquinolinates satisfactorily. A decrease in the $\frac{1}{2}\log K_1K_2$ is observed with increasing $\bar{n}$. For both the Cu and Zn 2-thienyl-8-hydroxyquinolinates, however, this decrease is small (*i.e.*, 0.02 units) and suggests that, perhaps, too great a significance should not be placed on the calculated values of K_1 for these complexes. These K_1 values should be accepted as good approximations only. The greater range in $\frac{1}{2}\log K_1K_2$ for the Co, Ni, and Cd complexes suggests that their calculated K_1 values can be accepted with more confidence.

The Cu(II) complex with 2,9-dimethyl-1,10-phenanthroline is an excellent example of eq. 1 yielding erroneous values of the successive formation constants. It is readily noted that the equilibrium data are distinctly separable into those at $\bar{n} \leqslant 1.3$ for which $K_1/K_2 < 10^{-2.4}$ and those at $\bar{n} > 1.3$ for which normal behavior is observed. Of special importance is the observation that $\log K_1$ for the individual data points at $\bar{n} > 1.3$ is equal to $\frac{1}{2}\log K_1K_2$ at $\bar{n} < 1.3$ which is possible only if $K_1 = K_2$. Such is not the case. It is evident that the inclusion of all the data in the calculation of the successive formation constants by the use of eq. 1 yields erroneous results. The values of the successive formation constants reported for the Cu(II) complex with 2,9-dimethyl-1,10-phenanthroline (1) are incorrect and further study is required. Hawkins and Perrin have previously pointed out several of the difficulties encountered in this complex system (9).

The results of this study clearly illustrate that the calculation of successive formation constants for systems for which $K_1 \leqslant K_2$ requires special precautions due to the increased importance of the experimental error and to the possible insensitivity of the data to both ligand addition reactions. These precautions must also be undertaken in higher ligand:metal complex systems such as the iron complexes with bipyridyl and 1,10-phenanthroline (4) for which $K_3 > K_1, K_2$. For these complexes, $\log K_1$, $\log K_2$, and $\log K_3$ were found to be 4.3, 3.7, and 9.5 and 5.8, 5.2, and 10.0, respectively. The very small ratio of $K_2/K_3 \simeq 10^{-4.8}$ strongly suggests the "instantaneous" formation of the tris-complex upon that of the bi-complex such that the equilibrium data may be insensitive to the second ligand addition reaction. Indeed, an insensitivity of the data to both the first and second ligand addition reactions was found for the 1,10-phenanthroline complex. Furthermore only the overall formation constant β_3 (where $\beta_3 = K_1K_2K_3$) had been reported previously (4).

The value of K_1 was obtained from measurements on solutions containing a large excess of iron (4). The values of $\log K_1K_2$ at the individual data points calculated using the values of K_1 and β_3 above in the equation

$$[3] \qquad \frac{\bar{n}}{(1-\bar{n})[L]} = K_1 + \frac{(2-\bar{n})[L]}{(1-\bar{n})} K_1K_2 + \frac{(3-\bar{n})[L]^2}{(1-\bar{n})} \beta_3$$

are summarized in Table 2. The great frequency with which negative values of K_1K_2 are obtained clearly demonstrates that the value of this

product cannot be gleaned from the equilibrium data available. Although the results are not shown herein, the values of $\bar{n}$ calculated with the use of the values of the formation constants obtained by Irving and Mellor (4) were unaffected by any terms containing the product K_1K_2. It is quite clear, therefore, that the value of K_2 for the iron complexes with bipyridyl and 1,10-phenanthroline are not obtainable with the data available.

The author wishes to express his thanks to Dr. A. Corsini of Department of Chemistry, McMaster University, for the use of the equilibrium data for the metal 2-thienyl-8-hydroxyquinolinates and to Dr. P. G. Manning of Department of the Environment, for reviewing this manuscript.

A Semi-empirical Analysis of the Electronic Spectrum and Molecular Structure of Formaldehyde

I. ABSAR,[1] C. S. LIN,[2] AND K. L. MCEWEN

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received July 26, 1971

The electronic transition energies and ionization potentials of formaldehyde have been calculated by a semi-empirical molecular orbital method, using several different ways of evaluating the diagonal matrix elements, in an attempt to adapt the Pariser–Parr–Pople method to the calculation of σ electron properties. The use of theoretically computed penetration integrals in this semi-empirical calculation lead to incorrect relative separation of the π-, σ-, and nonbonding molecular orbital energies, and hence to failure in predicting $n \rightarrow \pi^*$ and $n \rightarrow \sigma^*$ transition energies. A method is developed which reproduces the spectrum of formaldehyde (which includes n–π^*, π–π^*, and n–σ^* electronic transitions) satisfactorily. In paper II of this series, this method is applied to study the spectrum of HCN and CO_2.

Les énergies de transition électronique et les potentiels d'ionisation du formaldéhyde ont été calculés par la méthode semi-empirique des oribitales moléculaires en utilisant diverses méthodes permettant d'évaluer les éléments diagonaux de la matrice, en vue d'adapter la méthode de Pariser–Parr–Pople au calcul des propriétés des électrons σ.

L'utilisation, dans ce calcul semi-empirique, des intégrales de pénétration obtenues par des calculs théoriques, conduit à une séparation incorrecte entre les énergies des orbitales moléculaires π, σ et non-liante et par conséquent à un échec dans la prévision des énergies de transition $n \rightarrow \pi^*$ et $n \rightarrow \sigma^*$.

Une méthode est développée et reproduit de façon satisfaisante le spectre du formaldéhyde, qui comprend les transitions électroniques n–π^*, π–π^* et n–σ^*. Dans le mémoire suivant, cette méthode est appliquée à l'étude du spectre de HCN et de CO_2.

Canadian Journal of Chemistry, **50**, 646 (1972)

Introduction

In order to better understand the spectra of certain compounds of interest to spectroscopists, we have concerned ourselves with the problem of finding suitable molecular wave-functions, so that the various molecular electronic transition energies may be calculated. Theoretical as well as semi-empirical calculations have been done by various workers in attempts to tackle this problem. Theoretically computed transition energies have generally not been in agreement with the observed spectra, the n–π^* transition energies being calculated too low while the π–π^* transition energies being sometimes twice as much as the observed value. In many semi-empirical calculations, on the other hand, the σ electrons have usually been neglected by the use of the Π-approximation. In the few cases where σ electrons have been included in semi-empirical calculations, with the possible exception of the work of Del Bene and Jaffe (1) using a modified CNDO approximation, the results have generally failed to show the correct energy separation between the σ, π, and n (nonbonding) systems of electrons, even though these calculations have proved very successful in the evaluation of π–π^* transition energies. Also, while interpreting results most workers neglect to take into account the fact that the calculated values are for Franck–Condon transitions, and the experimental values quoted are those of the 0–0 transition.

In order to investigate several questions that arise in an application of the semi-empirical method, we have carried out a series of studies on formaldehyde, a compound which has been studied extensively both by theoretical calculations (2–7) and semi-empirical workers (1,8–14) and for which there are ultraviolet spectral and ionization potential data involving σ, π, and nonbonding electrons. We have tried to extend to the σ electron systems, the method developed by Pariser–Parr (15) and Pople (16), and have attempted to achieve the correct relative energy

separation between the σ, π, and nonbonding molecular orbitals.

Method

Starting from the molecular orbital formulation due to Roothaan (17) and using the LCAO form for the molecular orbitals; *i.e.*

$$[1] \qquad \psi_i = \sum_{\mu=1}^{\infty} \phi_\mu c_{\mu i}$$

where the ϕ_μ are atomic orbital wave-functions, one can write the following secular equations

$$[2] \qquad \sum_{\mu=1}^{\alpha} c_{\mu i}(H_{\mu\nu} - S_{\mu\nu}E_i) = 0,\ \nu = 1, 2, \cdots, \alpha$$

where

$$[3] \qquad S_{\mu\nu} = \int \phi_\mu^* \phi_\nu \, d\tau$$

and

$$[4] \qquad H_{\mu\nu} = \int \phi_\mu^* H \phi_\nu \, d\tau$$

H being the Hamiltonian operator. Neglecting spin–orbit, spin–spin, and relativistic effects one may write out the Hamiltonian for an n-electron system as $H^{\text{core}} + \frac{1}{2}\sum_i^n \sum_j^n 1/r_{ij}$, where H^{core} is the sum of the kinetic and potential energies of all electrons in the field of the core

$$[5] \qquad H^{\text{core}} = \sum_{i=1}^{n} [T(i) + V_{(i)}^{\text{core}}] = \sum_{i=1}^{n} H_{(i)}^{\text{core}}$$

Defining

$$[6] \qquad P_{\eta\delta} = 2\sum_i C_{\eta i}^* C_{\delta i}$$

where i refers to all filled orbitals, and

$$[7] \qquad H_{\rho\sigma}^{\text{core}} = \int \phi_\rho^* \left[\sum_i H_{(i)}^{\text{core}}\right] \phi_\sigma \, d\tau$$

one may write

$$[8] \qquad H_{\rho\sigma} = H_{\rho\sigma}^{\text{core}} + \sum_\eta \sum_\delta P_{\eta\delta}[(\rho\sigma|\eta\delta) - \tfrac{1}{2}(\rho\delta|\eta\sigma)]$$

where

$$[9] \qquad (\rho\sigma|\eta\delta) = \iint \phi_\rho^*(1)\phi_\sigma(1) \frac{e^2}{r_{12}} \phi_\eta^*(2)\phi_\delta(2) \, d\tau_1 \, d\tau_2$$

Adopting the notation that, if ϕ_μ is the atomic orbital under consideration on atom A and is denoted by μ, μ' indicates any atomic orbital on atom A other than ϕ_μ, and ν indicates any atomic orbital on any other atom (ν' is related to ν in the same manner as μ' is to μ) assuming zero overlap and zero diatomic differential overlap (16, 18), one arrives at the following matrix elements from eq. 8

$$[10] \qquad H_{\mu\mu} = H_{\mu\mu}^{\text{core}} + \tfrac{1}{2}P_{\mu\mu}(\mu\mu|\mu\mu) + \sum_{\substack{\mu' \\ (\mu' \neq \mu)}} \{P_{\mu'\mu'}[(\mu\mu|\mu'\mu') - \tfrac{1}{2}(\mu\mu'|\mu\mu')] + P_{\mu\mu'}(\mu\mu|\mu\mu')\} + \sum_\nu \left[P_{\nu\nu}(\mu\mu|\nu\nu) + \sum_{\substack{\nu' \\ (\nu' \neq \nu)}} P_{\nu\nu'}(\mu\mu|\nu\nu')\right]$$

$$[11] \qquad H_{\mu\nu} = H_{\mu\nu}^{\text{core}} - \tfrac{1}{2}P_{\mu\nu}(\mu\mu|\nu\nu)$$

and

$$[12] \qquad H_{\mu\mu'} = H_{\mu\mu'}^{\text{core}} - \tfrac{1}{2}P_{\mu\mu'}[(\mu\mu|\mu'\mu') - 3(\mu\mu'|\mu\mu')]$$

$$[13] \qquad H_{\mu\mu}^{\text{core}} = \int \phi_\mu^* \left[\sum_i \left(\frac{h^2}{8\pi^2 m} V_i^2 + V_{\text{A}}(i) + \sum_{\text{B} \neq \text{A}} V_{\text{B}}(i)\right)\right] \phi_\mu \, d\tau$$

To a first approximation

$$V_{\text{B}}(1) = Z_{\text{B}} \cdot \frac{e^2}{\bar{r}_{1\text{B}}}$$

where Z_{B} is the number of electrons contributed by atom B to the molecular orbital system being calculated; therefore

$$[14] \qquad \int \phi_\mu^* \sum_i V_{\text{B}}(i)\phi_\mu \, d\tau = -\sum_\nu Z_\nu(\mu\mu|\nu\nu)$$

where Z_ν denotes the number of electrons contributed by the atomic orbital ϕ_ν on atom B. More accurately one should add the penetration integral (B:$\mu\mu$) to the right-hand side of eq. 14 in order to take into account the interaction between an electron in ϕ_μ and the neutral atom B.

The penetration integral (B:$\mu\mu$) may be defined by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[15] $$(\mathrm{B}:\mu\mu) = [b|\mu\mu] + \sum_{\nu} Z_{\nu}(\mu\mu|\nu\nu)$$

where $[b|\mu\mu]$ stands for the nuclear (or atomic core) attraction of atom B for an electron in ϕ_μ.

The rest of the terms in eq. 13 may be defined as

[16] $$\int \phi_\mu^* \left(-\frac{h^2}{8\pi^2 m}\nabla^2 + V_{\mathrm{A}}\right)\phi_\mu \, d\tau = -W_\mu - \sum_{\mu'} z_{\mu'}[(\mu\mu|\mu'\mu') - \tfrac{1}{2}(\mu\mu'|\mu\mu')]$$

where W_μ is the energy of an electron in orbital ϕ_μ of atom A, and as suggested by Pariser and Parr (15), may be approximated by the ionization potential for ϕ_μ of the free atom A.

Calculation

The calculations reported in this paper are all valence electron SCF-LCAO-MO calculations using minimum basis Slater-type orbitals to represent the atomic wave functions.

In the present calculations, the W_μ of eq. 16 were approximated in each case by the appropriate valence state ionization potential involving an electron in the relevant atomic orbital of the free atom.

One-center Coulomb repulsion integrals of the type $(\mu\mu|\mu\mu)$ were evaluated using the Pariser approximation (19)

[17] $$(\mu\mu|\mu\mu) = I_\mu - A_\mu$$

where the relevant ionization potential, I_μ, and electron affinity, A_μ, are determined using atomic data (20). Theoretical values of all two-center electron repulsion integrals were computed from Roothaan's formulae (21). Semi-empirical values of two-center electron repulsion integrals of the type $(\mu\mu|\nu\nu)$ were evaluated by the Parr–Pariser type formula (15).

[18] $$(\mu\mu|\nu\nu) = \tfrac{1}{2}[(\mu\mu|\mu\mu) + (\nu\nu|\nu\nu)] - aR - bR^2$$

in which the parameters a and b are determined for any particular atomic pair by substituting into eq. 18 semi-empirical one-center integrals obtained from eq. 17, and theoretical values for $(\mu\mu|\nu\nu)$ computed for two large internuclear distances.

Penetration integrals were calculated using values of the quantities $[b|\mu\mu]$ and $(\mu\mu|\nu\nu)$ obtained from formulas given by Roothaan (21), and overlap integrals were obtained from the tables of Mulliken *et al.* (22). Since the values of penetration integrals and integrals of the form $(\mu\mu|\nu\nu')$ are relatively small, they were not semi-empirically readjusted, and the effect of neglecting these integrals altogether was investigated.

$H_{\mu\nu}^{\mathrm{core}}$ was equated to the resonance integral $\beta_{\mu\nu}$, and assumed to be directly proportional to the corresponding overlap integral. A value of $\beta_{\mu\nu} = -3.00$ eV was assigned to the resonance integral between π-atomic orbitals of a "standard double bond". This assignment is based on previous experience with ethylene (15) and formaldehyde (9), where the approximate value $\beta_{\mu\nu} = -3.00$ eV gave a satisfactory π–π^* transition energy. For resonance integrals

$$\beta_{\mathrm{XH}} = \tfrac{1}{2}(\beta_{\mathrm{X_2}} + \beta_{\mathrm{H_2}})$$

was used, $\beta_{\mathrm{X_2}}$ and $\beta_{\mathrm{H_2}}$ being evaluated at the internuclear distance R_{XH}.

McLachlan (23) has shown that corrections for the neglect of overlap can be introduced into eq. 10 by using modified core integral $\mathscr{H}_{\mu\mu}^{\mathrm{core}}$ instead of $H_{\mu\mu}^{\mathrm{core}}$, *i.e.*

[19] $$\mathscr{H}_{\mu\mu}^{\mathrm{core}} = H_{\mu\mu}^{\mathrm{core}} - \sum_{\nu} S_{\mu\nu}\beta_{\mu\nu} + \tfrac{1}{4}\sum_{\nu} H_{\nu\nu}^{\mathrm{core}} S_{\mu\nu}^2 + \tfrac{3}{4}\sum_{\nu,\delta} \beta_{\mu\nu} S_{\nu\delta} S_{\mu\delta}$$

where $\mathscr{H}_{\mu\mu}^{\mathrm{core}}$ as defined by eq. 19 implies a change of orbital basis to orthogonalized atomic orbitals (12), whereas $H_{\mu\mu}^{\mathrm{core}}$ is the same integral evaluated in terms of non-orthogonalized atomic orbitals. The effect of including this overlap correction in the diagonal matrix element was investigated.

The basic integrals over atomic orbitals required for formaldehyde are tabulated in Table 1. The molecular geometry for formaldehyde (24) and the coordinate system used are shown in Fig. 1. The z-axis is taken perpendicular to the plane of the paper.

In order to study the objectives as outlined in the introduction several calculations were done using different approximations for the matrix elements. In each calculation the secular equations were set up for both σ and π electron systems, and were brought to self-consistency considering the effect of π-polarity on the σ system and σ-polarity on the π system after each iteration. For this purpose a Fortran IV program was developed to run on the IBM 360-50 computer.

†2s atomic orbitals on atom A are denoted by the symbol s, and 2p atomic orbitals by the symbol p unless their direction is to be specified, in which case they are denoted by x, y, or z. A bar over p indicates an orbital at right angles to the 2p orbital without a bar.

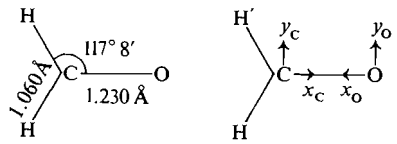

FIG. 1. Molecular geometry (22) and coordinate system for formaldehyde.

Discussion

Using eqs. 10, 11, and 12 as starting points for evaluating the various matrix elements, and employing values of one-center Coulomb repulsion integrals obtained semi-empirically from spectral data (25), several calculations were conducted in order to investigate: (*i*) the relative adequacy of the use of theoretical and semi-empirically adjusted two-center Coulomb repulsion integrals; (*ii*) the effect of neglecting penetration integrals and integrals of the form $(\mu\mu|\nu\nu')$; (*iii*) the effect of including the overlap correction to the diagonal matrix elements; (*iv*) the effect of neglecting resonance integrals for non-adjacent atoms.

It was found that exclusion of penetration integrals resulted in an improvement in the n–π^* transition energy, while inclusion of overlap correction led to a worsening of this number. This may be attributed to the theoretical values of penetration integrals being too large, and if they are to be included, the values should be scaled down semi-empirically. The inclusion of overlap correction implies a re-definition of the basis orbitals used, and it is then no longer consistent to calculate the electron repulsion integrals and penetration integrals using a Slater basis.

The Coulomb repulsion integrals of the type $(\mu\mu|\nu\nu')$ may be neglected without any drastic effects on the n–π^* or n–σ^* transition energies, but the neglect of resonance integrals for non-adjacent atoms improves the values of these transition energies appreciably. This is probably due to the reason that resonance integrals occur in the off-diagonal elements.

When theoretically calculated values are used for all the two-center Coulomb repulsion integrals, the values of n–π^* transition energies are greater than the observed value, while when all of these integrals are semi-empirically adjusted the n–π^* transition energies as well as the n–σ^* transition energies become too low. Good agreement with observed transition energies of all types is obtained when theoretical values of all σ–σ two-center Coulomb repulsion integrals and semi-empirically adjusted values for π–π and σ–π two-center Coulomb repulsion integrals are used. The results of a calculation with Coulomb repulsion integrals so evaluated, and neglecting penetration integrals, resonance integrals between non-adjacent atoms and integrals of the type $(\mu\mu|\nu\nu')$ are given in Tables 2 and 3.

Table 2 compares our orbital energies with those from an *ab initio* study (3) using a similar basis set, and those obtained from the CNDO and INDO methods. The negative of an orbital energy is an approximation to the vertical ionization energy needed to remove an electron from that orbital. Therefore, in the last column of Table 2, we have listed the negative of photoelectron ionization potentials (33). All our predicted ionization potentials on this basis are

in fairly good agreement with experiment, and consistently better than those predicted by CNDO and INDO methods. Also, our values are consistently slightly larger in magnitude than the experimental value, as opposed to the *ab initio* values which are sometimes larger and sometimes smaller. Table 2 also shows the dipole moment of formaldehyde. Our calculated value corresponds surprisingly well with the observed value, but this good agreement is probably accidental. However, it does seem safe to conclude that the σ contribution to the dipole moment of formaldehyde (0.104 D) is small as compared to the π-contribution (2.243 D). The

For personal use only.

main feature which distinguishes our wave functions from the *ab initio*, or CNDO or INDO wave-functions is that our wave-function shows the expected high polarity C^+—O^- of the π-molecular orbital.

Table 3 compares our calculated transition energies with the observed spectrum of formaldehyde. The observed 0–0 bands of the $^1A_1$–$^3A_2$ transition (26, 27) and the $^1A_1$–$^1A_2$ transition 26, 28, 29) have been reported at about 3.12 and 3.5 eV, respectively, while the maximum intensity bands corresponding to the vertical transitions have been estimated to be at 3.6 and 4.26 eV, respectively (30). Our calculated values of 3.694 eV for the $^1A_1$–$^3A_2$ transition and 4.104 eV for the $^1A_1$–$^1A_2$ transition are therefore in very good agreement with the experimental values; much better than those calculated by previous workers. These transitions are forbidden by symmetry but may be made allowed by changes in the geometry of the molecule; they are, however, expected to be weak in intensity. This is confirmed from both the observed and calculated intensities. As these are the n–π^* transitions, we may conclude that we have been able to satisfactorily fix the relative energy separation of the σ system and the π system of electrons.

Most previous workers (2, 6, 9, 12, 30) have assigned the $^1A_1$–$^1B_2$ transition (7.1 eV) to a n–σ^* excitation, and the $^1A_1$–$^1A_1$ transition (8.0 eV) to a π–π^* excitation. Our calculations show a n–σ^* transition at 7.275 eV which has the correct symmetry and the correct order of calculated intensity. Moreover, we have calculated a π–π^* configuration at 8.174 eV and a n–σ^* configuration at 8.155 eV. Both of these configurations have $^1A_1$ symmetry and will therefore mix. A configuration interaction calculation gives a $^1A_1^+$ state at 9.597 eV, which might correspond to the observed $^1A_1$–$^1A_1$ transition observed at 9.58 eV, and a $^1A_1^-$ state at 6.733 eV, which may be obscured by other transitions in the region, since it will be very weak due to cancellation of intensity.

Herzberg (31), following on the lines of Allison and Walsh (32), has assigned all transitions 7.1 eV and above to Rydberg series. This brings us to an interesting question: to what extent may the distinction between Rydberg states and non-Rydberg states be somewhat artificial? It seems from the present work that there could easily be states that from the "united atom" point of view must clearly be considered as Rydberg states, while from the present point of view of the separated atoms, they would not be considered as such.

Conclusion

We have shown that for formaldehyde molecule a semi-empirical calculation of π, σ, and nonbonded electron properties, including electronic spectra, ionization potentials, and dipole moment, can be made using essentially the Pariser–Parr–Pople approach. If penetration integrals are included in the calculation then the σ and π molecular orbitals are stabilized too much relative to the energy of the nonbonding orbital. If corrections to the diagonal matrix elements for neglect of overlap are included as well as penetration integrals, then the results are slightly better than if penetration integrals alone are included. The best results, however, are obtained if neither penetration integrals nor corrections for overlap are included, and the σ–σ Coulomb repulsion integrals are theoretical while the π–π, and σ–π Coulomb repulsion integrals are semi-empirically adjusted.

A Semi-empirical Analysis of the Electronic Spectra and Molecular Structures of Hydrogen Cyanide and Carbon Dioxide

I. ABSAR[1] AND K. L. MCEWEN

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received July 26, 1971

All valence electron molecular orbital calculations have been carried out on hydrogen cyanide and carbon dioxide using a minimum basis set of Slater-type orbitals by a semi-empirical SCF-LCAO-MO method described earlier for formaldehyde. Since many of the excited states of these molecules are bent, a series of calculations is carried out on hydrogen cyanide in the linear configuration and in bent configurations with H—C—N angles of 150°, 120°, and 90°, and on carbon dioxide in the linear configuration and bent configuration with O—C—O angle of 90°. The binding energy changes in various molecular orbitals on bending are used to interpret electronic spectra and are also compared with Walsh's curves.

Tous les calculs d'orbitales moléculaires d'électrons de valence ont été effectués sur l'acide cyanhydrique et le dioxyde de carbone en utilisant comme base minimum le système d'orbitales du type Slater par une méthode semi-empirique SCF-LCAO-MO décrite précédemment pour le formaldéhyde. Puisque plusieurs des états excités de ces molécules sont courbés, une série de calculs est effectués sur l'acide cyanhydrique dans la configuration linéaire et dans les configurations courbées avec des angles H—C—N de 150°, 120°, et 90° et sur le dioxyde de carbone dans la configuration linéaire et dans la configuration courbée avec un angle O—C—O de 90°. L'énergie de liaison varie suivant la courbure dans les différentes orbitales moléculaires qui sont utilisées pour interpréter les spectres électroniques et sont aussi comparées aux courbes de Walsh.

Canadian Journal of Chemistry, **50**, 653 (1972)

Introduction

Hydrogen cyanide and carbon dioxide are molecules for which there is available a fair amount of spectroscopic data, but there is only limited theoretical work. As many of the excited states of these molecules are highly bent (1–6), and as much of the experimental data are in the form of energies for 0–0 transitions, and also because by the presently available methods it is possible to calculate vertical transition energies only, a series of calculations has been conducted by varying the H—C—N and O—C—O angles in order to get a more comprehensive picture.

The calculations reported in this paper are all valence electron SCF-LCAO-MO calculations using minimum basis set of Slater-type orbitals to represent the atomic wave-functions. The method of calculation is the same as the best method described in the earlier paper on formaldehyde (7). For this method, the diagonal matrix elements $H_{\mu\mu}$ and the off-diagonal elements $H_{\mu\mu'}$ and $H_{\mu\nu}$ of the secular determinant may be represented by:

[1] $$H_{\mu\mu} = -W_\mu + \tfrac{1}{2}P_{\mu\mu}(\mu\mu|\mu\mu) + \sum_{\mu\neq\mu'}(P_{\mu'\mu'} - Z_{\mu'})[(\mu\mu|\mu'\mu') - \tfrac{1}{2}(\mu\mu'|\mu\mu')] + \sum_{\substack{\nu\neq\mu \\ \nu\neq\mu'}}[(P_{\nu\nu} - Z_\nu)(\mu\mu|\nu\nu)]$$

[2] $$H_{\mu\mu'} = -\tfrac{1}{2}P_{\mu\mu'}[(\mu\mu|\mu'\mu') - 3(\mu\mu'|\mu\mu')]$$

and

[3] $$H_{\mu\nu} = \beta_{\mu\nu} - \tfrac{1}{2}P_{\mu\nu}(\mu\mu|\nu\nu)$$

where $P_{\mu\nu}$ provide a description of electron distribution, $(\mu\eta|\nu\delta)$ represent Coulombic integrals of the type

$$\int \mu(1)\eta(1)\frac{e^2}{r_{12}}\nu(2)\delta(2)\,d\tau_1\,d\tau_2$$

The Greek letters μ and ν denote atomic orbitals on Atom A and any other atom B, respectively. The atomic orbitals with a prime, *e.g.*, μ', indicate any atomic orbitals of atom A, other than μ. W_μ is the ionization potential for orbital μ of the free atom A, Z_μ the number of electrons provided by orbital μ, and $\beta_{\mu\nu}$ is the resonance integral.

The basic integrals over atomic orbitals re-

*2s atomic orbitals on atom A are denoted by the symbol s, and 2p atomic orbitals by the symbol p unless their direction is to be specified, in which case they are denoted by x, y, z, σ, or π. A bar over p indicates an orbital at right angles to the 2p orbital without a bar.

quired for hydrogen cyanide and carbon dioxide are shown in Table 1. The basic molecular geometry and coordinate system for hydrogen cyanide is shown in Fig. 1 and that for carbon dioxide in Fig. 2; the z axis is perpendicular to the plane of paper in each case.

Discussion

A. Electronic Spectrum of Hydrogen Cyanide

Studies on the ultraviolet spectrum of hydrogen cyanide by Herzberg and Innes (1, 6, 8) and by Bancroft, Hollas, and Ramsay (9) show that the ground state of hydrogen cyanide is linear, and that there are three bent excited states, the

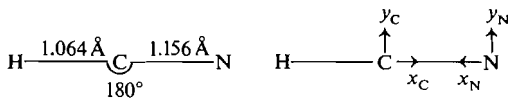

FIG. 1. Molecular geometry (21) and coordinate system for hydrogen cyanide.

α state which has symmetry A'' at about 6.5 eV, the β state with symmetry A'' at about 6.8 eV, and the γ state with symmetry A' at about 8.1 eV. Using the orbital diagram given by Walsh (10), the above five workers have identified the α state with the $^1A''$ state which arises from the bending of a linear $^1\Delta$ state (resulting from the π–π^* transition), and the γ state with the $^1A'$ state which arises from the bending of a linear $^1\Pi$ state (resulting from a n–π^* transition); however, they encountered difficulties in assigning the β state because according to Walsh's diagram (Fig. 3) all the other expected bent states have A' symmetry.

Herzberg and Innes (6, 8) have also reported a fourth excited state of hydrogen cyanide at about 8.9 eV, which we shall call the δ state. There is no indication as to whether this δ state is linear or bent and whether it is electronically of A' or A'' symmetry.

From the molecular orbitals for the linear molecule, and the hypothetical bent molecules with HCN bond angles of 150°, 120°, and 90° we have constructed an orbital diagram (Fig. 4) for hydrogen cyanide similar to that of Walsh (Fig. 3) for HAB molecules. The main difference between our results and Walsh's predictions is that the binding energy of the nonbonding orbital σ_3 actually increases with decrease in bond angle instead of decreasing as predicted by Walsh. Moreover, the binding energy of orbital σ_1, instead of remaining constant, also increases slightly with bending; and in the light of our results Walsh's prediction that there would be a large increase in binding energy on bending

[a]The nonbonding orbital denoted in this table by n is σ_3.

of one of the anti-bonding π orbitals seems to be somewhat exaggerated. These differences lead to the conclusion that all four excited states arising from π–π^* excitations are actually stabilized on bending (Table 2), so that there is another bent A'' state arising from the linear π–π^* excitation ($^1\Sigma^+$–$^1\Sigma^-$), which can perhaps be identified with the β state.

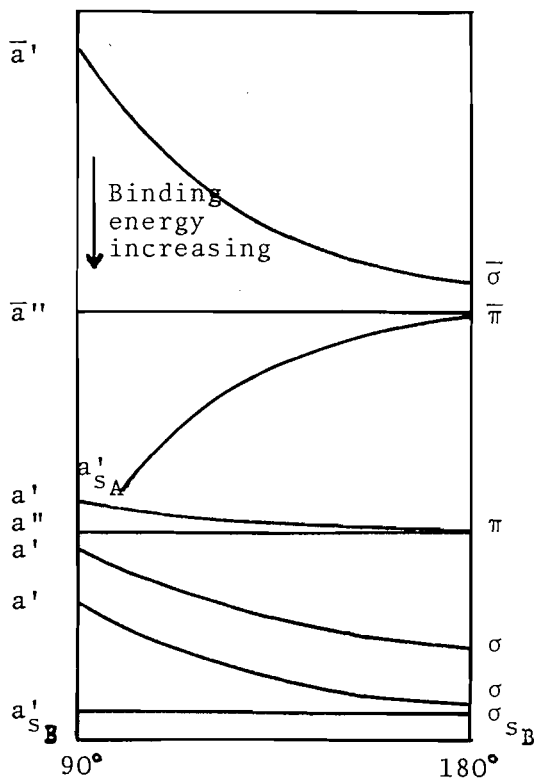

FIG. 3. Orbital diagram for HAB type molecules (from ref. 10).

The calculations for the electronic spectrum of hydrogen cyanide are summarized in Table 2. Note that all observed values of transition energies are for the 0–0 transitions from a linear ground state to a bent excited state, while the calculated values are either from a linear ground state to a linear excited state or from a hypothetical bent ground state to the corresponding bent excited state. This means that the reported

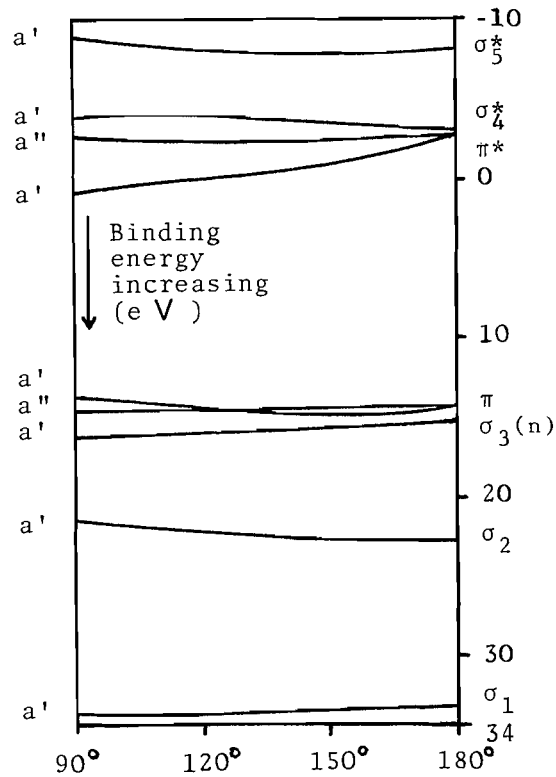

FIG. 4. Orbital diagram for hydrogen cyanide.

observed values contain an energy contribution equivalent to the energy difference between the linear ground state and the hypothetical bent ground state with the HCN angle corresponding to that of the equilibrium configuration of the excited state, in addition to the energy of transition from the hypothetical bent ground state to the corresponding excited state. Hence the lowest of the calculated values of a certain excitation energy should be slightly lower than the observed 0–0 value. The energies of the α and γ states fit very well with this expectation. The value given for the β state is for DCN, as the data for the corresponding system observed in HCN are rather fragmentary. The correct 0–0 value for the transition energy to the β state of HCN may possibly be slightly higher than for DCN, since the same trend is observed for the α states of HCN and DCN. Furthermore, the calculated value of 7.53 eV, which is higher than the observed 0–0 value for DCN, takes no account of stretching of the CH and CN bonds.

The δ state, if it should be bent and electronically of A' symmetry, could well be accounted for by the $^1A'$ state which results from the bending of the $^1\Pi$ state arising from the π–σ^* transition. If, on the other hand, the δ state is linear, it might arise from either the n–σ^* transition or the n–π^* transition depending on whether it is electronically A' or A'' (Table 2).

We may conclude, therefore, that this procedure of calculation can explain satisfactorily the observed spectral states of hydrogen cyanide to the extent that data are available.

B. Electronic Spectrum of Carbon Dioxide

The orbital diagram constructed from the molecular orbitals for the linear molecule and the hypothetical molecule bent to 90° is shown in Fig. 6 and compared with the general orbital diagram for BAB type molecules drawn by Walsh (11) and reproduced in Fig. 5. In the light of our calculation it appears that Walsh's view of the various changes in the orbital energies upon bending may be rather exaggerated. The main difference between our results and Walsh's predictions is that orbital $4\sigma_g$-a_1 favors a bent conformation instead of highly favoring the linear conformation as predicted by Walsh. Our results indicate that the $2\sigma_u$, $3\sigma_u$, ($1\pi_u$-b_1), $1\pi_g$, $5\sigma_g$ and $4\sigma_u$ orbitals favor the

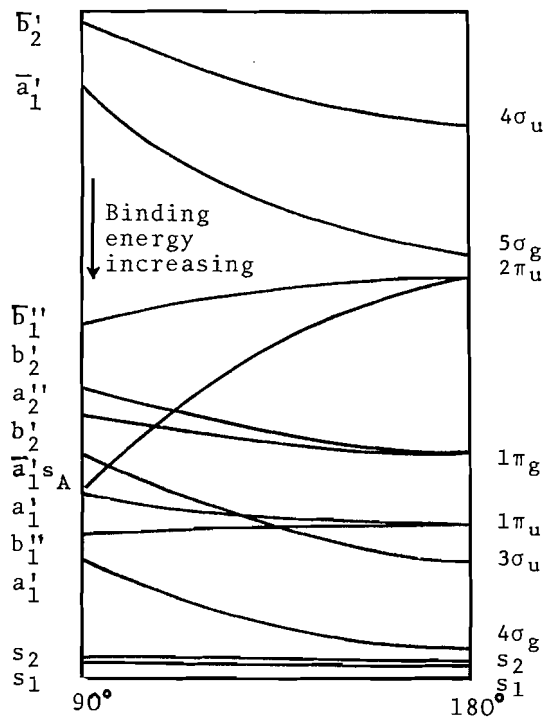

FIG. 5. Orbital diagram for BAB type molecules (from ref. 11).

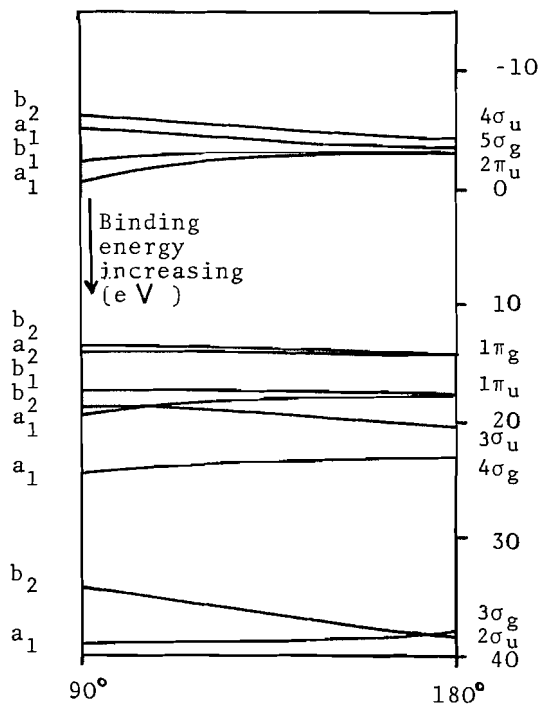

FIG. 6. Orbital diagram for carbon dioxide.

linear conformation while $3\sigma_g$, $4\sigma_g$, $(1\pi_u\text{-}a_1)$ and $2\pi_u$ orbitals favor the bent conformation. These differences lead to differences between our predictions about the stability of the linear or bent conformations of various states of the molecule and those made according to Walsh's scheme.

Carbon dioxide has been studied theoretically by Mulliken (12–15) and Mulligan (16). Mulliken's approach was to use a rough LCAO approximation coupled with experimental data and semi-empirical evidence. On this basis he predicted the various orbital energies for carbon dioxide (13). Mulligan (16) has conducted a more comprehensive and purely theoretical SCF-LCAO-MO calculation for linear carbon dioxide. The orbital energies obtained by Mulligan and the ones predicted by Mulliken are compared in Fig. 7 with the experimental values and the values obtained by the present semi-empirical SCF-LCAO-MO approach. Our calculation apparently gives the correct order for the orbital energies, in contrast with Mulligan's work where the order of $1\pi_u$ and $3\sigma_u$ orbitals is reversed. Experimental values have been reported by Tanaka, Jursa, and Le Blanc (17) and Tanaka and Ogawa (18).

Carbon dioxide does not show any absorption in the visible and near ultraviolet regions, but in emission, a group of bands is observed between 5000 and 3500 Å. Gaydon (2) suggested that the absence of any absorption bands in the visible and near ultraviolet regions may be due to the fact that the molecule is highly bent in its excited state. A detailed analysis of emission spectrum by Dixon (3) indicates a $^1B_2$ excited state with an O—C—O angle of about 122°; Dixon reports the 0–0 transition to this excited state to be at about 5.7 eV.

Price and Simpson (5) and Inn *et al.* (4) report two 0–0 transitions for the absorption systems between 1390 and 1220 Å to be at 8.99 and 9.06 eV and a vertical transition at about 9.3 eV. All of the bands in this region are weak and probably correspond to forbidden transitions becoming allowed upon bending.

There is a series of bands in the region starting at about 1750 Å and reaching a maximum at 1475 Å (4, 19, 20). The intensities and spacings of the bands are quite irregular. This system of bands is thought to contain a vertical transition at about 8.4 eV. Dixon (3) suggests that the upper state of this vertical transition may be the same as the upper state of the 0–0 transition at 5.7 eV.

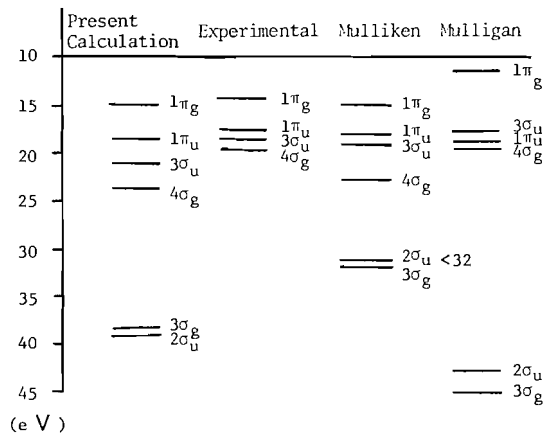

FIG. 7. Ionization energies for the ground state of carbon dioxide molecule. The values from the present calculation are compared with experimental values (17, 18), and those predicted by Mulliken (13), and by Mulligan (16).

Tanaka and Ogawa (18) and Tanaka *et al.* (17) have studied the short wavelength part of the spectrum and have classified transitions in Rydberg series starting at about 11.0 eV and converging to the various ionization potentials of carbon dioxide, and non-Rydberg series with 0–0 transitions at 10.6, 12.0 eV, and others at even higher energy.

Before we proceed to compare our results with the experimental spectrum, it may be of interest to contrast them with those obtained by the purely theoretical calculation of Mulligan (16) (Table 3).

All of our energy values are lower than those obtained by Mulligan for the corresponding transitions. This is what might be expected, since, as was seen for formaldehyde (7) and as is generally found to be the case, purely theoretical calculations give too high energy values for π–π^* and n–π^* transitions, sometimes as much as twice the observed value.

The results of the present calculations for the electronic spectrum of carbon dioxide are summarized in Table 4. The $1\pi_g \rightarrow 2\pi_u$ transition ($^1\Delta$–$^1B_2$) may correspond to the 0–0 transition at 5.7 eV, designated here as the α transition, and which has a bent upper state with $^1B_2$ symmetry, and the transition designated γ at 8.4 eV may correspond to the corresponding forbidden vertical transition; *i.e.*, as predicted by Gaydon

*The experimental spectrum contains the following transitions: 0–0 transitions at about 5.7 (designated α), 8.99 (designated β), 9.06 (designated β), 10.56, 10.64, and 11.98 eV; vertical transitions at about 8.4 (designated γ) and 9.3 eV (designated δ); Rydberg transitions at 10.98, 11.05, 11.38, 11.45, 12.31 eV and higher. A series of bands at 7.34, 7.41, 7.46, and 7.53 eV.

(2) and Dixon (3), the upper state of this transition is the same as the upper state of the 0–0 transition at 5.7 eV.

It should be noted that the 0–0 transition energy contains an energy contribution equivalent to the energy difference between the linear ground state and the hypothetical bent ground state, in addition to the energy of the transition from the hypothetical bent ground state to the corresponding excited state. On this basis then, two of the five configurations marked β should correspond to the upper state of the 0–0 transitions observed at 8.99 and 9.06 eV. Assignment with more certainty is not possible at the moment because the symmetry and geometry of the upper bent states of the observed transitions are not known. Three of the states marked β have $^1B_2$ symmetry.

The assignment of the α transition is in accord with the predictions of Walsh (11) and Mulliken (15). Mulliken (15) has assigned the 0–0 bands at 8.99 and 9.06 eV to the π_u–π_u^* transitions with upper states $^1\Delta_g$–$^1A_1$ and $^1\Sigma_g^-$–$^1B_1$; he has rejected Walsh's prediction that either corresponds to the $^1\Sigma_u^+$–$^1B_2$ state of the Π_g–Π_u^* transition on grounds of Mulligan's calculation and also because it is an allowed transition and thus should be intense.

Three of the states marked β, namely $^1\Sigma_u^+$, $^1\Pi_g^+$, and $^1\Pi_g^+$ resulting from $1\pi_g \rightarrow 2\pi_u$, $3\sigma_g \rightarrow$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$2\pi_u$, and $1\pi_g \rightarrow 5\sigma_g$ transitions, respectively, have $^1B_2$ symmetry in the bent form. Of the other two, $^1\Sigma_u^-$ resulting from $1\pi_g \rightarrow 2\pi_u$ has $^1A_2$ symmetry in the bent form and $^1\Delta_g$ resulting from $1\pi_u \rightarrow 2\pi_u$ has $^1B_1$ symmetry in the bent configuration. Since $^1\Sigma_u^+$ state of the $1\pi_g \rightarrow 2\pi_u$ transitions is an allowed transition and should be strong in intensity and since the observed bands are of weak intensity, it is safe to count this configuration out. However, more exact assignment has to await work on the symmetry of the upper states of these transitions.

The vertical transition designated δ at 9.3 eV may, however, be assigned with some confidence to the $^1\Pi_g^+$ states resulting from the $1\pi_g \rightarrow 5\sigma_g$ transition. If the upper state of this transition is the same as that of one of the transitions marked β, at least one of them may be assigned to the $^1B_2$ state from this transition.

The other higher transition energies calculated by us may correspond with some of the higher energy non-Rydberg series (17, 18) mentioned earlier.

Conclusion

We have shown that the spectra of HCN and CO_2 may be explained, using the same approach as was used earlier for CH_2O(7). The energies of the observed spectral states were explained satisfactorily, and some new assignments proposed. Further spectroscopic work needs to be done to show the reliability of our results. Two general conclusions that may be drawn from our work are that in any meaningful calculation of electronic spectra, it is not safe to ignore the σ electrons, and that in interpretation of spectra using Walsh's diagrams, it should be recognized that some of the predicted trends may be exaggerated.

Second Cross Virial Coefficients of Carbon Tetrachloride – Gas Mixtures Determined from Solubility Measurements at High Pressures[1]

S. K. GUPTA AND A. D. KING, JR.

Department of Chemistry, University of Georgia, Athens, Georgia 30601

Received August 31, 1971

The solubility of carbon tetrachloride in compressed helium, hydrogen, nitrogen, argon, methane, carbon dioxide, and ethylene has been measured over pressure ranges of 1–60 atm at temperatures ranging from −10 to 75 °C. Second cross virial coefficients representing carbon tetrachloride – gas interactions are evaluated from the data. It is shown that when allowance is made for the effects of quantum deviations and quadrupolar interaction on the critical temperatures and volumes of helium, hydrogen, and carbon dioxide, respectively, ordinary combining rules produce pseudocritical parameters which reduce all of the measured cross virial coefficients to a single function of reduced temperature. When reduced on a Boyle point basis, it is found that the data are best represented by virial coefficients corresponding to a 7-28 Mie type potential or a Kihara core potential having a core radius somewhat smaller than the carbon–chlorine bond length in carbon tetrachloride.

La solubilité du tétrachlorure du carbone dans l'hélium, l'hydrogène, l'azote, l'argon, le méthane, le dioxyde de carbone et dans l'éthylène comprimés a été mesurée, dans des domaines de pressions situés entre 1 et 60 atm, à des températures entre −10 à 75 °C. On a évalué les seconds coefficients croisés du viriel, qui représentent les interactions entre le tétrachlorure de carbone et le gaz, à partir des données. On démontre que, lorsque sont permis les effets de déviations quantiques et d'interaction quadrupolaire sur les volumes et températures critiques de l'hélium, de l'hydrogène et du dioxyde de carbone, respectivement, les règles ordinaires de combinaison produisent des paramètres pseudo-critiques qui réduisent tous les coefficients croisés du viriel en une fonction simple de température réduite. Quand on les réduit en se basant sur un point de Boyle, on trouve que les données sont mieux représentées par des coefficients du viriel correspondant à un type de potentiel 7-28 de Mie ou à un potentiel de noyau de Kihara ayant comme rayon du noyau une valeur sensiblement plus faible que la longueur de liaison chlore-carbone dans le tétrachlorure de carbone.

Canadian Journal of Chemistry, **50**, 660 (1972)

Introduction

Second cross virial coefficients are a potentially valuable source of information about the nature of intermolecular forces, both physical and chemical, that exist between molecules of different species in the gas phase.[1] They offer a considerable advantage over pure component virial coefficients as a means for studying intermolecular forces in that they allow one to investigate changes in potential energy brought about by selectively varying one member of a pair of interacting molecules while holding the other constant. This advantage is offset to some extent by the increased experimental difficulties encountered in making accurate determinations of cross virial coefficients of gaseous mixtures. In addition, second cross virial coefficients share a weakness common to all virial coefficients in that there is a wide range of temperature, encompassing the Boyle point, over which these coefficients are almost totally insensitive to the shape of the potential energy function describing the intermolecular interaction (2). Unfortunately, these temperature ranges often coincide with temperatures readily accessible in the laboratory.

Mixtures involving globular molecules such as the carbon tetrahalides, neopentane, etc., with simple gases are particularly attractive systems for studying intermolecular interactions between dissimilar molecules by virtue of the simple geometries involved. In a recent study of such a system, Douslin and co-workers determined very accurate values for the second cross virial coefficients of the tetrafluoromethane–methane system over temperatures spanning the Boyle point (3). They found that when reduced using pseudocritical constants derived from combining rules first propounded by Guggenheim and McGlashan (4), the cross virial coefficients did not satisfy the principle of corresponding states but rather deviated in a manner similar to that found for mixtures of neopentane, tetramethylsilane, and sulfur hexafluoride with methane (5). When the CF_4–CH_4 data were reduced on a Boyle point basis, however, the reduced cross virial coefficients followed the same corresponding states curve as

[1] An excellent review on this subject can be found in ref. 1.

those of the respective pure components. The Boyle point parameters of the CF_4–CH_4 system differed from the pseudo-Boyle point parameters generated using simple combining rules in a manner predicted by Hamann, who interpreted this as resulting from difference in shape of the potential functions describing the interaction between globular molecules and that for the small gas molecules (5).

In order to examine the nature of mixed interactions more fully, second cross virial coefficients of a related compound, carbon tetrachloride, with a series of light gases, have been determined from solubility measurements of CCl_4 in the respective gases. By limiting these measurements to systems involving one large globular molecule with a series of small gas molecules, geometric factors affecting the intermolecular potential can be expected to be reasonably constant, thus providing a more detailed picture regarding the role the smaller molecule plays in such interactions.

The experiments themselves are based upon the fact that the solubility of a liquid in a compressed gas is determined by two factors: variations in the fugacity of the liquid phase caused by hydrostatic pressure and dissolved gas, and deviations from ideal behavior in the fugacity of the liquid component in the gas phase. At the pressures of these experiments, concentrations of dissolved gas in the liquid phase are quite low so that the liquid phase exhibits ideal solution behavior. However, in the gas phase, deviations from ideality caused mainly by pair interactions between molecules of the liquid component and those of the gas are often quite significant. As a consequence, measurements of solubilities of liquids in compressed gases can be used to provide accurate values of second cross virial coefficients representing such deviations from ideality.

Experimental

The experimental technique used here for determining the solubility of CCl_4 in compressed gases is a modification of the method used by Prausnitz and Benson (6) and is described in detail in ref. 7. The method entails saturating the gas to be studied with CCl_4 vapor under pressure and subsequently expanding the high pressure vapor–gas mixture into a low pressure system where the CCl_4 vapor is removed from the gas stream by a series of cold traps maintained at -80 to -70 °C depending on the gas studied. The volume of the gas accompanying the vapor is measured with a wet test meter. In these experiments, the amounts of CCl_4 collected were relatively large, ranging from 0.5 to 8 g depending upon the temperature and duration of each run. The weights of CCl_4 collected in each cold trap were routinely examined to monitor the efficiency of the traps. The amount found in the last of the three traps averaged 0.4% and never exceeded 2% of the total weight collected. Before calculating mole fractions, each value for total weight recorded was corrected for losses of CCl_4 vapor under the assumption that the gas exiting the last trap was in equilibrium with solid CCl_4. These corrections seldom exceeded 1% except for the lowest temperature measurements (-10 °C) with hydrogen and helium where the calculated losses ranged up to 15% of the total CCl_4 trapped. In the lowest temperature runs with hydrogen, small but measurable amounts of water, as an impurity, were trapped out along with the CCl_4. Rather than prepurifying the hydrogen, impurity levels of water in the hydrogen were measured by passing large samples of the gas alone through the trapping section and the low temperature data for CCl_4 with hydrogen were corrected accordingly. The maximum correction occurred at -10 °C where it was estimated that 7% of the total weight collected was due to water vapor impurities in the hydrogen. At temperatures greater than 0 °C, the larger mole fractions of CCl_4 vapor made such corrections unnecessary. If each of these corrections is assumed correct to within 10%, the combined error in measured mole fraction amounts to about 2% for hydrogen at -10 °C. This has the effect of approximately doubling the error in second cross virial coefficient values over that found at higher temperatures.

Initial data taken at each temperature were examined for variations of measured CCl_4 concentration with flow rate indicating incomplete saturation. It was found that three equilibrium cells in series were necessary to insure saturation up to 25 °C, while two cells were sufficient for higher temperatures. Similarly, no trends with pressure were found in the cross virial coefficients calculated from the mole fraction data taken at different pressures.

The hydrocarbon gases used in these experiments (CP grade) were obtained from Matheson Co. Inc. The other gases, helium, hydrogen, nitrogen, and argon, were obtained from Selox Corp., having quoted purities of 99.995, 99.9, 99.9, and 99.995%, respectively. Reagent grade carbon tetrachloride was used in all experiments.

Results and Discussion

Under conditions where the concentration of gas dissolved in liquid carbon tetrachloride, X_1, is low, the vapor concentration of CCl_4, expressed as mole fraction Y_2, in equilibrium with the liquid phase is related to the total pressure P, by (6, 7)

$$[1] \quad Y_2 = \frac{(1 - X_1)P_2^0}{P}\left(\frac{\phi_2^0}{\phi_2}\right)\exp\left[\frac{V_2^{0(L)}(P - P_2^0)}{RT}\right]$$

Here $V_2^{0(L)}$ and P_2^0 are the molar volume and saturated vapor pressure of liquid CCl_4 at temperature T while ϕ_2^0 and ϕ_2 represent the fugacity coefficients of pure CCl_4 vapor and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

CCl_4 vapor in the dense gas, respectively. If contributions from third and higher virial coefficients are neglected, the fugacity coefficient of CCl_4 in a gaseous mixture can be expressed as

$$[2] \quad \ln \phi_2 = 2/V[Y_2 B_{22}(T) + Y_1 B_{12}(T)] - \ln Z$$

where Y_1 represents the mole fraction of diluent gas in the gas phase, V is the molar volume of the gas mixture, and the symbols $B(T)$ denote second virial coefficients representing deviations from ideality caused by pair interactions between species designated by the subscripts. Z is the compressibility factor for the gaseous mixture.

It is seen from eq. 1 that any given experimental measurement of the mole fraction of carbon tetrachloride vapor in some diluent gas at a known temperature and pressure and a knowledge of the liquid phase composition under these conditions are sufficient to evaluate the ratio of fugacity coefficients ϕ_2^0/ϕ_2. The second cross virial coefficient for this particular CCl_4–gas system can then be determined from this ratio through an iterative procedure using eq. 2 and a trial value of $B_{12}(T)$ in the appropriate virial expansions for V and Z to make initial estimates of these quantities. In the computations used here, gas fugacities along with

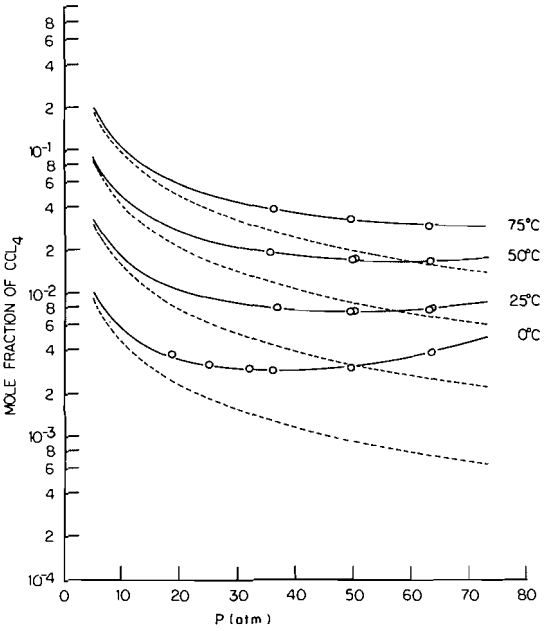

FIG. 2. Mole fraction of CCl_4 in methane as a function of pressure.

Henry's law constants obtained from data found in refs. 8 and 9 were used to calculate the mole fractions of dissolved gas, X_1 of eq. 1, as a function of pressure for the various gases used. In the case of helium for which no such data are available, it was assumed that the solubility of He in CCl_4 is the same as that in the physically similar liquid benzene (9). Because of the exceedingly low solubility of helium in these solvents, this approximation does not introduce any significant error in values of $B_{12}(T)$ derived from the experimental data. Values of pure component second virial coefficients used in eq. 2 are found in refs. 10–17.

The experimentally determined mole fractions of carbon tetrachloride vapor with the various gases studied are not tabulated here for the sake of brevity.[2] However, the data for two CCl_4–gas systems are shown graphically in Figs. 1 and 2. These systems were chosen because they illustrate the two limiting types of behavior exhibited by gaseous mixtures at high pressures. In Fig. 1, measured mole fractions of CCl_4 in He are compared with the hypothetical concentration of

CCl_4 that would exist if intermolecular forces were absent (calculated from eq. 1 letting $\phi_2^0/\phi_2 = 1$). It is seen that helium suppresses the vapor concentration, indicating that repulsive interactions exert a dominant role at these temperatures. In the case of CCl_4 with methane, Fig. 2, the opposite is true. Here attractive forces prevail, resulting in a significant enhancement of CCl_4 vapor concentration.

Second cross virial coefficients for the various carbon tetrachloride – gas mixtures have been calculated from the experimental mole fraction data and average values of these $B_{12}(T)$ are listed in column 3 of Table 1. With the exception of the −10 °C data discussed previously, the error limits quoted represent the average deviation from the mean. The cross coefficients are shown graphically in Fig. 3 along with values obtained previously by Prausnitz and Benson (6) for CCl_4 with H_2, N_2, and CO_2 at the higher temperatures. With the exception of nitrogen, the agreement between the data is seen to be reasonably good.

When compared with the data of Table 2, it is seen that with the exception of CO_2, the cross virial coefficients become more negative as the critical temperature and molecular polarizability of the gas increase as might be expected for mixed systems in which dispersion forces represent the dominant mode of attraction. The fact that CO_2 seems to have an unusually high critical temperature in comparison with the other gases, particularly ethylene, in Table 2, has been noted previously (18). This stems from the fact that carbon dioxide differs from the other gases of Table 2 in that its molecules, while not highly polarizable, possess a large quadrupole moment, so that angle dependent quadrupolar interactions play a significant role in determining its critical properties. As a result, experimental critical constants of CO_2 do not accurately reflect the extent to which carbon dioxide interacts with other molecules of systems in which dispersion forces predominate. It is possible, however, to make estimates of the critical temperature and volume that carbon

*Critical constant data are taken from ref. 33.
†Data taken from ref. 34.
‡Recommended values from ref. 35. Ethylene is assumed to be axially symmetric.
§Critical constants in parentheses for He, H_2, are "classical" values derived from reduced critical constants found in ref. 23.
‖Critical constants in parentheses for CO_2 reflecting dispersion contributions only from ref. 36.

dioxide would exhibit if quadrupolar interactions were absent using equations developed by Rowlinson and Cook (19, 20):

$$[3] \qquad T_e^c = T_0^c(1 + 2\delta^c)$$

$$[4] \qquad V_e^c = V_0^c(1 - \delta^c)$$

These equations relate the hypothetical critical temperature T_0^c, and volume V_0^c, that CO_2 would possess if dispersion forces alone were operative, to the corresponding experimentally determined properties T_e^c and V_c^c. The parameter δ^c, which serves as a measure of the importance of quadrupole–quadrupole forces relative to dispersion forces at the critical point has been assigned a value of 0.13 on the basis of independent thermodynamic data (18, 20). This value has been shown to be consistent with the directly measured value of the molecular quadrupole moment of carbon dioxide (21). Values for the hypothetical critical constants T_0^c and V_0^c, estimated from eqs. 3 and 4 with $\delta^c = 0.13$, are listed in parentheses after the experimental values for carbon dioxide. It is seen that they are intermediate with the values for methane and those of ethylene, as are the cross virial coefficients for this system.

A similar situation exists in the case of hydrogen and helium in that quantum effects significantly influence the physical properties of these substances at their critical points. For this reason, the experimental critical constants of these substances are inappropriate for correlating intermolecular interactions at higher temperatures where classical statistics prevail. "Classical" values for the critical constants of these compounds which do not reflect quantum effects can be readily derived by requiring that "classical" and experimental values for each critical constant be proportionate to the corresponding reduced quantities listed by de Boer (22). This procedure has an advantage over that used by Prausnitz *et al.* (23) for the purposes here in that no assumption is made regarding the critical compressibility factor in arriving at a classical estimate for the critical volume, although the values derived by each method are substantially the same. Classical values for critical temperatures and volumes of hydrogen and helium obtained in this manner are listed in parentheses in Table 2.

Figure 4 shows the graph that results when the data of Table 1 are plotted in reduced form using pseudocritical temperatures T_{12}^c, and volumes V_{12}^c, constructed according to the simple combining rules:

$$[5] \qquad T_{12}^c = (T_1^c T_2^c)^{1/2}$$

and

$$[6] \qquad V_{12}^c = \tfrac{1}{8}[(V_1^c)^{1/3} + (V_2^c)^{1/3}]^3$$

using quadrupole and quantum corrected critical constants for CO_2, He, and H_2. It is seen that the reduced cross virial coefficients correlate well in describing a single function of reduced temperature. The fact that the CO_2 data fall on this curve when the quadrupole corrected critical constants are used indicates that angle dependent interactions between CO_2 and CCl_4 make no

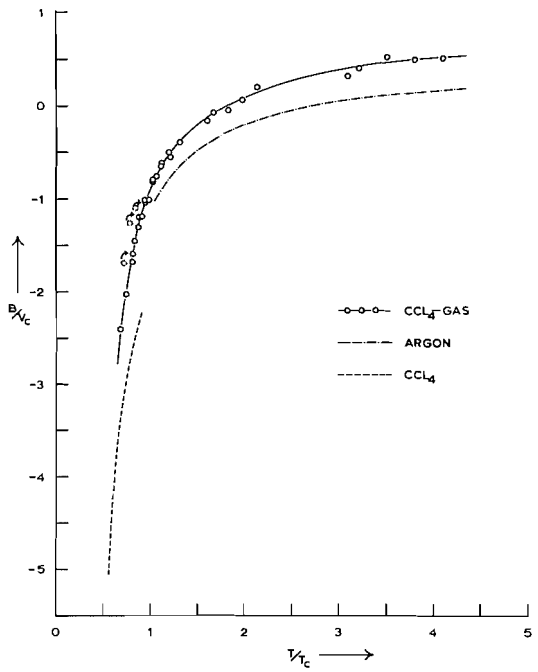

FIG. 4. Reduced virial coefficients as a function of reduced temperature. Broken circles denote CCl_4–CO_2 data reduced with uncorrected critical constants for CO_2.

significant contribution to the intermolecular potential energy. This is to be expected considering the weakness and short range nature of quadrupole – induced dipole and quadrupole–octupole forces. The broken lines shown in Fig. 4 represent the curves described by reduced pure component virial coefficients of CCl_4 and argon (taken as typical of the gases). Values recommended by Dymond and Smith (24) were used to generate these curves. It is apparent, as found by Hamann, Douslin, and co-workers (5, 3), that the virial coefficients for the mixed systems do not satisfy the principle of corresponding states but rather are displaced towards lower reduced temperatures from the pure component data.

Combining rules other than eqs. 5 and 6 were tested with these data under the assumption that a constant proportionality exists between the critical constants T^c and V^c and the respective molecular parameters ε and r^{*3} for all the pure substances involved; ε and r^* being the energy and distance parameters characterizing the interaction potentials of these pure substances. No improvement in the correlation among reduced cross virial coefficients resulted from using the Hudson and McCoubrey combining rule (25)

$$T_{12}^c = (T_1^c T_2^c)^{1/2} \frac{2(I_1 I_2)^{1/2}}{I_1 + I_2} \frac{2^6 V_1^c V_2^c}{[(V_1^c)^{1/3} + (V_2^c)^{1/3}]^6}$$

where I_i is the ionization potential of component i, and a decidedly poorer correlation resulted when the Fender and Halsey rule (26)

$$T_{12}^c = \frac{2T_1^c T_2^c}{T_1^c + T_2^c}$$

was used. Likewise, the use of a geometric mean combining rule for V_{12}^c (27) did not affect the scatter of data. The fact that neither the Hudson and McCoubrey combining rule nor the geometric mean combining rule for V_{12}^c affect the correlation among the reduced cross virial coefficients of the various CCl_4–gas pairs is not surprising considering the ratio of V_{12}^c calculated from a geometric mean to V_{12}^c of eq. 6 varies by only 15% in going from helium to ethylene.

Since the reduced virial coefficient data of Fig. 4 extend through the Boyle point, one can recast these data on a Boyle point reduction basis. In Fig. 5, the second cross virial coefficients

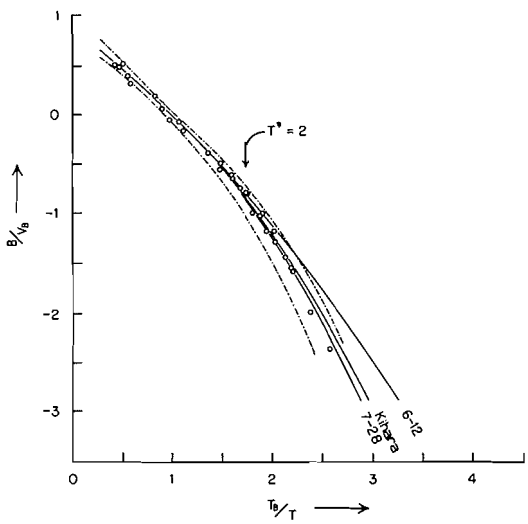

FIG. 5. Experimental data and virial coefficients calculated from various potentials reduced on a Boyle point basis. Dashed lines represent error bounds for the experimental data estimated from the standard error in the ratios relating Boyle point parameters to pseudocritical constants.

For personal use only.

reduced with the Boyle volume, $B_{12}(T)/V^{B}_{12}$, are shown plotted as a function of reciprocal reduced temperature. The transformation from Fig. 4 to Fig. 5 requires knowledge of the ratios V^{B}_{12}/V^{c}_{12} and T^{B}_{12}/T^{c}_{12}, where the Boyle temperature, T^{B}_{12}, is defined to be the temperature at which $B_{12}(T) = 0$ for a mixed system and the Boyle volume, V^{B}_{12}, is defined as

$$V^{B}_{12} = T\frac{dB_{12}(T)}{dT}\bigg|_{T=T_B}$$

These ratios were obtained through a least squares fit of a second degree polynomial to $B_{12}(T)/V^{c}_{12}$ data expressed as a function of T^{c}_{12}/T, yielding values of

$$T^{B}_{12}/T^{c}_{12} = 1.78 \pm 0.06$$

and

$$V^{B}_{12}/V^{c}_{12} = -(T^{c}_{12}/T)\frac{d(B_{12}(T)/V^{c}_{12})}{d(T^{c}_{12}/T)}\bigg|_{B_{12}(T)/V^{c}_{12}=0}$$

$$= 1.02 \pm 0.11$$

The family of curves in Fig. 5 represents the temperature dependence of reduced virial coefficients generated by various spherically symmetric potential functions. These curves clearly illustrate the point made by Klein (2) that second virial coefficients offer little discrimination between potential functions at temperatures greater than

$$T^* = T/(\varepsilon/k)_{6-12} = 2$$

The combining rules, eqs. 5 and 6, used to reduce the cross virial coefficients in Figs. 4 and 5 are, of course, empirical in nature. However, the fact that the reduced cross virial coefficients correlate well with the calculated curves over the entire range in the insensitive region ($T^* > 2$) of Fig. 5, gives one some confidence that they, in particular the combining rule for temperature, are appropriate for generating pseudoconstants representative of the energy and distance parameters of the interaction potential for dissimilar pairs. Outside the region of insensitivity (at temperatures lower than $T^* = 2$), the reduced cross virial coefficients describe a curve which approximates that generated by a 7-28 potential more closely than that of the more traditional 6-12 potential. Cross virial coefficients reduced using the Hudson–McCoubrey combining rule and those reduced using eq. 5 are indistinguishable within experimental error when recast on a Boyle point basis.

According to Pitzer's interpretation of the principle of corresponding states (28) in order for virial coefficients of a given class of compounds to correlate as a function of temperature: (*a*) the interactions between molecules must be described by a two-parameter potential function of the form

[7] $$\phi_{12}(r) = \varepsilon f(r^*/r)$$

with r^* and ε being distance and energy parameters characterizing the minimum of the potential well and, (*b*) the function, $f(r^*/r)$, must be the same for all members of a particular class. Since the data of Fig. 5 correlate well outside as well as inside the region of insensitivity, it can be inferred that carbon tetrachloride – gas interactions are adequately described by a single potential function of the form above and that a constant proportionality exists between the pseudocritical constants T^{c}_{12}, V^{c}_{12} of eqs. 5 and 6 and the corresponding molecular parameters ε, r^{*}[3], independent of the nature of the gas.

In previous studies concerning the properties of gaseous systems containing globular molecules, Hamann and co-workers (5, 29) proposed a specific potential function which is applicable, in principle, to these CCl_4–gas systems. According to this model, it is assumed that the overall interaction of two quasi-spherical molecules, or one such molecule and a small gas molecule, can be approximated by summing individual atom–atom interaction energies (assumed to be 6-12) and averaging the resulting potential over all orientations of the respective molecules. If it is assumed that the carbon tetrachloride and gas molecules differ in size to the extent that the polyatomic gases can be treated as being effectively monatomic in nature,[3] then according to the Hamann model, the potential function for the CCl_4–gas pairs becomes

[8] $$\frac{\phi_{12}(r)}{\varepsilon} = \left[C_1 + \frac{1}{5}\left(\frac{r^*}{\rho}\right)F_{10}\left(\frac{r^*}{r}\right)\right]\left(\frac{r^*}{r}\right)^{12} - \left[2C_1 + \left(\frac{r^*}{\rho}\right)F_4\left(\frac{r^*}{r}\right)\right]\left(\frac{r^*}{r}\right)^{6}$$

[3]This assumption is supported by the nearly identical values of the critical compressibility factors of the non-quadrupolar heavier gases; C_2H_4, CH_4, N_2, and Ar listed in Table 2.

where

$$F_n\left(\frac{r^*}{r}\right) \equiv \left\{ \frac{\left[1 - C_2\left(\frac{r^*}{r}\right)\right]^{-n}}{\left(\frac{r^*}{r}\right)} - \frac{\left[1 + C_2\left(\frac{r^*}{r}\right)\right]^{-n}}{\left(\frac{r^*}{r}\right)} \right\}$$

and

$$C_1 = \frac{\varepsilon'}{\varepsilon} \qquad C_2 = \frac{\rho}{r^*}$$

Here ρ is the carbon–chlorine bond distance in CCl_4 (taken to be 1.77 Å), r^* and ε are the force constants describing the interaction of gas molecules with the peripheral chlorine atoms of CCl_4, with ε' being the force constant characterizing interactions involving the central carbon atom and the gases.

Equation 8 satisfies the conditions outlined by Pitzer provided, (*a*) C_1 and C_2 are independent of the nature of the gas and (*b*) ε and r^{*3} are proportional to T^c_{12} and V^c_{12}, respectively. The London formulation of dispersion forces suggests that it is reasonable to expect C_1 to be constant; furthermore for values of C_1 ranging between 0 and 2, the overall potential function is almost totally insensitive to the value assigned to C_1. Thus, according to this model, CCl_4 molecules behave as if they consist only of chlorine atoms distributed symmetrically about the center of mass so that only parameters characterizing the chlorine atoms and their distribution in space are significant in determining the shape of the overall potential. The ratio, C_2, is just such a parameter and, as expected, the shape of the potential well of eq. 8 is considerably more sensitive to changes in this parameter. It is difficult to see how C_2 can remain constant independent of the gas involved since estimates of r^* based on collision radii listed in ref. 30 suggest that C_2 might be expected to vary some 30% in going from helium to ethylene. Nevertheless it will be assumed on the basis of the correlations in Figs. 4 and 5 that r^* takes on a constant value, taken to be 3.3 Å, the arithmetic mean of the van der Waals radius of the chlorine atom listed by Hildebrand (31) and that for argon found in ref. 30. It is seen in Fig. 6 that the potential function of eq. 8, calculated with

$$C_2 = \frac{1.77 \text{ Å}}{3.3 \text{ Å}} = 0.54$$

and C_1 equal to unity, indeed more nearly approximates the 7-28 potential than the broader well of the 6-12 potential. It is also seen in Fig. 6 that a Kihara core potential of the form

$$[9] \qquad \phi(r) = \varepsilon\left[\left(\frac{r^*}{r-a}\right)^{12} - 2\left(\frac{r^*}{r-a}\right)^{6}\right]$$

where a denotes the core radius of CCl_4, also approximates the 7-28 and Hamann potentials when the ratio $a/r^* = 0.413$. A comparison of this ratio to the ratio $\rho/r^* = 0.54$ of eq. 8 taken as typical for these CCl_4–gas systems indicates that a core radius 25% shorter than the C—Cl bond length is appropriate for describing these mixed interactions. This "shrinkage" reflects the effect of multiple attractions by peripheral chlorine atoms which are absorbed by the core radius when the Kihara core model is used to represent carbon tetrachloride–gas interactions. This decrease in core radius is virtually identical to that predicted (28) and later found (32) by Pitzer and Danon for interactions between globular molecules themselves. This suggests

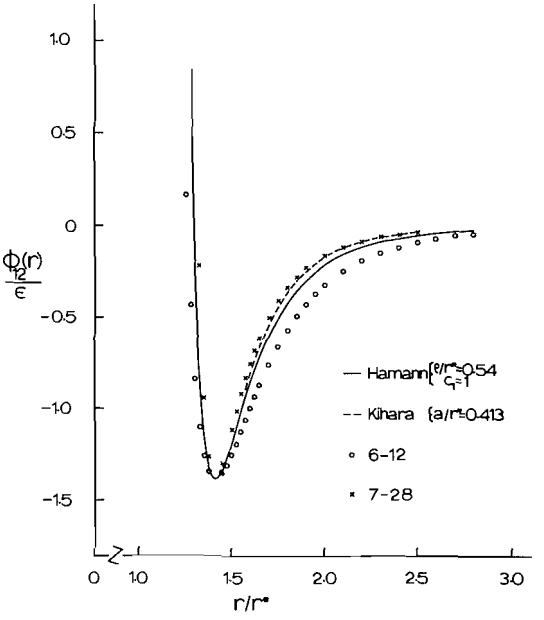

FIG. 6. Potential functions generating reduced second virial coefficients denoted by solid lines in Fig. 5.

that while less shrinkage occurs in globular molecule – gas interactions than when two globular molecules interact, it is accommodated by one rather than two cores, with the result that the core radii characterizing the globular molecule in these two types of systems are the same. Thus, through such cancellation effects, core radii take on the role of a true molecular parameter for the types of systems considered here.

2,4-Diazapentadienes. I. Prototropy, Cyclization, and Addition–Elimination

D. H. HUNTER AND S. K. SIM
Department of Chemistry, University of Western Ontario, London, Ontario

Received August 26, 1971

The preparations and reactions of a series of 1,3,5-triaryl-2,4-diaza-1,3-pentadienes (**1**) have been investigated. Products of cyclization (**2** and **4**), prototropy **3** and addition–elimination (**5**, **6**, and **7**) have been characterized. Also, the preparations and reactions of **3**, a new isomer of **1**, have been studied.

Les préparations et les réactions d'une série de triaryl-1,3,5 diazo-2,4 pentadiènes-1,3 (**1**) ont été étudiées. Les produits de cyclisation (**2** et **4**) de prototropie **3** et d'addition–élimination (**5**, **6**, et **7**) ont été caractérisés. On a également étudié les préparations et les réactions de **3**, un nouvel isomère de **1**.

Canadian Journal of Chemistry, **50**, 669 (1972)

Introduction

It was noted as early as 1837 (1) that benzaldehyde reacts with ammonia to produce the unique trimeric product, hydrobenzamide **1***a*. The observation of the isomerization of hydrobenzamide upon heating to form amarine **2***a* was reported in 1844 (2). While benzaldehyde was the first material studied, the generality to aromatic aldehydes of both these reactions was soon established.[1] A third isomer, isoamarine **4***a*, obtained by treatment of amarine under basic conditions was recognized in 1859 (4). The structural assignments came later (5). Since early investigations, hydrobenzamides **1** have been studied as gasoline antioxidant agents (6), as chelating agents (7), and for chemiluminescence properties (8). Similarly amarines **2** and isoamarines **4** have been studied for chemiluminescence (9), as precursors to the *d*-, *l*-, and *meso*-stilbene-diamines (10) and to the lophines (11).

The mechanism of formation of the hydrobenzamides **1** has received some attention (12), but the conversion of the hydrobenzamides **1** to amarines **2** has been essentially neglected (13). During the course of an investigation of this latter process, it has been possible to extend our understanding of the structures and reactions of these and related compounds. It is this aspect which is presented here and the mechanistic details of the hydrobenzamide **1** to amarine **2** interconversion are in the following article (14).

[1]For example, one of the earliest *chemical* works of Alexander Borodin reported on the reactions of the "cuminols" to form the isopropyl substituted hydrobenzamide and amarine. (3)

Results and Discussion

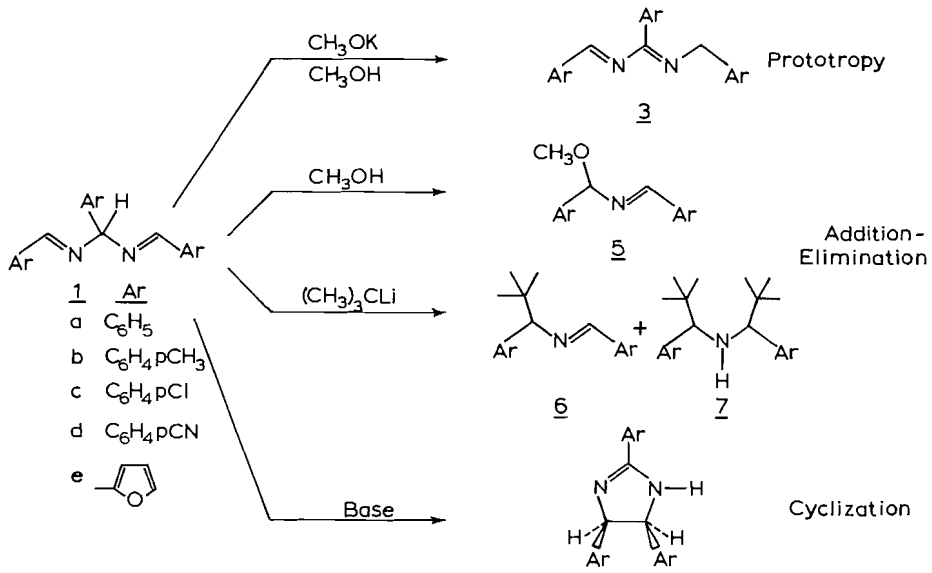
The preparations, structures, and reactions of the 1,3,5-triaryl-2,4-diaza-1,4-pentadienes (**1**) and of its isomers will be discussed and will be presented under separate headings for each isomer. Details of n.m.r. and i.r. spectra are to be found in the Experimental.

1,3,5-Triaryl-2,4-diaza-1,4-pentadienes (1)

Preparative procedures for **1** with various substituents have been numerous but all involve in essence the reaction of an aromatic aldehyde with ammonia with yields in the 50–80% region. As a complicating feature, **1** is prone to base-catalyzed reactions and thus the more acidic derivatives (*e.g.* **1***c* and *d*) must be generated under buffered conditions.

A rigorous structure assignment for **1** has not been made but only one geometric isomer of **1** has been obtained for each. Since the n.m.r. spectrum shows but one type of azomethine proton (15), the most likely configuration for **1** is the *anti,anti* form; *syn–anti* interconversions should be slow (16).

The reactions of **1** are summarized in Scheme 1 and can be placed in three categories: prototropy, addition–elimination, and cyclization. The cyclization reaction of **1**, as mentioned in the Introduction, was one of the first reactions observed but had long been considered a thermal reaction. The catalytic effect of amide ion had been noted but only in passing (17). We have found that there is indeed a relationship between reagent base strength and reaction rate consistent with base-catalysis. Thus the following provide preparative conditions for



SCHEME 1

2*a*: 0.5 *M* potassium *t*-butoxide–*t*-butanol at 25°, 0.1 *M* potassium amide–ammonia at −30°, and 0.8 *M* phenyllithium–THF at −80°.

The effect of substituents on **1** is also indicative of base-catalysis. Whereas the phenyl compound **1***a* reacts slowly at −80° with phenyllithium–THF, the *p*-cyanophenyl compound **1***d* reacts rapidly at −130°. The sensitivity of **1** to base is important preparatively; the *p*-chlorophenyl **1***c* and *p*-cyanophenyl **1***d* compounds are prepared under buffered conditions to avoid subsequent cyclization of the products.

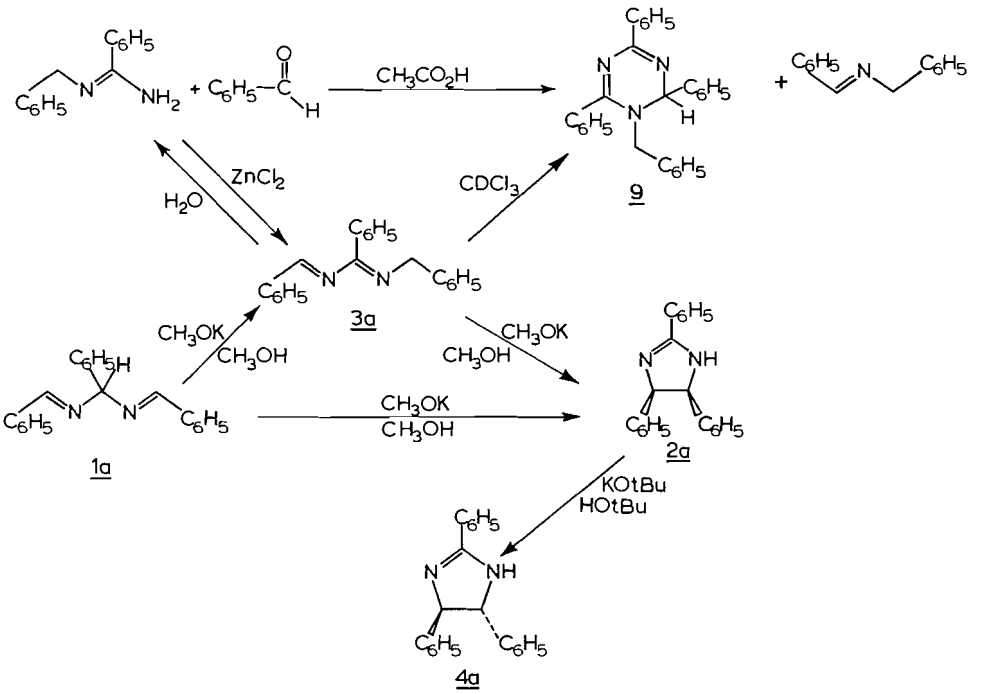
A unique feature of the reaction of **1***a* with potassium methoxide–methanol was the observation of a fourth and new isomer of **1** produced in significant amounts (~50%). This compound **3** apparently arises from a base-catalyzed 1,3-proton shift and the chemistry of **3** will be discussed further under a separate heading.

In contrast to the reaction in potassium methoxide–methanol, when **1***a* is refluxed in methanol for moderate periods of time, good yields (~70%) of *N*-benzylidene-α-methoxybenzylamine (**5**) are obtained. This would appear to be an acid-catalyzed reaction since **5** is not observed under basic conditions even when the base-catalyzed reactions are proceeding slowly. The overall reaction can be viewed as addition of methanol and elimination of benzaldehyde imine although the detailed process is probably more complicated.

Another marked change in reaction pathway occurs when comparing the reactions of phenyllithium and *t*-butyllithium. When **1***a* is treated with phenyllithium in THF at −80°, the only observable[2] product is **2***a*. However, with *t*-butyllithium in threefold excess in THF at −80° an 88% yield of *N*,*N*-di-(α-*t*-butylbenzyl)-amine **7** was obtained. The mixture of diastereomers was in the ratio of 12 to 1 as judged by n.m.r. With 1 equiv of *t*-butyllithium, 60% of *N*-benzylidene-α-*t*-butylbenzylamine (**6**) could be observed by n.m.r. and a 22% yield of α-*t*-butylbenzylamine could be isolated after hydrolysis. Thus the relative rates of the proton abstraction and addition reactions of **1***a* change by a factor of about 10^3 when changing from phenyllithium to *t*-butyllithium.

Complicated structure–reactivity relationships are observed for the addition reactions of organolithiums to carbon–carbon double bonds and have been interpreted in terms of varying states of aggregation and varying reactivity of the reagent (18). The ability of the nitrogen lone pair in **1** to act as a Lewis base towards the organolithium aggregates may well enhance the addition reactions relative to the proton abstraction reaction of the more agglomerated *t*-butyllithium and result in the observed changes.

[2]As much as 0.5% of the addition–elimination product analogous to **6** may be produced.



SCHEME 2

1,3,5-Triaryl-2,4-diaza-1,3-pentadienes (3)

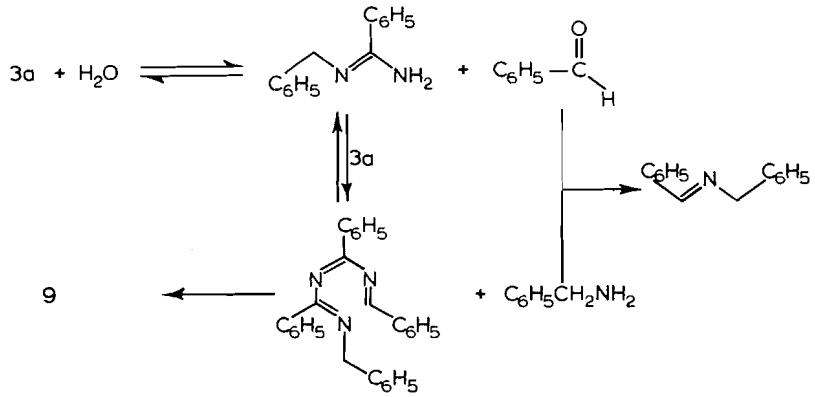
Examples of the C=N—C=N system are rare (19) and the observation of the base-catalyzed interconversion of **1***a* to **3***a* is the first example of prototropy in a 2,4-diazapentadiene system. The cyclization and prototropy of **1***a* are in close competition in CH_3OK–CH_3OH at 60° and **3***a*/**2***a* are produced in a ratio of 0.9. Both **3***b* and *c* have also been observed by n.m.r. when **1***b* and *c* were reacted in methanol–methoxide and the ratio of prototropy to cyclization proved to depend upon the substituent. Thus **3***b*/**2***b* were produced in a ratio of 1.2 and **3***c*/**2***c* in 0.5. While both **2** and **3** are also isomerized by base (Scheme 2) the conditions required are more severe than for the isomerization of **1**. Thus **3***a* reacts about 10^3 slower than **1***a* in CH_3OK—CH_3OH at 60° and **2***a* requires refluxing KO*t*Bu–HO*t*Bu.

The structure of **3***a* was deduced by i.r., n.m.r., mass spectrum, combustion analysis, and was verified by an independent synthesis. The structures of **3***b* and *c* were assigned on the basis of their n.m.r. spectra and by isolation of the *p*-substituted *N*-benzylbenzamidines after hydrolysis. The configuration is presumably *anti,anti*.

Distinctly different reactions are observed for **3***a* when it is treated with acid or with base. Base leads to cyclization with exclusive formation of **2***a*, whereas under apparently acidic conditions **3***a* appears to be converted to a triazine derivative **9** and *N*-benzylidenebenzylamine. The structure of **9** was verified by an independent synthesis. Experimentally **9** was observed as the decomposition product of **3***a* when n.m.r. samples were allowed to stand (*e.g.* $CDCl_3$ for three days) and **3***a* is the probable intermediate in the conversion of N-benzylidenebenzylamine and benzaldehyde into **9** when refluxed with acetic acid in benzene (Scheme 3).

2,4,5-Triarylimidazolines (2 and 4)

The preparative reactions for the *cis*-4,5-diarylcompounds (**2**, amarines) and the *trans*-4,5-diarylcompounds (**4**, isoamarines) are interesting from both a synthetic and a mechanistic point of view since each is formed quite selectively (<1 and <5% of the other cyclic isomer, respectively). Thus each diastereomer is obtained cleanly and in reasonable yield even though the preparations of both involve base-catalysis. The preparation of **2** from **1** requires



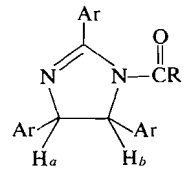
SCHEME 3

mildly basic conditions which depend upon the nature of the aromatic substituent while **4** is produced from **2** using considerably more vigorous conditions (*e.g.* KO*t*Bu–HO*t*Bu at reflux). Both **2** and **4** are sensitive to air oxidation which results in the production of lophines and thus the reactions must be carried out in an inert atmosphere.

The conversion of **2** to **4** by equilibration with base possibly involves the carbanion generated by abstraction of the benzylic proton. As expected **4** (*trans*-aryl groups) is greatly favored in the equilibrium mixture. Solutions of either **2** or **4** in 0.41 *N* potassium *t*-butoxide–*t*-butyl alcohol were heated to 100° for 18 and 30 h respectively, and then analyzed by n.m.r. The same mixture was obtained from either; 4% of **2** and 96% of **4**. The mechanism of the conversion of **1** to **2** is the subject of the following article.

The assignment of the configurations of **2** and **4** has been most rigorously demonstrated for amarine **2***a* and isoamarine **4***a*. The structure proofs have involved degradation to the stilbenediamines (10), synthesis from the stilbenediamines (5*a*) and, most convincingly, resolution of **4***a* (5*b*). As the results in Table 1 show, the methine–methine proton coupling constants for the *N*-benzoyl derivatives of **2***a* and **4***a* strongly support the assigned structures (20) and thus provide a basis for assignments to the other examples of **2** and **4**. A satisfying consistency between preparative procedure and coupling constants is observed for the *p*-chlorophenyl and α-furanyl compounds supporting both.

TABLE 1. Methine–methine coupling constants for the derivatives of **2** and **4**



Compound	J_{AB}
2*a*	8.4
2*c*	8.6
2*e*	8.6
4*a*	3.4
4*c*	3.9
4*e*	2.6

Experimental

The i.r. spectra were obtained with a Beckman IR-10. The n.m.r. spectra ($CDCl_3$ or CCl_4) were run on Varian HA-100, T-60, or A-60 spectrometers using internal TMS. Mass spectra were obtained using a Varian M-66 mass spectrometer. Melting points and boiling points are uncorrected. Microanalyses were run by A. B. Gygli, Toronto and Chemalytics, Inc., Tempe, Arizona.

1,3,5-Triaryl-2,4-diaza-1,4-pentadienes (1)

A variety of procedures has been used to prepare the various substituted hydrobenzamides **1**. Hydrobenzamide **1***a* was obtained in 84% yield (m.p. 101–102; lit. (10) 101–102°) from benzaldehyde in liquid ammonia. The i.r. (CCl_4) showed C=N at 1640 cm^{-1}. Concentrated ammonium hydroxide was used with *p*-tolualdehyde to yield 66% of material **1***b* (m.p. 88–90; lit. (21) 91°; i.r. C=N at 1630 cm^{-1}) and with furfuraldehyde to yield 46% of product **1***e* (m.p. 116–117; lit. (17) 115°). The i.r. showed C=N at 1635 cm^{-1}.

TABLE 2. The n.m.r. parameters for 1,3,5-triaryl-2,4-diaza-1,4-pentadienes

	Proton shift δ			
Aryl group	Aromatic	Azomethine	Methine	Methyl
Phenyl	7.7 (4H,m) 7.3 (11H,m)	8.4 (1H,s)	5.9 (1H,s)	
p-Tolyl	7.7 (4H,d) 7.4 (2H,d) 7.1 (6H,m)	8.4 (1H,s)	5.9 (1H,s)	2.3 (9H,s)
p-Chlorophenyl	7.8 (4H,d) 7.4 (8H,m)	8.4 (1H,s)	5.9 (1H,s)

Buffered solutions of ammonium hydroxide with ammonium chloride were used for *p*-chlorobenzaldehyde to produce **1***c* (50% yield; m.p. 84.5–85.5; lit. (12) 87–90°; i.r. C=N at 1635 cm^{-1}) and *p*-cyanobenzaldehyde to produce **1***d* (54% yield; m.p. 116.5–117; lit. (12) 130–132°). The i.r. showed C≡N at 2240 cm^{-1} and C=N at 1640 cm^{-1}.

The n.m.r. parameters for the hydrobenzamides **1** are given in Table 2.

2-cis-4,5-Triarylimidazolines (Amarines, 2)

(a) Phenyllithium in Tetrahydrofuran

The reaction of **1***a* typifies this procedure. A sample of **1***a* (2.5 g, 8.4 mmol) in 45 ml of freshly distilled THF at −78° under an argon atmosphere was reacted with 20 ml of 0.82 *M* phenyllithium in THF (16.4 mmol). The reaction mixture was allowed to warm to room temperature (*ca.* 2 h) and then 1.0 g (16.6 mmol) of acetic acid was added. After solvent evaporation, the residue was dissolved in ether and washed three times with water. After drying, the amarine **2***a* was precipitated as the hydrochloride by bubbling in excess dry hydrochloric acid. The precipitate was washed and dried to yield 99% of material m.p. 260–265°.

Compound **2***a* was recovered by reacting the hydrochloride with excess sodium hydroxide in aqueous THF. After the usual ether–water extraction process, the residue was recrystallized from ether to yield 80% of material m.p. 127–128° (lit. (10) 129–130°).

In this manner, the *p*-tolyl compound **2***b* (m.p. 126–128, lit. (21) 127°) was obtained in 42% yield upon recrystallization from 1:1 carbon tetrachloride–petroleum ether. The *p*-chlorophenyl **2***c*, compound upon recrystallization from carbon tetrachloride, was obtained in 78% yield (m.p. 176–177°).

The n.m.r. parameters for the amarines, **2**, are given in Table 3.

Anal. Calcd. for $C_{21}H_{15}N_2Cl_3$: C, 62.78; H, 3.78; N, 6.97. Found: C, 62.83; H, 3.66; N, 6.92.

(b) Potassium Amide in Liquid Ammonia

The phenyl **2***a* and α-furanyl **2***e* derivatives were prepared using the following procedure. A sample of **1***a* (3 g, 10 mmol) was added gradually to a refluxing solution of 150 ml of 0.1 *N* potassium amide in liquid ammonia. After stirring at reflux for 1 h, the ammonia was allowed to evaporate and the residue was dissolved in ether which was washed with water, dried, and solvent evaporated. The residue was recrystallized from petroleum ether to give a 63% yield.

Analogously the α-furanyl **2***e* compound was obtained in 60% yield (m.p. 115–116, lit. (17) 116°) upon recrystallization from benzene.

(c) Ammonium Hydroxide

The more acidic derivatives of **1** such as the *p*-chlorophenyl compound **1***c* could be cyclized with concentrated ammonium hydroxide by proceeding directly from the aldehyde to the imidazoline **2***c* without isolating the intermediate. Thus *p*-chlorobenzaldehyde (215 g, 1.5 mol) was heated at 50° for 10 h with 400 ml of concentrated NH_4OH. The resulting oil was dissolved in ether. The ether layer was extracted with 10% KH_2PO_4 solution (3 × 200 ml), then washed with water, dried, and evaporated to dryness. The product was recrystallized from carbon tetrachloride to give 92 g (45% yield) of product.

(d) Dimethylsulfoxide

A solution of **1***d* (7.2 g, 19 mmol) in 50 ml of dimethylsulfoxide was heated for 0.5 h on the steam bath and then poured into water. The precipitate was filtered and recrystallized from 95% ethanol to yield 59% of product which melted at 222–224° with decomposition.

Although a satisfactory combustion analysis was not obtained, the mass spectrum showed a parent peak at *m/e* of 373.

TABLE 3. The n.m.r. parameters for the 2-cis-4,5-triarylimidazolines (**2**)

*1,3,5-Triphenyl-2,4-diaza-1,3-pentadiene (**3**)*

(a) Isolation

A sample of **1***a* (20 g, 67 mmol) was stirred 20 h at room temperature in 200 ml of 0.5 *N* potassium methoxide–methanol. After solvent removal the residue was dissolved in 150 ml of ether and extracted ten times with 100 ml of 1 *M* KH_2PO_4 to remove the imidazoline **2***a*. The residue, after drying and solvent removal, was recrystallized from petroleum ether to yield 20% of product **3** (m.p. 82–84°).

Anal. Calcd. for $C_{21}H_{18}N_2$: C, 84.53; H, 6.08. Found: C, 84.51; H, 6.09.

The n.m.r. spectrum ($CDCl_3$) showed the azomethine proton as a singlet $\delta = 8.2$ (1H), the aromatic protons as multiplets (4H at 7.9 and 11H at 7.5), and the methylene protons as a singlet at $\delta = 4.7$ (2H). The i.r. spectrum showed the C=N stretches at 1635 and 1615 cm^{-1}.

(b) Synthesis

Benzaldehyde (5 g, 48 mmol) and *N*-benzylbenzamidine (22) (10 g, 48 mmol) and 0.2 g of a zinc chloride–*N*-benzylbenzamidine complex were refluxed for 8 h in 50 ml of toluene using a Dean–Stark water trap. After filtration and solvent removal the residue was recrystallized from about 100 ml of petroleum ether (60–80) to yield 40% of crude product m.p. 65–70°. Repeated recrystallization from pentane yielded material of m.p. 82–84°. Admixture with the material isolated previously showed no m.p. depression.

The zinc chloride complex was prepared by precipitation with water from a solution of 1 g *N*-benzylbenzamidine in 5 ml of ethanol and 5 ml of saturated aqueous zinc chloride.

(c) Hydrolysis

The reaction mixtures obtained by treating **1** with methanol–potassium methoxide were hydrolyzed by adding a large excess of water to the methanol solution and stirring for an additional 60 h at room temperature. The product mixture which contained **2**, the aromatic aldehyde, and the substituted *N*-benzylbenzamidine was extracted with ether which was washed twice with water and then with saturated $NaHCO_3$ to selectively remove the *N*-benzylbenzamidine. Treatment with base and extraction with ether yielded material of m.p. 72–73° (lit. (23) 77–78°) for the phenyl compound, material of m.p. 130–132° for the *p*-tolyl-compound and material of m.p. 123–124° for the *p*-chlorophenyl compound.

Anal. Calcd. for $C_{15}H_{18}N_2$: C, 80.61; H, 7.40. Found: C, 80.63; H, 7.61.

Anal. Calcd. for $C_{14}H_{12}N_2Cl_2$: C, 60.23; H, 4.33; N, 10.04. Found: C, 60.51; H, 4.15; N, 10.04.

*2-trans-4,5-Triarylimidazolines (Isoamarines, **4**)*

Except for the tricyano compound all the substituted imidazolines were prepared by approximately the same procedure. To a degassed solution of about 0.2 *N* potassium *t*-butoxide in *t*-butyl alcohol under an argon atmosphere was added an imidazoline to produce about a 0.1 to 1 *M* solution. After reflux for up to 13 h with t.l.c. monitoring, the reaction mixture was extracted with ether–water, the organic layer dried and evaporated.

The *p*-tolyl compound was obtained in 48% yield on recrystallization from 75% ethanol (m.p. 168–169°). The i.r. ($CHCl_3$) showed NH at 3400 and C=N at 1610 cm^{-1}.

Anal. Calcd. for $C_{24}H_{24}N_2$: C, 84.67; H, 7.11. Found: C, 84.83; H, 7.02.

Isoamarine (the phenyl compound) was obtained in 59% yield on recrystallization from 70% ethanol (m.p. 194–196°, lit. (10) 198–201°). The i.r. ($CHCl_3$) showed NH at 3420 and C=N at 1620 cm^{-1}.

The *p*-chlorophenyl compound was obtained in 69% yield on recrystallization from benzene (m.p. 193–194°).

TABLE 4. The n.m.r. parameters for the 2-*trans*-4,5-triarylimidazolines

Aryl group	Proton shift δ			
	Aromatic	Methine	Amine	Methyl
Phenyl	8.0 (2H,m) 7.4 (3H,m) 7.3 (10H,s)	4.9 (2H,s)	5.3 (1H)	
p-Tolyl	7.8 (2H,d) 7.2 (2H,d) 7.1 (8H,s)	4.8 (2H,s)	5.1 (1H)	3.4 (3H,s) 3.3 (6H,s)

p-Cyanophenyl	8.2 (2H,d) 8.0 (2H,d) 7.8 (4H,d) 7.5 (4H,d)	5.1 (2H,s)	4.5 (1H)	
α-Furanyl	7.5 (1H,m) 7.4 (2H,m) 7.1 (1H,d) 6.5 (1H,m) 6.3 (4H,s)	5.2 (2H,s)	5.0 (1H)	

TABLE 5. Properties of *N*-benzoyl- and acetylimidazolines

Parent compound	Melting point (°C)	Analysis								C=N cm^{-1}
		Calculated				Found				
		C	H	N	O	C	H	N	O	
2*a*	179	83.58	5.47	6.97	3.93	83.76	5.49	7.07	4.12	1620
4*a*	177–178	83.58	5.47	6.97	3.93	83.72	5.50	6.95	4.16	1620
2*c*	151–152	66.48	3.79	5.54		66.28	3.93	5.57		1620
4*c*	88–90	66.48	3.79	5.54		65.47	4.15	5.51		1620
2*e**	140–142	65.79	4.55	9.03		65.69	4.65	9.02		1630
4*e**	114–116	65.79	4.55	9.03		65.53	4.69	8.79		1630

*These are the *N*-acetyl derivatives; other results are the *N*-benzoyl derivatives.

The i.r. ($CHCl_3$) showed NH at 3400 and C=N at 1620 cm^{-1}.

Anal. Calcd. for $C_{21}H_{15}N_2Cl_3$: C, 62.78; H, 3.78; N, 6.97. Found: C, 62.55; H, 3.71; N, 6.86.

Isofurfurine (the α-furanyl compound) was obtained in 56% yield on recrystallization from 70% ethanol (m.p. 138–139°, lit. (24) 143°). The i.r. ($CHCl_3$) showed NH at 3410 and C=N at 1630 cm^{-1}. The *p*-cyanophenyl compound was prepared in an analogous procedure from tricyanoamarine except methanol – 0.34 *N* potassium methoxide was used with a 2 h reflux period. After the usual work-up a 30% yield of material m.p. 222–223° was obtained after recrystallization from 95% ethanol. A mass spectrum gave a parent ion peak at 373 *m/e* although a satisfactory combustion analysis was not obtained. The i.r. (Nujol) showed NH at 3360, C≡N at 2240, and C=N at 1605 cm^{-1}.

The n.m.r. parameters for the isoamarines **4** are given in Table 4.

N-Benzoylimidazolines

A mixture of 1 equiv of benzoyl chloride with 2 equiv of the substituted imidazoline in benzene (*ca.* 0.1 *M* solutions) was refluxed 1 h and then cooled. The precipitated hydrochloride was removed by filtration and the solvent evaporated. Petroleum ether was used for recrystallization and yields in the 70–90% range were obtained. Acetyl derivatives were prepared using acetyl chloride. The properties of both the benzoyl- and acetylimidazolines are given in Table 5. The n.m.r. parameters for the *N*-benzoylimidazolines are given in Table 6.

N-Benzylidene-α-methoxybenzylamine (5)

Compound **1***a* (10 g, 33 mmol) was refluxed in 100 ml of methanol for 2.5 h and the excess methanol was then film evaporated. Distillation of the residue yielded 5.2 g (70% yield) of product of b.p. 120° at 0.025 mm of Hg.

Anal. Calcd. for $C_{15}H_{15}NO$: C, 79.97; H, 6.71; N, 6.22. Found: C, 80.33; H, 6.77; N, 6.27.

TABLE 6. The n.m.r. parameters for *N*-benzoylimidazolines

	Proton shift δ			
		Methine		
Aryl group	Aromatics	A	B	J_{AB}
cis-Phenyl	7.80 (2H,m) 7.20 (18H,m)	5.74	5.56	8.4
trans-Phenyl	7.70 (2H,m) 7.30 (18,m)	5.30	5.24	3.4
cis-p-Chlorophenyl	7.70 (2H,d) 7.20 (15H,m)	5.63	5.57	8.6
trans-p-Chlorophenyl	7.70 (2H,d) 7.30 (15H,m)	5.15	5.07	3.9
cis-α-Furanyl	7.59 (1H,d) 7.21 (2H,m) 7.08 (1H,d) 6.55 (1H,m) 6.19 (4H,m)	5.67	5.51	8.6
trans-α-Furanyl	7.56 (1H,m) 7.40 (2H,m) 7.10 (1H,m) 6.52 (1H,m) 6.34 (4H,m)	5.54	5.31	2.6

In the n.m.r. spectrum ($CDCl_3$) the azomethine proton appeared as a singlet at δ 7.4 (1H), the aromatic protons as a multiplet 7.8 (2H) and as a multiplet 7.3 (8H), the methoxy protons as a singlet 2.3 (3H), and the benzyl proton as a singlet 5.5 (1H).

The i.r. spectrum (neat liquid) showed the C=N stretch at 1640 cm^{-1}.

α-t-Butylbenzylamine

To a degassed solution at −78° of **1***a* (3 g, 10 mmol) in 100 ml of THF, under an argon atmosphere was added slowly 5.5 ml (1.82 *M*, 10 mmol) of commercial *t*-butyllithium solution. The reaction mixture was quenched with excess water after being stirred 1 h at −78° and warming to room temperature. After solvent removal the residue was dissolved in ether, washed twice with water, the solution was dried and solvent evaporated. At this stage n.m.r. indicated the following mol %: 14% **1***a*, 10% **2***a*, 59% **6**, and 17% **7**.

Chromatography of this mixture on silica gel using 5% ether–pentane as eluent yielded a sample of the *N*-benzylidene-α-*t*-butylbenzylamine; m.p. 69–70° (lit. (25) m.p. 70.5 °C).

Anal. Calcd. for $C_{18}H_{21}N$: C, 86.01; H, 8.42. Found: C, 86.15; H, 8.31.

In the n.m.r. spectrum ($CDCl_3$) the azomethine proton appeared as a singlet δ 8.3 (1H), the aromatic protons as a multiplet (2H at 7.9 and 8H at 7.5), the benzyl proton as a singlet 4.0 (1H), and the *t*-butyl protons as a singlet 1.0 (9H).

The i.r. spectrum ($CHCl_3$) showed the C=N stretch at 1645 cm^{-1}.

The original reaction mixture also was hydrolyzed by stirring for 12 h in 10% hydrochloric acid and the acid solution was extracted with ether and again with ether after neutralization. This latter ether solution was dried, solvent evaporated, and the residue vacuum distilled to yield 22% of product (b.p. 40° at 0.025 mm lit. (26) 110–112 at 11 mm).

N,N-Di(α-t-butylbenzyl)amine (7)

Following the procedure reported above for α-*t*-butylbenzylamine, **1***a* (1 g, 3.3 mmol) was reacted with *t*-butyllithium (1.82 *M*, 5.5 ml, 10 mmol). The product was separated from the reaction mixture by chromatography with silica gel (50 g) using 2% ether in pentane. Vacuum distillation (b.p. 110° at 0.05 mm Hg) yielded 88% of product which was apparently about 12:1 mixture. In the n.m.r. of the major component of the diastereomers, the phenyl protons appeared as a broad singlet δ 7.2 (10H), the benzyl protons as a singlet 3.9 (2H), the amine proton as a broad singlet 2.0 (variable; 1H), and the *t*-butyl protons as a singlet at 0.90 (18H). The minor component showed a signal at δ 3.2 (benzyl proton) and at 0.95 (*t*-butyl protons).

The i.r. spectrum showed a very weak band at 3380 cm^{-1} for the N—H stretch (27).

Anal. Calcd. for $C_{22}H_{31}N$: C, 85.38; H, 10.10. Found: C, 85.54; H, 10.17.

1-Benzyl-2-hydro-2,4,6-triphenyl-s-triazine (9)

(a) Isolation

N-Benzylbenzamidine (10 g, 48 mmol), benzaldehyde (5 g, 48 mmol), and 2 ml of acetic acid were refluxed in 30 ml of benzene for 72 h. After a work-up involving ether–water extraction the residue contained *N*-benzylidenebenzylamine and **9**. Distillation under reduced pressure yielded 54%

of *N*-benzylidene-benzylamine (b.p. 100° at 0.025 mm, lit. (28) b.p. 122 at 0.5 mm) whose n.m.r. spectrum (CCl_4) showed the azomethine proton as a singlet at δ 8.30 (1H), the aromatic protons as multiplets at 7.70 (2H) and 7.30 (8H), and the methylene protons as a singlet 4.77 (2H). The distillation residue was recrystallized from 50% ethanol to yield 62% of material m.p. 135–136°.

The n.m.r. spectrum ($CDCl_3$) showed the aromatic protons as multiplets at δ 8.3 (2H) and 7.4 (18H), the methine proton as a singlet at 6.0 (1H), and the methylene protons as an AB quarter (δ_A 5.0, δ_B 4.1, and J_{AB} = 14 Hz).

The i.r. spectrum showed CH stretch at 3080, 2980 and C=N at 1610 cm^{-1}.

(b) Synthesis

2,4,6-Triphenyl-*s*-triazine was obtained in 88% yield from benzonitrile with chlorosulfonic acid (29). Upon recrystallization from toluene, material of m.p. 230–232° (lit. (29) m.p. 232°) was obtained.

1,2-Dihydro-2,4,6-triphenyl-*s*-triazine was prepared by lithium aluminum hydride reduction of 2,4,6-triphenyl-*s*-triazine (30). A 12% yield of material m.p. 170–172° (lit. (30) m.p. 175–177°).

The title compound was prepared by adding benzyl-chloride (0.58 ml, 5 mmol) to a degassed tetrahydrofuran solution (20 ml) of 1,2-dihydro-2,4,6-triphenyl-*s*-triazine (1.55 g, 5 mmol) that had been reacted with 1 equiv of 0.62 *N* phenyllithium–THF. Stirring for 12 h at room temperature showed incomplete reaction and the reaction mixture was then refluxed for 4 h. The solvent was evaporated and the reaction mixture extracted with ether–water, dried, and solvent evaporated. Chromatography on silica gel with 1:1 ether–pentane and recrystallization yielded 40% of material m.p. 142–143°.

Anal. Calcd. for $C_{28}H_{23}N_3$: C, 83.76; H, 5.59; N, 10.47. Found: C, 84.24; H, 5.59; N, 10.01.

Admixture of this material with the previously isolated material showed no m.p. depression.

The authors wish to thank the National Research Council of Canada for their financial assistance.

2,4-Diazapentadienes. II. A Carbanion Cyclization

D. H. HUNTER AND S. K. SIM
Department of Chemistry, University of Western Ontario, London, Ontario

Received August 26, 1971

The mechanism of the cyclization and 1,3-proton shift of 1,3,5-triaryl-2,4-diaza-1,3-pentadienes (**1**) catalyzed by phenyllithium and by potassium methoxide–methanol has been studied. On the basis of substituent effects, hydrogen–deuterium exchange, isotope effects, and solvent effects, it was deduced that both the cyclization and prototropy involve a common W-shaped carbanion which rapidly cyclizes. A kinetic deuterium isotope effect of 2 was calculated for protonation of this intermediate carbanion in methanol.

On étudie le mécanisme de cyclisation et de migration-1,3 de proton dans les triaryl-1,3,5 diaza-2,4 pentadiènes-1,3 (**1**) catalysées par le phényllithium et par le méthylate de potassium-méthanol. En se fondant sur les effets des substituants, de l'échange hydrogène–deutérium, des effets isotopiques et des effets de solvant, il en a été conclu que la cyclisation ainsi que la prototropie impliquent un carbanion commun en forme de W qui se cyclise rapidement. Un effet isotopique cinétique du deutérium d'une valeur de 2 a été calculé pour la protonation dans le méthanol de ce carbanion intermédiaire.

Canadian Journal of Chemistry, **50**, 678 (1972)

Introduction

The reaction of benzaldehyde with ammonia to form hydrobenzamide **1** and the 'thermal' isomerization of **1** to amarine **2** must stand among the first organic reactions studied (1). Yet surprisingly little attention has been paid to these and related molecules especially from a mechanistic point of view (2). Particularly intriguing to us was the highly stereoselective cyclization of **1** to form **2**, the cyclic isomer with the phenyl rings *cis* to each other. Since the preliminary report (3) which noted that this reaction was base-catalyzed and in which orbital symmetry was invoked, the study of this reaction using phenyllithium in THF has been further elaborated. Also the study has been extended using methanol–methoxide and examples of **1** substituted *p*, *p'*, *p''* in an attempt to obtain a more complete understanding of this reaction. The preparations, reactions, and structural assignments for **1** and related compounds have been described in the preceding article (4). As an example of the nomenclature to be used in the following sections, *p*-CH_3-**1** will refer to the tris-*p*-methyl substituted hydrobenzamide (1).

Results and Discussion

As indicated in Scheme 1, the cyclization of **1** to **2** is catalyzed by a variety of bases (4) (e.g. KO*t*Bu–HO*t*Bu at room temperature) and produces **2** highly selectively (< 1% of **4**). The *cis–trans* interconversion of **2** to **4** requires more vigorous conditions (*e.g.* KO*t*Bu–HO*t*Bu at reflux) thereby allowing a study of the base-catalyzed reactions of **1** under conditions where **2** is not reactive. The equilibrium mixture of **2** and **4** in *t*-butyl-alcohol at 100° contains 96% of **4** and 4% of **2** as might be expected.

Reactions with Phenyllithium

The results of treating **1** and its derivatives with phenyllithium in tetrahydrofuran are gathered in Table 1. As run 3 indicates, when **1** is reacted with an equivalent of phenyllithium at −78° and then warmed to room temperature, only **2** is observed by t.l.c. and n.m.r. in the reaction mixture and an 80% yield of **2** can be

isolated. As seen in runs 1 and 2, where the entire reaction was run at $-78°$ and quenched with excess acetic acid at the times indicated, the reaction is proceeding slowly and the rates are not highly reproducible except that not more than 1% of **4** is produced.

These observations can be generalized to *p*-CH_3, *p*-Cl, and *p*-CN-**1** (runs 4, 5, and 6) although there is a definite substituent effect upon the observed rate of reaction. This is exemplified by run 6 where *p*-CN-**1** is completely consumed in 1 min. The apparent order of reactivity is *p*-CN-**1** > *p*-Cl-**1** > **1** > *p*-CH_3-**1**.

The singular feature of all these reactions was the appearance of an intense color when the phenyllithium reagent was added. The color varied with the substituent and the visible spectrum obtained for **1** showed a long wavelength absorption maximum at 592 nm. The color faded to a light yellow when the reaction mixture was warmed to ambient temperature. It is tempting to ascribe the color to an anionic intermediate in the cyclization reaction and in an attempt to assess this hypothesis three experimental approaches were used: (*a*) quenching with CH_3CO_2D; (*b*) quenching with CH_3CO_2H with careful product analysis; and (*c*) irradiation of the colored solution. These are summarized in Scheme 2.

Runs 7, 8, and 9 report on the results obtained when the colored solutions obtained from **1**, *p*-Cl-**1**, and *p*-CN-**1** were quenched with CH_3CO_2D before complete conversion had occurred. Again the accelerating effect of the cyano grouping is observed (run 9), for even at $-130°$, with immediate quenching (at 1 min) about 50% reaction had occurred. The reaction mixtures were analyzed for deuterium incorporation into **1** and surprisingly none could be detected (<0.15 atoms D/molecule). These results require that the rate of proton abstraction from **1** by phenyllithium be slow at these temperatures and also if significant quantities of anionic intermediate are generated that quenching does not lead back to **1**.

In an attempt to obtain further information on the character of the possible carbanionic intermediate, the colored solutions obtained from **1** and *p*-Cl-**1** were quenched while cold after a short reaction period (run 14 for *p*-Cl-**1**) with excess acetic acid. An examination of the reaction product by n.m.r. revealed that about 1% of *p*-Cl-**3** was present and on work-up a sample of *N*-*p*-chlorobenzyl-*p*-chlorobenzamidine was isolated. The n.m.r. spectrum of the reaction mixture from **1** did not show **3** but a trace of *N*-benzylbenzamidine was observed upon hydrolysis.

The base-catalysis, the substituent effect, the color, and the quenching results with CH_3CO_2H all support the intermediacy of an anion generated by proton abstraction from **1**. However, from the small amounts of **3** and *p*-Cl-**3** isolated and from the lack of deuterium incorporation into **1** upon quenching with CH_3CO_2D, the concentration of anion must be small but still large enough to give an intense color. Assuming an extinction coefficient of about 10^5 (5), amounts of anion in the 1 to 0.001% range are suggested.

As further evidence of an anionic intermediate, the colored solution due to the reaction of **1** was irradiated with appropriate filters to isolate the long wavelength absorption band (runs 10, 11, 12, and 13). For the first time significant amounts of **4** now appeared and up to 10% of **4** in the cyclized products could be obtained by extended irradiation at −78°. The relative amount of **4** obtained was temperature dependent and by −20° the thermal cyclization of the anionic intermediate was sufficiently facile to exclude significant photochemical reaction. As reported in runs 15 and 16, both **2** and **4** are largely unaffected by irradiation under these conditions.

In summary, the reactions with phenyllithium suggest that the cyclization of **1** to **2** can occur through a carbanionic intermediate whose concentration is never large. This intermediate is formed by proton abstraction and can be trapped by protonation or irradiation. These results are summarized in Scheme 2.

Reactions with Methanol–Methoxide

A study of the reactions of **1** and substituted-**1** in methanol–potassium methoxide (0.02–0.2 M) mostly at 60° was made primarily in an attempt to further characterize any intermediates in the **1** to **2** conversion. As shown in Scheme 3, **3** was now observed as well as **2** and, as indicated by runs 17, 18, 19, 20, 21, and 22 of Table 2, **3** and **2** were produced in similar amounts although the ratio did depend upon the substituent.

The reaction proved to be first order in **1** over the range of concentrations studied, and as runs 18, 19, and 20 show both the ratio of **3** to **2** and the second order rate constant were reproducible within experimental error. From runs 17, 22 and runs 24 and 25 of Table 3, it is clear that electron-withdrawing substituents

have an accelerating effect upon the rate of reaction. Using the data of runs 17–22 and σ values, a ρ of 3.8 is calculated for the trisubstituted molecule.

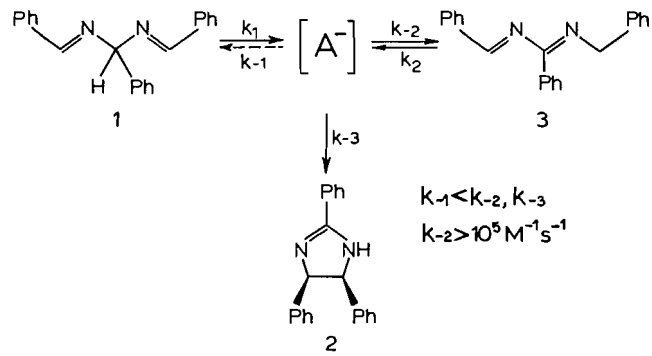
Treatment of **3** under the reaction conditions results in production of **2** but at a rate about 600 times slower than **1**. Thus for most reactions of **1** reported here, any **3** produced should not react further to any significant extent.

By analogy with the extensive studies on allylic, pentadienyl (7), and particularly the azallylic systems (8), the conversion of **1** to **3** must certainly involve an intermediate carbanion. The behavior of this intermediate was investigated using methanol-*O*-*d* and these results are included in Table 3. Of particular interest are runs 29, 35, and 37, for analysis of the recovered **1** for deuterium incorporation showed no observable uptake (<0.05 atom *D*/molecule) at >40% conversion. When **3** was analyzed for deuterium (run 29), only 0.86 atoms *D*/molecule were present showing that the isomerization had occurred with a low degree of intramolecularity (9). These results are consistent with an anionic intermediate(s) which protonates preferentially at the end carbon to yield **3** over **1**. Once formed, **3** returns to the anion considerably more slowly as evidenced by slow deuterium uptake and cyclization (runs 30 and 31). Thus the reaction of **1** can be studied under conditions where the products **2** and **3** are not significantly reactive.

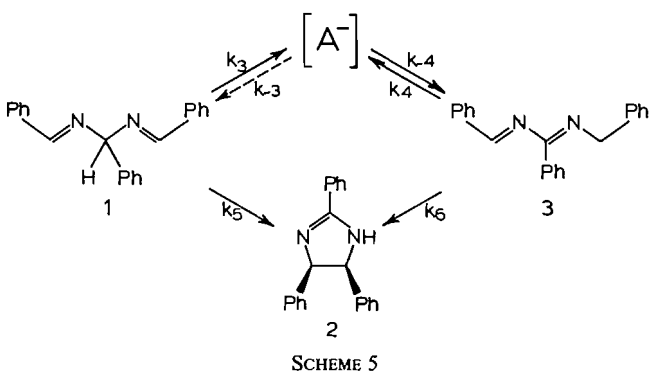
Reaction Schemes 4 and 5

One of the mechanisms considered, Scheme 4, has **1** lead only into a carbanion or carbanions which competitively reprotonate or cyclize. Since reprotonation (k_{-2}) should be occurring with rate constants of about 10^6 s^{-1} or greater in methanol (10), this scheme requires the cyclization rate constant (k_{-3}) to also be of this order of magnitude. This is several orders of magnitude greater than the rate constants which have been observed for electrocyclizations of other carbanions (*e.g.* heptatrienyllithium, 10^{-3} s^{-1} at $-30°$ (11); cyclooctadienylpotassium or -lithium, 10^{-5} s^{-1} at 30° (12); and pentadienyl not at all (13)) and thus the second mechanism was considered carefully.

In Scheme 5, the carbanions serve merely to



SCHEME 4



SCHEME 5

For personal use only.

interconnect **1** and **3**, and **2** arises from **1** not through an intermediate but a transition state. Thus possibly certain conformations of **1** would be more appropriate for cyclization with a bonding interaction across the 1 and 5 carbons occurring as the methine proton is being abstracted.

In an attempt to differentiate between these seemingly feasible mechanisms, the following results were obtained and analyzed.

Substituent Effects on the 3/2 Ratio

As the results of runs 17–22 and 25[1] indicate, the ratio of **3/2** depends upon the substituents in a systematic fashion with the more electron-withdrawing substituents resulting in a lower **3** to **2** ratio. Considering Scheme 5 first, the rate constants that determine the **3** to **2** ratio are k_3 and k_5. It would seem unlikely that both k_3 and k_5 would respond to the same degree to changes in the substituent. Delocalization at the 1, 3, and 5 positions should stabilize the full charge that is developing in the anion more than in the transition state leading to **2** which has bonding developing across the terminal carbons. Thus this scheme would predict that the **3** to **2** ratio should increase with more electron-withdrawing groups contrary to the observation.

In Scheme 4, the ratio of **3** to **2** is determined by k_{-2} and k_{-3}. How k_{-3} would respond to substituent is uncertain but it does not seem unreasonable that k_{-2} would decrease as the anion becomes more stabilized. Thus Scheme 4 does not seem inconsistent with the observations and the substituent effects favor the mechanism in which both the prototropy and cyclization proceed through carbanionic intermediates (Scheme 4).

Solvent Isotope Effect on the 3/2 Ratio

As summarized in Table 4, when methanol is replaced by methanol-*O*-*d*, the ratio **3/2** drops by about a factor of 2 for *p*-CH_3-**1**, **1**, and *p*-Cl-**1**. Returning to Scheme 5, the ratio of **3** to **2** is determined by k_3 and k_5 of which neither should be directly affected by the solvent isotope. In Scheme 4, k_{-2} and k_{-3} are the important kinetic parameters and while the solvent is not directly involved in k_{-3}, the step which determines k_{-2} is reprotonation in which the OH or OD bond of solvent is being broken. In going from CH_3OH to CH_3OD, k_{-2} should be reduced to the extent of the primary isotope effect. Thus Scheme 4 is consistent with the results of Table 4 and a solvent isotope effect of about 2 is observed.

TABLE 4. Ratio of **3/2** obtained in methanol and methanol-*O*-*d* at 60°

Runs	Substrate	Solvent	**3/2**
17	*p*-CH_3-**1**	CH_3OH	1.2
35, 36	*p*-CH_3-**1**	CH_3OD	0.5
18–20	**1**	CH_3OH	0.8
26–29	**1**	CH_3OD	0.4
22	*p*-Cl-**1**	CH_3OH	0.5
37	*p*-Cl-**1**	CH_3OD	0.3

Effect of Methanol Concentration on the 3/2 Ratio

In a further attempt to distinguish between Schemes 4 and 5, the effect of diluting the methanol solvent with dimethylsulfoxide was observed and these results are collected in Table 5. As can be seen from runs 20, 38, 39, and 40, as the percentage of dimethylsulfoxide is increased from zero to 80 weight %, the ratio **3/2** drops to about zero. Runs 41 and 42 demonstrate that with 80 weight % dimethylsulfoxide, **3** is being rapidly converted to **2** but at a rate sufficiently slow to indicate that in run 40, the amount of **3** produced must still be quite small.

The effect of added dimethylsulfoxide in methanol should be twofold: the concentration of methanol is reduced and also the ΔpK_a between the methanol and substrate should be reduced, resulting in a reduced rate of reprotonation (10). Applying this reasoning to Scheme 5 where k_3 and k_5 are product determining suggests that both should be increased similarly by the enhanced basicity of the methoxide. However, in Scheme 4, while k_{-3} should be unaffected, k_{-2} should be systematically reduced as dimethylsulfoxide is introduced.

Again the experimental results are in accord with Scheme 4. Important, however, is the observation that **2** is produced to the exclusion of **4** and thus, any anionic intermediates generated must find their way to **2** alone.

Exchange and Cyclization of 3

If Scheme 4 is obeyed and there is a common anionic intermediate for cyclization and reprotonation, then the same k_{-2} and k_{-3} should be observed starting from either **1** or **3**. Since $k_{-1} < k_{-2}$, k_{-3}, the ratio k_{-2}/k_{-3} can be

[1]As run 24 indicates, *p*-CN-**1** is so reactive that triethylenediamine was used as base. Controls were not run on *p*-CN-**3** but presumably it is still less reactive than *p*-CN-**1**.

calculated directly from the **3**/**2** ratio when **1** is the reactant. When **3** is the reactant k_{-2}/k_{-3} must be estimated from the rate of exchange of **3** relative to the rate of cyclization. The details of this calculation are included in the Appendix but in essence the results of runs 30 and 31 where **3** was reacted in CH_3OD were used to calculate the k_{-2}/k_{-3} ratio.

Beginning with **1** in CH_3OD, the k_{-2}/k_{-3} ratio is 0.4 and with **3** as substrate the ratio is 0.3 ± 0.1. The agreement is sufficiently good to again support Scheme 4. Scheme 5 is not inconsistent with these results but would require the fortuitous equality $k_3/k_5 = k_4/k_6$.

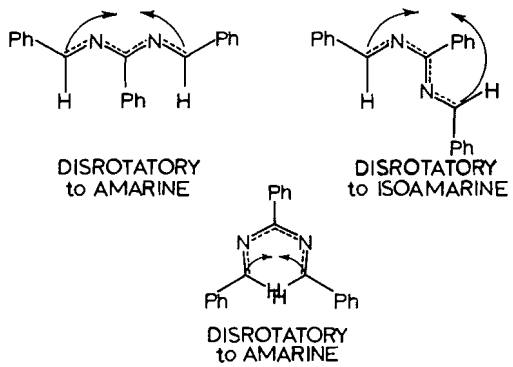
Carbanion Geometries

Having apparently established that Scheme 4 best represents the reactions of **1**, it is interesting to consider the possible character of the anionic intermediate or intermediates. Three basic skeletal geometries are available to a near planar carbanion, U, W and sickle, and each of these is shown in Scheme 6 with the phenyls arranged to give the most stable form.

If orbital symmetry restraints (14) are dominant, any concerted cyclization should occur in a disrotatory manner. Thus since only **2** is produced, the 'sickle' shape would not be the intermediate responsible for cyclization since it should lead to **4**. This leaves the U and W shapes as candidates. While the U-shaped carbanion would seem to be ideal for cyclization, the W-shaped anion is undoubtedly much more favored energetically and should be formed in great preference to the U shape.

Whatever anion is generated in methanol, its lifetime must be quite short ($<10^{-6}$ s) since reprotonation must be rapid (10). This brings into doubt the likelihood of geometric interconversions occurring prior to cyclization if the configurationally stable carbanions phenylallyllithium (15), 1-phenylbutenylpotassium (16), and pentadienyllithium (13) can be used as analogies. Life-times for rotational isomers in these molecules are of the order of 10^2–10^{-2} s near room temperature; considerably longer than the 10^{-8} s which might be needed to interconvert the W- and U-shaped anions. However, the rotational barrier around the 2,3-bond in this system might well be lower[2] since the two isolated parts are relatively stable.

[2]As emphasized by a referee.



SCHEME 6

A second factor bears on the question of initial formation of the thermodynamically more stable W-shaped carbanion followed by conversion to the U-shaped carbanion which cyclizes. The pathways from the W-shaped anion to the U-shaped anion or from the sickle-shaped anion to the U-shaped anion and from the U-shaped anion to the cyclized product were analyzed using molecular models. It is apparent that the energy surfaces for these processes cross and that the W-shaped anion or sickle-shaped anion could be diverted to cyclized products before reaching the U-shaped species.

Thus consideration of the possible geometries leads to the conclusion that the W-shaped anion is the one produced and rapid cyclization occurs either directly from this form or perhaps with prior conversion to the 'sickle' and then the U shape.

A complicating feature of direct cyclization from either the W or sickle shape is the recognition that the one or both nitrogen atoms rotate through 180° during the cyclization process. Orbital symmetry selects an initial disrotatory motion but if 1,5-bonding has not progressed to an important extent by the time the π-system is destroyed, symmetry rules need no longer apply. The possible involvement of a lone pair on nitrogen might complicate this simple picture.

Ion-pairing

Carbanions of different selectivity in their relative rates of cyclization and reprotonation are possible if ion pairs and dissociated carbanions were both being generated. In order to test whether the counterion might be affecting the relative amounts of cyclization and repro-

tonation, two experiments were run. In runs 18, 19, and 20 the base concentration was varied by a factor of 2.4 and resulted in no change in the ratio **3**/**2**. In run 21, the potassium ion was complexed with dibenzo-18-crown-6-ether (17) and again no change in **3**/**2** was observed. Again one carbanion is favored for both reprotonation and cyclization.

Reactivity of the Intermediate

If as has been considered above, the W-shaped anion is responsible for cyclization then the rate for this process must be high and the barrier to deformation must be low. In fact as discussed before, the barrier must be considerably lower than that observed for rotation around partial double bonds in other delocalized carbanions. The factor responsible for enhanced rotation in this system might well be thermodynamic, for rotational interconversions in phenylallyllithium and related compounds lead to products of the same or similar energy. The cyclization reaction of the carbanionic intermediate from **1** is undoubtedly highly exothermic. As a result 1,5-bonding interaction might account for the reduced barrier to cyclization.

Isotope Effects on Protonation and Deprotonation

The conversion of **1** to **2** and **3** provides one of the few opportunities to estimate a solvent isotope effect on the protonation of a short-lived carbanion in protic solvent. As was shown in Table 4 and discussed in the Solvent Isotope Effect section, the change in the ratio **3**/**2** should directly measure the primary isotope effect on k_{-2}. Within the accuracy of the **3**/**2** ratio a k_H/k_D of 2 ± 0.3 is observed.

The primary isotope effect for the conversion of **3** to carbanion has also been estimated from the results of runs 32, 33, and 34 of Table 3 (Appendix) and is k_H/k_D is $\geqslant 5$. In summary then the primary deuterium kinetic isotope effect on k_2 is ≥ 5 and on k_{-2} is 2.[3]

[3]The authors wish to thank R. D. Guthrie, University of Kentucky, for providing a preprint of electron-transfer results which also yielded a primary deuterium kinetic isotope for reprotonation of a carbanion. For the anion of 9-methoxyfluorene in methanol at 30°, $k_H/k_D = 5.3$. Although the reasons for the difference between the two systems are not established there may be a solvent isotope effect on the cyclization reaction.

Experimental

Solvents and Bases

Phenyllithium in tetrahydrofuran (THF) was prepared (19) as 0.7–0.8 *M* solutions. Methanol-*O*-*d* (0.99 atoms *D*/molecule) as analyzed by n.m.r. was prepared from dimethyl carbonate (20). Methanol was dried (<0.001 *M* in H_2O) and purified by distillation from magnesium (21). Dimethyl sulfoxide was distilled from lithium amide onto Molecular Sieves (freshly baked 4A). Tetrahydrofuran was freshly distilled from lithium aluminum hydride before use (<0.001 *M* in H_2O). The n.m.r. spectra were obtained in chloroform-*d* with TMS internal standard. Potassium methoxide in methanol (methanol-*O*-*d*) was prepared by reaction of freshly cleaned potassium with the alcohol and was stored under an argon atmosphere (<0.001 *M* in H_2O). All solvents and base solutions were analyzed for water using an Aquatest automatic Karl-Fisher titrator.

Compounds

The preparation and characterization of the substituted **1**, **2**, **3**, and **4** are to be found in the preceding paper (4).

Isomerization with Phenyllithium

To a degassed solution of **1** (0.1–0.05 *M*) in THF under an argon atmosphere at the indicated temperature was added dropwise the THF solution of phenyllithium. The characteristic blue color formed on addition of the first drop of base to the stirred solution. After complete addition (~2 min) the reaction mixture was stirred for the time indicated and then quenched by adding ~1.1 equiv of a 10 volume % solution of acetic acid in THF.

The THF was removed with a rotary evaporator and the residue worked-up with ether–water, extracting the ether layer twice with water. Drying and solvent evaporation yielded the crude reaction mixture. Products were analyzed by n.m.r. and t.l.c.

Samples for irradiation were treated in a similar manner, except the reactions were run in a cell with provision for cooling. A Hanovia 1000 W high pressure mercury lamp was used for irradiation. The long wavelength absorption band was isolated using a soft glass plate for primary filtering and either a Corning glass filter (type 2-62) or a combination of solution filters (cupric chloride and potassium dichromate (22)).

Isomerization and Exchange with Methanol–Methoxide

To the stirred, degassed methanol – potassium methoxide solution held at a constant temperature and under an argon atmosphere was added a THF solution of the substrate. The resulting solutions were 2–4 mol % in THF. At the time indicated, aliquots were removed and treated with ether–water. The ether layer was washed twice with water, dried, and solvent evaporated. The residual oils were analyzed by n.m.r. and t.l.c.

Mixtures of **2** and **3** could be separated by multiple extraction of **2** from the ether solution using 1 *M* potassium dihydrogen phosphate solution.

Samples of **3** were converted to *N*-benzoyl-*N'*-benzylbenzamidines for isotopic analysis by mass spectrometry. The procedure involved basic hydrolysis of **3** to *N*-benzylbenzamidine by treatment of the reaction mixture or isolated **3** with excess water. The *N*-benzylbenzamidine could be extracted from ether using saturated sodium bicar-

bonate. The aqueous layer was made basic with 6 *N* sodium hydroxide and extracted with ether. After washing, drying, and solvent removal the *N*-benzylbenzamidine was isolated. This product was reacted with 1 equiv of benzoyl chloride in benzene. Ether, saturated sodium bicarbonate, and water were used for extraction. The product was recrystallized from (1:1) benzene–hexane (m.p. 139–142°).

Analytical Procedures

The composition of mixtures of the hydrobenzamides, amarines, and *N*-benzylidene-*N*-benzylbenzamidines was normally determined by n.m.r. from the average of five integrations of the benzyl protons of each molecule. The complicating N—H protons were exchanged for deuterons where necessary.

Deuterium analyses of the isolated products or their derivatives were by mass spectrometry (Varian M-66) under conditions where P-1 peaks were absent. Usually the average of three scans of maximum scale expansion was obtained. In some cases n.m.r. integration was used for deuterium analysis again with maximum scale expansion.

The authors wish to thank the National Research Council of Canada for their financial assistance.

Appendix

Calculation of the ratio k_{-2}/k_{-3} of Scheme 4 using **3** as the substrate requires three separate pieces of evidence.

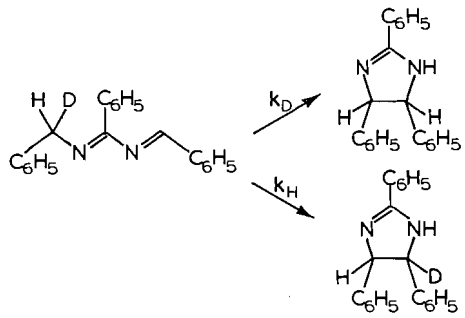
(a) Intramolecularity

Since **1** can be converted to **3** in CH_3OD without complete exchange occurring (run 29), the use of hydrogen–deuterium exchange as a quantitative measure of carbanion formation probably results in an underestimation of the extent of carbanion formation. One simplifying assumption is that the observed 14% intramolecularity (run 29) is a feature common to the carbanion whether formed from **1** or **3**. Thus in the following calculations it was assumed that exchange measured only 86% of the reacted material.

(b) Kinetic Deuterium Isotope Effect

In order to estimate the primary kinetic deuterium isotope effect, a sample of monodeuterio-**3** was employed (runs 32, 33, and 34) which had been isolated from a run similar to run 29. By deuterium analysis of the **2** generated at low conversion, the isotope effect could be estimated (see Scheme 7).

As expected the isolated **2** contained primarily d_1 material, but to make a more accurate determination of the isotope effect, it was necessary to correct for the fact that the



SCHEME 7

starting material (**3**) was only 77% d_1 and its composition changed to 66% d_1 during the reaction. This correction was applied crudely as follows: To obtain **2** of the observed isotopic composition ($\sim$65% d_1) from **3** of the composition of the starting material, an isotope effect of about 5 would be required; **3** of the composition observed at the end of the reaction ($\sim$66% d_1) would require a very large isotope effect. Thus the actual isotope effect is described as $k_H/k_D > 5$.

(c) Relative Rates of Exchange and Cyclization

The method employed to estimate k_{-2}/k_{-3} used the results of runs 30 and 31 to compare the relative amounts of cyclization and exchange. The results were fit to a scheme which allowed for the isotope effect and the further reaction of exchanged **3**. The technique is essentially that employed in an earlier study (18) and will not be described further. A ratio of 0.3 ± 0.1 for k_{-2}/k_{-3} fit the data best and proved to be insensitive to isotope effect.

Received September 23, 1971

Antimonic acid cannot be dehydrated by heating in air to give products of constant and reproducible weight without simultaneous reduction of some of the Sb^{V} to Sb^{III}. Neither anhydrous Sb_2O_5 nor the hydroxy oxide Sb_3O_6OH postulated by Dihlström and Westgren can be obtained by this method. Two well-defined products of the dehydration/decomposition are $Sb_2O_{4.35(5)} = Sb_6O_{13}$, which forms between 650 and 850°, and β-Sb_2O_4. The latter, and *not* Sb_2O_3, results on heating Sb_6O_{13} to 935°. Sb_6O_{13} has a cubic structure of the defect pyrochlore type, $a_0 = 10.303(1)$ Å, $x(O_2) = 0.4304(14)$. Combined evidence from X-ray diffractometry, density determination, and Mössbauer spectroscopy leads to $Sb^{3+}Sb^{5+}{}_2O_6O_{0.5}$ as the most probable structural formula.

The Mössbauer parameters of β-Sb_2O_4 are closely similar to those reported for α-Sb_2O_4, but the isomer shifts (relative to InSb at 77 °K) for Sb^{V} in antimonic acid and Sb_6O_{13} are significantly larger than those in α- and β-Sb_2O_4.

L'acide antimonique ne peut être déshydraté par chauffage à l'air pour donner des produits de poids constants et reproductibles sans produire une réduction simultanée d'un peu de Sb^{V} en Sb^{III}. On ne peut obtenir par cette méthode ni Sb_2O_5 anhydre ni l'hydroxyoxyde Sb_3O_6OH postulé par Dihlström et Westgren. Deux produits de la déshydratation/décomposition bien characterisés sont $Sb_2O_{4.35(5)} = Sb_6O_{13}$, qui se forme entre 650 et 850°, et β-Sb_2O_4. C'est ce dernier, et non pas Sb_2O_3, qui résulte du chauffage de Sb_6O_{13} à 935°. Sb_6O_{13} possède une structure cubique du type pyrochlore défectueux, $a_0 = 10.303(1)$ Å, $x(O_2) = 0.4304(14)$. Les données combinées de la diffraction aux rayons X, de la détermination de densité et de l'effet Mössbauer mènent à $Sb^{3+}Sb^{5+}_2O_6O_{0.5}$ comme formule structurale la plus probable.

Les paramètres Mössbauer du β-Sb_2O_4 sont très semblables à ceux rapportés pour α-Sb_2O_4, mais les déplacements isomères (relatifs à InSb à 77 °K) pour Sb^{V} dans l'acide antimonique et Sb_6O_{13} sont plus grands que ceux dans α- et β-Sb_2O_4.

Canadian Journal of Chemistry, **50**, 690 (1972)

Antimony has been reported to form oxides of formulae Sb_2O_3 (cubic, senarmontite; orthorhombic, valentinite), α-Sb_2O_4 (orthorhombic, cervantite), (1), β-Sb_2O_4 (monoclinic) (2), Sb_6O_{13} (3, 4), and Sb_2O_5 (5–13). In addition, an hydroxy oxide, Sb_3O_6OH, has been claimed to exist (14), and hydrated forms of Sb_2O_3 and Sb_2O_5 are known as antimonious and antimonic acids, respectively.

The existence of the two forms of Sb_2O_3 is unquestionable, and both the Sb_2O_4 dimorphs have been well characterized by single-crystal X-ray studies (1, 2). Both antimonious and antimonic acid may be readily prepared, although it is doubtful that their water content can be defined, as many authors have tried to do (9, 10, 15–18).

No conclusive evidence is available in the literature for the existence of Sb_6O_{13} and Sb_3O_6OH, which are claimed to form during the dehydration/decomposition of antimonic acid. The formula Sb_6O_{13} appears to have been assigned to an apparent "plateau" (~500–700°) on the isobaric (10 Torr) "equilibration" curve for antimonic acid (Fig. 1*a*) merely because it was the nearest "whole number formula" to the observed MW. The second plateau (~700–900°) on the curve was originally assigned to Sb_2O_4 (3). However, the material corresponding to this plateau gave an X-ray powder pattern of the cubic *pyrochlore* (*P*) type rather than that of Sb_2O_4, which prompted Dihlström and Westgren (14) to reassign the 700–900° plateau to the composition Sb_3O_6OH. This interpretation was based entirely on circumstantial evidence and no direct attempt was made to

verify the presence of the postulated OH group. The formula Sb_3O_6OH was chosen by analogy with the reported "ideal" formulae of minerals having the *P* structure such as pyrochlore itself ($NaCaNb_2O_6F$) and romeite ($NaCaSb_2O_6OH$); it was considered proven by the synthesis of the compound $BiTa_2O_6F$, which turned out to have a cubic structure of the *P* type (14). Since the presence of an OH group in the dehydration product obtained at 700° requires that either OH or water be present in all precursors, the formula Sb_6O_{13} assigned to the 500–700° product is not compatible with the formula Sb_3O_6OH claimed for the 700–900° material. Nevertheless, both these compounds are accepted by many present-day texts, as is anhydrous Sb_2O_5, whose formation by dehydrating antimonic acid was questioned as long ago as 1927 (4, 18).

The considerable age of most of the literature quoted in the foregoing, and our interest in compounds with the *P* structure (19), have prompted us to re-investigate the products of thermal dehydration/decomposition of antimonic acid. The minimum information required to establish the nature and identity of these products is reliable knowledge of their composition. Chemical analysis presents, however, numerous difficulties. The material is practically insoluble; its content of hydrogenic species may be very small, or it may depend on the exact conditions of sample preparation; and the difference between the formulae Sb_2O_4 and Sb_6O_{13}, for example, corresponds to a difference of only about 2 wt.% in the Sb content. Direct and indirect evidence from other methods is therefore desirable. In particular, since the Mössbauer effect in ^{121}Sb has been shown to yield useful information about the valency state *in situ* of antimony in compounds such as Sb_2O_3 (20–22), α-Sb_2O_4 (22), and a material referred to as Sb_2O_5 (21–23), it appeared that it should be useful in this study. The method is well suited for demonstrating the simultaneous presence of Sb^{III} and Sb^V as the absorption peaks for these valency states are well separated, having isomer shifts (relative to InSb) of about -3 to -6 mm/s and around $+9$ mm/s, respectively. In α-Sb_2O_4 the two absorption peaks have been reported to have equal areas (22). This suggests that measurement of Sb^{III}:Sb^V area ratios should enable Sb_2O_4 to be distinguished from, say, Sb_6O_{13} or Sb_3O_6OH, for which area ratios of 1:2 would be expected, or from products with intermediate Sb^{III}:Sb^V contents.

Experimental

Antimonic acid was prepared by hydrolysis of $SbCl_5$ (Baker & Adamson, 99%) in a mixture of ice and 30% H_2O_2. The white precipitate obtained was boiled for several hours and then washed by decantation, filtered, and dried to constant weight in air at room temperature; the drying process was followed by plotting a drying curve. The time taken to achieve constant weight was usually about 5 days. Preparations made in glass apparatus contained Na as an impurity. However, the use of Teflon vessels enabled a sample to be prepared whose spectrographic analysis was: Na, 0.01%; Bi, Pb, Cu, Al, Fe, 0.001%; all other elements, less than 0.001%.

All the antimonic acid preparations were only very sparingly soluble in all reagents tried, unless first the oxide was reduced in H_2 to the metal. Unfortunately, the temperature required to reduce the antimonic acid was also sufficient to cause some of the metal to vaporize. The following procedure was therefore used instead. All samples were first fired to constant weight at either 700 or 950° in air in a muffle furnace and the loss of weight noted. Infrared spectra of these products showed them to contain no detectable OH or H_2O. Next the products were fired for 8 h in a stream of H_2 at 635(5)° followed by cooling in H_2. If the X-ray powder photograph of this product showed lines other than those of Sb_2O_3 (either senarmontite or a mixture of senarmontite and valentinite) the sample was ground in an agate mortar and the firing repeated. When complete reduction to Sb_2O_3 had been accomplished, the weight loss, after correction for losses on grinding, could be used to calculate the MW of the initial material and also of the 700 and 950° intermediates. Knowing from the Mössbauer spectra that only Sb^V was present in antimonic acid,[3] the formula of the initial material could be calculated as $Sb_2O_5.nH_2O$. Since the infrared spectra showed the 700 and 950° products to contain no hydrogenic species, the formulae of these materials could also be derived. In each firing under H_2 a control sample of Sb_2O_3 was included to check that no reduction occurred beyond Sb_2O_3. There was no evidence of this taking place at 635(5)° on any firing. The method gave excellent reproducibility, with a maximum variation, on a formula of Sb_2O_4, of ± 0.05 on the oxygen figure.

Mössbauer Spectra

The Mössbauer spectrometer and computer fitting technique used have been described elsewhere (24). The source was 0.5 mCi ^{121}Sn in $BaSnO_3$ (New England Nuclear Corp.). Both source and absorber were maintained at liquid-nitrogen

[3]For the Sb^{III} absorption to be visible, the Sb^{III} content of the sample must be greater than about 5–10% of the Sb^V content, so that there is a possibility that a small amount of Sb^{III} could have been present. Its presence would mean only very slight changes in the formulae calculated for the antimonic acid samples (Table 1).

TABLE 1. Antimonic acid preparations

No.	Method	Formula	a_0, Å
180	Hydrolysis of $SbCl_5$ in ice	$Sb_2O_5.3.55H_2O$	10.338(5)
8*a*	Hydrolysis of $SbCl_5$ in ice and H_2O_2	$Sb_2O_5.3.67H_2O$	10.337(2)
61	Excess HNO_3 added to a solution of $KSb(OH)_6$	$Sb_2O_5.3.51H_2O$	10.378(2)

temperature whilst collecting the spectra. Isomer shift values are quoted with respect to InSb at 77 °K. Absorbers were prepared by dispersing the sample powder in acrylic disks, each disk containing about 10 mg/cm^2 of natural Sb. When asymmetry of a resonance peak was evident (*e.g.*, the Sb^{III} peak of sample 180*a*, Fig. 3*c*), the peak was treated as being due to an unresolved electric field gradient and fitted by an 8-line program similar to that described by Ruby *et al.* (20). The ratio of the quadrupole moments of the excited and the ground states was taken as 1.34 (25); the asymmetry parameter, which has only a small effect on the spectrum, was taken as zero.

If it is assumed that at 77 °K the recoil-free fractions for Sb^{III} and Sb^{V} atoms in non-equivalent crystallographic sites are essentially equal, the Sb^{III}:Sb^{V} area ratios of the absorption peaks can be equated with the corresponding ratios in mixed-valency samples. While in general this assumption can by no means be taken for granted, there are grounds for believing that for the compounds investigated here it cannot be far wrong and leads to reasonably realistic independent estimates of the Sb^{III}:Sb^{V} ratios.[4]

X-Ray Diffraction

Integrated X-ray intensities were obtained on a Philips powder diffractometer fitted with a focussing monochromator after the rotating specimen. Details of the wavelengths (Cu Kα), sample preparation, counting procedure, and powder photography have been described elsewhere (26, 27).

F-Refinements of the structure of Sb_6O_{13} (individual isotropic temperature factors) were carried out using atomic scattering factors for O^{2-} (28) and Sb^{3+}, Sb^{5+} (29), the latter corrected for dispersion (both parts, ref. 30). Full-matrix *ad hoc* programs and the weighting scheme $1/\sigma(I_0)$ were employed.

[4]For α-Sb_2O_4, in which Sb^{III} and Sb^{V} atoms occupy each its own type of site in a ratio 1:1 (1), Long *et al.* (22) under experimental conditions similar to ours obtained an area ratio which was at first stated to be close to unity but later (31) specified as 0.91(3). The ratio observed in the present work for β-Sb_2O_4 was 0.98(4), and for Sb_6O_{13} the ratio agreed reasonably well with the ratio obtained from chemical analysis (Tables 2 and 4). It seems that the observed area ratios tend to be smaller than ratios obtained from chemical analysis or from crystallographic considerations. However, the errors associated with the peak areas are sufficiently large that any small differences in the recoil-free fractions would not significantly alter the Sb^{III}:Sb^{V} ratio. It is of interest to note that in a recent investigation of non-stoichiometric pyrochlores resembling Sb_6O_{13} and containing simultaneously Sn^{2+} and Sn^{4+}, the recoil-free fractions of these two valency species have been shown to differ by less than 10% (35).

Other Methods

Infrared spectra were recorded with a Perkin–Elmer model 521 spectrophotometer. Specimens were prepared and examined both in the form of KBr pellets and as mulls in Nujol.

Thermogravimetric analysis curves were obtained on a Stanton model HT thermobalance in stagnant air with a linear heating rate of 6°/min. Densities of sample powders were determined by a method described in ref. 24.

Results and Discussion

Table 1 shows the formulae and the dimensions of the cubic unit cell of three preparations of antimonic acid after drying to constant weight at room temperature. The preparations had slightly different water contents, even though closely similar preparative procedures were used in each case.

Products Obtained by Firing Antimonic Acid below 900°

Figure 1*b* shows the t.g.a. curve obtained for preparation 8a.[5] The MWs at the "plateaus" are assigned from the chemical analysis of the products resulting at the corresponding temperatures. Allowing for different experimental conditions, the general shape of the curves in Fig. 1 *a* and *b* is much the same.[6]

The t.g.a. curves between room temperature and *ca.* 700° correspond to dehydration/decomposition of antimonic acid. Despite the apparent inflexion in the t.g.a. curve at about 400°, which might be interpreted as indicating the formation of Sb_2O_5, it was not possible to obtain under isothermal firing conditions any material of constant and reproducible weight other than the final 700° product, $Sb_2O_{4.35}$ (*vide*

[5]All preparations gave the same t.g.a. curves except for different initial MWs and hence longer, or shorter, dehydration/decomposition regions.

[6]Curve 1*a* represents, schematically, the average *oxygen* contents of the three sample runs reported in ref. 4. The water contents of the samples must be allowed for when comparing 1*a* with the t.g.a. curve 1*b*. At 200° this would increase the MW by an amount corresponding to 1.49–1.77H_2O.

infra). It must thus be concluded that the inflexion arises from a change in dehydration/-decomposition rate rather than from the formation of a discrete compound. The loss of water from antimonic acid was accompanied by reduction of some of the Sb^{V} to Sb^{III}, as noted already by Simon and Thaler (4) and by Natta and Baccaredda (18).

Direct evidence that all the antimony in the antimonic acid was pentavalent (Fig. 3*a*) and that reduction of Sb^{V} occurred during the firing was provided by the Mössbauer spectra. This evidence was especially valuable because the chemical analysis could not distinguish whether a weight loss corresponded to loss of water, OH, oxygen, or a combination of these species, and was therefore ineffective. The Mössbauer parameters for the various spectra are listed in Table 2.

The X-ray powder patterns of antimonic acid and of the products of isothermal firing were all well defined and of the cubic *P* type (space group *Fd3m*).[7] However, the relative intensities of the reflections changed with the firing temperature (Fig. 2). A structural rearrangement must therefore occur during firing. The large changes in intensities indicate that it is the cations that must undergo redistribution, since loss, or rearrangement, of the anions could not cause variations of this magnitude. The dependence of diffraction intensity on firing temperature supports the conclusion from the Mössbauer spectra, *viz.*, that firing antimonic acid does not merely cause a loss of adsorbed water.

Existence of Sb_2O_5

These results also explain the poor correlation of the X-ray powder patterns for "Sb_2O_5" compiled by Swanson *et al.* (12), who considered all the reported samples to be identical, whether hydrated or not. In fact some samples were antimonic acid, some were material dried at 100° or higher, and Swanson's own preparation, which had been fired to 780°, was in reality $Sb_2O_{4.35}$ (*vide infra*). This is the material whose powder pattern is listed in the 1966 edition of the ASTM X-ray powder data card file (No. 11-690) erroneously as Sb_2O_5. Our results also

[7]The similarity of the X-ray powder patterns of the dehydration products was pointed out already in refs. 3, 4, and 18.

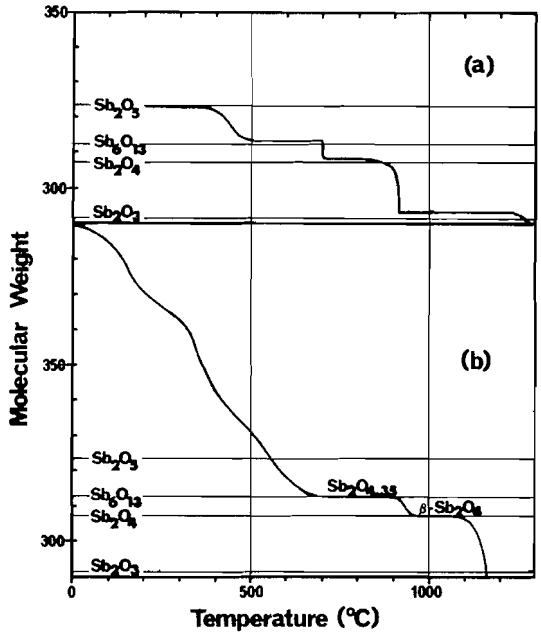

FIG. 1. Comparison of dehydration/decomposition curves of antimonic acid. (*a*) Isobaric "equilibrium" conditions (10 Torr; composite curve from data of ref. 4, see text). (*b*) Thermogravimetric analysis, this work (No. 8*a*; heating rate, 6°/min in stagnant air). Curve *a* represents, schematically, only the oxygen content of the solid.

explain the fact that some authors have found "Sb_2O_5" to be yellow, while others reported it to be white. We found, in agreement with ref. 18, that firing antimonic acid (which is white) to temperatures of 150 to 450° induced the development of a yellow color which intensified with increasing temperature. Firing to 650° produced $Sb_2O_{4.35}$ which was again white. Table 3 compares our preparations with those reported in the literature and shows the correlation possible if the above factors are taken into consideration.

A survey of "Sb_2O_5" samples used for previous Mössbauer studies also reveals that the authors did not in fact have samples of anhydrous antimony pentoxide. The material examined by Long *et al.* (22) was a commercial product marketed by the Research Organic/-Inorganic Chemical Co., Sun Valley, Calif., as "99.5% Sb_2O_5". Supposedly the same material was supplied to us; our analysis indicated a formula of $Sb_2O_5.3.61H_2O$. Whilst the difference in formulation does not invalidate those authors' assignment of the isomer shift for the observed absorption peak as being for Sb^{V}, it

*IS, isomer shift relative to InSb at 77 °K; QS, quadrupole splitting (e^2qQ); Γ, line width (full-width at half-height). The standard deviations are in units of the last decimal place; those for this work are quoted with 90% confidence limits.

†Converted to InSb as reference by adding 8.15(6) mm/s to the IS figures quoted in ref. 22.

‡The areas of the Sb^{III} and Sb^{V} absorptions were quoted as being equal, but no figure was given for their ratio. However, in a later publication Bowen *et al.* (31) refer back to ref. 22 and quote the Sb^{III}:Sb^{V} ratio as 0.91(3).

§It did not appear warranted to fit the 8-line quadrupole model to these spectra, as there was no visible asymmetry.

TABLE 3. Correlation of reported "Sb_2O_5" X-ray powder patterns with those of dehydration/decomposition products of antimonic acid investigated in this work

ASTM Card	Reference	Material	*a*, Å	Intensity of reflection 111	311	222	400	331	422	511 + 333	Radiation	Corresponds to (Fig. 2)
1-0154	13	Yellow	10.3	100	80	80	16	4	—	16	Mo Kα	*b*
2-1386†	18	"Antimonic anhydride" (Kahlbaum commercial reagent); yellow	10.2	40	40	60	40	—	20	50	Mo Kα	*a* to *b**
2-1383‡	18	$KSb(OH)_6 + HNO_3$; yellow	10.2	—	40	60	50	—	—	20	Mo Kα	?*
2-1385	18	Kahlbaum material dehydrated at 390°; yellow	10.3	20	—	60	20	—	—	50	Mo Kα	*d* to *e**
11-690	12	$Sb + HCl + HNO_3$; product fired at 780° for ½ h; white	10.305	27	22	100	30	4	2	6	Cu Kα	*e*
16-938§	14	White	10.30	—	60	100	80	20	20	60	Cr Kα	*e**

*The observed photographic intensities were originally estimated visually as "strong", "weak", etc. For inclusion in the ASTM file they were assigned the above numerical values. Comparison with our diffractometer intensities is therefore only very approximate, which makes a unique correlation of the material difficult. The standard ASTM conversion method gives a particularly bad agreement for card No. 16-938 (*cf.* the original table of intensities, ref. 14).

†At least 10 years old; stated to be $Sb_2O_5.H_2O$.

‡Five years old, dehydrated at 360°; stated to be $Sb_2O_5.3H_2O$.

§Listed as Sb_3O_6OH.

TABLE 4. Comparison of $Sb_2O_{4.35}$ preparations

Preparation	Method	Formula*	a_0, Å	Density, g/cm^3	Reference
117*a*	Hydrolysis of $SbCl_5$ in ice, Teflon apparatus; 735°/24 h	$Sb_2O_{4.40}$, $Sb_2O_{4.38}$	10.303(1)	5.62(1)	This work

"Sb_3O_6OH"	Sb + HNO_3; 780°/3 h		10.30†	5.78	14

*Duplicate results of chemical analysis. For method, see text.
†Converted from kX.

again discounts the claim that an oxide of formula Sb_2O_5 was examined. Other commercial products listed by the suppliers as "Sb_2O_5" have been found from our analysis to be either α-Sb_2O_4 (Fisher Certified Reagent), amorphous $Sb_2O_{4.3}$ (Baker Analyzed Reagent), or again, antimonic acid.

The Oxide $Sb_2O_{4.35}$ or Sb_6O_{13}

The first isothermally reproducible product obtained from firing antimonic acid appears at the plateau at 700–900° on the t.g.a. curve (Fig. 1*b*). It retains the cubic *P* structure (Fig. 2*e*) and was reproducible in composition from one preparation to another (Table 4). The MW obtained was 313.1(8), which corresponds to $Sb_2O_{4.35(5)}$ and could therefore be as well represented as being Sb_3O_6OH. However, its infrared spectra showed no sign of any OH or H_2O absorption peaks. Furthermore, the MW for Sb_3O_6OH (318.9 per 2 Sb) is outside the error margin of the chemical analysis. The Mössbauer spectrum of the $Sb_2O_{4.35}$ (Fig. 3*b*) contained two peaks corresponding to Sb^{III} and Sb^V, respectively, whose area ratio was 0.42(6) (Table 2). This compares to the ratio of Sb^{III}:Sb^V = 0.48(4) indicated by chemical analysis. From this combined evidence it must be concluded that antimony forms an oxide of formula $Sb_2O_{4.35(5)}$ which is thermally and chemically stable, and which is reproducible from one preparation to another. A material prepared by thermal decomposition of antimonic acid and having the formula proposed by Dihlström and Westgren on the basis of circumstantial evidence, does not exist.

Firing above 900°

When the oxide $Sb_2O_{4.35}$ is fired above 935° in air, a small loss in weight occurs. The product is β-Sb_2O_4. Its lattice parameters agree satisfactorily with those reported by Skapski and Rogers (1). These authors give 933(10)° as the temperature of formation of β-Sb_2O_4, in close agreement with the temperature observed by us.

The Mössbauer spectrum of the 935° product (Fig. 3*c*) showed two peaks of Sb^{III}:Sb^V area ratio 0.98(4) and thus supported our assignment of the identity of the product. The isomer shifts of the Sb^{III} and Sb^V absorptions were close to those obtained by Long *et al.* (22) for α-Sb_2O_4 (Table 2). This is not surprising when the similarity of the α and β structures is considered.

On the other hand, the isomer shift of the Sb^V absorption in β-Sb_2O_4 (No. 180*a*, Table 2) is significantly lower than that in $Sb_2O_{4.35}$ (Nos. 180*f* and 117*a*), indicating an increase in the s-electron density at the ^{121}Sb nucleus as compared with that in $Sb_2O_{4.35}$. This variation is not unexpected, as the Sb^V coordinations are slightly different in the two structures. In $Sb_2O_{4.35}$ the six nearest oxygen neighbors (at 1.957(18) Å)[8] are equidistant from the Sb^V atom, whereas in the monoclinic β-Sb_2O_4 the six Sb^V—O distances vary between 1.956(9) and 1.990(9) Å (2). Although the Sb^V environments in both these oxides are not of cubic symmetry, the electric field gradient produced is not sufficient to give an asymmetric quadrupole spectrum. It merely leads to a slight in-

[8]Owing to the incomplete occupation of the 16(*c*) equipoint in the structure of $Sb_2O_{4.35}$ the randomly distributed cation vacancies in 16(*c*) will affect the positions of their nearest oxygen neighbors in 48(*f*), thereby indirectly distorting the coordination octahedron about Sb^V in 16(*d*). The distance 1.957(18) Å determined from X-ray diffraction must thus be viewed as a mean of the (randomly) unequal Sb^V–O distances in the defect *P* structure (*cf.* also next section).

crease in the line width relative to that observed in InSb, 2.7(2) mm/s, for example.

Once formed, the β-Sb_2O_4 was thermally stable up to 1050°, and after being identified as such could be used as a reference standard in any subsequent gravimetric analysis of less reduced Sb oxides. The analytical figures obtained on this basis were always in excellent agreement with those obtained by the chemical analysis method described earlier.

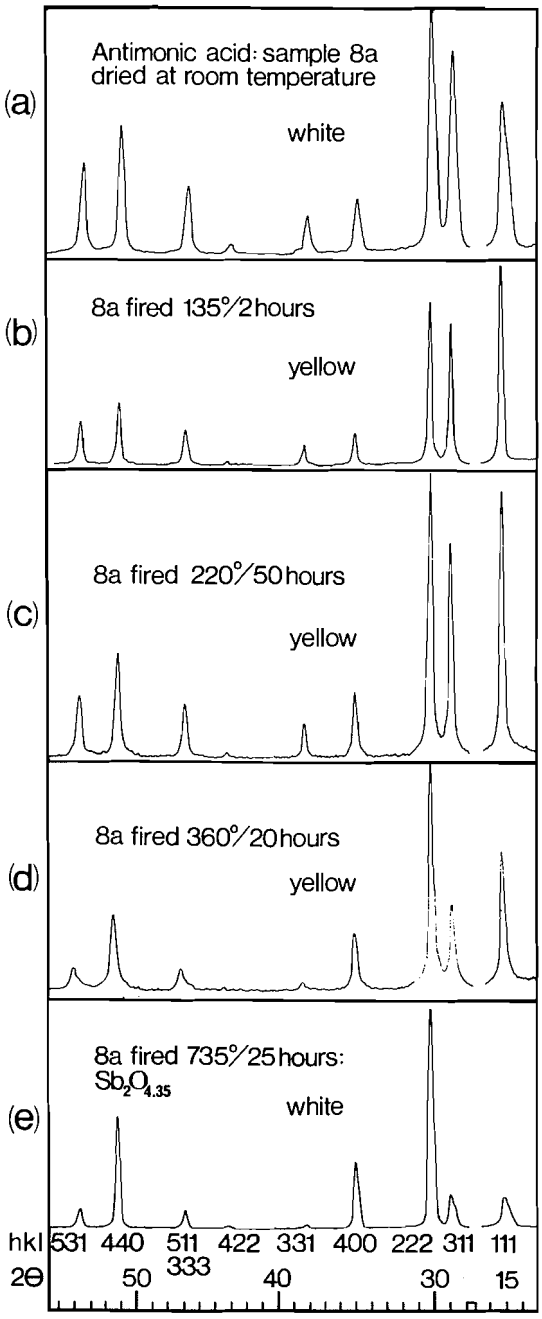

FIG. 2. X-Ray powder diffraction patterns of antimonic acid (No. 8*a*) fired to different temperatures in air (Cu Kα radiation).

Finally, at temperatures above 1050°, β-Sb_2O_4 vaporized without transforming first to Sb_2O_3. When firing was discontinued before all of the β-Sb_2O_4 had vaporized, no weight gain occurred on cooling the remaining material. This indicated that no oxidation took place on cooling. Powder photographs showed only β-Sb_2O_4 to be present. However, crystals of both Sb_2O_4 and Sb_2O_3 could be collected from the walls of the t.g.a. furnace, where they had been deposited as the result of the vaporization process.

Crystal Structure of $Sb_2O_{4.35} = Sb_6O_{13}$

A crystal-structure refinement from powder diffractometer intensities was carried out on $Sb_2O_{4.35}$ (No. 117*a*) to define the material further. The measured density of this sample along with its chemical analysis (Table 4) indicated an occupancy of the *P* unit cell which was very close to $8\ Sb^{III} + 16\ Sb^{V} + 52\ O = 4\ Sb_6O_{13}$. The most likely distribution amongst the *P* sites should then be

16(*c*)	16(*d*)	48(*f*)	8(*a*)
$8\ Sb^{3+}$	$16\ Sb^{5+}$	$48\ O^{2-}$	$4\ O^{2-}$

This model refined to a low value of *R* and gave small or very small correlation coefficients (Tables 5 and 6). Refinements allowing for simultaneous variation in the occupancies of 16(*c*) and 8(*a*) according to the formula $Sb_u^{3+}Sb_2^{5+}O_6^{2-}O_{(3u/2)-1}^{2-}$ showed that this model ($u = 1$) in fact gives the minimum *R* value (Fig. 4). When the statistical validity of models with other values of *u* was tested against $u = 1$ as the best model,[9] it was found that $u = 0.9$ could be rejected at significance levels between 50 and 5%, while $u = 1.1$ could be rejected at the 50% but not at the 25% significance level. All the other *u* values could be rejected at levels down to $\frac{1}{2}$% with the possible exception of $u = 1.2$, which was barely acceptable at the $\frac{1}{2}$% level. Probable occupancies of 16(*c*) between, approximately, 7.2 and 9.6 Sb could therefore also account for the observed diffraction intensities. A wide range of other conceivable ionic distri-

[9]The generalized discrepancy factor $R_w(u)$ was compared with R_w (1) as discussed by Hamilton (32).

*Only intensities corresponding to unique reflections were measured. The intensities have been normalized to $I_c(222)$. These normalized monochromatized integrated intensities are converted to conventional integrated intensities I_0' by multiplying by the ratio of the polarization factors, $(1 + \cos^2 2\theta)/(1 + 0.66 \cos^2 2\theta)$.

†Slight overlap with 11.3.3 + 973.

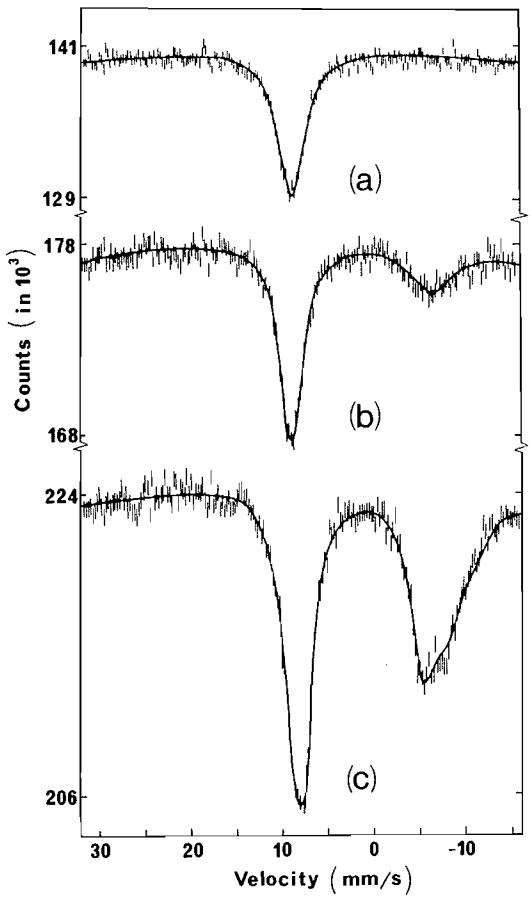

Fig. 3. Mössbauer ^{121}Sb spectra at 77 °K. (*a*) Antimonic acid (No. 180); (*b*) $Sb_2O_{4.35} = Sb_6O_{13}$ (No. 180*f*); β-Sb_2O_4 (No. 180*a*). The zero of the velocity scale refers to InSb at 77 °K.

butions was also tested and found to be unacceptable.

The value of the positional parameter $x(O_2)$ of the oxygen atom in 48(*f*), 0.4304(14), falls in the range expected for *2–5* oxide pyrochlores, from *ca.* 0.425 to 0.4375 (33).[10] The high values of the isotropic temperature factors $B(16c)$ and $B(8a)$ very likely have their origin in the incomplete occupancies of the two equipoints. In a stoichiometric *P* structure each oxygen atom O_1 in 8(*a*) is surrounded by four *A* cations in 16(*c*) at the corners of a regular tetrahedron. With the occupancies of 8(*a*) and 16(*c*) reduced by half there will be a high incidence of local situations where an O_1 atom will have only two Sb^{3+} atoms as nearest neighbors, and an Sb^{3+}

[10]Origin taken at center in 16(*c*) (*cf.* ref. 26).

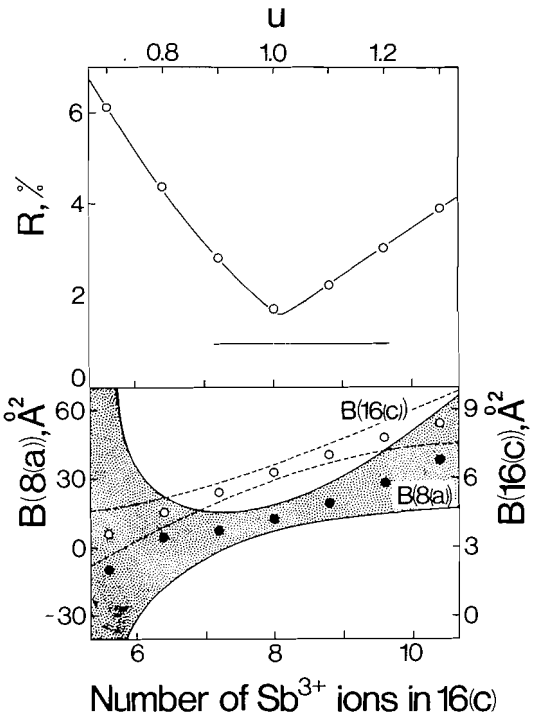

FIG. 4. Variation of the discrepancy factor R, and of the isotropic temperature factor $B(16c)$, with the assumed occupancy of the 16(c) equipoint in $Sb_u^{3+}Sb_2^{5+}O_6^{2-}O_{(3u/2)-1}^{2+}$ for the pyrochlore-structure model

16(c)	16(d)	48(f)	8(a)
$8u$ Sb^{3+}	16 Sb^{5+}	48 O^{2-}	$(12u-8)$ O^{2-}

The vertical width of the two B fields corresponds to the estimated standard deviation. The horizontal arrow indicates the 95% confidence limits of u.

atom will have only one instead of two O_1 atoms as its nearest oxygen neighbors. The adjacent vacancies will make the potential field in the immediate vicinity of an O_1 or an Sb^{3+} atom strongly asymmetric, and the resulting effective displacement of the scattering-charge centroids from the ideal parameter-free positions 8(a) and 16(c) will manifest itself by a decreased contribution to the diffraction intensity by charge at these sites. To compensate for the excess scattering charge introduced into the model through atomic scattering factors appropriate to the particular degree of random occupancy, the refinement leads to an abnormal increase in the temperature factors.

The above ionic distribution is similar to that assumed by Dihlström and Westgren for their hypothesized Sb_3O_6OH. The only difference is that for their formulation the 8(a) site would contain 8 OH^- instead of 4 O^{2-} ions. A refinement of our intensities using their model yielded, after 5 cycles, an R of 4.8% and an unacceptably high $B(8a)$ factor, 21.8(129) Å^2. This may again be taken as a confirmation that the oxide obtained from antimonic acid by firing at 700° is $Sb_2O_{4.35} = Sb_6O_{13}$ and not Sb_3O_6OH.

The apparent non-existence of Sb_2O_5 can be explained from an examination of the characteristics of the P structure. It has long been considered that the structure requires for its existence a basic network of filled 16(d) and 48(f) sites. Occupancy of the 16(c) sites is not essential, nor is that of the 8(a) sites. However, if ions are to occupy the 16(c) sites, they must be larger than those in the 16(d) sites, and the radius ratio of the 16(c) to 16(d) ions must fall within certain limits (33, 34). If antimonic acid is to conform to the above considerations, it must have a structure of the type

16(d)	48(f)
16 Sb^{5+}	32 O^{2-} + 16 OH^-

which corresponds to an overall formula of $Sb_2O_5.H_2O$.[11] Other structures are possible, however, with a greater proportion of OH^- ions in 48(f) and with OH^- also in 8(a). Dehydration of such material would lead to a decrease in the number of ions in 48(f) until for the formula Sb_2O_5 there would be only 40 O^{2-} ions left. The P structure could not support this deficiency in the 48(f) sites, so that either the material would convert to a structure of a different type, or else a rearrangement would occur in which some of the Sb^{5+} ions move into the 16(c) sites until the 48(f) sites become filled. However, if Sb^{5+} is to move into 16(c) it must become reduced to Sb^{3+} in order to satisfy the size requirement for this site. The structure that would result from the minimum amount of such rearrangement would have the ionic distribution

16(c)	16(d)	48(f)
$5\frac{1}{3}$ Sb^{3+}	16 Sb^{5+}	48 O^{2-}

or, for an integral number of ions in 16(c),

16(c)	16(d)	48(f)	8(a)
6 Sb^{3+}	16 Sb^{5+}	48 O^{2-}	1 O^{2-}

[11] This model (C) gave the best agreement, with visually estimated intensities, of the three models considered by Natta and Baccaredda (18).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

This last arrangement corresponds to an occupancy of 37.5% in 16(*c*) or $u = 0.75$ (Fig. 4), which does not agree as well with the X-ray intensities as does the arrangement with 8 Sb^{3+} ($u = 1$). It therefore seems that rearrangement on firing continues beyond the minimum required to fill the 48(*f*) sites, probably owing to such requirements as attainment of minimum lattice energy, etc.

Conclusions

1. There is no satisfactory evidence to-date for the existence of an anhydrous oxide of antimony having the formula Sb_2O_5. All references to this material in the literature can be shown to refer rather to hydrated Sb_2O_5 (antimonic acid) or to an oxide containing some Sb^{III}. Anhydrous Sb_2O_5 cannot be obtained from dehydration of antimonic acid by firing in air.

2. An oxide of formula $Sb_2O_{4.35(5)}$ is obtained by firing antimonic acid in air to 650–850°; the composition is equivalent to the formula Sb_6O_{13} within the stated experimental analysis error. This oxide has a cubic *P*-type structure, $a_0 = 10.303(1)$ Å. The X-ray powder diffractometer intensities observed for this material are best accounted for by the following arrangement of atoms in the unit cell:

16(*c*)	16(*d*)	48(*f*)	8(*a*)
8 Sb^{3+}	16 Sb^{5+}	48 O^{2-}	4 O^{2-}

The mean value of the positional parameter $x(O_2)$ of the oxygen atom in 48(*f*), 0.4304(14), is in the range expected for *2–5* oxide pyrochlores.

3. The hydroxy oxide Sb_3O_6OH proposed by Dihlström and Westgren (14) does not exist. The material investigated by these authors appears to be identical with the oxide Sb_6O_{13} described in the present work.

4. Sb_6O_{13} loses oxygen on firing to 935° and forms β-Sb_2O_4, *not* Sb_2O_3. β-Sb_2O_4 vaporizes above 1050° without first transforming into Sb_2O_3.

5. The Mössbauer parameters of β-Sb_2O_4 are closely similar to those reported for α-Sb_2O_4 by Long *et al.* (22). However, the isomer shifts observed for Sb^V in antimonic acid and its dehydration/decomposition products are significantly larger than those for α- and β-Sb_2O_4.

Note added in proof

The oxygen content of sample 180*f* was recently determined by neutron activation analysis using an Sb_2O_3 standard of 99.99% purity. The average of ten determinations (total counts accumulated, 10^6) was 22.01(9)%. This is in excellent agreement with the theoretical oxygen content of 22.11(20)% for the composition $Sb_2O_{4.32(5)}$ established by chemical analysis (Table 4). However, the Sb^{III}:Sb^V ratio corresponding to this analysis, 0.54(4), is higher than the Mössbauer area ratio for this material, 0.42(6).

We are indebted to Dr. M. Falk for placing at our disposal the infrared spectrophotometer. Financial support of this investigation by the National Research Council of Canada is hereby acknowledged. The neutron activation analysis was carried out by Mr. R. Dayal of the Department of Geology, Dalhousie University, to whom we wish to express our appreciation.

Influence of Surface Area Variation on the Kinetics of Hydration of Tricalcium Silicate

K. G. McCurdy and B. P. Erno

Department of Chemistry, University of Lethbridge, Lethbridge, Alberta

Received June 7, 1971

Tricalcium silicate reacts initially with aqueous solutions according to a rate law that is first order with respect to the mass of the solid. A kinetic investigation of the hydration of tricalcium silicate for fixed solid to solution, w/w, ratio has been conducted using samples of tricalcium silicate of different total surface area to volume ratios. Consideration of the p*H* independent rate constants indicates that the rate for the initial step in the hydration process is proportional to the surface area of the solid. Subsequent p*H* independent rate constants in the overall hydration process are surface area independent.

Le silicate tricalcique réagit en solution aqueuse, dans l'étape initiale, selon une cinétique du premier ordre par rapport à la masse du solide. La cinétique d'hydration du silicate tricalcique a été étudiée pour des poids fixes de solide et de solution, en utilisant des échantillons de silicate dont les rapports surface: volume varient. La vitesse d'hydration, indépendante du p*H*, indique qu'elle est proportionnelle à la surface du solide dans l'étape initiale. La non dépendance, au stade ultérieur, des constantes de vitesse du processus global de l'hydration vis-à-vis du p*H* montre qu'elles sont indépendantes de la surface.

Introduction

The heterogeneous chemical reaction of crystalline tricalcium silicate, Ca_3SiO_5, in aqueous systems has been investigated many times (1, 2). Recently some progress has been made in understanding the kinetics of the reaction (3–5). A previous publication from this laboratory (6) proposed a reaction mechanism for the hydration of tricalcium silicate in excess water at constant p*H*. The mechanism proposed was

[1] $$3CaO\cdot SiO_2(s) + nH_2O(l) \xrightarrow{k_1} 1.5Ca^{2+}(aq) + 3OH^-(aq) + 1.5CaO\cdot SiO_2(s)$$

[2] $$1.5CaO\cdot SiO_2(s) + nH_2O(l) \xrightarrow{k_2} 1.5Ca^{2+}(aq) + 3OH^-(aq) + SiO_2(aq)$$

[3] $$1.5CaO\cdot SiO_2(s) + SiO_2(aq) \underset{}{\overset{K_3}{\rightleftharpoons}} 1.5CaO\cdot SiO_2\cdot SiO_2(s)$$

[4] $$1.5CaO\cdot SiO_2\cdot SiO_2(s) + nH_2O(l) \xrightarrow{k_4} 1.5Ca^{2+}(aq) + 3OH^-(aq) + 2SiO_2(aq)$$

Here $SiO_2(aq)$ denote the total silica in solution, with the realization that it is distributed in solution among the species H_4SiO_4, $H_3SiO_4^-$, and $H_2SiO_4^{2-}$ as a function of the p*H* of the solution.

A subsequent investigation (7) reported results of the influence of p*H* on the various reactions in the sequence and led to the proposal that the rate constants are proportional to the hydrogen ion activity adsorbed, $(a_{H+})_{ads.}$, on the solid surface. The equilibrium written as reaction 3 was observed to be p*H* independent. The Langmuir adsorption isotherm was used to correlate the hydrogen ion activity on the surface with the hydrogen ion activity in the liquid phase.

Few previous investigations of the effect of particle size on the rates of hydration have been published. None of these have been conducted at constant p*H*.

According to Brunauer and Greenburg (1), Anderegg and Hubbel (8) found no difference in the rates of hydration of tricalcium silicate for fractions of solid with mean dimensions of 19, 22, and 25 μ. Brunauer and Greenburg (1) also describe a study by Sloan *et al.* (9) in which three fractions, 65–100, 100–200, and 200–300 mesh, tricalcium silicate were investi-

gated and no difference in the rates of hydration was observed.

Particle size or the surface area of powder has been proposed as having an effect on the hydration rate of tricalcium silicate (3, 10).

Surface area effects have been proposed for heterogeneous solid liquid reactions (11, 12).

The present investigation using tricalcium silicate with samples of particles of different diameters was undertaken to investigate the effect of the surface area of the tricalcium silicate on the kinetics of the reaction.

Experimental

Materials

The tricalcium silicate used in the present investigation has been previously described (7). The various particle size ranges were obtained by sieving the tricalcium silicate for thirty minutes on stacks of Endicott N.B.S. sieves. The particle sizes obtained are described in Table 1.

All solutions were prepared using double distilled water. All experiments were duplicated.

Equipment

The p*H* stat used was a Radiometer titrigraph SBR2C/-SBU1 composed of a TTT1 automatic titrator, SBR2C recorder, and SBU1 syringe burette. The titrant was delivered from a calibrated 0.5 ml syringe. A Radiometer G202C glass electrode and a K401 calomel reference electrode were used to monitor the p*H*.

Procedure

The reactions were carried out in 10 ml of solution in a reaction vessel in which an access port above the level of the solution was available for the introduction of the tricalcium silicate, 10 mg in all experiments in the present paper.

The solution was stirred and thermostated at 25 ± 0.05 °C. A stream of nitrogen was passed through water and then through the reaction solution to avoid carbonation.

An experiment was carried out by placing 10 ml of a 0.2 m*M* $Ca(OH)_2$ solution in the reaction cell. The p*H* of the solution was adjusted with a concentrated solution of HCl to the desired value. Chloride ion had previously been shown to not have an effect on the reaction under these conditions (6). The p*H* stat was set to maintain the p*H* of the solution at the preset value.

When thermal equilibrium had been attained the tricalcium silicate was introduced rapidly by means of a small funnel through the access port. The stat then recorded the volume of standardized HCl solution required to maintain the p*H* of the solution at the preset value.

The reaction was followed until no further addition of HCl was required for a period of 5 min.

Results and Discussion

Table 2 lists the experiments performed at the indicated p*H* and involving the specified sample of tricalcium silicate. The mathematical analysis for the rate constants involved the use of the differential form of the rate law for the formation of base (6).

$$[5]\quad \frac{d\,[OH^-]_T}{dt} = 3k_1([OH^-_{01}] - [OH^-_{t1}])$$

$$+ 3k_2(1.5CaO\cdot SiO_2) + 3k_4(1.5CaO\cdot SiO_2\cdot SiO_2)$$

In this equation OH^-_{t1} is the hydroxide liberated by the first reaction at time t and OH^-_{01} is the total amount of hydroxide that would be generated by completion of the first reaction. Parentheses denote concentrations of suspended solids in moles per liter and square brackets denote solute concentrations in moles per liter. In eq. 5 we have used the symbol $1.5CaO\cdot SiO_2$ to denote the amount of intermediate formed from eq. 1 that is free. The expression $1.5CaO\cdot SiO_2\cdot SiO_2$ denotes the

tricalcium silicate at various p*H* values indicated a p*H* dependence of rate constants k_1, k_2, and k_4 as determined by the previous method. McCurdy and Erno (7) reported that this p*H* dependence could be removed from the rate constants by proposing that they are proportional to the hydrogen ion activity adsorbed, $(a_{H+})_{ads.}$, on the solid surface.

The Langmuir adsorption isotherm (13) was used in the form

$$\bar{\theta} = \frac{\alpha\mu}{\alpha\mu + \upsilon}$$

Here α is the fraction of hydrogen ions striking the surface which adhere, μ is the number striking 1 cm^2 per unit of time, and υ is a constant for adsorption of hydrogen ions on the surface, $\bar{\theta}$ is the fraction of total surface covered at any time by hydrogen ions. If μ is proportional to $(a_{H+})_{aq}$ with proportionality constant, c, and the rate constants are proportional to the fraction of total surface covered by hydrogen ions, we have the following equation

$$k_n = k_n^1 \frac{\alpha[a_{H+}]_{aq}}{\alpha[a_{H+}]_{aq} + \upsilon/c}$$

where k_n^1 is the p*H* independent rate constant. The numerical value of n denotes a particular reaction step. A method was presented (7) for determining the value of k_n^1. The values of k_n^1 for the present investigation are reported in Table 3. The data in this table indicate a surface area effect in k_1^1 but k_2^1 and k_4^1 appear constant over the various surface area samples studied.

Surface Area Dependence of k_1^1

The numerical value of k_1^1 for the samples investigated in the present work reflects the effect of changing the ratio of the surface area of the solid to the volume of the solution with a constant mass of tricalcium silicate. Table 3 indicates an increase of the value of k_1^1 as the ratio of surface area of solid to volume of solution increases. The rate constant k_1^1 is by previous definition (7) the rate constant when the surface is completely covered with hydrogen ions. It would be anticipated then that k_1^1 should increase as the surface area increases. The following derivation is based on spherical particles although it applies as well to cylindrical particles in which end effects are neglected. If k_1^1 is proportional to A_s then

$$[8] \qquad k_1^1 = A_s k_1^{11}$$

where k_1^{11} is the proportionality constant. This can be written as

$$[9] \qquad k_1^1 = k_1^{11}\, 4\pi r^2 n$$

for spherical particles where r is the radius of a particle and n is the number of such particles. The value of n can be determined from the initial weight of the sample W_I and the density of the solid ρ as

$$[10] \qquad n = \frac{W_I}{\frac{4}{3}\pi r^3 \rho}$$

Then substituting for n in eq. 9 gives

$$[11] \qquad k_1^1 = k_1^{11} \frac{W_I^3}{\rho}\left(\frac{1}{r}\right)$$

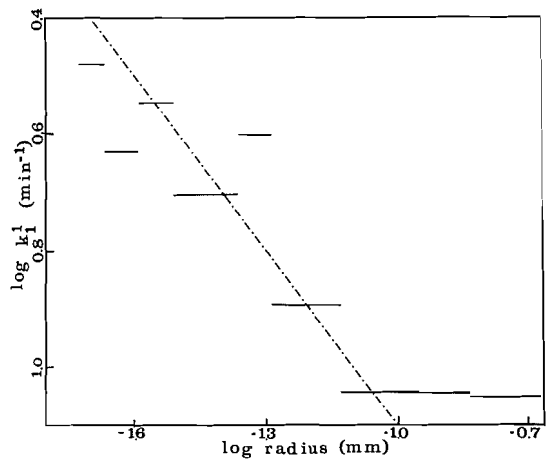

FIG. 1. Plot of log k_1^1 *vs.* log r. A line of slope minus one is drawn for reference-·-·.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Plots of $\log k_1^1$ *vs.* $\log r$ (obtained from Table 1) should be a straight line with a negative slope of unity. Figure 1 is a graphical representation of the data in Table 3 using the samples given in Table 1. A line of slope -1 is drawn for reference. The lengths of the horizontal lines indicate the range of particle radii in the various samples.

This dependence of k_1^1 on the surface area of the solid is in agreement with the results of the ball mill hydration (14) in which unhydrated solid is continually exposed to the solution by the grinding action. The ball mill hydration is much more rapid than paste hydration, and faster than bottle hydration.

Surface Area Dependence of the Reaction Rate Law for the Initial Step in the Reaction Sequence

The initial reaction in the hydration of tricalcium silicate has been shown to be first order with respect to the mass of the solid. A first order mechanism suggests a two dimensional attack with adsorption (15, 16). A cylindrical model for the solid particles in which end effects are neglected and adsorption included accounts for the observed first order kinetics. This model leads to a rate law that is second order in surface area.

There is a considerable amount of microscopic evidence to suggest that the particles of tricalcium silicate are approximately equidimensional. A spherical model would therefore seem to be more realistic. A rate law that is first order in mass of solid leads to a reaction that is 3/2 order in surface area for spherical particles. There is some evidence (11, 12) that dissolution reactions are second order in surface area. This second order effect is attributed to the fact that both reactants (lattice components in the surface and adsorbed H^+) depend on the surface area. If the hydration of spherical particles of tricalcium silicate was second order in surface area we should have observed a reaction that was 4/3 order in mass of tricalcium silicate. We were, however, unable to satisfactorily reproduce the rate of production of base using a 4/3 order reaction if, as was the case, the rate constant for reaction 1 was calculated from the integrated rate law and the amount of base generated at a short period of time (6). The rate of generation of base by the 4/3 order reaction using the integrated rate law was not fast enough in the later stages of the reaction to match the experimentally determined base.

Many explanations are possible for this observation, one is however in accord with a previously proposed mechanism. Stein and Stevels (17) proposed that tricalcium silicate reacts rapidly in aqueous media to form a first hydrate (F.H.). This hydrate has a molar ratio of lime to silica of approximately 3. Base would not liberate during its formation and therefore would not be detected by our method of analysis. Stein and Stevels suggest that this F.H. is converted into a second hydrate (S.H.) of approximate formula $(0.8–1.5)CaO \cdot SiO_2 \cdot nH_2O$. This second hydrate catalyzes the decomposition of first hydrate. We calculate a considerable amount of $1.5CaO \cdot SiO_2$ at short times by our mechanism (6). The suggestion that this hydrate is capable of catalyzing the conversion of F.H. into S.H. would lead to an order for the F.H. to S.H. conversion lower than that expected on the basis of a spherical model with adsorption. This appears to be the case in the present investigation. A spherical model with adsorption should lead to 4/3 order kinetics. We actually observe first order kinetics with respect to the mass of the solid.

Dielectric Studies. Part XXXII. Detection of High Frequency Absorption from Microwave Data

G. D. MARTIN AND S. WALKER[1]

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received August 26, 1971

The dielectric constants and losses have been determined for solutions of *o*-hydroxyacetophenone, 1-chloro- and 1-bromonaphthalene and 2-chloro- and 2-bromonaphthalene in dilute solutions of 15 °C involving a nonpolar solvent. Either seven or eight microwave frequencies were employed over a wide range from about 1 to 145 GHz, and the relaxation times of the molecules were such that the high frequency side of the Cole–Cole plot near the dielectric constant at high frequencies (ε_∞) was well defined. For these polar solutes in nonpolar solvents no high frequency deviations from the Cole–Cole plot are apparent in the plot itself based solely on microwave data. In a few cases the distribution parameter was negligible (less than 0.03) and in one case it was zero. In all cases a Cole linear plot and also a Brot plot revealed the existence of additional absorption to that contributed by molecular relaxation. Such additional absorption would have been difficult to be certain of from the Cole–Cole plot alone when the distribution parameter was either negligible or very small. The frequency points at about 70 and 145 GHz are invaluable in detecting such additional high frequency absorption contributions.

Les constantes diélectriques et les pertes ont été déterminées pour des solutions d'*o*-hydroxyacétophénone, de chloro-1 et bromo-1 naphtalène, en solutions diluées à 15 °C avec un solvant non polaire. Sept à huit fréquences micro-ondes ont été employées dans un intervalle de 1 à 145 GHz et les temps de relaxation des molécules étaient tels que la haute fréquence du tracé de Cole–Cole proche de la constante diélectrique à haute fréquence (ε_∞), était bien définie. Pour ces solutés polaires dans des solvants non polaires, il n'y a pas de déviations apparentes de hautes fréquences obtenues à partir du tracé de Cole–Cole, basées uniquement sur des données micro-ondes. Dans certains cas, le paramètre de distribution était négligeable (inférieur à 0.3) et nul dans un cas. Dans tous les cas, un tracé linéaire de Cole et de Brot, révélait l'existence d'une absorption additionnelle à celle contribuée par la relaxation moléculaire. Une telle absorption additionnelle aurait été difficile à identifier à partir du seul tracé de Cole–Cole où le paramètre de distribution était soit négligeable soit très petit. Les points de fréquences entre 70 et 145 GHz sont d'une valeur inestimable dans la détection d'une telle contribution à l'absorption des hautes fréquences.

Introduction

When the loss factor (ε'') is plotted against the dielectric constant (ε') for a wide range of frequency at a fixed temperature for a system characterized by one relaxation time a semi-circle results with its center on the ε' axis and intercepts of ε_0 and ε_∞ on this axis where the former corresponds with the low frequency side of the plot and the latter with the high frequency side. This plot is sometimes termed the Debye semi-circle (1). For systems with more than one relaxation time the ε'' against ε' plot leads to a semi-circle with its inclination to the ε' axis depressed by the angle $\alpha\pi/2$, where α is termed the distribution parameter and measures the width of the distribution of relaxation times about a most probable (mean) relaxation time (τ_0). This representation of ε'' against ε' has been termed the Cole–Cole plot (2). The equation from which the equation of the Debye semi-circle may be derived is (3)

$$[1] \qquad \varepsilon^* = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + i\omega\tau} = \varepsilon' - i\varepsilon''$$

The Cole–Cole equation, however, which assumes a continuous distribution of relaxation times about the mean relaxation is

$$[2] \qquad \varepsilon^* = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + (i\omega\tau_0)^{1-\alpha}}$$

Thus, when $\alpha = 0$, then the system is characterized by one relaxation time, and the Cole–Cole equation reduces to the Debye equation, and the system is said to exhibit Debye behavior. When $\alpha \neq 0$ the system would be described as deviating from Debye behavior.

Often no distinction in terminology is made between the Cole–Cole plot and the Debye semi-circle, and this procedure will be followed

[1]To whom correspondence should be addressed.

here. For cases though where $\alpha = 0$ it should be noted that the Cole–Cole plot could be termed the Debye semi-circle.

Much interest has centered on such plots, and one of the most recent developments is due to Leroy *et al.* (4) who have found deviations from the semi-circular Cole–Cole plot (2) at far infrared frequencies. It was thought worthwhile to determine whether deviations from the Cole–Cole plot could be detected for rigid polar molecules in dilute solution of a nonpolar solvent from microwave data. In addition it seemed desirable to find out which were the best procedures for detecting deviations from Debye behavior or indicating the existence of additional absorption processes other than that of molecular relaxation. If appreciable deviations do occur then false estimates of the dielectric constant at infinite frequency (ε_∞) would result since this is frequently obtained from the Cole–Cole plot. The consequences of this would be that data (5) derived from ε_∞, such as the dipole moment, would be inaccurate.

Clearly, the most useful frequencies in this type of study, apart from the most accurate static dielectric constant point, are the ones which lead to points on the ε_∞ side of the Cole–Cole plot and as close to ε_∞ as feasible. This object would be served by selecting polar molecules which have a long relaxation time. However, if the dielectric loss of the solutions becomes too low the accuracy of the measurement decreases, and thus the solutes selected for study and the concentration of their solutions were chosen bearing this in mind. As far as possible, the solutes were selected for examination in as dilute a solution as feasible in a nonpolar solvent with a view to minimizing internal field effects and complications due to molecular interaction.

Experimental

The dielectric constants and losses of the solutions were measured at microwave frequencies by methods which have been described previously (6, 7). The values at 8.313, 16.2, 23.98, and 34.86 GHz (X, P, K, and Q bands, respectively) were measured using a bridge technique (6), the accuracy of which has been discussed previously (7). The data at 1, 1.5, 2, and 2.5 GHz were obtained with a coaxial line method (8), and the data at 70.6 and 144.9 GHz were obtained using two very similar types of Michelson interferometer (9, 10). In order to examine the accuracy of the results from the higher frequency interferometer a plot was made of ε' and ε'' against mole fraction by C. S. Stewart in this laboratory for six solutions of chlorobenzene in benzene at 20 °C and 2.1 mm wavelength. Good linear plots were obtained and the results favorably compared with those obtained by Garg, Kilp, and Smyth (10). The ε' values of *n*-heptane and cyclohexane were also measured at (*a*) this wavelength and temperature and yielded values of 1.920 and 2.024, respectively, which is in excellent agreement with the values of 1.921 and 2.024 reported by these authors (10) and (*b*) at 70.6 GHz where the values were 1.921 and 2.024, respectively, which is to be expected since the dispersion in each case is negligible. The static dielectric constant of each solution was measured on a WTW Dipolmeter DM01 at a frequency of 2 MHz. The values of the refractive indices of the solutions for the sodium D lines were measured on a Carl Zeiss refractometer. All values of dielectric constant and loss were calculated from the experimental measurements by an IBM 360-40 computer.

In Table 1 are shown the observed and calculated values of dielectric constant and loss of the solutions, while in Table 2 the values of ε_0, n_D^2, ε_∞, the (mean) relaxation time (τ_0), and the distribution parameter (α) are given. The evaluation of the parameters ε_∞, τ_0, and α has been described previously (11). The values of the dielectric constant and losses at 70.6 and 144.9 GHz were not used in the calculation of ε_∞, τ_0, and α, since these two frequencies would be affected most if there was some abnormal dispersion in this region. The values of ε' and ε'' at 70.6 and 144.9 GHz were calculated from these parameters and then compared with the observed values (Table 1).

Discussion

Leroy *et al.* (4) give Cole–Cole plots (2) of trichloroethane in hexane, of pure trichloromethane, and of tribromomethane. In all three cases there is a marked deviation from a semi-circle at the high frequency end. For the trichloroethane in hexane the semi-circle curves in, corresponding to an "inertial effect", and for the other two it curves out, corresponding to an "excess absorption" (4). The experimental points which indicated these phenomena were obtained by interferometric methods in the far infrared region. As illustrated in Fig. 1 the present results, within experimental error, lie on a semi-circle. The highest frequency used for the present results was 144.9 GHz and that used by Leroy *et al.* was 6000 GHz. Both our 70.6 and 144.9 GHz points do not indicate any significant visual deviation from the Cole–Cole plot (Fig. 1).

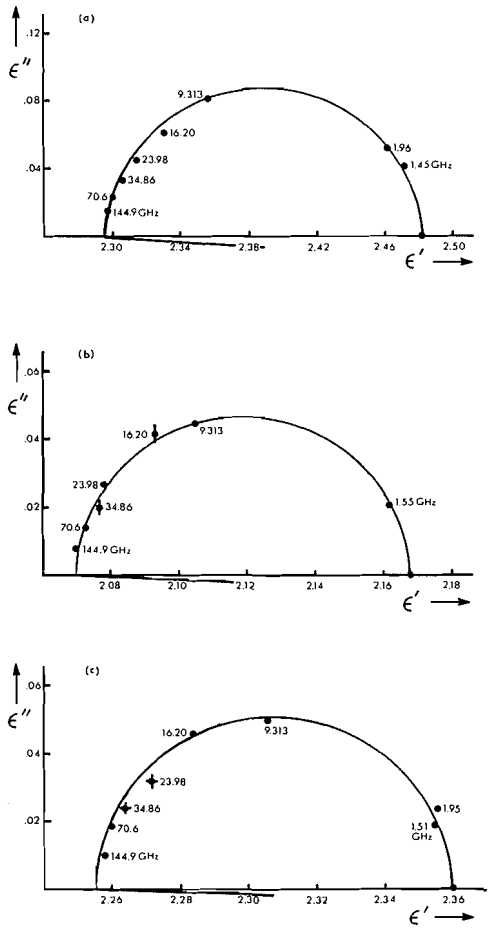

FIG. 1. Cole–Cole plots of (*a*) 1-chloronaphthalene in carbon tetrachloride; (*b*) 1-bromonaphthalene in cyclohexane; (*c*) *o*-hydroxyacetophenone in carbon tetrachloride at 15 °C.

Previous work by Antony and Smyth (12) indicated that for a dilute solution of *o*-hydroxyacetophenone in cyclohexane the distribution parameter (α) was zero. Our value of 0.01_8 for this solute in carbon tetrachloride cannot be regarded as a significant deviation from zero. In fact, the α values for 2-chloro- and 2-bromonaphthalene in carbon tetrachloride and 1-bromonaphthalene in cyclohexane are negligible, while the variation in α of 1-bromonaphthalene from 0.02_7 in cyclohexane to 0.04_6 in carbon tetrachloride must be ascribed to a solvent effect and not to a modification of the relaxation processes of the solute molecule. Thus, in almost all cases, α is either zero or tends to zero and the systems can almost be represented by Debye behavior. Hence, from a Cole–Cole plot type of representation, in the majority of these cases, it might seem that the molecular relaxation time contribution was either adequate or almost so to describe the absorption.

Plots other than the Cole–Cole exist for detecting the presence of an additional relaxation process(es). Two plots which have found frequent use and are attributable to Cole (13) are based on the equations

$$[3] \qquad \varepsilon' = -\tau(\omega\varepsilon'') + \varepsilon_0$$

$$[4] \qquad \varepsilon' = (1/\tau)(\varepsilon''/\omega) + \varepsilon_\infty$$

From eq. 3 a plot of ε' against $\varepsilon''\omega$ yields a straight line of slope $-\tau$ for one relaxation process while a plot of ε' *vs.* ε''/ω has a slope of $1/\tau$. These plots are shown for the present data in Fig. 2. For all solutions in Fig. 2*a* it can be seen that two intersecting straight lines are obtained and not one. In each case it is the 70.6 and 144.9 GHz points which define the second straight line, suggesting at least one other dispersion process is occurring. In the ε' *vs.* $\varepsilon''\omega$ plot it can also be seen that the slopes of the lines given by these two high frequency points are very much less steep than for the main relaxation processes (*i.e.* the second possible relaxation time, τ_2, is much shorter than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

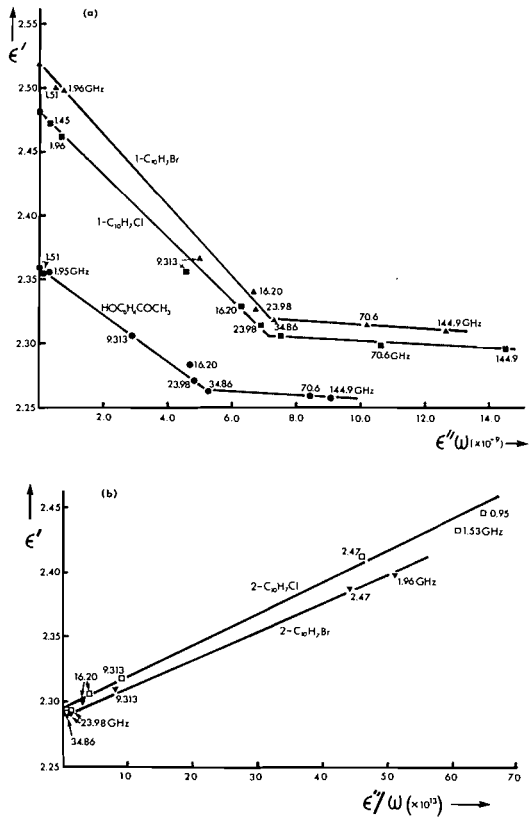

FIG. 2. Cole plots of (*a*) ε' *vs.* $\varepsilon''\omega$ for *o*-hydroxyacetophenone, 1-chloro- and 1-bromonaphthalene in carbon tetrachloride at 15 °C; (*b*) ε' *vs.* ε''/ω for 2-chloro-, and 2-bromonaphthalene in carbon tetrachloride at 15 °C.

the main relaxation process τ_1). For all solutions τ_2 values estimated from the slopes are shorter than 2 ps. Such a plot is therefore valuable in indicating that mm absorption cannot be accounted for in terms of the molecular relaxation time alone. However, it does not prove that the τ_2 relaxation time is meaningful in relation to a specific molecular motion and that the τ_2 process is of the Debye type, or that it is permissible to apply eq. 3 to estimate an additional relaxation time associated with the additional absorption.

It should be noted that for an ε' *vs.* ε''/ω plot in Fig. 2*b* a straight line appears to represent the data adequately. In this type of plot the high frequency points bunch together near the ordinate axis and the additional relaxation process(es) cannot be distinguished in these cases by the mm data.

Brot (14) deduced a useful equation relating the parameters ε', ε'', ε_0, ε_∞, ω, and τ which yields a straight line from the appropriate plot. This equation is

$$[5] \quad \omega/\varepsilon'' = [\tau/(\varepsilon_0 - \varepsilon_\infty)]\omega^2 + [(\varepsilon_0 - \varepsilon_\infty)\tau]^{-1}$$

From eq. 5 a plot of ω/ε'' *vs.* ω^2 spreads out the high frequency points, and two such plots are given in Fig. 3 which reveals that the absorption cannot be characterized solely by a molecular relaxation time.

The slope of the straight line through the experimental points in the 1.5 to 34.86 GHz region in Figs. 2*a* and *b*, based on eqs. 3 and 4, respectively, leads to a relaxation time value in agreement with the τ_0 values listed in Table 2 to better than 9%. Figure 3, however, which compresses these low frequency points is not a suitable plot for such a determination. The fact that the τ_0 and the value from the low frequency slope are in fairly close agreement (the error in τ_0 could amount to at least 5%) indicates that there is, at most, only a small contribution to the dielectric absorption at these frequencies from any higher frequency absorption processes.

Thus the plots based on eqs. 3 and 5 have indicated that the dielectric data cannot be characterized solely by a molecular relaxation time, and it has been the 70.6 and 144.9 GHz points which have been the critical ones. In

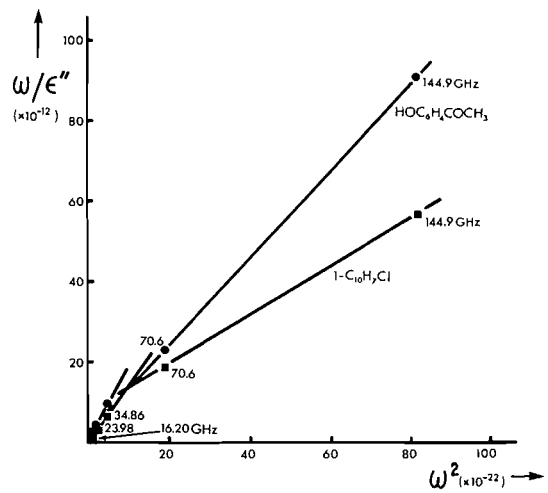

FIG. 3. Brot plot of ω/ε'' *vs.* ω^2 for *o*-hydroxyacetophenone and 1-chloronaphthalene in carbon tetrachloride at 15 °C.

particular the variation of ε'' at these frequencies has been critical in detecting deviations from Debye behavior, that is, the absorption cannot be accounted for in terms of one relaxation time. From Table 1 a comparison can be made between ε''_{obs} and ε''_{calc} for the 70.6 and also the 144.9 GHz points where their difference is seen to be between $+0.002$ to $+0.007$ for the 70.6 GHz and $+0.003$ to $+0.008$ for the 144.9 GHz points for all solutions; this is to be contrasted with all the 0.95 to 34.86 GHz points where the difference between the calculated and observed values of ε'', is, in general, of the order of ± 0.001 to ± 0.002. The observed losses at 70.6 and 144.9 GHz are therefore larger than the ones calculated based on the appropriate parameters in Table 2 indicating that the Debye and the Cole–Cole approach cannot account for all the absorption at these high frequencies; that is, some additional absorption remains to be explained.

Recent studies now have indicated that the far infrared absorption in polar and weakly polar liquids is not of the Debye type (15). It would then be reasonable to conclude that for the solutions studied here the value of τ_2 which may be deduced from Cole and Brot types of plots is not a satisfactory value in relation to a particular molecular motion since the corresponding process is not of the Debye type. From the plots in Figs. 2*a* and 3 it can be concluded though that for these systems there are not less than two absorption processes detectable in the frequency range examined and this is also true of the other systems examined here but not plotted.

Conclusions

The present results indicate that for current microwave data of a simple rigid polar solute molecule in a nonpolar solvent, no high frequency deviations from the Cole–Cole plot are apparent in the plot itself. When the distribution parameter is small (*e.g.* less than 0.03) it is difficult to distinguish by the Cole–Cole plot between this value and zero. In such a case, a better procedure to establish the presence of absorption in addition to that due to molecular relaxation is (*i*) to employ linear types of plots such as those due to Cole or Brot based on eqs. 3 and 5, (*ii*) to determine τ_0, ε_∞, and α from the microwave frequencies other than the 70 and 145 GHz points and use the estimated parameters to calculate the loss factor at these two frequencies. If $\varepsilon''_{obs} - \varepsilon''_{calc}$ emerges as a positive quantity significantly greater than the experimental error, then this indicates additional absorption. It should be noted that for these two frequencies the difference $\varepsilon'_{obs} - \varepsilon'_{calc}$, for the solutions studied here, was of the order of the experimental error and thus it is understandable that these points appear to fall on the Cole–Cole plot.

We wish to thank the National Research Council of Canada for the support which made this work possible and Mr. B. K. Morgan for invaluable technical assistance.

Urea–Boron Trihalide Adducts. I. The Boron Trifluoride Adduct of Tetramethylurea

J. S. HARTMAN AND G. J. SCHROBILGEN[1]

Department of Chemistry, Brock University, St. Catharines, Ontario

Received September 8, 1971

Evidence is presented that oxygen is the donor atom in the 1:1 adduct of tetramethylurea and boron trifluoride ($TMU.BF_3$). Hydrogen fluoride, a common impurity in boron trifluoride, leads to the formation of $TMU.H^+BF_4^-$ as well as $TMU.BF_3$. Exchange reactions among TMU, $TMU.H^+BF_4^-$ and $TMU.BF_3$ are investigated briefly. The results of the present investigation are compared with the results of a previous study which indicated that nitrogen is the donor atom in BF_3 adducts of some partially alkylated ureas.

Il est prouvé que l'oxygène est l'atome donneur dans le produit d'addition 1:1 de la tétraméthylurée avec le trifluorure de bore ($TMU.BF_3$). Le fluorure d'hydrogène, une impureté commune dans le trifluorure de bore, conduit à la formation de $TMU.H^+BF_4^-$ ainsi qu'à $TMU.BF_3$. Les réactions d'échange entre TMU, $TMU.H^+BF_4^-$ et $TMU.BF_3$ ont été brièvement étudiées. Les résultats de cette étude ont été comparés avec ceux d'une étude précédente dans laquelle il apparaît que l'azote est l'atome donneur dans les produits d'addition de BF_3 avec des urées partiellement alkylés.

Canadian Journal of Chemistry, **50**, 713 (1972)

Introduction

Ureas are well known to form 1:1 donor–acceptor adducts with boron trifluoride (1, 2), in which nitrogen and oxygen are possible donor atoms. Although oxygen has been shown to be the donor in closely related 1:1 adducts of amides with BF_3 and BCl_3 (3–5), Greenwood and Robinson have interpreted their n.m.r., i.r., and u.v. studies of BF_3 adducts of a number of partially-alkylated ureas as indicating that nitrogen is the donor atom (1). However, these studies were complicated by effects such as association of the adducts, probably as a result of N–H hydrogen bonding, and the results were not conclusive.

Although a comparison of the simple nitrogen and oxygen donors R_3N and R_2O shows that nitrogen is a better donor atom than oxygen toward BF_3 (6, 7), the effects of the donor atom can be greatly outweighed by the effects of adjacent groups in the donor molecule. Electron-withdrawing substituents or bulky substituents can greatly decrease the base strength of a potential donor atom. Thus in ureas, if canonical forms such as **1***b* and **1***c* are important enough sufficient electron density would be removed from the nitrogens and added to the oxygen that oxygen would become the preferred donor. As discussed by Greenwood and Robinson (1), a number of structural and chemical studies have shown that oxygen is the preferred donor atom in many urea complexes of a number of different elements, although a few complexes appear to be nitrogen-coordinated. In very strong acid solutions diprotonation of TMU occurs, with oxygen and one of the nitrogens being donor atoms (8). Although two donor sites of TMU are available to protons, only the 1:1 adduct with BF_3 has been reported. In the present paper we report variable-temperature n.m.r. studies which were undertaken to provide new evidence concerning the donor site in $TMU.BF_3$.

Experimental

Methylene chloride, used as the solvent in all of this work, was dried over P_2O_5 and vacuum distilled before use. Boron trifluoride (Matheson) was allowed to stand over sodium fluoride to remove hydrogen fluoride, then triply distilled under vacuum from a trap at $-78°$ to a trap at liquid nitrogen temperature, the initial and final cuts being rejected

each time. Tetramethylurea (Aldrich) and hydrogen fluoride (Matheson) were used without further purification.

Pure $TMU.BF_3$ was prepared on a vacuum line by condensing an excess of BF_3 onto a solution of TMU in CH_2Cl_2. The solvent was removed and the viscous residue dried at 80° under vacuum for 3 h. The low melting, extremely hygroscopic adduct was stored under vacuum over P_2O_5 until used. The adduct gave single ^1H and ^{19}F n.m.r. peaks. When the adduct was prepared by the procedure of Greenwood and Robinson (1), using commercial BF_3 direct from the cylinder, additional ^1H and ^{19}F peaks were observed.

$TMU.H^+.BF_4^-$ was prepared by treatment of a CH_2Cl_2 solution of pure $TMU.BF_3$ with hydrogen fluoride in a polyethylene vessel. Upon standing, colorless monoclinic crystals (m.p. 113–115°), moderately soluble in CH_2Cl_2, were obtained.

On standing for a month over calcium sulfate in a desiccator, a methylene chloride solution of $TMU.BF_3$ precipitated boric acid (m.p. 168.0–168.5°; lit. $169 \pm 1°$). The filtered solution gave a moderately soluble solid, m.p. 110–112°, which had the same ^1H and ^{19}F spectra as $TMU.H^+BF_4^-$.

Proton n.m.r. spectra were recorded at 60 MHz on a Varian Associates A-60 spectrometer equipped with a V-6040 variable temperature controller and variable temperature probe. ^{19}F spectra were recorded at 56.4 MHz on a Varian Associates DA-60IL spectrometer operating in HR sideband mode. The spectra were calibrated by the usual audio sideband method. Large ^{19}F chemical shifts (from $CFCl_3$) were calibrated by using 2500 Hz sidebands arising from a Hewlett–Packard 200 CDR audio oscillator. A Varian V-4540 variable temperature controller and variable temperature probe were used. Chemical shifts are given in p.p.m. to low field of TMS (^1H) and p.p.m. to high field of $CFCl_3$ (^{19}F).

Infrared spectra were obtained on a Perkin–Elmer Model 237B grating spectrophotometer. Spectra were recorded in CH_2Cl_2 solutions against a solvent blank using 0.1 mm solution cells with potassium bromide windows.

Results

The n.m.r. parameters of $TMU.BF_3$ and related compounds are listed in Table 1. Like free TMU (9), $TMU.BF_3$ and $TMU.H^+BF_4^-$ each give a single sharp methyl resonance at temperatures down to $-100°$, with no evidence for an amide-like *cis–trans* nonequivalence of methyl groups. Complexation of TMU with BF_3 shifts the ^1H n.m.r. peak 0.27 p.p.m. to low field and increases the ^{13}C–^1H coupling constant of the *N*-methyl groups by 3.2 Hz. At low temperatures the single room temperature ^{19}F peak at 149.2 p.p.m. is split into two peaks of relative areas 1:4 and relative chemical shift 0.064 p.p.m. This splitting can be attributed to a ^{10}B–^{11}B isotope shift, and its collapse at higher temperatures indicates rapid redistribution of fluorine among boron atoms (10, 11). In the presence of excess TMU the room temperature ^1H spectrum contained separate sharp singlets corresponding to TMU and $TMU.BF_3$. The ^{19}F spectrum contained the $TMU.BF_3$ peak as the only major peak; in some samples a second small peak could be detected at 151.2 p.p.m. In the presence of excess BF_3 the ^1H spectrum showed only the $TMU.BF_3$ peak, and the room temperature ^{19}F spectrum showed a single peak of chemical shift intermediate between BF_3 and $TMU.BF_3$, which indicated rapid fluorine exchange between free BF_3 and $TMU.BF_3$.

The ^1H spectrum of $TMU.H^+BF_4^-$ consisted of a sharp methyl singlet (3.12δ) and a broadened singlet with concentration-dependent chemical shift (about 11.4δ) arising from the added proton. The relative peak intensities were approximately 12:1. The ^{19}F spectrum consisted of a broadened singlet (peak width at half-height, 3.4 Hz) at 151.2 p.p.m. No fine structure could be observed, but in the presence of TMU (0.5 M) the signal was resolved to show an isotope shift, with the F-on-^{11}B portion split into a 1:1:1:1 quartet. These ^{19}F param-

TABLE 2. Some i.r. absorption frequencies in TMU and $TMU.BF_3$

Assignment*	Frequency (cm^{-1}) TMU	Frequency (cm^{-1}) $TMU.BF_3$	Complexation shift (cm^{-1})
Amide I (predominantly C—O stretch)	1636	1605	−31
Partially C—N stretch	1497	1550	+53

*Discussed in refs. 1 and 3.

eters agree closely with those observed for $(n\text{-}C_4H_9)_4N^+BF_4^-$ in CH_2Cl_2 (12).

Addition of $TMU.BF_3$ did not affect the ^1H or ^{19}F n.m.r. peaks of $TMU.H^+BF_4^-$. In contrast, addition of free TMU to $TMU.H^+BF_4^-$ had striking effects on the ^1H spectrum, as well as sharpening the ^{19}F signal as described above. Separate methyl resonances for TMU and $TMU.H^+$ could not be observed at any temperature down to −95°, indicating a rapid chemical exchange process. Titration of CH_2Cl_2 solutions of $TMU.H^+BF_4^-$ with free TMU led first to a down-field shift of the low-field proton absorption, followed by a reversal in the trend as more TMU was added (Fig. 1*a*). The single exchange averaged methyl peak shifted to higher field with increasing proportions of TMU (Fig. 1*b*).

When $TMU.BF_3$ was prepared directly from commercial BF_3, the ^1H and ^{19}F spectra were a superposition of the spectra of $TMU.BF_3$ and $TMU.H^+BF_4^-$. The $TMU.H^+BF_4^-$ peaks varied in size in different samples but always remained smaller than the $TMU.BF_3$ peaks. The chemical exchange behavior is that expected for a mixture of the two species. Thus on addition of free TMU the $TMU.BF_3$ ^1H peak is unaffected, but only a single averaged methyl resonance is observed for TMU and $TMU.H^+$. The assignment of the smaller ^{19}F resonance at 151.2 p.p.m. to BF_4^- was confirmed by a pronounced increase in its size, with no observable change in the isotope shift or the boron–fluorine coupling, when $(n\text{-}C_4H_9)_4N^+BF_4^-$ was added to the sample.

Infrared frequencies and BF_3 complexation shifts for two prominent bands of TMU and $TMU.BF_3$ are given in Table 2.

Discussion

The Donor Site in $TMU.BF_3$

(i) ^1H Nuclear Magnetic Resonance Evidence: Chemical Exchange

The single ^1H n.m.r. peak which is observed at temperatures as low as −100° is strong evidence that a rapid chemical exchange process is occurring in $TMU.BF_3$. In the slow-exchange

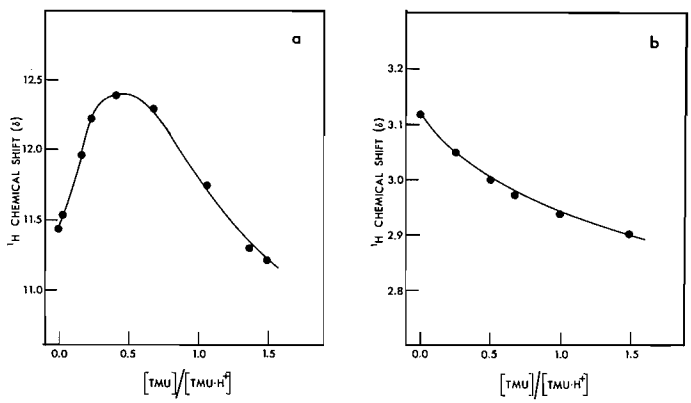

FIG. 1. Variation of the ^1H chemical shift of (*a*) the oxygen proton, (*b*) the CH_3 protons, of $TMU.H^+BF_4^-$ on titration with TMU.

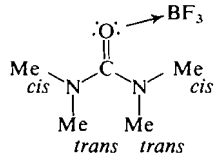
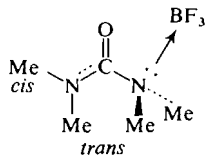
limit, either oxygen donation or nitrogen donation should give more than one ^1H peak. Oxygen donation would give separate peaks due to the methyl groups *cis* and *trans* to the carbonyl group (**2**), with the added possibility that *cis-trans* isomerism about the C=O bond (13) would result in unique environments for all four methyl groups. Nitrogen donation should



2



3

give separate resonances due to the free and complexed NMe_2 groups, with the uncomplexed NMe_2 group showing amide-like nonequivalence of methyls *cis* and *trans* to the carbonyl group (**3**). The observation of separate peaks for TMU and TMU.BF_3 when excess TMU is present rules out an averaging of methyl environments *via* rapid *inter*molecular exchange. Rapid *intra*molecular exchange of BF_3 between the two nitrogens or between nitrogen and oxygen cannot be excluded. However, in other BF_3 complexes with both oxygen (2, 10) and nitrogen (14) donors, breaking and reforming of donor–acceptor bonds is slow on the n.m.r. time scale at temperatures well above $-100°$. If nitrogen is the donor, an especially rapid transfer of BF_3 between the two nitrogens must be invoked to explain the single ^1H peak. If oxygen is the donor, rapid rotation about the "amide" C—N bonds can account for the averaging of the methyl environments without the need to invoke bond breaking. As in amides (15), the barrier to rotation about the C—N bond should increase on complex formation due to enhancement of the contribution of the resonance forms **1***b* and **1***c*. However, rotation could still be rapid in TMU.BF_3 at $-100°$. The inability to observe an amide type of *cis–trans* nonequivalence of *N*-alkyl groups in ureas has been discussed in terms of competitive conjugation of the two "amide" systems (16) and in terms of steric repulsion in TMU which prevents the C_2NCONC_2 skeleton from being completely planar (17). Both of these factors would remain effective in the complex and would lower the barrier to rotation about the C—N bond. Thus the single low-temperature ^1H resonance of TMU.BF_3 seems more consistent with oxygen donation.

(ii) ^{13}C–^1H Coupling in N-Methyl Groups

Henneike and Drago have used changes in ^{13}C–^1H coupling constants of *N*-methyl groups on complexation with BF_3 as an empirical test for the donor site in dimethylcyanamide (18). Complexation direct to the nitrogen of the *N*-methyl group was shown to cause large increases in $J_{^{13}C-^1H}$ (8–11 Hz in aliphatic amines), whereas complexation at a site two bonds farther removed, as in dimethylacetamide, causes much smaller increases (<1 Hz). According to this criterion, the increase in $J_{^{13}C-^1H}$ in TMU on complexation (3.2 Hz) is larger than that expected for oxygen donation but smaller than that expected for nitrogen donation. It appears to be somewhat more consistent with nitrogen donation than with oxygen donation, since a rapid chemical exchange of BF_3 between the two nitrogens could average a change in $J_{^{13}C-^1H}$ of 6.4 Hz to the observed value. However, the criterion of changes in $J_{^{13}C-^1H}$ has been applied to only a limited number of compounds (18) and may have limited applicability. Thus the ^{13}C–^1H coupling constant data do not exclude oxygen donation in TMU.BF_3.

(iii) ^{19}F Nuclear Magnetic Resonance Evidence

Table 3 gives the ^{19}F chemical shifts of a number of BF_3 adducts of simple oxygen and nitrogen donors. Whereas the nitrogen-donor adducts absorb over a range of 22 p.p.m. and the oxygen-donor adducts absorb over a range of 10 p.p.m., the adducts of the four simple aliphatic carbonyl donors in Table 3 absorb over a range of only 3.3 p.p.m. Since TMU.BF_3 absorbs in this same range, very close to the absorption of the closely related dimethylacetamide adduct, donation from the carbonyl oxygen is indicated. However, the wide range of chemical shifts for nitrogen donation covers the narrow range for carbonyl donation, so that nitrogen donation in TMU.BF_3 cannot be excluded on the basis of the ^{19}F chemical shift.

If nitrogen were the donor we would expect TMU.BF_3 to have some of the characteristics of amine adducts, such as splittings due to

TABLE 3. ^{19}F Chemical shifts of some BF_3 adducts*

Class of donor	BF_3 Adduct of	^{19}F chemical shift
	TMU	149.2
Carbonyl donors	Acetone	148.2
	Dimethylacetamide	148.6
	Methyl acetate	149.4
	Dimethylformamide	151.5
Ether donors	Diethyl ether	153.7
	Ethyl methyl ether	156.2
	Dimethyl ether	158.2
Nitrogen donors	Acetonitrile	142.3
	4-Methylpyridine	142.4
	Triethylamine	149.7
	Trimethylamine	164.1

*Methylene chloride solution, −80°, p.p.m. to high field of $CFCl_3$. The chemical shifts of some of these adducts have been reported (19), but a variety of solvents and reference compounds were used in the previous studies.

boron–fluorine coupling and boron–proton coupling in the ^{19}F and ^{1}H spectra, respectively (20). The absence of such splittings and the appearance of a ^{10}B–^{11}B isotope shift in the ^{19}F spectrum has been characteristic of oxygen donation in BF_3 complexes (10), and by these criteria oxygen should be the donor in TMU.BF_3, but again the evidence is not conclusive. The absence of splittings due to boron–fluorine coupling may be merely a characteristic of weak donation. Thus $CH_3CN.BF_3$, a weak nitrogen–donor complex, does not show such splittings.

(iv) Infrared Evidence

As discussed by Greenwood and Robinson (1), nitrogen coordination in ureas should cause an increase in the C—O stretching frequency because loss of resonance involving the coordinated nitrogen should give greater double bond character to the C—O bond. Conversely, oxygen coordination is known to decrease the vibrational frequency of this bond. In urea itself and in its adducts the principal modes of vibration are strongly coupled, and similar effects are operative in alkylated ureas (1). Since ureas can be considered to have two "amide" linkages to the carbonyl bond, the interpretation of their i.r. spectra is similar to that of amides. The complexities of amide i.r. spectra, and the effects of complexation to boron trihalides, have been discussed (3). In amides, the so-called Amide I band, which occurs in the 1600–1700 cm^{-1} region, arises mainly (>80%) from the carbonyl stretch. Following Greenwood and Robinson we assume that the band at highest frequency in TMU in this region is analogous to the Amide I band and is predominantly a C—O stretching mode. The shift of this band to lower frequency on complexation with BF_3 (Table 2) contrasts with the shifts of the analogous band in partially alkylated ureas to higher frequency (1) and indicates oxygen coordination rather than nitrogen coordination in TMU.BF_3.

The shift to lower frequency of the Amide I band of TMU on BF_3 complexation is much less (31 cm^{-1}) than the analogous shifts of the carbonyl stretching frequency in other bases (BF_3 complexation shifts: acetone, 70 cm^{-1} (21); acetophenone, 107 cm^{-1} (21); ethyl acetate, 119 cm^{-1} (22)). This can be attributed to contributions to the Amide I band by factors other than the C—O stretch. This is in line with related results for dimethylamides. When dimethylformamide and dimethylacetamide are complexed with BCl_3 the Amide I bands undergo negligible complexation shifts, although donation is known to be from oxygen (3). Because of the coupling of vibrations this result is still consistent with oxygen donation; nitrogen donation would require a pronounced shift to higher frequencies (3).

Assignment of the absorption at lower frequency (1497 cm^{-1} in TMU, Table 2), is not clear-cut, but by analogy with amides it should have a large component of C—N stretch. If so, the increase in the frequency of this peak on adduct formation is consistent with the greater contribution from structures **1***b* and **1***c* expected in the adduct.

The BF_3 complexation shifts of the Amide I band in partially alkylated ureas were consistently to higher frequencies, in both solution and solid state spectra (1). This does suggest nitrogen coordination, and it is possible that nitrogen coordination occurs in the less sterically hindered di- and trialkylureas but that a change to oxygen coordination occurs in TMU.BF_3. However, Greenwood and Robinson have presented evidence for association of the adducts in non-polar solvents, and there is i.r. evidence that uncomplexed partially alkylated ureas are themselves associated in non-polar solvents (23). Association could take place via strong inter-

molecular hydrogen bonding and would affect the i.r. frequencies. In view of these complicating factors the suggestion of nitrogen donation in the BF_3 adducts of partially alkylated ureas does not seem to be too strongly based. Hydrogen bonding is not possible in TMU or TMU.BF_3 and thus the results should be easier to interpret. Our results support oxygen donation in TMU.BF_3.

(v) Summary

No single one of the above lines of evidence is sufficient to establish oxygen as the donor site in TMU.BF_3. However, the different lines of evidence taken as a whole do establish oxygen donation with a fairly high degree of certainty.

Hydrogen Fluoride Contamination of Urea–BF_3 Adducts

Boron trifluoride is capable of increasing the Bronsted acidity of hydrogen fluoride so that the pair HF–BF_3 is a very strong acid (24), capable of protonating ureas:

$$[1] \qquad HF + BF_3 + \text{urea} \rightarrow \text{urea}.H^+BF_4^-$$

Our results demonstrate the ease with which TMU.BF_3 becomes contaminated with TMU.$H^+BF_4^-$. When sufficient precautions are taken to avoid HF contamination a single ^{19}F peak is observed for TMU.BF_3. A second ^{19}F peak, 2 p.p.m. to higher field, is diagnostic of the presence of BF_4^-. We find that commercial BF_3 may contain up to 20 mol% HF, if the BF_3 is taken from nearly-empty gas cylinders in which the less volatile HF has become concentrated. A brief study has shown that the effects of hydrogen fluoride on the ^{19}F spectra of dialkylamide-BF_3 and dialkylurea-BF_3 systems are similar to the effects in the TMU-BF_3 system.

Greenwood and Robinson reported that their BF_3 adducts of di- and trialkylated ureas gave two ^{19}F signals, a broad resonance at 148.5 ± 1 p.p.m. and a sharp peak at 150.5 ± 1 p.p.m. (1). No fine structure was reported. We can assign their smaller high-field peak to BF_4^-. Since good analyses were reported for the crystalline adducts, the impurity may have been formed on solution. If the solvent were not dry, traces of water might have given urea.$H^+BF_4^-$:

$$[2] \qquad \text{urea}.BF_3 + 3H_2O \rightarrow B(OH)_3 + 3HF + \text{urea}$$
$$HF + \text{urea}.BF_3 \rightarrow \text{urea}.H^+BF_4^-$$

This could explain the observation that the relative areas of the ^{19}F peaks depended on the solvent. In accord with a process such as [2], we have isolated boric acid and TMU.$H^+BF_4^-$ from a methylene chloride solution of TMU.BF_3 which have been allowed to stand in a desiccator for a month. The water required may have been abstracted from the calcium sulfate desiccant.

Exchange Processes Involving Protonated TMU

In TMU.H^+ the added proton is probably attached to the carbonyl oxygen, as indicated by previous work (25). Its ^1H chemical shift (11.4δ) is similar to that of protonated amides and esters which are known to be carbonyl donors. (8). The peculiar variation of the chemical shift of this proton on titration with free TMU (Fig. 1*a*) is apparently a result of hydrogen bonding effects. The observation of a single methyl resonance down to $-100°$ for TMU.$H^+BF_4^-$ indicates a low barrier to rotation about the "amide" C—N bonds, as in TMU and TMU.BF_3. This contrasts with *di*protonated TMU which has a very high barrier to rotation about the single remaining "amide" bond (8).

Whereas TMU and TMU.BF_3 give separate room temperature ^1H signals, only a single averaged methyl resonance is observed for TMU and TMU.H^+, even at $-100°$. On titration of TMU.$H^+BF_4^-$ with TMU the single methyl peak shifts to higher field and approaches the value for free TMU (Fig. 1*b*). Proton exchange among TMU molecules is fast on the n.m.r. time scale even at $-100°$, whereas BF_3 exchange is slow at room temperature. A similar difference of several orders of magnitude for H^+ and BF_3 exchange rates has been reported previously in the methanol–BF_3 system (26).

The occurrence of rapid proton exchange between base molecules can easily lead to difficulties in interpretation of ^1H n.m.r. spectra of BF_3 adducts. Such difficulties are especially likely to arise when the study is being carried out in the presence of excess base, and it is not recognized that varying amounts of the protonated base may be present in different samples. It is then difficult to account for the low-field shifts of "free base" peaks, with respect to their positions in the absence of the BF_3 adduct. It is also difficult to account for the presence of a second ^{19}F peak. Such a second peak has been observed in a number of studies of BF_3 adducts.

We thank the National Research Council for financial support, Dr. J. M. Miller for helpful discussions, and the Department of Chemistry, McMaster University, for the use of ^{19}F n.m.r. facilities.

Tricarbonylchromium π-Complexes of αβγδ-Tetraphenylporphin and its Metal Chelates

NIALL J. GOGAN AND ZAHIR U. SIDDIQUI
Memorial University of Newfoundland, St. John's, Newfoundland

Received September 24, 1971

Tricarbonylchromium π-complexes of αβγδ-tetraphenylporphin and its Cr(II), Mn(III), Ni(II), Cu(II), and Zn(II) chelates have been prepared. The complexes vary in stability with the Zn compound being the most stable. The complexes have been studied by their visible and i.r. spectra and their n.m.r. spectra where applicable. A study of the CO stretching vibrations in the i.r. shows no appreciable interaction between the two metals and arguments are made to show that this lack of interaction is due to absence of π interactions between the porphin and phenyl ring systems.

Les complexes π tricarbonylchrome des tétraphénylporphines αβγδ et de ses chélates avec le Cr(II), Mn(III), Ni(II), Cu(II), et Zn(II) ont été préparés. Ces complexes, de stabilité variable (ceux de Zn étant les plus stables), ont été étudiés par spectroscopie visible, i.r. et r.m.n. quand ce dernier était applicable. L'étude de la vibration de valence du CO à l'i.r. ne montre aucune interaction notable entre les deux métaux et les arguments avancés pour expliquer ce fait s'appuient sur l'absence des interactions π entre la porphine et les systèmes aromatiques.

Canadian Journal of Chemistry, **50**, 720 (1972)

Introduction

Many complexes containing two different transition metals have been prepared and studied. Most of these have the two metals either directly bonded or joined by simple bridges[1] and relatively few have the metals arranged in such a way that the two metals can interact only through the ligand system.[2] In this paper we wish to report the synthesis and study of complexes in this latter category. These consist of complexes of αβγδ-tetraphenylporphin (TPP) in which one transition metal is σ-bonded to the four central nitrogen atoms while a tricarbonylchromium group is π-bonded to a phenyl ring.[3] The general structure of these complexes is shown in Fig. 1.

The choice of TPP as a ligand in this study is particularly appropriate because porphyrins are perhaps the most important class of ligands which occur in nature. The study of these double metal complexes could help elucidate the electron distribution in porphyrins. Porphyrin metal chelates have been extensively studied and a good account of many of these studies is given in the book by Falk (1). Much work has been done on the metal chelates of TPP. These studies include their visible spectra (2), their i.r. spectra (3), as well as some work on their n.m.r. (4) and e.s.r. (5) spectra, and crystal structure determinations (6). There is some evidence from the i.r. studies (3) that electronic effects are transmitted from the central metal to the phenyl ring. Apart from the preparation of these complexes, the purpose of this study is to probe these effects.

A large number of tricarbonylchromium complexes of substituted benzenes have been prepared and studied. This work has been reviewed by Dobson *et al.* (7). A particularly interesting aspect of these complexes is that the positions of the carbonyl stretching vibrations are sensitive to changes in electron distribution

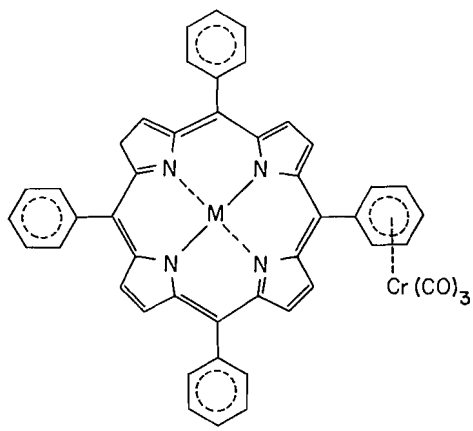

FIG. 1. Structures of the double metal complexes M-TPPCr(CO)$_3$.

[1]A selection of these are tabulated in Table 5 of the review by Abel and Stone (13).

[2]Most of the complexes in this category are tabulated in the review by Cais and Lupin (14).

[3]A preliminary communication of the preparation of the Zn complexes has been made previously (15).

in the benzene ring (8). In this study we use the carbonyl stretching vibrations to see if electronic effects are transmitted from the central σ-bonded metal to the tricarbonylchromium group.

Experimental

General

Visible spectra were recorded on a Perkin–Elmer 202 spectrometer, i.r. spectra on a Perkin–Elmer 457 spectrometer, and n.m.r. spectra on a Varian HA-100 spectrometer. Elemental analyses were determined by Schwarzkopf analytical labs., New York. Solution spectra were determined in spectroscopic grade solvents which had been deoxygenated before use by refluxing in a stream of pure nitrogen. Other solvents and chemicals were purified, if necessary, before use.

Preparations

TPP

TPP was prepared by the method of Adler *et al.* (9) by the reaction of pyrrole and benzaldehyde in refluxing propionic acid. It was purified by chromatography and recrystallized from benzene. Its visible spectrum agreed with the literature (2).

Co(II), Ni(II), Cu(II), and Zn(II) Chelates of TPP

The relevant metal acetate and TPP were refluxed in a mixture of chloroform and acetic acid (usually 1:5). The solvent was evaporated off *in vacuo*. The solid product was washed with water to remove any unreacted metal acetate. If any free TPP was present it was extracted in a Soxhlet apparatus with a mixture of methanol and ether (1:2). The product obtained was then recrystallized from suitable solvents. The visible spectra agreed with the literature (2).

Mn(III)TPPCl

TPP (2 g) and manganese acetate hydrate (1 g) were refluxed in 100 ml glacial acetic acid, for 4 h. Unreacted TPP and manganese acetate were removed from the solid product as described above. The resulting product (0.5 g) was refluxed in a mixture of 250 ml glacial acetic acid, 50 ml chloroform, and 2.5 ml concentrated hydrochloric acid for 3 h in a stream of air. The solvents were removed *in vacuo*. The solid product was washed with water and extracted with methanol in a Soxhlet apparatus. The product was recrystallized from benzene. Its visible spectrum was the same as that reported by Boucher (10).

Co(III)(TPP)(Pyridine)Cl

This compound was prepared by the method of Yamamoto and Tonomura (11) by the reaction of TPP, Co(II) acetate, pyridine, and hydrochloric acid in the presence of air. Its visible spectrum agreed with the literature (11).

Cr(II)TPP

TPP (0.5 g) and hexacarbonylchromium(0) (0.5 g) were refluxed in di-*n*-butyl ether for 6 h in an atmosphere of nitrogen containing small quantities of air. The solvent was evaporated *in vacuo* leaving a green solid. Its visible spectrum showed almost complete conversion to the metal chelate. The product was then purified by extraction into methanol to give a blue solid (visible maxima 398, 450, 568, and 607 nm). The analysis agreed with the formula $CrTPP{\cdot}4H_2O$. Its magnetic susceptibility obtained by the Faraday method gave 4.9 BM in keeping with a high spin d^4 system;[4] yield, 540 mg, 90%.

Anal. Calcd. for $C_{44}H_{36}N_4O_4Cr$: C, 71.73; H, 4.93; N, 7.60. Found: C, 70.96; H, 5.00; N, 7.62.

The Reaction of Hexacarbonylchromium(0) and Zn(II)TPP

Hexacarbonylchromium(0) (0.5 g) and Zn(II)TPP (0.5 g) were reacted together in 500 ml of di-*n*-butyl ether for 9 h in an atmosphere of nitrogen. The solvent was removed *in vacuo*. The resulting solid was chromatographed on Florisil to give two tricarbonylchromium(0) complexes and recovered Zn(II)TPP. $Zn(II)TPPCr(CO)_3{\cdot}2H_2O$; yield, 300 mg, 47%.

Anal. Calcd. for $C_{47}H_{32}N_4O_5CrZn$: C, 66.40; H, 3.79; N, 6.59. Found: C, 66.11; H, 4.06; N, 6.56.

The Reaction of Hexacarbonylchromium(0) and M-TPP (M = Mn(III)Cl, Co(II), Ni(II), and Cu(II))

The reaction was carried out in a manner similar to the reaction of Zn(II)TPP. In each case the solid product before chromatography showed two strong absorptions in the carbonyl stretching region of the i.r. After chromatography the tricarbonylchromium complex had either decomposed completely or the elemental analysis showed it to be partially decomposed.

The Reaction of Hexacarbonylchromium(0) and TPP

Hexacarbonylchromium(0) (0.5 g) and TPP (0.5 g) were refluxed in di-*n*-butyl ether for 6 h in an atmosphere of pure nitrogen. The solvent was removed *in vacuo*. The dry product showed four bands in the carbonyl stretching region of the i.r. Their relative intensities indicated them to be two sets of two bands with one set having maxima at 1990 and 1930 cm^{-1} and the other set, with about 10% of the intensity of the first, having maxima at 1970 and 1900 cm^{-1}. These latter bands disappeared when the solid was dissolved in $CHCl_3$ or CCl_4. Chromatography on Florisil yielded two bands. One has maxima in the carbonyl stretching region of the i.r. at 1990 and 1930 cm^{-1} and proved to be $TPPCr(CO)_3$. The second band was CrTPP.

The Reaction of Hexacarbonylchromium(0) and Co(III)TPP(pyridine)Cl

This reaction was carried out in a manner similar to the reaction with the other chelates. No tricarbonylchromium complex was formed and Co(II)TPP was recovered from the reaction.

Results and Discussion

Synthesis

All the metal chelates, M-TPP, have been reported previously with the exception of the chromium chelate.[4] Reaction of the metal chelates with hexacarbonylchromium(0) produced the tricarbonylchromium derivatives. In

[4]Recently, Fleischer and Srivastava (16) have reported the preparation of Cr(III)(OMe)TPP·2MeOH. They did not report the characterization of a Cr(II) compound but did observe an intermediate $Cr(CO)_3$ complex but apparently did not isolate it.

TABLE 1. The n.m.r. spectra of Zn complexes (τ)($CDCl_3$)

Complex	β-Pyrrole	Uncomplexed phenyl	Complexed phenyl
ZnTPP	1.17	1.80, 2.23	
$ZnTPPCr(CO)_3$	1.11	1.81, 2.25(3)*	3.33, 4.21(1)
$ZnTPP[Cr(CO)_3]_2$	1.09	1.83, 2.26(1)	3.44, 4.20(1)

*Numbers in parentheses denote relative intensities.

TABLE 2. Visible spectra of Zn complexes

Complex	nm ($\varepsilon \times 10^{-3}$)		
Zn-TPP	420 (600)	550 (22)	595 (6.0)
$Zn\text{-}TPPCr(CO)_3$	422 (230)	562 (13)	612 (6.3)
$ZN\text{-}TPP[Cr(CO)_3]_2$	424 (200)	570 (12)	621 (6.9)

the case of Zn(II)TPP a reasonably stable tricarbonylchromium complex was obtained with the structure shown in Fig. 1. A second complex was recovered with two phenyl rings complexed with tricarbonylchromium groups. Attempts to recrystallize these complexes slowly resulted in decomposition with Zn(II)TPP recovered. The other complexes could not be obtained pure due to decomposition. Thus satisfactory elemental analysis could not be obtained. The Mn(III)TPPCl tricarbonylchromium complex was particularly unstable and decomposed when attempts were made to isolate it. The Co(III)-TPPCl pyridine did not form a tricarbonylchromium complex. The reaction of TPP with hexacarbonylchromium(0) in refluxing di-*n*-butyl ether with rigorous exclusion of air resulted in the isolation of the tricarbonylchromium π-complex of TPP itself, Fig. 2. The tricarbonylchromium π-complex of CrTPP was also formed in this reaction but it decomposed when attempts were made to isolate it.

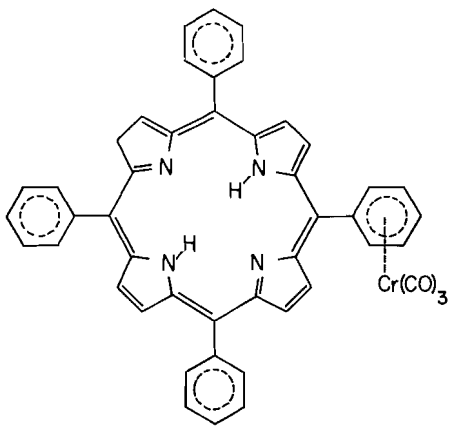

FIG. 2. Structure of the free base complex $TPPCr(CO)_3$.

Structure

Both complexes obtained from Zn(II)TPP showed strong carbonyl stretching absorptions in the i.r. at 1972 and 1902 cm^{-1} ($CHCl_3$) as expected for the tricarbonylchromium grouping. The n.m.r. spectrum of the Zn(II)TPPCr-$(CO)_3$ is shown in Fig. 3. The spin–spin splittings could not be resolved as in the case of TPP (4). The n.m.r. of the complex with two tricarbonylchromium groups attached is similar to Fig. 3 except the two groups of phenyl resonances are of equal intensity. The n.m.r. results are given in Table 1. The protons of the uncomplexed phenyl rings and the β-pyrrole proton are almost unchanged from those in Zn(II)TPP. The shift in phenyl proton resonance on attachment of a tricarbonylchromium group is comparable to that found between benzene and tricarbonylbenzenechromium(0). The relative intensities of the phenyl proton resonances are given in parentheses in Table 1 and agree with the assigned composition.

The visible spectra maxima of the Zn compounds (Table 2) show shifts to higher wavelength on addition of tricarbonylchromium groups. This was useful for determining whether the π-complex or the parent metal chelate was present. When the solid complexes were heated above 110 °C they decomposed giving the parent Zn(II)TPP. Similar decomposition also occur-

red when solutions of the complexes in chloroform were left standing for several hours. This behavior is typical of tricarbonylarenechromium compounds. The above data, together with the elemental analysis, show that the structure given in Fig. 1 is correct for Zn(II)-TPPCr(CO)$_3$ and that the second Zn complex has a second phenyl ring with a tricarbonylchromium group attached. This latter compound could exist in several isomeric forms

with the substituted *trans* α,γ-form (Fig. 4) being the most likely on steric grounds.

The general structural features of the other mixed transition metal complexes were deduced mainly by analogy to the zinc compounds. All showed two strong carbonyl stretching absorptions in the i.r. The visible spectra maxima are listed in Table 3. All the complexes showed the same general shift in the positions of their maxima to higher wavelength. All the complexes decomposed on standing in solution to the parent metal chelate, and some decomposed in the solid phase. The tricarbonylchromium complex of TPP gave an n.m.r. spectrum (Fig. 5). It also shows a shift in phenyl proton resonance due to complexation. However, the shift is not as great as that for the Zn complex and there is

overlap between the proton resonances of the complexed and uncomplexed phenyl rings.

Infrared Spectra and Electronic Effects

The striking feature of the i.r. spectra of the double metal complexes, MTPPCr(CO)$_3$ (Table 4) is the similarity in the positions of the carbonyl stretching vibrations. These occur at the same frequency within the experimental error. The free base complex TPPCr(CO)$_3$ was the only tricarbonylchromium complex in the series to show any significant difference in this respect. The higher wavelength (1990, 1930 cm^{-1}) in this complex means that there is less π-electron density on the carbonyl group's antibonding orbitals than in the metal complexes.

Figure 6 shows a qualitative molecular orbital scheme for the higher bonding orbitals of the metalloporphin system. The scheme is based on the work of Zerner and Gouterman (12). The variation in the number of σ and π electrons, indicated in Fig. 6, means that if there was either a σ or π effect or both, transmitted from the central metal to the carbonyl groups, it should be observable in a variation in the position of the carbonyl stretching vibrations. However, no variation was observed. If there was significant interaction between the π-systems of the porphin ring and the phenyl rings one would expect an appreciable effect on the tricarbonylchromium group. On the other hand, if the systems could interact only through the σ framework, the effect would be very small as the σ orbitals are localized on pairs of atoms. This interpretation is consistent with the X-ray work of Fleischer *et al.* (6) who showed that the phenyl rings in ZnTPP are perpendicular to the plane of the porphin system. This configuration would not allow any π interaction between the porphin and the phenyl rings. The present work, therefore, would suggest that the mutual configuration of the porphin and phenyl systems are perpendicular in solution, as well as in the solid. The results of Thomas and Martel (3) showed a variation of 5 cm^{-1} in the C—Cl stretching vibration position of *p*-chlorotetraphenylporphinmetals on changing the metals. This effect is rather small and is consistent with the above interpretation.

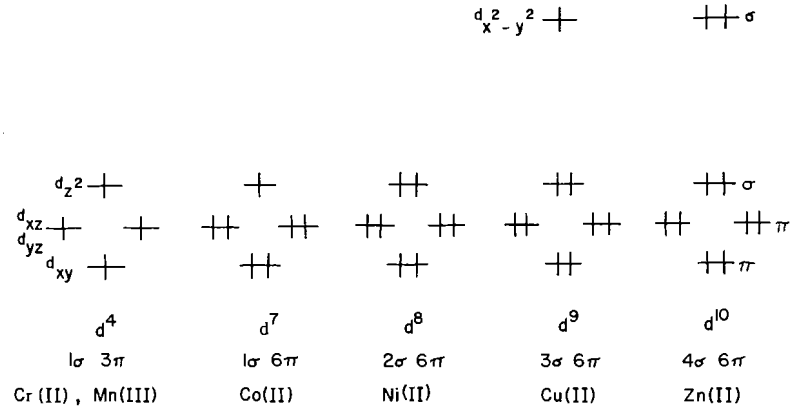

FIG. 6. Qualitative molecular orbital diagram for the central metal–porphin interaction.

A Synthetic Study in the Tricyclovetivene Series

A. DELJAC, W. D. MACKAY, CONNIE S. J. PAN, KAREL J. WIESNER, AND K. WIESNER
Natural Products Research Center, University of New Brunswick, Fredericton, New Brunswick

Received September 29, 1971

The total synthesis of racemic tricyclovetivene (**1***a*) and isomers (**1***b* and **26**) is described. The crucial reaction of the synthesis is a cyclization (**iii**) developed in this laboratory.

La synthèse totale du tricyclovetivène (**1***a*) racémique et de ses isomères (**1***b* et **26**) est décrite. L'étape cruciale de la synthèse est une cyclisation (**iii**) mise au point dans ce laboratoire.

Canadian Journal of Chemistry, **50**, 726 (1972)

In the course of model studies conducted in preparation to a total synthesis of songorine (**i**), we have discovered (1) a novel route to the C,D ring system of this alkaloid. The synthetic route involved the cyclization of compound **ii** in a basic or compound **iii** in an acidic medium. Both reactions were stereospecific and gave the products **iv** or **v** respectively. In order to explore further the scope and applicability of our method and also in order to ascertain the stereospecificity of the reaction in compounds not including a preformed bicycloheptane system as **ii** or **iii**, we decided to use the method in the synthesis of some sesquiterpene.

It appeared to us that the hydrocarbon tricyclovetivene (2) (**1***a*) might serve as a useful and, at the same time, profitable model for our synthetic scheme.

The readily available starting material, 1-methyl-indan-5-ol (**2**) (3) was converted to its allyl ether (**3**) by alkylation with allyl chloride in the presence of potassium carbonate and potassium iodide. A Claisen rearrangement of compound **3** at 185 °C gave the phenol (**4**) (i.r. hydroxyl at 3615 cm^{-1}; n.m.r., vinyl protons τ 3.96–5.16).[1] Since the rearrangement was expected to prefer the less hindered ortho position and since only one product was observed, it was preliminarily assumed that the product must indeed have the structure **4** (for proof, *vide infra*).

The phenol (**4**) was methylated with dimethyl sulfate and alkali to give the methoxy derivative (**5**). The unsaturated side chain was modified by a series of standard reactions (**6**–**8**) to prepare it for eventual cyclization. Treatment of **5** with sodium chlorate and a catalytic amount of osmium tetroxide gave the diol (**6**) which in turn underwent oxidative cleavage with sodium periodate to furnish directly the aldehyde (**7**) (i.r., aldehyde at 1725 cm^{-1}). Ketalization with ethylene glycol and *p*-toluenesulfonic acid gave the corresponding acetal (**8**).

Modification of the bicyclic system of **8** in preparation for cyclization was accomplished in the following two steps. The acetal (**8**) was subjected to a Birch reduction and the resulting dienol ether (**9**) was immediately hydrolyzed in aqueous methanolic oxalic acid to furnish the β,γ-unsaturated ketone (**10**) (i.r., ketone at 1720 cm^{-1}; n.m.r., no vinyl protons).

Cyclization of the β,γ-unsaturated ketone (**10**) was accomplished by heating in 80% acetic acid to furnish a mixture of tricyclic epimers (**11***a* and *b*) in a ratio of 2:3.[2] The stereochemistry of the hydroxyl in **11***a* and *b* remains undefined. This is unimportant since the asymmetry of the carbon carrying the hydroxyl will be subsequently removed by its reduction to a methylene. However, only two sharply melting diastereoisomers, **11***a*, m.p. 68–69 °C (ether–hexane) and **11***b*, m.p. 167–168 °C (ether) were isolated by fractional crystallization and thus it was clear that in each case the hydroxyl has a unique configuration. The i.r. spectra of the two epimers (**11***a* and *b*) both showed absorption maxima for the α,β-unsaturated ketone, 1685 cm^{-1} for **11***a* and 1680 cm^{-1} for **11***b* and the hydroxyl, 3625 cm^{-1} for **11***a* and 3615 cm^{-1} for **11***b*, with only minor differences in the fingerprint region. The n.m.r. spectrum showed a distinct difference for position of the methyl

[1]Only relevant spectral data are mentioned in the theoretical; for full spectral and characterization data see Experimental.

[2]Base-catalyzed cyclization of a corresponding β,γ-unsaturated keto aldehyde gave in this case no result.

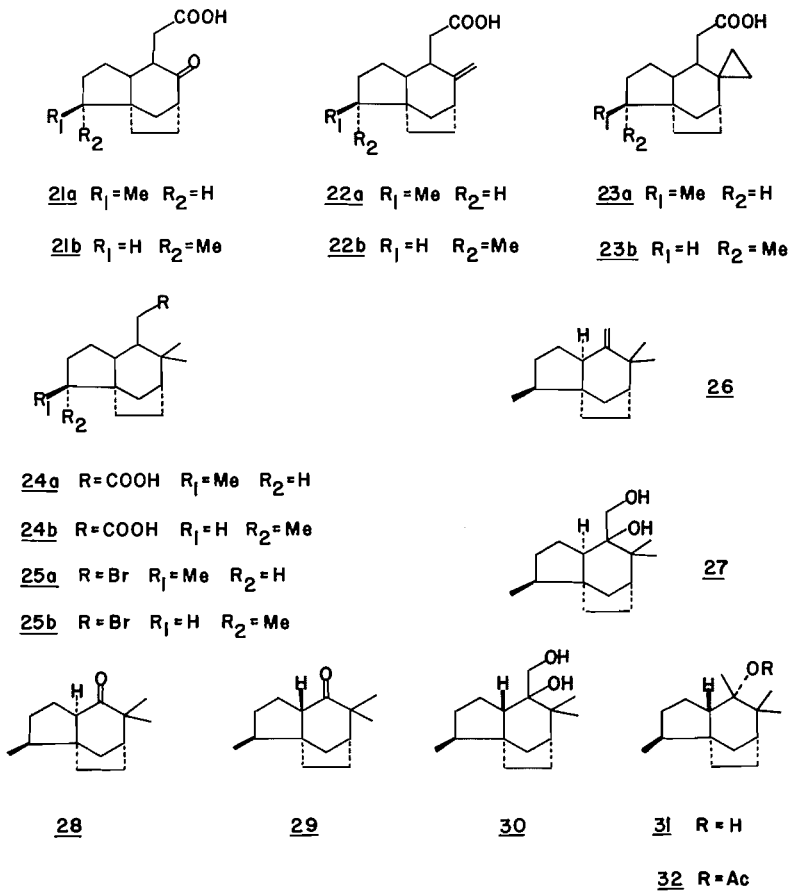
doublet, τ 9.04, $J = 7$ Hz for **11***a* and τ 8.85, $J = 7$ Hz for **11***b*.

The configurational assignments of the epimers (**11***a* and *b*) were made by comparing models and spectral data of the diketones (**12***a* and *b*) obtained via Jones' oxidation of the ketones (**11***a* and *b*). Models of these compounds showed that in epimer **12***a* the methyl group was directed away from the ketone while in epimer **12***b* the methyl group lay directly in the deshielding zone of the ketone. Accordingly, the n.m.r. spectra showed the methyl doublet of the ketone (**12***b*), τ 8.82, $J = 7$ Hz, definitely deshielded relative to the methyl doublet of ketone (**12***a*), τ 9.05, $J = 7$ Hz. The i.r. showed absorption maxima for the five-membered ketones, 1748 cm^{-1} for **12***a* and 1745 cm^{-1} for **12***b*. It is thus clear that the cyclization reaction with compound **10** is not stereospecific and that the stereospecificity previously encountered with **iii** must be due to the well known preference of the bicycloheptene system for exo attack by electrophillic reagents. Compounds **12***a* and *b* also provide conclusive evidence for our initial assumption about the course of the Claisen rearrangement, **3** → **4**. The presence in **12***a* and *b* of an α,β-unsaturated ketone (i.r., 1685 cm^{-1} for both) with one vinylic hydrogen which gives a singlet in the n.m.r. spectrum (τ 4.13 for both) does not allow any alternative structures for these two diastereoisomers. Although the alcohol (**11***b*) which has the undesired stereochemistry (for a tricyclovetivene synthesis) comprises 60% of the cyclized product mixture, it was, nevertheless, put to good use to find a possible synthetic pathway to convert the alcohol (**11***a*) to tricyclovetivene.

Acetylation of the alcohol (**11***b*) with acetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



anhydride and pyridine gave the acetate (**13***b*), which easily underwent hydrogenation in ethanol with palladium-on-charcoal to furnish the keto acetate (**14***b*) (m.p. 79–81 °C from hexane). It will be clear from the sequel that the hydrogenation was stereospecific and the hydrogens were added *trans* to the methyl group. Ketalization with ethylene glycol and *p*-toluenesulfonic acid gave the ketal (**15***b*), followed by hydrolysis in aqueous methanolic potassium hydroxide to yield the ketal alcohol (**16***b*). Treatment with carbon disulfide and methyl iodide resulted in formation of the ketal xanthate (**17***b*), which when pyrolyzed at 250 °C gave the unsaturated ketal (**18***b*). Hydrogenation over an excess of Raney nickel and deketalization in 80% acetic acid produced the tricyclic ketone (**20***b*) (DNP; m.p. 148–149 °C).

Stork alkylation of the ketone (**20***b*) with pyrolidine and ethyl bromoacetate followed by hydrolysis in methanolic potassium hydroxide yielded the keto acid (**21***b*). A Wittig reaction with methylidene-phosphorane was performed on the sodium salt of the carboxylic acid to give the unsaturated carboxylic acid (**22***b*), (n.m.r., vinyl protons at τ 5.47, $J = 14$ Hz). Simmons–Smith cyclopropanation of the olefin (**22***b*) with zinc–copper couple and diiodomethane produced the tetracyclic carboxylic acid (**23***b*), (n.m.r., cyclopropane methylenes at τ 9.67–9.87) which on hydrogenation over Adams catalyst gave the *gem*-dimethyl carboxylic acid (**24***b*) (n.m.r., *gem*-dimethyl singlets at τ 9.08 and 9.15).

Bromodecarboxylation using the modified Hunsdiecker method (4) with bromine and red mercuric oxide gave the tricyclic bromide (**25***b*) which when dehydrobrominated with lithium bromide and lithium carbonate in dimethylformamide produced the tricyclic hydrocarbon (**1***b*).

The second epimeric series possessing the natural tricyclovetivene methyl configuration (**11***a* to **25***a*) was processed by steps identical to those just discussed. (See Experimental for yield and physical properties of the compounds.)

Dehydrobromination of the tricyclic bromide (**25***a*) in the same manner used for **25***b* produced the tricyclic hydrocarbon (**26**).

By means of comparing the hydrocarbons **1***b* and **26** to natural tricyclovetivene (**1***a*) (2) it was now possible to establish the stereochemistry of the hydrogenated products (**14***a* and *b*) obtained from hydrogenation of the unsaturated ketones (**13***a* and *b*). The synthetic hydrocarbon (**26**) is not identical with tricyclovetivene (**1***a*) and must differ from it by the stereochemistry of the allylic proton. This is borne out by the fact that in the n.m.r. spectrum the doublets of the vinylic protons for **26** and tricyclovetivene (**1***a*) are significantly different (τ 5.17, $J = 5$ Hz; τ 5.33, $J = 8$ Hz respectively). It appears from models, that the vinylic protons in **26** and **1***a* must be strongly influenced by the configuration of the adjacent asymmetric center.

The synthetic hydrocarbon (**1***b*) is also not identical with tricyclovetivene (**1***a*) but the reason for this nonidentity must be only the configuration of the methyl group. This is borne out by the fact that the vinylic doublet in the n.m.r. spectrum of **1***b* is almost identical (τ 5.33, $J = 11$ Hz) with the same doublet in tricyclovetivene (**1***a*). It is thus clear that the methyl group influences the stereochemistry of the hydrogenation of the acetates (**13***a* and *b*) in such a manner that the hydrogenation proceeds always trans to this group.

Natural tricyclovetivene (**1***a*) and the synthetic epi-tricyclovetivene (**26**) were individually treated with osmium tetroxide to give the diols **30** and **27** respectively and these compounds were in turn cleaved with periodate to furnish the nor-ketones **29** and **28**, respectively. The "natural"[3] nor-ketone (**29**) (2) was epimerized in methanolic sodium methoxide to the "natural" nor-ketone (**28**) and the synthetic nor-ketone (**28**) was epimerized to the synthetic nor-ketone (**29**). The spectral data (i.r. and n.m.r.) of "natural" and synthetic nor-ketones (**28**) were completely superimposable as were the spectral data of "natural" and synthetic nor-ketones (**29**).

Since the Wittig reaction on the nor-ketones (**29**) gave a poor yield, the compounds were treated with methyl lithium yielding the synthetic and "natural" alcohols (**31**). Treatment with acetic anhydride in pyridine gave the unstable synthetic and "natural" acetates (**32**) which pyrolized *in situ* to give respectively synthetic racemic and "natural" tricyclovetivene (**1***a*), both with spectral data completely superimposable with those of natural tricyclovetivene (2). The reason why we have been able to cause elimination of the acetate (**32**) practically exclusively to form an exocyclic methylenic group must be its stereochemistry. The alcohol (**31**) has been produced by the action of methyl lithium on the nor-ketone (**29**) and very probably has the stereochemistry shown. As a consequence of this, a cyclic pyrolytic elimination of the acetate (**32**) to produce an endocyclic olefin is sterically impossible.

Experimental

Preparation of the Allyl Ether (3)

A solution of 1-methyl-indan-5-ol (**2**) (3) (14.6 g) in acetone (66 ml) was treated with potassium carbonate (14 g), potassium iodide (8.4 g), allyl chloride (9.6 g) and the mixture refluxed for 20 h. The resulting mixture was diluted with acetone, filtered, stripped of solvent to yield a residue which was dissolved in diethyl ether. The ethereal solution was washed twice with water, dried, and evaporated to yield 18.5 g of oil which was purified by silica gel (600 g, 20% benzene–light petroleum) column chromatography to furnish the allyl ether (**3**) (16.53 g, 88%) as a mobile oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{13}H_{16}O$: 188.1201. Found (mass spectroscopy): 188.1200.

The i.r. (CCl_4): 3080, 3012, 2955, 2860, 1640 (olefinic), 1610 cm^{-1} (aromatic). The n.m.r. (CCl_4): τ 3.07–3.51 (m, 3H, aromatic protons), 3.71–5.00 (m, 3H, vinyl protons), 5.60 (d, 2H, allyl ether methylenes), 8.75 (d, $J = 7$ Hz, 3H, methyl).

Rearrangement of 3 to 4

Allyl ether (**3**) (67 g) divided equally among four Pyrex ampoules, evacuated and sealed, was heated in an oil bath at 180–185 °C for 5 h. The combined contents were purified by silica gel (2 kg, 20% benzene in light petroleum) column chromatography to furnish the phenol (**4**) (38 g, 84%) as an oil homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{13}H_{16}O$: 188. Found (mass spectroscopy): 188.

The i.r. (CCl_4): 3615 (hydroxyl), 3540, 3080, 3010, 2955, 2860, 1630, 1615 cm^{-1}. The n.m.r. (CCl_4): τ 3.96–5.16 (m, 3H, vinyl protons), 6.71 (d, $J = 6$ Hz, 2H, allyl protons), 8.80 (d, $J = 7$ Hz, 3H, methyl).

[3]"Natural" should be understood to mean "obtained from natural tricyclovetivene".

Preparation of Methyl Ether (5)

A solution of the phenol (**4**) (37 g), sodium hydroxide (12 g), and dimethyl sulfate (22 ml) in water (80 ml) was stirred at room temperature for 1 h followed by addition of sodium hydroxide (2.4 g) in water (20 ml) and dimethyl sulfate (5 ml) and the total stirred of an addition 1 h. The mixture was diluted with diethyl ether and extracted twice with 10% aqueous sodium hydroxide which was in turn back extracted once with diethyl ether. The combined ethereal phases were dried and evaporated to give a residue which was purified on silica gel (1 kg, 20% benzene in light petroleum) column chromatography to yield the allyl methoxy compound (**5**) (33 g, 91%) as an oil homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{18}O$: 202.1358. Found (mass spectroscopy): 202.1352.

The i.r. (CCl_4): 3075, 2990, 2955, 2860, 2845, 1670 (olefinic), 1610 cm^{-1} (aromatic). The n.m.r. (CCl_4): τ 3.92–5.36 (m, 3H, vinyl protons), 6.36 (s, 3H, methoxyl), 6.72 (d, $J = 6$ Hz, 2H, allyl protons), 8.81 (d, $J = 7$ Hz, 3H, methyl).

Preparation of the Diol (6)

A homogeneous solution of the methyl ether (**5**) (2.02 g), tetrahydrofuran (25 ml), sodium chlorate (1.6 g), and water was treated with a solution of osmium tetroxide in tetrahydrofuran (1.0 ml, 80 mg/ml) and the total stirred at room temperature for 3 h. The solution was diluted with water and extracted with ether which in turn was dried and evaporated. The resulting residue was purified by silica gel (100 g, diethyl ether) column chromatography to yield the diol (**6**) (1.80 g, 76%) as an oil homogeneous in t.l.c.

Mol. Wt. for $C_{14}H_{20}O_3$: 236.1413. Found (mass spectroscopy): 236.1408.

The i.r. ($CHCl_3$): 3580 (hydroxyl), 3490, 2995, 2955, 2860, 1612 cm^{-1} (aromatic).

The n.m.r. ($CDCl_3$): τ 2.86–3.34 (m, 2H, aromatic protons), 6.26 (s, methoxyl), 8.80 (d, $J = 7$ Hz, 3H, methyl).

*Cleavage of **6** to the Aldehyde (7)*

A solution of the diol (**6**) (1.55 g) in tetrahydrofuran (20 ml) was treated with a solution of sodium periodate (15 g) in water (20 ml) and the total stirred at room temperature for 20 min. The mixture was filtered, diluted with diethyl ether, washed three times with water, dried, and evaporated to yield pure aldehyde (**7**) (1.32 g, 99%) as an oil, homogeneous in t.l.c.

Mol. Wt. for $C_{13}H_{16}O_2$: 204.1150. Found (mass spectroscopy): 204.1145.

The i.r. (CCl_4): 3000, 2955, 2860, 2840, 2720, 1725 (aldehyde), 1610 cm^{-1} (aromatic). The n.m.r. ($CDCl_3$): τ 0.40 (bs, 1H, aldehydic proton), 2.96–3.44 (m, 2H, aromatic protons), 6.24 (s, 3H, methoxyl), 8.76 (d, $J = 7$ Hz, 3H, methyl).

Preparation of the Acetal (8)

A solution of the aldehyde (**7**) (18 g), ethylene glycol (6.5 g), *p*-toluenesulfonic acid (0.5 g) all in benzene (600 ml) was refluxed over a water separator for 30 min. The cooled solution was washed with saturated sodium bicarbonate solution and water, dried, and evaporated to yield the acetal (**8**) (20.5 g, 100%) as an oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{15}H_{20}O_3$: 248.1413. Found (mass spectroscopy): 248.1406.

The i.r. (CCl_4): 2955, 2875, 1610 cm^{-1} (aromatic). The n.m.r. ($CDCl_3$): τ 2.90–3.34 (m, 2H, aromatic protons), 4.93 (t, 1H, acetal proton), 6.22 (s, 7H, methoxyl and acetal methylenes), 8.77 (d, $J = 7$ Hz, 3H, methyl).

Preparation of the Diene (9)

A solution of the ketal (**8**) (10 g) in diethyl ether (250 ml) and tertiary butanol (10 ml) was added dropwise over a period of 1/2 h to a stirred solution of lithium metal (20.7 g) in dry liquid ammonia (1000 ml) and the total stirred for 5 min, whereupon a solution of diethyl ether (20 ml) and tertiary butanol (250 ml) was added dropwise and the total stirred for an additional 24 h. Absolute ethanol (300 ml) was added until the blue color disappeared and the mixture was allowed to stand to evaporate the ammonia. The residue was taken up in ether, washed with saturated sodium chloride solution, dried, and evaporated. The resulting residue was purified by silica gel (500 g, benezene–ether) column chromatography to yield the diene (**9**) (6.5 g, 65%), homogeneous in t.l.c.

Mol. Wt. for $C_{15}H_{22}O_3$: 250. Found (mass spectroscopy): 250.

The i.r. (CCl_4): 2955, 2875, 1665 (olefinic), 1650 cm^{-1} (olefinic). The n.m.r. ($CDCl_3$): τ 5.08 (t, $J = 5$ Hz, 1H, acetal proton), 6.16 (s, acetal methylenes), 6.48 (s, 3H, methoxyl), 8.98 (d, $J = 7$ Hz, 3H, methyl).

Preparation of the β,γ-Unsaturated Ketone (10)

A solution of the diene (**9**) (1.0 g) in methanol (50 ml) was treated with a solution of oxalic acid (1.0 g) in water (10 ml) and the total stirred at room temperature for 45 min, followed by dilution with water and extraction with diethyl ether. The ethereal extract was washed with aqueous sodium bicarbonate solution and water, dried, and evaporated to give the ketone (**10**) (0.91 g, 100%) as an oil, homogeneous in t.l.c.

Mol. Wt. for $C_{14}H_{20}O_3$: 236. Found (mass spectroscopy): 236.

The i.r. (CCl_4): 2955, 2925, 2875, 2840, 1720 cm^{-1}, (ketone). The n.m.r. ($CDCl_3$): τ 5.02 (t, $J = 5$ Hz, 1H, acetal proton), 6.17 (s, 4H, acetal methylenes), 8.88 (d, $J = 7$ Hz, 3H, methyl).

Cyclization to the Alcohols (11a and b)

A solution of the ketone (**10**) (300 mg) in 80% acetic acid (3 ml) was heated in an oil bath at 80 °C for 3 h followed by evaporation of the solvent in high vacuum. The residue was purified by silica gel (20 g, benzene–ether) column chromatography to give the epimeric alcohols (**11***a* and *b*) (90 mg, 35%) as a semi-crystalline oil, appearing homogeneous in t.l.c. Dissolution of the mixture of epimeric alcohols in ether resulted in immediate crystallization of the alcohol (**11***b*), m.p. 167–168 °C. Repeated crystallizations succeeded in removing all this epimer from the mother liquors.

Anal. Calcd. for $C_{12}H_{16}O_2$ (mol. wt. 192) (alcohol **11***b*): C, 74.96; H, 8.39. Found (192 (mass spectroscopy)): C, 74.60; H, 8.32.

The i.r. (CCl_4): 3615, 3450, 2955, 2860, 1680 (α,β-unsaturated ketone), 1630 cm^{-1} (olefin). The n.m.r. ($CDCl_3$): τ 4.14 (s, 1H, vinyl proton), 5.51 (m, 1H, adjacent to OH), 8.85 (d, $J = 7$ Hz, 3H, methyl), λ_{max} (EtOH): 244.5 nm (11 700).

The oily residue from the mother liquors cyrstallized from ether–hexane to give the alcohol (**11***a*) m.p. 68–69 °C. Ratio of alcohols (**11***a* and *b*) was 2:3.

Anal. Calcd. for $C_{12}H_{16}O_2$ (mol. wt. 192) (alcohol **11***a*): C, 74.96; H, 8.39. Found (192 (mass spectroscopy)): C, 75.57; H, 8.35.

The i.r. (CCl_4): 3625, 3425, 2955, 2860, 1685 (α,β-unsaturated ketone), 1630 cm^{-1} (olefin). The n.m.r. ($CDCl_3$): τ 4.34 (s, 1H, vinyl proton), 6.09 (m, 1H, adjacent to OH), 9.04 (d, $J = 7$ Hz, 3H, methyl), λ_{max} (EtOH): 244.5 nm (11 100).

*Formation of the Diketones (**12***a and b)*

A solution of the alcohol (**11***b*) (150 mg) in acetone at 0 °C was treated dropwise with Jones' reagent to a slight excess followed by evaporation of the solvent. The residue was taken up in water extracted with ether, dried, and evaporated to give an oil which was purified by silica gel (20 g, benzene–ether) column chromatography to furnish the diketone (**12***b*) (99 mg, 66%), homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{12}H_{14}O_2$ (diketone **12***b*): 190.0994. Found (mass spectroscopy): 190.0990.

The i.r. (CCl_4): 2955, 2925, 2860, 1745 (five-membered ketone), 1685 (conjugated ketone), 1625 cm^{-1} (olefin). The n.m.r. ($CDCl_3$): τ 4.13 (s, 1H, vinyl proton), 8.82 (d, $J = 7$ Hz, 3H, methyl), λ_{max} (EtOH): 228.5 (10 000), 253 nm (7300).

The epimeric diketone (**12***a*) was obtained in the same manner.

Mol. Wt. Calcd. for $C_{12}H_{14}O_2$ (diketone **12***a*): 190.0994 Found (mass spectroscopy): 190.0990.

The i.r. (CCl_4): 2955, 2925, 2860, 1748 (five-membered ketone), 1685 (conjugated ketone), 1630 cm^{-1} (olefin). The n.m.r. ($CDCl_3$): τ 4.13 (s, 1H, vinyl proton), 9.05 (d, $J = 7$ Hz, 3H, methyl), λ_{max} (EtOH): 226 (9800), 251 nm (7400).

*Preparation of the Acetates (**13***a and b)*

A solution of the alcohol (**11***a*) (1.0 g) in acetic anhydride (4 ml) and pyridine (3 ml) was allowed to stand overnight followed by evaporation under high vacuum to give a thick oil which was purified by silica gel (40 g, 30% diethyl ether in benzene) column chromatography to yield the acetate (**13***a*) (1.22 g, 100%), homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{18}O_3$: 234.1256. Found (mass spectroscopy): 234.1250.

The i.r. (CCl_4): 2955, 2855, 1742 (acetate), 1685 (conjugated ketone), 1630 cm^{-1} (olefin). The n.m.r. ($CDCl_3$): τ 4.31 (s, 1H, vinyl proton), 5.11 (m, 1H, adjacent to acetate), 7.91 (s, 3H, acetate methyl), 9.01 (d, $J = 7$ Hz, 3H, methyl), λ_{max}(EtOH): 234 nm (13 100).

By the same method, acetylation of alcohol (**11***b*) (3.45 g) gave the acetate (**13***b*) (4.20 g, 100%) as an oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{18}O_3$: 234.1256. Found (mass spectroscopy): 234.1250.

*Preparation of Keto Acetates (**14***a and b)*

A mixture of the acetate (**13***a*) (1.0 g) and 10% palladium-on-charcoal (0.1 g) all in ethanol (30 ml) was hydrogenated for 3 h followed by filtration and evaporation. The resulting oil was immediately dissolved in acetone (20 ml) and treated with an excess of Jones' reagent followed by dilution with water and extraction with ether. The ethereal extract was dried, evaporated, and the residue purified by silica gel (35 g, 10% ether–benzene) column chromatography to yield the keto acetate (**14***a*) (758 mg, 75%) as a clear oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{20}O_3$: 236.1413. Found (mass spectroscopy): 236.1407.

The i.r. (CCl_4): 2955, 2860, 1740 (acetate), 1715 cm^{-1} (ketone). The n.m.r. ($CDCl_3$): τ 5.03 (m, 1H, adjacent to acetate), 7.95 (s, acetate methyl), 8.95 (d, $J = 6$ Hz, 3H, methyl).

By the same method, reduction of the acetate (**13***b*) (2.23 g) gave the acetate (**14***b*) (1.57 g, 70%) as an oil which crystallized from hexane, m.p. 79–81 °C.

Anal. Calcd. for $C_{14}H_{20}O_3$ (mol. wt. 236): C, 71.15; H, 8.51. Found (236 (mass spectroscopy)): C, 70.97; H, 8.35.

The i.r. (CCl_4): 2955, 2905, 2870, 1740 (acetate), 1715 cm^{-1} (ketone). The n.m.r. ($CDCl_3$): τ 4.60 (m, 1H, proton adjacent to acetate), 7.94 (s, 3H, acetate methyl), 9.01 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of the Ketal Acetates (**15***a and b)*

A solution of the keto acetate (**14***a*) (1.0 g), ethylene glycol (620 mg), and *p*-toluenesulfonic acid (50 mg) all in dry benzene (25 ml) was refluxed over a water separator for 2 h. The solution was cooled, washed with saturated sodium bicarbonate solution and water, dried, and evaporated to give the ketal acetate (**15***a*) (1.2 g, 100%) homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{16}H_{24}O_4$: 280.1675. Found (mass spectroscopy): 280.1668.

The i.r. (CCl_4): 2955, 2875, 1737 cm^{-1} (acetate). The n.m.r. ($CDCl_3$): τ 5.12 (m, 1H, adjacent to acetate), 6.12 (s, 4H, ketal methylenes), 7.94 (s, acetate methyl), 9.05 (d, $J = 6$ Hz, 3H, methyl).

By the same method, ketalization of the keto acetate (**14***b*) (580 mg) gave the ketal acetate (**15***b*) (678 mg, 97%) as an oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{16}H_{24}O_4$: 280.1675. Found (mass spectroscopy): 280.1670.

The i.r. (CCl_4): 2955, 2905, 2870, 1740 (acetate), 1245, 1045 cm^{-1}. The n.m.r. ($CDCl_3$): τ 4.87 (m, 1H, proton adjacent to acetate), 6.15 (s, 4H, ketal methylenes), 8.00 (s, 3H, acetate methyl), 9.10 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of the Ketal Alcohols (**16***a and b)*

A solution of the ketal acetate (**15***a*) (560 mg) in 5% methanolic potassium hydroxide (10 ml) was refluxed for 3 h. The solution was cooled, diluted with water, extracted with diethyl ether, dried, and evaporated to furnish the ketal alcohol (**16***a*) (480 mg, 100%) as an oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{22}O_3$: 238. Found (mass spectroscopy): 238.

The i.r. (CCl_4): 3620 (hydroxyl), 3495, 2950, 2875 cm^{-1}. The n.m.r. ($CDCl_3$): τ 6.14 (s, 4H, ketal methylenes), 8.95 (d, $J = 6$ Hz, 3H, methyl).

By the same method, hydrolysis of the ketal acetate (**15***b*) (572 mg) gave the ketal alcohol (**16***b*) (480 mg, 100%) as an oil homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{22}O_3$: 238.1569. Found (mass spectroscopy): 238.1567.

The i.r. (CCl_4): 3625 (hydroxyl), 3500, 2955, 2905, 2870,

1455, 1050 cm^{-1}. The n.m.r. ($CDCl_3$): τ 5.73 (m, 1H, proton adjacent to alcohol), 6.13 (s, 4H, ketal methylenes), 9.05 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of Xanthates (**17a** and **b**)*

A mixture of ketal alcohol (**16***a*) (480 mg), 75% sodium hydride in mineral oil (100 mg) all in tetrahydrofuran (25 ml) was refluxed for 1 h followed by cooling and addition of carbon disulfide (4 ml) with the total being heated for an additional $1\frac{1}{2}$ h. The mixture was again cooled and treated with methyl iodide (4 ml) followed by reflux for 1 h. The solvent was distilled off and the residue dissolved in benzene which in turn was washed with water, dried, and evaporated. Chromatography of the residue on silica gel (25 g, 10% ether–benzene) furnished the xanthate (**17***a*) (560 mg, 85%) as a yellow oil which crystallized from hexane, m.p. 108–109 °C.

Anal. Calcd. for $C_{16}H_{24}O_3S_2$ (mol. wt. 328): C, 58.51; H, 7.37; S, 19.53. Found (328 (mass spectroscopy)): C, 58.66; H, 7.40; S, 19.18.

The i.r. (CCl_4): 2950, 2875, 1230 cm^{-1} (xanthate). The n.m.r. ($CDCl_3$): τ 4.34 (m, 1H, proton adjacent to xanthate), 6.10 (s, 4H, ketal methylenes), 7.44 (s, 3H, xanthate methyl), 8.95 (d, $J = 6$ Hz, 3H, methyl).

By the same method, addition to the ketal alcohol (**16***b*) (770 mg) gave the xanthate (**17***b*) (890 mg, 84%) as an oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{16}H_{24}O_3S_2$: 328. Found (mass spectroscopy): 328.

The i.r. (CCl_4): 2950, 2870, 1220, 1060 cm^{-1}. The n.m.r. ($CDCl_3$): τ 4.13 (m, 1H, proton adjacent to xanthate), 6.10 (s, 4H, ketal methylenes), 7.40 (s, 3H, xanthate methyl), 9.07 (d, $J = 6$ Hz, 3H, methyl).

*Formation of the Olefins (**18a** and **b**)*

The xanthate (**17***a*) (328 mg) was pyrolyzed in an open Pyrex tube at 190 °C for 30 min followed by distillation to yield the olefin (**18***a*) (170 mg, 95%) as an oil b.p. 150 °C/1 mm, appearing homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{20}O_2$: 220. Found (mass spectroscopy): 220.

The i.r. (CCl_4): 3050 (olefin), 2950, 2875, 1650 (olefin), 1120 cm^{-1}. The n.m.r. ($CDCl_3$): τ 4.20 (m, 2H, vinyl protons), 6.10 (s, 4H, ketal methylenes), 9.12 (d, $J = 6$ Hz, 3H, methyl).

By the same method, the xanthate (**17***b*) (730 mg) was pyrolyzed to give the olefin (**18***b*) (502 mg) as a liquid, b.p. 250 °C/16 mm, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{20}O_2$: 220.1463. Found (mass spectroscopy): 220.1458.

The i.r. (CCl_4): 3050 (olefin), 2950, 2860, 1640 cm^{-1} (olefin). The n.m.r. ($CDCl_3$): τ 3.83–4.27 (m, 2H, vinyl protons), 6.10 (s, 4H, ketal methylenes), 9.10 (d, $J = 6$ Hz, 3H, methyl).

*Hydrogenation of the Olefins, **18a** and **b** to **19a** and **b***

A mixture of the olefin (**18***a*) (1.0 g) in ethanol (150 ml) and Raney nickel (40 g) was hydrogenated for 4 h followed by filtration and evaporation to yield the saturated ketal (**19***a*) (953 mg, 95%), homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{22}O_2$: 222. Found (mass spectroscopy): 222.

The i.r. (CCl_4): 2950, 2875, 1110 cm^{-1} (ketal). The n.m.r. ($CDCl_3$): τ 6.11 (s, 4H, ketal methylenes), 9.18 (d, $J = 6$ Hz, 3H, methyl).

By the same method, hydrogenation of the olefin (**18***b*) (502 mg) gave the saturated ketal (**19***b*) (408 mg) as an oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{22}O_2$: 222. Found (mass spectroscopy): 222.

The i.r. (CCl_4): 2950, 2860, 1102 cm^{-1} (ketal). The n.m.r. ($CDCl_3$): τ 6.09 (s, 4H, ketal methylenes), 9.13 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of the Tricyclic Ketones (**20a** and **b**)*

A solution of the ketal (**19***a*) (1.0 g) in 80% acetic acid was heated at 80 °C for 30 min followed by dilution with water and extraction with chloroform. The chloroform extract was dried and evaporated to furnish the tricyclic ketone (**20***a*) (802 mg, 100%) as an oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{12}H_{18}O$ (the ketone): 178. Found (mass spectroscopy): 178.

The i.r. (CCl_4): 2955, 2875, 1715 cm^{-1} (ketone). The n.m.r. ($CDCl_3$): τ 7.34, 7.84, 8.07, 8.47, 9.08 (d, $J = 6$ Hz, 3H, methyl).

Anal. Calcd. for $C_{18}H_{22}N_4O_4$ (dinitrophenylhydrazone, m.p. 156–157 °C): C, 60.32; H, 6.18; N, 15.64. Found: C, 59.45; H, 6.09; N, 15.93.

By the same method, deketalization of the ketal (**19***b*) (408 mg) gave the tricyclic ketone (**20***b*) (324 mg, 82% based on the xanthate (**17***b*)) as an oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{12}H_{18}O$: 178. Found (mass spectroscopy): 178.

The i.r. (CCl_4): 2955, 2875, 1715 cm^{-1} (ketone). The n.m.r. ($CDCl_3$): τ 7.33, 7.80, 8.33, 8.47, 9.06 (d, $J = 6$ Hz, 3H, methyl).

Anal. Calcd. for $C_{18}H_{22}N_4O_4$ (dinitrophenylhydrazone, m.p. 148–149 °C): C, 60.32; H, 6.18; N, 15.65. Found: C, 60.50; H, 6.12; N, 15.72.

*Preparation of the Keto Acids (**21a** and **b**)*

A solution of the tricyclic ketone (**20***a*) (600 mg) and pyrrolidine (1.19 g) in dry benzene (20 ml) was refluxed under nitrogen and a water separator for 15 h followed by replacement of the solvent with dry dioxane (15 ml). Ethyl bromoacetate (1.11 g) in dioxane (5 ml) was added dropwise over a period of 1/4 h and the mixture heated at 100 °C under nitrogen for 24 h, followed by evaporation of the solvent and treatment of the residue with water (20 ml) at reflux for 2 h. The cooled aqueous solution was extracted with diethyl ether and in turn washed with water, saturated sodium chloride solution, dried, and evaporated to give a residue (710 mg) which was saponified by refluxing in 1 *N* methanolic potassium hydroxide solution (15 ml) for 2 h. The reaction was stripped of solvent and the residue taken up in water, followed by extraction with diethyl ether which on drying and evaporation yielded starting ketone (**20**) (232 mg). The aqueous solution was acidified with 5% hydrochloric acid and extracted with diethyl ether and in turn washed with water, saturated sodium chloride solution, dried, and evaporated to give the keto acid (**21**) (266 mg, 72% with recovery) as a thick oil, homogeneous in t.l.c. Recycling furnished a 54% overall yield.

Anal. Calcd. for $C_{14}H_{20}O_3$ (mol. wt. 236): C, 71.16; H, 8.53; O, 20.31. Found (236 (mass spectroscopy)): C, 70.95; H, 8.55; O, 20.39.

The i.r. (CCl_4): 3525, 2950, 2860, 1715 (ketone), 1710 cm^{-1} (carboxylic acid). The n.m.r. ($CDCl_3$): τ 0.53 (bs. 1H, carboxylic acid proton), 9.05 (d, $J = 6$ Hz, 3H, methyl).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

By the same method, the tricyclic ketone (**20***b*) (340 mg) was alkylated to give the keto acid (**21***b*) (79 mg, 81% with recovery) as an oil, homogeneous in t.l.c. Recycling furnished a total of 225 mg (50%).

Mol. Wt. Calcd. for $C_{14}H_{20}O_3$: 236. Found (mass spectroscopy): 236.

The i.r. (CCl_4): 3530, 2960, 2875, 1715 cm^{-1} (carboxylic acid and ketone). The n.m.r. ($CDCl_3$): τ −0.17 (bs, 1H, carboxylic acid proton), 9.05 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of the Tricyclic Olefins (**22***a and b)*

A stirred suspension of oil-free sodium hydride (197 mg) in dimethylsulfoxide (20 ml) under nitrogen was treated with methyl triphenylphosphonium iodide (1.26 g) and stirred for 2 h followed by addition of a solution of the keto acid (**21***a*) (369 mg) in dimethylsulfoxide (5 ml) and the total stirred at room temperature for 4 h and at 75 °C for 24 h. The solution, cooled well, was acidified dropwise with 5% hydrochloric solution and in turn taken up in chloroform. The chloroform was washed with water and evaporated to give a residue which was taken up in 5% sodium hydroxide solution, washed with diethyl ether, and acidified with 5% hydrochloric acid. The aqueous mixture was extracted with diethyl ether, washed with water and saturated sodium chloride solution, dried, and evaporated to give the tricyclic olefin (**22***a*) (327 mg, 89%) as a thick oil, homogeneous in t.l.c.

Anal. Calcd. for $C_{15}H_{22}O_2$ (mol. wt. 234): C, 76.88; H, 9.46; O, 13.66. Found (234 (mass spectroscopy)): C, 76.58; H, 9.25; O, 13.71.

The i.r. (CCl_4): 3530, 2950, 2860, 1705 (carboxylic acid), 1640 cm^{-1} (olefin). The n.m.r. ($CDCl_3$): τ + 0.57 (bs, 1H, carboxylic acid proton), 5.42 (d, $J = 20$ Hz, 2H, vinyl protons), 9.18 (d, $J = 6$ Hz, 3H, methyl).

By the same method, the Wittig reaction on the keto acid (**21***b*) (235 mg) gave the tricyclic olefin (**22***b*) (181 mg, 78%) as a thick oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{15}H_{22}O_2$: 234.1620. Found (mass spectroscopy): 234.1616.

The i.r. (CCl_4): 3530, 3080, 2950, 2875, 1705 (carboxylic acid), 1635 cm^{-1} (olefin). The n.m.r. ($CDCl_3$): τ −0.83 (bs, 1H, carboxylic acid proton), 5.47 (d, $J = 14$ Hz, 2H, vinyl protons), 9.15 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of the Tetracyclic Carboxylic Acids (**23***a and b)*

A suspension of zinc–copper couple (338 mg), a few crystals of iodine, and a few drops of diiodomethane all in dry diethyl ether (5 ml) was stirred until the iodine color was absent followed by addition of diiodomethane (1.98 g) and the total refluxed for 1/2 h. The mixture was cooled and treated with a solution of the tricyclic olefin (**22***a*) (290 mg) in dry diethyl ether (5 ml) and the total refluxed for 4 days. The mixture was filtered, diluted with diethyl ether, washed with 5% hydrochloric acid and water followed by extraction with 5% sodium hydroxide solution which was in turn washed with diethyl ether, acidified with 5% hydrochloric acid, and extracted with diethyl ether. The ethereal extract was washed with water, saturated sodium chloride solution, dried, and evaporated to give the tetracyclic carboxylic acid (**23***a*) (214 mg, 70%) as a thick oil, homogeneous in t.l.c.

Anal. Calcd. for $C_{16}H_{24}O_2$ (mol. wt. 248): C, 77.37; H, 9.74; O, 12.88. Found (248 (mass spectroscopy)): C, 76.82; H, 9.61; O, 13.75.

The i.r. (CCl_4): 3525, 2945, 2865, 1705 cm^{-1} (carboxylic acid). The n.m.r. ($CDCl_3$): τ −1.10 (bs, 1H, carboxylic acid proton), 9.15 (d, $J = 6$ Hz, 3H, methyl), 9.65–9.87 (m, 4H, cyclopropane methylenes).

By the same method, from the tricyclic olefin (**22***b*) (152 mg) was prepared the tetracyclic carboxylic acid (**23***b*) (138 mg, 72%) as a thick oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{16}H_{24}O_2$: 248. Found (mass spectroscopy): 248.

The i.r. (CCl_4): 3530, 3075, 3005, 2955, 2875, 1705 cm^{-1} (carboxylic acid). The n.m.r. ($CDCl_3$): τ −0.73 (bs, 1H, carboxylic acid proton), 9.15 (d, $J = 6$ Hz, 3H, methyl), 9.67–9.87 (m, 4H, cyclopropane methylenes).

*Hydrogenation of **23***a and b to the Tricyclic Carboxylic Acids (**24***a and b)*

A mixture of the tetracyclic carboxylic acid (**23***a*) (660 mg) and Adams catalyst (660 mg) all in glacial acetic acid (20 ml) was hydrogenated at 2000 p.s.i. for 24 days at room temperature. The mixture was filtered and evaporated to furnish the tricyclic carboxylic acid (**24***a*) (562 mg, 84%) as a clear, colorless, thick oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{16}H_{26}O_2$: 250.1933. Found (mass spectroscopy): 250.1924.

The i.r. (CCl_4): 2950, 2865, 1705 cm^{-1} (carboxylic acid). The n.m.r. ($CDCl_3$): τ −0.20 (bs, 1H, carboxylic acid proton), 9.10 (s, 6H, two methyls), 9.15 (d, $J = 6$ Hz, 3H, methyl).

By the same method, hydrogenation of the tetracyclic carboxylic acid (**23***b*) (288 mg) gave the tricyclic carboxylic acid (**24***b*) (261 mg, 90%) as a thick oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{16}H_{26}O_2$: 250.1933. Found (mass spectroscopy): 250.1928.

The i.r. (CCl_4): 3530, 2950, 2870, 1705 cm^{-1} (carboxylic acid). The n.m.r. ($CDCl_3$): τ −1.30 (bs, 1H, carboxylic acid proton), 9.08 (s, 3H, methyl), 9.15 (s, 3H, methyl), 9.15 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of the Tricyclic Bromides (**25***a and b)*

A refluxing mixture of the tricyclic carboxylic acid (**24***a*) (550 mg) and red mercuric oxide (570 mg) in dry carbon tetrachloride (8 ml) was treated dropwise with a solution of bromine (422 mg) in dry carbon tetrachloride (2 ml) and the total refluxed for an additional 1 h. The mixture was filtered, diluted with carbon tetrachloride, washed with 5% sodium hydroxide solution, water, saturated sodium chloride solution, dried, and evaporated. The labile residue (594 mg) was immediately purified by preparative silica gel t.l.c. (light petroleum) to furnish the tricyclic bromide (**25***a*) (156 mg, 25%) as a clear colorless oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{15}H_{25}Br$: 285. Found (mass spectroscopy): m/e 286, 284.

The i.r. (film): 2950, 2865, 1470, 1235, 760 cm^{-1}. The n.m.r. ($CDCl_3$): τ 6.50 (m, 2H, protons α to bromine), 9.07 (s, 3H, methyl), 9.10 (s, 3H, methyl), 9.15 (d, $J = 6$ Hz, 3H, methyl).

By the same method, bromodecarboxylation of the tricyclic carboxylic acid (**24***b*) (260 mg) gave the tricyclic bromide (**25***b*) (103 mg, 36%) as a clear colorless liquid, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{15}H_{25}Br$: 285. Found (mass spectroscopy): 284, 286.

The i.r. (film): 2950, 2875, 1460, 1230 cm^{-1}. The n.m.r.

($CDCl_3$): τ 6.33–6.87 (m, 2H, protons α to bromine), 8.97 (s, 3H, methyl), 9.10 (s, 3H, methyl), 9.15 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of epi-Tricyclovetivene (**26**)*

A mixture of the tricyclic bromide (**25**) (150 mg), lithium bromide (277 mg), and lithium carbonate (235 mg) all in dimethylformamide (3 ml) was refluxed under nitrogen for 90 min. The mixture was diluted with ice-cold 5% hydrochloric acid until solution occurred, followed by extraction with diethyl ether. The ethereal extract was washed with 5% hydrochloric acid, water, saturated sodium chloride solution, and the ether fractionally distilled off. The residual liquid was purified by preparative silica gel t.l.c. (light petroleum) to furnish epi-tricyclovetivene (**26**) (92 mg, 85%) as a clear colorless liquid, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{15}H_{24}$: 204.1878. Found (mass spectroscopy): 204.1872.

The i.r. (film): 3075 (olefin), 2950, 2860, 1630 (olefin), 890 cm^{-1}. The n.m.r. ($CDCl_3$): τ 5.17 (d, $J = 4$ Hz, 2H, vinyl protons), 7.77 (bt, 1H, allyl proton), 8.85 (s, 3H, methyl), 8.92 (s, 3H, methyl), 9.15 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of the Methyl Epimer (**1b**) of Tricyclovetivene*

A mixture of the tricyclic bromide (**25***b*) (100 mg), lithium bromide (183 mg), and lithium carbonate (155 mg) all in dimethylformamide (2 ml) was refluxed under nitrogen for 90 min. The reaction mixture was cooled, diluted with ice-cold 5% hydrochloric acid until solution occurred, and extracted with ether. The ethereal extract was washed with 5% hydrochloric acid, water, dried, and the solvent fractionally distilled off. The residual liquid was purified by preparative silica gel t.l.c. (light petroleum) to furnish the methyl epimer (**1***b*) (35 mg, 49%) of tricyclovetivene as a clear colorless liquid, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{15}H_{24}$: 204.1878. Found (mass spectroscopy): 204.1875.

The i.r. (film): 3080 (olefin), 2940, 2860, 1635 (olefin), 1455, 1375, 890, 735 cm^{-1}. The n.m.r. ($CDCl_3$): τ 5.33 (d, $J = 11$ Hz, 2H, vinyl protons), 7.60 (bt, 1H, allyl proton), 8.45, 8.92 (s, 6H, 2 methyls), 9.15 (d, $J = 6$ Hz, 3H, methyl).

*Spectra of Natural Tricyclovetivene (**1a**)*

The i.r. (film): 3080 (olefin), 2940, 2860, 1635 (olefin), 1460, 1375, 890 cm^{-1}. The n.m.r. ($CDCl_3$): τ 5.33 (d, $J = 8$ Hz, 2H, vinyl protons), 7.47 (bt, 1H, allylic proton), 8.23, 8.57, 8.90 (s, 3H, methyl), 8.93 (s, 3H, methyl), 9.05 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of the Tricyclic Diol (**27**)*

A solution of epi-tricyclovetivene (**26**) (59 mg) in dry pyridine (1.1 ml) was treated with a tetrahydrofuran solution (1 g OsO_4/4 ml) of osmium tetroxide (0.32 ml) and the total stirred at room temperature for 3 h. The resulting black mixture was treated with a solution of sodium bisulfite (134 mg) in water (2.5 ml) and pyridine (1.5 ml) and the total stirred for 30 min at room temperature. The solution was extracted with methylene chloride, washed with saturated sodium chloride solution, dried, and evaporated. The residue was purified by preparative silica gel t.l.c. (chloroform) to give the tricyclic diol (**27**) 56 mg, 81% as a clear, colorless, thick oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{15}H_{26}O_2$: 238.1933. Found (mass spectroscopy): 238.1938.

The i.r. (film): 3400 (hydroxyl), 2950, 2865, 1465, 1025 cm^{-1}. The n.m.r. ($CDCl_3$): τ 6.50 (s, 2H, methylenes of primary alcohol), 7.83 (bs, 2H, exchanges with D_2O), 8.97 (s, 3H, methyl), 9.07 (s, 3H, methyl) 9.15 (d, $J = 6$ Hz, 3H, methyl).

*Cleavage of **27** to epi-Tricyclovetivene Nor-ketone (**28**)*

A homogeneous solution of the tricyclic diol (**27**) (56 mg) in tetrahydrofuran (1.5 ml) and water (1 ml) was treated with powdered sodium meta periodate (500 mg) and the total stirred at room temperature for 30 min. The mixture was filtered, diluted with diethyl ether, washed with water, saturated sodium chloride solution, dried, and evaporated to give epi-tricyclovetivene nor-ketone (**28**) (43 mg, 90%) as a clear colorless liquid, homogeneous on t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.1671. Found (mass spectroscopy): 206.1670.

The i.r. (film): 2950, 2860, 1695 cm^{-1} (ketone). The n.m.r. ($CDCl_3$): τ 7.70 (bt, 1H, proton α to ketone), 8.85 (s, 3H, methyl), 8.92 (s, 3H, methyl), 9.08 (d, $J = 6$ Hz, 3H, methyl).

*Epimerization of **28** to Tricyclovetivene Nor-ketone (**29**)*

A solution of epi-tricyclovetivene nor-ketone (**28**) (30 mg) in 1% methanolic sodium methoxide (1 ml) was refluxed for 15 h followed by evaporation of the solvent. The residue was diluted with water and extracted with diethyl ether which in turn was washed with water, saturated sodium chloride solution, dried, and evaporated. The residual liquid consisting of a 1:1 mixture of epimers (**28** and **29**) was purified and the epimers separated by preparative silica gel t.l.c. (10% diethyl ether–light petroleum). The unepimerized epimer (**28**) was exhaustively epimerized to yield a total of tricyclovetivene nor-ketone (**29**) (19 mg, 63%) as a clear colorless liquid, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.1671. Found (mass spectroscopy): 206.1670.

The i.r. (film): 2950, 2860, 1705 cm^{-1} (ketone). The n.m.r. ($CDCl_3$): τ 7.07 (bt, 1H, proton α to ketone), 8.80 (s, 3H, methyl), 8.95 (s, 3H, methyl), 9.01 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of the "Natural"[3] Tricyclic Diol (**30**)*

A solution of natural tricyclovetivene (**1***a*) (102 mg) in dry pyridine (2 ml) was treated with a solution (0.52 ml) of osmium tetroxide (1 g OsO_4/4 ml tetrahydrofuran) and the total stirred at room temperature for 3 h. The mixture was treated with a solution of sodium bisulfite (230 mg) in water (4 ml) and pyridine (2.5 ml) and stirred for 30 min at room temperature. The solution was extracted with methylene chloride, washed with saturated sodium chloride solution, dried, and evaporated. The residual oil was purified by preparative silica gel chromatography (chloroform) and crystallized from light petroleum to furnish the "natural" tricyclic diol (**30**) (100 mg, 84%) as white prisims, m.p. 86.5–87.0 °C (lit. (2) 84–84.5).

Anal. Calcd. for $C_{15}H_{26}O_2$ (mol. wt. 238: C, 75.58; H, 11.00; O, 13.42. Found (238 (mass spectroscopy)): C, 75.93; H, 10.84; O, 13.33.

The i.r. (film): 3500 (hydroxyl), 2950, 2865, 1465, 1025 cm^{-1}. The n.m.r. ($CDCl_3$): τ 6.20 (d, $J = 5$ Hz, 2H, methylene of primary alcohol), 7.27 (s, 1H, exchanges with D_2O), 7.67 (t, $J = 5$ Hz, 1H, exchanges with D_2O), 8.93 (s, 3H, methyl), 9.03 (s, 3H, methyl), 9.08 (d, $J = 6$ Hz, 3H, methyl).

*Cleavage of **30** to "Natural" Tricyclovetivene Nor-ketone (**29**)*

A homogeneous solution of the tricyclic diol (**30**) (90 mg) in tetrahydrofuran (2 ml) and water (1.5 ml) was treated with powdered sodium meta periodate (813 mg) and the total stirred at room temperature for 30 min. The mixture was filtered, diluted with diethyl ether, washed with water, saturated sodium chloride solution, dried, and evaporated to give "natural" tricyclovetivene nor-ketone (**29**) (77 mg, 99%) as a clear colorless liquid, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.1671. Found (mass spectroscopy): 206.1670.

The i.r. (film): 2950, 2860, 1705 cm^{-1} (ketone). The n.m.r. ($CDCl_3$): τ 7.07 (t, 1H, proton α to ketone), 8.80 (s, 3H, methyl), 8.95 (s, 3H, methyl), 9.01 (d, $J = 6$ Hz, 3H, methyl).

*Epimerization of "Natural" **29** to "Natural" epi-Tricyclovetivene Nor-ketone (**28**)*

A solution of the "natural" tricyclovetivene nor-ketone (**29**) (77 mg) in 1% methanolic sodium ethoxide solution (5 ml) was refluxed for 15 h followed by evaporation of the solvent. The residue was diluted with water, extracted with ether, washed with water, saturated sodium chloride solution, dried, and evaporated to give a 1:1 mixture of the epimers (**28** and **29**). The epimers were separated by preparative silica gel t.l.c. (10% diethyl ether–light petroleum). The unepimerized "natural" nor-ketone (**28**) was recycled to give a total of "natural" epi-tricyclovetivene nor-ketone (**28**) (39 mg, 50%) as a clear colorless oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.1671. Found (mass spectroscopy): 206.1670.

The i.r. (film): 2950, 2860, 1695 cm^{-1} (ketone). The n.m.r. ($CDCl_3$): τ 7.70 (bt, 1H, proton α to ketone), 8.85 (s, 3H, methyl), 8.92 (s, 3H, methyl), 9.08 (d, $J = 6$ Hz, 3H, methyl).

*Preparation of the Tricyclic Alcohol (**31**)*

A solution of the "natural" nor-ketone (**29**) (60 mg) in anhydrous ether (1 ml) was treated dropwise with an ethereal solution of methyl lithium (excess) and the total refluxed for 1 h. The reaction mixture was diluted with wet ether and in turn washed with water. The ethereal extract was dried and evaporated to yield the "natural" tricyclic alcohol (**31**) (60 mg, 93%) as an oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{15}H_{26}O$: 222.1984. Found (mass spectroscopy): 222.1977.

The i.r. (CCl_4): 3605 (hydroxyl), 2950, 2860, 1460, 1390, 1370 cm^{-1}. The n.m.r. ($CDCl_3$): τ 8.97 (s, 3H, methyl), 9.02 (s, 3H, methyl), 9.07 (s, 3H, methyl), 9.12 (d, $J = 6$ Hz, 3H, methyl).

By the same method, synthetic nor-ketone (**29**) (5.2 mg) was converted to the synthetic alcohol (**31**) (5.6 mg, 100%).

Analysis: all analytical data (i.r., n.m.r., mass, and t.l.c.) for synthetic alcohol (**31**) were superimposable with that shown above for "natural" alcohol (**31**).

*Conversion of the Alcohol (**31**) to Tricyclovetivene (**1a**)*

A solution of the "natural" alcohol (**31**) (90 mg) in anhydrous acetic anhydride (0.7 ml) and anhydrous pyridine (0.7 ml) was heated at 120 °C for 60 h. After cooling, the reaction mixture was chromatographed on a silica gel column (light petroleum) yielding a mixture of exocyclic and endocyclic olefins which was purified by gas–liquid phase chromatography (15 ft × 1/4 in. column of 30% SE-30 at 225 °C) to give the "natural" tricyclovetivene (**1a**) (7.5 mg) as an oil, homogeneous in t.l.c.

Analysis: all analytical data (i.r., n.m.r., mass, and t.l.c.) for "natural" tricyclovetivene were superimposable with that of natural tricyclovetivene.

By the same method, synthetic alcohol (**31**) (5.6 mg) was converted to racemic tricyclovetivene (**1a**) (1.5 mg).

Mol. Wt. Calcd. for $C_{15}H_{24}$: 204.1878. Found (mass spectroscopy): 204.1876.

The remaining recorded spectral data (i.r. and g.l.c.) were completely identical to that of natural tricyclovetivene.

We wish to thank the National Research Council of Canada, Ottawa, Canada, and Hoffmann-La Roche, Nutley, New Jersey, for financial support of these studies.

Photoelectron Spectra of Phosgene and Thiophosgene

DAVID CHADWICK[1]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received September 1, 1971

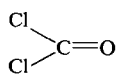
The high resolution photoelectron spectra of phosgene and thiophosgene have been obtained and, in each case, all ionization potentials up to 21.2 eV determined. The spectra are interpreted in terms of the molecular orbital structures and it is concluded that there is a strong interaction between the chlorine p_π "lone pair" electrons and those in the C=O or C=S π bond. The measured ionization potentials are compared with those calculated by the CNDO/2 method and with those obtained for similar molecules.

On a obtenu le spectre photoélectronique à haute résolution du phosgène et du thiophosgène et dans chaque cas, on a déterminé tous les potentiels d'ionisation jusqu'à 21.2 eV. On a interprété les spectres en termes de structures d'orbitales moléculaires et on a conclu qu'il existe une forte interaction entre la paire d'électrons libres du chlore p_π et ceux de la liaison π du C=O ou du C=S. On a comparé les potentiels d'ionisation mesurés à ceux calculés par la méthode CNDO/2 et ceux obtenus pour des molécules semblables.

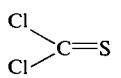
Canadian Journal of Chemistry, **50**, 737 (1972)

Introduction

The electronic structures of molecules containing chromophores such as the carbonyl or thiocarbonyl group have been the subject of extensive research, much of which has been devoted to studies of the electronic spectra of these molecules. Photoelectron spectroscopy (p.e.s.) is a direct method for obtaining the orbital structures of molecules. Detailed studies of the photoelectron spectra of simple carbonyl compounds, such as formaldehyde (1) and carbonyl fluoride (2), have been carried out, but the spectra of similar thiocarbonyl compounds have not been reported. In this paper the high-resolution HeI photoelectron spectra of phosgene (**1**) and thiophosgene (**2**) are presented.



1



2

Both spectra are interpreted in terms of nine ionization potentials (I.P.'s) below the 21.2 eV cutoff, with some bands overlapping in the phosgene spectrum. In each case, several of the bands exhibit resolvable fine structure due to vibrational excitation of the ion in the ionization process. For ionization from a non-degenerate orbital, only totally symmetric ionic vibrational modes can be excited. The measured vibrational frequencies may be compared with the known vibrational frequencies of the ground-state molecule. Such a comparison often indicates the bonding characteristics of the molecular orbital responsible for a particular ionization potential.

The overall agreement between the observed I.P.'s and values calculated by the CNDO/2 method is usually not good. However, it is often adequate and, in such cases, the calculations can be said to provide a reasonable description of the electronic structure of the particular molecule. In this work CNDO/2 calculations have been performed on both phosgene and thiophosgene and are found to predict some essential features of the p.e. spectra.

Experimental

The sample of phosgene was obtained from the Matheson Company and was used without further purification. Thiophosgene was obtained from K and K Laboratories. The initial photoelectron spectrum of thiophosgene revealed CS_2 as an impurity. This was eliminated by careful fractionation of the thiophosgene sample.

The spectra were recorded using the 584 Å (21.22 eV) helium I resonance line from a 2450 MHz microwave discharge. The spectrometer used employs a hemispherical electrostatic analyzer, the whole apparatus being similar in design and operation to the one described previously (3). The resolution (f.w.h.m.) of the instrument, as measured by the argon doublet, was 22 mV. Both the phosgene and thiophosgene spectra were calibrated by flowing a small quantity of xenon through the spectrometer simultaneously with the sample gas.

The Lyman β line was an apparent impurity in the light source, thereby causing the spectra to be unreliable around

20–21.2 eV. For this reason, the affected portions of the spectra are not reproduced in the figures.

Results and Discussion

The p.e. spectra of thiophosgene and phosgene are reproduced in Fig. 1*a* and *b*, respectively. In the case of Cl_2CS, nine I.P.'s are clearly observed below the 21.2 eV limit. Only seven bands are visible in the Cl_2CO spectrum, but the complex second band can be shown to be due to three I.P.'s. There are some noticeable similarities between the two spectra, particularly at higher binding energies. It would be more "natural" to consider the details of the Cl_2CO spectrum before that of Cl_2CS. However, it is convenient to discuss the Cl_2CS spectrum first, since the interpretation is facilitated by its straightforward appearance.

The theoretical I.P.'s have been calculated using the CNDO/2 method devised by Pople and co-workers (4). The 4 eV correction factor, which has been suggested (5) for molecules containing only first-row elements, has been used in this work. The geometry of phosgene was that obtained from a study of its microwave spectrum (6). In the case of thiophosgene, the C=S bond length assumed in the early electron diffraction work (7) has been used together with the same CCl_2 parameters as the phosgene molecule. This structure was assumed by Brand *et al.* in a study of the electronic spectrum of thiophosgene (8).

Thiophosgene

The measured adiabatic and vertical I.P.'s of Cl_2CS are given in Table 1. The observed vibrational spacings are also included. In assigning these vibrational frequencies to normal modes of the ion it has been assumed that the ion retains C_{2v} symmetry in all of the observed states. The vibrational frequencies of the ground-state molecule have been reported by Frenzel *et al.* (9) and are compared to the observed ionic frequencies in this work.

It is useful to consider briefly the features which can be expected in the $Cl_2C{=}S$ p.e.

spectrum. The p.e. spectrum of a thiocarbonyl compound similar to thiophosgene has not been reported, but results derived from the p.e. spectra of several organic sulfides (10) indicate that the first I.P. of $Cl_2C{=}S$ is from a sulfur "lone pair" orbital. Higher I.P.'s should arise from chlorine "lone pair" orbitals and a C=S π (b_1) orbital. The symmetry of the molecule (C_{2v}) results in four chlorine non-bonding orbitals, namely b_2, a_2, b_1, and a_1. A consideration of the dichlorethylenes (11, 12) and methylene chloride (13, 14) p.e. spectra leads one to anticipate I.P's arising from these four orbitals in the 11–13 eV range for Cl_2CS.

CNDO/2 calculations give the following orbital structure for Cl_2CS:

$$^1A_1,$$
$$\ldots(11a_1)^2(7b_2)^2(3b_1)^2(12a_1)^2(2a_2)^2(8b_2)^2(13a_1)^2(4b_1)^2(9b_2)^2$$

The calculated I.P.'s and orbital symmetries are included in Table 1 for comparison with the observed values. Agreement between the observed and calculated I.P.'s is not good, though it is significantly better at higher binding energies. The calculation appears to overestimate the separation between the non-bonding "lone pair" orbitals and the σ bonding orbitals.

First Band

The complex structure of the first p.e. band can be seen in Fig. 2*a*. The vertical I.P. at 9.84 eV is well defined, but the adiabatic I.P. and the ionic vibrational frequencies are dependent on the interpretation of the fine structure. Clearly, two or more normal modes are excited in the ion, one of which has a fairly high frequency (measured as $1060\ cm^{-1}$). This frequency is assigned to $\nu_1(a_1)$, the C=S stretching vibration, which has a value of $1135\ cm^{-1}$ in the groundstate molecule (9). If we take 9.68 eV to be the adiabatic I.P. (the first strong peak) and attribute the weak onset to "hot bands" of $\nu_3(a_1)$, the CCl_2 bending vibration, the secondary fine structure may be assigned to excitation of $\nu_2(a_1)$, the CCl_2 stretching vibration, and $\nu_3(a_1)$, or excitation of $\nu_3(a_1)$ only. This ambiguity arises because of the fact that in the groundstate molecule ν_2 is approximately twice ν_3. However, it is preferable to include the weak onset in a single progression in $\nu_3(a_1)$. The poor resolution at the onset may be due to the superimposition of a ν_3 "hot band" of the first strong peak. This interpretation results in an adiabatic I.P. of 9.61 eV and a vibrational interval of $265\ cm^{-1}$, which may be compared to the groundstate value of $295\ cm^{-1}$ for $\nu_3(a_1)$. The apparent loss of vibrational structure about 10.05 eV may be due to dissociation of the ion. No appearance potential data are available to confirm this interpretation.

This first band is readily assigned to ionization from the $9b_2$ sulfur "lone pair" orbital, because of its low binding energy. However, excitation of ν_1 and ν_3, plus the width of the band, points to significant delocalization. No doubt the excitation of ν_3 occurs because of some interaction between the $9b_2$ orbital and

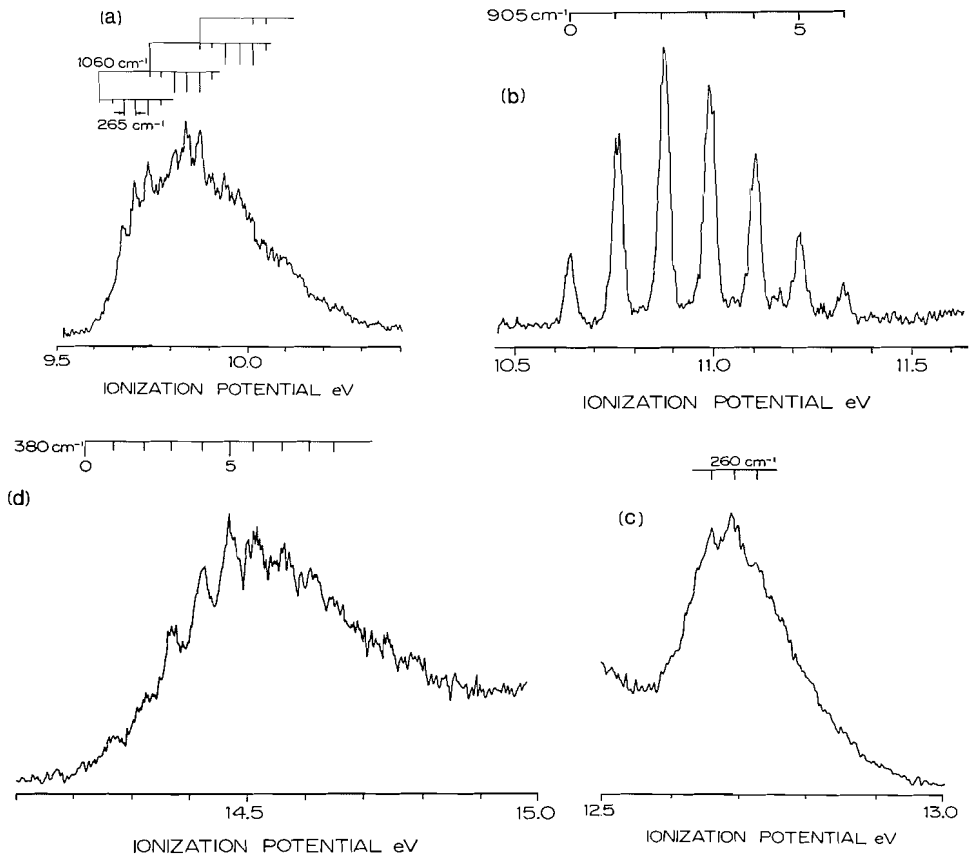

FIG. 2. Individual p.e. bands of thiophosgene.

the $8b_2$ chlorine "lone pair" orbital. Qualitatively, the CNDO/2 calculations are in agreement, as the highest orbital is predicted to be essentially a sulfur "lone pair" orbital with some 20% delocalization onto the chlorine atoms.

Second Band

The second p.e. band consists of a single vibrational progression of frequency 905 cm^{-1} from an adiabatic I.P. of 10.65 eV, Fig. 2*b*. The vibrational structure is attributed to $\nu_1(a_1)$, the C=S stretching frequency, which is considerably reduced from its groundstate value of 1135 cm^{-1} (9). Assignment of this band is straightforward. Excitation of $\nu_1(a_1)$ only and with reduced frequency suggests that the orbital responsible is mainly C–S bonding in character. At such binding energies, only the $4b_1$ C=S π orbital fits this description. However, the appearance of this p.e. band is deceptively simple since a consideration of the higher I.P.'s indicates that there is a large interaction between the C=S π orbital and the $3b_1$ chlorine "lone pair" orbital (see below).

Higher Ionization Potentials

The three bands occurring at vertical I.P.'s of 11.96, 12.38, and 12.69 eV are undoubtedly due to ionization from chlorine "lone pair" orbitals. Only on the fifth band, shown in Fig. 2*c*, is there any indication of resolvable vibrational structure. The tentatively measured frequency of 260 cm^{-1} probably corresponds to $\nu_3(a_1)$ which has a value of 295 cm^{-1} in the groundstate molecule (9). The integrated intensities of the three bands are approximately equal, indicating that only three orbitals are responsible, whereas four chlorine "lone pair" ionizations are excepted at these binding ener-

gies. In the order of increasing overlap these are $8b_2$, $2a_2$, $3b_1$, and $13a_1$, with the a_1 orbital at highest binding energy. Recently, Dixon *et al.* (14) have pointed out the importance of interactions between these and other orbitals in modifying this order for CH_2Cl_2. In view of the "conjugative" interaction between the π orbital and chlorine p_π "lone pair" orbitals in various chloroethylenes (11, 12), which include $Cl_2C{=}CH_2$, and the binding energy of the C=S π orbital ($4b_1$), it is reasonable to assume that the b_1 chlorine "lone pair" orbital in $Cl_2C{=}S$ has been lowered considerably in energy. Simple consideration of the band envelopes of the four higher I.P.'s assigns the sharp seventh band at a vertical I.P. of 15.11 eV to the $3b_1$ chlorine non-bonding orbital. Thus, the third, fourth, and fifth I.P.'s are due to the $8b_2$, $2a_2$, and $13a_1$ chlorine "lone pair" orbitals. The $2a_2$ orbital is the only valence orbital of that symmetry (excluding d orbitals) and, therefore, cannot interact with any other valence orbitals. On this basis, it should appear as the sharpest p.e. band arising from the chlorine "lone pair" orbitals. An interpretation of the p.e. spectrum of Cl_2O places the a_1 chlorine non-bonding level above the a_2 (15, 16). This inversion of the order on the basis of overlap considerations is attributed to a small interaction of the chlorine a_1 orbital with an a_1 σ bonding orbital at higher binding energy (16). In $Cl_2C{=}S$, the I.P.'s arising from σ bonding orbitals occur at much lower binding energy than those of Cl_2O. Hence, the $13a_1$ chlorine orbital should be above the $2a_2$ and, possibly the $8b_2$, since the first σ ionization is at 14.47 eV, only 2 eV higher than the chlorine non-bonding I.P.'s. Therefore, the I.P. at 12.69 eV is assigned to the $2a_2$ orbital. The narrow profile of the band and the excitation of ν_3, the CCl_2 bend, are consistent with the assignment. Experimentally there is no evidence for any particular ordering of the $13a_1$ and $8b_2$ orbitals since both should give rise to broad p.e. bands. The CNDO/2 calculations place the $13a_1$ above the $8b_2$. Despite this, the reverse order, expected on chlorine–chlorine overlap grounds, is preferable since this assignment is more consistent with the orbital structures of the dichloroethylenes (16). Summarizing, the third, fourth, and fifth ionizations are assigned to the $8b_2$, $13a_1$, and $2a_2$ chlorine "lone pair" orbitals, respectively.

Of the remaining four higher I.P.'s, only in the case of the sixth at 14.47 eV was any vibrational structure resolved. This consists of a single progression of frequency 380 cm^{-1} (Fig. 2*d*) and could be due to either $\nu_3(a_1)$ or $\nu_2(a_1)$, the CCl_2 stretching mode. The loss of vibrational structure at 14.7 eV may be due to dissociation of the ion. The I.P.'s at 14.47, 16.19, and 18.25 eV appear as broad photoelectron bands, which clearly demonstrates the bonding character of the parent orbitals. These three I.P.'s may be assigned to ionization from the $12a_1$, $7b_2$, and $11a_1$ σ bonding molecular orbitals which are predicted by the calculations to be at similar binding energies to the observed. On this basis the vibrational structure on the sixth band is due to $\nu_2(a_1)$ reduced from its groundstate value of 500 cm^{-1} (9).

The fact that the seventh band at 15.11 eV, attributed to the $3b_1$ ionization, is strikingly similar in appearance to the $2a_2$ band at 12.69 eV, supports these assignments. The large shift to higher binding energy of the $3b_1$ "lone pair" orbital is due to its interaction with the $4b_1$ C=S π orbital. An unperturbed value for the $3b_1$ chlorine I.P. must be approximately the same as the $2a_2$ I.P. (12.69 eV). Thus the interaction shifts the $3b_1$ orbital by about 2.5 eV. This places the unperturbed C=S π ionization at approximately 13 eV, which compares with the Π_u ionization in CS_2 at 12.83 eV (1).

The preferred assignment of the thiophosgene p.e. spectrum is indicated in Fig. 1*a* and in the orbital correlation diagram to be discussed later (Fig. 4). The orbital structure differs from that predicted by the calculations only in the inverse ordering of the $13a_1$ and $8b_2$ chlorine orbitals.

Phosgene

Table 2 contains the measured adiabatic and vertical I.P.'s of Cl_2CO and vibrational frequencies, where particular p.e. bands have been resolved. The following discussion concerning the assignment of the observed vibrational spacings to normal modes of the ion again assumes that the ion retains C_{2v} symmetry in all of the observed states. In support of this assumption, the molecule F_2BO, which is similar to Cl_2CO^+, possesses C_{2v} symmetry in both the ground and first-excited states (17).

Ionization potentials arising from an oxygen

†±40 cm^{-1}.

"lone pair" orbital (b_2), four chlorine "lone pair" orbitals (b_2, a_2, b_1, a_1), and a C=O π orbital (b_1) can be expected in the Cl_2C=O p.e. spectrum. As in the case of Cl_2C=S, some mixing of the two b_1 orbitals must occur. The orbital structure predicted by the CNDO/2 calculations on Cl_2C=O is:

$$^1A_1, \ldots(9a_1)^2(6b_2)^2(2b_1)^2(10a_1)^2(11a_1)^2(2a_2)^2(7b_2)^2(3b_1)^2(8b_2)^2$$

For convenience the theoretical I.P.'s and corresponding orbital symmetries are contained with the measured values in Table 2. Agreement is poor, although the correct number of I.P.'s is predicted.

First Band

Figure 3*a* shows the first p.e. band which occurs over 11.5–12.4 eV and consists of a long progression in an ionic vibrational mode of frequency 285 cm^{-1}. This measured frequency most probably corresponds to $\nu_3(a_1)$, the CCl_2 deformation, which has the same frequency in the groundstate molecule (18). The possibility that the observed ionic vibration is $\nu_2(a_1)$, the CCl_2 stretch, which has been greatly reduced from its groundstate value of 567 cm^{-1} (18), cannot be excluded. The measured adiabatic I.P. is in good agreement with the 11.77 eV value obtained by electron impact (19).

The broad nature of the band is indicative of a significant change in structure upon ionization and, therefore, it seems likely that the parent orbital has considerable bonding properties. In contrast, the first band in the p.e. spectrum of formaldehyde (1) is quite different in appearance and occurs at lower binding energies (10.88 eV). The strong 0–0 component demonstrates the non-bonding character of the orbital which is clearly the "lone pair" orbital localized on oxygen (b_2). The substitution of two chlorine atoms for the two hydrogens in H_2C=O would result in a stabilization of the b_2 oxygen "lone pair" orbital. The upper limit for this stabilization would be expected in F_2CO, where the first I.P. is a broad band in the 13–14 eV range (2). These considerations place the unperturbed oxygen b_2 ionization in fairly close proximity to the b_2 chlorine non-bonding I.P. Some ambiguity arises since it is possible that the unperturbed oxygen b_2 orbital would be more stable than the chlorine non-bonding b_2 orbital. In either case, any interaction would result in the highest orbital having b_2 symmetry. The I.P. of the b_2 oxygen "lone pair" in Cl_2CO may be estimated in the following way: the first I.P.'s of CH_3CHO, CH_3CFO, and CH_3CClO at 10.2, 11.8, and 11.1 eV, respectively, are all assigned to the removal of an electron from the oxygen "lone pair" orbital (20). Therefore, replacement of a hydrogen by a chlorine stabilizes the oxygen "lone pair" by 0.9 eV. Thus, two chlorines would be expected to produce a stabilization of about 1.8 eV. The corresponding I.P. in Cl_2CO may then be calculated to be 12.0 eV in reasonable agreement with the measured value of 11.83 eV. The reliability of this calculation may be tested by following the same procedure for the fluorides. The predicted

value for F_2CO is thus $10.2 + 2 \times 1.6 = 13.4$ eV compared to the observed binding energy of 13.6 eV (2). The agreement is not really surprising, since any halogen "lone pair" – oxygen "lone pair" interaction has been taken into account by the above method. Thus, the view is taken here that the highest orbital is derived from an oxygen "lone pair" with some delocalization onto the chlorine atoms (*i.e.* mixing of the two b_2 orbitals). The CNDO/2 calculations predict that the first I.P. arises from the $8b_2$ orbital which is strongly delocalized but has only O–Cl bonding character. This would explain the extensive excitation of ν_3. Comparing the first I.P.'s of Cl_2CS and Cl_2CO it may be noted that both are 0.5–1.0 eV lower than the corresponding I.P.'s of H_2O (12.61 eV) and H_2S (10.48 eV) (1). The greater excitation ν_3 in the case of Cl_2CO suggests that there is more delocalization of the oxygen "lone pair" than the corresponding orbital in Cl_2CS. No doubt this reflects the closer proximity in energy of the unperturbed b_2 "lone pair" of chlorine to that of oxygen than that of sulfur. The CNDO/2 calculations support this interpretation since the $9b_2$ orbital in Cl_2CS is predicted to be 80% localized on sulfur.

Photoelectron spectroscopy bands are often similar in profile to transitions in a Rydberg series converging to the corresponding I.P. In the vacuum u.v. spectrum of phosgene (21) several observed electronic transitions consist of long progressions with a vibrational interval of $\sim 280\ cm^{-1}$. It may be that these transitions form a part of a Rydberg series to the first I.P.

Second and Third Bands

The complex second band is reproduced in Fig. 3*b* and is clearly the result of three overlapping ionizations. It is not possible to determine accurately the vertical I.P.'s of the first two components so that both are assigned the value 12.6 ± 0.1 eV. A vibrational progression of frequency $290\ cm^{-1}$ is apparent on the third band at 13.50 eV (Fig. 3*c*), which probably corresponds to the CCl_2 deformation, $\nu_3(a_1)$.

The four I.P.'s observed in this region of the spectrum (12–14 eV) are assigned to the chlorine non-bonding orbitals, $7b_2$, $2a_2$, $3b_1$, and $11a_1$. In formaldehyde, the C=O π (b_1) ionization occurs in the 14–15 eV range (1) in close proximity to the highest binding energy chlorine "lone pair" ionization observed here (13.50 eV). It is likely that the $3b_1$ orbital is pushed to higher energy by interaction with the $2b_1$ C=O π orbital (see below). When this is taken into account the following order is obtained: $3b_1$, $7b_2$, $2a_2$, $11a_1$, which is also that predicted by the CNDO/2 calculations. However, since the a_2 orbital was concluded to be the highest binding energy chlorine non-bonding level in Cl_2CS and Cl_2O (15, 16), this must be true of Cl_2CO where the σ ionizations are at slightly lower binding energies than in Cl_2O. The observed progression in ν_3 is consistent with the assignment of 13.50 eV I.P. to be the $2a_2$.

Higher Ionization Potentials

Three bands occur in the 16–18 eV region of the spectrum. The fourth band is reproduced in Fig. 3*d* and the overlapping fifth and sixth bands are shown in Fig. 3*e*. Apart from the fifth band, the existence of vibrational structure is tentative. There is an indication of two vibrational modes of frequency $540\ cm^{-1}$ and $260\ cm^{-1}$ on the fourth band, the former being the more strongly excited, which may be assigned to $\nu_2(a_1)$ and $\nu_3(a_1)$ by comparison with the groundstate values of 567 and $285\ cm^{-1}$, respectively (18). The fifth band is comparatively narrow in appearance with a vibrational spacing of $280\ cm^{-1}$, which is attributed to $\nu_3(a_1)$. The overlapping sixth band is very broad and may have a highly anharmonic vibrational progression with an interval of approximately $1000\ cm^{-1}$. This would probably correspond to $\nu_1(a_1)$, the C=O stretching mode, greatly reduced from its ground state value of 1827 cm^{-1}. The broad nature of the individual peaks may be due to the short lifetime of the ion in this state or to excitation of a second vibration of frequency too small to be resolved. The ninth I.P. at 19.48 eV appears as a broad structureless band.

This portion of the Cl_2CO p.e. spectrum is similar to that of Cl_2CS and it is likely that the three broad bands arise from similar σ bonding molecular orbitals in the two molecules. The sharp band at 16.73 eV must be due to ionization from the $2b_1$ C=O π orbital. The calculated ordering for these higher binding energy orbitals is $10a_1$, $2b_1$, $6b_2$, and $9a_1$ in agreement with the above assignments. If H_2CO is taken as a model

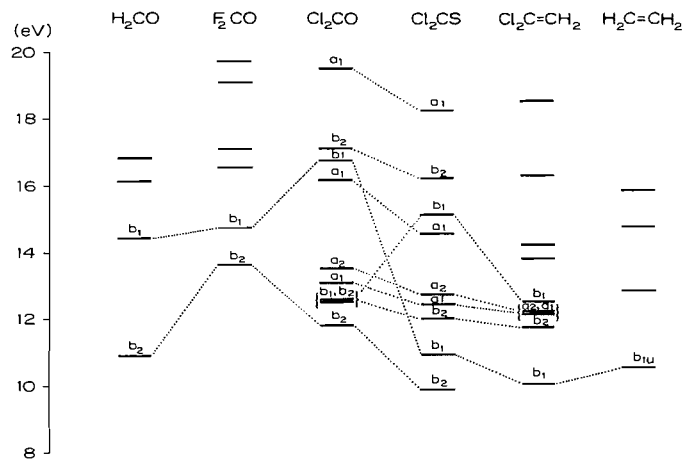

FIG. 4. Orbital correlation diagram.

for the unperturbed C=O π orbital (14.4 eV) (1), then the $2b_1$ orbital in Cl_2CO has been shifted to lower energy by 2.3 eV due to interaction with the $3b_1$ chlorine "lone pair" orbital. Presumably this interaction is responsible for the excitation of the CCl_2 deformation mode on ionization from the $2b_1$ orbital. The fact that the $3b_1$ orbital does not appear to shift to higher energy by a similar amount, infers that there is some interaction with the C=O π^* orbital which is also of b_1 symmetry and is the first excited state of the molecule (22).

The complete assignment is given in Fig. 1*b* and Fig. 4 and differs from that calculated by the reverse order of the $2a_2$ and $11a_1$ chlorine non-bonding orbitals.

General Comments

The orbital structures concluded for Cl_2CS and Cl_2CO may be conveniently compared with those derived for similar molecules by means of an orbital correlation diagram (Fig. 4). Photoelectron results for H_2CO (1), F_2CO (2), $CCl_2{=}CH_2$ (11, 12), and $CH_2{=}CH_2$ (3) have been included in Fig. 4. An important feature of the diagram is the marked variation in the binding energy of the b_1 chlorine "lone pair" orbital in Cl_2CS, Cl_2CO, and $Cl_2C{=}CH_2$. This reflects the changes in the unperturbed energies of the various π bonds. In contrast to the large π interaction in the chlorocompounds, the binding energy of the π orbital in F_2CO is virtually unchanged from the value for H_2CO. These results concerning the mixing of the two b_1 orbitals indicate that, in the chlorocompounds, the C—Cl bonds have considerable "π character". In view of the larger interaction in Cl_2CO and Cl_2CS than in $Cl_2C{=}CH_2$ (only 0.5 eV if ethylene is taken as a model for the unperturbed π orbital energy), the "π character" should be greater for the former two molecules. Evidence for this may be obtained from the chlorine nuclear quadrupole coupling constants in the groundstate molecules. These have been derived from the microwave spectra of Cl_2CO (6) and $Cl_2C{=}CH_2$ (23) and show that the extent of π contribution to the C—Cl bond is significantly greater in the former molecule.

Another noteworthy feature is the higher binding energy of the chlorine "lone pair" orbitals (neglecting interactions with bonding orbitals) in Cl_2CO than in Cl_2CS and $Cl_2C{=}CH_2$ due to the stronger inductive effect of the oxygen atom. As might be expected, all the σ levels in Cl_2CS are destabilized relative to corresponding orbitals in Cl_2CO.

I am grateful to the Research Council of Great Britain for the award of a NATO Fellowship. I wish to thank Professor C. A. McDowell and Professor D. C. Frost for encouragement throughout the course of this work and for kindly extending to me the facilities of their laboratories at the University of British Columbia. I am also indebted to Dr. F. G. Herring for the generous loan of a CNDO/2 computer program and to Dr. J. P. Crow for purifying the thiophosgene sample.

Infrared and Nuclear Magnetic Resonance Spectra of Methyl Titanium Halides

J. F. HANLAN[1] AND J. D. MCCOWAN[2]

Central Research Laboratory, DuPont of Canada, Kingston, Ontario

Received June 24, 1971

Nuclear magnetic resonance and infrared spectra have been obtained for CH_3TiCl_3, $(CH_3)_2TiCl_2$, and some related materials. The rather unusual n.m.r. data for these compounds and for $C_2H_5TiCl_3$ are compared with the results for related species involving Group IVA elements and the variations are discussed in terms of n.m.r. and bonding parameters. Exchange of methyl groups between CH_3TiCl_3 and $(CH_3)_2TiCl_2$ and between each of these compounds and $(CH_3)_2Zn$ has been studied by this means. Infrared data remain difficult to interpret, and unambiguous assignment of bands has not been achieved.

Les spectres r.m.n. et infrarouges de CH_3TiCl_3, $(CH_3)_2TiCl_2$ et de quelques substances apparentées, ont été obtenues. Les données r.m.n. inhabituelles obtenues pour ces composés et pour $C_2H_5TiCl_3$ sont comparées avec les résultats obtenus pour des espèces apparentées impliquant les éléments du groupe IVa; les variations observées sont discutées en termes de paramètres de liaison et r.m.n. L'échange des groupes méthyles entre CH_3TiCl_3 et $(CH_3)_2TiCl_2$ et entre chacun de ces composés et $(CH_3)_2Zn$, a été étudié par ces moyens. Les données infrarouges demeurent difficiles à interpréter et une attribution définitive des bandes n'a pas été effectuée.

The recent interest in both organometallic and transition metal chemistry has resulted in a rapid growth of knowledge of the preparation and characteristics of alkyl transition metal halides. Although attempts to prepare these materials date from the nineteenth century (1, 2), success was achieved only within recent years (3–5).

Because of the instability of alkyl titanium halides, spectroscopic studies have been difficult. Infrared spectra of CH_3TiCl_3 have been obtained under varied conditions (3, 6–9) but have been inadequate to permit an unequivocal assignment of bands. Although the existence of more highly methylated titanium halides has been established (10, 11), little is known of their i.r. spectra (7). Nuclear magnetic resonance spectra of these materials have not been previously published.

In the present work, n.m.r. was found to be the technique of choice to study formation and decomposition of methyl titanium trichloride and dimethyl titanium dichloride (12) since the starting material and decomposition products all display well resolved, single line resonances. Nuclear magnetic resonance data on the related species reported herein were obtained to assist us in our assignment and to provide additional insight into the rather unexpected line positions and shifts which were observed and possibly to assist in the explanation of the unusual chemistry of these species. A few new i.r. data were obtained to the same end.

Experimental

(i) Preparation of Materials

Solvents were purchased in pure grades, and sparged with dry nitrogen to remove oxygen and, in some cases, unacceptable stabilizers. All manipulations, including sparging of solvent, were performed in a chamber containing an atmosphere of dry nitrogen. $TiCl_4$ was similarly handled, except for the $TiCl_4$ enriched to 40% in ^{47}Ti, which was used as obtained from Orgmet Industries, Hampstead, N.H. This material, used in the preparation of enriched CH_3TiCl_3, had itself been prepared from enriched TiO_2 obtained from Oak Ridge National Laboratory, Oak Ridge, Tennessee.

$(CH_3)_3Al$ was used as obtained from the supplier, Texas Alkyls Incorporated, Pasadena, Texas. $(CH_3)_2Zn$ was prepared by the method of Elston as reported by Gray *et al.* (7).

$(CH_3)_2TiCl_2$ was prepared by adding approximately 50 ml of *n*-hexane and 2.2 ml of $TiCl_4$ to a dry, nitrogen filled vessel illustrated in Fig. 1. The vessel was then cooled by liquid nitrogen to -195 °C and 3.8 ml of $(CH_3)_3Al$ were added. The contents were brought slowly to room temperature with constant stirring.

The vessel was then cooled by dry ice/trichloroethylene to -80 °C, where $(CH_3)_2TiCl_2$ precipitated. The liquid phase was then withdrawn through the filter as were two subsequent washes with CCl_3F. The last traces of CCl_3F were removed by pumping the vessel to 10^{-3} Torr at -80 °C. The working solvent was then added, the vessel heated to room temperature, and the solution withdrawn through the filter.

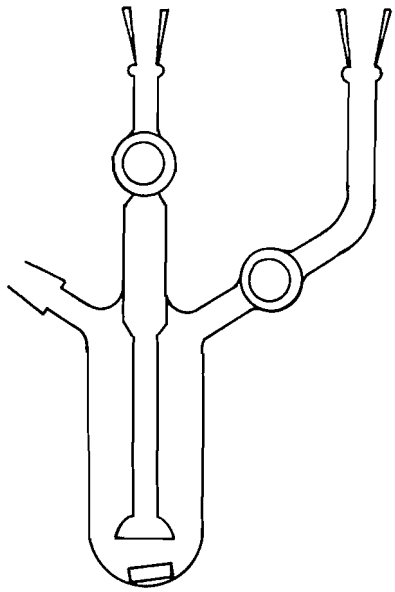

FIG. 1. Sample vessel used for preparations.

At first, CH_3TiCl_3 was prepared by a variation of the method by Karapinka *et al.* (6). The only change was omission of the vanadium binders during the second distillation. Subsequently it was found that mixing hexane solutions of $(CH_3)_2Zn$ and $TiCl_4$ maintaining a ratio of zinc-to-titanium of 0.49 produced a product of excellent quality. Solutions were mixed in the vessel shown in Fig. 1, and the liquid transferred through the filter in order to separate the zinc chloride precipitate. Precipitation and distillation were then carried out as before.

$C_2H_5TiCl_3$ was prepared by mixing $(C_2H_5)_2AlCl$ and $TiCl_4$ in CCl_3F solution at -60 °C with an Al/Ti ratio of 0.4. Solution was slowly warmed to room temperature, where it slowly turned a deep red color. It was then cooled to -60 °C. This material was used only to obtain a spectrum and was not isolated from the solution in which it was prepared.

For the i.r. spectral study, suitable mixtures of deuterated dimethyl zinc and titanium tetrachloride were prepared in hexane solution and run immediately. Time studies were made to assure us that species studied were as claimed.

Attempts to isolate ether-free tetramethyl titanium, which was expected to be of great spectroscopic interest, were totally unsuccessful.

(ii) Equipment and Techniques

Samples were prepared in a glove box under an atmosphere of dry nitrogen. Storage bottles, syringes, and other handling equipment were dried under vacuum and placed in the dry box in sealed vessels. Samples were sealed in n.m.r. tubes or in i.r. cells in the box. The complete absence of methoxy titanium or methoxy zinc resonances, the positions of which had been determined previously, was taken as evidence that oxygen had been excluded.

Nuclear magnetic resonance spectra were obtained using a Varian A60 spectrometer equipped with a low temperature probe. Peak positions were measured accurately using standard audio sideband techniques. Samples could be run within 3 min of preparation. Negligible temperature and concentration shifts were found over the ranges dictated by sample stability and equipment performance.

Infrared spectra were obtained in polyethylene cells on a Perkin–Elmer 621 spectrometer.[3]

Results

The n.m.r. data for methyl titanium trichloride, dimethyl titanium dichloride, and ethyl titanium trichloride are given in Table 1 for solutions in tetrachloroethylene and benzene. Included for comparison are the data for the corresponding carbon compounds, for biscyclopentadienyl titanium dimethyl, and for dimethyl zinc. Chemical shifts are reported in p.p.m. relative to tetramethylsilane (TMS) with minus or plus signs indicating downfield and upfield shifts, respectively. Since, in much of our work, TMS was in an interfering position and there was the possibility of methyl group exchange, cyclohexane and methylene chloride were used as internal standards. Separate experiments established the validity of conversion of chemical shift so obtained to values relative to TMS. Methyl titanium trichloride was also studied in solution in CCl_4 and CCl_3F with results the same as for the C_2Cl_4 solutions. We believe therefore that the reported results for C_2Cl_4 solutions can be compared with data for similar species in CCl_4 without confusion from solvent effects.

The data reported in Table 1 for ethyl titanium trichloride are based on a simple first order analysis. Diethyl titanium dichloride was found to be too unstable even at -60 °C to permit observation.

Early stages of the work were made difficult by the line breadth of the dimethyl titanium dichloride resonance. We found that a rapid exchange of methyl groups between $(CH_3)_2TiCl_2$ and $(CH_3)_2Zn$ broadens the n.m.r. spectra of these materials at ambient temperatures when both are present. In equimolar (10^{-1} *M*) solutions of $(CH_3)_2Zn$ and $(CH_3)_2TiCl_2$ in C_2Cl_4 the line widths at half-height (less the width in the absence of exchange) range from 1.4 Hz at -20 °C to 24.5 Hz at 40 °C. Using the

analysis for slow exchange (17) this gives pre-exchange lifetimes, τ, ranging from 13 to 0.23 ms.

An Arrhenius plot of these data yields an activation energy, E_a, *i.e.*:

$$k = \frac{p}{\tau} = k_0 \exp\left(\frac{-E_a}{RT}\right)$$

where k is the rate constant and p is the mole fraction of the components. Figure 2 portrays the best straight line, on a least squares basis, for these data and similar data for benzene solutions. Fewer points are obtainable in the latter case since benzene freezes at 4 °C and the upper temperature limit is determined by the onset of decay of $(CH_3)_2TiCl_2$ in both solutions. For C_2Cl_4 solutions an activation energy for CH_3 group exchange of 7.5 kcal/mol is obtained. The value for benzene is approximately the same but with a reduction of the frequency factor, k_0. This is consistent with the solvation of the titanium compound by the aromatic solvent that is indicated by the large chemical shift difference observed in the n.m.r. spectra (Table 1).

Experiments were carried out using $(CD_3)_2Zn$ to establish whether the methyl groups of CH_3TiCl_3 are also labile. A quantity of $(CD_3)_2$-Zn, in tetrachloroethylene solution, was added to slightly more than twice the amount of $TiCl_4$ in a n.m.r. tube thus creating a solution of CD_3TiCl_3 with a very small excess of $TiCl_4$ and a precipitate of $ZnCl_2$. To this was added a solution of $(CH_3)_2TiCl_2$. The known concentration of each species was compared with the integrated methyl group intensity of that species. A spectrum obtained 5 min after mixing showed that exchange was complete and deuterated

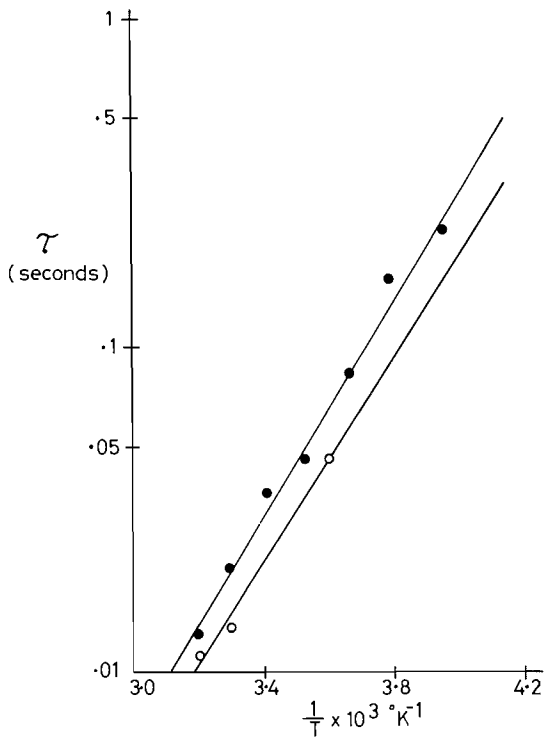

FIG. 2. Variation of pre-exchange lifetime, τ, with reciprocal temperature. ● C_2Cl_4 ○ C_6H_6.

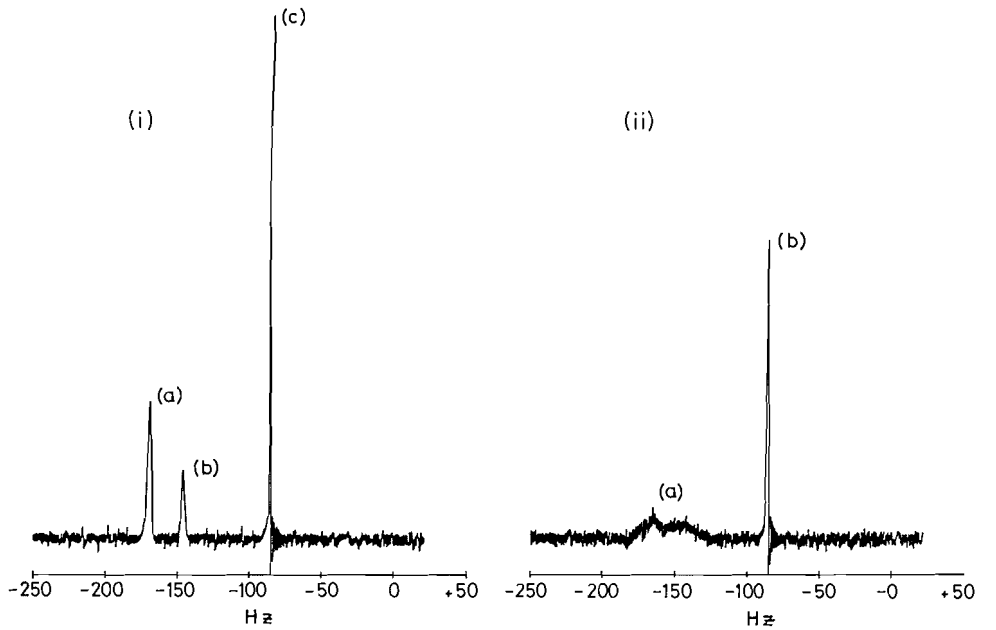

FIG. 3. Proton n.m.r. spectra of (*i*) CH_3TiCl_3 (*a*) and $(CH_3)_2TiCl_2$ (*b*) in C_2Cl_4 solution at 35 °C. Reference (*c*) is C_6H_{12}. (*ii*) Same species at 115 °C, showing CH_3TiCl_3 and $(CH_3)_2TiCl_2$ at (*a*) and C_6H_{12} at (*b*). All spectra are at 60 MHz.

methyls were found to be distributed proportionally between the two species. This exchange is not rapid on the n.m.r. time scale and little or no broadening is observed at ambient temperature. The n.m.r. spectra of a mixture of CH_3TiCl_3 and $(CH_3)_2TiCl_2$ at 35 °C and 115 °C, shown in Fig. 3 *a* and *b*, indicate a rapid exchange between the two species at elevated temperature. The broadening is not affected by the onset or progress of decomposition. These experiments provided proof that methyl group exchange was occurring and that the broadening was not due to complex formation or the presence of paramagnetic impurities.

The possibility of the methyl group protons coupling with the high spin titanium isotopes, ^{47}Ti (7.28%, $I = 5/2$) and ^{49}Ti (5.51%, $I = 7/2$), while remote, was important to us for quantitative accuracy. Also knowledge of any Ti–C–H coupling constant would be valuable for an understanding of the bonding in these species. We, therefore, prepared methyl titanium trichloride from $TiCl_4$ enriched to 40% in ^{47}Ti. No sidebands were observed and the integrated methyl group intensity was in complete stoichiometric agreement with the concentration of titanium analyzed chemically. Evidently quadrupolar relaxation completely decouples the proton spin from the titanium spin. It should be pointed out that in the symmetric environment of the probably tetrahedral tetramethyl titanium, this coupling might be observed as it has been for ^{27}Al ($I = 5/2$) in $Al(CH_3)_4^-$ (18). The data reported by Tabacchi and Jacot-Guillarmod are for $(CH_3)_4Ti$ in ethereal solution, $\delta = -0.68$, (19) and attached to strong complexing agents (20).

In Table 2 we list our *i.r.* results for $(CH_3)_2TiCl_2$, CD_3TiCl_3, and $(CD_3)_2TiCl_2$ along with those of Gray (8) and of van Looy *et al.* (9). Due to the lack of a suitable spectrometer on the site of this work and to the instability and sensitivity of the materials, our experimental work in this area is very limited. The data must therefore be regarded as incomplete and will not be discussed extensively.

Discussion

(i) Infrared

The only species for which satisfactory agreement exists is $(CH_3)_2TiCl_2$. The published spectrum of Gray *et al.* (7) shows a relatively greater intensity for the band at 462 cm^{-1} than we observed. This is probably due to the

presence in his sample of some CH_3TiCl_3 which has a strong band at 464 cm^{-1}. It is interesting to note that no sign of unreacted $(CD_3)_2Zn$ appears in our spectrum for $(CD_3)_2$-$TiCl_2$ although we know from our other work (12) that at this ratio excess $(CH_3)_2Zn$ appears in the n.m.r. spectra of such mixtures. Introduction of chloride causes the hydrogen resonance from CH_3—Zn to shift from +41 to +25 Hz. This was observed both in $(CH_3)_2Zn/TiCl_4$ systems and in experiments where HCl or $ZnCl_2$ were introduced into solutions of $(CH_3)_2Zn$. The complexing thus indicated would explain the absence of an *i.r.* band at 543 cm^{-1} from excess $(CD_3)_2Zn$, since this band assigned by van Looy (9) to the methyl rock would probably undergo a major shift. Attempts to investigate this phenomenon further by the preparation and isolation of a definite complex were unsuccessful although our work (unpublished) and that of others (21) on the system $(C_2H_5)_2Zn$ plus $ZnCl_2$ clearly demonstrate a progressive downfield shift of the n.m.r. resonances with increasing $ZnCl_2$, indicating a species such as "C_2H_5ZnCl".

It is, we feel, clear from the discrepancies in Table 2 for the deuterated species that the assignments for the i.r. spectra of CH_3TiCl_3 and $(CH_3)_2TiCl_2$ are far from settled. Reliance cannot be placed on the existing data for the deuterated species. In particular, *in situ* preparation of CD_3TiCl_3 is not satisfactory. The band at about 515 cm^{-1} observed by van Looy (9) and ourselves, both of whom used $(CD_3)_2Zn$ as a reagent, was not observed by Gray (7) who used $(CD_3)_6Al_2$ and is most probably a Zn—Cl stretch (*cf*: ν_3 of 516 cm^{-1} for $ZnCl_2$ vapor (22)). Study of purified, authentic samples of CD_3TiCl_3 and $(CD_3)_2TiCl_2$ should permit resolution of the problem since well characterized samples are certainly possible as is indicated by the good agreement for $(CH_3)_2$-$TiCl_2$ prepared quite differently by Gray and ourselves. Isolation of the bromide or iodide analogs in an effort to obtain additional information was attempted but not achieved. Preliminary n.m.r. evidence suggests that this is due to their insolubility in our conditions rather than their instability. The preparation of CH_3TiBr_3 reported by Thiele *et al.* (23) using somewhat different reaction conditions supports this suggestion.

(ii) Nuclear Magnetic Resonance

Nuclear magnetic resonance data on the alkyl derivatives of other transition metals are even more rare than the instances of the preparation of materials in this category (24, 25). Thus we have little prior information upon which to base comparisons. The alkyl derivatives of group IIB, IIIA, and IVA have been extensively studied. However, with the exception of the study by Beachell and Butter (15) of bis-cyclopentadienyl titanium derivatives, with their rather different bonding, and that of Burger and Neese (26) of the tris(dialkylamino) titanium alkyls, there is no other instance of n.m.r. data for species with presumed largely empty d orbitals. In the bidentate ligand adducts of CH_3TiCl_3 examined by Clark and McAlees (27) or tetramethyl titanium complexed (20) and in polar solvents (19), titanium will have acquired considerable electron density in its d orbitals. Since it is the

presence of unfilled d orbitals which probably provides the low energy path for the reaction which is suggested by the high reactivity of our compounds, it is useful to attempt to understand the implications of the rather unexpected chemical shifts found for the methyl and ethyl titanium chlorides.

While there is, of course, no reason to expect any great correspondence between n.m.r. results for titanium in Group IVB with the elements of Group IVA, the latter have been extensively studied and do provide a set of data for molecules of similar geometry and substitution. Further, it is interesting and perhaps valuable to consider the nature of the variations between titanium and Group IVA elements. It is immediately apparent from the data of Table 1 that the near identity of resonance positions for CH_3TiCl_3 and CH_3CCl_3 in spite of the difference in electronegativity of the central atom (1.6 for Ti and 2.5 for C (28)) indicates that other than inductive effects and simple bonding effects are operative. However, the value of 134 Hz for $J_{^{13}C-H}$ is typical for sp^3 hybridized C with a strongly electronegative substituent (29) and yields an s character, a_H^2 of 0.268 from the equation $J_{CH} = 500a_H^2$ and a Juan and Gutowsky substituent parameter, ΔX, of 0.072 (30). The coupling constant of 122 Hz of $(C_5H_5)_2Ti(CH_3)_2$ provides the corresponding values of $a_H^2 = 0.244$ and $\Delta X = -0.024$ which may reflect a relatively small inductive effect due to the cyclopentadienyl groups and hence more nearly equal C—Ti and C—H bonding for the methyl group.

Spiesecke and Schneider (31) have pointed out the pitfalls in attempts to provide simple correlations between chemical shifts and electronegativities. However, within similar series such correlations have proven satisfactory for methyl (16, 31–34) and ethyl (31, 35) derivatives. Table 3 presents the relevant data for the titanium and Group IVA derivatives. Chemical shifts of the methyl group plotted *vs.* n for the series $(CH_3)_nMCl_{4-n}$ provide good straight lines from which the shift per chlorine, δ/n, were obtained. Brown and Webster (14) have pointed out that the smaller value for the change of chemical shift with substitution of a Cl for a CH_3 group in the silicon series can be taken to imply an increased electron density at the silicon due to double bond character in the Si—Cl bond. This back donation of electron density via $d\pi$—$p\pi$ bonding is evidently even greater in the Ti—Cl bond and is consistent with the availability of empty d orbitals of titanium(IV). The even smaller value of δ/n and increased shielding for CH_3TiCl_3 and $(CH_3)_2TiCl_2$ in benzene solution suggests either that the solvation further augments the electron density at titanium or that the paramagnetic shift due to the benzene ring current is stronger in the trichloride than the dichloride due to more effective solvation. It is interesting to note that for $(C_5H_5)_2CH_3TiCl$ and $(C_5H_5)_2(CH_3)_2Ti$, δ/n is 0.62 (15) similar to that for C in Table 3. If this can be taken as the normal inductive effect for a Cl atom replacing a methyl group it suggests that no novel Ti—Cl or Ti—CH_3 bonding is present in the cyclopentadienyl derivatives.

The chemical shifts and electronegativities of

Si, Ge, and Sn are very similar. Hence, a plot of these two parameters for the series CH_3MCl_3 where M = C, Si, Ge, Sn, does not cover a sufficient range to make comparisons with the data for CH_3TiCl_3 very meaningful. However, one can obtain approximate effective electronegativities for the MCl_3 group from the data given by Spiesecke and Schneider (31) for a variety of compounds of the type CH_3X. These are given on Table 4 where the first line is the effective electronegativity from their data X ≠ halogen and the second line that for X = halogen. The electronegativities in the third line are calculated from the equation $E_x = 0.62\Delta + 2.07$ where $\Delta = \delta CH_3 - \delta CH_2$ given by Narasimhan and Rogers (35) for metal ethyl derivatives. The rather good agreement for the effective electronegativities $—CCl_3$, $—SiCl_3$, and $—TiCl_3$ between lines 2 and 3 of Table 4 is, we feel, largely fortuitous. Spiesecke and Schneider have indicated the important effect of magnetic anisotropy due to the X group in C_2H_5X compounds on the chemical shift of β-hydrogen. This effect is evident in the large downfield shift of the CH_3 group $C_2H_5TiCl_3$ (Table 1). The above authors provide a graphical presentation of the chemical shift of the CH_3 and CH_2 groups in C_2H_5X compounds. Our data for $C_2H_5CCl_3$ fit their lines for X ≠ halogen near an electronegativity of 3. However, the data for $C_2H_5TiCl_3$ do not even come close to fitting either the lines for X ≠ halogen or X = halogen and the implication is that the magnetic effect on the β-hydrogen is even greater for $—TiCl_3$ than for the strongly anisotropic iodine derivatives. Alternatively, the known instability toward alkene elimination of alkyltitanium derivatives having a β-hydrogen (37) may imply the origin of these unusual chemical shifts arises from an unusual electronic configuration, although the quite typical value of $J^{H-H} = 7.5$ Hz for the C_2H_5 group in $C_2H_5TiCl_3$ (Table 1) would not support this. Additional experimental data would be needed to permit the detailed analysis necessary to answer this question.

If the extrapolated value for $(CH_3)_4Ti$ of $\delta = 1.85$ is correct we would conclude from the data of Table 3 also that there is a major variation from accepted values indicated for the electronegativity of titanium, that is, Ti is apparently more electronegative than C. Alternatively a hybridization with substantial d character as proposed by Dijkgraaf and Rousseau (38) for titanium with novel effects on the shielding for the methyl groups may be the explanation. However, the orbital electronegativities calculated by Hinze and Jaffé (39) decrease markedly with increasing d character. Burger and Neese (26) calculate an electronegativity of 1.25 for Ti from their chemical shift data on tris(dialkylamino) titanium ethyl. It may be that the bonding is different for these species but we would prefer to suggest that, for transition elements, one must consider the group and cannot discuss a central atom alone. It is clear that the unusual chemical behavior of these species is reflected in the equally novel spectral properties.

Much of the work of this paper was done while the authors were members of the Central Research Laboratory of DuPont of Canada Limited. The interest and encouragement of Dr. M. Phibbs and the technical assistance of Messrs. M. Hughson and B. Landon are gratefully acknowledged.

Thermal Decomposition of Methyl Titanium Chlorides

J. D. McCowan[1] and J. F. Hanlan[2]

Central Research Laboratory, DuPont of Canada Limited, Kingston, Ontario

Received June 24, 1971

The thermal decomposition of CH_3TiCl_3 and $(CH_3)_2TiCl_2$ in C_2Cl_4 and C_6H_6 has been examined over the range 20 to 110 °C under a nitrogen atmosphere utilizing n.m.r. spectroscopy, mass spectroscopy, and elemental analysis. The reaction products are found to be the result of at least four separate, simultaneous, and competing reactions.

La décomposition thermique de CH_3TiCl_3 et de $(CH_3)_2TiCl_2$ dans C_2Cl_4 et C_6H_6 a été examinée sur une échelle de température allant de 20 à 110 °C, sous une atmosphère d'azote, et en utilisant la spectroscopie et RMN et de masse ainsi que l'analyse élémentaire. Les produits de la réaction sont le résultat d'au moins quatre réactions isolées, simultanées, et compétitives.

Introduction

Studies of the decomposition of alkyl titanium chlorides have yielded a diversity of views on the mechanism involved. The proposition that decomposition involved a radical attack upon the solvent (1, 2) has been effectively disproven as a general theory by de Vries (3), although radical attack may occur under special conditions (4). However the theory of de Vries leads to awkward explanations for the decomposition of methyl titanium halides, particularly the postulated existence of either CH_2 or CH_2TiCl_3 without supporting evidence.

The present work was designed to inquire into the decomposition of methyl titanium chlorides, with a view to either producing evidence to support one of the existing theories or uncovering an alternative.

Experimental

(i) Use of Nuclear Magnetic Resonance Spectroscopy

The decomposition of both methyl titanium trichloride and dimethyl titanium dichloride and the corresponding production of soluble hydrogen-bearing products such as methane, were conveniently followed by n.m.r. spectroscopy. Samples were made up in n.m.r. tubes to known concentrations and component ratios. Spectra were obtained periodically as required on a Varian A-60 spectrometer equipped with a variable temperature probe.

Samples were prepared in a dry nitrogen atmosphere using syringes of from 0.1 ml to 1.0 ml capacity. Samples involving study of more than a few hours duration were made up in tubes having a constriction near the top at which a flame seal was made after filling. Liquid volumes were chosen to minimize vapor volume. This decreased the proportion of volatile products which was in the gaseous phase and which was, consequently, not in the n.m.r. sample region.

Samples were stored, between spectral measurements, in a rotating drum which ensured continuous mixing by turning the samples end over end in a period of about 1 min. The drum for ambient temperature was constructed by boring holes in a polyethylene block. A second mixing drum, constructed from aluminum, was mounted in a modified laboratory oven. Light was excluded totally in storage and as much as possible during handling. Just prior to each n.m.r. determination, any solids were centrifuged to the top of the tube so as not to interfere with the homogeneity of the liquid phase. The solid was redispersed before returning the sample to the mixer.

Peak positions, and quantitative measurements of the concentration of each species, were obtained by comparison of spectra and integrated peak heights with those of a reference material of known concentration. This reference was usually cyclohexane, but cyclopentane, benzene, and dichloromethane were used on occasions when a search for some special phenomenon was made. Integral values used were the average of five or more consecutive runs.

Studies were made of the path of decomposition at 20, 50, 80, and 110 °C and in a variety of solvents. A few specialized experiments, such as continuous centrifuging to compact the solid or removal of the solid initially formed, were also performed.

(ii) Elemental Analyses

Elemental analyses were carried out by both chemical means (A. Bernhardt)[3] and by neutron activation analysis (General Atomic).[4] The first was used for carbon, hydrogen, and chlorine, and the second for zinc, chlorine, and titanium.

Solid decomposition products were isolated using fine porosity ground glass filter crucibles, dried by pumping to 10^{-4} Torr or better, sealed in glass and sent for analysis. A

few samples were sent in a moist condition as a test for volatile products.

Analysis of solids initially precipitated on mixing dimethyl zinc with titanium tetrachloride in a solvent were also carried out by methods analogous to those above. In this case speed was important and tests were made to ensure that filter porosity did not effect either the weight or nature of the product.

(iii) Mass Spectrometric Studies of the Nature of the Alkyl Content of the Solid Decomposition Products

Solid decomposition products were isolated as for elemental analysis, and sealed in a glass vessel designed for the purpose. D_2O was introduced and the resulting gaseous products analyzed by mass spectrometry.

(iv) Consideration of Errors

In the quantitative study of decomposition using n.m.r. spectroscopy, errors were introduced by syringe accuracy and handling, and by the reproducibility of the integrations by the spectrometer. Syringes of the most suitable size were used to minimize errors. Tests indicated that syringe errors are approximately 2 to 3% for any one measurement, giving a cumulative error of 5% from the double step of making the solution and drawing from it.

Errors in integration were minimized by running five integrals on each spectrum. Reproducibility of successive integrals was within 30%. This poor reproducibility arose since the spectra and integrals were obtained at low temperatures and the heater-sensor insert is subject to fluctuations in its position within the insert of the probe. Reproducibility of the average of successive sets of five integrals was within 10%.

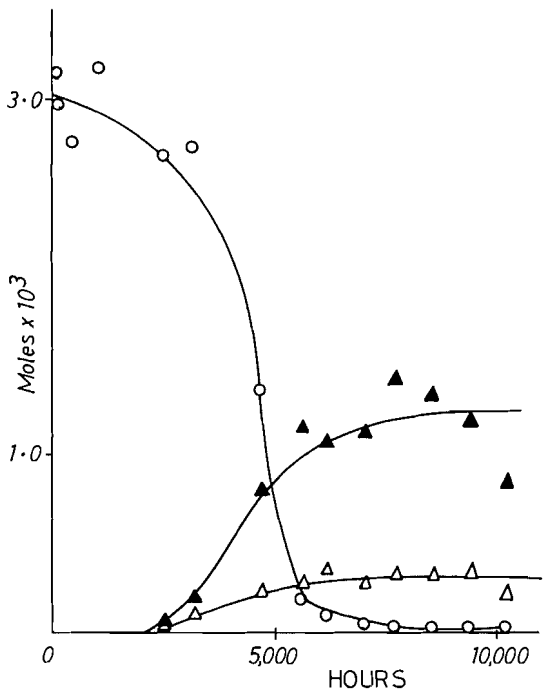

FIG. 1. Thermal decomposition at ambient temperature of initially 1.5 *M* CH_3TiCl_3 in C_2Cl_4. Symbols are: ○, CH_3TiCl_3; △, CH_4; ▲, C_2H_6.

(v) Materials

Trimethyl aluminum was used as obtained from Texas Alkyls.[5] Dimethyl zinc was prepared by the method of Elston (6). Analysis indicated a high degree of purity in both cases. Dimethyl titanium dichloride and methyl titanium trichloride were prepared by the methods described previously (5).

Tetrachloroethylene, benzene, cyclohexane, and titanium tetrachloride were bought in the purest available grades and sparged with dry nitrogen. Batches of tetrachloroethylene, containing a non-volatile inhibitor (*t*-butyl phenol) which was not removed by sparging, were found to give anomalous results. Air distillation of tetrachloroethylene led to formation of traces of Cl_3CCOCl which likewise interfered. Care had to be taken in the storage of tetrachloroethylene from which the inhibitor had been removed in order to prevent formation of interfering oxidation products.

All light sensitive materials were stored in darkened storage bottles. Thermally unstable materials were stored at −195 °C in the short period before use. Air and water sensitive materials were stored in glass vessels with double ground-glass stoppers. The vessels were kept in a nitrogen atmosphere.

Results

Soluble Decomposition Products

Almost two hundred samples, mainly $(CH_3)_2Zn/TiCl_4$ systems, were studied. Table 1 summarizes the effect on decomposition product distribution of variations in solvent, temperature, and means of preparation of CH_3TiCl_3 and $(CH_3)_2TiCl_2$. The eight representative runs in Figs. 1 to 8 illustrate the rates under varying conditions, as well as showing exact values of product distribution for their particular cases. The amounts of each species are plotted as calculated from the n.m.r. integrals, except for a 6% addition for CH_4 corresponding to the amount of CH_4 in the vapor phase. This correction is based on known solubility data and is constant because the volumes of reagent solution were chosen always to total 95% of the 1.95 ml total volume of the sealed n.m.r. tube. Figure 9 illustrates the reproducibility to be expected and the hydrogen balance obtained. The latter assumes, for reasons to be discussed, that one CH_2 exists in the solid decomposition products for each CH_4 formed.

In all $(CH_3)_2Zn/TiCl_4$ systems (*e.g.* Figs. 5, 7, and 8), the observed initial concentrations of CH_3TiCl_3 and of $(CH_3)_2TiCl_2$ are less than

TABLE 1. Decomposition products

System	Solvent	Soluble products by proton n.m.r.	
		At 25 °C	At 80 °C
CH_3TiCl_3	C_2Cl_4	CH_4, C_2H_6 both important, C_2H_6 being more abundant above initial CH_3TiCl_3 concentrations of ~ 1 *M*; traces of 1,1,2-trichloropropene-1, especially for very low initial concentrations*; traces of CH_3Cl	CH_4, C_2H_6, CH_3Cl, and 1,1,2-trichloropropene-1 are all abundant
CH_3TiCl_3	C_6H_6	CH_4, C_2H_6 both important, with abundance of C_2H_6 again favored by high initial concentrations of CH_3TiCl_3	
$(CH_3)_2Zn/TiCl_4$ ($Zn/Ti < 0.5$)†	C_2Cl_4	CH_4, C_2H_6, CH_3Cl all important. CH_3Cl abundance increases as Zn/Ti ratio decreases;‡ traces of 1,1,2-trichloropropene-1	CH_4, C_2H_6, 1,1,2-trichloropropene-1 all abundant, with relative amounts dependent on initial concentrations, and Zn/Ti ratio. CH_3Cl depends on Zn/Ti ratio as at 20 °C. 1,1,2-trichloropropene-1 favored by low initial concentrations of CH_3TiCl_3
$(CH_3)_2Zn/TiCl_4$ ($Zn/Ti < 0.5$)†	C_6H_6	CH_4 and C_2H_6 are abundant. Traces of toluene are found	CH_4, C_2H_6, and toluene are all abundant
$(CH_3)_3Al/TiCl_4$ ($Al/Ti < 0.33$)†	C_2Cl_4 or C_6H_6	Products closely parallel those in $(CH_3)_2Zn/TiCl_4$ systems of $Zn/Ti < 0.5$	1,1,2-trichloropropene-1 very abundant. CH_4, C_2H_6, and CH_3Cl all abundant, with CH_3Cl showing usual inverse dependence on ratio
$(CH_3)_2TiCl_2/CH_3TiCl_3$	C_2Cl_4	CH_4	
$(CH_3)_2Zn/TiCl_4$ ($Zn/Ti > 0.5$)	C_2Cl_4	CH_4, $(CH_3)_2Zn$§	CH_4, $(CH_3)_2Zn$§ and considerable 1,1,2-trichloropropene-1
$(CH_3)_2Zn/TiCl_4$ ($Zn/Ti > 0.5$)	C_6H_6	CH_4, $(CH_3)_2Zn$§	CH_4, $(CH_3)_2Zn$§ and traces of toluene, particularly at ratios near 0.5
$(CH_3)_3Al/TiCl_4$ ($0.33 < Al/Ti < 1.0$)‖	C_2Cl_4	CH_4, considerable 1,1,2-trichloropropene-1, and traces of C_2H_6	
$(CH_3)_2TiCl_2$	C_2Cl_4	CH_4	
$(CH_3)_3Al/TiCl_4$ ($Al/Ti > 1.0$)	C_2Cl_4	CH_4 and traces of 1,1,2-trichloropropene-1 and C_2H_6	

*No sign of products of further exchange, such as 1,1-dichloro-2-methylpropene-1 or 2,2-dichlorobutene-2 were observed in any of this work.
†At these ratios, CH_3TiCl_3 is observed and $(CH_3)_2TiCl_2$ is not.
‡For three samples all of identical initial CH_3TiCl_3 concentration but of Zn/Ti ratios of 0.15, 0.30, and 0.45, the CH_3Cl produced corresponded to 32, 15, and 5%, respectively, of the total soluble products observable by proton n.m.r.
§See Figs. 7 and 8.
‖At these ratios, both CH_3TiCl_3 and $(CH_3)_2TiCl_2$ are present, at least during part of the decomposition.

*All elements are given in equivalents $\times 10^2$. Total volume of solvent was 60 ml. No carbon and hydrogen measurements were made. Original components were measured by analysis. The number of equivalents of each element remaining in solution is determined by the difference of the component and product solid measurements.

would be expected from the stoichiometry. This is attributed to CH_3TiCl_3 complexing with solid $ZnCl_2$.

The role of the precipitated $ZnCl_2$ in realkylation of zinc (Figs. 7, 8) was explored by preparation of two identical n.m.r. samples, each containing 2.14×10^{-4} mol of $(CH_3)_2Zn$ and 1.45×10^{-4} mol of $TiCl_4$ in 1.85 ml of C_2Cl_4. One was mixed constantly so as to maintain a distribution of finely divided $ZnCl_2$ throughout the solution. The other was centrifuged constantly, to compact the $ZnCl_2$ and reduce its available surface area. In the latter, titanium chlorides formed by decomposition were deposited on the $ZnCl_2$ as they formed, further reducing the available area of $ZnCl_2$. In the mixed tube, 4.5×10^{-5} mol of $(CH_3)_2Zn$ and 7.2×10^{-5} mol of CH_4 were formed. In the centrifuged tube, 2.8×10^{-5} mol of $(CH_3)_2Zn$ and 1.12×10^{-4} mol of CH_4 were produced. In both cases, the quoted amount of $(CH_3)_2Zn$ is that formed in addition to the residual $(CH_3)_2Zn$ observed immediately after the formation of $(CH_3)_2TiCl_2$.

Rates of Decomposition

The shape of the n.m.r. tubes precluded good mixing. Coagulation and disintegration of solid products periodically occurred. Consequently, kinetic data obtained from these experiments are too unreliable to permit unequivocal assignment of particular rate laws. Nevertheless, as Fig. 9 illustrates, accuracy and reproducibility are sufficient to yield considerable information.

CH_3TiCl_3 in solution, even in $(CH_3)_2Zn/TiCl_4$ systems, decomposes unexpectedly slowly. Much more rapid is the decomposition of $(CH_3)_2TiCl_2$ and of CH_3TiCl_3 in the presence of $(CH_3)_2TiCl_2$. See Figs. 1–8.

An induction time exists for the decomposition of CH_3TiCl_3 at 20 °C, the formation of CH_4 and of C_2H_6 being associated with autocatalysis (Figs. 1, 2, 4).

Rates of formation of CH_3Cl, of 1,1,2-trichloropropene-1, and of toluene increase more rapidly with temperature than do those of CH_4 and C_2H_6.

Insoluble Decomposition Products

Elemental analyses of the solid decomposition products were obtained by both chemical methods and neutron activation analysis. Results obtained from both techniques had failings. Chemical methods indicated hydrogen contents in hydrogen-free test samples almost as great as those in the study samples. Chlorine analyses proved very accurate by chemical methods, but were more erratic in neutron activation data.

Despite these errors, some characteristics of the solids emerged clearly. The solids produced in CH_3TiCl_3 systems and in $(CH_3)_2Zn/TiCl_4$ systems of $Zn/Ti < 0.5$, have a Cl/Ti ratio very close to three, with virtually no non-volatile hydrocarbon content.

Solids produced by the thermal decomposition of $(CH_3)_2TiCl_2$ alone in solution have a Cl/Ti ratio close to 2, and a large hydrocarbon content, the nature of which is described subsequently. Solids produced by $(CH_3)_2Zn/TiCl_4$ systems of $Zn/Ti > 0.5$ have a Cl/Ti ratio intermediate between 2 and 3, and a moderate hydrocarbon content. Table 2 shows the results of the most self consistent set of analyses carried out on $(CH_3)_2Zn/TiCl_4$ systems.

A preliminary study of the nature of the hydrocarbon content of the solid was made by mass

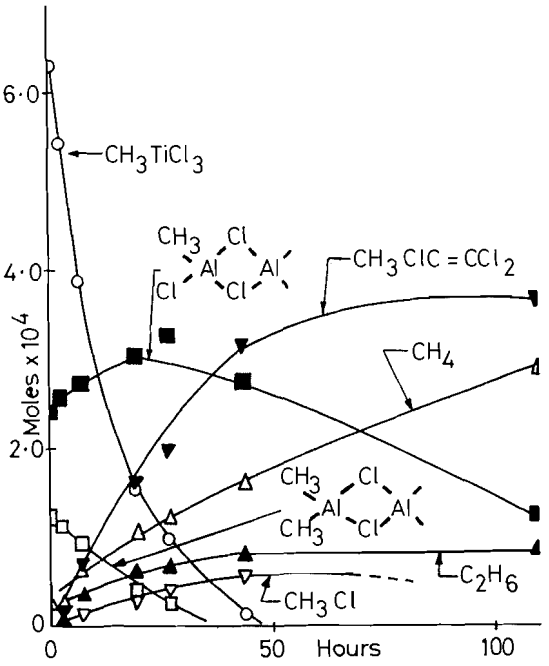

FIG. 6. Thermal decomposition at 80 °C of materials formed from 0.17 *M* $(CH_3)_3Al$ and 0.56 *M* $TiCl_4$ in C_2Cl_4. Symbols are: ○, CH_3TiCl_3; △, CH_4; ▲, C_2H_6; ▽, CH_3Cl; ▼, $CH_3ClC{=}CCl_2$.

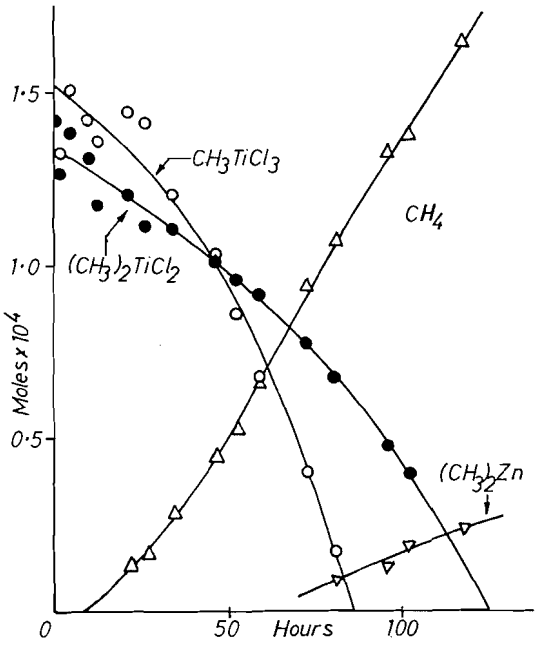

FIG. 7. Thermal decomposition at ambient temperature of materials formed from 0.11 *M* $(CH_3)_2Zn$ and 0.15 *M* $TiCl_4$ in C_2Cl_4. Symbols are: ○, CH_3TiCl_3; ●, $(CH_3)_2TiCl_2$; △, CH_4; ▽, CH_3Cl.

spectrometric analysis of the gases produced on adding D_2O or H_2O to the solids. Solids obtained from the thermal decomposition of *n*-hexane or C_2Cl_4 solutions of $(CH_3)_2TiCl_2$, and from *n*-hexane solutions of $(CH_3)_2Zn/TiCl_4$ systems were studied.

In deuterated systems, the relative abundance of the products observed decreased as CH_3D, CH_4, $C_2H_4D_2$, and C_2H_5D. Small amounts of higher alkyls observed in some samples appeared to arise from residual *n*-hexane. Slight amounts of more highly deuterated ethanes were observed. In the case of products from $(CH_3)_2TiCl_2$ solutions, the amounts of methane were from two to six times the amounts of ethanes. In the case of products of $(CH_3)_2Zn/TiCl_4$ systems of Zn/Ti ratios greater than one, the methanes to ethanes ratio was ten or more.

Discussion

The complexity of these reactions can lead to false conclusions if data from different systems are compared without knowledge of, or consideration of, the effects of different solvents, different temperatures, or different means of preparation. The experiments in this paper were carried out to provide a background of such knowledge against which more detailed and specific experiments could be judged. As such, they permit, when considered with the data of others (3, 4), postulation of a set of reactions which, while not entirely proven, provides a consistent explanation of both kinetic and polymerization observations.

(i) $(CH_3)_2TiCl_2$

It is our hypothesis that some unknown, otherwise unimportant mechanism produces traces of $TiCl_2$ in $(CH_3)_2TiCl_2$ systems. Reaction 1 then occurs on the crystal surface.[6]

[1] $$(CH_3)_2TiCl_2 + TiCl_2(s) \rightarrow 2CH_3{-}TiCl_2(s)$$

The solid so formed would have a valency intermediate between 2 and 3, depending on the extent to which reaction 1 occurs. Such an intermediate and variable valency explains the

[6]The notation R—$TiCl_n$(s) implies a surface R group on a titanium chloride lattice. It does not imply stoichiometric replacement of $1/(n+1)$ of the chlorines by alkyls.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

range of valencies reported for related systems (7, 8, 9, 10). A speculation that further alkylation of the surface may occur by the exchange reaction 2 is reasonable but unsupported.

[2] $(CH_3)_2TiCl_2 + Cl—TiCl_x(s) \rightarrow CH_3—TiCl_x(s) + CH_3TiCl_3$

Since CH_4 is formed without hydrogen contribution by the solvent, a minimum of two methyl groups in near proximity on the surface are therefore required. Reactions 1 and 2 continuously regenerate the required methyl population on the surface.

The preliminary mass spectrometric data do not unequivocally determine the nature of that portion of the carbon and hydrogen which is incorporated in the solid. The large amount of CH_3D produced on adding D_2O implies the existence of methyl groups attached to the metal atoms in the solid in keeping with the equation postulated. As did Rodriguez *et al.* (15, 16), we found small amounts of more highly deuterated methanes. Unlike Rodriguez *et al.*, we are reluctant to interpret these as other than the products of deuterium–hydrogen exchange either on the solid or on the inlet of the mass spectrometer. The former possibility would in itself be of interest. Isotopic exchange is well known for heavier transition metals (11, 12) and can occur quite rapidly for temperatures at least as low as 80 °C (13).

Small amounts of low molecular weight alkanes were observed in solution and rather larger amounts were produced by deuterolysis of the solid. The latter was principally $C_2H_4D_2$,

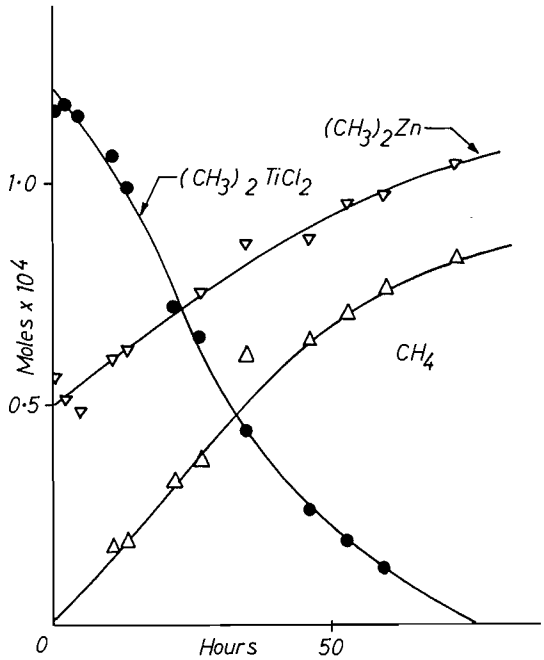

FIG. 8. Thermal decomposition at ambient temperature of materials formed from 0.11 *M* $(CH_3)_2Zn$ and 0.077 *M* $TiCl_4$ in C_2Cl_4. Symbols are: ●, $(CH_3)TiCl_2$; △, CH_4; ▽, CH_3Cl.

with significant amounts of C_2H_5D (14). Although no careful measurements of quantities were made, such material is not sufficient to complete the mass balance.

The configuration of the important solid state precursor of $C_2H_4D_2$ is uncertain. It is geometrically possible for a dimethylene group to "bridge" two adjacent titanium atoms along the

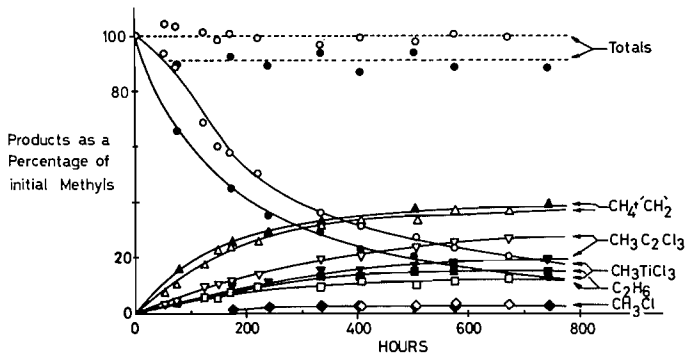

FIG. 9. Reproducibility test showing (*a*) amounts measured in two identical runs, one designated by open symbols and one by black symbols and (*b*) comparison of amounts of carbon and hydrogen in the products, assuming that one methylene exists as polymer or in the solid for each methane, with the amounts in the initial material.

For personal use only.

c-axis of a β-$TiCl_3$ structure. The C—C axis would be skewed relative to the *c*-axis if the carbons occupied Cl vacancies and considerable strain would be expected. However, such a species would explain the origin of both the $C_2H_4D_2$ and the small amounts of low molecular weight alkanes, since it could be released as ethylene and subsequently incorporated in polymer at some Ziegler site.

$(CH_3)_2Zn$ is regenerated where $(CH_3)_2TiCl_2$ is formed *in situ* in $(CH_3)_2Zn/TiCl_4$ systems. While this phenomenon is not essential to thermal decomposition, it is associated with it and must be explained concurrently. We believe that soluble CH_3ZnCl reacts with surface methyls according to reaction 3

[3] $$CH_3ZnCl + CH_3—TiCl_x(s) \rightarrow (CH_3)_2Zn + Cl—TiCl_x(s)$$

and that both CH_3ZnCl and $(CH_3)_2Zn$ are absorbed, to some extent, on the solid titanium chloride. $(CH_3)_2Zn$ formed by reaction 3 can then react with precipitated $ZnCl_2$ to generate more CH_3ZnCl. This is consistent with our experimental evidence that increasing the area of $ZnCl_2$ both retards CH_4 formation (by reducing the surface concentration of methyl groups through reaction 3) and accelerates $(CH_3)_2Zn$ formation (through permitting more rapid regeneration of CH_3ZnCl). This is consistent with n.m.r. mass balance data and with the high CH_3D content in the deuterolysis of $(CH_3)_2Zn/TiCl_4$ systems.

By contrast, $(CH_3)_3Al_2Cl_3$ produced in $(CH_3)_6Al_2/TiCl_4$ and $(CH_3)_4Al_2Cl_2/TiCl_4$ systems continues to methylate the solid, although slowly, and CH_4 continues to form (Fig. 6). Aluminum based systems therefore have a high surface concentration of methyl groups whereas with zinc based systems it is very low. If, as in Cossee's model (17), an active Ziegler site requires an alkyl bonded to a transition metal atom, such observations suggest an alternative to the explanation offered by Rodriguez and van Looy (18) for the difference in catalytic activity between $(CH_3)_3Al/TiCl_4$ systems and $(CH_3)_2Zn/TiCl_4$ systems.

(ii) CH_3TiCl_3

It is apparent from the diversity of products that the decomposition of CH_3TiCl_3 is more complicated than that of $(CH_3)_2TiCl_2$.

In C_2Cl_4, one obtains CH_4, C_2H_6, 1,1,2-trichloropropene-1, and CH_3Cl. In C_6H_6, the last two products are missing. In alkanes, CH_4, C_2H_6, and CH_3Cl occur (3, 4).

It is suggested that CH_4 formation is, at least in part, the product of $(CH_3)_2TiCl_2$ which has been formed through the equilibrium [4].

[4] $$2CH_3TiCl_3 \rightleftharpoons (CH_3)_2TiCl_2 + TiCl_4$$

Such a route is supported by the slight reduction in CH_4 production observed at low Zn/Ti ratios (where $TiCl_4$ is present in excess) and by the observation (3) that CH_4 is reduced relative to C_2H_6 and CH_3Cl by addition of $TiCl_4$ to CH_3TiCl_3 in *n*-heptane. Formation of $TiCl_2$ by decomposition can be expected to constantly increase the formation of $(CH_3)_2TiCl_2$ through removal of $TiCl_4$ according to reaction 5

[5] $$TiCl_2(s) + TiCl_4 \rightarrow 2TiCl_3(s)$$

and contributes to the observed autocatalysis.

In contrast to the high alkyl content in the solid produced in $(CH_3)_2TiCl_2$ systems through the operation of reactions 1 and 2, CH_3TiCl_3 systems show low alkyl contents. This is to be expected on the basis of the unimportance of reaction 1 (due to low $(CH_3)_2TiCl_2$ concentrations) relative to reactions 5 and 6.

[6] $$TiCl_2(s) + CH_3TiCl_3 \rightarrow CH_3TiCl_2 \cdot TiCl_3(s)$$

The highly methylated solid produced by reaction 1 leads to CH_4 formation, reduction of titanium and residual hydrocarbon in the solid. The solid produced by reactions 5 and 6 is trivalent with a small methyl content.

Ethane formation is also autocatalytic. Unlike de Vries (3), we did not observe that the decrease in CH_4 associated with excess $TiCl_4$ was paralleled by an increase in C_2H_6. However, excess $TiCl_4$ was present only in our $(CH_3)_2Zn/TiCl_4$ and $(CH_3)_3Al/TiCl_4$ systems, so the data are not strictly comparable.

The autocatalysis suggests that adsorption of CH_3TiCl_3 is a necessary step in C_2H_6 formation. It is reasonable to suppose that adsorbed CH_3TiCl_3 has a configuration and energy quite different from the solution species. Chlorine and titanium atoms are likely to enter lattice positions appropriate to the underlying β-$TiCl_3$ lattice. Such epitaxially induced changes are consistent with the observed increase in Ziegler

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

catalytic activity (3, 4) when $TiCl_3$ is introduced into a CH_3TiCl_3 solution.

CH_3Cl is believed to form according to reaction 7

[7] $CH_3TiCl_3 + TiCl_4 \rightarrow CH_3Cl + 2TiCl_3(s)$

Whether this reaction is influenced by the solid is not certain from the reaction rates. CH_3Cl is abundant only where $TiCl_4$ is present in excess. The low yields of CH_3Cl in CH_3TiCl_3 systems are attributed to the low $TiCl_4$ concentrations resulting from reactions 4 and 5. Direct reaction of two CH_3TiCl_3 to give CH_3Cl cannot be excluded.

Although in the work reported, CH_3Cl is produced in C_2Cl_4 and not in C_6H_6, reaction with the solvent is not believed to be important. Both de Vries (3) and Beermann and Bestian (4) have shown it to be produced in alkanes where no solvent chlorine atoms are available. The lack of CH_3Cl in C_6H_6 is attributed to solvation of CH_3TiCl_3 by benzene inhibiting the reaction. Benzene solvation is supported by n.m.r. data on the pre-exchange lifetime of methyl groups on titaniums in the two solvents.

As to the formation of 1,1,2-trichloropropene, it is known from separate studies that this product forms by simple ligand exchange for other alkyl metal/halogenated solvent systems, such as those shown in reactions 8 and 9.

[8] $(CH_3)_2Zn + 2C_2Cl_4 \rightarrow ZnCl_2 + 2CH_3C_2Cl_3$

[9] $2(CH_3)_3Al + 2C_2Cl_4 \rightarrow (CH_3)_4Al_2Cl_2 + 2CH_3C_2Cl_3$

Production of $CH_3C_2Cl_3$ in CH_3TiCl_3 systems is presumably by a similar route [10]. Toluene production in benzene systems may be analogous.

[10] $CH_3TiCl_3 + C_2Cl_4 \rightarrow TiCl_4 + CH_3C_2Cl_3$

It should be noted that $CH_3C_2Cl_3$ is produced much more abundantly in $(CH_3)_2Zn/TiCl_4$ systems than in CH_3TiCl_3 systems, presumably through the action of residual CH_3ZnCl or $(CH_3)_2Zn$ in the solid according to reaction 8.

(iii) Solutions Containing both $(CH_3)_2TiCl_2$ and CH_3TiCl_3

The case of the decomposition of mixtures of CH_3TiCl_3 and $(CH_3)_2TiCl_2$ in solution is of special interest because of the abrupt change in decomposition rate and product distribution that occurs. Addition of a trace of $(CH_3)_2TiCl_2$ to a solution of CH_3TiCl_3, or elevation of the Zn/Ti ratio to 0.55 from 0.45 in a $(CH_3)_2Zn/TiCl_4/C_2Cl_4$ system, results in relatively rapid decomposition of the methyl titanium trichloride and virtual disappearance of ethane and 1,1,2-trichloropropene-1 from among the products.

Figure 4 illustrates the extraordinary autocatalysis exhibited by CH_3TiCl_3 systems. It is invariably found that, notwithstanding the much greater thermal "stability" of CH_3TiCl_3, it is the first to disappear when mixed in solution with $(CH_3)_2TiCl_2$.

The rapid decomposition of CH_3TiCl_3 in these mixtures could be explained for $(CH_3)_2Zn/TiCl_4$ systems by reactions 4 and 11.

[11] $(CH_3)_2Zn + ZnCl_2 \rightleftharpoons 2CH_3ZnCl$

[11*a*] $(CH_3)_2Zn + ZnCl_2 \rightleftharpoons (CH_3)_2Zn{:}ZnCl_2$

$(CH_3)_2Zn$ thus formed would in turn alkylate the CH_3TiCl_3 to yield more $(CH_3)_2TiCl_2$. Such a system is illustrated in Fig. 7. However, Fig. 4 illustrates the decomposition of a $CH_3TiCl_3/(CH_3)_2TiCl_2$ system containing no zinc chloride, and consequently the rapid decomposition of the CH_3TiCl_3 in this case cannot be explained by introducing an alkyl zinc intermediate.

Moreover, the data shown in Figs. 1–3 indicate that the equilibrium constant for reaction 4 is very small. Consequently, the rapid decline in CH_3TiCl_3 concentration cannot be explained on the basis of the equilibrium [4] operating to replace decomposed $(CH_3)_2TiCl_2$, since the latter is at all times in much greater concentration than in the cases shown in Figs. 1–3. It is therefore concluded that CH_3TiCl_3 reacts directly with adsorbed $(CH_3)_2TiCl_2$ to form CH_4 or with a product of $(CH_3)_2TiCl_2$ decomposition, perhaps simply as in reaction 6.

Summary

CH_3TiCl_3 decomposes by several routes, including a free radical route in polar solvents (4, 20) not observed in our systems. In addition, alkyl analogues having a hydrogen on a carbon β to the metal may decompose by the path proposed by de Vries (3). Other alkyl titanium systems offer additional possibilities, such as intramolecular formation of CH_4 by abstrac-

tion of hydrogen from the amino group in $[(C_2H_5)_2N]_3TiCH_3$ (21).

For σ-bonded alkyl transition metal compounds, comparisons of "relative stabilities" are actually comparisons of "relative rates of decomposition" (19). Where there are many paths of decomposition, each affected differently by various parameters, predictions of "relative stabilities" based on data from different conditions are of dubious value. Moreover, any general explanation of thermal instability of σ-bonded organotransition metal compounds is likely to be more complex than those so far put forward (3, 22) if it is to account for all paths of decomposition.

The authors wish to acknowledge their debts to Dr. J. A. Stone, for assistance in interpreting mass spectrometric data, to Dr. M. K. Phibbs and other colleagues for useful discussions, and to Messrs. M. Hughson and B. Landon for their skillful technical assistance.

Erratum: Normal Coordinate Calculations of the Vibrations of Methylene Cyclopropane-h_6 and -d_6

J. E. BERTIE AND S. SUNDER

Department of Chemistry, The University of Alberta, Edmonton, Alberta

Received December 3, 1971

(Ref.: Can. J. Chem. **49**, 2229 (1971))

Canadian Journal of Chemistry, **50**, 765 (1972)

In Table 8 of a previous paper from this laboratory (1) the thermodynamic functions for C_4H_6 and C_4D_6 are presented. Due to a card punching error, which set the degeneracy of one of the modes in each molecule as 10 instead of 1, these thermodynamic properties are in error. The corrected properties are presented in Table 1, using the observed fundamental frequencies of assignment II and the A_2 mode frequencies from Model I (1).

When the A_2 mode frequencies from Model II (1) are used, the calculated values differ from those given in Table 1 in the following way for C_4H_6 and C_4D_6 (in parentheses): $(H_0 - E_0^0)/T$ is the same (greater by 0.02) at 150 °K; is greater by 0.1 (0.12) at 300 °K, and by 0.17 (0.20) at 500 °K; $-(G_0 - E_0^0)/T$ is the same at 150 °K, greater by 0.03 (0.05) at 300 °K, and by 0.09 (0.14) at 500 °K; S_0 is the same (greater by 0.02) at 150 °K, greater by 0.10 (0.18) at 300 °K, and by 0.27 (0.34) at 500 °K; C_p is greater by 0.03 (0.10) at 150 °K, by 0.28 (0.31) at 300 °K, and by 0.32 (0.25) at 500 °K.

TABLE 1. Thermodynamic functions for C_4H_6 and C_4D_6 at 1 atm pressure and for the ideal gaseous state*

T	$(H_0 - E_0^0)/T$		$-(G_0 - E_0^0)/T$		S_0		C_p

Optical Activities of Two Steroids Containing a Chiral Cyclopentene Ring

J. T. EDWARD, N. E. LAWSON,[1] AND (in part) DAPHNE L'ANGLAIS[2]
Department of Chemistry, McGill University, Montreal, Quebec
Received December 22, 1970[3]

The direction of the optical rotation of the steroid **3** can be reconciled with Brewster's rules, if account is taken of "bond fixation", but the direction of the optical rotation of **2** cannot be.

La direction de la rotation optique de la steroide **3** est en accord avec les reglements de Brewster, si on considère la "fixation des bondes", mais la direction de la rotation de **2** est en desaccord.
Canadian Journal of Chemistry, **50**, 766 (1972)

As part of a study (*cf.* ref. 1) of the Bamford–Stevens reaction (2–5), the *p*-toluenesulfonylhydrazone of equilenin methyl ether (**1**) was thermally decomposed in ethylene glycol in the presence of the sodium alkoxide. The product (m.p. 121–122°, $[\alpha]_D$ +24.3°) could be assigned the structure **2**[4] on the basis of its n.m.r. spectrum, which showed a doublet at δ 1.1 (methyl group at C-17) and no peaks due to olefinic protons. Further support for the structure **2** came from the u.v. absorption spectrum of the compound (Fig. 1), which showed a striking similarity to that of 2-vinylnaphthalene (7*b*) when the presence of the methoxyl group was taken into account, and from its dehydrogenation over 5% palladium-on-charcoal in boiling xylene to the phenanthrene derivative **3**. The properties of **3** agreed with those reported for this compound by Cohen *et al.* (8). These authors do not report the u.v. absorption characteristics of their compound; however, we found the spectrum of our compound **3** very similar to that reported for 2-methoxyphenanthrene (9).

The formation of **2** is to be expected; Johns (6) obtained similar rearrangement products from the Bamford–Stevens reaction of estrone

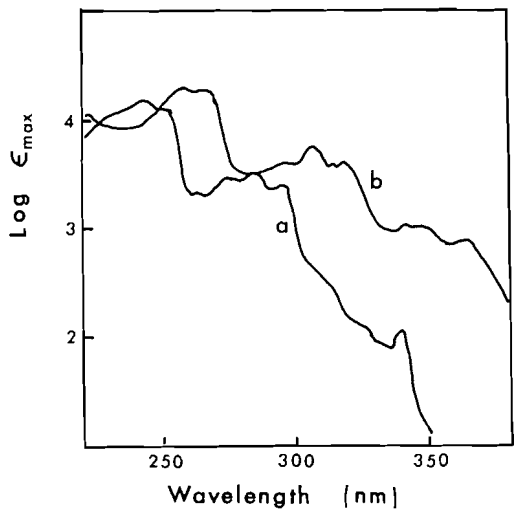

FIG. 1. The u.v. absorption spectra of 2-vinylnaphthalene (*a*) and of steroid **2** (*b*).

derivatives. These and other reactions (8, 10–12) in which a C-17 carbonium ion is formed at temperatures above 100° lead to a 1,2-shift of the 18-methyl group. In contrast, the C-17 carbonium ion formed at 0° in the nitrous acid deamination of 17-androstanylamine gives only the product of solvent attack at C-17 and no rearrangement (13).

Compounds **2** and **3** contain only one asymmetric carbon atom, and offer an opportunity to test Brewster's empirical rules (14, 16), by which the molecular rotation of a compound is calculated by addition of terms for chiral atoms and for chiral conformations. The molecular rotations found for solutions of **2** and **3** in chloroform are shown in Scheme 1, along with rotations taken from the literature for the model compounds **4** and **5**. Brewster (14) has shown

[1]Holder of a University Graduate Scholarship, 1966–1967.
[2]Holder of NRCC Studentships, 1961–1963.
[3]Revision received November 8, 1971.
[4]Johns (6) assigned this structure to a compound, m.p. 84–85°, $[\alpha]_D$ −1°, obtained by heating 17α-chloro-3-methoxyestra-1,3,5(10)-triene with potassium iodide and sodium acetate in ethanol at 125°, or by heating estradiol-3-methyl ether in boric acid at 280° or treating it with phosphorus pentachloride. Johns' assignment was based on elemental analysis and n.m.r. and u.v. absorption spectra λ_{max} 280 nm, log ε 3.41, in methanol). The last is more compatible with a compound having a methoxybenzene chromophore (7*a*), and suggests that possibly the elemental analysis was slightly in error.

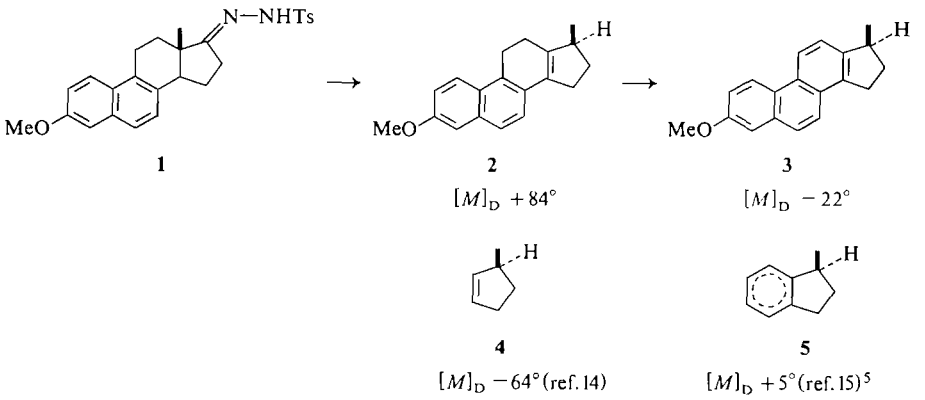
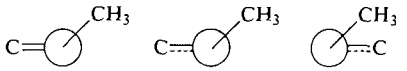


SCHEME 1

that the rotation of **4** is largely determined by the "conformational unit" (16) **6**, which is more important than the other conformational units in this molecule because vinyl carbon is more polarizable than the other groups present (14).



On the other hand, all of the bonds of the aromatic ring of the indan **5** are equivalent (contrary to early ideas of Mills and Nixon (17)), and in this molecule the two most important conformational units are **7** (negative contribution) and **8** (positive contribution). Consequently, the rotation of **5** is close to zero. If all the aromatic bonds in the phenanthrene **3** were equivalent, its rotation would also approximate zero; if the double bonds were "fixed" in the positions shown in **3**, its rotation would approximate that of **4**. In the event, its rotation is negative but smaller than that of **4**, showing some "fixation" of the double bonds. This accords with molecular orbital calculations and chemical evidence for such fixation (17).

The rotation of **2** would be expected, like that of **4**, to be negative as long as there is not also a contribution from the skewed vinylnaphthalene chromophore (18). Examination of Dreiding models of **2** shows two skewed vinylnaphthalene conformations of opposite chirality to be possible; neither conformation is notably disfavored over the other by non-bonded interactions. Measurements of the optical rotary dispersion of a dilute solution of **2** in dioxane showed no Cotton effect at wavelengths down to 240 nm, indicating possibly equal populations of the two conformations, and hence no contribution from a skewed vinylnaphthalene chromophore. The positive rotation of this compound consequently remains anomalous.

[5]Optical rotations in ref. 15 are reported for (*R*)-1-methylindan only up to a wavelength of 556 nm; the value for (*S*)-1-methylindan (**5**) was obtained by extrapolation and reversal of sign.

Experimental

For general experimental details, see ref. 19.

Equilenin Methyl Ether p-Toluenesulfonylhydrazone (1)

A solution of 0.94 g of equilenin methyl ether (20) and 1.2 g of *p*-toluenesulfonylhydrazine in 100 ml of 1:1 ether–ethanol containing one drop of concentrated hydrochloric acid was refluxed for 3 h. The solvent was evaporated under reduced pressure, and the solid residue was recrystallized from ethanol to give 1.4 g (93%) of **1**, m.p. 201°, ν_{max} (KBr) 1385 and 1170 cm^{-1}.

Anal. Calcd. for $C_{26}H_{28}N_2O_3S$: C, 69.66; H, 6.25; N, 6.24. Found: C, 69.97; H, 6.01; N, 6.06.

3-Methoxy-18-nor-17β-methylestra-1,3,5(10),6,8,13-hexaene (2)

Sodium (1.2 g) was dissolved in 60 ml of ethylene glycol and 1.2 g of **1** was added. The temperature of the mixture was raised to 170° over 1 h and held there for 30 min. The cooled solution was diluted with water and extracted repeatedly with ether. The ether extracts were combined, washed with water and with saturated sodium chloride, dried, and evaporated under reduced pressure. The residue was crystallized from ethanol to give 0.69 g of **2** containing one molecule of water of crystallization. Chromatography of the mother liquors on Woelm neutral alumina, grade III, raised the yield to 0.76 g (89%) of **2** m.p. 121–122°, $[\alpha]_D^{25}$ +24.3° (*c*, 0.10), δ 1.1 (doublet, J = 6.6 Hz, C-17 methyl), 2.1 (singlet, water of crystallization, disappeared on D_2O

For personal use only.

exchange), 3.9 (singlet, OCH_3), and 7.0–8.0 (multiplet, aromatic protons).

Anal. Calcd. for $C_{19}H_{20}O.H_2O$: C, 80.81; H, 7.85. Found: C, 80.80; 7.72.

Anal. Calcd. for $C_{19}H_{20}O$: C, 86.32; H, 7.63. Found (after drying at 80° over P_2O_5): C, 85.97; H, 7.80.

3-Methoxy-18-nor-17β-methylestra-1,3,5(10),6,8,11,13-heptaene (3)

A mixture of **2** (27 mg) and 5% palladium-on-charcoal (180 mg) in xylene (3 ml) was refluxed for 3 h while a slow stream of nitrogen bubbled through it. The solution was cooled, filtered, concentrated under reduced pressure, and the residue was crystallized from ethanol to give a virtually quantitative yield of **3**, m.p. 149–151° (lit. (8) m.p. 146.5–148.5°), $[\alpha]_D^{25} -7.4°$ (*c*, 0.14), λ_{max} (EtOH) (log ε_{max}) 263 (5.0), 282 (4.5), 291 (4.35), 303 (4.25), 308 (3.35), 325 (3.15), 332 (3.1), 342 (3.3), and 375 nm (2.25).

The *sym*-trinitrobenzene complex had m.p. 133–133.5° (lit. (8) m.p. 135.5–136.5°).

We are grateful to Professor Peter Morand for the o.r.d. curve, to Ayerst, McKenna, and Harrison Ltd. for generous gifts of starting materials, and to the Medical Research Council and National Research Council of Canada for financial support.

A Simplification in the Synthesis of Deoxyribooligonucleotides

S. A. NARANG,[1] K. ITAKURA,[2] AND R. H. WIGHTMAN[3]

Biochemistry Laboratory, National Research Council of Canada,[4] Ottawa, Canada K1A 0R6

Received December 29, 1971

The synthesis of oligonucleotides can be accomplished with no "protection" of the amino function in the case of adenine and guanine bases under the usual reaction conditions.

La synthèse d'oligonucléotides peut s'accomplir sans qu'on ait besoin de "protéger" la fonction amine dans le cas des bases adénine et guanine sous les conditions habituelles de réaction.

Canadian Journal of Chemistry, **50**, 769 (1972)

For the synthesis of oligonucleotides, it is generally conceded that the primary amino group of the heterocyclic bases must be protected ostensibly to prevent any reaction which might form complicating side-products (1). A number of blocking groups have been introduced for this purpose: acetyl (2), benzoyl or anisoyl (2), isobutyloxycarbonyl (3), and dimethylaminomethylene (4). However, there were scattered reports in the literature which inferred that blocking of the amino groups might not be necessary under the usual condensation conditions (5, 6).

This communication reports our preliminary findings that the synthesis of oligonucleotides can indeed be accomplished with no "protection" of the amino function in the case of adenine and guanine bases but not with cytosine. Our general procedure for synthesis and purification is outlined in Scheme 1. For example, 2-phenylmercaptoethyl 5′-phosphate deoxyadenosine or deoxyguanosine (**1**) was condensed with 3′-*O*-acetylthymidine 5′-phosphate (**2**) under the usual conditions (7). The composition of the crude reaction mixtures as well as yields[5] and purity of the desired products[6] were substantially the same whether the nucleotides involved had "protected" or free amino groups. In fact, we have noticed that chromatographic resolution of the unprotected nucleotides is generally better than those with protected amino groups. On the other hand, the condensation of phosphate protected deoxycytosine with 3′-*O*-acetylthymidine 5′-phosphate under the same conditions gave two components. The fast-moving component on t.l.c. (*ca.* 20% minor product) was identified as the desired 3′–5′ phosphodiester compound (by their u.v. spectra, mobility on t.l.c. in three solvent systems, bacterial alkaline phosphatase, spleen and snake venom phosphodiester treatments). Whereas the slow-moving component on t.l.c. (*ca.* 42% major product) was sensitive to bacterial alkaline phosphatase and snake venom phosphodiesterase enzymes but completely resistant to action of spleen phosphodiesterase. From this we inferred that this component might be a *N*-phosphorylated compound.

These observations show that the two units, adenine and guanine out of three basic units which have a primary amino group can be used in the synthesis of oligonucleotides without protecting their amino function. Application of these important observations should be a general asset in the long range synthesis of polynucleotides.

Kinetic Evidence for Predominant Oxygen Protonation of Amides

CLINTON R. SMITH AND KEITH YATES
Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received November 3, 1971

Comparison of rate data for the acid-catalyzed hydrolysis of amides, and model compounds for *O*- and *N*-protonated amides, provides strong evidence that amides protonate predominantly on oxygen in dilute as well as in concentrated aqueous acids, contrary to a recent proposal that the protonation sites are different in the two media.

La comparaison des données de vitesse dans le cas de l'hydrolyse des amides catalysée par les acides et des composés modèles pour les amides protonées en *O*- et *N*- fournit une preuve irréfutable que les amides sont protonées de façon prédominante sur l'oxygène dans les solutions d'acide, autant diluées que concentrées, contrairement à ce qu'on avait proposé quelques temps auparavant, soit que les sites de protonation soient différents dans ces deux milieux.

Canadian Journal of Chemistry, **50**, 771 (1972)

The fact that amides protonate predominantly on oxygen (**1**) in strongly acidic media has been established for some time (1, 2). Liler (3) has recently confirmed this from a study of the n.m.r. spectra of ^{15}N amides, but has also proposed that in dilute acid predominant protonation is on nitrogen (**2**). We now wish to present kinetic data on the acid-catalyzed hydrolyses of benzamide, methyl benzimidate, and benzoylimidazole, which along with other available kinetic data, can be used to test this proposal.

It has been suggested that acyl ammonium (**3**) (4) and acyl pyridinium salts (**5**) (5) would be reasonable models for the estimation of the reactivity of *N*-protonated amides. Although acetyl ammonium (6) and acetyl pyridinium salts (7) can be prepared, benzoylammonium (8) and benzoylpyridinium (7) salts are thermally unstable at room temperature. However, acylimidazole compounds (9) are readily available. Unlike in an *N*-protonated amide or in the acylammonium and pyridinium salts, the positive charge on nitrogen in a protonated acyl imidazole (**5**) is delocalized, and thus these cations would be expected to be less reactive than those with a full localized charge on nitrogen. Therefore their reactivity should represent a lower limit for the reactivity of an *N*-protonated amide. *N*-Acylimidazolium compounds are in fact known to be less reactive than acyl pyridinium ions (10). Edward and Meacock (11) have suggested that imidate salts (**6**) would be good models for oxygen protonated amides.

Thus we have the models shown in Scheme 1 for *N*- and *O*-protonated amides acting as substrates in hydrolysis reactions.

Rate data for the hydrolysis of acetamide, benzamide, and the corresponding *N*- and *O*-protonated models are given in Table 1. The rate data in 8 *M* HCl were available directly from the literature. The values in dilute and moderately concentrated H_2SO_4 were determined recently in our laboratories. Data for methyl acetimidate are not available. However,

TABLE 1. Relative rate of hydrolysis of amide and model compounds

Substrate	k_p^{rel}[a] (25 °C)			
	$[H_2SO_4] = 1.4$	$[H_2SO_4] = 8.9$	[HCl] = 0	[HCl] = 8
Benzamide[l,m]	1.0[d,k]	1.0[e,k]	1[b,f]	1[c,f]
Methyl benzimidate	9.6[k]	3.7[k]	6[f]	3[f]
Benzoyl imidazole	3.9×10^3 [k]	4.9×10^5 [k]	2×10^3 [g]	7×10^3 [g]
Acetamide[l,n]			2[h]	6[h]
N-Ethyl methyl acetimidate			4[i]	
Acetyl imidazole			3×10^3 [g]	4×10^3 [g]
Acetyl pyridinium chloride			1×10^6 [j]	

[a]Rate of hydrolysis relative to rate of hydrolysis of benzamide.
[b]k_p (benzamide) = 1.6×10^{-5} s^{-1}.
[c]k_p (benzamide) = 3.4×10^{-7} s^{-1}.
[d]k_p (benzamide) = 5.3×10^{-6} s^{-1}.
[e]k_p (benzamide) = 1.0×10^{-9} s^{-1}.
[f]Reference 11.
[g]Reference 9.
[h]Reference 17.
[i]Reference 18.
[j]Reference 10.
[k]This work.
[l]$k_p = k_{obs}(h_A + K_{SH}^+)/h_A$.
[m]$pk_{SH^+} = -1.7$, ref. 12.
[n]$pk_{SH^+} = -0.6$, ref. 12.

we have found (12) that one *N*-alkyl group has little effect on the rate constant for acid-catalyzed methyl benzimidate hydrolysis and it is assumed therefore that *N*-ethyl methyl acetimidate is a reasonable model for an oxygen protonated acetamide.

The rate constants listed in Table 1 are for the process:

$$SH^+ + H_2O \xrightarrow{k_p} \text{Products}$$

The observed rate constants for these moderately weakly basic amides have therefore been corrected for the extent of protonation of the substrate. To enable direct comparisons, the amide and imidate data in dilute HCl solution have been extrapolated to unit water activity (for the imidates this corresponds closely to the maximum rate of hydrolysis for water acting as a nucleophile). The values for the *N*-protonated models in dilute HCl are as reported by Marburg and Jencks (9) for unit water activity. It can be seen from Table 1 that in both the acetyl and benzoyl series the imidazole *N*-protonated models react at least 10^3 times as fast as the *O*-protonated models at both high and low acidity. In the acetyl series, the pyridinium compound reacts 10^6 times as fast as the *O*-protonated model. Therefore, it is reasonable that an *N*-protonated amide would react at least 10^3 times as rapidly as the *O*-protonated form. The imidates however, react at a very similar rate to amides. This fact has been established previously for the benzoyl series (11).

Thus if amides protonated exclusively on nitrogen in dilute acid, as Liler suggests, hydrolysis would occur through the very reactive *N*-protonated form, and the p*K*'s observed by the u.v. (13) and n.m.r. (14) would be those arising from *N*-protonation. However, this postulate is inconsistent with the rate data in Table 1 since the k_p values show that amides are about 10^3 to 10^6 times *less* reactive than would be expected from an exclusively *N*-protonated amide.

Two alternative possibilities are consistent with the rate data; firstly, that amides are predominantly oxygen protonated in dilute solution and react through a minor *N*-protonated form in very low concentration; secondly, that amides are predominantly oxygen protonated and also react through this form.[1] In both of these cases the rate data require that the extent of *N*-protonation be at least 10^5 times *less* than the extent of *O*-protonation in dilute acid and that this be the upper limit of *N*-protonation. A recent

[1]Neither of these possibilities is inconsistent with the n.m.r. evidence from dilute acid solution. A minor amount of rapid *N*-protonation would be sufficient to explain the n.m.r. equivalence of the groups attached to nitrogen observed in dilute acid (15, 16).

estimate of the relative pK's for O- and N-protonation of an amide by Fersht (5) yields a factor of 10^7 in favor of the former.

Relationship of ^{13}C to Vicinal ^1H Coupling to the Torsion Angle in Uridine and Related Structures[1]

R. U. LEMIEUX, T. L. NAGABHUSHAN,[2] AND B. PAUL[3]
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received December 29, 1971

Uracil was prepared enriched at C2 with carbon-13 and converted into uridine from which 2,5′-anhydro-1-β-D-*ribo*-furanosyl and 2,2′-anhydro-1-β-D-*arabino*-furanosyl uracil were prepared. The $^{13}C2$ to vicinal proton coupling constants for these compounds were measured and are compared in terms of the expected torsion angles defined by the two atoms. The evidence suggests the existence of a Karplus-type relationship as is found for vicinal proton coupling. The data establish the *anti* conformation for uridine in solution.

On a préparé l'uracile enrichi au C2 avec le carbone-13 et on l'a converti en uridine à partir duquel le 2,5′-anhydro-1-β-D-*ribo*-furanosyl et le 2,2′-anhydro-1-β-D-*arabino*-furanosyl uracile ont été préparés. Les constantes de couplage entre $^{13}C2$ et le proton vicinal pour ces composés ont été mesurées et comparées en termes des angles de torsion définis par les deux atomes. L'évidence suggère l'existence d'une relation de type Karplus telle qu'on en trouve dans le cas de couplage de protons vicinaux. Les résultats établissent la conformation *anti* pour l'uridine en solution.

Canadian Journal of Chemistry, **50**, 773 (1972)

The relationship between the torsion angle defined by vicinal hydrogens and their coupling constant (1–4) has had a profound influence on elucidation of configuration and conformational analysis. That a similar stereochemical – coupling constant relationship may exist for ^{13}C-atoms vicinal to hydrogen atoms is an obvious extension of n.m.r. to problems of stereochemistry. The availability of ^{13}C-enriched compounds has made possible in many cases the detection of such vicinal coupling constants using high resolution proton magnetic resonance (5–8) and more recently ^{13}C-magnetic resonance (9). Should it prove possible to establish a relationship between these coupling constants and

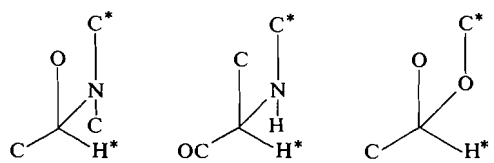
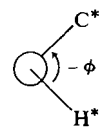
conformational features, then these developments would be of especially great interest to studies of the conformational properties of such important classes of compounds as the nucleic acids **1**, peptides **2** (10), and glycosides **3** (11) by providing estimates of the average torsion angle ϕ for the vicinal C* and H* atoms.



1 2 3



Karabatsos and coworkers (5–7) realized the possibilities of this coupling to study rotational isomerism and later showed (12) that, as expected from vicinal H–H coupling, vicinal ^{13}C–H coupling is much stronger for the atoms in *trans* than in *cis*-relationship. More recently, Perlin and Casu (8) found this situation present in the spectra of ^{13}C-enriched α-D-glucopyranose. However, it has become clearly apparent that, in contrast to H–H coupling constants, vicinal ^{13}C–H coupling constants are much more sensitive to structural parameters (electronegativity, heteroatom, carbon hybridization) other than steric relationships (7, 9). Nevertheless, the hope remained that useful empirical torsion angle – coupling constant relationships may exist for chemically closely related structures and perhaps especially when the ^{13}C and H atoms are bridged only through sigma bonds. This communication reports such results for nucleoside-

type bicyclic structures for which torsion angles can be roughly estimated from molecular models.

Uridine (**4**) was synthesized enriched (about 60%) with ^{13}C at the 2-position of the uracil residue using essentially published procedures (13, 14). The compound was then converted to the cyclonucleoside structures **5** (15) and **6** (16) following established methods. The coupling constants for this isotopically enriched carbon with the vicinal protons in these compounds (**4**, **5**, and **6**) were then determined as indicated in Table 1. The dihedral angles considered most probable in compounds **5** and **6** are also listed. Clearly, a Karplus-type relationship (3) is apparent. Furthermore, near zero coupling was found (17) for both H1 and H2 with the orthoester carbon of α-D-glucopyranose 3,4,6-triacetate 1,2-(methyl 1-^{13}C-orthoacetate). For this compound, the molecular model indicates that these atoms define near 90° torsion angles.

Uridine in aqueous solution is considered (18, 19) to exist extensively in the *anti*-conformation ($\phi_{C2,H1'} \simeq -30°$)[4] and that no change in the ribose–uracil torsion angle takes place over the temperature range 28–78°. The small change in $J_{C2,H1'}$ found for uridine at 26 and 67° in D_2O, namely, 2.3 and 2.4 Hz, respectively, confirms the latter conclusion and these coupling constants together with the data plotted in Fig. 1 suggest either $\phi_{C2,H1'}$ is about ±45° (*anti* conformation) or $\phi_{C2,H1'}$ is about ±120° (*syn* conformation). The latter conformation is highly implausible since the uracil residue would be strongly eclipsed with either the Cl—O4 or Cl—C2 bonds. The conformation of uridine was recently determined in the crystalline state (22). The compound was found to exist in two conformers per asymmetric crystal unit with $\phi_{C2,H1'} = -36$ and $-43°$. Thus it is apparent that the *anti*-conformation adopted by uridine in the crystal field is maintained in solution. It is noteworthy that esters (23, 24) and amides (10) tend to have the C=O and a vicinal C—H bond in opposition and defining a torsion angle of less than 60° and that the *anti*-conformation for uridine also possesses this conformational feature.

[4]The ϕ_{CN} designation (20) for defining sugar-base conformational relationships does not give a true torsion angle. Sundaralingam, (21) provides the designation χ for glycosidic torsion angles which for pyrimidine nucleosides correspond to $\phi_{C6,O4'}$ (O4′ is referred to as O1′).

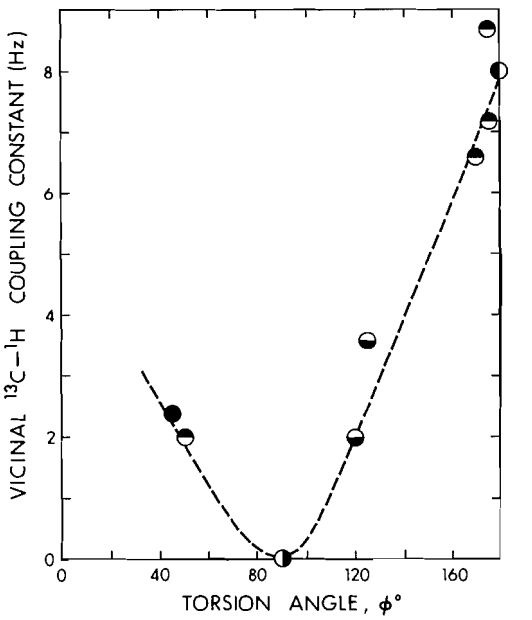

FIG. 1. Plot of the coupling constants *vs.* torsion angles defined by ^{13}C and vicinal protons in compounds **4** (●), **5** (◒), **6** (◓) (see Table 1), uracil (◐), and α-D-glucopyranose triacetate 1,2-(methyl orthoacetate) (◑).

Although the conversion of uridine into its 2′,3′-*O*-isopropylidine derivative did not alter $J_{C2,H1'}$, this coupling constant for 5′-deoxy-5′-iodo-2′,3′-*O*-isopropylidene 2-^{13}C-uridine in $CDCl_3$ was 5.0 Hz. Removal of the *O*-isopropylidene group caused the coupling constant to decrease to 2.9 Hz (acetone-d_6 – D_2O as solvent). It is therefore apparent that substitutional changes on the ribose portion of uridine can substantially influence the ribose-base torsion angle.

In conclusion, the results obtained indicate that measurement of vicinal ^{13}C to H couplings can be expected to provide information on conformational preferences for structural units as depicted in partial structures, **1**, **2**, and **3** and these matters are under active investigation in this laboratory.

Thermal Reactions of Sodium Azide in the Presence of Nitric Oxide and Hydrogen[1]

R. A. BACK AND W. NIP[2]

Division of Chemistry, National Research Council of Canada, Ottawa

Received October 12, 1971

Nitric oxide (120 Torr) strongly suppressed the thermal decomposition of NaN_3 at 350 °C. A relatively slow and complex reaction occurred instead, yielding N_2, N_2O, $NaNO_2$, and Na_2O. Isotopic experiments revealed that most of the N_2 (60–80%) came from the azide alone, some from NO alone (10–28%), and a small proportion (5–8%) was mixed, with one atom derived from each reagent. Nitrous oxide initially was derived entirely from NO.

Hydrogen (12–75 Torr) also suppressed the normal azide decomposition at 350 °C. In its place, a rapid reaction occurred, consuming H_2 and NaN_3 and producing N_2, NH_3, Na, and probably $NaNH_2$.

Both systems were complex and probably best described as concerted reactions between the azide and the added gas rather than reactions of NO or H_2 with transient nitrogen species formed in the thermal decomposition of the azide.

L'oxyde nitrique (120 Torr) supprime fortement la décomposition de NaN_3 à 350 °C. Une réaction, relativement lente et complexe se produit plutôt, résultant en N_2, N_2O, $NaNO_2$, et Na_2O. Les expériences isotopiques révèlent que la plus grande partie de N_2 (60–80%) vient de l'azide seul, un peu vient seulement de NO (10–28%), et une petite partie (5–8%) est mélangée, avec un atome venant de chacun des réactifs. L'oxyde nitreux, initialement, est dérivé entièrement de NO.

L'hydrogène (12–75 Torr) supprime aussi la décomposition normale de l'azide à 350 °C. Il se produit plutôt une réaction rapide consommant H_2 et NaN_3 et donnant lieu à N_2, NH_3, Na et probablement $NaNH_2$.

Les deux systèmes sont complexes et probablement mieux décrits comme étant des réactions concertées entre l'azide et le gaz ajouté plutôt que des réactions de NO ou H_2 avec des dérivés d'azote transitoires formés pendant la décomposition thermique de l'azide.

Canadian Journal of Chemistry, **50**, 777 (1972)

Introduction

Current theories of the decomposition of metal azides postulate a reaction between two N_3 species at a surface site, forming three N_2 molecules and leaving behind neutral metal atoms (1–6). This process is highly exothermic, and it has been suggested that electronically excited N_2 might be formed (7, 8). In a long series of experiments, Audubert and his collaborators observed emission of light from decomposing azides, which they attributed to excited N_2 molecules (8–14). Formation of free N_3 or N atoms in the decomposition has also been postulated.

A brief and unsuccessful search was made by Back *et al.* (15) for possible chemical reactions in decomposing azides similar to those of "active nitrogen" produced in an electric discharge. Several metal azides, decomposed in the presence of ethylene, yielded no HCN, and no NH_3 could be detected when barium azide was decomposed at 160 °C in the presence of H_2. The chemistry of possible reactive nitrogen species is now much better understood, and it appeared worthwhile to look again for evidence of their reactions in an azide decomposition. The present paper describes a brief study of the thermal reactions of sodium azide in the

presence of NO and H_2, using ^{15}NO in the former system to determine unambiguously the source of nitrogenous products.

Experimental

Weighed samples of NaN_3 (~50 mg) were placed on a shallow Pyrex dish 1 cm in diameter which rested on the bottom of a 100 ml spherical Pyrex flask attached to a vacuum line. Samples were heated under vacuum at about 200 °C for several hours to remove traces of water. The decomposition was begun by quickly raising a preheated fluidized sand bath around the flask, and stopped by removing it. Between experiments, sodium was removed from the dish and flask by washing with water and dilute acid. The course of the decomposition was followed by pressure measurements with a mercury manometer.

After an experiment with NO present, N_2 was removed through traps at −210 °C and measured in a gas burette. Nitric oxide was then removed at −184 °C, and condensible products remaining were measured in a gas burette. Gas chromatography and mass spectrometry were used to identify and analyse products. When NO was absent, non-condensible gases were removed at −196 °C. In the experiments with H_2, NH_3 was removed and measured in a gas burette or by titration with standard HCL.

Reagent-grade sodium azide (B.D.H.) in the form of a crystalline powder was used without further treatment. Hydrogen of high purity was taken from sealed Pyrex flasks (Airco). Nitric oxide (Matheson) was repeatedly fractionated by bulb-to-bulb distillation to remove other oxides of nitrogen present in small amounts. Nitric oxide and nitrogen containing about 95% N–15 were obtained from Biorad.

Results and Discussion

Preliminary experiments

Sodium azide was decomposed at 330, 340, and 350 °C, initially under vacuum, and in the presence of nitrogen and helium, to test the effect of inert gases on the decomposition. The usual S-shaped pressure–time curves were obtained (Fig. 1); the added gases affected both the induction periods and the maximum rates in much the same way as has been observed previously (2, 3, 6), but had no gross effect on the decomposition. If gross effects are observed with other gases, simple physical causes can thus be ruled out. In all these experiments, the final yield of N_2 was quantitative, leaving no undecomposed azide as has been observed under some conditions below 350 °C (4, 5).

Isotopically natural sodium azide was decomposed at 350 °C in the presence of 20 Torr of $^{15}N_2$, and no isotopic mixing was observed. This ensured that N_2 once produced did not undergo further exchange.

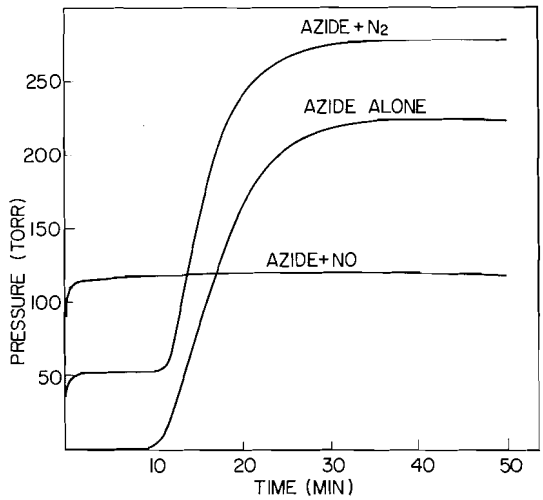

FIG. 1. The effect of N_2 and NO on the thermal decomposition of NaN_3 at 350 °C.

Sodium Azide–Nitric Oxide System

NaN_3 was heated at 350 °C with about 120 Torr of NO for times ranging from 7 to 75 min. The pressure remained virtually constant after the initial thermal equilibration (Fig. 1). Azide and NO were consumed while N_2 and N_2O were evolved in amounts roughly proportional to time, with $[N_2O]$ = about $\frac{2}{3}$ $[N_2]$. The rate of disappearance of azide was very much slower than that in the absence of NO, with typically about 5% decomposition after 75 min and no acceleration with time (*cf.* Fig. 1). If the reaction was stopped by cooling, the NO pumped away, and the residue reheated, for reaction times up to 30 min the residue decomposed exactly like pure NaN_3 under vacuum; for longer times, the residue decomposed more slowly than normal and showed longer induction periods (decomposition of the residue to completion in this way was used to estimate the undercomposed azide).

The NaN_3–NO system was complicated by secondary reaction of sodium with NO. This was studied by first pyrolyzing NaN_3 to completion, then cooling and pumping off the N_2, admitting NO (about 120 Torr), and reheating to 350 °C. A fairly fast reaction occurred, with a drop in pressure, which was complete within 2 or 3 min. NO was consumed, N_2 was evolved, and $NaNO_2$ and Na_2O were produced in very approximately equal amounts. These reactions were apparently complete in 2 or 3 min; at longer times there was a slow steady production

*Mixed N_2 contains one atom from the azide and one from NO and is calculated by correcting the $^{14}N^{15}N$ for isotopic impurity of both reagents.

of N_2O. The speed of reaction of sodium with NO at 350 °C probably ensures that in the decomposition of NaN_3 in the presence of NO, any Na formed would have reacted with NO almost as fast as it was produced. Some of the N_2 and N_2O formed thus probably came from this secondary reaction, as is borne out by the isotopic composition of the products (Table 1). Rapid removal of Na nuclei by reaction with NO probably also accounts for the marked retardation of the azide decomposition.

The isotopic composition of the N_2 formed in the reaction of $Na^{14}N_3$ and ^{15}NO is shown in Table 1 for a range of reaction times. The $^{15}N_2$ presumably came from the reaction of ^{15}NO with sodium or the thermal decomposition of the NO; there is relatively somewhat more at shorter times. In the last column it is seen that significant amounts of "mixed" N_2 were formed, with one atom from the azide and one from the NO.

The composition of the nitrous oxide formed also showed some evidence for isotopic mixing. In this case, however, the trend with reaction time indicated that initially, N_2O was derived almost entirely from the NO alone, suggesting that the mixed N_2O came from a secondary reaction of a product.

The reaction yielding mixed N_2 may be formally written as

$$Na^{14}N_3 + {}^{15}NO \rightarrow {}^{14}N_2 + {}^{14}N^{15}N + (NaO)$$

where (NaO) is a precursor of some more stable oxide of sodium. The amount of $^{14}N_2$ observed was not equal to the mixed N_2, however, but about 10 times larger, the excess representing presumably a more or less simple thermal decomposition of the azide alone. This may have been similar in mechanism to the normal azide decomposition, but strongly retarded by reaction of NO with the sodium nuclei which are thought to be involved in the rapid acceleration of the normal decomposition. The reaction yielding mixed nitrogen may correspond to the occasional interaction of NO with a transient N_3 species produced in the normal decomposition, but could equally well be a quite separate concurrent process. The NaN_3–NO system is clearly too complex to permit detailed conclusions about the mechanism from the present brief study.

Sodium Azide–Hydrogen System

This system was studied at 350 °C with initial pressures of H_2 ranging from about 12 to 75 Torr. Pressure–time plots are shown in Fig. 2.

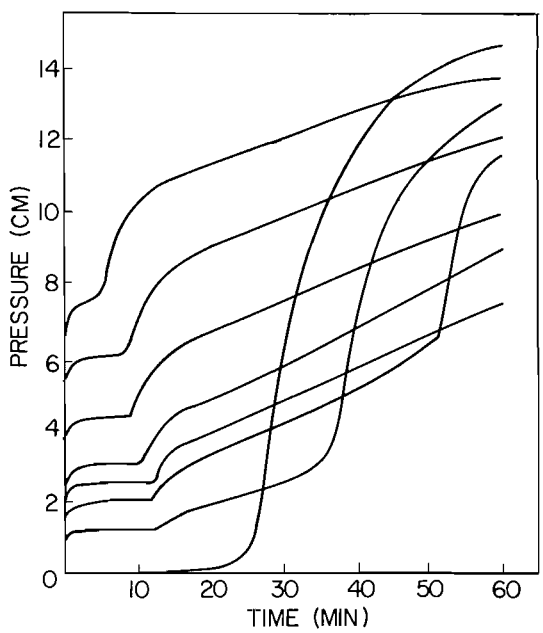

FIG. 2. Pressure changes during the reaction of NaN_3 in the presence of H_2 at 350 °C.

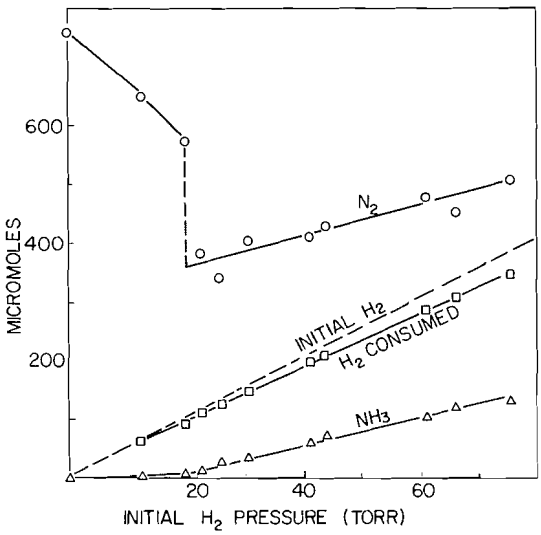

FIG. 3. Gaseous products and H_2 consumption in the reaction of NaN_3 with H_2 at 350 °C after 60 min reaction time.

After 60 min the vessel was cooled and the gases present (N_2, H_2, and NH_3) were removed, measured, and analyzed. Yields of N_2 and NH_3, together with H_2 consumed, are shown in Fig. 3 plotted against initial pressure of H_2, for a constant reaction time of 60 min.

Hydrogen consumption was virtually complete at low pressures, and even at the highest pressure of hydrogen, was almost 90% of that initially present. The NH_3 produced did not correspond to the loss of H_2. Hofmann and Hofmann (16) reported that sodamide, $NaNH_2$, was a major product in the thermal reaction of NaN_3 and H_2, and it very probably accounts for the rest of the hydrogen consumed in the present system. Sodium hydride, which seems to be the only other possible product, can be ruled out by its equilibrium dissociation pressure at 350 °C of about 62 Torr (17, 18), well in excess of the final H_2 pressure in all our experiments. No attempt was made to analyze for $NaNH_2$ or NaH. If it is assumed that NH_3 and $NaNH_2$ account for all the hydrogen consumed, and that no other undetected nitrogenous products were formed, then from the elemental ballances, $NaNH_2 = H_2$ consumed $-\frac{3}{2}NH_3$, and NaN_3 consumed $=\frac{2}{3}N_2 + \frac{1}{3}NaNH_2$. Plots of $NaNH_2$ yields and [NaN_3] consumed calculated from these relations are shown in Fig. 4. Finally, in Fig. 5, yields of NH_3 and $NaNH_2$ are shown as percentages of the azide consumed.

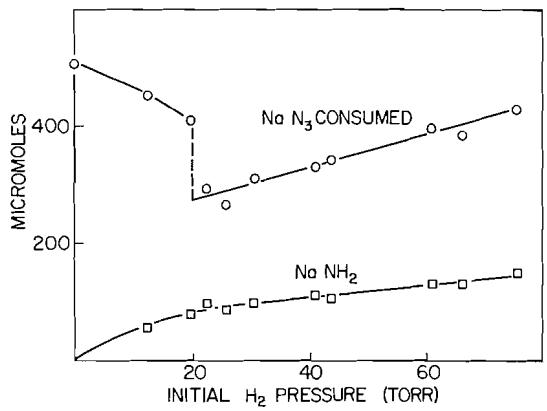

FIG. 4. Calculated amounts of $NaNH_2$ produced and NaN_3 consumed in the reaction of NaN_3 with H_2 at 350 °C after 60 min reaction time.

The pressure–time plots (Fig. 2) show a complex but systematic change with increasing pressure of H_2. After an induction period, a pressure rise ensued which was almost linear at the lowest H_2 pressure; at higher pressures it became resolved into a steep initial increase followed by a slower linear portion. With increasing H_2 pressure, the induction period became progressively shorter and the initial increase more rapid, while the slope of the linear portion remained almost constant. At the two lowest pressures of H_2, the linear increase was terminated by a sharp pressure rise very similar to that of the normal azide decomposition in the absence of hydrogen, but delayed in time. This,

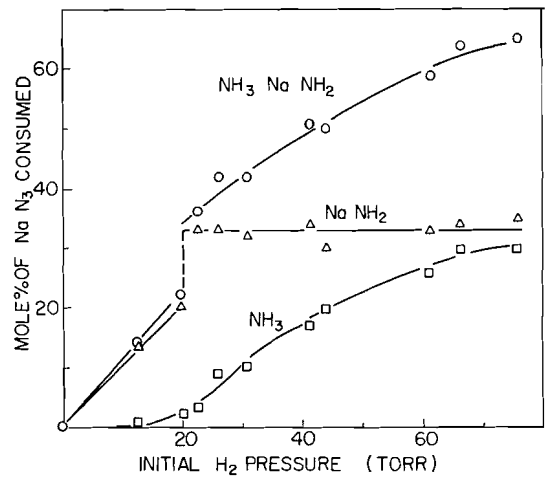

FIG. 5. Yields of NH_3 and $NaNH_2$ expressed as percentage of NaN_3 consumed in the reaction of NaN_3 with H_2 at 350 °C after 60 min reaction time.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

very probably, was in fact the normal azide decomposition, setting in after complete or nearly complete consumption of hydrogen (see Fig. 3). At higher pressures of H_2 this did not occur before the arbitrary termination of the reaction after 60 min, and it is this that accounts for the abrupt changes in some of the product yields between 20 and 30 Torr initial pressures of H_2 (Figs. 3–5).

The processes occurring in the NaN_3–H_2 system may be considered, formally at least, as the sum of the 3 reactions,

$$[1] \qquad NaN_3 \rightarrow Na + \tfrac{3}{2} N_2$$

$$[2] \qquad NaN_3 + H_2 \rightarrow NaNH_2 + N_2$$

$$[3] \qquad NaNH_2 + \tfrac{1}{2} H_2 \rightarrow Na + NH_3$$

In interpreting the pressure–time plots, note that reaction 2 causes no change in pressure. Thus the changes observed can be attributed to reaction 1, augmented by reaction 3 at higher pressures of H_2 as NH_3 becomes an important product. Measured pressure changes after 60 min are in close agreement with those calculated from product analysis and the assumption that reactions 1, 2, and 3 completely describe the system, which suggests that no other reactions of importance were occurring. Some tentative conclusions about the mechanisms of reactions 1, 2, and 3 can be drawn:

(*i*) Reaction 2 is probably a primary reaction occurring at the azide–gas interface.

(*ii*) Reaction 3 appears to be a secondary reaction between H_2 and $NaNH_2$. Sakurazawa and Hara (18) suggested the reaction $NaNH_2 + H_2 \rightarrow NaH + NH_3$, which under our conditions with NaH decomposing rapidly would be equivalent to reaction 3. Reaction of $NaNH_2$ with the Pyrex vessel is also a possible source of NH_3 (18).

(*iii*) Reactions 1 and 2 proceeded concurrently and competitively. The steady increase in the combined yields of $NaNH_2$ and NH_3 with increasing H_2 pressure (Fig. 5) suggests such a competition, and it appears that conversion of the azide to $NaNH_2$ or NH_3 via reactions 2 and 3 would become quantitative at sufficiently high pressure of hydrogen. An alternative to reaction 1 is the thermal decomposition of $NaNH_2$ to give $Na + \frac{1}{2}N_2 + H_2$, but the results do not support a secondary reaction of this sort.

(*iv*) The evidence suggests that reaction 1 is *not* simply the normal azide decomposition, and that reaction 2 is *not* a reaction of H_2 with a transient nitrogen species released in such a decomposition, nor a simple elementary reaction of H_2 with NaN_3, but rather that reactions 1 and 2 occur together in a concerted interdependent manner. The pressure–time plots indicate that an initial nucleation phenomenon is involved, and the mechanism could be quite similar to that of the azide decomposition, but with H_2 participating actively at the reaction sites.

Summary

The present work was undertaken to look for chemical reactions of possible transients generated in the thermal decomposition of NaN_3. Chemical interactions of the azide nitrogen with the reagent gas were indeed observed in both systems, which *could* have proceeded through such transient species. However, the course of the azide decomposition was so modified by both gases that it is difficult to distinguish between reaction of a transient from the decomposing azide and an actual concerted reaction between the azide and the reagent gas. Use of one of the less stable azides, perhaps $Ba(N_3)_2$ or AgN_3, which decomposes at lower temperatures and yields a less reactive metal would probably avoid some of these problems.

Trapped Electrons and Radicals in γ-Irradiated Propylene Carbonate Glasses[1]

ERIC A. SHAEDE[2]

Chemistry Department, The University of British Columbia, Vancouver 8, British Columbia

Received February 8, 1971[3]

Radicals formed by γ-irradiation of propylene carbonate (PC) glasses at 77 °K were studied by e.s.r. and optical spectroscopy. Trapped electrons were identified by their narrow ($\Delta H_{ms} = 4.5$ G) Gaussian e.s.r. line at $g = 2.0028$ which was completely resolved from the radical spectrum. The trapped electrons were unstable at 77 °K. They decayed fairly rapidly via a process exhibiting non-homogeneous kinetics believed to be reaction with positive ions. The temperature dependence of the e.s.r. spectra of the other radicals formed is discussed although conclusive assignment of the lines could not be made.

Ultraviolet photolysis of the radicals in the irradiated PC glasses produced new species identified as HCO, CO_3^-, and CH_3 by their characteristic e.s.r. spectra. In addition, a complex optical absorption band in the 500–750 nm region was assigned to a combination of the absorption bands of the CO_3^- radical anion and the HCO radical.

Les radicaux issus de l'irradiation γ des verres de carbonate de propylène (CP) à 77 °K, ont été étudiés par r.p.e. et spectroscopie optique. Les électrons piégés ont été identifiés en r.p.e. par leur courbe de gausse fine à $g = 2.0028$ complètement résolue à partir du spectre du radical. Les électrons ainsi piégés sont instables à 77 °K et disparaissent assez rapidement selon un mécanisme laissant supposer une réaction avec des ions positifs, d'après les cinétiques non homogènes observées. La variation en fonction de la température du spectre r.p.e. des autres radicaux formés est discutée bien que l'attribution définitive de ces courbes ne puisse être faite. La photolyse u.v. des radicaux issus de l'irradiation des verres en CP produit de nouvelles espèces identifiées à HCO, CO_3^- et CH_3 par leur spectre r.p.e. caractéristique. De plus, une bande d'absorption complexe dans la région de 500 à 750 nm est attribuée à une combinaison des bandes d'absorption du radical anion CO_3^- et du radical HCO.

Canadian Journal of Chemistry, **50**, 782 (1972)

Introduction

Cyclic organic carbonates are an unusual and interesting group of compounds whose radiation chemistry is virtually unexplored.[4] Propylene carbonate (4-methyl-2-dioxolone, to be referred to as PC for brevity) is the five-membered heterocyclic ring compound illustrated in Fig. 1. It is a very polar aprotic solvent with some extraordinary physical and chemical properties (1). These include a very large liquid range from less than −70 to +240 °C (1*a*), a high dielectric constant of 65 at room temperature (1*b*), a corresponding large permanent dipole moment of 4.94×10^{-18} e.s.u. cm (1*d*), and chemical stability towards strong reducing agents such as the alkali metals (1*g*). Like many other organic compounds with low freezing points, PC forms a glassy solid when rapidly cooled to 77 °K.

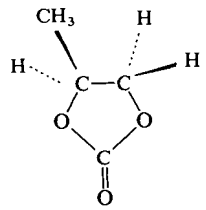

FIG. 1. One of the stereoisomers of propylene carbonate.

Studies of the radiolysis of frozen polar systems have been mainly concerned with water, its solutions, and the alcohols,[5] although ketones and ethers have been examined[6] and the very polar acetonitriles have been investigated (4). The weakly polar frozen systems which have been most extensively studied are the glassy ethers (5).

In virtually every saturated organic compound which forms a glassy solid, radiolytically generated species identified as trapped electrons have been discovered.[7] These entities are characterized by intense, near-infrared or visible optical absorption spectra and single, narrow, Gaussian-shaped e.s.r. lines near the free-spin g-value. The e.s.r. line is normally quite easily power-saturated (8). Photobleaching of the trapped electrons with light in the region corresponding to their optical absorption also occurs (9). The species may also be eliminated by added solutes of high electron affinity, such as naphthalene (10). Though normally stable for long periods of time in the very polar glasses at 77 °K (2), trapped electrons in the weakly polar systems (such as methyl tetrahydrofuran) are not stable and they decay via processes at least partially attributable to recombination with their parent ions (11).

By analogy with other highly polar compounds, propylene carbonate glasses should also trap electrons with a significant yield. In order to determine whether such trapping occurs, an investigation of the e.s.r. and optical spectra of irradiated PC glasses was undertaken.

Experimental

(i) Materials

Eastman Kodak practical grade propylene carbonate was dried for several days over molecular sieve. The dried solvent was then vacuum fractionated twice using a 4 ft glass column packed with glass helices; the middle 50% was collected each time and the purified solvent was stored under dry helium in a Pyrex dispensing flask. Conventional analyses (*i.e.*, mass spectrum, u.v., n.m.r., and i.r.) indicated that the purified PC was >99% pure.

Methanol was Fisher certified 99.9 mol% grade.

All other chemicals were analytical grade or equivalent.

(ii) Radiation Source

A 4000 C, ^{60}Co Gammacell was used for the irradiations. Doses ranged from 0.1 to 2 Mrads at a dose rate of about 0.3 Mrad/h.

(iii) Glass Preparation

Electron spin resonance measurements were made on glassy balls of PC, 2–3 mm in diameter, prepared by dropping the deoxygenated liquid into a Dewar of liquid nitrogen as described by Alger (12). The balls made in this manner were nearly perfect spheres, completely transparent, free from bubbles and cracks, and mechanically sound.[8]

For the optical studies, the sample of PC was sealed in a 1 cm^2 quartz spectrophotometer cell after thorough degassing by multiple freeze–pump–thaw cycles. When immersed in liquid nitrogen these samples usually became partially polycrystalline. On occasion, however, a reasonably transparent "glass" was formed with relatively few cracks and these samples were used.

(iv) Electron Spin Resonance Measurements

A Varian Associates E-3 spectrometer (x-band) was used for all measurements. The spectra were usually recorded with the sample balls in a quartz Dewar filled with liquid nitrogen. A custom-made quartz variable temperature Dewar cooled by gas flowing from a copper coil immersed in a liquid nitrogen bath was used for temperatures above 77 °K. The sample ball was supported in the center of this Dewar on the tip of a thin evacuated quartz tube which also contained the thermocouple. In practice, the Dewar was first cooled to the minimum possible temperature (about 85 °K) and the gas flow was then momentarily interrupted while a sample ball was quickly transferred from a liquid nitrogen bath and dropped into the top of the Dewar. (Continuous monitoring of the Dewar temperature indicated that during the transfer process the samples were probably warmed to about 95 °K before the gas flow was restarted.)

The magnetic field strength and field scan linearity were calibrated with a proton-probe gaussmeter and the microwave frequency was checked with a Hewlett–Packard model 5255A digital frequency counter. Microwave power levels were not calibrated and the values quoted herein are those read directly from the power attenuator control of the spectrometer.

g-Values were determined using a finely powdered sample of DPPH as the standard, taking $g = 2.0036$.

(v) Optical Measurements

Optical absorption spectra were recorded using a Cary 14 spectrophotometer. The sample cell was maintained at liquid nitrogen temperature in a quartz Dewar with optical windows. Nitrogen bubbling in the Dewar caused some "noise" problems but by using a slow scan rate and maximum pen damping, it was possible to obtain a reasonable signal-to-noise ratio. For measurements in the infrared region, the sample was protected from bleaching by the tungsten i.r. lamp source by placing a thick u.v.–visible cutoff filter (Corning #2-61) between the source and the sample.

Results

(i) Electron Spin Resonance Observations

The e.s.r. derivative spectra measured at 77 °K immediately following irradiation of the PC glasses are shown in Fig. 2. At the lowest power level available (~0.5 mW) a nine-line spectrum was observed (Fig. 2*a*) spread over a region some 130 G wide and centered at the free-spin g-value. Increasing the microwave power level caused the center line, A, to rapidly decrease in intensity until it was completely saturated at ~10 mW (Fig. 2*b*). The broad doublet signal labeled C was also saturated at

[7]For recent reviews on solvated and trapped electrons, see, for example, ref. 7.

[8]Attempts to prepare a glass in small bore quartz tubing always gave partially polycrystalline samples.

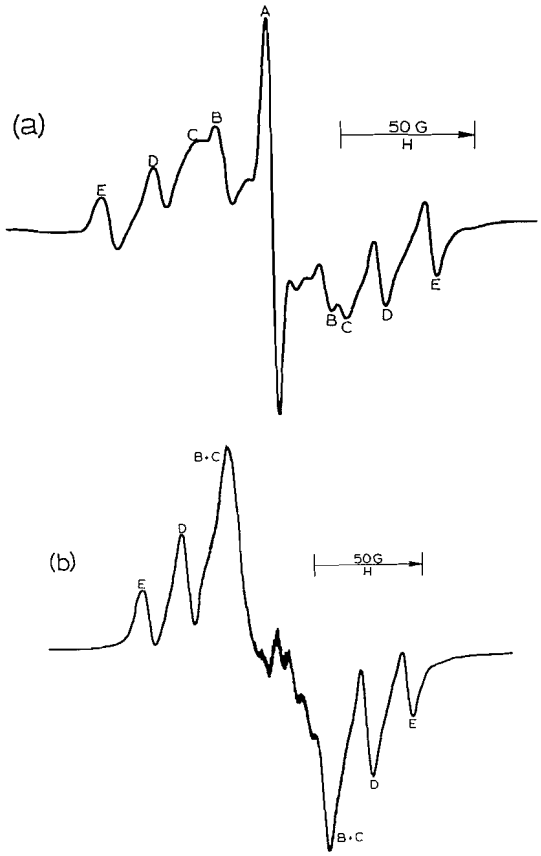

FIG. 2. Electron spin resonance derivative spectra of γ-irradiated glassy propylene carbonate at 77 °K immediately following irradiation. Dose ~0.8 Mrad (*a*) at low microwave power (~0.5 mW), (*b*) at higher microwave power (~10 mW).

this power level. A higher resolution scan of the central resonance line A is shown in Fig. 3 where the line-shape can be seen to be nearly Gaussian. The line-width, as measured between points of maximum slope, was found to be 4.5 ± 0.1 G and the *g*-value of the resonance was determined to be 2.0028 ± 0.0002.

Addition of carbon dioxide at atmospheric pressure to the PC samples did not measurably affect the e.s.r. spectra. However, both iodine and naphthalene removed the central line A as shown in Fig. 4. Iodine also eliminated some of the other paramagnetic species as can be seen in Fig. 4*a*. The naphthalene containing sample appeared dark green in color following radiolysis, indicating the presence of the naphthalene radical anion.

The intensity of the central resonance line A

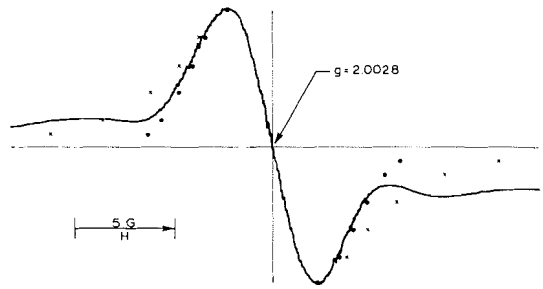

FIG. 3. High resolution e.s.r. scan of line A from Fig. 2*a*. ● = Gaussian, *x* = Lorentzian line-shape.

decreased fairly rapidly with time. Figure 5 shows this isothermal decay at 77 °K for several different initial irradiation times. Here the amplitude of the e.s.r. derivative signal is plotted on a logarithmic scale as a function of time following the end of the irradiation period. Since the line-width remained essentially constant, the amplitude of the derivative signal is a

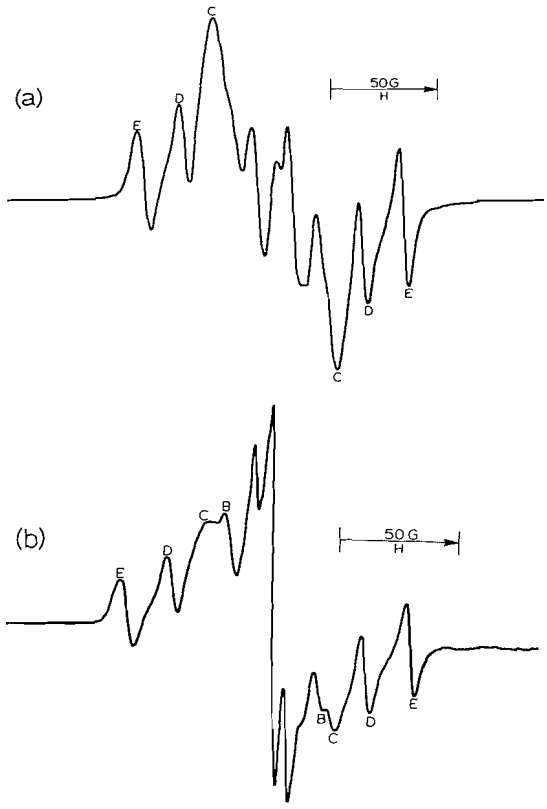

FIG. 4. Electron spin resonance derivative spectra of γ-irradiated glassy propylene carbonate at 77 °K (*a*) containing 0.02 M iodine, (*b*) containing 0.1 *M* naphthalene.

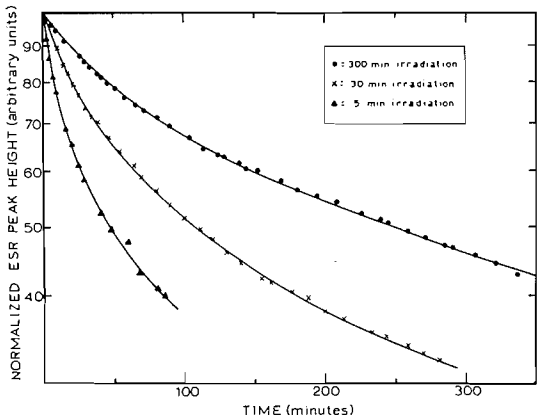

FIG. 5. Natural decay at 77 °K of the intensity of e.s.r. line A of Fig. 2*a* plotted on a logarithmic scale as a function of time after the irradiation. Dose rate ~5000 rads min^{-1}. Data are arbitarily normalized at 0 time.

reasonably good measure of spin concentration. (Note, however, that the sample sizes and cavity positions were not identical for the individual experiments and, therefore, the three sets of data are not inter-comparable on an *absolute* spin concentration basis.) The decay of resonance line A did not result in the production of any new paramagnetic species nor was there any noticeable change in the intensity of the other e.s.r. spectra.

Photolysis experiments performed using a filtered 100 W tungsten lamp showed that the e.s.r. spectra were unaffected by light with $\lambda > 500$ nm. However, the decay of the central resonance line A was significantly accelerated by light in the wavelength range below 500 nm.

Ultraviolet photolysis of unirradiated PC glasses at 77 °K with light from an unfiltered low pressure mercury lamp produced no paramagnetic species. Ultraviolet photolysis of the γ-irradiated sample, however, resulted in a dramatic color change with the samples becoming dark blue. The e.s.r. spectrum observed for the samples exposed only very briefly to the u.v. light is shown in Fig. 6*a*. A new, intense, asymmetric single line, labeled G, appeared downfield at $g \sim 2.015$ and a new asymmetric doublet, labeled H, was generated centered at the free-spin g-value and with hyperfine splitting of about 130 G. After prolonged exposure to the u.v. light, the samples became nearly colorless accompanied by the virtually complete disappearance of the asymmetric singlet G. The intensity of the doublet H was

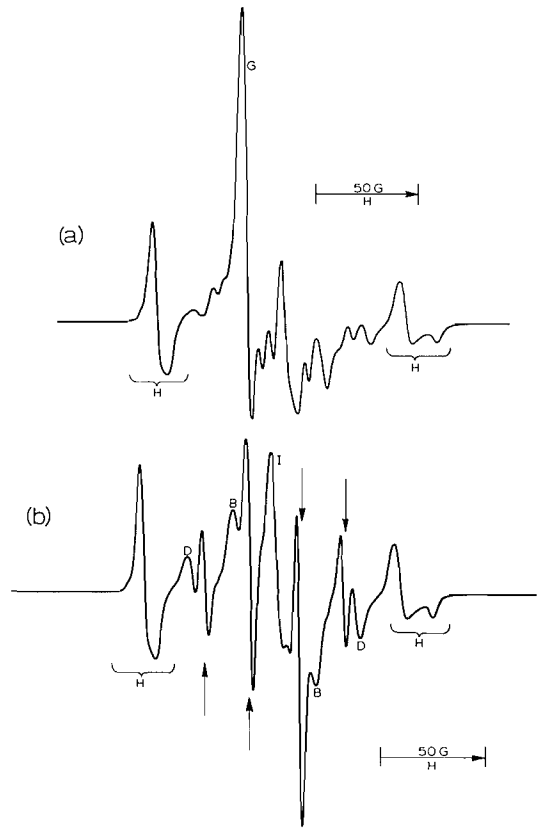

FIG. 6. Electron spin resonance derivative spectra of the γ-irradiated PC glasses at 77 °K (*a*) after brief u.v. photolysis, (*b*) after prolonged, intense u.v. photolysis; arrows indicate methyl radical quartet.

considerably diminished and a new quartet signal was produced as shown by the arrows in Fig. 6*b*. This new resonance was centered at $g = 2.0023$ with hyperfine splitting of 21 ± 2 G and a 1:3:3:1 relative line intensity. (Both signals G and H in Fig. 6*a* could also be bleached using red light from a He/Ne laser.)

When the PC glasses were warmed above 77 °K the central line A disappeared very rapidly apparently by the same mechanism as at 77 °K. At 110 °K the resolution of the remaining e.s.r. lines (B, D, E) improved due to the decay of the broad overlapping signal C. A new paramagnetic species characterized by a multiple line e.s.r. signal was formed as shown in Fig. 7*a*. The e.s.r. parameters of signals B, D, E, as measured from Fig. 7*a* were $g = 2.0023 \pm 0.0003$ and the hyperfine splittings were 42 ± 2, 83 ± 3, and 124 ± 4 G, respectively. All remaining paramagnetic species decayed rapidly above

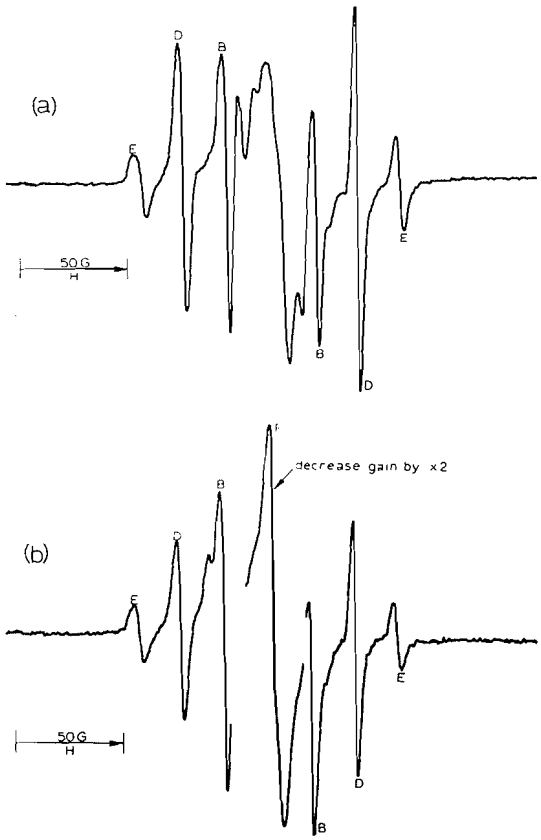

FIG. 7. Electron spin resonance derivative spectra of the γ-irradiated PC glasses (*a*) at ~110 °K after the thermal decay of some radicals, (*b*) at ~110 °K after exposure to u.v. light.

150 °K. Ultraviolet photolysis of the samples at 110 °K, after the disappearance of species C, did not produce the blue coloration or the e.s.r. signals observed after photolysis at 77 °K. Instead, the doublet signal D was observed to decrease in intensity with a concomitant production of a new resonance in the center of the spectrum as shown in Fig. 7*b*.

(ii) Optical Absorption Spectra

γ-Irradiation of the glassy PC at 77 °K imparted only a pale greenish color to the samples. This is in contrast to most other glassy materials which become intensely colored when irradiated at low temperatures (13).

The optical absorption spectrum recorded immediately after irradiation is represented by curve *1* of Fig. 8. There was a strong absorption band in the u.v. with λ_{max} below 280 nm, a

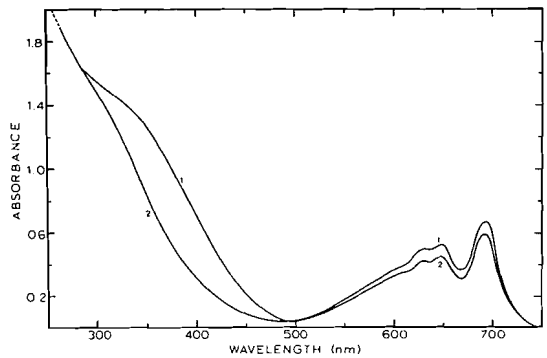

FIG. 8. Optical absorption spectra of γ-irradiated PC at 77 °K (sample partially crystalline) in a 1 cm cell. Curve *1* is the spectrum obtained immediately after the irradiation, curve *2* was obtained 24 h later. Dose ~1.3 Mrad.

shoulder on the u.v. band in the 300–500 nm region, and a complex band showing fine structure between 500 and 750 nm. No evidence was found for any absorption beyond 750 nm into the infrared. After a sample has remained in the dark at 77 °K for 24 h following irradiation, the magnitude of the absorption in the 300–500 nm region was greatly reduced as illustrated by curve *2* in Fig. 8. The intensity of the complex band between 500–750 nm, however, had only slightly decreased during this time.

Ultraviolet photolysis of the γ-irradiated samples caused them to become a deep blue color as noted above. The coloration was due to a very large increase in the intensity of the 500–750 nm absorption band, which is shown in more detail in Fig. 9.

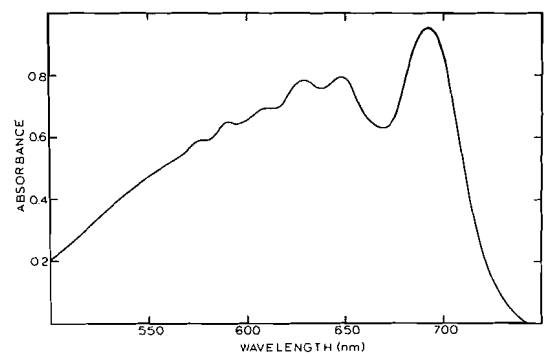

FIG. 9. Absorption spectrum in the 500–750 nm region for γ-irradiated PC after brief u.v. photolysis at 77 °K. The spectrum is attributed to a combination of the HCO and CO_3^- radical absorption bands.

Discussion

There are three different species which could give rise to the central narrow e.s.r. line A shown in Figs. 2*a* and 3. These are (*i*) trapped electrons, (*ii*) CO_2^- radical ions formed either from traces of CO_2 impurity or via molecular decomposition processes, and (*iii*) molecular anions of propylene carbonate (PC^-) produced by electron attachment to the carbonyl group. The latter two possibilities may be eliminated on the basis of the following arguments.

The CO_2^- radical ion has been observed in a number of irradiated crystalline systems (14) and it has been shown to be the species responsible for a narrow e.s.r. line observed in 3-methyl pentane (15). The narrow, easily saturated e.s.r. line in the irradiated PC glasses and its photobleaching characteristics are in fact similar to those observed by Johnson and Albrecht for CO_2^- in the 3-methyl pentane glasses (15). However, stringent precautions were taken in the preparation of the PC samples to avoid CO_2 contamination. In addition, CO_2 added to the samples at atmospheric pressure did not affect the e.s.r. spectrum, whereas Johnson and Albrecht found a very substantial increase in the relative intensity of the e.s.r. line. This leaves the possibility that CO_2^- may have been formed as a product of the radiation decomposition processes, most probably via a molecular anion such as PC^-. Although this is conceivable, there are two additional arguments against the involvement of CO_2^- in this system. The *g*-value of 2.0028 ± 0.0002 and the isotropic Gaussian line-shape of the narrow resonance in γ-irradiated PC are substantially different to those reported for the CO_2^- resonance in crystalline systems where an anisotropic line-shape is observed with $g_{av} \sim 2.001$ (14). (Unfortunately, Johnson and Albrecht did not report this information for CO_2^- in the glassy 3-methyl pentane.) In addition, the relatively fast spontaneous decay of the species is inconsistent with it being a molecular anion since molecular mobility should be very limited in the low temperature glass.

A molecular anion of PC might be formed in the irradiated glass by electron attachment to the carbonyl group. Indeed, such electron attachment is commonly observed in irradiated ketones (16). However, there is evidence that the carbonyl group in PC is not a typical "ketone type" $\rangle C{=}O$, but rather the double bond character should be considered as partially delocalized over the entire carbonate group. This is evident in the fact that PC does not show the characteristic $n \rightarrow \pi^*$ carbonyl band in its u.v. absorption spectrum. In addition, PC is unreactive with the alkali metals (1*g*) which suggests that electron attachment to the $\rangle C{=}O$ is not favored.

The observed properties of the e.s.r. line A clearly discount the possibility of it being due to a species such as PC^-. The small γ-proton hyperfine interactions and anisotropy due to confining the unpaired electron to a molecular orbital should result in a line-width much greater than the 4.5 G observed. In addition, one would expect the resonance of a large molecular anion to not saturate at such low power levels since it would be more effectively coupled to the environment. The natural decay of the species (which, as will be shown later, is characterized by non-homogeneous second-order kinetics) is also inconsistent with a large molecular anion.

The observed e.s.r. signal is, however, exactly that expected for trapped electrons in an organic glass. Trapped electrons produced in other organic glasses at liquid nitrogen temperature are characterized by narrow Gaussian e.s.r. lines near $g = 2.0023$ which are easily power saturated (7, 8). Thus, having eliminated the other likely candidates, it seems reasonable to assign the narrow line at $g = 2.0028$ to trapped electrons in the PC glasses.

Iodine and naphthalene are both known to be good electron scavengers (10) and thus they removed the trapped electron resonance as shown in Fig. 4. The absence of any e.s.r. resonance due to the expected product I_2^- (17) may be explained on the basis of a fast dissociation reaction to form an iodine atom and I^-. The iodine atom may then react with other radicals to cause the observed additional modifications to the e.s.r. spectrum. Naphthalene has been used as a trapped electron scavenger in other systems (10*b*) where the reaction produces the naphthalene radical anion (or its protonated form). In the present case the observed green color and the multiplet e.s.r. signal (Fig. 4*b*) indicate the presence of the naphthalene anion.

Having established that trapped electrons are formed in the irradiated PC glasses, the question of their optical absorption spectrum then arises.

In all other systems studied to date, trapped and solvated electrons are observed to have a broad asymmetric optical absorption band in the visible or near infrared (7). As will be shown later, the complex absorption band observed in the 500–750 nm region in PC (Figs. 8 and 9) can be attributed to a combination of the absorption bands of the CO_3^- and HCO radicals. Since no absorption was observed in the infrared region, the only remaining alternative for the trapped electron band is the absorption in the 300–500 nm region. The spectrum obtained by subtracting curve *2* from curve *1* of Fig. 8 is a broad band with a maximum at about 370 nm (3.4 eV) and a half width of approximately 0.9 eV. Because light in this wavelength range caused accelerated decay of the trapped electrons, it is reasonable to assign the absorption band to trapped electrons. Unfortunately, experimental difficulties prevented a detailed study of the decay of the optical band at 370 nm. Thus, confirmation of the assignment by a correlation of the optical decay with that observed by e.s.r. was not possible. While a trapped electron absorption band with λ_{max} in the violet region is unusual, it is not inconsistent with the physical properties of the solvent. On the basis of the high dielectric constant of PC (65 at room temperature, increasing to >90 below −60 °C (*1b*)) one would predict an absorption band for a solvated electron in the visible region and the trapped electron band should be blue shifted relative to that of the solvated species. Ekstrom (*7a*) has presented some data for trapped electrons in a glass composed of formamide +15% water at 77 °K where an absorption with a λ_{max} near 400 nm was apparently observed. (Pure formamide has a dielectric constant of 109.) In addition, if the rough correlation between room temperature dielectric constant and the optical absorption maxima observed for trapped electrons in a variety of organic glasses at 77 °K (*7a*) is extended, then a λ_{max} in the vicinity of 400 nm may be expected for trapped electrons in PC.

The apparent instability of the trapped electrons in the PC glasses is particularly surprising since electrons in most other polar glasses, for example the alcohols, are indefinitely stable (2). As shown in Fig. 5, the electrons decay rapidly with the *apparent* rate decreasing

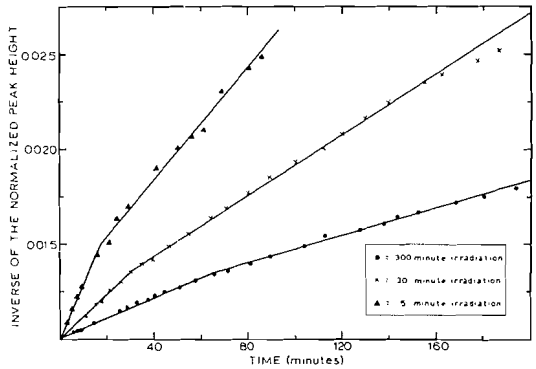

FIG. 10. Second-order kinetic analyses of the decay data from Fig. 5.

with increasing absorbed dose. The decay process is obviously not a simple electron attachment reaction with one of the solvent molecules surrounding the trapping site (as might be expected) since the decay curves are not linear on the logarithmic plot in Fig. 5, nor is any new paramagnetic species formed. The spontaneous decay is best rationalized on the basis of a non-homogeneous second-order reaction between the trapped electrons and positive ions. Second-order analyses of the data from Fig. 5 are presented in Fig. 10 where the inverse of the e.s.r. derivative signal amplitude is plotted as a function of time. The three sets of data all show two linear portions; an initial short period of faster decay, followed by a region of slower decay which is maintained for several half lives. From the results of the 5 min irradiation experiment, it is seen that nearly 50% of the electrons have decayed within 15 min after the end of the irradiation. Therefore, a large fraction of those produced during the early stages of the 30 and 300 min irradiations had already reacted before the irradiation was completed. Thus, the initial transient features indicated in the second-order plots (Fig. 10) are likely caused by the fast reaction of "short-lived" species formed during the latter stages of the irradiation period. These electrons may be those trapped so close to a positive ion that they are already effectively "captured" and thus, have no choice but to recombine. The remainder of the electrons are sufficiently distant from a positive ion that the trap energy is comparable to, or greater than,

For personal use only.

the Coulombic forces and therefore they have a relatively long lifetime governed mainly by diffusion.

It is difficult to determine whether the initial fast decay of the majority of the electrons occurs by the recombination process discussed above. In some of the glassy ethers, the trapped electrons also appear to be predestined to react with a particular positive ion (11) and thus, the decay rate is independent of the total number of positive charges present in the system. As a result the normalized decay curves for samples irradiated with different doses are superimposable over a considerable time range and dose variation. In the present system, it was not possible to compare the data in this manner since absolute spin concentrations could not be determined. In addition, the decay "half-lives" were shorter than the irradiation periods so that a clear interpretation of the kinetics of the fast decay was not possible.

One important implication of the instability of the electrons was to prevent an accurate measurement of their yield. In an early attempt to estimate $G(e_t^-)$, the intensity of the e.s.r. signals of the trapped electron in PC and CH_2OH radicals produced in irradiated methanol glasses were compared under carefully controlled conditions to eliminate sample size and cavity position factors. This crude comparison indicated a yield of trapped electrons of approximately $G(e_t^-) = 0.3$. However, because a long irradiation time was necessary to obtain a reasonable signal level in the small samples, the G value obtained is undoubtedly much smaller than the primary yield of electrons (perhaps by as much as a factor of 10) since a large fraction of them would have decayed during the irradiation period. In addition, the intensity of the e.s.r. line in PC may be substantially less than the "true" value because of partial microwave power saturation. In comparison with trapped electrons in other systems, 0.5 mW is a high power level and this could be causing some decrease in line intensity. γ-Radiolysis scavenger experiments (18) and pulse radiolysis studies (6) on liquid propylene carbonate have indicated that the yield of solvated electrons (or possibly reactive molecular anions) is about $G = 2$. One would expect an even higher total yield of trapped electrons in the glassy solid.

The other radicals produced by the radiolysis with significant yields could not be identified. As was shown in Fig. 2*a*, these radicals gave rise to an eight-line e.s.r. spectrum centered at the free-spin *g*-value. The relative ease of power saturation and the thermal instability of the broad doublet labeled C suggest that this resonance is due to a separate species. The hyperfine splitting of 58 ± 3 G implies the strong interaction of a single proton and the free-spin *g*-value suggests an electron excess radical.[9] The other six lines, labeled B, D, E in the spectrum illustrated in Fig. 2*a*, were shown to be associated with three independent radicals. Species B was removed by iodine as illustrated in Fig. 4*a* and it also decayed slowly over a period of several hundred hours. Ultraviolet photolysis of the irradiated samples at 110 °K preferentially removed species D and produced a new radical giving a single e.s.r. line as illustrated in Fig. 7*b*. Because of the apparent large doublet hyperfine splittings (42 ± 2, 83 ± 3, and 124 ± 4 *G* for B, D, E, respectively), the free-spin *g*-value and the isotropic line-shapes, these e.s.r. signals cannot be attributed to simple radicals such as HCO, HCO_2, OH, etc. In fact, it is difficult to even speculate as to their identity. The total radical yield as estimated by comparison with the CH_2OH radical generated in irradiated methanol was $G(R) \sim 4$.

Ultraviolet photolysis of the irradiated glasses at 77 °K did, however, produce radicals which could be identified. The e.s.r. spectrum shown in Fig. 6*a* may be interpreted as follows. The intense asymmetric line labeled G appeared to be formed as a result of the photolysis of the radical responsible for the broad doublet labeled C in Fig. 2*a*. In addition, this new radical was at least partially responsible for the blue coloration of the photolyzed sample. These inferences were supported by the fact that neither the e.s.r. line nor the blue color could be generated by u.v. photolysis of the samples at 110 °K when the broad doublet had been thermally removed. The blue coloration was due to a very large increase in the intensity of the 500–750 nm absorption

[9]The radical $CH_3\dot{C}OCH_2OC{=}O$, as suggested by one of the referees, could account for the observed broad doublet since in the rigid planar structure one of the β-protons could have a strong interaction with the unpaired electron.

band which was shown in Fig. 9. On the basis of the e.s.r. line at $g \sim 2.015$ and the position of the absorption band, the presence of the CO_3^- radical ion was indicated. CO_3^- has been observed spectroscopically in aqueous solution where a broad asymmetric optical absorption with $\lambda_{max} \sim 600$ nm was observed on flash photolysis or pulse radiolysis of carbonate solutions (19). Ershov *et al.* (20) reported essentially the same optical spectrum for CO_3^- produced in frozen aqueous carbonate glasses at 77 °K and also attributed an asymmetric e.s.r. line at $g_{av} = 2.011$ to the species.

It is therefore evident that the fine structure on the 500–750 nm band is really absorption due to a separate species superimposed on the broad structureless band of CO_3^-. The species believed responsible for these narrow bands is the HCO radical. The presence of HCO was confirmed by the asymmetric doublet e.s.r. signal, labeled H in Fig. 6*a*. This doublet was identical to that reported for HCO in other media (21) and to that observed for HCO radicals generated by u.v. photolysis of γ-irradiated methanol glasses (22). The HCO is also known to show at least seven narrow optical absorption bands in the region between 500 and 700 nm when trapped in a carbon monoxide matrix at 20 °K (23). Although the positions of the bands observed in PC at 77 °K (~690, ~650, ~630, ~610, ~590, and ~575 nm) do not agree precisely with those reported for the CO matrix (670, 635, 605, 579, 555, 533, and 510 nm) the differences are probably caused by the overlapping of the CO_3^- spectrum and rather poor resolution.

The presence of the weak optical absorption due to the CO_3^- and HCO radicals in the irradiated samples before u.v. photolysis (Fig. 8) indicates that these radicals may be formed with a small yield during the primary radiolysis processes. (The initial yield must be relatively small since the e.s.r. signals of these species are not observed in the original samples (Fig. 2*a*).) Alternatively, the small yield of the radicals may be the result of photolysis caused by Cerenkov radiation generated in the sample and liquid nitrogen.

If the samples were exposed to intense u.v. light for a long period of time, the CO_3^- radical was eventually bleached out and a new radical characterized by a quartet e.s.r. signal centered at the free-spin g-value with 21 ± 2 G hyperfine splitting was formed as indicated in Fig. 6*b*. This new e.s.r. signal can be assigned to the methyl radical (2, 22). This assignment is supported by the observation that these radicals were relatively unstable in the matrix at 77 °K and decayed rapidly over a period of a few hours.

Financial support of the National Research Council of Canada is gratefully acknowledged. The author is indebted to Professors D. C. Walker and F. G. Herring for helpful discussions and, in particular, thanks Mr. N. S. Dalal for assistance in the operation of the e.s.r. spectrometer and in the interpretation of the spectra.

Conformational Terminology for Crystalline Cellulose

P. R. SUNDARARAJAN[1] AND R. H. MARCHESSAULT

Département de Chimie, Université de Montréal, C.P. 6128, Montréal

Received August 26, 1971

Two different crystalline models of cellulose have received attention from crystallographers: the "straight chain" model of Meyer and Misch and the "bent chain" model of P. H. Hermans. We have examined these models and have given a mathematical interpretation of each in terms of the conformational angles ϕ and ψ and the glycosidic angle τ. For a given geometry of the glucose residue, the "straight chain" corresponds to a unique value of τ; for a value of τ greater than the unique value, two "bent chains" are possible, one allowing an intramolecular hydrogen bond (O-3...O-5′) and the other not. It is suggested that the former only be referred to as the Hermans conformation.

Au cours des années, les cristallographes ont proposé deux modèles différents pour la chaîne cellulosique: un modèle à chaîne "droite" et un modèle à chaîne "plissée". On a maintenant donné une interprétation mathématisée à ces deux modèles en se référant aux angles conformationnels: ϕ et ψ et l'angle glycosidique τ. Pour une géométrie fixe du résidu glucosidique, la chaîne "droite" correspond à une valeur unique de τ; pour un τ plus élevé que cette valeur unique, on retrouve deux chaînes "plissées" mais seulement une d'elle permet une liaison hydrogène intramoléculaire (O-3...O-5′). On propose que seulement cette dernière soit appelée la conformation de Hermans.

Canadian Journal of Chemistry, **50**, 792 (1972)

In the crystalline state (1) the β,D $(1 \rightarrow 4')$ glucan, cellulose, has an axial repeat of 10.3 Å. In 1937, Meyer and Misch (2) proposed a crystal structure based on the stereochemical knowledge of that time wherein a twofold screw axis ran along the cellulose chain and all glycosidic oxygens were coplanar. However, it was eventually realized (3) that this structure implied too close a contact between the C-6 and O-2′ atoms of contiguous residues. For this reason the "bent" chain conformation for the cellulose molecule, originally proposed by Hermans (4), because it allowed a favorable hydrogen bond between the O-3 hydroxyl of one residue and the O-5′ ring oxygen of the next, was favored by contemporary workers. The presence of this type of hydrogen bond is in keeping with the most straightforward interpretation of the polarized infrared spectra of cellulose (5).

Modern workers in the field of cellulose structure have had the benefit of accurate crystallographic data on simple organic molecules in general and carbohydrates in particular (6). This has provided information on bond lengths and bond angles of a kind which was not available to early workers. In addition, high speed computers have permitted a model building approach wherein the whole of conformational space is explored by rigid body transformation methods (7). This involves the assumption of rigid glucopyranose residues joined by a suitable β-glucoside bond angle with two rotational angles ϕ and ψ (rotation about C-1—O and O—C-4, respectively) which define all possible conformations for two contiguous glucose residues (8–9). When a chain is generated with ϕ,ψ constant for all pairs of neighboring glucose residues then a regular conformation is obtained. Thus each point in ϕ,ψ space defines a conformation where glucose residues occupy equivalent positions about an axis.

Various workers have reported conformational analyses of this type and Fig. 1 shows the contours of iso-n and iso-h for cellulose where n is the number of residues per turn of the helix and h is the advance per residue projected along the helix axis.

From this figure, it is seen that there are two positions on the (ϕ,ψ) map, where the chain with parameters $n = 2$ and $h = 5.15$ Å occurs. Of these, the position C_1 has been associated (8, 9) with the Hermans type of conformation since the C_1 position on the (ϕ,ψ) map allows the intramolecular hydrogen bond mentioned above. The position C_2 was claimed (8, 9) to be similar to the Meyer–Misch type of chain

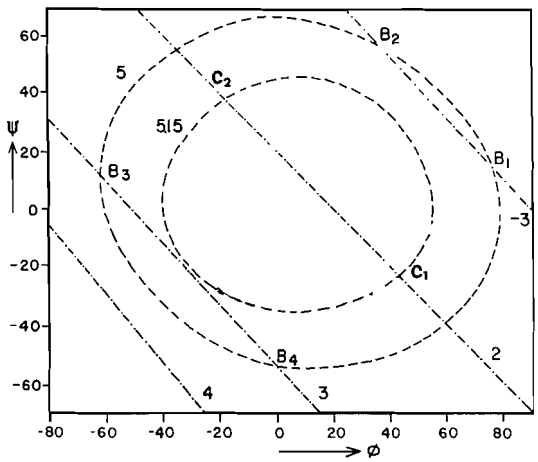

FIG. 1. Curves of *iso-n* (·-·-·) and *iso-h* (---) for the β,D(1→4′)glucan. C_1,C_2: positions of the chain with two-fold screw axis and a repeat of 10.3 Å. B_1,B_2: positions of the chain with threefold screw axis and a repeat of 14.85 Å (left-handed). B_3,B_4: same as B_1,B_2 but right-handed (taken in part from ref. 10).

(M.M. chain hereafter) due to the close contact between C-6 and O-2′ atoms, in position C_2 on the (ϕ,ψ) map. We have now examined the M.M. type of chain and deduced a few conclusions regarding the role of the angle (τ) at the bridge oxygen atom in the conformations of the cellulose chain.

The analysis of the coordinates given by M.M. shows that a value of 105° was used for the angle C—O—C at the bridge oxygen atom, which is close to the value of the angle H—O—H in water. The C-6 and O-2′ atoms are 2.68 Å apart, which according to the contact distance criterion (7) is only 0.02 Å less than the extreme limit. Further, in terms of the convention used in Fig. 1 for the conformational angles (ϕ,ψ), this structure corresponds to (ϕ,ψ) = (0°,0°). Fig. 2*a* shows the curve of $n = 2$ obtained using the M.M. coordinates and a value of 105° for τ. It is to be noted that while in Fig. 1 there are two positions (C_1 and C_2) where $n = 2$ and $h = 5.15$ Å are possible, in Fig. 2*a*, there is only one position where such a chain can be built mathematically. Using the M.M. coordinates, and a value of 112° for τ (Fig. 2*b*) there are two solutions possible for the chain, as observed in Fig. 1. Thus it is clear that while for $\tau = 112°$, there are two solutions of (ϕ,ψ) with $n = 2$, $h = 5.15$ Å they reduce to a unique solution as τ is reduced to a value of 105°. Among the two solutions for $\tau = 112°$, the position C_1 favors the O-3...O-5′ type of hydrogen bonding while the position C_2 gives rise to a close contact between C-6 and O-2′ atoms. For τ below the critical value of 105°, it would be impossible to construct a chain with the parameters $n = 2$, $h = 5.15$ Å. For the atomic parameters used for Fig. 1, the critical value of τ (τ_c) (below which $n = 2$, $h = 5.15$ Å would be impossible) turns out to be 109.5°.

Figure 3 shows the cellulose chain conformations in projection. Figure 3*a*, with $\tau_c = 105°$, depicts the straight chain conformation. The

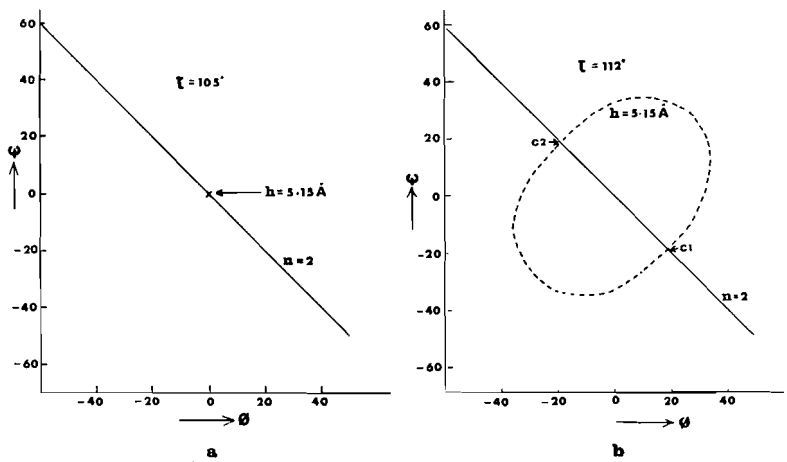

FIG. 2. Curves of *iso-n* = 2 (—) and *iso-h* = 5.15 Å (---) with the M.M. geometry for the glucose residue. (*a*) With $\tau = 105°$, as in the original M.M. structure. (*b*) With $\tau = 112°$.

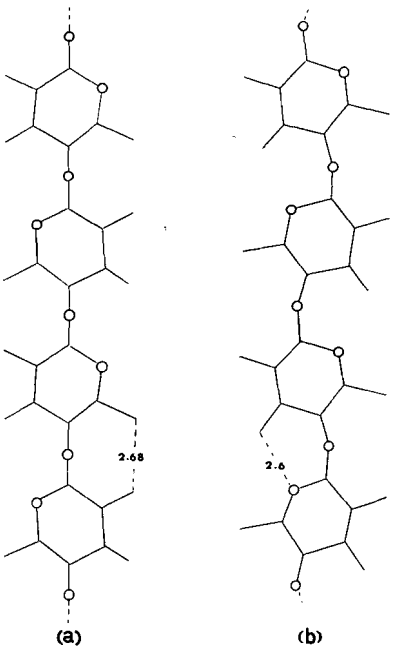

FIG. 3. Projection of the cellulose conformations: (*a*) "Straight chain" conformation, with $(\tau,\phi,\psi) = (105°,0°,0°)$ with M.M. geometry for the glucose residue. (*b*) "Hermans type" of bent chain conformation with $(\tau,\phi,\psi) = (117.5°,-40°,-20°)$ with the geometry of the glucose residue as in ref. 9.

straight chain appearance is due to the fact that $(\phi,\psi) = (0°,0°)$ and the atoms C-1, O-1, O-4, and C-4 of all the residues are coplanar. However, the bridge oxygens do not lie on the chain axis, as is obvious from Fig. 4*b* of ref. 2. Figure 3*b* shows the conformation C_1, which is similar to the Hermans bent chain conformation. The bent chain appearance is due to the slight rotation of the residues around the bonds C-1—O and O—C-4′ away from $(\phi,\psi) = (0°,0°)$ which is required by the fact that the bridge oxygen angle is not equal to τ_c. Thus the term straight chain conformation applies only to that conformation of the cellulose chain in which the τ is equal to τ_c and $(\phi,\psi) = (0°,0°)$. The position C_1 may be said to correspond to a "Hermans type of bent chain" conformation (Hermans conformation) and the position C_2 may be termed the "alternate bent chain" conformation. Only if C_1 and C_2 merge at $(\phi,\psi) = (0°,0°)$ can the chain be said to have the "straight chain" conformation.

The value of τ_c for a given n and h depends on the atomic parameters chosen for the monomer. While τ_c is 105° for the geometry used by Meyer and Misch, it turns out to be 109.5° for the geometry of the residue used by Gabbay *et al.* (10). Figure 1 also shows that for the chain with $n = 3$ and $h = 5$ Å, like the β,D $(1 \rightarrow 4')$ xylan, there are two positions B_3 and B_4 which represent right-handed helices and two positions B_1 and B_2 for left-handed. It was observed that on reducing the angle τ from 117.5° to $\tau = 115°$, B_1 and B_2 merge and give rise to a unique left-handed chain. Below the value of 115°, the curves of $n = 3$ and $h = 5$ Å do not meet, implying that such a chain would not be mathematically feasible for the given geometry of the pyranose residue.

Chemistry of Proximal π-Bond Systems. Part I. Synthesis of Vicinal Exocyclic Dimethylene Hydrocarbons

D. N. Butler and R. A. Snow
Chemistry Department, York University, Toronto, Ontario

Received June 14, 1971

Thirteen new bi- or polycyclic vicinal exocyclic dimethylene hydrocarbons (**10**–**22**) have been synthesized and some of their spectral properties recorded. The generally most useful synthetic route to such compounds utilizes base-catalyzed double elimination from *trans*-1,2-bis(hydroxymethyl)alkyl *p*-toluenesulfonates as the final step in the production of the conjugated diene.

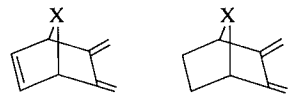
Treize nouveaux hydrocarbures (**10**–**22**), bi ou polycycliques, ayant des groupements diméthylènes exocycliques et vicinaux ont été synthétisés et quelques unes de leurs propriétés spectrales sont rapportées. La méthode de synthèse la plus efficace pour de tels composés consiste en une double élimination baso-catalysée à partir des *trans* bis(hydroxyméthyl)-1,2 alkyl *p*-toluènesulfonates; ceci constitue l'étape finale en vue de la formation des diènes conjugués.

Canadian Journal of Chemistry, **50**, 795 (1972)

Introduction

Interest in the chemistry of organic molecules containing proximal π-bonds is widespread in contemporary chemical literature (1). Perhaps the most interesting of this class of compounds are those in which the π-bonds are constrained in bi- and polycyclic hydrocarbons of known or predictable proximities by virtue of the fixed geometries of the ring systems involved, *e.g.* norbornadiene (2), barrelene (3), and bullvalene (4).

Most of the systematic work done, however, has been associated with endocyclic π-bonds. The synthesis of hydrocarbons of types **1** and **2** (where -X- represents any bridge) incorporating a vicinal exocyclic dimethylene bridge would allow a comparison of the effects of the possible mixing of the *cis*-diene π-orbitals with the endocyclic π-system of compounds **1** in the ground or first excited states with the situation as presented in compounds **2** where such mixing is not possible. Also, comparative chemistry (*e.g.* Diels–Alder additions) of **1** and **2** should reveal insights into the influence of ring size, state of hybridization, and -X-bridge geometric parameters on the transition states leading to the respective products. Such chemistry also generates many novel polycyclic systems, themselves potentially capable of further addition, thermal, or photochemical reactions. Accordingly, a synthetic program designed to provide a general high-yielding route to compounds of the type **1** and **2** was undertaken.



1 **2**

Of the compounds **3**–**22** below, **3**–**9** are known (5–8). The remainder (**10**–**22**) represent those of the many possible structures of (or related to) **1** and **2** which we have prepared to date. This paper describes their synthesis and offers general comments on the various methods available for the preparation of bridged vicinal dimethylene hydrocarbons.

Results and Discussion

The majority of the published syntheses of mono- and bicyclic vicinal exocyclic dimethylene hydrocarbons involves either acetate pyrolysis (route *i*, Scheme 1) (7, 9) or quaternary amine hydroxide (Hofmann elimination) pyrolysis (route *ii*, Scheme 1) (5) as the final diene producing step. The acetate route suffers from the high temperatures (400–500°) necessary to effect elimination and cannot be considered when the possibility of retro-Diels–Alder reaction exists.

In this present work, route *ii* was modified to employ pyrolysis under vacuum of the bis-(dimethylamine-*N*-oxides) (Cope reaction (10)). The temperatures used were a little lower than in the Hofmann procedure, but it was found that with large scale preparations (up to 0.5 mol) uncontrolled decomposition of the *N*-oxide sometimes took place.

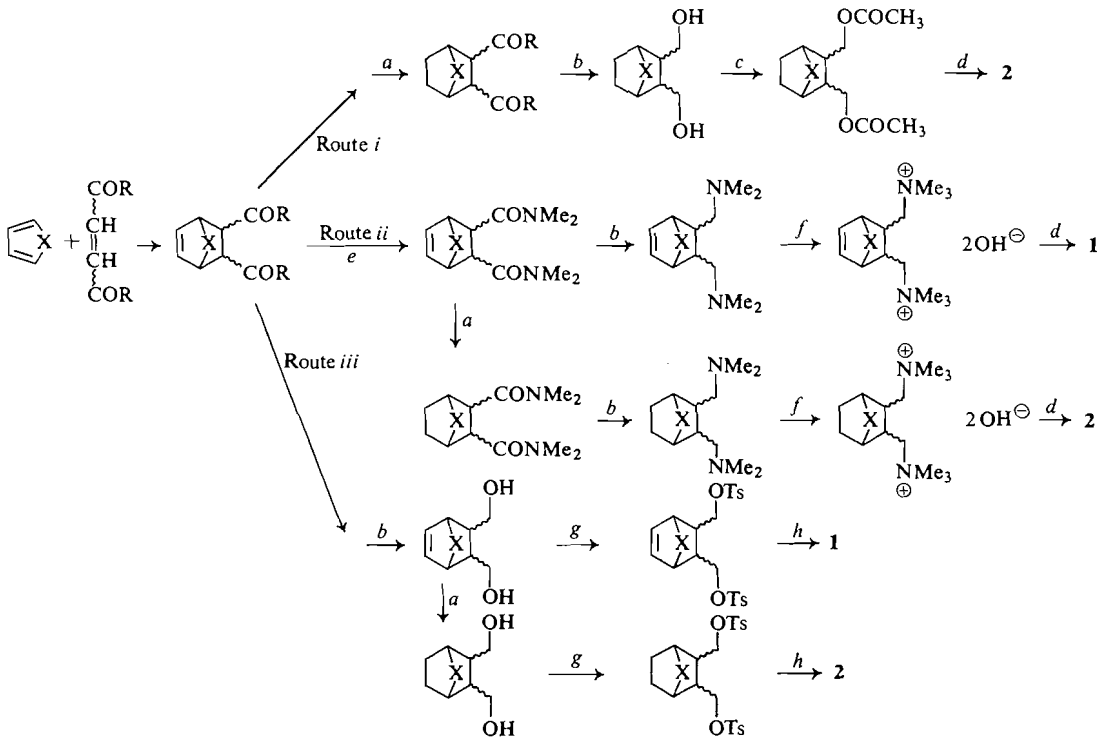

SCHEME 1. General routes to vicinal exocyclic dimethylene hydrocarbons.

After the tosylation/base-catalyzed elimination sequence (route *iii*, Scheme 1) had been developed in this laboratory, the synthesis of **23** (11) was published using exactly this method. This route proved to be the best in terms of overall yields, lack of hazard, and purity of product.

Compound **9** has been prepared using a modification of route *iii*, Scheme 1 (8) (as step *h*: sodium hydroxide/refluxing ethanol). However, the use of potassium *t*-butoxide in dimethyl sulfoxide at room temperature facilitated reaction and increased yields to *ca.* 95% from the *trans*-di-*p*-toluenesulfonate precursor.

Several other individual syntheses of vicinal exocyclic dienes have been published (12) but these are not considered to be generally useful.

The ten hydrocarbons **3–8**, **10**, **11**, **16**, and **17** were all prepared via the Cope reaction modification as the final step of route *ii*, Scheme 1. The starting materials for all these compounds were the known, respective Diels–Alder adducts of fumaryl chloride and the cyclic diene necessary to construct the ring system. Thus, the corresponding intermediate bisamides, bisamines, and bisamine oxides all have *trans* stereochemistry.

The remaining ten hydrocarbons **9**, **12–15**, and **18–22** were all obtained from the di-*p*-toluenesulfonate esters of the corresponding

bis-primary alcohols by treatment in dimethyl sulfoxide with potassium *t*-butoxide (route *iii*, Scheme 1). The starting compounds for the syntheses of hydrocarbons **9**, **12**–**15**, and **18** were again the fumaryl chloride adducts of the respective, necessary cyclic dienes. Catalytic hydrogenation reduced both double bonds of the diol intermediate from lithium aluminum hydride reduction of the cyclooctatetraene–fumaryl chloride adduct and thus furnished the necessary diol for compound **19**.

The known 1,4-etheno-1,2,3,4-tetrahydronaphthalene-(*trans*)-2,3-dicarboxylic acid dimethyl ester **24** (13) was reduced in lithium aluminum hydride/tetrahydrofuran to provide the necessary diol intermediate for hydrocarbon **21**, and after catalytic reduction, that for hydrocarbon **22**. The advisability for having a *trans* disposition of the vicinal hydroxymethyl functions in these syntheses was revealed when attempted *p*-toluenesulfonation of the *cis*-diol **25** from lithium aluminum hydride reduction of the anthracene–maleic anhydride adduct produced the known cyclic ether **26** (14).

28 29

Somewhat unexpectedly, the catalytic hydrogenation of the diol **27** reduced both double bonds, whereas the corresponding reduction of intermediate **28** (en route to **11**) hydrogenated only the disubstituted olefin. The stereochemistry of **13** and its preceding intermediates are not known but they presumably are the *syn* isomers if reduction proceeded to the least hindered side of **27**. The known *trans*-dimethyl ester **29** (15) provided the required intermediates for hydrocarbon **20** via the route *iii*, Scheme 1 sequence.

The physical, analytical, and spectroscopic data for the 13 new hydrocarbons (**10–22**) supporting the structural assignments are collected along with the unpublished spectra of the seven known compounds **3–9** in Tables 1 and 2. The exocyclic methylene absorption in the p.m.r. spectra all occur as two singlets or very narrow doublets between δ 5.25 and 4.60 p.p.m. and represent the "inside" and the "outside" vinyl protons. From the observed anisotropic effects of the olefinic bond (16) it is likely that the "inside" proton would be the more deshielded. The chemical shift difference in these two protons varies regularly with the size of the -X- bridge in the series **4**, **6**, and **8** and inversely to the carbon–carbon double bond stretching frequency in the i.r. spectra suggesting a systematic influence of geometrical parameters on these spectroscopic measurements. The u.v. spectra of those hydrocarbons not containing any aromatic rings easily divide into the two structure types **1** and **2** and clearly indicate the *cisoid* conformation of the diene moiety (17). We are investigating these geometric–spectroscopic relationships further as well as the Diels–Alder reactivity and electrocyclic chemistry of this series of related hydrocarbons.

Experimental

All melting points are uncorrected. The i.r. spectra were determined on a Unicam SP1000 spectrophotometer as liquid films or as KBr discs. The p.m.r. spectra were recorded on Varian HA100 or A60 instruments in carbon tetrachloride or deuteriochloroform using tetramethylsilane as the internal standard. Mass spectra were taken at 70 eV using a

Starting Materials — Diels–Alder Adducts

(*anti*)-Tricyclo[3.2.2.$0^{2,4}$]non-8-ene-(*trans*)-6,7-dicarbonyl chloride(18); (*anti*)-tricyclo[4.2.2.$0^{2,5}$]deca-3,9-diene-(*trans*)-7,8-dicarbonyl chloride (19); 7-isopropylidenebicyclo[2.2.1]-hept-5-ene-(*trans*)-2,3-dicarbonyl chloride (20); 7-diphenylmethylenebicyclo[2.2.1]hept-5-ene-(*trans*)-2,3-dicarbonyl chloride (21); 1,4-etheno-1,2,3,4-tetrahydronaphthalene-(*trans*)-2,3-dicarboxylic acid dimethyl ester (**24**) (13); pentacyclo[4.2.2.$0^{2,5}$.$0^{3,8}$.$0^{4,7}$]decane-(*trans*)-9,10-dicarboxylic acid dimethyl ester (**29**) (15).

Spiro[cyclopropane-1,7′-[5]norbornene]-(trans)-2′,3′-dicarbonyl Chloride

Fumaryl chloride (36 g) in dry ether (50 ml) was added dropwise over 1 h to an ice-cooled solution of spiro[2.4]-hepta-4,6-diene (22) (19 g) in dry ether (250 ml). The resulting solution was evaporated to a yellow–green oil which showed p.m.r. absorptions (CCl_4) at δ 6.18, m (2H); 3.93, m (1H); 3.16, d ($J = 5.5$ Hz) (1H); 2.90, m (2H); and 0.41 p.p.m., s (4H) consistent with the adduct structure. This oily dichloride was directly reduced to the corresponding diol without further identification (see below).

Preparation of Bis(N,N-dimethylamides)

The diacid chloride (0.1 mol) was dissolved in dry diethyl ether (70 ml) and slowly dropped into an ice-cooled solution of dimethylamine (0.5 mol) in dry diethyl ether (200 ml). After allowing the reaction mixture to come to room temperature, the dimethylammonium chloride was filtered off, washed with ether, and the filtrate evaporated to afford the crude bisamide. This was dissolved in benzene (100 ml) and passed through a bed of neutral alumina (Woelm: activity grade 1; 20 × 2.5 cm). A further 400 ml of benzene were passed through the column and the total eluate evaporated to leave the pure amides. The yields were almost quantitative. The analytical samples were either recrystallized from ether or sublimed.

The following new compounds were prepared by this method. (*anti*)-Tricyclo[3.2.2.$0^{2,4}$]non-8-ene-(*trans*)-6,7-bis-(*N,N*-dimethylcarboxamide), m.p. 122–123.5°.

Anal. Calcd. for $C_{15}H_{22}N_2O_2$: C, 68.67; H, 8.45; N, 10.68. Found: C, 68.42; H, 8.58; N, 10.46.

7-Isopropylidenebicyclo[2.2.1]hept-5-ene-(*trans*)-2,3-bis-(*N,N*-dimethylcarboxamide), m.p. 93.5–94.5°.

Anal. Calcd. for $C_{16}H_{24}N_2O_2$: C, 69.53; H, 8.75; N, 10.14. Found: C, 69.20; H, 8.59; N, 10.28.

The above two bisamides were subjected to catalytic hydrogenation in methanol using 10% palladium-on-charcoal as catalyst. After 1 mol of hydrogen had been absorbed, the catalyst was filtered off and the solvent removed under vacuum. The remaining dihydrobisamides were essentially pure. Analytical samples were recrystallized from ether. (*anti*)-Tricyclo[3.2.2.$0^{2,4}$]nonane-(*trans*)-6,7-bis-(*N,N*-dimethylcarboxamide), m.p. 135–136.5°.

Anal. Calcd. for $C_{15}H_{24}N_2O_2$: C, 68.15; H, 9.15; N, 10.60. Found: C, 68.14; H, 9.33; N, 10.34.

Preparation of the Bisamines

The above amides were individually reduced in diethyl ether using lithium aluminum hydride (1.2 mol/mol bisamide) by refluxing for 10 h. After this time a volume of 20% KOH solution (equal to the weight in grams of bisamide taken) was added dropwise, followed by an equal volume of water. After stirring for 2 h, this mixture was filtered, the precipitate washed well with ether, and the filtrate evaporated to give the crude bisamines as yellow oils. The yields were variable (50–85%) and these products were oxidized directly to the bisamine oxides.

Oxidation of Bisamines

The above bisamines were individually taken up in methanol (500 ml/mol) and 30% H_2O_2 (60 ml) added in 5 ml batches over 1 h. Further 60 ml portions of 30% H_2O_2 were added after 2 and after 6 h and the mixture allowed to stand overnight. The excess H_2O_2 was decomposed by the cautious addition of a small quantity of platinum black, and when no more oxygen was seen to be forming, the mixture was filtered and evaporated under vacuum to give the crude bis(amine-*N*-oxides) as viscous oils. They were directly pyrolyzed without further purification.

Pyrolysis of Bis(amine-N-oxides)

The bis(amine-*N*-oxides) (0.1–0.5 mol), contained in a 1 l round bottom flask connected to a liquid air cooled vacuum trap, were separately heated under vacuum (0.1 mm) using a free flame. Decomposition began from about 80° and heating was continued until all the contents of the flask had decomposed. Considerable charring occurred in most cases. The contents of the trap were extracted with petrol ether (30–60°) and washed three times with water. The combined extracts were dried over anhydrous magnesium sulfate, filtered, and evaporated at 25° (water pump pressure). The residue was taken up in petrol (10 ml) and passed through a short column of alumina (10 × 1.0 cm) using further solvent to wash the column. The total eluate was evaporated and the residue either vacuum transferred or recrystallized from methanol to afford the pure hydrocarbons (see Tables 1 and 2). The yields were 20–40% based on the bisamine taken.

Preparation of Diols and Di-p-toluenesulfonates

The diacid chloride (0.1 mol) in dry diethyl ether (70 ml) was slowly dropped into a stirred suspension of lithium aluminum hydride (0.2 mol) in 1:1 dry diethyl ether/dry tetrahydrofuran (300 ml). After the initial reaction had subsided, the mixture was subjected to reflux for 16 h and the excess hydride decomposed by the addition of a volume of 20% aqueous KOH solution (equal to the weight in grams of dichloride taken) followed by an equal volume of water. After stirring a further 2 h at room temperature, the precipitate was filtered, washed well with ether, and the total filtrate evaporated to afford the crude diol. In some of these reductions, the diol remained complexed to the precipitated alumina and was extracted therefrom with ethanol. If the diol crystallized, analytical samples were prepared by recrystallization from benzene or carbon tetrachloride. If it did not crystallize, it was converted to the di-*p*-toluenesulfonate directly. The yields varied from 50–80%.

In the case of the *trans*-dimethyl esters **24** and **29**, the above reduction was carried out in dry tetrahydrofuran rather than the mixed ether solvent.

The following pure diols were prepared by this method. They all exhibited strong hydroxyl absorption near 3350 cm^{-1} in their i.r. spectra. The di-*p*-toluenesulfonates were prepared by the standard method (*p*-toluenesulfonyl chloride/pyridine, 0 °C, overnight).

trans-7,8-Bis(hydroxymethyl)-(*anti*)-tricyclo[4.2.2.$0^{2,5}$]-deca-3,9-diene, m.p. 93–93.5°.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39. Found: C, 74.80; H, 8.13.

Di-*p*-toluenesulfonate, m.p. 159–160° (methanol).

Anal. Calcd. for $C_{26}H_{28}O_6S_2$: C, 62.38; H, 5.64. Found: C, 62.42; H, 5.73.

trans-2,3-Bis(hydroxymethyl)-1,4-etheno-1,2,3,4-tetrahydronaphthalene, m.p. 142–143°.

Anal. Calcd. for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46. Found: C, 77.57; H, 7.54.

Di-*p*-toluenesulfonate, m.p. 133–134° (methanol).

Anal. Calcd. for $C_{28}H_{28}O_6S_2$: C, 64.10; H, 5.38. Found: C, 64.12; H, 5.46.

The following diols were prepared by the above route but analytical samples were not secured. All showed consistent i.r. and p.m.r. spectra for the structures indicated:

trans-2′,3′-Bis(hydroxymethyl)spiro[cyclopropane-1,7′-[5]norbornene]. Di-*p*-toluenesulfonate, m.p. 120.5–121.5° (methanol).

Anal. Calcd. for $C_{25}H_{28}O_6S_2$: C, 61.45; H, 5.78. Found: C, 61.51; H, 5.88.

trans-9,10-Bis(hydroxymethyl)pentacyclo[4.2.2.$0^{2,5}$.$0^{3,8}$-.$0^{4,7}$]decane. Di-*p*-toluenesulfonate, m.p. 177–178° (methanol).

Anal. Calcd. for $C_{26}H_{28}O_6S_2$: C, 62.38; H, 5.64. Found: C, 62.55; H, 5.85.

trans-2,3-Bis(hydroxymethyl)-7-diphenylmethylenebicyclo[2.2.1]hept-5-ene. Di-*p*-toluenesulfonate failed to crystallize.

Catalytic Reduction of the Diols

The diols were reduced in methanol using 10% Pd-on-C as catalyst and isolated in the usual way. If they did not crystallize they were directly converted to the *p*-toluenesulfonates as above. The following pure diols and di-*p*-toluenesulfonates were obtained. All showed consistent i.r. and p.m.r. data for the structures indicated.

trans-7,8-Bis(hydroxymethyl)-(*anti*)-tricyclo[4.2.2.$0^{2,5}$]-decane, m.p. 82–83°.

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27. Found: C, 73.41; H, 9.97.

Di-*p*-toluenesulfonate, m.p. 178.5–179.5° (methanol).

Anal. Calcd. for $C_{20}H_{32}O_6S_2$: C, 61.88; H, 6.39. Found: C, 61.75; H, 6.51.

trans-2′,3′-Bis(hydroxymethyl)spiro[cyclopropane-1,7′-norbornane] di-*p*-toluenesulfonate, m.p. 110–111° (methanol).

Anal. Calcd. for $C_{25}H_{30}O_6S_2$: C, 61.20; H, 6.16. Found: C, 61.35; H, 6.08.

General p-Toluenesulfonate Elimination Procedure

To the di-*p*-toluenesulfonate (0.01 mol) dissolved in dimethyl sulfoxide (60 ml) was added powdered potassium *t*-butoxide (0.025 mol). The mixture darkened rapidly to deep green–brown and was stirred at room temperature for 5 h. The mixture was poured onto ice-water (200 g) and extracted with petroleum ether (30–60°) (4 × 30 ml). The combined extracts were washed with saturated sodium chloride solution (3 × 100 ml) to remove the dimethyl sulfoxide, dried over anhydrous magnesium sulfate, and evaporated to yield the crude hydrocarbon. The yields varied from 80–95%. The pure hydrocarbons were secured by chromatography in petroleum ether (30–60°) over alumina (Woelm: activity grade 1; 20 × 1 cm column), evaporation of the solvent under vacuum and sublimation or vacuum transfer at 40–140° and 0.01 mm depending on the melting or boiling point of the sample. The physical, analytical, and spectroscopic data are collected in Tables 1 and 2.

The authors wish to thank the National Research Council of Canada and the Department of University Affairs of the Province of Ontario for their financial assistance. Thanks are also due to Dr. B. H. Khouw for the measurement of mass spectra, and to Dr. C. E. Holloway for the measurement of the p.m.r. spectra.

Synthesis and Stereochemistry of Diastereoisomeric 1,3-Dimethylpiperidin-4-ols and Related Compounds

A. F. CASY AND W. K. JEFFERY

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alberta

Received October 8, 1971

The synthesis of *cis* and *trans* 1,3-dimethylpiperidin-4-ols and derived acetate, benzilate, and diphenylacetate esters is described. Configurations and preferred conformations of these derivatives are assigned on the basis of 4-methine and 4-hydroxyl p.m.r. characteristics. Conformational studies of esters of 1-methylpiperidin-3-ol and isomeric 3-tropanols are also described. Epimeric conjugate acids are well defined in 3-acetoxy-1-methylpiperidine hydrochloride as solute in $CDCl_3$.

La synthèse des *cis* et *trans* diméthyl-1,3 pipéridinols-4 et des esters qui en dérivent, acétates, benzylates, et diphénylacétates, est décrite. Les configurations et les conformations privilégiées de ces dérivés sont attribuées en se fondant sur les caractéristiques p.m.r. du méthine-4 et de l'hydroxyl-4. Les études conformationnelles des esters du méthyl-1 pipéridinol-3 et des tropanols-3 isomères, sont également décrites. Les acides conjugués épimères sont bien définis dans le chlorhydrate d'acétoxy-3 méthyl-1 pipéridine dissous dans le $CDCl_3$.

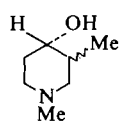
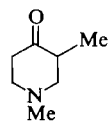
The *cis* and *trans* 1,3-dimethyl-4-piperidyl esters described in this paper were prepared as the steric analogs of cholinolytic esters of tropine and pseudotropine for use in structure-activity studies of drugs related to atropine. The parent piperidinols **1** were obtained by

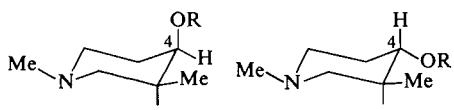


1



2

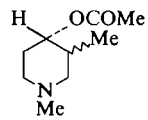
reduction of 1,3-dimethyl-4-piperidone (**2**) under various conditions. These reactions were first reported by Mistryukov (1) who separated the two alcohols by g.l.c. and column chromatography. He assigned configurations *cis* and



cis **3** *trans* **4**

a R=H
b R=COMe

trans to the initially and finally displaced isomers respectively, on the assumption of the *cis* isomer **3***a* having an axial (hindered), and the *trans* **4***a* an equatorial (accessible) hydroxyl function. These assignments are now confirmed by p.m.r. data, as shown later. We sought to achieve separation of the piperidinols **1** in bulk by crystallization of the base hydrochlorides. In this way only the *trans* salt could be separated from a total base mixture obtained from the piperidone **2** and LAH; treatment of the base recovered from the mother liquors with acetyl chloride in hot ethyl acetate, however, gave the *cis* acetate **5** hydrochloride from which



5

the alcohol could be derived after treatment of the free ester with LAH. It was later found that the *trans* ester **5** separated quantitatively during the reaction when the total piperidinols **1** were acetylated leaving the almost pure *cis* isomer in the mother liquors. Isomeric purity of the products was confirmed from their p.m.r. spectra (see below). This procedure was adopted as the best route to the pure *cis* and *trans* piperidinols **1**; it also enabled isomer ratios in the total products of various reductions of **2** to be calculated. The *trans*/*cis* ratio after LAH (2.3) was reasonably close to the reported (1) value of 1.7, while that after aluminum iso-

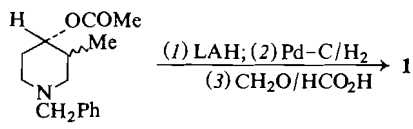
*When signals were broad (> 25 Hz) measurements were only accurate to about ±2 Hz because of difficulty in judging terminal limits of the bands while shallowness of the signal also prevented accurate measurement of $w_{1/2}$ values; greater degrees of accuracy were possible when signals were narrower as in spectra of *cis* derivatives.
†Signal within ring proton band.

propoxide (1.2, reported 0.56) reflects the operation of an equilibration process (2) which the modified procedure adopted here allows (reaction period increased from 3.5 to 9 h). Hydrogenation of **2** in ethanol at atmospheric pressure with platinum dioxide as catalyst gave the *cis* piperidinol **1** exclusively. This result was unexpected since Mistryukov (1) obtained a mixture (*trans*/*cis* ratio 2.2) after reduction under the same conditions but at high pressure. Reduction of the corresponding *N*-benzyl analog of **2** gave a mixture of piperidinols which could not be separated as their hydrochlorides; the *N*-benzyl acetate **6** hydrochlorides, however, could be separated readily by fractional crystallization of the total product derived from 1-benzyl-3-methyl-4-piperidone. The *cis* acetate was converted to the corresponding *N*-methyl-



6

piperidinol **1** in three steps as shown above. Diphenylacetates of the piperidinols **1** were obtained by use of diphenylacetyl chloride–benzene or, in better yield, by a transesterification procedure using methyl diphenylacetate (3). Benzilates of **1** were also made by a transesterification reaction.

The p.m.r. characteristics of the piperidinols **1** and derivatives which confirm **3** and **4** as the preferred conformations, respectively, of *cis* and *trans* isomers are as follows (details in Table 1).

4-Methine Signals. The *cis* signals[1] were about 0.5 p.p.m. lower field of the *trans* resonances in accord with an equatorial 4-H in **3** and an axial proton in **4** (4, 5). In most spectra of the piperidinols **1**, only the *cis* signal was resolvable but both isomeric signals could be identified in pyridine, a solvent which induces downfield shifts in protons adjacent to hydroxyl functions (6).[2] *cis* and *trans* 4-methine signals were well resolved in the spectra of esters in $CDCl_3$ as a result of downfield acylation shifts (7).

Further verification of preferred conformation follows from the broader base widths

[1]Here, "*cis* signals" refers to the resonance of the 4-methine proton in spectra of *cis* **3***a*; this and like abbreviations are used throughout this paper for brevity.

[2]In spectra of total piperidinols **1** in pyridine the two methine signals did not overlap and could be integrated separately; isomer ratios so derived agreed well with those calculated from yields of acetate hydrochlorides.

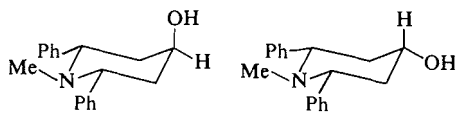
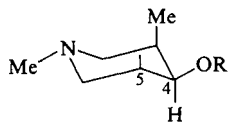
(b.w.) and widths at half height ($w_{1/2}$) of the *trans* methine signals, only the axial signal as in **4** receiving two large $^3J_{a/a}$ coupling contributions. Closest models for **3** and **4** are the 2,6-diphenylpiperidinols, **7** and **8** respectively, whose conformations are fixed by the bulky phenyl substituents (8).



7 4-H b.w. in $CDCl_3$ = 16.4 Hz

8 = 32.4 Hz

In **7** and **8**, methine protons are coupled to 4 vicinal protons whereas only three are involved in the 3-methylpiperidine derivatives. Hence 4-H signal dimensions observed (Table 1) are larger than those anticipated from the model values. In *cis* examples this result is evidence for significant contributions from inverted chair forms such as **9** in which an axial–axial coupling

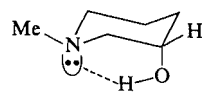


9
(R=H or COMe)

operates between 4-H and 5-H. In *cis* methiodides, populations of such chair forms will be very low as a result of 1,3 diaxial 1-Me/3-Me interactions, and 4-H signal dimensions are significantly reduced in the spectrum of the quaternary salt of *cis* **5**. In the spectrum of *cis* **1** methiodide recorded in DMSO-d_6 allowance needs to be made for HCOH coupling (see below), and the corrected b.w. (16–3.5 = 13.5 Hz) is consistent with that of the equatorial 4-H model **7**.

4-OH Signals. The p.m.r. parameters of hydroxyl proton signals are not normally characteristic because of their sensitivity to solvent, concentration, temperature, and other factors. However, when the OH group is strongly hydrogen bound as in solvent DMSO-d_6, the O*H* resonance position is relatively unaffected by small changes in the factors mentioned above, while ^3J coupling to α-protons may be detected and have stereochemical utility (9, 10). Coupling of this nature is not observed in aminoalcohols except when the basicity of nitrogen is eliminated as in methiodide salts (11).[3] In spectra of isomeric methiodides the *trans* OH signal (doublet δ 4.96) did not differ significantly in chemical shift from the *cis* (doublet δ 4.93) but the assignments **3***a* and **4***a* are confirmed by the larger ^3J values of the *trans* OH doublet (*trans* 5.5, *cis* 4.2 Hz) (10).

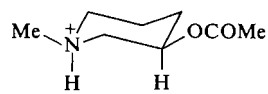
The conformation of 1-methylpiperidin-3-ol and its derivatives is of special interest. Evidence for a significant population of the axial conformer **10** is provided by (*i*) the fact that the



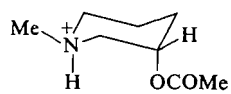
10

width of the 3-H resonance (b.w. 25 Hz, $w_{1/2}$ 14 Hz in CCl_4) is intermediate between that of the methine signals of the axial- and equatorial-OH models **7** and **8** respectively, and (*ii*) demonstration of an intramolecular N--HO bond in dilute solutions of the piperidinol (12). The 3-H signal b.w. of the acetate of 1-methylpiperidin-3-ol was close to that of the piperidinol, but that of the acetate hydrochloride in $CDCl_3$ was distinctly narrower. On closer inspection the signal near δ 5 was seen to be composed of overlapping broad and narrow multiplets typical of axial and equatorial methine signals respectively, a fact which was clearer in the 100 MHz spectrum (Fig. 1.).

In addition, the spectrum showed duplicate *N*-methyl doublets ($H\overset{+}{N}Me$ coupling) and OCO*Me* singlets, of about equal intensities. The results are evidence that epimeric conjugate acids (13*a*) arise when the basic ester is protonated, represented by structures **11** and **12** in their most probable conformations. The narrowness



11 (*cis*)



12 (*trans*)

[3]The HCOH coupling was not seen in the DMSO-d_6 spectra of hydrochloride salts of **1**, hence sufficient base must be present in equilibrium with the conjugate acid to catalyze proton exchange.

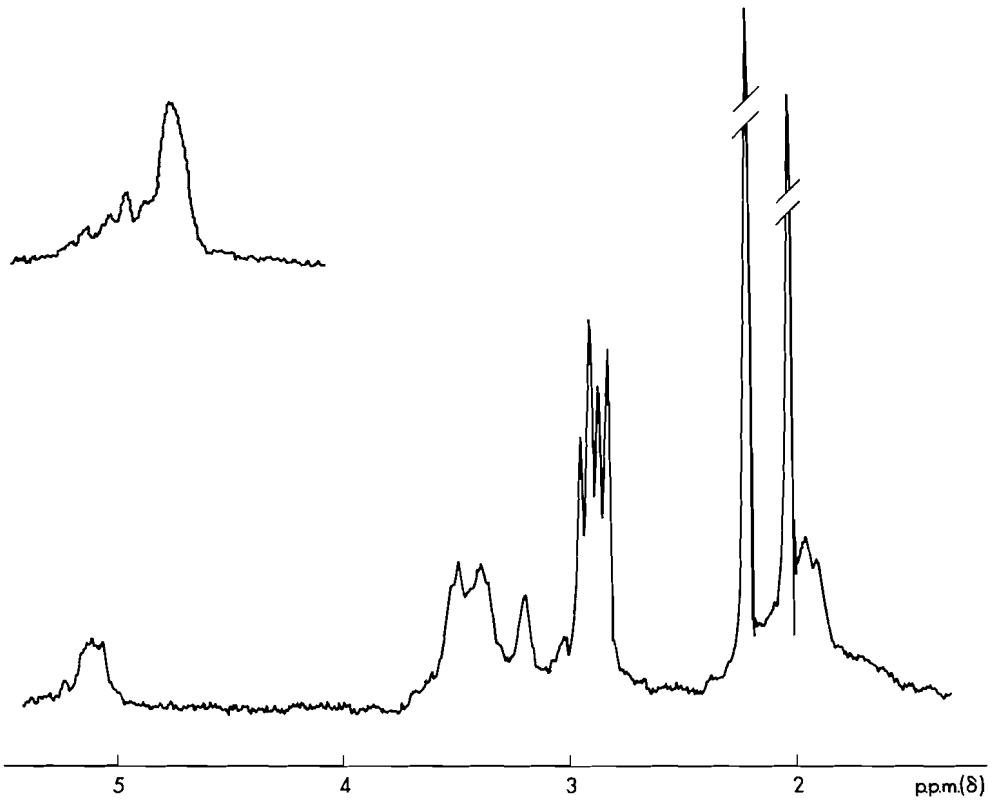


FIG. 1. The 60 MHz p.m.r. spectrum of 3-acetoxy-1-methyl-piperidine hydrochloride in $CDCl_3$. Insert is the 3-methine signal recorded at 100 MHz.

of one of the 3-H resonance bands ($w_{1/2}$ 8 Hz) is evidence against a high population of inverted forms of the *trans* isomer **12** which would have an axial 3-H proton. The lower field OCO*Me* signal (δ 2.23) is assigned to the *trans* isomer since the ester function is close to and will be deshielded by the charged $^+$NH group (13*b*); the *cis* OCOMe resonance (δ 2.03) is close to that of *trans* **4***b* hydrochloride (δ 2.06 in $CDCl_3$), a compound in which the ester substituent is equatorial and removed from the charged basic center. The higher field NMe signal is assigned to **12** on the basis of intensity comparisons and the probability, from studies of pyranose acetates (14), of the *N*-methyl protons being shielded more by an axial than equatorial acetoxy function. Axial and equatorial methine (*H*CO) signals are normally resolved in isomeric piperidinol acetates (see above) and the unusually low field position of the axial proton in the present case (Fig. 1), leading to signal overlap, must be due to its proximity to the deshielding $^+$NH group (see **11**). The relative peak heights of NMe and OCOMe signals in Fig. 1 reveal a small preference for the *trans* isomer **12** which may be stabilized by an

$$^+\text{NH}\text{----}\text{O}=\text{C}\begin{matrix}\diagup\text{O}\\ \diagdown\text{Me}\end{matrix}$$

bond[4] or by transannular interactions between the unit positive charge on nitrogen and the ether oxygen atom (15). The spectrum of the 3-piperidyl acetate salt in DMSO-d_6 showed a 3-H resonance more characteristic of an axial proton (b.w. 28 Hz) and single NMe and OCOMe resonances, hence the *trans* isomer **12** is less favored in this solvent. Evidence for favored axial OCOR conformers was also

[4]The i.r. evidence on this point was inconclusive since (in $CHCl_3$) $\nu_{C=O}$ of both *N*-methyl-3- and -4-piperidyl acetates increased by 15 cm^{-1} when hydrochlorides were examined over the concentration range 0.1–3%.

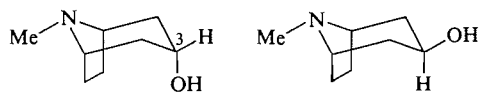
obtained from the spectrum of 1-methyl-3-piperidyl benzilate hydrochloride (3-H b.w. 21 Hz) in spite of the solvent being DMSO-d_6.

Proton magnetic resonance studies of tropine and pseudotropine have established their preferred conformation in solution as **13** and **14** respec-



13 **14**

tively, the piperidine ring being flattened at the C-3 end as a result of the bimethylene bridge linkage (16). It was of importance to determine whether esterification would affect these conformational preferences in view of the pronounced antimuscarinic properties of certain tropyl esters. The 3-H p.m.r. signal dimensions of acetate and benzilate salts of tropine in various solvents and of tropyl (±)-tropate (atropine) in D_2O fell in the range 15–16.5 Hz (b.w.) and 9.5–11 Hz ($w_{1/2}$), and did not differ significantly from those of tropine itself, *e.g.* atropine sulfate in D_2O, b.w. 16.5, $w_{1/2}$ 9.5 Hz. A bulky ester function does not therefore alter the preference of the piperidine ring of tropine for a chair conformation, thus the acyl moiety must be directed away from the bimethylene bridge. As anticipated, 3-methine p.m.r. characteristics of pseudotropyl acetate and benzilate (b.w. ~40 Hz) were very similar to those of pseudotropine itself. Duplication of N—Me signals in the spectra of tropyl and pseudotropyl acetate hydrochlorides in $CDCl_3$ gave evidence of the separate existence of epimeric conjugate acids in this solvent; as Closs found for pseudotropine (17), the minor N—Me signals fell to lower field of the major resonances, *e.g.* pseudotropyl acetate hydrochloride, ν_{NMe} δ 2.8 (major doublet), 2.97 (minor).

The spasmolytic and mydriatic activities of certain basic esters described here will be reported elsewhere.

Experimental

The p.m.r. spectra were recorded on a Varian A-60D spectrometer operating at 40 ± 1° with TMS as internal standard. Bases were recovered from hydrochloride salts by adding excess of aqueous ammonia and extracting with ether (extracts dried with Na_2SO_4). Salts were crystallized from ethanol–ether unless otherwise stated. Melting points were determined using a Thomas Hoover Capillary apparatus and are uncorrected.

Reduction of 1,3-Dimethyl-4-piperidone

The piperidone **2** (25.4 g) in ether (75 ml) was added to a stirred suspension of LAH (8 g) in ether (75 ml) at a rate which maintained gentle refluxing. The mixture was kept at the reflux temperature for 8 h, then cooled and decomposed with ice-water. The ether was decanted, dried (Na_2SO_4), and evaporated to leave the isomeric mixture **1** (21.5 g), b.p. 78°/1 mm, lit. 64°/0.25 mm (18). The base (4.3 g) in ethanol (50 ml) was acidified with hydrogen chloride and diluted with ether when *trans* **1** hydrochloride (2.7 g) separated, m.p. 184–186°, lit. 183–184° (1).

Anal. Calcd. for $C_7H_{16}ClNO$: C, 50.8; H, 9.7; N, 8.45. Found: C, 50.7; H, 9.9; N, 8.7.

The base (2 g) recovered from the mother liquors was heated under reflux with acetyl chloride (3.1 g) in ethyl acetate (105 ml) for 24 h. The mixture, on cooling and storage at 5°, deposited *cis* **5** *hydrochloride* (2.7 g), m.p. 145–146°.

Anal. Calcd. for $C_9H_{18}ClNO_2$: C, 52.1; H, 8.7; N, 6.7. Found: C, 51.9; H, 8.3; N, 7.05.

trans **1** was acetylated in the same way to give *trans* **5** *hydrochloride*, m.p. 208–210°.

Anal. Found: C, 52.2; H, 8.9; N, 6.95.

The *cis* acetate **5** (4 g) was reduced with LAH (1 g) as described above for **2** to give *cis* **1** (2.4 g), isolated as a *hydrochloride*, m.p. 110–111°.

Anal. Found: C, 50.7; H, 9.6; N, 8.1.

The total alcohols **1** (5 g) (derived from **2** and LAH) were acetylated with acetyl chloride (6.4 g) in ethyl acetate (150 ml) in the manner described above. The solution on cooling to room temperature deposited *trans* **5** hydrochloride (5.8 g), m.p. 208–210°. The *cis* salt (2.5 g), m.p. 143–145°, separated from the mother liquors after storage at 5° for 48 h. This procedure was adopted for the separation of isomers from all reduction experiments.

Reduction of **2** with aluminum isopropoxide was carried out by adding the piperidone (10 g) in isopropanol (180 ml) to a solution of the reagent (16 g) in isopropanol (100 ml) contained in a flask fitted with a Vigreaux column. The mixture was heated under reflux for 9 h at a rate to maintain slow distillation; the distillate gave a negative test for acetone (19) after 2–3 h. Most of the solvent was evaporated, the residue hydrolyzed with cold aqueous ammonia and the bases **1** (10 g) recovered by continuous extraction with ether. Catalytic hydrogenation of **2** was achieved by stirring a mixture of the piperidone (1 g), ethanol (150 ml), and platinum dioxide (150 mg) with hydrogen at room temperature and pressure. When uptake of hydrogen ceased the product was filtered and the filtrate evaporated to yield the piperidinols **1** (1 g). No reduction occurred when 10% palladium-on-charcoal was used as catalyst.

The following *methiodides* were prepared (all recrystallized from ethanol):

trans **1**, m.p. 161–163°.

Anal. Calcd. for $C_8H_{18}INO$: C, 35.45; H, 6.6; N, 5.2. Found: C, 35.6; H, 6.7; N, 5.05.

cis **1**, m.p. 208–210°.

Anal. Found: C, 35.5; H, 6.8; N, 5.4.

trans **5**, m.p. 192–193°.

Anal. Calcd. for $C_{10}H_{20}INO_2$: C, 38.4; H, 6.4; N, 4.5. Found: C, 38.4; H, 6.4; N, 4.1.

cis **5**, m.p. 184–185°.
Anal. Found: C, 38.3; H, 6.4.

1-Benzyl-3-methyl-4-piperidyl Acetates
(by M. M. A. Hassan)

The 1-benzylpiperidinol mixture (3 g) from 1-benzyl-3-methyl-4-piperidone and LAH was heated under reflux with acetyl chloride (2 g) and ethyl acetate (20 ml) for 8 h. On cooling the *trans acetate* **6** *hydrochloride* (1.0 g) separated, m.p. 255–256°.

Anal. Calcd. for $C_{15}H_{22}ClNO_2$: C, 63.5; H, 7.8; N, 4.9. Found: C, 63.8; H, 7.8; N, 4.95.

The mother liquors on storage at 5° gave *cis* **6** *hydrochloride* (1.8 g), m.p. 180–182°.

Anal. Found: C, 63.25; H, 7.65; N, 5.1.

cis 1-Benzyl-3-methylpiperidin-4-ol (3.9 g), derived as usual from *cis* **6** and LAH, was shaken with 10% palladium-on-charcoal (390 mg), ethanol (25 ml), and hydrogen at atmospheric pressure. When gas absorption ceased the mixture was filtered and the filtrate evaporated to yield oily *cis* 3-methylpiperidin-4-ol (1.9 g). This base was heated under reflux with formalin (5 ml), formic acid (5 g, 97%), and ethanol (100 ml) for 24 h. The solvents were then evaporated and an ethereal solution of the residue dried (Na_2SO_4). The dry base gave *cis* **1** hydrochloride (2.2 g), m.p. and mixed m.p. 109–111°.

Aromatic Esters of the Piperidinols **1**

The diphenylacetate of *cis* **1** was prepared using diphenylacetyl chloride by the method of Coan *et al.* (20), and was isolated as a *hydrobromide*, m.p. 202–204°.

Anal. Calcd. for $C_{21}H_{26}BrNO_2$: C, 62.4; H, 6.4. Found: C, 62.7; H, 6.4.

It gave a *methiodide*, m.p. 187–188° from ethanol.

Anal. Calcd. for $C_{22}H_{28}INO_2$: C, 56.8; H, 6.0. Found: C, 57.1; H, 6.0.

The diphenylacetate of *trans* **1** was obtained by ester exchange with methyl diphenylacetate following the method of Cannon (3), and was isolated as a *hydrochloride*, m.p. 122–124°.

Anal. Calcd. for $C_{21}H_{26}ClNO_2$: C, 70.1; H, 7.2; N, 3.9. Found: C, 70.0; H, 7.25; N, 4.0.

It gave a *methiodide*, m.p. 243–245° from ethanol.

Anal. Found: C, 57.2; H, 6.15.

Benzilates of **1** were obtained by the tranesterification procedure using methylbenzilate, and the following salts prepared:

trans **1** *Benzilate hydrochloride*, m.p. 183–184°.

Anal. Calcd. for $C_{21}H_{26}ClNO_3$: C, 67.2; H, 6.9; N, 3.9. Found: C, 66.9; H, 7.1; N, 3.6.

cis **1** *Benzilate hydrochloride*, m.p. 266–267°.

Anal. Found: C, 67.1; H, 7.0.

trans **1** *Benzilate methiodide*, m.p. 209–211° from ethanol.

Anal. Calcd. for $C_{22}H_{28}INO_3$: C, 54.8; H, 5.8. Found: C, 55.3; H, 6.1.

cis **1** Benzilate *methiodide*, m.p. 189–190° from ethanol.

Anal. Found: C, 54.9; H, 5.8.

Esters of 1-methylpiperidin-3-ol were prepared by methods described above. The acetate formed a *hydrochloride*, m.p. 143–144°.

Anal. Calcd. for $C_8H_{11}ClNO_2$: C, 49.6; H, 8.3; N, 7.2. Found: C, 49.7; H, 8.2; N, 7.45.

The benzilate gave a hydrochloride, m.p. 217–218° from acetone, lit. 221–223° (21).

Anal. Calcd. for $C_{20}H_{24}ClNO_3$: C, 66.4; H, 6.6. Found: C, 66.45; H, 6.5.

Esters of Tropine and Pseudotropine

Acetates and benzilates of isomeric 3-tropanols were obtained by the described methods. Salts isolated were as follows:

Tropyl acetate hydrochloride, m.p. 209–210°.

Anal. Calcd. for $C_{10}H_{18}ClNO_2$: C, 54.95, H, 8.2. Found: C, 54.6; H, 8.25.

Pseudotropyl acetate hydrochloride, m.p. 218–219° from ethanol.

Anal. Found: C, 54.95; H, 8.24; N, 6.6 (Calcd. 6.4).

Tropyl benzilate hydrochloride, m.p. 242–243°, lit. 239–240° (22).

Anal. Calcd. for $C_{22}H_{26}ClNO_3$: C, 68.15; H, 6.7; N, 3.6. Found: C, 67.95; H, 6.7; N, 3.8.

Pseudotropyl benzilate hydrochloride, m.p. 226–228°, lit. 232° (23).

Anal. Found: C, 67.9; H, 6.6; N, 3.6.

The authors thank the Defence Research Board of Canada for financial support and Dr. M. M. A. Hassan for carrying out reduction experiments on 1-benzyl-3-methyl-4-piperidone.

Steroids and Steroidases. XIII.[1] Illustrations of the Potential of Lithiodithiane–Epoxide Reactions for the Stereospecific Introduction of Substituents into the Steroid Nucleus

J. Bryan Jones and Roger Grayshan

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received August 30, 1971

The reactions of 2-lithio-1,3-dithiane with both 2α,3α- and 2β,3β-oxiranyl-5α-cholestane have been used to prepare both epimers of 2-methyl-3-oxo- and 3-methyl-2-oxo-5α-cholestane. The results obtained illustrate the potential of the dithiane-epoxide route as an attractive and versatile general procedure for the stereospecific introduction of substituents into alicyclic compounds. Furthermore, since for six-membered ring compounds the epoxide ring is opened in a *trans*-diaxial manner, the substituent is introduced into the thermodynamically less stable orientation. Subsequent isomerization to the preferred equatorial isomer is thus possible and accordingly, both epimers are obtainable from the same synthetic sequence.

On a utilisé les réactions du 2-lithio-1,3-dithiane avec le 2α,3α- et le 2β,3β-oxyranyl-5α-cholestane pour préparer les épimères du 2-méthyl-3-oxo- et du 3-méthyl-2-oxo-5α-cholestane. Les résultats obtenus illustrent le potentiel du dithiane-époxyde comme étant une procédure générale attractive et versatile pour l'introduction stéréospécifique de substituants dans les composés alicycliques. De plus, puisque le noyau époxyde, de façon *trans*-diaxiale pour les composés possédant un cycle à six, le substituant est introduit dans l'orientation la moins stable au point de vue thermodynamique. L'isomérisation subséquente en isomère équatorial plus stable est alors possible et à partir de cela, les deux épimères peuvent être obtenus à partir de la même séquence de synthèse.

Canadian Journal of Chemistry, **50**, 810 (1972)

As a result of our interest in the mechanism of action of the $\Delta^5 \rightarrow \Delta^4$-3-ketoisomerase of *P. testosteroni* (1*a*, *b*) we became interested in developing convenient and versatile routes to stereospecifically substituted steroids suitable for "mapping" the active site of the enzyme. Of the general routes surveyed those based on a lithiodithiane–epoxide reaction appeared the most attractive and examples of the feasibility and advantages of this approach have been reported in communication form (1*c*). This note records the experimental and other details omitted from the preliminary communication since it is now apparent that the human resources required to continue the project as originally planned are unlikely to become available in the foreseeable future.

The possibilities of achieving a satisfactory general method for introducing substituents into the steroid nucleus by exploiting the properties of epoxides was drawn to our attention by the previous application of the reactions of Δ^5-epoxides with Grignard reagents (2–5). Disappointingly, this approach to the stereospecific introduction of alkyl groups did not prove to be universally applicable since when the epoxide was not located at a ring junction, ring contraction predominated with both steroidal (6) and cyclohexene oxide (7) reactions.[2] However, the fact that the latter compound underwent the expected ring opening with 2-lithio-1,3-dithiane (9*a*, *b*) indicated that similar reactions could be expected in the steroid field, and accordingly the representative synthetic pathways outlined in Scheme 1 were investigated.

Conversion of 5α-cholestan-3β-ol to its tosylate followed by alumina-catalyzed elimination gave 5α-cholest-2-ene in 60% yield. Epoxidation with peracetic acid proceeded smoothly and a 90% yield of 2α,3α-oxiranyl-5α-cholestane (**1**) was obtained exclusively (10). None of the isomeric 2β,3β-epoxide was detectable in the reaction mixture. On treatment of the 2α,3α-epoxide **1** with 2-lithio-1,3-dithiane in dry tetrahydrofuran for 1 week, *trans*-diaxial opening of the oxirane ring occurred to give 80% of the 2β-dithianyl-3α-hydroxy derivative **2**. Desulfurization of **2** to 2β-methyl-5α-cholestan-3α-ol

[1] For part XII see ref. 1*a*.

[2] This complication can now be overcome by using organocopper analogues of the Grignard reagents (8).

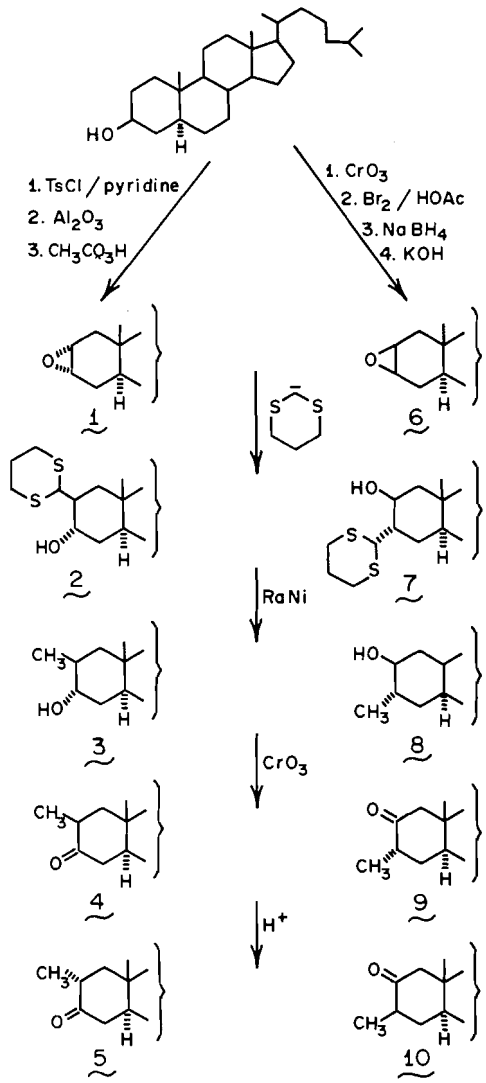

SCHEME 1

(**3**) with Raney nickel in ethanol was readily accomplished (85% yield).

Problems had been anticipated in achieving controlled oxidation of **3** to the axial-methyl ketone **4** without some epimerization occurring during the reaction or work-up procedures. However, the transformation proved surprisingly simple to accomplish and oxidation of the precursor alcohol **3** with Jones' reagent at 0° for 3 min afforded the thermodynamically unstable 2β-methyl-5α-cholestan-3-one (**4**) in quantitative yield. Under these conditions only a trace of the energetically preferred epimer **5** was detectable by t.l.c. analysis. As expected, subsequent isomerization of **4** to the equatorial 2α-methyl epimer **5** was readily effected (also in quantitative yield) by treatment with ethanolic sulfuric acid.

The corresponding reactions in the 2β,3β-epoxide series were equally facile. 2β,3β-Oxiranyl-5α-cholestane (**6**) was obtained in 35% overall yield from 5α-cholestan-3β-ol via the sequence of reactions indicated in Scheme 1 (9*c*). On treatment of **6** with lithiodithiane anion in dry tetrahydrofuran at 0° for 2 days, the β-epoxide ring opened smoothly, again in a *trans*-diaxial manner, to give 3α-dithianyl-5α-cholestan-2β-ol (**7**, 80%). Raney nickel desulfurization of **7** afforded a 70% yield of the 3α-methyl-2β-hydroxy compound **8**. Oxidation of the latter compound without incurring any epimerization at C-3 was effected with Jones' reagent at 0° for 1 min and the thermodynamically less favored 3α-methyl-2-ketone **9** was obtained in quantitative yield. Acid-catalyzed epimerization of **9** to its isomer **10**, in which the methyl group is in the more stable equatorial orientation, presented no problems and the 3β-methyl isomer was again isolated in quantitative yield.

Although pure samples of each **4**, **5**, **9**, and **10** have been obtained previously by other methods (11, 12), the routes to these types of compounds outlined in Scheme 1 represent a significant improvement over any of the synthetic pathways developed earlier. The facility with which reactions were achieved, and the excellent yields obtained at every stage, indicate that the dithiane-epoxide procedure has considerable potential for effecting the stereospecific introduction of a range of substituents into the steroid nucleus. The approach is an attractive one from several points of view. For example, the fact that cleavage of the epoxide ring by dithiane occurs in a *trans*-diaxial fashion ensures the introduction of the substituent into the thermodynamically less stable axial orientation. Subsequent isomerization to the corresponding equatorial compounds will then often be possible thereby enabling both epimers to be obtained from the same synthetic scheme. Furthermore, conversions of the dithiane group into other functions have been well documented (9*a*, *b*) and thus a variety of substitution pat-

terns can be elaborated from a single dithianyl intermediate.

Experimental

The i.r. and n.m.r. data were obtained on CCl_4 and $CDCl_3$ solutions, respectively. All compounds were purified until no impurities could be detected at least by g.l.c. analyses. The t.l.c. analyses were performed with silica gel G and the spots were visualized with iodine vapor or with a ceric sulfate in sulfuric acid spray. The p.l.c. separations were effected on plates up to 20 × 100 cm in size coated with 0.5 mm of silica gel G. All other analytical methods, the instrumentation used, criteria of purity, *etc.* were as described previously (1).

2β-(2-(1,3-Dithianyl))-5α-cholestan-3α-ol (2)

2α,3α-Oxiranyl-5α-cholestane (**1**) m.p. 104–105° (lit. m.p. 105–106° (10)) was obtained in 54% overall yield from 5α-cholestan-3β-ol according to the method of Fürst and Plattner (10). A solution of 2-lithio-1,3-dithiane was then prepared by the slow addition of *n*-butyl lithium (13.8 ml of a 1.6 *M* hexane solution, 22 mmol) to 1,3-dithiane (2.59 g, 22 mmol) in dry tetrahydrofuran (55 ml) at −20° under nitrogen (9*b*). After stirring for a further 1 h, a −20° solution of the 2α,3α-epoxide **1** (1.12 g, 2.9 mmol) in dry tetrahydrofuran (10 ml) was added and the mixture was kept at 0° for 1 week. The reaction solution was then poured into water (500 ml) and extracted with ether (4 × 50 ml). The combined ether extracts were washed with water (2 × 25 ml) and then dried ($MgSO_4$) and evaporated. The yellow gum obtained was purified by p.l.c. using firstly benzene, and then benzene–ether (5:1) as developing solvents. The 2β-(2-(1,3-dithianyl))-5α-cholestan-3α-ol (**2**) obtained was recrystallized from ether–methanol to give plates (1.24 g) m.p. 73–77°; i.r. 1278 and 915 cm^{-1} (dithianyl); n.m.r. δ 0.64 (C-18 CH_3), 0.85 (C-19 CH_3), 4.32 (1H, d, $J = 7$ Hz, $HCS_2C_3H_6$), and 4.26 p.p.m. (1H, m, C-3 H).

2β-Methyl-5α-cholestan-3α-ol (3)

2β-Dithianyl-5α-cholestan-3α-ol (**2**, 320 mg, 0.63 mmol) in ethanol (60 ml) was heated under reflux for 4 h with freshly prepared Raney nickel (3.5 g). The mixture was then filtered and the ethanolic filtrate evaporated. The several component crude product obtained was purified by p.l.c. using benzene as the developing solvent and recrystallization of the major fraction from ether–methanol gave 2β-methyl-5α-cholestan-3α-ol (**3**) as needles (140 mg), m.p. 117–118°;[3] n.m.r. δ 0.64 (C-18 CH_3), 0.82 (C-19 CH_3), 1.03 (3H, d, $J = 7$ Hz, C-2β CH_3), and 3.74 p.p.m. (1H, m, C-3β H).

Anal. Calcd. for $C_{28}H_{50}O$: C, 83.5; H, 12.5. Found: C, 83.2; H, 12.5.

2β-Methyl-5α-cholestan-3-one (4)

2β-Methyl-5α-cholestan-3α-ol (**3**, 70 mg, 0.17 mmol) in acetone (10 ml) was stirred at 0° for 3 min with Jones' reagent (containing 0.05 ml of 8 *N* chromic acid) and the mixture was then immediately poured into water (100 ml). Extraction with ether (3 × 50 ml) followed by evaporation of the dried ($MgSO_4$) extracts yielded 2α-methyl-5α-cholestan-3-one (**4**, 69 mg) containing only a trace (by t.l.c.) of its epimer **5**. Recrystallization of **4** from ether–methanol gave the pure compound as needles m.p. 97.5–98.5° (lit. m.p. 85–92°[3] (13), 96–97° (6)); n.m.r. δ 0.66 (C-18 CH_3), 0.76 (C-19 CH_3), and 1.04 p.p.m. (3H, d, $J = 7$ Hz, C-2 CH_3).

2α-Methyl-5α-cholestan-3-one (5)

Epimerization of 2β-methyl-5α-cholestan-3-one (**4**, 40 mg, 0.1 mmol) was effected by refluxing in ethanol (5 ml) containing 20% aqueous sulfuric acid (0.1 ml) for 2 h. The mixture was diluted with water (200 ml), extracted with ether (3 × 50 ml), and the dried ($MgSO_4$) ether extracts evaporated to give 2α-methyl-5α-cholestan-3-one (**5**, 39 mg). Recrystallization from ether–methanol afforded needles m.p. 118–120° (lit. m.p. 119–120° (11)); n.m.r. δ 0.68 (C-18 CH_3), 1.00 (3H, d, $J = 7$ Hz, C-2α CH_3), and 1.06 p.p.m. (C-19 CH_3).

3α-(2-(1,3-Dithianyl))-5α-cholestan-2β-ol (7)

2β,3β-Oxiranyl-5α-cholestane (**6**) m.p. 87–88° (lit. m.p. 90–91° (9*c*)) was prepared from 5α-cholestan-3-one in 30% overall yield by the method of Corey (9*c*). The 2β,3β-epoxide **6** (200 mg, 0.52 mmol) in dry tetrahydrofuran (2 ml) was then added to a solution of 2-lithio-1,3-dithiane (2 mmol, prepared as described above from 1,3-dithiane (235 mg, 2 mmol)) in dry tetrahydrofuran (5 ml) at −20° under nitrogen. After keeping for 2 days at 0° the reaction mixture was poured into water (100 ml) and extracted with ether (3 × 25 ml). The gum obtained on evaporation of the $MgSO_4$ dried ether solution was purified by p.l.c. using benzene, followed by benzene–ether (9:1) development. The 3α-(2-(1,3-dithianyl))-5α-cholestan-2β-ol (**7**) obtained was recrystallized from ether–methanol to give plates (218 mg) m.p. 158–159°; i.r. 1278 and 915 cm^{-1} (dithianyl); n.m.r. δ 0.64 (C-18 CH_3), 0.99 (C-19 CH_3), 4.21 (1H, d, $J = 8$ Hz, $HCS_2C_3H_6$), and 4.32 p.p.m. (1H, m, C-3α H).

Anal. Calcd. for $C_{31}H_{54}OS_2$: C, 73.4; H, 10.7; S, 12.7. Found: C, 73.7; H, 10.9; S, 12.7.

3α-Methyl-5α-cholestan-2β-ol (8)

3α-Dithianyl-5α-cholestan-2β-ol (**7**, 187 mg, 0.37 mmol) in ethanol (50 ml) was refluxed for 4 h with freshly prepared Raney nickel (2.5 g). Following removal of the nickel by filtration, the ethanolic solution was evaporated and the residual gum was purified by p.l.c. with benzene–ether (9:1) as the developing solvent. The 3α-methyl-5α-cholestan-2β-ol (**8**) obtained (102 mg) was recrystallized from ether–methanol as needles, m.p. 158–159°, n.m.r. δ 0.65 (C-18 CH_3), 0.93 (3H, d, $J = 8$ Hz, C-3α CH_3), 1.00 (C-19 CH_3), and 3.75 p.p.m. (1H, broad s, C-2α H).

Anal. Calcd. for $C_{28}H_{50}O$: C, 83.5; H, 12.5. Found: C, 83.8; H, 12.3

3α-Methyl-5α-cholestan-2-one (9)

3α-Methyl-5α-cholestan-2β-ol (**9**, 83 mg, 0.2 mmol) in acetone (10 ml) was stirred at 0° for 1 min with Jones' reagent (containing 0.059 ml of 8 *N* chromic acid). The mixture was then poured immediately into water (100 ml) and extracted with ether (3 × 50 ml). Evaporation of the dried ($MgSO_4$) ether solution gave 3α-methyl-5α-cholestan-2-one (**9**, 82 mg) which contained none (by t.l.c.) of the 3β-methyl

[3]The m.p. of this compound has previously been reported as 122–128° (13). However, the relatively broad melting range suggests that impurities were present in the latter sample. The ketone m.p. 85–92° derived from this material also appears to have been impure.

Carbon-13 Chemical Shifts of Methylcyclohexanes, Cyclohexanols, α- and β-D-Glucose and their Relation to Carbon Electron Densities from the Extended Hückel and Del Re Theories

N. CYR, A. S. PERLIN, AND M. A. WHITEHEAD
Chemistry Department, McGill University, Montreal 110, Quebec

Received July 28, 1971

An evaluation is made of the extent to which ^{13}C chemical shifts of diastereoisomeric cyclohexane derivatives and pyranoses are related to electron density. Values of the latter for carbon atoms in cyclohexane, methylcyclohexanes, cyclohexanols, and D-glucose are calculated using the Extended Hückel Theory (EHT), with and without iteration, and the Del Re theory. It is shown that when electronegativities of all of the atoms are similar then the theories do not give electron densities which correlate with the ^{13}C chemical shifts; when a strongly electronegative atom, such as oxygen, is present, the electron density differences are greater than the inaccuracy in the calculated individual densities and a fair correlation with ^{13}C chemical shifts is obtained. Iteration is shown to give lower carbon electron densities and a better correlation.

L'importance de la relation entre la densité électronique et les déplacements chimiques du ^{13}C est évaluée dans les dérivés diastéréoisomériques du cyclohexane et les pyranoses. Les densités électroniques sur les atomes de carbone dans le cyclohexane, les méthylcyclohexanes, les cyclohexanols et le D-glucose sont calculées par la "théorie de Hückel étendue" (THE) avec et sans iteration et par la théorie de Del Re. On montre que lorsque les électronégativités de tous les atomes sont semblables, les théories ne donnent pas les densités électroniques qui correspondent aux déplacements chimiques du ^{13}C; par contre lorsqu'un atome fortement électronique, tel l'oxygène, est présent, les différences dans les densités électroniques sont plus élevées que l'imprécision sur les densités individuelles calculées de sorte qu'une bonne corrélation avec les déplacements chimiques du ^{13}C est obtenue. On montre que l'iteration donne les densités électroniques plus faibles pour le carbone ainsi qu'une meilleure corrélation.

Introduction

Carbon-13 n.m.r. chemical shifts in cyclic compounds are influenced strongly by configurational and conformational factors. For example, in the cyclohexane series, most of the ^{13}C chemical shifts of isomers containing an axial group are found at higher fields than the shifts for the corresponding stereoisomers containing only equatorial groups (1–3). Similarly, higher chemical shifts are observed for aldohexopyranoses and aldohexopyranosides when one or more of the substituent groups is axially oriented (4, 5). Furthermore, the interaction energies of substituent groups in both series appear to be substantially reflected in the ^{13}C chemical shifts (3, 5).

In order to explain the ^{13}C chemical shifts, the total electronic structure of the molecule must be determined. Although ^{13}C chemical shifts depend on factors other than charge distributions on the carbon nuclei, it has been shown in a number of instances that charge density is the dominant factor (6–11). Thus, correlations of n.m.r. chemical shifts with charge distributions calculated by the Extended Hückel Theory (12), have been demonstrated for alkanes, halogenated alkanes, and alkenes. However, similar data are not available for alicyclic compounds and the sugars, nor for a comparison of geometric isomers.

Two relatively simple and dependable semi-empirical methods, the Del Re method (13), and the Extended Hückel M.O. method, have been employed in the current study to calculate the electronic structures of such compounds, the latter method being used both with and without iteration.

Calculations

The Extended Hückel Theory

The complete overlap matrix **S** is computed using overlap integral formulae (14) for Slater orbitals. The coulomb integral, H_{rr}, for each atomic orbital is taken to be the Valence State Ionization Potential (VSIP) of that orbital in the molecule, using Cusach's values (15), which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

are dependent on the charge at the nucleus and on the orbital populations of the nucleus considered. The resonance integral, H_{rs}, is given by (16):

$$[1] \qquad H_{rs} = \frac{(2 - S_{rs})(H_{rr} + H_{ss})S_{rs}}{2}$$

where S_{rs} is the overlap between the r-th and s-th atomic orbitals. The variational matrix equation is:

$$[2] \qquad \boldsymbol{HC = SCE}$$

solved by Lowdin's method (17). The solution of this equation provides orbital energies and the LCAO coefficients of the MO, subject to the Hückel approximations (18).

When the theory is made iterative, the second charge input density is corrected using the first input and first output charge densities according to the equation (19):

$$[3] \quad \text{Input } II = \text{Input } I - 0.1\,(\text{Input } I - \text{Output } I)$$

Calculations were carried out until the output charge density and the previous input charge density differed by less than 0.01.

The Del Re Theory

The Del Re method (13) for calculating charge densities has been employed without modification.

Geometries of the Molecules

(a) Cyclohexane and Methylcyclohexanes

The C—C and C—H distances used were 1.53 and 1.09 Å, respectively. All the bond angles were assumed to be regular tetrahedral. The methyl hydrogens were so arranged that the C—H bonds in the methyl groups were gauche to the ring C—C and C—H bonds.

(b) Cyclohexanol and Cyclohexanediols

The bond distances and bond angles used were: C—C = 1.53; C—H = 1.09; C—O = 1.43; O—H = 0.97 Å; ∠CCC = ∠CCH = regular tetrahedral; ∠COH = 107; ∠CCO = 112.5°; and the OH bonds were gauche to the ring C—H bonds.

(c) D-Glucoses

Although accurate X-ray data for the β-D-glucose structure in the crystal are known (20), the geometry was simplified slightly for the present calculations. The coordinates used for the carbons and ring oxygen were as shown in Table 1, whereas the atomic distances were: C—C = 1.53; C—O = 1.43; C—H = 1.06; O—H = 0.97 Å. All of the required interatomic distances were calculated from the atomic coordinates.

Results

(a) Methylcyclohexanes

The charge distributions of the following 15 compounds were calculated by the Extended Hückel method without iterating: cyclohexane; *e*- and *a*-methylcyclohexane; 1,1(*e*,*a*), 1,2(*e*,*e*), 1,2(*e*,*a*), 1,3(*e*,*e*), 1,3(*e*,*a*), 1,4(*e*,*e*), and 1,4(*e*,*a*) dimethylcyclohexane; 1,2,4(*e*,*e*,*e*), 1,2,4(*e*,*e*,*a*), 1,3,5(*e*,*e*,*e*), 1,1,2(*e*,*a*,*e*), and 1,1,3(*e*,*a*,*e*) trimethylcyclohexane.

The plot of charge densities against the observed ^{13}C chemical shifts for each of these compounds showed that there was no consistently close correlation between $\delta_{\text{p.p.m.}}$ and q. Since the second order paramagnetic term, which seems to be the most dominant in the ^{13}C chemical shifts, arises from the unbalance of electrons in orbitals with non-zero angular momentum (21), the carbon p orbital charge densities were also plotted against ^{13}C chemical shifts. Again, however, there was no satisfactory correlation between the carbon 2p orbital populations and the chemical shifts. The Del Re method (13) was also used to calculate charge densities for several of these methylcyclohexanes, but correlation with the chemical shifts was as poor as obtained by the non-iterative EHT.

Cyclohexane, *e*-methylcyclohexane and *trans*-(*e*,*e*)1,2-dimethylcyclohexane were then selected and their charge distributions were calculated by the EHT *with the iterative procedure*. After 8 ~ 10 iterations, the values became consistent

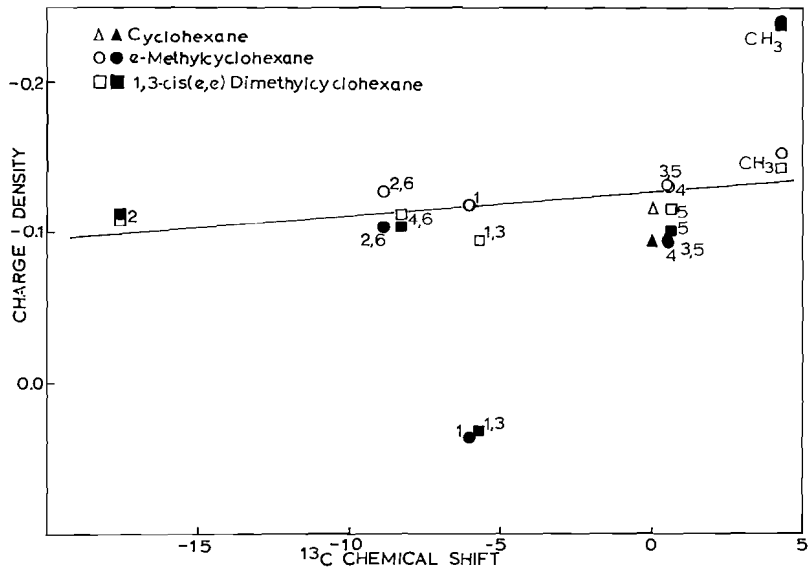

FIG. 1. A plot of ^{13}C chemical shifts (in p.p.m. from cyclohexane) against charge density obtained by the iterative (white) and non-iterative (black) EHT, for cyclohexane, *e*-methylcyclohexane, and *cis*-1,3-dimethylcyclohexane. (No correction has been made to account for *a*-methylcyclohexane to the ^{13}C chemical shift.) The straight line applies to the iterative data.

*From cyclohexane.

within the set limit (+0.01), and the overall charge differences between atoms in a molecule became much smaller. Calculated charges on carbons of the 1,3-dimethyl derivative are given in Table 2 together with their observed ^{13}C chemical shifts and the calculated empirical charge densities obtained by the Del Re method. A comparison of plots of charge densities with and without iteration for all three compounds is shown in Fig. 1. After several iterations a definite improvement in correlation between charge density and ^{13}C chemical shift is seen, although it is still not adequate to differentiate between stereoisomers. However, the iterative EHT is more successful than the Del Re theory in approaching a satisfactory correlation of $\delta_{p.p.m.}$ and q.

(b) Cyclohexanol and Cyclohexanediols

Another cyclohexane system, with one or two oxygen atoms, *i.e.*, cyclohexanol and cyclohexanediols, was then studied. The introduction of oxygen atoms should result in larger charge density differences, therefore decreasing the importance of any uncertainty in the calculation. A plot of calculated charge densities by the iterative EHT method against ^{13}C chemical shifts is shown in Fig. 2, and the values are tabulated in Table 3, together with the results of the non-iterative EHT method,[1] and the results from a Del Re calculation.

As seen from Fig. 2, the general correlation between charge densities and ^{13}C chemical shifts is good. However, the small high field shifts observed for 1,2-*cis*-(*e*,*a*) cyclohexanediol with respect to 1,2-*trans*-(*e*,*e*) cyclohexanediol are not reflected in the results of the present

[1]Iteration not only reduces the overall charge differences between atoms but, in several instances (Table 3), it produces a reversal in the order of charge densities, resulting in the much better correlation that is observed (Fig. 2).

method of calculation; the charge distributions in these two isomers are practically identical.

(c) α- and β-D-Glucose

Another system in which charge distributions were calculated includes α-D-glucose and β-D-glucose. The results are shown in Table 4 and in Fig. 3.

As in the cyclohexanediol series, each carbon charge density is well correlated with its ^{13}C chemical shift (5) within a given molecule as expected from previous calculation by the Del Re method (22, 23). However, the high field shift caused by introduction of the anomeric axial —OH group is not reflected in the calculations.

Conclusions and Discussion

The following conclusions can be drawn from the charge density calculations by the EHT and the Del Re methods:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

(*1*) The calculated charge densities by the EHT on atoms in the cyclohexanol system and in D-glucopyranoses, show an approximately linear correlation with observed ^{13}C chemical shifts.

(*2*) For the methylcyclohexane system where only carbon and hydrogen atoms are involved, the correlation is poor both by the EHT and the Del Re methods.

(*3*) The EHT results show no differentiation between small geometrical variations, such as changing a hydroxyl group from the equatorial orientation to the axial orientation, whereas the change in shielding is clearly detected by the high field shifts of ^{13}C signals.

The failure of the EHT method to differentiate between stereoisomers in which a group changes from equatorial to axial is probably due, at least in part, to the neglect of intratomic repulsion terms, both inter- and intraorbital, in the coulomb integrals H_{rr} making up the basis set of the calculation (24). The neglect of the intraorbital terms gives rise to the large charge density values and consequently high polarities in the C—H bonds when the non-iterative EHT is used, which are only partly offset in the interative EHT, whereas the interorbital repulsions would help to correct inaccuracies in the magnitude of the inductive effects (24). It is to be hoped that semi-empirical all valence electron methods such as the CNDO/BW (25, 26), which include electron–electron repulsion terms will be capable of differentiating between structural isomers.

(*4*) As seen from Tables 3 and 4, the Del Re method gives charge densities comparable with those of the iterative EHT and, unlike the non-iterative EHT, does not overestimate the charge densities. However, those charge densities for the cyclohexanol carbon atoms to which hydroxyl groups are bonded do not correlate with the observed ^{13}C chemical shifts, and this method is not applicable to stereoisomers.

Since EHT calculations generate energy criteria (12), energies for several of the molecules examined here were readily obtained. Particularly pertinent are values for the anomeric D-glucoses, for which some data are already available. Thus, Neely (27) has reported that the non-iterative EHT gives a value of 9 kcal/mol higher energy for α-D-glucose than for the β-anomer. In fact, the α-anomer is the less stable by 0.35 kcal/mol (28). By contrast we find a difference of only 0.5 kcal/mol by the non-iterative procedure and as much as 11 kcal/mol higher after 10 iterative procedures, although in favor of the β-anomer. Since the geometry of the molecules and the values for the matrix elements in Neely's calculation are slightly different from the present ones, *the parameters used in the EHT clearly have a large effect on the calculated energy values.* Among the methylcyclohexanes, the data obtained by non-iterative EHT imply that the introduction of an axial methyl group causes an increase in energy of ~10 kcal/mol over that of its equatorial counterpart, which is at least five times the accepted values (28, 29). Those large discrepancies indicate therefore that energy values derived from EHT data must be appraised with utmost care.

The authors express their thanks to the National Research Council of Canada for financial support, and Mr. E. Koller of the Pulp and Paper Research Institute of Canada for solving sets of linear equations.

Mass Spectra of Some Tropolones and Tropolone Methyl Ethers[1]

J. L. C. WRIGHT,[2] W. D. JAMIESON, S. SAFE, AND L. C. VINING

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received July 13, 1971

The mass spectra and fragmentation patterns of several tropolones and tropolone methyl ethers are reported. Deuteration studies confirmed that elimination of a formyl radical from 2-methoxytropone upon electron impact involves a specific rearrangement of the methoxyl group but sequential loss of carbon monoxide and a hydrogen radical from the ring are competing reactions. They also showed that in a dimethyl ether of anhydrosepedonin elimination of a formyl radical is completely suppressed. In the methyl ether of stipatatonic acid elimination of carbon monoxide is followed by expulsion of carbon dioxide with no loss of 29 mass units. The mass spectrum of [8-^{13}C]-anhydrosepedonin as well as the energy spectrum for sepedonin have been investigated. These results not only provide a plausible account of the fragmentation of tropolones following electron impact but also illustrate the effect of product ion stability in determining which among a number of alternative modes of fragmentation will be more probable.

La spectrométrie de masse et les types de fragmentation de plusieurs tropolones et de tropolones méthyléthers sont rapportés. Les études sur des composés deutérés confirment que l'élimination d'un radical formyl de la méthoxy-2 tropone par l'impact d'électrons implique un réarrangement spécifique du groupe méthoxy mais la perte ultérieure du monoxyde de carbone et d'un radical hydrogène du cycle sont des réactions compétitives. Elles montrent également que dans un éther diméthylé de l'anhydrosepedonine l'élimination d'un radical formyl est complètement supprimée. Dans l'éther méthylé de l'acide stipatatonique, l'élimination du monoxyde de carbone est suivie par l'expulsion de dioxyde de carbone sans perte de 29 unités de masse. Le spectre de masse de la [8-^{13}C]anhydrosepedonine aussi bien que le spectre des énergies pour la sepedonine ont été examinés. Ces résultats non seulement apportent une interprétation plausible de la fragmentation des tropolones suivant l'impact des électrons mais illustrent aussi l'influence de la stabilité des ions produits pour l'identification desquels un certain nombre de modes de fragmentation possibles seraient les plus probables.

The mass spectra of tropone, tropolone, and several derivatives have been examined by Wilson *et al.* (1) who reported that carbon monoxide was eliminated preferentially, leaving a fragment which decomposed as expected for the appropriate phenyl ion-radical. An apparent exception was tropolone methyl ether which gave a relatively intense fragment ion corresponding to the loss of 29 mass units. Budzikiewicz *et al.* (2) suggested that hydrogen transfer in the molecular ion *a* might give the species *b* which would then yield the stable oxonium ion *c* (Scheme 1). While investigating the fungal tropolone sepedonin (**1***a*), which is readily dehydrated (3) and gave a mass spectrum closely resembling that of anhydrosepedonin (**2***a*), we observed fragment ions at *m/e* 178 and 177 which could be attributed to the elimination of carbon monoxide and a formyl radical, respectively. The spectra showed a metastable ion at *m/e* 153.8 for the reaction (*d*, *m/e* 206) → (*e*, *m/e* 178) (Scheme 2) but none corresponding to the loss of 29 mass units from *d*. Instead, a metastable ion at *m/e* 176 accounted for *m/e* 177 as the product of H ejection from *m/e* 178.

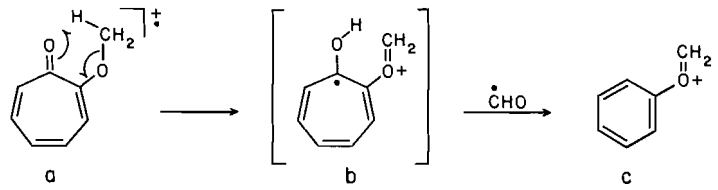
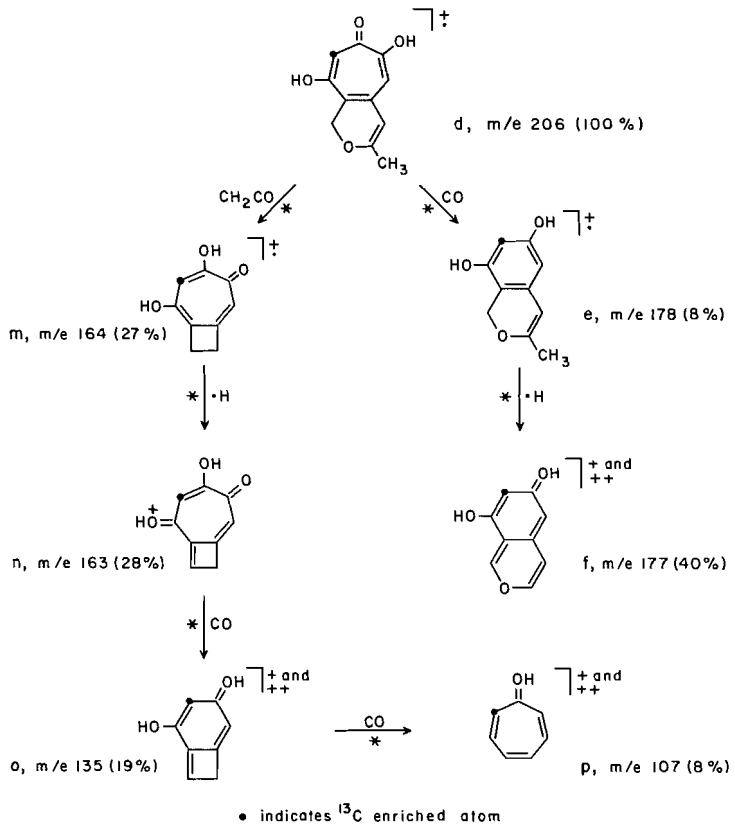


SCHEME 1



SCHEME 2

Mass spectra of the three anhydrosepedonin dimethyl ethers (4) all showed abundant molecular ions at *m/e* 234. In each spectrum the M − 29 peak at *m/e* 205 was substantial (in dimethyl ethers A and B it was the base peak) whereas the M − 28 peak was smaller. However, a strong metastable ion at *m/e* 204 again showed that M − 29 was formed, at least in part, by expulsion of H from M − 28.

To investigate whether loss of 29 mass units in tropolone methyl ethers does, in fact, proceed by the mechanism suggested by Budzikiewicz *et al.* we first reexamined the mass spectrum of 2-methoxytropone. As reported (1) the ion *c* at *m/e* 107 formed by expulsion of CHO from *a* was more intense (27% of base peak) than that of the M-CO ion at *m/e* 108 (11%). Metastable ions for these reactions were observed at *m/e* 84.5 and 85.8, respectively. No change occurred in the relative intensity of peaks in the *m/e* 105–108 region as the electron beam energy was lowered from 70 to 15 eV. To determine the origin of hydrogen in the formyl radical, 2-methoxytropone-d_3 was prepared. Its mass spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

showed a relatively small M-28 peak (*m/e* 111, 9%); the largest peak in the *m/e* 106–111 range corresponded to loss of CDO (*m/e* 109, 23%). Intense metastable ions were observed for both reactions (peaks at *m/e* 88.6 and 85.5, respectively) but none was found at *m/e* 87.1, the value expected for expulsion of CHO from the molecular ion. On the other hand, metastable ions were observed at *m/e* 137 and 109, corresponding to the reactions M → (M − 1) and (M-CO) → (M-CO − 1) respectively, while there was no evidence for similar expulsion of a deuterium atom.

We conclude that the M − 29 ion from 2-methoxytropone can be formed in three ways: (*i*) by loss of a tropolone H, then a CO radical, (*ii*) the reverse of (*i*), and (*iii*) by expulsion of a CHO radical where the H is derived from the methoxyl substituent as suggested by Budzikiewicz *et al.* (2). In each case the reactions are not accompanied by prior H/D equilibration.

The M − 29 ion from the anhydrosepedonin methyl ethers appears to be formed exclusively by successive loss of CO and then a hydrogen radical. The mass spectrum of anhydrosepedonin dimethyl ether A methoxy-d_6 (**2***b*) displayed a molecular ion at *m/e* 240 as well as intense ions at *m/e* 212 (M-CO, base peak) and *m/e* 211 (M-CHO, 36%). In contrast to 2-methoxytropone-d_3 it showed no ion at *m/e* 210 corresponding to loss of CDO. Metastable ions at *m/e* 187.3 and 210 indicated that the molecular ion (*g*, Scheme 3) first expelled CO to give an intermediate (*h*) which ejected H. However, it is unlikely that this H was lost from the tropolone ring, as in the fragmentation of 2-methoxytropone, since aromatization of the dihydropyran moiety would give the stable oxonium ion, *i*. Presumably because this more favorable path to an even electron ion is available the specific H transfer reaction (*a* → *b*) found with 2-methoxytropone is suppressed.

The mass spectrum of the parent anhydrosepedonin (**2***a*) can be accounted for similarly. Elimination of CO and a hydrogen radical produces the abundant ion at *m/e* 177, which was also present as the double ion at *m/e* 88.5. The resorcinol system is relatively stable (5) and again the most likely site of hydrogen elimination is from C-1 in the pyran moiety, giving the oxonium ion (*f*, Scheme 2) in which delocalization of charge among the three oxygens would lead to enhanced stability. Two additional tropolones **1***b* and **3**, derived from sepedonin (3) showed pairs of peaks in their mass spectra corresponding to the loss of 28 and 29 mass units from their molecular ions. In **3** these were similar in intensity, but in **1***b* the fragment at M − 29 was about 4 times as abundant as that at M − 28. Stipatatonic acid (**4**) and its dimethyl ether (**5**), which possess no hydrogens or hydrogen-bearing substituents at C-4 and -5, gave substantial M − 28 but no M − 29 peaks. Instead an intense ion was observed at M − 72, corresponding to loss of CO_2 from the M − 28 fragment. Again formation of a stable oxonium ion is probably responsible for channelling fragmentation of the tropolone ions into a single pathway.

Techniques have been described (6) for operating double-focussing mass spectrometers in a defocussed mode so ion products of "metastable" reactions can be observed directly and with greater sensitivity. They yield data which often establish unambiguously the occurrence of ion decompositions even where these may not

TABLE 1. Transitions detected in the energy spectrum of sepedonin

Voltage at ion current maxima (kV)	Daughter ions detected		Probable parent
	m/e	mass	*m/e*
4.96	67.5	135	163
5.15	164	164	206
"	53.5	107	135
"	53	106	135
5.56	39.5	79	107
"	39	78	107

have led to the usual "metastable-peaks" in the normal mass spectrum of the focussed ion beam. With a mass spectrometer of Mattauch–Herzog geometry, the photographic plate detector can yield high resolution data about daughter ions produced by ion decompositions in that part of the drift tube preceding the energy-focussing sector. Transitions detected by this means in the energy spectrum of sepedonin (Table 1) indicate that expulsion of ketene from the pyran moiety opens an alternative fragmentation pathway. The initial product ion *m/e* 164 is tentatively represented as *m* (Fig. 2). A large peak at *m/e* 43, established by a high resolution study to be mainly the CH_3CO ion, suggests that the C_2H_2O fragment can also be lost as an acetyl ion after H transfer. A metastable ion at *m/e* 162.1 indicates that the ion formed by loss of ketene eliminates a hydrogen radical to yield the ion *m/e* 163 which we represent as *n* although no definitive evidence for this structure was obtained. A group of ions at *m/e* 106–109 is probably similar to that observed by Shannon (7) in the mass spectrum of benzyl alcohol. They generate comparable series of daughter ions and, although depicted as cyclic structures, are likely to be highly unsaturated linear compounds (8).

In support of the fragmentation pathways postulated, the mass spectrum of [8-^{13}C] anhydrosepedonin (9) showed equally enhanced P + 1 peaks for all of the ions described except that at *m/e* 43. Loss of ketene during fragmentation after electron impact was also found to occur with two other natural products, fusarubin (10) and fulvic acid (11), which contain a dihydropyran moiety similar to that of sepedonin.

Experimental

Mass Spectra

Samples were vaporized directly into the ion source of a DuPont/CEC model 21-110B double-focussing mass spectrometer. The accelerating voltage was 8 kV, electron beam energy 70 eV (except as noted otherwise) and resolving power approximately 1:1500. The source temperature, initially below that required to volatilize the sample, was increased rapidly to 170° for sepedonin and anhydrosepedonin, or to 120° for the anhydrosepedonin dimethyl ethers. The spectra of 2-methoxytropone and its deuterated analogue were recorded between 0–25° using a controlled temperature probe (12).

Ion kinetic energy spectral data were obtained by variation of the ion accelerating voltage while the voltage applied to the plates of the energy-focussing sector (and, hence, the energy band passed) remained constant. Photographic plate (Ilford Q2) detection was used to record high resolution data concerning daughter ion species. Separate photoplate records were made for each band in the ion kinetic energy spectrum. For high resolution operation the object slit was adjusted to yield a resolving power of about 1:15 000.

2-Methoxytropone-d_3

Tropolone (122 mg) in dioxane (1 ml) was treated with deuterium oxide (1 ml) for 2 h and evaporated. An ethereal solution of diazomethane-d_2 was prepared by reacting *N*-methyl-d_3 *N*-nitroso-*p*-toluenesulfonamide (500 mg) in a mixture of ether (25 ml) and methanol-*d* (5 ml) with a solution prepared by dissolving clean sodium (200 mg) in deuterium oxide (0.5 ml). Diazomethane was distilled from the mixture and added to the tropolone. After 2 h at 4°, solvent and excess reagent were removed by evaporation.

Anhydrosepedonin Dimethyl Ether A-d_6

Anhydrosepedonin (40 mg) was gently boiled with a suspension of potassium carbonate (60 mg) in dry acetone (4 ml). Methyl iodide-d_3 (200 mg, 99 atom % excess) was introduced, with stirring, in four portions while heating was continued for 5 h. The filtered reaction mixture was evaporated to a yellow gum which, by preparative t.l.c. on silica gel HF_{254} (E. Merck, Darmstadt) with methanol–chloroform (1:20), showed a main component at R_f 0.63. This was extracted from the zone with ethyl acetate and crystallized from benzene as yellow needles (16 mg) identified by m.p. and u.v. absorption spectrum as anhydrosepedonin dimethyl ether A (3).

We are grateful to Mr. J. C. Berrigan and Mr. D. J. Embree for expert technical assistance.

3-Ketoglutarates: Compounds with Mn(II), Co(II), Ni(II), Cu(II), Zn(II), Mg, and Na[1]

F. W. YERHOFF[2] AND D. W. LARSON

Department of Chemistry, University of Saskatchewan, Regina, Saskatchewan

Received September 9, 1971

Where A designates the dinegative 3-ketoglutarate ion and L indicates a trinegative species (likely the enolate ion), the following compounds have been obtained: Na_2A, $NaCuL.XH_2O$, $MgA.XH_2O$, $MnA.XH_2O$, $CoA.XH_2O$, $NiA.XH_2O$. Hydration numbers are uncertain. Stoichiometry of Cu(II) and Zn(II) compounds could not be established. Structures have been assigned on the basis of the infrared spectra. Na_2A appears to be a simple ionic carboxylate. MgA, MnA, CoA, and NiA are assigned a similar structure, with unidentate carboxylate coordination and hydrogen-bonded coordination between the metal and the second carboxylate oxygen (through water). NaCuL is assigned a metal-bridged polymer structure. There is not significant metal interaction with the carbonyl oxygen in any of the proposed structures.

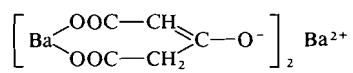
Où A désigne l'ion dinégatif cétoglutarate 3 et L indique une espèce trinégative (probablement l'ion énolate), les composés suivants ont été obtenus: Na_2A, $NaCuL.XH_2O$, $MgA.XH_2O$, $MnA.XH_2O$, $CoA.XH_2O$, $NiA.XH_2O$. Les nombres de molécules d'eau d'hydration sont incertains. La stoéchiométrie des composés Cu(II) et Zn(II) n'a pas pu être établie. Les structures ont été attribuées sur la base des spectres infrarouges. Na_2A paraît être un carboxylate ionique simple. Une structure similaire est attribuée à MgA, MnA, CoA et NiA avec une coordination carboxylate unidentate et une coordination liaison hydrogène entre le métal et le deuxième oxygène carboxylate (à travers l'eau). Une structure polymère pont métallique est attribuée à NaCuL. Il n'y a pas d'interactions métalliques significatives avec l'oxygène carbonyle dans aucune des structures proposées.

Canadian Journal of Chemistry, **50**, 826 (1972)

Introduction

Studies of the decomposition of 3-ketoglutaric acid (acetonedicarboxylic acid) in aqueous solutions, and the observed enhancement of the rate of decarboxylation in the presence of multivalent cations, have led a number of investigators to propose complexes in solution (1, 2). Several structures have been proposed through consideration of reaction mechanisms or by analogy with similar systems. Prue (1) and Hay and Leong (3) have suggested a ketonic chelate structure, involving coordination to the ketone carbonyl and one carboxylate. A bicyclic ketonic chelate, with coordination by both carboxylates and the ketone carbonyl, has been suggested for the Sr(II) complex in solution (4). It has been proposed (5) that the Cu(II) complex in aqueous media is markedly different in character from the complexes with divalent Co, Ni, and Zn.

Few solid 3-ketoglutarates have been reported, and little information on structure is available. Schroeter (6) describes two barium salts, with 1:1 and 3:2 metal-to-ligand ratios; to the latter, he assigns an enolic structure (without giving the basis for his suggestion):



There have been reports of a 2:3 salt with La^{3+} (7), a 1:1 salt with UO_2^{2+} (8), and a light-green crystalline Cu^{2+} salt (9). Larson and Lister (5) prepared compounds with Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and Na^+; but these were not studied extensively. In the present work, these five latter compounds have been studied, as well as those of Mn^{2+} and Mg^{2+}.

Experimental

Reagents and Apparatus

3-Ketoglutaric acid was obtained from Koch-Light Laboratories. A Bendix Model MA-1 (time of flight) mass spectrometer was used for studies of decomposition products. X-Ray diffraction patterns were obtained with a Philips powder camera, using glass capillaries and nickel filtered CuKα radiation.

Infrared spectra were run on KBr discs, containing 0.4–1.0 mg compound and 100–300 mg KBr. Comparison spectra

were obtained with a Beckman IR8 spectrophotometer; the wavenumber data in Table 4 were taken from spectra obtained (for the same KBr discs) with a Beckman IR-12 spectrophotometer.

Synthesis

Divalent metal 3-ketoglutarates were prepared from the metal chloride and/or carbonate. In the chloride synthesis, a cold concentrated solution of 3-ketoglutaric acid (3 *M*) was partially neutralized with NaOH and mixed with a cold concentrated solution of the metal chloride. In the case of copper, precipitation of a bright-green solid occurred immediately; for Co, Ni, Mn, and Zn, the mixture was added to a large excess of cold, well stirred absolute ethanol, which caused precipitation of a solid. (Similar addition to ethanol of the filtrate from the Cu preparation produced a precipitate which, as judged by infrared spectrum and analysis, was identical to the initial aqueous phase product.) In the alternative preparation, powdered metal carbonate was added to a cold aqueous solution of 3-ketoglutaric acid; the mixture was stirred for about 20 min and filtered by suction, the clear filtrate falling directly into excess cold absolute ethanol. As with the chloride preparation, the solid precipitate was filtered off, washed with absolute ethanol and ether, and dried *in vacuo*. The products were purified by preparing a saturated solution in cold dilute (0.05 *M*) 3-ketoglutaric acid and reprecipitating the solid in ethanol.

A non-aqueous preparation was used for the sodium compound: when solutions of sodium and 3-ketoglutaric acid were mixed, a white solid was precipitated from ethanol.

Decomposition Studies

Gases evolved during thermal decomposition of the sodium, nickel, and sodium copper compounds were examined by mass spectrometry. Samples were heated in a glass vacuum apparatus in steps (35 °C in 30 min); accumulated gas pressure was noted for each heating interval, and a sample of the collected gas was admitted to the mass spectrometer. Composition of the gases was determined by comparison of the mass spectra to published standard fragmentation patterns (10, 11). A separate thermogravimetric study was carried out on some of the compounds; samples were heated at rates between 2.5 deg min^{-1} and 5.0 deg min^{-1}.

Results

A noteworthy phenomenon was observed during development of the preparative procedures. Reversal of the solvent change procedure (*i.e.* addition of ethanol to the chloride or carbonate preparative solution) in the cases of Mn, Co, Ni, Zn, and Mg normally produced a liquid product. This second liquid phase varied from a mobile fluid near room temperature to a firm gum near 0 °C. The infrared spectra of these oils (taken of films between salt plates) were markedly similar to those of the solid compounds. The Mn, Co, and Ni oils were intensely colored in the same hue as the corresponding solid. No such liquid phase product was ever observed with copper. It was impossible to obtain a solid sodium compound directly from aqueous solutions by solvent change; however, a viscous yellow fluid, washed several times with absolute ethanol and ether and stored at low temperature, became crystalline.

Analysis and Properties

Elemental composition data are presented in Table 1. Expected values for certain stoichiometric compounds are given for reference. Hydration numbers could not be established; best fit to analytical results varied from $1.4H_2O$ to $2.6H_2O$ for the divalent metal compounds. Stoichiometry of the zinc and copper com-

*Relative intensities visually estimated for most prominent lines.

pounds could not be assigned. The sodium compound prepared in absolute ethanol was observed to be extremely hygroscopic.

The Mg, both Na and NaCu compounds are apparently stable at room temperature; all of the others show evidence of decomposition (gas evolution, and progressive changes in composition with time, consistent with decarboxylation).

Clear X-ray powder diffraction patterns were obtained for the NaCu and both Na compounds; three markedly dissimilar patterns occurred. Attempts to index the lines (Table 2) have only demonstrated that the structures are not likely simple ones of high symmetry. No diffraction lines were observed for the remaining compounds, even after they had been subjected to a variety of grinding and annealing procedures.

Decomposition Studies

All major peaks in the mass spectra of the gaseous decomposition products of the Ni, NaCu, and Na (non-aqueous preparation) compounds heated to 300 °C could be accounted for by the presence of CO_2, $(CH_3)_2CO$, and H_2O. The following mass peaks were used as quantitative measures of the amount of each component in an accumulated sample (12); as determined from standard disintegration patterns (10, 11), they represented approximately equal proportions of the total peak sum for each compound: for CO_2, 44; H_2O, 18; $(CH_3)_2CO$, 43 + 58. The fraction of a component in a collected gas sample (peak height ratio) multiplied by the observed gas pressure yields a semi-quantitative partial pressure (Table 3).

Infrared spectra of the solid residues of the Mg, Mn, Co, and Ni compounds heated to 75, 200, and 300 °C showed similar changes: appearance of broad metal carbonate bands; spectra of residues heated above 350 °C for several hours showed no absorptions in the range 4000–700 cm^{-1}. Residues of the Na and NaCu compounds heated at 300 °C for several hours showed only absorptions corresponding to those of sodium carbonate.

In the thermogravimetric studies the Co and Ni compounds showed similar patterns: a gradual weight loss from room temperature to 150 °C; a sloping plateau between 150 and 230 °C (23–27% weight loss for Co; 25–32% for Ni); sudden rapid weight loss at 235 °C; and constant weight to 300 °C (57% weight loss for Co; 62% for Ni). The NaCu compound samples showed: only slight loss to 135 °C (5%); rapid loss between 140 and 170 °C; a little further weight change when heated above 200 °C (plateau at 49% weight loss).

Discussion

Thermal Decomposition

The thermal decomposition data are consistent with the following decomposition reactions

[1] $Na_2C_5H_4O_5.H_2O \rightarrow CO_2 + (CH_3)_2CO + Na_2CO_3$

Release of equal volumes of CO_2 and $(CH_3)_2CO$ was shown in the mass spectra; the residue was apparently Na_2CO_3. (The sample used was from a non-aqueous preparation; however, water was present in the sample initially, and further hydration occurred on storage.)

†TR: trace.

[2] $2NaCuC_5H_3O_5.2H_2O \rightarrow 2CuO + CO_2 + 2(CH_3)_2CO + H_2O + Na_2CO_3$

Expected weight loss would be 50%; observed, 49%. There is a discrepancy between the two decomposition studies of $NaCuL.XH_2O$; whereas the thermogravimetry showed a rather narrow temperature range of decomposition in one step below 175 °C, the mass spectra suggest two stages, with additional CO_2 being released above 205 °C, after release of $(CH_3)_2CO$ has virtually ceased. It may be that the slower heating in the latter study allowed transient formation of $NaHCO_3$ or a cupric carbonate, which subsequently decomposed, releasing additional CO_2.

[3] $2NiC_5H_4O_5.2H_2O \rightarrow$ "$NiCO_3.Ni(C_4H_5O_3)OH.2H_2O$" $+ 2CO_2 + (CH_3)_2CO$

[4] "$NiCO_3.Ni(C_4H_5O_3)OH.2H_2O$" $\rightarrow$ $2CO_2 + (CH_3)_2CO$ + residue (Ni oxides, hydroxides)

For the nickel 3-ketoglutarate, both thermogravimetry and mass spectra of gaseous decomposition products suggest a two stage decomposition. While the second-stage evolution of CO_2 (see Table 3) could be explained by the intermediate formation of a nickel carbonate, this would not account for the pause in $(CH_3)_2CO$ evolution. This latter phenomenon could have arisen, as suggested in reaction 3, from the transient formation of a nickel acetoacetate compound (the product formulated is intended to present only the gross stoichiometry of the intermediate solids, not the structure). Predicted weight loss for reaction 3, 31%; observed in thermogravimetry, plateau, 25–32%. Predicted weight loss for reactions 3 and 4, 61%; observed, 62%. Thermogravimetry indicates a similar two stage decomposition of cobalt 3-ketoglutarate.

Infrared Data and Structures

Some information on structure can be obtained from an examination of the carboxylate and carbonyl absorptions of the ligand. Carboxylate groups have been shown by X-ray diffraction studies to coordinate with cations in four ways (13): (*1*) ionic, (*2*) unidentate, (*3*) bidentate, (*4*) bridging.

Sodium 3-Ketoglutarate

The spectrum of Na_2A shows a strong absorption at 1709 cm^{-1}, which corresponds to that expected for an uncoordinated ketonic carbonyl group. A very strong absorption at 1602 cm^{-1} can be attributed to a carboxylate antisymmetric stretch. Two strong peaks at 1387 and 1407 cm^{-1} may be due to a split carboxylate symmetric stretch, or the latter may be due to active methylene bending. This spectrum corresponds well in peak positions and relative intensities to that of sodium pyruvate (14), which has been shown by X-ray diffraction to have an ionic structure (15). Correspondence of carboxylate stretching and bending modes with

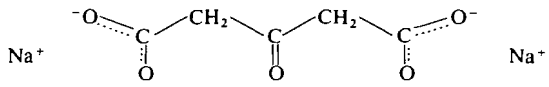
other ionic structures such as sodium malonate (16) is also good. Since the carbonyl seems not to be involved in coordination, a linear configuration is probable:



3-Ketoglutarates of Mg, Mn, Co, and Ni

The similarity of the spectra of these four compounds suggests that they may have the same type of structure; and consideration of the spectra as a group is useful, as trends over a series of metal ions may yield structural information. Peaks in the range 1386 to 1402 cm^{-1} (Table 4) may be assigned empirically to the symmetric carboxylate stretch; and peaks in the range 1587 to 1595 cm^{-1} to the corresponding antisymmetric mode. Peaks between 1703 and 1713 cm^{-1} are likely due to uncoordinated or very weakly coordinated ketonic carbonyls.

With change of metal ion in these four 3-ketoglutarates, symmetric and antisymmetric carboxylate absorptions are observed to shift in the same direction, with a shift to higher frequencies in the order: Co (1387, 1587 cm^{-1}) $\simeq$ Ni (1390, 1588 cm^{-1}) < Mn (1390, 1593 cm^{-1}) < Mg (1402, 1595 cm^{-1}). It has been shown (17) that for unidentate coordination antisymmetric and symmetric frequencies tend to move in opposite directions with change in metal, and that the increase in the antisymmetric frequency appears to follow the Irving–Williams order. Since the increase in frequency noted above is the opposite of the Irving–Williams order, and carboxylate frequencies shift in the same direction, it appears that unidentate coordination (which has been suggested in the proposed structures of the metal complexes in solution) does not occur in the solid state. This conclusion is supported by the persistence of a ketonic carbonyl absorption, which suggests that metal–carbonyl coordination is of little importance.

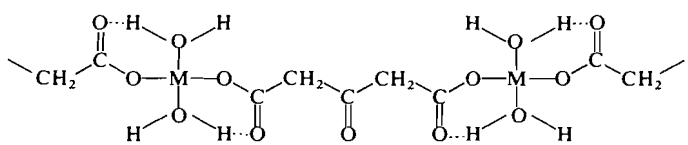
The small changes in carboxylate frequencies with change of cation suggest ionic coordination (as would be expected for the Mg compound); the spectra also indicate approximately equal C—O bonds. Bidentate and bridging structures would give such spectra; but these structures are not found in carboxylates of Mg, Mn, Co, and Ni. A more likely possibility is a structure similar to that of cobalt and nickel acetate tetrahydrates; these have been shown by X-ray diffraction (18) to have approximately equal carboxylate bond lengths (1.29, 1.31 Å). Although only one carboxylate oxygen is coordinated to the metal ion, the other is strongly hydrogen bonded to a water molecule coordinated to the same metal ion. While no comparative infrared studies of these acetates are available, the metal–oxygen distances (2.12 Å) suggest an essentially ionic interaction.

Below is a proposed structure, where M represents Mg, Mn, Co, or Ni. One could speculate on the possibility of a polymeric form for such compounds; it has been noted that these 3-ketoglutarates form apparently amorphous solids, and that unusual liquid phase products can be obtained in their preparation.

Sodium Copper 3-Ketoglutarate

In this spectrum, an absorption at 1448 cm^{-1} and a doublet at 1591 and 1610 cm^{-1} can be assigned to the symmetric and antisymmetric modes for the carboxylate. No ketonic carbonyl absorption is noted, confirming stoichiometric results which indicate a trivalent (enolic) form. This premise is further supported by the presence of a moderately strong absorption at 834 cm^{-1}, which can be attributed to an olefinic C—H in plane deformation, and an absorption at 1525 cm^{-1}, which may be due to the enolic C=C stretch absorption.

A bidentate chelate (with unidentate carboxylate coordination) would be expected to exhibit carboxylate stretch absorptions at frequencies similar to those for copper glycinate (1593, 1387 cm^{-1}) and copper α-alinate (1606, 1386 cm^{-1}) (17). The symmetric absorption frequencies are considerably lower than that



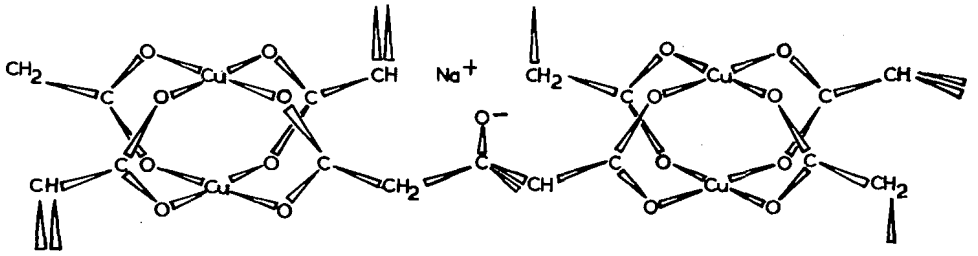


FIG. 1. Metal-bridged structure for NaCu 3-ketoglutarate.

assigned here (1448 cm^{-1}) for the NaCu compound. In copper malonate the symmetric absorption appears at an even lower frequency, 1371 cm^{-1} (19). There is much better agreement with frequencies noted in copper carboxylates known to have bridged structures; two examples are copper succinate (1608, 1432 cm^{-1}) (19), and levulinate (1600, 1450 cm^{-1}) (20).

Coordination between copper and the enol oxygen would be unlikely in a bridged structure (for steric reasons). The metal-bridged polymer structure in Fig. 1 suggests a free enolate. Assignments of free enolate absorptions in sodium (1360 cm^{-1}) and potassium (1408 cm^{-1}) acetylacetonates (21) are matched here by absorptions at 1385 or 1404 cm^{-1} (although the intensity of these peaks is rather low).

If the proposed structure for sodium copper 3-ketoglutarate is accepted, there remains the question of the driving force toward enolization. Perhaps an enolic form in the solid arises from enolization in solution. Although no structural work is available, it has been suggested (5) that the enolic form of the ligand is the primary complexing species with copper in aqueous solution. This could be due to preferential complexing of the enolic form of the ligand (with a subsequent shift in the keto–enol equilibrium), or to a direct interaction of copper with the ligand in a way which favours enolization.

It is interesting to note that a compound $CuA.XH_2O$ does not seem to occur, nor was it possible to prepare Na_3L; the occurrence of a trivalent 3-ketoglutarate species appears to be associated only with Cu(II). (Stoichiometry has not been assigned for the Cu and Zn compounds (see Table 1); the difficulty lies in the very low carbon-to-metal ratios, which preclude a simple formula $MA.XH_2O$. The infrared spectra are presented only for comparison.)

Summary

Compounds of 3-ketoglutaric acid with Mg, Na, and a number of divalent transition metals have been prepared. Where A designates the dinegative 3-ketoglutarate ion and L indicates a trinegative species, the following stoichiometries are indicated: $NaCuL.XH_2O$, $MgA.XH_2O$, $MnA.XH_2O$, $CoA.XH_2O$, $NiA.XH_2O$; hydration numbers are uncertain, but $X \simeq 2$.

The infrared spectra have been used to assign structures. A simple ionic structure is proposed for Na_2A. A modified ionic structure is proposed for the Mg, Mn, Co, and Ni compounds with a water molecule linking the metal ion to one of the carboxylate oxygens. $NaCuL.XH_2O$ is assigned a metal-bridged structure with a free enolate group.

Studies in Solubility Parameter Theory for Mixed Solvent Systems[1]

AVIJIT PURKAYASTHA AND JOHN WALKLEY[2]

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received August 9, 1971

Data are presented for the saturation solubility and partial molal volume of iodine in a mixed benzene–cyclohexane solvent and for the saturation solubility of stannic iodide in the same solvent mixture. A successful interpretation of these data in terms of solubility parameter theory is possible if we define an effective volume fraction term. This term reflects the immediate solvent environment of the solute molecule with the preferential solvation of the solute by one of the solvent molecules. Data for iodine in a mixed carbon tetrachloride–benzene solvent mixture and for iodine in a carbon tetrachloride–perfluoroheptane mixture are also interpreted in terms of the proposed theory.

Les résultats relatifs à la solubilité à saturation et au volume molaire partiel de l'iode dans un solvant mixte benzène–cyclohexane, ainsi que ceux relatifs à la solubilité à saturation de l'iodure stannique dans le même mélange de solvants, sont présentés. En fonction d'une théorie de paramètres de solubilité, une bonne interprétation de ces données est possible à condition de définir un terme de fraction de volume réel. Ce terme réflète l'environnement immédiat des molécules du soluté par le solvant ainsi que la solvatation préférentielle du soluté par l'une des molécules de solvant. Les résultats relatifs à l'iode dans un mélange de solvants tétrachlorure de carbone–benzène et ceux de l'iode dans un mélange de solvants tétrachlorure de carbone–perfluoroheptane, sont également interprétés en fonction de la théorie proposée.

Canadian Journal of Chemistry, **50**, 834 (1972)

Introduction

Many studies have been done on the correlation of the behavior of non-electrolyte solutions with the molecular parameters of the pure components and, in general, the theories developed have been of reasonable predictive value (1). Few studies have been done on systems of more than two components though the extension of present theories appears fairly simple. A particularly useful field of study is that of a dilute solute in a two component non-polar solvent mixture. Such systems, however, appear complicated by the preferential solvation of the solute molecule by one of the solvent species. To explain the dependence of the equilibrium constant for the iodine–pyridine charge transfer complex upon the solvent used, Christian was required to assume some degree of preferential solvation (2). A similar assumption is required to explain the diffusion coefficient values of iodine in various alcohol–hydrocarbon mixed solvents. Nakanishi *et al.* (3) proposed a mechanism that assumed the solute iodine molecule to spend more time in an environment preferentially composed of the energetically favored solvent molecule. An earlier study of the partial molal volume of bromine in mixed CCl_4–*c*-$C_4Cl_2F_6$ solvent by Smith and Walkley (4) showed the preferential solvation of the bromine by the CCl_4. This was such that at even a very low mole-fraction composition of CCl_4 in the solvent mixture the partial molal volume of the dissolved solute fell from its value in the pure chloro–fluorocarbon to a value similar to that in pure CCl_4. Our present study is concerned with the interpretation of the saturation solubility and partial molal volume of simple dilute solutes in two component non-polar solvents. Data are measured over the complete range of solvent composition. Recognizing the success of Hildebrand's solubility parameter theory in interpreting the saturation solubility behavior of dilute solutes in single component solvents we have chosen to extend his theory (5) to our two component solvent data. We have extended the theory by attempting to take into account the "preferential" nearest neighbor environment of the solute molecules. The theory is remarkably successful and offers an approach to the nearest neighbor environment which is necessary to the further interpretation of the diffusion and spectroscopic studies of these systems.

Experimental

The solvents (C_6H_6 and $c\text{-}C_6H_{12}$) were spectroscopic grade solvents and were used without further purification. The preparation of saturated iodine and stannic iodide solutions was by the same technique as described earlier by Walkley and Vittoria (6). The iodine concentration in the saturated solution was determined spectroscopically at 520 mμ and that of stannic iodide at 360 mμ. Aliquots from the saturated solution were diluted in the ratio 1:250 with cyclohexane before optical density measurements were made. Saturation solubility measurements were made over the complete range of composition of the solvent mixture. All data were measured at 25.00 ± 0.01 °C. For those experiments involving stannic iodide, photochemical decomposition of SnI_4 in solution was avoided by using black-painted dissolution cells.

The partial molal volume of iodine in the mixed solvent was measured using the dilatometric technique described by Hildebrand and Glew (7). The dilatometer was of 150 ml capacity and the capillary of 2 mm internal diameter. No temperature fluctuation of the liquid level in the capillary arm was observed and the scatter of individual experimental data allowed the partial molal volumes to be measured to a precision of 0.8%.

Results

Saturation solubility (mole fraction x_2^M) and partial molal volume ($\bar{V}_2$ cc mol^{-1}) of iodine in the mixed $C_6H_6 - c\text{-}C_6H_{12}$ solvent over the complete range of composition are given in Tables 1 and 3. In Table 2 saturation solubility

data for SnI_4 in mixed $C_6H_6-c\text{-}C_6H_{12}$ solvent are presented.

Discussion

The solubility parameter theory equation expressing the saturation solubility of a solute (x_2) in terms of its ideal solubility (a_2^i) and the δ-parameters of the solvent and the solute (δ_1 and δ_2) has been well tested (5). With the usual notation this equation is

$$[1] \qquad \ln a_2^i = \ln x_2 + \frac{\Phi_1^2 V_2^0}{RT}(\delta_2 - \delta_1)^2$$

Generally, for any chosen solute (of known δ_2 value) the equation is tested by comparing the experimental δ_1 value (for a range of solvents) to the thermodynamic value ((molar energy of vaporization/molar volume)$^{1/2}$). For a wide range of solute–solvent systems this self-consistency has been shown to exist (8).

For systems in which a solute is dissolved in a binary solvent mixture (of components *1* and *3*), it has been suggested (5) that eq. 1 could be rewritten as

$$[2] \qquad \ln a_2^i = \ln x_2^M + \frac{\Phi_M^2 V_2^0}{RT}(\delta_2 - \delta_M)^2$$

where

$$[3] \qquad \delta_M = \Phi_1\delta_1 + \Phi_3\delta_3$$

and Φ_M the volume fraction of the solvent mixture, *i.e.* $\Phi_1 + \Phi_3 \to 1$, $\Phi_2 \to 0$. In Tables 1 and 2 we make a comparison of δ_M(experimental) and the δ_M value given by eq. 3. It is seen that the comparison is bad. The experimental data allow δ_M, δ_1, and δ_3 to be calculated to an accuracy of 0.1% for a given value of δ_2. To better emphasize the role of δ_M we derive from eq. 1 and 2 the relationship

$$[4] \quad [\ln a_2^i - \ln x_2^M]^{1/2} = (\ln a_1^i - \ln x_2^3)^{1/2} - (\ln a_1^i - \ln x_2^3)^{1/2}\Phi_1\left(\frac{\delta_1 - \delta_3}{\delta_2 - \delta_3}\right)$$

where x_2^3 is the saturation solubility of solute (*2*) in the pure solvent component (*3*). We use eq. 4 for those systems for which $\Phi_2 \to 0$, *i.e.* $\Phi_1 + \Phi_3 = 1$. In the derivation of eq. 4 the dependence upon the solvent composition, Φ_1, arises solely through the definition of δ_M by eq. 3. The linear relationship expected between Φ_1 and the experimental quantity $(\ln a_2^i - \ln x_2^M)^{1/2}$ does not, however, depend upon the assumption of actual δ_i values. From the linear relationship expected of eq. 4 the intercept at $\Phi_1 = 0$ and the ratio of slope/intercept may be compared to experimental values. In Figs. 1 and 2 we plot $(\ln a_2^i - \ln x_2^M)^{1/2}$ *vs.* Φ_1 using our data for the systems $I_2-C_6H_6-c\text{-}C_6H_{12}$ and $SnI_4-C_6H_6-$

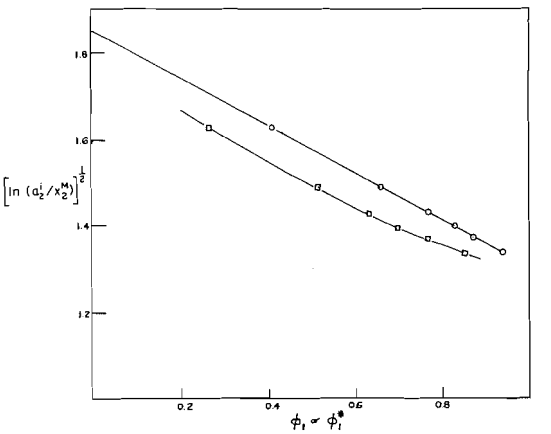

FIG. 1. Iodine in benzene–cyclohexane solvent, $[\ln (a_2^i/x_2^M)]^{1/2}$ plotted as a function of benzene volume fraction (□) and as a function of benzene "effective volume fraction" (○). Data at 25.0 °C.

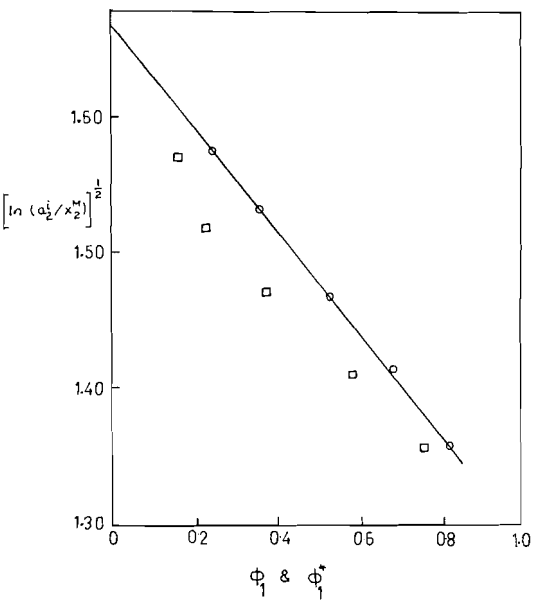

FIG. 2. Stannic iodide in mixed benzene–cyclohexane solvent; $[\ln (a_2^i/x_2^M)]^{1/2}$ plotted as a function of benzene volume fraction (□) and as a function of the benzene effective volume fraction (○). Data at 25 °C.

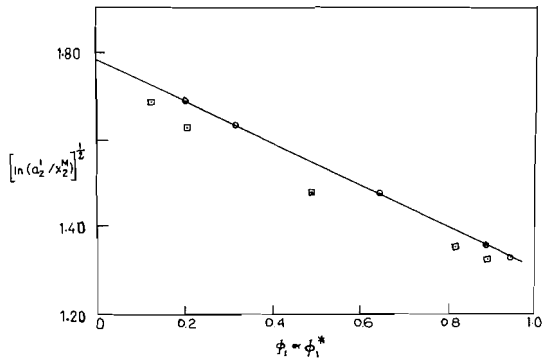

FIG. 3. Iodine in a mixed benzene carbon tetrachloride solvent; $[\ln (a_2^i/x_2^M)]^{1/2}$ plotted as a function of benzene volume fraction (□) and as a function of the benzene effective volume fraction (○). All data at 25 °C.

c-C_6H_{12} and in Fig. 3 using the data of Wood *et al.* (9) for the I_2–C_6H_6–CCl_4 system. It is seen that for all three systems the expected linearity is not observed.

From the graphical dependence discussed above and from the direct comparison of δ_M values it would appear that the definition of δ_M by eq. 3 is not acceptable. Following the suggestion that the immediate solvent environment is not reflected by the bulk solvent composition but requires the assumption of the preferential "solvation" by one of the solvent components we have attempted to define an "effective volume fraction", Φ_1^*, reflecting this solvation, and so define

$$[5] \qquad \delta_M = \Phi_1^*\delta_1 + \Phi_3^*\delta_3$$

Christian (2) suggested that the relative number of each of the two solvent molecules in the solute nearest neighbor environment could be regarded as a Boltzmann weighting term involving the heat of solution of the solute in each of the pure solvents. If we use this approach to calculate an "effective volume fraction" term then the comparison of experimental and theoretical δ_M values is no better than that found assuming the immediate solute environment to be represented by bulk solvent mixture composition.

The solvent environment of a solute molecule can be discussed in a simplistic way using the arguments of the quasi-lattice theory (5). For very dilute solutions Hildebrand has shown that this model leads to an expression for the heat of solution of the solute identical to that found from solubility parameter theory. Following this approach for those systems in which the solubility of the solute in the binary solvent mixture is small the nearest neighbor environment may be defined as

$$[6] \qquad \frac{\Phi_1^*}{\Phi_3^*} = \frac{\Phi_1(\delta_2 - \delta_3)^2}{\Phi_3(\delta_2 - \delta_1)^2} \qquad (\text{where } \Phi_1^* + \Phi_3^* = 1)$$

In eq. 6 the effective volume fraction terms are related to the bulk volume fraction terms by the inverse of the heats of mixing of the solute in each of the pure solvents. Using eq. 6 to define Φ_1^* and using eq. 5 to define δ_M it is easily shown that eq. 4 can be reformulated to require a linear relationship to exist between $(\ln a_2^i - \ln x_2^M)^{1/2}$ and Φ_1^*. In Figs. 1–3 such a linearity is seen to exist for each of the systems considered. The intercept values at $\Phi_1^* = 0$ and the expected values of $(\ln a_2^i - \ln x_2^3)^{1/2}$ are 1.663, 1.655; 1.840, 1.835; 1.785, 1.80; respectively for the three systems considered. Furthermore the ratio of slope/intercept for each of the three systems is found self-consistent with those δ values used in evaluating the Φ_1^* terms and satisfying the saturation solubility of the solute in each of the pure solvents (Table 3).

Benzene was chosen as one of the solvent components for the iodine solute study as it was anticipated that the well known charge transfer (10) interaction between them should make benzene the energetically preferred nearest neighbor. It is seen that the preferential solvation still exists when stannic iodide is made the solute and for this system no specific solute–solvent interaction occurs. As a final test of our $(\ln a_2^i - \ln x_2^M)^{1/2}$ *vs.* Φ_1 (or Φ_1^*) relation we plot in Fig. 4 the theoretical lines for the system iodine–CCl_4–n-C_7F_{16} (4). Only two data points exist for this system and we compare them to the theoretical lines calculated from the known solubility of iodine in the pure perfluorocarbon and the accepted δ values (5). The wide difference in the solute parameter (14.1) and that of one of the solvent pairs (6.0) puts a considerable strain upon the proposed theory. As may be seen, however, the data points lie on that line drawn using the effective volume fraction (Φ_i^*) term.

As a further test of the acceptability of the proposed "effective volume fraction" term we examine the partial molal volume data for

iodine in the mixed benzene–cyclohexane solvent. In terms of the mixed solvent δ_M parameter we may reformulate the usual equation relating the partial molal volume of the solute ($\bar{V}_2^M$) to the isothermal compressibility of the solvent β_M and the solubility parameters of solute and solvent as

$$[7] \qquad \bar{V}_2^M - \bar{V}_2^0 = n_M \beta_M V_2^0 (\delta_2 - \delta_M)^2$$

where V_2^0 is the reference volume of the solute (5). We can assume a value of unity for n_M (the ratio of the internal pressure to the cohesive energy density (5)) and define β_M in terms of the isothermal compressibility of the pure solvents without any loss in the predictive value of eq. 7 as, $\beta_M = \Phi_1\beta_1 + \Phi_3\beta_3$. Since eq. 7 cannot be rearranged allowing $\bar{V}_2^M$ to be directly analyzed in a manner emphasizing the dependence on Φ_1 or Φ_1^* we compare in Table 4 the experimental $\bar{V}_2^M$ values with those calculated from eq. 7 using either the bulk volume fraction or effective volume fraction definition of δ_M. It is obvious that an acceptable comparison with experiment is found only with the use of the effective volume fraction terms.

We have made experimental studies for systems for which in eq. 2 the approximation that $\Phi_M \rightarrow 1$ cannot be made, *e.g.* the naphthalene–CCl_4 – *c*-C_6H_{12} system as reported by Heric and Yeh (11). For these systems the "effective volume fraction" approach is again found necessary for the interpretation of the data. These systems often involve a maximum in the saturation solubility value (*i.e.* those for which $\delta_1 < \delta_2 < \delta_3$) but as the formulation of the saturation solubility equation is more complex they will be dealt with in another paper. It is clear that within its limitations solubility parameter theory may be extended so that the solubility thermodynamic properties of dilute solutes in two component solvent mixtures can be predicted.

Phase Relationships in the Calcium Chloride – Calcium Carbide System

J. F. MAILLOT

Department of Engineering, University of Moncton, Moncton, New Brunswick

AND

D. R. MORRIS

Department of Chemical Engineering, University of New Brunswick, Fredericton, New Brunswick

Received July 19, 1971

The system calcium chloride – calcium carbide has been examined by thermal analysis. The depression of the freezing point of $CaCl_2$ by CaC_2 is ideal. The system is a eutectic one, with a eutectic point at 90 mol% $CaCl_2$ at 740 °C. Carbon is believed to be present in the electrolyte as the so called acetylide ion C_2^{2-}. The melting point of pure $CaCl_2$ was found to be 775.2 ± 0.6 °C.

Le système chlorure de calcium – carbure de calcium a été examiné par analyse thermique. La dépression du point de congélation de $CaCl_2$ par CaC_2 est idéale. Le système est un eutectique, avec un point eutectique correspondant à 90% de moles de $CaCl_2$ à 740 °C. Le carbone est présent dans l'électrolyte sous forme d'ion acétylure C_2^{2-}. Le point de fusion de $CaCl_2$ pur est de 775.2 ± 0.6 °C.

Introduction

The solubility of calcium carbide in a number of fused salts was examined for the first time by Barber and Sloan (1) in 1961. Using the technique of equilibration and quenching they reported the solubility of CaC_2 in $CaCl_2$ to be 0.103 mole fraction at a temperature of 820 °C.

This system was used more recently by Hawkes and Morris (2) as an electrolyte in a galvanic cell designed to establish the activity of carbon in solid iron–carbon alloys.

In view of the importance of the $CaCl_2$–CaC_2 system in many of the projects derived from the above study it has been necessary to determine the relative solubility of these compounds. In this paper we present a partial phase diagram of the system determined by thermal analysis.

Experimental

Materials

The calcium carbide was prepared by direct synthesis from calcium and carbon following a technique developed by Aksaranan (3). After synthesis the purity level was 96–99 weight %; the principal impurity was calcium oxide. Dried reagent grade calcium chloride from Fisher Scientific Company was used in the experiments. The bulk of the water (about 25 weight %) was removed in a premelting stage while the purification stage was used to remove the calcium oxide hydrolysis product, according to the reaction

$$CaO + 2HCl \rightarrow CaCl_2 + H_2O$$

Apparatus and Procedures

The purification furnace and the operating procedure for the purification of $CaCl_2$ have been previously described by Kojima, Whiteway, and Masson (4) for the purification of inorganic fluorides. Anhydrous hydrogen chloride gas was bubbled through the molten chloride for 2 to 7 h, followed by dry argon. The freezing points of the mixtures were determined by the method of thermal arrests with the apparatus described previously by Bell and Masson (5), modified to enable evacuation of the furnace envelope. Melts were held in steel crucibles, 1 in. in diameter and 1.5 in. deep, equipped with a re-entrant well, which housed the junction of the thermocouple. Approximately 11 g of mixture were used in each experiment. The temperature was measured with a Pt/Pt – 13% Rh thermocouple calibrated periodically against copper, aluminum, and zinc, supplied by the U.S. National Bureau of Standards. A Texas potentiometric recorder with a full chart range of 2 mV was used to measure the electromotive force (e.m.f.). The recorder was calibrated after each series of measurements by a Leeds and Northrup potentiometer. The temperature of the furnace was controlled by a Honeywell program controller, actuated by a second thermocouple located close to the furnace winding. A linear cooling rate of 1 °C/min was used.

The use of steel crucibles and the blending of the anhydrous salts prior to melting gave homogeneous melts. Reproducibility of the melting points determination was ± 1.5 °C. Some experiments were conducted in graphite crucibles; these were unsatisfactory due to leakage of the melt through the pores of the graphite.

Analysis

The analytical procedure to determine the concentration of the principal constituents of the solution has been described by Aksaranan *et al.* (6). This is a development of the method proposed by Edwards (7) and used later by Morris and Harry (8). A weighed sample of the solidified calcium carbide – calcium chloride solution was hydrolyzed in a closed system. A sample of the gases thus liberated was analyzed using a gas partitioner which was calibrated previously with hydrogen–acetylene mixtures. This method permitted the direct analysis of the calcium metal content

and the calcium carbide. Total chloride and free oxide were determined by conventional analysis of the hydrolyzed sample.

Results and Discussion

Equilibrium between a pure solid A_rX_s (component 1) and a liquid mixture is described by the equation (9),

$$[1]\quad \frac{d \ln a_1}{d(1/T)} = \frac{d \ln N_A^r N_X^s}{d(1/T)} + \frac{d \ln \gamma_1}{d(1/T)} = \frac{-\Delta H_f}{R}$$

where a_1 and γ_1 are, respectively, the activity and activity coefficient of the solid A_rX_s in solution at equilibrium with the pure solid at temperature T. N_A and N_X are the Temkin ion fractions and ΔH_f is the heat of fusion of the pure A_rX_s.

Assuming the salts used in the present investigation to be fully ionized, $N_A \equiv N_{Ca^{2+}} = 1$, and $r = 1$. In the low concentration region the activity coefficient is unity and over the small temperature span involved, ΔH_f may be taken to be independent of temperature. Equation 1 then becomes, with $X \equiv Cl^-$ and $s = 2(CaCl_2)$,

$$[2]\quad 2 \ln N_{Cl^-} = \frac{\Delta H_f}{R}\left(\frac{1}{T_m} - \frac{1}{T}\right)$$

where T_m is the melting point of pure $CaCl_2$.

By definition, $N_{Cl^-} = (1 - N_Y)$ where N_Y is the total ion fraction of foreign anions and if N_Y is small relative to unity, $\ln (1 - N_Y) \simeq -N_Y$. Equation 2 becomes

$$[3]\quad -2N_Y = \frac{\Delta H_f}{R}\left(\frac{1}{T_m} - \frac{1}{T}\right)$$

Identifying Y as the divalent anion of a calcium salt, *e.g.* O^{2-} or $(C_2)^{2-}$, it is easily shown that $N_{CaY} = 2N_Y$ when N_Y is small, whence

$$[4]\quad N_{CaY} = \frac{\Delta H_f}{R}\left(\frac{1}{T} - \frac{1}{T_m}\right)$$

In the more general case and by further approximation, the van't Hoff relation is obtained

$$[5]\quad T_m - T = \Delta T \simeq \frac{RT_m^2}{\Delta H_f} \nu N_2$$

where ν is the number of foreign particles introduced into the solution per molecule of solute 2.

It follows from the above that measurement of the equilibrium temperature T for a system of known composition gives information regarding the species in solution and thermodynamic data in respect of the solution.

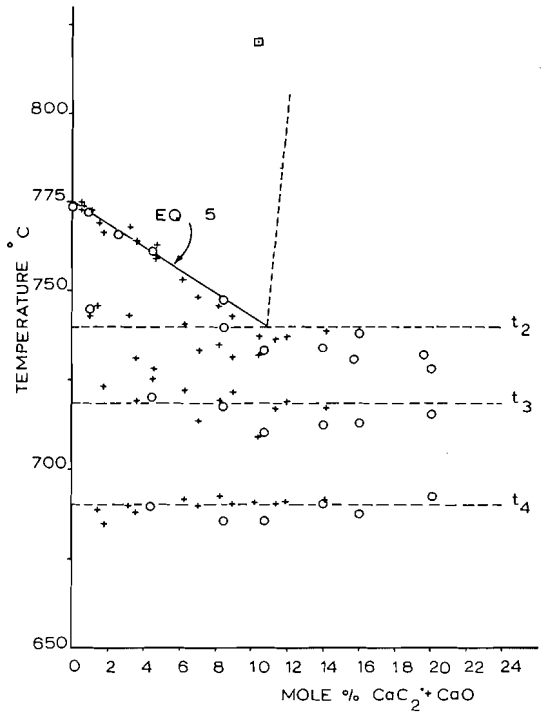

FIG. 1. Partial phase diagram of the pseudo binary system: $CaCl_2$ – (CaC_2 + CaO): ×, Observed thermal arrest temperatures; ○, ditto (melts not analyzed); ⊡, solubility datum point, ref. 1.

The temperatures associated with each thermal arrest are shown in Table 1. Also reported in the same table are the chemical analyses of the melts. Five constituents were found: $CaCl_2$, CaC_2, CaO, C, and Ca. The average mass balance percentage was 101.6%. The carbon contents are not reported; carbon was assumed to be insoluble in the melt.

Pseudo Binary System $CaCl_2$ – (CaC_2 + CaO)

It is evident from the chemical analysis of each sample that the depression of freezing point of the solvent, $CaCl_2$, may be attributed to the combined effects of calcium carbide, calcium oxide, and calcium, though the last may be neglected in view of the low concentration. A plot of the thermal arrests as a function of the system composition, on a carbon free basis is presented in Fig. 1. Included in this figure is the theoretical liquidus line corresponding to eq. 5. Using $T_m = 1048.2$ °K, $\Delta H_f = 6780$ cal/mol,

$v = 1$, the liquidus temperature t_l °C is given by

[6] $$t_l = 775.2 - 320\ N_{CaY}$$

From the experimental data, the following equation was derived

[7] $$t_l = 775.2 - (300 \pm 70)\ N_{CaY}$$

The close agreement between the theoretical line and the experimental data points suggests that no solid solution is formed. This absence of solid solution could be attributed to the difference of crystalline structures; calcium carbide has a cubic structure (10) while calcium chloride is tetragonal (11).

Ternary System $CaCl_2$–CaO–CaC_2

The results of the chemical analysis of the cryoscopic melts (Table 1) and the extensive scatter of the sub-liquidus thermal arrests observed (Fig. 1) suggested interpretation of these data in terms of the additive ternary system $CaCl_2$–CaO–CaC_2.

In general, the incorporation of a third component to a binary system lowers the binary eutectic temperature until with further addition the ternary eutectic point is reached. At this point the saturated liquid is in equilibrium with the three pure solids, assuming no solid solution. The four condensed phase, three component, system is then invariant. Thermal arrests would then be observed at the liquidus, the boundary curve (both variable with composition), and the ternary eutectic (invariant) (12).

It is evident from the thermal arrest data that the situation is more complex. Thus in general, the first arrest observed at (CaC_2 + CaO) concentrations less than about 10 mol% corresponds well to the liquidus, the second (not always observed) may be identified as the boundary curve temperature, and the third should then correspond to the ternary eutectic (invariant) temperature. However, the third (not always observed) arrest is not invariant, 718.0 ± 4.9 °C, but the fourth arrest is invariant within the limits of experimental error, 690.6 ± 2.4 °C.

The fourth arrest was observed in most melts as was also a fifth arrest, also invariant within the limits of experimental error, 672.1 ± 2.6 °C. Tests conducted in which the steel crucible used for containing the melts was charged with graphite powder or steel scrap also showed the last arrest; it should therefore not be considered in relation to the system under discussion.

An attempt has been made to construct the polythermal projection of the temperature–composition prism (the phase diagram) for the ternary system assuming the liquidus line to be straight. The boundary curve, representing the locus of points of three phase equilibrium may then be determined by graphical construction, since at the boundary curve temperature (t_2) for a given composition, the ratio of liquid to solid is given by the ratio $(t_m - t_1)/(t_1 - t_2)$. A short extrapolation of the boundary curve to the CaO-free axis of the phase diagram gives 10.0 mol % CaC_2, 740 °C for the eutectic of the CaC_2–$CaCl_2$ binary system. However, due to the relatively large uncertainties in the Δt terms of the above expression the boundary curve cannot be located with certainty at the present time.

Furthermore, neither t_3 nor t_4 can be regarded as the ternary eutectic of the system as defined above in view of the eutectic for the CaO–$CaCl_2$ binary system given by Threadgill (13), 30 mol % CaO, 597 °C. It is clear that resolution of these phenomena must await a more complete study of the phase equilibria in this ternary system.

Conclusions

(*1*) Aksaranan *et al.* (6) have established, from a thermodynamic argument that the heterogeneous equilibrium,

[8] $$CaC_{2(soln)} \leftrightharpoons Ca_{(soln)} + 2[C]$$

where [C] represents carbon in solid solution in the crucible, exists in the system CaC_2–$CaCl_2$. The presence of Ca is confirmed by the analytical data of Table 1. The liquidus line of Fig. 1 is consistent with a model in which the CaC_2 is ionized in the solution according to

[9] $$CaC_{2(soln)} \leftrightharpoons Ca^{2+} + C_2^{2-}$$

and in which no solid solution of CaC_2 in $CaCl_2$ occurs. Mitchell (14) reached similar conclusions in respect of the CaC_2–CaF_2 system.

(*2*) Interpretation of the sub liquidus thermal arrest data is complicated by contamination of the melt with O^{2-} ion, a consequence of the high reactivity of calcium carbide to oxygen. An attempt to construct a ternary phase diagram from the available data was unsatisfactory.

Reactions of Thiyl Radicals. VII. Photolysis of Methyl Sulfide Vapor[1]

P. M. RAO[2] AND A. R. KNIGHT

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received August 19, 1971

The photolysis of methyl sulfide vapor has been investigated as a function of substrate pressure, exposure time, and temperature in the wavelength range 2000 to 2300 Å. The effects of added propane, sulfur hexafluoride, and 2-methylpentane have been studied. The principal products of the decomposition are CH_4, C_2H_6, CH_3SSCH_3, and CH_3SH. The data indicate direct C—S bond scission in the primary process giving rise to "hot" CH_3 and CH_3S radicals. A mechanism in which disproportionation of methylthiyl radicals is a very minor process is proposed.

The reactions of CH_3 and CH_3S radicals with methyl sulfide have been examined also by photolyzing CH_3SSCH_3 and CH_3COCH_3 in the presence of CH_3SCH_3. Quantum yields at 2288 Å have been determined as a function of several variables. A number of rate parameters for the reactions of methyl radicals and methylthiyl radicals have been calculated.

On effectue la photolyse des vapeurs de sulfure de méthyle en fonction de la pression de substrat, du temps d'exposition et de la température dans un domaine de longueur d'onde de 2000 à 2300 Å. On étudie les effets de l'addition de propane, d'hexafluorure de soufre, et de 2-méthylpentane. Les principaux produits de décomposition sont CH_4, C_2H_6, CH_3SSCH_3, et CH_3SH. Les données indiquent une scission directe du lien C—S dans le procédé primaire donnant lieu à des radicaux CH_3 et CH_3S "chauds". On propose alors un mécanisme dans lequel la disproportionation des radicaux méthylthiyl est un procédé très secondaire.

Les réactions des radicaux CH_3 et CH_3S avec le sulfure de méthyle sont aussi examinées en photolysant CH_3SSCH_3 et CH_3COCH_3 en présence de CH_3SCH_3. Les rendements quantiques à 2288 Å sont aussi déterminés en fonction de plusieurs variables. On calcule aussi un certain nombre de paramètres de vitesse pour les réactions des radicaux méthyl et méthylthiyl.

Canadian Journal of Chemistry, **50**, 844 (1972)

Introduction

Some aspects of the photolysis of methyl sulfide have been investigated previously. Haines *et al.* (1) photolyzed liquid CH_3SCH_3 for 65 h and reported H_2 and CH_4 as products. Milligan *et al.* (2) found CH_4 and C_2H_6 along with methyl disulfide as products from the 2537 Å photolysis. Inaba and Ogoro (3) studied the gross features of the gas phase photolysis. They found CH_4, C_2H_6, CH_3SH, and CH_3SSCH_3 among the products. All yields, except that of the disulfide were reduced by addition of argon. Recently, Callear and Dickson (4) investigated the flash photolysis of CH_3SCH_3 at 1950 Å and established that the primary process was C—S bond scission producing CH_3 and CH_3S radicals. CH_2S was observed spectroscopically and was found to be quenched by the addition of nitric oxide.

Lossing and co-workers (5) examined the mercury photosensitized decomposition in a flow system coupled to a mass spectrometer. Relatively large yields of CH_3SH were detected and on the basis of that work a disproportionation/recombination ratio of 0.4 ± 0.1 was suggested. The photolysis of disulfides in a glass at 77 °K (6) has also yielded spectroscopic evidence of significant disproportionation of RS radicals.

The detailed investigation of the vapor phase photolysis of methyl sulfide reported here was undertaken to obtain further information about the nature of the reactions that occur in the system and kinetic data on CH_3S radical reactions, particularly the role of disproportionation of that species. Results obtained in this laboratory have indicated a maximum value of *ca.* 0.05 for the disproportionation/recombination ratio for thiyl radicals formed in the direct photolysis of thiols (7, 8) and disulfides (9, 10) in the vapor phase. In the liquid phase, disproportionation is virtually negligible (11).

Experimental

The photolysis was carried out in a conventional grease-free vacuum system previously described (9). The light

sources were a Hanovia type 30620 medium pressure mercury lamp filtered to remove wavelengths less than 2000 Å or, in one series of experiments, wavelengths less than 2300 Å; and a Phillips 93107 Cd-spectral lamp used in conjunction with a Baird-Atomic interference filter passing only the 2288 Å cadmium resonance line. Reaction cells were plane end quartz cylinders 5 cm in diameter with path length of 16 cm or 1 m. Methyl sulfide (Eastman) was purified by triple distillation at atmospheric pressure, degassing, and a further low temperature fractionation in the vacuum line. Impurities detected by g.c. were less than 0.01%. Methyl disulfide (Eastman) was purified in the same manner. Baker reagent acetone was used after degassing and trap-to-trap distillation at reduced pressure. Eastman 2-methylpentane was distilled in the vacuum system and the fraction condensable between −160 and −84 °C used.

At the conclusion of each reaction involving CH_3SCH_3, CH_4 was removed at −196 °C; C_2H_6 at −160 °C, and the remaining condensable products, including the substrate, analyzed by g.c. using a 6 ft tricresyl phosphate column. In experiments with addends, the addend was removed by trap-to-trap distillation prior to g.c. analysis.

Light intensities at 2288 Å for quantum yield determinations were found using the photolysis of acetone at 155 °C. The extinction coefficient for acetone at this wavelength was determined and a Beer–Lambert law calculation of the fraction absorbed by the actinometer at an acetone pressure of 200 Torr carried out. Φ(CO) was assumed to be unity and rate of carbon monoxide formation were determined by g.c. analysis using a molecular sieve column.

Results

In the photolysis of the substrate at 25 °C with effective radiation between 2000 and 2300 Å, CH_4, C_2H_6, CH_3SSCH_3, and CH_3SH accounted for 91–98% of the volatile products. No hydrogen was detected. The expected mass balance among the products, $[CH_3S] = [CH_3]$, where each term represents the total yield of products containing the indicated group, is not obtained. Although there are variations under different reaction conditions, products determined quantitatively showed in general a deficiency in sulfur containing compounds.

Irradiation of the substrate for periods of 24 h or more gives rise to a non-volatile oil that forms as droplets on the walls of the reaction vessel. Mass spectral analysis of the residue of evaporated $CHCl_3$ solutions of this material indicated a relatively high molecular weight (at least 258) mixture of compounds containing the CH_2S and CH_3S groups. Although it was not possible to identify definitively the components of the mixture, the presence of sulfur in the residue was confirmed by comparison of calculated and observed $^{34}S/^{32}S$ peak ratios. This aspect of the decomposition was not investigated further since during the long exposure times required to form sufficient non-volatile material for analysis, there would be significant secondary decomposition of initially formed higher molecular weight products.

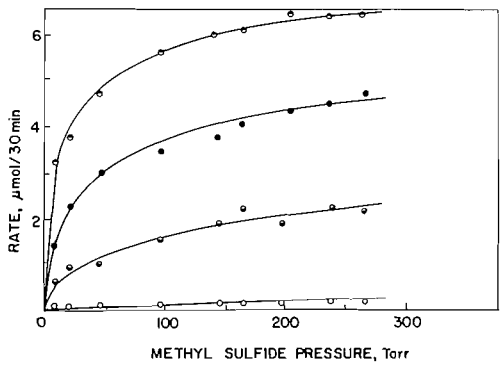

FIG. 1. Rate of formation of C_2H_6, ◓; CH_3SSCH_3, ●; CH_4, ◒; and CH_3SH, 0; as a function of methyl sulfide pressure at 25 °C for an exposure time of 30 min.

Figure 1 shows the rate of production of the principal products as a function of methyl sulfide pressure. The yield of CH_3SH is quite small, increasing more or less regularly from 0.045 μmol/30 min at $P(CH_3SCH_3) = 50$ Torr to 0.12 μmol/30 min when the substrate pressure was 282 Torr. It should be noted, however, that because of the minute CH_3SH yields, the experimental error in mercaptan rates is relatively large and it is therefore difficult to assess quantitatively the pressure dependence of this rate at low substrate pressures. The rate data actually obtained indicate that $R_{CH_3SH}/R_{CH_3SSCH_3}$ is less than *ca.* 0.03 for substrate pressures up to about 300 Torr.

Two series of experiments were carried out in a 1 m pathlength cell to permit small percent conversions but with sufficient absolute amounts of products for analysis. The results of the series at 20 Torr sulfide pressure are shown in Fig. 2. CH_3SH was not analyzed for in this series. The rate of formation of methyl disulfide is evidently very much less dependent on exposure time than that of either methane or ethane. In the second set of experiments carried out at 5 and at 20 Torr substrate pressure, the yields of both the thiol and disulfide were determined. The results, shown as the ratio of the rate of formation of CH_3SH and CH_3SSCH_3, are given in Fig. 3. They demonstrate that the relative amount of these products is dependent on both exposure

time and on substrate pressure. To establish the possible effects of surface reactions two sets of experiments were conducted in which the rates of CH_4, C_2H_6, and CH_3SSCH_3 formation were determined in a cylindrical cell of 172 cm^3 volume and compared with rates observed when the cell was filled with glass beads. The effective volume in the packed cell was 72 cm^3 and the surface volume ratio increased from 0.72 cm^{-1} in the unpacked cell to 18.4 cm^{-1} when the packing was present. The ratio of rates for the packed and unpacked vessel, R_P/R_U, observed were 0.31 for CH_4, 0.30 for C_2H_6, and 0.36 for CH_3SSCH_3 when the methyl sulfide pressure was 25 Torr and 0.47, 0.33, and 0.47 respectively, when 100 Torr substrate was photolyzed.

The effects of inert addends, propane and sulfur hexafluoride, were examined and the results are given in Table 1. As is apparent from the data, the rate of disulfide formation is virtually independent of addend pressure, while the yields of CH_4 and C_2H_6 are significantly pressure dependent. The ethane rates determined in the presence of added gases are likely accurate to no more than ±10% because of the difficulties in separating this product from the large amount of addend.

A series of experiments was carried out at each of four temperatures and yields measured as a function of 2-methylpentane pressure for the photolysis of 25 Torr CH_3SCH_3. Figure 4

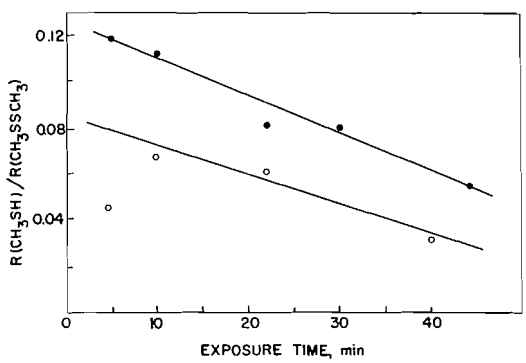

FIG. 3. $R_{CH_3SH}/R_{CH_3SSCH_3}$ as a function of exposure time for the photolysis of 5 Torr, ●; and 20 Torr, 0, of methyl sulfide in a 1 m cell at 25 °C.

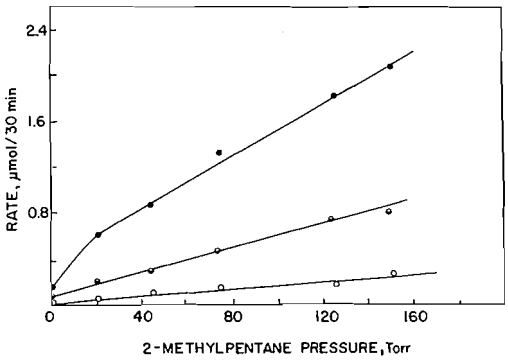

FIG. 5. Rate of formation of CH_3SH as a function of pressure of 2-methylpentane in the photolysis of 25 Torr methyl sulfide at 57 °C, 0; 104 °C, ◒; and 154 °C, ●.

shows the rates of formation of CH_4, C_2H_6, CH_3SSCH_3, and CH_3SH at 25 °C. The same measurements were made at 57, 104, and 154 °C and Fig. 5 shows the rates of CH_3SH formation at these temperatures. The rates for the other products were determined as well but the only aspect of these data relevant to the purpose of this series of experiments is the fact that at 154 °C the rate of CH_3SH formation exceeds that of all other products for P(2-methylpentane) > 75 Torr. The addend was chosen as a source of labile H-atoms because the vapor pressure characteristics of 2-methylpentane permitted its facile separation from reaction products. Furthermore, it would be expected to act as a rather efficient deactivator for vibrationally excited species in the system.

The most important feature of these results is the linear dependence of methanethiol rate on 2-methylpentane pressure and the fact that this rate increases significantly with temperature to the extent that CH_3SH is the major product of the reaction at 154 °C.

In comparing the rates for 30 min exposures at the four temperatures studied, it is to be noted that the effect of exposure time was determined only at room temperature. The relation between initial rates and those at 30 min may change with temperature, although the data in Fig. 2 indicate that the rates are strongly dependent on time primarily in the early stages of the reaction.

The role of CH_3S radicals in this system was further investigated by producing this species from the photolysis of CH_3SSCH_3. Mixtures of the disulfide and sulfide were photolyzed at 27 and 154 °C at wavelengths greater than

†Not determined.

2300 Å where the sulfide is transparent (12, 13). It is well established that the primary process in the disulfide is S—S bond cleavage (9–11). Thus under the conditions of this experiment the photolysis produced CH_3S radicals in the presence of CH_3SCH_3. The data are listed in Table 2. CH_3SH formation accounts for about 5% of thiyl radicals from the disulfide photolysis (9). At the higher temperature there is a significant increase in the rate of thiol formation, while production of CH_4 and C_2H_6 (likely originating from the disulfide decomposition) is not altered appreciably. The absolute yields of these two products is hardly above the limits of detection. If it is assumed that CH_3SH arises by abstraction of an H-atom by CH_3S, simple kinetic analysis of R_{CH_3SH} in the presence and absence of sulfide indicates that the ratio of rate for thiyl radical attack on CH_3SCH_3 and CH_3SSCH_3 is 0.4 ± 0.1.

Using the same effective wavelengths, acetone was photolyzed in another series of experiments in the presence of CH_3SCH_3 to obtain data on the attack of CH_3 radicals on the substrate. The results are listed in Table 3.

Finally, quantum yields at 2288 Å were de-

termined under a variety of pressure, temperature, and addend pressure conditions at two different light intensities. The results are given in Table 4. Because of the low effective intensity in the actinometry apparatus the exposure time was 1000 min, but percent conversions were comparable to those involved in the mercury lamp photolyses.

Discussion

The results obtained indicate C—S bond scission in the primary process, and the formation of the principal reaction products can be rationalized readily on that basis. It has been suggested previously that this primary process characterizes the liquid phase photolysis (1, 2), the Hg-sensitized decomposition (5), and the gas phase photolysis in both a conventional system (3) and in flash photolysis (4).

Ogoro and Inaba (3) proposed the initial formation of CH_3SCH_3* excited molecule which gives rise to CH_3 and CH_3S radicals in the absence of collisional deactivation. It appears, however, that the primary process can best be described in terms of direct C—S bond cleavage since the formation of CH_3SCH_3* in the primary process should be manifested by a decrease in the yields of *all* products in the presence of deactivating addends, an effect not found here.

The dependence of product yields on the pressure of the substrate itself, shown in Fig. 1, is most probably associated with light absorption characteristics. Absorption by CH_3SCH_3 in the wavelength region used here is comprised of two bands, one structureless band centered around 2040 Å and a system lying between 2150 and 2300 Å. The vibrational structure of the spectrum has been analyzed in detail (13) and the bands assigned to transitions involving excitation of a non-bonding electron from the S-atom to an antibonding orbital associated with the C—S bond. These workers suggest that the lower-energy excited states of CH_3SCH_3 are best described as initial members of a Rydberg series. At 2288 Å light absorption in the 16 cm path length cell should be complete at a sulfide pressure of 8 Torr. The initial sharp rise in yields as the substrate pressure is raised would correspond to increasing absorption. With the

For personal use only.

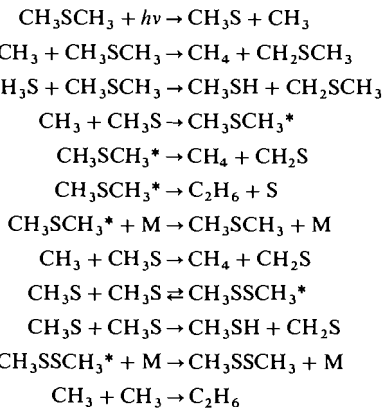
incident irradiation in the 2000–2300 Å range, the more gradual increase in rates at pressures above *ca.* 50 Torr may be due to increasing absorption of wavelengths where the extinction coefficient is relatively small. Methane, ethane, and methyl disulfide all show the same variation with substrate pressure. Because of the error in thiol rates at low substrate pressure it is not clear whether that product follows the same trend.

The main products and the principal features of the photolysis may be explained in terms of the mechanism shown by eqs. 1–12.



[1] $CH_3SCH_3 + h\nu \rightarrow CH_3S + CH_3$

[2] $CH_3 + CH_3SCH_3 \rightarrow CH_4 + CH_2SCH_3$

[3] $CH_3S + CH_3SCH_3 \rightarrow CH_3SH + CH_2SCH_3$

[4] $CH_3 + CH_3S \rightarrow CH_3SCH_3^*$

[5] $CH_3SCH_3^* \rightarrow CH_4 + CH_2S$

[6] $CH_3SCH_3^* \rightarrow C_2H_6 + S$

[7] $CH_3SCH_3^* + M \rightarrow CH_3SCH_3 + M$

[8] $CH_3 + CH_3S \rightarrow CH_4 + CH_2S$

[9] $CH_3S + CH_3S \rightleftarrows CH_3SSCH_3^*$

[10] $CH_3S + CH_3S \rightarrow CH_3SH + CH_2S$

[11] $CH_3SSCH_3^* + M \rightarrow CH_3SSCH_3 + M$

[12] $CH_3 + CH_3 \rightarrow C_2H_6$

On the basis of this reaction sequence the observed value for $R_{CH_3SH}/R_{CH_3SSCH_3}$ would be indicative of the *upper limit* for k_{10}/k_9. The actual rate constant ratio would be lower depending on the contribution of reaction 3 and the possible formation of some CH_3SH from $CH_3SCH_3^*$ to be discussed below. The graphs in Fig. 3 indicate that the ratio decreases from 0.12 to 0.08 as the CH_3SCH_3 pressure is increased from 5 to 20 Torr. The relatively minor importance of disproportionation is consistent with the thermochemical data for the process involved. Both reactions are exothermic, $\Delta H_9 = -78 \pm 2$ and $\Delta H_{10} = -42 \pm 8$ kcal (14). In the case of alkoxy radicals the exothermicities for CH_3O disproportionation and recombination are -78 ± 2 and -36.1 ± 1 kcal and there the disproportionation dominates completely (14). It is important to note, however, that the data for the CH_3SCH_3 photolysis points in general to H-atom abstraction as an important CH_3SH source, reaction 3. Disproportionation of CH_3S radicals is thus likely less important than indicated by the upper limit values of k_{10}/k_9.

Considering now the fate of radicals produced in the primary process, if 2288 Å, where there is a maximum in the absorption by CH_3SCH_3, is taken as a reference wavelength, the quantum energy is 126 kcal/mol. This is 54 kcal/mol in excess of the carbon–sulfur bond energy of 72 kcal/mol. Assuming that the excess energy is carried over by the two radicals in inverse proportion to their masses, the calculated excess energies are $E_{CH_3^*} = 41$ and $E_{CH_3S^*} = 13$ kcal/mol. These values, however, represent only approximate upper limits for excess energies. The pronounced vibrational structure in the CH_3SCH_3 spectrum (13) suggests there may be significant vibrational equipartition in the excited state and thus the calculation based on a simple mass effect may not be appropriate. The excess energy effect will nevertheless be present and should be manifested in CH_3 and CH_3S reaction rates characteristic of "hot" species.

In other systems, for example the photolysis of methyl iodide (15–17), "hot" methyl radicals have been shown to produce inordinately large yields of CH_4 via abstraction reactions that show little or no temperature dependence.

An Arrhenius plot for the formation of methane in this system, utilizing $\Phi(CH_4)$ values from Table 4, is linear and gives a value of 2.3 kcal/mol for the apparent activation energy. Thus although the CH_3^* abstraction reaction is not temperature independent, the apparent E_a value is appreciably lower than that for many other hydrogen atom abstraction reactions involving CH_3 radicals.

Further evidence for the participation of CH_3^* radicals comes from the results obtained in the photolysis of CH_3COCH_3 as CH_3 source in the presence of CH_3SCH_3 at 154 °C (Table 3). Assuming in the absence of the required data that the pre-exponential factors for reaction 2 and H-atom abstraction reaction from acetone are the same and taking E_a for the latter reaction as 9.5 kcal/mol, the rate constant ratio at 25 Torr sulfide indicates $E_{a2} = 9.3$ kcal/mol. In comparing this value to the 2.3 kcal/mol found when CH_3SCH_3 is the source of methyl radicals, it is to be noted that the apparent activation energy for reaction 2 represents an upper limit since CH_4 production from reaction 5, to be discussed below, would be expected to increase with temperature. The other possible source of methane, reaction 8, would not be expected to exhibit a temperature dependence.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The other characteristic that should be exhibited by CH_3* radicals is susceptibility to collision deactivation. The data in Table 1 show that C_3H_8 can effect such deactivation resulting in a decline in methane yields.

The energy carryover calculations indicate that methylthiyl radicals formed initially in this system are also hot. The rate data obtained permit determination of the activation energy of CH_3S hydrogen atom abstraction. An Arrhenius plot of R_{CH_3SH} values at zero addend pressure from Figs. 4 and 5 is linear and gives a value of 5.4 kcal/mol for the apparent activation energy of abstraction by CH_3S from the substrate. Any possible contribution from CH_3S disproportionation in reaction 10 would not be expected to change with temperature. Although the same comparison between hot and thermalized species carried out above for methyl radicals is not possible for CH_3S (methylthiyl radicals from the selective photolysis of CH_3SSCH_3 are themselves hot and thus the data in Table 2 do not apply to thermalized species), the value of the apparent activation energy is somewhat lower than might be expected for thermalized radicals.

The results can be used to exclude from consideration a number of possible reactions of CH_3S* radicals which might otherwise have to be included in a kinetic treatment of the system. The data in Table 2 show that when CH_3S* radicals are formed (from the CH_3SSCH_3 photolysis) in the presence of non-absorbing CH_3SCH_3, there is no significant production of C_2H_6 or CH_4 that might arise if either of the possible reactions,

[13] $CH_3S + CH_3SCH_3 \rightarrow CH_3SSCH_3 + CH_3$

[14] $CH_3S + CH_3SCH_3 \rightarrow CH_3SS + C_2H_6$

were occurring. Furthermore, CH_3SS radicals would lead to the formation of H_2S (16, 18) which was not detected here. This observation would also rule out another possible source of CH_3SS and CH_3 radicals,

[15] $CH_3S + CH_3S \rightarrow CH_3SS + CH_3$

Finally, unimolecular decomposition of methylthiyl radicals by either of

[16] $CH_3S \rightarrow CH_3 + S$

[17] $CH_3S \rightarrow CH_2S + H$

is not significant. Reaction 16 has an activation energy of at least 30 kcal/mol (3) while reaction 17 is endothermic to the extent of 45.5 kcal/mol (19).

It is instructive to consider the energetics of the two possible reactions between CH_3 and CH_3S radicals. Disproportionation, reaction 8, is exothermic by 56 kcal/mol, while $\Delta H = 72$ kcal/mol for reaction 4 if both species are thermalized. Carryover energies of one or both radicals would increase the exothermicity. Although the occurrence of the recombination process is indicated by the reactions that can be ascribed to subsequent decomposition of the CH_3SCH_3* molecule formed, it is not possible to assess quantitatively the importance of disproportionation. The formation of small amounts of C_2H_5SH and $C_2H_5SSC_2H_5$ which could come from reaction 8 followed by

[18] $CH_3 + CH_2S \rightarrow C_2H_5S$

and H-atom abstraction by C_2H_5S, as well as the possible formation of trithiane as a nonvolatile product, indicate that disproportionation may be occurring to some extent.

The two reactions of CH_3SCH_3* that may be occurring in this system are [5] and [6]. Both are exothermic, 66 and 26 kcal/mol respectively, but the reaction forming methane and thioformaldehyde is more favored energetically. Furthermore, the absence of S_2 in the flash photolysis of CH_3SCH_3 (4) suggests that reaction 6 is not an important mode of decomposition of excited methyl sulfide molecules.

The combination of two CH_3S radicals in process 9 yields CH_3SSCH_3* with minimum energy of the sulfur–sulfur bond and maximum energy given by the sum of the bond strength and the excess energy of the two CH_3S* radicals. The evidence in this system, and in the photolysis of the disulfide itself (8), indicates that an important reaction of CH_3SSCH_3* is the formation of two CH_3S radicals in the reverse of reaction 9. The stationary state concentration of CH_3S radicals is controlled in part by stabilization of CH_3SCH_3*. As the pressure is increased, $[CH_3S]$ is reduced via the deactivation process involving CH_3SCH_3*, but simultaneously there is increased stabilization of CH_3SSCH_3*, shifting the thiyl radical–disulfide equilibrium in favor of the latter. The observed results, which in general show an apparent insensitivity of disulfide yields to addend pressure, suggest that the enhancement of $R_{CH_3SSCH_3}$ due to stabilization of

hot disulfide molecules balances the decline to be expected if $[CH_3S]$ is reduced by stabilization of CH_3SCH_3*.

The results with 2-methylpentane as H-atom source indicate that abstraction by CH_3S radicals can be an important process at high addend pressure and increasing temperature.[3] Kinetic treatment of the results from this series of experiments can be used to obtain a rate parameter for CH_3S reactions.

At constant temperature, the alteration in R_{CH_3SH} with 2-methylpentane pressure may be employed to determine the ratio of rate constants for reaction 3 and abstraction from the addend

[19] $$CH_3S + 2MP \rightarrow CH_3SH + \dot{R}$$

(where 2MP represents the addend and $\dot{R}$, the alkyl radical resulting from the abstraction) assuming that reaction 3 is the sole source of CH_3SH in the photolysis of the pure substrate at higher temperatures. The calculated values of k_{19}/k_3 at 57, 104, and 154 °C, utilizing values of R_{CH_3SH} from Fig. 5, are listed in Table 5. Although these data suggest there may be a pressure dependence of the ratio that would be consistent with a contribution to CH_3SH formation from

[20] $$CH_3SSCH_3^* \rightarrow CH_3SH + CH_2S$$

the effect is not sufficiently large to indicate definitively an important role for this process.[4] Since the bond energies in the two H-atom

[3]Pryor and co-workers (20, 21) consider that the abstraction reaction RS + QH → RSH + Q, where QH is the hydrogen donor, is important with QH compounds having C—H bonds weaker than the RS—H bond (see also ref. 22).

[4]If reaction 20 is considered, the kinetic treatment of CH_3SH rates must then include reactions 3, 9, 11, and 19. A least squares analysis of the appropriate kinetic plot using data at 154 °C leads to a k_{19}/k_3 value of 1.85 at that temperature.

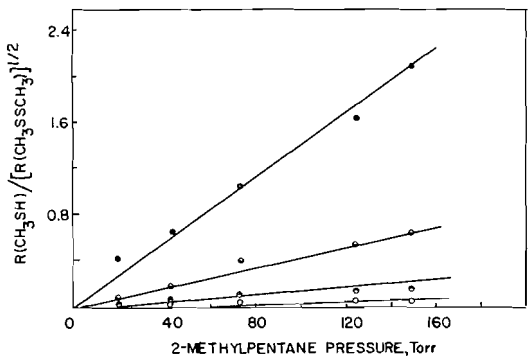

FIG. 6. $R_{CH_3SH}/(R_{CH_3SSCH_3})^{\frac{1}{2}}$ as a function of 2-methylpentane pressure in the photolysis of 25 Torr methyl sulfide at 25 °C, 0; 57 °C, ◓; 104 °C, ◒; and 154 °C, ●, at an exposure time of 30 min.

donors involved are quite different, the fact that k_{19} and k_3 are comparable over the temperature range investigated is further evidence for the participation of hot CH_3S radicals whose energy apparently attenuates the true activation energy difference that must surely exist between the reactions 3 and 19 and that would give rise to significantly different rate constants were only thermalized thiyl radicals involved.

Finally the variation of R_{CH_3SH} with addend pressure at each of the four temperatures investigated may be utilized to obtain the energy of activation for abstraction from 2-methylpentane. At each temperature it is assumed that CH_3SH production through reaction 3 will be independent of addend pressure and thus the mercaptan rate, $R^a_{CH_3SH}$ can be computed from $R^a_{CH_3SH} = R_{CH_3SH} - R^0_{CH_3SH}$ where $R^a_{CH_3SH}$ represents the amount of mercaptan formed via the abstraction process 19. If the recombination of CH_3S radicals, reaction 9, is used as reference

[21] $$R^a_{CH_3SH}/(R_{CH_3SSCH_3})^{\frac{1}{2}} = k_{19}/k_9(P_{2MP})$$

A plot of the left hand side of equation 21 as a function of addend pressure is given in Fig. 6. A plot of the slopes of these lines k_{19}/k_9 against $1/T$ is linear and gives $E_{a19} = \frac{1}{2}E_{a9} = 7.5$ kcal/mol which, making the usual assumption that the recombination has zero activation energy, represents the activation energy for abstraction from 2-methylpentane.

The study of methyl sulfide has yielded considerably more information about CH_3S radical reactions than previous investigations of the disulfide where thiyl radical recombina-

tion regenerates the substrate. Because of this advantage of the sulfides as substrate, studies are currently underway in this laboratory on the photolysis of methyl ethyl sulfide and diethyl sulfide.

For personal use only.

In 1932 an investigation of the alkaloids of *Dicentra canadensis* (Goldie) Walp. was reported (1). It was found that this plant contained five major alkaloids. Four of them were easily separated, purified, and characterized, namely bulbocapnine, corydine, isocorydine, and protopine. A fifth alkaloid, designated later (2) as F_{22}, was also present. It had an intense yellow–orange color and unusual chemical behavior. A preliminary characterization and elemental analysis showed, however, that it was a very complex alkaloid and the elucidation of its structure was postponed.

We have reinvestigated the yellow alkaloid, F_{22}, and found it to be a mixture of at least five components. Structure **1** has been proposed (3) for the major component, now called cancentrine, and structures **2** and **3** for two minor components called dehydrocancentrine-A and -B, respectively (4). We report here an account of some of the chemical and spectroscopic data which led to the structure of cancentrine.

The physical and spectroscopic properties[2] of the alkaloid suggested the presence of three methoxyl groups, one *N*-methyl group, one phenolic —OH group, one conjugated carbonyl group, and three pairs of aromatic protons in an ortho relationship to each other. Of the two nitrogen atoms in the molecule, one, not bearing a methyl group, was apparently non-basic. The presence of a phenolic hydroxyl group was confirmed by conversion of the alkaloid to an *O*-methyl ether (**4**) and an *O*-acetate (**5**). The mass spectra[3] though of great value later on, bore no similarity to that of any known dimeric benzylisoquinoline alkaloid. The u.v. spectra, too, were not characteristic of any known class of isoquinoline alkaloids and indicated the presence of a novel chromophore which imparted to the alkaloid its bright yellow color.

In an attempt to obtain structural information concerning its skeletal structure several chemical degradations were attempted. The alkaloid was stable to sodium borohydride but was reduced by both lithium aluminum hydride and zinc–hydrochloric acid with loss of its characteristic yellow color, but stable reduction products could not be isolated. The initial products decomposed rapidly to yield complex mixtures of intractable oils. Attempted cleavage of the molecule by sodium–liquid ammonia gave like results. An attempt at reductive acetylation (zinc–acetic anhydride–acetic acid) however, yielded two stable crystalline products very different from cancentrine. The spectral data on one of these products showed that extensive aromatization had taken place and that the

[1]Reference 3 is to be considered as part 1 in this series.

[2]A preliminary account of the spectroscopic properties of cancentrine has been presented (3). The p.m.r. data of cancentrine and its derivatives and the u.v. and i.r. data are reported in detail in the Experimental section.

[3]A complete listing of mass spectral peaks of **1**, 7, and **8** down to 5% intensity is available at the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

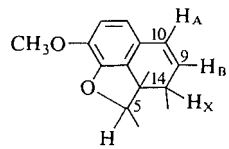
elements of C_3H_9NO had been lost from the original molecule including the oxygen atom of the original carbonyl group (as H_2O) and the *N*-methyl group (as C_3H_7N). The latter fragment corresponds exactly to the ethanamine bridge of the morphine alkaloids and thus constituted the first piece of structural information obtained. The existence of a morphine-like moiety in cancentrine was then quickly confirmed. Cancentrine methiodide was refluxed with acetic anhydride–sodium acetate, the expelled ethanamine bridge was isolated and characterized as *N*-methylethanolamine aurichloride. The sharp singlet at 4.88 δ in the p.m.r. spectrum of cancentrine could now be assigned to the proton at C-5 by analogy with the morphine alkaloids (5). All significant ions in the mass spectrum below *m/e* 243 could be similarly rationalized (6). The structures and properties of the products formed on acetolysis and the syntheses of their new ring systems will be published later.

The Hofmann degradation of cancentrine was then undertaken in order to effect a similar aromatization characteristic of most morphine alkaloids. Cancentrine methiodide was heated under reflux with 50% aqueous methanolic potassium hydroxide to give the methine **6** ($C_{37}H_{36}N_2O_7$). The i.r., u.v., and p.m.r. spectra of the methine were similar to that of cancentrine except that it now showed a broad singlet at 2.1 δ (6H) assigned to the *N*,*N*-dimethyl group and two olefinic protons due to the new double bond introduced. One of these is present in the same region as the aromatic protons while the other proton, H_9, appears at higher field as four lines coupled as it is to the olefinic proton at C-10 and the methine proton at C-14. The pattern is characteristic of the B part of an ABX system. It suggests the following structural feature in the molecule.



Methine **6** was converted to its *O*-methyl ether **7** by treatment with diazomethane and then by hydrogenation (H_2/Pt) to the dihydromethine *O*-methylether **8**. Compound **8** was also obtained by carrying out the hydrogenation first to give the dihydromethine **9** followed by methylation to the ether. Compounds **6** and **7** have a similar vinylic H_9 pattern in their p.m.r. spectra and are readily differentiated from **8** and **9** which lack the 9,10 double bond. All four compounds have the singlet attributed to the hydrogen at C-5 at 5.1–5.2 δ. Surprisingly, when **6** was converted to its methiodide and refluxed with alcoholic potassium hydroxide as before, the starting material was recovered unchanged even after 36 h. Only when the methiodide was refluxed with potassium *t*-butoxide in anhydrous tertiary butyl alcohol could the bis-methine **10** be obtained. Again, the expected aromatization had not occurred; simple elimination had taken place instead and the product obtained in high yield showed the presence of an extra vinylic unit and the absence of a *N*,*N*-dimethyl group in its p.m.r. spectrum.

Cancentrine, its simple derivatives **4** and **5**, and the Hofmann products, **6**–**10**, are all bright yellow compounds with very similar u.v. spectra and an i.r. band at 1660 ± 5 cm^{-1} associated with the carbonyl function. It would appear therefore that the two Hofmann degradations had achieved only simple, superficial changes and left intact the still unknown chromophoric system which must be associated with the carbonyl group. It must mean that the aromatization characteristic of morphine-like systems already demonstrated by the acetolysis experiment was blocked, in basic media, by some structural feature of the molecule. Several structures involving a morphine moiety linked through nitrogen and oxygen to an aporphine system were considered and discarded and several schemes devised to test these hypotheses were carried out. None of them was informative in a structural sense but some interesting products were isolated and characterized. As our supplies of cancentrine were not inexhaustible a search was begun for a suitable derivative for X-ray crystallographic analysis. The tendency of cancentrine and most of its derivatives to solvate made this much more difficult than expected and after about a dozen crystalline derivatives had been rejected we found that **8** as its hydrobromide was satisfactory. The results of the X-ray study have been reported briefly (3) and the structure of **8** which resulted is shown in the accompanying formula.

The novel *cis-s-trans-β*-amino-enone system which forms part of a modified cularine (7) system was now identified as the chromophore responsible for the long-wavelength absorption (8) and the non-basicity of the second nitrogen atom. Furthermore, the 'spiro' carbon atom, C-6, is clearly the structural feature that blocks aromatization by basic reagents whereas cationic attack at the carbonyl oxygen can be followed by ring expansion of the five-membered ring leading ultimately to phenanthrenoid systems. Reactions of this type will be discussed in detail in a subsequent publication.

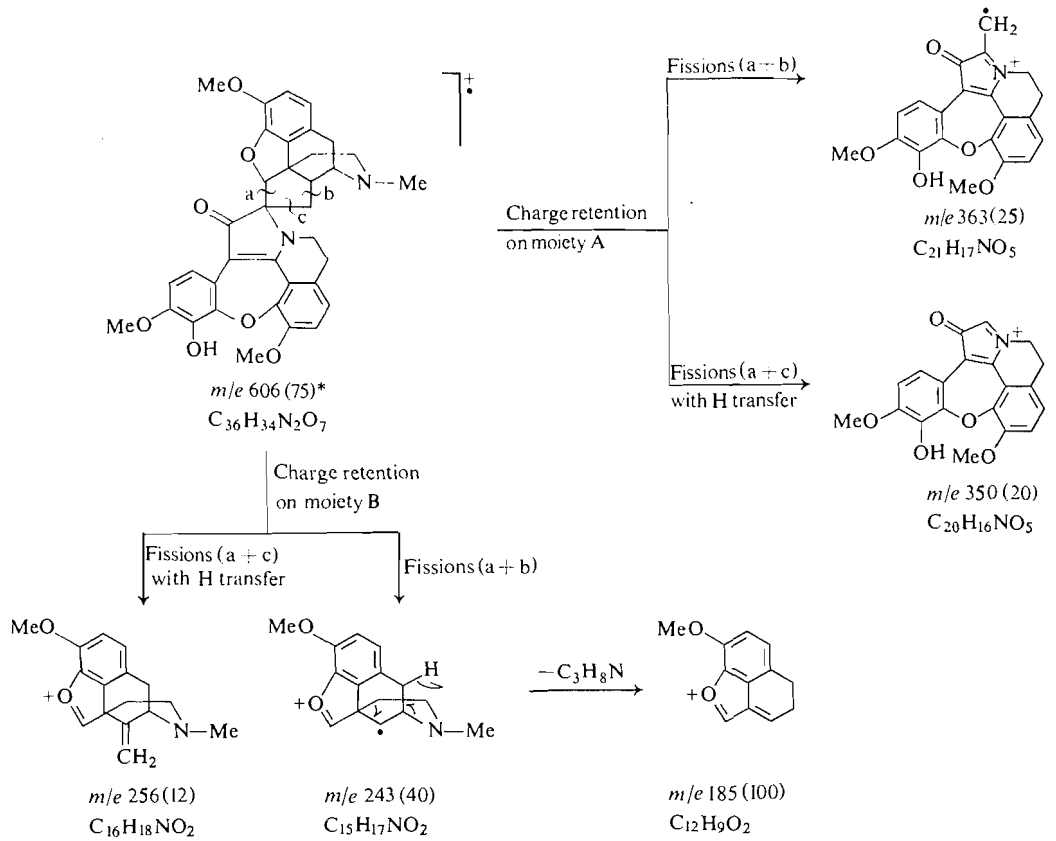
The u.v., i.r., and p.m.r. data of **4**–**10** already referred to, unambiguously indicate that they retain the basic framework of cancentrine. Thus only two problems remained in order to deduce the structure of cancentrine from **8**. The position of the phenolic hydroxyl group had to be ascertained and the *N*-terminus of the ethanamine bridge had to be established. Both problems were solved by further consideration of the p.m.r. spectra.

A comparison of the mass spectra of cancentrine and its *O*-methyl ether (see later) showed that the phenolic function was located in the cularine system while a comparison of the p.m.r. spectra of cancentrine and its *O*-acetate led to the conclusion that the phenolic function is para to the aromatic proton appearing at lowest field (9). It follows that the phenolic —OH group must be located at C-20 in cancentrine. This placement of the —OH group has been substantiated by nuclear Overhauser effect (n.O.e.) studies (10) which are discussed subsequently.

The second problem was resolved in the following way. Upon examination of a molecular model, it is apparent that the nitrogen of the ethanamine bridge may be attached to carbon atoms 5, 9, 10, or 14; carbon atom 8 is excluded on the basis that attachment at this site would cause too much strain in the system. Examination of the p.m.r. spectrum of **6** precludes C-5 and -14 as possible sites of attachment since the spectrum of **6** has an absorption at 5.18 δ typical of the hydrogen at C-5 in morphine systems and has two olefinic protons. Barring rearrangement in the formation of **6**, the nitrogen atom of cancentrine must be attached at C-9 or -10 with the former preferred on biogenetic grounds. That the nitrogen atom is indeed attached to C-9 was apparent (3) on careful comparison of the spectrum of cancentrine with that of codeine (5).

From a combination of decoupling and n.O.e. studies it is possible to assign many of the signals in the p.m.r. spectrum of **5**. The signal centered at 3.18 δ (one-half of an AB quartet) assigned to $H_{10\beta}$ was used as the point of reference. Irradiation of this signal causes a sharpening of the aromatic doublet centered at 6.65 δ which is therefore assigned to H_1. Irradiation of H_1 defines H_2 since an ortho coupling is removed at the doublet centered at 6.83 δ. An n.O.e. of 25% is observed at H_2 when the methoxyl signal 3.91 δ is saturated, thus defining the methoxyl resonance at C-3.

From chemical shift studies it was concluded that the low field proton of **5** at 7.88 δ was para to the acetoxy group and double irradiation has shown that this proton is ortho to a proton responsible for the doublet centered at 6.68 δ.



*Ion intensity as in parenthesis

SCHEME 1

An n.O.e. of 24% was observed for the latter when the methoxyl signal at 3.76 was irradiated. This defines the substitution pattern at positions 20–23. When the third methoxyl resonance at 3.85 δ was saturated an n.O.e. of 25% was observed for the proton centered at 6.98. Thus the following assignments could be made $H_1 = 6.65$, $H_2 = 6.83\ \delta$, $J_{1,2} = 9.0$ Hz; $H_{17} = 6.85$, $H_{18} = 6.98\ \delta$, $J_{17,18} = 8.5$ Hz; $H_{22} = 6.68$, $H_{23} = 7.88\ \delta$, $J_{22,23} = 8.0$ Hz. The resonances of the three methoxyls are also defined by the study.

The mass spectrum of cancentrine[4] provides a great deal of structural information and its interpretation is of value in solving future structural problems in the area (4). The molecular ion readily loses a methyl and a methoxyl radical but does not lose any other small fragments. Peaks of diagnostic value occur at *m/e* 363 and 350 with compositions $C_{21}H_{17}NO_5$ and $C_{20}H_{16}NO_5$. Further important ions occur at *m/e* 256, 243, and 185 with compositions $C_{16}H_{18}NO_2$, $C_{15}H_{17}NO_2$, and $C_{12}H_9O_2$, respectively. The latter ion is the base peak in the spectrum. The formation of these ions can be rationalized according to the sequence shown in Scheme 1. The molecule has a tendency to break into two parts: a 'cularine part' (moiety A) and a 'morphine part' (moiety B). Ions with the charge on moiety A appear at *m/e* 363 and 350 resulting from fission of bonds 'a' and 'b', and 'a' and 'c', respectively. The latter process is accompanied by hydrogen transfer. The same fissions can lead to ions with charge on moiety 'B' at *m/e* 243 and 256 respectively. The ion at *m/e* 243 through loss

[4]Cancentrine and its derivatives show strong molecular ions and weaker ions 14 mass units above M^+, a behavior similar to that of dimeric indole alkaloids (see Thomas and Biemann (18)).

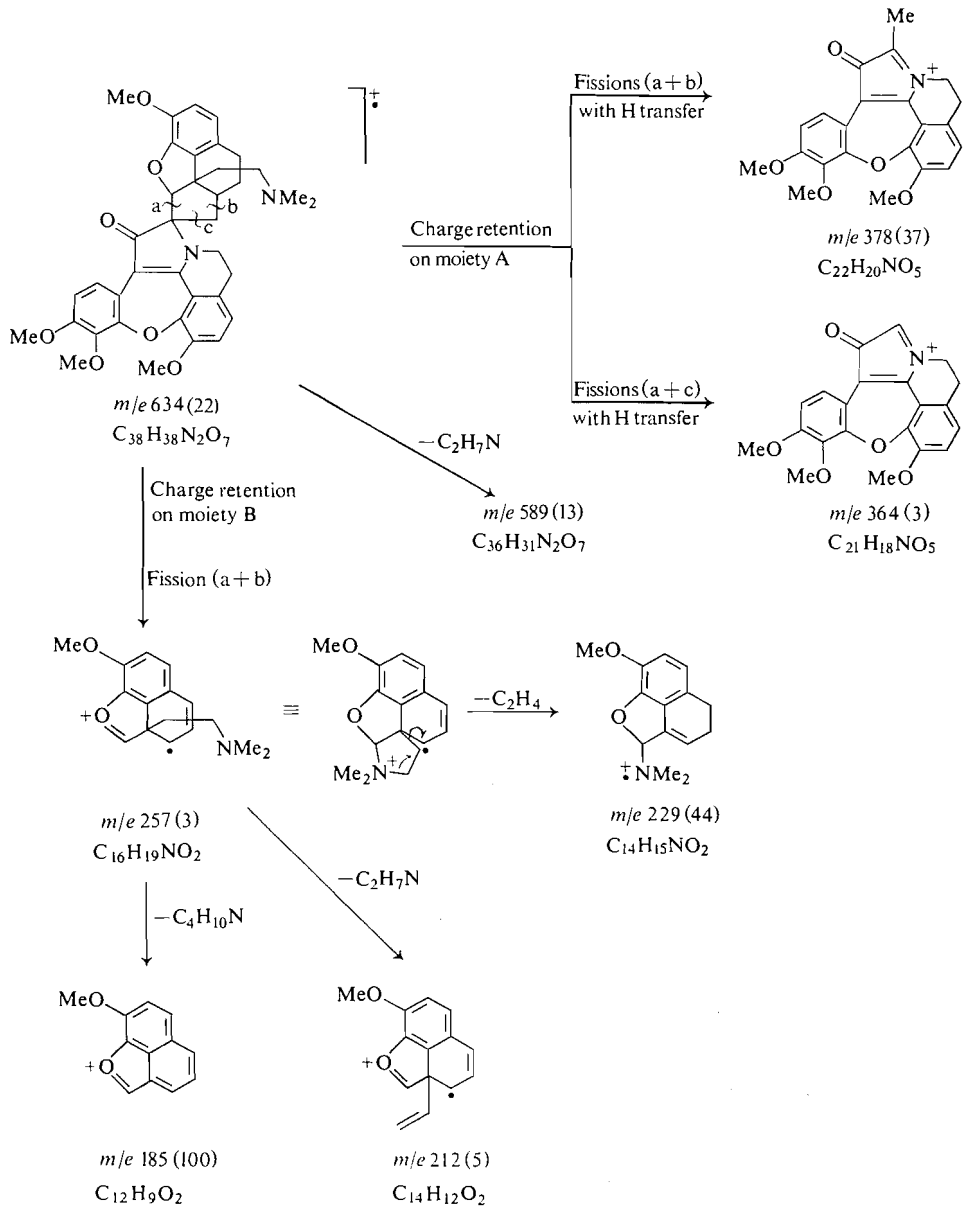

SCHEME 2

of C_3H_8N gives rise to the ion at *m/e* 185, the most intense in the spectrum. The ion at *m/e* 363 is accompanied by ions one mass unit higher and one and two mass units lower which differ in composition from *m/e* 363 by one or two hydrogen atoms. The same applies to the ions at *m/e* 350, 256, and 243. A cluster of ions centered at *m/e* 229 ($C_{14}H_{15}NO_2$) is apparently derived from moiety B of the molecule. The ion at *m/e* 226 ($C_{15}H_{16}NO$) may form from *m/e* 256 through loss of CH_2O. The spectrum of cancentrine also has a relatively intense ion at *m/e* 303 resulting from a doubly charged molecular ion.

The spectra of the *O*-methyl ether and the *O*-acetate of cancentrine show the shifts expected from methylation and acetylation of the

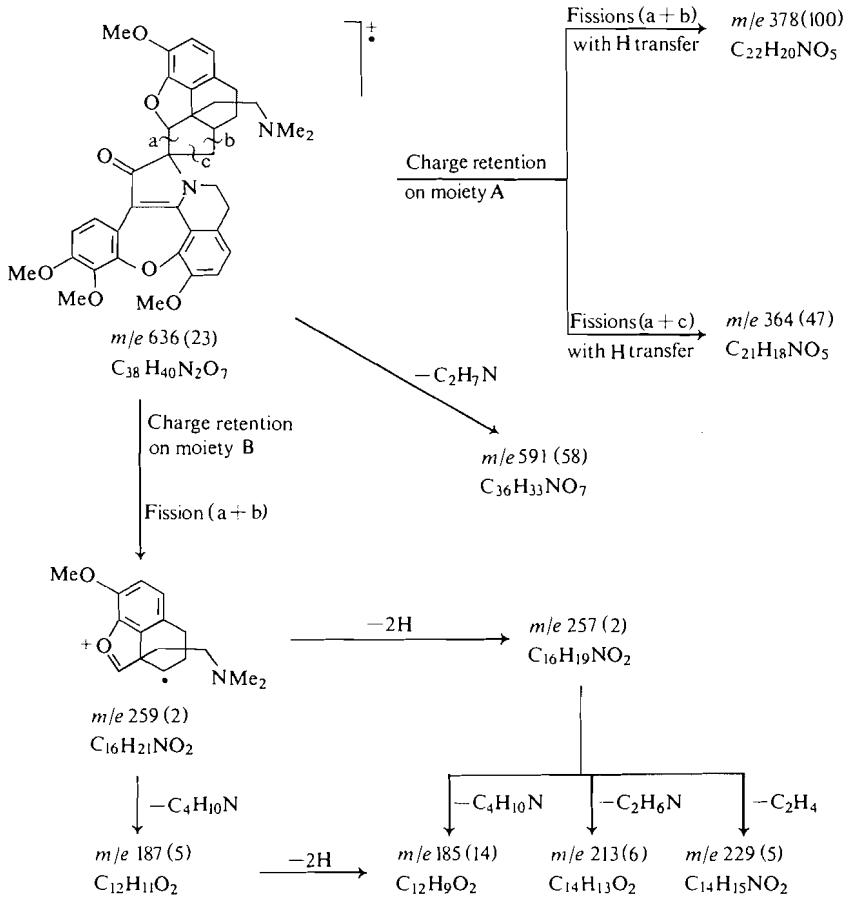
For personal use only.



SCHEME 3

phenolic hydroxyl group. The shifts allow the —OH group to be placed in moiety A of the molecule since only these ions are affected. For example in the case of *O*-methyl cancentrine ions at *m/e* 243 and 256 remained the same whereas the ions at *m/e* 350 and 363 had moved upwards by 14 mass units to *m/e* 364 ($C_{21}H_{18}NO_5$) and 377 ($C_{22}H_{19}NO_5$). The *O*-acetate shows a pronounced tendency to eliminate ketene so that the spectrum of the acetate has all the peaks associated with cancentrine itself as well as ions 42 mass units greater in those ions involving moiety A.

In Scheme 2 a fragmentation scheme for the methine-*O*-methyl ether **7** is proposed. This system breaks down in much the same way as cancentrine. The ions at *m/e* 378 and 364 are homologues of the corresponding ions in cancentrine. There appears to be only one mode of fission, (a + b) which produces an ion at *m/e* 257, leading to ions from moiety **B**. This ion can fragment in a straightforward way to *m/e* 185 and 212 as shown. The relatively intense ion at *m/e* 229 deserves comment. Its composition demands that it come from moiety **B**. A scheme for its formation is shown in which it is postulated that a new carbon–nitrogen bond is formed followed by expulsion of C_2H_4 from *m/e* 257.

The fragmentation of the dihydromethine-*O*-methyl ether **8** is shown in Scheme 3. The same ions from moiety A are found at *m/e* 378 and 364 as are found in the spectrum of **7**. Fission at 'a' and 'b' with charge retention of moiety **B** gives the ion at *m/e* 259. This ion may lose $C_4H_{10}N$ directly to give *m/e* 187, a relatively weak ion, or it may lose two hydrogen atoms to give *m/e* 257 and fragment in the same manner as the comparable ion derived from **7**. The lack of a 9,10

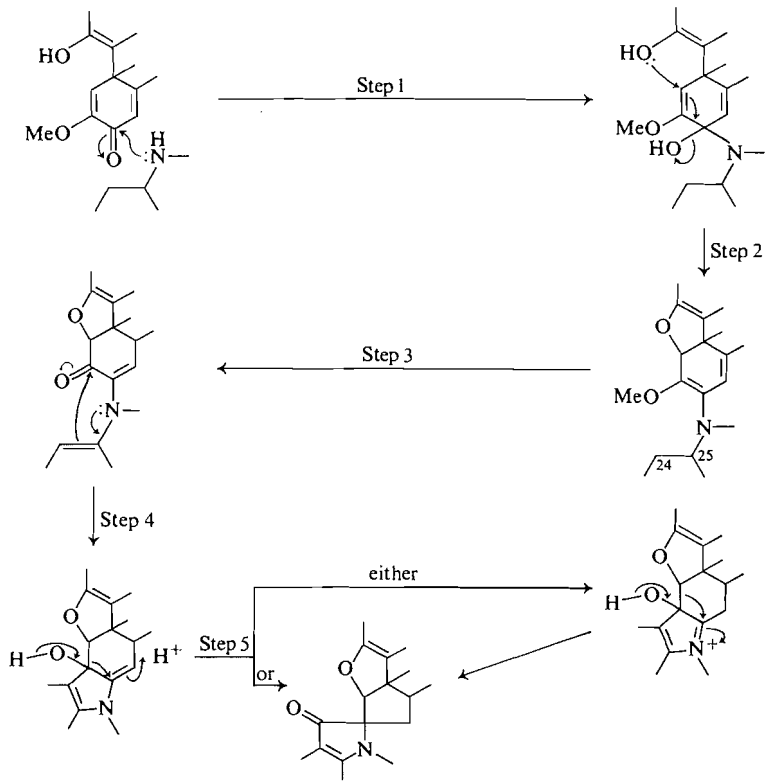
For personal use only.



SCHEME 4

double bond in **8** results in a greatly reduced intensity of the ion at *m/e* 185 and of all of the ions of moiety B. Because of the low intensities of *m/e* 257 and 259 it is possible that the ions at *m/e* 213 and 185 may in fact be derived from *m/e* 591.

A morphinandienone alkaloid, pallidine has recently been isolated (11) from *Corydalis pallida* a genus closely allied to *Dicentra*. The cularine alkaloids have been found only in these two genera. Neither type of alkaloid has hitherto been found naturally in a dimeric form and the substitution pattern of the known cularine alkaloids is different from that of the cularine half of cancentrine (12). However, the outstanding feature of cancentrine from a biogenetic point of view is the mode of linkage of the two constituent units.

In Scheme 4 we suggest a possible route to the spiro system based on known chemical and biosynthetic analogies. Step 1 represents the formation of the C_6—N bond by a nucleophilic addition similar to that in the *Erythrina* (13) alkaloids. This is followed in step 2, by closure of the furan ring and expulsion of the OH substituent in the generally accepted manner of morphine biogenesis. In step 3 we postulate hydrolysis of the enol ether and oxidation to produce a C_{24}—C_{25} dehydro derivative now set up for ring closure by enamine condensation in step 4 in a manner analogous to that postulated for the formation of chelidonine (14). Step 5 involves the formation of the spiro system by the rearrangement shown. A similar rearrangement with the same type of ring contraction has been demonstrated (15) in a morphine derivative. In this case it may involve the intermediacy of an immonium ion in a process reminiscent of the rearrangement of hydroxy and acyloxyindolenines to pseudoindoxyls (16).

Experimental

Methods

Melting points were determined on a Fischer Mel-Temp apparatus and are uncorrected. Mass spectra were recorded on a CEC 21-110 B double focussing mass spectrometer.

For high resolution work spectra were recorded on plates and accurate mass measurements were made using perfluorokerosene as a marker (17). The composition of all ions discussed in the paper have been checked by h.r.m.s. The p.m.r. spectra were recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V315 frequency counter incorporated in the instrument and are reported in p.p.m. (δ) from TMS. Double irradiation was achieved by employing a Hewlett–Packard 201 C audiogenerator at the desired frequency. A Beckmann IR10 spectrometer was used to record the i.r. spectra and a Coleman-Hitachi EPS-3T spectrometer was used for the u.v. spectra.

Cancentrine (1)

The isolation (1) of cancentrine and its purification (4) have already been described.

The u.v. spectrum: λ_{max}^{EtOH} 213, 230 (sh), 268, 291 (sh), 330 (sh), and 435 nm, log ε_{max} 4.80, 4.63, 4.32, 4.22, 3.62, and 3.82 respectively.

The i.r. spectrum: $\nu_{max}^{CHCl_3}$ 3450 and 1665 cm^{-1}.

The p.m.r. spectrum: 1.6–3.8 14H, aliphatic protons partially assigned; see (3); 2.51 (s) 3H, N—CH_3; 3.86 (s), 3H(OCH_3); 3.95 (s) 3H(OCH_3); 4.00 (s) 3H, OMe; 4.88 (s) 1H, C_5H; 6.5–7.2 (m) 5H, aromatic protons; 7.51 (d) 1H, $C_{23}H$.

Anal. Calcd. for $C_{36}H_{34}N_2O_7.3H_2O$: C, 65.42; H, 6.11; N, 4.24; 3 × OMe, 14.08. Found: C, 65.97; H, 5.78; N, 4.22; OMe, 13.87.

The molecular formula was confirmed by high resolution mass spectrometry (h.r.m.s.).

Calcd. for $C_{36}H_{34}N_2O_7$: 606.237. Found: 606.240.

Cancentrine Hydrochloride

The preparation has been described (2).

Anal. Calcd. for $C_{36}H_{34}N_2O_7.HCl.2H_2O$: C, 63.66; H, 5.78; N, 4.12; Cl, 5.23; 3 × OMe, 13.70. Found: C, 64.43; H, 5.77; N, 3.95; Cl, 5.69; OMe, 13.77.

Cancentrine-O-methyl Ether (4)

Cancentrine (200 mg) was dissolved in hot methanolic sodium hydroxide (30 ml, 1.0 g). Trimethylanilinium tosylate (250 mg) was added and the sodium salt which precipitated on cooling was filtered and washed with a little methanol. The filtrate was evaporated to dryness and heated in dimethyl sulfoxide (10 ml) at 120–125° for 2–3 h. The solution was cooled, poured into water, and extracted with chloroform several times. The chloroform extracts were dried and the solvent removed under reduced pressure. The residue was chromatographed on silica gel in benzene–methanol (9:1) and the first few fractions of the main yellow band collected. These were rechromatographed to remove the substantial amounts of unchanged cancentrine which ran only very slightly slower than the ether. Several variations of this procedure were tried with respect to solvent, period of heating, temperature, etc. Always significant amounts of cancentrine remained. When pure, the *O*-methyl ether crystallized from methanol–cyclohexane (32 mg, best yield), m.p. 269°.

The u.v. spectrum: λ_{max}^{EtOH} 210, 230 (sh), 269, 330 (sh), and 433 nm, log ε_{max} 4.83, 4.66, 4.22, 3.56, and 3.71 respectively.

The i.r. spectrum: $\nu_{max}^{CHCl_3}$ 1660 cm^{-1}.

The p.m.r. spectrum: 1.5–3.8, 14H, aliphatic protons; 2.52 (s) 3H, N–CH_3; 3.84 (s) 3H, OCH_3; 3.94 (s) 3H, OCH_3; 3.96 (s) 3H, OCH_3; 4.01 (s) 3H, OCH_3; 4.88 (s) 1H, C_5H; 6.5–7.2 (m) 5H, aromatic protons; 7.70 (d) 1H, $C_{23}H$.

Anal. Calcd. for $C_{37}H_{36}N_2O_7$: C, 71.60; H, 5.85; N, 4.51. Found: C, 71.70; H, 5.75; N, 4.46.

The molecular formula was confirmed by h.r.m.s.

Calcd. for $C_{37}H_{36}N_2O_7$: 620.252. Found: 620.253.

Cancentrine-O-acetate (5)

Cancentrine (100 mg) was refluxed with acetic anhydride (5 ml) in pyridine (10 ml) for ½ h. Most of the liquids were removed under reduced pressure, water (50 ml) added, and the aqueous mixture neutralized with sodium bicarbonate and extracted with chloroform. The chloroform extracts were dried, the solvent removed, and the residue chromatographed as before. The main yellow band was collected and the solvents removed. The residue was pure (t.l.c.) but resisted crystallization.

The i.r. spectrum: $\nu_{max}^{CHCl_3}$ 1770 and 1600 cm^{-1}.

The p.m.r. spectrum: 1.5–3.8, 14H, aliphatic protons; 2.46 (s) 3H, O=C—CH_3; 2.53 (s) 3H, N—CH_3; 3.76 (s) 3H, OCH_3; 3.85 (s) 3H, OCH_3; 3.91 (s) 3H, OCH_3; 4.85 (s) 1H, C_5H; 6.5–7.1 (m) 5H, aromatic protons; see text for analysis; 7.88 (d) 1H, $C_{23}H$.

The molecular formula was determined by h.r.m.s.

Calcd. for $C_{38}H_{36}N_2O_8$: 648.247. Found: 648.243.

Cancentrine Methine (6)

Cancentrine (400 mg) was dissolved in chloroform (50 ml) and methanol (10 ml) was added. Methyl iodide (20 ml) was added and the solution allowed to stand for 48 h at room temperature. The solvents were removed under reduced pressure and the residual methiodide crystallized from methanol (440 mg).

Cancentrine methiodide (400 mg), without further purification, was refluxed with 50% aqueous-methanolic potassium hydroxide (50 ml, 5 g KOH) for 24 h. Carbon dioxide was passed through the hot solution and the methanol evaporated, the solution cooled, and filtered. The solid was dried and chromatographed as before and the main yellow band collected. The solvents were removed and the residue was crystallized from methanol (240 mg), m.p. 230°.

The u.v. spectrum: λ_{max}^{EtOH} 227, 270, and 435 nm, log ε_{max} 4.61, 4.38, and 3.75 respectively.

The i.r. spectrum: $\nu_{max}^{CHCl_3}$ 3450 and 1660 cm^{-1}.

The p.m.r. spectrum: 1.6–3.8 11H aliphatic protons; 2.22 (s) 6H, 2 × N—CH_3; 3.87 (s) 3H, OCH_3; 3.99 (s) 3H, OCH_3; 4.00 (s) 3H, OCH_3; 5.18 (s) 1H, C_5H; 5.85 (q) 1H, C_9H; 6.35–7.40 6H, aromatic protons + $C_{10}H$; 7.52 (d) 1H, $C_{23}H$.

Anal. Calcd. for $C_{37}H_{36}N_2O_7$: C, 71.60; H, 5.85. Found: C, 71.45, 71.67; H, 5.76, 5.74.

The molecular formula was confirmed by h.r.m.s.

Calcd. for $C_{37}H_{36}N_2O_7$: 620.252. Found: 620.255.

Dihydrocancentrine Methine (9)

Cancentrine methine (100 mg) was dissolved in methanol (50 ml) and hydrogenated overnight at room temperature and pressure in the presence of Adams catalyst (20 mg). The catalyst was filtered off, the filtrate taken to dryness, and the residue crystallized from aqueous methanol (90 mg), m.p. 215°.

*Cancentrine Bis-methine (**10**)*

Cancentrine methine (200 mg) was dissolved in methanol (50 ml) and methyl iodide (5 ml) added. The solution was allowed to stand overnight at room temperature and the methine–methiodide which had crystallized out was filtered, washed with some methanol, and dried (220 mg). It was then refluxed in anhydrous tertiary butyl alcohol (50 ml) with potassium *t*-butoxide (200 mg). A strong fishy smell (probably trimethylamine) developed as the reaction proceeded. After 4 h the refluxing was stopped, the solvent removed under reduced pressure, water (50 ml) added, the mixture saturated with carbon dioxide. The precipitated yellow solid was filtered, washed, and dried and recrystallized from methanol (120 mg), m.p. 192°.

The u.v. spectrum: λ_{max}^{EtOH} 229, 270, and 438 nm, log ε_{max} 4.75, 4.52, and 3.84 respectively.

The i.r. spectrum: $\nu_{max}^{CHCl_3}$ 3440 and 1665 cm^{-1}.

Anal. Calcd. for $C_{35}H_{29}NO_7$: C, 73.03; H, 5.08; N, 2.43. Found: C, 73.20; H, 5.05; N, 2.80.

The molecular formula was confirmed by h.r.m.s.

Calcd. for $C_{35}H_{29}NO_7$: 575.201. Found: 575.198.

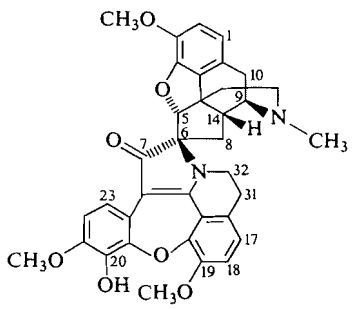
The structures of dehydrocancentrine-A and -B are elucidated by a combination of physical and chemical methods.

Les structures des déhydrocancentrines-A et -B ont été élucidées au moyen de méthodes physiques et chimiques.

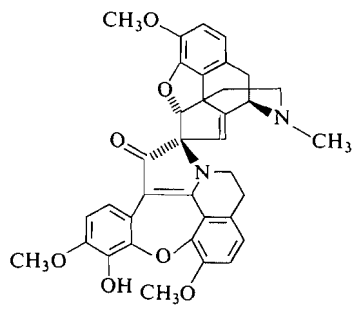
Canadian Journal of Chemistry, **50**, 862 (1972)

Recently we reported the characterization and structural elucidation of a new dimeric benzylisoquinoline alkaloid, cancentrine (1, 2). Here we describe two new alkaloids, dehydrocancentrine-A (**2**) and dehydrocancentrine-B (**3**), closely related in structure to cancentrine (**1**). Both alkaloids are found in *Dicentra canadensis* (Goldie) Walp. in very small amounts and were separated from cancentrine by chromatography.

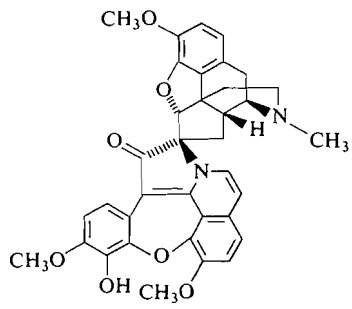
Dehydrocancentrine-B is a red alkaloid with the following u.v. spectrum: λ_{max}^{EtOH} 216 (sh), 242, 270 (sh), 310 (sh), 370, 446, 492, and 525 (sh) nm; log ε_{max} 4.86, 4.78, 4.23, 4.16, 3.90, 4.00, 3.95, and 3.85, respectively. It has i.r. bands at 3450 (OH), 1660 (C=O), and 1630 (C=C) cm^{-1}. In its mass spectrum the molecular ion appeared at *m/e* 604 corresponding to an elemental composition of $C_{36}H_{32}N_2O_7$. The fragmentation pattern is very similar to that of cancentrine (2), with the exception that the ions due to the 'cularine' part (moiety A) appear two mass units lower than in the case of cancentrine, indicating that the double bond must be located in the cularine part of the molecule. The only available position is at C_{31}—C_{32} and the fragmentation pattern is rationalized accordingly (Scheme 1). Only the formation of the most abundant ions is represented. The elemental compositions in parentheses were determined by high resolution mass spectrometry. Fissions 'a' and 'b' (2) taking place as indicated lead to two fragment ions, one corresponding to the morphine part (moiety B) which fragments further in exactly the same manner as in cancentrine, and the other corresponding to the cularine part, now two mass units lower (at *m/e* 361) than the corresponding ion in cancentrine. Fissions a and b also proceed with H transfer to give an ion at *m/e* 362. Alternatively, fragmentation at 'a' and 'c' with hydrogen transfer from the 'morphine' to the 'cularine' moiety leads to ions at *m/e* 256 and 348, the latter again being two mass units



1

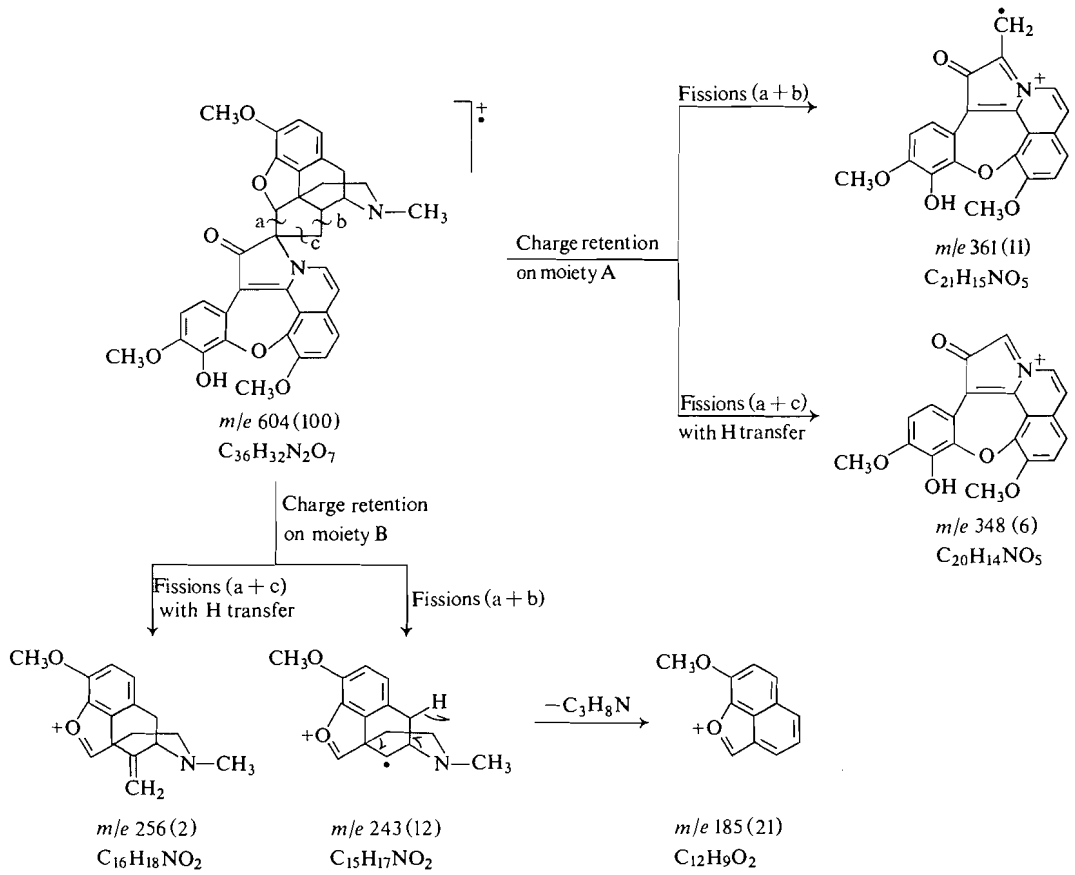


2



3

[1]For Part II, see ref. 2.



SCHEME 1

lower than the corresponding ion in cancentrine. These ions do not appear to fragment further.

The p.m.r. spectrum confirms this placement of the double bond at C_{31}—C_{32}. The spectrum displays a sharp singlet at 2.50 δ (3H) corresponding to one *N*-methyl group, three sharp singlets at 3.84 (3H), 3.90 (3H), and 3.99 δ (3H) due to the three aromatic methoxyls, a sharp singlet at 4.84 δ (1H) attributed to the 5β proton, and the three aromatic AB systems (6H). A fourth new AB system due to the double bond at C_{31}—C_{32} is partly masked by the aromatic hydrogens but one half of it is clearly seen at 6.25 δ (1H) with a coupling constant $J_{AB} = 7.0$ Hz.

Dehydrocancentrine-A is a yellow alkaloid with the following u.v. spectrum: λ_{max}^{EtOH} 216, 269, 296 (sh), and 445 nm; log ε_{max} 4.77, 4.36, 4.29, and 3.87, respectively. It has i.r. bands at 3440 (OH), 1660 (C=O), and 1620 (C=C) cm^{-1}. Its high resolution mass spectrum has a molecular ion at *m/e* 604 corresponding in composition to $C_{36}H_{32}N_2O_7$. The 100 MHz p.m.r. spectrum of dehydrocancentrine-A (in $CDCl_3$) has all the characteristic peaks of cancentrine (2), namely, three aromatic methoxyls at 3.80 (6H) and 3.93 δ (3H), one *N*-methyl singlet at 2.53 δ (3H), and six aromatic hydrogens forming three AB systems. There is also a sharp singlet at 5.04 δ as in the case of cancentrine but integrating for more than one proton. The spectrum was therefore recorded in DMSO-d_6 where it showed two sharp singlets at 5.05 and 5.26 δ integrating for one proton each and attributed to the 5β hydrogen and a vinylic hydrogen, respectively. The vinylic proton is not coupled to any other proton in the spectrum and, therefore, the double bond in **2** must be

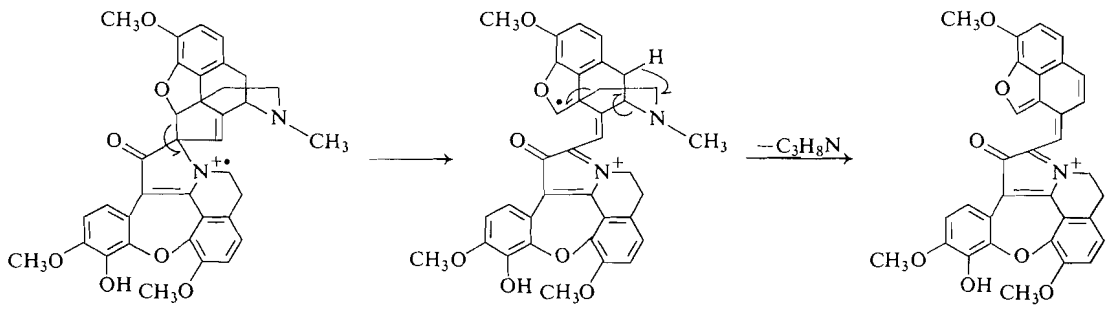

SCHEME 2

located at C_9—C_{10} or C_8—C_{14}. A double bond at C_9—C_{10} would be at a bridgehead position, and therefore the structure of dehydrocancentrine-A is represented as in formula **2**.

This structure is in accord with the fragmentation pattern revealed in the mass spectrum. The only important fragment ion is formed by loss of the nitrogen bridge from the molecular ion giving rise to the ion at *m/e* 546 (Scheme 2). This is typical of the morphine alkaloids (3). The ion at *m/e* 546 has no tendency to fragment further because of its aromatic character. This behavior of **2** is strikingly different from that of cancentrine and its derivatives, and constitutes a good example of how a small structural change in a molecule can have a dramatic effect upon its fragmentation pattern. Both the molecular ion, *m/e* 604, and the fragment ion, *m/e* 546, have homologous ions 14 mass units above and below, apparently resulting from *trans* methylation processes at the high source temperatures required for volatilization of these high molecular weight compounds. Dehydrocancentrine-B behaved similarly but to a lesser degree.

Finally, the position of the hydroxyl group in **2** and **3** was shown to be identical with that in cancentrine by catalytic hydrogenation of the alkaloids to the latter compound. In the case of **2** a small amount of another yellow compound probably the C-14 epimer, was also formed and detected by t.l.c. Dehydrogenation of cancentrine over 5% palladium–charcoal in boiling naphthalene gave *inter alia* **2** and **3** in low yield and only detectable by t.l.c. Since the relative stereochemistry of cancentrine is known (1), these results support the stereochemical assignments made for the alkaloids in structures **2** and **3**.

Experimental

Methods

Melting points were determined on a Fisher Mel-Temp apparatus and are uncorrected. Mass spectra[2] were recorded on a CEC 21-110B double focussing mass spectrometer. For high resolution work, spectra were recorded on plates and accurate mass measurements were made using perfluorokerosene as marker (4). The p.m.r. spectra were recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ (unless otherwise specified) using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V315 frequency counter incorporated in the instrument. A Beckmann IR 10 spectrometer was used to record the i.r. spectra and a Coleman-Hitachi EPS-3T spectrometer was used for the u.v. spectra.

The Purification of Cancentrine and Isolation of Dehydrocancentrine-A and -B

Crude cancentrine (5) when chromatographed on a t.l.c. plate (silica gel) in benzene–methanol (4:1) proved to be a mixture of several compounds. The major component cancentrine (90%) had a R_f of about 0.35 in the system, while dehydrocancentrine-A ran about 20% faster and dehydrocancentrine-B almost overlapped with cancentrine (*ca.* 2% faster).

Cancentrine (10 g) was chromatographed on a large column of silica gel (85 × 3 cm; 70–325 mesh ASTM; E. Merck) in benzene–methanol, 9:1. The column was eluted slowly over several days and the relevant fractions collected.

The solvents were removed and the residues crystallized from methanol. Dehydrocancentrine-A (40 mg), m.p. 194°. Dehydrocancentrine-B could only be induced to crystallize after repeated chromatography to separate it completely from cancentrine (25 mg), m.p. 206°. The molecular formulae were determined by high resolution mass spectrometry.

Dehydrocancentrine-A: Calcd. for $C_{36}H_{32}N_2O_7$: 604.221. Found: 604.224.

Dehydrocancentrine-B: Calcd. for $C_{36}H_{32}N_2O_7$: 604.221. Found: 604.221.

[2]A complete listing of mass spectral data may be found in the Depository of Unpublished Data, National Science Library, National Research Council, Ottawa, Canada K1A 0S2.

Hydrogenation of Dehydrocancentrine-A and -B

Dehydrocancentrine-A (20 mg) in methanol (25 ml) was hydrogenated overnight at room temperature and pressure in the presence of Adams catalyst (10 mg). The solution was filtered and the methanol removed from the filtrate under reduced pressure. A small specimen of the residue when tested by t.l.c. (silica gel; benzene–methanol, 4:1) showed the presence of cancentrine (*ca.* 90%) and another yellow compound (*ca.* 10%) with R_f about half that of cancentrine. The bulk of the crude product was therefore purified by column chromatography and crystallized from $CHCl_3$–MeOH (12 mg), m.p. 235°. The i.r. spectrum of the product and its behavior on t.l.c. were identical with that of cancentrine.

Dehydrocancentrine-B (5 mg) was similarly hydrogenated, in this case, a single product was obtained. Its. i.r. spectrum and t.l.c. behavior were identical with that of cancentrine.

Dehydrogenation of Cancentrine

Cancentrine (1 g) was refluxed in naphthalene (5 g) with 5% palladium–charcoal (100 mg) for 3 h. Most of the naphthalene was sublimed out on a steam bath under reduced pressure and a small specimen of the residue was then examined by t.l.c. using the same system as before. It proved to be a very complex mixture containing a large proportion of unchanged cancentrine but the presence of both dehydrocancentrine-A and -B was clearly evident. The bulk of the dehydrogenation product was then chromatographed on a column of silica gel as before and the relevant fractions taken. These fractions when examined by t.l.c. in comparison with authentic samples, confirmed the presence of dehydrocancentrines-A and -B, but it was not possible to obtain these small amounts of material sufficiently pure to induce crystallization.

We thank the National Research Council of Canada for financial support of this work.

Organic Sulfur Mechanisms. 12. Reaction of Sulfenes with Triphenylphosphine[1]

J. F. KING, E. G. LEWARS, AND L. J. DANKS

Department of Chemistry, University of Western Ontario, London 72, Ontario

Received September 16, 1971

Phenylmethanesulfonyl chloride (**1***a*) and 2,4-dinitrophenyl phenylmethanesulfonate (**1***b*) react with a mixture of triphenylphosphine and triethylamine to give the benzyltriphenylphosphonium salts (**2**) in 32 and 87% yields, respectively. Methanesulfonic anhydride (**1***c*) similarly gives the methyltriphenylphosphonium salt. These reactions evidently constitute the first illustrations of the reaction of a sulfene with a trivalent phosphorus compound.

Le chlorure de phénylméthanesulfonyle (**1***a*) et le dinitrophényl-2,4 phénylméthanesulfonate (**1***b*) réagissent avec un mélange de triphénylphosphine et de triéthylamine pour donner des sels de benzyltriphénylphosphonium avec respectivement des rendements de 32 et 87%. L'anhydride méthanesulfonique (**1***c*) conduit d'une façon similaire au sel de méthyltriphénylphosphonium. Ces réactions constituent les premiers exemples de la réaction d'un sulfène avec un composé trivalent du phosphore.

Canadian Journal of Chemistry, **50**, 866 (1972)

Addition of nucleophilic reagents to sulfenes ($RR'C{=}SO_2$) is probably the most important reaction of these useful and highly reactive intermediates. There are no reports, however, on the reaction of sulfenes with trivalent phosphorus compounds, and, as part of our general study of the reactions of sulfenes (ref. 1 and earlier work cited), we decided to look into the possibility of reaction between a sulfene and a tertiary phosphine.

Accordingly phenylmethanesulfonyl chloride (**1***a*) was treated with a mixture of triethylamine and triphenylphosphine in the hope that the sulfonyl chloride would be attacked by the amine to give the sulfene faster than it is reduced by the triphenylphosphine (2). The reaction gave benzyltriphenylphosphonium chloride (**2***a*) (see eq. 1) mixed with the corresponding phosphonium phenylmethanesulfonate (**2***d*) (the total yield of the phosphonium ion was 32%).

[1] $$RCH_2SO_2Z + Ph_3P \xrightarrow{Et_3N} RCH_2\overset{+}{P}Ph_3\ Z^-$$

1 **2**

a R = Ph; Z = Cl

b R = Ph; Z = 
c R = H; Z = OSO_2CH_3

d R = Ph; Z = OSO_2CH_2Ph

Triphenylphosphine oxide and triphenylphosphine sulfide were also isolated but these probably arose by the direct reduction of the sulfonyl chloride by the phosphine, since they are also obtained when triethylamine is left out of the reaction; the phosphonium salts are not formed under the latter conditions. Horner and Nickel (2) have reported the formation of triphenylphosphine oxide on reaction of triphenylphosphine and benzenesulfonyl chloride. Theirs is clearly a reaction which cannot involve a sulfene, and presumably takes place by attack of the phosphine on the chlorine with displacement of the sulfinate anion. Pearson's "hard-soft-acid-base" (HSAB) theory (3) suggested that the direct reaction of the phosphine and the sulfene precursor **1** might be slowed if the chlorine were replaced by a "harder" function capable of acting as a leaving group. Singh in these laboratories (4) had shown that 2,4-dinitrophenyl phenylmethanesulfonate (**1***b*) and related esters give products evidently derived from phenylsulfene. When **1***b* was treated with triphenylphosphine alone for 3 h little reaction was observed, but with a mixture of triethylamine (1 mol) and triphenylphosphine (3 mol), benzyltriphenylphosphonium 2,4-dinitrophenoxide (**2***b*) was isolated in good (87%) yield. Sulfur dioxide was also generated in the reaction, which is apparently complete in less than 1 min. The salt **2***b* was not obtained crystalline; it was characterized by conversion to and formation from benzyltriphenylphosphonium

3 4 5 2

chloride (**2***a*). Essentially the same result was obtained with equimolar amounts of **1***b*, the amine and the phosphine.

Methanesulfonyl chloride with triethylamine and triphenylphosphine gave no sign of any methyltriphenylphosphonium species. This is not very surprising since sulfene formation with triethylamine is about 1000 times slower with methanesulfonyl chloride than with phenylmethanesulfonyl chloride (5). It is unlikely that the corresponding change in the rate of the triphenylphosphine reduction is as large, and hence it would be expected that the reduction would be relatively much faster than sulfene formation from methanesulfonyl chloride. 2,4-Dinitrophenyl methanesulfonate also gave no phosphonium salt. It was found that 2,4-dinitrophenyl methanesulfonate did not react with triethylamine even on standing for a number of hours, and it is therefore likely that again, sulfene formation was not sufficiently fast to compete with other reactions. Methanesulfonic anhydride (**1***c*), however, gave a moderate yield of the methyltriphenylphosphonium ion, characterized as the bromide (41% yield). No systematic study varying either the sulfonyl chloride or phosphine was attempted, though our results suggest a somewhat limited generality for this reaction. The reaction of tributylphosphine and triethylamine with **1***b* showed no sign of the phosphonium salt.

To account for the formation of the phosphonium salts **2** we suggest the mechanism summarized in eq. 2 as a reasonable possibility. The cyclic intermediate **4** could conceivably be formed by a direct cycloaddition onto the sulfene **3**, or perhaps via the zwitterionic species **6** and **7**. The intermediacy of **4** is, of course, not required by the available data; the ylide **5** could arise directly from either of the zwitterions, such a process being particularly simple from **7**, the zwitterion deriving from "abnormal attack" (6) on the sulfene. The ylide **5** would be expected to pick up a proton very rapidly from the triethylammonium ion formed as a by-product from the original sulfene generation. In the present system in which sulfene is formed by removal of HZ (in eq. 1) with base, the presence of a conjugate acid capable of protonating the ylide cannot be avoided without introducing further complications. We tried to carry out the reaction with triphenylphosphine using the Staudinger–Pfenninger diazoalkane and sulfur dioxide procedure for forming sulfenes (7). No sign of any ylide was found, though this could be due merely to preclusion of the sulfene formation by a faster reaction between the phenyldiazomethane and triphenylphosphine (*cf.* ref. 8).

$$\overset{-}{R}CH{-}SO_2\overset{+}{P}Ph_3 \qquad RCH(SO_2^-)\,{}^+PPh_3$$

6 7

Experimental

Melting points were determined in capillary tubes with a Gallenkamp apparatus and are uncorrected.

The i.r. spectra were recorded in CH_2Cl_2 solutions, unless stated otherwise, with a Beckman IR-20A or IR-10 instrument.

The n.m.r. spectra were recorded in $CDCl_3$ solutions, unless stated otherwise, with a Varian T-60 spectrometer. The band positions are reported in p.p.m. downfield from TMS as internal reference (δ scale).

Analytical t.l.c. was carried out with silica gel (Camag DF5, containing u.v. indicator) on microscope slides. Preparative t.l.c. was carried out with *ca.* 1.0 mm thick layers of silica gel (Camag DF5, containing u.v. indicator) on 20 × 20 cm glass plates. Unless stated otherwise, t.l.c. chromatograms were developed with CH_2Cl_2–MeOH, 100:15 (v/v), analytical chromatograms were made visible with iodine vapor, and preparative chromatograms by the quenching of the u.v. phosphor.

Solvents were removed from solutions with a Büchi rotary evaporator in conjunction with a water aspirator. Dichloromethane solutions were dried by passing them through a small plug of cotton wool before evaporation.

The term "separation into polar and nonpolar fraction with silica gel" as used here means that the CH_2Cl_2 solution was swirled with about 10 times its weight of t.l.c. silica gel, filtered through a sintered glass funnel, and the filtrate again treated with silica gel and filtered. The CH_2Cl_2 filtrates then contained the "nonpolar" material. Extraction of the silica gel with CH_2Cl_2–MeOH (100:15, v/v) gave a solution of the "polar" material. Unless otherwise stated, recrystallization was effected from dichloromethane–hexane.

2,4-Dinitrophenyl Phenylmethanesulfonate (1b)

Triethylamine (4.37 ml, 3.19 g, 31.5 mmol) was added

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with stirring to a solution of phenylmethanesulfonyl chloride (6.0 g, 31.4 mmol) and 2,4-dinitrophenol (27.8 g, 151 mmol) in dichloromethane (400 ml). After stirring for 30 min, the solution was washed repeatedly with aqueous sodium bicarbonate until the aqueous layer was pale yellow, then passed through a small plug of cotton wool and concentrated to *ca.* 40 ml. Enough hexane was added to the bright red solution to make it slightly cloudy, then dichloromethane was added till the solution was again clear; crystallization began at once. The product consisted of light yellow prisms, m.p. 111–114.5°; yield 7.1 g (67%). The n.m.r. spectrum showed absorption at δ 8.87 (d, $J = 2.4$ Hz, 1H), 8.45 (d of d, $J = 2.4$ and 6.0 Hz, 1H), 7.3–7.7 (m dominated by spike at 7.50, 6H), 4.80 (s, 2H).

Anal. Calcd. for $C_{13}H_{10}N_2O_7S$: C, 46.15; H, 2.98; N, 8.28; S, 9.48. Found: C, 46.10; H, 3.06; N, 8.32; S, 9.34.

Reaction of 2,4-Dinitrophenyl Phenylmethanesulfonate with Triethylamine and Triphenylphosphine

(1) Identification of Benzyltriphenylphosphonium 2,4-Dinitrophenoxide

2,4-Dinitrophenyl phenylmethanesulfonate (169 mg, 0.50 mmol) in dichloromethane (10 ml) was added from a syringe over 50 min under nitrogen to a stirred solution of triethylamine (71 μl, 52 mg, 0.51 mmol) and triphenylphosphine (394 mg, 1.50 mmol) in dichloromethane (5 ml). The bright golden-yellow solution was stirred a further 3 h, at the end of which time t.l.c. showed the absence of 2,4-dinitrophenyl phenylmethanesulfonate. The dichloromethane solution was washed once with an equal volume of water. Evaporation of the pale yellow aqueous layer gave a slightly sticky yellow solid, 17 mg, the n.m.r. spectrum of which showed it to be essentially triethylammonium 2,4-dinitrophenoxide. Evaporation of the bright golden yellow dichloromethane layer gave a slightly sticky orange solid, 543 mg. This was separated into polar and nonpolar fractions with silica gel. The nonpolar fraction, 276 mg, was shown to be triphenylphosphine by direct comparison with an authentic sample. The polar material was a bright yellow foam, 233 mg. Comparison with authentic triphenylphosphonium 2,4-dinitrophenoxide by n.m.r., i.r., and t.l.c. indicated that this material was essentially triphenylphosphonium 2,4-dinitrophenoxide (yield *ca.* 87%). This material (the foam could be broken up to give a non-crystalline solid) failed to crystallize, but its identity was firmly established by conversion to benzyltriphenylphosphonium chloride and 2,4-dinitrophenol as follows. A 1.7 × 22 cm Dowex 1-X2 resin column was washed successively with saturated aqueous potassium chloride, water, and methanol. A methanolic solution of the phosphonium salt from the reaction was passed through the column, eluting with methanol. Evaporation of the eluate and recrystallization gave very pale yellow microprisms, m.p. 317–322°, 167 mg (89% based on the phosphonium dinitrophenoxide, 77% from 2,4-dinitrophenyl phenylmethanesulfonate); mixed t.l.c. of this with authentic benzyltriphenylphosphonium chloride (see below) gave one spot. Recrystallization gave colorless prisms, m.p. 326.5–329.5°, mixed m.p. with authentic benzyltriphenylphosphonium chloride of m.p. 325–329°, 325.5–328.5° (9). The i.r. spectrum was identical with that of the authentic phosphonium chloride. Further elution of the column with methanolic hydrogen chloride (*ca.* 2 *N*) and evaporation of the eluate gave 2,4-dinitrophenol as a pale yellowish solid, 81 mg (101%). Mixed t.l.c. with authentic 2,4-dinitrophenol gave one spot. Recrystallization gave yellowish-brown platelets, m.p. 111–112°, mixed m.p. with authentic 2,4-dinitrophenol (m.p. 112–113°), 111–113°. The i.r. spectrum was identical with that of authentic 2,4-dinitrophenol.

(2) Identification of SO_2

In another experiment, the reaction solution was slowly swept with nitrogen and the gases passed through a trap cooled in Dry Ice–acetone. The dichloromethane in the trap was shown to contain sulfur dioxide (*ca.* 17%) by its smell and by i.r. and u.v. spectrometry.

(3) Use of One Equivalent of each Reactant

When 1 equiv of each of the three reactants was used, the yield of benzyltriphenylphosphonium 2,4-dinitrophenoxide was *ca.* 85%.

When a dichloromethane solution of 2,4-dinitrophenyl phenylmethanesulfonate was added all at once to a dichloromethane solution of triethylamine and triphenylphosphine (1 equiv of each reactant), a transient red color was seen; in *ca.* 1 s this faded, giving an orange solution. The t.l.c. of the reaction solution, performed within 1 min of addition of the 2,4-dinitrophenyl phenylmethanesulfonate, was identical to that after 3 h, indicating that the reaction was complete within 1 min.

Treatment of 2,4-Dinitrophenyl Phenylmethanesulfonate with Triphenylphosphine in the Absence of Triethylamine

When the reaction was carried out as described above but omitting the triethylamine, after 3 h t.l.c. showed mainly the starting materials, and no trace of the phosphonium salt. Preparative t.l.c. (dichloromethane) led to the recovery of most of the starting materials.

Benzyltriphenylphosphonium 2,4-Dinitrophenoxide (2b)

An anionic resin column was made up by washing a 7 × 2 cm Dowex 1-X2 column successively with aqueous methanolic potassium 2,4-dinitrophenoxide (prepared by adding a saturated methanolic solution of 4.4 g (24 mmol) of the phenol to an aqueous solution of 1.62 g (11.7 mmol) of potassium carbonate), water, and methanol. Benzyltriphenylphosphonium chloride (**2a**) (9) (388 mg, 1.0 mmol) in methanol was passed through the column, eluting with methanol. Evaporation of the eluate gave a bright yellow foam, 484 mg (90%), which did not crystallize, ν_{max} 1603, 1552, 1310, 1126 cm^{-1}; δ 8.70 (d, $J = 3.6$ Hz, 1H), 7.4–8.1 (m, strong spike at 7.75, *ca.* 17H), 6.9–7.4 p.p.m. (m, *ca.* 5H).

Reaction of Phenylmethanesulfonyl Chloride (1a) with Triethylamine and Triphenylphosphine

A solution of phenylmethanesulfonyl chloride (188 mg, 0.98 mmol) in dichloromethane (10 ml) was added under nitrogen over 1 h to a stirred solution of triethylamine (141 μl, 103 mg, 1.02 mmol) and triphenylphosphine (800 mg, 3.05 mmol) in dichloromethane (6 ml); the bright yellow solution was stirred for another 3 h. After this time, the solution was washed once with an equal volume of water, and the aqueous and organic layers were examined.

Evaporation of the aqueous layer gave a white solid, 149 mg, which was shown by t.l.c. and i.r. and n.m.r. spectrometry to be largely triethylammonium chloride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Evaporation of the dichloromethane layer gave a yellow solid, 929 mg, which was separated into polar and nonpolar fractions with silica gel. The nonpolar material, 573 mg, was shown by t.l.c. and i.r. spectrometry to be triphenylphosphine contaminated with a modest amount of triphenylphosphine sulfide and a trace of triphenylphosphine oxide. The polar fraction was a white foam, 303 mg. This was subjected to preparative t.l.c. (dichloromethane–methanol, 100:10, v/v, two developments), which gave essentially three bands.

The most polar band represented a white solid, 138 mg. This was shown by direct comparison (t.l.c., i.r., n.m.r.) with an authentic mixture to be a *ca.* 60:40 (mol basis) mixture of benzyltriphenylphosphonium chloride and phenylmethanesulfonate. The yield of phosphonium salts was thus 0.31 mmol (32%).

The band of intermediate polarity corresponded to a white solid, 114 mg, shown by i.r. and n.m.r. spectrometry and t.l.c. to be triphenylphosphine oxide. The least polar material was a white solid, 28 mg, ν_{max} 1117 cm^{-1} which was not investigated further.

Benzyltriphenylphosphonium Phenylmethanesulfonate

(1) Preparation of Benzyl Phenylmethanesulfonate

Triethylamine (2.19 ml, 1.60 g, 15.8 mmol) was added over 6 min to a stirred solution of phenylmethanesulfonyl chloride (3.09, 15.7 mmol) and benzyl alcohol (1.70 g, 15.7 mmol) in dichloromethane (50 ml). The reaction mixture was stirred for 20 min, then washed once with an equal volume of water, passed through cotton wool, and concentrated until crystallization started. Hexane was then added and the solid filtered off and washed with hexane. The product was a colorless microcrystalline solid, 1.3 g, m.p. 80.5–81.5°. The mother liquors yielded 0.5 g of colorless microcrystalline solid, m.p. 93–94°. The i.r. and n.m.r. spectra of the two crops were identical, they were indistinguishable on t.l.c., and the mixed m.p. was 80–81°, showing that benzyl phenylmethanesulfonate is dimorphic. The total yield was 1.8 g (44%). The n.m.r. spectrum showed singlets at 7.35 (10H), 5.07 (2H), and 4.30 p.p.m. (2H); the i.r. had very strong bands at 1357, 1169, and 936 and 916 cm^{-1}.

(2) Conversion of Benzyl Phenylmethanesulfonate to Benzyltriphenylphosphonium Phenylmethanesulfonate

Benzyl phenylmethanesulfonate (262 mg, 1.0 mmol) and triphenylphosphine (262 mg, 1.0 mmol) were refluxed for 9 h in ethanol-free chloroform. The solution was concentrated and hexane was added until cloudiness was seen. Colorless prisms were deposited, 461 mg (88%), m.p. 182–185°; δ 7.3–7.9 (m, *ca.* 15H), 6.8–7.3 (m, *ca.* 10H), 4.87 (d, $J = 14$ Hz, 2H), 4.03 (s, 2H); ν_{max} 1178, 1107, 1031 cm^{-1}.

Anal. Calcd. for $C_{32}H_{29}O_3SP$: C, 73.26; H, 5.57. Found: C, 73.19; H, 5.12.

Reaction of Phenylmethanesulfonyl Chloride with Triphenylphosphine in the Absence of Triethylamine

A solution of triphenylphosphine (280 mg, 1.07 mmol) in dichloromethane (10 ml) was added dropwise to a stirred solution of phenylmethanesulfonyl chloride (200 mg, 1.05 mmol) in dichloromethane (2 ml). After 15 min, t.l.c. showed triphenylphosphine and a trace of starting material, together with a third component. More triphenylphosphine (37 mg) in dichloromethane (1 ml) was added, and after a further 20 min the solution was evaporated and subjected to preparative t.l.c. The most mobile band afforded a solid, 215 mg, which was recrystallized to give 50 mg of triphenylphosphine sulfide, the identity of which was established by direct comparison (m.p., i.r.) with an authentic sample. The mother liquors gave material of m.p. 82–89°, the i.r. spectrum of which showed it to be largely phenylmethanesulfonyl chloride. The least mobile band afforded triphenylphosphine oxide (258 mg), as shown by the i.r. spectrum of the material.

Another reaction, using sufficient triphenylphosphine to react with all the phenylmethanesulfonyl chloride, gave a reaction mixture in which no products containing the benzyl moiety were detected (n.m.r.).

Reaction of 2,4-Dinitrophenyl Phenylmethanesulfonate with Triethylamine and Tri-n-butylphosphine

2,4-Dinitrophenyl phenylmethanesulfonate (84.5 mg, 0.25 mmol) in dichloromethane (2.0 ml) was added under nitrogen over 7 min to a stirred solution of triethylamine (35 μl, 36 mg, 0.25 mmol) and tri-*n*-butylphosphine (59 μl, 50 mg, 0.25 mmol) in dichloromethane. The solution was stirred for a further 2.5 h, then the dichloromethane was replaced by deuteriochloroform and the n.m.r. spectrum of the reaction mixture was taken. This showed that benzyltri-*n*-butylphosphonium ion was absent and indicated the presence of a little starting **1***b*; t.l.c. (benzene) showed that tri-*n*-butylphosphine was absent. Authentic benzyltri-*n*-butylphosphonium chloride was prepared essentially as described by Smith and Winbush (10) except that chloroform rather than ethanol was used as the reaction solvent.

Reaction of Methanesulfonic Anhydride with Triethylamine and Triphenylphosphine

Methanesulfonic anhydride (11) (348 mg, 2.0 mmol) in dichloromethane (10 ml) was added under nitrogen to a stirred solution of triethylamine (0.282 ml, 2.04 mmol) and triphenylphosphine (1.57 g, 6.0 mmol) in dichloromethane (10 ml). The yellow solution was stirred for a further 20 min, then the reaction mixture was separated into nonpolar and polar fractions with silica gel. A methanol solution of the polar material was passed through an anionic resin column (Rexyn 203, bromide form, 7 × 2 cm), eluting with methanol. The methanol was removed, affording a yellow solid, 758 mg, the n.m.r. spectrum of which indicated it to be a mixture of triethylammonium bromide, methyltriphenylphosphine bromide, and a little triphenylphosphine oxide; t.l.c. was consistent with this. Preparative t.l.c. led to the isolation of triethylammonium bromide (80 mg), methyltriphenylphosphonium bromide (295 mg, recrystallized to give colorless prisms, m.p. 226–227°, mixed m.p. with authentic phosphonium bromide (12) (of m.p. 226.5–229°) 226.5–229; identity further confirmed by n.m.r. and i.r. spectra and by t.l.c.), and triphenylphosphine oxide (257 mg).

Reaction of Methanesulfonyl Chloride with Triethylamine and Triphenylphosphine

Methanesulfonyl chloride (0.156 ml, 2.0 mmol) was treated with triethylamine in the same way as was methanesulfonic anhydride. Separation into polar and nonpolar fractions and t.l.c. led to the isolation of triphenylphosphine oxide (282 mg) and triethylammonium chloride (148 mg) in addition to unidentified material (67 mg) which from its

n.m.r. spectrum could not contain more than 35 mg (yield <6%) of methyltriphenylphosphonium chloride (if any at all).

Reaction of 2,4-Dinitrophenyl Methanesulfonate with Triethylamine and Triphenylphosphine

2,4-Dinitrophenyl methanesulfonate (13) (65.5 mg, 0.25 mmol) was mixed with equimolar amounts of both triethylamine and triphenylphosphine in dichloromethane (2 ml total), and allowed to react for 1⅔ h; the mixture was then washed with water. The aqueous layer gave 25 mg of material identical in i.r. spectrum with triethylammonium 2,4-dinitrophenoxide. The organic phase gave 105 mg of material which after work-up yielded triphenylphosphine oxide (70 mg), identified by t.l.c. and n.m.r.; there was no sign of any methyltriphenylphosphonium ion.

In a separate experiment it was found that 2,4-dinitrophenyl methanesulfonate underwent little reaction with triethylamine under these conditions even after *ca.* 24 h.

Reaction of Phenyldiazomethane with Sulfur Dioxide, Triphenylphosphine, and Triethylammonium Chloride

Triphenylphosphine (262 mg, 1.0 mmol) and triethylammonium chloride (138 mg, 1.0 mmol) were dissolved, under nitrogen, in sulfur dioxide (*ca.* 10 ml) at −10°. The mixture was stirred under nitrogen and a solution of phenyldiazomethane (**14**) (118 mg, 1.0 mmol) in ethyl ether (7.7 ml) was added over *ca.* 1 min. The mixture was allowed to stand at room temperature for 1 h with exclusion of moisture, then the ether was removed to give a yellow solid, 601 mg, the n.m.r. spectrum of which showed the absence of benzyltriphenylphosphonium chloride.

Mass Spectrometry of some Nuclear Substituted Styryl Ketones

P. J. SMITH[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

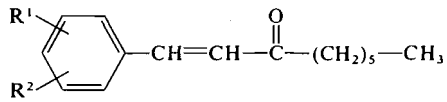
AND

J. R. DIMMOCK AND W. G. TAYLOR[2]

College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan

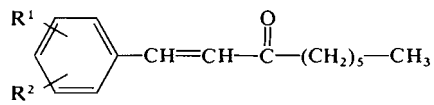
Received August 31, 1971

The mass spectra of a series of nuclear substituted styryl ketones with the structure



and several related compounds have been determined. The major fragmentation pathways include such processes as an aromatic substitution reaction occurring in the molecular ion as well as the McLafferty rearrangement. Only one of the two possible α-cleavages at the carbonyl function was observed. The major decomposition processes are outlined and compared with the recent results of a study on α,β-unsaturated aliphatic ketones. Mechanistic pathways are suggested for the formation of the major fragment ions.

Les spectres de masse d'une série de styryle cétones, substituées sur le noyau aromatique de structure



et de quelques composés apparentés, ont été déterminés. Les processus majeurs de la fragmentation incluent aussi bien des réactions de substitution aromatique se faisant sur l'ion moléculaire, que des transpositions du type McLafferty. Seul un des deux clivages possibles en α de la fonction carbonyle a été observé. Les processus majeurs de décomposition sont esquissés et comparés avec les résultats récents obtenus avec des cétones aliphatiques α,β-insaturées. Des mécanismes sont proposés pour rationaliser les principaux ions fragments.

Canadian Journal of Chemistry, **50**, 871 (1972)

Introduction

The mass spectrometry of α,β-unsaturated cyclic ketones have been reported previously (1, 2). It is only recently that the modes of fragmentation of α,β-unsaturated acyclic ketones have been studied in detail (3, 4).

α,β-Unsaturated ketones are alkylating agents and react with nucleophiles including thiols (5, 6). We have been interested in some nuclear substituted styryl ketones (7, 8) for this reason. The results of the mass spectral study of these compounds are reported in this paper and compared with those obtained from the study of the α,β-unsaturated aliphatic ketones (4).

Results and Discussion

The compounds which have been investigated are those shown in series 1 as well as several related derivatives as shown in series 2. The mass spectra are reproduced in Figs. 1–10.

The olefinic double bond in compounds **1–9** were shown from their n.m.r. spectra to have the *trans* arrangement.

A feature of particular interest in the spectra of compounds **1–9** is the presence of an M-H and/or an M-Cl peak. In all cases the process resulting in the loss of chlorine from the parent ion was confirmed by the observation of the appropriate metastable ions. It has been suggested (9, 10) that the species corresponding to these peaks arises from an intramolecular aromatic substitution reaction occurring in the

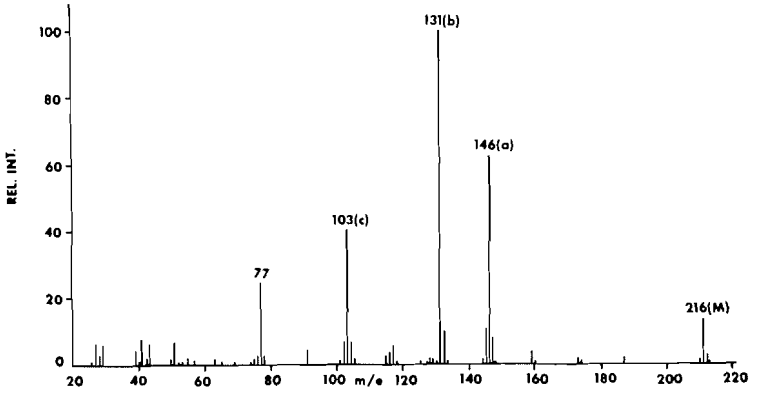

FIG. 1. Mass spectrum (70 eV) of **1**.

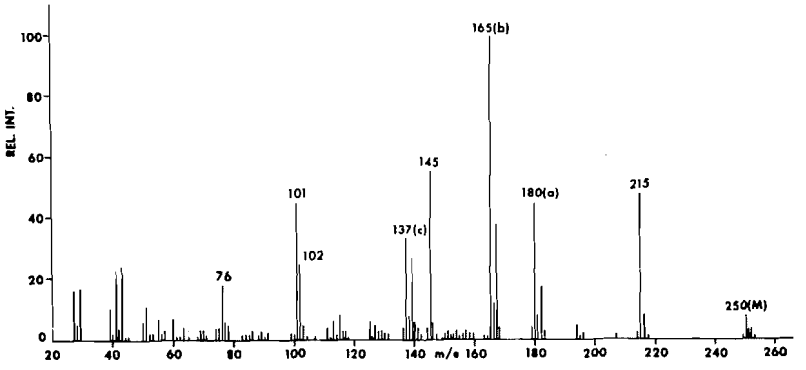

FIG. 2. Mass spectrum (70 eV) of **2**.

molecular ions with the formation of a relatively stable benzopyrylium ion. For this process to be operative a prior *trans* to *cis* isomerization in the molecular ion is necessary.

We suggest that attack of the carbonyl oxygen occurs only at the positions ortho to the styryl double bond since only when a chlorine is in this position is a peak observed for the loss of halogen from the molecular ion (see Scheme 1). In fact, the spectrum of the 2,6-dichloro compound, **5**, Fig. 5, has the M-Cl peak as the base peak, *m/e* 249, and does not exhibit an M-H peak. Compounds such as the 4-Cl, **3**, and the 3,4-dichloro, **6**, however, do not exhibit an M-Cl peak but only M-1 peaks corresponding to the loss of a hydrogen atom.

The relative intensity of the M-H and the M-Cl peaks in the spectrum of the 2-chloro substrate, Fig. 2, is noteworthy. The formation

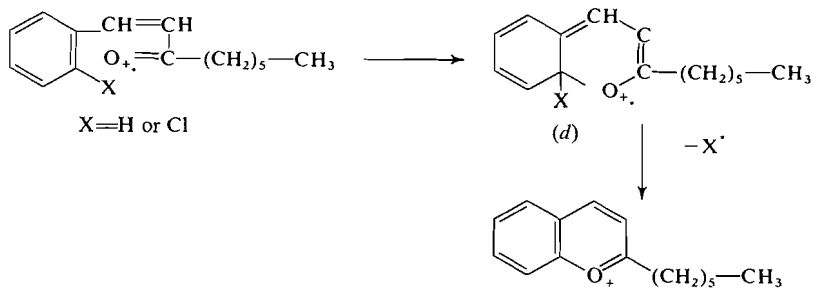
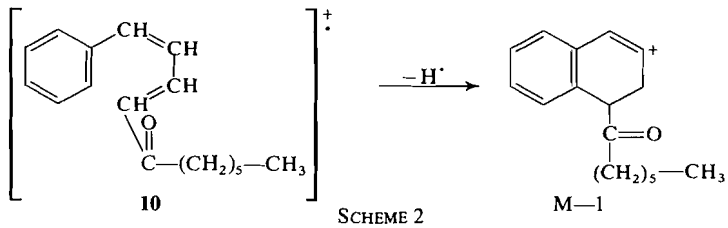


SCHEME 1



SCHEME 2

of the intermediate (*d*) might be expected to be retarded when attack occurs at the carbon bearing the chlorine for steric reasons and thus result in a greater peak intensity from the M-H process as compared with the loss of chlorine from the molecular ion. The fact that the loss of chlorine is much more favored than the loss of hydrogen, [M-Cl]/[M-H] is approximately 36:1, suggests that the steric factors are relatively unimportant compared to the leaving ability of the ortho substituent.

The spectrum of compound **10**, $C_6H_5CH{=}CH{-}CH{=}CH{-}\overset{\overset{O}{\|}}{C}{-}(CH_2)_5{-}CH_3$, Fig. 10, also exhibits an M-1 peak. By analogy to the styryl ketones the ion corresponding to this peak might arise via a similar intramolecular aromatic substitution reaction (Scheme 2).

A very prominent peak in all the spectra, except for compounds **8** and **9** where the alkyl side chain is less than three carbon atoms in length, corresponds to the McLafferty rearrangement product, ion (*a*). The appropriate

(*a*) (*a*) − Cl·

SCHEME 3

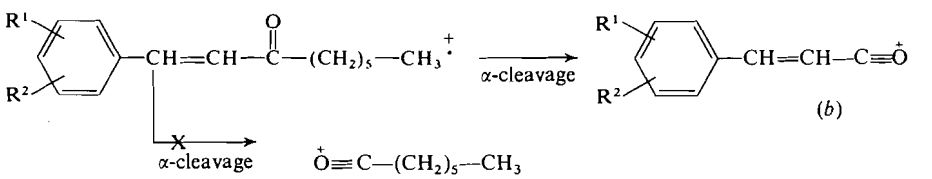
metastable peak was observed in all cases. Only the McLafferty product along with the molecular ion and the M-Cl ion from the ortho-substituted compounds was observed when the spectra were recorded at 15 eV.

Sheikh *et al.* (4), in the detailed study of α,β-unsaturated aliphatic ketones, found that the McLafferty rearrangement product, from such ketones as $CH_3(CH_2)_3CH{=}CH{-}\overset{O}{\overset{\|}{C}}{-}C_5H_{11}^n$, lost a methyl radical as shown by a strong metastable peak. It was proposed that this loss might proceed via a resonance form of the McLafferty product rather than through the keto form.[3] We have not found any evidence of a metastable peak corresponding to this loss of methyl in the present series of compounds. The chloro substituted compounds, **2**–**6**, however, all showed an intense metastable peak corresponding to the loss of a halogen atom from the McLafferty rearrangement product to give an ion at *m/e* 145 for **2** and **3** and an ion at *m/e* 179 for compounds **4**–**6**. This loss of halogen appears to be independent of the position of chlorine on the ring relative to the styryl double bond contrary to the results observed for the loss of halogen from the molecular ion. As expected, there was not a peak in the mass spectrum of **7**, corresponding to the loss of $N(CH_3)_2$ from the rearrangement product.

The loss of halogen from the McLafferty rearrangement ion, (*a*), could presumably proceed via a combination of either a simple bond cleavage process or via a cyclization similar to that represented for the loss of an ortho chlorine from the parent ion in the case of those substrates with a 2-chloro substituent (Scheme 3). That the latter pathway is followed to some extent is shown by the fact that the rearrangement product from all the compounds studied lost a hydrogen atom except the 2,6-dichloro substrate where an ortho hydrogen is not available.

In the study of the α,β-unsaturated aliphatic ketones, $R^1{-}CH{=}CH{-}\overset{O}{\overset{\|}{C}}{-}R$, Sheikh *et al.* (4) found that a general fragmentation was the cleavage of the vinylic double bond leading to the loss of R^1, C_4H_9, from the molecular ion. This *a priori* unfavorable vinylic bond rupture with loss of a substituted phenyl radical was not observed in the spectra of the present series of compounds. This presumably is a result of the conjugation in the molecular ion of the styryl ketones which would make such a bond cleavage unfavorable.

Contrary to the observation in the aliphatic series (4), where both product ions resulting from cleavage α to the carbonyl were noted, the present investigation revealed only one α-cleavage product, (*b*) (Scheme 4). The preferred α-cleavage to give ion (*b*) is probably due to



m/e 113

SCHEME 4

[3]It has been shown that the McLafferty product does not ketonize in cyclic ketones (11), malonic esters (11), and substituted barbituric acids (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

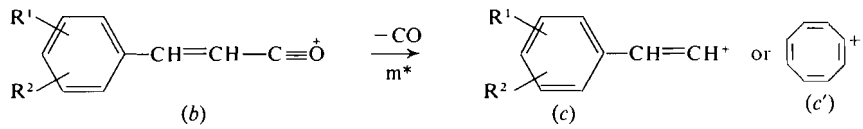
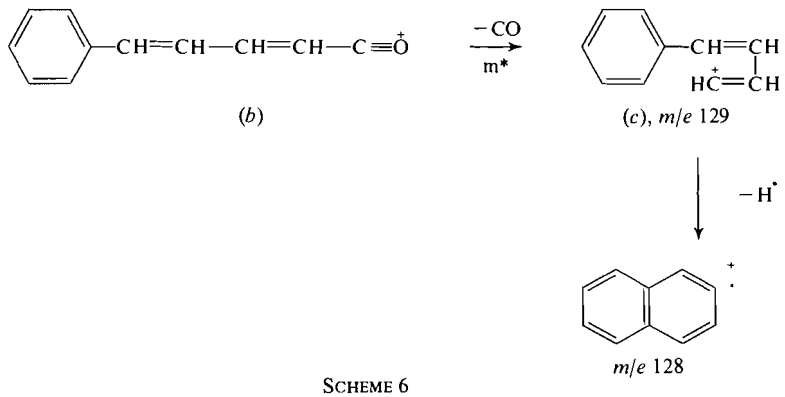


SCHEME 5



SCHEME 6

the fact that (*b*) is considerably more stable than the ion at *m/e* 113. In fact, ion (*b*) represented the base peak in all the spectra determined except for substrate **5**, the 2,6-dichloro compound which had as its base peak, the M-Cl ion. A metastable ion was observed for the above α-cleavage process only in the spectra of compounds **8**–**10**.

A fragmentation pathway common to all of the compounds studied, as confirmed by the appropriate metastable peaks, was the conversion of ion (*b*) to ion (*c*) or (c^1) (Scheme 5). Such a process leading to a vinylic cation, (*c*), was expected to be unfavorable. The results can be rationalized in terms of the structure (c^1) and as well by the favorable loss of the neutral molecule, carbon monoxide.

The formation of an ion of structure (*c*), *m/e* 129, in the case of compound **10** resulted in the facile loss of a hydrogen atom to form an ion at *m/e* 128, probably possessing a naphthalene structure (Scheme 6).

Ion (*c*), *m/e* 103, formed during the fragmentation of compounds **1** and **8**, confirmed by the appropriate metastable ions, lost C_2H_2 to give the relatively intense ion, $C_6H_5^+$. The corresponding ions, (*c*) *m/e* 137, however, from the mono chloro substrates; *i.e.*, **2**, **3**, and **9**, decomposed by first losing Cl· or HCl followed by a subsequent loss of acetylene. Both steps of this fragmentation route were confirmed by metastable ions. It is noteworthy that the ion (*c*), derived from **7**, the dimethylamino compound, is reasonably stable as evidenced by very little subsequent fragmentation from this ion. This could be due to the electron-donating power of the para-dimethylamino function.

Ion (*c*), *m/e* 171, derived from the dichloro substituted compounds, first lost a chlorine atom to give an ion at *m/e* 136 as confirmed by a metastable ion. Loss of a hydrogen from *m/e* 136 yields an ion at *m/e* 135 which subsequently loses HCl to give an ion at *m/e* 99 as shown by a metastable peak. The ion at *m/e* 101 resulting from the loss of the two halogens from (*c*), *m/e* 171, decomposed by loss of C_2H_2 to give $C_6H_5^+$.

As expected for those compounds with six carbon atom side chains, compounds **1**–**7** and compound **10**, an ion produced by γ-cleavage was observed, M-C_3H_7, as well as the appropriate metastable peak. Peaks observed in all the spectra except for compounds **8** and **9** at *m/e* 43 and 41 probably arise from the hydrocarbon side chain. Such peaks are absent in

the spectra of **8** and **9** which do not have the appropriate number of carbon atoms in the alkyl group.

Experimental

Mass spectra were determined by Mr. D. Bain with an MS-12 mass spectrometer operating at 70 eV and an ion source temperature of 100°. The samples were introduced via the direct probe technique. Melting points and boiling points are uncorrected. Microanalyses were performed by Dr. F. B. Strauss, Microanalytical Laboratories, Oxford, England and Mr. R. M. Smith of the College of Pharmacy, University of Saskatchewan, Saskatoon. Gas–liquid chromatography was performed on a Pye Series 104 Gas Chromatograph equipped with a flame ionization detector. The glass column (5 ft × 0.25 in. o.d.) was packed with 4% SE-30 on acid washed and silanized 100/120 mesh Chromosorb W. The column temperature ranged from 110–250° and the nitrogen flow rate was 50 ml/min.

*General Procedure for the Preparation of Substituted 1-Phenyl-1-nonen-3-ones (Table 1, **1–6**)*

A mixture containing 2-octanone (0.60 mol), the appropriate aromatic aldehyde (0.50 mol), sodium hydroxide (0.25 mol), and water (300 ml) was heated under reflux with vigorous mechanical stirring for 24 h. After cooling to room temperature, the mixture was extracted with benzene, the organic extracts were washed with water and dried ($MgSO_4$). The benzene was evaporated *in vacuo* to give a crude product and unreacted aldehyde and 2-octanone were removed by distillation. The residue was purified by repeated distillation or recrystallization.

*1-Phenyl-1-penten-3-one (**8**)*

This compound was prepared from 2-butanone and benzaldehyde by the general method described previously. Four recrystallizations from petroleum ether (b.p. 40–60°) gave pure **8** (35%); m.p. 38–40°; lit. (15) m.p. 38–39°.

Anal. Calcd. for $C_{11}H_{12}O$: C, 82.46; H, 7.55. Found: C, 82.43; H, 7.41.

*1-(p-Chlorophenyl)-1-penten-3-one (**9**)*

The title compound was prepared (25%) by the general procedure described earlier (12 h reflux with mechanical stirring). Five recrystallizations from isopropanol gave the analytical sample, m.p. 77°.

Anal. Calcd. for $C_{11}H_{11}ClO$: C, 67.87; H, 5.70. Found: C, 67.95; H, 5.71.

*1-Phenyl-1,3-undecadien-5-one (**10**)*

A solution of sodium ethoxide (10% w/v, 10 ml) was added with vigorous mechanical agitation to a mixture of cinnamaldehyde (0.15 mol) and 2-octanone (0.15 mol) at 0°. The reaction mixture was stirred for 3 h, cooled to −10° for 48 h, and then water (100 ml) was added. The mixture was extracted with ether, washed with water, and dried ($MgSO_4$). Removal of the solvent *in vacuo* gave crude **10** as a yellow powder. Three recrystallizations from ether gave pure **10** (37%) as colorless crystals, m.p. 75–77°; lit. (16) m.p. 68°.

Anal. Calcd. for $C_{17}H_{22}O$: C, 84.25; H, 9.15. Found: C, 84.00; H, 9.12.

The authors wish to thank the National Research Council for a grant enabling the purchase of a A.E.I. MS-12 mass spectrometer to be made. One of the authors (W.G.T.) thanks the Medical Research Council for providing a studentship and financial support was also provided by Smith Kline and French Laboratories of Philadelphia, Pennsylvania. Our thanks are also extended to Mr. G. B. Baker and Miss J. L. McGillivray of the College of Pharmacy who prepared two of the compounds described in this work.

Isomeric Pyrimidone and Uracil Derivatives Obtained by Reaction of Barbiturates with Diazomethane[1]

G. A. NEVILLE AND H. W. AVDOVICH

Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada

Received June 25, 1971

A re-examination of some recently reported studies by Ito *et al.* (1) of the action of diazomethane on barbituric acid, 1-methylbarbituric acid, and 5-ethyl- and 5-phenylbarbituric acids has resulted in the assignment of structures for some of the various possible positional isomers. These reactions were found to be more complex than previously indicated.

Les récentes études effectuées par Ito *et al.* (1) sur l'action du diazométhane sur l'acide barbiturique, l'acide méthyl-1 barbiturique, et sur les acides éthyl-5 et phényl-5 barbituriques, ont été réexaminées dans le but d'attribuer des structures à quelques uns des nombreux isomères de position possibles. Ces réactions semblent beaucoup plus complexes qu'on l'avait d'abord supposé.

Canadian Journal of Chemistry, **50**, 880 (1972)

Introduction

In a recent paper, Ito *et al.* (1) reported some results from the methylation of barbituric acid and its *N*-methyl, 5-alkyl, and 5,5-dialkyl derivatives with diazomethane. Unfortunately these workers encountered many of the same difficulties regarding structural assignment of the various possible isomeric pyrimidone and uracil derivatives formed on reaction of these barbiturates with diazomethane as we had experienced earlier with similar treatment of 1,5-dialkylbarbituric acids (2, 3). Although many new *O*-methyl and *N*-methyl derivatives of the tautomeric barbiturates are formed in these reactions, their positional isomerism is not easily elucidated from the usual p.m.r., i.r., and mass spectral data, and they are not easily or unambiguously obtained by alternative syntheses. It is the purpose of this communication to compare our findings with those of the Japanese workers and to reassess their structural conclusions on the basis of solvent and shift reagent studies of the various products by p.m.r. spectrometry.

In arriving at these structural assignments, use has been made of the relatively new paramagnetic shift reagent, tris-(dipivalomethanato)europium, $Eu(DPM)_3$, (4–6) and of the somewhat more common solvent effects in p.m.r. spectrometry. It appears, however, that this is the first example of the application of these techniques for structural elucidation of substituted pyrimidines. Various applications of the $Eu(DPM)_3$ shift reagent have been reviewed recently (7) together with an interpretation of the effect in terms of reversible complexation leading to pseudocontact shifts. In contrast, the magnitude and sign of proton resonance solvent shifts have been rationalized by means of reference plane rules (8–10) based on studies of various ketones and ethers. These rules have been generalized (11, 12): protons lying in front of the plane will tend to be deshielded in benzene (relative to an "inert" solvent) while those behind the plane will tend to be shielded in benzene. The shifts ($\Delta = \delta CCl_4 - \delta C_5H_5N$ p.p.m.) observed for pyridine are in general more negative than the corresponding benzene-induced shifts (13). The carbonyl plane "rule" is also applicable to pyridine-induced solvent shifts in some ketones (14), but the reference plane is displaced so that it passes through the α-carbons rather than the carbonyl carbon (13).

Some use has been made of the solvent shifts for methoxy-group resonances induced by trifluoroacetic acid (TFA) (15, 16) as an aid to structural elucidation. The downfield shift by TFA ($\Delta = \delta CCl_4 - \delta TFA$ p.p.m.) for methoxy-group resonances of several methoxybenzenes has been attributed to protonation of the methoxy-group (15) whereas with flavones protonation by TFA at both methoxy and carbonyl groups has been proposed (16).

Results

Methylation of Barbituric Acid and N-Alkyl Derivatives

When Ito *et al.* (1) treated a cold suspension of barbituric acid in ether with diazomethane for 10 min, they obtained as their major product (74%) a substance (m.p. 224–225° dec.) which they claimed to be 1-methyl-6-methoxyuracil (**1***b*) solely on the basis of p.m.r. spectral data in trifluoroacetic acid (TFA). We have also obtained this substance as the major derivative under similar conditions based on the similarity of chemical shift data in TFA; however, our material melts nearly 10° higher. Chemical shift data (Table 1) from solvent studies on both this compound and the isomeric *N*-methyl analog **1***c* indicate that **1***b* is the correct structure for this compound.

TABLE 3. Chemical shifts in p.p.m. downfield from TMS internal reference for **2**

Solvent	H(C-5)	OMe (C-2)	OMe (C-6)	N-Me

$\Delta_{0.031\ M\ Eu(DPM)_3}^{0.20\ M\ CDCl_3}$	−1.40	−0.30	−0.15	−1.30
$\Delta_{C_6H_6}^{CCl_4}$	−0.32	+0.70	+0.82	−0.05
$\Delta_{TFA}^{CCl_4}$	−1.02	−0.35	−0.37	−0.43

In addition to the above compound, we obtained a second derivative (2%), not reported by the Japanese workers, which was shown to be 1,2-dihydro-2,6-dimethoxy-3-methyl-4-oxopyrimidine (**2**) by comparison of p.m.r. spectra (Table 3) with those of the same compound obtained by isomerization of *sym*-tri-

methoxypyrimidine with methyl iodide. We also isolated a small quantity (10%) of 6-methoxyuracil (**1***a*) (m.p. 264–269° dec.) which was not found in this reaction by the Japanese workers. The same *O*-monomethyl compound was reported much earlier by Arndt (17) to be formed from barbituric acid with diazomethane.

Treatment of 1,3-dimethylbarbituric acid and 1,3-diethylbarbituric acid with excess diazomethane gives 1,3-dimethyl-6-methoxyuracil (**1***d*), first prepared by Biltz and Wittek (18), and 1,3-diethyl-6-methoxyuracil (**1***e*), a new derivative. Whereas the chemical shift data for 1,3-dimethyl-6-methoxyuracil (**1***d*) (Table 1) and 1,3-diethyl-6-methoxyuracil (**1***e*) (Table 2) confirm the expected structures, the relatively small differences in chemical shift between the protons of the *N*-alkyl substituents provide little assurance for the assignment of frequencies to the appropriate *N*-alkyl group.

In contrast to the Japanese workers who reported that treatment of 1-methylbarbituric acid with excess diazomethane over a 2 h period yields a mixture of 3-methyl-6-methoxyuracil (**1***c*)(77%), 1-methyl-6-methoxyuracil(**1***b*)(15%), and 1,3-dimethyl-6-methoxyuracil (**1***d*) (3%), we found that similar treatment of 1-methylbarbituric acid gives 1,3-dimethyl-6-methoxyuracil (**1***d*) as the major product. Again, the p.m.r. spectral evidence provided by Ito *et al.* (1) serves only to differentiate the two compounds **1***b* and *c*, but it remains inadequate as the sole basis of the assignment of structure to these positional isomers.

Methylation of 5-Ethyl- and 5-Phenylbarbituric Acid

The main product of the action of excess diazomethane on 5-ethylbarbituric acid for a 10 min period is 4,6-dimethoxy-5-ethylpyrimidone-2 (**3**) as previously reported (1). Our chemical shifts for **3** in TFA (Table 4) are identical with those reported by the Japanese workers; however, we were able to establish the non-equivalence of the two methoxy groups of **3** in TFA by scanning with the 100 Hz sweep width and confirmed the non-equivalence by observing slightly larger differences in the chemical shifts in $CDCl_3$ and pyridine solution.

On treating 5-phenylbarbituric acid overnight with excess diazomethane, Ito *et al.* (1) obtained a product (**4**) in low yield which they recognized

to be an *N,O,O*-trimethyl derivative. Although this compound was characterized by melting point, microanalysis, u.v., and p.m.r. spectra, these workers were not able to assign one of the three possible structures **4***a*, *b*, or *c* to the new derivative. In repeating this work, we also obtained **4** as the major product for which we have assigned the structure **4***a* on the basis of solvent and reagent shift studies (Table 5). In addition, we obtained 2,4,6-trimethoxy-5-phenylpyrimidine (**5**) as a minor product.

Discussion

Assignment of Structures

The compounds 1-methyl-6-methoxyuracil (**1***b*) and 3-methyl-6-methoxyuracil (**1***c*) were readily differentiated, and their structures were confirmed on the basis of solvent and shift reagent studies. In these compounds, the carbonyl oxygen at C-4 is expected from electronic considerations to be more favored for protonation than the ureido oxygen, and some evidence for protonation in such systems has been reported (19). From the chemical shift data (Table 1), it is seen that the largest downfield shifts in TFA relative to $CDCl_3$ ($\Delta^{CDCl_3}_{TFA}$) are given by the C-5 protons in each of **1***b* and *c* consistent with the above hypothesis. In addition, the methyl protons at N-3 of **1***c* show the next largest $\Delta^{CDCl_3}_{TFA}$ downfield shift appropriate to their proximity to a center inductively favored for development of positive charge. Because these properties also favor the C-4 oxygen as the donor for pseudocontact complexation (7) with $Eu(DPM)_3$, the marked deshielding of the C-5 and N-3 protons of **1***c* by $Eu(DPM)_3$, relative to their chemical shifts in $CDCl_3$, confirms the structure for 3-methyl-6-methoxyuracil (**1***c*).

The major product obtained by isomerization of *sym*-trimethoxypyrimidine with methyl iodide, which was also shown to be identical to a minor derivative resulting from methylation of barbituric acid, was deduced to have the structure 1,2-dihydro-2,6-dimethoxy-3-methyl-4-oxopyrimidine (**2**) from consideration of various solvent effects (Table 3) in addition to the shifts induced by $Eu(DPM)_3$. The relatively large and nearly equal upfield shifts for the C-2 and -6 methoxy protons of **2** in benzene relative to carbon tetrachloride ($\Delta^{CCl_4}_{C_6H_6}$) together with the smaller downfield shifts for the C-5 and N-methyl protons of **2** are compatible with the generalized reference plane rules for benzene solvent effects (11, 12). Additional support for the assignment of structure **2** to the major isomerized product is provided by the $\Delta^{CCl_4}_{TFA}$ downfield shifts (Table 3) which are largest for the C-5 and *N*-methyl protons consistent with the view that the C-4 oxygen is favored for protonation. On the same basis, complexation involving the C-4 oxygen with $Eu(DPM)_3$ would be expected to result in large downfield shifts for the C-5 and *N*-methyl protons of **2** as confirmed by the data in Table 3.

Only three possible positional isomers, **4***a*, *b*, or *c*, may be written for the major *O,O*-dimethyl-*N*-methyl derivative isolated from the reaction of 5-phenylbarbituric acid with diazomethane. The benzene solvent shifts relative to CCl_4 (Table 5) appear to favor **4***c* whereas the TFA solvent shifts tend to support structure **4***a* more than **4***b*. In contrast, the shifts observed with $Eu(DPM)_3$ demonstrate unequivocally

that the *N*-methyl and phenyl groups are adjacent to the carbonyl function.

It is also noteworthy that the multiplet character for the phenyl proton signal of **4***a* in $CDCl_3$ alone suggests coplanarity of the phenyl ring with the pyrimidine ring. Addition of $Eu(DPM)_3$ reagent causes the multiplet to appear as two new multiplets integrating for two and three protons, respectively. Since the two proton multiplet is at lowest field, this pattern appears to arise from the two adjacent ring protons that would be proximate to the carbonyl group in the coplanar model.

Frequency Assignment to N-Alkyl Protons and Non-equivalence of Methoxy Groups

Very small differences in chemical shift (p.p.m.) were observed between the two *N*-methyl frequencies of 1,3-dimethyl-6-methoxyuracil (**1***d*) in $CDCl_3$ (0.03), CCl_4 (0.09), C_6H_6 (0.04), C_5H_5N (0.20), and TFA (0.02) (Table 1). These small differences together with the small distinctions afforded by the values for $\Delta^{CCl_4}_{C_6H_6}$, $\Delta^{CCl_4}_{C_5H_5N}$, and $\Delta^{CCl_4}_{TFA}$ (Table 1) do not provide much assurance for the correct assignment of frequencies to the respective *N*-methyl groups of **1***d*. A similar situation was found to exist for 1,3-diethyl-6-methoxyuracil (**1***e*) (Table 2). In assigning these frequencies initially, the protons of the alkyl group at N_3 in both **1***d* and *e* were assumed to be in a more deshielding environment than those at N_1. These frequency assignments were then checked for consistency of their induced shifts by studying the effect of the $Eu(DPM)_3$ shift reagent on the N_3-alkyl and C-5 protons where the largest deshielding effects were expected for complexation at the C-4 carbonyl oxygen. The correctness of the initial frequency assignments and the assumption on which they were based are supported by the downfield shift of -0.70 p.p.m. for the N_3-methyl protons of 1,3-dimethyl-6-methoxyuracil (**1***d*) which is intermediate in magnitude between the downfield shifts for the C-5 and N_1-methyl protons of **1***d* (Table 1). An even more striking differentiation of the alkyl group frequencies is provided by $Eu(DPM)_3$ with 1,3-diethyl-6-methoxyuracil (**1***e*) where the N_3-methylene protons experience comparable deshielding (-1.55 p.p.m.) to the C-5 proton (-1.20 p.p.m.) in comparison to the N_1-methylene protons (-0.56 p.p.m.). The methyl protons of the N_3-ethyl substituent are similarly clearly distinguished from those of the N_1-ethyl group.

4,6-Dimethoxy-5-ethylpyrimidone-2 (**3**) is an almost symmetrically substituted molecule. Unfortunately the poor solubility of **3** in $CDCl_3$ precludes its study with the $Eu(DPM)_3$ shift reagent as a means of checking the assigned frequencies of the observed non-equivalent methoxy groups. In making the frequency assignments of Table 4, it was assumed that the C-4 methoxy group is in a more deshielded environment than the C-6 methoxy group because of the planar C=N—C=O moiety of the ring. The compound is also too insoluble in either carbon tetrachloride or benzene; thus, the limited chemical shift data are insufficient to settle this mute and interesting fine structural feature.

Experimental

Apparatus

The p.m.r. spectra were obtained with a Varian A-60A spectrometer from solutions (solvents indicated in Tables 1–5) usually 10–15% by weight in solute. No concentration effects were observed upon dilution, and chemical shifts, reported in p.p.m. downfield from tetramethylsilane (TMS) internal reference, are considered accurate to ± 0.02 p.p.m.

Melting point determinations were made either with a Thomas Unimelt capillary apparatus and reported uncorrected or with a precision melting apparatus (20) (prec.) containing Dow 550 fluid and utilizing Anschutz immersion thermometers.

Microanalyses were done by Bernhardt Mikroanalytisches Laboratorium, 5251 Elback uber Engelskirchen, Fritz-PreglStrasse 14–16, West-Germany.

Conditions of Methylation

Ethereal solutions of diazomethane were prepared from Diazald (Aldrich) according to the method of de Boer (21) and used immediately. In studying the methylations reported by the Japanese workers (1), we employed conditions judged to be similar to those indicated; namely, suspensions of reactants in anhydrous diethyl ether at ice-bath temperature were treated with excess cold ethereal diazomethane. We terminated reactions at the indicated time by adding a few drops of acetic acid.

Methylation of Barbituric Acid

Barbituric acid (1.00 g, B.D.H.) in diethyl ether (25 ml) was treated with excess ethereal diazomethane (75 ml) for 10 min.

6-Methoxyuracil (1a)

The solid phase (A) of the reaction mixture was separated from its supernatant liquid (B). On extraction with boiling absolute ethanol (C), phase A provided an insoluble fraction (0.11 g), m.p. 264–269° (dec.), whose structure was established from p.m.r. spectra (Table 1) to be 6-methoxyuracil (**1***a*). No improvement in the melting behavior of **1***a* was obtained following successive recrystallization from water,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

and mass spectral analysis confirmed the expected molecular weight.

*1-Methyl-6-methoxyuracil (**1***b*)

On cooling, the hot supernatant liquid (C) yielded solid m.p. 210–245°. Subsequent recrystallizations from absolute ethanol raised the melting range to 235.5–239° (~50 mg). The p.m.r. spectral data (Table 1) indicated this material to be the same derivative (**1***b*) as reported by the Japanese workers (1) except for our higher melting range. The molecular weight was confirmed by mass spectrometry, and the structural assignment was verified by solvent and reagent shift studies as discussed above. The p.m.r. spectral examination of the mother liquor concentrate from phase C revealed a mixture of **1***a* and *b*.

*1,2-Dihydro-2,6-dimethoxy-3-methyl-4-oxopyrimidine (**2**)*

On rotary evaporation, the major supernatant liquid (B) provided an oil whose p.m.r. spectrum in TFA showed it to be rich in an *N*-methyl-dimethoxy derivative. By extracting an aqueous solution of this oil with carbon tetrachloride and treating the combined extracts with heptane and a little chloroform while employing ice-bath cooling, crystallization was induced. There was just sufficient material obtained for successive p.m.r. spectra in $CDCl_3$ and TFA (Table 3) which, on recovery, showed undepressed melting with admixed **2** obtained by isomerization of *sym*-trimethoxypyrimidine with methyl iodide.

Preparation of sym-Trimethoxypyrimidine

A methanolic solution (25 ml) of 2,4,6-trichloropyrimidine (5.0 g, 0.027 mol, Aldrich) was added in small portions to a freshly prepared solution of sodium methoxide (2.5 g, 0.108 mol, sodium/50 ml methanol). Vigorous exothermic reaction proceeded with precipitation of sodium chloride. The reaction mixture was allowed to cool to room temperature after which it was filtered. The filtrate was evaporated and the resulting residue was treated with chloroform to remove additional inorganic material. The oil obtained by stripping the chloroform crystallized on standing. Two recrystallizations from heptane provided crystals (0.9 g) melting 50–52°; lit. m.p. 53° (22). The p.m.r.: δ($CDCl_3$/TMS) 3.93, s, 6H(OCH_3 at C-4 and -6); 3.98, s, 3H(OCH_3 at C-2); 5.72, s, 1H(C-5).

Isomerization of sym-Trimethoxypyrimidine

sym-Trimethoxypyrimidine (0.75 g, 0.0044 mol, m.p. 50–52°) was dissolved in excess freshly distilled methyl iodide (20 ml), and the solution was heated under reflux for 30 h. The oil obtained after rotary evaporation showed evidence of being a three component mixture. On treatment with hot heptane, this mixture formed a small quantity of insoluble residue (X) while the remainder dissolved in the supernatant liquid (Y). Recrystallization of X from chloroform–petroleum ether gave the minor product of this isomerization identified from p.m.r. and mass spectra as 1,3-dimethyl-6-methoxyuracil (**1***d*) which we also found to be the major product in the 24 h methylation of barbituric acid with diazomethane.

On cooling, the supernatant liquid (Y) deposited a solid (m.p. 85–94°) whose p.m.r. spectra indicated the major compound to be a dimethoxy-monomethyl derivative. The mother liquor from this solid was found to contain mainly starting material and some of the minor product (**1***d*). The basis for assigning the structure 1,2-dihydro-2,6-dimethoxy-3-methyl-4-oxopyrimidine (**2**) to the major isomerization product is provided in the discussion.

Preparation of 1-Methylbarbituric Acid

Diethyl malonate (20 ml, 0.125 mol, n_D^{20} 1.4138, Aldrich) was condensed with methylurea (9.5 g, 0.130 mol, m.p. 82–90°, Aldrich) using freshly prepared sodium ethoxide (5.8 g, 0.252 mol of sodium/160 ml absolute ethanol). When a thick paste formed after the mixture had been heated under reflux for 3 h, the mixture was distilled to remove most of the ethanol. The cooled residue was treated with water (100 ml) then warmed to dissolve the cake. The solution was then acidified (7 ml concentrated H_2SO_4/100 ml H_2O). The solution was extracted with chloroform (4 × 30 ml) and evaporation of the combined extracts gave the crude solid (3.7 g, m.p. 98–115°). Recrystallization from ethanol gave crystals (2.1 g) melting 131.8–132.6° (prec.) lit. m.p. 132–133° (23). The p.m.r. δ($CDCl_3$/TMS): 3.30, s, 3H(N-CH_3); 3.65, s, 2H(C-5); 8.43, b, 1H(NH).

Methylation of 1-Methylbarbituric Acid

1-Methylbarbituric acid (0.5 g, m.p. 131.8–137.6°) in diethyl ether (25 ml) was treated with excess ethereal diazomethane (75 ml) over a 2 h period. The solid phase (A) of the reaction mixture was separated from the supernatant liquid (B). Solid A (70 mg) melted broadly and showed no improvement after recrystallization from ethanol. The p.m.r. spectra of the material in TFA indicated a complex mixture of several minor components.

*1,3-Dimethyl-6-methoxyuracil (**1***d*)*

Rotary evaporation of supernatant liquid (B) gave solid (430 mg, m.p. 120–145°) shown by p.m.r. spectra to be rich in 1,3-dimethyl-6-methoxyuracil (**1***d*). Subsequent recrystallization from chloroform–petroleum ether gave material (250 mg, m.p. 156–160°) which was confirmed by p.m.r. (Table 1) and mass spectra to be 1,3-dimethyl-6-methoxyuracil (**1***d*) and identical to that reported by Ito *et al.* (1) and by Biltz and Wittek (24).

Preparation of 5-Ethylbarbituric Acid

Diethyl ethylmalonate (20.0 g, 0.106 mol, n_D^{20} 1.4164, Aldrich) was condensed with urea (6.5 g, 0.108 mol) using freshly prepared sodium ethoxide (4.95 g, 0.219 mol of sodium/130 ml absolute ethanol). A thick paste formed during 4 h heating under reflux. The mixture was filtered while still warm, and the solid was dissolved in hot water (40 ml) and acidified to Congo red with concentrated hydrochloric acid. The instantly formed precipitate was recrystallized from boiling water to obtain solid (7.8 g) melting 193.0–194.0 (prec.); lit. m.p. 190° (25); 193–194° (26). The p.m.r. δ(TFA/TMS): 1.13, t, 3H(CH_3 of Et); 2.37, m, 2H(CH_2 of Et); 3.77, t, 1H(C-5); 9.95, b, 2H(NH); $J_{CH_2CH_3}$ = 7.0; J_{H_5,CH_2} = 3.4 Hz.

Methylation of 5-Ethylbarbituric Acid

5-Ethylbarbituric acid (1.00 g, m. 193–194°) in diethyl ether (25 ml) was treated with excess ethereal diazomethane (75 ml) during a ten minute interval. The reaction mixture was separated into a solid phase (M) and the supernatant liquid (N).

*4,6-Dimethoxy-5-ethylpyrimidone-2 (**3**)*

Pulverization of the solid phase (M) with chloroform left an insoluble fraction which was shown to be mainly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

starting material. On evaporation, the chloroform extract gave solid (25 mg, m. 203–213°, dec.) whose p.m.r. spectra (Table 4) showed the compound to be 4,6-dimethoxy-5-ethylpyrimidone-2 (**3**) and identical to that reported by Ito *et al.* (1) except that non-equivalence of the two methoxy groups was observed in TFA, $CDCl_3$, and pyridine solution.

Exploratory investigation of the supernatant liquid (N) revealed a mixture of *N*-methylated derivatives present in very small quantity.

Preparation of 5-Phenylbarbituric Acid

Diethyl phenylmalonate (20.0 g, 0.0846 mol, n_D^{20} 1.4913, Aldrich) was condensed with urea (5.1 g, 0.090 mol) using freshly prepared sodium ethoxide (3.9 g, 0.170 mol of sodium/150 ml absolute ethanol). After 1½ h heating under reflux, a thick paste formed. The mixture was acidified while still warm to p*H* ~ 2 with 20% aqueous HCl (~ 100 ml). The remaining insoluble material was collected and found to melt at 252–257°. The p.m.r. δ(DMSO-d_6/TMS): 4.83, b, 1H(C-5); 7.37, s, 5H(C_6H_5); 11.3, b, 2H(NH). When the product could not be recrystallized from boiling water, ethanol, methanol, dioxane, glacial acetic acid, acetonitrile or ethyl acetate, a portion of the material was recrystallized from dimethylformamide to obtain a solid, m.p. 255–258°; lit. m.p. 264–266° (27).

Methylation of 5-Phenylbarbituric Acid

5-Phenylbarbituric acid (1.00 g, m.p. 252–257°) in diethyl ether (25 ml) was treated with excess ethereal diazomethane (75 ml) over a 24 h period.

3-Methyl-2,6-dimethoxy-5-phenylpyrimidone-4 (4a)

The reaction mixture was separated into a solid phase (A) (25 mg), which was shown to be starting material, and supernatant liquid (B). Evaporation of B gave a residue which when crystallized from chloroform – petroleum ether gave crystals (0.19 g, m.p. 148–154°) (C) and mother liquor (D). Further recrystallization of C from chloroform – petroleum ether gave solid melting 154–156.5° and having chemical shifts in TFA (Table 5) identical to those reported by Ito *et al.* (1) for their dimethoxy-*N*-methyl derivative (**4***a*, *b*, or *c*) of 5-phenylbarbituric acid. On the basis of solvent and shift-reagent p.m.r. studies, this compound was shown to have structure **4***a*.

Evaporation of mother liquor (D) gave solid (0.5 g) from which the minor product (50 mg), 2,4,6-trimethoxy-5-phenylpyrimidine (**5**) was separated from more of the major derivative, **4***a*, by successive crystallization from heptane.

Preparation of 1,3-Diethylbarbituric Acid

1,3-Diethylbarbituric acid was prepared following the procedure of Biltz and Wittek (24) by heating an acetic acid solution (20 ml) of *sym*-diethylurea (10.0 g, 0.0862 mol, Aldrich) and malonic acid (10.0 g, 0.0962 mol, Aldrich) under reflux on a water bath at 50–60° while acetic anhydride (20 ml, 0.212 mol) was added over a 40 min interval. Heating of the mixture was continued for an additional 6 h after which water (10 ml) was added, and the mixture was heated for ½ h at 70°.

The reaction mixture was distilled at reduced pressure to remove glacial acetic acid and acetic anhydride. The crude residue was dissolved in hot water (40 ml) and acidified with concentrated HCl (1 ml). On cooling in a refrigerator, the solution deposited crystals (1.6 g), m.p. 52.6–53.4° (prec.); lit. m.p. 52° (24). The p.m.r. δ($CDCl_3$/TMS): 1.22, t, 6H(CH_3 of NEt); 3.63, s, 2H(C-5); 3.93, q, 4H(CH_2 of NEt); $J_{CH_2CH_3}$ = 7.3 Hz.

Preparation of 1,3-Diethyl-6-methoxyuracil (1e)

1,3-Diethylbarbituric acid (0.50 g, 0.0027 mol, m.p. 52.6–53.4°) was dissolved in methanol (25 ml) at ice-bath temperature and treated with cold ethereal diazomethane (120 ml). Reaction was immediate and upon reaching completion with excess diazomethane, the mixture was evaporated to obtain an oil. Crystals (m.p. 56–63°) were obtained from a chloroform – petroleum ether solution of the oil during slow evaporation. Recrystallization of the solid from heptane gave crystals melting 68.2–69.6°; p.m.r. shifts (Table 2).

Photolysis of Ammine and Alkylamine Chromium(III) Complexes in Water and Dimethylsulfoxide: Mechanistic Evidence from Luminescence and Medium Effects[1]

COOPER H. LANGFORD[2] AND LEIGH TIPPING

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received September 30, 1971

Photosolvolysis of $Cr(NH_3)_6^{3+}$, $Cr(NH_3)_5Cl^{2+}$, $Cr(CH_3NH_2)_5Cl^{2+}$, and $Cr(CH_3CH_2NH_2)_5Cl^{2+}$ in water and DMSO is described. Phosphorescence of $Cr(NH_3)_6^{3+}$ is completely quenched in base but loss of NH_3 is not. This implies that photosolvolysis arises in the quartet excited state and not the phosphorescent doublet. The increase in ammine quantum yield in DMSO as compared to water can be understood in terms of a tetragonal distortion model for the quartet which also accommodates phosphorescence activation energy data. Unfavorable solvation of Cl^- of $Cr(RNH_2)_5Cl^{2+}$ (R = H, CH_3, CH_3CH_2) after tetragonal distortion can also explain the reversal of solvent effect in these systems wherein quantum yields are lower in DMSO than in water for both release of RNH_2 and Cl^-.

On décrit ici la photosolvolyse de $Cr(NH_3)_6^{3+}$, $Cr(NH_3)_5Cl^{2+}$, $Cr(CH_3NH_2)_5Cl^{2+}$, et $Cr(CH_3CH_2NH_2)_5Cl^{2+}$ dans l'eau et le DMSO. La phosphorescence de $Cr(NH_3)_6^{3+}$ est complètement empêchée dans la base, mais la perte de NH_3 ne l'est pas. Cela implique que la photosolvolyse a son origine de l'état excité quadruplet et non pas du doublet phosphorescent. L'augmentation du rendement quantique d'amine dans le DMSO telle que comparée à l'eau peut être expliquée en termes de modèle à distorsion tétragonale pour le quadruplet, ce qui concorde bien avec les données d'énergie d'activation de la phosphorescence. Une solvatation défavorable de l'ion Cl^-, du $Cr(RNH_2)_5Cl^{2+}$ (R = H, CH_3, CH_3CH_2) après distorsion tétragonale peut aussi expliquer le renversement de l'effet de solvant dans ces systèmes où les rendements quantiques sont plus faibles dans le DMSO que dans l'eau et où dans les deux cas on a dégagement de RNH_2 et Cl^-.

Canadian Journal of Chemistry, **50**, 887 (1972)

Introduction

For some years now, there has been an active interest in photosubstitution reactions of Cr(III) complexes. (A comprehensive review considering in detail most of the observations noted briefly in this introduction will be found in ref. 1.) Quite a number of complexes of local O_h symmetry undergo remarkably comparable photosubstitution reactions under irradiation in their first quartet bands. Examples include $Cr(OH_2)_6^{3+}$ photoexchange with a quantum yield, ϕ, of ~ 0.1; $Cr(NCS)_6^{3-}$ with a photoaquation yield, ϕ, ~ 0.3; and $Cr(NH_3)_6^{3+}$ with $\phi \sim 0.4$. The approximate wavelength independence of such yields early led Schlafer's group and Plane's group to suggest that reaction was from the low lying ^2E state reached by intersystem crossing. This idea is satisfactory to account for reactions of O_h complexes, but Adamson has emphasized its inadequacy for mixed ligand complexes. In these systems, there is large selectivity with respect to which ligand is lost, and some evidence of wavelength dependence of ratios of yields for different reaction modes has been presented. Adamson emphasizes that, at the least, some reaction via the lowest quartet ($^4T_{2g}$ in O_h symmetry) is required to explain such results.

Chen and Porter (2) have recently observed that only 50% of the thiocyanate yielded from *trans* $Cr(NH_3)_2(NCS)_4^-$ can be quenched by the doublet quenching reagent $Cr(CN)_6^{3-}$. This observation provides essentially conclusive evidence for 50% of the thiocyanate loss occurring from the quartet prior to intersystem crossing. Moreover, Porter suggests that the quenched thiocyanate yield may originate from the thermal repopulation of the quartet. The solvent and temperature dependence of phosphorescence intensity from several Cr(III) complexes in solution has recently been reported from this laboratory (3). The results lend suggestive support to Porter's idea since they show that a principal pathway of doublet relaxation has an activation energy of 8 to 14 kcal mol^{-1} and is most plausibly assigned to quartet repopulation.

To complete our introduction, we note one more central fact about ammine complexes like $Cr(NH_3)_5Cl^{2+}$. The selectivity in photoaqua-

tion is the reverse of selectivity in thermal aquation. In photosubstitution, ammine yields are much higher than chloride yields. This report considers the problems of photolysis $Cr(NH_3)_6^{3+}$, $Cr(NH_3)_5Cl^{2+}$, and $Cr(NH_2R)_5Cl^{2+}$ as they depend upon the change of solvent from H_2O to $(CH_3)_2SO$ (DMSO), a change leading to increase in phosphorescence intensity from $Cr(NH_3)_6^{3+}$, and as they depend upon changing pH from 3 to 12 which leads to quenching of $Cr(NH_3)_6^{3+}$ phosphorescence.

Experimental

Synthesis of Complexes

The preparation of chloropentakisalkylaminechromium(III) followed ref. 4. The purity of the compounds was confirmed by comparing spectra with those previously reported (5). The hexammine chromium(III) nitrate had previously been prepared. Its purity was confirmed spectrophotometrically (6).

Irradiation and Actinometry

The irradiation apparatus has been described (7). Chemical actinometry employed the reineckate system characterized by Wegner and Adamson (8). Total absorbance of light was achieved by irradiating 0.010 M complex solutions in 10 cm quartz spectrophotometer cells in which solutions were mixed by periodic shaking. All yields were corrected for thermal reaction carried out under identical conditions. Conditions were chosen to make thermal corrections very small.

Analytical Schemes

(i) ΔpH Method. Solutions of $Cr(NH_2R)_5Cl^{2+}$ and $Cr(NH_3)_6^{3+}$ were made up in 1.00×10^{-3} M $HClO_4$ with either $NaClO_4$ or $NaNO_3$ added to bring ionic strength to 0.50. Amine release and formation of aquo product were determined by using an Accumet model 210 pH meter and Riccieri and Schlafer's pH change calculation (9).

(ii) Spectrophotometric Analysis. $Cr(NH_3)_6^{3+}$ has extinction coefficients of 18 and 12 at 500 and 510 nm, $Cr(NH_3)_5OH^{2+}$ has an extinction coefficient of 43 at 510 nm, and $Cr(NH_3)_5OH_2^{3+}$ has an extinction coefficient of 32 at 500 nm. These differences were exploited using a Gilford 240 spectrophotometer to determine extent of reaction in solutions initially at p$H = 3$ and 12 after low conversion ($\leq 10\%$). Spectrophotometry was also applied to the reaction of $Cr(NH_3)_6^{3+}$ in DMSO. The extinction coefficient of $Cr(NH_3)_5DMSO^{3+}$, obtained by treating the chloride with $AgNO_3$, is 39 at 500 nm.

(iii) Amine titration in DMSO. Amine and alkylamine yields in DMSO were determined by titration of liberated base with 0.0100 M $HClO_4$. Reaction solutions were mixed with equal volumes of water and pH electrodes were preconditioned in DMSO–water mixtures.

(iv) Chloride titration. The small chloride yields were determined by potentiometric titration of Cl^- with 1.00×10^{-3} M $AgNO_3$ using a microburette, a Ag/AgCl electrode, a calomel electrode, and a Leeds and Northrup student potentiometer. There is no chloride blank in the system.

Phosphorescence Measurements

Phosphorescence spectra were recorded with an Aminco–Bowman spectrofluorimeter equipped with an R446S phototube from Aminco and 2 mm slits.

Results

In Table 1, quantum yields for the various reactions studied are collected with the exception of data on reactions of $Cr(NH_3)_6^{3+}$ as a function of pH which appear in Table 2. Table 3 records the pH dependence of intensity of 660 nm phosphorescence as a function of pH. Two comments are in order about Tables 2 and 3. First, pH dependence was examined only in solutions which could be maintained without buffers. This is because there was some evidence that buffer anions might be involved in quenching processes. Second, the reactions in base were examined at 0 °C to eliminate substantial thermal corrections. Figure 1 shows the emission spectra of $Cr(NH_3)_6^{3+}$ at p$H = 2$ and p$H = 12$.

Discussion

(1) Base Quenching and the Role of the Quartet

Hydroxide ion appears to quench the ^2E state of $Cr(NH_3)_6^{3+}$ effectively. At p$H = 12$, the emission is less than 5% of that observed at p$H = 3$. That is, perhaps, a reasonable result since we have failed to observe luminescence in solution from complexes of the type Cr-

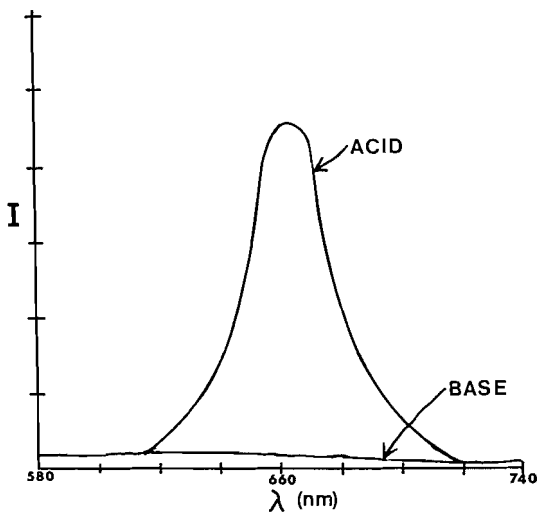

FIG. 1. Phosphorescence spectrum of $Cr(NH_3)_6^{3+}$ in acid (p$H = 2$) and base (p$H = 12$) under excitation at 465 nm. The blank superimposes on the result for basic solution.

pH	Intensity (arbitrary units)
2.0	32
3.0	32
4.0	30
11.0	0.5
12.0	0.5
13.0	0.5
Blank (distilled H_2O)	0.5

*$\lambda_{excitation} = 465$ nm; $\lambda_{emission} = 660$ nm; slit width = 2 mm. The temperature dependence of this emission is characterized by an activation energy of 10.4 kcal mol^{-1} in H_2O. Corresponding studies in DMSO give an activation energy of 14 kcal mol^{-1} (3).

$(NH_3)_5X^{2+}$ (3) and a kinetically reasonable process for carrying the doublet through $Cr(NH_3)_5NH_2^{2+}$ in the presence of OH^- can be envisioned which does not require an unreasonable acidity constant. But, whatever the mechanism of hydroxide quenching, an argument parallel to Chen and Porter's (2) analysis of $Cr(NH_3)_2(NCS)_4^-$ leads to the conclusion that a *large part* of the ammine loss from $Cr(NH_3)_6^{3+}$ originates from the quartet prior to intersystem crossing because no more than one third appears to be subject to quenching. Since the main pathway of doublet relaxation in acid solution appears to be via thermal return to the quartet (3), it is probable that the part of the yield that is quenched also corresponds to reaction from the quartet when that state is reached by thermal repopulation.

(2) DMSO Effect on the Photolysis of $Cr(NH_3)_6^{3+}$

DMSO is observed to increase the ammine quantum yield from $Cr(NH_3)_6^{3+}$ and to increase the activation energy for phosphorescence decay. Base quenching and phosphorescence data require that we look at the properties of the quartet. To interpret the facts, we propose a specific speculative model for the behavior of a quartet excited state of $Cr(NH_3)_6^{3+}$ which we hope may prove useful in much of Cr(III) photochemistry. This model is based on Hammond's suggestion (10) that photoreaction results from internalization of electronic excitation and is best viewed as a problem in the theory of radiationless deactivation analogous to the problem of return of the excited state to the ground state. In particular, one feature of a "reactive" excited state should be its resemblance to the primary photoproduct so that its wavefunctions overlap those of the product to a degree competitive with the overlap with ground state wavefunctions.

The electronic configuration of a quartet octahedral Cr(III) complex is $t_{2g}^2 e_g$ in which a single σ^* orbital is occupied as in the ground state of a Cr(II), d^4, complex. The structure of Cr(II) complexes suggests that the vibrationally equilibrated Cr(III) complex should be subject to a strong tetragonal distortion. The doublet excited state with the configuration t_{2g}^3 has a potential surface very similar to the ground state as indicated by the correspondence between absorption and emission maxima (3) and a recent detailed analysis of the vibrational structure of phosphorescence (11). Figure 2 shows an *impression* (which can be only that in two dimensions) of the potential surfaces for the states ^2E and $^4T_{2g}$ as a function of a "tetragonal distortion parameter". Quartet surfaces with similar energy minima can cross the ^2E surface at higher energies as tetragonal distortion at the minimum increases. Such a model can explain higher activation energy for $^2E \rightarrow {}^4T$ thermal repopulation as a consequence of greater tetragonal distortion in the vibrationally equilibrated quartet. It also suggests why doublet relaxation occurs via the quartet; the ground state, ^4A, and the ^2E cross only at very high energies. Returning to reactivity, the less distorted quartet may be thought of as crossing the ground state at lower energy, and the more distorted quartet should cross the potential surface of a primary photo product related to O_h symmetry by a tetragonal distortion at lower energy. One (but only one) primary photo product would be a nearly square pyramidal nearly five coordinate intermediate that is suggestive of the commonly discussed transition state of thermal substitution.

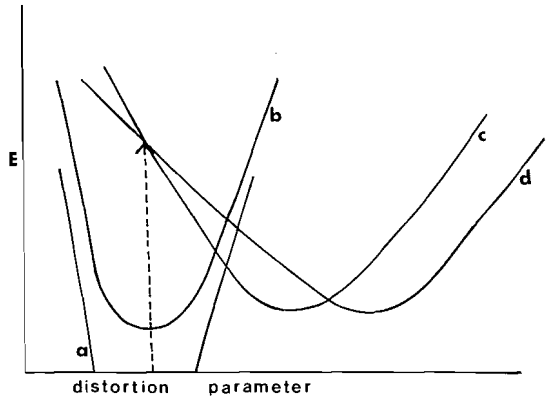

FIG. 2. An impression of the potential surfaces for the electronic states of $Cr(NH_3)_6^{3+}$ of interest in this study as a function of a "distortion parameter". The curves represent: (*a*) the $^4A_{2g}$ ground state; (*b*) the ^2E_g excited state; (*c*) the $^4T_{2g}$ excited state in aqueous solution; (*d*) the $^4T_{2g}$ excited state in DMSO solution.

(3) Effect of DMSO on the Photolysis of $Cr(NH_2R)_5Cl^{2+}$

The speculative model of the previous section can also accommodate the significant reversal of DMSO effect in the monochloro complexes. In this case, yields of RNH_2, and even more Cl^-, appear to be reduced by DMSO. If tetragonal distortion does occur along the axis including the *low field* Cl^- ligand, destabilization resulting from occupancy of a σ^* orbital will presumably be less, *and* destabilization due to occupancy of a π^* (t_{2g}) orbital (rendered antibonding by the Cl^- lone pairs) will also be minimized. But such a favored quartet requires projection of a Cl^- ligand into the solvent, and DMSO is known to be a poor solvent for Cl^- ion (12). So it is reasonable to assume that the H_2O and DMSO potential surfaces appear in reverse order from the way they are shown in Fig. 2. Distortion is smaller in DMSO. The profound reduction in Cl^- yield in DMSO means that relaxation of the distorted quartet to yield free Cl^- ion is quite unfavorable, but similarly, a less distorted quartet would be unfavorable as well to amine release.

We thank Dr. M. Parris for gifts of compounds and guidance in the synthesis of alkylamine complexes. Dr. Noel Kane-Maguire supplied phosphorescence data and valuable advice. Discussions with Dr. V. S. Sastri contributed significantly to formulation of the problem.

Intermolecular Potentials from Differential Cross Sections: Ar + Ar

FERENC KALOS[1] AND ARTHUR E. GROSSER
Department of Chemistry, McGill University, Montreal, Quebec

Received September 23, 1971

The angular distribution of Ar + Ar scattering at $E = 9.16 \times 10^{-14}$ erg was measured out to the rainbow pattern (supernumerary rainbow and part of the rainbow peak) by the crossed molecular beam technique, with mass spectrometric detection. This distribution was compared to calculated differential cross sections. Total cross sections, and spectroscopic constants for Ar_2 were also calculated. The trial potentials were L.J.-12,6, L.J.-20,6, a modified Lennard–Jones potential (L.J.-14,12,8,6) and the Bobetic–Barker potential. The Bobetic–Barker potential is the one most consistent with cross section and spectroscopic experiments.

On a mesuré la distribution angulaire de la diffusion de Ar + Ar à $E = 9.16 \times 10^{-14}$ erg jusqu'au structure "arc-en-ciel" (l'arc-en-ciel supernuméraire et une partie du pic de l'arc-en-ciel) par la technique du faisceau moléculaire croisé, avec détection par spectrométrie de masse. On a comparé cette distribution aux sections efficaces différentielles. On a aussi calculé les sections efficaces totales et les constantes spectroscopiques pour Ar_2. Les potentiels d'essai étaient L.J.-12,6, L.J.-20,6, un potentiel de Lennard–Jones modifié (L.J.-14,12,8,6) et le potentiel de Bobetic–Barker. Le potentiel de Bobetic–Barker était celui qui se rapprochait le plus des expériences de la diffusion et des expériences spectroscopiques.

Canadian Journal of Chemistry, **50**, 892 (1972)

Introduction

The elucidation of the argon pair potential has recently received considerable attention: transport and virial data were analyzed by Dymond and Alder (1); Barker *et al.* (2–4) made use of the properties of the solid in addition to the virial data; the Ar_2 absorption spectrum in the vacuum ultraviolet was recently reported by Tanaka and Yoshino (5), and calculated vibrational energy levels for different potential functions have been compared with these data (6–7). Molecular beam measurements of the total scattering cross section at high energies (8–10) yielded the best available information on the interaction at short range, and such measurements at thermal energies (11) showed agreement with the calculated long-range force constant, C_6.

Measurements of the differential scattering cross section are potentially useful for the elucidation of the intermolecular potential in the region of the well. The first such measurements on Ar + Ar by Williams *et al.* (12) were confined to very small scattering angles, but since then, measurements extending into the region of rainbow scattering were reported by Cavallini *et al.* (13), who interpreted their data in terms of an assumed Lennard–Jones-12,6 potential. After a similar simple procedure of analysis, the measurements made in this laboratory (14) showed agreement with the results of Cavallini *et al.*[2] We have now elaborated a more refined scheme of analysis for our differential cross section measurements: properly velocity- and angle-averaged cross sections (*i.e.* theoretical angular distributions in the lab system) are calculated for various trial potentials and a matching of the measured angular distribution is attempted by trial and error. This procedure is more reliable than matching the locations only of the differential cross section extrema.

Experimental

The crossed molecular beam apparatus and the experimental technique have been described previously (14, 15). Briefly, a velocity selected primary beam ($v_0 = 518$ m/s) was crossed with a nozzle beam ($v_0 = 547$ m/s, speed ratio = 12.7). This arrangement resulted in a 17% FWHH spread in the relative velocity. The scattered species were detected by an ultrahigh vacuum mass spectrometer.

Calculations

Identical boson differential cross sections were evaluated for thirty trial potentials by the partial wave formula. The phase shifts η_l were obtained via the WKB approximation (for including symmetry oscillations, and fitted the data with a multiparameter potential.

[1]Present address: Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139.

[2]Note added in proof: Parson, Siska, and Lee (23) have carefully measured the Ar + Ar differential cross section,

$0 \leqslant l \leqslant 200$), and via the Born approximation (for $202 \leqslant l \leqslant 500$) for the r^{-6} term of the potentials. The WKB phase shifts were evaluated using quadratures, and analytic integration from large r (where $V(r) \sim 0$); only every fourth phase ($\Delta l = 8$) was calculated, the others were obtained by interpolation of $\eta = \eta(l)$.[3]

The velocity and angle averaging of the computed cross sections, which was required for the comparison with the experiments was made the following way: the velocity distributions of the beams and the angular distribution of the wide (7.9° FWHH) secondary beam were each replaced by 3-point discrete distributions. As calculating cross sections for $3^3 = 27$ different energies did not appear necessary, this 27 point "overall" distribution was regrouped into 6 sets, mainly according to the value of the relative velocity. The beam velocities and crossing angle were averaged within each set, and then phase shifts were calculated for the collision energy of each set. The center-of-mass angles and Jacobians of transformation corresponding to certain laboratory angles (every $\frac{1}{4}°$) were then computed[4] (17) using the parameters (v_1, v_2, and crossing angle) of the set. The differential cross section was evaluated at these angles, transformed to the lab system, and these cross section contributions from the six sets were summed with proper weights. To account for the angular resolution of the detector and for the spread of the primary beam an angular averaging over a triangular distribution (0.75° FWHH) was made.

The mismatch between experiment and calculation was assumed to be given by χ^2. After subdividing the angular range into a number (4–8) of regions, χ^2 was evaluated for $I(\theta_L)$ *vs.* θ_L by

$$\chi^2 = \sum_{\text{regions}} \left\{ \frac{\left(\sum_{\substack{\text{points} \\ \text{in region}}} [I_{\text{expt}} - I_{\text{calc}}] \right)^2}{\sum_{\substack{\text{points} \\ \text{in region}}} I_{\text{calc}}} \right\}$$

Calculations of χ^2 for different numbers of regions reduced the uncertainty in its value.

[3]The phase shifts were compared with exact numerical calculations. The exact phase shift computer program (16) was kindly provided by Professor B. C. Eu.

[4]A correction was included for the use of a density detector.

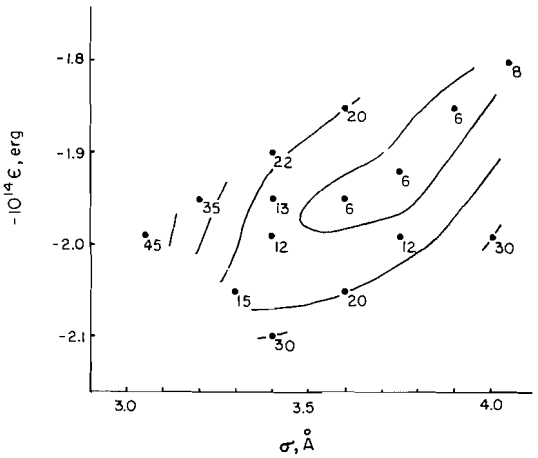

FIG. 1. Map of the fits by L.J.-12,6 potentials. The numbers mapped are 100 χ^2, and the contour lines represent equally good fits. The coordinate axes are the size parameter and well depth of the potential.

Total cross sections were also evaluated from the calculated phase shifts.

The spectroscopic constants have also become an important test of argon potentials since the Ar_2 spectra are now available (5). WKB eigenvalues and spectroscopic constants were also calculated for the trial potentials.

Results and Discussion

The trial potentials employed to fit the angular distribution were: the L.J.-12,6 and L.J.-20,6 potential functions, a modified Lennard–Jones potential, which will be discussed at a later point, and the Bobetic–Barker (3) multiparameter potential. Although it would be desirable to fit with a *flexible* multiparameter potential instead of the somewhat unrealistic L.J.-potential functions, the present experimental data would not be sufficient to establish the parameters of such a potential with any precision.

Lennard–Jones-n,6 Potentials

The results of fitting with L.J.-12,6 potentials are shown in Fig. 1; Table 1 lists the more successful potentials. A number of potential parameter combinations gave equally good fits and they are shown in Fig. 2. They illustrate that measurements of high angular and energy resolution and of high precision are required if a unique potential is to be deduced from differential cross section measurements alone. also includes the total cross sections and spectroscopic constants. Bruch and McGee (6) have pointed out that agreement with experiment of ω_e and $\omega_e\chi_e$ should be more conclusive than the eigenvalues themselves.

As there is general agreement (1–3, 13, 18, 20) on the value of the size parameter, $\sigma = 3.4 \pm 0.05$ Å, it seems reasonable to apply this constraint to the L.J.-12,6 potentials, making potentials 2 and 20 the "best", with $\varepsilon = 2.00\,(\pm 0.07) \times 10^{-14}$ erg. This ε is in agreement with the differential cross section results of Cavallini *et al.* (13), but not with the transport data of Hogerworst (18), who found $\varepsilon(12,6) = 1.87 \times 10^{-14}$ erg, nor with the value deduced by Tanaka and Yoshino (5): $\varepsilon = 1.82 \times 10^{-14}$ erg. Searcy *et al.* (19) deduced even smaller well depths from the location of the first few quantum oscillations in the differential cross section, but we find many potentials yield similar interference patterns in the low angle region.

But even though the scattering data can be fitted fairly well by some L.J.-12,6 potentials, none of them yields the proper spectroscopic constants or total cross section. The L.J.-20,6 potential was much better in these latter respects, but did not fit the experimental angular distribution (Fig. 3).

Other Potentials

A modified Lennard–Jones, or 14,12,8,6 potential, as given by

$$[1] \qquad V(\rho) = 4\varepsilon_\infty(1 - A\rho^{-2})(\rho^{-12} - \rho^{-6})$$

where

$$[2] \qquad \rho \equiv r/\sigma$$

The curves show calculated distributions for the following L.J.-12,6 potentials: -·- No. 25, — No. 11, --- No. 24, ··· No. 28. (The scale factor between the calculated curves and the experimental data was established by minimizing χ^2.)

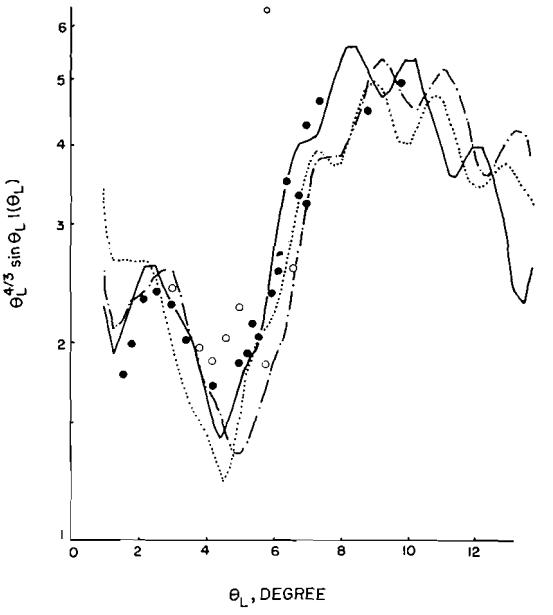

FIG. 3. The angular distribution of scattering in the laboratory system, weighted by $\theta_L^{4/3} \sin \theta_L$. The curves show calculated distributions for the following potentials: — No. 1, Bobetic–Barker; -·-·- No. 10, modified L.J.; ··· No. 42, L.J. – 20,6.

and

$$[3] \qquad \varepsilon_\infty \equiv C_6/4\sigma^6$$

has two adjustable parameters, σ, and the mixing coefficient, A. It employs the precisely known value (21, 22) of C_6 as an additional constraint. The purpose of this potential is to provide a two-parameter function which (by eq. 3) yields the correct long-range interaction. In fact, this potential closely resembles the Bobetic–Barker potential, as shown in Fig. 4. This potential family did not yield very good fits to the angular distribution, but was successful in reproducing $\omega_e\chi_e$.

The Bobetic–Barker potential[5] fits the experimental angular distribution very well (Fig. 3, Table 1*b*) and is much better than even the best L.J.-12,6 potentials in agreeing with the spectroscopic constants and total cross section.

In conclusion, while none of the potentials were able to reproduce the scattering, spectroscopic, and total cross section results, the Bobetic–Barker potential is most consistent with the data.

The Master Equation for the Dissociation of a Dilute Diatomic Gas. VI. Solution of Coupled Sets of Master Equations

D. L. S. McELWAIN AND H. O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received October 18, 1971

Three coupled sets of master equations, representing the equilibration of $X_2 + Y_2 \rightleftarrows 2XY$ via atoms only, have been solved by the normal-mode technique; the set of 57 simultaneous differential equations describing the $H_2/D_2/2HD$ system was considered as a suitable trial model. It was found that at times (t) in excess of the longest vibrational relaxation time, even though some of the populations in the system appeared highly non-Boltzmann, all the phenomenological rate constants were well-behaved: they were either constant and obeyed the rate–quotient law, or they were dependent on t^2.

The paper concludes with a discussion of the information required before a full solution of the $X_2 + Y_2 \rightleftarrows 2XY$ reaction could be contemplated, and suggests methods by which an approximation to such a solution could be obtained.

Les trois ensembles couplés d'équations principales qui représentent l'équilibration de $X_2 + Y_2 \rightleftarrows 2XY$ à partir des atomes seuls, ont été résolus par la technique des modes normaux; l'ensemble des 57 équations différentielles simultanées qui décrit le système $H_2/D_2/2HD$ a été choisi comme modèle d'étude. On a constaté alors qu'aux temps (t) supérieurs au temps de relaxation vibrationnelle le plus long, toutes les constantes de vitesse phénoménologique avaient un bon comportement et cela, malgré un écart notable à la distribution de Boltzmann des populations du système dans certains cas. Ces vitesses étaient soit constantes et suivaient la loi en $1/k$ soit qu'elles dépendaient de t^2.

La note conclut par une discussion sur l'information exigée avant d'envisager la résolution complète de $X_2 + Y_2 \rightleftarrows 2XY$ et suggère des méthodes à partir desquelles une solution approchée peut être obtenue.

Canadian Journal of Chemistry, **50**, 897 (1972)

Introduction

Earlier papers in this series (I–5) have been concerned with the dissociation and recombination of a homonuclear diatomic gas at infinite dilution in a bath of *totally* inert atoms, and at such temperatures that rotational equilibration can be considered infinitely rapid.[1] In most of this work, the H_2 molecule has been used as a model, and having only 15 vibrational levels, can be represented by a set of 16 simultaneous differential equations; Part V addressed itself to the problem having a rather more dense energy-level spectrum, using D_2 as a model, and giving rise to a master equation of order 23. It is hoped that in future work, a more realistic description of the dissociation and recombination of a dilute homonuclear diatomic gas can be achieved by considering both rotational and vibrational interchanges; it should be mentioned in passing that for H_2, this will require the solution of almost 400 simultaneous differential equations and the assignment of some 70 000 translational–vibrational transition probabilities; for D_2 the problem is even more forbidding, with almost 700 simultaneous differential equations and some 200 000 translational–vibrational transition probabilities.

This paper addresses itself to a different problem, that of the solution of coupled sets of master equations. The need to solve coupled sets of master equations arises as soon as one tries to extend the very simple model with which we have worked so far in two very necessary directions: (*a*) The inclusion of bound states of MX in the dissociation–recombination scheme, *i.e.*

[1] $$X_2 + M \rightleftarrows X + X + M$$

[2] $$X_2 + M \rightleftarrows MX + X$$

[3] $$MX + M \rightleftarrows M + M + X$$

Here there are two coupled sets of equations, one representing reaction [1] as before and one representing reaction [3] (having one equation for each vibrational level of X_2 and MX, respectively), and they are coupled by two mechanisms, one through the atomic species which they share in common, and the other through the series of reaction [2]. In the face of a complete lack of any knowledge of the rates of reaction [2] as a function of the vibrational energy contents of both X_2 and MX, we felt that the exercise of solving these two coupled sets of

[1]Equations taken from papers in this series and used in the present paper are prefixed with the part numbers in Roman numerals.

equations would not advance our understanding significantly at the present time. We therefore turned our attention to

(*b*) The dissociation of a dilute heteronuclear diatomic gas, *i.e.*

[4] $$XY + M \rightleftarrows X + Y + M$$

[5] $$X + X + M \rightleftarrows X_2 + M$$

[6] $$Y + Y + M \rightleftarrows Y_2 + M$$

In this case, we have three sets of master equations, coupled via X and Y atoms. The complete description of the dissociation–recombination process for a heteronuclear diatomic molecule at experimentally attainable dilutions would also require the inclusion of reactions such as

[7] $$X + Y_2 \rightleftarrows XY + Y$$

[8] $$X_2 + Y \rightleftarrows XY + X$$

[9] $$X_2 + Y_2 \rightleftarrows 2XY$$

with a separate rate constant for each vibrational level of either reactants or products; and not to mention several permutations of reactions [2] and [3]. For the time being, reactions [7]–[9] must be omitted from the reaction scheme for two reasons. First, as in (*a*) above, we have no knowledge of the individual rate coefficients. Second, if we use the equilibration of $H_2 + D_2 \rightleftarrows 2HD$ as the simplest possible model for this type of reaction, we have to solve a set of 57 simultaneous differential equations, 15, 18, and 22 equations, respectively, representing the bound vibrational states of H_2, HD, and D_2, with one equation each for H and D atoms. Even excluding reactions [7], [8], and [9], we were unable to solve these 57 simultaneous equations by standard methods *e.g.* fifth-order Runge–Kutta, and it is clear therefore that the solution of the simple system of reactions [4], [5], and [6] at infinite dilution presents a problem which must be overcome before a complete solution to the heteronuclear diatomic dissociation reaction can even be contemplated; it is to this problem that we address ourselves in this paper.

Whilst it is not the aim of this work to try to describe the H_2/D_2 equilibration reaction, we prefer to maintain some contact with reality by performing our calculations within the experimental temperature range for the reaction. Shock-tube studies of the H_2/D_2 reaction have now been reported between 1000 and 3000 °K (6, 7), and we have performed our calculations for temperatures of 1500 and 2000 °K; the former is the lowest temperature at which our normal-mode procedure works well for H_2 and D_2 because of cancellation difficulties (3, 5) and the latter is the temperature to which most of our previous work relates. Following our previous philosophy (1–3, 8), it is assumed that translational and rotational equilibration occur instantaneously as the shock wave passes, and that reaction then proceeds to take place, starting with all the diatomic molecules in their $v = 0$ states. It is assumed that the translational–vibrational transition probabilities for H_2, HD, and D_2 have energy and temperature dependences given by eq. III(1) and that the energy-level spacings are those of Kolos and Wolniewicz (9, 10). The insensitivity of the overall behavior to imperfections in these assumptions is now well documented (2–4). Finally, it was assumed that at equilibrium there were 3.5×10^{16} molecules/cc each of $(H_2 + \frac{1}{2}H)$ and of $(D_2 + \frac{1}{2}D)$, the number of HD molecules being determined by the value of the appropriate equilibrium constant, which was calculated from the accepted energy-level scheme (10) by standard statistical mechanical methods. Thus, at 1500 and 2000 °K, respectively, there were 2.844×10^{17} and 2.780×10^{17} total (H + D) atoms (free and combined) per cc in the system, together with 3.5×10^{19} inert particles per cc. This choice of conditions facilitated comparison of the behavior of H_2 and D_2 in the mixed system with their separate behavior in earlier calculations (2, 3, 5) in which the total initial number of molecules was 3.5×10^{16} per cc in either case.

Normal-mode Factorization

Since the 57 simultaneous differential equations representing the system of reactions

[3*a*] $$HD + M \rightleftarrows H + D + M$$

[4*a*] $$H + H + M \rightleftarrows H_2 + M$$

[5*a*] $$D + D + M \rightleftarrows D_2 + M$$

in the translational–vibrational regime cannot be solved readily by conventional numerical methods, we follow our previous procedure (3) and recast them into normal modes. As far as possible, we will retain the same symbols as in that treatment, using unprimed symbols to describe the H_2 system, primed symbols for HD, and double-primed symbols for D_2. To recapitulate briefly, n_i represents the population of state $v = i$ of H_2 in molecules/cc. P_{ji} is the probability per collision of a transition from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

state i to state j, and $\bar{P}_{ni}$ is the probability per collision of dissociation; $\tilde{n}_i$ represents the equilibrium population of state i at the temperature in question, and $\xi_i = n_i/\tilde{n}_i$. Thus, n_i' and n_i'' represent populations for HD and D_2, respectively, but to avoid as far as possible multiple superscripts, n_H ($=\frac{1}{2}[H]$) will be used for n_n and n_D ($=\frac{1}{2}[D]$) for n_n'' (there is no meaning to the quantity n_n'); also, a prime on a symbol implies that the subscripts carry primes. The numbers of bound vibrational levels are $n = 15$, $n' = 18$, and $n'' = 22$, and thus the 57 equations are

$$(1)\qquad \frac{dn_i}{dt} = [M]Z\left[\sum_{j=0}^{n-1}(P_{ij}n_j - P_{ji}n_i) + (\bar{P}_{in}n_H^2 - \bar{P}_{ni}n_i)\right] \qquad 0 \leqslant i \leqslant (n-1)$$

$$(2)\qquad \frac{dn_H}{dt} = [M]Z\left[\sum_{i=0}^{n-1}(\bar{P}_{ni}n_i - \bar{P}_{in}n_H^2) + \tfrac{1}{2}\sum_{i'=0}^{n'-1}(\bar{P}'_{ni}n_i' - \bar{P}'_{in}n_Hn_D)\right]$$

$$(3)\qquad \frac{dn_i'}{dt} = [M]Z\left[\sum_{j'=0}^{n'-1}(P'_{ij}n_j' - P'_{ji}n_i') + (\bar{P}'_{in}n_Hn_D - \bar{P}'_{ni}n_i')\right] \qquad 0 \leqslant i' \leqslant (n'-1)$$

$$(4)\qquad \frac{dn_D}{dt} = [M]Z\left[\sum_{i''=0}^{n''-1}(\bar{P}''_{ni}n_i'' - \bar{P}''_{in}n_D^2) + \tfrac{1}{2}\sum_{i'=0}^{n'-1}(\bar{P}'_{ni}n_i' - \bar{P}'_{in}n_Hn_D)\right]$$

$$(5)\qquad \frac{dn_i''}{dt} = [M]Z\left[\sum_{j''=0}^{n''-1}(P''_{ij}n_j'' - P''_{ji}n_i'') + (\bar{P}''_{in}n_D^2 - \bar{P}''_{ni}n_i'')\right] \qquad 0 \leqslant i'' \leqslant (n''-1)$$

The following detailed-balancing relationships hold:

$$(6)\qquad P_{ij}\tilde{n}_j = P_{ji}\tilde{n}_i \qquad \bar{P}_{in}\tilde{n}_H^2 = \bar{P}_{ni}\tilde{n}_i$$

$$(7)\qquad P'_{ij}\tilde{n}'_j = P'_{ji}\tilde{n}'_i \qquad \bar{P}'_{in}\tilde{n}_H\tilde{n}_D = \bar{P}'_{ni}\tilde{n}'_i$$

$$(8)\qquad P''_{ij}\tilde{n}''_j = P''_{ji}\tilde{n}''_i \qquad \bar{P}''_{in}\tilde{n}_D^2 = \bar{P}''_{ni}\tilde{n}''_i$$

These relationships are particularly important in establishing the required values for $\bar{P}_{in}$, $\bar{P}'_{in}$, and $\bar{P}''_{in}$. In terms of the reduced variable ξ_i, ξ_i', and ξ_i'', and writing $Q_{ij} = [M]ZP_{ij}$, etc., eqs. (1) to (5) become

$$(1a)\qquad \frac{d\xi_i}{dt} = \sum_{j=0}^{n-1}Q_{ji}(\xi_j - \xi_i) + \bar{Q}_{ni}(\xi_H^2 - \xi_i)$$

$$(2a)\qquad \frac{d\xi_H}{dt} = \tilde{n}_H\sum_{i=0}^{n-1}\bar{Q}_{in}(\xi_i - \xi_H^2) + \tfrac{1}{2}\tilde{n}_D\sum_{i'=0}^{n'-1}\bar{Q}'_{in}(\xi_i' - \xi_H\xi_D)$$

$$(3a)\qquad \frac{d\xi_i'}{dt} = \sum_{j'=0}^{n'-1}Q'_{ji}(\xi_j' - \xi_i') + \bar{Q}'_{ni}(\xi_H\xi_D - \xi_i')$$

$$(4a)\qquad \frac{d\xi_D}{dt} = \tilde{n}_D\sum_{i''=0}^{n''-1}\bar{Q}''_{in}(\xi_i'' - \xi_D^2) + \tfrac{1}{2}\tilde{n}_H\sum_{i'=0}^{n'-1}\bar{Q}'_{in}(\xi_i' - \xi_H\xi_D)$$

$$(5a)\qquad \frac{d\xi_i''}{dt} = \sum_{j''=0}^{n''-1}Q''_{ji}(\xi_j'' - \xi_i'') + \bar{Q}''_{ni}(\xi_D^2 - \xi_i'')$$

or, in more compact matrix notation

$$(9)\qquad \frac{d}{dt}\begin{pmatrix}\boldsymbol{\xi}\\ \xi_H\\ \boldsymbol{\xi}'\\ \xi_D\\ \boldsymbol{\xi}''\end{pmatrix} = \mathscr{A}\begin{pmatrix}\boldsymbol{\xi}\\ \xi_H\\ \boldsymbol{\xi}'\\ \xi_D\\ \boldsymbol{\xi}''\end{pmatrix} + \xi_H^2\begin{pmatrix}\bar{\boldsymbol{Q}}\\ \tilde{n}_Hw\\ \mathbf{0}\\ 0\\ \mathbf{0}\end{pmatrix} + \xi_H\xi_D\begin{pmatrix}\mathbf{0}\\ \frac{1}{2}\tilde{n}_Dw'\\ \bar{\boldsymbol{Q}}'\\ \frac{1}{2}\tilde{n}_Hw'\\ \mathbf{0}\end{pmatrix} + \xi_D^2\begin{pmatrix}\mathbf{0}\\ 0\\ \mathbf{0}\\ \tilde{n}_Dw''\\ \bar{\boldsymbol{Q}}''\end{pmatrix}$$

where

$$[\bar{Q}]_i = \bar{Q}_{ni}$$

and

$$w = -\sum_{i=0}^{n-1} \bar{Q}_{in}$$

likewise for primed and double-primed quantities. The matrix $\mathscr{A}$ has the form

$$\mathscr{A} = \begin{pmatrix} \mathbf{A} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \tilde{n}_H \boldsymbol{u}^T & 0 & \frac{1}{2}\tilde{n}_D(\boldsymbol{u}')^T & 0 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{A}' & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & 0 & \frac{1}{2}\tilde{n}_H(\boldsymbol{u}')^T & 0 & \tilde{n}_D(\boldsymbol{u}'')^T \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{A}'' \end{pmatrix} \tag{10}$$

where

$$u_i = \bar{Q}_{in} = [\bar{Q}]_i \tilde{n}_i / \tilde{n}_H^2$$

and

$$A_{ij} = (1 - \delta_{ij})Q_{ji} - \delta_{ij}\left[\bar{Q}_{ni} + \sum_{k=0}^{n-1}(1 - \delta_{ki})Q_{ki}\right]$$

again, likewise for primed and double-primed quantities.

Now, following very closely our transformation of a single master equation to normal modes (3), we transform the composite vector $\boldsymbol{\xi}$ to a composite $\boldsymbol{\psi}$ by

$$\boldsymbol{\psi} = \mathbf{T}\boldsymbol{\xi} = \tilde{\mathbf{S}}\mathbf{E}\boldsymbol{\xi}$$

where

$$(E)_{ij} = \tilde{n}_i^{1/2}\delta_{ij}$$

and $\tilde{\mathbf{S}}\mathbf{E}\mathbf{A}\mathbf{E}^{-1}\mathbf{S} = \mathbf{D}$, a diagonal matrix; likewise $\mathbf{A}'$ and $\mathbf{A}''$. In detail

$$\begin{pmatrix} \boldsymbol{\psi} \\ \boldsymbol{\psi}_H \\ \boldsymbol{\psi}' \\ \boldsymbol{\psi}_D \\ \boldsymbol{\psi}'' \end{pmatrix} = \mathbf{T}\begin{pmatrix} \boldsymbol{\xi} \\ \boldsymbol{\xi}_H \\ \boldsymbol{\xi}' \\ \boldsymbol{\xi}_D \\ \boldsymbol{\xi}'' \end{pmatrix} \tag{11}$$

where

$$\mathbf{T} = \begin{pmatrix} \tilde{\mathbf{S}}\mathbf{E} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \tilde{n}_H & \mathbf{0} & 0 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \tilde{\mathbf{S}}'\mathbf{E}' & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & 0 & \mathbf{0} & \tilde{n}_D & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{S}}''\mathbf{E}'' \end{pmatrix}$$

Thus eq. (9) becomes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$(12)\quad \frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\boldsymbol{\psi}\\ \psi_{\mathrm{H}}\\ \boldsymbol{\psi}'\\ \psi_{\mathrm{D}}\\ \boldsymbol{\psi}''\end{pmatrix}=\begin{pmatrix}\mathbf{D} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0}\\ \tilde{n}_{\mathrm{H}}^2(\boldsymbol{\alpha})^{\mathrm{T}} & 0 & \frac{1}{2}\tilde{n}_{\mathrm{H}}\tilde{n}_{\mathrm{D}}(\boldsymbol{\alpha}')^{\mathrm{T}} & 0 & \mathbf{0}\\ \mathbf{0} & \mathbf{0} & \mathbf{D}' & \mathbf{0} & \mathbf{0}\\ \mathbf{0} & 0 & \frac{1}{2}\tilde{n}_{\mathrm{H}}\tilde{n}_{\mathrm{D}}(\boldsymbol{\alpha}')^{\mathrm{T}} & 0 & \tilde{n}_{\mathrm{D}}^2(\boldsymbol{\alpha}'')^{\mathrm{T}}\\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{D}''\end{pmatrix}\begin{pmatrix}\boldsymbol{\psi}\\ \psi_{\mathrm{H}}\\ \boldsymbol{\psi}'\\ \psi_{\mathrm{D}}\\ \boldsymbol{\psi}''\end{pmatrix}$$

$$+\psi_{\mathrm{H}}^2\begin{pmatrix}\boldsymbol{\alpha}\\ w\\ \mathbf{0}\\ 0\\ \mathbf{0}\end{pmatrix}+\psi_{\mathrm{H}}\psi_{\mathrm{D}}\begin{pmatrix}\mathbf{0}\\ \frac{1}{2}w'\\ \boldsymbol{\alpha}'\\ \frac{1}{2}w'\\ \mathbf{0}\end{pmatrix}+\psi_{\mathrm{D}}^2\begin{pmatrix}\mathbf{0}\\ 0\\ \mathbf{0}\\ w''\\ \boldsymbol{\alpha}''\end{pmatrix}$$

where $\psi_{\mathrm{H}}=n_{\mathrm{H}}=\frac{1}{2}[\mathrm{H}]$ replaces what we previously (3) called ϕ; α_i, etc. $=(\boldsymbol{u}^{\mathrm{T}}\mathbf{E}^{-1}\mathbf{S})_i$, etc. for primed and double-primed indices. In expanded form (12) is

$$(13)\qquad \dot{\psi}_i(t)=d_i\psi_i(t)+\alpha_i n_{\mathrm{H}}^2(t)\qquad 0\leqslant i\leqslant(n-1)$$

$$(14)\qquad \dot{\psi}_i'(t)=d_i'\psi_i'(t)+\alpha_i' n_{\mathrm{H}}(t)n_{\mathrm{D}}(t)\qquad 0\leqslant i'\leqslant(n'-1)$$

$$(15)\qquad \dot{\psi}_i''(t)=d_i''\psi_i''(t)+\alpha_i'' n_{\mathrm{D}}^2(t)\qquad 0\leqslant i''\leqslant(n''-1)$$

$$(16)\qquad \dot{n}_{\mathrm{H}}(t)=\tilde{n}_{\mathrm{H}}^2\sum_{i=0}^{n-1}\alpha_i\psi_i(t)+wn_{\mathrm{H}}^2(t)+\tfrac{1}{2}\left[\tilde{n}_{\mathrm{H}}\tilde{n}_{\mathrm{D}}\sum_{i'=0}^{n'-1}\alpha_i'\psi_i'(t)+w'n_{\mathrm{H}}(t)n_{\mathrm{D}}(t)\right]$$

$$(17)\qquad \dot{n}_{\mathrm{D}}(t)=\tilde{n}_{\mathrm{D}}^2\sum_{i''=0}^{n''-1}\alpha_i''\psi_i''(t)+w''n_{\mathrm{D}}^2(t)+\tfrac{1}{2}\left[\tilde{n}_{\mathrm{H}}\tilde{n}_{\mathrm{D}}\sum_{i'=0}^{n'-1}\alpha_i'\psi_i'(t)+w'n_{\mathrm{H}}(t)n_{\mathrm{D}}(t)\right]$$

As was noted in eq. III(11), the integral form of eq. (13) is

$$(18)\qquad \psi_i(t)=\psi_i(0)\,\mathrm{e}^{d_it}+\alpha_i\int_0^t\mathrm{e}^{d_i(t-\tau)}\,n_{\mathrm{H}}^2(\tau)\,\mathrm{d}\tau$$

where, for $0\leqslant i\leqslant(n-2)$, the d_i are large in magnitude and negative; hence an asymptotic expansion can be made in powers of d_i^{-1}, retaining only one term, *i.e.*

$$(19)\qquad \psi_i(t)=\psi_i(0)\,\mathrm{e}^{d_it}+\alpha_i d_i^{-1}n_{\mathrm{H}}^2(0)\,\mathrm{e}^{d_it}-\alpha_i d_i^{-1}n_{\mathrm{H}}^2(t)\qquad 0\leqslant i\leqslant(n-2)$$

with similar results for $\psi_i'(t)$, $0\leqslant i'\leqslant(n'-2)$ and $\psi_i''(t)$, $0\leqslant i''\leqslant(n''-2)$. Thus only five differential equations remain

$$(13a)\qquad \dot{\psi}_{n-1}(t)=d_{n-1}\psi_{n-1}(t)+\alpha_{n-1}n_{\mathrm{H}}^2(t)$$

$$(14a)\qquad \dot{\psi}_{n-1}'(t)=d_{n-1}'\psi_{n-1}'(t)+\alpha_{n-1}'n_{\mathrm{H}}(t)n_{\mathrm{D}}(t)$$

$$(15a)\qquad \dot{\psi}_{n-1}''(t)=d_{n-1}''\psi_{n-1}''(t)+\alpha_{n-1}''n_{\mathrm{D}}^2(t)$$

$$(16a)\qquad \dot{n}_{\mathrm{H}}(t)=\tilde{n}_{\mathrm{H}}^2\alpha_{n-1}\psi_{n-1}(t)+\left[w-\tilde{n}_{\mathrm{H}}^2\sum_{j=0}^{n-2}\alpha_j^2d_j^{-1}\right]n_{\mathrm{H}}^2(t)+\tilde{n}_{\mathrm{H}}^2\sum_{j=0}^{n-2}\alpha_j[\psi_j(0)+\alpha_jd_j^{-1}n_{\mathrm{H}}^2(0)]\,\mathrm{e}^{d_jt}$$
$$+\tfrac{1}{2}\Bigg\{\tilde{n}_{\mathrm{H}}\tilde{n}_{\mathrm{D}}\alpha_{n-1}'\psi_{n-1}'(t)+\left[w'-\tilde{n}_{\mathrm{H}}\tilde{n}_{\mathrm{D}}\sum_{j'=0}^{n'-2}(\alpha_j')^2(d_j')^{-1}\right]n_{\mathrm{H}}(t)n_{\mathrm{D}}(t)$$
$$+\tilde{n}_{\mathrm{H}}\tilde{n}_{\mathrm{D}}\sum_{j'=0}^{n'-2}\alpha_j'[\psi_j'(0)+\alpha_j'(d_j')^{-1}n_{\mathrm{H}}(0)n_{\mathrm{D}}(0)]\,\mathrm{e}^{d_j't}\Bigg\}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$(17a)\quad \dot{n}_D(t) = \tilde{n}_D^2\alpha''_{n-1}\psi''_{n-1}(t) + \left[w'' - \tilde{n}_D^2 \sum_{j''=0}^{n''-2} (\alpha''_j)^2 (d''_j)^{-1}\right] n_D^2(t)$$
$$+ \tilde{n}_D^2 \sum_{j''=0}^{n''-2} \alpha''_j \left[\psi''_j(0) + \alpha''_j (d''_j)^{-1} n_D^2(0)\right] e^{d''_j t}$$
$$+ \tfrac{1}{2}\left\{\tilde{n}_H\tilde{n}_D\alpha'_{n-1}\psi'_{n-1}(t) + \left[w' - \tilde{n}_H\tilde{n}_D \sum_{j'=0}^{n'-2} (\alpha'_j)^2 (d'_j)^{-1}\right] n_H(t) n_D(t)\right.$$
$$\left. + \tilde{n}_H\tilde{n}_D \sum_{j'=0}^{n'-2} \alpha'_j \left[\psi'_j(0) + \alpha'_j (d'_j)^{-1} n_H(0) n_D(0)\right] e^{d'_j t}\right\}$$

Equations (13*a*)–(17*a*) retain the symmetry characteristic of the reaction scheme.

Organization of the Calculation

The solution of the problem proceeds in the following way. First, the matrices **A**, **A**′, and **A**″ are constructed from the assumed translational–vibrational transition probabilities according to eq. (10), and each is diagonalized separately by methods described elsewhere (2, 11); for temperatures above 1500 °K, this is relatively straightforward if a wordlength of about 30 decimal places is available. The factorization into three separate calculations at this stage is due to the fact that the off-diagonal blocks in eq. (10) are all zero: they would only be non-zero if a collision with the third body were to bring about transmutations between H_2, HD, and D_2, *i.e.* only if the species H, D, H_2, HD, or D_2 were considered as third bodies in non-dilute systems; in such cases, sets of master equations would not only be coupled through the products H and D as they are here, but also through the third bodies, and the solution of such a complicated problem seems intractable in the present state of the art.

An initial distribution is then chosen, and for these calculations we always chose the reactants to be either $H_2 + D_2$, all in $v = 0$ and $v'' = 0$, or pure HD, all in $v' = 0$, together with the usual excess of inert gas M. These distributions are then transformed first to $\xi(0)$ etc. and then to $\psi(0)$ etc. using the eigenvectors **S**, **S**′, and **S**″ (eq. 11). Five differential equations (13*a*)–(17*a*) are then constructed and solved by a fifth-order Runge–Kutta procedure (12) using a step length chosen to be consistent with the desired accuracy; as explained previously (3) this has to be very short at the beginning but, as time progresses, can be made longer and longer as the large (and negative) d_i terms die out of the equations. Here, we used an empirical criterion for "desired accuracy": that the rate constants, as discussed below, were the same whether calculated from the eigenvalues d_{n-1}, d'_{n-1}, and d''_{n-1} by eqs. III(21) and III(22): from the instantaneous values of the upward and downward fluxes by equations II(6*b*) and II(11*b*), which are the differential forms of the rate expressions for dissociation and recombination respectively, or from the total amount of product formed in the given time via the appropriate integrated law; (*cf.* our earlier discussions of eq. II(7*b*) and of eqs. III(21) and III(22) which show that all three methods should agree once the time is sufficiently long that the induction period can be ignored). It is of interest to note that we had to use an order-of-magnitude shorter step length than calculations on H_2(3) or D_2(5) alone would have suggested in order to attain this consistency of the rate constants; perhaps this is in some way related to the fact that in all attempts to solve the original set of 57 equations by direct integration, the indications always were that a shorter step length was required, but we could never achieve it!

Having solved these five simultaneous differential equations (13*a*)–(17*a*) to the desired precision out to the particular time t, the ψ_i, ψ'_i, and ψ''_i are generated from the ψ_{n-1}, ψ'_{n-1}, ψ''_{n-1}, n_H and n_D by the $(n-1)$, $(n'-1)$, and $(n''-1)$ sets of algebraic equations (19), (19′), and (19″). The ψ_i are then transformed back to the ξ_i, and thence to the n_i, using the transformation $\mathbf{T}^{-1}\boldsymbol{\psi}$, since by eq. III(10)

$$\psi_i = \sum_{j=0}^{n-1} \tilde{S}_{ij}\tilde{n}_j^{1/2}\xi_j \qquad 0 \leqslant i \leqslant (n-1)$$

Using an IBM 360/50 machine, the three diagonalizations took altogether approximately 1 h of computer time for each temperature; thereafter, the integration was quite rapid (about 10^{-3} s of reaction time per min of computing). The time-consuming nature of the diagonalizations is to some extent a reflection of the unsuitable nature of our particular machine for these kinds of calculation; the word length is too short, and cumbersome four-length arithmetic has to be used; the same three matrices can be diagonalized with the required precision on a CDC 6600 machine in about 2 min.

Results

Tables 1 and 2 show sample population distributions for the time $t = 10^{-4}$ s for the dissociation of HD and for the reaction of H_2 with D_2, respectively. The data for H_2 and D_2 in Table 2 are indistinguishable from the distributions that H_2 and D_2 would have at the same time if they were dissociating *alone* under the same conditions. Qualitatively then, the description of each of the three dissociation processes is very similar to that which we have already described (2) but with one small difference. That is, that when a H_2 or a D_2 molecule dissociates into atoms, not only can the H or D atoms recombine back to the parent molecules, but they find another sink into which they can be trapped with a partner of the opposite kind. These product molecules appear to be

formed with grossly non-Boltzmann population distributions amongst the vibrational levels.

Because there are apparently such distorted population distributions, at least in the product molecules, it is of interest to calculate the phenomenological rate constants for dissociation and recombination in the system. As standards for comparison, Table 3 presents the recombination and dissociation rate constants for H_2, HD, and D_2 calculated from the eigenvalues d_{n-1}, d'_{n-1}, and d''_{n-1} by equations III(21) and III(22). Note that k'_d lies between k_d and k''_d for reasons already explained (5). Note also that k'_r is roughly twice as big as the mean k_r and k''_r as required by the standard definitions due to the difference in symmetry number between homo- and hetero-nuclear diatomic molecules. The rate constants for these processes can be calculated from the population distributions and transition probabilities, as described before (2), the data in Table 1 yielding k'_d, k_r, and k''_r, and Table 2 k_d, k''_d, and k'_r. It turns out that all six rate constants are identical to those calculated from the eigenvalues, despite the fact that the population distributions of the newly formed product molecules look distorted. It is not surprising that the dissociation rate constants can be defined, since the population distributions of the reactants are so little affected by the alternative channel(s) open to the atoms, but perhaps it is surprising that the recombination rate constants are so well-behaved; however, inspection of the H_2 data in Table 1 reveals that the product-molecule distributions are similar to those obtaining in normal recombinations (2, 3, 13) apart from a rather large scaling factor. The effect of successively closer vibrational level spacings in H_2, HD, and D_2 also shows up in Tables 1 and 2: for the newly formed product molecules, there is both a better equilibration amongst the lower vibrational states, and a faster path for molecules down to the lower levels as the vibrational spacings come closer together (5).

One can define another kind of rate constant from the data in Tables 1 and 2, *viz.*

HD dissociation

$$(20)\quad R_{H_2} = k_f[M]\{[HD]^2 - K_m[H_2][D_2]\}$$

$$(20'')\quad R_{D_2} = k''_f[M]\{[HD]^2 - K_m[H_2][D_2]\}$$

$$(21')\quad -R_{HD} = k'_{dd}[M]\{[HD]^2 - K_m[H_2][D_2]\}$$

H_2/D_2 reaction

$$(20')\quad R_{HD} = k'_f[M]\{[H_2][D_2] - K_m^{-1}[HD]^2\}$$

$$(21)\quad -R_{H_2} = k_{dd}[M]\{[H_2][D_2] - K_m^{-1}[HD]^2\}$$

$$(21'')\quad -R_{D_2} = k''_{dd}[M]\{[H_2][D_2] - K_m^{-1}[HD]^2\}$$

with

$$(22)\quad K_m = \frac{[HD]^2}{[H_2][D_2]} = \frac{k_{dd}}{k_f} = \frac{k'_f}{k'_{dd}} = \frac{k''_{dd}}{k''_f}$$

The rate constants defined by eqs. (21), (21'), and (21'') are trivial, since the rate of disappearance of the diatomic in question is also related to the rate constant to be found in Table 3, *e.g.* at early times, neglecting the back reaction, we can write

$$(23)\quad k_{dd}[H_2][D_2] = k_d[H_2]$$

whence k_{dd} is simply $k_d/[D_2]$.

On the other hand, the rate constants for the formation of diatomics expressed in terms of the diatomics are not trivial, since they turn out to be time-dependent. The time dependency arises very simply, since using eq. (20') as an example, at early times before back reaction commences but long compared with the induction period, one can write (2)

$$\begin{aligned} R_{HD} &= k'_r[M][H][D] \\ &= k'_r[M]\{2k_d[M][H_2]t\}\{2k''_d[M][D_2]t\} \\ &= 4k'_rk_dk''_d[M]^3[H_2][D_2]t^2 \end{aligned}$$

whence

$$(24')\quad k'_f = 4k'_rk_dk''_d[M]^2t^2$$

The population distributions such as are shown in Tables 1 and 2, when cast in the form of eqs. (20), (20′), and (20″), all give t^2-dependent k_f rate constants conforming to eq. (24) etc., thus demonstrating the internal consistency of our population distributions and the accuracy of the integration. Had the rate expressions (20) and (21) excluded the term in [M] on the right hand side, eqs. (23) and (24) would have been appropriately different, but eq. (24) would still retain its dependence on t^2. In recent months, rate constants having a *first-power* t-dependence have been reported in two instances, in shock-tube studies of reactions in H_2/D_2 and HCl/D_2 systems (7, 14).

Towards a Complete Solution of the Heteronuclear Diatomic Dissociation Problem

The main purpose of the work described in this paper has been to show that although the 57 simultaneous differential equations representing the vibration–dissociation coupling of HD at infinite dilution cannot be solved by conventional integration, they can be solved by the normal-mode approach. It would seem therefore that the present type of solution represents a good starting point upon which to base an attempt at a complete solution of the problem, since it seems more than likely that even if rate coefficients were known for reactions [7], [8], and [9] with X = H and Y = D, direct numerical integration would fail as it did here. It is clearly a great simplification that the phenomenological rate constants are well-defined and well-behaved even though the population distributions are as far from Boltzmann as they appear to be in Tables 1 and 2. Thus, it seems that the first attempts at a complete solution should try to superimpose the atomic exchange reactions [7] and [8], and the molecular exchange reaction [9] on population distributions such as those presented in Tables 1 and 2. The effect of including such reactions will be to perturb the population distributions slightly, just as happens when vibration–vibration coupling is included into a simple vibration–dissociation coupling scheme; however, these changes in population are small (8) and would therefore not alter the overall rate appreciably. What will happen, however, is that the perturbation of the population distribution will be different for different concentrations of reactants, and so one will not find simple orders in the reactants, as we have explained previously (8): (*cf.* also ref. 15); we feel therefore that Kaufman's criticism (16) of Bauer's work on *this particular count* should be softened slightly. Thus, at the present stage of the art, given correct rate coefficients for the atomic and molecular exchange reactions between each pair of vibrational levels of reactant and product, one should easily predict the correct overall rate with moderate accuracy. One will not however be able to predict the order in reactants, nor the temperature coefficient of the rate; these must await the development of better integration techniques than those at present available.

As far as the special case of the H_2/D_2 system is concerned, there have been several discussions of the reaction (6, 7, 15, 17) and related ones (14, 18) using both normal Boltzmann and slightly perturbed distributions of reactants. Inspection of Tables 1 and 2, in the light of the results of ref. 8 discussed above, shows that no serious fallacy is introduced by assuming equilibrium population distributions, at least as far as the overall rate is concerned. Thus, with X = H and Y = D, reactions [7] and [8] are many orders of magnitude too slow to give the experimentally observed rates of equilibration of H_2 and D_2, as has been pointed out several times (6, 7, 15, 18). One is therefore left with the paradox that although most theoretical predictions put the activation energy barrier for the molecular exchange [9] very high indeed (19–22), that reaction would have to be very fast indeed to account for the observed rates (6, 15, 16, 23). In fact, if the observed Arrhenius temperature coefficients of around 40 kcal/mol can be assumed to be lower limits to the critical energy, any single molecular exchange process would need to have a P-factor of the order of 10^2 or more to account for the observed rates, which seems unlikely: there are however several such possible processes, and taken all together, they could collectively give rise to the observed rate if most of them had P-factors of the order of 10; this same factor of 10 arises in a somewhat different guise in other treatments (15). Thus, either the critical energy for the molecular exchange reaction is rather less than 40 kcal, although some theoretical predictions place it nearer 140 kcal, or there is some other exchange mechanism that has not yet been considered. The mechanism which is the subject of this paper is of course far too slow, as illustrated by the comparison of the extents of reaction shown in

Tables 1 and 2 with the experimental observation that complete equilibration is achieved in the order of 1 ms; however, this rate does have a t^2-dependence and accelerates rapidly as time progresses. Clearly the resolution of this paradox will require much detailed work along the lines suggested by Kaufman (16) and by Belford and Strehlow (23); however, an experimental search for an unsuspected source of atoms (24),[2] building up linearly with t, would seem to be well worthwhile in view of the recent discovery of a time-dependent rate (7), for whilst the model proposed by Kern and Nika does account for the observed form of the time dependence, it too fails to account satisfactorily for the high rate of the reaction. Also, the homogeneous ortho–para conversion of H_2 should have a similarly time-dependent rate law; the study of this reaction in a shock tube would present significant technical problems, but would be important not only for its own intrinsic interest, but also to throw more light on the isotopic exchange problem.

[2]Craig has calculated for us the rate of scrambling of H_2 and D_2 that would occur in the combustion of 20 p.p.m. O_2 in a 98:1:1 Ar:H_2:D_2 mixture and confirmed Schott's conclusion, quoted by Bauer and Ossa (6): thus, free O_2 which is present in these sorts of quantities (7) is certainly not responsible; it would seem that any other likely impurity atoms would have to be introduced into the shock-tube system during fabrication or cleaning processes (25).

n-Butylamine Adsorption onto Amorphous Silica

COLIN CLARK-MONKS[1] AND BRYAN ELLIS
Department of Glass Technology, University of Sheffield, Sheffield 10, Yorkshire, England

Received June 29, 1971

Gravimetric and infrared spectroscopic observations of *n*-butylamine adsorption onto silica have shown that strong adsorption is associated primarily with *isolated* surface hydroxyl groups and also with some *vicinal* surface groups. Adsorbed material can be totally removed from the surface by outgassing at elevated temperature (to 200 °C) without irreversible changes to the underlying surface. The interaction between adsorbed amine and ethylene oxide vapor has been investigated and a possible reaction mechanism is presented.

Les observations spectroscopiques infrarouge et de gravimétrie sur l'adsorption de la *n*-butylamine sur la silice ont montrées qu'une forte adsorption est essentiellement due à la présence de groupes hydroxyles isolés de surface et également à la présence de groupes vicinaux de surface. Les produits adsorbés peuvent être complètement éliminés de la surface par un dégazage à température élevée (200 °C) et ceci sans changement irréversible des surfaces sous-jacentes.

Canadian Journal of Chemistry, **50**, 907 (1972)

Introduction

The mechanism of amine adsorption onto siliceous surfaces has been the subject of several investigations (1,2–3,4) and it would appear that strong adsorption onto surfaces with low concentrations of surface hydroxyl groups is often associated with *isolated* hydroxyl units. *Isolated* hydroxyl groups are defined as groups which do not undergo interaction with other surface hydroxyl groups, being further than ~3 Å from their nearest neighbors. Other surface hydroxyl groups are close enough together to undergo mutual interactions and are usually classified as *vicinal* units. There has been some speculation on the precise nature of the adsorbed amine species, and the formation of a quaternary ammonium surface group has been postulated (2); however, this view is not confirmed by us.

In the present work, a detailed examination of *n*-butylamine adsorption onto a well-characterized silica surface has been carried out in order to ascertain the applicability of earlier suggested adsorption mechanisms, and the interaction of the adsorbed amine species with ethylene oxide vapor has been investigated. Both gravimetric and infrared spectroscopic observation of the adsorption behavior have been employed. The silica adsorbent used was amorphous, had a surface area of 356 ± 7 m^2/g, and a surface hydroxyl group concentration of 3.1 groups/100 Å^2 of which approximately 1.4 groups/100 Å^2 are considered to be *isolated* units. Characterization of the silica surface (17) has been previously reported (5).

[1]Present address: Technical Centre, Fiberglas Canada Ltd., P.O. Box 3005, Sarnia, Ontario.

Experimental

Adsorption was measured gravimetrically in a McBain–Bakr type of balance utilizing a fused silica spring. The balance system could be evacuated to a pressure of 10^{-6} Torr and was thermostatted in an air bath: the use of a furnace enabled adsorbent sample temperatures to be raised from ambient to 450 °C.

Infrared spectra were recorded using a cell which enabled direct observation of adsorption onto pressed silica discs. The cell was constructed from brass with removable potassium bromide windows which were polished before each experiment, and was similar to the design given by Kagel and Hersher (6). It was connected to a conventional vacuum rack. All spectra were corrected for background absorption due to vapor in the cell.

The amorphous silica used was a particulate pyrogenic material[2] and was thoroughly outgassed between 100 and 110 °C prior to experiment. Adsorbates used were *n*-butylamine (G.P.R.) and ethylene oxide (G.P.R.), and were thoroughly outgassed *in situ* before use.

Apparatus and experimental techniques are further detailed in ref. 5.

Results and Discussion

The adsorption isotherm measured gravimetrically at 23 °C was of the B.D.D.T (7) Type II, with a strong *irreversible* adsorption (8) being found on subsequent outgassing (Fig. 1). *Irreversibly* adsorbed material W_{irr}, was found

[2]Cab-O-Sil S17 (Cabot Carbon Ltd.).

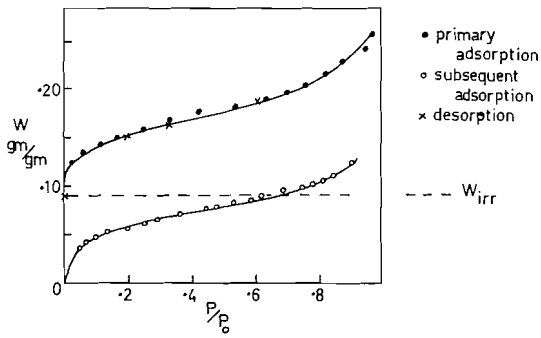

FIG. 1. Adsorption isotherms of *n*-butylamine onto the silica. $T = 23$ °C. ●, primary adsorption; ○, subsequent adsorption; X, desorption; --- W_{irr}.

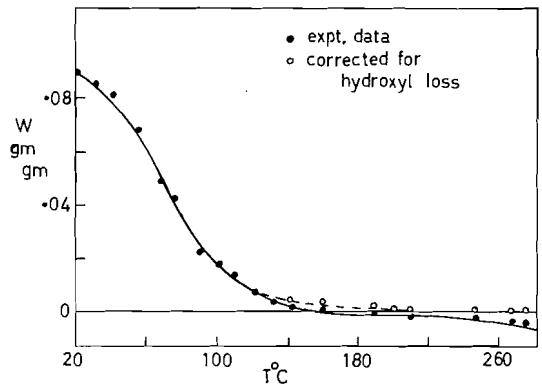

FIG. 2. Loss of *irreversibly* adsorbed *n*-butylamine with temperature (*in vacuo*).

to be 0.0893 g/g which is equivalent to 2.1 molecules/100 Å^2. Although *irreversible* adsorption may be associated with *isolated* surface hydroxyl groups as suggested elsewhere, in the present case adsorption must also be associated with other surface groups since the *isolated* site concentration is only approximately 1.4 groups/100 Å^2. Analysis of the secondary reversible adsorption isotherm using the B.E.T. equation (9) yields a "monolayer" capacity of $W_m = 0.466$ g/g which is equivalent to 1.1 molecules/100 Å^2, and it is interesting to note that $W_m + W_{irr} \simeq 3.2$ molecules/100 Å^2, which is similar to the total surface hydroxyl group concentration; therefore, adsorption in the first complete adsorbed layer may be in a 1-to-1 ratio with surface hydroxyl groups. Consideration of the adsorbate molecular shape and size (chain length >5 Å) shows that interaction with the surface must occur with the chain "end" to give such a result, and this is consistent with the conclusions advanced by Ross and Taylor (2). The latter authors also present isosteric heats of adsorption which show that there is a strong lateral interaction between adsorbed molecules containing amine groups. This indicates that there is some tendency to clustering around the primary adsorption sites.

An investigation of the outgassing characteristics of the silica plus *irreversibly* adsorbed material showed a gradual removal of material with increasing temperature (1 °C/min) until apparently total loss by 200 °C, Fig. 2. Correction of the total weight loss for surface hydroxyl group condensation (5) would agree with complete desorption of the amine which is later shown to be correct by infrared spectroscopy. Thus, there must be a strong but reversible surface interaction which may be consistent with the concept of an adsorbed quaternary ammonium species (2). This is not, however, confirmed by the present study. The adsorption residence time has been shown to depend critically on the energy of adsorption (10): thus, the present desorption results are readily interpreted qualitatively as showing that there is a distribution of site energies and that for some sites the adsorption energy must be high (>15 kcal/mol).

In order to properly clarify the nature of the interactions occurring, direct infrared spectroscopic observation of adsorption onto a pressed silica disc has been employed as previously described (5). The behavior on degassing at increased temperatures after adsorption of *n*-butylamine at room temperature is shown by the infrared spectra in Fig. 3. The silica has been thermally pretreated in air at 810 °C so that the available surface contained only *isolated* hydroxyl groups. Deuteration of this silica disc had previously shown that all the hydroxyl groups present were available to adsorbing vapors (5). Other spectra for adsorption onto a silica disc which had been thermally pretreated at 440 °C, and a disc which had not been thermally treated but which was pre-deuterated, are presented in Fig. 4. The spectra presented demonstrate that adsorption of *n*-butylamine is indeed primarily associated with the *isolated* surface hydroxyl sites because of the perturbation of the absorption band at 2.67 μ (3.63 μ, deuterated) which is assigned to those groups (4, 5, 11–13). Perturbation occurs with the appearance of a broad band around 3.5 μ superimposed on absorption bands

at 2.95 to 3.05 μ (unperturbed N—H vibrations (14)) and at 3.45 μ (C—H vibrations) due to adsorbed *n*-butylamine. Similar effects have been previously recorded by Basila (1) for the adsorption of diethylamine onto silica. Evacuation at 30 °C following the adsorption of *n*-butylamine left a strongly adsorbed residue which, in the case of the thermally pretreated samples, remained with the perturbation of approximately all the *isolated* surface groups. In the case of the predeuterated sample (Fig. 4), adsorption and subsequent outgassing were suspected to have removed some of the deuterated hydroxyl groups by exchange with the reversibly adsorbed *n*-butylamine: the outgassed sample (with *irreversibly* adsorbed amine) was therefore re-deuterated by two exposures to saturated D_2O vapor for 2 min. The intensities of the absorption bands due to *irreversibly* adsorbed amine were not visibly affected by re-deuteration and the resulting spectrum was found to exhibit only a small proportion of residual *isolated* surface groups (peak height of the 3.63 μ absorption band $<10\%$ of the pre-

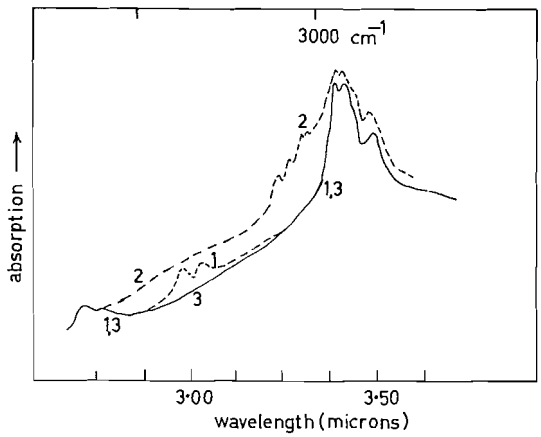

FIG. 5. Ethylene oxide adsorbing onto *irreversibly* adsorbed *n*-butylamine, $T = 30$ °C. Trace *1*, *irreversibly* adsorbed amine on silica disc; trace *2*, with ethylene oxide vapor present at 70 τ for 5 min; trace *3*, outgassed (10^{-4} τ) following trace *2*.

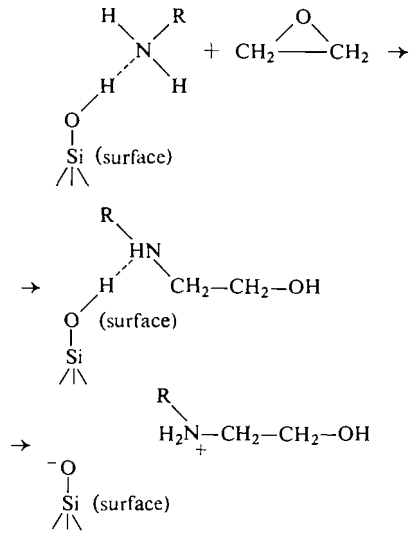
adsorption height). Re-deuteration also only has a small effect on the intensity of the absorption band near to 3.9 μ (which is assigned to *vicinal* surface groups (13), and the spectrum is only marginally different to the final trace presented in Fig. 4*b*. It is therefore concluded that although *irreversibly* adsorbed *n*-butylamine is primarily associated with *isolated* surface sites, some is also associated with *vicinal* surface sites (on the thermally untreated silica sample) which was concluded previously from consideration of the gravimetric data.

The observed outgassing behavior of the pretreated (810 °C) silica disc with *irreversibly* adsorbed *n*-butylamine, Fig. 3 shows that adsorbed species are completely removed by outgassing at 140 °C. Therefore, these observations demonstrate that no permanent and completely irreversible effects occur and that *irreversibly* adsorbed *n*-butylamine can be removed without affecting the surface structure, which supports the gravimetric evidence.

From the present infrared data, it appears unlikely that primary amines primarily adsorb as a quaternary ammonium species (2). Amine salts $(—NH_3)^+$ are reported to show an absorption band for N—H stretching vibration near to 3.2 μ (14), and whilst the spectra presented in Figs. 3 and 4 are not sufficiently well-defined to show beyond doubt that the amine salt is not formed it is clear that the unperturbed $—NH_2$ vibrations (14) (2.95 and 3.05 μ) are still present, which would not be the case if most of the amine had formed a quaternary ammonium species.

Confidence in the conclusion that the $—NH_2$ absorption bands are present in Figs. 3 and 4 is increased by the disappearance of these bands when ethylene oxide is adsorbed onto a silica with preadsorbed *n*-butylamine, Fig. 5. The adsorption of ethylene oxide onto this silica has been described previously (5) and it was shown that the adsorption at room temperature was completely reversible. The nature of the principal surface reaction between ethylene oxide and strongly adsorbed *n*-butylamine is not completely elucidated, but could possibly be formally represented as

[1]



The formation of the quaternary ammonium species in this case may be allowed since a secondary amine is generally considered to be more basic than a primary amine (15). Such a reaction may satisfactorily explain the strong adhesion of epoxy resins cured with primary amines to siliceous surfaces (16) since ethylene oxide can be considered to be analogous to the resin end groups. However, the possibility of more than one surface reaction occurring should not be excluded and the real situation is probably highly complex.

These investigations therefore show that strong adsorption of *n*-butylamine onto silica surfaces occurs at room temperature onto primarily the *isolated* surface hydroxyl groups

For personal use only.

but also involves other *vicinal* surface groups. The adsorbed species can be totally removed by outgassing at elevated temperatures without any permanent effects on the underlying surface structure. Previously suggested quaternary ammonium salt formation would now appear unlikely on the basis of the present infrared spectroscopic data.

The Crystal and Molecular Structure of bis(triphenylphosphine)-(ethylene)platinum, $(PPh_3)_2PtC_2H_4$

P.-T. CHENG AND S. C. NYBURG

Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received September 1, 1971

The X-ray crystal structure analysis of the triphenyl–phosphine platinum ethylene complex $(PPh_3)_2PtC_2H_4$ is reported. The crystals belong to the monoclinic system $a = 16.46(3)$, $b = 10.85(2)$, $c = 17.85(3)$ Å, $\beta = 100.5(1)°$, space group $P2_1/a$, $Z = 4$ molecules per cell.

The ethylene C—C distance of 1.434(13) Å is in accord with that found when other transition elements form metallo-cyclopropanes. The structure has been refined by anisotropic full-matrix least-squares, the final R-factor being 0.043 for 4174 observed reflections.

On rapporte l'analyse par rayons-x de la structure cristalline du complexe triphénylphosphine éthylène platine, $(PPh_3)_2PtC_2H_4$. Les cristaux appartiennent au système monoclinique $a = 16.46(3)$, $b = 10.85(2)$, $c = 17.85(3)$ Å, $\beta = 10.05(1)°$, au groupe spatial $P2_1/a$, $Z = 4$ molécules par maille.

La distance C—C dans l'éthylène de 1.434(13) Å est concordante avec celle qu'on trouve quand d'autres éléments de transition forment des métallo-cyclopropanes. La structure a été raffinée par la méthode anisotropique matricielle des moindres carrés, le facteur R final étant de 0.043 pour les réflexions 4174 observées.

Canadian Journal of Chemistry, **50**, 912 (1972)

Introduction

The primary problem concerning the nature of the bonding of unsaturated molecules to transition metals is whether, when a carbon–carbon double bond is involved, the system should be described as a metallo-cyclopropane derivative or a π-adduct of the metal. The Dewar–Chatt–Duncanson (D–C–D) (1) representation of the bonding between ethylene and transition metals allows any reasonable oxidation state of the metal. In the case of platinum, the oxidation state could be between Pt(0) and Pt(II) depending upon the extent of back-donation.

Crystallographic data are accumulating on certain closely related complexes, *e.g.* $(PPh_3)_2PtC_2(CN)_4$ (2), $(PPh_3)_2PtC_2Cl_4$ (3), and $(PPh_3)_2NiC_2H_4$ (4). In order to make a critical appraisal of the D–C–D model and to learn the role played by the electron-withdrawing groups —CN and —Cl we have undertaken a three-dimensional X-ray analysis of the ethylene complex $(PPh_3)_2PtC_2H_4$, a brief report on which has already been published (5).

Experimental

The crystals of the ethylene adduct were supplied by Cook of this Department. They are colorless cuboids, stable under X-irradiation with major crystal forms {011}, {01$\bar{1}$}, and {100}. Unit cell dimensions were determined by measuring eleven 2θ, χ, and ϕ settings of strong ($h00$), ($0k0$), and ($00l$) reflections and refining by least squares. The crystal data are as follows:

$C_{38}H_{34}P_2Pt$ f.w. = 747

Monoclinic, $a = 16.46(3)$, $b = 10.85(2)$, $c = 17.85(3)$ Å, $\beta = 100.5(1)°$. $V = 3135$ Å^3, $\rho_0 = 1.56(1)$, $Z = 4$, $\rho_c = 1.58$ (25 °C; MoKα, $\lambda = 0.7107$ Å, $\mu = 47.7$ cm^{-1}).

Intensity data were collected by automated diffractometer using MoKα radiation in 2θ scan mode at 1° min^{-1} with $0 \leqslant \sin\theta \leqslant 0.4$. The scanning range at low 2θ was 1.6°. The crystal used was a small cube with *ca.* 0.3 mm edge and no absorption corrections were applied to the intensity data. The weighting scheme used was (6)

$$\sigma^2(F^2) = I/(LP)^2 + CF^4$$

where I is peak plus background intensity and C was taken as 0.02 to allow for instrumental instability. Of the 4678 independent reflections collected, 504 had $F^2 \leqslant \sigma(F^2)$ and were considered unobserved.

Determination of the Structure

From the Patterson function, the Pt atom coordinates were determined. (Space group $P2_1/a$ has four equivalent positions: (x, y, z), $(\bar{x}, \bar{y}, \bar{z})$, $(\frac{1}{2} + x, \frac{1}{2} - y, z)$, and $(\frac{1}{2} - x, \frac{1}{2} + y, \bar{z})$). Refinement was carried out using the full-matrix least-squares program XFLS (7). Atomic form factors used were those derived from Hartree–Fock wave functions (8), allowance being made for anomalous scattering. After three cycles of anisotropic refinement, the conventional R-factor converged smoothly to 0.047. In the last cycle, the largest shift was about 0.8σ and no abnormal thermal parameters were observed. At this stage the refinement of the non-hydrogen atomic positions was considered complete. The final positional and thermal

parameters and their estimated standard deviations are given in Tables 2 and 3.

All phenyl hydrogen atom positions were then calculated from a local program, using C...H = 1.07 Å. The hydrogen atoms were assigned the same thermal parameters as the carbon atoms to which they are bonded. Structure factor calculations, including contributions from these hydrogen atoms, lowered the *R*-factor to 0.043.

A difference Fourier synthesis at this stage gave no clearly defined ethylenic hydrogen atoms. The diffuse regions of electron density which were observed suggested that the hydrogen atoms were displaced somewhat away from the Pt atom to give a nonplanar ethylene molecule. It is impossible to be certain of this effect, however; if it were genuine it would resemble the displacements found for CN in $(PPh_3)_2PtC_2(CN)_4$ (2) and for Cl in $(PPh_3)_2PtC_2Cl_4$ (3).

The final bond distances and angles in the molecule are shown in Fig. 1 (*a*) and (*b*), the average standard deviations of the phenyl ring angles being 0.8°. Final F_o and F_c values have been placed in the Depository for Unpublished Data.[1]

Discussion

A diagram of the molecule viewed normal to the central coordination plane is given in Fig. 2. Important bond lengths of this and related complexes are given in Table 1.

The 1.434(13) Å C—C bond length is consistent with the length of 1.43 Å found in the

nickel analog (4). It is also compatible with the electron spectroscopic result (9) that there is a 0.8-electron transfer from Pt to C_2H_4. This $Pt \rightarrow C_2H_4$ back donation is sufficient to change the C=C bond to one with significant single bond character. Although this bond is shorter than the 1.49(5) Å found in $(PPh_3)_2PtC_2(CN)_4$ (2), the difference is not statistically significant; however, it is significantly shorter than the 1.62(3) Å found in $(PPh_3)_2PtC_2Cl_4$ (3). The shortest C—C bond of this type is found in Zeise's salt $KPtCl_3(C_2H_4).H_2O$, 1.37(3) Å (10), where however, the C—C vector is not in the coordination plane, but almost perpendicular to it (84°).

The Pt—C distances, 2.116(9) and 2.106(8) Å, are similar to those found in other platinum–olefin complexes, namely 2.10(3), 2.12(3) Å in $(PPh_3)_2PtC_2(CN)_4$, 2.02(3), 2.05(2) Å in $(PPh_3)_2$-PtC_2Cl_4. They are also compatible with the 1.98(1) and 2.00(1) Å found in $(PPh_3)_2NiC_2H_4$. Estimates of radii of transition elements atoms in their zero oxidation state do not seem to have been made. However the fact that the metallic

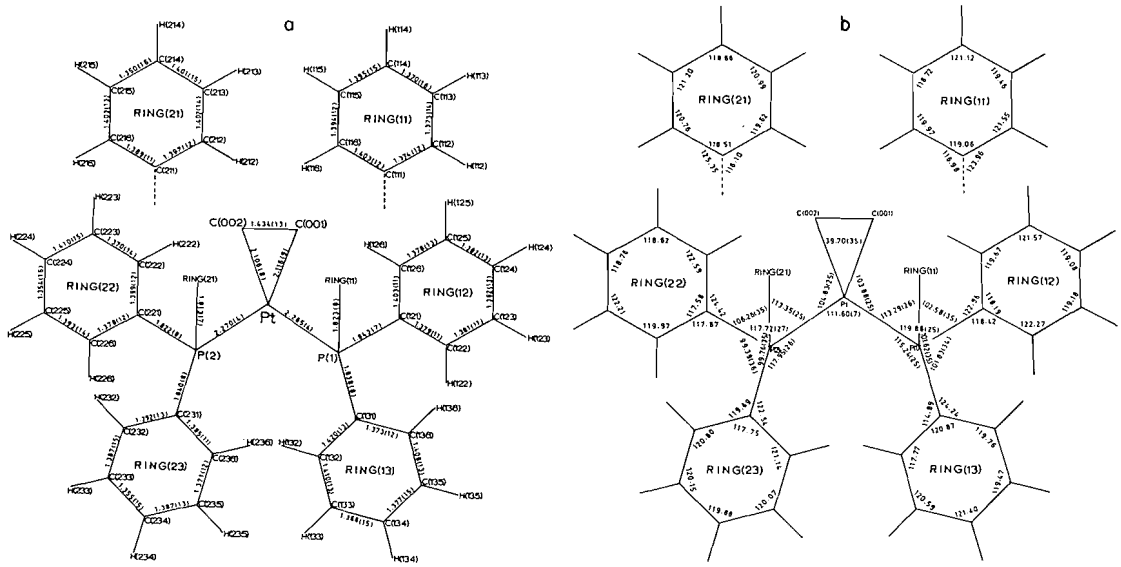

FIG. 1. (*a*) Bond lengths, (*b*) bond angles.

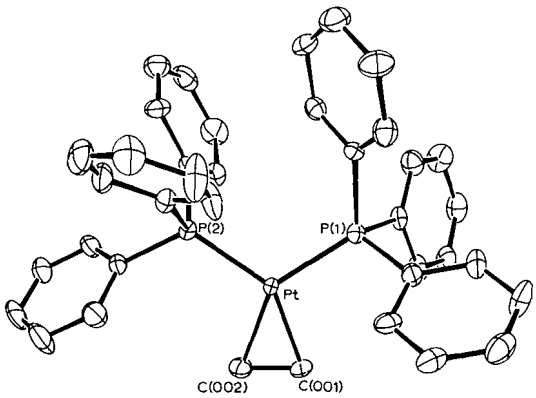

FIG. 2. Molecule of $(PPh_3)_2PtC_2H_4$ with 30% probability thermal ellipsoids.

radius of the Pt atom is estimated to be some 0.14 Å greater than the metallic radius of Ni is in accord with these results.

The Pt—P distances, 2.265(4) and 2.270(4) Å, are also compatible with, although shorter than, those found in the other complexes of known structure, namely 2.288(8), 2.291(9) Å in $(PPh_3)_2PtC_2(CN)_4$, 2.278(8), 2.292(7) Å in $(PPh_3)_2PtC_2Cl_4$; the shortenings are marginally significant.

The four atoms attached directly to the Pt atom are closely coplanar, the best least-squares plane, in real orthogonal coordinates, X along x and Z along z^* is $0.7158X + 0.4427Y - 0.5401Z = -0.2513$ with deviations of atoms (in Å) from this plane as follows: Pt, −0.0033; P(1), −0.0054; P(2), +0.0074; C(001), +0.0174; C(002), −0.0161. When the P—Pt—P and C—P—C parts are considered separately there is an interplanar angle of 1.6° between planes P—Pt—P and C—Pt—C, significantly smaller than that found in the related complexes, 8° in $(PPh_3)_2PtC_2(CN)_4$ and 12° in $(PPh_3)_2PtC_2Cl_4$. However, no close intramolecular or intermolecular contacts have been reported for any of the crystals of these complexes, so that observed non-coplanarities may be a feature of the isolated molecules. A modification of the Dewar–Chatt–Duncanson representation has been proposed (11) to rationalize these observations; it allows the metal-to-ligand back donation to involve both d_{xz} and $d_{x^2-y^2}$ (or d_{xy}) electrons. However, the involvement of the d_{xz} electrons in $(PPh_3)_2PtC_2H_4$ would be negligible since the central coordination plane is very close to planar.

We are grateful to Professor C. D. Cook and Mr. K. Y. Wan for helpful discussions. Thanks are due to National Research Council of Canada for generous financial support.

Quaternary Nitrogen Heterocycles. I. Equilibrium and Spectral Data for Pseudobase Formation by the *N*-Methyl Cations of Diazanaphthalenes

JOHN W. BUNTING AND WILLIAM G. MEATHREL
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received October 18, 1971

Equilibrium constants have been measured at 25° for the formation of pseudobases from the 2-methylphthalazinium, 1-methylquinoxalinium, 1-methyl-1,5-naphthyridinium, 6-methyl-1,6-naphthyridinium, 7-methyl-1,7-naphthyridinium, 1-methyl-1,8-naphthyridinium, 1-methyl-3-nitroquinolinium, and 2-methyl-4-nitroisoquinolinium cations. Ionization constants have also been obtained for ionization of some of these pseudobases to alkoxide anions. For each cation the site of hydroxide attack has been determined by comparison of the u.v. and p.m.r. spectra of the pseudobases, the corresponding methoxide adducts, and the lithium aluminum hydride reduction products. In all cases, except for the 1-methylquinoxalinium cation, only one major pseudobase species is present in solution, and ring-opening does not occur to any appreciable extent. The pseudobase of the 1-methylquinoxalinium cation exists in equilibrium with a considerable amount of its covalent hydrate from addition of water across the C_3—N_4 bond.

Les constantes d'équilibre ont été mesurées à 25° pour la formation de pseudobases à partir des cations méthyl-2 phthalazinium, méthyl-1 quinoxalinium, méthyl-1 naphthyridium-1,5, méthyl-6 naphthyridium-1,6, méthyl-7 naphthyridium-1,7, méthyl-1 naphthyridium-1,8, méthyl-1 nitro-3 quinolinium, et méthyl-2 nitro-4 isoquinolinium. Les constantes d'ionisation ont été aussi obtenues pour l'ionisation de quelques de ces pseudobases en anions alkoxyde. Pour chaque cation, le site d'attaque de l'hydroxyde a été déterminé par comparaison des spectres u.v., et r.m.p. des pseudobases, des composés d'addition méthoxyde correspondants et des produits de réduction par l'hydrure de lithium aluminium. Dans tous les cas, à l'exception du cation de la méthyl-1 quinoxalinium, il n'y a seulement qu'une espèce pseudobase majoritaire présente en solution, et l'ouverture du cycle ne se produit pas dans un pourcentage appréciable. La pseudobase du cation de la méthyl-1 quinoxalinium existe en équilibre avec un pourcentage important de son hydrate covalent résultant de l'addition de l'eau sur la liaison C_3—N_4.

Although pseudobase formation by quaternary nitrogen heterocycles in aqueous alkaline solutions is a generally accepted phenomenon (1, 2), there are few recent studies of this reaction in the aromatic nitrogen heterocycles. Beke (3) has reviewed studies of pseudobase formation in partially saturated nitrogen heterocycles (mainly naturally occurring 3,4-dihydroisoquinoline derivatives such as berberine and cotarnine), and has discussed the problem of ring–chain tautomerism which may occur in these systems between the pseudobase and a ring-opened amino-aldehyde. The evidence for pseudobase formation in quaternary hetero-aromatic systems rests mainly on the studies of Hantzsch (4), Decker (5), and Aston and Lasselle (6), although the structure of Hantzsch's often quoted (1, 2) "bimolecular ether", which is believed to be formed from the pseudobase of the 1-methylquinolinium cation, has recently been shown to be in error (7, 8).

There has been little attempt to correlate equilibria and kinetics of pseudobase formation with the structure of the quaternary ion. For the equilibrium (eq. 1) between the quaternary heterocyclic cation (Q^+) and the corresponding

[1] $$Q^+ + OH^- \rightleftharpoons QOH$$

pseudobase (QOH), we may define an equilibrium constant, K (eq. 2). Cooksey and Johnson (9), who have measured equilibrium constants for pseudobase formation by the *N*-cyano and *N*-methyl cations of some substituted quinolines and isoquinolines, have preferred to use the constant, K_{ROH}, (eq. 3) which is

[2] $$K = \frac{[QOH]}{[Q^+][OH^-]}$$

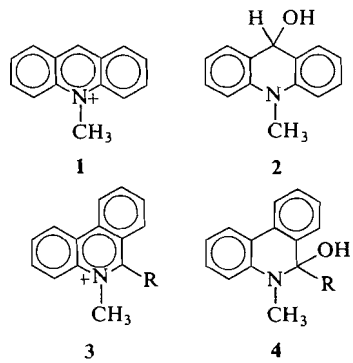
[3] $$K_{ROH} = \frac{[H^+][QOH]}{[Q^+]}$$

related to K through the ionic product of water, K_W, by $K = K_{ROH}.K_W$. The definition of K_{ROH} is similar in form to that of a classical Bronsted-acid ionization constant. It is convenient to express these equilibrium constants as pK_{ROH}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

values, which are analogous to pK_a values for Bronsted acids, and which denote the pH at which the quaternary ion and pseudobase are present at equal concentrations. We shall use this formulation throughout the present paper. In sufficiently alkaline solutions the pseudobases may also lose a proton to form a pseudobase anion (QO^-) (an alkoxide ion) (9), and we shall denote the ionization constant for this process by K_{RO^-}.

For the 1-methylquinolinium and 2-methylisoquinolinium cations, appreciable pseudobase formation occurs only at pH values where subsequent irreversible reactions predominate (4, 5, 9), and consequently pK_{ROH} values for these cations cannot be measured directly. The presence of electron-withdrawing substituents makes the cations much more susceptible to nucleophilic attack by hydroxide ions, and reduces the pK_{ROH} values sufficiently that these values may be measured in pH regions where irreversible reactions are negligible (9). Apart from the studies by Johnson and coworkers, the only other pK_{ROH} values in the literature appear to be those for the *N*-methylacridinium cation (**1** $\rightleftharpoons$ **2**, $pK_{ROH} = 9.75$) (10), and the *N*-methylphenanthridinium (**3** (R = H) $\rightleftharpoons$ **4** (R = H), $pK_{ROH} = 10.4 \pm 0.2$) (11), and 5,6-dimethylphenanthridinium (**3** (R = Me) $\rightleftharpoons$ **4** (R = Me), $pK_{ROH} = 10.1 \pm 0.2$) (11) cations.



1 **2** **3** **4**

The lack of a comprehensive study of pseudobase formation by quaternary aromatic nitrogen heterocycles is rather surprising in view of the extensive investigations which have been made on the closely related covalent hydration of nitrogen heteroaromatic cations in aqueous acid (12–14). Numerous studies (15–18) have also been made on the formation of Meisenheimer complexes by the addition of nucleophiles to various electron-deficient aromatic molecules. The formation of these anionic covalent complexes is quite analogous to pseudobase formation, since both reactions involve nucleophilic attack on electron-deficient aromatic systems and result in loss of aromaticity because of the production of a saturated carbon atom in the ring.

As the initial step in a study to further the quantitative understanding of the influence of the structure of the heterocycle on pseudobase formation, we wish to report a study of the pseudobase formation by the *N*-methyl cations of phthalazine, quinoxaline, quinazoline, and the 1,*x*-naphthyridines ($x = 5$–8).[1] In addition to the measurement of pK_{ROH} and pK_{RO^-} (where accessible) values for each of these cations, we have determined the site of hydroxide attack by u.v. and p.m.r. spectral techniques.

Results

In each of phthalazine, quinoxaline, 1,5-naphthyridine, and 1,8-naphthyridine the two nitrogen atoms are equivalent and consequently the site of methylation in unequivocal. For 1,6- and 1,7-naphthyridine, in each of which the ring-nitrogen atoms are not equivalent, methylation with methyl iodide has been shown (21) to occur exclusively[2] on the isoquinoline-type nitrogen atom (*i.e.*, N-6 and -7 respectively). It has recently been shown (23) that methylation of quinazoline with methyl iodide produces a mixture of the 3-methyl- and 1-methylquinazolinium cations in the ratio of 5:1.

The u.v. spectra of each of the diazanaphthalene cations examined were pH dependent in aqueous solution. Typical spectra are shown in Figs. 1 (1-methyl-1,5-naphthyridinium iodide) and 2 (1-methylquinoxalinium iodide). The

[1]We have also confirmed that the 2-methylcinnolinium ion, which was believed by early workers to be the 1-methylcinnolinium ion (19, 20), does not form a pseudobase in aqueous alkali, but undergoes a demethylation reaction to give cinnoline as the major product (19).

[2]Jones and Wagstaff (22) have claimed the presence of 5–10% 1-methyl-1,6-naphthyridinium cation from the methylation of 1,6-naphthyridine. This claim is based on the observation of a small peak (δ 4.62 in DMSO-d_6) in the p.m.r. spectrum of their crude reaction product which they assign to the N-1 methyl protons of this cation. This peak was not present in our product.

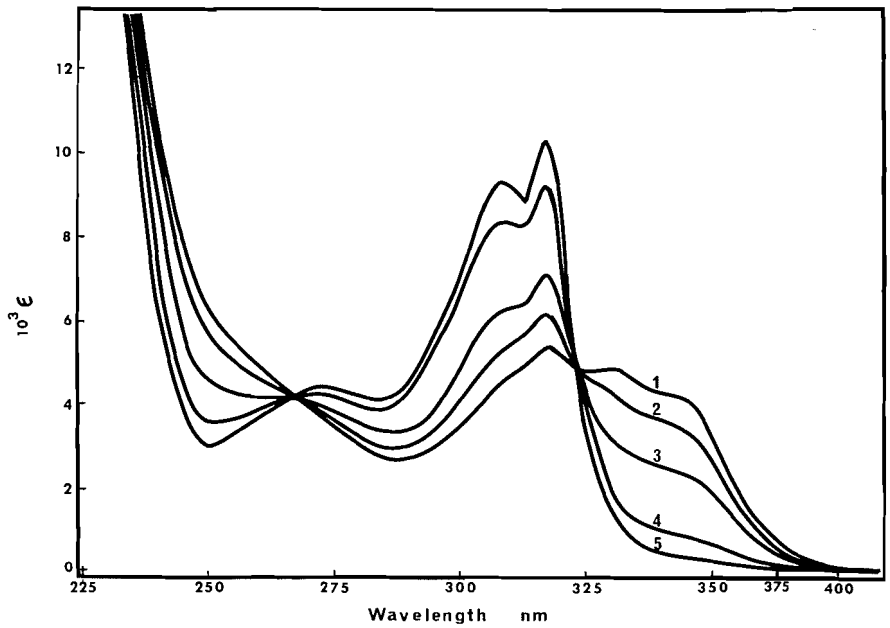


FIG. 1. The u.v. spectrum of 1-methyl-1,5-naphthyridinium iodide in water: 1, pH = 13.4; 2, pH = 13.0; 3, pH = 12.5; 4, pH = 12.0; 5, pH = 9.0.

presence of clean isosbestic points and the reversibility of the spectra upon re-acidification of alkaline solutions indicates that true equilibria, are being observed. The presence of two successive equilibria, as is apparent for the 1-methylquinoxalinium cation in Fig. 2, was also observed for the 2-methylphthalazinium cation, the 3-methylquinazolinium cation, and the 1-methyl-3-nitroquinolinium and 2-methyl-4-nitroisoquinolinium cations, but not for any other cation at less than pH 14. The u.v. spectral data for each species are collected in Table 1.

An equilibrium constant was calculated for each reaction for which an u.v. spectral change was observed. These constants are given, along with appropriate experimental data, in Table 2.

For the 1-methylquinolinium cation, pseudobase formation in aqueous solutions at pH < 15 is insufficient to allow spectroscopic observation. Above pH 15, u.v. spectral changes are apparent, but these are irreversible upon acidification. These changes seem to be due to the formation of 1-methyl-2-quinolone which has been isolated from more concentrated solutions of 1-methylquinolinium iodide in strong aqueous alkali. This product is presumably produced via the corresponding pseudobase which would be formed by hydroxide attack at C-2 of the heterocyclic cation. The data of Cooksey and Johnson (9) indicate that the difference in pK_{ROH} for five correspondingly substituted 1-methyl- and 1-cyano-quinolinium cations is $\Delta pK_{ROH} = 17.5 \pm 0.5$. If we use this ΔpK_{ROH} and the pK_{ROH} value (−1.05) for the unsubstituted 1-cyanoquinolinium cation (9), we may estimate the pK_{ROH} for pseudobase formation from the 1-methylquinolinium cation by hydroxide attack at C-2 to be $pK_{ROH} = 17.5 + (-1.05) = 16.5 \pm 0.5$. This value is consistent with the lack of observable reversible u.v. spectral changes at pH < 15, although it does not definitely establish that C-2 is preferred over C-4 as the site of hydroxide attack in the 1-methylquinolinium cation.

The 2-methylisoquinolinium cation has a pH-independent u.v. spectrum below pH 14. In more basic solutions, spectral changes do occur, but these changes are only partially reversible upon acidification. This suggests that an irreversible reaction is also occurring in addition to pseudobase formation, and 2-methyl-1-isoquinolone has been isolated from more concentrated solutions of this cation. The pK_{ROH} values are available (9) for only two pairs of corre-

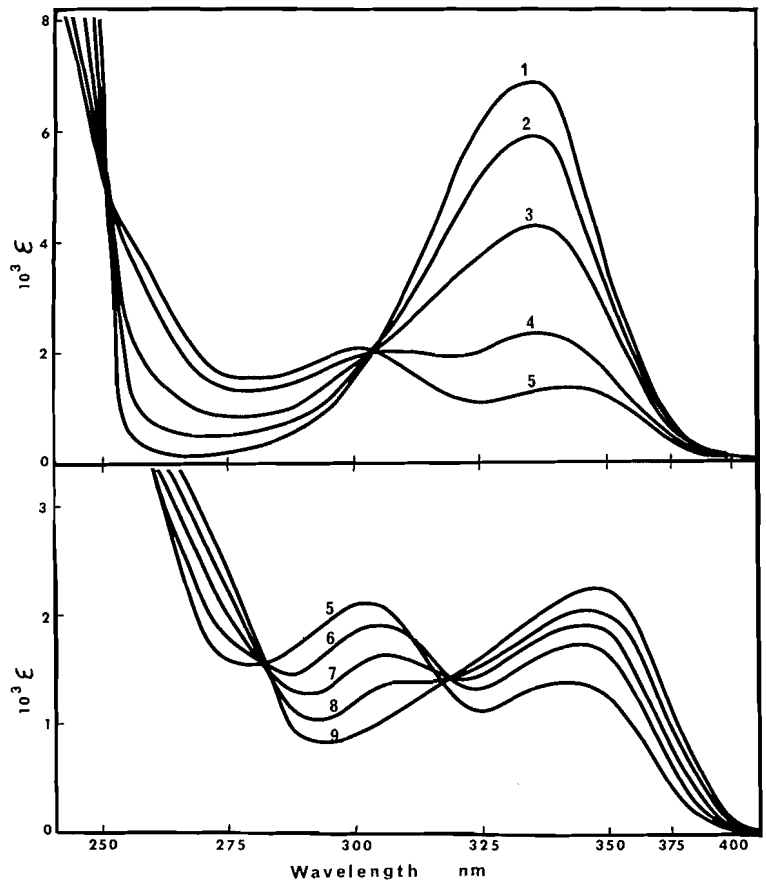

FIG. 2. The u.v. spectrum of 1-methylquinoxalinium iodide in water: 1, pH = 3.6; 2, pH = 7.9; 3, pH = 8.6; 4, pH = 9.2; 5, pH = 10.4; 6, pH = 11.9; 7, pH = 12.5; 8, pH = 13.0; 9, pH = 14.0.

spondingly substituted 2-methyl- and 2-cyano-isoquinolinium cations. The ΔpK_{ROH} values for 5-bromo and 4-bromo substitution are 17.3 and 17.2 respectively, although there is considerable experimental error in pK_{ROH} values of the 2-methylisoquinolinium cations used to calculate ΔpK_{ROH}. Using the $pK_{ROH}(-2.0)$ for the 2-cyanoisoquinolinium cation (24), we estimate $pK_{ROH} = 17.3 + (-2.0) = 15.3$ for the 2-methylisoquinolinium cation, which is consistent with the observed lack of spectral change for solutions of this cation at pH < 14.

The *N*-methyl-1,*x*-naphthyridinium cations have previously been oxidized (21, 25) with

[4]

alkaline potassium ferricyanide to keto products. These oxidations are believed to proceed via the pseudobase intermediates (**5**–**8**) (*e.g.* eq. (4)). To assume from these oxidation studies that **5**–**8** are the major pseudobase species present in alkaline solutions of these cations would be akin to the assumptions made by early workers in this field, and which resulted in much confusion about the nature of pseudobase equilibria (3). It is possible that any, or all, of **5**–**8** are only minor components of the total mixture of pseudobase species, but nevertheless, give rise to the kinetically controlled major oxidation products.

It is well known (26) that quinolinium derivatives are susceptible to nucleophilic attack at C-4 as well as at C-2, and the above oxidation studies cannot rule out the possibility that the pseudobases from the 1-methyl-1,5-naphthyridinium and 1-methyl-1,8-naphthyridinium cations may be mixtures of the pseudobases arising from hydroxide attack at C-4 and -2, with the latter pseudobase being much more readily oxidized than the former. In isoquinolinium derivatives, nucleophilic attack almost invariably occurs at C-1 (27). However, we feel that it is unreasonable to arbitrarily rule out **9** and **10** as species which are possibly present in appreciable amounts in the equilibrium pseudobase mixtures. The presence of the pseudobases in the ring-opened forms, *e.g.*, **11**, also cannot be ruled out by the isolation of the above oxidation products, since the ring-opened and ring-closed forms of each pseudobase will always be in equilibrium.

We have sought spectral evidence by which we might assign the structures of the major pseudobase species which are present in aqueous

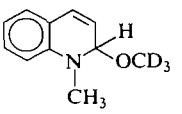
alkaline solutions of the heterocyclic cations included in the present study. It is not possible to obtain p.m.r. spectra of the pseudobases themselves in aqueous alkaline solution. Oils separate from these solutions at p.m.r. spectral concentrations. The main components of these oils are the oxidation products mentioned above, and are presumably formed by reactions similar to those which give rise to 1-methyl-2-quinolone in alkaline solutions of the 1-methylquinolinium cation. We have therefore measured u.v. and p.m.r. spectra for each cation in basic methanol solutions, and these spectral data are given in Table 3. It was hoped to identify the site(s) of methoxide attack from the p.m.r. spectrum of the reaction product, and then to compare the u.v. spectrum of each methoxide adduct with that of the corresponding pseudobase. Unlike the pseudobases, the methyl ethers can neither be easily oxidized to keto derivatives, nor can they undergo ring-opening reactions. Thus, a comparison of the u.v. spectra of corresponding methyl ethers and pseudobases will also be useful in determining whether appreciable amounts of ring-opened species, *e.g.* **11**, are present in equilibrium with the pseudobases.

Table 3 also contains spectral data for the dihydroheterocycles obtained by the reduction of each heterocyclic cation with 1 equiv of lithium aluminum hydride in ether. Reduction of both the 1-methylquinolinium and 2-methylisoquinolium cations with this reagent cannot be forced beyond the 1,2-dihydro stage (28). Use of a limited quantity of reducing agent ensured that the reduction of each of the *N*-methylnaphthyridinium cations occurred only in the much more reactive pyridinium ring. The p.m.r. spectrum of the reduction product of the 1-methylquinoxalinium cation confirms that this reduction cannot be stopped at the dihydro stage but proceeds to give 1-methyl-1,2,3,4-tetrahydroquinoxaline (29).

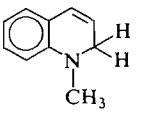
Discussion

1-Methylquinolinium Cation

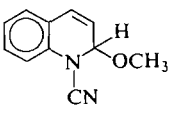
Initially, upon dissolution of 1-methylquinolinium iodide in basic methanol-d_4(3 $M CD_3O^-$), the p.m.r. spectrum indicates a three proton singlet at δ 3.12 (N—CH_3), a five proton multiplet (δ 6.6–7.3), and a multiplet centered at δ 5.70 which integrates for slightly less than two



12



13



14

protons. The integration of this latter multiplet is time dependent, gradually decreasing relative to the other peaks, until eventually it becomes a time-insensitive one proton doublet centered at δ 5.66 ($J = 10$ Hz), with no concurrent change having occurred in the other peaks in the spectrum. We attribute this spectrum to 1,2-dihydro-2-trideuteromethoxy-1-methylquinoline (**12**) which is formed by attack of methoxide ion upon C-2 of the heterocyclic cation. This assignment is in good agreement with the spectrum of 1,2-dihydro-1-methylquinoline (**13**) which has been shown (30, 31) to be the reduction product of the 1-methylquinolinium cation by lithium aluminum hydride: ($CDCl_3$) δ 2.72, N—CH_3 (singlet, 3H); δ 3.99, H-2 (doublet of doublets, 2H, $J_{23} = 4$ and $J_{24} = 1.8$ Hz); 5.50–5.78, H-3 (multiplet, 1H, $J_{23} = 4$ and $J_{34} = 10$ Hz); 6.1–7.2, aromatic protons plus H-4 (multiplet, 5H). The coupling constants $J_{23} = 4$, $J_{24} = 1$, and $J_{34} = 10$ Hz, which are almost substituent independent, are typical of 1,2-dihydroquinolines and are sufficiently distinctive to differentiate the 1,2-dihydroquinolines from the corresponding 1,4-dihydroquinolines (31, 32). Thus, the spectrum of the methoxide adduct may be assigned as: δ 6.6–7.3, aromatic protons plus H-4; 5.66, H-3; 5.7, H-2, which exchanges with solvent deuterium in a base-catalyzed process. The C-3 and -4 protons have similar chemical shifts in **12** and **13**, while H-2 is approximately 1.7 p.p.m. (the solvents are different) further downfield in **12** than in **13** as expected from the substituent effect of the methoxyl group. The spectrum assigned to **12** is also in good agreement with that of 1-cyano-1,2-dihydro-2-methoxyquinoline (**14**) (32): (CCl_4) δ 6.02, H-2; 5.64, H-3; 6.78, H-4 ($J_{34} = 9.8$ Hz).

Further confirmation of the 1,2-dihydroquinoline structure for the methoxide adduct was provided by its u.v. spectrum. An absorption maximum in the vicinity of 340 nm is typical of the spectra of 1,2-dihydroquinolines (30, 33, 34), while 1,4-dihydroquinolines with no chromophoric substituents do not have absorption maxima above 300–310 nm (31, 32,

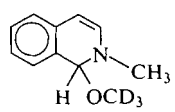
35). The spectrum of the methoxide adduct of the 1-methylquinolinium cation has a maximum at 335 nm, and is thus consistent with the presence of a 1,2-dihydroquinoline system.

Both the u.v. and p.m.r. spectral evidence are consistent with predominant methoxide attack at C-2 in the 1-methylquinolinium cation, and any product arising from C-4 attack can only be present to an extent less than 5%. It is also reasonable to assume, that in aqueous alkaline solutions, hydroxide ion would also preferentially attack this cation at C-2.

2-Methylisoquinolinium Cation

The p.m.r. spectrum of the 2-methylisoquinolinium cation in basic methanol-d_4 is readily assigned to 1,2-dihydro-1-trideuteromethoxy-2-methylisoquinoline (**15**): δ 7.1–7.4, aromatic protons (multiplet, 4H); 6.60, H-3 (doublet, 1H, $J_{34} = 7.5$ Hz); 5.66, H-4 (doublet, 1H, $J_{34} = 7.5$ Hz); 6.10, H-1 (singlet, 1H—but decreases with time due to exchange with solvent D); 3.22, *N*-CH_3 (singlet, 3H). The coupling constant, $J_{34} = 7.5$ Hz, is typical of 1,2-dihydroisoquinolines (32), and the methoxyl substituent effect on a singlet (2.0 p.p.m. relative to 1,2-dihydro-2-methylisoquinoline (Table 3)) is further evidence of methoxide attack at C-1. The u.v. spectra of the methoxide adduct (in methanol) and 1,2-dihydro-2-methylisoquinoline (in chloroform) are also quite similar, having long wavelength maxima at 334 and 328 nm, respectively. Thus, the spectral evidence is in accord with preponderant methoxide attack (and by implication, hydroxide attack) occurring at C-1 in the 2-methylisoquinolinium cation.

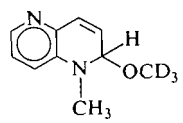


15

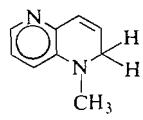
We have discussed the spectral data of these quinoline and isoquinoline derivatives in some detail, because we now wish to use these spectra as reference data for the assignment of structures to the pseudobases formed by hydroxide attack on the *N*-methyl cations of the diazanaphthalenes.

1-Methyl-1,5-naphthyridinium Cation

The u.v. spectrum of an alkaline solution of this cation has an absorption maximum at 342 nm, which is typical of 1,2-dihydroquinoline derivatives. The absorption maxima in the spectra of the methoxide adduct (345 nm) and lithium aluminum hydride reduction product (335 nm) are also indicative of 1,2-dihydroquinoline derivatives. These structural assignments are confirmed by p.m.r. spectral data. Thus, for the methoxide adduct, the protons in the dihydropyridine ring are assigned: δ 5.60, H-2 (doublet, 1H, $J_{23} = 4.5$ Hz); 6.12, H-3 (doublet of doublets, 1H, $J_{23} = 4.5$, $J_{34} = 10$ Hz); 7.03, H-4 (doublet, 1H, $J_{23} = 10$ Hz). These coupling constants are typical of 1,2-dihydroquinoline derivatives, and the methoxide adduct may be confidently assigned the structure **16**.



16



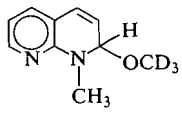
17

The chemical shift of H-2 is very similar to that for the same proton in the corresponding quinoline derivative **12**, while H-3 is further downfield due to the presence of N-5 and no longer overlaps with H-2. While H-4 is also presumably further downfield than in **12**, it is now clearly distinguishable from the aromatic protons H-6, -7, and -8 which have suffered even larger shifts as a result of the presence of N-5. The p.m.r. spectrum (Table 3) of the lithium aluminum hydride reduction product can likewise be confidently assigned to **17** by comparison with the spectrum of 1,2-dihydro-1-methylquinoline.

The similarity of the u.v. spectrum of the pseudobase to the spectra of **16** and **17**, which are definitely established as 1,2-dihydro-1,5-naphthyridines by their p.m.r. spectra, indicates that the predominant pseudobase species of the 1,5-naphthyridinium cation is **5**.

1-Methyl-1,8-naphthyridinium Cation

The u.v. spectra of this cation in aqueous alkali (p*H* 14) and basic methanol are very similar. Both spectra have absorption maxima at 330 nm and are completely reversible to the spectrum of the cation upon acidification. The p.m.r. spectrum of the methoxide adduct in basic methanol-d_4 may be assigned to **18** as follows: δ 3.27, *N*-CH_3 (s, 3H); 5.75–5.95, H-2 and -3 (m, 2H); 6.65–7.05, H-4 and -6 (m, 2H); 7.50, H-5 (doublet of doublets, 1H, $J_{56} = 7$,



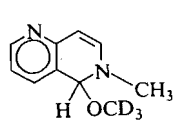
18

$J_{57} = 2$ Hz); 8.10, H-7 (doublet of doublets, 1H, $J_{67} = 5.5$, $J_{57} = 2$ Hz). The multiplet centered at δ 5.85 collapses on standing to a doublet ($J_{34} =$ 10 Hz) as a result of the exchange of H-2 for solvent deuterium (*cf.* 1-methylquinolinium cation). A similar spectral assignment (Table 3) is also consistent with the lithium aluminum hydride reduction product of the cation being 1,2-dihydro-1-methyl-1,8-naphthyridine.

Thus, the similarity of the u.v. spectra of the pseudobase from the 1-methyl-1,8-naphthyridinium cation and **18** indicate that **8** is the predominant pseudobase species present in aqueous alkaline solutions of this cation.

6-Methyl-1,6-naphthyridinium Cation

Aqueous alkaline solutions of this cation have an absorption maximum at 340 nm. In basic methanol this maximum is at 337 nm, while the spectrum of the lithium aluminum hydride reduction product has a maximum at 333 nm. These latter two maxima are at slightly longer wavelengths than in the corresponding isoquinoline derivatives, but the identity of these species as 1,2-dihydroisoquinoline derivatives is readily confirmed from their p.m.r. spectra (Table 3). In each case, the pair of doublets, with coupling constant 7.5 Hz for protons corresponding to H-3 and -4 of a 1,2-dihydroisoquinoline system is clearly visible. In the 1,6-naphthyridine series these protons (H-7 and -8) appear at δ 6.86 and 5.61 for the methoxide adduct and 6.31 and 5.22 for the reduction product, which are in close agreement with the chemical shifts for H-3 and -4 in the corresponding isoquinoline derivatives. In addition, the H-1 singlet of 1,2-dihydro-2-methylisoquinoline is 2.0 p.p.m. further upfield than in its 1-methoxy derivative, and a similar difference (1.7 p.p.m.) is observed for H-5 of the corresponding 5,6-dihydro-1,6-naphthyridine derivatives. Hence the structure of the methoxide adduct of the 6-methyl-1,6-naphthyridinium cation can confidently be assigned as **19**, and the similarity of the u.v. spectra of **19** and the pseudobase indicate that the predominant pseudobase species present in aqueous alkaline solutions of this cation is **6**.



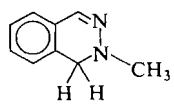
19

7-Methyl-1,7-naphthyridinium Cation

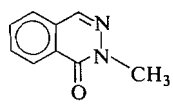
The p.m.r. spectra of this cation in basic methanol-d_4 and of its lithium aluminum hydride reduction product are readily assigned to 1,2-dihydroisoquinoline derivatives, *i.e.*, 7,8-dihydro-1,7-naphthyridines (Table 3). The u.v. spectra of the pseudobase (λ_{max} 320 nm) and the methoxide adduct (λ_{max} 316 nm) are very similar, and consequently the predominant pseudobase species present in alkaline solutions of this cation can be assigned structure **7** and so results from hydroxide attack at C-8.

2-Methylphthalazinium Cation

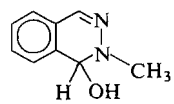
The reaction of this cation in aqueous alkaline solutions was first investigated by Gabriel and Muller in 1895 (36), and more recently by Smith and Otremba in 1962 (37). In both studies, the only products isolated were 1,2-dihydro-2-methylphthalazine (**20**) and 2-methyl-1-phthalazinone (**21**). It has been assumed (38) that these products arise from the disproportionation of an initially formed pseudobase **22**, although this species has not previously been confirmed as a component of the reaction mixture.



20



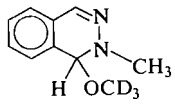
21



22

The p*H* dependence of the u.v. spectrum of this cation indicates the occurrence of two equilibria in alkaline solutions for which we have measured pK_a values of 11.04 and 13.0. We have confirmed that only **20** and **21** may be extracted from concentrated solutions of this cation in the region p*H* 10–13. However, chloroform extracts from very alkaline solutions (5 *N* KOH) contain a product with p.m.r. spectrum ($CDCl_3$): δ 3.38 (s, 3H), 5.75 (s, 1H), 7.23–7.57 (m, 5H). This spectrum is very similar to that of solutions of this cation in basic methanol-d_4 and which we assign to the methoxide adduct **23** as follows;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



23

δ 3.40, N-CH_3 (s, 3H); 5.71, H-1 (s, 1H); 7.30–7.60, aromatic protons plus H-4 (m, 5H). Thus, the species extracted from strong alkali may be assigned the pseudobase structure **22**, and this assignment of structures **22** and **23** is also consistent with the spectrum of 1,2-dihydro-2-methylphthalazine (Table 3). The u.v. spectra of aqueous solutions of pH 12 and 15 are very similar (λ_{max} 302 and 312 nm, respectively), and so the observed equilibria may be assigned to pseudobase formation ($pK_{ROH} = 11.04$) and ionization of the pseudobase ($pK_{RO^-} = 13.0$).

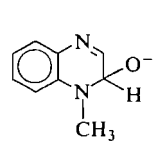
Anion formation seems to stabilize the pseudobase with respect to disproportionation to **20** and **21**. The pseudobase also does not tend to disproportionate at an appreciable rate in chloroform solution.

1-Methylquinoxalinium Cation

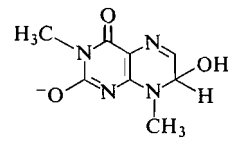
The u.v. spectra of dilute aqueous alkaline solutions (pH 10.5) and basic methanolic solutions of this cation are very similar. Each spectrum has two absorption maxima; 301 and 340 nm (pH 10.5); 304 and 344 nm (CH_3O^-/CH_3OH). In more alkaline aqueous solutions (pH 14.5), the only maximum is at 347 nm. Two ionization constants (8.62 and 12.62) were obtained from the pH dependence of the u.v. spectrum.

Although aqueous solutions of the 1-methylquinoxalinium ion in dilute alkali (pH 9–12) are turbid at p.m.r. spectral concentrations, solution is complete in stronger alkali. The p.m.r. spectrum in 3 M NaOD in D_2O may be assigned to the anion **24** of the pseudobase from hydroxide attack at C-2: δ 3.05, N-CH_3 (s, 3H); 5.15, H-2 (d, 1H, $J = 3$ Hz); 6.7–7.3, aromatic protons (m, 4H); 7.67, H-3 (d, 1H, $J = 3$ Hz). This assignment of H-2 and -3 agrees well with the chemical shifts for the pyrazine ring protons in **25** (39): δ 5.20, 7.05 (doublets, $J = 3$ Hz).

The p.m.r. spectrum of the 1-methylquinoxalinium cation in basic methanol-d_4 is more complex than would be expected for 1,2-dihydro-2-trideuteromethoxy-1-methylquinoxaline: δ 3.17, 3.23 (singlets); 4.62 (s); 5.37 (d, $J =$ 3 Hz); 6.67 (s); 6.9–7.5 (m); 7.66 (d, $J = 3$ Hz).

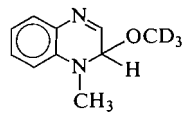


24

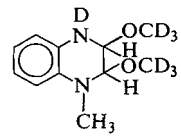


25

The doublets at δ 5.37 and 7.66 are of equal intensity and integrate for one quarter of the area of the multiplet, 6.9–7.5. The singlet at δ 6.67 is twice as intense as the singlet at 4.62. Integration of the peaks at δ 3.17 and 3.23 is difficult since they tend to overlap with one another and also with the signals from a small amount of solvent protiated methyl groups. Assignment of δ 7.66 to H-3, 5.37 to H-2, and 6.9–7.5 to the aromatic protons of **26**, would be consistent with the assignment made above for **24**. We suggest that the remaining peaks could then reasonably be assigned to the tetrahydroquinoxaline derivative (**27**), which would be formed by addition of a molecule of methanol across the C_3—N_4 bond of **26**. This assignment

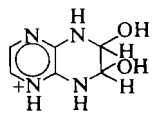


26



27

requires the chemical shifts of all the aromatic protons in **27** to be the same (δ 6.67), and also the chemical shifts of H-2 and -3 to be the same (δ 4.62) within the resolution obtained. As supporting evidence that the chemical shifts of the four aromatic protons in **27** should be similar, we note that the aromatic protons of o-phenylenediamine (in $CDCl_3$) give rise to only one signal (δ 6.68) and the signals from the aromatic protons of 1-methyl-1,2,3,4-tetrahydroquinoxaline occur as a very narrow multiplet centered at δ 6.60 ($CDCl_3$). The chemical shift (δ 4.62) for H-2 and -3 in **27** agrees well with the reported chemical shifts for the corresponding protons in **28** (δ 4.63) and **29** (δ 4.72, 4.83) (40).



28

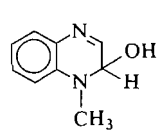
The tendency of quinoxaline derivatives to add two molecules of nucleophilic reagents to form tetrahydro derivatives is well known. Thus, quinoxaline itself readily adds two molecules of hydrogen cyanide or bisulfite ion across the 1,2- and 3,4- C=N bonds (41); 2,4-dihydroxypteridines add two equivalents of bisulfite ion in the pyrazine ring (42); and the cations of 1,4,5-triazanaphthalene, 1,4,5,8-tetra-azanaphthalene, and pteridine form covalent dihydrates by the addition of two molecules of water to the pyrazine ring (40, 43). We believe that this current observation of the addition of methoxide ion and methanol to the *N*-methylquinoxalinium cation represents the only case in which an appreciable amount of a dihydroquinoxaline monoadduct has been shown to be in equilibrium with the tetrahydroquinoxaline diadduct. The relative proportions of **26** and **27** in solution are independent of methoxide concentration from 0.01–3 *M*. From the integral ratios of (*i*) the aromatic proton peaks, and (*ii*) the H-2 proton peaks at several different base concentrations, we have estimated that the equilibrium mixture consists of 60% **26** and 40% **27**.

These observations on the reaction of the 1-methylquinoxalinium cation in basic methanol, raise the possibility that the pseudobase formed in aqueous alkali by hydroxide addition at C-2 may be sufficiently susceptible to addition of a molecule of water across the C_3—N_4 double bond, that appreciable amounts of the tetrahydroquinoxaline (**30**) may be present in dilute aqueous alkali (p*H* 9–12). As noted above, the quinoxaline pseudobase is insufficiently soluble in dilute aqueous alkali to allow a p.m.r. spectral investigation. However, the similarity of the u.v. spectra of the *N*-methylquinoxalinium cation in dilute aqueous alkali (λ_{max} 301, 340 nm) and basic methanol (λ_{max} 304, 344 nm) strongly suggests that **30** is present. Maxima in the vicinity of 300 nm are not typical of the spectra of 1,2-dihydroquinoline derivatives (30, 33, 34), but are typical of 1,2,3,4-tetrahydroquinoline derivatives (*e.g.*, 1,2,3,4-tetrahydroquinoline in ethanol, 299 nm (34); 1-methyl-1,2,3,4-tetrahydroquinoxaline in $CHCl_3$, 313 nm (Table 3)). We feel that the maxima at 304 and 344 nm in basic methanol solution should be assigned separately to **27** and **26**, respectively. This assignment then suggests that in dilute aqueous alkali the pseudobase **31** (λ_{max} 340 nm) is in equilibrium with a considerable amount of its covalent hydrate **30** (λ_{max} 301 nm). This conclusion is further supported by the fact that in strongly alkaline solutions, where we have shown by p.m.r. spectroscopy that only the anion **24** is present in any appreciable amount, the u.v. spectrum (Fig. 2) has only the absorption maximum (347 nm) typical of a 1,2-dihydroquinoline derivative. Thus the anion **24** is less susceptible to covalent hydration of the C_3—N_4 bond than the corresponding neutral molecule **31**.

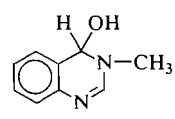
30



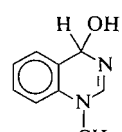
31

1- and 3-Methylquinazolinium Cations

The 3-methylquinazolinium cation is known to undergo hydroxide attack at C-4 to give the pseudobase **32** (44). More recently, we have shown that the 1-methylquinazolinium cation also undergoes hydroxide attack at C-4 to give the pseudobase **33** (23). The formation of both these pseudobases is complicated by their facile protonation to give the resonance-stabilized cations **34** and **35**. We have measured a pK_a value for protonation[3] of **32** of 7.77 ± 0.06 at 25° (Albert *et al.* (44) give 7.64 at 20°), and the free 1- and 3-methylquinazolinium ions are never present in aqueous solution to any appreciable extent. It is therefore not possible to measure pK_{ROH} values for these ions by any direct method, although they must each be less than 7.



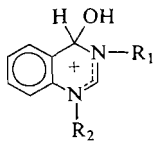
32



33

It would be useful to have estimates of pK_{ROH} values for these ions for comparison with the other diazanaphthalene cations in the present study, and to this end we have made use of the observation that the electronic effect of a pyridine-type ring nitrogen atom is very similar

[3]The pK_a for **33** is not known since it has never been obtained free of **32**. However, the basicities of **32** and **33** should be quite similar.

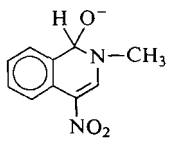


34 $R_1 = H$; $R_2 = CH_3$
35 $R_1 = CH_3$; $R_2 = H$

to that of a nitro group in the corresponding position of a homocyclic ring (45). Thus, we have measured the pK_{ROH} values for the 1-methyl-3-nitroquinolinium cation (6.74 ± 0.06) and for the 2-methyl-4-nitroisoquinolinium cation (5.03 ± 0.04) as models for the 1-methyl- and 3-methylquinazolinium cations, respectively.

The 1-methyl-3-nitroquinolinium cation has previously been shown (46) to undergo hydroxide attack at C-4 and so is directly comparable with the 1-methylquinazolinium cation, although the value of 6.94 should only be considered as an upper limit for pK_{ROH} for the latter species, since it is not possible to allow for steric effects from the presence of the nitro group ortho to C-4.

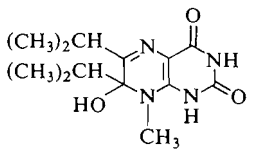
The 2-methyl-4-nitroisoquinolinium cation has not been previously studied, however, it is to be expected that it will be most susceptible to nucleophilic attack at C-1 (comparable to C-4 in the 3-methylquinazolinium cation) as are other isoquinolinium derivatives. The p.m.r. spectrum in strong alkali (3 *N* NaOD/D_2O) is consistent with the structure **36** for the pseudobase anion: δ 3.48, *N*-Me (s, 3H); 5.74, H-1 (s, 1H); 8.52, H-3 (s, 1H); 7.1–7.3, 8.33, aromatic protons (m, 4H). Although attack at C-3 cannot be definitely ruled out, we feel that it is unlikely that the nitro group will have sufficient influence to produce this abnormal mode of attack. This is substantiated by the fact that nucleophilic attack at C-2 between the nitro group and ring-nitrogen atom in the 1-methyl-3-nitroquinolinium ion is less important than at C-4 (46). Hence, the 2-methyl-4-nitroisoquinolinium cation should be an excellent model for the 3-methylquinazolinium cation, and since the nitro group is well removed from the site of hydroxide attack at C-1, the pK_{ROH} value for the 3-methylquinazolinium cation is probably quite close to 5.0.



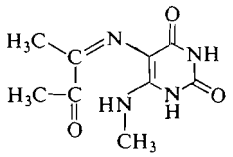
36

General Comparison of N-Methyl Diazanaphthalene Cations

Our spectral data establish that in all cases (except for the 1-methylquinoxalinium cation) there is only one major pseudobase species present in aqueous alkaline solutions of the cations that we have examined. Such studies will not, however, detect the presence of small amounts of other species (*e.g.*, from attack at C-4 in quinolinium ions or at C-3 in isoquinolinium ions). Much early work on the pseudobases was related to the possibility of their ring-opening to give amino-aldehydes (3). We have found no evidence for any significant amount of ring-opening of the pseudobases formed from the *N*-methyl cations of the diazanaphthalenes. In all cases, there is a close correspondence between the u.v. spectra of the pseudobases and the corresponding methoxy derivatives which cannot undergo ring-opening. The presence of any appreciable amount of the ring-opened species should be readily apparent since these species have quite distinctive u.v. spectra as a result of the increased conjugation in these molecules compared to the corresponding pseudobases; *e.g.*, **37**, λ_{max} 316 nm; **38**, λ_{max} 394 nm (39).



37



38

All of our data are consistent with the activation of heterocyclic cations to nucleophilic attack by the presence of a strongly electron-withdrawing azine nitrogen atom. The data of Table 2 indicate that there is little difference in the susceptibilities of the various *N*-methylnaphthyridinium cations to pseudobase formation. Thus the pK_{ROH} values for all the *N*-methyl-1,*x*-naphthyridinium cations lie in the range 12.4–13.1.

The presence of a further ring-nitrogen atom in the pyridine ring of a quinolinium or isoquinolinium cation usually causes a drastic increase in susceptibility to pseudobase formation

(*e.g.*, 1-methylquinoxalinium and 1- and 3-methylquinazolinium cations) although this effect may be attenuated to some extent (as in phthalazinium derivatives) if the electronic effect of the second nitrogen atom must be transmitted predominantly through the quaternary nitrogen to the site of nucleophilic attack.

The experimental pK_{ROH} value for the 1-methylquinoxalinium cation is not strictly comparable to the other values in Table 2 if a considerable amount of **30** is present as we have suggested. In this case, the measured value, pK^{app}_{ROH}, is defined by eq. 5, and the true pK_{ROH} for

$$[5] \qquad K^{app}_{ROH} = \frac{[H^+]([QOH] + [\mathbf{30}])}{[Q^+]} = K_{ROH}\left[1 + \frac{[30]}{[QOH]}\right]$$

the 1-methylquinoxalinium cation will be less than pK^{app}_{ROH} (8.62) by an amount equal to the value of log (1 + [**30**]/[QOH]). By assuming that the ratio of tetrahydro- to dihydroquinoxaline species in water will be similar to that found in methanol (2:3), we estimate a value of $pK_{ROH} \approx 8.4$ for the *N*-methylquinoxalinium cation. Similarly, for alkoxide ion formation from the pseudobase **31**, the measured value, $pK^{app}_{RO^-}$, is also a "mixed" constant, and is defined by eq. 6.

$$[6] \qquad K^{app}_{RO^-} = \frac{[H^+][QO^-]}{[QOH] + [\mathbf{30}]} = \frac{K_{RO^-}}{1 + \frac{[30]}{[QOH]}}$$

The presence of strongly electron-withdrawing substituents close to the hydroxyl group is necessary in order to increase the acidity of the pseudobases sufficiently to give pK_{RO^-} values less than 14 (Table 2). Anion formation by pseudobases of the *N*-methylnaphthyridinium cations is not appreciable in solutions of p*H* less than 14, which is in agreement with the data of Cooksey and Johnson (9) for anion formation by the pseudobases of the 1-methyl-5-nitroquinolinium cation ($pK_{RO^-} \sim 15$) and the 1-methyl-6,8-dinitroquinolinium cation ($pK_{RO^-} = 14.3$).

Experimental

Materials

Quinoline, isoquinoline, acridine, phthalazine, quinazoline, and quinoxaline were obtained commercially. 1,5-Naphthyridine (25), 1,6-naphthyridine (47), 1,8-naphthyridine (48), and 3-nitroquinoline (49) were synthesized as described in the literature. The synthesis of 4-nitroisoquinoline will be described separately.[4] 1,7-Naphthyridine was synthesized by a modification of the method of Baumgarten and Cook (50) for substituted 1,7-naphthyridines. 3-Nitro-4-picoline (4 gm) was converted to *N*-(3-amino-4-picolylidene)-*p*-toluidine (51). This crude product was dissolved in absolute ethanol (10 ml) and cooled in an ice bath. Aqueous potassium hydroxide (1 *N*; 1 ml) was added, and then cold acetaldehyde (2 ml) was added dropwise to the stirred iced solution. After refluxing for 2 h, the cooled solution was diluted with water (50 ml) and extracted with chloroform (3 × 50 ml). These combined extracts were extracted with hydrochloric acid (15%; 4 × 25 ml). These acid extracts were basified (KOH) and then re-extracted with chloroform. After drying over anhydrous magnesium sulfate and evaporation of the chloroform, 1,7-naphthyridine (147 mgm) was obtained by chromatographing the residue on a silica gel column with ethanol as eluent.

Methylations

The heterocyclic base was treated with excess methyl iodide, either neat or during reflux in a suitable solvent (acetone or ethanol). After removal of the solvent and excess methyl iodide, the solid residues were recrystallized to constant melting points which were in agreement with literature values. The only quaternary heterocyclic iodide that has not been previously reported is 2-methyl-4-nitroisoquinolinium iodide, m.p. 208–210°.

Anal. Calcd. for $C_{10}H_9IN_2O_2$: C 38.0; H 2.85; N 8.86. Found: C 38.0; H 3.07; N 8.68.

Reductions

The quaternary salt (100 mg) was suspended in anhydrous ether (30 ml) and lithium aluminum hydride (50 mg) was slowly added with stirring. After 5 min, the reaction mixture was poured into ice-water (50 ml). The aqueous layer was extracted with ether, and after drying over magnesium sulfate, the ether was removed on the rotary evaporator. The p.m.r. spectra of the oily products were recorded immediately, since these dihydronaphthyridines tend to decompose on standing in a similar manner to 1,2-dihydro-1-methylquinoline (30).

Methods

The p.m.r. spectra were obtained on a Varian T-60 spectrometer, using tetramethylsilane as an internal standard in $CDCl_3$ and CD_3OD solutions, and sodium 2,2-dimethyl-2-silapentane-5-sulfonate in D_2O. The u.v. spectra were recorded on a Unicam SP-800 spectrophotometer and absorption maxima were checked manually on a Beckman DU-2 instrument.

Spectrophotometric determinations of pK_{ROH} and pK_{RO^-} values were made as described by Albert and Serjeant (52) on a Beckman DU-2 spectrophotometer with cell compartment thermostatted at 25 ± 0.1°. In several cases, the optical density of the pure pseudobase species was not directly obtainable owing to subsequent reactions at high p*H* values, and so this value was obtained from the ordinate intercept of a plot of D *vs.* $a_{H^+}(D - D_c)$ where D_c is the optical density

[4] J. W. Bunting and W. G. Meathrel, Organic Preparations and Procedures International, submitted for publication.

of the pure heterocyclic cation and D is the optical density of a solution of the cation at hydrogen ion activity a_{H^+}. Specific experimental details for each compound are included in Table 2. Errors quoted are the greatest deviation from the average. Buffer solutions were those described by Perrin (53) (pH 2–10.6) and Bates (54) (pH 11–13). Solutions of pH greater than 13 were made up by dilution of standard potassium hydroxide solutions (55). All pH values below 13 were checked on a Corning Model 12 Research pH Meter. The potentiometric titration of 2-methyl-4-nitroisoquinolinium iodide was also performed according to Albert and Serjeant (56) using standard 0.05 M potassium hydroxide solution as titrant.

This research was supported by a grant from the National Research Council of Canada and a Province of Ontario Graduate Fellowship (W.G.M.).

Substituent Effects in Dye-sensitized Photooxidation Reactions of Furans[1]

R. H. YOUNG, R. L. MARTIN, N. CHINH, C. MALLON, AND R. H. KAYSER

Department of Chemistry, Georgetown University, Washington, D.C. 20007

Received March 13, 1970[2]

The problems encountered in the normal method used to determine β values (rate of decay of singlet oxygen divided by the rate of its reaction with an organic compound) are discussed. The use of dilute solutions of organic acceptors for our measurements was found to give more reproducible values and simplified kinetics. These β values were used to obtain relative rate constants for a variety of substituted furans. Hammett plots were made to quantitate the substituent effects in order to explore the nature of singlet oxygen in the dye-sensitized photooxidation reactions of these furans. The calculated ρ values were compared with other photooxidation and Diels–Alder reactions. Hammett ρ values in a series of solvents were also calculated for the reaction of singlet oxygen with 2-arylfurans and increasing ρ values were correlated with decreasing solvent polarity.

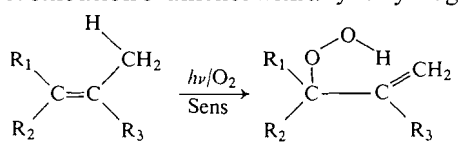
On discute des problèmes rencontrés dans la méthode normale utilisée pour déterminer les valeurs de β (vitesse de désintégration de l'oxygène singulet divisée par la vitesse de sa réaction avec un composé organique). On trouve que l'utilisation de solutions diluées d'accepteurs organiques pour nos mesures donne des valeurs plus reproductibles et une cinétique simplifiée. On utilise les valeurs de β pour obtenir les constantes de vitesse relatives pour une variété de furannes substitués. On trace les graphes de Hammett pour concrétiser les effets de substituants afin d'explorer la nature de l'oxygène singulet dans les réactions de photooxydation sensibilisées au colorant de ces furannes. Les valeurs calculées de ρ sont comparées avec d'autres réactions d'oxydation et de Diels–Alder. On calcule aussi les valeurs de ρ de Hammett pour une série de solvants dans le cas de la réaction de l'oxygène singulet avec les 2-arylfurannes et on fait la corrélation entre des valeurs de ρ croissantes avec la polarité décroissante du solvant.

Canadian Journal of Chemistry, **50**, 932 (1972)

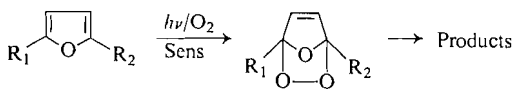
Introduction

There has been a recent revival of interest in the photooxidation of organic compounds. A number of recent reviews on photooxidation reactions aptly illustrate the large amount of recent work and current interest in this area (1). The postulated reactive intermediate in such photooxidations, singlet oxygen ($^1\Delta_g$), has been described as an electrophilic, discriminating species (2) which is "Diels–Alder-like" in its reactions (3). These reactions have also been described as being concerted in nature (1*b*, 4).

The involvement of singlet oxygen in type II dye-sensitized photooxidation reactions is well established (3, 5, 6). There is a variety of different reactions that would fall into this class of photooxidation reactions (1*b*). These include the photooxidation of alkenes with allylic hydrogens:



and the addition of singlet oxygen in a Diels–Alder manner to conjugated dienes:



In some cases the initial photooxidation product is unstable and subsequent products are isolated.

Foote has studied the substituent effect for the photooxidation of substituted 2-aryl-3-methyl-2-butenes and obtained a Hammett ρ value of -0.93 (in methanol) when using σ constants (1*a*, 7). This low ρ value was said to indicate little polar character in the transition state of the reaction. However, even with this small substituent effect one might have expected the product ratio to vary with the substituent. In addition to a concerted mechanism, the substituent effect could be explained either by the formation of a partial charge-transfer complex as an initial

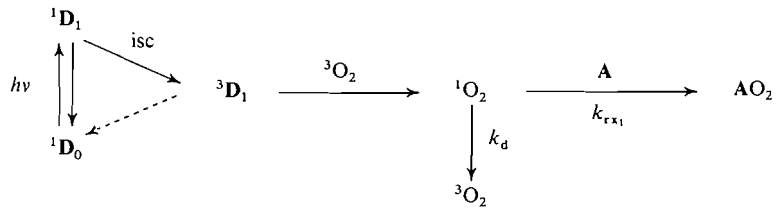


SCHEME 1

intermediate, or by the formation of a reactive intermediate as suggested by Kearns for such reactions (8). Substituent effects on subsequent reactions which would affect product ratios would be difficult to predict.

We have carried out a similar study of substituent effects for the photooxidation reaction of a series of substituted furans in order to compare these reactions with the results obtained by Foote and to typical Diels–Alder reactions.

Method

The most widely accepted mechanism (1) for photooxidation reactions is outlined in Scheme 1, where **A** is the organic acceptor; **D** is the sensitizer; isc is intersystem crossing; k_{rx_1} is the rate constant for the reaction; and k_d is the rate constant for the decay of singlet oxygen to ground state oxygen.

The velocity for the disappearance of A would then be given by:

$$-\frac{d[\mathbf{A}]}{dt} = K\frac{k_{rx_1}[\mathbf{A}]}{k_{rx_1}[\mathbf{A}] + k_d} = K\frac{[\mathbf{A}]}{[\mathbf{A}] + \beta}$$

where K is the rate of formation of singlet oxygen and $\beta = k_d/k_{rx_1}$.

Usually this β value is determined by plotting $1/\Phi_{-A}$ or $1/(-d[\mathbf{A}]/dt)$ *vs.* $1/[\mathbf{A}]$ when the values of β and [**A**] are comparable. However, the errors in this method are estimated to vary from $\pm 30\%$ up to $\pm 400\%$ (9). Competitive reactions used to determine relative β values were found to be more satisfactory and usually are acceptable when following product appearance (9). This latter method suffers from the limitations of g.l.p.c., the method most commonly used for analysis of these competitive reactions.

From the above equation it can be seen that at higher concentrations of **A** errors in the measurement of the velocity of the photooxidation reaction become magnified in the calculation of the β value for a particular reaction. We found some initial difficulties when using the standard method (a plot of $1/d[\mathbf{A}]/dt$) *vs.* $1/[\mathbf{A}]$) for the determination of β values. The errors in this method were such that small differences in the β values for some acceptors (2-arylfurans) could not be determined with any accuracy. It is only at low concentrations of acceptor ($[\mathbf{A}] \ll \beta$) that the maximum difference in the velocities of these reactions will be realized. At these lower concentrations of acceptors not only does one get maximum differences in velocity but the kinetics are simplified to pseudo first order. Then as the substituents of the furan are changed (all reaction conditions remaining constant) the relative β values (k_{rx_1} (rel.) $\equiv 1/\beta$ (rel.) for these reactions can be easily calculated from the slopes of first order plots. This method should enable even

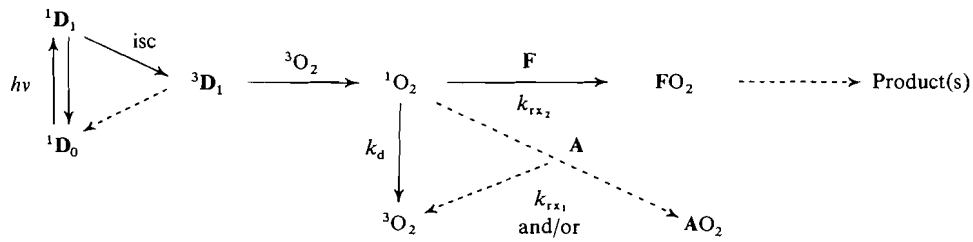
$$-\frac{d\mathbf{A}}{dt} = K\frac{[\mathbf{A}]}{\beta}$$

$$\beta = \frac{k_d}{k_{rx_1}}$$

small differences in the rate constant (k_{rx_1}) to be meaningful. The method was used to obtain relative β values for a series of furans, principally the 2-arylfurans and is referred to as method A in this paper. Absolute β values were determined by relating these relative β values to that of 2,5-diphenylfuran which was determined by our alternate method (method B). Some preliminary results using method A for the 2-arylfurans were reported earlier (10).

For some furans method A was not applicable as it required the *change* in concentration of the furan acceptor to be followed at low concentrations (concentrations lower than the β value are necessary). For this and other reasons we have developed an alternative method (method B) for the direct determination of β values for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



SCHEME 2

photooxidation reactions. This method is given in detail elsewhere (11).

Briefly the reaction scheme involved can be illustrated as Scheme 2, where **D** is a dye-sensitizer (Rose Bengal or methylene blue); **F** is a very reactive species (such as 1,3-diphenylisobenzofuran); and **A** is any compound which can quench the reaction between singlet oxygen and compound **F** either by reaction with the singlet oxygen (which occurs for all compounds in this paper) or by enhancing the intersystem crossing of singlet oxygen to ground state oxygen (unlikely to be important for the furans (12)). The technique involves working at very low concentrations of **F** and applying a Stern–Volmer quenching plot, the slope of which will be equivalent to k_{rx_1}/k_d or $1/\beta$. As shown elsewhere, this method gives quite acceptable results as compared to literature values (11).

These methods were applied to the determination of the β values for a large group of substituted furans and the results are recorded in Table 1. The versatility of these two methods is exemplified by their application to the reactions of singlet oxygen with a wide variety of furans.

Results and Discussion

The addition of singlet oxygen has been suggested to be mechanistically related to the Diels–Alder reaction (3). Little work has been done to confirm this suggestion. For this reason we have looked at some substituent and solvent effects on the dye-sensitized photooxidation reaction of a series of furans as examples of dienes. If singlet oxygen is a dienophile it is of interest to compare its reactivity to that of other dienophiles.

Hammett ρ plots were made for the reactions between singlet oxygen and a number of different substituted furans (eqs. 1–3).

The negative slope for the Hammett plots in all cases illustrates the electrophilic character of singlet oxygen. The low values obtained indicate only a small increase in polarity in the transition state of the reaction.

The ρ value for the reaction between singlet oxygen and the furans with substituents directly attached to the furan ring (including the phenyl-substituted furans) was calculated assuming that the σ values for the 2- and 3-substituents were equivalent to σ para and σ meta, respectively. There is a precedent for this assumption for

[1]  (methanol) $\rho = -2.48 \pm 0.21$

[2]  (methanol) $\rho = -0.836 \pm 0.085$[3]

[3]  (methanol) $\rho = -0.699 \pm 0.051$

[3]This value differs only slightly from that previously reported (10). This is due to recently repeating this experiment using an improved, more automated technique.

*Values determined by method B are for quenching of singlet oxygen, presumably by reaction with singlet oxygen.
†From ref. 11.

furans with substituents at the 2 and 3 positions of the furan molecule (21). However, our application deviates in that not only is there a para relationship between the substituent at the 2 position of the furan relative to the reactive site at the 5 position (assuming that —Ö— ≡ —C=C—) (21) but the reaction also involves bond formation at the site of the substituent. This is based on the assumption that there is a concerted addition of singlet oxygen to furan. (In a two-step addition reaction with a reaction at the 5 position, the rate determining step would involve a reasonable para type substituent interaction only.) It is possible that the inductive and resonance effects of the substituent at the 2 position on both the 2 and 5 positions would be important and linearly related. In addition, as the attacking dienophile (singlet oxygen) is small and most of the substituents are about the same size, variations in steric interactions should not be of major importance. For these reasons the assumption that σ para will represent the relative effect of the substituents on the electronic demands of the dienophile is probably a good one.

The three substituted furans involve a meta relation with C-5 and an ortho relation to C-2. For the attack of a dienophile on furan both σ meta and σ ortho should be considered for the 3-substituents. In our case only the 3-phenyl and the 3,4-diphenylfurans present this problem. The rate constants for these compounds correlate well with the other furans with the assumption that σ meta approximates the total inductive and resonance effects ($\sigma_p = -0.01$ and $\sigma_m = 0.06$). Again steric effects do not appear to be significant for these compounds.

Solvent Effects

In addition we have expanded this work to investigate the effect of other solvents on the photooxidation reaction of these furans. Previously solvent effects on the rate of reaction have been difficult to rationalize because the solvent can affect both the rate constant of reaction (k_{rx}) and the rate constant of decay (k_d) and hence the ratio of these two (β value) is ineffective for the study of solvent effects.

However, in the investigation of the changes in the calculated Hammett ρ value for reactions in various solvents we are looking at the effect of the solvent on relative rate constants of reaction only, and not the solvent effect on the rate constant of decay. Often there is a correlation between Hammett ρ values and the rate constant for reactions. The results from reactions in a series of solvents are given in Table 2.

[4]  $\rho = -3.12$ (*vs.* σ^+) ref. 22

[5]  (chloroform) $\rho = -4.6$ ref. 23, our calculations *vs.* σ^+

[6]  (ethanol) $\rho = -2.27$ ref. 24

TABLE 2. Hammett ρ values for the photooxidation of 2-arylfurans in different solvents

Solvent	ρ	$1/\varepsilon$	$1/\beta_{rel}$*
Dioxane	−2.13	0.453	—
n-Butanol	−1.03	0.0585	1.00
Methanol	−0.84	0.0308	2.02
Glycol	−0.45	0.0264	5.64
Water	−0.15	0.0127	3.27

*Determined for 2-(*p*-methoxyphenyl)furan.

It can be seen from Table 2 that there is a reasonable correlation between the Hammett ρ values and the polarity of the solvent. This is additional evidence for a *slightly* polar species being involved in the reaction of these furans with singlet oxygen.

In addition the effect of solvent on β values (for the 2-(*p*-methoxyphenyl)-furans) is largely due to its influence on the rate constant of reaction (k_{rx}). However, the β value in water is smaller than that for the less polar glycol solvent in contrast to expectations based on the Hammett ρ values. This may well indicate that the solvent is affecting the lifetime of singlet oxygen (k_d). This was later confirmed and is reported elsewhere (11). At the time of this observation this was the first evidence as to what role the solvent plays in photooxidation reactions (10).

The calculated Hammett ρ values for the photooxidation reactions of the furans can be related to a number of other reactions and interactions. Some of these are given in eqs. 4–9.

The Hammett ρ values calculated for the reaction between singlet oxygen and the directly substituted furans (1) ($\rho = -2.48$) can be compared to that calculated for reaction (4) ($\rho = -3.12$). Although the actual diene and reaction conditions vary it does appear that there may be a similarity in electrophylic character of the dienophiles. In comparison with the photooxidation of anthracene, (5), it is not surprising to see that this reaction yields a calculated Hammett ρ value ($\rho = -4.6$) which is higher than that obtained for the furans for two reasons:

(*1*) The less polar solvent should increase the calculated ρ value similar to the results reported in Table 2.

(*2*) The reactivity of anthracene with singlet oxygen is lower than furan with singlet oxygen and hence more susceptible to substituent effects.

The high ρ value does suggest the possibility for an unsymmetrical dipolar transition state during the cycloaddition reaction of singlet oxygen with anthracene.

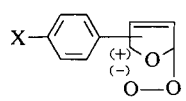
In addition correlations between the photooxidation of the aryl-substituted furans and various other reactions, [6] and [7], can be made. It appears that singlet oxygen is less susceptible to the electronic effects of the substituents than is dimethyl acetylenedicarboxylate, but more susceptible than maleic anhydride.

The low Hammett ρ values calculated from the reactions of singlet oxygen with the 2- and 3-arylfurans (-0.836 and -0.699) compare favorably with that calculated by Foote from his photooxidation reactions of the 2-aryl-3-methyl-2-butenes in methanol (-0.93) (7). This illustrates the similarity of substituent effects on both classes of photooxidation reactions.

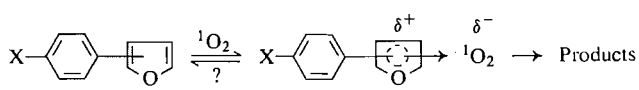
It is reasonable to expect a higher ρ value ($\rho = -2.46$) to be calculated for the reaction of singlet oxygen with the directly substituted furans than for the 2-aryl- and 3-arylfurans. The substituents in the latter cases are further removed from the reaction sites. In all cases the low Hammett ρ values indicate that the formation of a completely dipolar intermediate, **1**, is



1

unlikely in methanol. In addition to the formation of a slightly polar transition state in a concerted cycloaddition mechanism, the negative slope of the Hammett plot could be due to the formation of a partial charge-transfer complex, **2**, with the π electrons as suggested by Koch (27) (Scheme 3).

The possibility that this could be real is enhanced when the Hammett ρ values from the photooxidation reactions are compared with that calculated from the quenching reactions of singlet oxygen by a number of substituted *N,N*-dimethylanalines. In the latter case we have recently found that the Hammett plots are a good probe of the mechanism of the quenching of singlet oxygen by amines (26) (Scheme 4).



2

SCHEME 3

$$^1O_2 + NR_3 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [^1O_2 \cdots\cdots NR_3]^{\delta^- \quad \delta^+} \xrightarrow{k_2} {}^3O_2 + NR_3$$

SCHEME 4

When singlet oxygen is quenched by the substituted *N,N*-dimethylanilines it was found that the Hammett ρ value was -1.7 (26). This value emphasizes the importance of the formation of the charge-transfer-like complex in the course of the quenching reaction. Clearly this must be kept in mind when considering photooxidation *reaction* mechanisms. It is conceivable that the substituent effect which is measured may result from the pre-equilibrium formation of a charge-transfer-like complex.

Conclusions

We have compared the photooxidation reactions of a number of furans to similar photooxidation reactions of alkenes, anthracenes, and to Diels–Alder reactions. We suggest that the mechanism of the reaction of singlet oxygen with the furans may be a concerted one-step addition to the diene and/or involve a pre-equilibrium complex. The lack of symmetry of some of the furans may cause some dissymmetry in the transition state, for example the 2-arylfurans. A correlation between the Hammett ρ values and the polarity of the solvent for a series of solvents confirms the expected solvent effect on the rate constant of reaction. Further evidence suggests that the solvent may also be affecting the rate constant for the decay of singlet oxygen. The solvent effect on the rate constant of reaction and on the rate constant of decay was later confirmed and is reported elsewhere (11).

Experimental

The kinetics studies were carried out using either an Aminco-SPF-125 spectrofluorometer or an Aminco filter fluorometer. The experimental procedure for the kinetic methods is given in detail in ref. 11.

The furans were obtained from a variety of sources. Furan and furfuryl alcohol were obtained from Aldrich and were redistilled prior to use. The 2-methoxyfuran and

2-acetylfuran were obtained from Aldrich and used as received. The furfural was obtained from Aldrich and was freshly distilled under vacuum (b.p. 54–55 °C/17 mm) prior to use.

2-Methylfuran was obtained from Eastman Chemicals and was redistilled. 2,5-Dimethylfuran was obtained from Research Organic/Inorganic Chemical Corporation and was redistilled. Furfural amine was obtained from Commercial Solvents Corporation and redistilled prior to use. The 2,5-diphenyl furan was obtained from Dr. A. Trozolo of Bell Laboratories and was used as received.

The 2-arylfurans were prepared by the method used by Ayres and Smith (24) and the 3-arylfurans prepared by a modification of the Wynberg method (19, 28).

The 3,4-diphenylfuran was prepared by the method according to Farnum and Burr (29) and by a Friedel–Crafts reaction of the 3,4-dibromotetrahydrofuran on benzene (19) followed by aromatization with sulfur.

The preparation of the 2- and 3-arylfurans and the products of their photooxidation reactions will be reported in detail in a later paper.

We would like to thank the Research Corporation and the donors of the Petroleum Research Fund, administered by the American Chemical Society (G-3021-A4) for partial support of this research. We would also like to acknowledge the American Instrument Company for the loan of a SPF-125 spectrophotofluorometer, and the National Science Foundation for support of C.M. (N.S.F. Undergraduate Research Participant, Summer 1969).

Fully Fluorinated Alkoxides. Part VI. Derivatives of Hydroxyhexafluoroisobutyric Acid

J. T. PRICE, A. J. TOMLINSON, AND C. J. WILLIS[1]

Chemistry Department, University of Western Ontario, London 72, Ontario

Received October 5, 1971

Hydroxyhexafluoroisobutyric acid, $HOC(CF_3)_2COOH$, $H_2(HHIB)$, gives complexes with a variety of metals, acting as a chelating, dinegative ligand. Derivatives prepared include $[B(HHIB)_2]^-$, $[M(HHIB)_2]^{2-}$ (M = Ni, Cu, Co), $[M(HHIB)_3]^{3-}$ (M = Al, Cr, Mn, Fe), and mixed ligand complexes of Cu and Ni with HHIB and nitrogen- or phosphorus-containing ligands. In some cases, the HHIB anion appears to act as a tridentate ligand through carboxylate bridging. HHIB is close to water in the spectrochemical series.

L'acide hydroxyhexafluorobutyrique, $HOC(CF_3)_2COOH$, $H_2(HHIB)$, donne des complexes avec une variété de métaux, agissant comme ligand chélaté, dinégatif. Les dérivés préparés incluent $[B(HHIB)_2]^-$, $[M(HHIB)_2]^{2-}$ (où M = Ni, Cu, Co), $[M(HHIB)_3]^{3-}$ (M = Al, Cr, Mn, Fe) et des ligands mixtes du Cu et du Ni avec HHIB et des ligands contenant de l'azote et/ou du phosphore. Dans quelques cas, l'anion HHIB semble agir comme ligand tridenté au moyen de ponts carboxylates. HHIB se situe près de l'eau dans la série spectrochimique.

Canadian Journal of Chemistry, **50**, 939 (1972)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

We have previously reported the use of perfluoropinacol, $HOC(CF_3)_2C(CF_3)_2OH$, (PFP) as a bidentate ligand forming stable, cyclic, derivatives of main group elements (1) and complexes with a variety of transition elements (2). In terms of the chelate ring structure, there is an obvious resemblance between these complexes and the familiar series of oxalato-complexes, although the acidity of PFP [$pK_a = 5.95$ (3)] is less than that of oxalic acid ($pK_a = 1.23$).

A third compound, structurally related to both of the above molecules, and having potential application as a chelating ligand, is hexafluoro-2-hydroxyisobutyric acid, $HOC(CF_3)_2COOH$, $H_2(HHIB)$.[2] This acid is readily made by hydrolysis of the cyanohydrin of hexafluoroacetone (4, 5) and has a pK_a of 2.1. Simple monobasic salts (*e.g.* with Cs^+ cation) are readily prepared, but the acid shows no evidence of a second dissociation in aqueous solution. This behavior is similar to that of PFP, and in both cases the stability of the singly ionized molecule may be attributed to intramolecular hydrogen bonding. However, it was expected that the presence of two trifluoromethyl groups in the HHIB molecule would increase the acidity of the hydroxylic proton so that, in complex ions, chelation would occur as the dinegative, bidentate ligand $^-OC(CF_3)_2COO^-$, (HHIB), rather than as a uninegative, bidentate species similar to the ion $HOC(CH_3)_2COO^-$, found with hydroxyisobutyric acid and other unfluorinated α-hydroxyacids (6).

Isolation of a range of stable complexes has confirmed that $H_2(HHIB)$ does behave in the expected manner. Complexes have been prepared of the types $[M(HHIB)_3]^{3-}$ ($M = Al^{3+}$, Cr^{3+}, Mn^{3+}, Fe^{3+}); $[M(HHIB)_2]^{2-}$ ($M = Co^{2+}$, Ni^{2+}, Cu^{2+}); $[M(HHIB)_2]^-$ (M = B), and mixed complexes including HHIB and other ligands. Although structures cannot be assigned with certainty in all cases, sufficient information is now available to give some idea of the properties of HHIB as a ligand. Compounds were prepared by interaction of $H_2(HHIB)$ with various metal ions, generally in methanolic solution, at suitable p*H*. The range prepared is shown in Table 1, and includes derivatives of all first-row transition elements from V to Cu. Electronic spectra are given in Table 2. Specific aspects of these compounds will now be discussed for the various elements.

Vanadium

As has been done with many other ligands, it was convenient to make the vanadyl complex $[VO(HHIB)_2]^{2-}$. This had a magnetic moment of 1.76 B.M., in the expected range; *cf.* $VO(acac)_2$ (acac = acetylacetone), $\mu_{eff} = 1.73$ B.M. (7). The electronic spectrum also re-

[1]To whom inquiries should be addressed.

[2]Throughout this paper, the acid is abbreviated to $H_2(HHIB)$ and the di-anion to HHIB.

*d.r. = diffuse reflectance. Molar extinction coefficients in parentheses.

sembled that of similar vanadyl complexes, which have been extensively studied (7, 8). By analogy with the results of Ballhausen and Gray (7), the absorption bands at 13 700 and 16 000 cm^{-1} in the complex $[VO(HHIB)_2]^{2-}$ may be assigned to the $^2B_2 \rightarrow {}^2E(I)$ and $^2B_2 \rightarrow {}^2B_1$ transitions respectively. In the complex $VO(acac)_2$ they are found at 12 800 and 17 300 cm^{-1}. However, the same authors assign a band at 18 800 cm^{-1} in the spectrum of $[VO(tartrate)_2]^{2-}$ to the latter transition, so the assignments in $[VO(HHIB)_2]^{2-}$, where a band appears at 18 500 cm^{-1}, cannot be regarded as definite.

The complex crystallizes as a monohydrate, and the water molecule may possibly be coordinated to the vanadium atom *trans* to the oxygen atom. This would not affect the tetragonal symmetry of the ion, and would therefore have little effect on its properties. However, Jones has suggested (9) that only molecules with strong donor properties are capable of such coordination to five-coordinate vanadyl complexes.

Chromium

The geometry of the ion $[Cr(HHIB)_3]^{3-}$ cannot be exactly octahedral, as the ligand is unsymmetrical. However, the properties of the metal ion are consistent with its being regarded as at the center of an octahedral distribution of oxygen atoms. The visible spectrum shows bands at 16 800 and 22 700 cm^{-1} very similar to those observed in the hydrated $[Cr(H_2O)_6]^{3+}$ species at 17 400 and 24 700 cm^{-1} and assigned to the $^4A_{2g} \rightarrow {}^4T_{2g}(F)$ and $^4A_{2g} \rightarrow {}^4T_{1g}(F)$ transitions respectively (10). These figures lead to a

Dq value of 1700 cm^{-1} for HHIB, the same as that for water and very close to that of the oxalate ion (1740 cm^{-1}).

The analogous PFP complex of Cr^{3+} has not yet been prepared. The reason for this difference in behavior between HHIB and PFP is not obvious, but may be connected with a difference in the pK_a's of the two compounds.

Manganese

Here, as with chromium, a difference between PFP and HHIB was observed. The former gives the Mn(II) complex $[Mn(PFP)_2]^{2-}$ (2), whereas in the latter case oxidation by air occurs rapidly to give Mn(III) in the ion $[Mn(HHIB)_3]^{3-}$. Such ready oxidation has been noted previously in the formation of the complex $Mn(acac)_3$ (11). The validity of the formulation of the HHIB complex as an Mn(III) compound is shown by its magnetic moment of 4.95 B.M. [*cf.* $Mn(acac)_3$, 4.95 B.M. (12); $Mn(C_2O_4)_3^{3-}$, 4.81 B.M. (13)] and its visible spectrum, which shows a very broad absorption with a maximum at 21 800 cm^{-1} [*cf.* $Mn(H_2O)_6^{3+}$, $\nu = 22\,000$ cm^{-1} (14)].

Iron

The Fe(III) complex, $[Fe(HHIB)]_3^{3-}$, formed readily, as does the PFP complex. It had a magnetic moment of 5.84 B.M., similar to those of $[Fe(PFP)_3]^{3-}$ (6.0 B.M.), $Fe(acac)_3$ (5.95 B.M.) (15), and $[Fe(C_2O_4)_3]^{3-}$ (5.75 B.M.) (13). As is common with Fe(III) complexes, where there are no spin-allowed transitions, the electronic spectrum was very weak. Only one absorption was found in the solution spectrum ($\nu = 22\,000$ cm^{-1}), and meaningful assignments cannot be made.

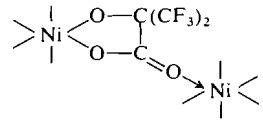
Cobalt

The only cobalt complex isolated was the compound $Cs_2Co(HHIB)_2 \cdot 2H_2O$. This we presume to contain Co(II) in the six-coordinate ion $[Co(HHIB)_2(H_2O)_2]^{2-}$. However, its magnetic moment of 3.88 B.M. is unusually low, being equal to the spin-only value. Orbital contributions usually increase magnetic moments in Co(II) complexes above the spin-only value (16), typical values being in the range 4.5–5.1 B.M.

The visible spectrum of the complex is similar to that of the octahedral aquo complex, but shows some additional splitting which presumably results from departure from perfect octahedral symmetry.

Nickel

The Ni(II) complex, $[Ni(HHIB)_2]^{2-}$, differs considerably from the corresponding nickel complex of PFP in being green and paramagnetic ($\mu_{eff} = 3.06$) with visible spectra typical of octahedral Ni(II), whereas the PFP complex is purple, diamagnetic, and square planar. This difference we ascribe to additional coordination from the carboxylate oxygen in the ligand, making it effectively tridentate, a process common for oxalates but not possible in the PFP complex:



Such a structure would be broken down in solution, with solvent molecules replacing the bridging carboxylate groups around nickel, and, consistent with this, some differences are observed between the diffuse reflectance and methanol solution spectra.

Copper

The Cu(II) complex, $[Cu(HHIB)_2]^{2-}$, has a magnetic moment of 1.85 B.M. and is presumed to have a square planar arrangement of ligands, although the possibility of carboxylate bridging, similar to that suggested for nickel, cannot be entirely eliminated.

Mixed Ligand Complexes

The coordination of HHIB to Cu^{2+} or Ni^{2+} in the presence of nitrogen bases gives rise to a variety of mixed ligand complexes. Those isolated were of two stoichiometries; $en_2Ni(HHIB)_2$ and $en_2Cu(HHIB)_2$ (en = ethylenediamine), and $enCu(HHIB)_2$ and $(TMED)Cu(HHIB)_2$ (TMED = Tetramethylethylenediamine). The last two complexes showed several absorptions in their i.r. spectra in the region 2000–2700 cm^{-1}, characteristic of amine salts, while the remaining parts of their i.r. spectra were very similar to the salt $K_2[Cu(HHIB)_2]$ (Table 3). They may therefore be formulated as the amine salts $[H_2en]^{2+}[Cu(HHIB)_2]^{2-}$ and $[H_2TMED]^{2+}[Cu(HHIB)_2]^{2-}$.

In the other complexes, where there are two molecules of nitrogen base present for each

metal atom, absence of absorption in the 2000–2700 region rules out amine salts, while magnetic moment and visible spectra on the nickel complex suggest octahedral coordination. While a definite assignment of structure cannot be made, we suggest that one end of each HHIB ligand has been displaced to give the carboxylate complexes $HOC(CF_3)_2COOM(en)_2OOCC(CF_3)_2OH$ (M = Ni, Cu). No O—H absorption can be definitely assigned in the i.r. spectrum, but we have commented before on the difficulty of observing O—H frequencies in complexes of this type (17).

The two mixed ligand phosphine–HHIB complexes prepared were $(PEt_3)_2Ni(HHIB)$ and (diphos)Ni(HHIB) (diphos = 1,2-bisdiphenylphosphinoethane). Both were orange–yellow and diamagnetic, and are presumed to be square planar. They were conveniently made by the reaction of PEt_3 or diphos with the ion $[Ni(HHIB)_2]^{2-}$; only in the former case was the displacement of HHIB reversible.

The remaining mixed ligand complex characterized had a stoichiometry corresponding to K_2[(PFP)Ni(HHIB)]. Formulation as the double salt, $K_2Ni(PFP)_2.K_2Ni(HHIB)_2$, seems unlikely, as the magnetic moment of the compound (μ_{eff} = 3.21 B.M.) showed all nickel present to be paramagnetic and octahedral, whereas $K_2Ni(PFP)_2$ is diamagnetic. Its color, moreover, is orange, while $K_2Ni(PFP)_2$ is purple and $K_2Ni(HHIB)_2$ is yellow-green. Presumably some carboxylate bridging is present, bringing the coordination of the nickel up to six, but present evidence is not sufficient to determine the precise mode of attachment of the ligands.

Non-transition Element Complexes

The expected boron and aluminum complexes, $[B(HHIB)_2]^-$ and $[Al(HHIB)_3]^{3-}$ were readily prepared. Attempts to make a neutral tetrahedral complex, *e.g.* $Si(HHIB)_2$, were unsuccessful, but reaction of HHIB with hexamethyldisilazane gave the bis(trimethylsilyl) derivative $Me_3SiOC(CF_3)_2C(O)OSiMe_3$.

Infrared Spectra

Chelation of HHIB to metal ions would be expected to influence the frequency of the carboxylate stretching and bending modes, the alcoholic C—O stretch, and perhaps the C—C stretching mode. Frequencies associated with these vibrations are shown in Table 3. In addition, all complexes showed strong absorptions in the region 1150–1300 cm^{-1} associated with the CF_3 groups.

Considerable similarity is apparent between the spectra of all complexes. In particular, no significant difference is seen in the carboxylate frequencies in the nickel and copper complexes, where carboxylate bridging was postulated above on other evidence. Such coordination, if present, is presumably weak in nature.

It was not possible to make a definite assignment of frequencies associated with metal–oxygen bonds, since the region 450–600 cm^{-1}, where they might be expected, was complicated by the presence of C—F bending modes.

Isomerism in HHIB Complexes

Since the HHIB molecule is an unsymmetrical chelating agent, isomerism may be expected in the various complexes. Optical isomerism is possible for the tetrahedral species $[B(HHIB)_2]^-$,

*Notes: (*a*) Oxidation to Mn(III) was complete after stirring in air 30 min. (*b*) Carried out under nitrogen. (*c*) diphos added in MeOH/THF solution. (*d*) Ratio HHIB/PFP/Ni was 1:1:1. (*e*) Made by adding en to the preceding complex in EtOH. (*f*) KOH added to p*H* 6, then TMED added.

and geometric (*cis–trans*) isomerism for square planar ions $[M(HHIB)_2]^{2-}$, while the tris-chelated species $[M(HHIB)_3]^{3-}$ can show both geometric and optical isomerism.

In no case was any evidence found for the presence of more than one isomer, nor was it possible to decide which configuration was present. In the square planar complexes, a *trans*-configuration might be thought more likely on steric grounds, but no definite evidence is available. Crystallographic structure determinations are now in progress in an attempt to elucidate this point.

Conclusions

From the range of complexes prepared in this work, it appears that $H_2(HHIB)$ acts as a ligand in a manner resembling PFP or oxalic acid rather than its unfluorinated analogue. Although usually bidentate, there is some evidence for additional coordination through carboxylate bridging. Electronic spectra are generally similar to those of aquo complexes, placing HHIB close to water in the spectrochemical series.

Experimental

General

Volatile materials were manipulated on a conventional vacuum line. Infrared spectra were recorded on a Beckman IR-10 instrument and visible/u.v. spectra on Beckman DK-1 and Cary 14 instruments. Magnetic moments were determined at 25° by the Gouy method using $Hg[Co(CNS)_4]$ as standard. Microanalyses were performed by Alfred Bernhardt Laboratories. All analytical data are shown in Table 1.

Hydroxyhexafluoroisobutyric Acid

Hexafluoroacetone (50 g, 0.32 mol) was bubbled into a solution of potassium cyanide (17 g, 0.31 mol) in dried diethyl ether/tetrahydrofuran (400 ml, 5% THF v/v) at −30° over a 2 h period with stirring. Removal of solvent *in vacuo* gave the potassium salt of hexafluoroacetone cyanohydrin. Sulfuric acid (250 ml) was added and the resulting solution held at 180° for 48 h, during which time $H_2(HHIB)$ (38 g, 78%) distilled out. The product was recrystallized from benzene and had m.p. 81°.

Cs(HHIB)

$H_2(HHIB)$ (1.0 g, 4.7 mmol) was added to cesium hydroxide (0.7 g, 4.7 mmol) in water (10 ml). Cesium chloride (1.0 g) was added and the solution allowed to evaporate slowly. Crystals separating were recrystallized from 2-propanol to give the cesium salt of HHIB.

Complexes of HHIB

Most of the complexes were prepared by substantially the same route. The metal ion, usually as the sulfate, was mixed with a suitable quantity of $H_2(HHIB)$ in methanol or ethanol. The appropriate amount of base (CsOH, KOH, en, or phosphine) was then added and any precipitate (Cs_2SO_4, etc.) removed. The solution was then evaporated *in vacuo*, and the resulting complex recrystallized. Conditions for these preparations are listed in Table 4.

Cs[B(HHIB)$_2$]

Trimethyl borate (0.5 g, 5.0 mmol) was added to $H_2(HHIB)$ (2.1 g, 10 mmol) in methanol/benzene (15 ml) and the solution heated under reflux for 2 h. Removal of solvent left a gelatinous residue, which was added to aqueous cesium hydroxide (0.75 g, 5 mmol) containing cesium chloride (1 g). Crystals of $Cs[B(HHIB)_2]$ separated on evaporation and were recrystallized from 2-propanol.

Trimethylsilyl 2-Trimethylsiloxy-2-trifluoromethyl-3,3,3-trifluoropropionate

H_2(HHIB) (2.1 g, 10 mmol) and hexamethyldisilazane (4.8 g, 30 mmol) were heated to 80° for 4 h. Fractional distillation gave the trimethylsilyl-substituted product (b.p. 40°, 0.1 mm).

Hydrolysis of Sulfamoyl Chlorides. II. Hydrogen Participation in the Hydrolysis of Diethyl and Methylethylsulfamoyl Chlorides[1]

E. C. F. Ko[2] AND R. E. ROBERTSON

Department of Chemistry, University of Calgary, Calgary, Alberta

Received October 19, 1971

Diethylsulfamoyl chloride (**2**) hydrolyzes eight times faster than dimethylsulfamoyl chloride (**1**). In **2** the secondary deuterium isotope effect was found to be about 2, hence hydrogen participation is important in the hydrolysis of this compound. The temperature coefficient of the enthalpy of activation ($\Delta C_p^{\ddagger}$) is exceptional (-39 cal mol^{-1} deg^{-1}) for a reaction presumably following an S_N1 mechanism. The kinetic solvent isotope effect was normal for such a mechanism. The corresponding value of $\Delta C_p^{\ddagger}$ for the hydrolysis of piperidylsulfamoyl chloride (**4**) was about the same as found for **2** while the value for the methylethyl isomer (**3**) was -66 cal deg^{-1} mol^{-1}, an intermediate value supporting an explanation based on solvent exclusion. Experiments in mixed solvents support the hypothesis that solvent reorganization is the major factor in determining the value of $\Delta C_p^{\ddagger}$ for **2** but not for **4**.

Le chlorure de diéthylsulfamoyle (**2**) hydrolyse huit fois plus vite que le chlorure de diméthylsulfamoyle (**1**). Dans **2**, l'effet isotopique secondaire du deutérium est trouvé à peu près égal à 2, par suite la participation de l'hydrogène est importante dans l'hydrolyse de ce composé. Le coefficient de température de l'enthalpie d'activation ($\Delta C_p^{\ddagger}$) est exceptionnel (-39 cal mol^{-1} deg^{-1}) pour une réaction suivant probablement un mécanisme S_N1. L'effet isotopique cinétique du solvant était normal pour un tel mécanisme. La valeur correspondante de $\Delta C_p^{\ddagger}$ pour l'hydrolyse du chlorure de pipéridylsulfamoyle (**4**) a été environ la même que celle trouvée pour **2** tandis que la valeur de l'isomère méthyléthyl (**3**) était de -66 cal deg^{-1} mol^{-1}, valeur intermédiaire étayant une explication fondée sur l'exclusion de solvant. Des expériences dans des solvants mélangés étayent l'hypothèse que la réorganisation du solvant est le facteur principal dans la détermination de la valeur de $\Delta C_p^{\ddagger}$ pour **2** mais non pas pour **4**.

Canadian Journal of Chemistry, **50**, 946 (1972)

The enthalpy of activation ($\Delta H^{\ddagger}$) for the hydrolysis of dimethylsulfamoyl chloride (**1**) (1) in water is characterized by a large negative temperature coefficient ($\Delta C_p^{\ddagger} = -76$ cal deg^{-1} mol^{-1}) a relatively small kinetic solvent isotope effect ($k_{H_2O}/k_{D_2O} = 1.30$) compared to the values found for other sulfonyl chlorides (2) and a small inverse γ-secondary deuterium isotope effect (1). Hall (3) has shown the rate of hydrolysis of **1** to be insensitive to weak or bulky nucleophilic reagents but accelerated by strong nucleophiles, a fact confirmed by Rogne (4). On the basis of these mechanistic indicators the conclusion that hydrolysis of **1** in water follows an S_N1 mechanism seems reasonable. However, we disagree with Hall as to the reason for the change over in mechanism in this particular case compared to the normal S_N2 mechanism found for the solvolysis of many other sulfonyl chlorides (5). We prefer to attribute the change in mechanism for the dimethylsulfamoyl chloride to effective steric hindrance to nucleophilic approach, rather than to enhanced electron release by the dimethylamino group. Thus the secondary γ-deuterium isotope effect found in the hydrolysis of dimethylsulfamoyl chloride was only about 1/6 value found for the ionization of dimethylamine (6). Moreover, in view of the small inverse secondary deuterium isotope effect found for the dimethyl compound, there seemed no obvious electron-release mechanism which could account for the large ($8\times$) acceleration in the rate of hydrolysis for the hydrolysis of diethylsulfamoyl chloride (**2**).

Thus the work reported here began with a search to identify the source of the accelerated rate of hydrolysis for the diethylsulfamoyl chloride and was subsequently extended to include the kinetics of the hydrolysis for methyl-ethyl (**3**) and piperidyl sulfamoyl chlorides (**4**).

Results and Discussion

The experimental procedures and calculations have been described previously (7). Details concerning the synthesis, characterization of the

reactants, and solvents are given after this discussion.

Rate data determined by a conductance method are good to better than 1% for repetitive runs over a reasonable range of temperatures. These were fitted by the method of least squares to the empirical three constant equation

$$[1] \qquad \log k = A_1 + A_2/T + A_3 \log T$$

The corresponding constants for each compound are given in Table 1. These constants provide a convenient means of calculating rates for intermediate temperatures.

Granted the assumptions of the transition state hypothesis and the admissibility of attenuating the rate-temperature relationship, the empirical constants in Table 1 may be used to calculate the corresponding pseudothermodynamic parameters $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ (8). The values so calculated are given in Table 2. The errors in the rate determination for the hydrolysis of the *n*-propylsulfamoyl chloride are somewhat larger than normally acceptable for the determination of $\Delta C_p^{\ddagger}$ over the temperature range experimentally available, a fact we attribute to the low solubility of this compound. The rate constants for this compound ±1% are included in Table 4 for comparison.

TABLE 3. Relative hydrogen bonding tendencies for certain sulfamoyl chlorides

Compound	$\Delta\nu$ (cm^{-1})*
p-ClC_6H_4OH	0.0
$(CH_3)_2NSO_2Cl$	62.0
$(C_2H_5)_2NSO_2Cl$	65.0
CH_3SO_2Cl	65.0

*$\Delta\nu$(cm^{-1}) is the displacement of the complex band from that of the free *p*-chlorophenol (9).

According to the tests introduced by Kartha *et al.* for measuring the relative availability of unshared electrons for hydrogen bonding (9), these compounds show about the same tendency for hydrogen bonding as other sulfonyl chlorides (Table 3). Of course the conditions of the comparisons in Table 3 are quite different from those in our experiments, but if anything tend to accentuate hydrogen bonding.

The small inverse secondary deuterium isotope effect found for the hydrolysis of **1** appeared to

†Reference 1.

cancel the possibility that some electron release mechanism provided for the eight-fold increase in the rate of hydrolysis of **2** and a four-fold increase for **3** (Table 4). An examination of space-filling models showed that in these cases the sulfur group was effectively shielded from nucleophilic attack compared to *e.g.* methanesulfonyl chloride. In addition it was noted that the α-hydrogens were in a favorable configuration for hydrogen participation and could be activated by the adjoining methyl group. Hence the deuterated isomer $(CH_3CD_2)_2NSO_2Cl$ was synthesized and was shown to hydrolyze with a much reduced rate $k_H/k_D \simeq 2$, a value in the same range as found for the corresponding isotope effect from the hydrolysis of 3-methyl-2-butyl-bromide (10) and the corresponding mesylate in acetic acid (11), for *cis*-cyclopentyl-d_1 and *cis*-cyclohexyl-d_1 chlorides (12), *t*-butyl chloride (13), and the *cis*-4-*t*-butyl-cyclohexyl brosylate (14). All of these compounds on solvolysis show a relatively large secondary deuterium isotope effect $k_H/k_D \geqslant 2$. Shiner and Jewett attribute the large isotope effect in the case of the last example to the formation of a bridged non-classical carbonium ion (14) and the same description might well be applied to the examples given above. In the case of the diethylsulfamoyl-chloride, the ethyl groups block off nucleophilic attack on sulfur even more effectively than the methyl groups in **1** and the change in the secondary deuterium isotope effect from 0.95 to about 2 seems convincing evidence for hydrogen participation. In view of the favorable configuration noted above, such a conclusion was not too surprising, but for the same reason the value of $\Delta C_p^{\ddagger}$ (-39 cal mol^{-1} deg^{-1}) found for the hydrolysis of **2** was without precedent.

TABLE 5. First order rate constants in D_2O and k.s.i.e. for the hydrolysis of RSO_2Cl at 15°

R	$10^3 k_{D_2O}$ (s^{-1})	k.s.i.e.	Reference
$(C_2H_5)_2N$	8.239	1.29	This work
$C_5H_{10}N$	2.319	1.30	" "
$(CH_3)_2N$	—	1.33	1
C_6H_5	—	1.58	2
$(CH_3)_3CCl$	—	1.38 at 10°	15

The value of $\Delta C_p^{\ddagger}$ for the hydrolysis of the piperidyl compound, **4**, was about the same as found for **2** while the methyl-ethyl compound (**3**) had a value intermediate between that of **1** and **2**. The kinetic solvent isotope effect (k.s.i.e.) was about the same value as found for *t*-butyl chloride (15) (Table 5) and lower than found for the hydrolysis of other sulfonyl chlorides (2).

Previous to this work, in every example where a halide was expected to hydrolyze by the S_N1 mechanism, the enthalpy of activation was characterized by a large negative temperature coefficient in the order of -70 to -80 cal deg^{-1} mol^{-1} or possibly more negative (8). This was considered both normal, in view of repeated recurrence, and reasonable, since the transition state for this mechanism involved a greater degree of charge separation, hence a greater degree of solvent reorganization than characterized those solutes hydrolyzing by an S_N2 mechanism. Of course, solvent reorganization is but one of the possible causes of a temperature coefficient for $\Delta H^{\ddagger}$ though it is the one most easily identified. Impurities reacting at comparable rates to give ions (16), mixed kinetics (17), or partitioning of the type discussed by Alberg and Robinson (18) and by Scott and Robertson (19) are all possible sources

of non-zero $d\Delta H^{\ddagger}/dT$. In the present investigation careful analysis of starting material and of products gave no indication of impurities nor any reason to doubt that the reaction was analogous to the hydrolysis of the dimethylsulfamoyl chloride where the value of $\Delta C_p^{\ddagger}$ was found to be -76 cal deg^{-1} mol^{-1}.

Robertson and Sugamori (20) have shown in a detailed investigation of the hydrolysis of *t*-butyl chloride in acetonitrile–water mixtures that the addition of 5 mol % cosolvent changes the water value of $\Delta C_p^{\ddagger}$ of -80 cal deg^{-1} mol^{-1} to about -44 cal deg^{-1} mol^{-1}. There was no reason to suspect a change in mechanism for such a minor change in solvent, hence the large change in the value of $\Delta C_p^{\ddagger}$ was associated with a corresponding change in the solvent structure in the initial state and a corresponding reduction in solvent reorganization in the activation process. Applying the same test to **1** and **2** the value of $\Delta C_p^{\ddagger}$ for the dimethyl isomer was reduced from -76 ± 1 to -44 ± 1 cal deg^{-1} mol^{-1}, while the value for the diethyl isomer was reduced from -39 ± 2 to -25 ± 2 cal deg^{-1} mol^{-1}, approximately in the same proportion. Since we could find no evidence from rate measurements or from analytical sources to suggest that the value of $\Delta C_p^{\ddagger}$ for **2** was caused by molecular complexity or adventitiously, we concluded that the difference between the $\Delta C_p^{\ddagger}$ values for **1** and **2**, **3** and **4** for hydrolysis in water represented a real difference in the degree of solvent reorganization.

A straightforward rationalization of these results would be that the diethyl and piperidyl isomers offered sufficient steric hindrance to solvation that the effect of charge development at the transition state for these members was not sufficient to overcome water–water interaction, under the conditions of the experiments. The intermediate value of $\Delta C_p^{\ddagger}$ found for the methyl-ethyl isomer can be regarded as support for this explanation. While qualitatively acceptable, the difference seems too large: the value of -39 cal deg^{-1} mol^{-1} is more positive than for most halides (8). The possibility that **2** can react by mixed kinetics, *i.e.* with hydrogen participation and in the absence of this effect (11) is considered unlikely for two reasons. If direct solvent reaction is unlikely in the case for **1** for steric reasons, it will be even more unlikely in the case of **2**. An even better argument against a shift in the relative importance of k_s and k_Δ (11) is the constancy of k_H/k_D over the experimental temperature range, Table 6. An alternative suggestion which is advanced without further support is that the rate controlling step is the formation of the non-classical ion (14) and the transition state in this step comes at an early stage in charge development. But the fact that the same value of $\Delta C_p^{\ddagger}$ was found for the piperidyl isomer makes such a suggestion less likely than one based on solvent exclusion. Thus it appears that the hydrolysis of a halide in water by what would be considered an S_N1 mechanism need not necessarily be accompanied by a large degree of solvent reorganization and this implies a corresponding reduction in solvation of the transition state contrary to the classical requirement. However, in so far as we are aware a large negative value of $\Delta C_p^{\ddagger}$ (*e.g.* -80 cal deg^{-1} mol^{-1}) is still a general characteristic of an ionizing mechanism for halides in water. What is not left in doubt is that the temperature coefficient of $\Delta H^{\ddagger}$ ($\Delta C_p^{\ddagger}$) can give notice of differences in mechanism undetected by other indicators.

TABLE 6. Secondary deuterium isotope effect, k_H/k_D for the hydrolysis of $(CH_3CD_2)_2NSO_2Cl$ and its undeuterated analogue in water

*Calculated from A_1, A_2, and A_3 in Table 1.
†Observed.

Finally we draw attention to the parallel correlation between the values of $\Delta H^{\ddagger}$ and $T\Delta S^{\ddagger}$ obtained for solvolysis of these compounds in water and in water containing 5 mol % acetonitrile (Fig. 1). In water it is surprising to note that the point corresponding to **4** lies closer to **1** than to **2**. Were the plot representative of solvent reorganization as judged by comparative values of $\Delta C_p^{\ddagger}$, **4** would be expected to lie closer to **2**. Against this apparent discrepancy we may cite a fact which points to some unspecified factor influencing the value of $\Delta C_p^{\ddagger}$ obtained for **4**. Whereas the value of $\Delta C_p^{\ddagger}$ for **2** was changed from -39 to -25 cal

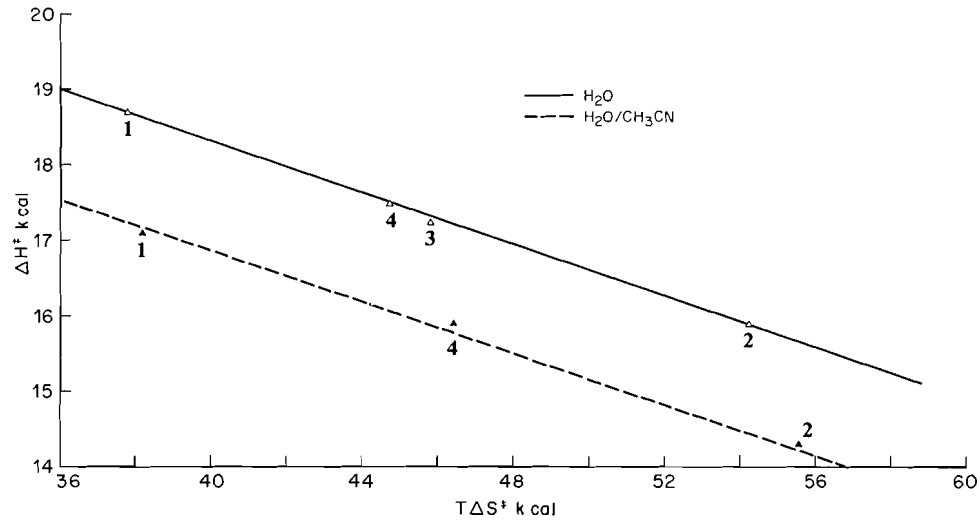

FIG. 1. Correlation of $\Delta H^{\ddagger}$ and $T\Delta S^{\ddagger}$ values for hydrolysis of a series of sulfamoyl chlorides.

TABLE 7. Physical properties of sulfamoyl chlorides RSO_2Cl boiling points and n.m.r. characteristics

†The quintet observed is formed from the overlap of a quartet and a triplet.

deg^{-1} mol^{-1} on changing to the solvent mixture containing 5 mol % acetonitrile, the value for **4** was reduced by only 5 cal deg^{-1} mol^{-1}.

Experimental

Materials

Substituted sulfamoyl chlorides were prepared as previously outlined (1). The boiling points, comparable with those reported in the literature (21, 22) and the characteristics of n.m.r. spectra for these chlorides are summarized in Table 7.

The diethylsulfamoyl chloride -d_4 was checked by v.p.c. on Bendix 2500 analytical gas chromatograph using a 6 ft × $\frac{1}{4}$ in. glass column packed with 5% SE-30 on Chromosorb W. The retention times under the same conditions (3 min; column temperature = 100°) for deuterated and the undeuterated chlorides are comparable. Diethylamine-αd_4. DCl was prepared by the method reported by Werner (23). Acetaldehyde-αd_1 (Merck Sharp and Dohme, 1 g) was added to a solution of ammonium chloride-d_4 (Merck Sharp and Dohme) in D_2O (1 g, ND_4Cl in 4 ml D_2O). The solution was refluxed gently at first (~40 °C) and then at high temperature (not over 120°) overnight. The solution was then concentrated on a vacuum line to half of its volume and unreacted ND_4Cl was filtered off. The filtrate was then refluxed with fresh acetaldehyde-αd, (1 g) overnight. The solvent was evaporated to dryness on a vacuum line, and the residue was sublimed to collect diethylamine-αd_4 DCl (yield 0.9 g); no α-H by n.m.r.

Attempts made to synthesize di-isopropyl, diacetyl, phthalimidyl, and acetyl methyl sulfamoyl chlorides met with total failure. The first three reactions did not work, probably due to bulky amino groups. An attempt to synthesize acetyl methyl sulfamoyl chloride from acetamide and sulfuryl chloride gave a product b.p. 52°/3 mm Hg; n.m.r.: singlet at 6.53 τ. We are still trying to identify this product.

Methods for purification of solvents for measurement of rate and for product analysis were exactly similar to those outlined in the previous paper (1).

Acid-catalyzed Reactions of Cyclobutanones. II.[1] Generation of Acylium Ions from β,γ-Unsaturated Cyclobutanones

E. LEE-RUFF

Department of Chemistry, York University, Toronto, Ontario

Received October 5, 1971

Acid-catalyzed rearrangement of 3-methylene-2,2,4,4-tetramethylcyclobutanone (**1**) gave the γ-lactone of 2,2,3,4-tetramethyl-4-hydroxyvaleric acid. Reaction of 2,2,4,4-tetramethylcyclobutane-1,3-dione (**5**) with PPA gave diisopropylketone with evolution of carbon dioxide. Acylium ions are postulated as intermediates in both these reactions.

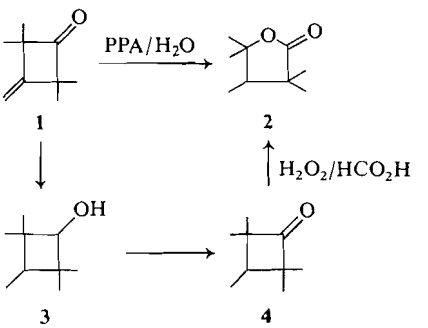
La transposition acido-catalysée du méthylène-3 tétraméthyl-2,2,4,4 cyclobutanone (**1**) conduit à la γ-lactone de l'acide tétraméthyl-2,2,3,4 hydroxy-4 valérique. La réaction de la tétraméthyl-2,2,4,4 cyclobutanedione-1,3 (**5**) avec le PPA conduit à la diisopropylcétone avec dégagement de dioxyde de carbone. Les ions acyliums sont postulés comme intermédiaires dans ces deux réactions.

Canadian Journal of Chemistry, **50**, 952 (1972)

The acid-catalyzed rearrangement of exocyclic α,β-unsaturated cyclobutanones has been shown to involve acylium ions as intermediates (1). The strain involved in having two sp^2 centers in an already strained cyclobutane ring (E_{strain} 26 kcal/mol) (2) would permit pathways of high activation energies in medium ring systems to operate in small rings. We wish to report some novel ring opening reactions of β,γ-unsaturated cyclobutanones in the presence of strong acid.

Rearrangement of 3-Methylene-2,2,4,4-tetramethylcyclobutanone (1) in Polyphosphoric Acid

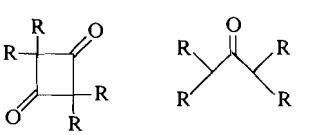
Ketone **1** was prepared according to Hannon (3). Reaction of ketone **1** in polyphosphoric acid (PPA) (50/50 mixture of P_2O_5 and H_3PO_4) at 100° for 1 h resulted in a smooth conversion to the lactone **2** (see Scheme 1). Its structure was deduced from analytical and spectroscopic data as well as independent synthesis. Atmospheric hydrogenation of **1** resulted in an 80/20 mixture of the over-reduced alcohol **3** and the saturated ketone **4**. Jones oxidation of this mixture gave a quantitative yield of **4** which under Baeyer–Villiger oxidation conditions resulted in the exclusive formation of lactone **2**, identical in all respects with the sample obtained from the acid reaction of ketone **1**.



SCHEME 1

Reactions of 1,3-Cyclobutanediones in PPA

Commercial 2,2,4,4-tetramethylcyclobutane-1,3-dione (**5**) subjected to PPA at 100° for 1 h gave diisopropylketone (**6**) as the major product. Its structure was obtained from spectral data as well as comparison with an authentic sample.



5 R = CH_3 **6** R = CH_3

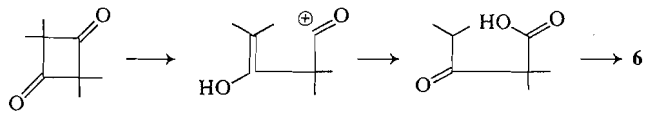
SCHEME 2



5 10 11

SCHEME 3

Evolution of carbon dioxide accompanied the acid reaction as evidenced by a positive test in passing the evolved gas through an aqueous solution of barium hydroxide under a stream of nitrogen. Under the same conditions 2,2,4,4-tetraphenylcyclobutane-1,3-dione (**5***a*) was inert.

Discussion

The formation of γ-lactone **2** from 3-methylene-2,2,4,4-tetramethylcyclobutanone (**1**) can be envisaged to proceed by Scheme 2. Although the carbonyl group in **1** would be preferentially protonated over the exo-methylene function, an equilibrium between the two species is established. Ring opening of **7** could compete over any other reaction pathway from the protonated ketone **1** to give acylium ion **8** which, upon reaction with water, gives rise to the β,γ-unsaturated carboxylic acid **9**. The cyclization of **9** to its lactone under the strong acid conditions is a common reaction.

A similar mechanism can be invoked for the formation of diisopropylketone from 2,2,4,4-tetramethylcyclobutane-1,3-dione (**5**). Protonation and ring opening could conceivably give rise to the acylium ion **10** (Scheme 3). Hydroxylation could result in the formation of 2,2,4-trimethyl-3-oxovaleric acid (**9**) which under these conditions could readily decarboxylate to diisopropylketone (**6**). The valeric acid derivative **9** was prepared from its methyl ester (4) which in turn is readily available from the alkali ring opening of 2,2,4,4-tetramethylcyclobutane-1,3-dione in methanol. Under the acid conditions it was shown that **9** gave a quantitative yield of ketone **6**.

Under completely anhydrous conditions 2,2,4,4-tetramethylcyclobutane-1,3-dione (**5**) has been reported to undergo an acid-catalyzed rearrangement to give lactone **12** (5) (eq. 1). In

[1] 
5 12

this case the acylium ion (aluminum chloride complex) cyclizes by intramolecular addition of enolate ion. The inertness of 2,2,4,4-tetraphenylcyclobutane-1,3-dione (***4a***) to acid-catalyzed ring opening lies in the inherent stability of the phenyl substituents. A similar kind of rearrangement would disrupt the aromaticity of one of the phenyl substituents.

Experimental

Melting points are uncorrected. The i.r. spectra were recorded with a Unicam SP 1000 instrument. The n.m.r. spectra were measured with a Varian A-60 and a Varian HA-100 instrument. Samples were dissolved in CCl_4 solution using tetramethylsilane as the internal standard. Vapor phase chromatography was performed on a Varian Aerograph 90-P instrument using 3% SE-30 on a Varaport 30 column at an operating temperature of 100°.

3-Methylene-2,2,4,4-tetramethylcyclobutanone (1)

This ketone was prepared by the method of Hannon in a private communication (3) which is described below.

For personal use only.

The monophenylimine of 2,2,4,4-tetramethylcyclobutane-1,3-dione (2.0 g) (6) in 10 ml ether was added in one lot to a stirred suspension of triphenylphosphonium methyl iodide (4.2 g) and potassium *t*-butoxide (1.2 g) in sodium dried ether (50 ml) under an atmosphere of nitrogen. The canary-yellow colored mixture was stirred overnight, diluted with water, and extracted with ether. The ether layer was then dried over anhydrous magnesium sulfate and the ether was evaporated under vacuum. The solid residue was taken up in petroleum ether (b.p. 40–60°) and the solution cooled in ice. The triphenylphosphine oxide which precipitated (2.5 g) was removed by filtration and the filtrate extracted with a solution of 80% methanol: water (2 × 100 ml). This solution was back-extracted with petroleum ether and the combined petroleum ether lots washed with water and dried over magnesium sulfate. Removal of the petroleum ether left an oil which could be crystallized by scratching (1.8 g) m.p. 45–47°. The solid was purified by evaporative distillation (60°/3 mm) m.p. 47–48°.

The imine of 3-methylene-2,2,4,4-tetramethylcyclobutanone (0.9 g) was stirred and refluxed with 50% acetic acid (50 ml). A solid collected in the reflux condenser in a few minutes. This was washed back into the solution and refluxing continued for 1 h. After cooling, the excess acetic acid was destroyed by addition of solid sodium bicarbonate. The mixture was then extracted with ether and the ether layer was washed with water until neutral, dried over anhydrous magnesium sulfate, and evaporated to give an oil. The oil mixture was sublimed at room temperature at 25 mm pressure to give a crystalline material, m.p. 43–44° (lit. 42–43° (3)).

Reaction of 3-Methylene-2,2,4,4-tetramethylcyclobutanone (1) with PPA

A mixture of 500 mg of **1** and 1 g of PPA (1:1 mixture of P_2O_5 and H_3PO_4 aged for 24 h at 100°) was heated at 100° for 1 h in a flask equipped with a condenser. Water (5.0 ml) was added to the cooled mixture and 50 ml of ether was added for extraction. The ether layer was washed neutral with water, dried over anhydrous magnesium sulfate, and the ether evaporated to give an oil which crystallized after scratching. The crystalline mixture was purified by preparative v.p.c. to give a crystalline material (**2**) m.p. 55–56°; i.r.: 1775 cm^{-1} (C=O stretch); n.m.r.: 0.94 (3H, d, J = 7.5 Hz), 1.03 (3H, s), 1.01 (3H, s), 1.22 (3H, s), 1.33 (3H, s), 2.00 p.p.m. (1H, q, J = 7.5 Hz); *m/e* 156, (base peak 42 *m/e*).

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.2; H, 10.3. Found: C, 69.0; H, 10.4.

Hydrogenation of 3-Methylene-2,2,4,4-tetramethylcyclobutanone (1)

Ketone **1** (500 mg) in 10 ml of ethyl acetate and 100 mg of PtO_2 was placed in an atmosphere of hydrogen overnight. The catalyst was filtered off and the ethyl acetate evaporated to give an oil which showed two peaks on v.p.c. in a ratio of 4:1. Both peaks were collected and had the following spectroscopic data. The major peak (**3**) was an oil, i.r.: 3420, 1120, 1065, 1015 (alcohol) cm^{-1}; *m/e*: 142. The minor peak (**4**) also was an oil, i.r.: 1786 cm^{-1} (C=O stretch, cyclobutanone); *m/e*: 140 (10 eV).

Jones Oxidation of the Hydrogenation Products of Ketone 1

The mixture (400 mg) obtained from the hydrogenation of ketone **1** was dissolved in 5.0 ml of acetone. To the cooled (0°) solution was added, dropwise, Jones reagent (7) until the yellow color persisted. Methanol was added dropwise until the yellow color disappeared. The solution was taken up in 50 ml ether, washed with water until neutral, dried over magnesium sulfate, and evaporated to give an oil **4** which had an identical i.r. spectrum with the minor component obtained from the hydrogenation of ketone **1**. The v.p.c. retention times were also identical.

Baeyer–Villiger Oxidation of Ketone 4

A mixture of 300 mg of ketone **4**, 1.0 ml of formic acid, and 0.5 ml of 30% H_2O_2 was stirred for 3 h. To this mixture was added 30 ml of ether. The ether extract was washed with 10% sodium bicarbonate solution and then 10% sodium sulfite solution, dried over anhydrous magnesium sulfate, and evaporated to give 270 mg of an oil which crystallized after scratching. This was further purified by preparative v.p.c. to give a crystalline product **2** m.p. 54–56°, which had identical i.r. and n.m.r. spectra with the material obtained from the acid reaction of ketone **1**, mixed m.p. 54–55°.

Reaction of 2,2,4,4-Tetramethylcyclobutane-1,3-dione (5) with PPA

A mixture of 1.0 g of **5** and 1.0 g of PPA was stirred at 100° for 1 h in a flask equipped with a condenser. Water (3.0 ml) was added to the cooled mixture. This was taken up in 50 ml of ether. The ether extract was washed with water until neutral, dried over anhydrous magnesium sulfate, and evaporated to give 800 mg of an oil which on v.p.c. showed two major peaks and one minor peak (<2% of mixture). The two major peaks were collected. The more polar one proved to be identical with 2,2,4,4-tetramethylcyclobutane-1,3-dione (**5**) by comparison of its i.r. spectrum and v.p.c. retention time. The less polar product showed i.r. and n.m.r. spectra identical with commercial sample of diisopropyl ketone. In a second run the gas evolved in the acid reaction was detected as CO_2 as evidenced by precipitation of $BaCO_3$ from an aqueous solution of barium hydroxide as the gas was passed through.

Reaction of 2,2,4,4-Tetraphenylcyclobutane-1,3-dione (4a) with PPA

The same procedure as for the PPA reaction with ketone **6** was repeated with 500 mg of ketone **6a**. After the usual work-up the starting material was recovered unchanged as shown by t.l.c., i.r., and n.m.r. spectra.

2,2,4-Trimethyl-3-oxovaleric Acid Methyl Ester

Dione **6** (2.0 g) in 10 ml of methanol containing 1.5 g of Na_2CO_3 and 5.0 ml of water was stirred at room temperature for 30 min. The mixture was taken up in 60 ml of ether, washed neutral with water, and evaporated to give 1.7 g of an oil, b.p. 92–93° (25 mm); i.r. 1720 (C=O, ketone), 1750 cm^{-1} (C=O stretch of ester); n.m.r.: 0.93 (6H, d, J = 7 Hz), 1.21 (6H, s), 2.71 (1H, q, J = 7 Hz), 3.55 p.p.m. (3H, s); *m/e*: 172.

2,2,4-Trimethyl-3-oxovaleric Acid (9)

A methanolic solution (5.0 ml) of 1.0 g of the methyl ester of **9** and 300 mg of sodium hydroxide was stirred at room temperature. Ether (25 ml) and water (5.0 ml) were added. The aqueous solution was separated and acidified with concentrated HCl solution. The acidified solution was re-extracted with 30 ml of ether. The ether layer was washed with water until neutral, dried over magnesium sulfate, and

evaporated to give 400 mg of an oil, b.p. 104° at 0.5 mm (lit. 105° at 0.5 mm (8)); i.r.: 3400–3100, 1720 cm^{-1} (carboxylic acid, broad peak): n.m.r.: 10.42 (1H, s, exchangeable with D_2O), 2.90 (1H, q, $J = 7$ Hz), 1.32 (6H, s), 1.03 p.p.m. (6H, d, $J = 7$ Hz).

*Reaction of 2,2,4-Trimethyl-3-oxovaleric Acid (**6**) with PPA*

The acid **6** (300 mg) was treated with PPA (0.5 g) using the identical procedure as described above for ketone **5**. Using the same work-up conditions 200 mg of an oil was obtained whose i.r. and n.m.r. spectra were identical with those of a commercial sample of diisopropyl ketone.

The author would like to thank the National Research Council of Canada for their financial support of this research.

Received November 29, 1971

Canadian Journal of Chemistry, **50**, 955 (1972)

When recalibrating the Stark cell during the determination of the dipole moment of 1,3-dioxane, an error was discovered in the earlier calibration, which had been used in the calculations of the dipole moments of tetrahydropyran (1) and morpholine (2). Correcting this calculation error and using the same experimental data (1, 2) the corrected values are:

	μ_a(D)	μ_c(D)	μ(D)
Tetrahydropyran	1.39(0.02)	0.74(0.02)	1.58(0.03)
Morpholine	1.53(0.01)	0.27(0.01)	1.55(0.02)

The μ values agree well with those measured in benzene solution of 1.55 (3) and 1.52 D(4), respectively.

Also in Table IX of the morpholine publication (2), the transition given as 2_{12}–3_{22} is actually 2_{21}—3_{22}.

Separation of Gas Mixtures by Accommodation Pumping

I. H. DOETSCH AND S. A. RYCE

Department of Chemistry, University of Victoria, Victoria, British Columbia

Received October 5, 1971

Enrichment of helium–argon gas mixtures by accommodation pumping in a 10-stage pump is described. With the warm half of the pump at room temperature, pumping ratios are reported for cold surfaces at 77, 195, and 273 °K.

L'enrichissement de mélanges gazeux hélium–argon, au moyen d'un pompage avec une pompe à 10-temps, est décrit. Avec une chaleur, moitié de celle de la pompe à la température de la pièce, les rapports de pompage sont rapportés pour des surfaces froides à 77, 195, et 273 °K.

Canadian Journal of Chemistry, **50**, 957 (1972)

Introduction

In recent studies Hobson (1–3) described a new development in vacuum pumping termed accommodation pumping, which is operative in the free-molecular and transition flow region. It is postulated by Hobson that the observed pumping action is a consequence of the difference in thermal accommodation between warm gas molecules impinging upon cold surfaces and cold molecules striking warm surfaces.

A typical pump, illustrated in Fig. 1, consists of volumes A and B connected by a U-tube made of Pyrex glass. The arm of the pump connected to B is smooth (untreated), whereas the tubulation adjoining A is "atomically rough" (leached in HCl). The pump contains helium or other gases at sufficiently low pressures such that the mean free path is greater than the internal diameter of the Pyrex U-tube. Typically for 8 mm i.d. of the tube, a suitable helium pressure is 10^{-4} Torr or less. With the assembly at a uniform temperature no pressure difference exists between volumes A and B, *i.e.*, $P_A = P_B$. However, when the U-tube is partially immersed in a cold bath at temperature T_1, a pumping action develops such that $P_A > P_B$. An atomistic interpretation of the phenomenon is that molecules arriving at a rough surface from both warm and cold regions are highly accommodated. On the smooth surfaces of the U-tube, however, collisions of warm molecules with cold surfaces are more likely to result in specular reflection than collisions of cold molecules with warm surfaces (1, 4). Thus in the temperature transition region in the smooth arm of the U-tube, molecules on the average maintain more readily

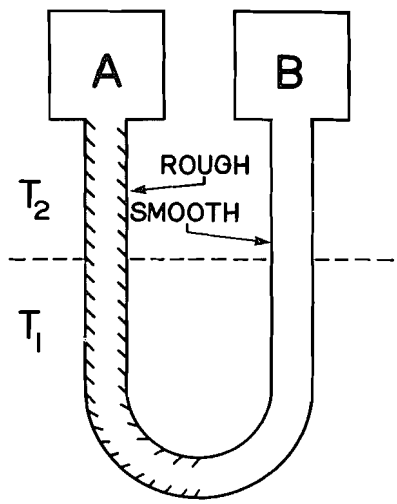

FIG. 1. Schematic of an accommodation pump. If $T_1 < T_2$, then $P_A > P_B$.

their velocity component in the direction leading to volume A. The net result of this action is an increase in the pressure ratio, P_A/P_B, over the value of unity for $T_2 = T_1$.

Following the notation of Hobson we have

$$[1] \qquad P_A/P_B = a^n$$

where a is the pressure- or pump-ratio for a single stage pump as described above, and n is the number of stages in series. Values of pump ratios for the inert gases in Pyrex systems were shown by Hobson to decrease with an increase in molecular weight. They ranged from 1.18 for helium to 1.05 for xenon. With a multistage pump ($n = 28$; $T_1 = 77$ °K; $T_2 = 295$ °K), pressure ratios for He of better than 20:1 were achieved. Hobson drew attention to the fact that accommodation pumps have no moving parts, require no working fluid, apparently have no low pressure limit and thus may have potential application as practical pumping devices.

It has occurred to us that the accommodation pumping principle may have applicability with some unique characteristics for the separation or enrichment of gas mixtures. For a binary mixture the ratio of the partial pressures of components 1 and 2 in volume A relative to that in volume B can be simply related to the individual pumping ratios. From eq. 1 we obtain

$$[2] \qquad (P_{1A}/P_{2A})/(P_{1B}/P_{2B}) = (a_1/a_2)^n$$

where the numerical subscript identifies the component.

If $a_1 = a_2$, no separation occurs. However, when $a_1 > a_2$, an enrichment in component 1 of the composition of volume A should accompany the net rise of pressure in A. Simultaneously volume B should be at a lower total pressure with an enrichment in component 2.

We report results of preliminary studies on the separation of mixtures of helium and argon by accommodation pumping. In qualitative agreement with eq. 2 significant enrichments were obtained.

Pumping ratios were obtained for helium and argon in single and ten-stage pumps at three values of T_1 ranging over about 200°. Pumping action was observed with a temperature difference ($T_2 - T_1$), of as little as 25°, with T_1 at 0 °C. An increase in the pumping efficiency of argon relative to helium was noted with an increase in the value of T_1.

Experimental

The apparatus consisted of a modified version of the system described by Hobson (1). Standard ultra-high vacuum procedures were employed to obtain background pressures of less than 10^{-9} Torr. Pressure measurements were performed with Veeco RG-75 ionization gauges generally operated at 1.0 mA emission current and thoroughly outgassed prior to measurement. Gauge pumping was observed in most cases but was considered to be of negligible influence on the determination of accommodation pumping ratios in the pressure range investigated. The relative sensitivities of the two gauges were obtained with the system at room temperature over the pressure ranges of interest. In all cases measurements were conducted at pressures requiring no correction for background gases.

Research grade helium and argon were employed in all experiments. The pump was immersed halfway in ice, Dry Ice–acetone, or liquid nitrogen, the top half always remaining at room temperature. The actual accommodation pumps consisted of 8 mm i.d. Pyrex (Corning No. 7740) tubing made into a single and a decade stage pump. The atomically rough surfaces (side A) were obtained by leaching in boiling 0.05 *N* HCl for about 100 h (1).

Pumping ratios were obtained individually with helium and argon at three values of T_1, *i.e.*, 77, 195, and 273 °K, both for the single and decade stage pumps.

Mixtures of helium and argon were tested in the decade pump only, for two values of T_1, 77 and 195 °K. Three sample flasks (A, B, and C) were initially attached to the accommodation pump. Flask A was connected to the roughened arm; B and C were attached to the smooth side of the pump. After introduction of the gas mixture into the system, sample flask C was severed from the apparatus by collapsing the connecting tubing with a torch to ascertain the initial composition of the gas mixture. Subsequently, the lower half of the decade pump was immersed in a cold bath to initiate pumping action. One of two procedural variations was followed after attainment of equilibrium. Either samples A and B were removed while the pump was cold or the cold pump was first fused at a raised section in the center loop and the system allowed to attain room temperature before subsequent sample removal. Since argon adsorbs appreciably at liquid nitrogen temperature, only the latter procedure permits the determination of the entire argon composition and allows the final composition of flasks A and B to be related to the initial composition in C.

Mass spectrometric analyses of the contents of the sample flasks were carried out with a Perkin–Elmer Hitachi RMU-7 instrument. Standard break-seal procedure through a common manifold was used to introduce the samples.

Results and Discussion

The general observations reported by Hobson (1) concerning the operation of accommodation pumps have been confirmed.

(a) Single Gas Analysis

Accommodation pumping ratios obtained in this work are shown in Table 1 for helium and argon at three values of T_1. No data have been

10	273	—	<1.01	—	<1.01

previously reported for values of T_1 at other than liquid nitrogen temperatures. It is of interest to note that a measurable pumping effect is observed with a temperature difference $(T_2 - T_1)$ as little as 25 °C for both gases.

A comparison of our multiple stage pumping ratios with those of Hobson (1) is not directly possible due to differences in the number of stages employed. However, if eq. 1 is assumed to be valid, the data can be evaluated in terms of the single stage pumping ratio, a, as shown in Table 2. It appears from these data, that eq. 1 is not, in fact, generally followed and that pumping efficiency probably decreases from some ideal value with an increase in the number of stages.

Hobson (1) has suggested that the pumping ratios of heavier gases might be improved relative to helium for larger values of T_2. Although we have not as yet tested this prediction, we have detected an increase in the pumping efficiency for argon relative to helium as the value of T_1 increases and possibly as the value of n decreases. These results are shown in Table 3. As in the case of Hobson's prediction for a change of T_2, the observed effect in changing T_1 can be interpreted as arising from a relative increase in specular reflections for argon as compared to helium at higher temperatures (5).

TABLE 3. Values of (a^n_{Ar}/a^n_{He})

1	0.89	0.97	~1.00
10	0.70	0.90	0.98

(b) Gas Mixtures

Binary mixtures of helium and argon were analyzed as previously described at total pressures between 10^{-4} and 10^{-2} Torr. This pressure region was chosen as a compromise to the opposing requirements of high precision in the gas analysis and maximum efficiency in accommodation pumping.

In those experiments at liquid nitrogen temperature in which the pump was severed while cold, the actual pumping effect for argon was partially masked by the subsequent desorption of argon from the warmed-up pump surfaces. The two severed halves of the system had nearly identical volumes so that any changes in the argon distribution between the final systems

*Samples A and B removed with pump cold.
†Samples A and B removed with severed pump warm.

would be less likely to result from unequal cold surface-to-volume ratios. As an additional check, the same experiments were conducted at Dry Ice temperature and flasks A and B removed while the pump was cold.

Measurements are recorded in Table 4 as ratios of helium-to-argon uncorrected for the sensitivity of the mass spectrometer for the individual gases. Thus these data are not actual pressure ratios, and have no significance when compared within each column, since the partial and total pressures varied in each experiment. However, it is immediately apparent that the helium-to-argon ratio is greater in the rough arm of the pump than the smooth, as predicted. Sample C falls between the values for A and B (with the exception of the anomaly in trial 4).

The above results demonstrate the ability of accommodation pumps to partially separate gaseous mixtures. More detailed studies of the phenomenon are planned with a residual gas analyzer attached directly to the pump.

The authors gratefully acknowledge financial support of this work by the National Research Council of Canada. Discussions with Dr. J. P. Hobson were very helpful in furthering the project.

Nuclear Recoil Reactions in Organomanganese Compounds. VI. $IMn(CO)_5$ and $BrMn(CO)_5$

I. G. DE JONG AND D. R. WILES

Chemistry Department, Carleton University, Ottawa, Canada

Received July 19, 1971

Radiochemical reactions of ^{82}Br, ^{128}I, and ^{56}Mn have been studied in neutron-irradiated $BrMn(CO)_5$ and $IMn(CO)_5$. The parent compounds were found to contain 49 and 28% of the ^{82}Br and ^{128}I, but only 6 and 10% of the ^{56}Mn, respectively. The dimeric $[XMn(CO)_4]_2$ accounted for 28% of the ^{82}Br, but only about 2% of the ^{56}Mn. Some $^{56}Mn_2(CO)_{10}$ was also found. The radiochemical yields of several products were found to increase substantially on thermal treatment of the target material.

Reaction pathways are suggested which can account for the thermal effects, which involve halogen atom transfer and carbonyl transfer in the solid.

Des réactions radiochimiques de ^{82}Br, ^{128}I, et ^{56}Mn ont été étudiées dans l'irradiation neutronique de $BrMn(CO)_5$ et $IMn(CO)_5$. Les composés parents sont trouvés, contenant respectivement: 49 et 28% de ^{82}Br et ^{128}I, mais seulement 6 et 10% de ^{56}Mn. Le dimère $[XMn(CO)_4]_2$ rend compte pour sa part de 28% de ^{82}Br et seulement d'environ 2% de ^{56}Mn. Un peu de $^{56}Mn_2(CO)_{10}$ est aussi trouvé. Les rendements radiochimiques de plusieurs produits augmentent nettement avec le traitement thermique de matériaux cible.

Des voies de réactions sont suggérées pouvant rendre compte des effets thermiques, qui mettent en oeuvre le transfert atome d'halogène et le transfert carbonyle dans le solide.

Canadian Journal of Chemistry, **50**, 961 (1972)

Introduction

During the course of this study of the chemical behavior of ^{56}Mn atoms following their production by the $^{55}Mn(n,\gamma)$ reaction, we have observed several interesting aspects of the chemistry of isolated atoms and groups in manganese carbonyl compounds. Since the ligands involved have been entirely organic (—H, $—CH_3$, $—C_6H_5$, Cp), it appeared useful to extend our study to include some rather more electronegative ligands.

Recent evidence has led us to suspect (1, 2) that the $\cdot Mn(CO)_5$ radical is formed, or reformed, first and the other ligand is bonded later. Thus the (oversimplified) reaction series would be

$$[1] \quad Mn + CO + L \rightarrow Mn(CO)_5 + L \rightarrow LMn(CO)_5$$

and not

$$[2] \quad Mn + CO + L \rightarrow MnL + CO \rightarrow LMn(CO)_5$$

or

$$[3] \quad Mn + CO + L \rightarrow LMn(CO)_x + CO \rightarrow LMn(CO)_5$$

In particular, it is found for the compounds $LMn(CO)_5$, L = H (or D), CH_3, or C_6H_5, that the yield of radioactive $L^*Mn(CO)_5$ is qualitatively parallel to the readiness of the exchange of $L^*Mn(CO)_5$ with $IMn(CO)_5$ (the prefix asterisk indicates that the atom is radioactive). While no direct connection has been proven, it is highly suggestive of a stage such as $[L + Mn(CO)_5]$ being involved.

By changing the ligand L from the hydrocarbon ligands to a halogen, it seemed that if reaction 2 or 3 were the case, strong differences in the yields ought to result from the change in the ligand.

A further point regarding the choice of ligand is that both iodine and bromine themselves produce radioisotopes on neutron irradiation, so that the chemical behavior of two different elements could be studied in the same molecule. At the outset one can anticipate the exchange reactions of the ligands will be much more probable than those of the central atom. That is, the reaction

$$[4] \quad {}^*I + IMn(CO)_5 \rightarrow {}^*IMn(CO)_5 + I$$

is readily conceivable, while the reaction

$$[5] \quad {}^*Mn + IMn(CO)_5 \rightarrow I{}^*Mn(CO)_5 + Mn$$

seems to be less likely. The question then is whether this does make much of a difference to the yields of radioactive labelled products and if so, whether the effects can be isolated.

Experimental

The general nature of the experiments has been described earlier (3). The various compounds used were prepared as

TABLE 1. Radiochemical yields of ^{128}I, ^{82}Br, and ^{56}Mn in various chemical forms by neutron irradiation (at − 78 °C) of $IMn(CO)_5$ and $BrMn(CO)_5$[a]

Product	Yield (%) for target = $IMn(CO)_5$	Yield (%) for target = $BrMn(CO)_5$
$*XMn(CO)_5$	28.5	49
$X*Mn(CO)_5$	10.3	6.5
$[*XMn(CO)_4]_2$	—	28
$[X*Mn(CO)_4]_2$	1.7	2.0
$Mn_2(CO)_{10}$	3.0	1.9

[a]These data refer to samples given no thermal treatment following neutron irradiation. Chemical processing occurred at room temperature.

follows: (*i*), $IMn(CO)_5$, from $Mn_2(CO)_{10}$ and I_2 (4). (*ii*), $[IMn(CO)_4]_2$ by thermal decomposition of $IMn(CO)_5$ in cyclohexane under reflux (5). (*iii*), $BrMn(CO)_5$ from $Mn_2(CO)_{10}$ and Br_2 in cyclohexane at room temperature (6). (*iv*), $[BrMn(CO)_4]_2$ by thermal decomposition of $BrMn(CO)_5$ in refluxing hexane. (*v*), Purification was done by sublimation *in vacuo* and in the case of the pentacarbonyls also by silica gel chromatography. All synthetic work was performed in the dark, in nitrogen. Purity was checked using the infrared spectra taken on a Perkin–Elmer 237B.

Separation of the carrier species ($XMn(CO)_5$, $[XMn(CO)_4]_2$, and $Mn_2(CO)_{10}$) was effected using a combination of differential leaching and chromatography on silica gel and alumina columns. The dimeric species are markedly less soluble, so that the other compounds can be easily leached out into cold petroleum ether. Following this step, further purification is readily achieved by column chromatography. The remaining dimeric $[IMn(CO)_4]_2$ was chromatographed on silica gel using 5% $CHCl_3$ in petroleum ether. The dimeric $[BrMn(CO)_4]_2$ was not easily chromatographed, and was purified by fractional sublimation *in vacuo*, first at 55 °C to remove $BrMn(CO)_5$ and $Mn_2(CO)_{10}$ and then at 115 °C to sublime the $[BrMn(CO)_4]_2$.

Radioactivity measurements on the samples were made on the 847 keV γ of ^{56}Mn, the 445 keV γ of ^{128}I, and the 554 keV and 777 keV γ-rays of ^{82}Br. The statistical uncertainty in the data is estimated to be less than 5% of the reported value, except for $Mn_2(CO)_{10}$, which is 10%.

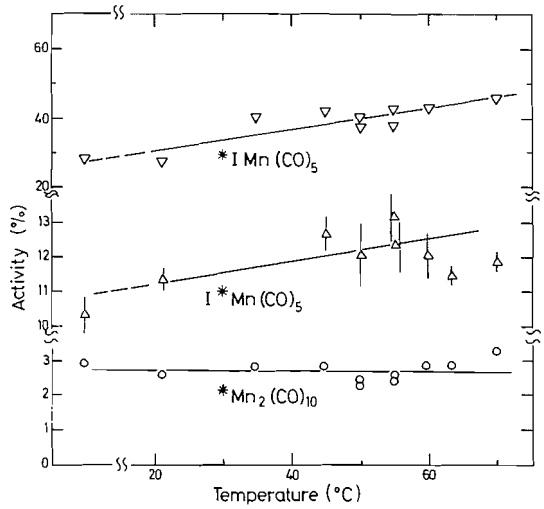

FIG. 1. Thermal annealing data for solid $IMn(CO)_5$ targets. Neutron irradiation at − 78 °C. Thermal treatment was for 6.0 min in all cases.

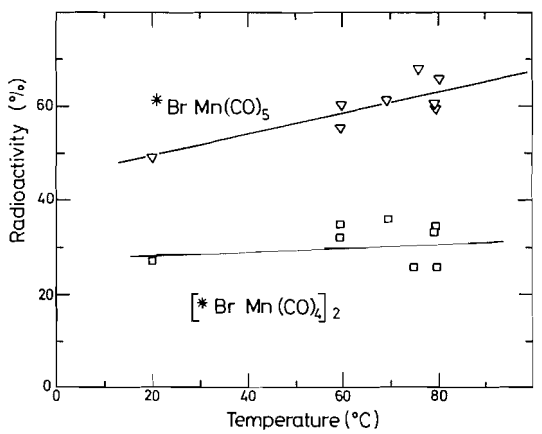

FIG. 2. Thermal annealing data for ^{82}Br containing products from solid $BrMn(CO)_5$ targets. Thermal treatment was for 6.0 min in all cases.

Results and Discussion

The results obtained from samples given no thermal treatment are given in Table 1, where the bromine data refer to 35.9 h ^{82}Br. Unfortunately we were unable to effect satisfactory separation quickly enough to get values for the 18-min ^{80}Br. For similar reasons some of the data for 25-min ^{128}I are less precise than those for the 2.58 h ^{56}Mn.

It is apparent from the data of Table 1 that in each case the yield of the radioactive halogen is greater than that of the radiomanganese in the same product compound. The yields in the dimeric compounds are considerably lower than those in the monomers, as perhaps might be expected, since the target matrix is that of the monomer.

The effect of thermal annealing on the radiochemical yields is shown in Fig. 1 for $IMn(CO)_5$ and in Figs. 2 and 3 for ^{82}Br and ^{56}Mn, respectively, in $BrMn(CO)_5$. From these figures it is evident that the various bromine- or iodine-containing products show largely parallel behavior with respect to the annealing temperature, and that different product compounds from the same target are not similar. We see

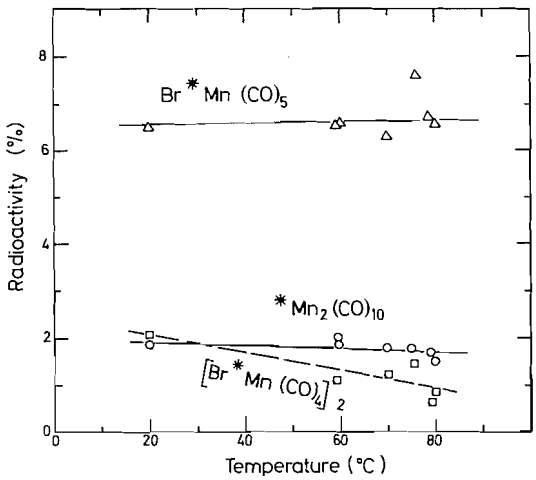

FIG. 3. Thermal annealing data for ^{56}Mn-containing products from solid $BrMn(CO)_5$ targets. Thermal treatment was for 6.0 min in all cases.

that (*a*) $*XMn(CO)_5$ shows a strong increase in yield; (*b*) $I*Mn(CO)_5$ has a much weaker increase while $Br*Mn(CO)_5$ remains unchanged; (*c*) $*Mn_2(CO)_{10}$ shows practically no effect; (*d*) $[*BrMn(CO)_4]_2$ seems to increase somewhat; (*e*) $[X*Mn(CO)_4]_2$ decreases.

Recent work by Groening and Harbottle (7) showing a distinctly stepwise increase of the retention in $Mo(CO)_6$ emphasizes that it is not safe to regard the *apparently linear* behavior shown in these figures as anything more precise than an *average trend.* To the extent that the straight lines may be valid representations of the data, the parameters of these lines are given in Table 2. Here again it is emphasized that the various product compounds have different thermal properties. This is evident in the values of α and of α/Y_{20}, which give the absolute and the relative temperature effects, respectively. In order to interpret the data, we make the *postulate* that, during the 6-min thermal treatment, only the one last ligand necessary to give a recoverable product is added by solid state reaction.

$*Mn_2CO_{10}$

The only exchange reactions which could reasonably give $*Mn_2CO_{10}$ are reactions of $*Mn(CO)_5$ with $XMn(CO)_5$ or with Mn_2CO_{10}.

$$\left.\begin{matrix}[6a]\ XMn(CO)_5 \\ [6b]\ Mn_2(CO)_{10}\end{matrix}\right\} + *Mn(CO)_5 \rightarrow *Mn_2(CO)_{10} + \begin{cases}\cdot X \\ \cdot Mn(CO)_5\end{cases}$$

TABLE 2. Parameters for the equation $Y_T = Y_{20} + \alpha\tau$, where Y_T is the radiochemical yield at temperature $T(°C) = 20 + \tau$

Target	Product	α	α/Y_{20}
$IMn(CO)_5$	$*IMn(CO)_5$	0.3	10×10^{-3}
	$I*Mn(CO)_5$	0.03	3×10^{-3}
	$[I*Mn(CO)_4]_2$	[a]	
	$Mn_2(CO)_{10}$	~0.000	~0
$BrMn(CO)_5$	$*BrMn(CO)_5$	0.24	5×10^{-3}
	$Br*Mn(CO)_5$	~0	~0
	$[*BrMn(CO)_4]_2$	0.04	1.5×10^{-3}
	$[Br*Mn(CO)_4]_2$	−0.02	-17×10^{-3}
	$Mn_2(CO)_{10}$	~0	~0

[a]This compound is distinctly non linear in its temperature dependence, and falls to about 0.6% in the vicinity of 60°.

These reactions have both been found earlier (1) not to occur in solution to a detectable extent during the short time of the experiment, and thus need not be considered further. As to solid state reactions, the data show that none occurs between 20 and 80 °C, since the yield of $*Mn_2(CO)_{10}$ is unchanged on heating. The same result was found on neutron irradiation of $Mn_2(CO)_{10}$. Since it has been shown (3) that reaction 6*b* does not occur at temperatures up to 60 °C, we feel it unlikely that reaction 6*a* plays a part. We conclude thus, that the observed $*Mn_2(CO)_{10}$ is formed by a very early epithermal (or prethermal) reaction.

$X*Mn(CO)_5$

For these species we must find a mechanism which distinguishes the different behaviors of the bromine and iodine compounds. The exchange reaction

$$[7]\quad *Mn(CO)_5 + XMn(CO)_5 \rightleftarrows X*Mn(CO)_5 + \cdot Mn(CO)_5$$

has been shown to occur rapidly for the iodine compound in petroleum ether solution, and presumably must also be rapid for X = Br. Thus, whether the species in the solid is $*Mn(CO)_5$ or $X*Mn(CO)_5$ could not be distinguished by the present data. Thus reaction 7, although possible, does not account for our data. The only other reaction consistent with the $I*Mn(CO)_5$ data is the transfer of a CO group in the solid compound

$$[8]\quad I*Mn(CO)_4 + IMn(CO)_5 \rightarrow I*Mn(CO)_5 + IMn(CO)_4$$

The existence of a $*Mn(CO)_4$ group in the solid state might also account for the data, through a reaction analogous to [8] followed then by

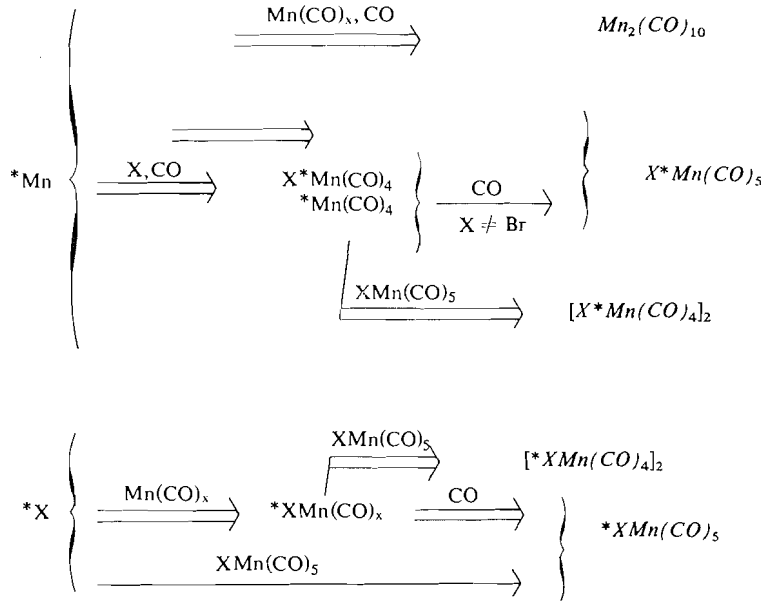

SCHEME 1. Schematic representation of possible reaction paths, both thermal and prethermal, to account for the observed radiochemical yields. ⇒ indicates a prethermal reaction, too fast to be observed, → indicates a reaction occurring during the annealing. Species in italics are the final observed *products*.

reaction 7. Participation of $*Mn(CO)_5$, as this last would suggest, is supported by the slight decrease in the yield of $I*Mn(CO)_5$ at $T \lesssim 60$, the temperature at which $\cdot Mn(CO)_5$ was found to decompose in crystalline $Mn_2(CO)_{10}$.

It seems, then, that the most likely route for formation of $I*Mn(CO)_5$ is through $I*Mn(CO)_4$ (or $*Mn(CO)_4$) formed epithermally and converted through reaction 8 (and reaction 7) to the final product. It is evident from the data for unannealed samples that a considerable amount of $X*Mn(CO)_5$ is formed prior to any heating, presumably by epithermal reactions.

In seeking an explanation for the absence of an annealing effect on $Br*Mn(CO)_5$ we can exclude differences in the lability of CO between the two compounds. While no direct information seems to be available on solid state exchanges, the indications from solution reactions (8) point to a greater CO lability in $BrMn(CO)_5$ than in $IMn(CO)_5$, while the data require quite the reverse. The remaining possibility is that the hypothetical starting compound for the annealing reaction 8, $BrMn(CO)_4$, is unstable even at room temperature so that either reaction 8 goes to completion very early or the $BrMn(CO)_4$ must decompose on being heated. The $Br*Mn(CO)_5$ which is found must then have been formed at a stage prior to the annealing.

*XMn(CO)$_5$

The bromine and iodine compounds behave in a qualitatively very similar manner in producing $*XMn(CO)_5$. One sees from Table 2 that the α values do not differ significantly, and that the values of α/Y_{20} are also similar. It is clear, then, that if reaction 8 is correctly applied to $X*Mn(CO)_5$, and the explanation regarding $Br*Mn(CO)_5$ is valid, this reaction path cannot be used to explain the data for $*XMn(CO)_5$.

The most reasonable reaction to be invoked is the exchange

$$[9] \qquad *X + XMn(CO)_5 \rightarrow *XMn(CO)_5 + X$$

which is able to account fully for the solid state reaction, in which the yields of both $*IMn(CO)_5$ and $*BrMn(CO)_5$ increase markedly during the annealing. It is apparent that if this same reaction were to occur rapidly in solution, then the final yield values would not be temperature dependent, since the two reactions would be indistinguishable. That reaction 9 evidently does not occur in solution may be due to rapid scavenging of the halogen atom, or to slowness

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the exchange in solution; we have not investigated these possibilities further.

$[*XMn(CO)_4]_2$ and $[X*Mn(CO)_4]_2$

Little can be said about these two compounds except to point out their occurrence as radioactive species. The fact that the radiochemical yield of $[Br*Mn(CO)_4]_2$ decreases during annealing while that of $[*BrMn(CO)_4]_2$ increases suggests the intervention of one or more intermediate species about which we have no further information. That the yield of the bromine-labelled dimer is an order of magnitude greater than that of the ^{56}Mn-labelled dimer points to different mechanisms of formation for the two. The fact that also the yields of the ^{82}Br- and ^{56}Mn-labelled monomers are in roughly the same ratio as of the dimer suggests that the developments may be parallel, following a different initial reaction. It seems reasonable to speculate that the precursor might be $XMn(CO)_x$ whose formation with *X is expected to be much more favorable than with *Mn. Following this, the reactions can be either CO transfer as in reaction 8 or dimerization.

Summary

In summary, it seems possible that the initial formation of $X*Mn(CO)_5$ and $*XMn(CO)_5$ may perhaps proceed through pathways similar to those in $RMn(CO)_5$. The effect of thermal treatment can only be explained through different reactions: addition of CO to $X*Mn(CO)_4$ to give $X*Mn(CO)_5$ and exchange of uncombined *X with the matrix to give $*XMn(CO)_5$.

We conclude that the formation of the observed radioactive products is consistent with the reactions shown schematically in Scheme 1.

We express our gratitude to the National Research Council of Canada for financial support, and to Atomic Energy of Canada, Limited, for providing neutron irradiation facilities.

Determination of Conditions for the Suppression of $CH_3 + Sb(CH_3)_2 \rightarrow Sb(CH_3)_3$ and Evaluation of $D[(CH_3)_2Sb—CH_3]$

S. J. W. PRICE AND J. P. RICHARD

Chemistry Department, University of Windsor, Windsor 11, Ontario

Received October 25, 1971

The pyrolysis of trimethylantimony has been studied in a toluene carrier flow system over the temperature range 690–803 °K (total pressures 3.6–173.4 mm, contact times 1.0–13.5 s, decomposition 3.9–89.5%). The progress of the reaction was followed by measuring the amount of methane, ethane, and ethylbenzene formed. In 23 runs the undecomposed alkyl was also determined. The quantity found was in agreement with that expected from the product analysis if three methyl radicals are released for each molecule undergoing reaction. No heterogeneous reaction was detected.

Deuterium labeling led to the conclusion that regeneration of the parent alkyl occurred during the course of the decomposition. This regeneration reaction was effectively eliminated by working at toluene pressures above 150 mm. Least squares analysis of the results obtained under conditions where regeneration should not be important given

$$\log_{10} k/s^{-1} = 15.33 - (55\,900 \pm 1\,000)/2.3RT$$

The activation energy should be a good approximation to $D[(CH_3)_2Sb—CH_3]$.

Significant decomposition of $SbCH_3$ probably does not occur. It seems most likely that free Sb is formed via $2Sb(CH_3) \rightarrow Sb(CH_3)_2 + Sb$.

La pyrolyse du triméthylantimoine a été étudiée dans un système courant porteur de toluène sur la gamme de température de 690–803 °K (pressions totales 3.6–173.4 mm, temps de contact 1.0–13.5 s, décomposition 3.9–89.5%). La progression de la réaction est suivie en mesurant la quantité de méthane, d'éthane et d'éthylbenzène formée. Dans 23 essais, le produit alkylé non décomposé a été également déterminé. La quantité trouvée était en accord avec celle attendue à partir de l'analyse du produit dans le cas où les trois radicaux méthyle sont libérés pour chaque molécule qui subit des changements. Aucune réaction hétérogène n'a été détectée.

Le marquage au deutérium amène à la conclusion que la regénération du groupe alkyle d'origine se produit durant le temps de la décomposition. Cette réaction de regénération a été complètement éliminé en travaillant à des pressions de toluène supérieures à 150 mm. L'analyse des résultats par la méthode des moindres carrés dans des conditions où la regénération ne serait pas importante, a donné:

$$\log_{10} k/s^{-1} = 15.33 - (55\,900 \pm 1\,000)/2.3RT$$

L'énergie d'activation serait une bonne approximation à $D[(CH_3)_2Sb—CH_3]$.

Une décomposition notable de $SbCH_3$ ne se produit probablement pas.

Il semble beaucoup plus vraisemblable que l'antimoine libre se forme par la réaction $2Sb(CH_3) \rightarrow Sb(CH_3)_2 + Sb$.

Canadian Journal of Chemistry, **50**, 966 (1972)

Introduction

The pyrolysis of trimethylantimony has been previously studied in a toluene carrier flow system by Price and Trotman-Dickenson (1). The reaction was homogeneous but otherwise was not simple. The yields of methane and ethane fell far below the amount that would be expected if each alkyl molecule undergoing reaction released three methyl radicals. Furthermore, the overall rate constant, based on either volatile product analysis or antimony recovery from the reaction vessel, increased as the initial concentration of the alkyl decreased. At an initial concentration of 8×10^{-9} mol/cc they report

$$\log_{10} k/s^{-1} = 15.2 - 57\,000/2.3RT$$

based on metal recovery.

Previous work in this laboratory has shown that in similar studies ethylbenzene is always a significant product (2–5). The present work was undertaken to determine if inclusion of ethylbenzene in the product analysis would lead to a material balance or whether it would still be necessary to postulate formation of a polymer of the type $(SbCH_3)_n$. It was also hoped to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

establish whether or not the fractional order behavior was due to regeneration of the parent alkyl and if so to try to find conditions such that the initial decomposition step could be isolated.

Experimental

Materials

(*a*) Dimethylmercury was taken from a stock prepared from mercuric chloride and methyl magnesium iodide (6–8). It had been stored under its own vapor pressure at room temperature. Vapor pressure measurements gave $\log_{10} P/\text{mm} = 7.61 - 1728/T$ (20 to 40 °C) in agreement with previous results (9, 10). The Raman spectrum was checked using a Spectra-Physics model 700 Raman Spectrometer equipped with a He–Ne gas laser. The following spectrum was obtained: 514(s), 1181(s), 2912(s), 2990(w) cm^{-1} in agreement with previously reported spectra (11, 12).

(*b*) Dimethylmercury-d_6 was prepared and stored in the same way (CD_3MgI used). Vapor pressure $\log_{10} P/\text{mm} = 6.97 - 1509/T$ (0 to 45 °C). Raman spectrum 472(s), 908(s), 2110(s), 2222(w) cm^{-1} in agreement with a previous study (11). An n.m.r. spectrum was taken using a Jeolco C60HL with TMS as external standard. No signals were obtained indicating that no significant amounts of undeuterated or partially deuterated alkyl were present.

(*c*) Trimethylantimony was prepared by heating antimony powder, dimethylmercury, and a trace of mercuric chloride in a sealed tube at 150 °C for at least 60 h (13). The product was separated by fractional distillation in an inert atmosphere. Vapor pressure $\log_{10} P/\text{mm} = 7.72 - 1696/T$ (8 to 40 °C) in agreement with reported values (1, 13–15). Raman spectrum: 188(s), 513(s), 1194(w), 1210(s), 2905(s), 2987(w) cm^{-1} in agreement with reported spectra (16). Nuclear magnetic resonance spectra (TMS as external reference): singlet at 1.3×10^{-6}.

(*d*) Trimethylantimony-d_9 was prepared ($Hg(CD_3)_2$ used) and purified in the same way as the undeuterated alkyl. Vapor pressure $\log_{10} P/\text{mm} = 7.61 - 1651/T$ (8 to 40 °C). Raman spectrum: 159 (s), 472 (s), 925(s), 942(w), 2112(s), 2239(w) cm^{-1}. As in the case of $Hg(CD_3)_2$, no n.m.r. signal was observed.

(*e*) Toluene from sulfonic acid (Eastman Organic X325) was used. Gas chromatographic analysis detected traces of xylenes and ethylbenzene. These were reduced to less than 40 p.p.m. by a fractional distillation in which a large tail fraction was discarded. The toluene was refluxed over sodium for 24 h and then degassed by bulb-to-bulb distillation.

Apparatus and Procedure

The experiments were carried out in a system similar to that used in previous work (17). The reaction vessel had a volume of 135 cc. To test for surface effects a vessel was packed with small quartz tubes. This vessel had a volume of 101 cc and a surface-to-volume ratio 20 times that of the unpacked vessel. Both vessels were treated with hot concentrated nitric acid before use. The residual acid was baked out under vacuum after the vessels were installed in the reaction system.

The gaseous products were analyzed using a Perkin–Elmer model 154 gas chromatograph equipped with a 1/4 in. × 6 ft silica gel column. The column was maintained at 80 °C, and a helium flow rate of 20 cm^3 per min was used.

The liquid products which condensed along with the toluene in an acetone – Dry Ice trap were analyzed using a Perkin–Elmer model 800 gas chromatograph equipped with a 150 ft × 0.02 in. i.d. Golay column coated with poly(propylene glycol). (Isothermal operation at 60 °C, flow rate 10 cm^3 per min.)

The mass spectrometric analyses were carried out using an AEI MS10 c2 mass spectrometer. Samples were handled in a conventional vacuum system and were admitted to the mass spectrometer through a porous leak. Gaseous products could be analyzed as obtained. In order to analyze the toluene solution collected in a trap at the outlet of the furnace for the extent of deuteration of the alkyls the solution was fractionally distilled and the first few drops used for mass spectral analysis. The yields were based on the most abundant isotopes of Sb and Hg, 121 and 202, respectively. Parent peaks were used with suitable correction for isotopic interferences (particularly from Hg199). As required analyses were carried out for $Sb(CH_3)_3$, $Sb(CH_3)_2CD_3$, $Sb(CD_3)_2CH_3$, $Sb(CD_3)_3$, $Hg(CH_3)_3$, $HgCH_3CD_3$, and $Hg(CD_3)_2$ at $m/e = 166$, 169, 172, 175, 232, 235, and 238, respectively.

Analysis of a grey deposit found at the outlet of the reaction zone for antimony was carried out by dissolving the deposit in hot concentrated HCl/Br_2. The resulting solution was treated with a saturated Na_2SO_3 solution to reduce the antimony and was then analyzed by titration with bromate (18).

Results and Discussion

The results obtained with $P > 150$ mm along with a few illustrative runs at 17 mm are given in Table 1. Pertinent features of these runs plus a large number of other runs at approximately 17, 30, 47, and 97 mm are given in Table 2 and Fig. 1. The results may be discussed in terms of the following mechanism:

$$[1] \quad Sb(CH_3)_3 \rightarrow Sb(CH_3)_2 + CH_3$$

$$[2] \quad Sb(CH_3)_2 \rightarrow SbCH_3 + CH_3$$

$$[3] \quad 2SbCH_3 \rightarrow Sb(CH_3)_2 + Sb$$

$$[4] \quad CH_3 + C_6H_5CH_3 \rightarrow C_6H_5CH_2 + CH_4$$

$$[5] \quad 2CH_3 \rightarrow C_2H_6$$

$$[6] \quad CH_3 + C_6H_5CH_2 \rightarrow C_6H_5CH_2CH_3$$

$$[7] \quad 2C_6H_5CH_2 \rightarrow (C_6H_5CH_2)_2$$

plus other minor processes characteristic of toluene carrier work (10). Very slight traces of ethylene were found in a few runs.

The runs at 17 mm in Table 1 were done under conditions similar to those used in the original toluene carrier study (1). In that study it was assumed that only negligible amounts of ethylbenzene were formed. This assumption was obviously incorrect.

*A, reaction vessel volume 156 cc; P, runs in packed vessel.

In the present work rate coefficients were calculated from the usual first order equation

$$k = \frac{2.303}{t_c} \log\left(\frac{1}{1-x}\right)$$

The fraction decomposed, x, may be calculated in two ways.

(*i*) From product analysis

$$x = \frac{\text{moles}(CH_4 + C_6H_5C_2H_5) + 2(\text{moles}\,C_2H_6)}{3(\text{moles}\,Sb(CH_3)_3\,\text{used})}$$

(*ii*) From alkyl recovery

$$x = \frac{g_{\text{alkyl used}} - g_{\text{alkyl recovered}}}{g_{\text{alkyl used}}}$$

The values of x calculated by these two methods for 23 runs are compared in Table 2. The basic agreement indicates that inclusion of reaction 6 in the mechanism resolves the discrepancy in the values of k_g and k_m reported in the original study (1). It is therefore not necessary to postulate the formation of a polymer of the type $(SbCH_3)_n$.

TABLE 2. Percent decomposition by product analysis and alkyl recovery

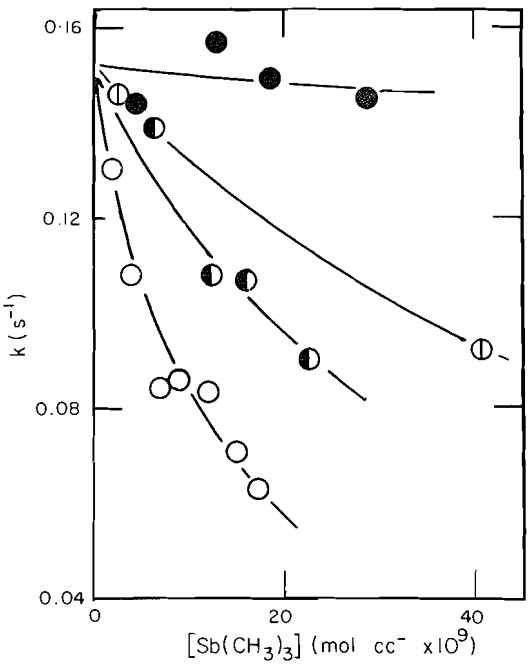

FIG. 1. Effect of alkyl concentration and toluene pressure on the first-order rate constant for the decomposition of $Sb(CH_3)_3$. The runs used were carried out between 753.0 and 755.9 °K. All points shown have been corrected to 755 °K. ○, 17 mm; ◐, 48 mm; ⦶, 97 mm; ●, 160 mm.

Even with a material balance a major problem still exists. The set of runs shown in Fig. 1 performed at 17 mm and 755 °K shows a dependence of k on the alkyl concentration similar to that determined by the previous workers (1). The dependence obviously diminishes as the toluene pressure is increased and in fact appears to be essentially negligible at 160 mm.

The observed concentration effect may be attributed to reaction −1 and possibly reaction 8. This may be seen by

$$[-1] \quad Sb(CH_3)_2 + CH_3 \rightarrow Sb(CH_3)_3$$

$$[8] \quad 2Sb(CH_3)_2 \rightarrow Sb(CH_3)_3 + SbCH_3$$

considering the results of a number of runs carried out using mixtures of either $Sb(CH_3)_3$ and $Sb(CD_3)_3$ or $Sb(CH_3)_3$ and $Hg(CD_3)_2$. These runs were carried out in total darkness as it was determined that methyl group exchange occurred at room temperature in the presence of light.

When $Sb(CH_3)_3$–$Sb(CD_3)_3$ mixtures were pyrolyzed at 17–20 mm toluene pressure extensive group exchange was observed as shown by the appearance of major peaks at $m/e = 169$ and 172 in the mass spectrum of the products. When $Sb(CH_3)_3$–$Hg(CD_3)_2$ mixtures were used (under the conditions used these two alkyls decompose at comparable rates) peaks appeared at 169, 172, and 175 with the major new peak being that at 169. As expected the lifetime of $HgCD_3$ was too short to allow time for formation of any measurable quantity of $HgCH_3CD_3$. It is therefore also highly unlikely that $HgCD_3$ will have time to react with $Sb(CH_3)_2$. The regeneration procedure in this mixture which leads to $Sb(CH_3)_2CD_3$ must then be $Sb(CH_3)_2 + CD_3 \rightarrow Sb(CH_3)_2CD_3$.

It was not possible to make quantitative comparisons between the $Sb(CH_3)_3$–$Sb(CD_3)_3$ and the $Sb(CH_3)_3$–$Hg(CD_3)_2$ systems. The extent of CD_3 group exchange in the latter system suggests that reaction −1 must be a major process in regeneration of alkyl in the $Sb(CH_3)_3$ pyrolysis. However, a significant contribution from reaction 8 cannot be ruled out.

When the toluene pressure was increased to 160 mm no mixing could be detected. This is in agreement with the essentially first order behavior shown at this pressure in Fig. 1 and with the results of the three runs at approximately 736 °K and 170 mm shown in Table 1.

The fact that the curves in Fig. 1 all extrapolate to approximately the same rate constant indicates that at least to a large extent the previously reported pressure dependence (1) was really just an observation of the decreasing extent of alkyl regeneration with increasing toluene pressure. In considering the magnitude of the effect of toluene concentration it should be remembered that in addition to reducing the CH_3 concentration by enhancing reaction 4, increasing the toluene pressure from 17 to 160 mm should increase k_2 by almost a factor of 3 (3). The toluene will also act as a third body in reaction 5 but this will be of less importance.

Basically then it is expected that the results obtained at 151–173 mm (Table 1) should have been obtained under conditions such that each $Sb(CH_3)_3$ undergoing reaction 1 releases three methyl radicals by a sequence of reactions in which the release of the first CH_3 is rate controlling and that under the conditions used no significant regeneration of alkyl will have occurred. The Arrhenius plot of results obtained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

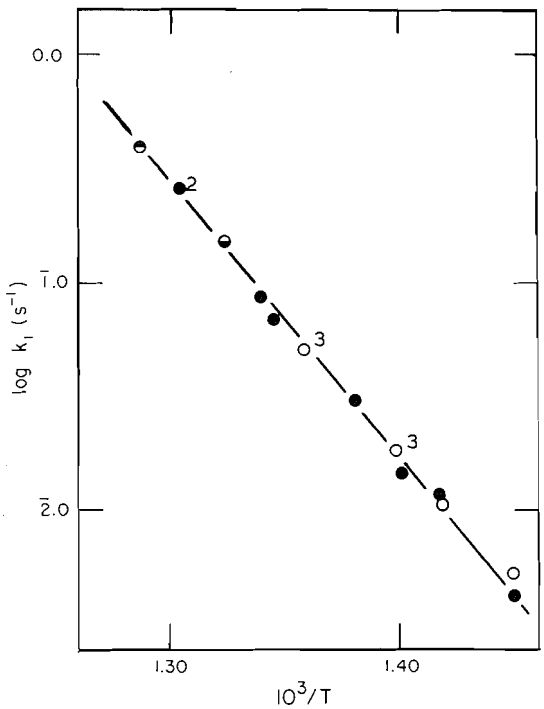

FIG. 2. Arrhenius plot of k_1 (toluene pressure >150 mm). ○, unpacked vessel; ●, packed vessel; ◒, zero concentration value from Fig. 1; ◓, zero concentration value at 776 °K obtained from extrapolation similar to that in Fig. 1 using results at 17, 29, and 48 mm with concentrations from 1.9–32 × 10^{-9} mol cc^{-1}.

under these conditions is shown in Fig. 2. The agreement between the experiments in the packed and unpacked vessel indicate that no detectable heterogeneous reaction is occurring Least squares analysis gives

$$\log_{10} k_1/s^{-1} = 15.33 - (55\,900 \pm 1\,000)/2.3RT$$

The observed activation energy should be a good approximation to $D[(CH_3)_2Sb—CH_3]$.

From ΔH^0_{f298} ($Sb(CH_3)_3$, g) = 1.4 kcal mol^{-1} (13), ΔH^0_{f298} (CH_3) = 33.2 kcal mol^{-1} (19) and ΔH^0_{f298} (Sb, g) = 62.7 kcal mol^{-1} (19) the sum

[3*a*] $$SbCH_3 \rightarrow Sb + CH_3$$

of the dissociation energies of reactions 1, 2, and 3*a* should be 160.9 kcal at 298 °K or approximately 158 kcal at 0 °K. Allowing a combined pressure dependence of E_2 and E_{3a} of 4 kcal then gives $E_2 + E_{3a} = 98$ kcal mol^{-1}.

At the temperatures and pressures used the A factor for reaction 2 should have a maximum value of about 10^{15}. If decomposition occurs via reactions 1, 2, and 3*a*, bearing in mind that three methyl radicals are obtained for each molecule undergoing reaction 1, then k_1 must be significantly smaller than k_2 and k_{3a}. Taking the rather conservative estimate that $2k_1 = k_2 = k_3$ leads to what should be considered a maximum value of $E_2 = 54$ kcal mol^{-1}. This then requires that $E_{3a} \geqslant 44$ kcal mol^{-1} and therefore the minimum value of A_3 would have to be $10^{12.1}$ s^{-1}, a value which is probably at least a factor of 10 too high (5).

The material balance indicated by the results in Table 2 rules out the formation of any major products other than CH_4, C_2H_6, $C_6H_5C_2H_5$, and Sb. However, further tests were made to see if any antimony containing compounds other than the parent alkyl could be detected. Negative results were obtained from both flame and electron capture gas chromatography. The only involatile products observed were dibenzyl and a grey deposit at the outlet of the furnace which on analysis showed 96.4% antimony. This deposit was built up over a number of runs and may have been subject to limited oxidation. However, the possibility that small amounts of $(SbCH_3)_n$ may have been present cannot be ruled out.

In conclusion it seems highly unlikely that reaction 3*a* occurs to any appreciable extent. The main steps in the decomposition of $Sb(CH_3)_3$ should be adequately represented by reactions 1, −1, 2, 3, and 8 with reactions −1 and 8 effectively suppressed at the temperatures and alkyl concentrations used in the present work when $P_{toluene} > \sim 150$ mm.

The Kinetics of the Insertion Reaction of Tin(II) Chloride with a Mono-substituted Derivative of Cyclopentadienyliron Dicarbonyl Dimer

P. F. BARRETT AND W. J. JACOBS
Department of Chemistry, Trent University, Peterborough, Ontario

Received October 18, 1971

The kinetics of the thermal insertion reaction of $SnCl_2$ with the metal–metal bonded complex $(\pi\text{-}C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$ have been studied by following the change in the visible spectrum in THF over the temperature range 40.0 to 55.0 °C. The data are consistent with a two-stage mechanism involving the formation of an intermediate in which the iron–iron bond has been broken but the carbonyl bridges are left intact. From the activation enthalpy of 23.4 ± 0.5 kcal/mol for the formation of the intermediate it is concluded that the triphenyl phosphite has brought about a weakening of the iron–iron bond.

Les cinétiques de la réaction thermique d'insertion de $SnCl_2$ avec le complexe à liaison métal–métal $(\pi\text{-}C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$ ont été étudiés en suivant la variation dans le spectre visible, dans le THF sur un intervalle de température de 40.0 à 55.0 °C.

Les résultats sont compatibles avec un méchanisme en deux étapes comprenant la formation d'un intermédiaire dans lequel la liaison fer–fer a été cassé mais les ponts carbonyls sont gardés intact.

De l'enthalpie d'activation de 23.4 ± 0.5 kcal/mol pour la formation de l'intermédiaire on conclut que le triphényl phosphite occasionne l'affaiblissement de la liaison fer–fer.

Canadian Journal of Chemistry, **50**, 972 (1972)

Introduction

The kinetics of the insertion reaction of tin(II) halides into the metal–metal bond of $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ has recently been reported and the data interpreted in a way to give an estimate of the iron–iron bond strength of 32 kcal/mol (1). Haines and du Preez (2, 3) have prepared a number of tertiary phosphine and phosphite mono-substituted derivatives of $[\pi\text{-}C_5H_5Fe(CO)_2]_2$. The triphenyl phosphite complex, $(\pi\text{-}C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$, was proposed to exist in solution as a mixture of *cis* and *trans* isomers containing two carbonyl bridges each but exchanging via a non-carbonyl bridged species analogous to the exchange proposed for the unsubstituted $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ (4 and references therein). It was also found that tin(II) chloride reacted readily with the triphenyl phosphite derivative to produce $\pi\text{-}C_5H_5Fe(CO)_2Sn(Cl)_2Fe(CO)P(OC_6H_5)_3\pi\text{-}C_5H_5$ as the major product in which insertion of the tin(II) chloride has occurred (2).

We have begun in this laboratory a series of kinetic studies in an attempt to determine the effect of substituents on the strength of metal–metal bonds and in this paper report the kinetic investigation of the thermal insertion of $SnCl_2$ into the iron–iron bond of tricarbonyl(triphenylphosphite)di-π-cyclopentadienyldiiron, $(\pi\text{-}C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$.

Experimental and Results

Materials

Tricarbonyl(triphenylphosphite)di-π-cyclopentadienyldiiron, $(\pi\text{-}C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$, was prepared by the method of Haines and du Preez (3). Anhydrous tin(II) chloride and bromide were prepared as reported earlier (1). Tetrahydrofuran was purified by refluxing over sodium wire, and was freshly distilled and degassed by repeated freezing and thawing on a vacuum line before being used in the kinetic runs.

Reactions of Tin(II) Chloride with $(\pi\text{-}C_5H_5)_2Fe(CO)_3P(OC_6H_5)_3$

Haines and du Preez have pointed out that tin(II) chloride reacts readily with $(\pi\text{-}C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$ to produce the insertion product as well as other products including $[\pi\text{-}C_5H_5Fe(CO)_2]_2SnCl_2$ (2). We have confirmed these findings and have also shown two other possible reaction products to be $\pi\text{-}C_5H_5Fe(CO)_2SnCl_3$ and $\pi\text{-}C_5H_5Fe(CO)P(OC_6H_5)_3SnCl_3$. The former complex was identified from its properties quoted in the literature (5, 6). The ratio of the various products formed was highly sensitive to the degree of exposure of the reaction mixture to air. If only moderate care was taken to exclude air with nitrogen the products were almost exclusively a 50–50 mixture of the two —$SnCl_3$ species. With careful exclusion of air the product was mainly the insertion product with small amounts of $\pi\text{-}C_5H_5Fe(CO)P(OC_6H_5)_3SnCl_3$ and the unsubstituted insertion product $[\pi\text{-}C_5H_5Fe(CO)_2]_2SnCl_2$. Similar results were observed using $SnBr_2$.

To obtain the maximum yield of the insertion product, 50 ml of THF were refluxed under nitrogen for about 30 min to eliminate air. The degassed solvent was transferred to a second flask containing 0.5 g $(\pi\text{-}C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$ and 0.22 g $SnCl_2$ also under nitrogen. The resulting solution was refluxed for about 1 h, the solvent removed under reduced pressure, and the residue recrystallized from

dichloromethane and pentane. The first two products to come out of the solution were small amounts of π-$C_5H_5Fe(CO)P(OC_6H_5)_3SnCl_3$ and $[\pi$-$C_5H_5Fe(CO)_2]_2SnCl_2$ but the bulk of the product was the insertion product, π-$C_5H_5Fe(CO)_2Sn(Cl)_2Fe(CO)P(OC_6H_5)_3\pi$-$C_5H_5$. Some difficulties were encountered in isolating this species because of its high solubility and tendency to come out of solution as an oil.

The microanalyses were performed by A. B. Gygli, Microanalysis Laboratory, Toronto, Ontario.

Kinetics

The thermal insertion of tin(II) chloride into the metal–metal bond of $(\pi$-$C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$ was studied by following the disappearance of the starting material at 560 nm using a Unicam SP800 spectrophotometer. There was some formation of the $-SnCl_3$ products initially, but then for at least 50% reaction, the insertion product was formed cleanly as indicated by the presence of an isosbestic point at 514 nm during this period. For each run 10 ml of a tin(II) chloride solution was made up in a glove bag in an atmosphere of nitrogen using degassed THF. This solution was then used to completely fill a 1 cm stoppered silica cell containing an amount of $(\pi$-$C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$ required to give an approximately 4×10^{-3} *M* solution. The cell containing the reaction solution was then quickly transferred to a thermostated cell holder in the spectrophotometer.

Pseudo first-order kinetics were observed in all cases with the tin(II) chloride in excess. Plots of log $(A_t - A_\infty)$, where A_t and A_∞ refer to the absorbances at 560 nm at times t and ∞, respectively, were linear during the time that the spectra passed through the isosbestic point at 514 nm, or about 50% reaction. A_∞ was calculated from a plot of the absorbance at 514 nm (the wavelength of the isosbestic) against the absorbance at 560 nm (the kinetic wavelength) for solutions containing different concentrations of pure π-$C_5H_5Fe(CO)_2Sn(Cl)_2Fe(CO)P(OC_6H_5)_3\pi$-$C_5H_5$ in 0.5 *M* $SnCl_2$ solutions in THF. From the absorbance at the isosbestic point in a given run the theoretical A_∞ could be determined from this graph.

The pseudo first-order rate constants, k_{obs} are plotted in Fig. 1 as a function of tin(II) chloride concentration. The line drawn through the experimental points is a theoretical one calculated on the basis of rate parameters derived by a least-squares treatment (7).

Discussion

Figure 1 shows the variation of the pseudo first-order rate constants k_{obs} with the concentration of tin(II) chloride for the thermal reaction of $(\pi$-$C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$ with excess

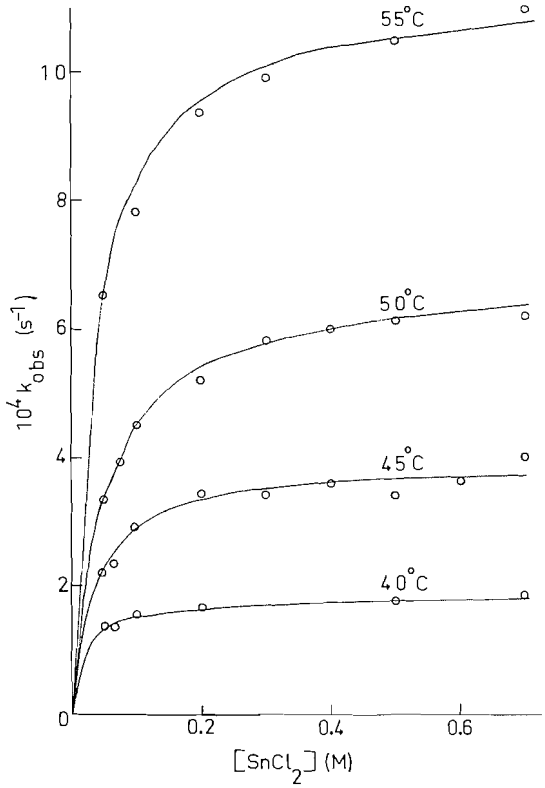

FIG. 1. Plot of the observed pseudo first-order rate constant *vs.* tin(II) chloride concentration for the thermal reaction $(\pi$-$C_5H_5)_2Fe(CO)_3P(OC_6H_5)_3 + SnCl_2 \rightarrow \pi$-$C_5H_5Fe(CO)_2Sn(Cl)_2Fe(CO)P(OC_6H_5)_3\pi$-$C_5H_5$ in THF. The curves drawn through the experimental points are theoretical lines calculated from the rate constants in Table 1.

$SnCl_2$ in THF at the temperatures indicated on the curves. As discussed previously for the insertion reaction of $SnBr_2$ with $[\pi$-$C_5H_5Fe(CO)_2]_2$ (1) the nature of this variation is consistent with the following two-stage mechanism:

$$A_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A_2^* \xrightarrow[B]{k_2} ABA$$

where A_2 represents the metal–metal bonded iron complex $(\pi$-$C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$, A_2^* is a reactive intermediate, B is the tin(II) chloride, and ABA the insertion product. The rate equation for this reaction assuming the concentration of A_2^* to be small and invoking the steady state approximation for its concentration is

$$[1] \quad \frac{d[A_2]}{dt} = \frac{k_1 k_2 [B]/k_{-1}}{1 + k_2[B]/k_{-1}}[A_2] = k_{obs}[A_2]$$

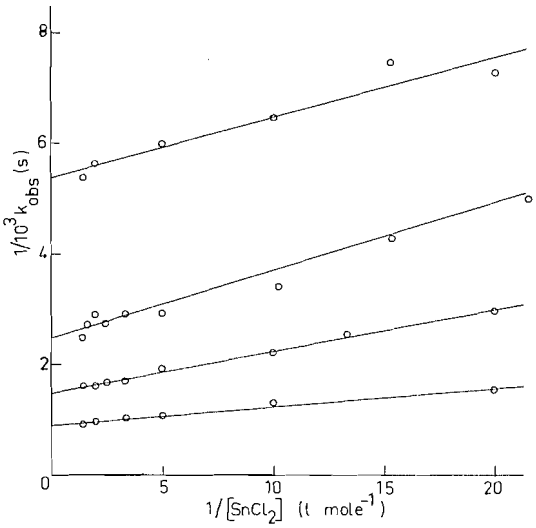

FIG. 2. Plot showing linear relationship between values of $1/k_{obs}$ and $1/[SnCl_2]$ taken from Fig. 1. The straight lines are least-squares plots and lead to the rate constants given in Table 1.

From eq. 1 the following expression can be obtained

$$[2] \qquad 1/k_{obs} = 1/k_1 + k_{-1}/k_1k_2[B]$$

and a plot of $1/k_{obs}$ against $1/[B]$ should yield a straight line with slope k_{-1}/k_1k_2 and intercept $1/k_1$. Figure 2 shows plots of this type for the reaction of $(\pi\text{-}C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$ with $SnCl_2$ and indicates that the data are in fact consistent with the proposed two-stage mechanism. The kinetic parameters together with their standard deviations are shown in Table 1 and were obtained from a least-squares treatment assuming equal uncertainties for all values of k_{obs}. The activation enthalpies and entropies and their standard deviations were obtained from a weighted least-squares treatment of the kinetic parameters (7).

Attempts were made to study the analogous insertion reaction using $SnBr_2$ instead of $SnCl_2$ but were not particularly successful. Although the reaction was very similar to that with $SnCl_2$, spectra of the reaction mixtures at various times drifted slowly but steadily from what should have been an isosbestic point. This suggested that some decomposition or side reactions were occurring but further attempts to remove oxygen from the system were not sufficient to eliminate the problem, and kinetic plots were gradual

TABLE 1. Kinetic parameters for the $SnCl_2$ thermal reaction*

Temperature (°C)	10^4k_1 (s^{-1})	$10^2k_{-1}/k_2$ (mol l^{-1})
40.0	1.86±0.06	2.1±0.3
45.0	3.95±0.12	3.9±0.3
50.0	6.71±0.08	5.0±0.2
55.0	11.2 ±0.3	3.7±0.3

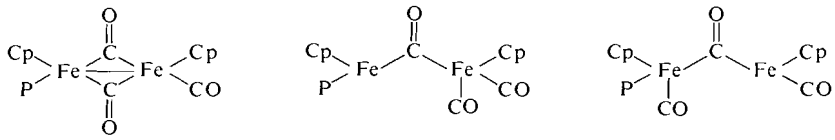
*The uncertainties are standard deviations; $\Delta H_1^{\ddagger} = 23.4 \pm 0.5$; $\Delta H_{-1}^{\ddagger} - \Delta H_2^{\ddagger} = 5 \pm 2$ kcal mol^{-1}; $\Delta S_1^{\ddagger} = -0.6 \pm 1.6$; $\Delta S_{-1}^{\ddagger} - \Delta S_2^{\ddagger} = 9 \pm 5$ cal mol^{-1} deg^{-1}.

curves rather than straight lines. However, estimates of k_{obs} from the reactions indicated that the rate was independent of the concentration of $SnBr_2$ and that k_{obs} was approximately equal to the limiting value for k_1 obtained from the $SnCl_2$ reactions. This would suggest that k_2 was considerably greater for the $SnBr_2$ reaction than for the $SnCl_2$ reaction. This greater reactivity of $SnBr_2$ has also been observed in the insertion of tin(II) halides into the metal–metal bonds of $[PBu_3Co(CO)_3]_2$ (8), $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ (1), and $[\pi\text{-}C_5H_5NiCO]_2$ (9). No evidence was obtained for a second order contribution to the rate as is observed in the reactions of $[PBu_3Co(CO)_3]_2$ and $[\pi\text{-}C_5H_5NiCO]_2$.

The activation parameters given in Table 1 are all concerned in total or in part with the formation or destruction of the reactive intermediate A_2^* and in order to say anything meaningful about these parameters it is necessary to postulate the possible nature of this intermediate. Since the original complex, $(\pi\text{-}C_5H_5)_2Fe_2(CO)_3P(OC_6H_5)_3$, exists mainly as a carbonyl bridged species in solution **1** (3), it would appear reasonable to suggest that the intermediate is also a carbonyl bridged species. Such intermediates have been postulated for the insertion reaction of $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ (1) and $[PBu_3Co(CO)_3]_2$ (8) and also for ligand substitution reactions of $Mn_2(CO)_{10}$ (10), $Re_2(CO)_{10}$ (11), and their derivatives. There are two possible forms of such a reactive intermediate, **2** and **3**, but we cannot predict which would be formed on the basis of steric and electronic considerations.

The activation energy required to break both carbonyl bridges in $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ has been estimated to be about 13 ± 2 kcal/mol (4). Because of the lowering of the carbonyl bridging as well as the terminal stretching frequencies in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



1 2 3

the phosphite substituted complex it has been suggested that the increased electron density on the metal due to the replacement of CO by phosphite is redistributed via π-bonding between the metal and the bridging carbonyl groups (3). For this reason it would appear that the carbonyl bridges are strengthened compared with the unsubstituted dimer and the energy required to break both bridges would be in excess of 13 kcal/mol. If the value of 23.4 kcal/mol for $\Delta H^{\ddagger}$ can be considered to be the energy required to break one carbonyl bridge plus one iron–iron bond, and if the energy required to rupture one carbonyl bridge is $\geqslant 7$ kcal/mol, an upper limit of about 16 kcal/mol can be placed on the energy to break the iron–iron bond. This value is only one half the value estimated at 32 kcal/mol for the iron–iron bond strength in the unsubstituted dimer $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ (1).

On substitution of one CO by $P(OC_6H_5)_3$ the $\Delta S_1^{\ddagger}$ for the insertion reaction is reduced from $+45.5$ to -0.6 cal mol^{-1} deg^{-1}. This drastic change in $\Delta S_1^{\ddagger}$ seems unreasonable in view of the similarities proposed for the mechanisms and reactive intermediates in the two reactions. Although the open structure of the intermediates might accommodate more molecules of solvation than the reactants and give rise to a negative contribution to $\Delta S_1^{\ddagger}$, and although this contribution might be expected to be greater for the more polar $P(OC_6H_5)_3$ complex, these solvation effects could not account for such a large reduction in the $\Delta S_1^{\ddagger}$.

An alternative formulation for the reactive intermediate in the reaction of the $P(OC_6H_5)_3$ substituted complex is one in which only the iron–iron bond is ruptured and the two carbonyl bridges are left intact. This would seem reasonable if in fact the carbonyl bridges are strengthened by the presence of the $P(OC_6H_5)_3$ group as discussed above. The formation of an intermediate of this sort would be expected to involve a very small entropy change as is found experimentally. On the basis of this formulation of the intermediate the $\Delta H^{\ddagger}$ of 23.4 kcal/mol can be interpreted directly as the energy required to break the iron–iron bond, compared with 32 kcal/mol estimated in the unsubstituted dimer. Although the structure of the intermediate cannot be determined unequivocally, the latter proposal in which only the iron–iron bond is broken appears to agree better with the experimental data.

In the case of metal–metal bonds between transition metals in low oxidation states, ligands attached to the metals might be expected to play two opposing roles in their effect on the metal–metal bond strength. Substitution of carbon monoxide by poorer π-electron acceptor ligands would be expected to increase the electron density on the metal resulting in an expansion of the metal's filled non-bonding orbitals. This could result in increased repulsion between the metals due to interactions of these filled orbitals and lead to a weakening of the metal–metal bond. At the same time, however, the σ-bonding orbitals of the metal would also be expanded and the resulting increase in overlap would be expected to strengthen the metal–metal bond.

The former effect seems to predominate in the case of $[\pi\text{-}C_5H_5Mo(CO)_3]_2$. When this dimer is reacted with $P(OC_6H_5)_3$, the disubstituted dimer, $[\pi\text{-}C_5H_5Mo(CO)_2P(OC_6H_5)_3]_2$, is obtained. With the poorer π-bonding ligands $P(C_2H_5)_3$ and $P(n\text{-}C_4H_9)_3$, however, salt-like compounds of the type $[\pi\text{-}C_5H_5Mo(PX_3)_2(CO)_2][\pi\text{-}C_5H_5Mo(CO)_3]$ are formed (12). Thus the better π-bonding ligand $P(OC_6H_5)_3$ favors substitution while $P(C_2H_5)_3$ and $P(n\text{-}C_4H_9)_3$ apparently lead to repulsive interactions which result in the destruction of the metal–metal bond. On the basis of our study of the insertion reactions, the substitution of one carbonyl group in $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ by $P(OC_6H_5)_3$ also appears to result in a reduction in the metal–metal bond strength. Substitution of second carbonyl group could lead to such a weakening of the metal–metal bond that the disubstituted complexes might not exist, and in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

fact efforts to prepare these disubstituted complexes have not been successful (3).

Structure cristalline et moléculaire du thiocyanate mercurique

A. L. Beauchamp et D. Goutier
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 17 septembre, 1971

$Hg(SCN)_2$ cristallise dans le système monoclinique, groupe spatial $C2/m$, $a = 10.878$ Å, $b = 4.042$ Å, $c = 6.435$ Å, $\beta = 95.28°$, $Z = 2$. La structure est résolue par la méthode de Patterson et l'affinement sur 217 réflexions observées indépendantes conduit à un facteur résiduel $R = 0.032$. Le mercure occupe les centres de symétrie de la maille et les atomes de soufre des groupes SCN, situés sur les plans de réflexion, assurent au mercure une coordination caractéristique linéaire. Le mercure interagit faiblement avec quatre atomes d'azote de molécules voisines, qui assurent l'environnement octaédrique au métal.

$Hg(SCN)_2$ crystals belong to the monoclinic space group $C2/m$ with $a = 10.878$ Å, $b = 4.042$ Å, $c = 6.435$ Å, $\beta = 95.28°$, and $Z = 2$. The structure was solved by the Patterson method and refined on 217 independent observed reflections to a R factor of 0.032. All the atoms are found on the planes of symmetry of the unit cell with mercury occupying centrosymmetric positions and forming collinear Hg—S bonds to two coplanar SCN groups. An octahedral environment is achieved through weak interaction of mercury with the nitrogen atoms on four neighboring molecules.

Canadian Journal of Chemistry, **50**, 977 (1972)

Introduction

Dans les composés qu'il forme avec l'ion thiocyanate SCN^-, le mercure bivalent se lie de préférence à l'atome de soufre. L'étude cristallographique de certains composés thiocyanatomercuriques semble indiquer une variation sensible de la longueur de la liaison Hg—S en fonction du nombre de coordination caractéristique (1) du mercure. Ainsi, on rapporte des liaisons Hg—S de 2.31 et 2.32 Å pour les molécules ClHgSCN et BrHgSCN, respectivement, où le mercure possède un nombre de coordination caractéristique de deux (2). Dans le sel complexe $K_2[Hg(SCN)_4]$, quatre atomes de soufre assurent au mercure une coordination caractéristique tétraédrique et on a observé des distances Hg—S de 2.54 Å (3). Enfin, dans le complexe *cis*-$Hg(SCN)_2$(1,10-Phénanthroline)$_2$, molécule monomère où le mercure est hexacoordonné, on observe des distances Hg—S voisines de 2.60 Å (4).

Bien que cette variation de la longueur de la liaison mercure–soufre semble significative, elle repose sur un nombre limité de données. En outre, dans certains cas, l'incertitude sur les distances interatomiques est mal connue. Il paraît donc souhaitable de recueillir des données additionnelles sur la longueur de la liaison Hg—S dans certains composés thiocyanatomercuriques. C'est dans ce but que nous avons déterminé la structure du thiocyanate mercurique.

Puff et Becker (5) ont mesuré la densité et les paramètres de maille de $Hg(SCN)_2$ et indiqué que les groupes spatiaux $C2$, Cm et $C2/m$ sont tous trois compatibles avec les absences systématiques notées. Cooney et Hall (6) ont conclu que les spectres de vibration de ce même composé favorisent le groupe centrosymétrique $C2/m$. Les résultats rapportés par ces auteurs sont largement confirmés par le présent travail.

Partie expérimentale

Formule = $Hg(SCN)_2$ Poids moléculaire = 316.75.

Maille monoclinique, groupe $C2/m$, $a = 10.878(8)$ Å, $b = 4.042(4)$ Å, $c = 6.435(6)$ Å, $\beta = 95.28(2)°$, $V = 281.7$ Å^3, $Z = 2$, $\rho_o = 3.71$ g cm^{-3} (5), $\rho_c = 3.734$ g cm^{-3}, $\mu = 282$ cm^{-1}, (20 °C, MoK$\bar{\alpha}$ 0.71069 Å, MoKβ 0.63225 Å).

L'évaporation lente d'une solution de $Hg(SCN)_2$ (Fisher Reagent) dans un mélange 1:1 eau–acétone a produit un dépôt de cristaux aciculaires b incolores. Une aiguille sectionnée de manière à obtenir un cristal de dimensions 0.062 mm × 0.090 mm × 0.029 mm a été utilisée tout au long de ce travail. Les diagrammes de Weissenberg et de précession ont permis de confirmer les paramètres de maille rapportés par Puff et Becker (5).

La détermination précise des paramètres de maille et les mesures d'intensité ont été effectuées sur un diffractomètre automatique Picker FACS-1. Les pics MoKβ de 8 réflexions distribuées sur l'ensemble de la sphère et comprises entre $18° \leqslant 2\theta \leqslant 27°$ ont d'abord été centrées dans l'ouverture du compteur par ajustement programmé des angles ω, χ, et 2θ de l'instrument. Ces valeurs d'angles ont ensuite permis d'affiner les paramètres cristallins par la méthode des moindres carrés décrite par Busing et Levy (7). Les déviations standard rapportées plus haut sont tirées des résultats du dernier cycle d'affinement.

Les intensités ont été mesurées avec la radiation MoKα

filtrée au zirconium, selon la technique du balayage $\theta/2\theta$ à raison de 1° (2θ) par min. Le balayage s'étendait sur un intervalle 2θ minimum de 1.60° centré sur le pic. A chacune des limites du balayage, le bruit de fond était compté durant 20 s. Les intensités des réflexions témoins 021, 401, et 003 ont été recueillies toutes les 30 mesures et n'ont manifesté aucune variation significative.

Les intensités intégrées des 743 réflexions (avec $h + k = 2n$) dans toute la sphère de 1.08 $Å^{-1}$ ($2\theta \leqslant 45°$) ont été mesurées. Quatre mesures ayant une intensité inférieure à 15% du bruit de fond ont été rejetées. Un facteur de transmission calculé selon l'équation des faces du cristal a servi à corriger chaque réflexion pour l'absorption. Après transformation des indices, ces données ont fourni 217 réflexions observées indépendantes (hkl, $hk\bar{l}$), qui ont été ensuite corrigées pour les effets de Lorentz et de polarisation.

Les calculs ont été effectués sur l'ordinateur CDC6400. Les versions modifiées des programmes suivants ont été utilisées: Ahmed et Huber, NRC-2 (traitement préliminaire des données); Ahmed et Singh, NRC-3 (correction pour l'absorption); Prewitt, SFLS5 (moindres carrés à matrice entière); Zalkin, FORDAP (cartes de Fourier et de Patterson); Johnson, ORTEP (traçage des figures).

Détermination de la structure

L'extinction systématique de toutes les réflexions dont $h + k \neq 2n$ conduit aux trois groupes spatiaux monocliniques $C2$, Cm, et $C2/m$. Dans les trois cas, les deux atomes de mercure doivent occuper une position spéciale d'ordre 2. On leur assigne arbitrairement les coordonnées (0,0,0) et $(\frac{1}{2},\frac{1}{2},0)$ respectivement, ce qui équivaut à déterminer l'origine de la maille cristalline.

Les atomes légers peuvent être localisés grâce à une synthèse tridimensionnelle de Patterson. La position relative des atomes de mercure permet de prévoir que les pics Hg—Hg se confondent avec l'origine et le centre de la face C de la maille de Patterson. Par ailleurs, à multiplicité égale, l'intensité des pics devrait varier dans l'ordre Hg—S > Hg—N > Hg—C > S—S. Sur la carte d'une portion représentative de la maille ($\frac{1}{4}$ de maille, $0 \leqslant u < \frac{1}{2}$, $0 \leqslant v < \frac{1}{2}$, $0 \leqslant w < 1$), on observe plusieurs pics de hauteurs diverses, qui se trouvent tous dans le plan $v = 0$. Les trois pics les plus intenses, situés respectivement à (0.13,0,0.32), (0.26,0,0.23) et (0.36,0,0.16), adoptent une disposition qui rappelle nettement le segment linéaire S—C—N. Leurs hauteurs relatives permettent de les identifier comme étant des pics Hg—S, Hg—C, et Hg—N de même multiplicité. Pour le groupe $C2/m$, on peut vérifier que les vecteurs interatomiques mercure–soufre (–azote ou –carbone) produisent 4 pics de multiplicité 4 par maille de Patterson, soit un seul par quart de maille. Par contre, pour les groupes $C2$ ou Cm, ces 4 pics se scindent en 8 pics de multiplicité 2 par maille, soit 2 pics par quart de maille. La présence d'une seule série de pics Hg—S, Hg—C, et Hg—N ne présentant pas de dissymétrie semble donc favoriser le groupe centrosymétrique $C2/m$. Néanmoins, la résolution limitée inhérente à la synthèse de Patterson ne permet pas d'exclure totalement de très légers écarts à la centrosymétrie, fait dont nous avons tenu compte lors de l'affinement.

Si le groupe est $C2/m$, le soufre, le carbone et l'azote occupent chacun une série de sites $4i$ $(x,0,z;\ \bar{x},0,\bar{z};\ \frac{1}{2}+x,\frac{1}{2},z;\ \frac{1}{2}-x,\frac{1}{2},\bar{z})$ (8). Dans chaque cas, x et z sont identiques aux valeurs de u et w lues sur la carte, puisque le mercure occupe l'origine de la maille cristalline. A l'aide des coordonnées ainsi déterminées, nous avons retrouvé sur la carte les pics peu intenses S—S, S—N, et S—C. La position de tous les atomes des deux molécules $Hg(SCN)_2$ se trouve ainsi déterminée.

Affinement

Les paramètres structuraux ont été affinés par moindres carrés à matrice entière. Les facteurs de diffusion f, ainsi que les facteurs de dispersion $\Delta f'$ et $\Delta f''$ du mercure et du soufre, proviennent de Cromer et Waber (9). Nous avons d'abord affiné la structure selon le groupe centrosymétrique $C2/m$, puis considéré les groupes $C2$ et Cm, afin de déterminer s'il existe des écarts significatifs à la centrosymétrie.

(*a*) Groupe $C2/m$. Nous avons affiné simultanément le facteur d'échelle, les coordonnées atomiques et les facteurs thermiques ajustables. Quatre cycles de moindres carrés avec des facteurs thermiques isotropes et des poids unitaires ont donné un facteur $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ de 0.112. Dans les cycles suivants, nous avons utilisé des facteurs thermiques anisotropes et appliqué à chaque réflexion un poids w calculé selon l'équation $w = 1/(a + b|F_o| + c|F_o|^2)$, les constantes a, b, et c (3.64, −0.29, 0.007) étant ajustées de manière à assurer une distribution uniforme de l'écart pondéré moyen en fonction de $|F_o|$ et de $\sin\theta/\lambda$. Après cinq cycles, le facteur R s'établissait à 0.032, alors que le facteur $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ était de 0.038. Les paramètres affinés sont réunis dans le Tableau 1. Une carte différence de Fourier calculée avec ces paramètres ne comportait que quelques pics significatifs (0.7–1.3 e/$Å^3$), tous situés à moins de 1.5 Å du mercure.[1]

(*b*) Groupe $C2$. Dans la maille de symétrie $C2$, le soufre,

TABLEAU 2. Distances interatomiques et angles de liaison dans $Hg(SCN)_2$*

Liaisons	Distance (Å)	Liaisons	Angle (deg)
Hg—S(*a*)	2.381(6)	S(*b*)—Hg—S(*a*)	180 (sym.)
S(*a*)—C(*a*)	1.62 (2)	N(*a*+)—Hg—N(*b*−)	180 (sym.)
C(*a*)—N(*a*)	1.18 (3)	N(*a*−)—Hg—N(*b*+)	180 (sym.)
Hg—N(*a*+)	2.81 (1)	N(*a*−)—Hg—N(*b*−)	88.0 (4)
		N(*a*−)—Hg—N(*a*+)	92.0 (4)
		N(*a*−)—Hg—S(*a*)	88.2 (3)
		N(*b*−)—Hg—S(*a*)	91.8 (3)
		Hg—S(*a*)—C(*a*)	97.6 (5)
		S(*a*)—C(*a*)—N(*a*)	177.5 (13)
		Hg—N(*a*+)—C(*a*+)	132.7 (11)

*(*a*) $x,0,z$; (*b*) $\bar{x},0,\bar{z}$; (*a*+) $x-\frac{1}{2},\frac{1}{2},z$; (*a*−) $x-\frac{1}{2},-\frac{1}{2},z$; (*b*+) $\bar{x}+\frac{1}{2},\frac{1}{2},\bar{z}$; (*b*−) $\bar{x}+\frac{1}{2},-\frac{1}{2},\bar{z}$. Les déviations standard sur les distances tiennent compte des déviations standard sur les paramètres de maille.

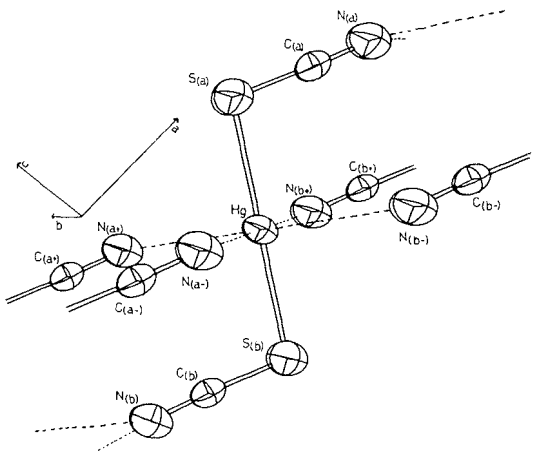

FIG. 1. Environnement du mercure dans le cristal de $Hg(SCN)_2$. Le mercure, situé sur le centre de symétrie à l'origine, et les groupes S(*a*)—C(*a*)—N(*a*) et S(*b*)—C(*b*)—N(*b*) centrosymétriquement équivalents, se trouvent sur le plan de symétrie $y = 0$ de la maille. Les autres atomes sont équivalents aux précédents par centrage de la face C et occupent les plans de symétrie à $y = \frac{1}{2}$ (*a*+ et *b*+) ou $y = -\frac{1}{2}$ (*a*− et *b*−). Les ellipsoïdes ont été tracées à partir des facteurs thermiques anisotropes et correspondent à un niveau de probabilité de 50%.

l'azote et le carbone occupent chacun une position générale *4c*. Au départ de l'affinement, nous avons utilisé les paramètres structuraux du Tableau 1. Dans ce groupe, les coordonnées *y* et les facteurs thermiques β_{12} et β_{23} des atomes légers sont également ajustables (10). Au point de convergence, l'écart entre les paramètres affinés et les valeurs correspondantes du Tableau 1 ne dépasse pas la somme de leurs déviations standard respectives. Les facteurs $R = 0.032$ et $R_w = 0.038$ sont identiques aux valeurs obtenues pour le groupe *C*2/*m*. Comme ces facteurs ne diminuent pas en passant du modèle *C*2/*m* (23 paramètres ajustables) au modèle *C*2 (32 paramètres ajustables), le groupe centrosymétrique *C*2/*m* est favorisé avec un degré de probabilité très élevé (11).

(*c*) Groupe *Cm*. Les atomes légers se trouvent nécessairement à proximité des plans de réflexion à $y = 0$ et $\frac{1}{2}$. Il n'est donc pas possible de les disposer sur des positions générales, puisque les distances entre des atomes situés à x,y,z et $x,\bar{y},z$ serait extrêmement courte. Le soufre, le carbone et l'azote constituent donc chacun deux paires non-équivalentes occupant des positions spéciales *2a*. Nous avons tenu compte de cette distribution des atomes sur les équipoints pour déterminer, à l'aide du Tableau 1, les coordonnées de départ.

L'affinement selon le groupe *Cm* ne converge pas. Au cours de cinq cycles successifs, les paramètres oscillent constamment autour de leurs valeurs initiales et le facteur *R* demeure au voisinage de 0.042. On observe une corrélation très élevée (coefficients de corrélation 0.80–0.95) entre les coordonnées *x* (ou *z*) d'atomes identiques supposés non-équivalents d'une part, entre ces mêmes coordonnées et les facteurs β_{ij} correspondants d'autre part. Ces résultats nous paraissent suffisants pour rejeter le groupe *Cm*.

En conclusion, l'affinement ne révèle pas d'écarts significatifs à la centrosymétrie. Nous admettons donc que la structure définie selon le groupe centrosymétrique *C*2/*m* est juste. Notons que Cooney et Hall ont tiré la même conclusion à la suite d'une étude des spectres de vibration de $Hg(SCN)_2$ (6).

Description de la structure et discussion

Les atomes se trouvent tous sur les plans de symétrie de la maille. L'atome de mercure et son environnement sont représentés à la Fig. 1.

Le Tableau 2 comporte un choix de distances interatomiques et les valeurs de certains angles. Les deux atomes de soufre S(*a*) et S(*b*) équivalents par centrosymétrie sont les seuls voisins immédiats du mercure et lui assurent une coordination caractéristique linéaire. L'angle Hg—S—C de 97.6(5)° est comparable à ceux qu'on observe généralement pour les groupes SCN coordonnés par le soufre (12). Les liaisons S—C (1.62(2) Å) et C—N (1.17(3) Å) possèdent les longueurs habituelles (13) et sont collinéaires

For personal use only.

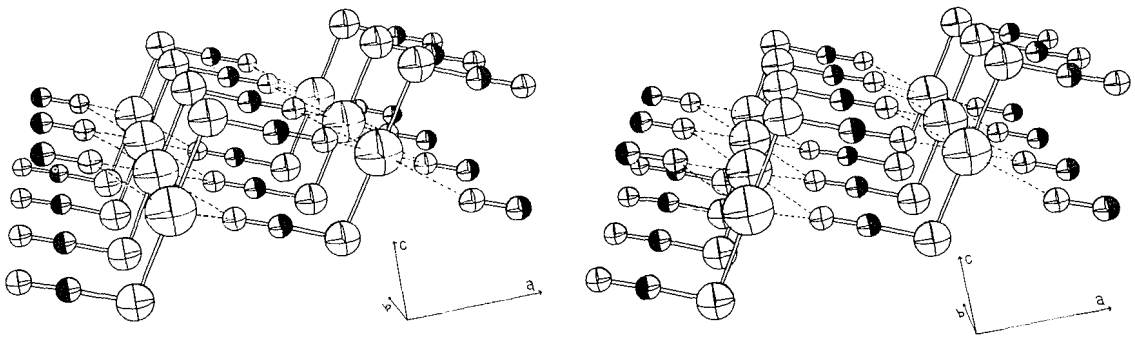

FIG. 2. Projection stéréoscopique d'une couche constituée de molécules $Hg(SCN)_2$ reliées entre elles. Les atomes sont représentés par des sphères et identifiés à la Fig. 3. Les traits pointillés indiquent les interactions intermoléculaires Hg—N. L'axe cristallographique *b* coincïde avec une rangée d'atomes de mercure.

aux erreurs expérimentales près (∠ S—C—N 177.5(13)°). La distance Hg—S de 2.381(6) Å est légèrement plus élevée que la somme des valeurs admises pour les rayons covalents du soufre (1.04 Å) et du mercure bicoordonné (1.30 Å) (1).

A l'état solide, plusieurs composés mercuriques bicovalents adoptent un empilement qui permet au métal d'interagir avec des atomes donneurs de molécules voisines. La Fig. 1 montre que le mercure est entouré de quatre atomes d'azote et possède ainsi un nombre de coordination *effectif* (1) de six. Les distances Hg—N (2.81(1) Å), toutes égales par symétrie, sont inférieures à la somme des rayons de van der Waals (3.1 Å) (1) et comparables aux distances Hg—N (2.74 Å) observées pour $Hg(CN)_2$ (14). Le mercure se trouve donc au centre d'un octaèdre constitué de quatre atomes d'azote et de deux atomes de soufre, ces derniers occupant des sommets opposés. Les angles S—Hg—N et N—Hg—N sont tous très voisins de 90 ou 180° selon le cas, de sorte que l'écart à la symétrie idéale D_{4h} est minime.

La Fig. 2 révèle la disposition relative de ces polyèdres dans le cristal. Des octaèdres voisins se partagent une arête N—N pour former une rangée infinie parallèle à l'axe *b*. Les rangées adjacentes sont décalées de *b*/2 l'une par rapport à l'autre, mais les segments S—Hg—S sont tous parallèles. Ces rangées se soudent l'une à l'autre par l'intermédiaire du carbone, qui relie chaque atome de soufre d'une rangée à un atome d'azote de la rangée voisine. Il en résulte des couches parallèles au plan *ab*, comme l'indique la Fig. 3. Entre ces couches, il n'existe apparemment que

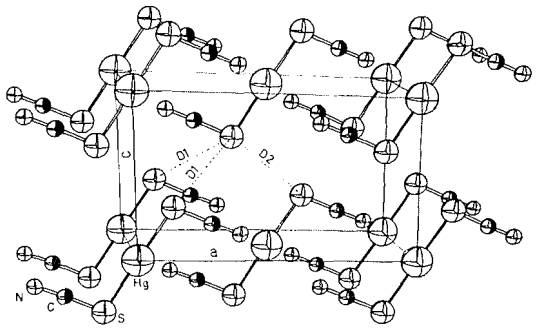

FIG. 3. Empilement des couches dans le cristal de $Hg(SCN)_2$. Les atomes sont représentés par des sphères. Entre atomes de couches différentes, seules les distances S—S ($D1 = 3.916(7)$ Å et $D2 = 3.747(7)$ Å) se rapprochent de la somme des rayons de van der Waals (3.6 Å).

des interactions faibles. Certains contacts S—S (3.75 et 3.92 Å) entre atomes de couches différentes sont les seuls qui se rapprochent de la somme des rayons de van der Waals (3.6 Å). Cette faible cohésion entre les couches est en accord avec la grande facilité de clivage des cristaux selon le plan *ab*.

La liaison Hg—S (2.381(5) Å) du thiocyanate mercurique est comparable à celles de CH_3-$SHgSCH_3$ (2.36(5) Å) (15) et du cinabre HgS (2.36(~5) Å) (16), mais sensiblement plus longue que celle de ClHgSCN (2.31(~2) Å) et BrHgSCN (2.32(~2) Å) (2). Ces composés ressemblent tous au thiocyanate, puisque le mercure *y* possède un nombre de coordination caractéristique de deux et complète sa coordinence effective par interaction avec des atomes voisins. Cependant, l'incertitude sur les longueurs de liaisons de certains composés et

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

relativement élevée. Il est donc prématuré de tirer des conclusions quant aux influences spécifiques de l'halogène ou du groupe rattaché au soufre. Une étude dans ce sens nécessiterait d'autres mesures plus précises de la longueur des liaisons Hg—S.

Nous tenons à remercier J. Hubert pour son intérêt et sa participation à la rédaction du présent manuscrit. Nous remercions également le Conseil National de Recherches du Canada pour une subvention de recherches.

Secondary Kinetic Isotope Effects in Bimolecular Nucleophilic Substitutions. V. The Role of the Solvent in the Reaction Between Methyl Iodide and Pyridine[1]

K. T. LEFFEK AND A. F. MATHESON[2]

Chemistry Department, Dalhousie University, Halifax, Nova Scotia

Received September 29, 1971

Secondary kinetic deuterium isotope effects are presented for the reaction of methyl-d_3 iodide and pyridine in four different solvents. Calculations on mass and moment of inertia change with deuteration in the initial state and an assumed tetrahedral transition state, together with internal rotational effects, are used to rationalize the inverse isotope effects. It is concluded from the variation of the isotopic rate ratio, that the transition state structure varies with solvent.

Les effets secondaires isotopiques cinétiques de deuterium sont présentés pour la réaction de l'iodure de méthyle d_3 et la pyridine dans quatre solvants différents. Les calculs de masses et de moments d'inertie qui varient avec la deutération dans l'état initial et un état de transition tétrahédrique supposé, conjointement avec les effets de rotation interne, sont utilisé pour rationaliser les effets isotopiques inverses. On conclut de la variation du rapport des vitesses isotopiques que la structure de l'état de transition varie avec le solvant.

Canadian Journal of Chemistry, **50**, 982 (1972)

Introduction

Several reports of secondary deuterium isotope effects in Menschutkin reactions between alkyl halides and sulfonates and tertiary amines have been made (1–5) and several different approaches have been used to rationalize the inverse isotope effects ($k_H/k_D < 1$) which have been usually observed. All of these have been at least partially successful despite the fact that the role of the solvent has always been assumed to introduce no rate change, an assumption which has some limited experimental basis (6–8). In this paper, secondary isotope effects measured in four different solvents are presented and an attempt is made to account for their magnitude, and at the same time use the rate ratios to draw some general conclusions about the role of the solvent in Menschutkin reactions.

The temperature dependence study of the isotope effect for the reaction of 2-picoline and methyl-d_3 iodide in solvent benzene reported in 1965 (1) gave values of $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})$ and $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ which were unusual at the time, in that the rate change was due almost entirely to a difference in the entropies of activation between the normal and deuterated compounds. When a correlation of the enthalpy and entropy contributions to the secondary deuterium isotope effect for 16 nucleophilic substitutions at saturated carbon was made (9), the result which presented the greatest anomaly was that for 2-picoline and methyl iodide.

It may be postulated that the anomalous behavior is due to the unusually non-specific role of the solvent. This is based partly on an analogy with the temperature dependence of the isotope effect of the thermal racemization of 9,10-dihydro-4,5-dimethyl-d_6-phenanthrene in both benzene and *n*-heptane measured by Mislow *et al.* (10). This result was not included in our correlation (9) because the reactions are not nucleophilic substitutions, but if the enthalpy and entropy contributions to the isotope effects for these reactions are plotted, they fall well below both lines, in a qualitatively similar manner to those for the 2-picoline–methyl iodide reaction in benzene. It would seem reasonable to assume that the specific role of the solvent in the racemization reactions would be minimal since the formation of the transition state involves no charge formation or destruction nor any electron redistribution. From the similar isotope effects, it may be inferred that a non-specific role toward the carbon seat of reaction is played by the solvent benzene in the Menschutkin reaction, although this may not be true for all solvents.

Origin of the Secondary Isotope Effect in Menschutkin Reactions

Leffek and MacLean (1) suggested that a substantial part of the isotope effect for the reaction of methyl-d_3 iodide and 2-picoline in benzene arose from an increase in the size of the barrier to rotation of the CH_3 and CD_3 groups on passage from the initial state to the transition state, which produced a positive $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ and also a positive $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})$ (which cancelled the negative zero-point energy contribution to the latter). At about the same time, Wolfsberg and Stern (11) developed a theoretical treatment which accounted for temperature independent isotope effects in terms of opposing changes in force constants during the activation process. Subsequently Brown and McDonald (4) interpreted secondary isotope effects in general, with particular reference to the reaction of substituted pyridines and methyl iodide, as a manifestation of the steric difference between normal and deuterated compounds. Kaplan and Thornton (5) also proposed a steric explanation for the inverse isotope effect, measured at a single temperature, for the reaction of *N,N*-dimethyl-d_6-aniline and methyl *p*-toluenesulfonate in nitrobenzene, and Leffek and Matheson (9) showed, by a temperature dependence study, that the rate change was predominantly an enthalpy of activation effect. However, the problem of the temperature independent effect (rate change due to entropy of activation effect only) has not been completely solved and we have carried out further calculations on model systems to reassess the contributions from the several sources.

Leffek and MacLean considered the mass and moment of inertia contributions to the isotope effect only qualitatively and assumed them to be small. We have now reconsidered some transition state models and found that if a tetrahedral transition state is assumed, *i.e.* identical to the final state, simply a mirror image of the initial state configuration, significant entropy of activation effects may result. The calculations were made following Wolfsberg and Stern (11) in a manner explained in the previous paper of this series (9). The initial state, CH_3Y, was assumed to have a C—Y bond length of 2.00 Å and the mass of Y was taken as 120.5 a.w.u. 109.5° was used for all the bond angles in the initial state and the transition state. Bond lengths for C—H and C—D were maintained at 1.07 Å (*i.e.* anharmonicity neglected) and atomic masses C = 12.0, H = 1.006, D = 2.012 were used. Table 1 shows some results of these calculations, from which it may be seen that, for this model system, closer approach of the nucleophile (X) gives a more positive value of $\Delta\Delta S_I^{\ddagger}$ and hence of $\Delta\Delta S_{MMI}^{\ddagger}$. Smaller changes in $\Delta\Delta S_{MMI}^{\ddagger}$ are produced by mass variation of X, since $\Delta\Delta S_I^{\ddagger}$ and $\Delta\Delta S_M^{\ddagger}$ vary in an opposing manner. The latter term is dominant, so that the reduction of the mass of X, compared to that of Y, yields a positive $\Delta\Delta S_{MMI}^{\ddagger}$.

TABLE 1. Calculated $\Delta\Delta S^{\ddagger}$ (cal mol^{-1} deg^{-1}) contributions from mass and moment of inertia changes for a nucleophilic substitution with a tetrahedral transition state

Transition state variables				
C—X[a] length (Å)	Mass of X[a] (a.w.u.)	$\Delta\Delta S_I^{\ddagger}$ [b]	$\Delta\Delta S_M^{\ddagger}$ [b]	$\Delta\Delta S_{MMI}^{\ddagger}$ [b]
1.0	120.5	+0.153	0.0	+0.153
2.0	120.5	0.0	0.0	0.0
3.0	120.5	−0.048	0.0	−0.048

2.0	120.5	0.0	0.0	0.0
2.0	180.75	+0.013	−0.020	−0.007

[a] X is the attacking nucleophile.
[b] $\Delta\Delta S^{\ddagger} \equiv (\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$.

In order to apply these general conclusions to the reaction of methyl iodide with 2-picoline, which is not a single atom nucleophile as used in the above calculation, only the nitrogen atom of the amine was considered, but it was assigned a mass of 93 a.w.u. This cut-off procedure has been discussed by Wolfsberg and Stern (11, 12) in their work with the force constant model. They have shown that this simplifying technique is a useful one in the qualitative understanding of the isotope effect. Making the assumption that the transition state is well advanced towards product, and that specific solvation is negligible, the formation of the transition state in the reaction of amine and methyl iodide will result in a bond contraction from 2.1 (C-1) to 1.47 Å (C—N), and a mass decrease from 127 (iodine) to 93 (2-picoline). Each of these factors will tend to reinforce the other to yield a positive $\Delta\Delta S_{MMI}^{\ddagger}$. It is difficult to give a reliable value for $\Delta\Delta S_{MMI}^{\ddagger}$ but +0.1 cal mol^{-1} deg^{-1} would be a reasonable estimate.

TABLE 2. Second-order rate constants and isotopic rate ratios for the reaction of methyl and methyl-d_3 iodide with pyridine at 50 °C

Solvent	CH_3I 10^4k_2(l mol^{-1} s^{-1}) (± standard error)	CD_3I 10^4k_2(l mol^{-1} s^{-1}) (± standard error)	k_H/k_D (± standard error)

2-Butanone	7.73 ± 0.07	9.03 ± 0.07	$0.85_7 \pm 0.010$
Ethanol	1.41 ± 0.01	$1.60 \pm 0.00_5$	$0.88_2 \pm 0.006$

[a]Reference 1.
[b]Literature values $10^4k_2 = 23.80$ (ref. 15), 21.30 (ref. 16) l mol^{-1} s^{-1}.

Thus, even though a tetrahedral product-like transition state may not be the most realistic, and there is evidence in the literature that in some solvents it is not (13), it is one possible way to account for part of the experimental value of +0.25 cal mol^{-1} deg^{-1} found for $\Delta\Delta S^{\ddagger}$ for this reaction (1).

The $\Delta\Delta H^{\ddagger}$ value is still best interpreted as a cancellation between a positive component from the changes in the barrier to internal rotation and a negative component from the zero-point energy source. Even with an assumed tetrahedral transition state there is evidence from Raman spectra (14, 15) that a small overall increase in the carbon–hydrogen vibrational frequencies will occur during the activation process.

The Dependence on Solvent of the Secondary Isotope Effect

The postulate that there is no specific involvement of the benzene solvent in reactions of methyl iodide and tertiary amines and that this is the reason why this particular reaction shows a poor correlation on the $\Delta\Delta H^{\ddagger}$ *vs.* $T\Delta\Delta S^{\ddagger}$ plot (9) leads to the conclusion that the secondary isotope effect should change when the solvent is changed to one having greater specific solvation with the transition state. This has been tested using several solvents, two dipolar aprotic solvents and one protic solvent, ethanol, in addition to the original benzene. The results are shown in Table 2. The rate constants for the reaction in benzene and nitrobenzene are in reasonable agreement with previous measurements (16, 17) and the 2-butanone and ethanol constants are of the same order of magnitude as earlier measurements in mixed solvents of acetone–water and ethanol–water (18). It may be noted, although it is not a novel observation, that the reaction rates do not follow the Hughes–Ingold theory of solvent effects (19) in that the reaction is not fastest in the most polar solvent, ethanol, nor do the rates correlate with the dielectric constants of the media. However, the rate is slowest in the least polar solvent, benzene, in agreement with the postulated minimal solvation stabilization of the transition state.

The isotopic rate ratios, also, do not correlate with solvent polarity, the bulk dielectric constant, nor with some of the empirical solvent parameters compiled by Reichardt (20). However, there is some indication of a parallel between the rate ratios and specific solvent–solute interactions. One measure of specific solvent–solute interactions has been advanced by Bellamy *et al.* (21) who measured the frequency shift for the stretching frequency of X—H dipoles between the vapor and dissolved species for a large number of solvents. Using the N—H bond of pyrrole as the X—H dipole the relative frequency shift $10^3\Delta\nu/\nu$, where $\Delta\nu$ is the X—H stretching frequency in the vapor minus that in the solvent, has a value of 20.4 for benzene, 22.9 for nitrobenzene, and 35 to 47 for ketones (39.6 for acetone). Limited though the data are, they do show that the greater the ability of the solvent to interact specifically with a dipole, the larger is the isotope effect. We suggest that as the specific solvent interaction increases as the solvent is changed, the transition state comes earlier on the reaction coordinate, *i.e.* is more like the usual trigonal-bipyramidal S_N2 transition state. Under these circumstances, increased crowding due to stiffening of the out-of-plane vibrational frequencies will render $\Delta\Delta H^{\ddagger}$ increasingly negative, yielding a larger inverse isotope effect.

Thus, the change in kinetic isotope effect with solvent may be interpreted in terms of the

amount of specific solvation of the transition state by the solvent, and the effect that this has upon the geometry of the transition state.

Experimental

Materials

The solvents nitrobenzene and 2-butanone were dried over calcium sulfate, fractionally distilled at atmospheric pressure, and the center cut of the distillates collected. Ethanol was dried by the method of Lund and Bjerrum and distilled.

Commercial methyl iodide and methyl-d_3 iodide were distilled immediately before use. Pyridine was dried first with potassium hydroxide pellets and then with calcium hydride. After fractional distillation the central cut was stored in an opaque container over calcium hydride and under nitrogen.

Kinetics

Each reactant, cooled to minimize volatilization, was weighed and quickly transferred to a 10 ml volumetric flask, dissolved in solvent and made up to the mark. Experiments were performed to determine the initial concentration of alkyl halide by titration, but the direct weighing technique gave more consistent and reliable results. The reaction mixture was prepared by mixing the appropriate volumes of the 10 ml stock solutions and injecting the mixture into a conductivity cell of 5 ml capacity (LKB-Producter AB Sweden). After temperature equilibration in a constant temperature oil-filled bath, conductivity measurements were taken at appropriate intervals of time and converted to concentrations by means of a previously determined calibration curve. The calibration curve had been set up using both methylpyridinium iodide and methyl-d_3 pyridinium iodide and the points for both compounds fell on a single smooth curve. Second-order rate constants were calculated from the integrated second-order equation.

A preliminary investigation for each reaction series was made to determine the optimum molar ratio of the reactants and the percent reaction range to yield consistent and reproducible rate constants. Identical conditions were then used for the deuterated analogue. The initial concentration of methyl iodide was always 2×10^{-2} *M* and the initial pyridine concentration was 0.1 *M* in nitrobenzene and 2-butanone and 0.2 *M* in ethanol. The reaction range, expressed as a percentage of initial methyl iodide consumed was 15–50% in nitrobenzene, 5–18% in 2-butanone, and 15–30% in ethanol. The second-order rate constants reported in Table 2 are the means of from two to four runs carried out for each reaction. A sample run is given in Table 3.

Secondary Kinetic Isotope Effects in Bimolecular Nucleophilic Substitutions. VI. Effect of α and β Deuteration of Alkyl Halides in their Menschutkin Reactions with Pyridine in Nitrobenzene[1]

K. T. LEFFEK AND A. F. MATHESON[2]

Chemistry Department, Dalhousie University, Halifax, Nova Scotia

Received September 29, 1971

A survey of kinetic, secondary deuterium isotope effects, for α, β, and γ deuterated alkyl halides reacting with pyridine in nitrobenzene solvent has been made. α-Deuterium effects have been measured for eight compounds, β-deuterium effects for four compounds, and one rate ratio for γ-deuteration is reported. The possible errors in the rate ratios for β-deuterated compounds, resulting from the elimination side reaction have been determined. The results are discussed in terms of transition state structure.

Une étude sur la cinétique des effets isotopiques secondaires du deutérium a été effectuée sur les halogénures d'alkyle α, β, et γ deutérés qui réagissent avec la pyridine dans le nitrobenzène. Les effets du deutérium en α ont été mesurés au moyen de huit composés, les effets du deutérium en β au moyen de quatre composés, et on rapporte un rapport de vitesse pour la deutération en γ. Les erreurs possibles dans les rapports de vitesse pour les composés β-deutérés, et qui résultent d'une réaction annexe d'élimination, ont été déterminées. Les résultats sont discutés en fonction de la structure de l'état de transition.

Canadian Journal of Chemistry, **50**, 986 (1972)

Introduction

Although many secondary deuterium isotope effects have been measured for nucleophilic substitutions at saturated carbon, systematic studies involving changes in the leaving group, the alkyl group, and the position of deuteration are not common. Robertson and co-workers (1–4) have provided the most complete set of data for solvolysis reactions in water of alkyl halides and sulfonates, and Brown and McDonald (5) have reported a series of measurements on various substituted deuterated pyridines reacting with alkyl iodides in nitrobenzene solvent. This paper presents a set of isotopic rate ratios for the reaction of a single nucleophile pyridine, with various deuterated alkyl compounds in the same solvent, nitrobenzene.

Results and Discussion

α-Deuterium Effects

In Table 1 the second-order rate constants and isotopic rate ratios are shown for α-deuterated alkyl iodides, bromides, and tosylate. The reactions were followed conductometrically for all but the methyl bromide reaction, for which the sealed tube technique was used with analysis for bromide ion by titration. All of the rate constants are at 50 °C, except for ethyl bromide, which was run at 35 °C.

The result of changing the leaving group from iodide, to bromide, to tosylate is to decrease the isotope effect, *i.e.* to bring the rate ratio closer to unity. This change is analogous to the behavior of methyl compounds solvolyzing in water (1) and if the rate ratios are plotted against $E_n - E_l$, where E_n is the Edward's nucleophilicity factor (6, 7) of the incoming nucleophile and E_l that of the leaving group, the three points yield a line parallel but not coincident with the one plotted by Seltzer and Zavitsas (8, 9). The order magnitude of the isotope effect (I > Br > OTs for inverse effects or OTs > Br > I for normal effects) has been explained (10, 11) for limiting solvolytic reactions proceeding via ion-pairs, in terms of the effect of the leaving group on the initial state. However, the non-solvolytic Menschutkin reaction is known to pass through an S_N2 transition state, and this transition state might be expected to yield a significant contribution to the isotope effect. In another non-solvolytic reaction, that of thiosulfate ion with methyl-d_3 iodide, bromide, and tosylate, the rate ratios contrast with the series above in

giving values of 1.058, 1.031, and 1.12, respectively (9).

The ethyl-αd_2 iodide and bromide reactions give exactly the same rate ratio of 0.967 and isopropyl-αd_1 iodide gives a more normal ratio than the corresponding bromide. Thus the change in isotope effect between iodide and bromide leaving groups depends upon the alkyl radical and, therefore, is probably related to a large extent to the control of the transition state structure by the alkyl radical.

The trend towards a normal (> 1) rate ratio with α-methylation of the alkyl group for a constant leaving group is also observed in Table 1 and appears to be a general phenomenon (1, 2). This has been interpreted in zero-point energy terms, assuming that the $\Delta H^{\ddagger}$ isotope effect dominates that of $\Delta S^{\ddagger}$, which is true for several S_N2 reactions (12–14). The argument is that a tight S_N2 transition state, such as that for a methyl compound leads to an increase in the C—H bending frequencies during activation, which in turn leads to a faster rate for the deuterium compound than for the protium compound (15). A looser transition state resulting from charge delocalization within a carbon skeleton such as an isopropyl group, yields less increase (or in some cases a decrease) in the C—H (C—D) bending modes of vibration on going from the initial to the transition state and therefore a smaller inverse isotope effect. This implies that for isopropyl compounds, bond breaking is more important than bond making and that the entering and leaving groups are held, presumably by the steric effects of the methyl groups, at a greater distance from the α-C—H (or C—D) bond, which would, therefore, be relatively free in the transition state with respect to the bending vibrations. Thus the methyl halides have tighter transition states than ethyl or isopropyl halides and larger inverse isotope effects and, of the two halides, the larger iodide has the greater inhibition of the C—H and C—D bending vibrations in the transition state and hence the larger inverse isotope effect. For the methyl compounds, the more polarizable the leaving group, I > Br > OTs on the Edwards *E* scale (6, 7), the greater will be the degree of bond making in the transition state and hence the more crowded it will be, giving rise to a larger isotope effect.

The inverse isotope effect observed with isopropyl-αd_1 bromide may be due to the fact that a larger excess (eightfold) of nucleophile was used for this compound than for the others, which was necessitated by practical reasons. With such a large excess of pyridine the reaction tends to be a pyridinolysis, since the pyridine will tend to solvate the transition state preferentially, compared to nitrobenzene. This effective change to a solvent of more specific solvating power (16) will give a transition state for the reaction more reactant-like (17) and therefore more crowded with a larger isotope effect.

β-Deuterium Effects

Secondary β-deuterium isotope effects in S_N2 reactions present a problem in that some amount of E2 side reaction usually occurs concurrently and the elimination of a β-hydrogen (or deuterium) in the E2 reaction introduces a primary deuterium isotope effect of large magni-

tude, typically a factor of 4 to 8 for the rate ratio (18, 19) although much larger values have been observed (20–22).

While the percentage of E2 to the total reaction is expected to be small for the quaternization reaction (23), it is apparent that even a small percentage could give rise to misleading, small, overall normal isotope effects. In order to determine the magnitude of this source of error a careful product analysis was carried out for the reactions of isopropyl iodide and bromide, for which the E2 side reaction is known to be larger than for the ethyl and *n*-propyl halides (24). The total product formed was obtained by potentiometric titration with aqueous silver nitrate and the elimination products were estimated by a non-aqueous acid–base titration following Brown and Cahn (25) plus, in the case of the iodide, a spectrophotometric determination of iodine which was presumed to have been formed by oxidation of some of the hydriodic acid (25). The analytical results are compiled in Table 2. As expected, the proportion of elimination is greater for the iodide than for the bromide (24). The value of 2% for the iodide may be compared with Brown and Cahn's approximate figure (25) of 3% for equal initial molar concentrations of methyl substituted pyridines and isopropyl iodide in the same solvent.

The possible error introduced into the secondary isotope effect by the elimination reaction may be estimated as follows:

$$S_N2 \text{ rate} = k_s[RX][C_5H_5N]$$

$$E2 \text{ rate} = k_E[RX][C_5H_5N]$$

$$\text{Observed rate} = k_{obs}[RX][C_5H_5N]$$

$$= (k_E + k_s)[RX][C_5H_5N]$$

$$[1] \qquad \left(\frac{k_H}{k_D}\right)_{obs} = \frac{k_E^H + k_s^H}{k_E^D + k_s^D}$$

If the secondary isotope effect, k_s^H/k_s^D, is assumed to be unity and the primary isotope effect k_E^H/k_E^D is written 'x', eq. 2 is obtained by dividing the numerator and denominator of eq. 1 by k_E^D.

$$[2] \qquad \left(\frac{k_H}{k_D}\right)_{obs} = \frac{x(k_s^H/k_E^H + 1)}{x.k_s^H/k_E^H + 1}$$

The numerical value of k_s^H/k_E^H for isopropyl iodide and bromide may be calculated from the figures in Table 2 as 49 and 133, respectively.

The observed rate ratio for isopropyl iodide, assuming no secondary isotope effect and a typical primary isotope effect ($x = 7$) would be $(k_H/k_D)_{obs} = 1.017$ and the largest possible ratio ($x = 700$) would be 1.020. For isopropyl bromide primary isotope effects of 7 and 700 would give rate ratios of 1.006 and 1.007. Therefore, for these small amounts of elimination the maximum error is about the same percentage as the elimination is of the total reaction.

Second-order rate constants for some β-deuterated alkyl halides and their isotopic rate ratios are shown in Table 3. In determining the isotope effects, the normal compound was always run simultaneously with the deuterated sample to eliminate errors such as temperature fluctuation and where the α and β effects were measured at widely separated time intervals, slight differences in k_H are noted. The corrected rate ratio was calculated assuming a primary isotope effect on the elimination reaction of 7. The elimination percentage was not investigated for the ethyl and *n*-propyl halides since it is expected to be very small indeed for these compounds (24).

TABLE 3. Second-order rate constants and isotopic rate ratios for the reaction of β-deuterated alkyl halides with pyridine at 50.0 °C in nitrobenzene solvent

	$10^6 k_H$(l mol^{-1} s^{-1}) (± standard error)	$10^6 k_D$(l mol^{-1} s^{-1}) (± standard error)	k_H/k_D (observed)	k_H/k_D* (corrected)	(k_H/k_D) per D (corrected)
Ethyl iodide	151.5±0.1	149.6±0.9	$1.01_3 \pm 0.006$	—	1.00_4
n-Propyl bromide	13.26±0.15	13.23±0.14	$1.00_2 \pm 0.015$	—	1.00_1
Isopropyl iodide	9.66±0.04	9.23±0.04	$1.04_7 \pm 0.006$	1.03_0	1.00_5
Isopropyl bromide	0.972±0.008	0.885±0.005	$1.09_9 \pm 0.011$	1.09_1	1.01_5

*Corrected assuming a primary isotope effect of 7 for the elimination reaction.

The results in Table 3 show that only in the isopropyl halides is the β-deuterium isotope effect significant, with the bromide giving a rate decrease with deuteration three times larger than the iodide. The direction and magnitude of the effects are not surprising in comparison to those observed in the water solvolysis reactions (4). Since the hydrolysis reactions give a temperature independent isotope effect for isopropyl compounds (26), it is not possible to specify the origin of the isotope effects in the pyridine reaction. However, that normal effects are observed does allow the conclusion that within the S_N2 mechanism there is a trend to a less crowded (or possibly a more S_N1-like) transition state for secondary compounds than for primary compounds, since this type of structure is required for normal isotope effects whether the explanation is made in terms of the hyperconjugative effects (27) or in terms of internal rotational contributions (26, 28).

The greater magnitude of the rate change for the bromide leaving group than for the iodide again indicates, as found for the α-effect that the iodide has a tighter, more crowded transition state. This trend is in agreement with the β-effect observed by Strecker and Elias (29) for the radiochloride exchange with isopropyl chloride ($k_H/k_D = 1.12$).

γ-Deuterium Effect

The relative rates of reaction were measured for *n*-propyl-γd_3 bromide and its normal analogue giving 13.32 and 13.26×10^{-6} l mol^{-1} s^{-1} respectively, possibly an inverse isotope effect of about $\frac{1}{2}$%, but the two rates are barely significantly different. This result is very similar to the γ-effect observed for *n*-propyl-γd_3 bromide reacting with thiosulfate ion (30) in 50% v/v ethanol–water $k_H/k_D = 0.990$ and very much smaller than the 8% inverse effect found for the same compound solvolyzing in water (3).

From these three results there appears to be an approximate correlation between the β and γ isotope effects with the β rate ratio becoming larger than unity as the γ rate ratio becomes less than unity. This suggests that both these effects depend on transition state geometry and is in accord with the earlier explanations (3), which postulated that the greater the β-hydrogen atom interaction with the central carbon atom p-orbital in the transition state (hyperconjugation), the greater would be the steric inhibition of the vibrations of the γ-hydrogens. The amount of hyperconjugation will be directly related to the degree of incipient positive charge on the central carbon atom in the transition state. Thus, for the three S_N2 reactions of *n*-propyl bromide, it may be concluded that the pyridine reaction has no such charge (or no S_N1 character or no ion-pair character), the thiosulfate ion reaction has a very small amount, and the hydrolysis a slightly larger amount.

Experimental

Materials

Nitrobenzene solvent was dried over anhydrous calcium sulfate and distilled at atmospheric pressure, boiling range 210.5–211 °C. Pyridine was dried with potassium hydroxide pellets and then with calcium hydride before fractional distillation. Material boiling between 115.2 and 115.7 °C was collected and stored in an opaque container over calcium hydride and under nitrogen.

Methyl bromide, previously cooled to −80° in an acetone–Dry Ice slurry was allowed to volatilize at 25–30°, passed through wash towers of concentrated sulfuric acid and glass wool, and collected and stored at −80°. All the other alkyl halides were dried over anhydrous calcium sulfate and fractionally distilled, after which they were stored in opaque containers in an atmosphere of nitrogen and over copper. Methyl tosylate was distilled under vacuum.

Commercial samples of methyl-d_3 bromide, ethyl-αd_2 iodide and bromide, *n*-propyl-αd_2 bromide, *n*-propyl-βd_2 bromide, isopropyl-βd_6 iodide and bromide, and *n*-propyl-γd_3 bromide were used without further purification. Commercial methyl-d_3 iodide was redistilled and stored in opaque sealed tubes. Methyl-d_3 tosylate, prepared by Jackson (9), was redistilled under vacuum. Ethyl-βd_3 iodide was prepared by reaction of ethyl-βd_3 tosylate (0.01 mol) with a slurry of dry potassium iodide (0.03 mol) in diethylene glycol (2 ml). The product was distilled from the reaction mixture at 45–50 °C under reduced pressure and collected in a liquid N_2 trap. After several redistillations the ethyl-βd_3 iodide was stored in an opaque sealed tube, under nitrogen, over copper. The yield was 59%. The absence of hydrogen on the β-carbon atom was confirmed by n.m.r. spectroscopy.

Isopropyl-αd_1 halides were prepared from isopropyl-αd_1 alcohol (Merck, Sharp & Dohme Ltd.) via the *p*-bromobenzenesulfonate (brosylate). The general method of Sekera and Marvel (31) was used to convert the alcohol to the brosylate, by reaction with *p*-bromobenzenesulfonyl chloride in anhydrous pyridine at −5 °C. A 57% yield of brosylate was obtained, melting at 31–32 °C. Isopropyl-αd_1 brosylate was converted to the iodide and bromide by reaction with the appropriate solid potassium halide, as described for ethyl-βd_3 iodide. Crude yields of about 60% were obtained and the halides were purified for kinetic work by g.l.c. using a very low column temperature. The deuteration of the compounds was confirmed by the n.m.r. spectra.

Analyses for Elimination Products

Ten sealed tubes each containing 4.402 ml of reaction mixture were prepared and allowed to react at 50° for about ten half-lives. For the isopropyl iodide reaction the substrate concentration was 0.0483 *M* and that of the pyridine 0.227 *M*, with a reaction time of 39 days. The corresponding figures for the isopropyl bromide reaction were 0.0973, 0.778 *M*, and 117 days. The total halide concentrations were determined by potentiometric titration against standard silver nitrate solution of approximately the same molarity as that of the pyridinium halide. Sharp end-points were obtained using wet acetone as solvent. Both reactions were found to be about 98% complete with respect to the isopropyl halide.

The hydrohalic acid concentrations were determined by potentiometric titration of the sample against potassium hydroxide in isopropanol solvent under an atmosphere of nitrogen. Blank titrations were run and the analyses corrected.

In the isopropyl iodide reaction a visible concentration of iodide was produced and this was estimated spectrophotometrically. A calibration curve of $\log_{10}$ (% transmittance), at a wavelength of 480 nm, *vs*, iodine concentration was set up by preparing solutions of iodine in a mixture of *N*-ethylpyridinium iodide and pyridine in nitrobenzene. This graph was linear. The ethyl product was used to stimulate the reaction mixture rather than the isopropyl compound because solutions of isopropylpyridinium iodide tend to redden on standing. Thus the iodine concentration recorded in Table 2 may have come from some decomposition of the substitution product as well as the elimination reaction, and the percentage elimination is, therefore, a maximum figure.

Kinetic Measurements

The runs were followed conductometrically in a manner very similar to that previously described (17), except for those involving methyl bromide. A calibration curve was constructed for each alkyl halide reaction and they were all very similar in form to that for trimethylphenylammonium tosylate in nitrobenzene (14). The conductivities were converted to concentrations and the second-order rate constants were calculated from the integrated second-order equation. The kinetics were followed to various reaction percentages up to 50% for most of the alkyl halides, but only up to 10% for the isopropyl compounds. The pyridine was always in excess, ranging from a factor of 2 to a factor of 8.

The methyl bromide runs were carried out using a sealed tube technique, similar to that described previously (28).

Kinetic Study of the Pyrolysis of Formaldehyde

C. J. CHEN AND D. J. MCKENNEY
Department of Chemistry, University of Windsor, Windsor, Ontario
Received August 17, 1971

Kinetics of the thermal decomposition of pure formaldehyde were studied over a temperature range of 466–516 °C and a pressure range of ~50–160 Torr. Arrhenius parameters and rate laws were determined for carbon monoxide, hydrogen and methanol as follows:

$$\frac{d[CO]}{dt} = [10^{11.8\pm0.4} \exp(-34\,400 \pm 1\,300/RT)][CH_2O]^{1.8}$$

$$\frac{d[H_2]}{dt} = [10^{8.7\pm1.0} \exp(-34\,000 \pm 3\,600/RT)][CH_2O]^{1.6}$$

$$\frac{d(CH_3OH)}{dt} = [10^{12.6\pm0.9} \exp(-36\,800 \pm 3\,600/RT)][CH_2O]^2$$

A mechanism is postulated which is qualitatively consistent with the experimental results but the activation energy for reaction 1

[1] $$2CH_2O \rightarrow CH_2OH + CHO \quad E = 37 \text{ kcal/mol}$$

is ~15 kcal/mol lower than predicted from recent thermochemical data, suggesting the possibility of a heterogeneous reaction.

Les cinétiques de la décomposition thermique du formaldéhyde pur sont étudiées dans un intervalle de température de 466–516 °C et un intervalle de pression de 50–160 Torr. Les paramètres d'Arrhénius et les lois de vitesse sont déterminés pour le monoxyde de carbone, l'hydrogène et le méthanol comme suit:

$$\frac{d[CO]}{dt} = [10^{11.8\pm0.4} \exp(-34\,400 \pm 1\,300/RT)][CH_2O]^{1.8}$$

$$\frac{d[H_2]}{dt} = [10^{8.7\pm1.0} \exp(-34\,000 \pm 3\,600/RT)][CH_2O]^{1.6}$$

$$\frac{d(CH_3OH)}{dt} = [10^{12.6\pm0.9} \exp(-36\,800 \pm 3\,600/RT)][CH_2O]^2$$

Un mécanisme est admis qui est qualitativement compatible avec les résultats expérimentaux mais l'énergie d'activation pour la réaction 1

[1] $$2CH_2O \rightarrow CH_2OH + CHO \quad E = 37 \text{ kcal/mol}$$

est ~15 kcal/mol plus faible que prévu à partir des récents résultats thermochimiques suggérant la possibilité d'une réaction hétérogène.

Canadian Journal of Chemistry, **50**, 992 (1972)

Introduction

In spite of the fact that formaldehyde is an important intermediate in many gas phase reactions (1–4) the detailed kinetics and mechanism of the pyrolysis is not completely established. Many photochemical investigations have been made (*e.g.* ref. 5) yet considerable doubt remains with regard to specific kinetic and thermochemical values related to CH_2O, CHO, CH_2OH, etc. (6).

The major process in the thermal decomposition is clearly a free radical chain reaction yielding CO and H_2 at temperatures above ~450 °C (7). Methanol is a relatively minor product which becomes increasingly important as the temperature is decreased (8). Klein *et al.* (7) proposed that methanol is produced by a homogeneous molecular reaction, whereas Calvert and Steacie (9) suggested a heterogeneous process. Gay *et al.* (10) detected CH_3O radicals mass spectrometrically at shock tube temperatures.

There are significant discrepancies in the measured activation energies. Fletcher (11) obtained 44.5 kcal/mol at 783–883 °K, while Gay *et al.* (10) calculated a value of 27.8 kcal/mol at 1535–2100 °K. Longfield and Walters (8) obtained 31 kcal/mol for methanol formation

at 666–731 °K. A simple Rice–Herzfield mechanism predicts an activation energy greater than 60 kcal/mol and does not account for CH_3OH formation.

The decomposition was shown to be second-order in the shock-tube work, approximately second-order at lower temperatures, and all mechanistic interpretations have been made on the assumption of straightforward second-order kinetics.

This work was undertaken with the intention of resolving some of the questions pertaining particularly to the low (< 700 °C) temperature results.

Experimental

Experiments were carried out in a conventional static vacuum system similar to that previously described (12). Formaldehyde was prepared by heating paraformaldehyde (Fisher "purified") under vacuum following an adaptation of Spence and Wild's (13) procedure. The storage vessel and connecting tubing were thoroughly dried and degassed using a yellow flame while pumping prior to the admission of formaldehyde. After six distillations, freshly prepared formaldehyde was stored at − 196 °C.

Carbon monoxide was analyzed by gas chromatography using a thermal conductivity detector and a 6 ft, 1/4 in. i.d. molecular sieve 5A column at 90 °C. Hydrogen yields were calculated by difference from pressure measurements of the non-condensible fraction. CH_2O was analyzed on a 6 ft, 1/4 in. Polypak column at 90 °C, using the thermal conductivity detector and also along with the CH_3OH determinations using a flame ionization detector and an ethofat (10% supported on Chromosorb T) column at 115 °C (14).

Pyrolyses were carried out over a temperature range of 466–516 °C (± 0.25 °C). No detectable temperature gradient over the length of reaction vessel was observed. The reactor was a 277 cc quartz cylinder, $S/V \simeq 1.3\ cm^{-1}$, and dead space < 2%.

"Conditioning" was accomplished by twice washing with hot (~ 80 °C) concentrated HNO_3, returning the vessel to the furnace and pumping for several hours. After a few runs the results became fully reproducible.

Between runs the reactor was evacuated to $< 10^{-4}$ Torr.

Results[1]

Virtually no polymerization took place in the storage vessel for periods of many weeks provided it remained condensed at − 196 °C. Slight polymerization occurred however, during the periodic warming of the trap when samples were taken for reaction. Analyses of the reactant gas by g.c. indicated < 0.01% H_2O and < 0.05% CH_3OH present as impurities. These could not be removed by as many as six distillations. A thin polymer film slowly accumulated (particularly) in the traps of the analytical system.[2]

In addition to CO, H_2, and CH_3OH, slight traces of two unidentified compounds (apparently secondary products) formed at rates of $< 10^{-11}$ mol/cc s were found among the products. Compounds looked for and *not* found were glyoxal, carbon dioxide, formic acid, dimethyl ether, and methane. Minor polymerization processes in the analytical system hindered precise analyses of small quantities of CH_3OH, yields of which were shown to be a function (exponential or higher order) of the length of time the products were held in the cold traps prior to g.c. analysis. For example the measured CH_3OH yield decreased by > 40% when the analysis was delayed by ~ 40 min. Since the amount of CH_2O was always many orders of magnitude larger, a relatively small loss by polymerization of the aldehyde was hardly noticeable but resulted in a major loss of CH_3OH. Similar decreases were observed for the secondary products. In addition, loss rates were not always reproducible. As a result a systematic study of secondary products was not attempted.

In the case of the CH_3OH, enough analyses were carried out to obtain a rate constant for a temperature of 418 °C. Otherwise estimates were made based on the difference between carbon monoxide and hydrogen yields. Consideration of the stoichiometric equations,

$$CH_2O \rightarrow CO + H_2$$
$$2CH_2O \rightarrow CH_3OH + CO$$

shows any excess of CO to be equal to the yield of CH_3OH.

Initial rates of carbon monoxide and hydrogen were calculated from slopes of yield–time plots. Figure 1 shows typical plots for carbon monoxide for five different initial pressures at 516 °C. Reaction times were generally varied from 6 to 120 s depending on the reaction rate. Decompositions were always < 5%. All plots showed good linearity, but extrapolated through a positive intercept (with the exception of CH_3OH

[1]Tables of analytical and kinetic data have been placed in the Depository of Unpublished Data, National Science Library, National Research Council, Ottawa, Canada K1A 0S2. Photocopies may be obtained upon request to the Depository.

[2]Polymerization is facilitated by adsorbed water and methanol (15).

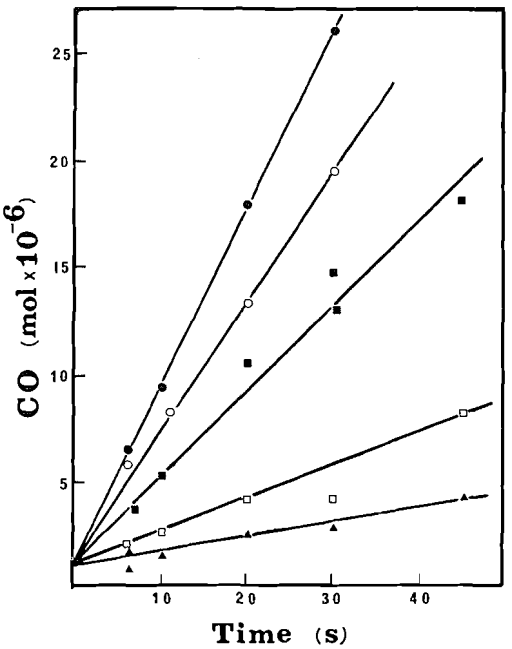

FIG. 1. Yield–time plot for carbon monoxide at 516.6 °C over five different initial formaldehyde pressures (Torr). ● 162.0; ○ 143.5; ■ 115.0; □ 71.0; ▲ 50.0.

which passed through the origin. Double logarithmic plots of initial rate *vs.* formaldehyde concentration had slopes of 1.8 ± 0.03 for carbon monoxide and 1.6 ± 0.04 for hydrogen. Similar plots for estimated methanol production showed an order of 2.0 ± 0.05. (Error limits indicate maximum uncertainty in slopes.) At higher pressures of formaldehyde the yields of carbon monoxide were approximately double those of hydrogen but the ratio decreased to about 1.3 at 50 mm pressure.

Arrhenius plots (Fig. 2) yielded the following rate constants for CO, H_2, and CH_3OH yields.

$$k_{CO} = 10^{11.8 \pm 0.4}\, e^{\frac{-34\,400 \pm 1\,300}{RT}}\ \text{cc}^{0.8}/\text{mol}^{0.8}\ \text{s}$$

$$k_{H_2} = 10^{8.7 \pm 1.0}\, e^{\frac{-34\,000 \pm 3\,600}{RT}}\ \text{cc}^{0.6}/\text{mol}^{0.6}\ \text{s}$$

$$k_{CH_3OH} = 10^{12.6 \pm 0.9}\, e^{\frac{-36\,800 \pm 3\,600}{RT}}\ \text{cc/mol s}$$

The uncertainty limits in these values are generous estimates of the maximum probable error. The hydrogen data were somewhat more scattered than in the carbon monoxide case as a result of the combined errors in the carbon monoxide analysis and manometer readings. The ratio CO/H_2 appears to increase with decreasing temperature if the data taken at 71 mm pressure of formaldehyde are neglected. If the trend is significant it implies that the activation energy for hydrogen production should be ~4 kcal greater than that for carbon monoxide production. Figure 2 also shows some results of previous research for comparison.

Discussion

There is no doubt that the pyrolysis of formaldehyde occurs predominantly by a chain mechanism (7) and for a compound as apparently simple as CH_2O the possible schemes would appear to be rather limited. Gay *et al.* (10) pyrolyzed formaldehyde over the temperature range of 1500 to 2100 °K in a shock tube, and considered a number of possible mechanisms. They were unable however, to establish conclusively which one was correct. Their detection of the methoxyl radical (CH_3O) mass spectrometrically points to the homogeneous formation of methanol since heterogeneous reactions were ruled out in their study. Many schemes were attempted in this work before deciding to discuss our data in terms of mechanism II of Gay *et al.* (10). At the lower temperatures involved in this work their scheme (below) had to be modified slightly (addition of reaction 3 and the third body required in reaction 6).

[1] $2CH_2O \rightarrow CH_2OH + CHO$

[2] $M + CH_2OH \rightarrow CH_2O + H + M$

[3] $CH_2OH + CH_2O \rightarrow CH_3OH + CHO$

[4] $M + CHO \rightarrow H + CO + M$

[5] $H + CH_2O \rightarrow H_2 + CHO$

[6] $M + 2CHO \rightarrow 2CO + H_2 + M$

Application of the steady state approximation leads to the following rate expressions, if at low temperature $k_3 > k_2$, $k_4 > k_2$, and the third body, M, corresponds to CH_2O.

$$[7]\quad \frac{-d[CH_2O]}{dt} = 3k_1[CH_2O]^2 + k_4\left(\frac{k_1}{k_6}\right)^{1/2}[CH_2O]^{3/2}$$

$$[8]\quad \frac{d[CO]}{dt} = 2k_1[CH_2O]^2 + k_4\left(\frac{k_1}{k_6}\right)^{1/2}[CH_2O]^{3/2}$$

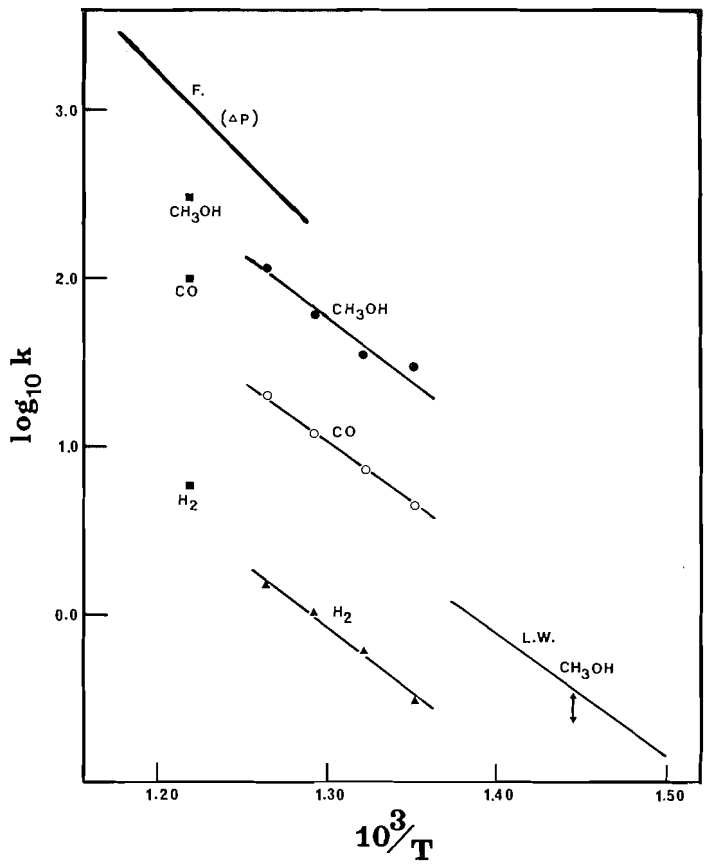

FIG. 2. Arrhenius plots for methanol, carbon monoxide, and hydrogen production. Results of some previous research are also shown. ● CH_3OH production (estimated); this work. ○ CO production; this work. ▲ H_2 production; this work. ↕ CH_3OH production (direct analyses); this work. ■ Calculated from Klein *et al.* (7) for products indicated. F from Fletcher (11); manometric data. L. W. from Longfield and Walters (8). CH_3OH analyses. Units: k_{CH_3OH} (cc/mol s); k_{CO} ($cc^{0.8}/mol^{0.8}$ s); k_{H_2} ($cc^{0.6}/mol^{0.6}$ s); k_{Δ_p} (cc/mol s).

$$[9]\quad \frac{d[H_2]}{dt} = k_1[CH_2O]^2 + k_4\left(\frac{k_1}{k_6}\right)^{1/2}[CH_2O]^{3/2}$$

$$[10]\quad \frac{d[CH_3OH]}{dt} = k_1[CH_2O]^2$$

Benson and O'Neal (16) recommended $k_4 = 10^{13.7}\exp(-19\ \text{kcal}/RT)$ and $k_2 = 10^{13.05}\exp(-29\ \text{kcal}/RT)$. k_3 can be estimated as $10^{11}\exp(-6\ \text{kcal}/RT)$ by comparison with similar abstraction reactions (17). At 500 °C, $k_3/k_2 \simeq 10^4$.

The rate of formation of carbon monoxide was 1.8 order with respect to formaldehyde, suggesting that both terms in eq. 8 are about equally important. In the hydrogen case the observed 1.6 order is in agreement with eq. 9 providing the second term dominates. Equations 8 and 9 are identical except for the factor of 2 appearing in eq. 8. This accounts for the higher order observed for CO. Reaction orders obtained in this work were supported by replotting Fletcher's (11) manometric data which led to 1.7 order dependence on formaldehyde pressure.

Rates of disappearance of CH_2O could not be determined precisely because measurements necessitated taking small differences of relatively large quantities, in addition to the occasional loss of small amounts in the analysis due to polymerization with the resultant uncertainties (±3%) being generally larger in magnitude than the rates to be measured. However, qualitative results showed approximate agreement with eq. 7.

The rate law for methanol production agreed with eq. 10.

Reactions 2, 4, and 6 were assumed to be in

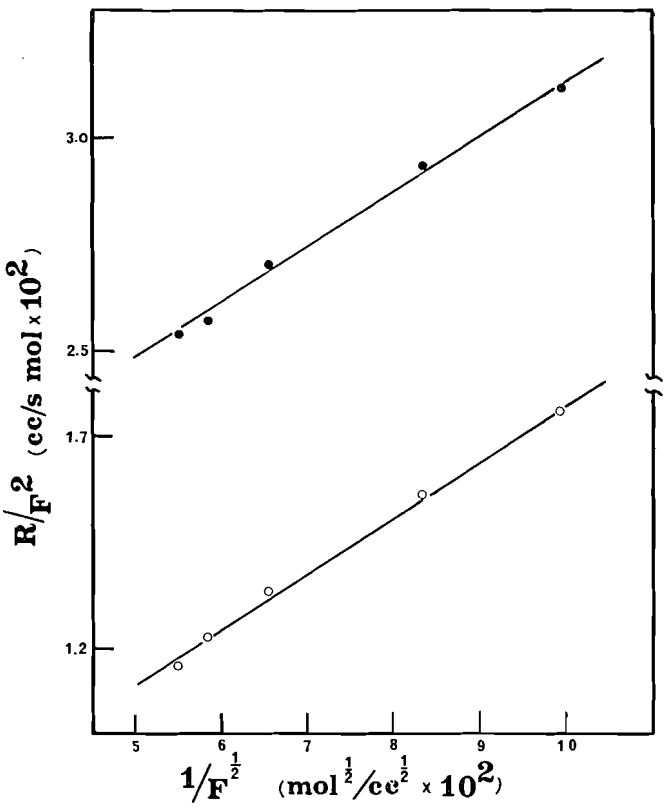

FIG. 3. Typical plots of initial rates divided by formaldehyde concentration squared *vs.* the reciprocal of the square root of formaldehyde concentration. Temperature 516.6 °C (eqs. 8 and 9). ● carbon monoxide data; ○ hydrogen data.

their pressure-dependent regions, an assumption justified by comparison with other three-, five-, and six-atom unimolecular processes (16) in roughly the same temperature and pressure range.

The derived rate laws were tested by appropriate plots of the experimental data. Typical plots of initial rate divided by formaldehyde concentration squared ($R(CO)/F^2$ and ($R(H_2)/F^2$) against $1/F^{1/2}$ at 516.6 °C are shown in Fig. 3. According to eqs. 8 and 9 the slopes and intercepts of such plots yield values of $k_4(k_1/k_6)$ and k_1. Subsequent Arrhenius plots produced eqs. 11–14. Equations 13 and 14 are

$$[11] \quad \log \{k_4(k_1/k_6)^{1/2}\}_{CO} = (8.4 \pm 0.3) - (32\,200 \pm 2\,200)/2.3RT$$

$$[12] \quad \log \{k_4(k_1/k_6)^{1/2}\}_{H_2} = (8.0 \pm 1.0) - (32\,600 \pm 1\,000)/2.3RT$$

$$[13] \quad \log (k_1)_{CO} = (12.2 \pm 0.6) - (37\,200 \pm 1\,200)/2.3RT$$

$$[14] \quad \log (k_1)_{H_2} = (11.4 \pm 0.3) - (36\,700 \pm 2\,750)/2.3RT$$

to be compared with that obtained from the experimental expression derived from estimated rates of methanol production (Fig. 2), eq. 15.

$$[15] \quad \log (k_1)_{CH_3OH} = (12.6 \pm 0.9) - (36\,800 \pm 3\,600)/2.3RT$$

(The subscripts on the left hand terms refer to CO, H_2, and CH_3OH plots.) Agreement is quite satisfactory in all cases.

While the above plots and derived parameters lend substantial support to the proposed mechanism, calculated thermochemical values show serious disagreement with these activation

energies. For example using more recent data from Fletcher and Pilcher (6), ΔH_f^0 (CH_2O) = -25.9 ± 0.11 kcal/mol, D(H—CHO) = 88.5 ± 0.9 kcal/mol, and from Fisher and Henderson (18), ΔH_f^0 (CH_2OH) = -8.4 ± 3.0 kcal/mol and calculating ΔH_f^0 (CHO) = 10.5 kcal/mol, ΔH^0 for reaction 1 is equal to 53.9 kcal/mol. At about 700 °K, $\Delta C_p T_0 \simeq 1.5$ kcal/mol and assuming $E_{-1} \simeq 0$, then $E_1 \simeq 52.4$ kcal/mol.

The value of the C—H bond dissociation energy in formaldehyde has been in dispute for many years (see for example (6, 19, 20) and references cited therein). Even using a "low" value (~ 80 kcal/mol) and a consistent set of enthalpies the result is still some 11 kcal/mol higher than the E_1 estimated from our experimental data.

The apparent low value for E_1 may imply a wall reaction in the initiation step, but the existing evidence on this point is inconclusive. Firstly, the existence of a positive intercept in the yield–time plots (Fig. 1) suggests possible participation of a rapid wall reaction in the very early stages of a "run" and since these intercepts were always effectively independent of initial pressure, the effect cannot be attributed to impurities. Secondly, heterogeneous reactions can be particularly troublesome when hydrogen production is relatively important (at least in paraffin pyrolyses) (21). Thirdly, decomposition rates are reported to be sensitive to the treatment and history of the reaction vessel (7). On the other hand, it has been shown (7, 8) that the reaction is more or less independent of the surface to volume ratio, hence a compensating termination step would be required. In addition, wall processes appear to be unlikely in view of the relatively close agreement between our low temperature data and those at shock wave temperatures (10).

Our data are reasonably consistent with the more recent pyrolysis studies (7, 10). For example, use of our rate constant for carbon monoxide formation (see Fig. 2), leads to calculated rates within approximately a factor of two of those observed by Klein *et al.* (7) at 547 °C.

The high temperature data of Gay *et al.* (10) are not shown in Fig. 2 but a long extrapolation of our results yields a rate constant (1500–2000 °K) ~ 20 times less than theirs. Fletcher's (11) early data based on a manometric study produced rate constants considerably higher than ours. The reason for the discrepancy is not clear. Fletcher did not elaborately dry his formaldehyde claiming that the reaction was unaffected by water vapor. He also observed higher rates using freshly prepared paraformaldehyde, possibly indicating the presence of traces of oxygen. Contamination of this sort could account for the higher rates.

Longfield and Walter's (8) data shown in Fig. 2 were based on four experiments over the temperature range of 393–458 °C and involved analyses of methanol. In this work 15 runs were carried out at 418 °C, leading to the result indicated by the double headed arrow (deviation) in Fig. 2. The agreement is apparently quite satisfactory. There are reasons, however, for doubting the accuracy of the rates based on methanol analyses. Losses were inevitable in all determinations due to polymerization and possibly secondary reactions. Our results indicate that these losses could be relatively large (order of magnitude). We therefore favor estimates based on the difference between CO and H_2 yields as more accurately representing initial rates of formation of methanol neglecting the small error due to possible termination products such as glyoxal.

According to the mechanism k_{CO} and k_{H_2} (observed) is given approximately by $k_4 (k_1/k_6)^{1/2}$. Using $E_4 \simeq 15$ (22), $E_6 \simeq 0$ and $E_1 \simeq 37$, then $E_{calc} \simeq 33.5$ as compared with $E_{exp} = 34$. The agreement may be fortuitous however, since E_1 was not independently determined. Use of Benson and O'Neal's (16) value, ($E_4 = 19$ kcal/mol) still leads to reasonable agreement. Using $E_1 \simeq 52$ (calculated above) yields $E_{calc} \simeq 41$ or 45, respectively.

Organic Free Radical and Metal Complexes. 2,2-Diphenyl-1-picrylhydrazyl with Cu(I)

F. LEH[1] AND J. K. S. WAN

Department of Chemistry, Queen's University, Kingston, Ontario

Received August 16, 1971

Reactions of Cu(I)Cl, $Cu(II)Cl_2$, Cu(II) acetylacetonates, and Cu(II) *N*-methylsalicylalidiiminate with the stable free radical 2,2-diphenyl-1-picrylhydrazyl have been investigated. In all cases Cu(II) was reduced and the organic radical behaved as an electron donor-ligand to form complexes containing Cu(I). These novel free radical Cu(I) complexes were characterized by various spectroscopic methods, including e.s.r.

Les réactions des acétylacétonates de Cu(I)Cl, $Cu(II)Cl_2$, Cu(II) et du *N*-méthylsalicylalidiiminate de Cu(II) avec le radical libre stable diphényl-2,2 picryl-1 hydrazyl, ont été étudiés. Dans tous les cas Cu(II) a été réduit et le radical organique se conduit comme un ligand donneur d'électrons pour former des complexes contenant Cu(I). Ces nouveaux complexes radicaux libres Cu(I) ont été caractérisés par plusieurs méthodes spectroscopiques, dont la résonance du spin électronique.

Introduction

The stable free radical 2,2-diphenyl-1-picrylhydrazyl (DPPH) has been investigated extensively in solution and in the solid state by e.s.r. (1), n.m.r. (2), and optical absorption spectroscopy (3). Several diamagnetic monoalkali salts M^+ $DPPH^-$ have been prepared and characterized (4) and the reactions of DPPH with acidic centers in minerals have recently been investigated (5). Some preliminary observations on the reactions of Cu(II) acetylacetonates (6) and iron(II) (7) with DPPH have been reported. However, no details regarding the nature and products of the reactions have been published. In this paper we wish to report some evidence for the formation of Cu(I)DPPH complexes from the reactions of a variety of copper compounds with DPPH.

Experimental

Optical spectra were recorded with a Unicam SP 800 spectrophotometer and i.r. data were obtained from mull samples with a Perkin–Elmer 180 spectrometer with sodium chloride optics. Proton n.m.r. spectra were taken on a Bruker HX-60 high resolution instrument locked on tetramethylsilane as an internal standard. The e.s.r. spectra were obtained with a Varian V4502 spectrometer and spectral analysis was carried out by means of spectra simulation on an IBM 360/50 computer. Mass spectra were recorded on a JEOL high resolution mass spectrometer; the samples were introduced via the heated inlet at 100 °C and perfluorokerosene was used as mass standard.

[1]Postdoctoral Fellow, 1970–1972.

Satisfactory elementary analyses were performed by Schwarzkopf Microanalytical Laboratory. Molecular weights were determined by means of a Hewlett Packard vapor pressure osmometer with chloroform as solvent at 37.6 °C, using purified benzil as the standard.

Preparation of Mono(DPPH) Cu(I) Chloride

This complex was prepared by the following different methods.

(*a*) A solution of DPPH (0.39 g) in chloroform (20 ml) was added to a solution of Cu(II) chloride (0.34 g) in ethanol (10 ml). After 14 h the resulting solution was evaporated to half-volume and cooled in an ice-bath. The brown crystals were filtered off, washed with ether and ethanol, and dried (0.30 g, 61.4% yield), m.p. 174 °C (dec.).

Anal. Calcd. for DPPH–CuCl (mol. wt. 493): Cu, 12.8. Found (475 ± 25): Cu, 11.7.

(*b*) A mixture of DPPH–H (2,2-diphenyl-1-picrylhydrazine, 0.39 g) in chloroform (20 ml) and Cu(II) chloride (0.34 g) in ethanol (10 ml) was allowed to react for 14 h. The solvent was evaporated under vacuum and brown crystals were recovered and recrystallized (0.31 g, 63.3% yield), m.p. 177 °C (dec.).

Anal. Found for DPPH–CuCl (468 ± 25): Cu, 11.6.

(*c*) A brown solution resulted when excess Cu(I) chloride was suspended in an acetone solution of DPPH (0.39 g). The unreacted Cu(I) chloride was filtered off and the brown crystals were recrystallized from chloroform and ether, yield: 49.9%, m.p. 178 °C (dec.).

Anal. Found for DPPH–CuCl (475 ± 25): Cu, 11.8.

Preparation of Mono(DPPH) Cu(I) Acetylacetonate

Bis(acetylacetonate) Cu(II) (0.5 g) and DPPH (0.8 g) were dissolved in hot methanol (50 ml) and allowed to stand for 1 h at 60 °C. Evaporation of the solvent and recrystallization from chloroform–ether gave brown crystals (0.5 g, 50% yield), m.p. 145 °C (dec.).

Anal. Calcd. for DPPH–Cu(I) acetylacetonate (mol. wt. 556.6): C, 49.59; H, 3.41; Cu, 11.4. Found (535 ± 30): C, 50.6; H, 3.5; Cu, 10.8.

*w, weak; m, medium; s, strong; vs, very strong; (acac), acetylacetonate; (tfacac), trifluoroacetylacetonate; (salm), *N*-methyl salicylaldiiminate.

Preparation of Mono(DPPH) Cu(I) Trifluoroacetylacetonate

A solution of bis(trifluoroacetylacetonate) Cu(II) (0.74 g) in hot methanol was added to DPPH (0.80 g) in 50 ml methanol and the mixture was gently heated for 1 h. Evaporation of the solvent and recrystallization from chloroform–light petroleum ether gave brownish grey crystals (0.63 g, 40.9% yield), m.p. 148 °C (dec.).

Anal. Calcd. for DPPH–Cu(I) trifluoroacetylacetonate (mol. wt. 610.5): Cu, 10.4. Found (581 ± 30): Cu, 10.1.

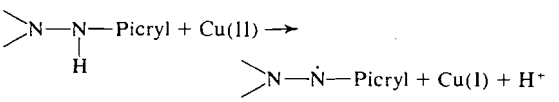
Preparation of Mono(DPPH) Cu(I) N-Methyl Salicylaldiiminate

Bis(*N*-methyl salicylaldiiminato) Cu(II) (0.65 g) and DPPH (0.8 g) were dissolved in hot methanol (60 ml) and allowed to stand for 1 h at 60 °C. The solution began turning brown after several minutes; chromatography on silica gel and addition of diethyl ether yielded dark brown crystals (0.72 g, 50% yield), m.p. 151 °C (dec.).

Anal. Calcd. for DPPH–Cu(I) *N*-methyl salicylaldiiminate (mol. wt. 591.5): C, 52.74; H, 3.38; Cu, 10.7. Found (607 ± 30): C, 53.1; H, 3.5; Cu, 10.0.

Results and Discussions

Free radical complexes of the formulae DPPH–CuL (where L is one of the following: chloride ion, acetylacetone, trifluoroacetylacetone, *N*-methyl salicylaldiimine) have been synthesized by the reactions of Cu(I)Cl or $Cu(II)L_2$ with DPPH or DPPH–H in organic solvents. This type of complex containing the free radical ligand DPPH is novel and a report (8) on other metal complexes with organic radical ligands such as α,α′-bipyridyl and *O*-phenanthroline has only recently appeared. In the present study it is interesting to note that the DPPH–H is a stronger reducing agent than tertiary phosphines, since triphenylphosphine fails to reduce Cu(II) acetylacetonate to form the Cu(I) complex (9). In the reaction of DPPH–H, the primary reaction suggested by a referee could be:



Using DPPH as the starting reagent in ethanol leads to the same product. This is probably due to the well known fact that DPPH is rather unstable in ethanol (10) and presumably reduces to give the DPPH–H.[2]

The i.r. absorption data of these DPPH–CuL complexes are given in Table 1. The assignments are based on the frequencies previously reported for Cu(II) acetylacetonates (11), Cu(II) bis-salicylaldehydeethylenediiminate (12), and those for the free radical DPPH. The C=O and C=N absorption bands are stronger in DPPH–CuL complexes than in their parent compounds and may be caused by the transmission of electron effects from the nitro substituents on the picryl ring moiety through the metal atom to the chelates of the complexes. For the assignments of the metal-oxygen stretching bands of acetylacetonate complexes, Nakamoto *et al.* (13) show the Cu(II)—O stretching mode occurring at 455 cm^{-1}. We tentatively assign the Cu(I)—O stretching at 450 and 448 cm^{-1} for DPPH–Cu(I) acetylacetonate and DPPH–Cu(I) trifluoroacetylacetonate, respectively. The two

bands of the DPPH–Cu(I) *N*-methyl salicylaldiiminate at 458 and 646 cm^{-1} are assigned to the Cu—O and Cu—N vibrations, respectively.

Most organic radicals in dilute solutions have relatively long electron spin relaxation times resulting in very broad nuclear resonance signals. The proton resonance of the picryl ring of the free radical ligand DPPH can not be observed in solutions at various temperatures, but appears in the spectra of DPPH–CuL complexes by coordination. It seems likely that the use of coordination to study the n.m.r. of organic radicals will prove to be generally helpful in systems where the radicals have long relaxation times. The p.m.r. data for the DPPH–CuL complexes are presented in Table 2. The assignments for picryl ring, phenyl ring, and methyl protons are based on their intensities and previous observations of 2,2-diphenyl-1-picrylhydrazine (4, 14). In the spectrum of the uncomplexed DPPH, some small but definite spin density (1) on the picryl ring probably renders the picryl ring proton signals too broad for detection. When the DPPH is complexed to the Cu(I) ion via the picryl ring, the coordination could twist the picryl ring more out of the plane of the unpaired electron orbital, thus reducing the probability of spin delocalization and sharpening the picryl proton peaks for observation. For the observed small paramagnetic shift in these complexes, some remaining negative spin density is probably transferred directly from the picryl ring to the Cu(I) ion with the result that the absorption of the two picryl ring protons is displaced towards lower field. For the DPPH–Cu(I) acetylacetonates, the shift is slightly increased as the methyl group is replaced by an electron-withdrawing trifluoromethyl group.

The most characteristic physical property of these complexes DPPH–CuL is their paramagnetism due to the presence of an unpaired electron in the ligand DPPH; this has been studied by e.s.r. The spectra of polycrystalline samples of DPPH–CuL is found to consist of a single narrow symmetrical line centered at $g = 2.002$. In degassed dilute benzene solution, these complexes exhibit e.s.r. spectra of a major quintet with relative intensities approximately 1:2:3:2:1. The experimental spectra were analyzed in terms of two non-equivalent nitrogens (15, 16) with the larger nitrogen hyperfine coupling constant assigned to the picryl nitrogen, N_1 (15, 17). These coupling constants are reported in Table 3. In the case of DPPH–CuCl, further hyperfine structures arising from the interactions with the ring protons were also observed. It is seen from Table 3 that the ratio of A_{N_2}/A_{N_1} depends upon the nature of the chelates L. Walter (18) has rationalized substituent effects in terms of the relative impor-

		252	shoulder
Cu(II) trifluoroacetylacetonate	$CHCl_3$	680	34
		298	24000
DPPH–Cu(I) trifluoroacetylacetonate	$CHCl_3$	302	26170
Cu(II) *N*-methylsalicylaldiiminate	CH_3OH	635	99
		354	9804
		297	9400
		271	23180
		241	48040
DPPH–Cu(I) *N*-methylsalicylaldiiminate	CH_3OH	341	shoulder
		317	shoulder
		296	36830
		244	36560

tance of the following canonical forms in DPPH:

$$\underset{\mathbf{1}}{Ph_2N_{(2)}—\dot{N}_{(1)}—Picryl} \longleftrightarrow \underset{\mathbf{2}}{Ph_2^{+}\dot{N}_{(2)}—\dot{N}_{(1)}=Picryl^{-}}$$

Thus the electron-withdrawing nitro substituents in the picryl ring will stabilize form **2** relative to form **1**. Similarly, metal coordination with the picryl ring decreases the unpaired electron density on the picryl nitrogen and thus stabilizes the structure **2**.

The absence of the familiar characteristic Cu(II) e.s.r. signals in DPPH–CuL complexes is taken as evidence for Cu(I) formation. In addition, integration of the experimental e.s.r. signal intensities indicates approximately one unpaired electron per complex molecule.

The optical absorption band of the DPPH–CuL complexes together with those of their parent compounds are listed in Table 4. The distinct feature of the complexes spectra (Figs. 1 and 2) is the absence of both the absorptions at ~530 and ~670 nm which are present in the DPPH ligand and the parent Cu(II) compounds. The former absorption is due to the conjugated resonance structure of DPPH (3)

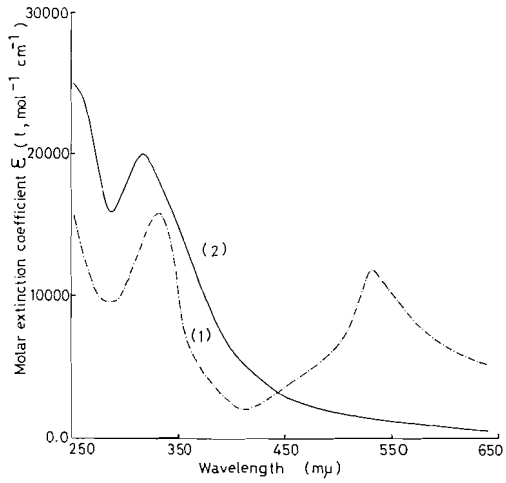

FIG. 1. Optical absorption spectra of: (*1*) DPPH and (*2*) DPPH–CuCl complex in chloroform.

while the latter has been assigned (19) to the P_π–d_π transition in the Cu(II) acetylacetonates. Cotton and co-workers (19) also suggested that the band at ~250 nm in the Cu(II) acetylacetonate spectra is a charge transfer band involving the promotion of a π-bonding electron

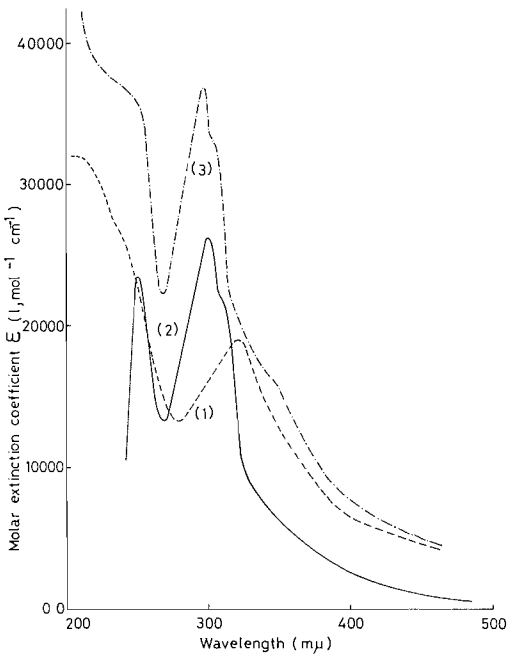

FIG. 2. Optical absorption spectra of: (*1*) DPPH–Cu(I) acetylacetonate in methanol, (*2*) DPPH–Cu(I) trifluoro-acetylacetonate in chloroform, and (*3*) DPPH–Cu(I) *N*-methyl salicylaldiiminate in methanol.

or a non-bonding electron of the oxygen to a metal orbital. However, in the DPPH–CuL complexes, bands in the 250 nm region are not resolved; the band at ~300 nm is probably due to an electronic transition in the diphenylamino moiety of the DPPH ligand (3) or a mixture of this with a π–π^* transition (19, 20) in the complexes.

Unlike the parent Cu(II) acetylacetonates, the DPPH–CuL complexes do not exhibit their parent peaks in their mass spectra, although they were expected to be thermally stable at temperatures well below their melting points. The relative intensities of all copper-containing ions and major ions from the ligand DPPH in the mass spectra of the complexes are given in Table 5. The abundant ions $[DPPH]^+$, $[CuC_6H(NO_2)_2]^+$, $[CuL]^+$ characterize the primary fragmentation of CuDPPH and CuL bonds in the complexes. The peaks at $m/e = 255$, 228, 170, 169, 168, 167, and 77 could be due to further fission of the $[DPPH]^+$ ion and indeed the base peak which appears in the mass spectra of all the complexes corresponds to the $[(C_6H_5)_2N]^+$ ion. For the DPPH–Cu(I) acetylacetonates, peaks at $m/e = 148$, 133, and 105 are consistent

with the fragmentation pattern of the $[CuL]^+$ ion (21).

Based upon the results presented, we conclude that we have synthesized some novel DPPH–CuL complexes and the complex formation is probably via the coordination of the Cu(I) ion with the picryl ring of the DPPH.

The authors are grateful to Professor K. E. Russell for many helpful discussions. This research is supported by the National Research Council of Canada and the Department of Public Health.

A Quantum Chemical Conformational Analysis of the Ethylenediamine Molecule

N. HADJILIADIS, A. DIOT, AND T. THEOPHANIDES
Department of Chemistry, University of Montreal, Montreal, Quebec

Received July 16, 1971

The conformational analysis of the ethylenediamine molecule has been studied by the LCAO-EHMO calculation method. The results indicate that the most stable conformation of the molecule is the *gauche* form, in which the angle N—C—C—N is *ca.* 63.0° measured from the *cis* form. This is in agreement with experimental data and can explain the fact that the ethylenediamine in its chelate complexes is always in the *gauche* form. In addition, the present results indicate that the *trans* form is the next most stable conformation of ethylenediamine in agreement with experimental results on bridging ethylenediamine metal complexes.

L'analyse conformationnelle de la molécule de l'éthylène diamine a été étudiée par la méthode de LCAO-EHMO. Le calcul indique que la conformation la plus stable est la forme *gauche*, avec un angle diédral N—C—C—N de 63.0°. Le résultat est en accord avec les résultats expérimentaux et explique la formation des complexes chélatés et pontés de cette molécule.

Introduction

Several complexes of ethylenediamine with different metal ions have been prepared and studied. In these complexes the ethylenediamine molecule serves as a chelating agent, or gives the so-called bridged type complexes, where the two nitrogen atoms are bound with two metal ions. In all the chelated complexes of ethylenediamine the organic molecule has the *gauche* form. This has been proved in several cases by X-ray crystallography (1–3), while in the bridged complexes, the ethylenediamine is in the *trans* form (4–6), with a C_{2h} symmetry.

Although the complexes of ethylenediamine have been thoroughly studied, little is known about the conformation and stability of the conformers of the free ethylenediamine molecule. Infrared and Raman spectra of the liquid and solid ethylenediamine have been explained satisfactorily by assuming the *cis* conformer present as the major contributor of the spectra (7, 8).

A recent short communication (9) showed by gas electron diffraction studies that ethylenediamine is predominantly in the *gauche* form, with the dihedral angle N—C—C—N of 64.0 ± 5.0°, as measured from the *cis* position.

Results and Discussion

The present work reports the results of calculations on the ethylenediamine molecule using the extended Hückel theory, LCAO-EHMO method with the aid of the CDC-6400 computer and the program developed by Hoffmann and co-worker (10). In these calculations intermolecular interactions are not taken into account, *e.g.*, hydrogen bonding, aggregation, etc., and only one isolated molecule is considered. It is known that the above method gives excellent agreement with experimental conformational studies, (11–13) and predicts reliably the molecular structure.

Allen and Russel (13) have discussed at great length the reliability of this method. Blyholder and Coulson (12) recently concluded "that this method gives reasonably satisfactory results...".

The present result is another example confirming the usefulness of this essentially *naive and crude*[1] EHMO method, which appears to work so well in predicting preferred equilibrium conformations. Kier (11*a*), who made similar calculations, concludes that the EHMO method works well, because it includes in the input the precise 3-dimensional coordinates of the atoms.

We believe that the method will continue to work reasonably well as long as the simple sums of one-electron energies behave approximately as the true molecular energies, *i.e.*, the nuclear–nuclear repulsions and the electron–electron repulsions cancel out roughly (10*c*) or their difference varies slowly with distance.

In order of stability the *trans* conformer comes next to the *gauche* form. The small difference in energy between the 63° and 180° configurations

[1]We should like to express our appreciation to the referee who so forcefully pointed this out.

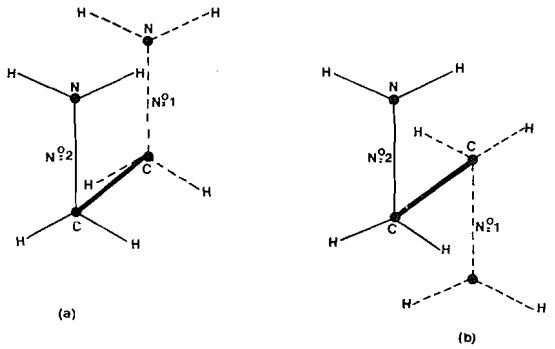

FIG. 1. Geometry of (*a*) *cis* and (*b*) *trans* ethylenediamine.

(Fig. 1) of the order of 0.05 eV (~1 kcal) suggests that the ethylenediamine molecule prefers the *gauche* conformation for normal chelates and the *trans* conformation for bridged complexes. The *cis* isomer is not favored energetically and this explains the non-existence of *cis*-chelated complexes.

The small difference of energy between the *gauche* and the *trans* conformers is also in perfect agreement with the gas electron diffraction study (9). The experimental radial distribution curves showed two peaks, one outstanding around 2.85 Å corresponding to the *gauche* conformation and one small peak around 3.8 Å indicating the presence of a small fraction of *trans* conformer (9).

Calculations

The MO's are obtained from eq. 1,

$$[1] \qquad \Phi_j = \sum_k \sum_r C_{jr_k}\chi_{r_k}$$

c_{jr_k} being the LCAO coefficients and χ_{r_k} being the normalized atomic orbitals of Slater's type. The overlap integrals, eq. 2,

$$[2] \qquad S_{r_k s_l} = \int \chi_{r_k}\chi_{s_l}\, d\tau$$

are calculated from Mulliken's formulas (14). The coulomb integrals for an orbital i ($\alpha_i = H_{ii}$) are taken as the appropriate valence state ionization potentials and the resonance integrals ($\beta_{ij} \equiv H_{ij}$) are computed from eq. 3,

$$[3] \qquad H_{ij} = 0.5\, K\,(H_{ij} + H_{jj})S_{ij}$$

where $K = 1.75$. The values of ionization potentials and of the Slater's coefficients were taken from the tables of Pilcher and Skinner (15, 16), correspondingly (Table 1).

TABLE 1. Values of ionization potentials and of Slater's coefficients

Valence shell	μ	H_{ii} (eV)
H (1s)	1.000	−13.6
C (2s)	1.625	−20.78
C (2p)	1.625	−11.31
N (2s)	1.950	−27.70
N (2p)	1.950	−14.78

TABLE 2. Values of angles and interatomic distances utilized

Bonds	Angle (deg)	Bond	Distance (Å)
HCH	109.27	CC	1.54
NCH	109.27	CC	1.47
HCC	109.27	CH	1.094
HNC	112.5	NH	1.011
NCC	109.8		

Accordingly, the secular determinant was set up and solved. The interatomic distances and the angles were taken from previous works (17–19, 3), in order to have the best representation of the molecule. The same values (Table 2) were also

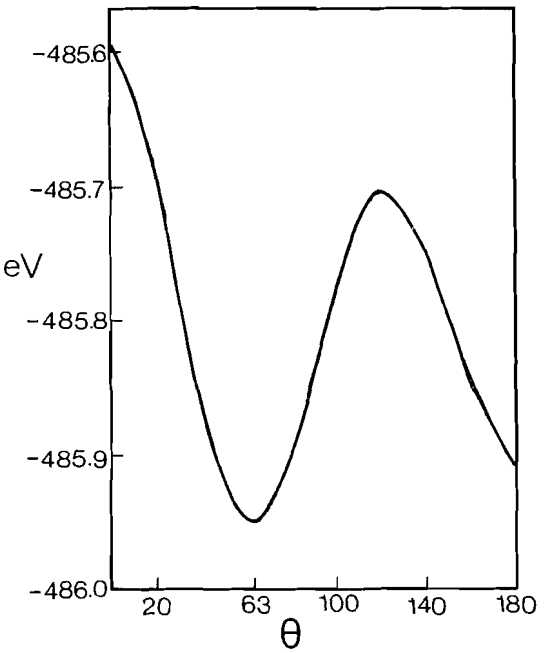

FIG. 2. Variation in energy going from the *cis* to the *trans* form. The abscissa represents the dihedral angles (θ) of each conformer with respect to the *cis* form.

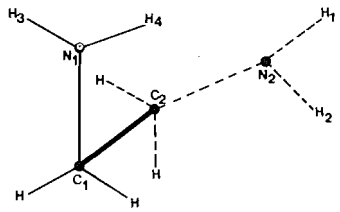

FIG. 3. The dihedral angle (θ) of the plane $C_1C_2N_2$ with respect to the *cis* form is approximately 63.0°. The H_1 is in the plane of $C_1C_2N_2$ and the H_2 to its right. The plane $C_1N_1H_4$ makes an angle of 57.0° with the $N_1C_1C_2$ plane, and the plane $C_1N_1H_3$, makes an angle of 63.0° with the plane $N_1C_1C_2$.

used in an infrared and Raman study with a normal coordinate analysis of the molecule (8).

In the first place, the calculations of the total electronic energy were performed on the *cis* form of the molecule, and the H—N—H angle was bisected by the N—C—C—N plane (Fig. 1*a*). Then the C—N bond No. 1 was rotated successively with a rotation interval of 20° until the *trans* form (180°) was obtained (Fig. 1*b*). In the vicinity of the minima, rotation intervals of 2° were also carried out to exactly determine the minimum of the potential.

The examination of the total electronic energy corresponding to these different geometries (Fig. 2) indicated that the most stable conformation of the molecule corresponded to a dihedral angle N—C—C—N of approximately 63.0°, with respect to the *cis* form.

The study of the rotation of the two NH_2 groups with respect to each other also indicated that the most stable conformation of the molecule is the *gauche* form as shown in Figs. 3 and 4.

This work was supported by the National Research Council of Canada. We would like to express our thanks to Professor S. Fliszar for the program utilized and for many discussions relating to the problems covered in this paper.

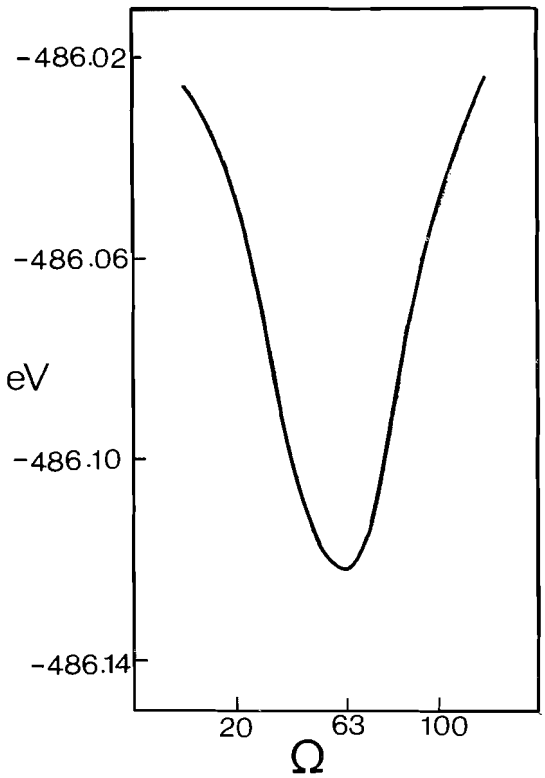

FIG. 4. Variation in energy by fixing the position of the $N_2H_1H_2$ group and rotating the $N_1H_3H_4$ group. The abscissa represents the dihedral angles (Ω) between the planes $C_1N_1H_3$ and $N_1C_1C_2$ (see Fig. 3).

Reactions of 1,2,5-Triphenylphosphole and its Oxide, Sulfide, and Selenide with some Transition Metal Halides

D. BUDD, R. CHUCHMAN, D. G. HOLAH, A. N. HUGHES, AND B. C. HUI

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received September 14, 1971

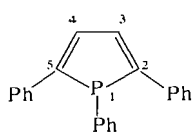
Reactions of 1,2,5-triphenylphosphole (TPP) and 1,2,5-triphenylphosphole oxide (TPPO), sulfide (TPPS), and selenide (TPPSe) with some transition metal halides have been studied in dry, oxygen-free organic solvents. The reactivity of these ligands is clearly a function of the oxidation states of the metal, with the order being M(II) < M(III) < M(IV) < M(V). For example the ligands do not react with the metal(II) halides (Mn, Fe, Ni), while rapid reactions occur with niobium(V) and tantalum(V). Iron(III) and copper(II) are both reduced by TPP. The complexes resulting from these studies are mostly simple adducts of the various metal halides, although other species such as phospholium salts $[TPPH^+][MCl_6^-]$ and oxytrichloride adducts, MOX_3.TPPO (M = Nb, Ta) are also described. In the phospholium salts, the phosphole ring is protonated at the phosphorus atom which is in direct contrast to pyrrole derivatives. The origin of the oxygen atom in the oxytrichloride complexes is discussed and compared with data on the analogous triphenylphosphine oxide systems, where cleavage of the P=O bond occurs.

Les réactions du triphényl-1,2,5 phosphole (TPP) et du triphényl-1,2,5 phosphole oxyde (TPPO), sulfure (TPPS), et séléniure (TPPSe) avec quelques halogénures de métaux de transition ont été étudiées dans des solvants organiques secs, en l'absence de tout oxygène. La réactivité de ces ligands est clairement fonction des états d'oxydation du métal, l'ordre étant M(II) < M(III) < M(IV) < M(V). Par exemple les ligands ne réagissent pas avec $M(II)X_2$ (Mn, Fe, Ni) tandis que des réactions rapides ont lieu avec le niobium (V), le tantale (V); le fer (III) et le cuivre (II) sont tous deux réduits par le TPP. Les complexes résultant de ces études sont pour la plupart des composés d'addition simple avec les divers halogénures métalliques bien que d'autres espèces telles que les sels de phospholium $[TPPH]^+[MCl_6]^-$ et des composés oxytrichlorés d'addition MOX_3. TPPO (M = Nb, Ta) sont aussi décrites. Dans les sels de phospholium, le cycle phosphole est protoné sur l'atome de phosphore ce qui est en contraste direct avec les dérivés du pyrrole. L'origine de l'atome d'oxygène dans les complexes oxytrichlorés est discutée et comparée avec les données des systèmes analogues de l'oxyde de triphénylphosphine où le clivage de la liaison P=O a lieu.

Canadian Journal of Chemistry, **50**, 1008 (1972)

Introduction

The coordinating properties of tertiary phosphines with transition metals have been extensively studied, but their fully unsaturated five-membered heterocyclic counterparts, the phospholes (*e.g.* **1**), which probably have considerable aromatic character (1), have not been investigated extensively as coordinating species.



1

This is probably due to their relative inaccessibility until recently and also to their much lower basicity (1) which is evident in both their organic and inorganic reactions. This lower basicity of phospholes as well as other physical evidence, such as a low pyramidal inversion barrier (2), have been taken as evidence for the extensive delocalization of the phosphorus non-bonding electron pair into the phosphole ring (for a discussion of the aromatic character of the phosphole system, see ref. 3). If this is so, then presumably the phospholes will be weaker electron donors than the phosphines.

In one of the few studies of the phosphole system, it was found (4) that 1,2,3,4,5-pentaphenylphosphole reacts with $Fe(CO)_5$ to give P-bonded pentaphenylphosphole iron tetracarbonyl but that the reaction with $Fe_3(CO)_{12}$ gives pentaphenylphosphole iron tricarbonyl, in which bonding to the iron is through the diene π system of the heterocyclic ring. Similar reactions have been observed between 1,2,5-triphenylphosphole (**1**, TPP) and iron carbonyls (5) and P-bonded phosphole complexes have been obtained from carbonyls of chromium, molybdenum, tungsten, and nickel. Further-

more, the use of phosphole and phospholene cobalt carbonyl complexes as catalysts in hydroformylation reactions has also been reported (6). TPP also reacts with the chlorides of some 4d and 5d elements and adducts of Hg(II), Pd(II), Pt(II), and Rh(III) halides have been reported (7).

Phosphole oxide complexes have received brief mention (4, 5) in connection with their π-bonded $Fe(CO)_3$ complexes but otherwise have not been investigated as coordinating species. Similarly, phosphole sulfides and selenides have received little attention except by Braye *et al.* (4) who found that treatment of 1,2,3,4,5-pentaphenylphosphole sulfide with iron carbonyls results in complete cleavage of the P=S bond to give only the pentaphenylphosphole–$Fe(CO)_4$ complex. In short, most of the few reported reactions with phosphole derivatives have been with zero valent metal species.

Reactions of triphenylphosphine oxide, sulfide, and selenide with metal halides, particularly those of niobium(V) and tantalum(V) have been investigated by several groups (8–11). Thus, a direct comparison with the corresponding phosphole systems is possible and the influence of the heterocyclic ring and possible steric effects of the bulky phenyl groups may be ascertained. Examination of reactions of a wide range of transition metal halides in various oxidation states with the phosphole systems should also lead to information on the electronic structures of the ligands.

Results and Discussion

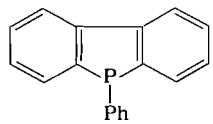
The fact that the phosphorus lone pair of electrons is not readily available for σ-bonding is immediately apparent by the fact that TPP does not react, under any of the conditions employed in this work, with the chlorides (anhydrous and hydrated) of silver(I), manganese(II), iron(II), cobalt(II), nickel(II), thorium(IV), and uranium(IV), although phosphine complexes of these metals, except for the last two (12), are well established (13).

However, with an approximately 1:1 ratio of TPP:$CuCl_2$ in methanol solution, a yellow crystalline diamagnetic solid of composition CuCl.TPP is obtained. A complex of the same stoichiometry can also be prepared as a white crystalline solid from the reactions between DBP[1] and copper(II). Also, reactions between freshly prepared copper(I) chloride and the phospholes **1** and **2** in methanol under reflux yield the same compounds (identical infrared spectra and X-ray powder diffraction patterns) as the complexes from the copper(II) reactions. It is well known that salts of copper(II) are readily reduced by tertiary phosphines and arsines (14) and this, together with the formation (15) of $CuCl.Ph_3P$ from Ph_3P and CuCl emphasizes the close resemblance between phospholes and Ph_3P in this system.

The reaction between iron(III) chloride and TPP in methylene chloride solution also results in reduction of the metal with the formation of iron(II) chloride and oxidation of the phosphole to the corresponding oxide TPPO. In the presence of an excess of iron(III) chloride, the complex $FeCl_3.2TPPO.0.5CH_2Cl_2$ is formed.

However, the chlorides and bromides of niobium(V) and tantalum(V) react readily with TPP producing 1:1 crystalline complexes (except for $NbBr_5$ which gives an oil). The iodides do not react, probably because the bonding energy is offset by greater steric interactions. The ready reaction of the phosphole in these cases is rather surprising in view of its much weaker basicity compared with tertiary phosphines (1), together with the fact that it reacts only slowly as a weak nucleophile with the strongly electrophilic dimethyl acetylenedicarboxylate (16), and shows no reaction with most of the above mentioned metal halides. With niobium(V) and tantalum(V) halides, the reaction begins immediately on addition of dry methylene chloride or benzene to a mixture of the reactants, and virtually quantitative yields of the 1:1 adducts are obtained when the mixtures are heated under reflux for 2 h. In this system, therefore, it appears that the energy barrier to reaction is substantially reduced and this is probably a function of the ability of these

[1]Work is currently being carried out in these laboratories on the donor properties of DBP, 9-phenyl-9-phosphafluorene **2**, a dibenzophosphole derivative.



2

metal ions to accept electrons (note that niobium(V) and tantalum(V) readily accept electrons in the formation of 1:1 complexes with other poor donors, such as ethers and thioethers (17)).

The weakness of the metal phosphorus bond in these adducts is shown by their rapid hydrolysis on exposure to air and by the immediate displacement of the phosphole by coordinating solvents such as acetonitrile and (even) ether. On the other hand, ether does not displace Ph_3P from the $TaCl_5.Ph_3P$ complex nor is the latter as sensitive to hydrolysis by atmospheric moisture as is the phosphole adduct. However, the phosphole complexes are stable when stored under dry nitrogen and, indeed, $TaCl_5$.TPP sublimes unchanged at 155 °C under high vacuum (10^{-6} Torr).

When anhydrous HCl is bubbled through benzene solutions of $TaCl_5$.TPP and $NbCl_5$.TPP, crystalline products rapidly appear. The same products are also formed when the above benzene solutions are exposed to ethanol vapor in the glovebox atmosphere, or when trace amounts of ethanol, water, or hydrogen peroxide (30%) are added directly. (Note that there is no reaction when dry oxygen is bubbled through the solutions.) Chemical analyses of the products, together with the assignment of a sharp absorption band in the infrared spectrum at 2400 cm^{-1} to a P^+—H stretching frquency (18) suggest that the products should be formulated as phospholium salts $[TPPH^+][MCl_6^-]$ (M = Nb, Ta). Furthermore, when anhydrous DCl is passed into a benzene solution of $TaCl_5$.TPP (or when a trace of D_2O is added directly), the corresponding $[TPPD^+][TaCl_6^-]$ complex is produced showing the P—D stretching frequency at 1753 cm^{-1} (18) and having an X-ray powder pattern identical with that of $[TPPH^+][TaCl_6^-]$.

Methylene chloride appears to be the only solvent in which the phospholium salts show any real stability and even in this solvent, extensive decomposition occurs when the solutions are allowed to stand. However, molar conductivities measured rapidly in freshly prepared solutions (Table 1) are consistent with the complexes being formulated as 1:1 electrolytes. Thus the site of protonation in TPP (at least under conditions employed in this work) is the phosphorus atom. This is in contrast to pyrroles which protonate on the 2 or 3 positions of the ring (19) depending upon the substitution pattern. A further discussion of protonated phospholes is the subject of a separate communication (20). In reactions where ethanol was added directly to the $TaCl_5$.TPP solution, traces of an uncharacterized product containing metal, halide, ethoxy, and ligand were observed, indicating that the proton probably originates from the hydroxyl group of the ethanol.

TABLE 1. Molar conductivity data

Complex	Concentration (M)	Molar conductivity (ohm^{-1} cm^{-1} mol^{-1})
$[TPPH^+][TaCl_6^-]$	7.5×10^{-4}	6.6
$[Et_4N^+][I^-]$	1.85×10^{-3}	10.7
$[Et_4N^+][Cl^-]$	1.16×10^{-3}	8.25
β-$TaCl_5$.TPPO	5.5×10^{-3}	0.060
$Fe(S_2CN\ Et_2)_3$	1.07×10^{-3}	0.061

The orange crystalline $[TPPH^+][TaCl_6^-]$ complex is stable in air for several hours but is instantly hydrolyzed on addition of wet organic solvents. Attempts to replace $[TaCl_6^-]$ with other anions such as Cl^- and $[BPh_4]^-$ resulted in decomposition of the phospholium salt, probably indicating that a favorable lattice energy is required (and obtained) with the $[MCl_6^-]$ ions (M = Nb,Ta). The niobium complex appears to be much less stable, decomposes rapidly in air, and is generally much more difficult to isolate from the reactions described above than is the tantalum compound.

That this reaction is not restricted to TPP is apparent from the ease with which molecules such as $[Ph_3PH^+][TaCl_6^-]$ and $[DBPH^+][TaCl_6^-]$ are formed, although in these cases protonation at the phosphorus atom is not unexpected since both Ph_3P and DBP are considerably more basic than the phosphole. Other transition metal ions, such as $ZnCl_4^{2-}$, $FeCl_4^-$, UCl_6^{2-}, $PtCl_6^{2-}$, *etc.* do not appear to stabilize phospholium ions. For example the reaction of anhydrous $FeCl_3$ with TPP (2:1) and dry HCl in benzene, produces an extremely air-sensitive complex which shows in its infrared spectrum, a P—H stretching frequency at 2410 cm^{-1} and bands probably associated with the $FeCl_4^-$ anion at 335 and 390 cm^{-1} (21). This, together with chemical analyses, indicates that the complex could possibly be formulated as $[TPPH^+][FeCl_4^-].FeCl_3$ (*cf.* a double salt $[(pyH^+)$-

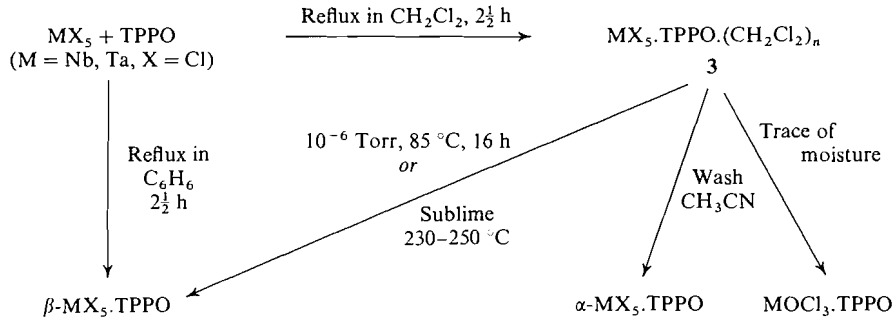

FIG. 1. Reactions of TPPO with niobium(V) and tantalum(V) halides.

$(FeCl_4^-)]_2.(pyH^+Cl^-)$ (py = pyridine) has been reported (22)). Similar reactions carried out with the $FeCl_3$:TPP ratio 1:1 result in the formation of a yellow hygroscopic solid which appears to be $[FeCl_2(TPP)_2^+][FeCl_4^-]$.

The donor properties of the phosphole system appear to be only marginally improved by incorporating an oxygen atom onto the phosphorus. Thus, no reaction was observed between 1,2,5-triphenylphosphole oxide (TPPO) and iron(II), nickel(II), and copper(II) chlorides after prolonged heating under reflux in methylene chloride or ethanol solution, while traces of a product were obtained from manganese(II). Cobalt(II) is the most reactive of the divalent 3d metals towards TPPO producing, in methylene chloride, a bright green solid, although all attempts to purify the complex (*e.g.* recrystallization, sublimation, and chromatography) resulted in decomposition. Bands in the visible (16 700 cm^{-1}) and near infrared (5900 cm^{-1}) regions in the reflectance spectrum of the crude compound strongly suggest the presence of tetrahedral cobalt(II) as is the case (23) with tertiary phosphine oxide complexes of cobalt(II) and therefore the complex is probably $CoCl_2.2TPPO$. A rapid reaction of TPPO also occurs with $FeCl_3$ producing $FeCl_3.2TPPO.0.5CH_2Cl_2$ and with thorium(IV) and uranium(IV) chlorides producing $MCl_4.2TPPO$ (M = Th,U) and $ThCl_4.3TPPO$. The halides $TaCl_5$ and $NbCl_5$ react immediately with TPPO to give 1:1 adducts in several crystalline forms, depending on the reaction conditions. These results are summarized in Fig. 1. Both α- and β-MX_5.TPPO can be converted back into the solvated adduct **3** by recrystallization from methylene chloride. Similar reactions occur with the pentabromides of both metals.

When the tantalum chloride adduct **3** (Fig. 1) is allowed to stand in a rubber-stoppered tube for several weeks, an orange colored precipitate of the oxytrichloride adduct $TaOCl_3.TPPO$ slowly forms. The origin of the oxygen atom in this species is of special interest in view of the oxygen abstraction from phosphine oxides by niobium(V). Thus, Fairbrother *et al.* (10) found that the reaction of $NbCl_5$ with an excess of Ph_3PO leads to the formation of $NbOCl_3.2Ph_3PO$ and probably Ph_3PCl_2, although the latter was not isolable. Other workers (8, 9, 11) report similar results although with $TaCl_5$, only the 1:1 complex, $TaCl_5.Ph_3PO$ was observed (8, 11). Fairbrother *et al.* (10) did obtain $TaOCl_3.2Ph_3PO$ but only by reacting $TaCl_5$ with $(Ph_3PO)_2.H_2O_2$, where the peroxide probably serves as the oxygen source. In view of the weaker P=O bond in the phosphole oxides (24) compared with Ph_3PO, it would appear likely that oxygen abstraction from this group should occur, particularly in reactions between $NbCl_5$ and TPPO.

However, no evidence for this was observed in reactions between either $TaCl_5$ or $NbCl_5$ with TPPO. Thus, when a benzene solution of $TaCl_5.TPPO$ is heated under reflux for up to 16 h with a 2 *M* excess of TPPO, no evidence (infrared, mass spectral) for cleavage of the P=O bond by formation of either a P-dichloride or the phosphole itself is observed. Indeed methylene chloride solutions of $TaCl_5.TPPO$ are stable indefinitely when kept in a ground-glass stoppered tube indicating clearly that in reactions producing $MOCl_3.TPPO$ complexes the oxygen atom comes from trace amounts of oxygen or water diffusing into the system and not from the P=O group. With the $NbCl_5.TPPO$ reaction, even a 1:3 molar ratio of reactants

*Figures in parentheses are the shifts for similar Ph_3PO complexes together with the appropriate reference.
†Also shows a very strong absorption at 800 cm^{-1} due to the Ta=O group.
‡Impossible to unambiguously assign the P=S frequency and therefore either of the two figures may be correct.

produced only a trace (< 2%) of $NbOCl_3$.TPPO. This is not unreasonable in the light of the ready formation of NbX_5.TPPO (X = Cl,Br) from reactions between NbX_5 and TPPSe when oxygen is not rigorously excluded, *i.e.* oxygen pick-up in these cases appears to be at the phosphorus atom to form TPPO and *not* at the metal to form the Nb=O linkage. The reason for the difference in behavior between Ph_3PO and TPPO towards $NbCl_5$ is not clear.

Coordination of the ligand through the oxygen atom is confirmed in all the above mentioned complexes by shifts in the P=O stretching frequency on complexation (25). The shifts (Table 2) range from only 11 cm^{-1} for the crude cobalt(II) complex where interaction between the oxygen atom of the ligand and the metal is clearly extremely weak, to ~130 cm^{-1} for some of the niobium(V) and tantalum(V) species. In all cases, (except $TaOCl_3$.TPPO) the metal–oxygen bonds for the phosphole oxides are much weaker than for phosphine oxides. The complexes $ThCl_4$.3TPPO and UCl_4.2TPPO, along with several other complexes in the literature, show a splitting of the P=O band, the origin of which is not clearly understood (25–27). The remainder of the infrared spectrum of each compound is generally very similar to that of the free ligand except for the strong metal–halide absorptions in the 260–380 cm^{-1} region. The complexity of the spectra in the 300–500 cm^{-1} region rendered impossible the assignment of the M—O stretching frequency.

The phosphole sulfide (TPPS) and selenide (TPPSe) do not react with the divalent metals nor with thorium(IV) and uranium(IV). TPPS does, however, form a weak complex with $FeCl_3$, but on recrystallization of this, $FeCl_3$.2TPPO is formed. TPPS reacts with a slight excess (~10%) of $TaCl_5$ in benzene to give $TaCl_5$.TPPS.C_6H_6 from which the benzene is removed under high vacuum giving α-$TaCl_5$.TPPS. When the reaction is carried out in methylene chloride or benzene using strictly 1:1 ratios, a solvated adduct $TaCl_5$.TPPS.0.5CH_2Cl_2 of the β-phase is obtained. These observations are similar to those of Brown *et al.* (8) who noted that with $TaCl_5$ and $TaBr_5$, triphenylphosphine sulfide and the corresponding selenide give two different crystalline phases depending on the rate of crystallization. However, the reaction of $TaCl_5$ with TPPSe in both methylene chloride and benzene gives only a solvated β-phase (for which the X-ray powder pattern is identical with that

of β-$TaCl_5$.TPPS). With neither the sulfide nor the selenide was any abstraction by the metal of S or Se from the P=S or P=Se bonds observed, although both are substantially weaker than the P=O bond. Thus, the ligands TPPS and TPPSe are recovered intact on hydrolysis of the complexes, and high vacuum sublimation of $TaCl_5$.TPPS gives a mixture of the 1:1 adduct with some ligand. Similar observations have been recorded for substituted phosphine sulfides (8, 9, 11).

Tentative assignment of the P=S stretching frequencies are made in Table 2, and are in the general range expected for such molecules (18). Shifts of the P=S vibration on coordination of TPPS to niobium(V) and tantalum(V) are about 20 cm^{-1} (compared to 40–50 cm^{-1} in triphenylphosphine sulfide complexes). The P=Se shifts are extremely small, reflecting the weakness of the M—Se bond. The M—S, M—Se, and M—P frequencies, which would be expected to occur in the 200–400 cm^{-1} region have not been identified, largely because of the intense and very broad M–chlorine stretching frequencies which occur in this general region.

The very limited solubility of the niobium, tantalum, thorium, and uranium complexes precluded n.m.r. and molecular weight measurements. However, the fact that β-$TaCl_5$.TPPO is a non-electrolyte in methylene chloride (Table 1) is not inconsistent with the metal being 6-coordinate in this and similar molecules. The actinide complexes are too insoluble for conductivity studies, but the multiple P=O stretching frequencies in their infrared spectra could indicate the presence of non-equivalent ligands.

In summation, therefore, the donor properties of TPP, TPPO, TPPS, and TPPSe towards transition metals are extremely weak, especially with the lower valent metal salts. Their behavior towards Nb(V) and Ta(V) halides appears to follow rather closely the behavior of their triphenylphosphine analogues, although the greater basic strengths of the latter make them more powerful donors. Even with these strongly electron accepting metal halides, the weakness of the M—P bond in the phosphole complexes is evident and is consistent with the relative inaccessibility of the phosphorus lone pair brought about by delocalization into the ring, although steric effects may also be involved. Moreover, the heterocyclic ring clearly affects the electron density at the oxygen atom in the TPPO complexes where infrared data show the weaker TPPO—M link compared with the Ph_3PO—M bonds. A later publication will in fact concern TPPO complexes of rhodium where bonding to the metal occurs through the π system of the ligand (28).

Experimental

Niobium(V), tantalum(V), thorium(IV), and uranium(IV) halides were prepared by standard methods and purified by vacuum sublimation prior to use. The ligands TPP, TPPO, TPPS, and TPPSe were prepared as described by Campbell *et al.* (29). DBP was prepared by the method of Hoffmann (30) and its oxide by the reaction of H_2O_2 on the phosphole in methanol. Deuterated sulfuric acid (isotopic purity 99%) was obtained from Stohler Isotope Chemicals. Where necessary, reactions were carried out in a dry nitrogen-filled glove box (~100 p.p.m. oxygen). All solvents were degassed and stored over freshly activated molecular sieve (4A) under nitrogen. Methylene chloride and benzene were distilled from calcium hydride prior to degassing.

Physical Measurements

All physical measurements were carried out as previously described (31).

Analyses

Metal analyses (Nb, Ta, Th, U) were performed gravimetrically by hydrolysis of the complexes in an ethanol–aqueous ammonia solution followed by ignition of the precipitated hydroxide to the oxide. Chloride in the supernatant liquid was determined as silver chloride. Analytical data are recorded in Table 3. Where the ligand (TPPS) was not decomposed by the hydrolysis procedure, it was extracted into methylene chloride and determined spectrophotometrically (25 970 cm^{-1}, $\log \varepsilon$, 4.1 (29)). Organic microanalyses were carried out under the supervision of W. J. Buis at the Institute for Organic Chemistry, TNO, Utrecht, the Netherlands, and on a Perkin–Elmer 240 elemental analyzer in the Science Instrumentation Laboratory at this University.

Syntheses

1. CuCl.L (L = TPP, DBP)

A mixture of TPP (0.94 g) and $CuCl_2.2H_2O$ (0.59 g) in methanol (100 ml) was heated under reflux for 2 h, producing a yellow crystalline product (0.74 g, 90%, m.p., 251°).

The same product was also obtained by heating under reflux in methanol (150 ml) a mixture of TPP (0.44 g) and CuCl (0.12 g) for 4 h. The yellow filtrate, on evaporation, yielded a yellow crystalline solid which was recrystallized from benzene.

CuCl.DBP was prepared from either copper(II) or copper(I) following the procedures outlined above as a white crystalline solid, m.p. 254–256°.

2. Attempts to Prepare $[TPPH^+][FeCl_4^-]$

Freshly prepared anhydrous $FeCl_3$ and TPP in a ratio of 2:1 were suspended in purified benzene under a dry nitrogen atmosphere. Anhydrous HCl (dried with conc. H_2SO_4) was passed into the reaction mixture for ~1 h with stirring.

TABLE 3. Chemical analyses

*Ligand percentages, determined spectroscopically.

The mixture turned gummy and finally solidified, when the solid was separated and washed with benzene.

Similarly the reaction of TPP and anhydrous $FeCl_3$ in a ratio of 1:1 with HCl yielded a hygroscopic yellow solid which was recrystallized from chloroform.

3. $FeCl_3.2L$ (L = TPPO, TPPS, DBPO)

A mixture of TPPO (0.90 g) and $FeCl_3.6H_2O$ (0.37 g) was heated under reflux in methylene chloride (50 ml) for 4 h. The cooled reddish-brown solution was filtered and a brown crystalline solid separated as the solvent was removed (quantitative yield), m.p. 176–178°.

The other Fe(III) complexes were prepared similarly in methylene chloride solution, *n*-hexane being added to precipitate the compounds. Thus, $FeCl_3.2DBPO$ showed a m.p. of 168–170° while $FeCl_3.2TPPS$ decomposed on recrystallization.

4. $CoCl_2.2TPPO$

A mixture of TPPO and $CoCl_2.6H_2O$ (2:1 mole ratio) in methylene chloride was heated under reflux for 5 h. The reaction mixture was cooled and the excess of cobalt chloride was filtered off. The green filtrate was then evaporated to dryness and the residue recrystallized from 1:1 CH_2Cl_2/C_6H_6 solution as green needles (m.p. 257°). However, the product was contaminated with traces of unreacted ligand. Unsuccessful attempts were made to purify the complex by recrystallization, sublimation, and chromatography.

5. $MCl_4.2TPPO$ (M = Th,U), $ThCl_4.3TPPO$

These complexes were made by mixing the appropriate mole ratios of metal halide and TPPO in ethanol. The 1:2 complex formed immediately while the 1:3 complex formed after the mixture was heated under reflux for 12 h. The products which are air stable, were washed with ethanol and dried under high vacuum (10^{-6} Torr) for 12 h. $ThCl_4.3TPPO$ dissolves in methylene chloride from which $ThCl_4.2TPPO$ is precipitated on addition of pentane.

6. $TaCl_5.TPP$ ($NbCl_5.TPP$, $TaBr_5.TPP$)[2]

A mixture of $TaCl_5$ (0.65 g) and TPP (0.60 g) in methylene chloride/pentane (8:1) (9 ml) was heated under reflux for $2\frac{1}{2}$ h. The resulting dark-brown solution was centrifuged, stoppered, and cooled overnight, when dark-brown crystals (0.6–0.8 g, ~66%) were deposited. These were vacuum dried.

7. $[TPPH^+][TaCl_6^-]$ ($[TPPD^+][TaCl_6^-]$, $[TPPH^+][NbCl_6^-]$)

Anhydrous HCl (or DCl)[3] was bubbled through a benzene solution (8 ml) of $TaCl_5.TPP$ (0.5 g) producing immediately an orange solid. This was washed with benzene (3 × 6 ml), dried, and dissolved in methylene chloride. Addition of dry pentane immediately precipitated the orange product (~0.15 g) which was quickly centrifuged off and dried under vacuum. If the methylene chloride solution is allowed to stand for any length of time an unidentified yellow solid precipitates.

[2]The complexes shown in parentheses were isolated and identified by the fact that their X-ray powder patterns are identical with that of the compound for which the analyses are listed in Table 3.

[3]Made by heating dry sodium chloride (5 g) with degassed D_2SO_4 (0.5 ml).

8. $[Ph_3PH^+][TaCl_6^-]$, $[DBPH^+][TaCl_6^-]$

Treatment of a benzene solution (~5 ml) of $TaCl_5.Ph_3P$[4] and $TaCl_5$.DBP[4] (0.5–0.8 g) with anhydrous HCl resulted in the quantitative precipitation of white solids which were washed with benzene (2 × 5 ml), dried, and recrystallized from methylene chloride-pentane.

9. $TaCl_5.TPPO.CH_2Cl_2$ *(*$TaBr_5.TPPO.CH_2Cl_2$, $NbX_5.TPPO.CH_2Cl_2$, $X = Cl, Br$*)*

$TaCl_5$ (0.65 g) and TPPO (0.67 g) in methylene chloride (10 ml) were heated under reflux for 2 h. The resulting bright-red solid (~1 g, 80%) which was formed was dissolved in methylene chloride and recrystallized by slow evaporation of solvent to 1/3 volume. If the solid was precipitated by addition of pentane the solvent content varied between 0.5 and 1.5 mol.

10. α-$TaCl_5.TPPO$ *(*α-$NbCl_5.TPPO$*)*

When the solvated adduct (9) (0.5 g) was washed with acetonitrile (3 × 5 ml), it changed to a flocculent orange-red solid which was vacuum dried.

11. β-$TaCl_5.TPPO$ *(*β-$NbCl_5.TPPO$*)*

(*a*) The β phase was quantitatively obtained by heating (85 °C, 16 h) the adduct (9) under high vacuum (10^{-6} Torr). It also sublimed (together with some TPPO) when the adduct (9) was heated (230–250 °C) under high vacuum (10^{-6} Torr). (*b*) To a suspension of $TaCl_5$ (0.87 g) in benzene (10 ml), TPPO (0.82 g) was added and the mixture heated under reflux for $2\frac{1}{2}$ h. The red crystalline solid (~1.3 g, 80%) which separated was recrystallized from hot benzene.

12. $TaOCl_3TPPO$ *(*$NbOCl_3.TPPO$*)*

A methylene chloride solution (9 ml) of the adduct (9) (0.25 g) was set aside for 1 week in a rubber-stoppered tube. An orange solid (~30 mg) formed on the walls of the tube. This deposition was accelerated by direct exposure to the glove box atmosphere and frequent stirring. After two weeks, the solid (0.15 g, 70%) was removed, washed with methylene chloride (2 × 5 ml), and dried under vacuum.

13. $TaCl_5.TPPS.C_6H_6$ *(*$NbCl_5.TPPS.C_6H_6$*)*

A mixture of $TaCl_5$ (0.64 g) and TPPS (0.56 g) in benzene (5 ml) was heated under reflux for 2 h. The resulting deep-red solution was set aside for several hours during which large dark-red crystals (0.6 g, 50%) were deposited. More product was obtained by slow evaporation of the remaining solution.

14. α-$TaCl_5.TPPS$ *(*α-$NbCl_5.TPPS$*)*

The adduct (13) was pumped under high vacuum (10^{-6} Torr) at 85 °C for 6 h, yielding a red-brown solid.

15. β-$TaCl_5.TPPS$ *(*β-$NbCl_5.TPPS$*)*

A mixture of $TaCl_5$ (1.0 g) and TPPS (1.0 g) in methylene chloride or benzene (10 ml) was heated under reflux for $2\frac{1}{2}$ h. The crystalline solid (1.2 g, 60%) which was deposited on cooling was dried to a red-brown solid under high vacuum (10^{-6} Torr) at 85 °C for 14 h.

16. β-$TaCl_5.TPPSe$ *(*β-$NbCl_5.TPPSe$*)*

A mixture of $TaCl_5$ (1.1 g) and TPPSe (1.3 g) in benzene (10 ml) was heated under reflux for $2\frac{1}{2}$ h. The red-brown crystalline solid (1.5 g, 65%) which was formed was recrystallized from benzene solution and pumped under high vacuum (10^{-6} Torr) at 85° for 14 h.

In the corresponding $NbCl_5$ reaction, oxygen must be rigorously excluded to prevent the formation of $NbCl_5$.TPPO.

We thank the Senate Research Committee of Lakehead University and the National Research Council of Canada for generous financial support of this work.

[4]To our knowledge, these compounds have not been prepared previously although the analogous niobium complex, $NbCl_5.Ph_3P$ has been reported (32) and was characterized on the basis of a chloride analysis of 22.10%. However, the theoretical percentage of chloride in $NbCl_5.Ph_3P$ is 33.35%. The tantalum complex was prepared by adding Ph_3P (0.75 g) to a suspension of $TaCl_5$ (0.96 g) in benzene (5 ml). The mixture was heated under reflux for $1\frac{1}{2}$ h, producing a bright yellow solution from which the yellow product was crystallized on addition of pentane.

Anal. Calcd. for $TaCl_5.Ph_3P$: Ta, 28.86; Cl, 28.28. Found: Ta, 28.7; Cl, 28.1.

$TaCl_5$.DBP was made in an analogous manner.

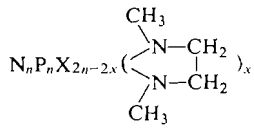
Introduction

The reactions of cyclic phosphonitrilic chlorides (chlorocyclophosphazenes) with monofunctional amines have been investigated in considerable detail and different substitution pathways have been recognized (1). Geminally substituted spirocyclic derivatives of $N_3P_3Cl_6$ have been prepared from the difunctional amine, *o*-phenylenediamine (2). More recently the reactions of cyclic phosphonitrilic fluorides with amines, *e.g.* Me_2NH (3–5), $MeNH_2$ (4, 5), or Me_3SiNMe_2(3), have been shown to follow a non-geminal substitution pathway and, under appropriate conditions, good yields of the monoamino derivatives can be obtained. Deamination by hydrogen chloride or bromide provides an expeditious route to the corresponding monohalogeno or non-geminally substituted halogeno derivates of cyclic phosphonitrilic fluorides (3–7) which are otherwise difficult to purify (8, 9). In an attempt to extend this synthetic route to the preparation of *gem*-dihalogenophosphonitrilic fluorides we have investigated the reactions of *N,N'*-dimethylethylenediamine with the cyclic phosphonitrilic halides $N_nP_nX_{2n}$ ($n = 3, 4$; X = Cl, F). Geminal substitution occurs to give spiro halogenophosphonitrilic imidazolidines of the type



$(n = 3, x = 1, 2; n = 4, x = 1)$

Particularly in the case of $N_4P_4F_8$ oily, presumably polymeric, products were also formed. The reactions of the spiro compounds with hydrogen chloride or bromide gave adducts which could not be converted to the corresponding *gem*-dihalogenophosphonitrilic fluorides.

Experimental

General

The preparations of the phosphonitrilic imidazolines were carried out under an atmosphere of nitrogen, which was replaced by air in the work-up procedure. Hydrocarbon solvents were redistilled from calcium hydride before use. The following chemicals were obtained commercially and used without further purification: anhydrous diethyl ether (Mallinckrodt), hydrogen chloride, hydrogen bromide, dimethylamine (Matheson), *N,N'*-dimethylethylenediamine (Columbia Organic), dichlorodimethylsilane (Peninsular Chem Research), and potassium fluorosulfite (Ozark-Mahoning). $N_3P_3Cl_6$ and $N_4P_4Cl_8$ were purchased from Alfa Inorganics and recrystallized from petrol (30–60°) before use. $N_3P_3F_6$ and $N_4P_4F_8$ were prepared from the corresponding chlorides by the reaction with potassium fluorosulfite in paraffin oil at *ca.* 110° (10). 1,2,2,3-Tetramethyl-1,3-diaza-2-silacyclopentane was prepared by the method of Abel and Bush (11).

The following instruments were used for spectroscopic studies: ^1H n.m.r. spectra (Varian A60 and HA100), ^{19}F n.m.r. spectra (Varian HA100 operating at 94.1 MHz), i.r. spectra (Perkin–Elmer 337 and 621), mass spectra (Varian Atlas CH-5 operating at 70 eV and an accelerating voltage of 3 kV). The ^{19}F n.m.r. spectra were obtained for saturated solutions in benzene with CCl_3F as internal standard.

Carbon, hydrogen, and nitrogen analyses were carried out in this department by Mrs. S. Swaddle and Mr. R. Davidson, and by Organic Microanalyses, Montreal, Quebec who also performed the halogen analyses.

Preparation of gem-N,N'-Dimethylethylenediaminotetrafluorocyclotriphosphonitrile

(a) From N,N'-Dimethylethylenediamine

Hexafluorocyclotriphosphonitrile (27.0 g, 0.108 mol) in diethyl ether (250 ml) was cooled to −15° and *N,N'*-dimethylethylenediamine (19.1 g, 0.216 mol) in ether (100 ml) was added dropwise with continual stirring. After the addition was complete, the reaction mixture was allowed to come to room temperature and the insoluble *N,N'*-dimethylethylenediamine hydrofluoride was filtered off. Removal of solvent from the filtrate yielded white crystals of *gem*-N,N'-dimethylethylenediaminotetrafluorocyclotriphosphonitrile (13.6 g, 0.046 mol) which, after recrystallization from petroleum ether (30–60°), had m.p. 97°.

Anal. Calcd. for $C_4H_{10}F_4N_5P_3$: C, 16.2; H, 3.4; N, 23.6. Found: C, 16.1; H, 3.7; N, 23.9.

(b) From 1,2,2,3-Tetramethyl-1,3-diaza-2-silacyclopentane

Hexafluorocyclotriphosphonitrile (5.4 g, 0.024 mol) and 1,2,2,3-tetramethyl-1,3-diaza-2-silacyclopentane (3.5 g, 0.024 mol) were heated at 80° for 2 h in a sealed Carius tube under vacuum. Vacuum transfer gave difluorodimethylsilane (2.3 g, 0.024 mol) and a white solid which, after recrystallization from ether, was identified as *gem*-N,N'-dimethylethylenediaminotetrafluorocyclotriphosphonitrile (4.5 g, 0.015 mol) from its m.p. 93–95°, ^1H n.m.r. spectrum, and analysis.

Anal. Found: C, 16.4; H, 4.0; N, 22.9.

(c) From gem-N,N'-Dimethylethylenediaminotetrachlorocyclotriphosphonitrile

gem-N,N'-Dimethylethylenediaminotetrachlorocyclotriphosphonitrile (1.9 g, 0.005 mol) and an excess of potassium fluorosulfite (9.6 g) were heated to 105° for 4 h in paraffin oil (20 ml). White crystals were collected by sublimation (25°/0.01 mm) and identified as *gem-N,N'*-dimethylethylenediaminotetrafluorocyclotriphosphonitrile (0.25 g, 0.0007 mol) from the ^1H n.m.r. spectrum and m.p. 95°.

Preparation of gem-Bis(N,N'-dimethylethylenediamino)-difluorocyclotriphosphonitrile

In one preparation of *gem-N,N'*-dimethylethylenediaminotetrafluorophosphonitrile the insoluble white precipitate (mainly dimethylethylenediamine hydrofluoride) was heated under reflux with diethyl ether for 15 min. After filtration of the solution, white crystals began to precipitate which were identified as *gem*-bis(*N,N'*-dimethylethylene-

For personal use only.

diamino)difluorocyclotriphosphonitrile (0.41 g, 0.0016 mol), m.p. 174°.

Anal. Calcd. for $C_8H_{10}F_2N_7P_3$: C, 27.8; H, 5.8; N, 28.4. Found: C, 27.2; H, 5.8; N, 27.8.

Preparation of gem-N,N'-Dimethylethylenediaminohexafluorocyclotetraphosphonitrile

Octafluorocyclotetraphosphonitrile (4.3 g, 0.013 mol) in toluene (150 ml) was cooled to − 78° and *N,N'*-dimethylethylenediamine (2.3 g, 0.026 mol) in toluene (50 ml) was added dropwise to the cooled solution with continual stirring. After the addition was complete, the solution was allowed to stir for a further 30 min at − 78°, and then the insoluble amine hydrofluoride was filtered off before the solution was allowed to come to room temperature. Solvent was removed rapidly on a rotary evaporator and finally on the vacuum line in a sublimation apparatus. The solid residue sublimed (25°/0.01 mm.) to give white crystals of *gem-N,N'*-dimethylethylenediaminohexafluorocyclotetraphosphonitrile (0.5 g, 0.0014 mol), m.p. 40° (dec.).

Anal. Calcd. for $C_4H_{10}F_6N_6P_4$: C, 12.6; H, 2.6; N, 22.1. Found: C, 12.8; H, 2.7; N, 22.2.

The residue from the sublimation, a brown oil containing some crystals, was chromatographed on a florisil column using petroleum ether (30–60°) as eluant to give impure *gem-N,N'*-dimethylethylenediaminohexafluorocyclotetraphosphonitrile.

Anal. Found: C, 13.2; H, 2.7; N, 20.4.

Preparation of gem-N,N'-Dimethylethylenediaminotetrachlorocyclotriphosphonitrile

Hexachlorocyclotriphosphonitrile (5.3 g, 0.015 mol) in ether (700 ml) was cooled to − 78°. *N,N'*-Dimethylethylenediamine (2.7 g, 0.031 mol) in ether (150 ml) was added dropwise over a period of 3 h to the cooled solution with continual stirring. The solution was allowed to reach room temperature overnight and then the insoluble amine hydrochloride was filtered off (1.9 g, 0.012 mol). Solvent was removed on the rotary evaporator, and the residue dissolved in hot hexane (150 ml). Insoluble material (0.13 g) was filtered off, and solvent was removed from the filtrate which deposited white crystals of *gem-N,N'*-dimethylethylenediaminotetrachlorocyclotriphosphonitrile (2.5 g, 0.007 mol), m.p. 114–116°.

Anal. Calcd. for $C_4H_{10}Cl_4N_5P_3$: C, 13.2; H, 2.8; N, 19.3; Cl, 39.1. Found: C, 13.1; H, 3.1; N, 19.2; Cl, 38.7.

Preparation of gem-Bis(N,N'-dimethylethylenediamino)-dichlorocyclotriphosphonitrile

Hexachlorocyclotriphosphonitrile (1.5 g, 0.0043 mol) and *N,N'*-dimethylethylenediamine (2.4 g, 0.028 mol) were heated at reflux in ether solution for 2 h. The insoluble amine hydrochloride (1.3 g, 0.0081 mol) was filtered off, and removal of solvent gave a white solid which, after recrystallization from toluene, was identified as *gem*-bis(*N,N'*-dimethylethylenediamino)dichlorocyclotriphosphonitrile (1.3 g, 0.0035 mol), m.p. 208° (dec.).

Anal. Calcd. for $C_8H_{20}Cl_2N_7P_3$: C, 25.4; H, 5.3; N, 25.6. Found: C, 24.7; H, 6.0; N, 24.4.

Preparation of gem-N,N'-Dimethylethylenediaminohexachlorocyclotetraphosphonitrile

Octachlorocyclotetraphosphonitrile (4.8 g, 0.010 mol) in ether (600 ml) was cooled to 0° and *N,N'*-dimethylethylenediamine (1.8 g, 0.020 mol) in ether (150 ml) was added dropwise during 3 h with continual stirring. The solution was allowed to come to room temperature overnight. The insoluble amine hydrochloride (1.5 g, 0.009 mol) was filtered off and solvent was removed to give a solid residue which was treated with boiling hexane. Insoluble material (0.28 g) was filtered off and removal of some solvent from the filtrate caused the precipitation of white crystals of *gem-N,N'*-dimethylethylenediaminohexachlorocyclotetraphosphonitrile (1.5 g, 0.003 mol), m.p. 91–92°.

Anal. Calcd. for $C_4H_{10}Cl_6N_6P_4$: C, 10.0; H, 2.1; N, 17.5; Cl, 44.7. Found: C, 9.6; H, 2.3; N, 17.2; Cl, 44.8.

Reaction of gem-N,N'-Dimethylethylenediaminotetrafluorocyclotriphosphonitrile with Anhydrous Hydrogen Chloride

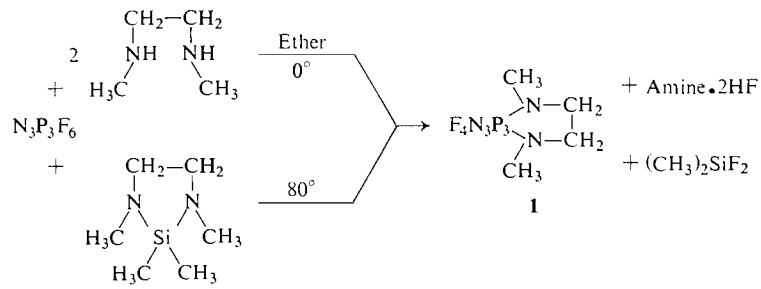
gem-N,N'-Dimethylethylenediaminotetrafluorocyclotriphosphonitrile (0.87 g, 0.0029 mol) and an excess of anhydrous hydrogen chloride were heated in a sealed Carius tube under vacuum for 16 h at 130°. Vacuum transfer of the volatile products gave only unreacted hydrogen chloride. The white solid residue, which was stable at 160°, was tentatively identified as an adduct $N_3P_3F_4$ $(CH_3NCH_2CH_2NCH_3)_x$HCl ($x = 1$ or 2).

Anal. Calcd. for the mono-adduct: C, 14.5; H, 3.3; N, 21.1. Calcd. for the di-adduct: C, 13.0; H, 3.2; N, 18.9. Found: C, 13.9; H, 4.1; N, 20.0.

The i.r. spectrum (Nujol mull) 1280s, 1140w, 1115w, 1060s, 920s, 840sh, 810s, 727m, 670w, 505s cm^{-1}.

Discussion

The trimeric phosphonitrilic fluoride, $N_3P_3F_6$, reacts with either *N,N'*-dimethylethylenediamine in ether or, preferably, 1,2,2,3-tetramethyl-1,3-diaza-2-silacyclopentane in a sealed tube to



1

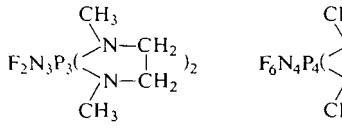
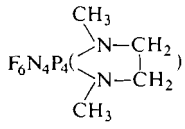
For personal use only.

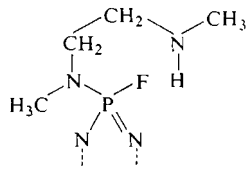
give *gem*-*N*,*N*′-dimethylethylenediaminotetrafluorocyclotriphosphonitrile (**1**) (see Scheme 1). Some of the disubstituted compound **2** was also isolated in the reaction with *N*,*N*′-dimethylethylenediamine.



2



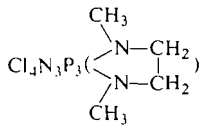
3



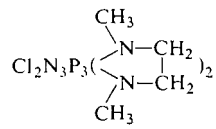
A

Similar reactions using the tetrameric fluoride, $N_4P_4F_8$, were mostly unsuccessful, yielding only a colorless oil which on standing turned brown, became more viscous, and after several days solidified. However, low yields of **3** were obtained from *N*,*N*′-dimethylethylenediamine using *dilute* solutions of the reactants in toluene at $-78°$ followed by a rapid work-up procedure. Apparently in the case of the tetramer the formation of a linear polymer is favored over the formation of the spiro derivative. Nucleophilic substitution by a difunctional amine will likely be a stepwise process, with the substitution of a fluorine by one of the amino groups as the first step. There are now two substitution processes that the monoamino derivative, **A**, can undergo. (*a*) The second amino group can substitute at the same phosphorus atom yielding a spiro derivative, or (*b*) the second amino group can substitute at a phosphorus atom on another phosphonitrilic molecule leading to the formation of linear polymers.[2] Consideration of cyclization kinetics shows that dilute solutions will favor the formation of the spiro derivative over the linear polymers as found experimentally.

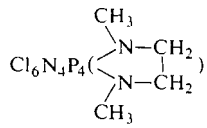
It has previously been observed that other imidazolidines show a tendency to polymerize. For example, 1,2,2,3-tetramethyl-1,3-diaza-2-silacyclopentane polymerizes to a highly viscous liquid on standing, particularly in the presence of ammonium sulfate (11). The polymerization is reversible on heating. Similar behavior has been reported for the corresponding germanium imidazolidine, but attempts to prepare the tin analog gave a viscous liquid, apparently polymeric (12).



4



5

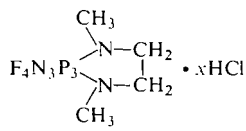


6

Both $N_3P_3Cl_6$ and $N_4P_4Cl_8$ react with *N*,*N*′-dimethylethylenediamine in a large volume of ether at $-10°$ to give good yields of the corresponding monosubstituted spiro compounds, **4** and **6**. The disubstituted derivative **5**, was obtained from $N_3P_3Cl_6$ and an excess of *N*,*N*′-dimethylethylenediamine under reflux in ether. More vigorous reaction conditions are apparently necessary to prepare the trisubstituted spiro compound.

Fluorination of the chloride **4** with potassium fluorosulfite in paraffin oil gave the corresponding fluoride **1**. Fluorination of the corresponding chlorides has also been used to prepare *cis*- and *trans*-1,3-$N_3P_3F_4(NMe_2)_2$ (6), $N_4P_4F_5(NMe_2)_3$, and $N_4P_4F_4(NMe_2)_4$ (from SbF_3) (7), and 1,2-$N_3P_3F_4(NH_2)_2$ (from CsF in acetonitrile) (13).

The reaction of an excess of anhydrous hydrogen chloride with **1** yielded an adduct tentatively identified as



($x = 1$ or 2)

which was thermally very stable. An adduct is also formed initially in the reaction of $N_3P_3F_5NMe_2$ with hydrogen halides, but in this case heating effects decomposition (3–5).

$$N_3P_3F_5NMe_2.HX \xrightarrow[>70°]{HX} N_3P_3F_5X + Me_2NH.HX$$

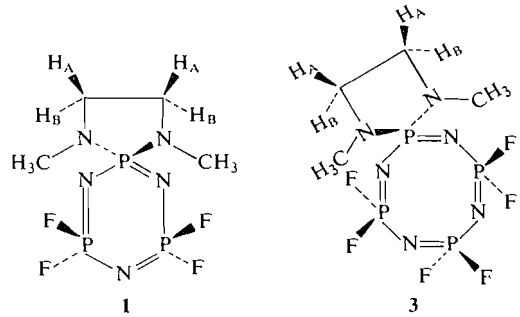
(X = Cl, Br)

[2]Non-geminal substitution on the same phosphonitrilic molecule is considered to be unlikely for steric reasons.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The greater stability of the adduct in the case of the spiro compound may indicate a more basic exocyclic nitrogen than in $N_3P_3F_5NMe_2$. Some evidence to support this suggestion comes from measurements of the shifts in ν(C—D) of deuteriochloroform solutions of the compounds relative to ν(C—D) for pure deuteriochloroform. For $N_3P_3F_5NMe_2$, $\Delta\nu = 65\ cm^{-1}$ compared to $\Delta\nu = 77\ cm^{-1}$ for the spiro compound **1**. However, reservations have been expressed concerning this method of measuring base strengths (14).

The geminal structure of **1** (see Fig. 1) is indicated by its ^{19}F n.m.r. spectrum which shows only one doublet ($\delta = 68.4$ p.p.m., $J'_{PF} = 930$ Hz) corresponding to the $\equiv PF_2$ fluorines. The disubstituted compound **2** also shows a $\equiv PF_2$ doublet ($\delta = 65.5$ p.p.m., $J'_{PF} = 800$ Hz) and is thus assigned a geminal structure. The ^{19}F n.m.r. spectrum of **3** shows two doublets of relative intensity (2:1) ($\delta = 67.6$ p.p.m., $J'_{PF} = 840$ Hz; $\delta = 68.7$ p.p.m., $J'_{PF} = 835$ Hz) which have chemical shifts which are similar to those of *gem*-$N_4P_4F_6Cl_2$ (8) rather than those of non-geminal-$N_4P_4F_6(NMe_2)_2$ (3). The two doublets can therefore be assigned to nearest neighbor and antipodal $\equiv PF_2$ groups, respectively.



1 3

FIG. 1. Spiro fluorophosphonitrilic imidazolidines: *gem*-(*N*,*N*′-dimethylethylenediamino)tetrafluorocyclotriphosphonitrile (**1**) and *gem*-(*N*,*N*′-dimethylethylenediamino)-hexafluorocyclotetraphosphonitrile (**3**).

The ^1H n.m.r. spectra of the phosphonitrilic imidazolidines are shown in Figs. 2 and 3. The spectra of both **1** and **3** show two doublets of relative intensities 3:2, the doublet to low field is therefore assigned to the methylene protons and the doublet to high field to the *N*-methyl

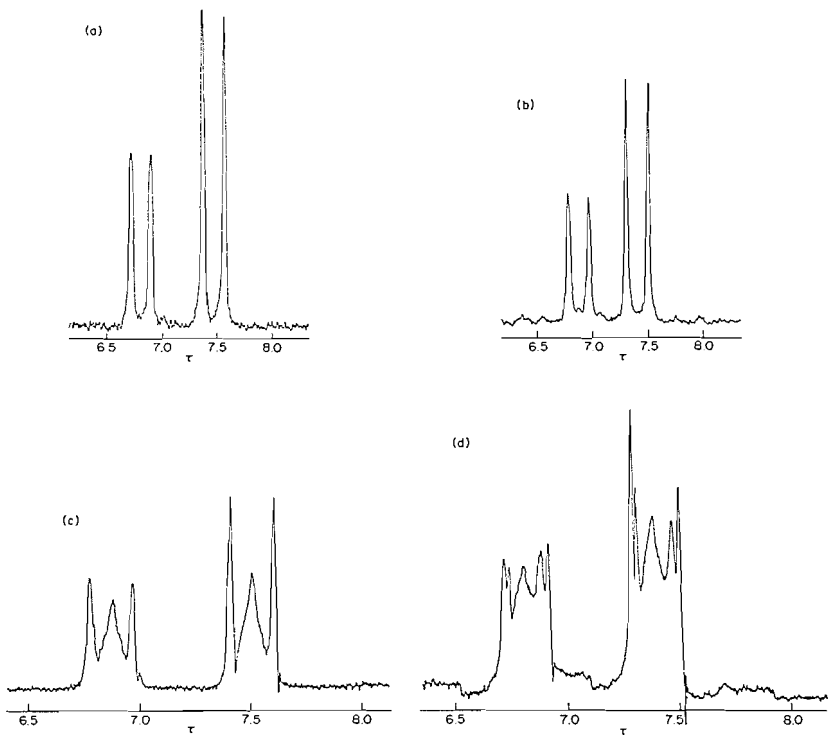


FIG. 2. The ^1H n.m.r. spectra of (*a*) *gem*-(*N*,*N*′-dimethylethylenediamino)tetrafluorocyclotriphosphonitrile (**1**); (*b*) *gem*-(*N*,*N*′-dimethylethylenediamino)hexafluorocyclotetraphosphonitrile (**3**); (*c*) *gem*-bis(*N*,*N*′-dimethylethylenediamino)-difluorocyclotriphosphonitrile (**2**); (*d*) *gem*-bis(*N*,*N*′-dimethylethylenediamino)dichlorocyclotriphosphonitrile (**5**).

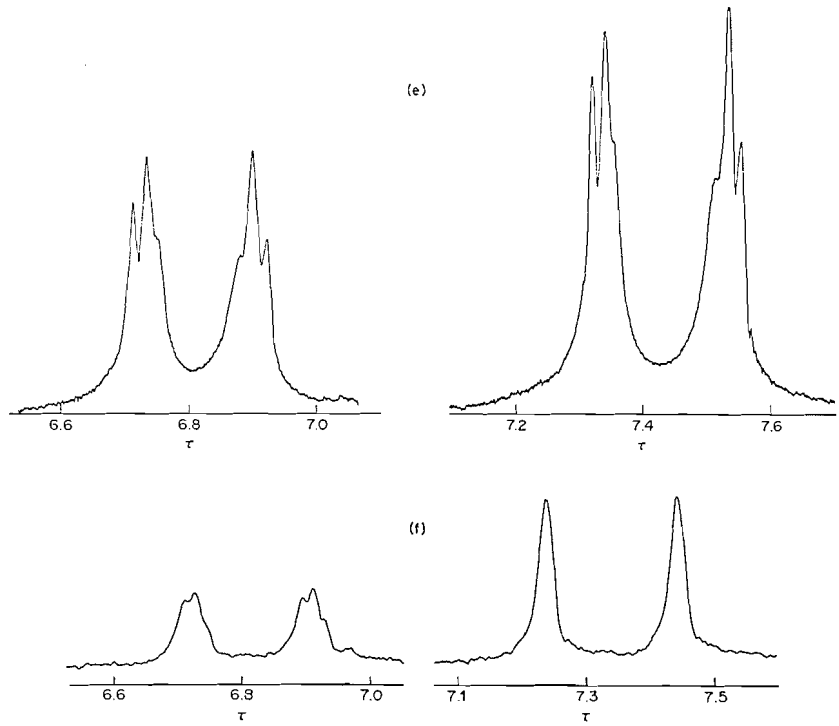

FIG. 3. The ^{1}H n.m.r. spectra of (*e*) *gem*-(*N*,*N*'-dimethylethylenediamino)tetrachlorocyclotriphosphonitrile (**4**); (*f*) *gem*-(*N*,*N*'-dimethylethylenediamino)hexachlorocyclotetraphosphonitrile (**6**).

protons. The separation of the doublets is independent of field strength and hence is assigned to ^{31}P–N–C–^{1}H coupling. These spectra confirm the geminal structures of **1** and **3** since a doublet of doublets is expected for non-geminal substitution *cf.* dimethylaminofluorophosphonitriles (3).

The apparent chemical equivalence of the methylene protons H_A and H_B in the ^{1}H n.m.r. spectra of the fluorophosphonitrilic imidazolidines **1** and **3** is perhaps unexpected and persists even at $-80°$. It should be noted however that unexpectedly simple ^{1}H n.m.r. spectra have previously been observed for the methylene protons in both phosphorus (15, 16) and boron (11) imidazolidines.

In the present examples a number of possible explanations can be given for this observation. Either (*a*) inversion, which is rapid with respect to *ca.* 0.01 s is occurring at the nitrogen atoms of the imidazolidine ring or, less likely (*b*) the imidazolidine ring is planar, or (*c*) protons H_A and H_B show accidental chemical shift equivalence. The sharp doublet observed for the *N*-methyl protons could arise if the *N*-methyl groups are (*a*) *cis*-oriented to the ring, or (*b*) coplanar with a planar ring (*i.e.* attached to trigonal nitrogen atoms), or (*c*) *trans* and inverting rapidly on the n.m.r. time scale. However, it excludes the possibility that the *N*-methyl groups are in a fixed *trans* position.

The ^{1}H n.m.r. spectra of the chlorides **4** and **6**, Fig. 3, are similar to those of the corresponding fluorides **1** and **3** except that splitting of the methylene proton doublets and of the *N*-methyl proton doublets (resolved for **4** only) into triplets is observed. This additional splitting (*ca.* 1 Hz) is probably due to long range coupling with the neighboring $\equiv PCl_2$ phosphorus atoms. Such interactions have previously been observed in the ^{1}H n.m.r. spectra of *cis*- and *trans*-1,3-$N_3P_3Cl_4(NMe_2)_2$ (6).

The ^{1}H n.m.r. spectra of the disubstituted compounds **2** and **5**, Fig. 2, are clearly not first-order and, in particular, a broad absorption is observed between the components of both the methylene proton doublet and the *N*-methyl proton doublet. This type of spectrum is

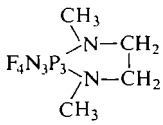
characteristic of an $X_nAA'X'_n$ system (17) and has been observed for a large number of dialkylaminophosphonitrilic derivatives (3, 6, 18). The separation of the two outer components of these signals is $|J_{AX} + J_{AX'}|$. The spectrum of the chloride **5** shows further splitting of the outer components into doublets, presumably due to long range coupling with the unique $\equiv PCl_2$ phosphorus atom.

Table 1 shows the relevant ^{1}H n.m.r. parameters for a series of heterosubstituted imidazolidines. The chemical shifts for the methylene protons indicate the following order of electron withdrawal by phosphorus substituents, O=P—C_6H_5 > $N_3P_3X_4$ ~ $N_4P_4X_6$ > P—CH_3 > P—C_6H_5 (X = F, Cl).

The i.r. spectra of the phosphonitrilic imidazolidines are reported in Table 2. The actual symmetry of



is at most C_{2V} (planar imidazolidine and phosphonitrilic rings) and is probably lower. The degeneracy of the ring vibration ν_{as}(PNP) and 1200–1300 cm^{-1} is therefore removed and peaks are observed at *ca.* 1250 cm^{-1} (**1**) and at 1240 and 1208 cm^{-1} (**2**). The decrease in ν_{as}(PNP) compared to $N_3P_3F_6$ (1290 cm^{-1}) (19) is consistent with weakening of the endocyclic π-bonding on replacement of fluorine by the less electronegative amino substituents, and is also observed for the tetrameric derivative (**3**)ν_{as}(PNP) 1385 cm^{-1} *cf.* ν_{as}(PNP) 1419 and 1438 cm^{-1} for $N_4P_4F_8$ (10). Other assignments can be made from a knowledge of the i.r. spectra of the phosphonitrilic fluorides (20) and chlorides (21) and their dialkylamino derivates (3). C—N antisym stretching 1160–1170 cm^{-1}; C_2NP sym. stretching 1030–1040 cm^{-1}; PF_2 asym. stretching 700–800 cm^{-1}; PCl_2 sym. and asym. stretching 500–600 cm^{-1}; and PF_2 deformation 480–500 cm^{-1}.

The partial mass spectra of the spiro compounds (**1**) and (**3**) and of $N_3P_3F_5NMe_2$, for

comparison, were obtained. Noteworthy features include the fact that the parent ions exhibit the strongest peak in the spectra of the spiro compounds, (*m/e* 297, **1**; *m/e* 389, **3**) whereas the ion $N_3P_3F_5^+$ (*m/e* 230) is predominant in the spectrum of $N_3P_3F_5NMe_2$. The P + 1 peaks are larger than expected on the basis of natural isotopic abundances, especially for the spiro compounds. This may be due to the formation of a protonated ion PH^+, which suggests that the exocyclic nitrogen atom is more basic in the spiro compound than in $N_3P_3F_5NMe_2$ (*cf.* adduct formation with hydrogen halides). Strong peaks corresponding to fluorophosphonitrilic hydride ions *e.g.* $N_3P_3F_4H_2^+$ (*m/e* 213) were observed in the spectra of all three compounds. Halogenophosphonitrilic hydrides are not known although extensive attempts have been made to prepare them[3] (22, 23).

Received March 5, 1971[3]

The n.m.r. and mass spectral data are used to show that chloroacetylation of 1-azaphenothiazine gave 1-hydroxy-2-chloroacetyl-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt and not the expected 10-chloroacetyl-1-azaphenothiazine.

On utilise les données de r.m.n. et de spectrométrie de masse pour montrer que la chloro-acétylation de la 1-azaphénothiazine donne le sel interne suivant: l'hydroxyde de 1-hydroxy-2-chloro-acétyl-6-thia-10*b*-aza-2*a*-azoniaacéanthrylène et non pas le 10-chloroacétyl-1-azaphénothiazine auquel on s'attendait d'abord.

Canadian Journal of Chemistry, **50**, 1026 (1972)

Introduction

The synthesis of 10-chloroacetyl-1-azaphenothiazine was the initial key step in making one of several series of phenothiazine compounds (1) of potential therapeutic value. It is well known that phenothiazine can be chloroacetylated under a variety of conditions to yield 10-chloroacetylphenothiazine (2). However, treatment of 1-azaphenothiazine[4] in such standard reactions did not produce the desired 10-chloroacetyl-1-azaphenothiazine, nor indeed any identifiable product. A relatively pure product was eventually obtained in consistent yields by treating 1-azaphenothiazine (**1**) with chloroacetic anhydride and chloroacetic acid in dry dioxane and shown to be 1-hydroxy-2-chloroacetyl-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt (**2**).

[2]Present address: Department of Medicinal Chemistry, School of Pharmacy, State University of New York at Buffalo, Buffalo, N.Y. 14214.

[3]Revision received December 20, 1971.

[4]The 1-azaphenothiazine was prepared by direct thionation of 2-anilinopyridine in the presence of an iodine catalyst; see ref. 22.

Experimental

Melting points were determined on a Hoover Uni-melt apparatus and are uncorrected. The 60 MHz n.m.r. spectrum was determined on a Varian A-60 n.m.r. spectrometer and the 220 MHz spectra were determined on a Varian 220 MHz n.m.r. spectrometer, using tetramethylsilane as the internal standard. The mass spectra were determined on the AEI MS-902 high resolution mass spectrometer, modified to permit metastable scanning, at 70 eV and temperature of approximately 200° via the direct insertion probe. High resolution mass measurements were made at approximately 20 000 resolution (10% valley definition) using the electrical peak matching technique with perfluorotributylamine as standard. All measurements were within ±3 p.p.m. of the calculated values. The i.r. spectra were determined on a Beckman IR-8 instrument. Microanalyses were performed by either F. and E. Pascher, West Germany or Geller Laboratories, U.S.A.

Chloroacetylation of 1-Azaphenothiazine

A stirred mixture of 1-azaphenothiazine (50.0 g, 0.25 mol), chloroacetic anhydride (54.0 g, 0.32 mol), and chloroacetic acid (75.0 g, 0.79 mol) in 250 ml of dry dioxane was refluxed for 1 h. The hot mixture was poured into 1 l of hot water and the precipitate was collected and washed with warm 95% ethanol until the washings were colorless. The product (1-hydroxy-2-chloroacetyl-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt (**2**)) was obtained as a fluffy, yellow–green solid, (43.0 g) m.p. 275–277° (dec.); i.r. absorption (KBr) at 3150, 1672, 1613, 1486, 1439, 1389, 1362, 1333, 1282, 1253, 1188, 1140, 1092, 1029, 983, 843, 787, 766, 752, 730, 715, 653 cm^{-1}; *m/e* 318, 316 (M^+, $C_{15}H_9ClN_2O_2S$), 281, 267 ($C_{14}H_7N_2O_2S$), 253, 239, 225, 211, 200, 199 ($C_{11}H_7N_2S$), 184, 172, 168, 155, 140, 109, 108, 99, 98.

Anal. Calcd. for $C_{15}H_9ClN_2O_2S$: C, 56.87; H, 2.86; N, 8.85. Found: C, 56.99; H, 3.18; N, 8.60.

The chloroacetylation of 1-azaphenothiazine was attempted under basic conditions in a number of modifications. The best yield (40%) was obtained when a stirred mixture of 1-azaphenothiazine (1 mol), chloroacetyl chloride (2 mol), and excess potassium carbonate was refluxed for 3 h

in dioxane. The yield was unpredictable and the product was impure. After many recrystallizations from glacial acetic acid, the same fluffy, yellow–green solid, m.p. 275–277° (dec.), was obtained.

Hydrolysis of the Chloroacetylation Product

1-Hydroxy-2-chloroacetyl-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt was added to a mixture of concentrated hydrochloric acid (5 ml) and glacial acetic acid (15 ml) and refluxed for 15 min. The reaction mixture was made basic with sodium hydroxide solution and the resultant precipitate was collected. Recrystallization from 95% ethanol yielded 1-hydroxy-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt (**6**) as a buff colored solid, m.p. 198–199°. The average yield was approximately 50%.

Anal. Calcd. for $C_{13}H_8N_2OS$: C, 64.97; H, 3.35; N, 11.65. Found: C, 64.71; H, 3.62; N, 11.05.

Reaction of the Chloroacetylation Product with Piperidine

A stirred mixture of 1-hydroxy-2-chloroacetyl-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt (20.0 g, 0.07 mol), piperidine (18.8 g, 0.22 mol), and *N,N*-dimethylformamide (200 ml) was heated on a boiling water bath for 1 h. After cooling overnight in a refrigerator, the resultant precipitate was collected and washed with water. The filtrate and washings were poured into 1 l of water previously made alkaline (sodium carbonate) and the mixture filtered. The total solid collected was combined and recrystallized from isopropanol (charcoal) to yield fine yellow needle crystals, 18.0 g, m.p. 177–179° (dec.) (77%). This was shown to be 1-hydroxy-2-piperidinoacetyl-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt (**3**); n.m.r. in benzene-d_6 (220 MHz): δ 1.41 (m, 2H, γ protons of piperidine), 1.70 (m, 4H, β protons of piperidine), 2.84 (t, 4H, α protons of piperidine), 4.02 (s, 2H, methylene), 5.85 (m, 2H, H_2 and H_3), 6.40 (q, 1H, H_6), 6.51 (m, 1H, H_7), 6.71 (m, 1H, H_8), 9.23 (q, 1H, H_9), and 9.36 (q, 1H, H_4) p.p.m.; the signals at 5.85 and 9.36 p.p.m. form an ABX system (**5**), $J_{AB} = 8.0$, $J_{AX} = 7.0$, $J_{BX} = 0.8$ Hz; $H_A = 5.87$ and $H_B = 5.85$ p.p.m.; the signals at 6.40, 6.51, 6.71, and 9.23 p.p.m. represent four adjacent protons in an aromatic system (**4**), $J_{9,8} = 8.4$, $J_{9,7} = 1.3$, $J_{6,7} = 7.7$, $J_{6,8} = 1.7$, $J_{7,8} = 7.4$ Hz; *m/e* 365 (M^+, $C_{20}H_{19}N_3O_2S$), 282 ($M - C_5H_9N$), 267, 253, 240 ($C_{13}H_8N_2OS$; 282 – $CH_2{=}C{=}O$), 225, 211, 200 ($C_{11}H_8N_2S$), 199, 184, 172, 168, 166, 155, 140, 109, 108, 99, 98 ($C_6H_{12}N$).

Anal. Calcd. for $C_{20}H_{19}N_3O_2S$: C, 65.73; H, 5.24; N, 11.50. Found: C, 65.57; H, 5.54; N, 10.91.

The oxalate was prepared by mixing the amine (0.5 g) in warm, dry benzene (150 ml) with an equimolar concentration of anhydrous oxalic acid, also in dry benzene. The mixture was allowed to cool, when the salt precipitated as a yellow solid, m.p. 232.5–233° (dec.).

Anal. Calcd. for $C_{22}H_{21}N_3O_6S$: C, 58.00; H, 4.65. Found: C, 57.57; H, 4.95.

The methyl iodide derivative was prepared by mixing equimolar concentrations of amine and methyl iodide in dry benzene and allowing to stand overnight. The derivative was a yellow solid, m.p. 229.5–230° (dec.).

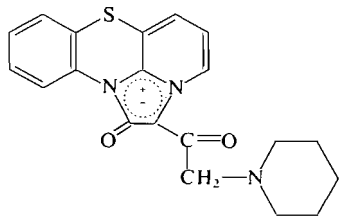
Results and Discussion

The chloroacetylation product would not form a hydrochloride salt, in sharp contrast to normal 10-substituted-1-azaphenothiazines which readily form quaternary salts at N-1 (3). Since the compound also lacked absorption characteristic of amine N—H stretch (3300–3500 cm^{-1})[5] or protonated ammonium $\overset{+}{N}$—H stretch (2300–2500 cm^{-1}), it was deduced that both the N-1 and the N-10 positions of the azaphenothiazine nucleus must be substituted and that there must be a cationic site.

In polar solvents, at temperatures of 100° or higher, the chloroacetylation product reacted with secondary amines to form a series of new compounds (4) in which the chlorine atom is replaced by the amine moiety, showing that the chlorine atom is covalently bonded and that the anionic site must be provided by an oxygen atom.

The mass spectrum confirmed the molecular formula as $C_{15}H_9ClN_2O_2S$ and showed a base peak at *m/e* 267 (loss of CH_2Cl) and ions at *m/e* 281 (loss of Cl) and 239 (loss of $COCH_2Cl$), proving that the chloroacetylation product contains a chloroacetyl residue.

The low solubility of the chloroacetylation product in all common organic solvents precluded determination of n.m.r. spectra. The piperidine condensation product (**3**) was soluble in deuteriochloroform and the 60 MHz spectrum showed signals attributable to the α, β, and γ protons of the piperidine ring, an isolated methylene unit, a complex five proton multiplet in the aromatic region (6.89 p.p.m.), a one proton multiplet at 9.04 p.p.m., and a one proton multiplet at 9.59 p.p.m.



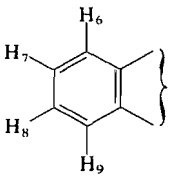
3

The 220 MHz spectrum in deuteriochloroform did not permit unambiguous assignments to be made for the lowfield protons but use of benzene-d_6 produced some dramatic solvent shifts and permitted interpretation of the resulting 220 MHz spectra. Analysis of these latter

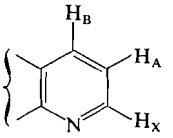
[5]The i.r. spectrum of 1-azaphenothiazine in carbon disulfide exhibited absorption at 3390 cm^{-1}, attributed to the N—H stretching of the secondary amine function.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

n.m.r. spectra showed that the piperidine derivative (1-hydroxy-2-piperidinoacetyl-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt) contained four adjacent protons in an aromatic system in which one (H_9 in structure **4**; quartet at 9.23 p.p.m.) is experiencing a strong deshielding effect. The remaining three lowfield protons are accounted for by an ABX system (5) with three adjacent protons in an aromatic ring, with one of the three again experiencing a strong deshielding effect (H_X in structure **5**; quartet at 9.36 p.p.m.).

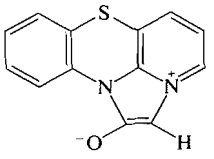


4



5

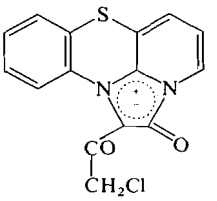
These data, together with mass spectral data from the piperidine derivative (6–10) (see Experimental) are consistent with the mesoionic structure **2** for the chloroacetylation product and structure **3** for the piperidine condensation product. Formation of structure **2** can be accounted for by initial chloroacetylation at N-10, followed by ring closure and proton abstraction to produce 1-hydroxy-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt (**6**). Further chloroacetylation of this with concomitant proton abstraction would yield structure **2**.



6

There are precedents for formation of cyclic structures such as is suggested here (11, 12). Proton abstraction to form structure **6** would presumably be driven by the formation of the aromatic mesoionic system. There is also ample precedent in the chemistry of mesoionic systems (13–15) for subsequent acylation of **6**. The final proton abstraction would again be driven by the formation of a stable aromatic system. The hydrolysis product (**6**) must be formed by reversal of the second acylation step.

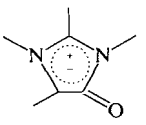
None of the data presented thus far will allow differentiation between the postulated structure (**2**) given for the chloroacetylation product and the isomeric structure **7**. Mechanistically, one



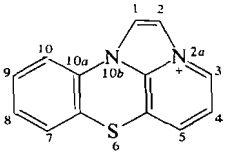
7

must decide whether N-1 or -10 of 1-azaphenothiazine is acylated in the first step. Jones and Katritzky (16) have studied potentially tautomeric pyridines and have found that 2-aminopyridine and 2-(methylamino)pyridine are acetylated exclusively (acetic anhydride/acetic acid) at the exocyclic nitrogen. Based on this information, preference is given to structure **2** as the chloroacetylation product of 1-azaphenothiazine. Supporting evidence for this selection has very recently been obtained in a study directed toward the chloroacetylation of aminosubstituted 2-aminopyridines (17).

The mesoionic 1,3-diazol-4-one system (**8**) is known (15, 18–21) but the chloroacetylation product (**2**) represents a new ring system (**9**) which is 6-thia-10*b*-aza-2*a*-azoniaaceanthrylene.



8



9

The chloroacetylation product is therefore 1-hydroxy-2-chloroacetyl-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt, the hydrolysis product (**6**) is 1-hydroxy-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt, and the piperidine derivative (**3**) is 1-hydroxy-2-piperidinoacetyl-6-thia-10*b*-aza-2*a*-azoniaaceanthrylene hydroxide inner salt.

The authors would like to thank Mr. Walter Kremers for technical assistance throughout the project, Mr. W. Garland of the School of Pharmacy, University of California, for the

mass spectral determinations and metastable scanning, and Dr. R. Reavill of the Division of Pure Chemistry, National Research Council of Canada, Ottawa, for assistance with some of the n.m.r. work.

Field and Resonance Components of Substituent Effects in Relation to the Hammett Equation

L. D. HANSEN[1] AND L. G. HEPLER

Department of Chemistry, University of Lethbridge, Lethbridge, Alberta

Received October 29, 1971

Following Swain and Lupton's analysis of substituent effects, we have taken $\Delta G^0 = a_e t_e + a_r t_r$ for a typical substituent effect reaction. In this equation a_e and a_r are substituent constants for electrostatic field and resonance effects while t_e and t_r are corresponding transmission coefficients. Both substituent constants and t_r are taken to be independent of solvent and temperature, while t_e is taken to depend on both solvent and temperature. General conclusions based on analysis of this model are the following. (*i*) A Hammett $\rho\sigma$ equation with constant σ values that are valid over a range of temperatures for a variety of reactions in several solvents can be obtained only when either the field or the resonance interaction is negligible compared with the other. (*ii*) A Hammett $\rho\sigma$ equation can be expected to hold for "similar" reaction series in a given solvent at one temperature even when both the field and resonance interactions are important. (*iii*) An isoequilibrium or isokinetic relationship can be expected only when the field interaction is dominant.

The general equations leading to these and other conclusions are presented so that one can later insert appropriate mathematical descriptions of detailed models and thereby obtain information about specific reactions.

En suivant l'analyse de Swain et Lupton sur les effets de substituants, nous avons pris $\Delta G^0 = a_e t_e + a_r t_r$ pour une réaction à effet de substituant typique. Dans cette équation a_e et a_r sont les constantes des substituants pour un champ électrostatique et pour des effets de résonance tandis que t_e et t_r sont les coefficients de transmission correspondants. Les constantes des substituants et t_r sont pris indépendamment du solvant et de la température et t_e dépend sur le solvant et la température. Les conclusions générales fondées sur l'analyse de ce modèle sont les suivantes. (*i*) Une équation de Hammett $\rho\sigma$ avec des valeurs constantes σ qui sont valables dans une gamme de températures pour une variété de réactions dans plusieurs solvants est obtenue seulement quand à la fois l'interaction de champ ou de résonance sont négligeables comparativement aux autres. (*ii*) On peut espérer une équation de Hammett $\rho\sigma$ pour des séries de réactions "similaires" dans un solvant donné à une température même lorsque les interactions de champ et de résonance sont importants. (*iii*) On peut attendre une relation d'isoéquilibre ou d'isocinétique seulement quand l'interaction de champ est prédominante.

Les équations générales amenant telles ou telles conclusions sont présentées autant que l'on peut insérer des descriptions mathématiques appropriées de modèles détaillées et par là obtenir une information sur les réactions spécifiques.

Canadian Journal of Chemistry, **50**, 1030 (1972)

Partly in response to the proliferation of sets of σ parameters designed to account for substituent effects on a huge variety of reactions, Swain and Lupton (1) have carried out a thorough statistical analysis that has led to a number of empirically useful and theoretically important conclusions.

The statistical analysis by Swain and Lupton (1) provided convincing evidence that all of the various sets of substituent constants in present or past use can be expressed as linear combinations of two terms, each of which may be regarded as representing one kind of interaction of substituent with reaction center. Although the validity of their statistical analysis is totally independent of the names assigned to these kinds of interactions and also independent of subsequent descriptions of these interactions, Swain and Lupton (1) have quite reasonably taken the two terms to represent field and resonance effects. Here it should be noted that they have carefully excluded from consideration those reactions in which steric effects could be significant.

In their efforts to separate field and steric effects, it was necessary for Swain and Lupton (1) to make (very reasonable) assumptions about certain substituents. In this connection they wrote the following: "...are convinced that the Hammett equation and other *free*-energy correlations work in spite of entropy variations, ..., and that such effects can be considered as sub-

components of the field effect". A recent thermodynamic analysis (2) of the Hammett equation has shown that entropy changes must be proportional to enthalpy changes if the $\rho\sigma$ relationship is to be exactly valid over a range of temperature. Good correlations of entropy and enthalpy changes with σ values have in fact been observed for several reaction series. On the other hand, as recognized by Swain and Lupton (1) and others (2), the Hammett equation does work (fairly well, not exactly) for many reaction series in which there are substantial variations from the enthalpy–entropy proportionality.

The ideas of the above discussion, combined with recognition that interpretation of entropy and enthalpy changes is often an important part of gaining some detailed understanding of substituent effects, have led us to include temperature and solvent as variables so that application of classical thermodynamics to an equation of the form suggested by Swain and Lupton (1) can lead to information about enthalpy and entropy changes in relation to substituent effects.

Before proceeding with our extension of the ideas of Swain and Lupton (1), it is worthwhile to write down one explicit chemical reaction equation to illustrate a substituent effect. Partly because effects of substituents on acidities as measured by acid ionization equilibrium constants are a common method of obtaining various σ values, and partly because of a later specific application of our theoretical equations to proton transfer reactions, we choose the following illustrative reaction equation:

[1] $$XPBH^{z}(S) + PB^{z-1}(S) = XPB^{z-1}(S) + PBH^{z}(S)$$

In this equation we have used (S) to emphasize that each solute species is in some solution and interacts with the solvent in ways that must be considered in relation to substituent effects. The letters X, P, and B represent the substituent, the "parent structure" (such as a benzene ring), and the basic site (such as $-COO^-$ or $-NH_2$), while z and $z-1$ represent integral charges. In all of our following discussion and development of theoretical equations we are concerned with quantities that refer to reaction series of type [1], with realization that analogous equations can be written to represent other reaction series.

In a few instances we have experimental results that refer directly to reactions of type [1]. More often, however, we have equilibrium constants for ionization of the parent acid (K_{PBH}) and the substituted acid (K_{XPBH}) that must be combined to give $K_1 = K_{XPBH}/K_{PBH}$ and thence $\Delta G_1^0 = \Delta G_{XPBH}^0 - \Delta G_{PBH}^0$. In similar fashion we can obtain ΔH_1^0 and ΔS_1^0 values from the experimental values for ionization of $XPBH^z$ and PBH^z. In all that follows we shall be concerned with thermodynamic quantities that refer to reactions of type [1], but note that similar equations can be written in terms of rate constants rather than equilibrium constants, and thus in terms of activation parameters such as $\Delta G^{\ddagger}$ and $\Delta H^{\ddagger}$.

Following Swain and Lupton (1), we consider substituent effects in terms of an appropriate combination of "field" and "resonance" components. For our present purposes, it is most convenient to use terminology similar to that of Swain and Lupton (1) with some of our own symbols.

We begin by taking the resonance contribution to the free energy (ΔG_r) of a reaction of type [1] to be given by a product of a substituent constant (a_r) times a transmission coefficient (t_r) so that we have

[2] $$\Delta G_r = a_r t_r$$

The substituent constant a_r depends only on the substituent while t_r depends on the parent skeleton P and on the ability of B to conjugate (resonance) with substituent X. We take both a_r and t_r to be independent of solvent, temperature, and pressure.

The field contribution to the free energy (ΔG_e), which can in principle be evaluated by way of classical electrostatic calculations, is similarly taken to be a product of substituent (a_e) and transmission (t_e) terms so that we have

[3] $$\Delta G_e = a_e t_e$$

Again, the substituent constant depends only on the substituent. The electrostatic field transmission coefficient depends on solvent, temperature, and pressure as well as on P and B.

The electrostatic models and derived equations of Kirkwood and Westheimer (3), Sarmousakis (4), and Tanford (5) provide considerable information about t_e, but for now we shall avoid any specific statements about the mathematical description of t_e while we develop the general consequences of eqs. 2 and 3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

We now combine eqs. 2 and 3 to obtain the total ΔG^0 for reactions of type [1] as

$$[4] \qquad \Delta G^0 = \Delta G_e + \Delta G_r = a_e t_e + a_r t_r$$

Here it should be emphasized that the form of eq. 4, as a sum of two terms is a direct consequence of the demonstration by Swain and Lupton (1) that a huge range of non-steric substituent effects can be described by appropriate linear combinations of two constants per substituent. Although we have followed Swain and Lupton (1) and others in assigning supposedly descriptive names to these terms, it must be understood that our conclusions (except where explicitly stated otherwise) are independent of our choice of names and mental pictures of the interactions that lead to these terms. However, we have gone beyond Swain and Lupton (1) in specifying that one of these terms is solvent, temperature, and pressure dependent.

Further combination of eq. 4 with the Hammett equation ($\log K_1 = \rho\sigma$) and $\Delta G^0 = -RT \ln K$ leads to

$$[5] \qquad a_e t_e + a_r t_r = -2.3RT\rho\sigma$$

This application of eq. 4 can apply accurately only when certain conditions are met, which we now explore.

In the special case where $a_e t_e = 0$ (or, more reasonably, $a_e t_e \ll a_r t_r$), we simplify eq. 5 to

$$[6] \qquad (t_r/T)(-a_r/2.3R) = \rho\sigma$$

Identification of (t_r/T) with ρ and $(-a_r/2.3R)$ with σ is consistent with our original definitions of a_r and t_r. This identification tells us that ρ should be a linear function of T^{-1}, as it is known to be (2).

Although there are some substituents that exert only a very small field effect ($a_e \simeq 0$), any extensive series of substituents will include some for which $a_e \neq 0$. Further, we have $t_e = 0$ only in the unattainable cases of infinite dielectric constant for solvent and infinite "internal dielectric constant" of reacting species or of infinite separation of substituent from reaction center. Thus neither a_e nor t_e can generally be zero, and we do not expect eq. 6 to be generally appropriate. It is still possible, however, that eq. 6 can be applicable as a good approximation to a reaction series involving highly conjugated species (so that resonance is important) in which the substituents are very far from the reaction center. For such reaction series, t_e could be so small and t_r so large that $a_e t_e \ll a_r t_r$.

Another special case is where $a_r t_r = 0$ (or $a_r t_r \ll a_e t_e$) so that eq. 5 becomes

$$[7] \qquad (t_e/T)(-a_e/2.3R) = \rho\sigma$$

Identification of (t_e/T) with ρ and of $(-a_e/2.3R)$ with σ is again consistent with our original definitions. Because t_e is clearly some function of the dielectric constant of the solvent, which depends on temperature, we must postpone comment on the temperature dependence of ρ in this case.

There are numerous substituents for which $a_r \simeq 0$, and numerous reaction series involving non-aromatic structures (represented by P in reaction 1) for which $t_r \simeq 0$. Thus we should expect to find that it is appropriate to interpret linear free energy relationships for many reaction series in terms of eq. 7.

The special cases that lead to eqs. 6 and 7 are so restrictive that we now turn to a more general justification for the widespread empirical successes of the Hammett equation. It is clear that any proportionality between the two additive terms on the left hand side of eq. 5 will suffice, but it is also clear that a_e and a_r are proportional to each other only for carefully selected substituents rather than for a wide range of substituents. We must therefore turn to detailed consideration of t_e and t_r.

The transmission coefficient t_r for resonance effects depends only on the particular reaction series under consideration (P and B in reaction 1) and is therefore a constant when only the substituent X is varied. Similarly, t_e is independent of X and is a constant when P, B, solvent, temperature, and pressure are held constant. Thus for a series of reactions (only X variable) at any specified temperature and pressure in a specified solvent, the ratio of these transmission coefficients is also a constant as indicated by

$$[8] \qquad t_r/t_e = b$$

The "constant" b is a function of solvent, temperature, and pressure because t_e is some function of the temperature and pressure dependent dielectric properties of the solvent.

Substitution of eq. 8 into eq. 5 now leads to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$$[9]\quad \left[\frac{t_e}{T}\right]\left[-\frac{a_e + a_r b}{2.3R}\right] = \left[\frac{t_r}{T}\right]\left[-\frac{(a_e/b) + a_r}{2.3R}\right] = \rho\sigma$$

We identify the t/T terms with ρ and the terms containing a_e, a_r, and b with σ and see that it is possible to obtain a linear free energy relationship of the form of the Hammett equation even when there are substantial contributions from both field and resonance effects. However, the presence of b in the terms we identify with σ has important consequences that we must consider carefully.

Since b is a function of temperature and solvent, we see that the original definition of σ as independent of temperature and solvent cannot be both generally and exactly true. That is, one may obtain a good $\rho\sigma$ correlation for a particular reaction in a given solvent at any one temperature, but at another temperature or with a different solvent, it will in general be necessary to use different values of σ (possibly only slightly different) as well as different values for ρ.

Equation 9 also shows that the Hammett equation with a single set of σ values cannot be generally applicable to different reactions series (P and B varied). This is because the value of the "constant" b depends on the particular reaction series (particular P and B) under consideration. However, the empirical successes of the Hammett equation suggest that the value of b is approximately constant (in a particular solvent at a specified temperature) as long as P and B are not changed too drastically, which can account for successful use of reaction independent σ values in these cases.

Now we summarize our conclusions based on eq. 9 as follows. (*i*) Only in the case of $b \simeq 0$ (field effects much larger than resonance effects) can we generally expect to find σ values that are independent of reaction, solvent, and temperature. When $b \simeq 0$, eq. 9 reduces to eq. 7. (*ii*) For "similar" reaction series b may be sufficiently close to a constant that σ values can appear to be independent of the particular reaction under consideration.

The presence of b (a function of temperature) in eq. 9 has consequences with respect to ΔH^0, ΔS^0, and ΔC_p^0 that are considered following application of some classical thermodynamic relationships to eq. 4.

We now differentiate eq. 4 with respect to temperature at constant pressure to obtain

$$[10]\quad \Delta S^0 = -a_e(\partial t_e/\partial T)_p$$

and combine eq. 10 with eq. 4 to obtain

$$[11]\quad \Delta H^0 = a_e t_e + a_r t_r - a_e T(\partial t_e/\partial T)_p$$

Now the ratio of ΔH^0 to ΔS^0 is

$$[12]\quad \frac{\Delta H^0}{\Delta S^0} = T - \frac{t_e}{(\partial t_e/\partial T)_p}\left[1 + \frac{a_r t_r}{a_e t_e}\right]$$

$$[12']\quad \frac{\Delta H^0}{\Delta S^0} = T - \frac{t_e}{(\partial t_e/\partial T)_p}\left[1 + \frac{a_r b}{a_e}\right]$$

Further differentiation of eq. 11 with respect to temperature leads to

$$[13]\quad \Delta C_p^0 = -a_e T(\partial^2 t_e/\partial T^2)_p$$

Thus the ratio of ΔS^0 to ΔC_p^0 is

$$[14]\quad \Delta S^0/\Delta C_p^0 = (\partial t_e/\partial T)_p/T(\partial^2 t_e/\partial T^2)_p$$

Differentiation of eq. 4 with respect to pressure at constant temperature leads to

$$[15]\quad \Delta V^0 = a_e(\partial t_e/\partial P)_T$$

and the ratio of ΔS^0 to ΔV^0 is

$$[16]\quad \Delta S^0/\Delta V^0 = -(\partial t_e/\partial T)_p/(\partial t_e/\partial P)_T = (\partial P/\partial T)_{t_e}$$

The linear relationship between ΔS^0 and ΔV^0 that is predicted by eq. 16 has been observed and discussed in another connection previously (6). Unfortunately, we have few experimental data that yield reliable ΔC_p^0 values and are therefore unable to make any definitive statement about the general applicability of eq. 14. We do, however, note that there is some empirical evidence from thermodynamic studies of the ionization of aqueous acids for a (roughly) linear relationship between ΔS^0 and ΔC_p^0 as required by eq. 14.

Accuracy of most experimental data is such that we are often limited to consideration of ΔH^0 and ΔS^0 (and maybe more especially $\Delta H^\ddagger$ and $\Delta S^\ddagger$) as temperature independent quantities. It then follows from $d\Delta H^0/dT = \Delta C_p^0$ and $d\Delta S^0/dT = \Delta C_p^0/T$ that we must often take $\Delta C_p^0 = 0$. From eq. 13 we have, therefore

$$[17]\quad (\partial^2 t_e/\partial T^2)_p = 0$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and thence

[18] $t_e = C_1 + C_2T \qquad (\text{when } \Delta C_p^0 = 0)$

in which C_1 and C_2 are constants of integration. Now the ratio of transmission coefficients (eq. 18) becomes

[19] $b = t_r/(C_1 + C_2T) \qquad (\text{when } \Delta C_p^0 = 0)$

Substitution of eq. 18 in eq. 12 gives us

[20] $\Delta H^0/\Delta S^0 = -(C_1/C_2) - (a_r t_r/C_2 a_e)$

This eq. 20 shows that the ratio $\Delta H^0/\Delta S^0$ is a function of substituent, and that there should not be any general correlation of ΔH^0 with ΔS^0 for a reaction series that includes any wide range of substituents. This statement is entirely consistent with our earlier discussion of the consequences of the presence of b (a function of temperature) in the terms identified with σ in eq. 9. In the special case of negligible resonance contribution (*i.e.*, $t_r \simeq 0$), eq. 20 reduces to

[21] $\Delta H^0/\Delta S^0 = -(C_1/C_2) = \beta_i$

in which β_i is a constant for a particular reaction series in a specified solvent and is called the isoequilibrium (or isokinetic) temperature (2).

The treatment above shows that a simple isoequilibrium (or isokinetic) relationship can be generally expected only when temperature independent substituent effects (here called resonance effects that are described in terms of a_r and t_r) are very small compared to temperature dependent substituent effects (here called field effects that are described in terms of a_e and t_e). Thus we see that the requirements of an isoequilibrium (or isokinetic) relationship are more stringent than the requirements for a $\rho\sigma$ relationship for a reaction series in a specified solvent at a given temperature. This is a necessary requirement for any theory of substituent effects because there are numerous examples of reaction series for which there is a fairly good $\rho\sigma$ correlation while ΔH^0 and ΔS^0 vary in apparently erratic ways.

Possibly the most impressively extensive empirical support for an isoequilibrium relationship of the form of eq. 21 is provided by the linear relationship between ΔG^0 and ΔS^0 reported by Christensen, Izatt, and Hansen (7) for ionization of a large number of carboxylic acids. (Note that the isoequilibrium relationship $\Delta H^0/\Delta S^0 = \beta_i$ combined with $\Delta G^0 = \Delta H^0 - T\Delta S^0$ gives $\Delta G^0 = (\beta_i - T)\Delta S^0$, which is a linear relationship between ΔG^0 and ΔS^0.) It is consistent with a variety of evidence that field effects are more important than resonance effects for ionization of carboxylic acids, which in turn is consistent with our general equations and simplifications for the special case of resonance effects being small compared with field effects.

Now we turn to consideration of reaction series for which both ΔH^0 and ΔS^0 vary with temperature and for which we therefore have $\Delta C_p^0 \neq 0$. If we take ΔC_p^0 to be the same non-zero constant for each reaction in a particular series of reactions (only X variable), the solution of differential equation 13 leads to t_e being a function of a_e, which is contrary to the definitions of these quantities. Thus if $\Delta C_p^0 \neq 0$, it must be some function of substituent X and thence of a_e. Taking as the simplest case $\Delta C_p^0 = C_3 a_e$, the solution of differential equation 13 is

[22] $t_e = C_1 + C_2T - C_3T \ln T$

Substitution of eq. 22 in eq. 12 gives

[23] $$\frac{\Delta H^0}{\Delta S^0} = T - \frac{C_1 + C_2 - C_3T \ln T}{C_2 - C_3(1 + \ln T)} - \frac{a_r t_r}{a_e[C_2 - C_3(1 + \ln T)]}$$

Because eq. 23 is a function of substituent, we should not expect any general simple correlation between ΔH^0 and ΔS^0 values for any reaction series that includes a substantial range of substituents. Again, this statement is entirely consistent with our earlier discussion of eq. 9. In the special case where $t_r \simeq 0$, eq. 23 reduces to $\Delta H^0/\Delta S^0 = f(T)$ in which $f(T)$ is independent of substituent. Thus, for a reaction series in which field effects are dominant, we should expect to find a linear relationship between ΔH^0 and ΔS^0, with the slope depending on the temperature. Those who enjoy doing second order differential equations beyond the range of applicability of the model or accuracy of experimental data may express ΔC_p^0 as a function of temperature in eq. 13. Results that are obtained in this way are the same as above in that $\Delta H^0/\Delta S^0$ is in general a function of both temperature and substituent that reduces to a function of temperature when $t_r \simeq 0$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In earlier discussions of eq. 7, which applies when resonance effects are negligible compared to field effects, we identified t_e/T with ρ and then postponed consideration of the temperature dependence of ρ. For the common case in which we are only justified in taking $\Delta C_p^0 = 0$, we have t_e expressed as a linear function of temperature in eq. 18, which leads to

$$[24] \qquad \rho = C_2 + (C_1/T)$$

It has previously been shown (2) that ρ is a similar function of temperature when the Hammett equation is valid over a range of temperature, and it has been shown in this paper that the Hammett equation with temperature and reaction independent σ can be generally valid only when field effects are dominant.

When $\Delta C_p^0 \neq 0$, we have obtained a more complicated expression for t_e as a function of temperature (eq. 22), which leads to

$$[25] \qquad \rho = (C_1/T) + C_2 - C_3 \ln T$$

Thus when $\Delta C_p^0 \neq 0$ we have ρ only approximately linear in T^{-1}, with the deviations from linearity of the form required by previous (2) classical thermodynamic analysis of the Hammett equation.

The thorough statistical analysis by Swain and Lupton (1) has clearly shown that there is no general empirical justification for consideration of more than two kinds of independent (non-steric) interactions leading to substituent effects. On this basis we are restricted to two additive terms in eq. 4. There are, however, a few reaction series involving ionization of aqueous acids for which we have unusually extensive and accurate data that can lead to empirical justification for a third additive term in eq. 4 and thence to extensions of many of the following equations. But at present we can only add a third term to eq. 4 by assuming a much more specific and detailed model for the interaction mechanisms of substituent with reaction center and for solutes with solvent than is appropriate in this paper. We shall return to this question in connection with subsequent investigations of the relationships between the general conclusions of this paper and earlier investigations of substituent effects (2–5).

Nuclear Magnetic Resonance Studies of the Solution Chemistry of Metal Complexes. III. Acetylglycine Complexes of Cadmium, Zinc, and Lead[1]

DALLAS L. RABENSTEIN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received September 30, 1971

The aqueous solution chemistry of the cadmium, zinc, and lead complexes of acetylglycine has been investigated by proton magnetic resonance spectroscopy. These systems were investigated as models for the interaction of cadmium, zinc, and lead with the C-terminal end of peptides and proteins. The acid ionization constant of acetylglycine ($pK_a = 3.44$) and the formation constants of the cadmium ($\log K_{f1} = 1.23$), zinc ($\log K_{f1} = 0.86$), and lead ($\log K_{f1} = 1.38$, $\log K_{f2} = 1.20$) complexes at 25 °C were determined from chemical shift measurements ($K_{f1} = [ML^+]/[M^{2+}][L^-]$; $K_{f2} = [ML_2]/[ML^+][L^-]$). The rates of exchange of the peptide proton of acetylglycine in the free and complexed forms with solvent protons were measured from exchange-broadened n.m.r. spectra. The exchange rate of the peptide proton increases when the acetylglycine is complexed by these metals; in the case of the cadmium–acetylglycine complex the exchange rate is 53 times faster. The potential metal ion binding sites at the C-terminal end of peptides are discussed, and the possibility of chelation through an oxygen atom of the carboxylate group and an atom of the peptide linkage is considered.

La chimie des solutions aqueuses de complexes d'acétylglycine avec le cadmium, zinc, plomb a été étudiée pour la résonance magnétique nucléaire. Ces systèmes ont été choisis comme modèles pour l'étude de l'interaction du cadmium, zinc et plomb avec le carbone terminal des peptides et protéines. Les constantes d'ionisation acide de l'acétylglycine ($pK_a = 3.44$) et les constantes de formation des complexes avec le cadmium ($\log K_{f1} = 1.23$), zinc ($\log K_{f1} = 0.86$) et plomb ($\log K_{f1} = 1.38$, $\log K_{f2} = 1.20$) ont été déterminées à 25 °C par les mesures du déplacement chimique ($K_{f1} = [ML_2]/[M^{2+}][L^-]$; $K_{f2} = [ML_2]/[ML^+][L^-]$). Les vitesses d'échange avec le solvant du proton peptidique de l'acétylglycine, sous ses formes libre et complexée, ont été mesurées à partir de la bande large d'échange du spectre r.m.n. La constante de cet échange croît lorsque l'acétylglycine est complexé par ces métaux; dans le cas du complexe avec le cadmium, l'échange est 53 fois plus rapide. Les sites potentiels de liaison de l'ion métal avec le carbone terminal des peptides sont discutés, la possibilité de chélation avec un atome d'oxygène du groupe carboxylate et un atome de la liaison peptidique est considérée.

Canadian Journal of Chemistry, **50**, 1036 (1972)

Introduction

Structural studies of several metal-containing biological molecules have revealed that binding of a metal ion by a protein may involve functional groups separated by many amino acid residues along the chain (2). To a first approximation, the donor groups have been considered to act independently of one another with respect to the metal ion, except for steric interactions between them. Within this approximation, simple amino acids and peptides have been used as models for the study of metal–protein interactions (3).

We are presently investigating the interaction of metal ions with the potential coordination sites of peptides and proteins. In this paper, we wish to report the results of a proton magnetic resonance study of the interaction of a model compound for the C-terminal carboxylic acid group with the metal ions cadmium, zinc, and lead. Acetylglycine was chosen as the model compound because it has the peptide linkage characteristic of the C-terminal amino acid residue of a protein chain. In addition, there are no other coordination sites in acetylglycine known to form strong complexes with these metal ions. The complexation reactions have been quantitatively characterized from the dependence of the chemical shifts of the acetylglycine protons on solution conditions. The exchange kinetics of the peptide proton of both free and complexed acetylglycine have been determined by lineshape analysis of the collapse of spin–spin coupling to the peptide proton.

[1]For Part II, see ref. 1.

Experimental

Chemicals

Acetylglycine (Eastman Organic Chemicals) and reagent grade metal nitrate salts were used as received. Standardized solutions of the metal salts were prepared by the methods of Schwarzenbach (4).Tetramethylammonium (TMA) nitrate was prepared by titration of a 25% aqueous solution of

TMA hydroxide (Eastman Organic Chemicals) with HNO_3 to a neutral p*H*.

pH Measurements

All p*H* measurements were made at 25 °C with an Orion Model 701 p*H* meter equipped with a standard glass electrode and a fiber-tip, saturated calomel reference electrode. Saturated potassium acid tartrate and 0.01 *M* sodium tetraborate buffers, p*H* 3.56 and 9.18 at 25 °C, were used to standardize the p*H* meter.

Nuclear Magnetic Resonance Measurements

Nuclear magnetic resonance spectra were obtained on a Varian A-60D high-resolution spectrometer at a probe temperature of 25 ± 1 °C. Spectra were recorded at sweep rates of 0.1 Hz/s both for chemical shift measurements and line-shape measurements; sweep widths of 50 Hz were used. For line-shape measurements, each spectrum was recorded four or five times and the spectra were averaged.

Solutions used in the n.m.r. studies were prepared in distilled water from the appropriate amounts of crystalline acetylglycine and standardized metal nitrate solution. KNO_3 was added to the solution containing only acetylglycine to give an ionic strength comparable to that of the solutions containing the metal nitrates. HNO_3 or KOH was added to bring the solutions to the desired p*H* values. TMA nitrate was added to each solution at a concentration of approximately 0.01 *M* as a reference compound for chemical shift measurements, negative shifts representing resonances downfield from the central resonance of the TMA triplet. The central resonance of TMA is 3.17 p.p.m. downfield from the methyl resonance of sodium 3-(trimethylsilyl) 1-propane sulfonic acid (TMS*). At p*H* values greater than ~8, some hydrolysis of the peptide linkage occurred as indicated by drifting of p*H* to lower values. To minimize error due to changes in p*H*, n.m.r. spectra were obtained immediately after each sample was prepared. Successive scans showed little change in chemical shift or in line shape so that the change in p*H* while in the n.m.r. probe is considered to be small.

Results

Interpretation of the Nuclear Magnetic Resonance Spectra

The n.m.r. spectrum of the carbon-bonded protons of acetylglycine at p*H* 4.50 is shown in Fig. 1. The multiplet pattern for the methylene protons is a doublet of quartets resulting from spin–spin coupling to the peptide proton ($^3J_{HH} = 5.9$ Hz) and long-range coupling to the methyl protons ($^5J_{HH} = 0.3$ Hz). The spin states of the methyl protons which give rise to the quartet structure are given under the resonances for the methylene protons. These will be discussed with regard to the determination of the peptide proton exchange kinetics in a later section. Some structure appears in the resonance for the methyl protons, probably from coupling to both the peptide proton and the methylene protons. Due to the small coupling involved,

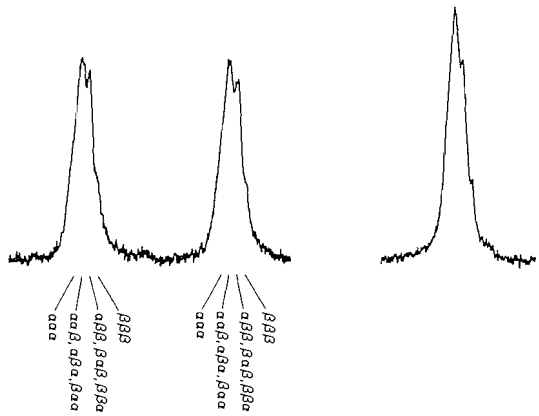

FIG. 1. 60 MHz proton n.m.r. spectrum of the carbon-bonded protons of acetylglycine at p*H* 4.50. The spin states of the methyl protons which give rise to the quartet structure are indicated below the resonances for the methylene protons.

however, it is not possible to determine the multiplicity of the methyl resonance. Similar long-range coupling through the same system of chemical bonds has been observed for *N*-methylacetamide (5).

Resonance patterns for the methylene protons at several p*H* values are shown in Fig. 2. The doublet of quartets collapses to a single quartet

when the rate of exchange of the peptide proton with solvent protons is fast.

Chemical shifts of the resonances for the methyl and methylene protons are p*H*-dependent due to ionization of the carboxylic acid proton. The p*H*-dependence of the chemical shift of the methylene protons is shown by Curve *A* in Fig. 3. The chemical shift of the methyl protons changes from 66.5 to 67.9 Hz as the p*H* value is increased from 1.22 to 5.89.

Addition of an equimolar concentration of cadmium nitrate, zinc nitrate, or lead nitrate changes the p*H*-dependence of the chemical shifts of the methylene protons, as shown in Figs. 3, 4, and 5. In particular, the shift accompanying ionization of the carboxylic acid proton occurs over a lower p*H* range indicating displacement by the metal ion. At high p*H*, the chemical shift is different in the presence of the metal ions indicating different chemical shifts in the complexed and uncomplexed acetylglycine. With the metal containing solutions, the chemical shifts of the methyl protons leveled off at 67.5 Hz, independent of the metal ion.

The resonances for the methylene protons in the metal containing solutions also consist of a doublet of quartets, however, collapse to a single quartet begins at a lower p*H* when the metal ions are present. Because of precipitation, it was not possible to observe the ultimate collapse to a single quartet. The precipitates are probably metal hydroxides. The highest p*H* values that could be reached before precipitation for solutions containing 0.20 *M* metal nitrate and 0.20 *M* acetylglycine were 7.3, 6.2, and 5.6 for the cadmium, zinc, and lead systems.

Determination of the Acid Ionization Constant

Temperature 25 °C.

is occurring are the sums of the chemical shifts of the protonated and ionized forms, weighted according to the relative concentration of each species (6).

$$[1] \qquad \nu_{obsd} = P_{HL}\nu_{HL} + P_L\nu_L$$

where P is the fractional population of each species.

$$[2] \qquad 1 = P_{HL} + P_L$$

HL and L^- represent protonated and ionized acetylglycine, and ν the chemical shift of the acetylglycine in the species indicated. Ionization of the carboxylic acid proton is quantitatively expressed by the constant K_a, defined as

$$[3] \qquad K_a = \frac{[H^+][L^-]}{[HL]}$$

When $[HL] = [L^-]$, *i.e.* when $P_{HL} = P_L$, $K_a = [H^+]$. Equation 1 indicates that the K_a of acetylglycine equals the $[H^+]$ at which ν_{obsd} is midway between ν_{HL} and ν_L. A value for K_a of 3.64×10^{-4} was obtained in this way from the data in Fig. 3.

Determination of the Formation Constants

When some acetylglycine is complexed, the observed chemical shifts are a measure of the amount of complex formed from which the formation constants can be evaluated. The observed chemical shifts are the sums of the chemical shifts of the various protonated species, weighted according to the relative concentration of each species (7).

Acetylglycine complexes of varying stoichiometry presumably can form via a series of stepwise reactions. The formation constants for ML^+ and ML_2 are defined as follows

$$[4] \qquad K_{f1} = \frac{[ML^+]}{[M^{2+}][L^-]}$$

$$[5] \qquad K_{f2} = \frac{[ML_2]}{[ML^+][L^-]}$$

In this work, the solutions contained equimolar amounts of acetylglycine and metal nitrate. A consideration of the formation constants of the acetic acid complexes of these metal ions suggests that, for these solution conditions, ML^+ is the predominant acetylglycine complex. The observed chemical shift for this situation is given by eq. 6.

$$[6] \qquad \nu_{obsd} = P_{L_f}\nu_{L_f} + P_{ML}\nu_{ML}$$

where L_f is the uncomplexed ligand ($[L_f] = [L^-] + [HL]$) and ν_{L_f} is the chemical shift of acetylglycene at the particular p*H* in the absence of a complexing metal ion. Substitution of $1 - P_{ML}$ into eq. 6 for P_{L_f} and rearrangement leads to eq. 7.

$$[7] \qquad P_{ML} = \frac{\nu_{obsd} - \nu_{L_f}}{\nu_{ML} - \nu_{L_f}}$$

P_{ML} is related to the concentration of complex by eq. 8.

$$[8] \qquad [ML] = P_{ML}[L_t]$$

where $[L_t]$ is the total acetyl glycine concentration.

The chemical shift of acetylglycine in the complexed form is required for calculation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the concentration of complex by this method. Equation 6 indicates that when ν_{obsd} equals ν_{L_f}, ν_{ML} equals ν_{obsd}. Thus ν_{ML} is equal to ν_{obsd} at the pH where the chemical shift *vs.* pH curve for acetylglycine crosses the chemical shift *vs.* pH curve for an acetylglycine solution containing the complexing metal ion.

Formation constants were calculated from the chemical shift data presented in Figs. 3, 4, and 5. The concentration of ML^+ was calculated for each data point using eqs. 7 and 8. The concentrations of uncomplexed metal and ligand were then obtained by difference. The concentration of uncomplexed ligand in the ionized form was calculated as $\alpha_1[L_f]$ where $\alpha_1 = K_a/(K_a + [H^+])$. Formation constants determined in this way were constant and independent of pH for the cadmium and zinc systems, and for the lead system at pH less than *ca.* 2.5. The values obtained are log $K_{f1} = 1.23$ with a standard deviation of 0.07 for cadmium, 0.86 with a standard deviation of 0.06 for zinc, and 1.38 with a standard deviation of 0.02 for lead at pH less than 2.5. Literature values are log $K_{f1} = 1.13$, 0.71, and 1.40 for cadmium, zinc, and lead, respectively, at an ionic strength of 0.4 and a temperature of 30 °C (8).

The dependence on pH in the lead system at pH greater than 2.5 indicates that, in this pH region, the lead system is not adequately described by considering only formation of PbL^+. Chemical shift data at pH greater than 2.5 were further evaluated to obtain K_{f2}. In this pH range, the observed chemical shift is given by eq. 9.

$$[9] \qquad \nu_{obsd} = P_{L_f}\nu_{L_f} + P_{PbL}\nu_{PbL} + P_{PbL_2}\nu_{PbL_2}$$

Assuming that the chemical shift of acetylglycine in PbL_2 equals its chemical shift in PbL^+, eq. 9 becomes

$$[10] \qquad \nu_{obsd} = P_{L_f}\nu_{L_f} + P_{L_c}\nu_{L_c}$$

where $P_{L_c} = P_{PbL} + P_{PbL_2}$. These relationships were used to calculate K_{f2} from the data in Fig. 5; a value of 16.0 with a standard deviation of 1.3 was obtained. No literature value is available for comparison with K_{f2}. To check the validity of the method used, the formation constants for the lead complexes of acetic acid, $Pb(OAc)^+$ and $Pb(OAc)_2$, were determined. As in the lead–acetylglycine system, the chemical shift of acetic acid in $Pb(OAc)_2$ was assumed to be the same as its chemical shift in $Pb(OAc)^+$. Formation constants obtained from chemical shift data are log $K_{f1} = 2.16$ and log $K_{f2} = 0.83$. Literature values for these formation constants are log $K_{f1} = 2.18$ and log $K_{f2} = 0.74$ (9).

Determination of the Rate of Peptide Proton Exchange

Collapse of the doublet of quartets to a single quartet as the pH is increased (Fig. 2) is due to an increase in the rate of exchange of the peptide proton with solvent protons. Two reactions considered to be possible exchange pathways in the pH region where collapse occurs are (5, 10–12)

$$[11] \qquad CH_3CONHCH_2CO_2^- + H_2O \overset{k_1}{\rightleftharpoons} CH_3CO\bar{N}CH_2CO_2^- + H_3O^+$$

$$[12] \qquad CH_3CONHCH_2CO_2^- + OH^- \overset{k_2}{\rightleftharpoons} CH_3CO\bar{N}CH_2CO_2^- + H_2O$$

The average lifetime, τ, of the peptide proton before transfer from acetylglycine is the kinetic parameter measured by n.m.r. Equation 13 is the rate equation for the above reactions in terms of this parameter.

$$[13] \qquad \frac{1}{\tau} = k_1 + k_2[OH^-]$$

The lifetime of the peptide proton was obtained from n.m.r. spectra in the pH range where collapse from a doublet of quartets to a single quartet takes place. Sheinblatt has previously reported the results of an n.m.r. study of the exchange kinetics of the peptide proton of acetylglycine (12). In his line-shape analysis of the collapsing spectra, the approximation apparently was made that the quartets are single lines. In the present work, exchange rates were determined from small amounts of collapse, especially in the presence of metal ions, which made it necessary to use a more rigorous line-shape treatment that included the quartet structure.

Collapse of the quartet structure by peptide proton exchange is due to exchange of the methylene protons between the eight environments giving the eight lines in the doublet of quartets. Spectra were simulated as a function of the lifetime of the peptide proton with Bloch phenomenological equations modified for trans-

fer of magnetization by eight-site exchange. This approach is valid for this system because the coupling is first-order (13). The treatment of McConnell and Meiboom was used to obtain modified Bloch equations for eight-site exchange (14, 15).

In simulating exchange-collapsed spectra, it was assumed that the spin states of the methyl protons (indicated in Fig. 1) do not change upon exchange of the peptide proton (13). Thus, exchange occurs only between those lines for which the spin states of the methyl protons are the same. The probabilities that the spin state of the peptide proton either will or will not change upon exchange are essentially equal. A line width of 0.32 Hz was used for each of the eight lines in the doublet of quartets in the absence of exchange. This value was obtained by comparing spectra calculated for different line widths with the experimental spectrum in Fig. 1.

The lifetime of the peptide proton at a particular p*H* value was obtained by comparing the partially collapsed spectrum with computer-simulated spectra. The most convenient parameters to measure from the simulated and observed spectra were line widths and valley-to-peak ratios. These parameters from simulated spectra were plotted *vs.* τ, and experimental τ values were obtained from experimental spectra using these plots.

The inverse of the lifetime of the peptide proton at several p*H* values in the region where collapse occurs is listed in Table 1. The experimental uncertainties in the τ values are from 10 to 15%. According to eq. 13, the intercept of a plot of $1/\tau$ *vs.* hydroxide concentration is k_1 and the slope is k_2. Treating the data with standard least-squares techniques (16), the intercept is essentially zero and the slope is $3.75 \times 10^6\ M^{-1}\ s^{-1}$ with a standard deviation of 0.18×10^6. The value obtained by Sheinblatt for k_2 is $2.7 \times 10^6\ M^{-1}\ s^{-1}$ (12). The theoretical spectra in Fig. 2 were computer-simulated for lifetimes calculated from the p*H* values indicated and the rate constant obtained in the present work.

When the solution contains acetylglycine and equimolar amounts of cadmium, zinc, or lead, collapse begins at significantly lower p*H* values than in the absence of complexing metal, indicating an acceleration of the rate of exchange upon complexation. The exchange kinetics of the complexed species can be obtained by modifying eq. 13 to include the complex. The resulting equation is

$$[14] \qquad \frac{1}{\tau} = k_2\beta_1[OH^-] + k_3\beta_2[OH^-]$$

where $\beta_1 = [\text{Acetylglycine}]_{\text{uncomplexed}}/[\text{Acetylglycine}]_{\text{total}}$ and $\beta_2 = [\text{Acetylglycine}]_{\text{complexed}}/[\text{Acetylglycine}]_{\text{total}}$. β_1 and β_2 were calculated at the p*H* of a particular data point using the formation constants determined above. k_3 was then determined using the k_2 reported above and the $1/\tau$ obtained by comparing experimental and computer-simulated spectra.

Measurement of k_3 was possible only for the cadmium complex; precipitation of presumably $Pb(OH)_2$ and $Zn(OH)_2$ prevented reaching p*H* values at which there was sufficient collapse for reliable measurement in the lead and zinc systems. However, some broadening of each of the quartets was observed at the highest p*H* values reached with the lead and zinc systems whereas in the absence of these metal ions no broadening was observed at similar p*H* values. Therefore, peptide proton exchange is faster also in the acetylglycine complexes of lead and zinc than in the uncomplexed form.

Data for the peptide proton exchange in the cadmium system are: $pH = 6.70$, $1/\tau = 5.0$; $pH = 6.84$, $1/\tau = 5.9$; $pH = 6.93$, $1/\tau = 6.7$; $pH = 7.09$, $1/\tau = 8.9$; $pH = 7.26$, $1/\tau = 13.3$. Evaluation of these data by eq. 14 yields a value of $2.0 \times 10^8\ M^{-1}\ s^{-1}$ with a standard deviation of 0.28×10^8 for the rate constant for exchange of the peptide proton in the cadmium–acetylglycine complex.

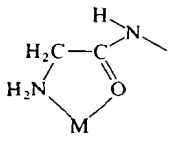
Discussion

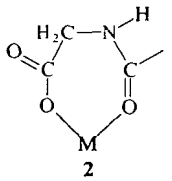
The chemical shift data in Figs. 3, 4, and 5 indicate that acetylglycine is coordinated to cadmium, zinc, and lead. The carboxylate group is coordinated as evidenced by displacement of the ionization of the carboxylic acid proton to a lower p*H* region. The peptide linkage might also be coordinated to give a chelate structure; the peptide linkage is known to be a site of metal-binding in some simple dipeptides and tripeptides when coordination occurs at the N-terminal amino group (17). Binding of the peptide linkage has been proposed via the carbonyl oxygen, the protonated peptide nitrogen, and the deprotonated peptide nitrogen (17). Incomplete collapse of the multiplet structure from coupling to the peptide proton of acetylglycine indicates that in not more than a small fraction of the complexed species could the peptide proton be ionized. From previous work Co(II), Ni(II), Cu(II), and Pd(II) are the only divalent metals known to promote ionization of the peptide nitrogen with subsequent bonding at the deprotonated site (17–20). Therefore, any coordination of cadmium, zinc, or lead to the peptide linkage of acetylglycine in the p*H* regions studied in this work would be to the protonated peptide linkage.

Of the two potential coordination sites in the protonated peptide linkage, the carbonyl oxygen is considered the more basic site on the basis of n.m.r. studies of protonation of the amide linkage (5) and crystallographic (3, 21) and infrared (22, 23) studies of binding to the peptide linkage. Thus, when a metal ion is chelated at the N-terminal end of a peptide, as in the dipeptide and tripeptide complexes of several metal ions, chelation is through amino nitrogen atoms and carbonyl oxygen atoms (**1**).



1

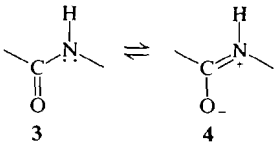
Chelation at the C-terminal end through an oxygen atom of the carboxylate group and the oxygen atom of the peptide linkage would lead to **2**. The seven-membered chelate ring in **2** is likely to be less stable than the five-membered ring in **1** (24), suggesting that the situation for chelation at the C-terminal end of peptides is not so ideal as at the N-terminal end.



2

The formation constants for the acetylglycine complexes of cadmium, zinc, and lead also suggest that, if coordination does occur to the peptide linkage, it does not contribute significantly to the stability of the complex. The formation constants of complexes of these metals with a series of carboxylic acids, including acetylglycine, have been correlated with the basicity of the carboxylic acids, with no need for invoking chelation in the acetylglycine complexes (8).

Rabin and others have proposed that the peptide linkage exists as a resonance hybrid, primarily of the two forms



3 **4**

and that coordination at the oxygen, as in **1**, increases the importance of **4** (25). If so, coordination at the oxygen would tend to enhance the acidity of the peptide proton. In this work, it was found that coordination of acetylglycine to cadmium, zinc, and lead increases the rate of exchange of the peptide proton with solvent protons. In the cadmium complex, exchange is 53 times as fast as in uncomplexed acetylglycine. The increased lability may result from an inductive effect through the coordinated carboxylate group, or by interaction of the carbonyl oxygen of the peptide linkage with the metal. Interpretation of these results in terms of binding to the peptide linkage must await a better understanding of inductive effects on peptide proton exchange (11).

Photoreactions of Nitroso Compounds in Solution.[1] XX. Photoreduction, Photoelimination, and Photoaddition of Nitrosamines

Y. L. CHOW, M. P. LAU, R. A. PERRY, AND J. N. S. TAM

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received June 9, 1971

It has been established that alkylnitrosamines undergo photoreduction in methanol solutions in the presence of an acid to give the parent amine, formaldehyde, and *N*-aminoformamide. Where it is possible, an exchange reaction between the δ-hydrogen and the nitroso group is also observed during this photolysis. However, photoelimination also occurs in competition with photoreduction, the extent of which is dependent on the rates of the two photoprocesses. In aqueous solutions, *N*-nitrosamines predominantly undergo photoelimination. Those nitrosamines that undergo rapid photoelimination or photoreduction do not efficiently add to olefins photolytically. Conversely if photoaddition is retarded, a nitrosamine takes elimination or reduction pathways. Excitation of $n \rightarrow \pi^*$ or $\pi \rightarrow \pi^*$ transition band of *N*-nitrosamines gives virtually the same photoreaction patterns. Minor differences in the photoproducts are attributed to other secondary reactions.

Il a été établi que les alkylnitrosamines sont photoréduites dans des solutions de méthanol en présence d'un acide pour donner l'amine apparentée, du formaldéhyde et du *N*-aminoformamide. Lorsque c'est possible, on observe aussi une réaction d'échange entre l'hydrogène-δ et le groupe nitroso durant cette photolyse. Toutefois, la photoélimination arrive aussi en compétition avec la photoréduction, dont l'importance dépend des vitesses des deux procédés photolytiques. En solutions aqueuses, les *N*-nitrosamines subissent la photoélimination de façon prédominante. Ces nitrosamines qui subissent une photoréduction ou une photoélimination rapide ne s'additionnent pas photolytiquement aux oléfines de façon efficace. D'autre part, si la photoaddition est retardée, une nitrosamine entreprend un mécanisme d'élimination ou de réduction. L'excitation de la bande de transition $n \rightarrow \pi^*$ ou $\pi \rightarrow \pi^*$ des nitrosamines donne virtuellement les mêmes modèles de photoréaction. Des différences mineures dans les photoproduits sont attribuées à d'autres réactions secondaires.

Canadian Journal of Chemistry, **50**, 1044 (1972)

Previously we have demonstrated that an alkylnitrosamine is photolabile in the presence of an acid when irradiated in a Pyrex apparatus (>280 nm) (1, 2). Thus an aqueous solution of *N*-nitrosopiperidine (**1***a*) containing hydrochloric acid is photolytically decomposed to 2-piperidonoxime (**3***a*) and "isotripiperidein" (2). This process will be termed as photoelimination since various evidence indicates that the initial step of the reaction is the elimination of HNO to give alkylideneimine **2** (2–4). Examples of the photoinitiated addition of alkylnitrosamines to olefins (5–8), dienes (9), and acetylenes (10) have been described. This process, which also requires the presence of an acid, has been referred to as photoaddition. We have found that a nitrosamine also undergoes photolytically initiated reduction in the presence of an acid; the term photoreduction will be employed in describing this process. Further it has been observed that the pattern of these photodecompositions is virtually independent of the type of electronic excitation, *i.e.*, $n \rightarrow \pi^*$ or $\pi \rightarrow \pi^*$.

Through kinetic studies by flash excitation techniques we have recently demonstrated that the common reactive intermediate, aminium radical, is responsible for these photoreactions (1). In the light of this knowledge it is timely to discuss various photoprocesses and clarify the scope of these photoreactions.

Results

When a methanol solution of *N*-nitrosopiperidine (**1***a*) was photolyzed in the presence of hydrochloric acid, a large amount of piperidine (as its hydrochloride) was obtained and the expected photoelimination products were obtained in very low yields. This led us to re-examine carefully the photolysis both in methanol and in water solutions with respect to the different electronic excitations. Generally nonconjugated alkylnitrosamines show absorption maxima for the $n \rightarrow \pi^*$ transition band at ~340 nm and for the $\pi \rightarrow \pi^*$ transition at 230–240 nm with minima located at about the 300–320 nm region. For excitation of the $n \rightarrow \pi^*$ band, a filter solution of 2,7-dimethyl-3,6-diazacyclohepta-1,6-diene perchlorate was used to cut off the light energy below 340 nm.

TABLE 1. Photolysis of *N*-nitrosopiperidine

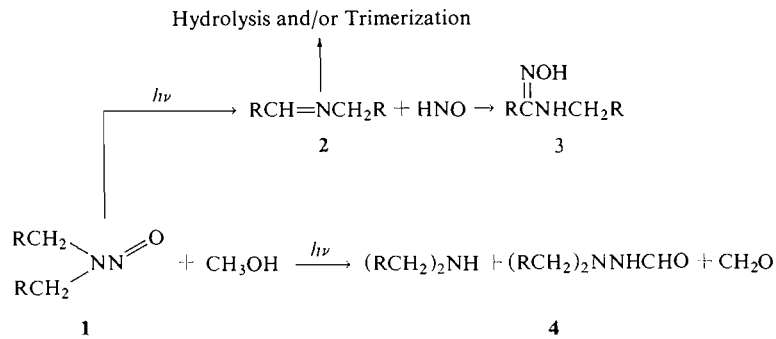
Solvent	Type of irradiation	% yield			
		Piperidine HCl	Amidoxime **3***a*	Isotripiperidein	Other
H_2O	254 nm	24	—	19	—
H_2O	>340 nm	—	31	39	*
MeOH	254	42	2.2	—	†
MeOH	>340	57	3.5	—	‡

*2-Piperidone (1%) was also isolated.
†*N*-Piperidinoformamide (20%) and formaldehyde (as 2,4-DNPH) were isolated.
‡Formaldehyde (as 2,4-DNPH) and *N,N,N',N'*-bispentamethyleneurea were isolated.

For irradiation of the $\pi \rightarrow \pi^*$ band, a low pressure mercury resonance lamp (90% of energy output at 2537 Å) and a nickel sulfate solution were used so that the incident light energy in the 340–420 nm region was nil.

The results of the photolysis of *N*-nitrosopiperidine (**1***a*) under various conditions are summarized in Table 1 in which the percent yield of the products represents the percentage actually isolated. The photolysate after irradiation in methanol with the 254 nm light source was carefully analyzed and small amounts of 2-piperidonoxime (**3***a*) (2) and *N*-piperidinoformamide (**4***a*) were determined in addition to piperidine hydrochloride. From the methanol distillate, formaldehyde was isolated as its 2,4-DNPH derivative. The structure of formamide **4***a* was determined by direct comparison with an authentic sample prepared by a standard method (11), and by mass spectrometry in which the compound exhibited strong mass ions at 99 and 83 assignable to the fragments of M^+—CHO and M^+—NHCHO. It is pertinent to mention that the n.m.r. spectrum of formamide **4***a* (and other analogous compounds **4**) showed that the signal of the NH proton was coupled with the aldehyde proton ($J = 11$ Hz) indicating the former was not exchanging rapidly. However, in the photolysate obtained from the >340 nm irradiation, no trace of formamide **4***a* could be detected.

The photolysis of **1***a* was repeated in aqueous solutions with these two different light sources (Table 1). Careful analysis of the photolysate



a R = $-CH_2CH_2CH_2-$
b R = C_4H_9
c R = C_6H_5

obtained from the >340 nm irradiation showed that oxime **3***a* (31%), "isotripiperidein" (39%) (2), and a trace amount of 2-piperidone had been formed; the last compound was assumed to be formed by hydrolysis of oxime **3***a*. These compounds were typical photoelimination products. Piperidine hydrochloride, if formed to a small extent, might have escaped detection. In contrast, irradiation with the 254 nm light source gave piperidine hydrochloride and "isotripiperidein" but no oxime **3***a*. The actual percent yields of these compounds were probably higher since recovery from aqueous solutions was generally not quantitative due to the compounds' high solubility in water. In each case, it was demonstrated that the photolysis did not take place in the absence of an acid.

Several nitrosamines were photolyzed in methanol in order to determine the photoreduction pattern. The pertinent cases will be discussed here. The complex photolysate from *N*-nitroso-di-*n*-pentylamine was analyzed to give valeraldehyde (35%), the parent amine (12%), *N*-di-*n*-pentylaminoformamide (**4***b*, 3%), 4-(*N*-nitrosohydroxylamino)-dipentylamine (**5**, 7%), and *N*-*n*-pentyl-pentanamidoxime (**3***b*, 1.5%); *n*-pentylamine was also isolated. Valeraldehyde was derived from the photoelimination product, imine **2***b*, through hydrolysis. The structures of both formamide **4***b* and amidoxime **3***b* were inferred after comparison of their spectral data with that of homologous compounds (2, 4) (see Experimental).

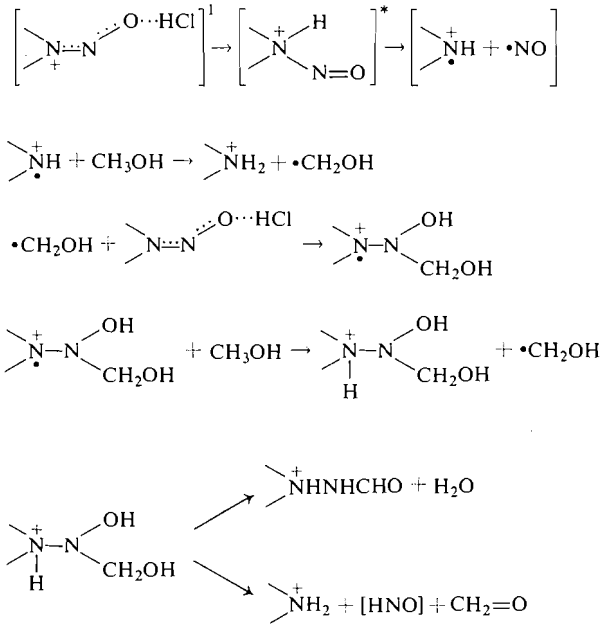
The molecular formula of nitrosohydroxylamine **5** was ascertained by high resolution mass spectrometry to be $C_{10}H_{23}N_3O_2$. The i.r. spectrum of this compound exhibited the major absorptions observed in the spectrum of 1-piperidino-2-(*N*-nitrosohydroxylamino)-3,3-dimethylbutane (8); this suggested the presence of a —N(NO)OH group. The location of the nitrosohydroxylamino group as shown in **5** was determined by n.m.r. decoupling experiments[2] by establishing that the methyl doublet (τ 8.59) was coupled with the methine proton (τ 5.7) with a coupling constant of 6.5 Hz. Nitrosohydroxylamine **5** and formamide **4***b* were, however, not detected when nitrosamine **1***b* was photolyzed with the >340 nm light source. The isolated photoproducts were amidoxime **3***b* (10%), valeraldehyde (>29%), and the parent amine (22%).

The photolysis of *N*-nitrosodibenzylamine in methanol solution with the 254 nm light source was gradually retarded as it proceeded due to an internal filter effect. It was assumed that the photoproducts were acting as internal filters to slow down the photoprocess. From the photolysate, *N*-benzylbenzamidoxime (**3***c*, 20%) (4), benzylamine (55%), and benzaldehyde (as its 2,4-DNPH) and its oxime were isolated; all these photoproducts were typical of photoelimination. Dibenzylamine was not isolated. In view of this result, the photolysis of *N*-nitroso-1,2,3,4-tetrahydroisoquinoline in methanol solution (7) was reinvestigated with the >340 nm light source. From the photolysate, 1-oximino-1,2,3,4-tetrahydroisoquinoline (7) was isolated in 87% yield and the parent amine only in 3% yield. The photoreduction was therefore very inefficient.

Photolysis of a methanol solution of *N*-nitroso-2-methyl-piperidine with the 254 nm light source gave a rather intractable crude product from which *N*-(2-methylpiperidino)formamide (**6**, >15%) was isolated. Under the same conditions, *N*-nitroso-*N*-methyl-cyclohexylamine (2) was photolyzed to give a 60% yield of *N*-methylcyclohexylamine. In addition, photodecomposition of *N*-nitroso-*N*-methylpentylamine *N*-nitroso-2-butylaminoethanol, and *N*-nitroso-2-(*t*-butylamino)ethanol were also investigated, but no radical departure from the above decomposition pattern was observed. The details of these photolyses are described in the thesis by one of us (12).

When a methanol solution of *N*-nitrosopiperidine and cyclohexene was irradiated with the 254 nm light source, 2-piperidinocyclohexanone (**7**, *ca.* 8%) and the corresponding oxime (**8**, 42%) (5) were isolated. Though the yield of the oxime estimated from the spectral data was about 60%, the isolation was hampered by the presence of a large amount of tarry product. The yields of both tar and the ketone were cut down to negligible amounts when the photoaddition was carried out with >340 nm irradiation. An excellent yield of oxime **8** was isolated readily from this photoaddition.

[2]The decoupling experiments have been carried out with a Varian HA-100 spectrometer through the kind assistance of Professor K. R. Kopecky to whom we are very grateful.



SCHEME 2

Discussion

From the kinetic studies by flash excitation, we have shown that a singlet excited nitrosamine–acid complex rapidly decays to the corresponding aminium radical. It is this aminium radical that undergoes elimination, reduction, and addition reactions (1). It has been noted that in photolyses of certain nitrosamines in methanol solution, instead of the expected reaction products, variable amounts of the parent amine have been isolated (2, 6, 7). Since nitrosamines have been shown to be stable in the absence of irradiation (2), the transformation to the parent amine is probably derived from a light-catalyzed process. That oxidation–reduction processes are involved in this transformation is readily shown by isolation of the formamides **4** and formaldehyde that are derived from oxidations of methanol. In an ethanol solution photolysis, acetaldehyde has been isolated (13) as the oxidation product, although the yields of both acetaldehyde and formaldehyde have not been quantitatively determined. The formyl group of the formamides **4** is apparently derived from oxidative coupling with methanol. In view of the known capacity of aminium radical to abstract hydrogen (14, 15) the following mechanism is suggested to account for the redox process. The ketyl radical $\cdot CH_2OH$ is proposed as a convenient carrier for the oxidation process and its formation is facilitated by the readily abstractable α-hydrogen.

The formation of hydroxylamine **5** in the photolysis of nitrosamine **1***b* can be regarded as an intramolecular oxidation process in which abstraction of the δ-hydrogen is favored by an entropy gain. This leads to the formation of the δ-nitroso compound which subsequently adds HNO to give **5** (8). The intramolecular exchange reaction between a hydrogen atom and a nitroso group has ample analogy in the Barton reaction (16) and nitrosamide photolysis (17, 18); the Hofmann–Löffler–Freytag reaction (15, 19) follows a similar reaction mechanism. An intermolecular hydrogen–nitroso group exchange reaction involving a labile allylic hydrogen has also been observed in the photolysis of **1***a* in the presence of Δ^9-octaline (20).

In the absence of hydrogen atom donating substrates, piperidinium radical preferentially undergoes photoelimination as shown in the photolysis of **1***a* in aqueous solutions. The proposed mechanism requires the elimination

9 10 7

SCHEME 3

of an α-hydrogen atom from the aminium radical using nitric oxide as acceptor. The probability of elimination in an aminium radical is dependent upon the nature of the C—H bond to be broken and upon the steric factors around the C—H bond. Even in a methanol solution, the photoelimination takes place during photolysis of **1***b* since the rate of elimination is competitive with that of reduction (1). Since the elimination process is greatly facilitated by the involvement of a labile benzylic hydrogen in the photolysis of **1***c*, no photoreduction has been observed (3, 4). On the basis of a similar argument, the elimination process should dominate the photolysis of *N*-nitroso-1,2,3,4-tetrahydroisoquinoline; in this case, photoreduction has been observed to only a minute extent. It is pertinent to point out that in this case the photoelimination exclusively involves the benzylic hydrogen at the C-1 position.

On the other hand, it has been reported previously (5) that *N*-nitrosojervine and *N*-nitroso-*trans*-decahydroquinoline undergo photoreduction in methanol solutions faster than photoelimination, resulting in the exclusive formation of the parent amines. Photolyses of other nitrosamines indicate that the two rates are comparable and give both types of products (5). The structural features that facilitate photoreduction are however obscure at this stage. From the flash excitation studies of *N*-nitrosopiperidine it is shown that photoelimination is a unimolecular reaction while photoreduction is biomolecular (1). Since the latter rates are faster (1) than the former, for certain nitrosamines it is possible to adjust conditions so that one type of reaction takes place exclusively.

However, the formation of piperidinium chloride in the photolysis of **1***a* in an aqueous solution cannot be viewed as a photoreduction process, similar to that proposed in a methanol solution, since water is a poor hydrogen atom donating solvent. The photoelimination products, amidoxime **3***a* and "isotripiperidein", have been shown to be stable under the irradiation conditions with 254 nm light source.[3] Since the decay of the aminium radical is strictly first order and much slower than in methanol (1), an alternative mechanism for the formation of piperidinium chloride is required. It is envisaged that a photoinitiated hydrolysis of nitrosamine is responsible for this process; the details remain to be clarified.

An inspection of results shows that there are some superficial differences between $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ band photolysis. For example, in methanol it appears that formamide **4** is formed only in the irradiation with the 240 nm light source but not with the >340 nm source. In aqueous solution amidoxime **3***a* is not formed when $\pi \rightarrow \pi^*$ band of **1***a* is irradiated. Since these results are reproducible, it must be an intrinsic characteristic of the photoreaction. The causes effecting these discrepancies may be more than the wavelength effect of the light source. This difference may be ascribed to a secondary photoreaction in the irradiation with the 254 nm light source. Alternatively it may be due to a trivial difference in the vibrationally excited level of the intermediate in the respective cases.

Photoaddition of *N*-nitrosopiperidine to cyclohexene initiated by the 254 nm light source is as effective as that initiated by the >340 nm light source. However, in the former case a tarry by-product and cyclohexanone **7** are formed to a considerable extent apparently due to secondary photoreactions. Such secondary photoreactions are frequently observed phenomena; for example, photolysis of *N*-nitrosamides by $\pi-\pi^*$ band excitation generally causes a disproportionation of the *C*-nitroso compound intermediate (17, 18). It may be suggested that ketone **7** is formed via nitrate **10** from the nitroso intermediate **9** by analogy to the mechanism proposed in the photolysis of *N*-nitrosamides

[3]The protonated forms of **3***a* and isotripiperidein are not likely to serve as a source of hydrogen donor due to the polar effects of the aminium radical. We have not isolated other products that can be accounted for such secondary reaction.

(see Scheme 3) (17, 18). More complex reaction mixtures have been obtained in the photoaddition of **1***a* to cyclooctene and 3,3-dimethyl-1-butene with the 254 nm light source (12). Particularly in the latter case, the yield of the oxime corresponding to **8** is very low indicating the occurrence of extensive secondary photoreactions; the reasons for these secondary reactions have been discussed (8).

The success of photoaddition in methanol solutions under the present conditions is apparently dependent upon the competing rate of addition of aminium radical relative to the rates of reduction and elimination. The rate of addition of piperidinium radical (from **1***a*) to cyclohexene is about 5000 times faster than the reduction as has been shown by flash photolysis (1). It is readily understandable that the photoaddition predominates when cyclohexene is added to the irradiation mixture. Photoaddition of **1***a* to 3,3-dimethyl-1-butene is retarded by steric hindrance as has been previously discussed (8). In the latter photolysis, it is not surprising that the photoreduction product (**4***a*) has been isolated (8). On the other hand, *N*-nitroso-1,2,3,4-tetrahydroisoquinoline undergoes photoelimination so rapidly that no photoaddition to styrene can be observed (7). Styrene has been shown to be a far more reactive olefin than cyclohexene towards photoaddition since the rate determining step is an electrophilic attack of an aminium radical (6, 7).

Experimental

Unless specified otherwise, n.m.r. spectra were recorded with a Varian A 56/60 spectrometer in $CDCl_3$ using TMS as the internal standard, i.r. spectra in Nujol mulls or neat liquid with a Perkin–Elmer model 457 grating spectrophotometer, u.v. spectra with a Unicam SP 800 spectrophotometer, and mass spectra with an Hitachi RMU-6E instrument at 80 eV. Melting points were determined with a Fisher–Johns hot-stage and were uncorrected. Microanalyses were performed by Dr. A. Bernhardt, Elbach, West Germany.

General Procedure of Photolysis

Previously described photolysis procedures (2) were followed with two different light sources. For irradiation at $n \rightarrow \pi^*$ transition band (>350 nm) a Hanovia medium pressure mercury lamp was used in conjunction with a filter solution of 2,7-dimethyl-3,6-diazacyclohapta-1,6-diene perchlorate (0.1 g/1 l of water). The cold filter solution was circulated through the cold finger. This system permitted the irradiation at >350 nm.

For irradiation at $\pi \rightarrow \pi^*$ transition band of *N*-nitrosamines, a Nester Faust Model NFUV-300 low-pressure mercury resonance lamp (90% of the light output at 2537 Å) was employed; a saturated nickelous sulfate solution was used as a filter. The lamp was placed in a quartz cold finger through which the filter solution was circulated. This setup allowed us to excite the $\pi \rightarrow \pi^*$ transition band of nitrosamine (λ_{max} 230–240 nm) leaving the >340 nm region opaque.

The photolysis products were isolated in the usual way (2) and separated by column chromatography. The percentage yields of the products are summarized in Table 1. Authentic *N*-piperidino-formamide (**4***a*) was prepared by reacting *N*-aminopiperidine with formic acid and was recrystallized from petroleum ether to give white crystals: m.p. 76–78° (lit. m.p. 77–78°) (11); i.r. 3180, 3100, 1730, 1645, 657 cm^{-1}; n.m.r. τ 1.67 (d, $J = 10$ Hz, collapsed to singlet on D_2O exchange), 2.15 (NH), 7.27, and 8.4; *m/e* (%) 128 (M^+, 3), 99 (46), 83 (81), 55 (100) and 41 (35).

Anal. Calcd. for $C_6H_{12}N_2O$: C, 56.23; H, 9.44; N, 21.86. Found: C, 56.40; H, 9.43; N, 22.02.

Photolysis of N-Nitroso-2-methylpiperidine

A solution of *N*-nitroso-2-methylpiperidine (7.9 g) and concentrated hydrochloric acid (8.0 ml) in methanol (240 ml) was photolyzed with the 254 nm light source for 10 h. The photolysate was worked-up in the usual manner. The 2,4-DNPH of formaldehyde was isolated from the distillate. The parent amine was isolated as the hydrochloride from the residue of the photolysate. Chromatography of the basic extract gave *N*-(2-methyl-piperidino)formamide (**6**, 15%) as colorless crystals: m.p. 72–73°; i.r. 3200, 3080, 2725, 2670, 1694, 1660, 740, and 650 cm^{-1}; n.m.r. τ 8.92 (d, $J = 6$ Hz, 3H), 8.38 (6H), 6.91 (m, 1H), 2.31 (d, $J =$ 11 Hz, NH), 1.77 (d, $J = 11$ Hz, collapses to singlet on D_2O exchange); *m/e* (%) 143 (6), 142 (M^+, 4), 127 (27), 113 (45), 97 (100), 69 (52), 55 (70).

Anal. Calcd. for $C_7H_{14}N_2O$: C, 59.20; H, 9.85; N, 19.72. Found: C, 59.03; H, 9.71; N, 19.65.

Photolysis of N-Nitrosodibenzylamine (1c)

A solution of the nitrosamine (5.45 g) and concentrated hydrochloric acid (2.5 ml) in methanol (240 ml) was photolyzed with the 254 nm light source. The absorption at 340 nm decreased rapidly during the first hour but slowed to a static state after 2 h. The residue yielded benzylamine hydrochloride (1.69 g), after removal of a major portion of the methanol: m.p. 249–254°; n.m.r. (D_2O) τ 2.72 (5H), 6.03 (s, 2H). The mother liquor was analyzed in the usual manner. Upon chromatography the neutral extract gave benzaldehyde (910 mg), the nitrosamine (304 mg), and benzaldehyde oxime (211 mg). The basic extract was chromatographed to afford *N*-benzylbenzaldoxime (**3***c*, 1.02 g, 108–111°) (4) and benzylamine (80 mg).

Photolysis of N-Nitrosodipentylamine (1b)

A solution of the nitrosamine (4.36 g) and concentrated hydrochloric acid (5 ml) in methanol (240 ml) was photolyzed with the 254 nm light source for 3.5 h. After the usual working-up valeraldehyde (35%, as 2,4-DNPH, m.p. 103–105°), di-*n*-pentylamine (12%), and *n*-pentylamine were isolated. In addition, *N*-di-*n*-pentylaminoformamide (**4***b*) was isolated from the basic fraction as a colorless oil (3%); i.r. 3290, 3150, 1680, 1080, 1050, and 1005 cm^{-1}; n.m.r. τ 9.17 (t, 6H), 7.4 (5, 4H), and 1.85 (singlet after D_2O exchange); *m/e* (%) 200 (M^+ 7), 171 (10), 157 (1), 143 (94), 115 (56), 113 (28), 98 (99), 87 (41), 73 (100), and 43 (100).

Mol. Wt. Calcd. for $C_{11}H_{24}N_2O$: 200.1524. Found: 200.1526.

Similarly, *N*-pentylpentamidoxime (**3***b*) was also isolated as a colorless oil (1.5%): i.r. 3410, 3220, 1640, 942, 900, and 690 cm^{-1}; n.m.r. τ 9.08 (t, 6H), 7.82 (m, 2H), 6.9 (t, 2H); *m/e* (%) 186 (M^+ 22), 171 (8), 157 (15), 129 (22), 112 (42), 87 (97), and 30 (100).

Mol. Wt. Calcd. for $C_{10}H_{22}N_2O$: 186.1732. Found: 186.1728.

The basic aqueous solution was evaporated to dryness and the solid residue was extracted with methylene chloride to give a solid (395 mg). This solid was recrystallized from chloroform to afford colorless crystals of 4-(*N*-nitrosohydroxylamino)dipentylamine (**5**): m.p. 188–190°; i.r. 2680, 2480, 1600, 1395, 1230, 1200, 1145, 930, and 900 cm^{-1}; n.m.r. (D_2O) τ 5.7 (m, 1H), 7.01 (t, $J = 4$ Hz, 4H), 8.59 (d, $J =$ 6.5 Hz), and 9.05 (t, 3H); *m/e* (%) 217 (M^+ 3), 187 (7), 160 (22), 130 (100), 113 (15), 100 (100), and 98 (39).

Mol. Wt. Calcd. for $C_{10}H_{23}N_3O_2$: 217.1790. Found: 217.1785.

In a separate experiment, the nitrosamine (3.88 g) and concentrated hydrochloric acid (4 ml) in methanol (230 ml) were photolyzed with the >340 nm light source for 2 h. After the usual working-up valeraldehyde (as 2,4-DNPH, 1.6 g), *N*-pentylvaleroamidoxime (**3***b*, 375 mg, 10%), and di-*n*-pentylamine hydrochloride (22%) were isolated. In spite of a careful investigation, formamide **4***b* and *N*-hydroxylamine **5** were not obtained.

Photoaddition of N-Nitrosopiperidine to Cyclohexene

A solution of *N*-nitrosopiperidine (3.17 g), cyclohexene (2.72 g), and concentrated hydrochloric acid (3.5 ml) in methanol (240 ml) was photolyzed with the 254 nm light source for 1.5 h. The photolysate was analyzed in the usual manner (5, 6) to afford recovered nitrosamine (350 mg) in the neutral extract. A dark tarry material was in the basic extract and showed a medium absorption at 1710 cm^{-1}. The first crop of 2-piperidinocyclohexanone oxime (780 mg) was obtained by recrystallization of the crude resin. The mother liquor was chromatographed to afford 2-piperidinocyclohexanone (**7**, *ca.* 450 mg) and its corresponding oxime (**8**, 1.26 g). The fractions containing the ketone were collectively treated with hydroxylamine to give the oxime.

A solution of *N*-nitrosopiperidine (11 g), cyclohexene (9 g), and concentrated hydrochloric acid (15 ml) and methanol (450 ml) was photolyzed with the >350 nm light source. The usual analysis gave a basic extract which was crystallized to give oxime **8** (9.6 g); m.p. 102–105°. The residue (8 g) from the mother liquor was chromatographed on an alumina column to give oxime **8** (5.4 g) and a small amount of ketone **7**.

Photoreactions of Nitroso Compounds in Solution.[1] XXI. Stereochemical Course of Photoaddition of Nitrosamines to some Cyclic Olefins and Conformational Isomers Generated by $A^{1,3}$-Interaction

Y. L. CHOW, S. C. CHEN, K. S. PILLAY, AND R. A. PERRY
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received June 9, 1971

The results of the photoadditions of *N*-nitrosopiperidine and *N*-nitrosodimethylamine to three substituted cyclohexenes are discussed in terms of an "electrophilic" free radical attack of the aminium radicals generated from the photolysis of the nitrosamines. The photoaddition to 4-*t*-butylcyclohexene gave all four possible oximes; the axial approach of the aminium radical was preferred over the equatorial approach. The photoadditions to 3-methylcyclohexene are highly stereoselective giving oxime pairs **1**–**2** and **4**–**5**. Both oximes in each pair have 2-amino and 6-methyl substituents in *trans*-relation; but locked in the alternative conformations through $A^{1,3}$ interaction of the oximino group. In this addition the aminium radical almost exclusively approaches the C-1 carbon of the most stable conformer from the axial side. The steric hindrance to all possible axial and equatorial approaches to conformers of olefins have been compared. Piperidinium radicals, however, abstract an allylic hydrogen from $\Delta^{9,10}$-octaline since the steric hindrance in the addition process is too great to overcome. The hydrogen abstraction process leads to an intermolecular hydrogen–nitroso group exchange reaction which is similar to that in the photolysis of nitrosamides. A pathway is suggested to account for the generation, *in situ*, of the heteroannular diene **28** from which oxime **17** could be derived by photoaddition in 1,4-mode.

On discute les résultats de photoadditions de *N*-nitrosopipéridine et de *N*-nitrosodiméthylamine à trois cyclohexènes substitués en termes d'une attaque par radical "électrophile" des radicaux aminium provenant de la photolyse des nitrosamines. La photoaddition au 4-*t*-butylcyclohexène a donné les quatre oximes possibles; l'approche axiale du radical aminium avait priorité sur l'approche équatoriale. Les photoadditions au 3-méthylcyclohexène sont très stéréosélectives, donnant les paires d'oxime **1**–**2** et **4**–**5**. Les deux oximes dans chaque paire ont les substituants 2-amino et 6-méthyle en relation *trans*; par contre ils sont figés dans des conformations alternatives par interaction $A^{1,3}$ du groupe oximino. Dans cette addition, le radical aminium approche presque exclusivement le carbone C-1 du conformère le plus stable par son côté axial. On a comparé l'empêchement stérique à toutes les approches axiales et équatoriales possibles sur des conformères d'oléfines. Toutefois, les radicaux pipéridinium enlèvent un hydrogène allylique au $\Delta^{9,10}$-octaline puisque l'empêchement stérique dans le procédé d'addition est trop important pour l'empêcher. Ce procédé d'abstraction d'un hydrogène nous amène à une réaction intermoléculaire d'échange de groupe hydrogène–nitroso, qui est semblable à celle qu'on rencontre dans la photolyse des nitrosamides. On suggère un mécanisme qui tient compte de la formation, *in situ*, du diène **28** hétéroannulaire à partir duquel l'oxime **17** pourrait être dérivé par photoaddition par un mode 1,4.

Canadian Journal of Chemistry, **50**, 1051 (1972)

Introduction

Photoaddition of a nitrosamine to a carbon–carbon double bond is an extraordinary reaction in that both acid-catalysis and photoenergy are required (2–4). The photoaddition occurs with a short chain process as suggested by the quantum yield of $2 \sim 3$. On the other hand, it is neither retarded by the presence of air (2) in the solution, nor in the presence of a quencher such as a diene (5). Recent work from this laboratory by the technique of flash excitation has established that the primary photoprocess is the decay of a singlet excited nitrosamine to aminium radical which initiates the addition to a double bond (6). Due to the cationic charge, an aminium radical is expected to be a very strong electrophilic species. The reactivity of the latter is, however, expected to be strongly under the influence of steric factors since even the smallest aminium radical, dimethylamino radical, is equivalent in size to isopropyl radical. In order to evaluate the steric factors controlling the stereochemical course of the photoadditions to olefins, photoaddition to 3-methyl- and 4-*t*-butylcyclohexenes and $\Delta^{9,10}$-octaline were studied.

Results

The conditions of the photoaddition have been described and discussed in our previous publications (2–4) and, in the present case, are also outlined in the Experimental. When a

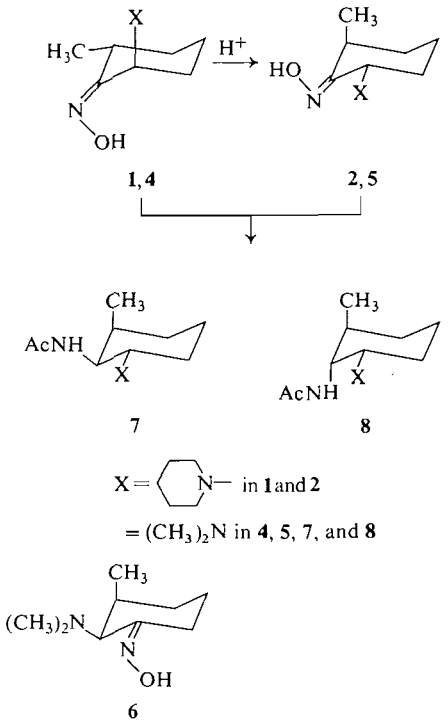

SCHEME 1

methanol solution containing equimolar quantities of *N*-nitrosopiperidine and 3-methylcyclohexene was irradiated in the presence of hydrochloric acid, two photoadducts, *syn,trans*-2-piperidino-6-methylcyclohexanone oxime[2] (**1**) and *anti,trans*-2-piperidino-6-methylcyclohexanone oxime (**2**), were obtained in 13 and 16% yield, respectively. In addition a small amount of *N*-piperidinoformamide (**3**) (1) was also isolated; but the amount of the neutral product was very small. In the presence of an excess of *N*-nitrosopiperidine and irradiation with a uranium glass filter, the yields of oximes **1** and **2** rose to 21 and 50%, respectively. Again no appreciable amount of the neutral product was obtained.

Both oxime **1** and **2** had the correct elemental analysis for the molecular formula of a 1:1 adduct, and exhibited characteristic i.r. absorption for the oxime group (7). The *anti*-oxime **2** dissolved readily in an aqueous solution of cupric sulfate (10%) to give a deep green solution indicating that chelation of the cupric ion had occurred[3] (8, 9). The blue color of cupric sulfate was, however, not affected when a methanol solution of the *syn*-oxime **1** was added. The presence of the *anti*-configuration in **2** and the *syn*-configuration in **1** were thus indicated.

The n.m.r. spectra provide information with regard to the configuration and conformation of the adducts and the relevant results are summarised in Table 1. The assignments of the lower field signals to C-2 and -6 protons are facilitated by the fact that the C-6 proton is coupled to the C—CH_3 group. The triplet ($J = 3.5$ Hz) at τ 6.18 in the spectrum of **1** is readily assigned to the C-2 equatorial proton while the C-6 proton is located at about τ 7.6 and partially hidden by the α-methylene signal of the piperidine ring. The chemical shift of the C-6 axial proton is comparable to that of the *anti*-α-axial proton of 4-*t*-butylcyclohexanone oxime (τ 7.95) (10) supporting the assignment of the axial orientation. The double doublet at τ 6.83 in the spectrum of **2** is assigned to the C-2 axial proton on the basis of the coupling constant. The broad multiplet at τ 6.35 ($w_{1/2} = 25$ Hz) is assigned to the equatorial proton at C-6 on the basis of the chemical shift value.[4] The orientations of the methyl group, equatorial in **1** and axial in **2**, are further supported by the observation that the coupling constant of the methyl group with the C-6 methine proton is larger for **2** (7 Hz) than for **1** (6.5 Hz); the coupling constant of an axial methyl proton with the vicinal methine proton in cyclohexane derivatives has been shown to be generally larger than that of the alternative conformation (11). Thus oximes **1** and **2** both possess piperidine and methyl groups oriented in a 1,3-*trans* relation and as the consequence of the $A^{1,3}$ interaction due to the oximino group (12, 13), the conformation of the ring is locked in the alternative orientations as shown. In agreement with this, oxime **1** was readily isomer-

[2]The *syn–anti* notation refers to the configuration of the oximino group and *cis–trans* notation is reserved for the configuration of the ring system. For the definition of *syn–anti* configuration, see ref. 2.

[3]So far, cupric sulfate tests of other *syn–anti* isomers have been successful, except in one bicyclic case. The *syn*-isomer of 2-*exo*-dimethylaminobicyclo[2,2,1]heptan-2-one oxime gave green coloration (unpublished results from this laboratory).

[4]The unpublished results from our laboratory show that the chemical shifts of the *syn*,equatorial proton at C-2 in various cyclohexanone oximes are as follows: 4-*t*-butylcyclohexanone oxime, τ 6.64; *cis*-3,5-dimethylcyclohexanone oxime, τ 6.68; 3-*t*-butylcyclohexanone oxime, τ 6.68.

*The spectra of oximes **4** and **5** were recorded with a Varian HA-100.

ized to **2** in the presence of hydrochloric acid; while the reverse isomerization did not take place. This is to be expected as piperidine ring is "bulkier" than methyl group.

The photoaddition of *N*-nitrosodimethylamine to 3-methylcyclohexene was run with a Rayonet photochemical reactor. The major photoadducts were *syn,trans*-2-dimethylamino-6-methylcyclohexanone oxime (**4**) and *anti,trans*-2-dimethylamino-6-methylcyclohexanone oxime (**5**) in 15 and 20% yield, respectively. A small amount (2%) of what appeared to be *anti,trans*-2-dimethylamino-3-methylcyclohexanone oxime (**6**) was also isolated. The proof of the structures and conformations of oximes **4** and **5** follows the same arguments as those used in the cases of **1** and **2**. In the present case the assignments of the protons and the configurations of the oximes were placed on a firmer basis by decoupling experiments; the relevant results and some examples of the decoupling are given in Table 1 and Figs. 1 and 2.

In both cases, the decoupling experiments (Figs. 1 and 2) related not only the signals of the C-6 proton and the *C*-methyl protons; but also located the signal due to the C-3 proton. The chemical shifts and the coupling patterns of the C-2 proton in **4** and **5** confirmed beyond any doubt their orientation as equatorial and axial, respectively. The narrow triplet, due to the C-6 proton in **5**, when decoupled from the *C*-methyl group, clearly indicates that the proton was equatorially oriented (Fig. 2*b*). The same decoupling operation in **4**, however, did not afford a clear coupling pattern. Judging from the width at half-height of the decoupled signal, an axial orientation of the C-6 proton was indicated.

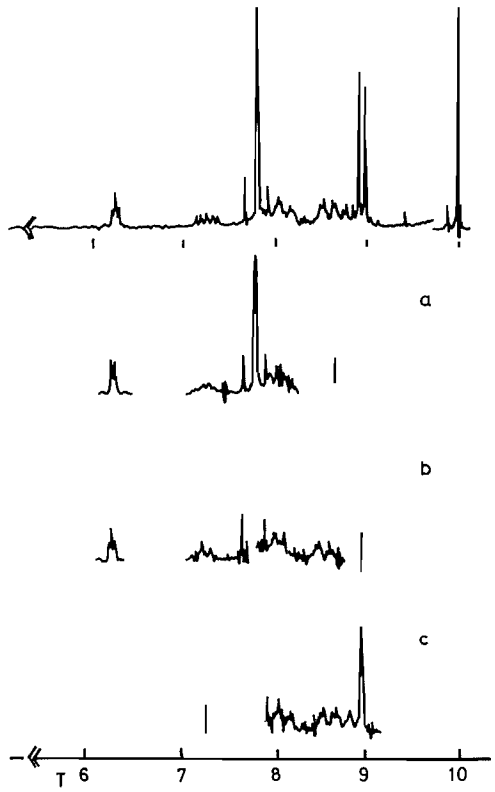

FIG. 1. The n.m.r. spectrum (100 MHz) of *syn,trans*-2-dimethylamine-6-methylcyclohexanone oxime (**4**) in pyridine: (*a*) irradiation at τ 8.78, (*b*) irradiation at τ 8.95, and (*c*) irradiation at τ 7.25.

The n.m.r. data shown in Table 1 and the decoupling results described above firmly placed

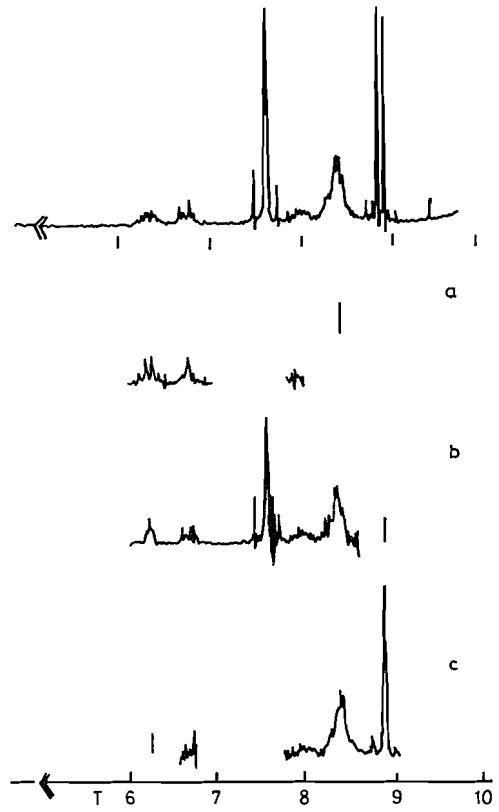

FIG. 2. The n.m.r. spectrum (100 MHz) of *anti,trans*-2-dimethylamino-6-methylcyclohexanone oxime (**5**) in pyridine: (*a*) irradiation at τ 8.35, (*b*) irradiation at τ 8.86, and (*c*) irradiation at τ 6.34.

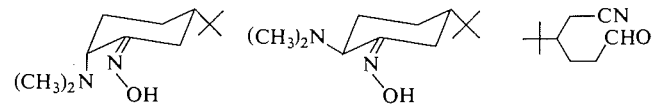
the configuration and conformation of oximes **4** and **5** as shown. This is similar to the relation of oximes **1** and **2**; where they are forced to assume the alternative conformation though possessing the common *trans*-configuration at 2-amino-6-methyl groups. Further corroboration that oxime **5** possessed the *anti,trans*-configuration was given by the appearance of a deep green color on treatment with a copper sulfate solution.

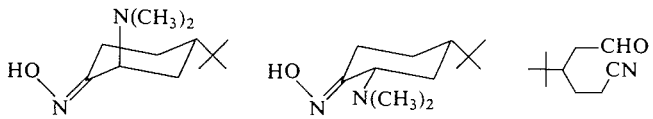
The third isomer in the photoaddition of *N*-nitrosodimethylamine to 3-methylcyclohexene was obtained in a small quantity and was suggested to have the structure **6** on the basis of the following evidence. The *anti*-configuration of the oximino group was indicated according to the positive copper sulfate test (8, 9) exhibited by the compound.[3] The superimposed n.m.r. signal at τ 7.25 ~ 7.15 was integrated to be equivalent to two protons. One of these was clearly due to the C-6 equatorial proton as shown by a doublet ($J = 14$ Hz), each portion of which was further broadened. The remaining signals could be interpreted as a doublet with coupling constant of 2–3 Hz. The orientation of the equatorial 2-amino group and the axial 3-methyl group were suggested on the basis of the conformational energy of the substituents, which should have the *cis*-relation as indicated by the coupling constant of the methine protons. The structure **6** was also favored on consideration of the steric course of the approach of the reactant (*vide infra*).

In order to relate the configuration of oximes **1** and **2**, both compounds were reduced separately with lithium aluminum hydride followed by acetylation. From both operations the crude acetamide was shown to contain the same major and minor products; although the ratio from each preparation was slightly different. Both major and minor product acetamides showed i.r. absorption characteristic of the acetamido group, and an appropriate mass spectral pattern. The major product acetamide was shown to be 1-acetamido-2-*trans*-piperidino-6-*cis*-methylcyclohexane (**7**) and the minor one 1-acetamido-2-*cis*-piperidino-6-*trans*-methylcyclohexane (**8**).

The major product acetamide **7** exhibited n.m.r. signals at τ 3.35 and 6.30, the latter of which was sharpened to a double doublet ($J = 11$ and 4 Hz) when the former was removed by D_2O exchange. These results indicated that the τ 6.30 signal was due to the C-1 proton, oriented axially. The n.m.r. spectrum of the deuteriochloride of **7** exhibited the axial C-1 methine proton at τ 5.85 as a double doublet and the axial C-2 methine proton at τ 6.55 as a triplet each of which was further split to a doublet ($J = 11$ and 4.5 Hz). The orientations of the substitutions around the cyclohexane ring were such that both the 1-acetamido and 2-amino groups were equatorial and the 6-methyl was axial. The shifts of both the C-1 and -2 protons downfield as the consequences of the protonation of **7** were unusual. The minor acetamide **8** was obtained in impure state and showed a triplet n.m.r. signal at τ 5.98 ($J = 5.5$ Hz), indicating that the C-1 methine proton was equatorial. Although the signal due to the C-2 methine proton could not be observed clearly,



9 11 13



10 12 14

the configuration of **8** was provisionally assigned on the basis of the mechanism of the reduction.

The photoaddition of *N*-nitrosodimethylamine to 4-*t*-butylcyclohexene under the usual conditions afforded four isomeric oximes, *anti*, *cis*-2-dimethylamino-5-*t*-butylcyclohexanone oxime (**9**), *anti,trans*-2-dimethylamino-4-*t*-butylcyclohexanone oxime (**10**), *anti,trans*-2-dimethylamino-5-*t*-butylcyclohexanone oxime (**11**), and *anti-cis*-2-dimethylamino-4-*t*-butylcyclohexanone oxime (**12**), in that order of decreasing yield. The last two compounds were obtained in semi-pure state; each of which was contaminated by a small amount of the other. All four oximes **9**–**12** were shown to possess the *anti*-configuration as evidenced by positive cupric sulfate tests (8, 9). This was in agreement with the exclusive formation of the *anti*-oxime in the photoaddition to cyclohexene (2).

Oximes **9** and **11** were both transformed to 5-cyano-4-*t*-butyl-pentanal (**13**) through the Beckmann cleavage reaction (14–16). Pentanal **13** was characterized as 2,4-dinitrophenylhydrazone (2,4-DNPH, m.p. 127–128°). In the same manner, oxime **10** was cleaved to afford a different compound, 5-cyano-3-*t*-butylpentanal (2,4-DNPH, m.p. 125–126°). Due to the limited quantity available, oxime **12** was not cleaved in the same manner. While the i.r. and n.m.r. spectra of the two pentanals were distinctly different, it was not possible to establish the position of the *t*-butyl group unambiguously. This information enabled us to conclude that oximes **9** and **11** were the epimeric pair at the C-2 position having the same arrangement of the substituents around the cyclohexane ring. It is also clear that oxime **10** had a different arrangement of the substituents than oximes **9** and **11**. Oxime **10** was perhaps epimeric to oxime **12**.

The i.r. spectra of oxime **9** and **11** exhibit the C=N stretching band at 1650 and 1647 cm^{-1}, respectively, whereas the corresponding bands of **10** and **12** appear at 1670 and 1675 cm^{-1}, respectively, indicating their structural similarity (7). The mass spectra of oximes **9**–**10** determined under identical conditions are shown in Fig. 3 and unequivocally demonstrate that oximes **9** and **11** are one epimeric pair, while oximes **10** and **12** are the other. The significant feature of the mass spectra of oximes **9** and **11** is the most intense mass peak at *m/e* 84 which has been shown to correspond to the $C_5H_{10}N^+$ ion (**9***c*, 84.0812); but not to the $C_6H_{12}^+$ ion (84.0936) by exact mass determination (Found: 84.0811). A fragmentation scheme of oxime **9** or **11** to give **9***c* via **9***b* is proposed (see Scheme 2). This demands that the dimethylamino group must be related to the *t*-butyl group in a 1,4-orientation on the cyclohexane ring. The most intense mass peak at *m/e* 137 in the mass spectra of oxime **10** and **12** has been shown to correspond to the $C_9H_{15}N^+$ ion (**10***d*, 137.1204) by an exact mass determination (Found: 137.1178). This ion of *m/e* 137 is probably related to the ion of *m/e* 97 as proposed in Scheme 3. This scheme suggests that the *t*-butyl and the oximino groups are related in 1,4-fashion.

It is our aim now to ascertain the relative position of the *t*-butyl group in the respective pair of oximes. For this purpose, n.m.r. spectroscopy is shown to be the less ambiguous method.

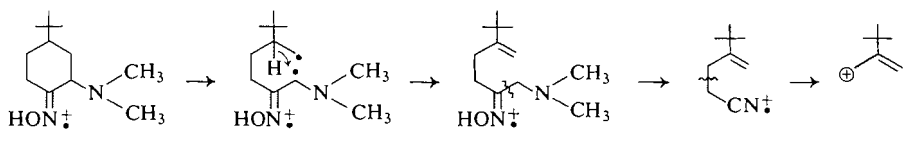

SCHEME 3

The n.m.r. results for these four oximes are summarized in Table 2 in which both the chemical shifts and coupling constants of oxime **9** have been confirmed by decoupling experiments. In all four n.m.r. spectra, the signals due to C-6 equatorial[4] and C–2 protons were readily identified in the range τ 6.25–6.45 and τ 7.25–6.79, respectively (Table 2). The C-2 proton in oxime **9** was equatorially oriented and that in oxime **11** axially, as shown by the coupling

*The decoupling experiments also show that the chemical shifts of C-3 equatorial and C-6 axial are at τ 7.73 and 8.18, respectively.

†The decoupling experiments also show that the chemical shift of the C-6 axial proton is at τ 8.38.

‡The doublet is further broadened by small couplings.

patterns of the proton. The former is shown as a narrow triplet and the latter as a double doublet with a large and a small coupling constant. On the same grounds the C-2 proton of oxime **10** was assigned to the equatorial orientation and that of oxime **12** to the axial orientation. It was noted that in both pairs the chemical shifts of the axial protons (**11** and **12**) appeared at lower field than those of the equatorial protons (**9** and **10**). A similar reversal of the relative chemical shift positions for axial and equatorial protons was also found in α-bromocyclohexanones (17) and could be related to the conformation of the ring with respect to the anisotropic effects of the π-bond system.

The C-6 equatorial proton in all four oximes resonated in the expected range, in agreement with *syn*-α-equatorial protons of substituted cyclohexanone oximes with "frozen" conformations.[4] In all four oximes this proton signal was split to a doublet by the C-6 axial proton by a large geminal coupling constant. In oximes **9** and **11**, each signal was further broadened to the unresolved doublet by a small coupling (2–3 Hz) with C-5 (the carbon carrying the *t*-butyl group) axial proton. In the corresponding pair of oximes **10** and **12**, each signal of the doublet was weakly coupled (*ca.* 3 Hz) with the two C-5 protons as shown by the broad signal in **10** and the unresolved triplet in **12**. Furthermore, by the decoupling experiments, the C-6 axial proton in oximes **9** and **11** was shown to be a triplet and a double doublet, respectively, exhibiting large coupling constants (12 and 11 Hz, respectively) with the C-5 axial proton. This evidence allows us to place the *t*-butyl group at C-5 position for oximes **9** and **11** and at C-4 position for oximes **10** and **12**.

Photoaddition of *N*-nitrosopiperidine to Δ^9-octaline (**15**) was investigated under the standard photolysis conditions from which Δ^9-decalone-1 oxime (**16**, 30%) and 5-piperidino-Δ^9-decalone-1 oxime (**17**, 9%) were isolated. The isolation of these anomalous products was accompanied by a small yield of *N*-piperidinoformamide (3). For oxime **16**, the C=N stretching absorption at 1640 cm^{-1} and the u.v. absorption maximum at 237 nm indicated the presence of the con-

jugated enone oxime chromophor. Since the n.m.r. spectrum of oxime **16** did not show signal below τ 6, except the broad OH signal at τ 0.5, the tetra-substituted double bond was established. The identity of oxime **16** was established by the trans-oximation reaction with levulinic acid to give Δ^9-decalone, which was characterized by formation of its 2,4-DNPH. The melting points of oxime **16** and its derivatives are identical with those reported by Hückel and Blohm (18) and those by Campbell and Harris (19).[5] The configuration of oxime **16** must have the OH portion of the oximino group oriented *anti* to the olefinic bond since the alternative configuration would cause severe $A^{1,3}$ interaction (12, 13). The partially resolved triplet at τ 7.38 ($J = 6.5$ Hz) was assigned to two C-2 protons and the multiplet at τ 7.84 to the six allylic protons. The former assignment was justified in view of the similarity of the chemical shift to that of the α-*cis* protons of cyclohexanone oxime (τ 7.54). The magnetic equivalence of these C-2 protons also indicated that oxime **16** was flexible and rapidly interchanging among various conformations.

The basic oxime **17** contained a piperidine ring and the basic skeleton of oxime **16** as shown by i.r. (1633 cm^{-1}) and u.v. (237 nm) absorptions and the elemental analysis. The n.m.r. spectrum was not readily analyzable due to extensive overlapping of the signals (with the exception of the multiplet signal at τ 6.85 due to the tertiary allylic proton adjacent to the piperidino ring). Oxime **17** was transformed under the conditions of Semmler and Hofmann (20) to 1,2,3,4-tetrahydro-1-piperidino-5-aminonaphthalene (**19**), which exhibited appropriate mass peaks at *m/e* 230, 216, and 145 corresponding to the ions of M^+, $(M\text{-}NH_2)^+$ and $(M\text{-}C_5H_{10}N)^+$. The conclusion that the two amino groups were oriented in the 1,5-relation was supported by the comparable u.v. absorption curves of **19** and its dihydrochloride with those of 1-amino-5-di-(2′-chloroethylamino)-1,2-3,4-tetrahydronaphthalene and its dihydrochloride (21).[6] Structures **20** and **21**, the alternative possibilities to oxime **17** and aniline **19**, were not rigorously excluded. In view of the failure of the oxime and the aniline derivative to form Cu^{2+} or Ni^{2+} complexes (22), structures **20** and **21** could not be considered probable structures. From the mechanistic considerations (*vide infra*), no logical pathway could be formulated to arrive at structure **20**.

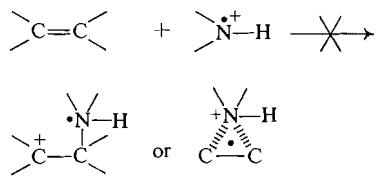
[5]The structure **16** was first suggested by Hückel and Blohm; but Campbell and Harris later erroneously reassigned the same compound to $\Delta^{8,9}$-decalone-1 oxime.

[6]The authors are grateful to the Director, Institute of Chemical-Pharmaceutical Research, Bucharest, Romania for the authentic samples.

Discussion

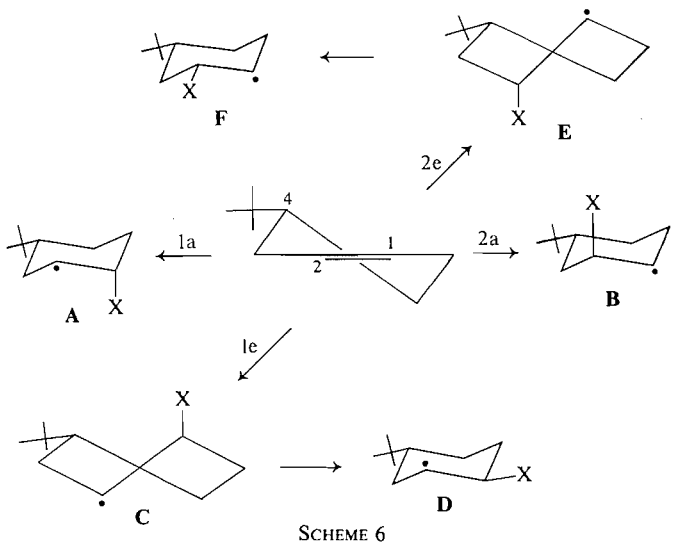
We have demonstrated that the primary photoprocess of a nitrosamine, in the presence of an acid, is the generation of the corresponding aminium radical from the singlet excited state of a nitrosamine–acid association complex (16). Further we have shown that piperidinium radical reacts with cyclohexene with a bimolecular rate constant of 2.4×10^7 M^{-1} s^{-1} (6). Although the aminium radical may be considered as an electrophilic species, it attacks a carbon–carbon double-bond by a purely free radical mechanism (see Scheme 5). However, it does not behave as an electrophilic reagent since a purely electrophilic attack would result in an electronic configuration of the nitrogen outer shell in excess of the limit imposed by the octet rule (see **22**). Further, a bridged aminium radical, such as **23**, cannot be rationally proposed as an intermediate on the same basis. The following discussion is based on free-radical addition of the aminium radical.

The investigation of the photoaddition to 4-*t*-butylcyclohexene, a conformationally "frozen" cyclohexene, affords an insight into the steric course of the initial attack of an aminium radical on the olefinic bond (Scheme 6). Although a more complex mixture of adducts has been obtained from the addition to this cyclohexene, the process is mechanistically less complicated since the olefinic bond is relatively free from a direct steric influence of the remote 4-*t*-butyl group. The isolation of all four possible oximes **9**–**12** indicates that the attack of the



22 **23**

SCHEME 5



SCHEME 6

dimethylaminium radical is not stereospecific; but is stereoselective. Thus the aminium radical initiates the addition by preferentially attacking the C-1 position over the C-2 position. Between two available approaches to the respective carbon atom of the double-bond, it prefers to take the axial approach at both C-1 and -2 positions to give the intermediates **A** and **B**, respectively. The axial approach of the aminium radical at C-1 position (**A**) involves a nonbonded interaction from the C-5 axial hydrogen while that at C-2 (**B**) involves a similar interaction from the C-4 axial hydrogen. The latter is clearly more severe than the fomer due to compression from the 4-*t*-butyl group in **B**. The equatorial approaches[7] of the aminium radical at the C-1 and -2 positions led to the energetically unfavorable boat conformations **C** and **E**, respectively, that invert to chair conformations **D** and **F**. During the inversion of the boat conformation in **C** and **E**, the amino group would encounter eclipsing strain from the neighboring axial hydrogens. The total energies required in these two cases are apparently greater than those required in the axial approaches. It is not difficult to understand that the steric strain exerted by the C-3 axial hydrogen in **E** is more severe, owing to compression of the 4-*t*-butyl group. The same order of selectivity has been observed in the addition of methylthiyl radical to 4-*t*-butylcyclohexene (23). A similar steric effect has been shown in the light-induced addition of methane- and ethanethiol to *trans*-Δ^2-octaline to give a mixture in which the axial attack predominates over the equatorial one by a factor of *ca.* 10–1 (24). Since the "bulk" of the dimethylaminium radical is expected to be somewhat greater than that of the thiyl radicals, the lower selectivity observed in the present addition signifies that the aminium radical is more aggressive toward electrophilic attack, causing less stereochemical discrimination.

In the photoaddition to 3-methylcyclohexene (Scheme 7), the conformational equilibrium of the initial-state conformations has to be taken into account and the unknown steric strain imposed by the C-3 methyl group on various approaches of aminium radical has to be considered. It has been shown by a gas phase equilibrium (25), and supported by the recent theoretical calculation (26), that 3-methylcyclohexene exists mainly (85–90%) in the conformation with the methyl group at pseudoequatorial orientation. The conformer with the methyl group in pseudoaxial orientation, however, is also present in significant concentration. An attack of an aminium radical at the C-2 position in both conformations is considered to be severely restricted by compression of the C-3

[7]Strictly speaking, the mode of the attack leading to **C** and **E** is not precisely equatorial in conformational definition. If the attack and the inversion of the ring take place in a rapid succession, the net result and energetics can be approximated as an equatorial approach.

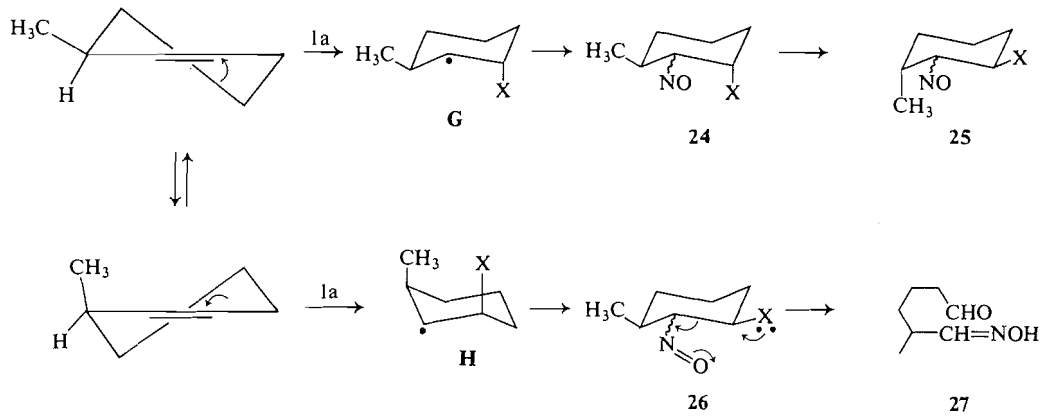
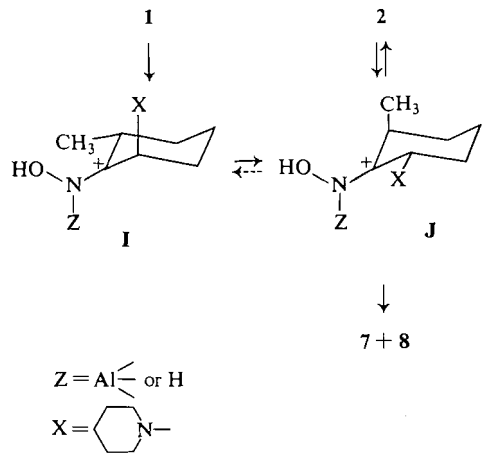


SCHEME 7

methyl group. The less hindered approaches at C-1 position in both conformations are visualized to follow the lowest energy pathways with axial approaches, for reasons similar to those stated in the previous case, leading to two possible intermediates with 1,3-*trans* (**G**) and 1,3-*cis* orientation (**H**). The latter intermediate appears less likely to form due to the 1,3-diaxial interaction between the amino and the methyl groups. The isolation of isomeric oximes (**1**–**2** and **4**–**5**) with two substituent groups (methyl and amino) solely in *trans*-orientation is in full accord with this argument. In both cases, the oxime pair is derived from tautomerization of the single *C*-nitroso compound in different conformations (**24** and **25**). The ratio in each pair is controlled by the rate of inversion, in competition with the rate of tautomerization. A small amount of the minor product **6** obtained in the photoaddition of *N*-nitrosodimethylamine apparently arises from an attack of dimethylaminium radical at the C-2 position. In accordance with the preferred axial approach of dimethylaminium radical, the *trans*-orientation of the substituents is assigned to **6**. Since piperidinium radical is "bulkier" than dimethylaminium radical, it is not surprising that the possible corresponding minor product in the photoaddition of *N*-nitrosopiperidine is not found.

The isomeric pairs of oximes (**1**–**2** and **4**–**5**) are interesting cases in which the 2-dimethylamino and 6-methyl groups, though in *trans*-relation in both cases, are locked in the alternative conformation by severe $A^{1,3}$ interactions generated by the oximino group (12, 13). The



SCHEME 8

ready isomerization of oxime **1** to oxime **2** in an acidic solution is a good proof of the isomeric pair and apparently occurs through an intermediate such as the protonated species **I** (Scheme 8). The latter has been relieved of the $A^{1,3}$ interaction of the oximino group and rapidly inverts to more stable **J**; followed by deprotonation of **J** to give **2**. The result of the lithium aluminum hydride reduction of **1** and **2** can be explained on the same grounds. In both reductions the product-forming step, with hydride attack at the C-1 position, takes place from the common intermediate **J** to afford the observed configurational isomers **7** and **8**.

It is speculated that *C*-nitroso compound **26** (derived from **H**), though not a favored product, may also be formed in small quantity during photoaddition to 3-methylcyclohexene. The

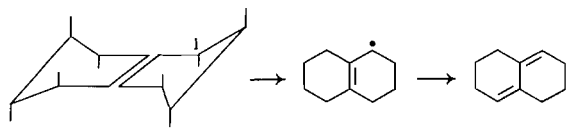
tautomerization of **26** is certainly unlikely, since this process would entail a prior inversion to the 2,6-diaxial conformation of the substituents; the energy barrier of which appears to be too great to overcome (12). Among various other alternative decomposition routes, the cleavage pathway to **27** may be possible in analogy to the similar cleavage reaction observed previously (4). It is suspected that aldehyde **27** may have undergone various aldol condensations leading to a tarry material under the conditions of the experiment.

The photolysis of *N*-nitrosopiperidine in the presence of $\Delta^{9,10}$-octaline does not lead to the formation of a regular addition product. The failure of the addition can be traced to the 1,3-diaxial interactions due to the axial and pseudo-axial hydrogens. These hinder the approaches of piperidinium radical to the carbon–carbon double-bond. Since the addition pathway is sterically blocked, *N*-nitrosopiperidine undergoes an intermolecular hydrogen–nitroso group exchange reaction. The latter reaction is a process similar to Hofmann–Löffler–Freytag reaction (27), and is related to nitrosamide photolysis (28). Formation of oxime **16** must have taken place via hydrogen abstraction by the piperidinium radical to give **K**, which scavenges a nitroso group to afford the precursor to **16**. Such a hydrogen-abstraction process has been shown to take place between the piperidinium radical and methanol (1) although the rate is slower by 5000 times than its addition to cyclohexene according to flash excitation studies (6). This process also has been proposed as the initial step in Hofmann–Löffler–Freytag reaction (27). Indeed *N*-piperidinoformamide and *N*-dimethylaminoformamide, photoreaction products between the nitrosamines and methanol (1), have been isolated in these cases and also during other photoadditions. The present intermolecular hydrogen–nitroso group exchange reaction with an allylic hydrogen is so far the first instance observed in the photoreaction of nitrosamines.

The minor product of oxime **17** in this photoreaction can be derived from the photoaddition to a diene such as **28** in analogy to the established photoaddition pattern to dienes (5, 29). Since the olefin **15** used in this experiment has been shown, by v.p.c., to be completely free of diene **28**, this diene must be generated *in situ* during the photolysis. It is suggested that a hydrogen atom acceptor interacts with intermediate **K** to provide the heteroannular diene **28** (Scheme 9).



SCHEME 9

Experimental

Unless specified otherwise the i.r. spectra were recorded with a Perkin–Elmer 457 spectrometer in Nujol mulls or in liquid film, the mass spectra with an Hitatchi RMU-6E mass spectrometer (80 eV), and the n.m.r. spectra with a Varian A56/60 spectrometer in $CDCl_3$ solution using TMS as the internal standard. The decoupling experiments of n.m.r. spectroscopy were carried out with a Varian HA-100 spectrometer through the kind assistance of Professor K. R. Kopecky, The University of Alberta, Edmonton, Alberta. The melting points were measured with a Fisher–Johns hotstage and were corrected. The microanalyses were performed by Dr. A. Bernhardt, Elbach, West Germany.

Addition of N-Nitrosopiperidine to 3-Methylcyclohexene

(*a*) A methanol solution (320 ml) of *N*-nitrosopiperidine (4.75 g, 41.5 mmol), 3-methylcyclohexene (4.0 g, 41.5 mmol, Aldrich Chemical Co.), and concentrated hydrochloric acid (4.4 ml, 48 mmol) was irradiated with a 200 W Hanovia medium pressure mercury lamp (654A-36) for 2 h. The solvent was distilled off under reduced pressure, and the residue was treated with water (20 ml) and extracted with ether (30 ml × 3). The ether extract was dried ($MgSO_4$) and evaporated, leaving a light brown liquid (242 mg). Chromatography of this liquid on a silicic acid column (12 g) eluting with chloroform gave, after recrystallization from petroleum ether, *N*-piperidinoformamide (**3**), m.p. 70–72°, whose i.r. and n.m.r. were identical with those of an authentic sample (1).

The aqueous solution of the photolysate was then made basic with a saturated Na_2CO_3 solution. The white precipitate formed from the basic solution was filtered, dried in a desiccator to give crude crystals (4.03 g) which contained two compounds as indicated by t.l.c. analysis. One gram of this mixture was chromatographed on basic alumina (35 g). Elution with benzene (500 ml) gave *syn,trans*-2-piperidino-6-methylcyclohexanone oxime (**1**, 258 mg); m.p. 164–166° (dec.); i.r. 3350, 1670, 1135, 935, 740 cm^{-1}.

Anal. Calcd. for $C_{12}H_{22}N_2O$: C, 68.53; H, 10.54; N, 13.32. Found: C, 68.71; H, 10.43; N, 13.37.

Elution with 50% chloroform in benzene (100 ml) gave a mixture of **1** and isomer **2** (254 mg) in a ratio of *ca.* 1:10. Subsequent fractions from the same eluent (400 ml) contained *anti,trans*-2-piperidino-6-methylcyclohexanone oxime (**2**, 124 mg); m.p. 156–158° (dec.); i.r. 3250, 1670, 960, 880, and 800 cm^{-1}.

Anal. Calcd. for $C_{12}H_{22}N_2O$: C, 68.53; H, 10.54; N, 13.32. Found: C, 68.71; H, 10.43; N, 13.37.

The total yields of **1** and **2** were 13 and 16%, respectively. When a mixture of **1** and **2** was irradiated under the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

conditions of the photoaddition, the ratio of **1** to **2** was not changed.

(*b*) A methanol solution (200 ml) of 3-methylcyclohexene (2.0 g, 20.8 mmol), *N*-nitrosopiperidine (4.75 g, 41.5 mmol), and concentrated hydrochloric acid (4.4 ml, 52 mmol) was irradiated with a 200 W Hanovia lamp using a uranium glass filter. After complete disappearance of the nitrosamine absorption ($6\frac{1}{2}$ h), the photolysate was worked-up in the similar manner as described above. The acidic extract gave a mixture (220 mg) of recovered nitrosamine and amide **3** as indicated by i.r. spectroscopy and t.l.c. The yellowish basic extract was chromatographed to give oxime **1** (940 mg, 21.4%) and **2** (2.2 g, 50%).

Isomerization of syn,trans-2-Piperidino-6-methylcyclohexanone oxime (1)

A solution of oxime **1** (340 mg, 16 mmol) and hydrochloric acid (0.5 ml, 6 mmol) in methanol (40 ml) was stirred at 60° for 6 h. The resultant solution was worked-up in the usual manner to give a solid (320 mg) whose n.m.r. showed two pairs of doublets at τ 8.87 ($J = 7$ Hz) and 8.92 ($J = 6.5$ Hz), due to oximes **2** and **1** respectively, with an integration ratio of *ca.* 1:3. Silicic acid t.l.c. of this mixture eluted with 25% methanol in chloroform exhibited two spots at R_f 0.87 and 0.56, corresponding to oxime **1** and **2**, respectively. This mixture was chromatographed on a basic alumina column (10 g) to give pure oxime **2** (32 mg) together with recovered compound **1**.

Addition of N-Nitrosodimethylamine to 3-Methylcyclohexene

In a manner similar to the previous photolysis, a methanol solution (360 ml) of *N*-nitrosodimethylamine (3.08 g, 40.5 mmol), the olefin (4 g, 41.5 mmol) and concentrated hydrochloric acid (4 ml, 48 mmol) was irradiated using a single Rayonet RPR 3500 Å lamp. The photolysis was complete after 12 h. The methanol was removed under vacuum leaving a crude mixture which was treated with acetone to give a crystalline precipitate. The crystals were removed by filtration to give the hydrochloride of *anti,cis*-2-dimethylamino-3-methylcyclohexanone oxime (**6**) (400 mg). The hydrochloride was treated with saturated $NaHCO_3$ solution (20 ml) to give a suspension, which was filtered to give the free base (**6**, 159 mg, 2.3%). Recrystallization once from methanol and sublimation gave an analytical sample of **6**; m.p. 110–111.5°; i.r. 3230, 1655, 960, 925, and 885 cm^{-1}; n.m.r. τ 0.05 (s, 1H, D_2O exchangeable), 6.75–7.15 (m, 2H), 7.7 (m, superimposed, 1 H), 7.75 (s, 6H), 9.10 (d, $J = 7$ Hz, 3H).

Anal. Calcd. for $C_9H_{18}N_2O$: C, 63.49; H, 10.66; N, 16.45. Found: C, 63.44; H, 10.52; N, 16.28.

After removal of **6**, the filtrate was worked-up in the usual manner to give a basic fraction (3.2 g) which was chromatographed on a basic alumina column (100 g). A solid eluted with benzene was identified as *syn,trans*-2-dimethylamino-6-methylcyclohexenone oxime (**4**, 1.05 g, 15.2%), which was sublimed to give a pure compound; m.p. 121–122°; i.r. 3360, 2800, 1670, 995, 935 cm^{-1}.

Anal. Calcd. for $C_9H_{18}N_2O$: C, 63.49; H, 10.66; N, 16.45. Found: C, 64.61; H, 10.74; N, 17.07.

Further elution with 10% methanol in chloroform gave a solid, which was recrystallized from isopropanol to give *anti,trans*-2-dimethylamino-6-methylcyclohexanone oxime (**5**, 1.4 g, 20%); m.p. 105.5–107°; i.r. 3250, 3100, 1655, 1505, 960, and 900 cm^{-1}.

Anal. Calcd. for $C_9H_{18}N_2O$: C, 63.49; H, 10.66; N, 16.45. Found: C, 63.42; H, 10.96; N, 16.22.

Photoaddition of N-Nitrosodimethylamine to 4-t-Butylcyclohexene

4-*t*-Butylcyclohexene was prepared from an isomeric mixture of 4-*t*-butylcyclohexanols (Aldrich) according to the method of Sicher and co-workers (30).

Photoaddition of *N*-nitrosodimethylamine to 4-*t*-butylcyclohexene was carried out using a single Rayonet RPR 3500 Å lamp. A solution of the nitrosamine (2.22 g, 30 mmol), the olefin (4.15 g, 30 mmol), and concentrated hydrochloric acid (2.6 ml, 31 mmol) in methanol (300 ml) was photolyzed to completion (3 h). The photolysate was concentrated, neutralized ($NaHCO_3$ solution), and cooled to furnish a crystalline precipitate (500 mg). The crystals were removed by filtration, and shown by t.l.c. to contain exclusively one compound. Recrystallization twice from ethanol gave *anti,cis*-2-dimethylamino-5-*t*-butylcyclohexanone oxime (**9**); m.p. 200–201°; i.r. 3170, 3060, 1650, 1365, 962, 942, and 905 cm^{-1}.

Anal. Calcd. for $C_{12}H_{24}N_2O$: C, 67.88; H, 11.39; N, 13.19. Found: C, 67.86; H, 11.18; N, 13.16.

The aqueous filtrate was basified (Na_2CO_3) and extracted with CH_2Cl_2 (40 ml × 3), dried (Na_2SO_4), and evaporated to dryness. The gummy residue was chromatographed on a basic alumina column (100 g) in which 100 ml fractions were collected. Fractions 1–10 eluted with benzene gave a trace of a liquid which was not investigated. Fractions 11–14 eluted with $CHCl_3$ gave a mixture of two compounds. These fractions were combined for further purification. Fractions 15–18 gave exclusively one crystalline compound (283 mg). A small portion was sublimed to furnish pure *anti,trans*-2-dimethylamino-5-*t*-butylcyclohexanone oxime (**11**); m.p. 169–172°; i.r. 3160, 1647, 1367, 1040, 986, 932 cm^{-1}.

Fractions 19–22 from 5% methanol in $CHCl_3$ gave a resinous substance (336 mg) which on treatment with methanol afforded a crystalline solid (100 mg). Sublimation yielded pure *anti,cis*-2-dimethylamino-4-*t*-butylcyclohexanone oxime (**12**), m.p. 161–163°; i.r. 3200, 1675, 1367, 1060, 962, and 930 cm^{-1}. The last fraction eluted with 10% methanol in $CHCl_3$ gave a resin. Attempts to purify this substance were unsuccessful.

Fractions 11–14 obtained above were further chromatographed on a silicic acid column (50 g). The first fraction eluted with $CHCl_3$ (1 l) was *anti,trans*-2-dimethylamino-4-*t*-butylcyclohexanone oxime (**10**, 443 mg), recrystallized from ethyl acetate; m.p. 130–132°; i.r. 3200, 3100, 1670, 984, 960, 928, 918 cm^{-1}.

Anal. Calcd. for $C_{12}H_{24}N_2O$: C, 67.88; H, 11.39; N, 13.19. Found: C, 67.84; H, 11.17; N, 13.09.

Further elution with $CHCl_3$ (200 ml) gave a mixture of **9** and **10** (60 mg). Elution with 1% methanol in chloroform (700 ml) gave a single compound **9** (285 mg). The total yields of oximes **9**, **10**, **11**, and **12** were 13, 7.3, 4.5, and 1.6%, respectively.

Beckmann Cleavage of Oximes 9 and 11

A solution of oxime **9** (340 mg, 1.6 mmol) in a mixture of dioxane (30 ml) and water (5 ml) was placed in a 50 ml beaker, in which p*H* electrodes were immersed. The beaker was set in a water bath regulated at 45° on a magnetic stirrer. To the stirred solution, finely pulverized *p*-toluenesulfonylchloride (610 mg, 3.2 mmol) was added portionwise and subsequently neutralized with 2 *N* NaOH solution to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

p*H* 7 after each addition so as not to bring the p*H* of the solution below 6. When all of the *p*-toluenesulfonylchloride had been introduced, the solution was allowed to cool to room temperature, then poured onto ice flakes (50 g). The ether extracts were dried (Na_2CO_3) and evaporated to give a liquid mixture (333 mg), which was purified on a silicic acid column (16 g). Elution with benzene gave *N,N*-dimethyltoluenesulfonamide (98 mg). The next fraction eluted from the same solvent gave a mixture (71 mg). Subsequent fractions gave a liquid, exhibiting a single spot on t.l.c. This liquid was tentatively assigned as 5-cyano-4-*t*-butylpentanal **13** (50 mg): i.r. 2880, 2715, 2250, 1725, and 1168 cm^{-1}; n.m.r. τ 0.34 (t, $J = 1$ Hz, 1H), 6.35 (m, 2H), 7.67 (m, 2H), 8.0 (m, 1H), 8.5 (m, 2H), and 9.02 (s, 9H). The 2,4-DNPH derivative of **13** was prepared in the usual manner to afford a yellow precipitate which was recrystallized from ethanol; m.p. 127–128° (dec.); n.m.r. τ −0.9 (s, 1H), 1.0 (d, $J = 2.5$ Hz, 1H), 1.75 (dd, $J = 2.5$ and 9.5 Hz, 1H), 2.45 (t, $J = 4.5$ Hz, 1H), 7.35–7.75 (m, 4H), 8.00 (m, 1H), 8.35–8.60 (m, 2H), 9.00 (s, 9H); *m/e* 345(14), 224(14), 206(23), 91(28), and 57(100).

A solution of oxime **11** (91 mg, 0.43 mmol) in a mixture of water (1 ml) and dioxane (10 ml) was similarly reacted as described above with *p*-toluenesulfonylchloride (82 mg, 0.86 mmol). The reaction mixture was worked-up to give 5-cyano-4-t-butylpentanal which was identical with that obtained from oxime **9**.

*Cleavage of Oxime **10***

In a similar fashion, oxime **10** (260 mg, 1.25 mmol) in dioxane (4.0 ml) and water (1.0 ml) was treated with *P*-toluenesulfonylchloride (466 mg, 2.5 mmol) giving a mixture of the sulfonamide and a ω-cyanoaldehyde; the latter was purified by chromatography to give 5-cyano-3-t-butylpentanal (**14**, 102 mg): i.r. 2885, 2720, 2260, 1725, 1095 cm^{-1}; n.m.r. τ −0.15 (t, $J = 1.5$ Hz, 1H), 7.40–7.80 (m, 4H), 8.10 (m, 2H), 8.60 (m, 1H), and 9.10 (s, 6H). The 2,4-DNPH derivative was prepared by the usual method to give the hydrazone of **14**: m.p. 125.5–126.5°; *m/e* 347(100), 224(16), 206, 152(52), and 83(74).

*Preparation of $\Delta^{9,10}$-Octalin (**15**)*

Crude $\Delta^{9,10}$-octalin was prepared according to Dauben and co-worker (31). Isomeric 2-decanol (Aldrich) (47.7 g, 310 mmol) was dehydrated with boric acid (19.5 g, 87 mmol) and isomerized with phosphorus pentoxide (12.3 g) to give a mixture of octalins, b.p. 190–196° (28.9 g, 69%). The crude product contained 73% of **15** as indicated by v.p.c. analysis. This mixture was fractionally distilled on a spinning band column to give 7.3 g (25%) of **15**, which showed single peak on v.p.c. (SE 30% column at 225°) analysis and whose n.m.r. spectrum exhibited two superimposed multiplets at τ 8.25 and 8.42 of 1 : 1 integration ratio. The i.r. showed three main absorptions at 2920, 1445, and 1161 cm^{-1}.

Addition of N-Nitrosopiperidine to $\Delta^{9,10}$-Octalin

A methanol solution (170 ml) of *N*-nitrosopiperidine (1.66 g, 14.5 mmol), $\Delta^{9,10}$-octalin (2.0 g, 14.7 mmol), and concentrated hydrochloric acid (1.4 ml, 17 mmol) was photolyzed in a Rayonet photoreactor using a 350 mμ lamp. After completion of the photolysis (3 h), the photolysate was concentrated, treated with water (10 ml), and extracted with ether (30 ml × 3). The ether solution was dried ($MgSO_4$) and evaporated to give a solid (760 mg, 30%). This solid was recrystallized from methanol and sublimed to give an analytical sample of Δ^9-decalone-1 oxime (16); m.p. 146–147° (lit. m.p. 147° (18)); i.r. 3300, 1640, 1025, and 960 cm^{-1}; n.m.r. τ −0.5 (s, 1H, D_2O exchangeable), 7.38 (t, $J = 6.5$ Hz, 2H), 7.84 (m, 6H); *m/e* 165(50), 148(100), 131(25), 119(25).

After work-up in the usual manner, the basic extracts gave a viscous liquid (895 mg), which was treated with methanol to give a crystalline precipitate. Recrystallization once from methanol yielded colorless needles of 5-piperidino-Δ^9-decalone oxime (**17**); m.p. 178–180°; i.r. 3230, 1633, 980, and 943 cm^{-1}; n.m.r. τ 0.3 (s, 1H, D_2O exchangeable), 6.85 (m, 1H), 7.30–7.90 (m, 10H), and 8.20–8.65 (m, 12H); *m/e* 248(18), 231(43), 148(51), 86(100).

Anal. Calcd. for $C_{15}H_{24}N_2O$: C, 72.54; H, 9.74; N, 11.28. Found: C, 72.74; H, 9.59; N, 11.13.

The mother liquor after removal of **17** was chromatographed on a silicic acid column (40 g). A solid (84 mg) eluted with $CHCl_3$ was identified as *N*-piperidinoformamide by direct comparisons with an authentic sample prepared from *N*-aminopiperidine and formic acid (1). The subsequent eluate from 5% methanol in $CHCl_3$ was found to be **17** (122 mg). The last fraction eluted with 10% methanol in $CHCl_3$ gave a gummy substance (50 mg), from which no pure compound could be isolated. Total yield of **17** was 402 mg (9%).

*Deoximation of **16***

Oxime **16** (100 mg, 0.6 mmol) was mixed with levulinic acid (2.7 ml) and 1.2 *N* hydrochloric acid (0.3 ml). The mixture was heated under reflux for 3 h. The resultant solution was then basified with saturated Na_2CO_3 solution, extracted with CH_2Cl_2 (30 ml × 3). The extracts were washed with water, dried (Na_2SO_4), and evaporated to give an impure substance (100 mg). The liquid ketone **18** (72 mg, 79%), i.r. 2930, 2865, 1660, 1632 cm^{-1}, was obtained by chromatography through a silicic acid column (35 g) eluting with $CHCl_3$. The 2,4-DNPH derivative of ketone **18** was obtained as a red solid and was recrystallized from ethanol to give crimson crystals; m.p. 265–266°, (lit. m.p. 264.5–265.5° (32)); i.r. 3330, 1620, 1585, 1330 cm^{-1}; *m/e* 331(21), 330(100), 119(21), 91(25).

*Aromatization of **17***

The oxime **17** (140 mg, 5.7 mmol) in acetic anhydride (0.2 ml) and acetic acid (1 ml) was placed in a two-necked pear-shaped flask equipped with a gas inlet and a condenser whose exit was attached to a calcium chloride tube. The mixture was saturated with anhydrous hydrogen chloride for 2 h at room temperature and then heated on a water bath for an additional 4 h. The resultant dark brown solution was evaporated to dryness under vacuum. The residue was treated with isopropanol to give 1,2,3,4-tetrahydro-1-piperidino-5-aminonaphthalene dihydrochloride (**19**, 92 mg, 61%) which was recrystallized from isopropanol m.p. 214–217° (dec.); i.r. 3410, 3315, 2525, 1625, 1600, 795, 720 cm^{-1}; n.m.r. (D_2O) τ 2.30–2.55 (m, 3H), 6.40–6.66 (m, 5H), 6.70 (t, $J = 6$ Hz, 2H); u.v. (MeOH) 210 and 250 nm.

The free base of **19** (53 mg) was obtained by dissolving the hydrochloride (80 mg) in saturated Na_2CO_3 solution and extracting with $CHCl_3$ (20 ml × 3). Sublimation of the crude product in a sealed tube gave a colorless liquid, 1,2,3,4-tetrahydro-1-piperidino-5-aminonaphthalene; i.r. 3460, 3370, 1640, 1575, 1325, 795 cm^{-1}; n.m.r. τ 1.90–2.40 (m, 2H), 2.63 (t, unresolved, $J = 6.5$ Hz, 1H), 6.70 (s, 2H,

D_2O exchangeable), 7.60 (m, 6H); u.v. (MeOH) 212 nm (ε 1.86×10^3), 235 (ε 11.5×10^2), 287 (ε 2.5×10^2); *m/e* 230(1), 146(12), 145(22), 130(100). The absorption spectra (in H_2O; 190–450 nm) of arylamine **19** were unaffected in the presence of Cu^{2+} or Ni^{2+} ion.

The u.v. absorption maxima of 1-amino-5-di(2-chloroethylamino-1,2,3,4-tetrahydro) naphthalene were at 209, 235, and 285 nm and its dihydrochloride at 208 and 235 nm.

Lithium Aluminum Hydride Reduction of Oxime **2** *and* **1**

To a suspension of LAH (164 mg, 3.2 mmol) in anhydrous tetrahydrofuran (THF, 10 ml), a solution of oxime **2** (300 mg, 1.4 mmol) in THF (10 ml) was added dropwise with stirring. The grey suspension was stirred for 1 h at room temperature and subsequently heated under reflux for 4 h. The resultant reaction mixture was decomposed with water, and magnesium sulfate was added to aid the coagulation of aluminum hydroxide. The solid was filtered and washed with THF. The THF solution was evaporated to give crude amines as colorless liquid (202 mg, 72%), i.r. 3400, 1590, 1165, and 110 cm^{-1}.

The crude amine mixture was acetylated with acetic anhydride and fused sodium acetate. After the usual work-up the crude acetamide exhibited two pairs of n.m.r. signals at 8.00 and 9.13 in one hand and τ 7.95 and 9.00 on the other: the ratio of the former pair to the latter pair was 3.5:1. The crude product was chromatographed on a silicic acid column to give two compounds. The less polar compound was contaminated by acetamide **7** and was the minor product 1-acetamido-2-*cis*-piperidino-6-*trans*-methylcyclohexane (**8**): i.r. 3300, 1645, and 1540 cm^{-1}; n.m.r. τ 5.98 (t, $J = 5.5$ after D_2O exchange), 7.95 (s, 3H), and 9.00 (d, $J = 7$ Hz). The major product (more polar) was sublimed to give 1-acetamido-2-*trans*-piperidino-6-*cis*-methylcyclohexane (**7**); m.p. 130–132°; i.r. 3250, 1635, 1555, and 1280 cm^{-1}; n.m.r. ($CDCl_3$) τ 3.35 (broad, 1H, D_2O exchangeable), 6.30 (m, $W_{1/2}$ *ca.* 20 Hz after D_2O exchange, 1H), 7.5 (m, 5H), 8.00 (s, 3H), and 9.13 (d, $J = 7$ Hz, 3H); n.m.r. (D_2O–DCl) τ 5.80 (dd, $J = 4$ Hz and 11 Hz), 6.65 (m, 5H); *m/e* 238(4), 179(13), 164(12), 124(100), and 84(31). The hydrochloride of **7** was recrystallized from 2-propanol; m.p. 254–256° (dec.); i.r. 3170, 2650, 1670, 1555, and 1290 cm^{-1}; n.m.r. ($CDCl_3$) τ 5.85 (dd, $J = 11$ and 4 Hz, 1H), 6.55 (dt, $J = 11$ and 4.5 Hz, 1H), 7.85 (s, 3H) and 8.79 (d, $J = 7$ Hz, 3H).

Oxime **1** (358 mg, 1.7 mmol) was reduced with LAH (196 mg, 5.2 mmol) and acetylated in the similar manner as described above. The crude acetamide showed similar n.m.r. spectra as that obtained above but the ratio of **7** to **8** was 5:1. On chromatograph of the mixture on alumina, acetamide **7** and the corresponding hydrochloride were obtained. The hydrochloride of **7** was readily soluble in chloroform and could be sublimed. The acetamide **8** was isolated in semi-pure state.

The authors are grateful to the National Research Council of Canada and to the President's Research Fund of Simon Fraser University for financial support.

Photoreactions of Nitroso Compounds in Solution.[1] XXII. Stereochemical Consequences of the Photoaddition of *N*-Nitrosopiperidine to Conjugated Acyclic Dienes: a Nuclear Magnetic Resonance Study of Enone Oximes

Y. L. CHOW, C. J. COLÓN, H. H. QUON, AND T. MOJELSKY

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received June 9, 1971

In the presence of an acid, photoexcited *N*-nitrosopiperidine adds to conjugated acyclic 1,3-dienes to give the 1,4-adducts as the major product in addition to 1,2-adducts. In the photoaddition to 1,3-pentadienes the reverse 4,1-adduct and 4,3-adducts are also identified. These results suggest that a singlet photoexcited *N*-nitrosopiperidine–acid complex rapidly decays to piperidinium radical which irreversibly attacks the dienes as the first step, followed by either a short propagation step or a termination step to give *C*-nitroso compounds. The *C*-nitroso compounds are rapidly removed by irreversible tautomerization to the final oximes. The reactivity of the piperidinium radical toward conjugated double bonds decreases in the order of $RCH{=}CH_2$ > *cis*-RCH=CHR > *trans*-RCH=CHR. This mechanism is in accord with the following stereochemical results. Firstly, the newly-formed double bond in the 1,4-adduct (or the adduct of the reverse orientation) is exclusively *trans*-oriented. Secondly, the remaining double bonds in the 1,2-adducts maintain their original stereochemistry.

The stereochemistry of the photoadducts, enone oximes **1**–**11**, was determined by means of n.m.r. spectroscopy. From the correlation of the n.m.r. chemical shifts of these enone oximes it has been shown that (*i*) the α-olefinic proton generally resonates at a lower field than the β-olefinic proton (with one exception) and (*ii*) in changing from $CDCl_3$ to an aromatic solvent the α-olefinic proton and the α′-alkyl protons are deshielded by 0.3–0.05 p.p.m. while the β-olefinic proton is shifted only slightly either to a higher or a lower field. It is observed that the order of the chemical shifts of the olefinic protons and the aromatic solvent effects on the chemical shifts in these enone oximes are both opposite to those observed in enone systems.
